Fig. 1. Histograms of simulated measured radioactivity *vs.* time for 30-sec eluted fractions. Upper chromatograms with approximately 49 cps background are for ^{3}H BaP reaction product eluates and lower chromatograms with approximately 16 cps background represent corresponding ^{14}C BaP components from samples. AHH enzymatic activities for the incubations of the combined ^{3}H BaP and ^{14}C BaP mixtures with initial concentrations such that [^{3}H-BaP] = 10[^{14}C-BaP]: (a) 10^{-3} I.U./l. and (b) 10^{-5} I.U./l.

Fifteen replicates were done for each simulated variation in combinations of: (a) nine combinations of reactant concentrations, with ^{3}H BaP concentrations of 10^{-2}, 10^{-3} and $10^{-4}M$ and ^{14}C BaP concentrations varied in factors of 10 between 10^{-3} and $10^{-7}M$, but always lower than the ^{3}H BaP concentration, *i.e.*, providing relative (^{3}H BaP/^{14}C BaP) concentrations ranging between 10^{-1} and 10^{-4}, (b) 20 values for AHH reaction rates for the sample solution varying between 10^{-2} I.U./l. to 2×10^{-8} I.U./l., and (c) three values for uncertainties in extraction/concentration/dilution efficiencies ($\pm$s, $\pm$2s, and $\pm$3s; see Table 1 for values). Other values were held constant: (a) 10-min counting times were used, (b) 60-min enzymatic incubations were assumed, (c) specific activities of 500 and 325 mCi/mmole for ^{3}H-labeled and ^{14}C-labeled BaP, respectively, (d) 100 ml for the sample incubation volume, 1.00 ml for the combined ^{3}H and ^{14}C mixture's resulting concentrate, and 0.100 ml used for separation by HPLC, and (e) background count rates of 49 cpm for ^{3}H and 16 cpm for ^{14}C.

Simulated measured radioactivities for each labeled form of each metabolite were saved and those data were later used to calculate Q-ratios for metabolite-label pairs and corresponding conventional ^{14}C-ratio results. Means (x) and standard deviations (s) were computed and data quality was estimated as x/s for each compared set. Confidence ranges ($x \pm s$) were calculated for Q-ratio results and for conventional results for various replicate sets and were plotted *vs.* AHH enzymatic activities for sample solutions under otherwise identical conditions.

Procedure for laboratory studies: test organisms

S-10 fraction microsomes were collected as 60-min $\times$ 60,000 $\times$ **g** centrifugate, obtained from 20-min $\times$ 20,000 $\times$ **g** supernatant of liver tissue homogenized in 1% potassium chloride. Livers were excised from Sprague–Dawley rats (approximately 200 g) and treated immediately for microsomal collection. Microsomes were stored at $-80°$ for future use if not used immediately after preparation.

Microsomes were incubated with NADPH, glucose-6-phosphate and glucose-6-phosphate dehydrogenase in oxygen-saturated 0.1M phosphate buffer at pH 7.5 and radiolabeled BaP

dosage commpounds at 37.5°. After a two-hour incubation, the metabolism was halted by the addition of acetone. The incubates were then saturated with sodium chloride and extracted four times with ethyl acetate. Descriptions of reagent volumes and concentrations may be found elsewhere.[2,3] The extracts were evaporated to dryness at 25° under a $N_{2(g)}$ stream and the residue partially dissolved into 1.0 ml of methanol. A 50-μl aliquot of each methanolic concentrate was taken for separation by HPLC with the effluent being mixed with scintillation cocktail just prior to flow-through counting. The outflow from the Model 171 counter was collected as one-minute fractions in glass scintillation vials and each was counted for 20 min on a multichannel LSC.

Data were plotted as histograms and net activities calculated for the eluted components. Eluate radioactivities were then used for Q-ratio computations, for conventional comparisons using ^{14}C-ratios and for statistical calculations.

RESULTS AND DISCUSSION

Computer simulations

Dual-label chromatograms from simulations were developed to generate histograms representing collected fraction radioactivities *vs.* time (Fig. 1) that mimic chromatograms expected from corresponding biological experiments.[2,6] The simulated chromatograms represented a wide range of variations in peak areas, including those for which all metabolite peaks' radioactivities were easily calculated [Fig. 1(a)] and others for which many eluates were below the limits of reliable measurement [Fig. 1(b)], with some circumstances allowing easy measurement of one labeled form but difficult-to-unfeasible measurements for the other.

Intrasample Q-ratio comparisons show Q_{ij} values which closely approximate unity, as predicted by theory (Figs. 2 and 3). The relative uncertainties, *e.g.*, relative standard deviations for Q_{ij} values within a replicate set, are often slightly worse than relative uncertainties for ratios of corresponding single-label ^{14}C-ratios; however, results found for single-label ratios vary considerably, with no theoretically predicted value achieved. Also, the Q_{ij} ratios are only slightly affected by large variations in extraction/concentration/dilution efficacies (see Fig. 2). As expected, lower measured activities yield less precise results (Fig. 3), but the Q-ratio results maintain their tendency toward unity, unless the uncertainties of measured activities are overwhelming. Consequently, testing of the null hypothesis, that the measured reaction products are unaffected by impurities or isotope effects, is dramatically more powerful if Q-ratio comparisons are used instead of conventional approaches with ^{14}C-ratios.

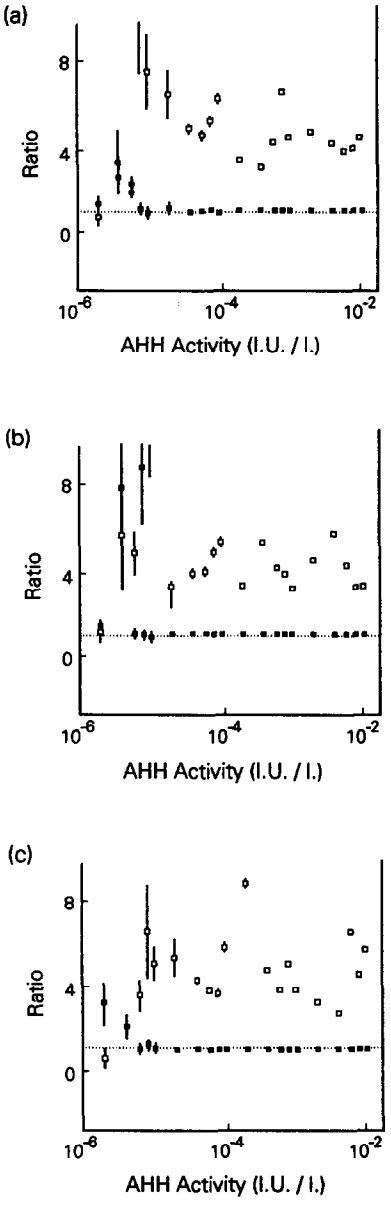

Fig. 2. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intrasample Q-ratios (■) or corresponding ratios using only the C-label data (□): These figures show results for three levels of extraction/concentration/dilution uncertainties: (a) ±10% and ±5% (RSD), (b) ±20% and ±10% (RSD), and (c) ±30% and ±15% (RSD) for 9-hydroxy BaP and 3-hydroxy BaP, respectively. These data were attained with intrasample comparisons between 9-hydroxy BaP and 3-hydroxy BaP.

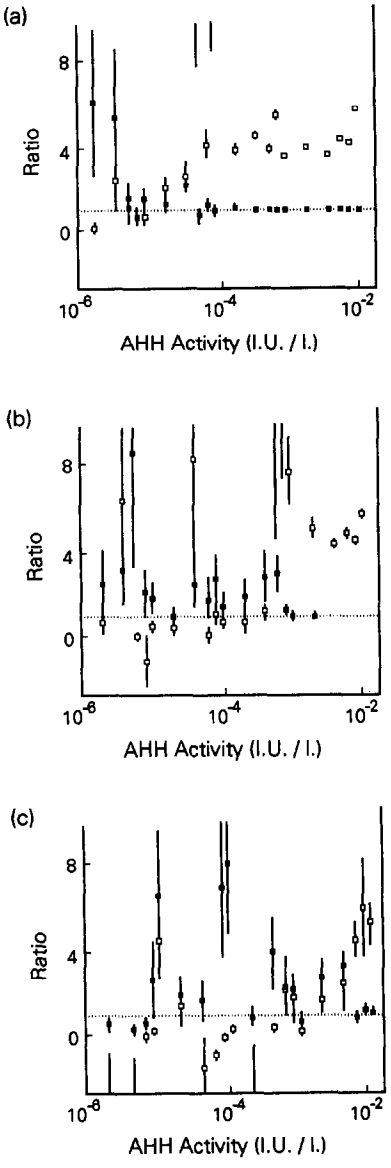

Fig. 3. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intrasample Q_{ij} ratios (■) or corresponding ratios with only the C-label data (□): these figures show results for three levels of components radioactivities resulting from initial incubation concentrations such that (a) $[^3\text{HBaP}] = 10^2[^{14}\text{CBaP}]$, (b) $[^3\text{HBaP}] = 10^3[^{14}\text{CBaP}]$ and (c) $[^3\text{BaP}] = 10^4[^{14}\text{CBaP}]$. Data are for intrasample comparisons between 9-hydroxy BaP and 3-hydroxy BaP metabolism products, with extraction/concentration/dilution uncertainties of ±10% (RSD) for 9-hydroxy BaP and ±5% (RSD) for 3-hydroxy BaP.

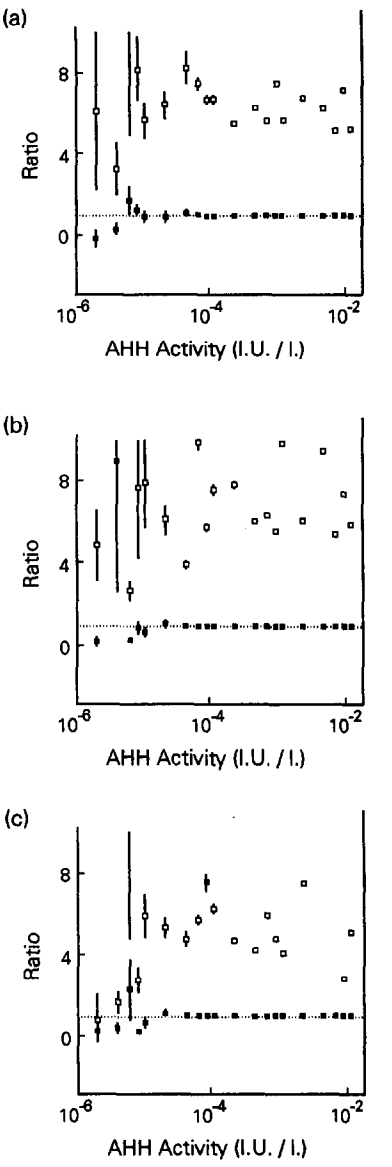

Fig. 4. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intersample $Q_{12,i}$-ratios (■) and corresponding ratios with only C-label data (□). These figures show results for three levels of extraction/concentration/dilution uncertainties: (a) ±10% (RSD), (b) ±20% (RSD) and (c) ±30% (RSD). These data are for intersample comparisons *vs.* a reference set of 15 replicate incubations with AHH enzymatic rates of 10^{-3} I.U./l., with each individual datum for 6,12 BaP dione being compared to averaged 6,12 BaP dione data of the reference set.

Intersample comparisons, relative to a specified component from a specified replicate sample set, show dramatic benefits for Q-ratios. The advantage of using Q-ratios, rather than corresponding conventional comparisons via singly labeled reaction products, is distinct. The conventional methods' results are typically somewhat more precise for individual selected comparisons among replicates, partly because fewer radioactivity measurements are used. However, conventional comparisons yield results which vary widely between such comparisons (see Fig. 4). More importantly, the Q-ratio results yield theoretically predictable values, *i.e.*,

$Q_{12,i} = 1$ for the null hypothesis, while conventional comparisons results are disparate and reveal no such predicted value.

Intersample comparisons for selected pairs of products, relative to corresponding pairs from a specified replicate sample set also yield theoretically predictable results via Q-ratios, *i.e.*, $Q_{ij,12} = 1$ for the null hypothesis (see Fig. 5). Conventional comparisons' results among replicate sets are somewhat more precise, in general, but their results vary widely between such comparisons and do not yield theoretically predictable values.

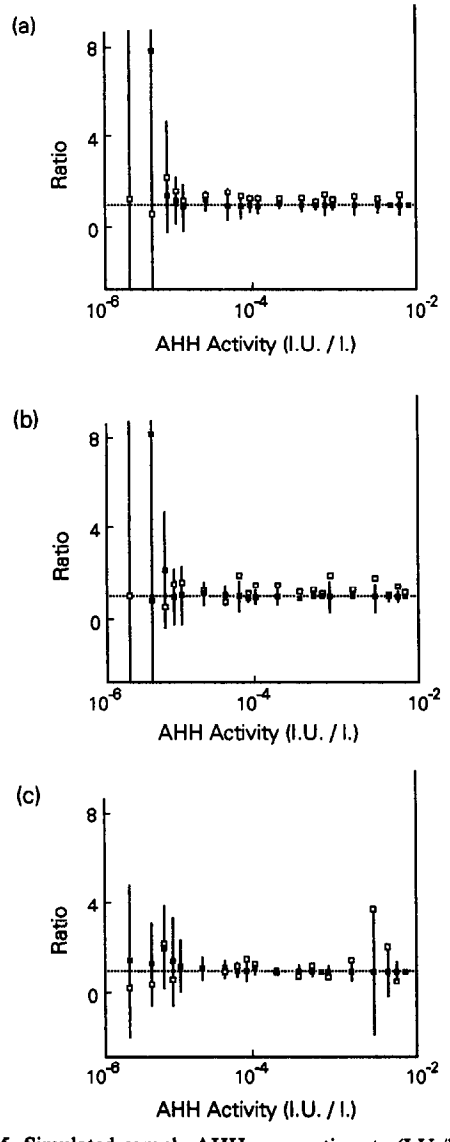

Fig. 5. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intersample $Q_{ij,12}$-ratios (■) and corresponding ratios with only C-label data (□). These figures show results for 6,12 BaP dione at three levels of extraction/concentration/dilution uncertainties: (a) ±10% (RSD), (b) ±20% (RSD) and (c) ±30% (RSD). These data are for intersample comparisons *vs.* a reference set of 15 replicate incubations with AHH enzymatic rates of 10^{-3} I.U./l., with individual data for intrasample ratios between 6,12 BaP dione and 3-hydroxy BaP being compared to corresponding averaged 6,12 BaP dione *vs.* 3-hydroxy BaP ratios of the reference set, with extraction/concentration/dilution uncertainties of ±15% (RSD), ±10% (RSD) and ±5% (RSD), respectively, for the 3-hydroxy BaP data of the reference set.

As extraction/concentration/dilution imprecisions increase greatly, corresponding Q-ratios become a little less precise, but are relatively insensitive to great changes in pretreatment effectiveness. Moreover, the predictability, *i.e.*, the uncertainty for unity in the null hypothesis, changes only slightly due to those somewhat larger standard deviations in the Q-ratios (see Figs. 2, 4 and 5). Thus, use of the Q-ratios substantially reduces difficulties encountered due to large variations in recovery efficiencies and other pretreatment variables.

As the AHH enzymatic activity increases, the Q-ratios become relatively more precise, but are not dramatically better above a certain threshold region for AHH enzymatic activity (see Figs. 2–5) and depend upon the concentrations of selected metabolites formed (see Figs. 3, 6 and 7). This is apparent for intrasample Q-ratios as shown in Fig. 2, and for intersample Q-ratios depicted in Figs. 4–7. However, low component concentrations, typical of very low initial concentrations of reactant or of very low AHH activity, *e.g.*, $< 10^{-5}$ I.U./l., result in either large s/x ratios with wide confidence ranges or immeasurable values which are shown in the figures as zero values.

Increased numbers of replicates enhance data quality for Q-ratios. As expected, improvements are significant for low numbers of replications, *e.g.*, 2 *vs.* 3, but the added relative advantage for high numbers of trials is much less dramatic. Thus, one may select a number of replicates which allows for appropriate statistical comparisons, *e.g.*, 3–5, and save the expense of using many repetitions of the corresponding experiments; when using conventional single-label comparisons, even very high numbers of replications do not result in the excellent predictability offered by only a few replicates with the Q-ratios.

Use of the dual-label procedure discussed above has the potential for dramatically improving statistical evaluations of interferences in reaction product formation experiments. This is mainly due to the theoretically valid predictability for the Q-ratios, *i.e.*, $Q = 1$ for the null hypothesis. Also, because the components are

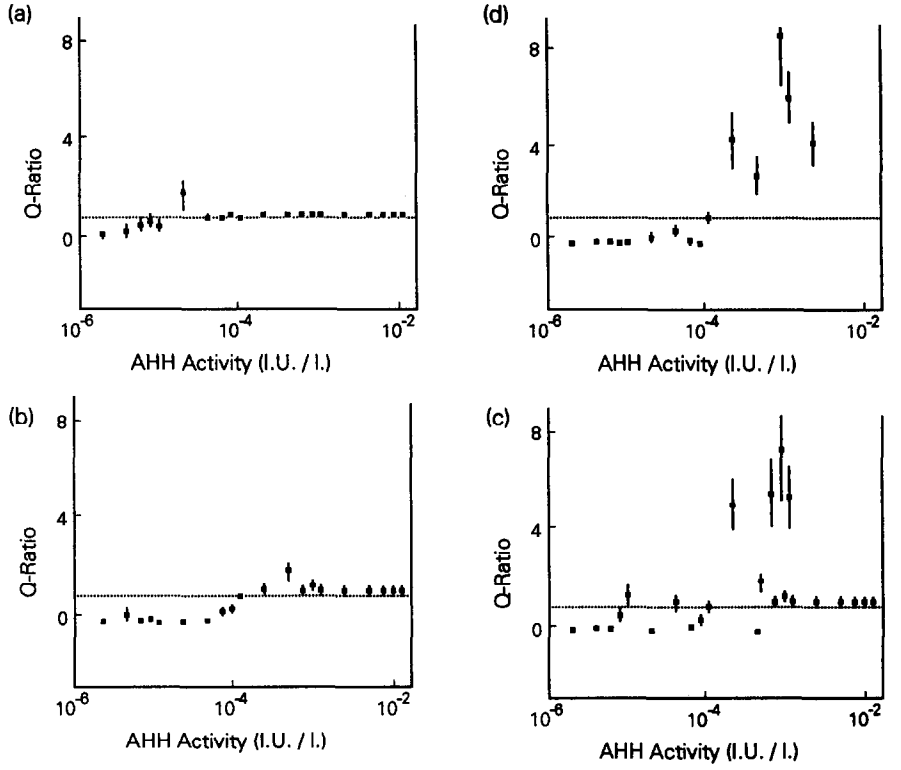

Fig. 6. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intersample $Q_{12,i}$-ratios for four levels of components' radioactivities resulting from initial concentrations such that (a) [^{3}HBaP] = 10 [^{14}CBaP], (b) [^{3}HBaP] = 10^2[^{14}CBaP], (c) [^{3}HBaP] = 10^3[^{14}CBaP] and (d) [^{3}HBaP] = 10^4[^{14}CBaP]. Data are for intersample comparisons *vs.* a reference set of 15 replicate incubations with AHH enzymatic rate of 10^{-4} I.U./l, with individual data for 3,6 BaP dione being compared to averaged 3,6 BaP dione data of the reference set, with extraction/concentration/dilution uncertainties of ±10% (RSD) for the 3,6 BaP dione.

chemically alike and treated identically, contributions due to uncertainties in recoveries, volume measurements, *etc.* are reduced appreciably, resulting in small standard deviations for corresponding Q-ratios. Moreover, because of the mathematical form of these ratios, requirements for identifying all eluates, obtaining pure analyte reference compounds, and carefully defining specific activities and some other variables may be obviated.

Experimental measurements

Results of laboratory tests with microsomes are consistent with the simulated results discussed above. For replicates obtained by splitting individual samples after incubation but prior to pretreatments and separations, Q-ratios were typically 1.0 ± 0.06 (RSD; $n = 5$) for comparisons relative to 3-OH-BaP. Corresponding values for conventional ratios for the same radioactivity data, based upon comparisons of ^{14}C data only, varied dramatically with percent RSD values between 50 and 300%, with no discernible tendency toward unity. All these results were somewhat worse than predicted by theory, perhaps due to interferences from other components and drifting chromatogram baselines. However, the marked advantages predicted for the Q-ratio, as discussed above, were corroborated by the experimental results.

These dual-label techniques are powerful for assessing problems due to isotope effects or impurities in reaction studies and should be adaptable to isotope-selective measurements such as emission spectrometry, mass spectrometry and resonance spectroscopic methods, which would allow for use of nonradioactive compounds. Additionally, they could be easily used for both biological and nonbiological reaction systems such as photodegradations or pyrolyses.

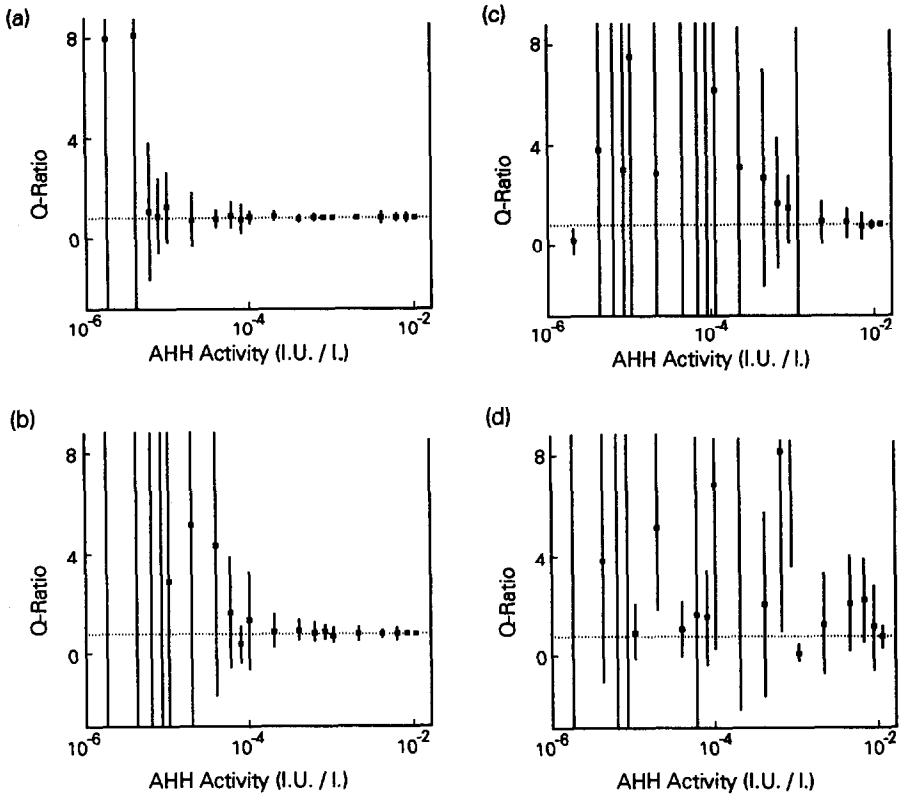

Fig. 7. Simulated sample AHH enzymatic rate (I.U./l.) *vs.* intersample $Q_{ij,12}$-ratios for four levels of components' radioactivities resulting from initial concentrations such that (a) $[^3HBaP] = 10[^{14}CBaP]$, (b) $[^3HBaP] = 10^2[^{14}CBaP]$, (c) $[^3HBaP] = 10^3[^{14}CBaP]$ and (d) $[^3HBaP] = 10^4[^{14}CBaP]$. Data are for intersample comparisons *vs.* a reference set of 15 replicate incubations with AHH enzymatic rate of 10^{-4} I.U./l., with each individual data for intrasample ratio between 1,6 BaP dione and 3-hydroxy BaP being compared to averaged 1,6 BaP dione *vs.* 3-hydroxy BaP data of the reference set, with extraction/concentration/dilution uncertainties of $\pm 5\%$ (RSD) for both components.

(*Received* 20 *June* 1991. *Revised* 2 *October* 1991. *Accepted* 2 *October* 1991)

Summary—The reagent bis(acetylpivalylmethane)ethylenediimine has been examined for the HPLC separation of copper(II), nickel(II), palladium(II) and oxovanadium(IV) chelates on reversed phase HPLC columns (250 × 4 mm) packed with Hypersil ODS, 5 μ and (150 × 3.9 mm) Nova Pak C_{18} with guard column. The complexes are eluted with a binary mixture of methanol and water or methanol, acetonitrile and water. Detection is achieved with a UV detector. The solvent extraction procedure is used for the determination of copper and nickel simultaneously at microgram levels, corresponding to ng levels and pg levels respectively, per injection. The method has been applied to the determination of copper and nickel in a coin, nickel–aluminum alloy and water samples.

The use of high performance liquid chromatography (HPLC) for the separation and determination of organic compounds is extensive, but a number of reports on the corresponding use of HPLC for inorganic determinations have also appeared.[1–3] The tetradentate ketoamine Schiff bases are interesting, because they form neutral and highly stable copper(II), nickel(II), palladium(II) and oxovanadium(IV) chelates and involve fewer interferences.[4,5]

Belcher *et al.*[6] have used bis(acetylpivalylmethane)ethylenediimine (H_2APM_2en) for the solvent extraction and gas chromatographic (GC) determination of copper and nickel in alloy samples and copper in drinking water. Dilli and Patsalides[7] have applied H_2APM_2en as derivatizing reagent for the determination of vanadium in petroleum crudes and fuel oils by gas chromatography. In the present work, a similar procedure has been used for the solvent extraction of copper and nickel, for determination by HPLC.

EXPERIMENTAL

The reagent bis(acetylpivalylmethane)ethylenediimine (H_2APM_2en) and its copper and nickel complexes were prepared as reported by Belcher *et al.*[6]

A column (250 × 4 mm) packed in the laboratory with Hypersil ODS, 5 μm, diameter particles, or a Nova Pak C_{18} (150 × 3.9 mm) with ODS guard column (Waters) was used.

Procedures

Solvent extraction. An aliquot of sample (1–2 ml) containing copper and nickel (2–120 μg) separately or in a mixture was transferred to a well-stoppered test tube (10 ml) to which was added 1 ml of sodium acetate (1*M*) to adjust the pH within 7–8. Reagent H_2APM_2en (1.5 ml) [0.2*M* in ethanol:water (2:1)] was added and the contents were warmed on a water bath at 70–80° for 15 min. After cooling, cyclohexane (2 ml) was added and copper and nickel were extracted by shaking with a mechanical shaker for 30 min. The organic layer was separated and one-half (1 ml) transferred to another test tube and evaporated to dryness. Methanol (1 ml) was then added and the methanolic solution (1 μl) was injected on the Nova Pak C_{18} reversed phase column with ODS guard column. The complexes were eluted with methanol:water (87:13) at a flow-rate of (0.7 ml/min). The detection was carried out with a UV detector at 260 nm.

Dissolution method. To a solution (1–2 ml) containing 2–20 μg of copper and nickel was added 1 ml of sodium acetate (1*M*) to adjust the pH within 7–8, followed by 2 ml reagent

solution (0.02*M*) in methanol. The contents were warmed on a water bath at 70–80° for 15 min. After cooling the mixture, 2 ml of methanol were added and the contents were mixed thoroughly by shaking on a mechanical shaker for 30 min. Finally, the volume was adjusted to 10 ml with methanol. The solution (1–5 μl) was injected on the HPLC column as described in solvent extraction.

Analysis of copper in a coin

To the copper coin (3.004 g) was added 20 ml of *aqua regia* [hydrochloric acid:nitric acid (3:1)] and the mixture was heated gently to near dryness. Hydrochloric acid (10 ml) was added and the mixture was again heated to dryness. To the residue was added water and the volume was adjusted to 100 ml. A 1-ml aliquot of the solution was further diluted to 100 ml. The solution (0.4 ml) was transferred to a well-stoppered test tube and 0.3 ml of ammonium fluoride (1*M*) were added and the procedure followed as for solvent extraction.

Analysis of nickel in nickel–aluminum alloy

Nickel–aluminum alloy (0.2 g) was dissolved in *aqua regia* as for the copper coin. After necessary dilution extractions were carried out, using the procedure described in solvent extraction.

The amount of copper and nickel in the samples was evaluated from standard calibration curves prepared from known amounts of copper and nickel.

Analysis of copper in water samples

Distilled water (10 ml) from a copper still and collected in a copper tank, and 10 ml of domestic water from a stainless steel tank collected after allowing water to flow for 5 min were analysed with the solvent extraction procedure, except that 3 ml of reagent was used and 5 μl of the final solution was injected.

The calibration curve was prepared from doubly distilled water containing 5–70 μg of copper per 10 ml, using the same procedure as for the analysis of samples.

RESULTS AND DISCUSSION

The separation of copper(II) and nickel(II) complexes was investigated on a Hypersil ODS column. Complete separation between reagent, nickel and copper was obtained, when the complexes were eluted with a ternary mixture of methanol:acetonitrile:water (68:13:19) with retention volumes of 4.84 and 5.33 ml for nickel and copper complexes, respectively, using a flow-rate of 0.7 ml/min (Fig. 1). We should note that separation from the oxovanadium and palladium complexes was also complete (retention volumes of 2.62 and 3.69 ml, respectively (see Fig. 1).

In order to use the separation for the quantitative determination of copper and nickel by using solvent extraction procedures, the optimum conditions for the extraction of copper and nickel were confirmed. The effects of variation in pH, solvent, reagent concentration, heating and shaking time were investigated for the extraction of 50 μg of copper and nickel. It was observed that sodium acetate (1*M*, 1–2 ml), covered the pH range between 7–8 (adjusted to 7.5) satisfactorily for the maximum extraction of copper and nickel. The solvents n-hexane, cyclohexane, benzene and toluene were tested for the extraction of copper and nickel. Cyclohexane gave more reproducible results and was therefore used for the extraction of copper and nickel. The reagent concentration (0.02*M*, 1.5 ml) proved adequate for the extraction of

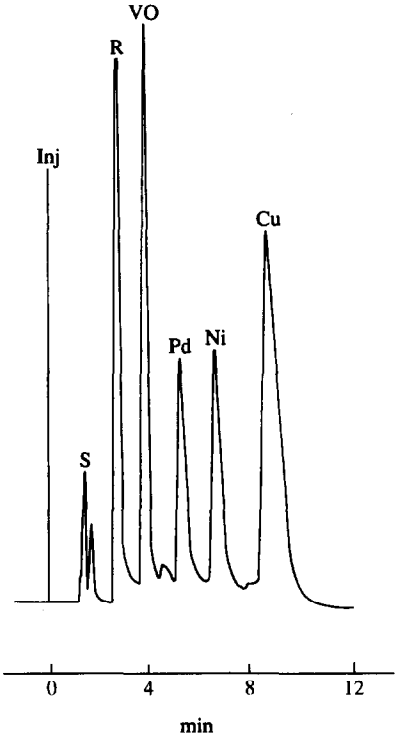

Fig. 1. HPLC separation of reagent, oxovanadium, palladium nickel and copper chelates of H_2APM_2en on column (250 × 4 mm) packed with Hypersil ODS, 5 μ. Elution: Methanol:acetonitrile:water (68:13:19). Flow-rate: 0.7 ml/min; UV detection at 300 nm.

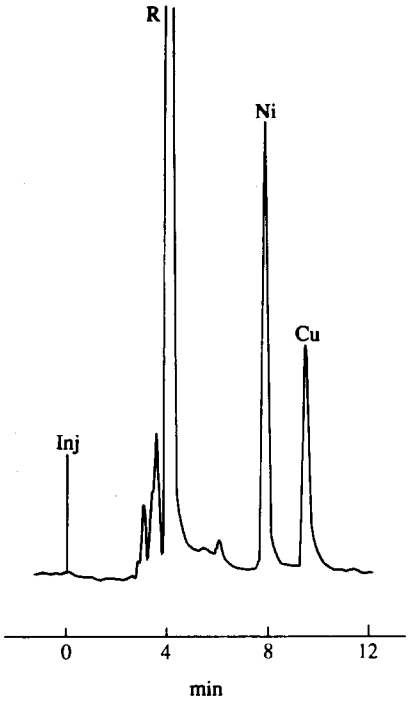

Fig. 2. HPLC separation of copper and nickel chelates extracted with H_2APM_2en on Nova Pak C_{18} column with guard ODS column. Elution: Methanol:water (87:13). Flow-rate 0.7 ml/min; UV detection at 260 nm.

10–120 μg of metal ions. The heating time of 15 min at 70–80° and a shaking time of 30 min enable the extraction of copper and nickel quantitatively and reproducibly.

The reversed phase HPLC column, Nova Pak C_{18} with guard ODS column, was used because of the ease of separation of copper and nickel from each other and from the excess of the reagent with a binary mixture of methanol:water (87:13) (Fig. 2). However, it required evaporation of the extracting solvent and redissolution in methanol before HPLC determination. We therefore considered dissolving the copper and nickel complexes in methanol or a mixture of methanol and acetonitrile, after complexation in the aqueous phase to obviate the need for the extraction of complexes in cyclohexane. This would also enable one to inject directly the complexes on the reversed phase HPLC column. The dissolution method was therefore investigated for the preparation of solutions. It was observed that the method provided similar results to those obtained with the solvent extraction procedure when the solution contained 2–20 μg of copper and nickel. However, when the amount of copper and nickel in the solution increased, some difficulties were encountered in the preparation of clear solutions. Reproducible results were thus not obtained. In the place of methanol, a mixture of methanol:acetonitrile (1:1) was also tried, but no improvement in the results was obtained. The solvent extraction, procedure was therefore used for the quantitative determination of copper and nickel.

In order to assess the reagent for the HPLC determination of copper and nickel simultaneously, using the solvent extraction procedure different amounts of copper and nickel in 10 ml of water were taken and after complexation and extraction in cyclohexane, 1 ml of extract was evaporated and redissolved in 1 ml of methanol. A 1-μl aliquot of the solution was injected on the HPLC column. The average peak height of at least two injections was measured and linear calibration curves were found in the range 10–120 μg and 10–80 μg of copper and nickel, respectively, in the original solution. The relative standard deviation of six replicates was found to be within $\pm 2.6\%$. The detection limits were found to be 20 ng (copper) and 40 ng (nickel) in an aliquot, when the complexes were extracted in 1 ml of cyclohexane and 0.5 ml of the extract was evaporated, the complexes were redissolved in 0.5 ml of methanol, and 4 μl of solution was injected at the optimized conditions of the HPLC determination.

Finally, in order to examine the use of the reagent for the determination of copper and nickel in samples, a coin, a nickel–aluminum

Table 1. Results of analysis of copper and nickel by RP-HPLC

Sample	Metal ion	Amount found by HPLC	Amount found by AA	Expected values
Copper coin	Copper	$54.1\% \pm 1.5\%$	$57.2 \pm 1\%$	—
Nickel–aluminum alloy	Nickel	$48.0\% \pm 1.0\%$	—	50%
Water sample from copper still	Copper	360 ± 12 μg/l	—	—
Water sample from metallic tank	Copper	182 ± 10 μg/l	—	—

alloy and water samples were analysed. The results in Table 1 are within the reasonable range of the expected values or those obtained by atomic absorption.

POLAROGRAPHIC ANALYSIS OF THE MIXED-LIGAND SYSTEM Cu(II)–GLYCINE–GLYCINATE

J. C. RODRIGUEZ PLACERES,* T. BORGES MIQUEL, G. RUIZ CABRERA and M. T. SANZ ALAEJOS

Departments of Physical Chemistry and Analytical Chemistry, University of La Laguna, Tenerife, Canary Islands, Spain

(*Received* 3 *April* 1989. *Revised* 31 *July* 1991. *Accepted* 27 *September* 1991)

Summary—The polarographic method has been applied to the study of the mixed-ligand system Cu(II)–glycine–glycinate, in aqueous medium, at $I = 1.0M$ ($NaClO_4$) and $25 \pm 0.1°$. The stabilization of the mixed complex $[CuG(G^-)]^+$ has been made clear and its stability constant ($\beta_{11} = 1 \times 10^9$) has been determined. The stability constants of the complexes $[CuG]^{2+}$ ($\beta_{10} = 17$), $[CuG_2]^{2+}$ ($\beta_{20} = 230$), $[Cu(G^-)]^+$ ($\beta_{01} = 2.1 \times 10^8$) and $[Cu(G^-)_2]$ ($\beta_{02} = 1.7 \times 10^{15}$) have also been calculated.

The general interest in the study of mixed complexes and metal ion–amino-acid complexes has been made clear.[1,2]

Earlier, we undertook determination of the stability constants of the complexes of Cu(II) with glycine (G) and glycinate (G^-),[3] and clearly showed the increased stabilization by co-ordination of two ligands: $[CuG]^{2+}$ ($\beta_{10} = 59$), $[CuG_2]^{2+}$ ($\beta_{20} = 510$) and $[Cu(G^-)_2]$ ($\beta_{02} = 1.7 \times 10^{15}$).

In that paper,[3] studying the system Cu(II)–glycinate ion, the value for β_{01} obtained from the ordinate by extrapolation of $B' = \beta_{01} + \beta_{11} G_T$ was of the order of 10^{12}, much greater than the mean value reported in the literature, 1.8×10^8, and leading to an abnormally high value many orders of magnitude greater than the value predicted from the equations due to Watters and DeWitt[4] which would be 10^9. This surprising discrepancy required, on the one hand, ratification with further complementary studies, and on the other, determination of the stability constant of the mixed-ligand complex $[CuG(G^-)]^+$ under different experimental conditions.

Morever, our work on determination of the free concentration of ligands[5,6] induced a critical review of the proposed values for the stability constants of the complexes formed with the undissociated amino-acids.

The object of this work was to throw more light on these aspects of the equilibria in the Cu(II)–glycine–glycinate system.

*Author for correspondence.

EXPERIMENTAL

A Metrohm E506 polarograph and E505 polarographic stand were used in recording i–E curves. A saturated calomel electrode and a platinum electrode were employed as the reference and auxiliary electrodes, respectively. The temperature was always $25 \pm 0.1°$ and the drop time was set at 3 sec. The ionic strength was maintained constant at $1.0M$ by addition of sodium perchlorate. The pH measurements were made with a Radiometer pHM84 digital pH-meter and a GK2401C combination electrode. For five studies at variable pH the metal concentration was $1 \times 10^{-5}M$; for the three studies at constant pH, it was $1 \times 10^{-4}M$.

The cupric perchlorate was prepared beginning from cupric oxide and perchloric acid, both Merck p.a., and was standardized complexometrically; the glycine and sodium perchlorate were also Merck p.a.

The values taken for the acidity constants[7] were $pK_{a1} = 2.36$ and $pK_{a2} = 9.56$.

THEORY

If the molecule of neutral glycine (G) and the glycinate ion (G^-) are considered to be possible ligands of Cu(II), the Schaap and McMasters[8] F_{00} function will be developed as follows:

$$F_{00} = \{1 + \beta_{10}[G] + \beta_{20}[G]^2\} + \{\beta_{01} + \beta_{11}[G]\}[G^-] + \{\beta_{02}\}[G^-]^2 \quad (1)$$

Since the Cu(II)–glycinate system was studied by varying the pH of the initial solution in a range where $G_T = [G] + [G^-]$ is fulfilled

(G_T = total glycine concentration), then by substitution in (1) and rearranging, we obtain

$$F_{00} = \{1 + \beta_{10}G_T + \beta_{20}G_T^2\} + \{-\beta_{01} - 2\beta_{20}G_T + \beta_{01} + \beta_{11}G_T\}[G^-] + \{\beta_{20} - \beta_{11} + \beta_{02}\}[G^-]^2 \quad (2)$$

and if we bear in mind that β_{10} and β_{20} are negligible relative to both β_{01} and β_{02}, and that all the other constants are also negligible relative to β_{02}, then

$$F_{00} = \{1 + \beta_{10}G_T + \beta_{20}G_T^2\} + \{\beta_{01} + \beta_{11}G_T\}[G^-] + \{\beta_{02}\}[G^-]^2 \quad (3)$$

Therefore:

$$F_{00} = A' + B'[G^-] + C'[G^-]^2 \quad (4)$$

and A′, B′ and C′ can be calculated in the usual way.

The C' values will be those of β_{02}, and those of B' will enable the stability constants of the complexes $[Cu(G^-)]^+$ and $[CuG(G^-)]^+$ to be determined.

Certain studies were made at constant pH but with modification of the total concentration of amino-acid so that [G] and [G⁻] vary with G_T. At these low values of pH it is to be expected that the high concentration of the undissociated amino-acid relative to that of the glycinate ion largely compensates for the much lower stability constants of its copper complexes and that these can be determined. Bearing in mind the expression for K_{a2}, equation (1) can be transformed into:

$$F_{00} = 1 + \{\beta_{01}(K_{a2}/[H^+] + \beta_{10}\}[G] + \{\beta_{02}(K_{a2}/[H^+])^2 + \beta_{11}(K_{a2}/[H^+]) + \beta_{20}\}[G]^2 \quad (5)$$

Table 1. Cu(II)–glycinate–$NaClO_4$ system: range of concentrations of the different species

Study	pH limits	G_T, 10^{-2}M	[G⁻], 10^{-3}M	[G] 10^{-2}M
I	7.01_5/7.87	9.98/9.86	0.283/1.974	9.96/9.67
II	7.05/9.10	9.97/9.42	0.307/24.25	9.93/6.99
III	7.10_5/8.23	49.7/47.6	1.737/21.26	49.5/45.5
IV	6.65_5/7.43	74.8/73.2	1.031/5.386	74.7/72.7
V	6.65/7.71	99.5/96.6	1.223/13.45	99.4/95.2

and, since pH = constant, we can write

$$F_{00} = 1 + B''[G] + C''[G]^2 \quad (6)$$

where B'' and C'' can be calculated in the usual way and will enable all the constants of the complexes to be determined, if the different values of pH are known.

On the other hand if the pH required is very low, the concentration of the glycinium ion, HG^+, may be high and even modify the ionic strength. This effect can be minimized by decreasing G_T as required.

RESULTS AND DISCUSSION

Cu(II)–glycinate system

The five studies were made with variation of the pH of an initial solution, and thus the concentration of the different forms of glycine between the limits indicated in Table 1.

For every solution studied, the polarograms showed good symmetry and a regular outline, and reduction by a reversible two-electron process was indicated by the plots of $\log[(\bar{i}_d - \bar{i})/\bar{i}]$ *vs.* $-E$. The plot of F_{01} *vs.* [G⁻] was a straight line, Fig. 1, which ratifies the theoretical approach and allows B' and C' to be obtained, by a least-squares method; the values are presented in Table 2.

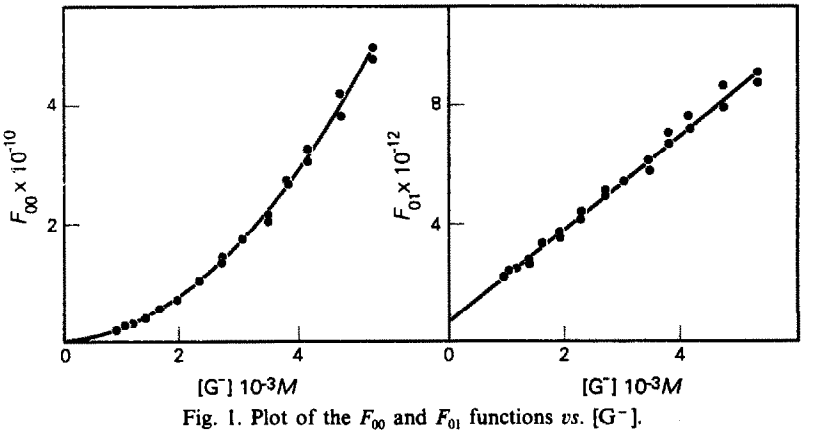

Fig. 1. Plot of the F_{00} and F_{01} functions *vs.* [G⁻].

Table 2. Cu(II)–glycinate–$NaClO_4$ system: values of B' and C'

Study	B'	C'
I	1.77×10^{11}	1.93×10^{15}
II	4.23×10^{11}	1.96×10^{15}
III	5.36×10^{11}	1.55×10^{15}
IV	6.93×10^{11}	1.57×10^{15}
V	10.25×10^{11}	1.67×10^{15}

The good concordance between the values of C' indicates the goodness of the determinations and of the stability constant calculated therefrom: $\beta_{02} = 1.7 \times 10^{15}$. This value is in good agreement with those obtained potentiometrically by Mercier and Pâris[9] ($\beta_{02} = 1.6 \times 10^{15}$) and spectrophotometrically by Mercier *et al.*[10] ($\beta_{02} = 1.9 \times 10^{15}$) under the same conditions of ionic medium and temperature.

The B' values of the order 10^{11}–10^{12}, much higher than β_{01}, ratified our preceding results and observations, and indicated the suitability of examining the mixed-ligand complex $[CuG(G^-)]^+$ under different experimental conditions, *viz.* at low pH.

Mixed-ligand Cu(II)–glycine–glycinate system

Three studies of this system, at constant pH and variation of the total concentration of glycine between the limits indicated in Table 3, were made.

The polarograms showed good symmetry and regular outline, for all the solutions studied, and the logarithmic plots revealed that a two-electron reduction was involved. Beginning from the reversible asymptote, the reversible half-wave potentials were determined.

Table 3. Cu(II)–glycine–glycinate–$NaClO_4$ system: range of concentrations of the different species

Study	pH	G_T, M	$[G^-]$, 10^{-8}M	[G], 10^{-2}M
VI	$3.23_5/3.21$	0.1/1.0	4.10/38.42	8.67/86.03
VII	3.29/3.27	0.1/1.0	4.79/39.57	8.92/86.33
VIII	3.30/3.29	0.2/1.0	9.80/46.53	17.84/86.44

Study	Mean pH	B''	C''
Ref. 3	2.87	58.7	—
Ref. 3	2.87	59.2	498
Ref. 3	2.87	59.1	526
VI	3.22	115.1	965
VII	3.26	110.1	1209
VIII	3.29	133.5	1266

The plots of F_{00} and F_{10} *vs.* concentration of glycine are shown in Fig. 2. The values of B'' and C'' were obtained by least-squares, and are shown in Table 4 together with those of our earlier[3] paper.

From the plot of B'' *vs.* $K_{a2}/[H^+]$ in Fig. 3, $\beta_{10} = 17$ and $\beta_{01} = 2.1 \times 10^9$ were obtained by least-squares. The good concordance between these and the values reported in the literature[3,11,12] is noteworthy.

From equation (5) it can be proved that the plot of $C'' - \beta_{02}\,(K_{a2}/[H^+])^2$ *vs.* $K_{a2}/[H^+]$ must be a straight line, with intercept β_{20} and slope β_{11}. Least-squares treatment of this dependence, Fig. 4, gives $\beta_{20} = 230$ and $\beta_{11} = 1 \times 10^9$. The value of β_{11} is in acceptable agreement with the only two literature values:[13,14] 7.6×10^8 and $(0.92\text{–}2.5) \times 10^9$.

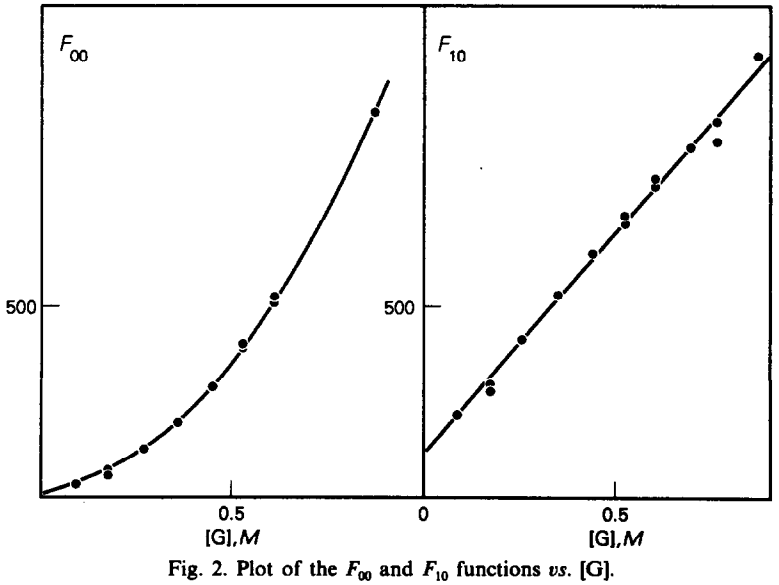

Fig. 2. Plot of the F_{00} and F_{10} functions *vs.* [G].

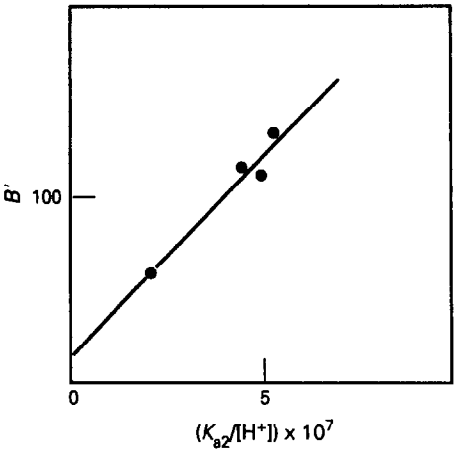

Fig. 3. Plot of B″ *vs.* $(K_{a2}/[H^+])$.

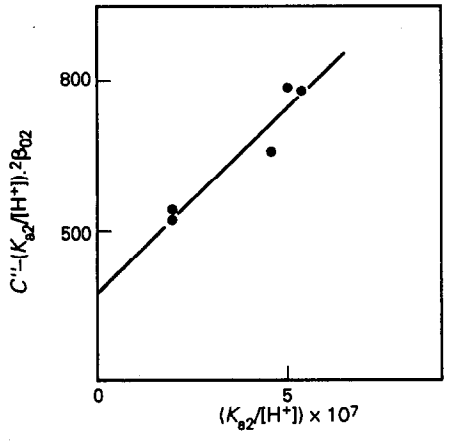

Fig. 4. Plot of $C'' - (K_{a2}/[H^+])^2\beta_{02}$ *vs.* $(K_{a2}/[H^+])$.

The value determined for β_{11}, and its concordance with the reported data in the literature and with that statistically predictable from the Watters and DeWitt's equation[4] ($\beta_{11} = 1.3 \times 10^9$), cast doubt on the abnormally high value obtained from the B' data[3] at high pH, $\beta_{11} \simeq 10^{12}$.

The resolution of these unexpected discrepancies is being further investigated.

ANIONIC RESPONSES OF ELECTROCHEMICALLY SYNTHESIZED POLYPYRROLE FILMS

AODHMAR CADOGAN,* ANDRZEJ LEWENSTAM and ARI IVASKA†
Laboratory of Analytical Chemistry, Åbo Akademi University, SF-20500 Turku-Åbo, Finland

(*Received* 23 *September* 1991. *Revised* 13 *November* 1991. *Accepted* 14 *November* 1991)

Summary—Conducting polypyrrole films with thickness of about 8 μm were prepared on platinum by continuous scanning in 0.1*M* pyrrole and 0.1*M* electrolyte (LiCl, $LiBF_4$ or $NaBF_4$). Scan-rates of 10, 20 and 50 mV/sec with scan-times of 30, 45 and 60 min were used. The potentiometric response of the films was tested over a range of anions. Films were found to be anion-sensitive but very non-selective. The influence of the doping cation was also investigated.

Progress continues into the development and investigation of electrodes incorporating modified membranes capable of sensing ions, molecules and large biomolecules. These sensing devices and in particular those sensitive to small ions (Ion–Selective Electrodes) have found wide applications in the industrial, clinical, environmental and pharmaceutical areas. Since the introduction of organic conducting polymers and in particular electrochemically synthesized polymers such as polypyrrole and polyphenylene, first reported by Diaz and coworkers,[1] numerous publications have appeared on the subject.[2–6] While the primary interest has been in the use of these polymers as charge storage materials[7] and electrochromic devices,[8] they can also function as organic electrode materials[9] and protecting films on semiconductor devices to prevent photocorrosion.[10]

Several papers have emerged describing the use of modified conducting polymers as gas sensors,[11–13] for immobilization of enzymes[14,15] or even as a method of pH control.[16] Ikarijama *et al.*[17] reported the use of polypyrrole as a detector for anions in a FIA system based on the doping effect of anions in the flowing stream on a polypyrrole film held at its doping potential. Dong *et al.* have reported chloride and perchlorate sensors also based on polypyrrole.[18,19]

Even though the practical process in performing electrochemical polymerization is straightforward and simple, the chemical processes leading to film formation are complicated and therefore the nature of the resulting film and its response are ultimately affected by many factors such as solvent, impurities in the solvent, temperature, applied potential, electrode substrate and the type and concentration of the doping salt. We describe here the electrochemical preparation of thick polypyrrole layers on platinum with three commonly used doping salts and we report the performance of the various films as potentiometric anion sensors.

EXPERIMENTAL

Reagents

Pyrrole (Py) obtained from Merck was purified by double distillation and stored at low temperature protected from light. Analytical grade reagent salts obtained from Merck and Fluka were used without further purification and dissolved in distilled, demineralized water.

Apparatus

A Princeton Applied Research Corporation model 273 Potentiostat/Galvanostat with software version 2.00 was used for the electrochemical polymerizations and cyclic voltammetry. The potentiometric measurements of the polypyrrole films were performed with an Orion Research Expandable Ion Analyser EA 940 in conjunction with an Orion Ag/AgCl reference electrode. A Perkin–Elmer 56 pen recorder was used for the traces. The electrochemical cell was a conventional three electrode system. The working electrode was a platinum 3-mm diameter disc electrode. The counter electrode was a glassy-carbon rod and the reference electrode

was aqueous Ag/AgCl satd. KCl. All electrodes were from Metrohm. The platinum surface was polished to a mirror finish with 1-μm diamond paste followed by 0.3 μm aluminium oxide paste. All solutions were degassed by bubbling with high purity nitrogen and all electropolymerizations were performed under nitrogen. The scanning electron microscope (SEM) measurements were done with a Cambridge Instruments Stereoscan 360.

Polypyrrole film preparation

Polypyrrole (PPy) films were prepared by continuous scanning in 0.1M pyrrole and 0.1M electrolyte aqueous solutions from 0.0 to 1.0 V. Three different salts (LiCl, $LiBF_4$ and $NaBF_4$) were used as the doping electrolytes. PPy films were synthesized with scan-rates of 10, 20 and 50 mV/sec and scanning times of 30, 45 and 60 min were used. The films were activated by soaking in 0.1M solutions of the doping salt for at least three hours after preparation to allow the films to reach a stable rest potential. The potentiometric response of each electrode was recorded after 6 min. In some cases the potential of the electrode continued to drift beyond that period and when they showed no indications of stabilizing a reading, no stable potentiometric response (npr) was recorded. Scanning electron microscope (SEM) measurements of films formed at 20 mV/sec for 45 min with 0.1M $NaBF_4$ as the doping salt showed an average film thickness of 7–8 μm with a slight thickening of the film at the outer edges 10–11 μm.

RESULTS AND DISCUSSION

Table 1 shows the slopes of the potentiometric responses of the PPy film electrodes to the small Cl^- anion and the larger BF_4^- anion recorded in the concentration range of 0.1–0.001M. In each case the cation is the same as the one used in the electropolymerization. The error in the slopes given in Table 1 varies in the range of 0.1–4.0 S.D. units. This error can be regarded to be very high and is a direct reflection of the difficulty in making reproducible films. The linear range for electrodes incorporating the BF_4^- doping anion was 10^{-1}–$10^{-3}M$ and somewhat better for elec-

Table 1. Response slopes of polypyrrole film electrodes in solutions of chloride and tetrafluoroborate, 0.001–0.1M, in each case the potentials were recorded with the same cation as used in the synthesis. Equilibration time in each solution was 6 min

†npr = no stable potentiometric response.

trodes containing Cl^- as the anion, typically 10^{-1}–$10^{-4}M$. Membranes incorporating $NaBF_4$ tended to lose their potentiometric properties after 24–48 hr of continuous contact with the aqueous electrolyte but electrodes incorporating LiCl and $LiBF_4$ salts showed better stability with time.

The results in Table 1 indicate clearly that better slopes were observed for the smaller Cl^- than for the bigger BF_4^- anion. This is especially pronounced in the cases where Cl^- was used as the doping anion in preparing the film. It is obviously easier for the smaller Cl^- anion to be intercalated in the polymer film and to show an anionic potentiometric response when the film is in contact with the electrolyte solution.

Effect of scanning time/film thickness

The thicker films, formed at 45 and 60 min, showed stable responses to both chloride and tetrafluoroborate anions. With thinner films (<30 min scanning time) a Nernstian response was observed for a few minutes. This was then followed by drift of the potential at all concentration levels stabilizing at the rest potential of the PPy in the supporting electrolyte used. If scanning periods longer than 60 min were used, the polymer growth went beyond the platinum over the Teflon surround and the film became very brittle and difficult to remove intact from the platinum. If membranes were made too thick, they tended to lift off the platinum surface following long periods of soaking in aqueous solutions. This behaviour is obviously due to overoxidation of the polymer material which is an unavoidable result of long polymerization times in electrochemical synthesis of conducting polymers.

Effect of scan rate

As can be seen in Table 1, rather good responses to the anions studied were obtained with 20 mV/sec and 50 mV/sec scan-rates for the electropolymerization. The response was somewhat poorer when a 10-mV/sec scan-rate was used with having the same scan time.

Selectivity towards other anions

Figure 1 shows the absolute potentials of the response of electrode #21 in Table 1, prepared in $NaBF_4$, to other electrolyte solutions across the concentration range 10^{-1}–$10^{-4}M$. The electrode was soaked in a $0.01M$ solution of each interfering ion for 20 min before measuring the response. There is virtually no selectivity

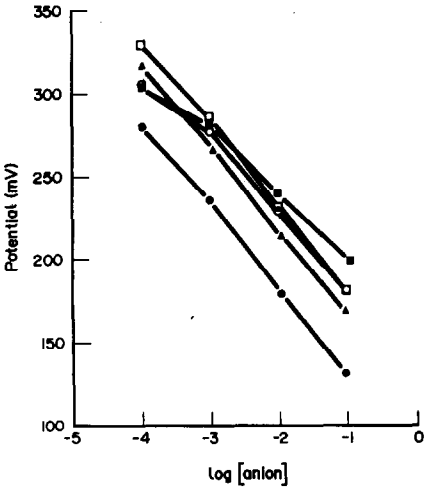

Fig. 1. Calibration curves for a PPy film electrode prepared in $0.1M$ pyrrole and $0.1M$ $NaBF_4$ with a 20-mV/sec scan-rate and a 60-min scan-time over the potential range 0.0–1.0 V. Response to sodium salts of —□— Cl^-, —○— ClO_4^-, —▲— NO_3^-, —■— BF_4^- and —●— SCN^- are shown. The equilibration time is 6 min for each solution. The electrode is soaked for 20 min in each new electrolyte before calibration.

between the various anions. The electrode responded well to Cl^-, ClO_4^-, NO_3^- and had a slightly poorer response to BF_4^- with some selectivity over SCN^-. Similar plots were obtained for PPy electrodes based on the LiCl and $LiBF_4$ doping salts.

Effect of doping anion and counter cation

Although many papers on the subject of conducting PPy films deal with the effect of the electrolyte on the morphology and the conductivity of the polymers very little attention has been given to the effect of the electrolyte on the potentiometric response of a polymer membrane. Table 2 shows a comparison of the responses in terms of slope for the three doping electrolytes (LiCl, $LiBF_4$ and $NaBF_4$) to various solutions of sodium and lithium salts. The errors in the values of the slopes are in the same range as the errors in Table 1. It should be emphasized that no thorough error analysis was done either for the values given in Table 1 or in Table 2. Due to the high errors involved it is more appropriate to follow the general trends shown by the films rather than the absolute values of the slopes. In practically all cases the PPy films responded better in the electrolyte containing the same cation as that used for the electrochemical synthesis. The size of the intercalating anion used in the electrochemical polymerization is known to affect

Table 2. Slopes (mV/decade) of polypyrrole electrodes formed by constant scanning in 0.1*M* pyrrole and 0.1*M* aqueous electrolyte solutions. Electrodes as in Table 1

Doping electrolyte		LiCl	$LiBF_4$	$NaBF_4$

SCN^-	Na^+	−52.5	−57.1	−53.1

the structure of the resulting polymer, but the cation seems to have some effect on the doping/undoping, in our study of the potentiometric, behaviour of the polymer film. No clear and definite explanation of this behaviour of the PPy film can be given at this stage. The same type of cation behaviour was also noted by Marque *et al.*[20] in their studies on the electrolyte effects of poly (3-methylthiophene) films.

CONCLUSIONS

Thick PPy films electropolymerized in LiCl, $LiBF_4$ and $NaBF_4$ display a potentiometric response to anions. In all cases the films responded better to the smaller chloride anion than the larger tetrafluoroborate anion. Of the three doping anion systems investigated, the best sensitivity to the BF_4^- anion was obtained with $NaBF_4$ as the doping salt. The thickness of the PPy film was found to be very important. In order to obtain stable potentiometric responses thicker films are required but at the same time overoxidation of the polymer material should be avoided. All the PPy membranes display a sensitivity to anions but from the selectivity data it can be seen that there is not much discrimination between the different anions. Although the responses of the films investigated were not exactly Nernstian nor selective enough to be used as individual "ions" sensors, the anionic responses of polypyrrole films may be exploited in other ways. The observed cationic sensitivity of the potentiometric response will make it even more difficult to make PPy membranes selective to individual anions due to the presence of cations in the sample solutions. Nevertheless success in preparing anion selective PPy membranes has been claimed earlier by one research group.[18,19]

One of the main advantages of conducting polymer membranes is that the conductivity/redox state at the bulk polymer can be externally controlled. They also possess other advantages such as insolubility in organic and inorganic solvents and low resistance and may find further use in the area of all solid state electrodes.

(*Received* 20 *August* 1991. *Revised* 28 *October* 1991. *Accepted* 29 *October* 1991)

Summary—The electrochemistry of gallium(III) perchlorate in dimethylsulfoxide (DMSO) and acetonitrile (MeCN) at a mercury drop electrode is described and compared to that in water. The reduction of 2,2′-bipyridine (DIPY) and its interaction with free protons in the solvents mentioned is also surveyed. The electrochemistry of tris-(2,2′-bipyridine) gallium(III) perchlorate was studied in DMSO and MeCN. A gallium metal deposit is obtained by reduction of the complex compound in the first solvent, whereas lower valence gallium–DIPY species are obtained in the second. The existence of different catalytic prepeaks in DMSO is described. The first catalytic peak, which renders a metal deposit, is studied in detail, together with the possible interference of oxygen and free protons. These studies serve the basis of future development of an analytical procedure for the determination of trace concentrations of gallium.

The electrochemical reduction of gallium(III) in acidic aqueous media is a highly irreversible process[1] which has challenged many authors in the past to seek conditions to lower its overpotential. Different supporting electrolyte compositions have been tried in polarographic studies[2] to obtain a reversible process. Of special interest are thiocyanate or salicylic acid-based electrolytes.[3]

A sodium thiocyanate electrolyte together with high sodium perchlorate concentration has proved to be effective in achieving a reversible reduction[4,5] and has been used in thorough studies of phase-selective anodic stripping analysis (PSAS) of trace concentrations of gallium.[6,7] The concurrent effects of SCN^-, high ionic strength and temperature indicate[2] the existence of a highly solvated (possibly polynuclear) ionic structure of aquo gallium(III) in acidic media which would be responsible for the irreversibility observed. The role of SCN^- could be considered in the light of ligand catalysis,[8] whereas the beneficial effect of sodium perchlorate has been attributed to sodium ion,[9] which has a role in determining the double layer structure and potential difference profile or favours the formation of ion pairs, which would facilitate the reduction of gallium(III). However, the high salt concentration required (4–6*M* sodium perchlorate) is a clear disadvantage when determining trace concentrations of gallium due to metal impurities introduced by the reagents. This effect is especially important in anodic stripping voltammetry where zinc can form an intermetallic compound[10] which precludes the detection of gallium below $2 \times 10^{-7}M$.

In the present work we explore the possibility of using non-aqueous media (DMSO and MeCN) and organic ligands in lower concentration to obtain electrocatalytic reduction of gallium(III). The exclusion of water, the adsorption of the ligand on the mercury electrode surface and its ability to act as a charge transfer bridge should contribute to a more facile and reversible process.

2,2′-Bipyridine fulfils all the ligand requirements and is therefore our first choice. Its electrochemistry and metal complex compounds in water have been reviewed[11] and it has been used in the determination of cobalt by a.c. polarography, based on catalytic reduction in acetate–ammonia buffer.[12] It is also known to form a stable gallium(III) complex.[13]

Our results in DMSO show the existence of a catalytic process which could be the basis for developing analytical procedures to determine

gallium, using either the cathodic or the anodic process.

EXPERIMENTAL

Instrumentation

The cyclic voltamperograms were obtained with an EG & G Princeton Applied Research polarographic analyzer model 384B provided with a 303A static mercury drop electrode (HMDE), a Houston Instrument model DMP-40 plotter, glass cells and a silver/silver chloride reference electrode filled with an aqueous tetramethyl ammonium chloride (TMACl) solution. The TMACl concentration was adjusted so that the reference electrode potential was that of a saturated calomel electrode (SCE). Ring-disc electrode voltamperograms were obtained with a Pine Instruments Company ASRE rotator provided with a GC ring–GC disc (GC: glassy carbon) electrode tip (disc radius, $r_1 = 0.382$ cm, inner ring radius, $r_2 = 0.416$ cm, outer ring radius, $r_3 = 0.556$ cm, collection efficiency $N = 0.418$) controlled by an ASR speed control. Potential control was provided by a model RDE 3 bipotentiostat. Voltamperograms were recorded on a Hewlett Packard measurement plotting system model HP 7090 A.

Chemicals

Acetonitrile (MeCN, >99% purity) and dimethylsulfoxide (DMSO, >99% purity) were from Aldrich. Tetraethyl ammonium perchlorate (TEAP) used as supporting electrolyte was made by neutralization of 20% (w/w) aqueous solution of tetraethyl ammonium hydroxide (Aldrich) with 70% perchloric acid ("Baker Analyzed", J. T. Baker Chemical Company) and recrystalization from absolute ethanol (Merck, *p.a.*). Gallium(III) perchlorate [$Ga(ClO_4)_3.6H_2O$] was prepared by dissolving 6*N* gallium metal (Strem chemicals) in 70% perchloric acid ("Suprapur" Merck) following a known procedure.[14] The tris-(2,2′-bipyridine) gallium(III) perchlorate [$Ga(DIPY)_3(ClO_4)_3$] was synthesized by reaction of $Ga(ClO_4)_3$-$6H_2O$ with 2,2′-bipyridine (DIPY) (Aldrich) in absolute ethanol following a known procedure.[13] Solutions were degassed with high purity argon (INDURA). High purity distilled water[15] was used when required.

All stock solution volumes were delivered with Gilson Pipetman micropipettes (models P20 and P200).

Procedure

The required amount of TEAP, $Ga(ClO_4)_3$-$6H_2O$, $Ga(DIPY)_3(ClO_4)_3$, and DIPY were weighed out directly into the cell, and 10 ml of the appropriate solvent were added, before each cyclic voltammetry experiment. When studying the [DIPY]:[Ga] ratio, a 0.1*M* DIPY stock solution in MeCN was used. Calibration plots were obtained by adding increasing amounts of a 1×10^{-2} or $4 \times 10^{-2}M$ $Ga(DIPY)_3(ClO_4)_3$ stock solution in DMSO. When studying the effect of free protons, a tritrated 0.48*M* perchloric acid stock solution in 50% MeCN + 50% DMSO was used. (Warning: concentrated perchloric acid and DMSO form an explosive mixture, therefore it is advisable to dilute perchloric acid with MeCN first, and then complete to the final volume with DMSO).

RESULTS AND DISCUSSION

Electrochemistry of gallium(III); solvent effect

The irreversible reduction of gallium perchlorate in aqueous sodium perchlorate solution is illustrated by the cyclic voltamperogram in Fig. 1(a). A single three-electron cathodic peak is observed at −1.6 V, which can overlap with two less distinct cathodic peaks (not shown) at less negative potentials, if gallium(III) has hydrolyzed to any extent before the experiment. The relative heights of these cathodic peaks are

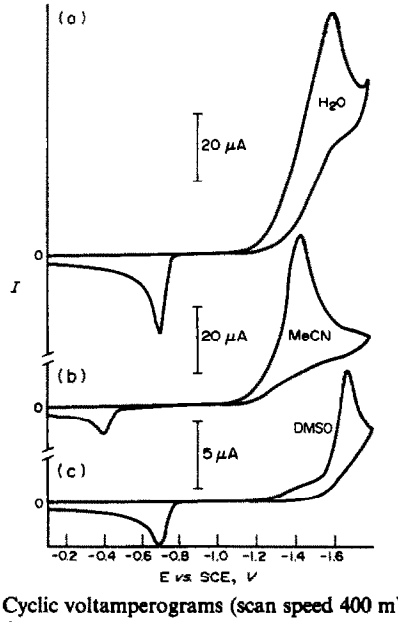

Fig. 1. Cyclic voltamperograms (scan speed 400 mV/sec) of $2 \times 10^{-3}M$ $Ga(ClO_4)_3.6H_2O$ at a HMDE in different solvents: 0.6*M* aqueous $NaClO_4$ pH 2.2 (a); 0.1*M* TEAP, MeCN (b); 0.1*M* TEAP, DMSO (c).

pH dependent and are attributed to the presence of different polynuclear hydroxylated gallium(III) species.[2] A single anodic peak is observed at −0.7 V on the reverse scan, which is due to the stripping of gallium deposit to produce gallium(III), as one can infer from its shape, peak potential and anodic stripping experiments (its height increases linearly with deposition time).

The ratio of anodic/cathodic peak currents increases when decreasing the scan speed, as would be expected for a metal deposit, but the ratio of anodic/cathodic charge (measured at 10 mV/sec) is unity. This is consistent with an overall electrode reaction

$$Ga(III) + 3e^- \xrightarrow{(Hg)} Ga(Hg)_x$$

The cathodic peak current has a linear dependence on $v^{1/2}$, and $\Delta E_p = E_{p,a} - E_{p,c}$ is a function of scan speed v.

If the sodium perchlorate supporting electrolyte is replaced by TEAP, no gallium(III) reduction is observed before the solvent cathodic limit. The addition of sodium perchlorate after adding TEAP produces a well-defined cathodic peak at a more negative potential than with pure sodium perchlorate. Sodium ion has been suggested[9] to have an important role by determining the structure of the double layer and potential difference profile or by favouring the formation of ion pairs. This would facilitate the reduction of gallium(III) in water.

The behaviour of gallium(III) in MeCN is shown in Fig. 1(b). The cathodic peak is shifted to −1.4 V, whereas the anodic peak is observed at −0.4 V. The cathodic peak current increases linearly with v rather than $v^{1/2}$. The ratio of anodic/cathodic charges is less than one, even at low scan speed. This, together with changes in peak shape (at 1000 mV/sec), splitting (at 50 mV/sec) and formation of small bumps on the reverse scan, suggests a change in the reaction mechanism which may involve stabilization and adsorption of lower oxidation state gallium species.

The shift of peak potentials observed is attributed to the lower solvating power of this solvent as compared to water. Labilization of the polynuclear hydroxylated gallium(III) species would facilitate its reduction while on the reverse process, dissolution of gallium metal would be less favoured in a less-solvating media.

Figure 1(c) shows the redox behaviour of gallium(III) in DMSO. The cathodic peak potential is only slightly negative to that in water while the anodic peak potential is coincident. The cathodic peak current increases linearly with $v^{1/2}$ at lower scan speed while it increases linearly with v at higher scan speed. The ratio of anodic/cathodic charge is close to unity at low scan speed whereas the magnitude of the cathodic peak current is significantly lower than in the two previous solvents. DMSO is closer to water in solvating power than MeCN. This explains the small or nil potential shifts observed. However, its viscosity is clearly higher than that of the other two solvents, what accounts for the smaller currents observed. The effect of voltage scan-rate on the cathodic peak is indicative of a reaction mechanism more similar to that in aqueous media.

The presence of sodium ion is not essential to facilitate the gallium(III) reduction in both aprotic solvents.

One can conclude from these experiments that changing from aqueous to non-aqueous solvents is not sufficient to obtain a reversible reduction. Also small amounts of water, either present in the solvents or incorporated as hydration water by the $Ga(ClO_4)_3 \cdot 6H_2O$, may still remain strongly bound to the gallium(III) so that the energy barriers for metal reduction are still very high.

Electrochemistry of DIPY; solvent effect and catalytic proton reduction

The electrochemical activity of the ligand DIPY is also influenced by the solvent. Figure 2(a) shows the cyclic voltamperogram of DIPY in DMSO. The first cathodic peak at −2.14 V is a reversible process. Its peak current increases linearly with $v^{1/2}$ and a corresponding anodic peak is observed on the reverse scan. This is a one-electron process that involves the reduction of the aromatic ring.

$$DIPY + e \rightleftharpoons DIPY^-$$

The second cathodic peak at −2.57 V has no anodic peak associated on the reverse scan. Its height is twice that of the first peak and increases linearly with $v^{1/2}$ only at very low scan speeds. The peak potential becomes more negative when increasing the scan-rate.

This suggests a two-electron process followed by a chemical step:

$$DIPY + 2e \rightarrow DIPY^{2-}$$

$$DIPY^{2-} + 2H^+ \rightarrow DIPYH_2$$

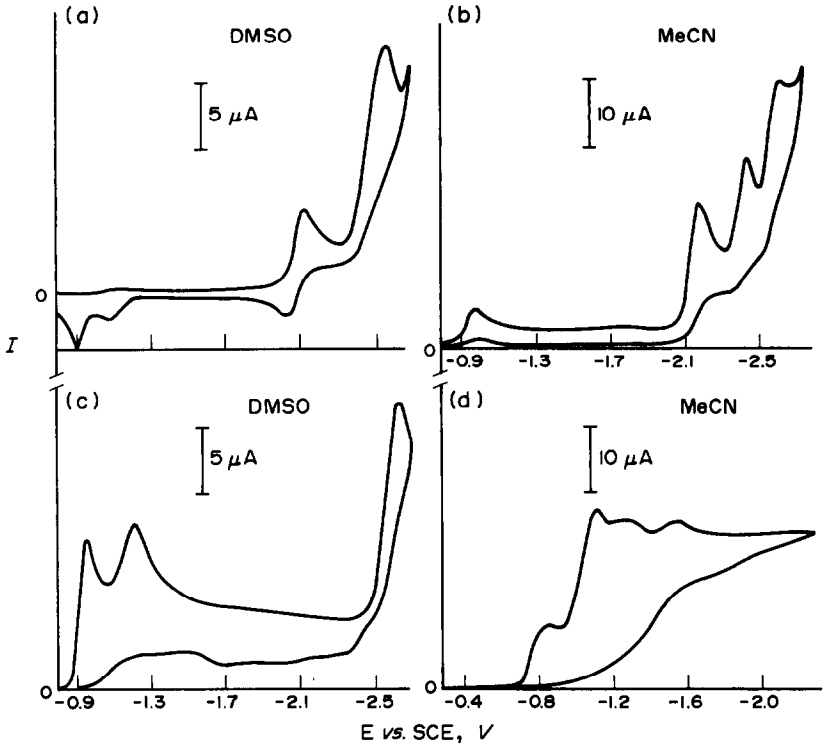

Fig. 2. Cyclic voltamperograms (scan speed 200 mV/sec) of $2 \times 10^{-3}M$ DIPY ($0.1M$ TEAP) at a HMDE in DMSO (a) and MeCN (b). Effect of protons (added as $HClO_4$) is shown for $2 \times 10^{-3}M$ DIPY, $8.4 \times 10^{-3}M$ $HClO_4$ (c) and $5 \times 10^{-3}M$ DIPY, $4.8 \times 10^{-3}M$ $HClO_4$ (d).

The highly reactive dianion reacts with protons from traces of water present in the solvent.[10]

A different behaviour is observed in the less solvating MeCN. Figure 2(b) shows the cyclic voltamperogram, with three equal height cathodic peaks at -2.17, -2.43 and -2.62 V. None of them shows an associated anodic peak on the reverse scan. Their heights increase linearly with $v^{1/2}$ only in a limited scan speed range in the lower end, and their potentials shift negatively with increasing scan-rate. The lower stability of anion radicals in this solvent as compared to DMSO suggests a different reaction mechanism involving three one-electron reduction steps which produce non-oxidizable species that cannot be detected on the reverse scan:

$$\text{DIPY} + \text{H}^+ + e \rightarrow \text{DIPYH} \qquad Ep = -2.17\ \text{V}$$

$$\left.\begin{array}{l}\text{DIPYH} + e \rightarrow \text{DIPY}^- + \text{H}^\cdot \\ (2\text{H}^\cdot \rightarrow \text{H}_2)\end{array}\right\} \qquad Ep = -2.43\ \text{V}$$

$$\left.\begin{array}{l}(\text{DIPY}^- + \text{H}^+ \rightarrow \text{DIPYH}) \\ \text{DIPYH} + \text{H}^+ + e \rightarrow \text{DIPYH}_2\end{array}\right\} \qquad Ep = -2.62\ \text{V}$$

The proton source is the residual water present in the solvent.

The anodic peaks at -1.1 and -0.9 V observed in DMSO are not observed in MeCN and can be attributed to the stepwise (one electron each) oxidation of the final product $DIPYH_2$. The higher solvating power of DMSO would favour those processes, by better solvation of the resulting protons, while in MeCN these oxidations are out of the potential span available with the 384B.

The addition of free protons (as perchloric acid) has a different effect on the electrochemistry of DIPY in both solvents. Figure 2(c) shows the observed behaviour in DMSO. The two initial cathodic peaks at -2.14 and -2.57 V are replaced by a single irreversible peak at a slightly more negative potential (-2.64 V) with a height corresponding to a two-electron process. At the same time, two new cathodic peaks with no associated anodic peaks on the reverse scan emerge at -0.96 and -1.21 V. The more negative peak increases with proton concentration, and its peak potential is coincident with that of the reduction of free protons in this solvent. The less negative peak increases with

DIPY concentration. These peaks are associated with the processes:

$$2H^+ + 2e \rightarrow H_2 \qquad Ep = -1.21\ V$$

$$\left.\begin{array}{l} H^+ + e \rightarrow H^{\cdot} \\ H^{\cdot} + DIPY \rightarrow DIPYH \end{array}\right\} Ep = -0.96\ V$$

Figure 2(d) shows the observed behaviour in MeCN. The three initial cathodic peaks are completely suppressed by excess protons. New cathodic peaks are observed at −0.84, −1.12, −1.27 and −1.56 V with no associated anodic peaks on the reverse scan.

The −0.84 V peak increases with DIPY concentration while the −1.12 V peak increases with proton concentration. These two are associated with the reduction of free protons, which is now observed at less negative potentials because of the lower solvating power of MeCN as compared to DMSO.

$$2H^+ + 2e \rightarrow H_2 \qquad Ep = -1.12\ V$$

$$\left.\begin{array}{l} H^+ + e \rightarrow H^{\cdot} \\ H^{\cdot} + DIPY \rightarrow DIPYH \end{array}\right\} Ep = -0.84\ V$$

The other two cathodic peaks observed in MeCN, but not in DMSO, are attributed to the reduction of protonated DIPY species which can exist in MeCN but not in DMSO due to the higher solvating power of the latter on the protons present.

$$DIPYH_2^{2+} + e \rightarrow DIPYH_2^{+} \qquad Ep = -1.27\ V$$

$$DIPYH_2^{+} + e \rightarrow DIPYH_2 \qquad Ep = -1.56\ V$$

Electrochemistry of $Ga(DIPY)_3(ClO_4)_3$ and solvent effect

A cyclic voltamperogram obtained in DMSO is shown in Fig. 3(a). Cathodic peaks at −1.16, −1.30, −1.50, −1.69 and −1.85 V are observed on the forward scan. When solid $Ga(DIPY)_3(ClO_4)_3$ is added directly into DMSO, a gradual increase of the −1.69 V peak is observed during the first few scans. This peak potential is coincident with that observed for $Ga(ClO_4)_3 \cdot 6H_2O$ in this solvent as shown in Fig. 1(c) and is less pronounced in a dryer DMSO, which suggests that some degree of ligand substitution by solvent or residual water has occurred upon dissolution. The other cathodic peaks are of equal height at this scan speed (200 mV/sec). When increasing the $Ga(DIPY)_3(ClO_4)_3$ concentration, the first reduction peak at −1.16 V increases and shifts

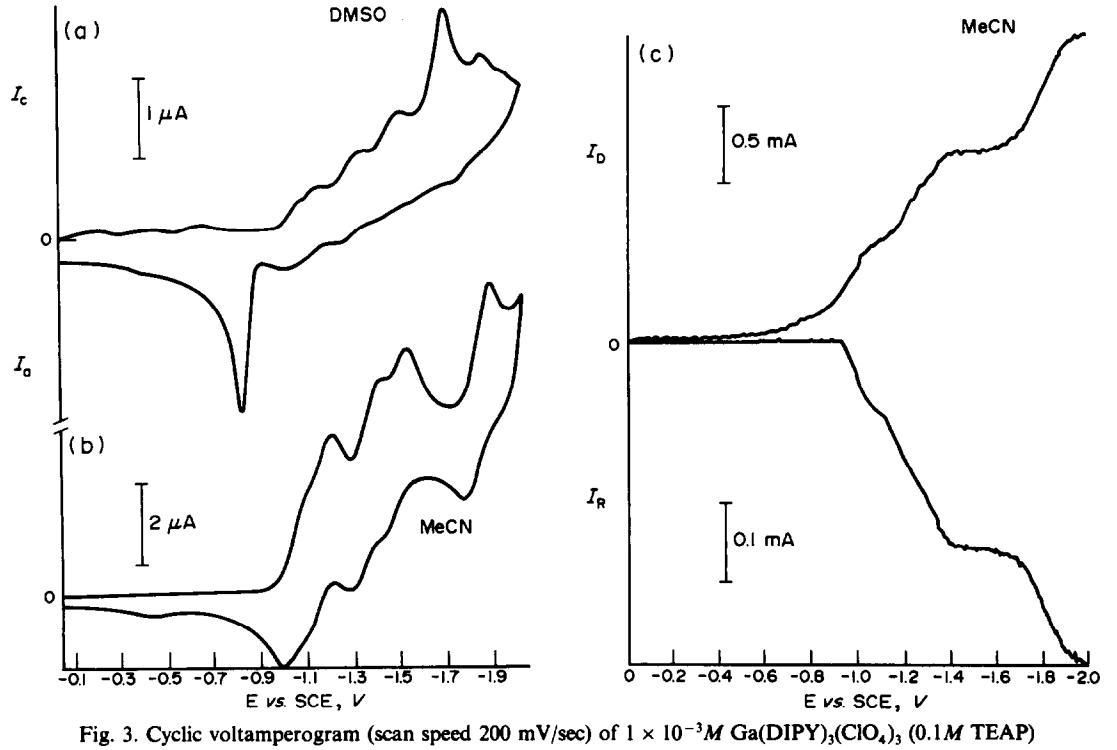

Fig. 3. Cyclic voltamperogram (scan speed 200 mV/sec) of $1 \times 10^{-3} M$ $Ga(DIPY)_3(ClO_4)_3$ (0.1 M TEAP) at a HMDE in DMSO (a) and MeCN (b). Rotating(GC)ring–(GC)disc electrode voltamperogram (2000 rpm; $E_R = 0.000$ V) of the same solution in MeCN; upper curve, reduction at the disc electrode; lower curve, oxidation at the ring electrode (c).

negatively, but it is gradually replaced by a more positive reduction peak. The relative heights of all the reduction peaks change with concentration, as if different species in equilibrium were involved; they become more distinct and their peak potentials gradually shift negatively.

While these peaks become more important, the -1.69 V peak decreases as the scan speed decreases. This is consistent with the existence of different Ga–DIPY species being reduced at different electrode potentials and the rather slow equilibrium displacement between the Ga–DIPY species as they are consumed by the electrode reaction.

On the reverse scan, a single important anodic peak is observed at -0.82 V which is about 0.12 V more negative than the gallium stripping peak observed for $Ga(ClO_4)_3 \cdot 6H_2O$ in DMSO as shown in Fig. 1(c). The -0.82 V peak corresponds to the dissolution of the gallium deposit facilitated by DIPY complexing of the resultant soluble species.

Different scan reversal potentials were tested, coming immediately after each of the cathodic peaks described. A clear gallium stripping peak was obtained for all the cases.

The electrochemical behaviour in MeCN shown in Fig. 3(b) is completely different. Comparatively higher currents are obtained as a result of higher diffusion coefficients in this less viscous solvent. All the cathodic peaks but that at -1.69 V obtained in DMSO are also observed in MeCN. This is an indication that ligand substitution has not occurred upon dissolution of the solid $Ga(DIPY)_3(ClO_4)_3$ in this solvent.

On the reverse scan, clear distinct anodic peaks associated with each of the corresponding cathodic peaks described are observed, but, except for a small bump at -0.4 V, no gallium deposit stripping peak is obtained.

This is consistent with the generation of a lower oxidation state gallium–DIPY species of different metal:ligand ratios at each cathodic peak, which are stable in this solvent to the point of being detected on the reverse scan and to hinder further reduction to gallium metal.

The generation of soluble species was confirmed from rotating ring-disc collection efficiency experiments carried out on a GC–GC electrode since the voltammetric behaviour was the same as at a mercury electrode in this solvent. Figure 3(c) shows different species that are detected at the ring (held at $E_d = 0.000$ V) while the disc is scanned negatively. For each reduction wave at the disc, a corresponding oxidation wave is obtained at the ring. The reduction at -0.75 V, which shows no oxidation current at the ring, is due to residual oxygen. The corresponding superoxide ion is not detected because of its reaction with the gallium species, which also explains the collection efficiencies observed below the theoretical value.

From these experiments, one can conclude that a ligand catalysed reduction of gallium(III) to gallium metal can be obtained with DIPY in DMSO but not in MeCN. The role of solvent can be understood by the ability of DMSO to displace DIPY from the coordination sphere, producing species with less steric hindrance, which can better approach the electrode surface either to be adsorbed or coordinate with adsorbed DIPY. Electron bridging through adsorbed DIPY would facilitate the gallium(III) reduction to gallium metal.

The electrochemical activity of this ligand is observed at more negative potentials, as shown in Fig. 2, but the presence of protons can interfere.

First cathodic peak of $Ga(DIPY)_3^{3+}$ in DMSO

The overall reaction for this peak produces a gallium deposit which is clearly observed on the reverse scan of a cyclic voltamperogram. When increasing scan speed, a negative shift of the cathodic peak potential and a gradual distortion are obtained, whereas the anodic peak does not shift. The reaction rate requires a rather slow scan speed to get a well shaped cathodic peak. Great benefit is obtained from increasing the DIPY concentration well over the stoichiometric ratio. Figure 4(a) shows a typical cyclic voltamperogram for a solution containing DIPY:Ga = 300:1, and Fig. 4(b) shows the effect of increasing DIPY:Ga ratios on both cathodic and anodic peak currents. When the ratio is increased from the stoichiometric value to 150, both peaks are nearly doubled. A further increase in the ligand:metal ratio has little effect on the cathodic peak and a negative effect on the anodic peak. The anodic peak potential is not affected by increasing the DIPY:Ga ratio, whereas the cathodic peak potential shifts positively. The magnitude of this potential shift is proportional to log [DIPY]. These results are an indication that shifting of complex species equilibria and adsorption of DIPY on the electrode surface play an important role on the reaction mechanism in this solvent.

With a $10^{-3}M$ $Ga(DIPY)_3(ClO_4)_3$ solution with excess DIPY in DMSO (DIPY:Ga = 100), the effect of scan speed was explored over the range 20–2000 mV/sec. The cathodic peak currents ($I_{p,c}/\mu A$) fit the equation $I_{p,c} = 0.1333\ v^{1/2} + 9.0 \times 10^{-2}$, ($r = 0.9991$), which is indicative of a diffusion-controlled current.

Calibration plots were obtained by starting with $0.015M$ (for the range 10^{-5}–$10^{-4}M$ gallium) and $0.15M$ (for the range 10^{-4}–$10^{-3}M$ gallium) DIPY concentrations and adding increasing amounts of $Ga(DIPY)_3(ClO_4)_3$. Cathodic peak currents ($I_{p,c}/\mu A$) obtained at 40 mV/sec give linear plots which fit the equations $I_{p,c} = 1294.0\ [Ga] + 1.04 \times 10^{-3}$, ($r = 0.9999$) for the 10^{-5}–$10^{-4}M$ range and $I_{p,c} = 1061.3\ [Ga] - 1.7 \times 10^{-3}$, ($r = 0.9992$) for the 10^{-4}–$9 \times 10^{-4}M$ range. Higher concentrations give a negative deviation.

Oxygen and free proton interference

The possible interference of oxygen was studied by cyclic voltammetry at an HMDE and by rotating GC ring–GC disc electrode voltammetry.

Oxygen is reversibly reduced to superoxide ion in DMSO[16] at a less negative potential than $Ga(DIPY)_3^{3+}$. The −0.80 V cathodic peak of oxygen is preceded by a less negative potential peak (−0.58 V) and the superoxide oxidation peak is not observed when $Ga(DIPY)_3^{3+}$ is added into solution, as shown in Fig. 5(b). The cathodic peaks of $Ga(DIPY)_3^{3+}$ in the presence of excess DIPY [Fig. 5(a)] are hindered by dissolved oxygen, while the gallium stripping peak is completely suppressed [Fig. 5(b)].

A collection efficiency experiment is shown in Fig. 5(c) and (d). Superoxide generated by reduction of oxygen on the disc electrode is clearly detected by oxidation on the ring electrode [Fig. 5(c)] but when $Ga(DIPY)_3^{3+}$ plus excess DIPY are added, superoxide is not detected at all [Fig. 5(d)]. DIPY itself has no effect.

All of these results are an indication of a chemical reaction between superoxide ion and the gallium–DIPY species, which interferes with the DIPY catalyzed reduction of gallium(III). The −0.58 V peak is due to the oxygen reduction facilitated by the following chemical reaction, while the absence of a gallium stripping peak shows that the species resulting from this reaction cannot be reduced to gallium

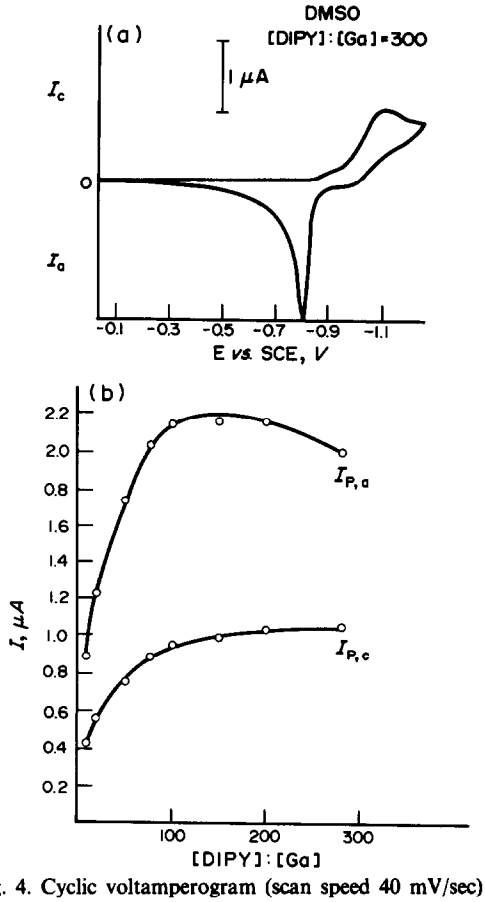

Fig. 4. Cyclic voltamperogram (scan speed 40 mV/sec) of $1 \times 10^{-3}M$ $Ga(DIPY)_3(ClO_4)_3$ ($0.1M$ TEAP) at a HMDE in DMSO in the presence of excess ligand; [DIPY]:[Ga] = 300 (a). Effect of other [DIPY]:[Ga] ratios on the cathodic ($I_{p,c}$) and anodic ($I_{p,a}$) peak currents are shown in (b).

metal. Interactions between superoxide ion and transition metal ions have been described elsewhere,[17] but to our knowledge no reference to a gallium(III)—superoxide interaction has been given.

The effect of free protons added as perchloric acid was studied by cyclic voltammetry. The cathodic peak corresponding to the catalyzed reduction of gallium(III) is enhanced by the acid but it overlaps with the catalyzed reduction of free protons which is observed at a less negative potential.

The cyclic voltamperogram prior to [Fig. 6(a)] and after [Fig. 6(b)] the addition of perchloric acid shows this interference, which has to be considered when designing an analytical procedure based on this catalytic process. However, the presence of a controlled concentration of protons could be beneficial in the case of the anodic peak. Figure 6(c) shows a plot of gallium stripping peak currents *vs.* acid

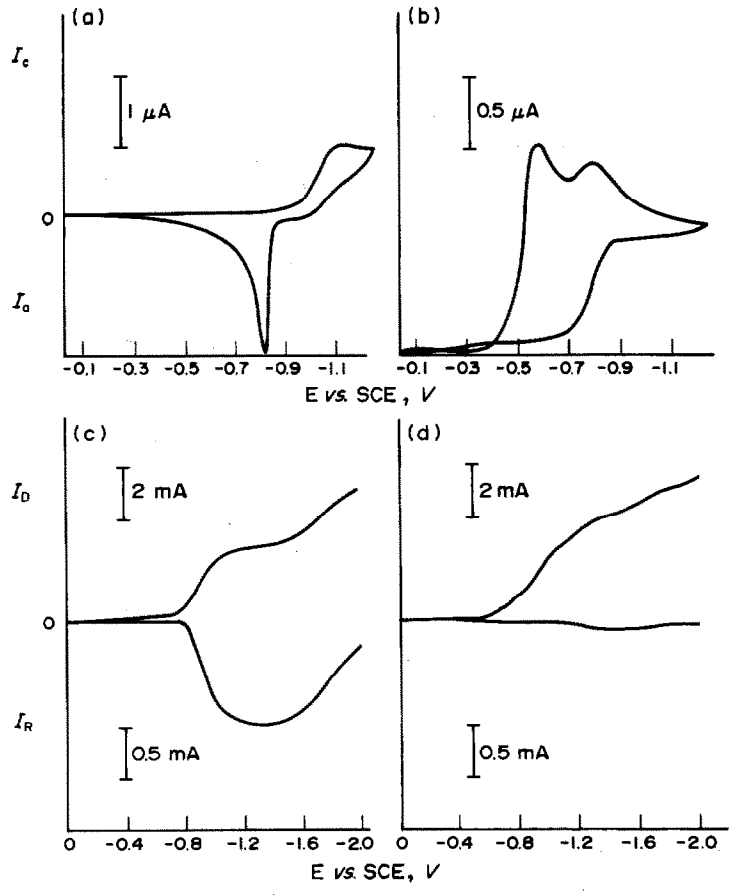

Fig. 5. Cyclic voltamperogram (scan speed 40 mV/sec) of $1 \times 10^{-3}M$ $Ga(DIPY)_3(ClO_4)_3 + 0.15M$ DIPY ($0.1M$ TEAP) at a HMDE in DMSO, after argon (a) and air (b) saturation. Rotating (GC) ring–(GC) disc electrode voltamperogram (2000 rpm; $E_R = 0.000$ V) of an air-saturated $0.1M$ TEAP solution in MeCN, before (c) and after (d) addition of $1 \times 10^{-3}M$ $Ga(DIPY)_3(ClO_4)_3 + 0.1M$ DIPY; upper curve, reduction at the disc electrode; lower curve, oxidation at the ring electrode.

concentration. Current enhancement is obtained with $1 \times 10^{-3}M$ acid concentration. Higher concentrations produce a gradual current decrease.

This positive effect could be useful in an analytical procedure based upon the anodic stripping of gallium.

One can understand this effect by considering that DIPY is a bidentate ligand with two basic nitrogens. The protonation of one of the nitrogens on a coordinated DIPY would labilize to some extent the electroactive Ga–DIPY species, facilitating and accelerating its reduction to gallium metal.

CONCLUSIONS

A catalytic cathodic peak is observed for the reduction of gallium(III) to gallium metal in DMSO with an excess of 2,2′-bipyridine. While free protons can interfere with this process due to the catalytic action of the ligand on the proton reduction, the anodic peak corresponding to gallium stripping is enhanced by their presence. The oxygen interference observed is due to a direct interaction between the superoxide generated by oxygen reduction and the metal ion, which precludes the metal deposition, making solution degassing a stringent requirement. The ligand electrochemistry does not interfere with the gallium reduction and the characteristics of both cathodic and anodic peaks make them attractive for the development of analytical procedures to determine traces of gallium(III). The direct use of the cathodic process may prove to be restricted by the interference of free protons, however the characteristics of the anodic peak are appropriate for anodic stripping analysis. One possible way to separate gallium(III) from its mineral matrix, and incorporate it into a non-aqeuous medium, is via solvent extraction[18] as gallium chloride.

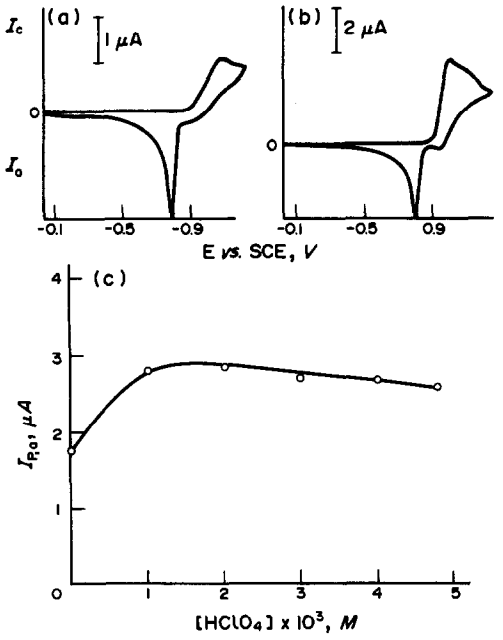

Fig. 6. Cyclic voltamperogram (scan speed 40 mV/sec) of $1 \times 10^{-3}M$ $Ga(DIPY)_3(ClO_4)_3 + 0.15M$ DIPY ($0.1M$ TEAP) at a HMDE in DMSO prior to (a) and after (b) the addition of $2 \times 10^{-3}M$ $HClO_4$. The effect of $HClO_4$ concentration on the anodic peak current for the same solution as in (a) is illustrated in (c).

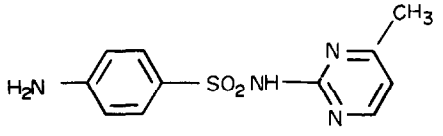
ELECTROANALYTICAL STUDY OF SULPHAMERAZINE AT A GLASSY-CARBON ELECTRODE AND ITS DETERMINATION IN PHARMACEUTICAL PREPARATIONS BY HPLC WITH AMPEROMETRIC DETECTION

J. M. PINGARRON CARRAZON, A. DOMINGUEZ RECIO and L. M. POLO DIEZ*
Department of Analytical Chemistry, Faculty of Chemistry, Complutense University of Madrid, 28040-Madrid, Spain

(*Received* 11 *April* 1990. *Revised* 29 *July* 1991. *Accepted* 2 *August* 1991)

Summary—An electroanalytical study of the oxidation of sulphamerazine at a glassy-carbon electrode has been made by use of different voltammetric techniques. The limiting current is diffusion-controlled, at pH 7.0, for sulphamerazine in the concentration range 2.0×10^{-5}–$1.0 \times 10^{-4}M$. The limits of determination found for differential pulse voltammetry at a stationary electrode and at a rotating electrode were 5.9×10^{-6} and $3.3 \times 10^{-6}M$ respectively. A reversed-phase HPLC method with amperometric detection for the analysis of sulphamerazine, sulphadiazine and phthalylsulphathiazole mixtures has been developed, and applied to a commercial pharmaceutical preparation.

Sulphamerazine (**I**) and other sulphonamides are extensively used for the treatment of bacterial infections of the gastrointestinal tract. Analytical techniques used to determine sulphamerazine include liquid chromatography,[1,2] gas chromatography,[3] thin-layer chromatography,[4,5] spectrophotometry,[6] mass spectrometry,[7] thermal analysis,[8] potentiometric titration,[9] photometric titration[10] and a.c. polarography.[11] Here we describe an electroanalytical study of the oxidation of sulphamerazine at a glassy-carbon electrode and its use for determination of sulphamerazine by anodic voltammetry at low concentrations.



I

Sulphamerazine pharmaceutical preparations usually also contain other sulphonamides, such as sulphadiazine and phthalylsulphathiazole, so its direct voltammetric determination in these formulations is not possible. In earlier papers we described electroanalytical studies of the oxidation of sulphadiazine,[12] and of succinylsulphathiazole and phthalylsulphathiazole[13] at a glassy-carbon electrode (GCE), by different voltammetric techniques, and applied differential pulse voltammetry to determine these sulpha drugs in pharmaceutical preparations. This work is now extended to develop an HPLC method with amperometric detection for the analysis of a mixture of sulphamerazine, sulphadiazane and phthalylsulphathiazole.

EXPERIMENTAL

Apparatus

A multifunctional electroanalytical system consisting of an Amel 551 potentiostat, an Amel 560 interface, an Amel 566 function generator, and a Hewlett-Packard 7035 B X–Y recorder was used. A Metrohm E 506 Polarecord equipped with an E 505 polarographic stand, and Metrohm E 510 pH-meter were also used.

Chromatographic separation of sulphadiazine, sulphamerazine and phthalylsulphathiazole was achieved with a Waters Liquid Chromatograph consisting of a WISP 710 B automatic injector, a model 590 solvent-delivery pump and an electrochemical detection system comprised of a Metrohm 641 VA-Detector in conjunction with a Metrohm 656 Electrochemical Detector. The analytical column was a 150 × 4 mm i.d. Nucleosil 5 C_{18} column (Technorama).

*Author for correspondence.

Electrodes and electrochemical cell

A Metrohm 6.1204.000 GC rotating disc electrode, also used as a stationary electrode, served as the working electrode for the electroanalytical study of sulphamerazine. An Ingold 10 303 3000 saturated calomel reference electrode and a platinum wire counter-electrode were used. A double-wall Metrohm EA 867-20 polarographic cell was employed.

A Metrohm 6.0805.010 GCE as working electrode, a Metrohm 6.0727.000 Ag/AgCl/KCl 3*M* reference electrode and a gold auxiliary electrode built into the detector cell were used in the electrochemical detection system.

Reagents

Stock solutions (0.010*M*) of sulphamerazine, sulphadiazine and phthalylsulphathiazole (Sigma) were prepared in 0.020*M* sodium hydroxide. A Britton–Robinson buffer solution, containing each component acid at 0.2*M* concentration, was used as supporting electrolyte. All chemicals used were of analytical grade. Water was obtained from a Milli-Q (Millipore) purification system.

The mobile phase used for the HPLC was a 70:30 v/v mixture of 30 m*M* acetate buffer (pH 5.0) and methanol (HPLC grade, Mallinckrodt).

The method was validated by analysis of "Bio Hubber simple" tablets (Hubber, S.A.), prescribed for treatment of infections of the gastrointestinal tract. Each tablet has the following nominal composition: streptomycin (hydrochloride), 25 mg; phthalylsulphacetamide, 100 mg; sulphadiazine, 75 mg; sulphamerazine, 75 mg; phthalylsulphathiazole, 100 mg; saccharin (sodium salt), 10 mg.

Pretreatment of the indicator electrodes

For the electroanalytical study of sulphamerazine, before each scan the GCE was immersed in 95% ethanol for 1 min with continuous stirring, and then similarly in chloroform. The electrode was then cleaned carefully with non-abrasive tissue paper soaked in chloroform, and dried with a dry tissue.[14] Next, the GCE was immersed in 2*M* sodium hydroxide for 1 min with continuous stirring, and finally rinsed with distilled water and dried.

The GCE used in the electrochemical detection system was pretreated as above, every day. Finally, the electrode was kept in the mobile phase used, at 1.30 V *vs.* the reference electrode, for 20 min.

Procedure

Several "Hubber" tablets were finely ground and homogenized. A weight of powder equivalent to the average weight of a tablet was stirred with 50 ml of methanol for about 5 min, and then diluted with water to about 100 ml with continuous stirring. Any insoluble matter was filtered off on a medium porosity acid-washed paper, and washed with two 10-ml portions of water. The filtrate and washings were accurately diluted to 1 litre with water, and 10 ml of this solution were transferred into a 50-ml standard flask and diluted to volume in order to obtain sulpha drug concentrations close to $5.0 \times 10^{-5}M$. A 10-μl portion of this solution was injected into the HPLC column, and chromatographed at 1 ml/min flow-rate. The potential applied to the indicator electrode was 1.15 V *vs.* the reference electrode. A single calibration point was used for each drug, with a 10-μl injection of a $5.0 \times 10^{-5}M$ standard solution.

RESULTS AND DISCUSSION

Electroanalytical study of sulphamerazine

Sulphamerazine exhibits one well-defined oxidation wave (or peak) at the GCE for all the voltammetric techniques used. Deaeration of the test solution was shown to be unnecessary under the recommended working conditions.

Voltammetry at a rotating disc electrode. The effect of pH on $E_{1/2}$ and the limiting current (i_L) is shown in Fig. 1. The $E_{1/2}$ *vs.* pH plot shows four regions of linearity, the intersection points indicating the pK_a values of the reduced and oxidized forms of the electroactive species.[15] The shape of this plot agrees quite well with that of the corresponding plots for sulphadiazine[12] and

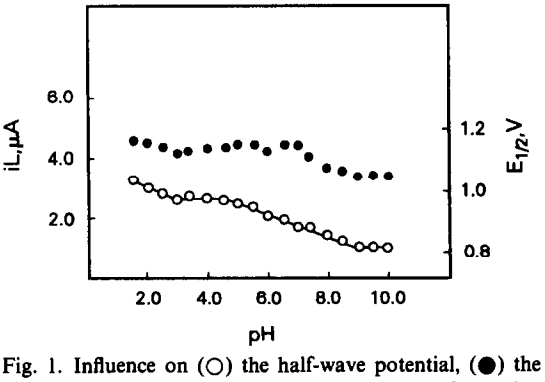


Fig. 1. Influence on (○) the half-wave potential, (●) the limiting current for anodic voltammetry at a GC rotating disc electrode. Sulphamerazine $6.0 \times 10^{-5}M$; ω 1500 rpm; scan rate 50 mV/sec.

Table 1. Analytical characteristics of the methods for the determination of sulphamerazine: pH 7.0 Britton–Robinson buffer

Voltammetric technique	RSD, %	Determination limit, M	Detection limit, M
Linear sweep/ rotating GCE	1.9	2.2×10^{-5}	6.6×10^{-6}
Linear sweep/ stationary GCE	3.7	1.5×10^{-5}	4.5×10^{-6}
Differential pulse/ stationary GCE	1.7	5.9×10^{-6}	1.9×10^{-6}
Differential pulse/ rotating GCE	2.4	3.3×10^{-6}	1.0×10^{-6}

phthalylsulphathiazole.[13] The intersection points found at pH 3.0 and 9.0 correspond to deprotonation of the amine and the amide groups of sulphamerazine respectively. Likewise, the pK_a value of the sulphamerazine oxidation product was 4.5. For pH values higher than 10.0, the wave is poorly defined, which prevents accurate measurements of $E_{1/2}$ values. The limiting current remains practically constant up to pH 7.0; at pH values higher than 7.0 i_L begins to decrease; pH 7.0 was chosen for the further electroanalytical studies.

Fick's law is obeyed in the concentration range 2.0×10^{-5}–$1.0 \times 10^{-4}M$ sulphamerazine for different rotation rates in the range 1000–2500 rpm, suggesting that the limiting current is probably diffusion-controlled in this concentration range.

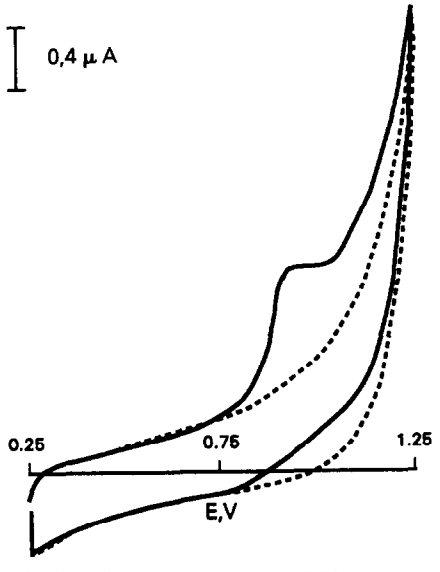

Fig. 2. Cyclic voltamperograms at a GCE: (----) $0.1M$ pH 7.0 Britton–Robinson buffer; (——) $6.0 \times 10^{-5}M$ sulphamerazine and $0.1M$ pH 7.0 Britton–Robinson buffer.

Levich's law is also obeyed for rotation rates of 500–3000 rpm within the concentration range 2.0×10^{-5}–$1.0 \times 10^{-4}M$ (as an example, the i_L *vs.* $\omega^{1/2}$ plot for $6.0 \times 10^{-5}M$ sulphamerazine yields an r value of 0.9996), confirming that the limiting current is diffusion-controlled at the concentration levels studied.

These results allow a method to be developed for the determination of sulphamerazine by use of a calibration graph. The analytical characteristics of the method for a rotation rate of 1500 rpm are summarized in Table 1. The relative standard deviation was calculated for a concentration level of $6.0 \times 10^{-5}M$ sulphamerazine. The limit of determination was calculated according to the $10s$ criterion,[16] and the detection limit was defined as $3s/m$,[17] where s is the standard deviation ($n = 10$) of the signal for $3.0 \times 10^{-5}M$ sulphamerazine aliquots and m is the slope of the calibration graph.

Linear sweep voltammetry at a stationary electrode. Voltamperograms obtained at pH 7.0 showed a well developed oxidation peak at a potential of 1.20 V.

The plots of i_p against sulphamerazine concentration for potential-scan rates (v) of 20, 50 and 100 mV/sec were linear ($r = 0.9995$, 0.9996 and 0.9987 respectively) over the concentration range 2.0×10^{-5}–$1.0 \times 10^{-4}M$.

The linearity ($r = 0.9990$) of the i_p *vs.* $v^{1/2}$ plot for $8.0 \times 10^{-5}M$ sulphamerazine in the range 10–200 mV/sec for v shows that the oxidation current is diffusion-controlled.[18]

The analytical characteristics of the method based on the linear i_p *vs.* concentration plot, for $v = 50$ mV/sec, with the criteria mentioned above, are also summarized in Table 1. The relative standard deviation was calculated for a concentration of $6.0 \times 10^{-5}M$ ($n = 10$), and the limits of determination and detection were

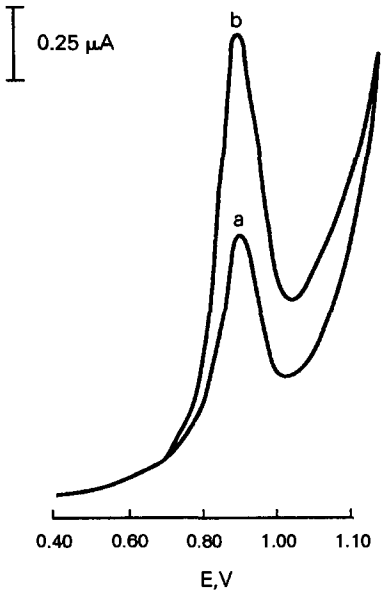

Fig. 3. Differential pulse voltammetry of $6.0 \times 10^{-5}M$ sulphamerazine, scan rate 10 mV/sec; ΔE 50 mV. (a) stationary GC electrode; (b) rotating GC disc electrode, $\omega = 1500$ rpm.

calculated from the standard deviation ($n = 10$) for $3.0 \times 10^{-5}M$ sulphamerazine.

In a reverse scan to cathodic potentials at $v = 50$ mV/sec, no reduction peak appeared in the potential range studied (Fig. 2), which indicates non-reversibility of the electrode process. However, a small shoulder appears in the sweep toward negative potentials, which probably indicates that a further reaction takes place after the initial anodic reaction.

Differential pulse voltammetry at a stationary electrode. From the E_p–pH plot for $5.0 \times 10^{-5}M$ sulphamerazine, with $\Delta E = 50$ mV, the pK_a values of the protonated amine and of the amide groups of sulphamerazine were found to be 3.0 and 8.8 respectively, while the pK_a value of the sulphamerazine oxidation product was 4.6. These results are very similar to those obtained by using the rotating disc electrode. The i_p–pH plot indicated that the highest sensitivity was reached at pH 7.0.

The i_p *vs.* pulse amplitude plot for $4.0 \times 10^{-5}M$ sulphamerazine shows good linearity over the ΔE range 5–50 mV, but deviates from linearity at higher values of ΔE. The upper value of the linear range was chosen for the further electroanalytical study.

The ranges of linearity obtained for the i_p *vs.* sulphamerazine concentration plots were $1.0 \times 10^{-5} - 1.0 \times 10^{-4}M$ ($r = 0.9999$), with slope and intercept of 1.9×10^4 μA.l.mole^{-1} and -0.04 μA, and 7.0×10^{-6}–$1.0 \times 10^{-5}M$ ($r = 0.9990$), with slope and intercept of 2.4×10^4 μA.l.mole^{-1} and -0.11 μA.

The analytical characteristics of the method based on these calibration graphs are summarized in Table 1. The relative standard deviation was calculated for $4.0 \times 10^{-5}M$ sulphamerazine ($n = 10$). The limits of determination and detection were calculated from 10 replicate measurements of $9.0 \times 10^{-6}M$ sulphamerazine.

Differential pulse voltammetry (dpv) at a rotating disc electrode. This technique gave a significantly greater peak current than that for dpv at a stationary electrode (Fig. 3). The i_p increases with rotation rate of the electrode, the i_p *vs.* $\omega^{1/2}$ plot for $6.0 \times 10^{-5}M$ sulphamerazine being linear ($r = 0.998$) over the range 500–3000 rpm. The plot of i_p *vs.* sulphamerazine concentration at pH 7.0, $\Delta E = 50$ mV and 1500 rpm, was linear between 4.0×10^{-6} and $1.0 \times 10^{-5}M$.

The analytical characteristics of the method based on this calibration graph are given in Table 1. The relative standard deviation was calculated for a concentration level of $7.0 \times 10^{-6}M$ ($n = 10$). The limits of determination and detection were calculated from the standard deviation ($n = 10$) for $5.0 \times 10^{-6}M$ sulphamerazine. These results show that the sensitivity is about twice as great as that for dpv at a stationary electrode.

An additional conclusion from Table 1 is that the precision obtained by voltammetry at a rotating disc electrode and by differential pulse voltammetry at a stationary electrode allows their use for quality control work.

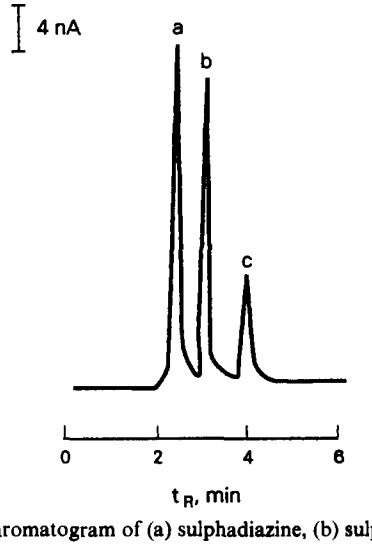

Fig. 4. Chromatogram of (a) sulphadiazine, (b) sulphamerazine and (c) phthalylsulphathiazole, with amperometric detection. Concentration of each compound $5.9 \times 10^{-5}M$. Injection volume 10 μl.

Determination of sulphamerazine, sulphadiazine and phthalylsulphathiazole in pharmaceutical preparations by HPLC with amperometric detection

The results reported above for sulphamerazine, together with knowledge of the oxidative voltammetric behaviour of sulphadiazine and phthalylsulphathiazole at the GCE,[12,13] allowed amperometric detection of a mixture of these three sulpha drugs after their separation by reverse-phase HPLC.

The potential applied to the GCE was 1.15 V. Because our main interest was the determination of sulphamerazine, this value was chosen after studying the effect on the peak height obtained for $5.0 \times 10^{-5}M$ sulphamerazine when the potential applied to the electrode was varied from 1.00 to 1.30 V. This potential was also enough to provide detection of the other two sulpha drugs.

Figure 4 shows a chromatogram obtained from a mixture containing each sulpha drug at $5.0 \times 10^{-5}M$ level as described in the procedure. The capacity factors were 0.8, 1.3 and 2.8 for sulphadiazine, sulphamerazine and phthalylsulphathiazole respectively, and good resolution was obtained. The analysis time was 4.5 min, and the response factors were 1.0, 1.1. and 0.3 for sulphamerazine, sulphadiazine and phthalylsulphathiazole respectively.

Linear calibration graphs were obtained for all three drugs within the range 1.0×10^{-5}–$9.0 \times 10^{-5}M$.

"Bio Hubber simple" tablets were then analysed, with one-point calibrations, as specified in the procedure. Results obtained from 5 determinations yielded sulphadiazine, sulphamerazine and phthalylsulphathiazole contents of 70.5 ± 0.9, 70.6 ± 1.8 and 94.6 ± 1.5 mg respectively, the confidence interval being calculated for a significance level of 0.05 (RSD values were 1.0%, 2.1% and 1.3% respectively). The accuracy of the proposed method was evaluated by recovery studies after adding 150 μl of each sulpha drug stock solution to the analytical solution of the pharmaceutical product. Results from five determinations yielded mean recoveries of 97% for sulphadiazine and 98% for sulphamerazine and phthalylsulphathiazole, the relative standard deviations being 2.0, 2.4 and 2.2% respectively (the confidence intervals of the mean recoveries were ± 2.5, ± 3.0 and ± 2.7% respectively).

Acknowledgement—The authors thank Dr. B. Cañas Montalvo for this help in the HPCL experiments.

STUDY OF THE REACTION OF COMPLEXATION OF PENICILLIN V WITH COBALT(II) IN METHANOLIC MEDIUM

JUAN HERNANDEZ MARTINEZ, PEDRO J. MARTINEZ, PILAR GUTIERREZ and MA ISABEL MARTINEZ
Department of Physical Chemistry, Faculty of Pharmacy, University of Granada, Granada, Spain

(*Received* 25 *July* 1991. *Revised* 18 *November* 1991. *Accepted* 21 *November* 1991)

Summary—As shown by spectrophotometry, two specific complexes with stoichiometry 1:1 and 2:1 are formed when penicillin V reacts with cobalt(II) in a methanolic medium. Stability constants are determined at 20°, as well as the molar absorptivities at 510 nm. The results obtained are: $\log \beta_{1:1} = 1.67 \pm 0.01$ $l \cdot mole^{-1}$ and $\log \beta_{2:1} = 5.76 \pm 1.01$ $l^2 \cdot mole^{-2}$, $\epsilon_{1:1} = 13.62 \pm 0.73$ and $\epsilon_{2:1} = 12.95 \pm 0.61$ $l \cdot mole^{-1} \cdot cm^{-1}$.

Penicillin and ampicillins interact with metallic ions forming complexes.[1–6] To study the chelation sites we took an aminopenicillin which has two sites of chelation, one formed for the aminic group of the lateral chain and the C=O group in the β-lactam ring and the other formed by the carboxylate group and the tertiary nitrogen of the said ring.[7] Pivampicillin has been used, which, once the carboxylate group has been esterificated, has only one site of chelation, the one formed by the aminic group of the lateral chain and the C=O of the β-lactam ring.[8] In this work we have used penicillin V without the aminic group in the lateral chain as a ligand and therefore only one chelation site is present, formed by the carboxylate group and the tertiary nitrogen of the β-lactam ring.

The union from this nitrogen has greater access to the lone pair of electrons on the nitrogen compared with that in normal amides, due to the spatial structure of the β-lactam ring. The stability constants and molar absorptivities at 20° of the penicillin V complexes with cobalt(II) were calculated in methanolic medium.

EXPERIMENTAL

Materials

All chemicals used in this study were reagent grade. Potassium penicillin V (purer than 99%) was from Sigma. Cobalt(II) nitrate hexahydrate and methanol were purchased from Merck and used as provided without further purification.

Instruments

A Bausch & Lomb Spectronic 2000 spectrophotometer, a Selecta thermostat (±0.1°), an Amstrad PC-1512 computer equipped with a plotter sekonic spl-410 and 1-cm thick spectrophotometric cells were used.

Spectra

To prove the formation of the complexes we recorded spectra (between 850 and 400 nm) of methanolic solutions which contained penicillin V ($2.66 \times 10^{-2} M$); cobalt(II) nitrate ($1.33 \times 10^{-2} M$) and also a mixture of these solutions. The spectra obtained are shown in Fig. 1.

	$CH_2OCOC(CH_3)_3$	Pivampicillin
	H	Penicillin V

Scheme 1

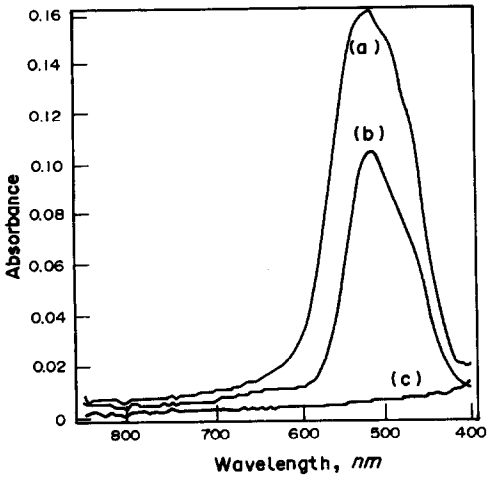

Fig. 1. Absorption curves of methanolic solutions: (a) cobalt(II) $1.33 \times 10^{-2}M$ (b) penicillin V $2.66 \times 10^{-2}M$ (c) penicillin V–cobalt(II) at the same concentrations. $T_a = 20°$.

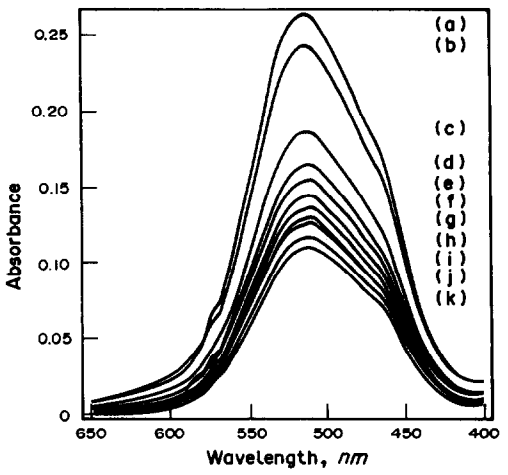

Fig. 2. Absorption curves of methanolic solutions [series (b)] of potassium penicillin V 2.72, 2.50, 2.00, 1.76, 1.67, 1.58, 1.50, 1.43, 1.36, 1.30, $1.25 \times 10^{-2}M$ and cobalt(II) nitrate at the same concentrations respectively at 20°.

In order to characterize the influence of concentration of the reagents and determine the number of absorbant species, the visible absorption spectra of methanol solutions of potassium penicillin V and cobalt(II) nitrate hexahydrate were studied in four different series, where the concentration of the metal remained constant ($1.2 \times 10^{-2}M$) and that of penicillin V was varied to obtain different molar ratios.

Solutions with an excess of metal. We registered the spectra of methanolic solutions which contained a constant cobalt(II) concentration ($1.2 \times 10^{-2}M$) while that of penicillin V was variable (4.8×10^{-3}–$1.2 \times 10^{-2}M$). The solutions thus prepared had molar ratios between 0.4:1 and 1:1.

Solutions with a constant molar ratio of reactives of 1:1. In this case the stoichiometric relation was kept constant and we varied the concentrations of penicillin V and metal.

Solutions with a molar ratio of reactives between 1:1 and 2:1. In this series the ligand concentrations were between 1.44×10^{-2} and $2.64 \times 10^{-2}M$.

Solutions with a constant molar ratio of reactives of 2:1. We varied the concentration of penicillin V and metal but always maintained the 2:1 stoichiometric relation.

All these experiments have been realized in a methanolic medium with a temperature of 20°.

Figures 2 and 3 show some spectra obtained.

Number of absorbant species and stoichiometry of complexes

Coleman's matrix method[10] was applied in graphic form to the absorbance data obtained in the previous section in order to find the number of absorbant species. Job's method[11] was employed to determine the stoichiometric balance of the complexes.

Stability constants and molar absorptivity coefficients of complexes

These values were calculated from the absorbance data of the various methanolic solutions at different concentrations of ligand and metal with the MINISPEF program.[12] This program can calculate the optimum values of the overall stability constants and molar absorptivities of a maximum of 8 species formed by the reaction which can be expressed as:

$$qM + pL + rH^+ \rightleftharpoons M_qL_pH_r^+ \qquad (1)$$

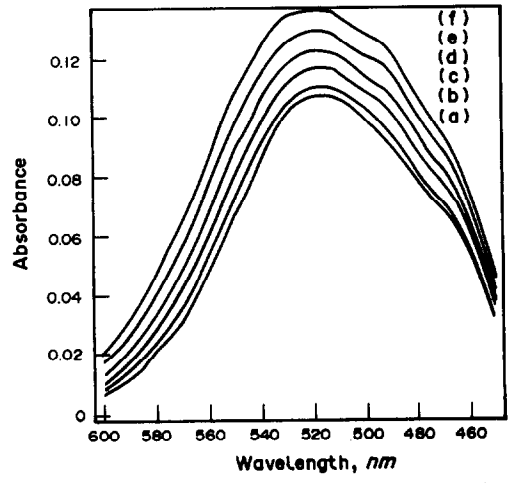

Fig. 3. Absorption curves of methanolic solutions (series c) of cobalt(II) nitrate $1.2 \times 10^{-2}M$ and potassium penicillin V 1.44, 1.68, 1.92, 2.16, 2.40, $2.64 \times 10^{-2}M$ at 20°.

where q or r can be zero. The stability constants are defined as:

$$B = [M_qL_pH_r]/[M]^q[L]^p[H^+]^r \quad (2)$$

The logarithms of the overall stability constants and the molar absorptivities are treated as unknown parameters. The MINISPEF program calculates those values which yield the minimum sum of the squares of the residuals (U) of the measured (A_{meas}) and calculated (A_{cal}) absorbances, together with the probable errors.

$$U = \sum_i (A_{meas,i} - A_{cal,i})^2 \quad (3)$$

RESULTS AND DISCUSSION

Figure 1 shows how the absorbance at 510 nm for penicillin V–cobalt(II) in a 2:1 ratio does not correspond to the sum of the absorbances of the separated reactives, which shows the formation of one or more complexes.

To study the number of species present in solutions, Coleman's test was applied to the four series of solutions previously described.

Application of Coleman's test to absorption data of methanolic solutions shows the existence of two absorbant species. This can be deduced by the groups of straight lines obtained representing A_{ij}/A_{580j} *vs.* A_{510j}/A_{580j} (Fig. 4). These two species can be attributed to cobalt(II) which is found in equilibrium with a 1:1 stoichiometric complex.

In a second series of solutions, Coleman's test was applied to the absorbance data obtained in the experimental section. Graphic representation leads to a group of straight lines radiating from the origin (Fig. 5), which demonstrates the existence of only one absorbant species in solution that can be assigned to a stoichiometric complex of 1:1.

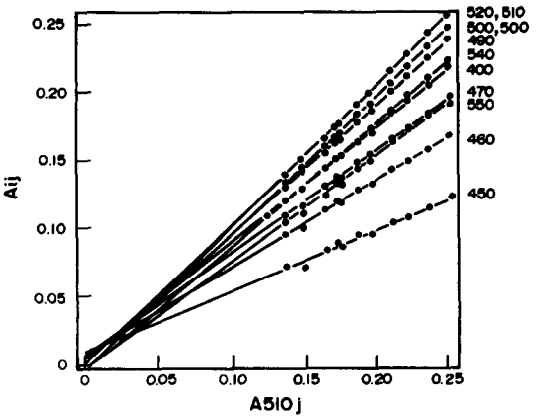

Fig. 5. Coleman's test for one species applied to the data of series (d).

The application of Coleman's test on the third series of solutions led to a group of straight lines similar to those described in Fig. 4, which confirms the existence of two absorbant species which could correspond to stoichiometric complexes 1:1 and 2:1 which are found in equilibrium.

For the fourth series of solutions Coleman's test was applied. The result is a group of straight lines coinciding at the origin very similar to those described in Fig. 5, which confirm the existence of only one absorbant species that can be assigned to the stoichiometric complex 2:1.

To determine the stoichiometry and in accordance with Job's method, the absorbance, once corrected due to the absorbance of cobalt(II), was graphically represented *vs.* the molar fraction of penicillin (Fig. 6). A maximum molar fraction of 0.66 can be seen, which

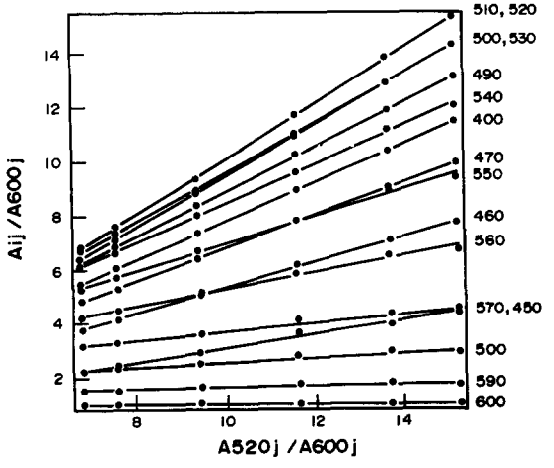

Fig. 4. Coleman's test for two species applied to the data of series (c).

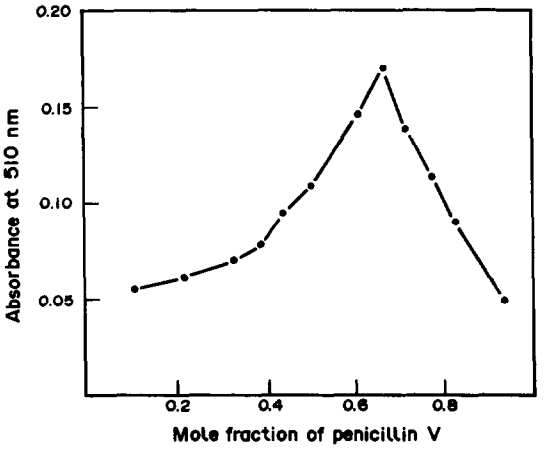

Fig. 6. Job's plot. The sum of concentration of reactants, penicillin and cobalt(II) was 0.06M.

Table 2. Stability constants (20°) and molar absorptivity at 510 nm with its probable errors and the squares of residuals (U), for the Co(II)–penicillin V complexes

Complex	log β	ϵ_{max}, $l \cdot mole^{-1} \cdot cm^{-1}$	ϵ_M	U
1:1	1.67 ± 0.01	13.62 ± 0.73	6.74	3.88×10^{-5}
2:1	5.76 ± 1.01	12.95 ± 0.61	6.74	1.33×10^{-4}

ϵ_M = Absorption coefficients of the metal at the wavelength of the absorption maximum of the complexes.

indicates the existence of a stoichiometric complex of 2:1. Variation in the slope for a molar fraction of around 0.5 can be observed, confirming the existence of a stoichiometric complex of 1:1.

All of this permits us to conclude the following reaction scheme:

$$\text{Pen V} + \text{Co(II)} \xleftrightarrow{K_1} \text{Pen V Co}$$

$$\text{Pen V Co} + \text{Pen V} \xleftrightarrow{K_2} (\text{Pen V})_2\,\text{Co}$$

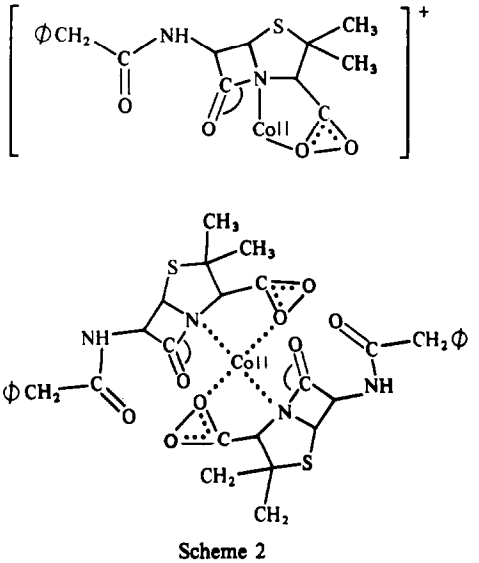
We used the MINISPEF program[12] to calculate the absorbance data of 510-nm solutions of reactives in molar ratios of 2:1 and 1:1 (Table 1) to calculate the stability constants, log $\beta_{1:1}$ and log $\beta_{2:1}$, and the molar absorptivities to 510 nm, $\epsilon_{1:1}$ and $\epsilon_{2:1}$ of the formed complexes.

In both cases and in accordance with previous results we consider that only one complex is respectively formed for each, 2:1 and 1:1.

The global stability constants and the molar absorption coefficients are represented in Table 2 as is the square of the residuals (U).

The U values obtained (Table 2) show the difference between the absorbance data measured and the calculated absorbance to be less than ± 0.005, which falls within the margin of spectrophotometric error. Furthermore, the values of molar absorption coefficients of the metallic ion, ϵ_M, found by applying the calculation program, agree with those experimentally determined. These facts constitute a validity test to the finding about the number of complexes formed in each case, as in their stoichiometry.

The stability constants of the compounds of penicillin V–cobalt(II) are very high. This can



Scheme 2

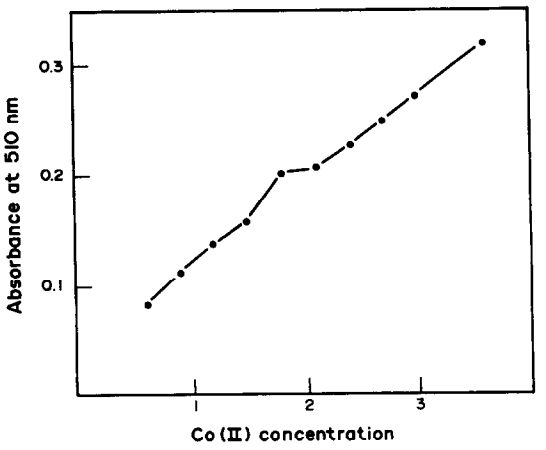


Fig. 7. Curve of spectrophotometric valoration of penicillin V with cobalt(II) in methanolic medium at 510 nm.

indicate that the compounds formed are chelates and therefore penicillin V acts as a bidentate ligand.

As penicillin V is not an aminopenicillin it does not have an amino group in the lateral chain; it can be considered that the coordination is done by the carboxylate group and the tertiary nitrogen of the β-lactam ring, which can be drawn for both stoichiometries.

The high stability values found can be attributed therefore to the methanolic medium, where the reaction occurs easier than in water.

The formation of the complexes, of a high formation constant (Table 2), could be used as a base for the spectrophotometric analysis of penicillin V with a solution of cobalt(II) at 510 nm. The end-point of the analysis (maximum light absorption) takes place at a 1.3:1 molar ratio of the reactants according to Fig. 7. With this method concentrations of penicillin V between 2×10^{-2} (absorbance 0.1) and $6 \times 10^{-2} M$ (highest solubility concentration) could be analysed.

Summary—In the presence of polyvinylalcohol (PVA-124) and polyethylene glycol monooctylphenyl ether (emulsifier OP), cadmium ions(II) can form a colour ion-association complex with both Bromopyrogallol Red (BPR) and Crystal Violet (CV). In the NH_3–NH_4Cl medium, the ion-association complex has a composition of Cd:BPR:CV = 1:1:2, and its corresponding molecular formula is $[CV]_2[Cd(BPR)]$. The maximum absorption of the colour complex is located at 654 nm with an apparent molar absorptivity of 1.79×10^5 l.mole^{-1}.cm^{-1}. Beer's law is obeyed for cadmium over the range 0–10 μg/25 ml. A highly sensitive spectrophotometric method for trace cadmium in water and zinc was developed with good precision and accuracy. The mechanism of the reaction is also discussed.

It is well known that many cadmium compounds are very toxic to the environment and humans. Therefore, the determination of cadmium is important.

Bromopyragallol Red (BPR) has been widely used as a reagent in spectrophotometry, but is little used for the determination of cadmium. Xu *et al.* have studied the formation of the cadmium complex with both BPR and cetyltrimethyl ammonium bromide (CTAB), and have observed a molar absorptivity of 4.2×10^4 l.mole^{-1}.cm^{-1}.[1]

In recent years, several spectrophotometric methods based on coloured ternary complex systems have been recommended for the determination of cadmium(II).[2–4] Some of these are ion-association complexes,[5,6] in which the cadmium complex anion is a simple inorganic complex (*e.g.* $[CdI_4^{2-}]$). Synergistic chromophoric reactions by double chromogenic reagents for the determination of cadmium have not been reported.

In the work presented here, the complex formation of the double chromogenic reagents, Bromopyrogallol Red (BPR) and Crystal Violet (CV), with cadmium(II) was studied. In an NH_3–NH_4Cl medium (pH 8.5), cadmium ions form an ion-association complex with a composition of Cd:BPR:CV = 1:1:2. In the presence of polyvinylalcohol (PVA-124) and polyethylene glycol monooctylphenyl ether (emulsifier OP), the stability and sensitivity are enhanced. The maximum absorption of the complex was located at 654 nm with an apparent molar absorptivity of 1.79×10^5 l.mole^{-1}.cm^{-1}, which is much higher than those reported earlier for the cadmium complex with BPR (8.0×10^3 l.mole^{-1}.cm^{-1}), and BPR–CTAB (4.2×10^4 l.mole^{-1}.cm^{-1}). Beer's law is obeyed for cadmium over the concentration range 0–10 μg/25 ml. This method has been applied to the determination of cadmium in water and zinc with good precision and accuracy.

EXPERIMENTAL

Apparatus

A Perkin–Elmer Model Lambda-17 UV-Vis spectrophotometer was used.

Reagents

All the reagents used were of analytical reagent grade. Distilled water was used throughout.

BPR and OP were obtained from Shanghai Chemical Reagent Works, CV from (Germany) and PVA-124 from (Japan).

Stock standard solution of cadmium(II), 1 mg/ml. A 1.6308-g sample of cadmium(II) chloride (oven-dried at 105° for 4 hr) was dissolved in water and made up to 1000 ml. Working solutions were prepared by suitable dilution.

NH_3–NH_4Cl buffer solution, pH = 8.5. Prepared by dissolving 40.0 g of ammonium chloride and 8.80 ml of concentrated ammonium hydroxide in water and diluting to 500 ml with water.

BPR, 1.00×10^{-3}M in 50% ethanol.
CV, 1.00×10^{-3}M in water.
PVA-124, 2.0% (w/v) in water.
Emulsifier OP, 1.0% (v/v) in water.

Procedures

NH_3–NH_4Cl buffer solution (pH = 8.5) 3.50 ml, 5.00 μg of cadmium standard, 0.80 ml BPR ($1.00 \times 10^{-3}M$), 1.00 ml CV ($1.00 \times 10^{-3}M$), 2.00 ml PVA-124 (2.0%) and 0.40 ml of emulsifier OP (1.0%) were added to a 25-ml calibrated flask (whilst mixing thoroughly), then diluted to the mark with water and mixed well. The resulting mixture was allowed to stand for 5 min, and then the absorbance was measured at 654 nm with a 1-cm cell against a reagent blank.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the reagents and their cadmium(II) complex were measured over the range of 600–800 nm (see Fig. 1). The absorption maximum of the complex occurred at 654 nm.

Effect of pH

The method was examined in various pH buffer solutions, *e.g.* NH_3–NH_4Cl buffer solution (pH = 8.0, 8.5, 9.0, 9.5, 10.0), CH_3COOH–CH_3COONa buffer solution (pH = 4.7), NaH_2PO_4–Na_2HPO_4 (pH = 7.2). In all systems, pH = 8.5 seems optimal. The absorbance of the complex was maximal and constant when adding at least 2.00 ml of NH_3–NH_4Cl buffer solution (pH = 8.5) and was unstable below 2.00 ml, (the other reagent amounts were the same as described in Procedures), therefore 3.50 ml was selected as optimal.

Effect of amount of BPR and CV

When $1.00 \times 10^{-3}M$ BPR and CV were varied respectively from 0.40 to 1.00 ml and from 0.80 to 1.50 ml (the other reagent amounts were the same as in Procedures), the absorbance of the complex was maximal and constant, so use of 0.80 ml of BPR and 1.00 ml of CV were recommended for the determination.

Effect of PVA-124 and emulsifier OP

It has been reported[7] that an increase in detection sensitivity and stability results from the addition of some micromolecular compounds (PVA, arabic gum, *etc.*) and non-ionic surfactants (OP, Tween, *etc.*) to coloured ion-association complex systems. In the work presented here, the absorbance remains stable for 4 hr with PVA-124 and OP, but only 40 min without them. Also, a higher sensitivity system can be obtained by the addition of PVA-124 and OP (see Fig. 2). When PVA-124 (2.0%) and OP (1.0%) were varied respectively from 1.00 to 3.00 ml and from 0.20 to 0.50 ml, the absorbance of the complex was maximal and constant, so that the use of 2.00 ml of PVA-124 and 0.40 ml of OP was recommended.

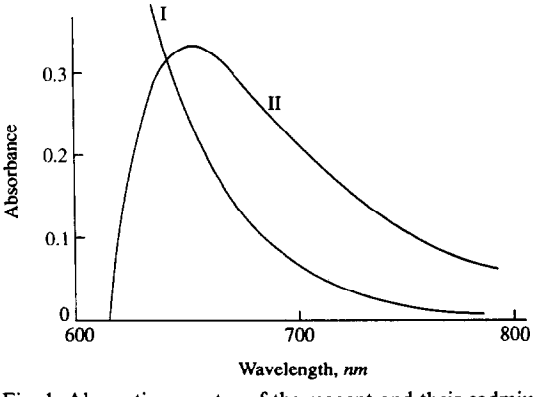

Fig. 1. Absorption spectra of the reagent and their cadmium(II) complexes, for 5 μg/25 ml Cd(II). Curve I: BPR–CV (agains water as reference). Curve II: Cd(II)–BPR–CV (against reagent as reference).

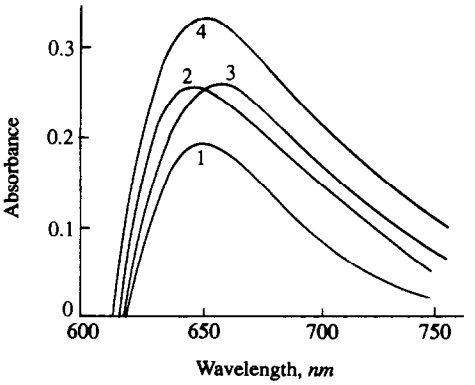

Fig. 2. Effect of PVA-124 and emulsifier OP on absorbance of the complex for 5 μg/25 ml Cd(II). Curve I: Cd–BPR–CV complex. Curve II: Cd–BPR–CV complex with PVA-124. Curve III: Cd–BPR–CV complex with OP. Curve IV: Cd–BPR–CV complex with both PVA-124 and OP.

Calibration curves

Beer's law was obeyed over the cadmium concentration range 0–10 μg/25 ml. The simple linear regression calibration equation can be represented by:

$$A = 0.064C + 0.0052 \ (C = \mu g/25 \text{ ml})$$

with a correlation coefficient of 0.9988. The apparent molar absorptivity obtained from the calibration equation was 1.79×10^5 $l.mole^{-1}.cm^{-1}$.

Detection limits

The detection limits, C_L, were determined by repeatedly measuring the absorbance of the blank solutions. The value of standard deviations of the blank measurements for a water sample was estimated by extrapolation after analysis of suitable samples containing low (less than 10 C_L) concentrations of cadmium, and for a high purity zinc sample not containing cadmium (less than C_L). From the standard deviations of the blank measurements, the detection limit (3 times the standard deviation of the blank) was 0.017 μg/ml for the water sample and 0.026 μg/ml for the zinc sample.

Interferences

The selectivity of the proposed method was investigated by determining 5.00 μg of cadmium in the presence of various other ions. The results indicated that K^+, Na^+, NH_4^+, NO_3^-, Cl^- and SO_4^{2-} do not interfere, even when present in large excess. The tolerable amounts of other diverse ions giving a maximum error of $\pm 4\%$ in the determination are summarized in Table 1.

The reaction mechanism and the composition of the complex

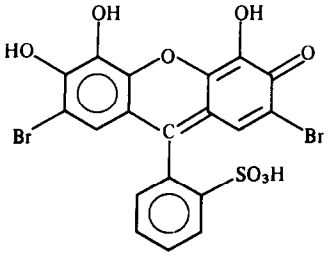
An increase in the absorption intensity of the cadmium complex results from synergistic chromophoric reactions by the double chromogenic reagents.[8] The apparent molar absorptivity of the Cd(II)–BPR–CV system was about twenty times that of the binary system [8.0×10^3 $l.mole^{-1}.cm^{-1}$ for the Cd(II)–BPR system].

The composition of the complex was studied by the molar-ratio,[9] slope-ratio[10] and logarithmic equilibrium shift methods.[11] A molar-ratio of Cd to BPR of 1:1 was found by both the molar-ratio and slope-ratio methods. The stoichiometry of the Cd and CV was studied by the logarithmic method of equilibrium shift. A 1:2 stoichiometric ratio of Cd to CV was observed. So the molar ratio of Cd to BPR and CV was Cd:BPR:CV = 1:1:2. From the composition of the complex and the reagent properties, it follows that the reaction may be presented by:

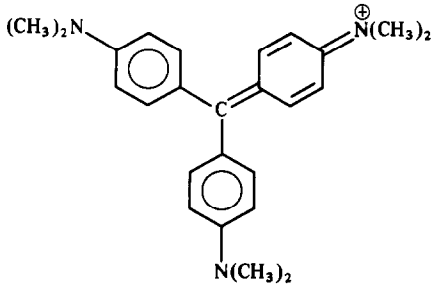
$$Cd^{2+} + BPR + 4OH^- = [Cd(BPR)]^{2-} + 4H_2O$$

$$[Cd(BPR)]^{2-} + 2CV^+ = [CV]_2[Cd(BPR)]$$

The structures of BPR and CV are as follows:



BPR



CV

Table 1. Influence of the diverse ions on the determination of cadmium(II), (5.0 μg/25 ml)

Tolerated ratio to Cd (w/w)	Ions	Tolerated ratio to Cd (w/w)	Ions

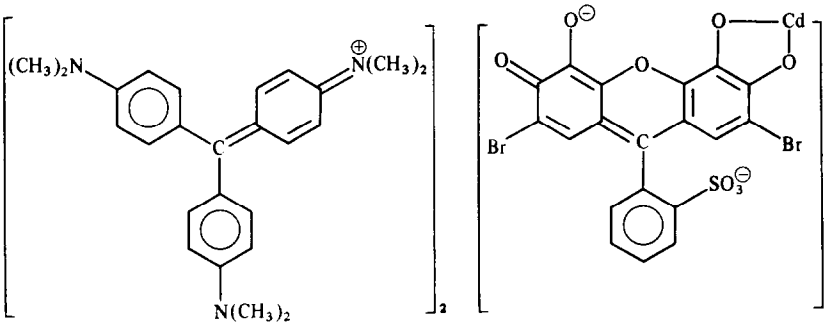
		5.00	6.88	103	105
		7.00	8.12	94	93

The coloured ion-association complex is a neutral complex with the following possible structure:



Application to water and zinc samples

The method was tested on water and zinc samples. The results are given in Table 2 and recovery of added cadmium is presented in Table 3.

The determination of trace cadmium in water

A volume of water sample (containing up to 10 μg of cadmium) was added to a 25-ml calibrated flask, and the pH was adjusted to 7 with ammonium hydroxide and hydrochloric acid (if necessary 2.00 ml of 0.02*M* tartaric acid was added). The remaining procedures were the same as that stated above.

The determination of trace cadmium in zinc

Sample solution of zinc: a 0.2000-g zinc sample was placed in a 50-ml beaker; and then 3 ml of hydrochloric acid (1:1) and 3 drops of hydrogen peroxide (30%) were added successively to the beaker. The resulting mixture was boiled for a few minutes, and then cooled and

transferred to a 100-ml standard flask, diluted to the mark with water and mixed.

Reagent blank solution of high purity zinc (Cd < 0.08 μg/g) The procedure was the same as for the sample solution, except that high purity zinc was used.

By pipette, a 10.00 ml portion of the zinc sample solution was added to a 25-ml calibrated flask (if necessary, 2.00 ml of 0.02*M* tartaric acid was added). The remaining procedures were the same as above.

CONCLUSION

The method is simple and convenient for the determination of cadmium in water and zinc samples. The results obtained show that the precision and accuracy are satisfactory.

ON THE DETERMINATION OF THE FREE CONCENTRATION OF LIGANDS

J. C. RODRIGUEZ PLACERES,* M. T. SANZ ALAEJOS and F. J. GARCIA MONTELONGO

Departments of Analytical Chemistry and Physical Chemistry, University of La Laguna, 38204-La Laguna, Tenerife, Canary Islands, Spain

(*Received* 27 *March* 1989. *Revised* 25 *October* 1991. *Accepted* 10 *November* 1991)

Summary—Working with a sufficient excess of any of the protonated forms of a ligand is shown to guarantee the validity of the determination of its free concentration when calculated by disregarding complexing effect. This result significantly extends the possibilities of studying the stability constants of co-ordination systems.

Many methods for determination of the stability constants of metal ion–ligand systems require previous knowledge of the concentration of the free ligand. Thus, it is necessary to work with a large excess of the ligand with respect to the metal ion in order that the free ligand concentration can be considered to be approximated by its total concentration. This requirement has greatly limited the analysis of many complexation equilibria, for which it was not feasible to work under such conditions.

An approach permitting this difficulty to be overcome is presented in this work.

THEORY

The presence of a ligand in solution with a metal ion will cause establishment of the corresponding complexation equilibria, together with those of protolytic reactions of the ligand. The equations which permit the calculation of the free concentration of the ligand must be determined.

The first case to be considered is the simplest, that of a monoprotic complexing species, X, capable of forming a single complex species, MX, with a metal ion, M. The equilibria to be considered are:

$$HX \rightleftharpoons H + X \quad K_a = \frac{[H][X]}{[HX]}$$

$$M + X \rightleftharpoons MX \quad \beta = \frac{[MX]}{[M][X]}$$

For simplicity, charges on species are omitted throughout.

The total concentration of ligand will be given by:

$$X_T = [X] + [HX] + [MX]$$

$$= [X] \times \left\{ \frac{K_a + [H] + K_a \dfrac{[MX]}{[X]}}{K_a} \right\}$$

which can be rearranged to:

$$X_T = [X] \left\{ \frac{[H] + K_a \left(1 + \dfrac{[MX]}{[X]} \right)}{K_a} \right\} \qquad (1)$$

from which the fractions of each ligand species can readily be determined, as a function of the total concentration of ligand:

$$\psi_0 = \frac{[HX]}{X_T} = \frac{[H]}{[H] + K_a \left(1 + \dfrac{[MX]}{[X]} \right)} \qquad (2)$$

$$\psi_1 = \frac{[X]}{X_T} = \frac{K_a}{[H] + K_a \left(1 + \dfrac{[MX]}{[X]} \right)} \qquad (3)$$

These equations allow the calculation of the free concentration of the ligand species in solution. However, their use for this purpose requires prior knowledge of the stability constants, the values of which are the object of the research requiring the knowledge of [X]. If no complexa-

10^{-2}	1.010	1.5	2	2	2	2
10^{-4}	1.000	1.010	1.5	2	2	2
10^{-6}	1.000	1.000	1.010	1.5	2	2
10^{-8}	1.000	1.000	1.000	1.010	1.5	2
10^{-10}	1.000	1.000	1.000	1.000	1.010	1.5

tion is taken into account, equations (2) and (3) would reduce to:

$$\psi'_0 = \frac{[HX]'}{X_T} = \frac{[H]}{[H] + K_a} \tag{4}$$

$$\psi'_1 = \frac{[X]'}{X_T} = \frac{K_a}{[H] + K_a} \tag{5}$$

and utilization of these equations for calculation of the concentration of the ligand species does not require any knowledge about the formation constant of the complex. The conditions under which the simplest equations (4) and (5) can be applied to study of complexation constants without any significant error must be found, however.

Equating equations (3) and (5) for a given value of X_T gives

$$\frac{[X]'}{[X]} = \frac{[H] + K_a\left(1 + \frac{[MX]}{[X]}\right)}{[H] + K_a} \tag{6}$$

which relates the two concentrations [X] and [X]′. These two values will become closer as the quotient [MX]/[X] decreases. In the limit, where this quotient is zero (non-existence of complex), these concentrations would be equal. [X] and [X]′ will be closer, the greater the concentration of ligand with respect to that of the metal ion M.

However, the acidity constants of the ligand and of the pH of the medium will also have great influence on the final result. In order to visualize this triple dependence, values of [X]′/[X] for various values of each of these factors are shown in Tables 1–5, where the [X]′/[X] values have been rounded off from the computed values (*e.g.*, 1.00999900 to 1.010).

It can be seen that, for a marked excess of ligand, *i.e.*, [MX]/[X] = 0.01, the ratio [X]′/[X] is practically unity for any value of the acidity constant and the pH. When [MX]/[X] > 0.01, the deviation of [X]′/[X] from unity increases as [MX]/[X] increases.

For the particular case studied, working with excess of ligand ensures the validity of calculations of its free concentration from the simple equation (5), disregarding the complexing effect.

For the HX species, and from equations (2) and (4), the quotient between the "apparent" and "true" concentrations will be:

$$\frac{[HX]'}{[HX]} = \frac{[H] + K_a\left(1 + \frac{[MX]}{[X]}\right)}{[H] + K_a} \tag{7}$$

which is identical with equation (6), indicating that the relative error of the determination of the concentration of both these ligand species is

10^{-10}	1.000	1.000	1.000	1.000	1.000	1.005

the same. This result could be expected since [X] and [HX] are related by the acidity constant, K_a.

An excess of X relative to M allows [HX] to be calculated by the simplified equation (4) irrespective of its actual value; this is surprising, since it would be intuitively expected that if no excess of the HX species exists with respect to M, the complexation equilibrium in which X is involved could significantly affect [HX]′. The reason, of course, is that the M–X–H system behaves as a buffer system over a certain range of concentration ratios.

A similar conclusion may be reached by expressing equations (2) and (3) as a function of [HX] instead of [X], by using the expression for K_a, thus:

$$\psi_0 = \frac{[HX]}{X_T} = \frac{[H]}{[H] + K_a + K_a\frac{[MX][H]}{K_a[HX]}} = \frac{[H]}{[H]\left(1 + \frac{[MX]}{[HX]}\right) + K_a} \tag{8}$$

$$\psi_1 = \frac{[X]}{X_T} = \frac{K_a}{[H] + K_a + K_a\frac{[MX][H]}{K_a[HX]}} = \frac{K_a}{[H]\left(1 + \frac{[MX]}{[HX]}\right) + K_a} \tag{9}$$

These equations yield

$$\frac{[HX]'}{[HX]} = \frac{[H]\left(1 + \frac{[MX]}{[HX]}\right) + K_a}{[H] + K_a} \tag{10}$$

and

$$\frac{[X]'}{[X]} = \frac{[H]\left(1 + \frac{[MX]}{[HX]}\right) + K_a}{[H] + K_a} \tag{11}$$

from which the same considerations as before can be established, when a sufficient excess of [HX] is present relative to the concentration of metal ion.

That is, it is sufficient to work with an excess, relative to M, of the protonated ligand form, HX, in order to determine accurately the true free concentration of X, by way of the simplified equation [5], which does not take into account the complexation equilibrium.

Therefore, an excess of the free ligand under study, [X], with respect to the metal ion M, is unnecessary, for the true concentration [X] to be calculable by means of the simplified equation (5), irrespective of its value. Even if [X] is much smaller than the total concentration of the metal ion, $[X] \ll [M]_{total}$, the true value of [X] can be calculated, provided that the concentration of HX, which itself does not complex M, is in sufficient excess relative to $[M]_{total}$.

The equations for more complex systems are presented in Tables 6–9. In all these cases it can be proved that the considerations shown above for the simplest system are valid. Thus a simple method is established for calculating the free concentrations of all the possible species of a substance susceptible to multiple protonation, and hence for studying co-ordination systems without the need to work with excess of the complexing ligand form. To this end, it is sufficient that the concentration of any one of the ligand species or, in general, the total concentration, X_T, is much greater than that of the metal ion.

It is evident that this result has many applications in the study of metal-ion complexes and would allow study of systems which have not been analysed until now because of the limitations imposed by the impossibility of working with excess of free ligand. It also opens up the possibility of more readily studying mixed-ligand complexes with different complexing species present in the protonation equilibria.

(*Received* 18 *February* 1991. *Revised* 11 *July* 1991. *Accepted* 30 *August* 1991)

Summary—The kinetic behaviour of Cl^-, Br^- and SCN^- exchanges on hydrous tin oxide have been investigated under conditions of particle diffusion and the limited bath technique. Values for the diffusion coefficients, energy of activation and entropy of activation have been calculated. The data obtained have been compared with those reported for other organic and inorganic exchangers.

Hydrous oxides exhibit a high selectivity to some elements and their exchanging properties are often connected with a fairly good stability towards high temperature and ionizing radiations. The factors underlying the behaviour of hydrous oxides as ion exchangers are not clearly understood and contradictory data are often obtained.[1,2] Various works have been carried out to clarify different aspects of the ion exchange behaviour of hydrous oxides. Towards this goal, several studies have been carried out on the ion exchange properties of hydrous tin(IV) oxide,[3–14] for which various composition and ion exchange characteristics have been reported by different investigators, whereas hydrous tin(IV) oxide has been shown to have anionic and cationic ion exchange properties in acidic and alkaline media, respectively.[5–15] Though some kinetic studies have been performed in this laboratory on hydrous oxides;[16–18] such studies on inorganic ion exchangers are generally lackadaisical.[2]

In the present paper, the kinetics of exchange of Cl^-, Br^- and SCN^- with OH^- on hydrous tin oxide are described, and the thermodynamic parameters for the exchange are calculated. The data obtained for this material are compared with those for organic resins and other inorganic exchangers.

EXPERIMENTAL

Reagents

Boiled distilled water and analytical grade chemicals were used.

Hydrous tin oxide. Hydrous tin oxide was prepared by acidification of a sodium stannate solution with nitric acid, followed by treatment of the obtained precipitate with 0.1*M* nitric acid and finally by a prolonged washing with distilled water. After washing, the sample was dried at 50°, immersed in hot water to remove the trapped air, redried at 50°, and stored in a nitrogen atmosphere over saturated ammonium chloride solution.

Kinetic measurements

The radius of the particle of the sieved fractions was determined by measuring the diameter of 100 particles with an optical microscope. The particles were assumed to be spherical and the mean equivalent radius was calculated.

Rates of exchange were determined by the "limited bath technique". A certain weight of the OH^--form of the exchanger was shaken in a thermostatic bath at the desired temperature with a certain volume of (NaX + HX) solution (X = Cl^- or Br^-) of 0.11*M* total halide molarity and 0.01*M* acid concentration. Experiments with SCN were performed at nitric acid and sodium thiocyanate concentrations of 0.01 and 0.1*M*, respectively. The experiments were conducted at a volume of 25 ml/g of solid. After measured time intervals, samples of the supernatant solution were removed for analysis to determine the extent of exchange. The experiments were conducted at 30, 45 and 60° (±1°). In kinetic experiments the results agreed to ±6% for reaction times ≤one minute. At higher reaction times, a better agreement of ±3% was obtained.

*Author for correspondence.

Analysis

The concentration of Cl^-, Br^- and SCN^- ions was determined by volumetric analysis with a standard solution of silver nitrate.[19] Duplicates of the experiments have shown that the results are reproducible to $\pm 3\%$.

RESULTS AND DISCUSSION

Under the conditions of particle diffusion control, a relatively large particle size of the exchanger and vigorous shaking, the following equation applied, provided that the particle diffusion is the rate controlling mechanism.[20]

$$F(t) = 1 - \frac{6}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{n^2} \exp(-n^2 Bt). \qquad (1)$$

where $F(t)$ is the fractional attainment of equilibrium, n is an integer, $B = \pi^2 D_i / r^2$, in which D_i is the effective diffusion coefficient of the exchanging ion inside the exchanger and r is the radius of the particle. When $F(t)$ is less than about 0.4, equation (1) can be approximated to a simpler form.[21]

$$F(t) = \frac{6}{r} (D_i t/\pi)^{1/2} \qquad (2)$$

which hold to a fairly good approximation. Therefore, a plot of $F(t)$ against the square root of the contact time must give a straight line passing through the origin in the region in which $F(t)$ is less than 0.4.

The study of the effect of concentration on the rate of exchange for Cl^-/OH^- at 30° showed that at concentrations higher than $0.05M$, the rate was independent of the concentration of solutions; the straight lines between $F(t)$ and $t^{1/2}$ had the same slope within the experimental errors. When the chloride ion concentration was $0.01M$, however, the rate was much slower than that obtained for the solutions $\geqslant 0.05M$. In addition, linearity between $F(t)$ and $t^{1/2}$ did not hold. These facts show that at $0.11M$ concentration (generally used in this work) of Cl^-, particle diffusion is the controlling mechanism and film diffusion can be excluded.[20]

The plots *Bt vs. t* for the exchange of Cl^-, Br^- and SCN^- on hydrous stannic oxide at different conditions are given in Figs. 1–4. These figures show that straight lines passing through the origin are obtained, which is further proof of a particle diffusion mechanism. The *Bt–t* plots were used instead of equation (2), because the fast rate of the exchange reaction causes a decrease in the number of experimental points falling within the limit of the validity of the equation [$F(t) \leqslant 0.4$]; due to a technical difficulty.

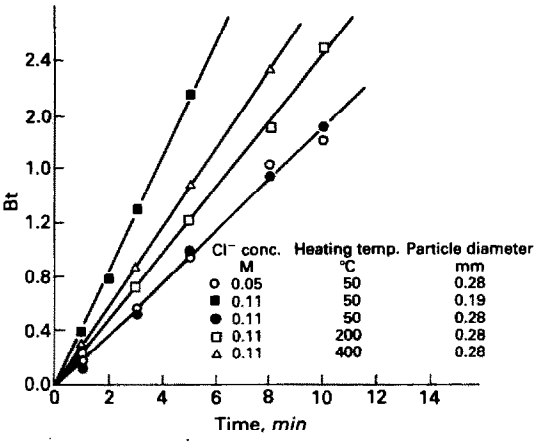

Fig. 1. *Bt vs. t* plots for exchange of Cl^- at 30° on hydrous tin oxide at different conditions.

The effect of the particle size on the rate of exchange for $0.11M$ Cl^- concentration is shown in Fig. 1. Here, *Bt* values were calculated from the measured values of $F(t)$ by using the equation derived by Reichenberg:[22]

$$Bt = 2\pi - \pi^2 3F(t) - 2\pi[1 - \frac{\pi}{3} F(t)]^{1/2} \qquad (3)$$

This equation gives a fairly good approximation in the region where $F(t)$ is less than 0.85.[22] Figure 1 shows that the rate of exchange of Cl^- ion on hydrous tin oxide increases with the decrease of particle diameter, although the effective diffusion coefficients are approximately

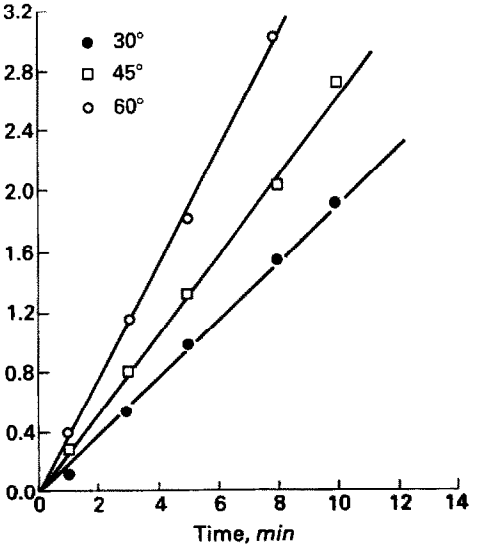

Fig. 2. *Bt vs. t* plots for exchange of Cl^- at different temperatures on hydrous tin oxide.

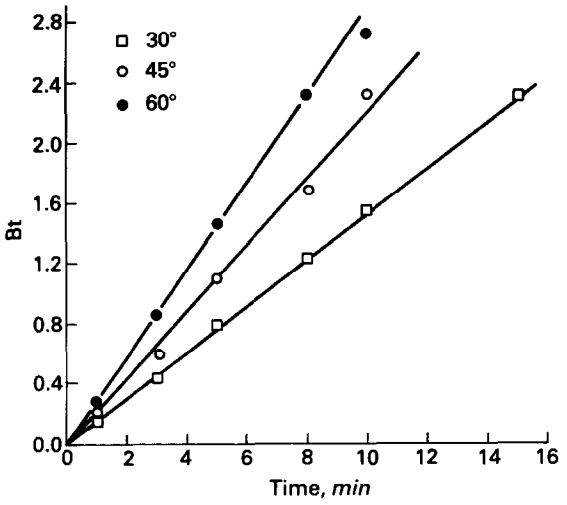

Fig. 3. *Bt vs. t* plots for exchange of Br^- at different temperatures on hydrous tin oxide.

constant (Table 1). This indicates that under these conditions, the rate-determining step is diffusion through the particles.

Figure 1 and Table 1 show an appreciable increase of D_i with an increase in the heating temperature from 50 to 400°. The heating of the same sample of hydrous tin oxide[13,23] increases the porosity and pore size, crystallinity and the pK value of the base behaviour of the remained active sites, due to condensation of the surface OH groups, but decreases the surface area and the pK value of the acid behaviour of these sites (OH groups), in addition to the reduction or elimination of water molecules inside the matrix. The increase of the pK value of the base behaviour decreases the mobility inside the

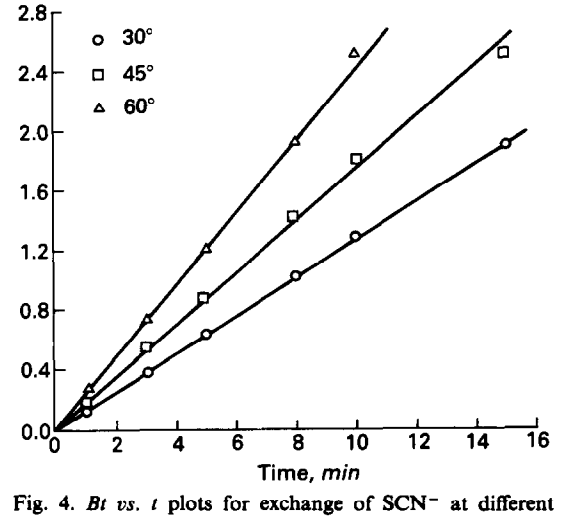

Fig. 4. *Bt vs. t* plots for exchange of SCN^- at different temperatures on hydrous tin oxide.

Table 1. Effective diffusion coefficients at 30° of Cl^- exchange system in hydrous tin oxide at different conditions

Initial Cl^- conc., M	Heating temp. of solid, °C	Particle diameter, *mm*	D_i ($\times 10^{12}$), m^2/sec
0.11	50	0.28 ± 0.025	6.63
0.06	50	0.28 ± 0.025	6.63
0.11	50	0.19 ± 0.03	6.41
0.11	200	0.28 ± 0.025	8.28
0.11	400	0.28 ± 0.025	8.84

particles due to the increase of electrostatic interaction between the anion and the exchange sites.[13] This is not the case and this effect is minor compared to effects of porosity, pore size and crystallinity. Higher porosity means more free water inside the structure which facilitates ion diffusion.[24] The results of the porous texture[13] showed that the most probable hydraulic pore radius, r_h, for the sample dried at 50° is about 0.5 nm, while some widening of the pores occurs at 100–200°, where r_h is around 0.7 nm. This means, the increase of the exchanger rate for the sample heated at 200° may be partly due to the increase of r_h from about 0.5 to 0.7 nm. The further increase of the exchange rate for a sample heated at 400° may be partly due to the further increase of the diffusion coefficient produced by the increase of r_h to about 2.5 nm. Also, the X-ray diffraction patterns of the same sample[13] showed that the crystallinity increases with an increase in heating temperature which may be due to the gradual growth of particles. If the retarding effect of pore walls on the diffusion of ions is small in a well-ordered exchanger matrix, the effective diffusion coefficient of ions may be increased by crystallization of the material. As an example, Nancollas reported that the effective diffusion coefficient of sodium ions in hydrous thorium(IV) oxide was increased by the crystallization of the matrix.[25] Therefore, it may be stated that the porous texture together with the crystallinity have the more important roles of determining the ion mobility inside the matrix.

The initial pH of the solution changes with time during the ion exchange process; this is due to the anion uptake by the solid being accompanied by the release of OH^- in solution. At equilibrium, the pH has a constant value (final pH) which gives an indication about the ion exchange process and the ion uptake in the solid. The percent uptake of Cl^- at 30° on hydrous tin oxide at different

Table 2. Sorption and pH variation at 30° for uptake of Cl^- by hydrous tin oxide under various conditions at liquid: solid ratio (V/m) 25 ml/g

Initial Cl^- conc., M	Initial pH	Heating temp. of solid, °C	Final pH	% Uptake
0.11	2.02	50	2.23	3.37
0.06	2.01	50	2.20	5.96
0.11	2.02	200	2.18	2.73
0.11	2.02	400	2.12	1.88

conditions is given in Table 2. This table shows an increase in pH values due to the release of OH^- ions in solution, since hydrous tin oxide behaves as an anion exchanger in acidic solutions.[5,6,15,23]

The plots of Bt *vs.* t for the exchange of Cl^-, Br^- and SCN^- on hydrous tin oxide dried at 50° are given in Figs. 2, 3 and 4, respectively, for the particle diameter 0.28 ± 0.02 mm at the reaction temperatures 30, 40 and 60°. It is seen from these figures that straight lines passing through the origin are obtained in all cases. The values of D_i obtained under the different conditions are given in Table 3.

The values of the diffusion coefficient obtained (Table 3) for Cl^- and Br^- on hydrous tin oxide are less than that obtained for a strongly anionic resin,[26] but much higher than those for hydrous ceria.[27] On polystyrene resin, D_i for Cl^- and Br^- are reported to be 4.89×10^{-7} and 3.92×10^{-7} cm²/sec, respectively.[26] For hydrous ceria, however, the values of the effective diffusion coefficients are much smaller and are reported to be 42×10^{-10} and 94×10^{-10} cm²/sec for Cl^- and Br^-, respectively.[27] The D_i value of Cl^- at 30° on zirconia, given by Misak *et al.*[28], is 7.8×10^{-8} cm²/sec. Thus, the comparison of the values of the diffusion coefficient reported herein with those of organic resins and other inorganic exchangers indicates that hydrous tin oxide gives rates of exchange less than those of strongly anionic resins but nearly equal to those for some inorganic exchangers.

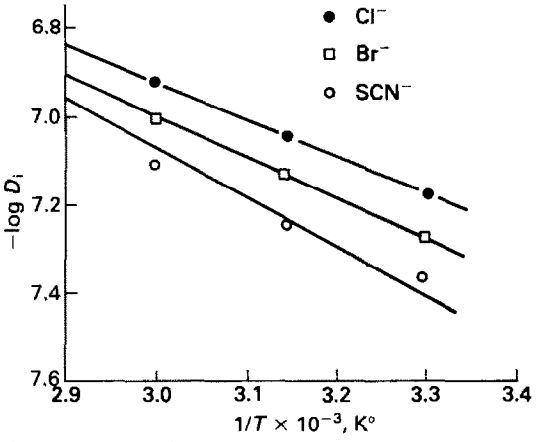

Fig. 5. Arrhenius plots for exchange of Cl^-, Br^- and SCN^- on hydrous tin oxide.

When log D_i is plotted against $1/T$ (Fig. 5), straight lines are obtained, enabling the energy of activation (E_a) and the pre-exponential constant (D_o) to be estimated from an Arrhenius equation

$$D_i = D_o \exp(-E_a/RT)$$

The entropy of activation ($\Delta\overset{*}{S}$) can then be calculated from D_o by substituting in the equation proposed by Barrer *et al.*[29]

$$D_o = 2.72\,(KTd^2/h) \exp(\Delta\overset{*}{S}/R),$$

where K is the Boltzmann constant, T is 273K, d is the average distance between two successive positions in the process of diffusion which was taken as 0.5 mm and h is Planck's constant.

Comparing the diffusion coefficient values (Table 3) at any given temperature it is seen that these are always in the order, $SCN^- < Br^- < Cl^-$. Activation energy values are in the order $SCN^- > Br^- > Cl^-$. It is to be noted that electron affinity follows the reverse of the latter trend; the respective values for the above ions being 209, 329 and 348 kJ/mole. The negative values for the entropy of activation given in Table 3, suggest that upon exchange of these anions no significant structural change occurs in hydrous tin oxide.

ORGANOPHOSPHORUS REAGENTS AS EXTRACTANTS—PART 3. SYNERGIC EFFECT OF TRIPHENYL PHOSPHINE OXIDE AND BIS(DIPHENYL PHOSPHINYL) ALKANES ON EXTRACTION OF IRON(III) FROM THIOCYANATE MEDIUM WITH 2,4-PENTDIONE

(*Received* 8 *March* 1991. *Revised* 20 *June* 1991. *Accepted* 26 *August* 1991)

Summary—The extraction of iron(III) from thiocyanate medium was carried out with a synergic combination of 2,4-pentdione (Hacac) and either triphenyl phosphine oxide (Ph_3PO) or *bis* (diphenylphosphinyl) alkanes, $Ph_2P(O)(CH_2)_n \cdot P(O)Ph_2$ [ligand abbreviation, n: $dpeO_2$, 2; $dpbO_2$, 4]. Iron(III) was quantitatively separated from its binary mixture with chromium(III), manganese(III), cobalt(II), nickel(II), zinc(II), cadmium(II), mercury(II), lead(II), magnesium(II) and from steel samples. Copper(II) and silver(I) however, interfered. The percentage extraction was 99.0%. The respective extraction constants, K_{HA}, K_L or K_{syn}, for the extracted species, $[Fe(NCS)(acac)_2(H_2O)]$ (HA = Hacac), $Fe(NCS)_3L_2$ [L = Ph_3PO, $dpeO_2$ or $dpbO_2$], or $Fe(NCS)(acac)_2L$ were found to be: K_{HA}, 1.48×10^3, K_L, 1.80×10^2 (L = Ph_3PO), 2.02×10^2 (L = $dpeO_2$ or $dpbO_2$) and K_{syn} 1.87×10^6 (L = Ph_3PO), 2.56×10^6 [L = $dpeO_2$ or $dpbO_2$].

Trioctyl phosphine oxide (TOPO) acts as a synergist in the extraction of iron(III), using 1-phenyl-3-methyl-4-(trifluoroacetyl) pyrazole-5-one from aqueous solution (pH 1.5–2.8).[1] Similarly, TOPO–Hacac extracts iron(III) in the presence of perchlorate ions.[2,3] However, no efforts have been made for the separation of iron(III) from various binary, ternary mixtures or steel samples with these reagents. Organophosphorus reagents with aryl substituents on phosphorus are believed to be better extractants than those with alkyl groups.[4]

Recently, we have reported the extraction of silver(I) with Ph_3PO[5] and also used Ph_3PO as a synergist in the extraction of cobalt(II)/zinc(II) with 8-hydroxyquinoline.[6] This paper reports a new and novel method for separating iron(III) from a series of binary mixtures and steel samples, using a simple and readily available combination of Ph_3PO with Hacac. The extraction ability of Ph_3PO is compared with those of its bis (tertiary phosphine oxide) analogues, $Ph_2P(O)(CH_2)_nP(O)Ph_2$ (n = 2,4). The synergic potential of thiocyanate induced extraction of iron(III) with mixed-reagents was demonstrated recently.[7]

*Author for correspondence.

EXPERIMENTAL

Reagents and apparatus

Ammonium ferrous sulphate (Mohr salt) and potassium thiocyanate (KSCN) were of analytical grade and were purchased from Glaxo, Bombay. 2,4-Pentdione (Hacac) and triphenyl phosphine (Ph_3P) were purchased from Sisco-Chem-Industry, Bombay and used as received. 1,2-Ethylene bis(diphenylphosphine) (dpe) and 1,4-butylenebis (diphenyl phosphine) (dpb) were prepared and purified by the literature procedure.[8] All the metal salts were of laboratory reagent grade and were standardized before use. The phosphine oxides, Ph_3PO, $dpeO_2$ and $dpbO_2$, were prepared by oxidation of the corresponding phosphines with potassium permanganate in acetone.[9] Spectrophotometric measurements were made with a Shimadzu UV–visible (UV-240) recording spectrophotometer.

Stock solutions

A stock solution of iron(III) for extraction/calibration containing 10 mg of Fe per 100 ml was prepared from ferrous ammonium sulphate (0.070 g, $1.79 \times 10^{-3}M$) by treating it with 5 ml of concentrated nitric acid followed by the addition of 3.884 g of potassium thiocyanate

(0.4M after removal of the acid) and dilution to 100 ml. The pH of the solution was 2.77–2.80. Alternatively, the stock solution of iron(III) can be made by treating 0.070 g of Mohr salt with 5 ml of 30% hydrogen peroxide. Evaporate to dryness, add 0.5 ml of concentrated hydrochloric acid and 10 ml of distilled water. Then add potassium thiocyanate as above and make up to 100 ml. Similarly, stock solutions of Hacac, Ph_3PO, $dpeO_2$ and $dpbO_2$ of molarities 0.1M each were prepared in $CHCl_3$. The stock solutions of metal ions of different molarities tested for their interference, if any, were prepared and standardized with EDTA (Xylenol Orange as indicator).[10]

For estimation of extracted iron, the thiocyanate method was employed,[7] measuring the absorbance of the red solution at a λmax of 460 nm with a recording UV–Vis spectrophotometer. (The manually operated spectrophotometer VSU2-P instrument gave λmax at 510 nm for the thiocyanate complex.[7])

Procedure for thiocyanate extraction

An aqueous phase containing 2 ml of iron(III) solution with thiocyanate and 3 ml of distilled water was equilibrated with 5 ml of Hacac in $CHCl_3$ (range 0.01–0.10M, see Fig. 1) in a round-bottomed flask with a magnetic stirrer. The equilibrium time was found to be 30 min. After allowing the contents to stand for a further 10–15 min, the two layers were separated and iron(III) from the organic layer was transferred to an aqueous layer by stripping it with a solution of 1 ml of concentrated nitric acid and 4–5 ml of distilled water. After this, evaporate the aqueous solution to dryness to remove excess nitric acid and then add a few ml of distilled water and 5 ml of 0.01M potassium thiocyanate solution. Make the volume to 10 ml and measure the absorbance at 460 nm as before. Determine iron from a calibration curve. Similarly, iron left in the original aqueous layer after extraction was determined with 0.01M potassium thiocyanate. (If 1 ml of concentrated hydrochloric acid is used for stripping, its removal is not necessary.) The procedure for extraction of iron(III) with Ph_3PO, $dpeO_2$ or $dpbO_2$ was similar, in which Hacac in $CHCl_3$ was replaced with a phosphine oxide [range 0.01–0.10M, see Fig. 1 (b–d)].

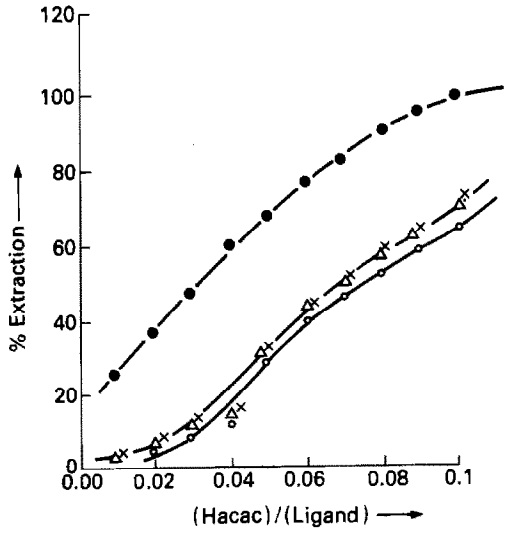

Fig. 1. Plot of % extraction *vs.* (a) ● [Hacac] (b) ○ [Ph_3PO] (c) △ [$dpeO_2$] (d) * [$dpbO_2$]

Synergic extraction

Three synergic systems were developed for enhanced extraction of iron(III) from the thiocyanate medium. One synergic system involves the equilibration of 2 ml of iron(III) solution ($1.79 \times 10^{-3}M$) with 5 ml of 0.05M Hacac and 5 ml of 0.01M Ph_3PO solutions in $CHCl_3$ and 8 ml of distilled water (for keeping the volumes of the two phases the same). For other systems, 2 ml of iron(III) solution was equilibrated with 5 ml of 0.04M Hacac and 5 ml of 0.01M $dpeO_2$ or $dpbO_2$ solutions in $CHCl_3$ and 8 ml of distilled water. The equilibrium time was 15 min instead of 30 min with Hacac alone. The rest of the procedure was similar to above.

Separation of iron(III) from binary mixtures and steel samples

Varying amounts of a metal salt (0.01M) were added to the above synergic combinations for testing their interference. The metals added were estimated by EDTA titration in order to check any possible transfer of the metal to the organic layer.[10] Various metal salts used were: $CrCl_3$ (hydrated), $MnSO_4H_2O$, $CoCl_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, $CoSO_4 \cdot H_2O$, $Co(CH_3CO_2)_2 \cdot 4H_2O$, $NiCl_2 \cdot 6H_2O$, $Ni(NO_3)_26H_2O$, $Ni(CH_3CO_2)_2 \cdot 4H_2O$, $Cu(CH_3CO_2)_2 \cdot H_2O$, $CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2$, $CuSO_4 \cdot 5H_2O$, $ZnSO_4 \cdot 7H_2O$, $ZnCl_2$, $Zn(CH_3CO_2)_2 \cdot 2H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$, $CdCl_2$, $HgCl_2$, $AgNO_3$, $MgCl_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 6H_2O$, $MgSO_4 \cdot 7H_2O$ and $Pb(CH_3CO_2)_2$.

By using the synergic combination Hacac–Ph_3PO, a new method was developed to separate iron(III) from steel samples. The method is as follows: weigh 0.100 g of the steel sample (blade) and treat it with 5 ml of concen-

trated hydrochloric acid to dissolve the sample and then add 5–10 ml of concentrated nitric acid. Evaporate the solution to dryness, repeat the process with another 5 ml of nitric acid, add a few milliliters of water and 3.88 g of potassium thiocyanate and make up volume to 100 ml with distilled water. Take 0.2 ml of this solution and equilibrate for 15 min with 5 ml of 0.05*M* Hacac in $CHCl_3$ and 5 ml of 0.01*M* Ph_3PO in $CHCl_3$ and 9 ml of distilled water. Separate the two layers and estimate iron from each layer as described earlier to determine extraction efficiency. In order to check whether iron was quantitatively extracted from the steel sample, iron was also determined from a steel sample with the thiocyanate method or the 1,10-phenanthroline method.[11]

RESULTS AND DISCUSSION

The extraction of iron(III) from 0.4*M* potassium thiocyanate with Hacac in $CHCl_3$ can be represented by the equation:

$$Fe^{3+} + mSCN^- + nHacac \overset{K_{HA}}{\rightleftharpoons} Fe(acac)_n(SCN)_{m-n} + nHSCN \quad (1)$$

The extraction of iron increases with an increase in concentration of Hacac and becomes quantitative at about 0.1*M* Hacac [Fig. 1(a)]. From Fig. 2(a), which is a plot of log *D vs.* log [Hacac], it can be seen that for 0.01–0.07*M* Hacac concentration, the slope of the line is 2, suggesting $Fe(SCN)(acac)_2$(hydrated) as the extracted species and for 0.075–0.10*M* Hacac concentration, the slope was 3, suggesting $Fe(acac)_3$ as the extracted species.

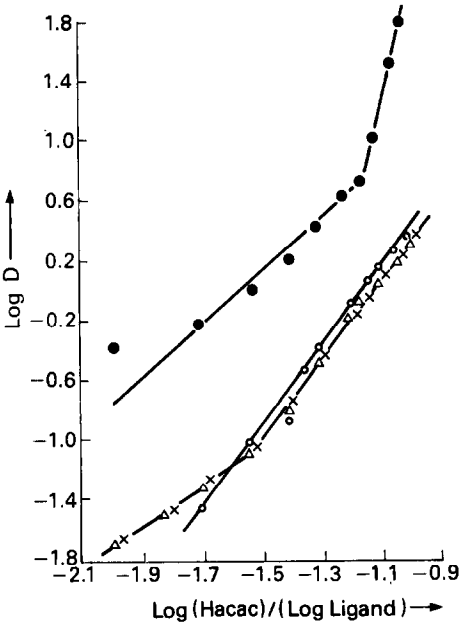

Fig. 2. Plot of log *D vs.* (a) ● Log [Hacac] (b) ○ Log [Ph_3PO] (c) △ Log [$dpeO_2$] (d) * Log [$dpbO_2$]

In order to develop a synergic system, consisting of Hacac and tertiary phosphine oxides, the extraction of iron(III) with Ph_3PO, $dpeO_2$ or $dpbO_2$ was also carried out separately. The extraction of iron(III) in the presence of SCN^- with Ph_3PO, $dpeO_2$ or $dpbO_2$ can be written as shown in equation (2):

$$Fe^{3+} + 3SCN^- + nL \overset{K_L}{\rightleftharpoons} Fe(SCN)_3L_n \quad (2)$$

(L = Ph_3PO, $dpeO_2$ or $dpbO_2$).

Again from the log *D vs.* log [Ph_3PO] plot [Fig. 2(b)], the slope of the line is 2.2, suggesting that iron(III) was extracted as $Fe(NCS)_3(OPPh_3)_2$. The extraction with Ph_3PO increases with an increase in its concentration from 0.01–0.10*M* [Fig. 1(b)], but the maximum extraction was 65.4% at 0.10*M* Ph_3PO. The extraction with $dpeO_2$ or $dpbO_2$ was slightly better, but even here no quantitative extraction could be achieved at 0.1*M* $dpeO_2$ or $dpbO_2$ concentration [Fig. 1(c) and 1(d)]. From log *D vs.* log [L] plots [Fig. 2(c) and 2(d)], the species were found to be $Fe(SCN)_3L_{1.5-2}$ (L = $dpeO_2$ or $dpbO_2$).

The synergic extraction of iron(III) with Hacac and the phosphine oxide ligands may be represented as shown in equation (3).

$$Fe^{3+} + mSCN^- + nHacac + pL \overset{K_{syn}}{\rightleftharpoons} [Fe(SCN)_{m-n}(acac)_nL_p] + nHSCN \quad (3)$$

(L = Ph_3PO, $dpeO_2$ or $dpbO_2$).

Again, for a linear plot of log *D vs.* log [Hacac] at fixed Ph_3PO concentration, the slope of the line was 2, indicating that only two Hacac molecules are attached to iron(III) in the synergic species. Similarly, from the plot of log *D vs.* log [Ph_3PO] at fixed Hacac concentration [Fig. 3(a)], the slope of one indicates the attachment of only one Ph_3PO molecule. Thus, iron(III) was extracted as $Fe(SCN)(acac)_2(OPPh_3)$. Hence, the enhanced Hacac extraction is attributed to the replacement of water by Ph_3PO from $Fe(SCN)(acac)_2(H_2O)$, the species when Hacac alone is the extractant.

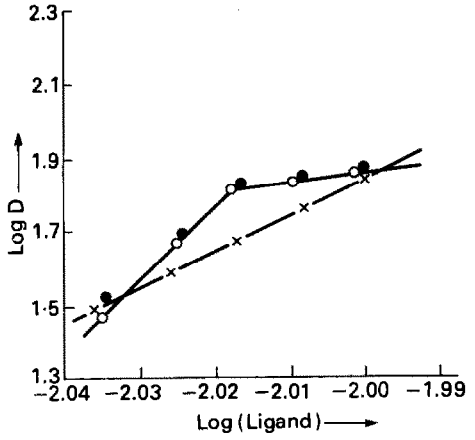

Fig. 3. Plot of log D *vs.* (a) * Log [Ph_3PO] (b) ○ Log [$dpeO_2$] (c) ● Log [$dpbO_2$] (Constant [Hacac])

Similarly, from the linear plot of log D *vs.* log [Hacac] at constant $dpeO_2$ or $dpbO_2$ concentration, the slope of the line was 2. And the plot of log D *vs.* log [L] (L = $dpeO_2$ or $dpbO_2$) at fixed Hacac concentration, showed slopes of one in each case [Fig. 3(b) or 3(c)]. From these studies, the extracted species was identified as $Fe(SCN)(acac)_2L$ (L = $dpeO_2$ or $dpbO_2$).

A 0.05M Hacac solution shows 68.5% extraction of iron(III) while 0.01M Ph_3PO shows no measurable extraction; however, the combination of the two gives 98.5% extraction indicating synergism enhancement of 30%. Similarly, using 0.04M Hacac shows 61.0% extraction while 0.01M $dpeO_2$ or $dpbO_2$ shows no extraction and the combination of the two again shows 99.0% extraction with a synergism of 37%. The increase in chain length from $n = 2$ to 4 made no impact. Since only one coordination site is undergoing replacement of water by a phosphine oxide, the possibility of a chelate effect is remote. A plausible explanation for the higher synergism shown by bisphosphine oxides is the enhanced hydrophobic environments generated by the bulky diphosphine oxides *vs.* Ph_3PO.

By following the procedure as described in the literature[12,13] the expressions for D can be written as:

$D = K_{HA}$ [Hacac]^2
[from equation (1), 0.01–0.07M Hacac range].

$D = K_L$ [L]^2 [from equation (2)].

$D = K_{syn}$ [Hacac]^2 [L] [from equation (3)].
(L = Ph_3PO, $dpeO_2$ or $dpbO_2$).

Using linear regression analysis,[14,15] the values of K_{HA}, K_L and K_{syn} were calculated (Table 1). This table shows that K_L and K_{syn} for bidentate ligands ($dpeO_2$ or $dpbO_2$) are somewhat higher than for Ph_3PO.

The stability constant ($\beta = K_{syn}/K_{HA}$) for the synergic reaction:

$$Fe(SCN)(acac)_2(H_2O) + L \overset{\beta}{\rightleftharpoons} Fe(SCN)(acac)_2L + H_2O \quad (4)$$

(L = Ph_3PO, $dpeO_2$ or $dpbO_2$).

was $1.26 \times 10^3 M^{-1}$ for $Fe(NCS)(acac)_2(Ph_3PO)$ and $1.73 \times 10^3 M^{-1}$ for $Fe(NCS)(acac)_2(L)$ (L = $dpeO_2$ or $dbbO_2$). This shows that the stability of the synergic species was similar for all three types of ligands.

Separation of iron(III) from different metal ions and steel samples

The separation of iron(III) from the binary mixtures of different metal ions was carried out with synergic combination (Hacac and Ph_3PO). Iron(III) was separated from chromium(III), manganese(II), cobalt(II), nickel(II), zinc(II), cadmium(II), mercury(II), lead(II) and magnesium(II); however copper(II) and silver(I) interfered. There was no effect of Cl^-, NO_3^-, CH_3COO^- or SO_4^{2-} ions tested (added as sodium salts) on extraction of iron(III). In the case of chromium(III), it was initially noted that multiple extraction was needed for extraction when chloride was the anion. But later the effect was traced to the presence of hydrochloric acid possibly associated with chromium chloride [obtained from treatment of $Cr(CH_3CO_2)_3$ with concentrated hydrochloric acid] and formation of Fe–SCN ... $HCrCl_4$ species appears likely. The addition of concentrated hydrochloric, nitric, ethanoic or sulphuric acids interfered in the extraction. Thus, from the above, thiocyanate induced extraction of iron(III) is highly specific

Table 1. The extraction constant data

Species	K values	σ*
$[Fe(SCN)(acac)_2(H_2O)]$	1.48×10^3 (K_{HA})	11.5
$[Fe(SCN)_3L_2]$		0.129
L = Ph_3PO	1.80×10^2 (K_L)	
L = $dpeO_2$ or $dpbO_2$	2.02×10^2 (K_L)	0.143
$[Fe(SCN)]acac)_2(L)]$		
L = Ph_3PO	1.87×10^6 (K_{syn})	19.8
L = $dpeO_2$, $dpbO_2$	2.56×10^6 (K_{syn})	20.2

*The standard deviation (σ) was calculated by using the equation: $\sigma = \sqrt{\Sigma(D_{cal} - D_{exp})^2/n_p - 1}$ where D_{exp} is the experimental value of the distribution coefficient and D_{cal} is the corresponding value calculated from K by a computer program and n_p is the number of experimental points.

in the presence of other ions and quantitative. Iron(III) present up to 10^{-6} g per ml could be readily extracted.

A new method of separation of iron(III) from a number of steel samples (*i.e.*, from blades of different quality) is reported by using the synergic combination Hacac–Ph_3PO. The percentage of iron(III) from steel samples selected for extraction was found to be $72.00 \pm 0.10\%$. The percentage of iron(III) in the steel sample was $71.00 \pm 0.02\%$ as checked by the 1,10-phenanthroline or thiocyanate method.[11] Thus, it is demonstrated that the Hacac–Ph_3PO (or Hacac–$dpeO_2$ or –$dpbO_2$) combination is a simple and novel method of quantitative separation of iron(III) present in different samples.

Effect of different solvents

Finally, the same percentage extraction was obtained when chloroform was replaced by benzene or toluene in the synergic system, Hacac–Ph_3PO–SCN^-. However, Ph_3PO was poorly soluble in carbon tetrachloride, n-hexane, or cyclohexane and thus they could not be studied.

Summary—The protonation constants of some substituted 4-quinolone carboxylic acid anions (ofloxacin, pefloxacin and ciprofloxacin) were determined in lithium chloride solution of various concentrations at 293, 303 and 313 K using the pH-metric and spectrophotometric methods. The values of thermodynamic parameters (ΔG, ΔH and ΔS) for the first protonation step of these anions in 0.1*M* lithium chloride at 293 K, are reported. The formation of intramolecular hydrogen bonds is discussed.

Ofloxacin (**I**), pefloxacin (**II**) and ciprofloxacin (**III**) are broad spectrum antibiotics developed during the last decade.[1] They all possess a carbonyl group in position "4" thus, they are often referred to as 4-quinolones. These quinolone carboxylic acids are active against many gram-positive and gram-negative bacteria.[2–4] Increase in their antibacterial activity is greatly influenced by substituent groups at positions 6, 7 and 8.[5] The antibacterial activity of 4-quinolones is pH-dependent since they act by inhibition of bacterial DNA gyrase, a process which depends upon both the pH and concentration of the acid.[1] Therefore, the examination of protonation equilibria in 4-quinolone acid solutions is essential in understanding their antibacterial activity. Furthermore, the investigation of the complexing ability of these ligands towards some essential bio-elements and $Al^{(III)}$ and $Mg^{(II)}$ ions is of interest since they may interact with other drugs, during the parallel therapy [especially with antacids containing $Al^{(III)}$ and $Mg^{(II)}$ ions in drug formulation] as well as with the essential metal ions in the serum [$Fe^{(III)}$, $Cu^{(II)}$ *etc.*]. For such investigations the determination of their thermodynamic parameters is needed in order to quantitatively characterize these interactions.

Protonation constants of anionic forms of (**I**)–(**III**) 4-quinolones have not been reported in the literature so far, hence present work is aimed at the determination of protonation constants of these compounds at various temperatures and ionic strengths of the lithium chloride medium using the pH and spectrophotometric measurements.

EXPERIMENTAL

Reagents

Ofloxacin [abbreviated as H(ofl)] was from Hoechst (Frankfurt am Main, F.R.G.), purity 100%, pefloxacin-methanesulphonate dihydrate (H_2pef 2 H_2O), Rhone (Pulenc, France) purity 99.6% and ciprofloxacin hydrochloride monohydrate (H_2cip H_2O), Bayer (Leverkusen, F.R.G.) purity 99.5%. Standardization was performed by potentiometric titration, showing the high purity of the acids. The lithium chloride p.a. Merck (Darmstadt, F.R.G.) was used as ionic medium. Carbonate-free sodium hydroxide solution, standardized with potassium hydrogenphthalate, was used as titration agent. Hydrochloric acid solution was prepared from "Suprapure" hydrochloric acid (Merck) and standardized against tris(hydroxymethyl) aminomethane. The pH-meter was adjusted with the phosphate buffer, pH = 7.00 ± 0.02

and phthalate buffer, pH = 4.01 ± 0.01, at 293 K (products of Radiometer). The stock solution of acids (nominally $5.00 \times 10^{-3} M$) were prepared by dissolution of a weighed amount of solid substances, at room temperature. The working solutions were made by dilution of stock solutions and addition of lithium chloride and water until the volume reached 25.00 ml. For preparation of the solutions doubly distilled water, degassed with purified nitrogen gas, was used.

Instrumentation and procedure

The following equipment was used: a PHM-62 Radiometer (Denmark) pH-meter with combined GK 2401C electrode, a TTT-60 titrator with ABU-12 burette (Radiometer), a UV–Vis Shimadzu (Japan) model 2100 spectrophotometer with 1-cm quartz cells, an IR Perkin–Elmer (U.S.A.) Model 137 spectrophotometer and an NMR Bruker (F.R.G.) Model WM-250 spectrometer operating at 200 MHz. The calculations were performed on a PC AT 386/25 compatible computer equipped with an i387 coprocessor.

The electrochemical cell, filled with working solution, was immersed in a paraffin-oil thermostat and a constant temperature was maintained within ±0.02 K. Titrations were performed at 293, 303 and 313 K. The nitrogen gas, purified by passing through the series of washing bottles (10% sulphuric acid, 10% sodium hydroxide, Fieser's solution, water and lithium chloride solution, same as used for the medium in working solutions) was bubbled through the cell. Sodium hydroxide ($0.0874 M$) was added stepwise, every 20 min and pH readings were recorded every minute until stable values within ±0.01 pH units were obtained. The electrode system was calibrated, in terms of hydrogen ion concentration according to Irving *et al.*[6] Dilute hydrochloric acid solutions (2.5 and $5.0 \text{m}M$) were titrated with standard alkali under the same medium and temperature conditions as the test solutions. The value of p[H] (−log[HCl]) was calculated at various points on the titration curves and subtracted from the pH values read from the pH-meter. In this way, the calculated values of the correction factor, A, according to the equation:

$$\text{pH} = \text{p[H]} + A \qquad (1)$$

were used in the conversion of the pH readings (obtained in test solution titrations) into p[H]. The final volume of solution, at the end of titration, did not exceed 26.0 ml, so that it may be assumed that the total concentration of acid was kept constant during the titration (change in concentration less than 4%).

UV spectra were taken in the 200–400-nm wavelength range in water, methanol and ethanol as solvents. IR spectra were obtained with the potassium bromide pellet technique. ^{1}H-NMR spectra of ciprofloxacin were taken in d_6-DMSO at pH ~ 3.5 and in D_2O at pD ~ 10.0. Chemical shifts are reported relative to DDS in ppm.

RESULTS AND DISCUSSION

Potentiometric measurements

The protonation constants of ofloxacin, pefloxacin and ciprofloxacin were determined in 0.10, 0.05 and 0.02*M* lithium chloride medium at 293 K as well as in 0.1*M* lithium chloride at 293, 303 and 313 K. Owing to low concentrations of the acids used, the ionic strength of the solutions was assumed to be equal to the concentration of the ionic medium.

In each medium concentration at least two titrations were carried out with various acid concentrations (2.5 and 4.0m*M*) in the pH range 4.0–10.5. Approximately 60–70 pH-volume readings were taken.

The protonation constants, defined according to the equilibrium:

$$iH + L \leftrightharpoons H_iL; \quad K_i = \frac{[H_iL]}{[H][H_{i-1}L]} \qquad (2)$$

L = ofl, pef or cip

were estimated by use of the general equation:

$$\log K_i = \log \frac{(1-a+n-i)C_{H_nL} - [H] + [OH]}{(a-n+i)C_{H_nL} + [H] - [OH]} + p[H] \qquad (3)$$

where K_i is the ith protonation constant of L and a is the degree of titration.* Obtained values of protonation constants were further refined with the aid of the general least-squares program SUPERQUAD.[7,8] The constants were calculated by minimizing the error-square sum, U of potentials:

$$U = \sum w_i (E_{obs} - E_{calc})^2 \qquad (4)$$

where E_{obs} is a potential obtained from the measured value of p[H] according to the formula:[7]

$$E_{obs} = 10 + RT/F \times p[H] \qquad (5)$$

and E_{calc} refers to the potential calculated from the trial values of protonation constants. The weighting factor, w_i, is defined as the reciprocal of the estimated variance of measurement:

$$w_i = 1/\sigma^2 = 1\Big/\left[\sigma_E^2 + \left(\frac{\partial E}{\partial V}\right)\sigma_V^2\right] \qquad (6)$$

where σ_E^2 and σ_V^2 are the estimated variances of the potential (*i.e.*, due to pH) and volume readings, respectively. The quality of fit was judged by the values of sample standard deviation, s, and the goodness of fit, χ^2 (Pearson's test). At $\sigma_E = 0.01$ pH and $\sigma_V = 0.003$ ml, the values of s, in different sets of titrations were between 1.4 and 1.8 and χ^2 was between 1.4 and 12.9, thus indicating a good fit of experimental data. In some titrations the resultant statistics were unacceptable ($s > 3.0$ and $\Delta \log K > 0.15$). It was thought that this may be caused by the errors in alkali and total proton concentrations. Therefore, these quantities were refined together with $\log K$. The alkali concentration changed from the initial value of 0.0874 to 0.0862*M* and total proton concentration changed by 0.8%. These changes resulted in much better statistics ($s < 2.0$, $\Delta \log K < 0.02$) and improved scatter of residuals. In cases where no better statistics were obtained the titration was discarded.

The calculated values of protonation constants are presented in Table 1 together with calculated standard deviations given in parenthesis.

The calculated standard deviations in protonation constants reflect only the random errors, inherent to experiments. In order to calculate total absolute errors in protonation constants, other sources of errors, such as standardization and dilution of reagents, calibration of pH-meter, *etc.*, were considered. The error-propagation law gives the absolute error in $\log K$ as:

$$\Delta \log K = \sum \frac{\partial \log K}{\partial X_i} \Delta X_i \qquad (7)$$

where pH, volume of base added, V and equivalence volume, V_{eq} (which accounts for errors in reagents standardization) where taken as independent variables, X_i. Absolute errors in these values were: $\Delta pH = 0.01$, $\Delta V = 0.003$ ml and $\Delta V_{eq} = 0.01$ ml. Partial derivatives were calculated according to Still.[9] It was found that total absolute errors in all protonation constants are less than 0.04 log units.

Table 2. Thermodynamic parameters of the first dissociation step of 4-quinolone acids at a temperature 293 K and ionic strength $\mu = 0M$, ΔG, kJ/mole, ΔH, kJ/mole, ΔS, J mole^{-1} K^{-1}

	Ofloxacin	Pefloxacin	Ciprofloxacin
ΔG	−46.1	−41.5	−48.4
ΔH	−17.3	−10.5	−16.1
ΔS	98	106	110

Thermodynamic protonation constants at zero ionic strength, at 293 K have been determined by extrapolation of the straight line log K_i *vs.* $\sqrt{\mu}$ and they are also given in Table 1. Changes in thermodynamic functions, ΔG, ΔH and ΔS, related to the first protonation step of ligands, at 293 K, were calculated by use of the equation:[10]

$$\log K_1 = -\frac{\Delta H}{RT} + \frac{\Delta C_p}{R} \ln T + \frac{\Delta S - \Delta C_p}{R} \quad (8)$$

$$\Delta G = \Delta H - T\Delta S$$

by plotting log K_1 *vs.* $1/T$ and assuming $\Delta C_p = 0$ over the temperature range investigated. The values obtained are presented in Table 2.

There are two available protonation sites in ofloxacin, *i.e.*, nitrogen at position 4′ in piperazinyl substituent and the carboxylate group. The protonation constant for $i = 1$, in Table 1 refers to protonation of the carboxyl group at position 3 since ofloxacin was originally in the base form with respect to piperazinyl nitrogen, and no free strong acid was added prior to titration. It may be concluded, judging by the value of the obtained constant, that the protonation constant K_1 of pefloxacin and ciprofloxacin also refers to protonation of the carboxyl group. The second protonation constant of pefloxacin, K_2 refers to protonation of the methylsulphonic group ($CH_3SO_3^-$) since pefloxacin was originally in the form of methanesulphonate, while in ciprofloxacin the K_2 refers to protonation of the nitrogen in the piperazinyl substituent. The log K_2 value for ciprofloxacin is 6.34 and for piperazine[11] 5.68, thus the basic character of piperazinyl nitrogen in ciprofloxacin is more pronounced than in piperazine.

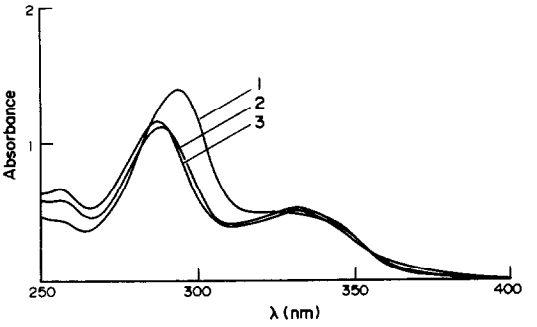

Fig. 1. Spectra of ofloxacin: (1) 0.1M HCl, (2) pH = 5.94, (3) 0.1M NaOH.

Spectrophotometric measurements

The spectra of ofloxacin, pefloxacin and ciprofloxacin solutions ($4.00 \times 10^{-5}M$) at pH values between 4.0 and 10.0, and in 0.1M sodium hydroxide as well as in 0.1M hydrochloric acid were recorded in the wavelength range 200–400 nm at 293 K. The pH of the solutions was adjusted by the buffers prepared according to Perrin.[12] Part of the spectra obtained are shown in Fig. 1 (ofloxacin), Fig. 2 (pefloxacin) and Fig. 3 (ciprofloxacin).

Spectra exhibit two well defined bands; the higher energy band is symmetric, while the lower energy band is asymmetric with a shoulder for ofloxacin. For pefloxacin and ciprofloxacin this band is split at pH values higher than 7.3 into two close bands. A higher energy band, centred at 280 nm may be attributed to the $\pi \rightarrow \pi^*$ transition in the

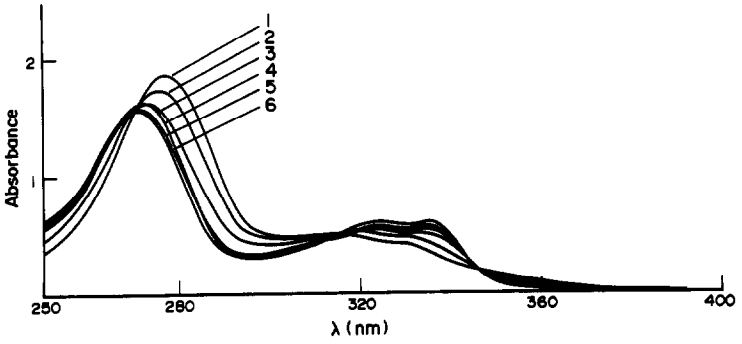

Fig. 2. Spectra of pefloxacin: (1) 0.1M HCl, (2) pH = 5.90, (3) pH = 6.55, (4) pH = 7.27, (5) pH = 8.33, (6) 0.1M NaOH.

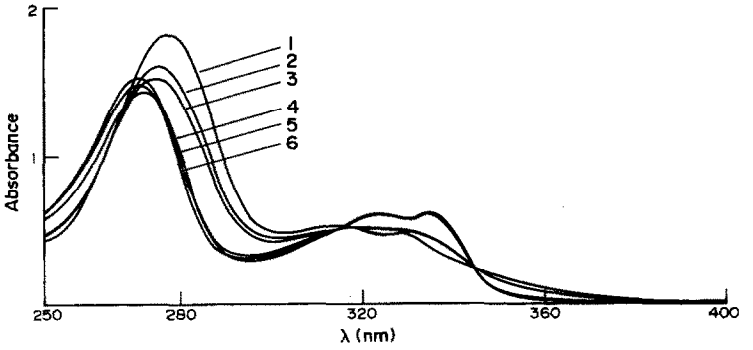

Fig. 3. Spectra of ciprofloxacin: (1) 0.1*M* HCl, (2) pH = 5.77, (3) pH = 5.90, (4) pH = 7.27, (5) pH = 8.33, (6) 0.1*M* NaOH.

quinolone nucleus whilst the broad, lower energy band, situated at 310–350 nm may partly arise from the piperazinyl substituent. The position and intensity of all bands are pH-dependent. The values of protonation constants and molar absorptivities of each species in solution were calculated with the aid of SQUAD[13] and SPECFIT[14] programs. Both programs were compiled with MicroWay's NDP386 v. 3.1 Fortran compiler. The performance of both programs was nearly equal though SPECFIT ran a bit faster and needed less iterations to achieve convergence. The data used for calculation comprised 10 spectra for each acid, between pH 5.0–9.0 in the 250–360-nm wavelength interval; absorbance readings were taken every 5 nm. Both programs gave nearly the same results (the differences in calculated constants and molar absorptivities were less than 1%). The calculated values of protonation constants, molar absorptivities and wavelengths of maximum absorption, are presented in Table 3.

The standard deviation of absorbance data was less than 1.5×10^{-3} and standard deviations of protonation constants were in the range 0.03–0.05 log K units, indicating a good fit of the data. The log K_1 values obtained are within 0.2 log K units of potentiometrically determined values, whilst the values determined for log K_2 show better agreement with potentiometric data.

Comparison of the acid strength shows that the pefloxacin is stronger than the other two acids (dissociation of the carboxyl group). The strength of the acids studied here, with respect to dissociation of the carboxyl group at position 3 is primarily determined by two effects: (a) the resonant acid-weakening effect in the quinolone nucleus and (b) the hydrogen bond between carbonyl oxygen (at position 4) and hydrogen from the carboxyl group. The strength of the resonant effect depends upon the mobility of the free electron pair located on nitrogen at position 1. This in turn, depends on the nature of the substituent on that nitrogen. As can be seen from formulae **I–III**, all the substituents on nitrogen at position 1 exhibit a positive inductive effect but the ethyl substituent in pefloxacin is in this respect stronger than the other two. It should lead to a slight decrease in negative charge located on the carbon at position 3 (*meta* with respect to nitrogen) thus giving rise to an increase in acidity. It would be of interest to compare the strength of the acids **I–III** with unsubstituted 4-quinolone-3-carboxylic acid. However, to the best of our knowledge there is presently no available data in the literature. It

Table 3. Spectral characteristics and log K values determined for 4-quinolone acids at 293 K

has been reported that structurally similar nalidixic acid,[16] which has a naphthyridine nucleus, possesses a dissociation constant $pK_a = 6.0$. Such an increase in acidity, in comparison with quinolone acids, may be explained in terms of a negative resonant effect from the pyridine part of the naphthyridine nucleus.

The second effect playing an important role in the acid strength of 4-quinolone acids is the formation of hydrogen bonds. As can be seen from formulae **I–III** the formation of *intra*molecular hydrogen bonds is accompanied by closing the six membered ring leading to an increase in the stability of the bond. The PMR spectrum of ciprofloxacin in D_2O, at pD ~ 10.0 consists of two well-resolved resonances at 1.1 and 1.3 ppm arising from cyclopropan hydrogens (CH_2) and a singlet at 3.6 ppm (CH), two sharp multiplet resonances at 3.1 and 3.3 ppm from piperazinyl hydrogens, two doublets centred at 7.5 and 7.9 ppm from hydrogens belonging to the quinolone nucleus and a singlet sharp resonance at 8.46 ppm belonging to hydrogen in piperazine substituent bonded to nitrogen. In d_6-DMSO the position of resonances are only slightly changed, however at 9.30 ppm a broad low-intense resonance appears, arising from the hydrogen of the carboxyl group. The shape and position of this resonance indicate that the hydrogen of the carboxyl group is involved in the hydrogen bond. The position and shape of this resonance was virtually unchanged upon dilution. The formation of an *intra*-molecular hydrogen bond is supported by UV spectral data obtained in methanol and ethanol solvents. The position of the higher energy peak was almost unchanged with respect to water. The peak intensity slightly increased when changing from ethanol to methanol and water. Ciprofloxacin was practically insoluble in n-hexane, dioxane and $CHCl_3$, so that the spectra in these solvents could not be obtained. The IR spectrum shows a band at 3550 cm^{-1} of medium intensity and a weak band at 3400 cm^{-1}; both are attributed to the stretching vibrations of the associated OH^- group.[17] In the carboxylate stretching region two sharp intensive bands occur at 1720 and 1650 cm^{-1}, indicating the presence of a hydrogen bond.[17]

PRECONCENTRATION OF TRACE AMOUNTS OF MANGANESE FROM NATURAL WATERS BY MEANS OF A MACRORETICULAR POLY(DITHIOCARBAMATE) RESIN

M. C. YEBRA-BIURRUN,* M. C. GARCÍA-DOPAZO, A. BERMEJO-BARRERA and M. P. BERMEJO-BARRERA

Department of Analytical Chemistry, Nutrition and Bromatology, Chemistry Faculty, University of Santiago de Compostela, 15706-Santiago de Compostela, Spain

(*Received* 2 *September* 1991. *Revised* 15 *October* 1991. *Accepted* 24 *October* 1991)

Summary—A chelating poly(dithiocarbamate) resin (PDTC) with macroreticular support is characterized as effective collector for traces of manganese from natural waters. Using small PDTC columns preconcentration of manganese can be achieved even at high flow-rates (5–6 ml/min) and sample volumes (1500 ml). Accordingly, PDTC resin is used for the preconcentration of manganese from water samples prior to its determination by flame atomic-absorption spectrometry. A series of ions abundant in natural waters do not interfere. The sensitivity and detection limit were 2.5 and 0.5 μg/l., respectively. The relative standard deviations of the results for a manganese concentration of 40–400 μg/l. are in the range 1.1–6.2%. In mineral and tap waters analysed, the manganese concentration range was between 2.9 and 30.8 μg/l.

Manganese is an important element from the environmental perspective, being essential for organisms and plants. However, excessive intake can cause lesions.[1]

In general, concentrations of manganese in fresh waters[2] are in the range 0.02–130 μg/l. Therefore the determination of this metal ion often requires atomic spectrometric methods offering low detection limits, for instance AAS combined with preconcentration techniques.[3] An important technique used for the collection of manganese from water samples is ion-exchange. The iminodiacetate-containing resin Chelex-100 is the most commonly employed chelating resin for the removal and preconcentration of trace heavy metals from waters.[4–7] However, that technique is rather time-consuming (sample flow-rates of 1–2 ml/min) and suffers from the fact that removal of calcium and magnesium from the resin prior to elution of trace metals requires careful washing procedures.[6,7] Some work has been done to synthesize and use the preconcentration chelating collectors containing the dithiocarbamate group which forms chelates with a relatively wide variety of metal ions. Horváth and Barnes[8] evaluated the alteration of chelating efficiency of a poly(dithiocarbamate) resin caused by thiocyanate contamination for copper, cobalt and iron(III). Van Berkel and Maesson[9] described a method for the determination of traces of transition elements in seawater and biological materials with sample enrichment by a PDTC resin, but at the pH used (pH 5) the sequestration of manganese is poor. Leyden and Luttrell[10] used a chelating collector containing dithiocarbamate groups with a matrix of silica gel. Manganese reaches a 90% extraction level with this sorbent at pH 9.5. Imai *et al.*[11] synthesized dithiocarbamate celluloses and investigated the pH dependency of the adsorption of various metal ions by four DTC celluloses: the adsorption of manganese increased sharply in the alkaline region.

The application of a poly(dithiocarbamate) resin (PDTC) with macroreticular support to the determination of manganese in natural waters is reported here. The synthesis and characterization of this resin have been described elsewhere.[12] According to Yebra-Biurrun *et al.*[12] the PDTC resin revealed no affinity for alkali and alkaline earth elements. Moreover, very high preconcentration factors could be achieved at high flow-rates using flame atomic absorption spectrometry (FAAS) for the determination of analytes, *e.g.*, manganese.

EXPERIMENTAL

Apparatus

Glass chromatography columns (10 mm inner diameter, 200 mm long) were used.

*Author for correspondence.

A Crison standard pH-meter with electrode INGOLD U 455 and a Perkin–Elmer 5000 atomic absorption spectrophotometer were also used. An oxidizing air-acetylene flame was used under the conditions recommended by the instrument manufacturer for manganese (279.5 nm).

All chemical appliances, such as bottles, columns, flasks and tubes were prepurified before use with 10% nitric acid (12 hr) and rinsed with ultrapure water twice.

Reagents and solutions

All chemicals were of analytical reagent grade. Ultrapure water of 18.3M Ω cm specific resistivity was obtained from a Milli-Q water system (Millipore Corp.) and was used throughout.

Poly(dithiocarbamate) resin with macroreticular support (20–30 mesh) was synthesized as described in a preceding work.[12] The resin synthesis was carried out in three steps:

(1) Chloromethylation of Amberlite XAD-4 resin.
(2) Amination of chloromethylated resin.
(3) Introduction of dithiocarbamate group. After 6 days of reaction sulphur content is 15% (≈2.35 mmoles of dithiocarbamate/g of resin).

Stock metal ion solutions (1000 μg/ml) were prepared in 1M nitric acid from high-purity metal salts. Nitric acid (8M aqueous solution), and ammonia solution (25%) (d = 0.91 kg/l.) were used.

Certified Reference Material Simulated Fresh Water IAEA/W-4 was obtained from the International Atomic Energy Agency (Vienna, Austria).

Standards and samples were stored in precleaned polypropylene bottles.

Procedure for preliminary studies

The sorption of manganese was studied by a dynamic method, passing a solution of the metal through a column filled with PDTC resin. Firstly, 25 ml of ultrapure water and then the metal standard solution at pH 10 were passed through the resin (the effect of pH on degree of sorption has been studied previously[12]). Subsequently, the trace metals were eluted with 8M nitric acid. Manganese was determined by FAAS.

Blanks of ultrapure water were processed with the same procedure as the metal standards.

Recommended procedure for natural waters

Resin preconditioning. Prior to passage of a sample for preconcentration, the analytical column filled with the resin (0.5 g) was conditioned with about 25 ml of ultrapure water at pH 10.

Water samples (100 ml) were adjusted at pH 10 with ammonia and passed at 4 ml/min through the column. The sorbed metals were eluted with 5 ml of 8M nitric acid. The concentration of manganese was determined by FAAS.

For calibration, standard solutions containing between 0–400 μg/l. of manganese were used. Standards were treated in the same way as the samples. Calibration is linear in the eluates by as much as 2 μg/ml manganese.

The equation obtained for calibration curve was:

$$A = 2.7 \times 10^{-4} + 4.2 \times 10^{-4} \times \text{concentration of Mn } (\mu g/l.)$$

$r = 0.9999$ where A = absorbance.

RESULTS AND DISCUSSION

Procedure optimization

Effect of flow rate. The effect of flow rate on the sorption of manganese was studied in the range 0.7–10 ml/min. The volume of sample passed through the columns was 100 ml and sample concentration was 100 μg/l. manganese. The resin capacity was 9.1 μmoles/g for manganese.[12] Table 1 shows that quantitative manganese recoveries can be attained at a flow rate ≤5 ml/min. Thus, for further separation experiments a flow rate of 4 ml/min was chosen.

Effect of sample volume. The influence of the solution volume on manganese sorption was studied by passing 100, 300, 500, 1000 and 1500-ml sample volumes through the column at a constant flow rate of 4 ml/min.

According to Table 2, the manganese recovery (*e.g.*, 10 μg/l.) is practically independent of

Table 1. Effect of flow rate in the retention of manganese*

Flow-rate, *ml/min*	% Retention
0.7	100.3
2	97.5
4	97.5
8	86.0
10	80.2

*Mn concentration in standards was 100 μg/l.

Table 2. Effect of sample volume on sorption of manganese* (five replicates)

Sample volume, *ml*	[Mn] found, *μg/l.*	RSD, %
100	10.00	3.0
300	9.83	1.2
500	9.70	1.0
1000	9.75	0.7
1500	9.73	0.7

*Amount of poly(dithiocarbamate) resin: 0.5 g. Mn concentration in standards was 10 μg/l.

Table 4. Effect of pH on retention of manganese* (five replicates)

pH	% Retention (mean)	RSD, %
4	58.8	1.2
6	94.1	0.7
8	94.1	0.5
10	97.1	0.4
12	97.1	0.5

*Manganese concentration was 1 μg/ml.

the chosen sample volume, which is important for applications in water analysis.

Effect of eluent volume. A significant preconcentration of metals from natural waters can only be effected if the volume of the eluate is small relative to the initial sample volume. For this reason 3, 5, 10, 15, 20 and 25-ml volumes of 8*M* nitric acid were studied for manganese elution. As can be seen in Table 3, a volume of 5 ml of 8*M* nitric acid is sufficient for quantitative elution of manganese.

Effect of pH on degree of sorption. The effect of pH on the degree of sorption was studied for 1 μg/ml manganese (25 ml sample). The pH interval studied was 4–12, and a pH of 10 was chosen for optimal preconcentration of manganese (Table 4).

Effect of other ions. Since the main constituents of natural waters (calcium, magnesium and the alkali metals) are not retained on poly(dithiocarbamate) resin, the effect of other ions on the separation of manganese was studied. A series of important ions (*e.g.*, Al^{3+}, Cu^{2+}, Zn^{2+}, Fe^{3+}, Si(IV), Cl^-, SO_4^{2-} and NO_3^-) present in natural waters (mineral and tap water) were studied. Their concentration range was chosen according to average concentration values calculated for natural waters.[2]

The analytical signal from solutions containing only manganese was compared with that from solutions containing the interfering element and manganese.

Table 3. Effect of eluent volume (8*M* nitric acid) on recovery of manganese* (five replicates)

Eluent volume, *ml*	% Recovery (mean)	RSD, %
3	89.8	0.6
5	97.7	0.7
10	97.4	1.7
15	97.6	2.5
20	97.7	2.3
25	98.5	0.8

*Mn amount was 5 μg.

Results expressed in % relative absorption are shown in Table 5. 100 ± 5% relative absorption were considered as negligible interference. According to the above findings none of these elements interfere on the separation and determination of manganese.

Reproducibility and recovery from the ion-exchange column

The recovery and reproducibility of the combined procedure were studied by carrying out five determinations of solutions containing 0, 40, 100, 200 and 400 μg/l. Mn.

Manganese assays were carried out as described above, both with and without preconcentration by the ion-exchange process. The recovery experiments with the above solutions prove that manganese in the solution can quantitatively be extracted by the PDTC resin (Table 6). The average manganese retention was 97.2%. The relative standard deviations (s_r) in the range 1.1–6.2% obviously depending on the manganese concentration.

Hence the resin provides a reliable way for manganese preconcentration.

Table 5. Effect of foreign cations and anions on the separation and determination of manganese*

Table 6. Reproducibility of the combined procedure

Mn, μg/l.	Recovery*, %	RSD, %
40	97.3	6.2
100	97.0	4.0
200	97.8	2.5
400	97.5	1.1

*Calculated from Recovery (%) = [A(with resin)/[A (without resin)] × 100, where A is absorbance.

Detection limit and sensitivity

The detection limit was 0.5 μg/l. manganese (based on 3 times the standard deviation of the blank) for 100 ml of samples and the sensitivity of the method (related to $A = 0.0044$) was 2.5 μg/l. manganese. The quantitation limit, defined as 10 times the standard deviation of the blank was 1.7 μg/l. manganese.

The detection limit, sensitivity and quantitation limit can be decreased by one order of magnitude by increasing the sample volume (*e.g.*, 1000 ml).

Accuracy of the method

To study the accuracy of the method, certified reference material simulated fresh water IAEA/W-4 of IAEA with a manganese content of 23–27 μg/l. was analysed. The manganese content obtained was 23.5 μg/l.

Application to natural waters

The method outlined here was applied to samples of water from different sources in order to determine their manganese content (Table 7).

Water samples were taken from the municipal water supply of several townships of Galicia (Spain) and various brands of bottled Galician mineral waters.

CONCLUSIONS

The capabilities of macroreticular PDTC resin to collect quantitatively manganese in trace concentrations from natural waters with little pretreatment has been demonstrated. This resin is an effective means for separation and concentration of manganese (and other trace metals, *e.g.*, lead(II), cadmium(II), copper(II), iron(III), zinc(II), *etc.*) from complex matrices prior to quantitation by FAAS, owing to its low affinity to alkali and alkaline earth elements. Chelex-100, similarly applicable for manganese collection, has a potentially serious disadvantage since the resin has a considerable affinity for alkali and alkaline earth metals.[13] Since the ion-exchange separation described in the present paper can be performed more or less automatically and a little sample volume and a high flow-rate can be used to shorten the analysis time, many samples can be analysed within a short period. Thus, the combined procedure is suitable for the routine determination of manganese in natural water even in the μg/l. range.

A RAPID COMPLEXOMETRIC SCHEME FOR ANALYSIS OF IRON, ALUMINIUM, CALCIUM AND MAGNESIUM IN SLAGS

K. C. GHOSH, B. C. MUKHERJEE, N. N. GANGULY, M. YUSUF and V. N. CHOUDHURY
National Metallurgical Laboratory, Jamshedpur 831007, India

(*Received* 3 *May* 1991. *Revised* 17 *October* 1991. *Accepted* 17 *October* 1991)

Summary—A simple and rapid complexometric method has been developed for the simultaneous determination of iron, aluminium, calcium and magnesium in a single solution in slags. Phosphorous and small amounts of chromium (1.5 mg) and vanadium (1 mg) do not interfere in the titration. Titanium and manganese are suitably masked with lactic acid and tetra sodium pyrophosphate, respectively. In a suitable aliquot, iron is titrated at pH 2 with EDTA, using sulphosalicylic acid as indicator. To this solution, excess disodium 1,2-cyclohexane diamine tetra acetic acid (DCTA) is added and aluminium is titrated by titrating the excess DCTA with standard copper sulphate solution at pH 3.5, using 1-(2-pyridylazo)-2-naphthol (PAN) as an indicator. A known excess of EDTA is added, the pH is raised to 10 and calcium and magnesium are jointly titrated by titrating the excess EDTA with copper sulphate solution, using PAN indicator. The Ca–EDTA complex is demasked with ammonium oxalate at pH 5 and the released EDTA equivalent to calcium is titrated with copper sulphate solution at pH 10 with PAN indicator. Results of analysis compare favourably with certified values and values obtained by standard methods for BCS and other slags. A set of five samples can be analysed for iron, aluminium, calcium and magnesium in four hours as compared to three days by the classical conventional method.

The chemical composition of slag depends on the raw materials used and the production conditions. Since the composition of the slag varies from lot to lot, a rapid and accurate evaluation of a slag composition by chemical analysis is essential for quality control of the raw materials and the finished products.

The classical methods[1] for determination of alumina, calcium and magnesium in slags are the well-known oxinate, oxalate and pyrophosphate methods, respectively, which are tedious and time consuming. In most of the complexometric methods of determination, calcium and magnesium are usually titrated together with EDTA at pH 10 in an ammoniacal buffer and then calcium alone in another aliquot at pH 12 when magnesium precipitates as hydroxide.[2-6] Manganese, if present in slags, interferes seriously with the EDTA titration of calcium and magnesium by precipitating out as brown manganese hydroxide which absorbs metallochromic indicator to yield an unsatisfactory end point. Therefore, it is essential to separate manganese by the lengthy process of sulphide precipitation[1] or mercury cathode electrolysis[7] prior to the titration of calcium and magnesium with EDTA. Solvent extraction procedures for removal of manganese with diethyl dithiocarbamate[8] and oxine[9] have also been reported. Titanium,[10,11] chromium[2] and vanadium[12] seriously interfere with aluminium as they form stable complexes with EDTA at pH 3.5–5.5. The interference of phosphate[13] in the titration of calcium and magnesium at pH 10 has also been reported. However, no attempt has yet been made to develop a rapid complexometric method for the simultaneous determination of iron, aluminium, calcium and magnesium in a single solution in slags in the presence of titanium and manganese.

As iron, aluminium, calcium and magnesium form stable complexes with EDTA at different pH values, a simple and rapid complexometric scheme has been developed based on this property for the simultaneous determination of these elements in slags in a single solution, using lactic acid[11] and tetra sodium pyro-phosphate[14] as masking agents for titanium and manganese respectively.

EXPERIMENTAL

Reagents

Unless otherwise stated, all reagents were of analytical reagent grade and all solutions were prepared in a one-litre calibrated flask with redistilled water.

EDTA solution. Two solutions (0.025 and 0.01*M*) were prepared by dissolving 9.306 and 3.7225 g, respectively, of disodium ethylene diamine tetra acetate dihydrate in water and diluting to volume.

DCTA solution. Two solutions (0.025 and 0.01*M*) were prepared by dissolving 8.659 and 3.4636 g, respectively, of 1,2-diaminocyclohexane tetra acetic acid in 100 ml of 1*M* sodium hydroxide solution and 200 ml of water, and diluting to volume.

Standard copper sulphate solution. Two solutions (0.025 and 0.01*M*) were prepared by dissolving 6.25 and 2.5 g, respectively, of $CuSO_4.5H_2O$ in water and diluting to volume.

Aluminium solution. A 0.025*M* solution was prepared by dissolving 0.675 g of aluminium foil (99.99%) in hydrochloric acid (1 + 1) and diluting to the mark.

Calcium chloride solution. A 0.025*M* solution was prepared by dissolving 2.5 g of dried (150°) calcium carbonate in 5 ml of 12*M* hydrochloric acid and 25 ml of water. The solution was boiled, cooled and diluted up to the mark.

Magnesium chloride solution. A 0.01*M* solution was prepared by dissolving 2.03 g of $MgCl_2.6H_2O$ in water and diluting to volume.

Iron solution. A 0.01*M* solution was prepared by dissolving 0.56 g of pure iron wire in 10 ml of concentrated hydrochloric acid and diluting to volume.

Ammonia–ammonium chloride buffer (pH 10). Prepared by dissolving 67.5 g of ammonium chloride in 250 ml of water and 570 ml of liquid ammonia and diluting to volume.

Ammonium acetate, 25%. Prepared by dissolving 25 g of ammonium acetate in 100 ml of water.

Ammonium oxalate, 5%. Prepared by dissolving 5 g of ammonium oxalate in 100 ml of water.

Lactic acid, 10%. Prepared by diluting 10 ml of lactic acid to 100 ml with water.

Tetra sodium pyrophosphate, 10%. Prepared by dissolving 10 g of tetra sodium pyrophosphate in 100 ml of water.

1-(2-Pyridylazo)-2-naphthol (PAN), 0.05%. Prepared by dissolving 50 mg of the indicator in 100 ml of methanol.

Sulphosalicylic acid (solid).

Foreign ion solution. All solutions were prepared in a 250-ml calibrated flask.

Titanium (1 mg/ml). A 0.416-g sample of ignited titanium dioxide was fused with 4 g of potassium bisulphate. After cooling the fused mass was dissolved in 50 ml of 10% sulphuric acid and diluted to volume with water.

Chromium (1 mg/ml). A 0.707-g sample of dried (180°) potassium dichromate was dissolved in water and heated with 5 ml of concentrated hydrochloric acid and 15 ml of ethyl alcohol. The solution was cooled and diluted to volume with water.

Phosphorous (1 mg/ml). A 1.258-g sample of sodium dihydrogen orthophosphate was dissolved in water and diluted to volume.

Manganese (1 mg/ml). A 0.687-g sample of anhydrous manganese sulphate was dissolved in water containing 1 ml of concentrated sulphuric acid and diluted to volume.

Vanadium (1 mg/ml). A 0.574-g sample of ammonium metavanadate was dissolved in water and diluted to volume.

Procedure

Preliminary tests. A series of tests on synthetic solutions were carried out to ascertain the recovery of known amounts of iron, aluminium, calcium and magnesium in the presence of potential interferents like titanium, manganese, chromium, phosphorous and vanadium that would be encountered in the analyses of slags. Based on these experiments, a procedure was developed for the analyses of slags which is given below.

Dissolution. The sample (0.5 g) was treated with 20 ml of 12*M* hydrochloric acid and 5 ml of 16*M* nitric acid in a beaker and the mixture was carefully evaporated to dryness. A few ml of hydrochloric acid and 100 ml of water were then added and the solution was boiled. The solution was cooled and filtered through Whatman No. 40 filter paper with pulps. The residue was washed with dilute hydrochloric acid (1 + 9) 5–6 times with hot water. After removing the silica with hydrofluoric acid, the residue was fused with 2–3 g of potassium bisulphate and the cooled melt was dissolved in 5% hydrochloric acid on heating, and added to the main filtrate. The solution was transferred to a 250-ml calibrated flask and diluted to volume.

Titration of iron. A 50-ml portion of the sample solution was taken in a beaker and diluted with 50 ml of water. Ammonium hydroxide (1 + 1) was added until the solution became turbid. The turbidity cleared with a minimum quantity of dilute hydrochloric acid (1 + 3). A few drops were added in excess to adjust the pH to *ca.* 2. Then 50 mg of sulphosalicylic acid indicator were added and the solution

was warmed. This solution was titrated with standard 0.01*M* EDTA solution with constant stirring to a sharp colour change from violet to a colourless or pale yellow solution.

Titration of aluminium. After titration of iron, a known aliquot of 0.025 or 0.01*M* DCTA was added depending upon the alumina content of the sample. Then 10 ml of 10% lactic acid were added to mask titanium. The pH of the solution was adjusted to 3.5 with 25% ammonium acetate solution. The solution was just warmed and titrated the excess DCTA with 0.025 or 0.01*M* copper sulphate solution, using ten drops of PAN indicator to a sharp colour change from yellow to violet.

Titration of calcium plus magnesium. A 50-ml portion of 0.025*M* excess EDTA was added to the titrated solution after aluminium determination and 5 ml of 10% tetra sodium pyrophosphate were added to mask manganese. The pH of the solution was adjusted to 10 with ammonia buffer. The solution was warmed and the excess of EDTA was titrated with 0.025*M* copper sulphate solution with ten drops of PAN indicator to a sharp colour change from yellow to violet. This titre value corresponds to the sum of calcium and magnesium.

Titration of calcium. After the titration of calcium plus magnesium, the pH of the solution was reduced to 5 with dilute hydrochloric acid (1 + 3). Then 20 ml of 5% hot ammonium oxalate solution were added to precipitate calcium as calcium oxalate. The solution was digested for 20 min, cooled and transferred along with the precipitate to a 250-ml standard flask. The solution was diluted to the mark with the washings.

A 100-ml portion of the solution was filtered dry and then 10 ml of the ammonia buffer (pH 10) were added. The solution was warmed and the liberated EDTA equivalent to calcium was titrated with 0.025*M* copper sulphate solution with ten drops of PAN indicator until the colour turned violet, which lasted for 15–30 sec. The volume of EDTA was subtracted from the sum of calcium and magnesium titre value. The difference is the volume of EDTA required to titrate the magnesium.

A blank was also run but showed no significant amounts of iron, aluminium, calcium and magnesium.

RESULTS AND DISCUSSION

Table 1 shows the results of determination of iron, aluminium, calcium and magnesium in the presence of potential interferents like phosphorus, chromium, vanadium, titanium and manganese in synthetic solutions. Chromium[2] and vanadium[12] seriously interfere with aluminium as they form stable complexes with EDTA at pH 3.5–5.5. In the present method DCTA was preferred to EDTA in the titration of aluminium at pH 3.5, for its better selectivity in the presence of chromium[15] and vanadium.[16] It was found that chromium and vanadium up to 1.5 and 1 mg, respectively, did not interfere in the titration of aluminium at pH 3.5. More than 1.5 mg of chromium seriously interfered in the titration of aluminium due to the formation of a purple complex of Cr–DCTA. Vanadium more than 1 mg could not be tolerated as the transition of colour change of the indicator was not sharp. However, the chromium and vanadium content in slags is not usually more than 1% of each.

Phosphate[13] interferes in the titration of calcium and magnesium at pH 10. In the present method the phosphate interference was obviated by back titration of excess EDTA with copper sulphate so that all calcium present combined with EDTA. There is no evidence of the complexation of copper with phosphate and as expected phosphorus up to 16 mg did not

interfere (Table 1). Actually in synthetic solution phosphorus was added in excess of that normally found in slags.

Titanium and manganese seriously interfere with the determination of aluminium and magnesium, respectively, as they form stable complexes at pH 3.5 and 10 (Table 1). In the present method lactic acid[11] was used to mask titanium and addition of 10 ml of 10% lactic acid was found to mask up to 7 mg of titanium as shown in Table 2. However, for more than 7 mg of titanium, the end point was sluggish. Fog[17] used potassium cyanide for masking manganese in EDTA titration of magnesium. In the present method cyanide cannot be used as a masking agent because copper sulphate is used as back titrant. The interference due to manganese was eliminated by complexing it with tetra sodium pyrophosphate.[14] The stability constant of the manganese–pyrophosphate complex is not known. However, it was observed that in the presence of tetra sodium pyrophosphate, manganese does not react with EDTA. This shows that the manganese–pyrophosphate complex must be more stable than the manganese–EDTA complex. In the present method it was observed that 5 ml of 10% tetrasodium pyrophosphate were able to mask up to 12 mg of manganese (Table 3). The concentration of masked manganese is well above the concentration of manganese found in slags.

Table 4 shows the results of analysis of iron, aluminium, calcium and magnesium in some slags by the proposed method. The results of

Table 4. Determination of Fe, Al_2O_3, CaO and MgO in slags

†Standard conventional method.

analysis are in very good agreement with the certified values and the values obtained by the standard conventional method. Though the value of calcium oxide reported by the proposed method is higher than the certified value, the deviations reported in the Table are within the precision of the method.

The proposed method is simple, rapid and accurate, and avoids multi-separation steps that are often involved in the standard conventional methods. A set of five samples can be analysed for iron, aluminium, calcium and magnesium in four hours as compared to three days by standard conventional methods.

WASTE WATER ANALYSIS BY PURGE AND TRAP CAPILLARY GC–FTIR SPECTROMETRY

J. PHILIPPAERTS, C. VANHOOF and E. F. VANSANT
University of Antwerp, Universiteitsplein 1, 2610 Wilrijk, Belgium

(*Received* 9 *February* 1991. *Revised* 29 *July* 1991. *Accepted* 4 *September* 1991)

Summary—Gas chromatography with Fourier transform infra-red spectroscopic detection (GC–FTIR) is used for the analysis of waste water samples. Compared to GC–MS, this technique offers a more complete identification of organic compounds. Lower concentrations of organic volatiles however require preconcentration techniques such as a Purge and Trap (P&T) preconcentrator. Using this combination, concentrations of organic volatiles in the ppb range can be detected and positively identified.

The analysis of waste water containing volatile organic compounds is often carried out by gas chromatography with mass spectrometric detection (GC–MS). Due to the high sensitivity of the detector it is even possible to sample the vapor phase above the water surface (head space analysis). In this way, detection problems which are caused by the water are avoided. However, using the mass spectrometer as a detector, a lot of compounds can only be partially identified.[1] The compound functionality can be recognized in this way, but useful information is obtained about the aliphatic portion of the molecules. Here IR-spectra can give additional (or complementary) information.[2,3] The IR spectra clearly show the functional groups of a compound and allow an accurate identification. The possibility of GC–FTIR to distinguish isomeric forms, contrary to GC–MS, makes it an interesting analytical tool to determine and identify volatiles. Conventional gas chromatography–Fourier transform infra red (GC–FTIR) measurements, however, also deal with problems when waste water is injected "as such". Concentrations are limited to the parts per thousand and ppm ranges since the injected volumes are only microlitres and the IR-detection requires several nanograms of the products. Water can damage the potassium bromide lightpipe windows and disturb the measurements. Since the IR detection limits are much higher than MS,[4] the head space analysis technique is not suitable here. When the concentration of volatile compounds is very low (ppm to ppb range), extraction or preconcentration procedures are necessary.

The IR detection problem can be solved by the use of Purge and Trap (P&T) preconcentrators.[5] This method is already widely used in combination with gas chromatography and GC–MS. One might expect that, when coupled with GC–FTIR, the suitability of this method will be enhanced. Indeed, the analysis of volatiles in water or solids (*e.g.*, soils) using this technique allows for detection of very small amounts of compounds (down to the ppb-range). This paper demonstrates the performance in the case of waste water samples.

EXPERIMENTAL

Different types of aqueous mixtures and waste water samples were analysed with the Purge and Trap capillary GC–FTIR system.

Synthetic aqueous mixtures were prepared by adding compounds to water so that for each component a final concentration of 0.5 ppm was obtained. The 50 ppb and 10 ppb samples were prepared by diluting the original 0.5 ppm sample. The organic compounds given in Table 1 are the components of the mixture which is described further in this paper.

An unknown waste water sample, obtained from a petrochemical company was also analysed. Furthermore, the performance of a substrate to efficiently remove the organic compounds or pollutants from water is shown. The substrate used for the removal of organic compounds was a synthetic zeolite, silicalite, obtained from Union Carbide.

For each analysis a sample of 5 or 25 ml was taken in a 5- or 25-ml fritted sparge tube of a

2-Chlorotoluene	Dimethylamine
N,N-Dimethylaniline	

Tekmar LSC 2000 Purge and Trap Concentrator. The purge conditions depended on the type of sample used (see Table 2).

The volatiles are trapped on a Tenax column which is then desorbed at room temperature for the removal of adsorbed water (dry purge). After desorption at 200°, the effluents are transferred through a heated glass-lined transfer line (180°) to a trap at −120° of a capillary interface. After the transfer, the interface is heated very quickly to 200° so that an "on column" injection can take place (injection over 2 min). A HP 5890 GC is used, which communicates with the Nicolet computer of the FTIR-spectrometer (Model 20SX). The Tekmar concentrator automatically gives the start signal when the injection begins.

A wall-coated open tubular (WCOT) fused silica (25 m × 0.32 mm I.D., 0.4 μm CP-Sil-5 CB) column was used with a He flow of 0.8 ml/min. Before the entrance of the light pipe, an additional He flow of 0.4 ml/min (make up gas) was added in order to obtain a good transport of the column output. This also reduces tailing effects.[6]

The temperature program for all the analyses was a constant temperature at 30° for three minutes, then a gradual increase of 10°/min to 200°, which is then held until all compounds are eluted.

The medium band MCT (mercurium–cadmium–tellurium)-detector takes 7 scans/sec at 8 cm^{-1} resolution. For analysis of the compounds the GC elutes past the light pipe and the IR spectra are measured in real time using a gold coated 1.0 mm × 15.0 cm proprietary light pipe (at 220°). The GC column is connected directly to the light pipe inlet in order to reduce the dead volume. The outlet of the light pipe is connected to the FID detector of the GC.

The spectral search was carried out with the Aldrich Vapor Phase library containing the spectra of about 5000 compounds.

RESULTS AND DISCUSSION

Synthetic mixtures

The 640–1200 cm^{-1} reconstruction chromatograms obtained from the analysis of the 0.5 ppm, 50 ppb and 10 ppb synthetic aqueous samples are plotted in Fig. 1. From the 19 compounds in the mixture, 14 could be detected and completely identified in the 0.5 ppm sample (in one experiment α chloro-*p*-xylene was also detected). In the 50 ppb and the 10 ppb mixture, respectively 13 and 11 compounds were still detectable with complete identification (Table 3).

Of the 5 undetectable compounds in the 0.5 ppm sample, 3 were alcohols and one was an amine. These types of compound are known to possess a low purge efficiency due to their high aqueous solubility. Therefore their detection limit is higher than 0.5 ppm.

From these results it can be concluded that the detection limits for several compounds are in the low ppb range. Indeed, note that neither the GC-program, nor the column was optimized for the analysed compounds.

Waste water

The waste water sample contained rather high concentrations of volatile organic compounds, so that a "fingerprint" of the major organic compounds was obtained by purging for only two minutes at 45 ml/min. The upper curve in Fig. 2 shows the Gram–Schmidt reconstruction

Table 2. Purge conditions for aqueous samples

the major compounds detected in this waste water with the complete (+) or partial (≈) identification as obtained by the library search. Figure 3 shows the spectral quality of a low-intensity peak in the chromatogram (indicated by an arrow) and the best library search result from the Aldrich Vapor Phase library.

Note that isopropanol and 2-ethoxyethanol are detectable in this waste water mixture while they are not observed in the synthetic mixtures. These observations indicate that the concentrations of these compounds are significantly higher than 0.5 ppm.

The P&T–GC–FTIR analysis method was also used to analyse various waste water samples and to study the selective adsorption

of the organic compounds on different sorbents effective in the removal of the organic pollutants. This is demonstrated in Fig. 4, which shows the Gram–Schmidt reconstruction chromatogram of the waste water (sample A) and, using the same purge conditions, of the waste water after a 5-min contact time between 100 ml of waste water and 1 gram of a highly siliceous aluminosilicate (silicalite) (treated sample B). The selectivity depends upon the nature of the organic compounds as can be seen with this technique for each type of waste water.

A second contact (again for 5 min) between the former water sample and one gram of fresh silicalite (treated sample C) resulted in an almost "clean" water as shown by the reconstruction chromatogram in Fig. 4C. Compounds with a low boiling point (*e.g.*, acetone) are still present in rather high concentrations, indicating the lower capacity of the silicalite for these compounds. This phenomenon might be explained by break through effects.

Table 4. Major compounds detected in the waste water sample

Peak number	Retention time, *min*	Compound identification	Best library search result
1	2.33	+	Acetone
2	2.48	+	Isopropylacetate
3	3.12	+	1-Propanol
4	4.06	+	2-Methyl-1-propanol
5	5.91	+	2-Ethoxyethanol
6	8.33	≈	Dichloroethylene
7	11.20	+	Phenol
8	12.55	≈	2-Tert.butyl-5-methyl-cyclohexanol

+: complete identification.
≈: partial identification.

In order to identify the compounds in this last water sample, the purge conditions were changed (6 min purge at room temperature, 12 min dry purge) so that the detection of these compounds (Table 5) could be enhanced.

Many organic alcohols are observed, indicating the relationship between group functionality and adsorption phenomena in the waste water treatment with silicalite under conditions as described above.

CONCLUSION

The Purge and Trap preconcentration technique was used in combination with GC–FTIR. It displays several advantages over GC–MS. The detection of low concentrations of organic volatiles is combined with superior identification power.

Applications to waste water prove sensitive, reproducible and less time-consuming than extraction techniques. Various types of volatiles can be identified completely by this analysis method and the purification by adsorbers can be directly assessed. By selecting a suitable substrate organics are very efficiently removed from the waste water.

APPLICATION OF REDOX REACTIONS IN SPECTROPHOTOMETRY—I

THE IRON(III)/1,10-PHENANTHROLINE COMPLEX AS A REAGENT FOR THE DETERMINATION OF SOME ANIONS AND ORGANIC COMPOUNDS

S. KOCH and G. ACKERMANN
Bergakademie Freiberg, Fachbereich Chemie, 0-9200 Freiberg, Germany

(*Received* 12 *February* 1990. *Revised* 5 *November* 1991. *Accepted* 20 *November* 1991)

Summary—It is shown that the complex of iron(III) with 1,10-phenanthroline(phen) is suitable as a reagent for determination of some anions and organic compounds. By a redox reaction with the analytes the reagent forms the intensely coloured chelate $[Fe(phen)_3]^{2+}$, which is extractable as an ion-association complex with a suitable counter-ion and allows the development of sensitive spectrophotometric methods of determination. Besides the fundamentals, some remarks on analytical applications are given.

There are comparatively few spectrophotometric methods for the determination of anions. Many of them are indirect methods based on the effect of side-reactions in methods for determination of cations. Another possibility is the use of redox reactions giving products which are suitable for photometric determination.[1,2]

Redox reactions can be described by the generalized formula

$$m\mathrm{Ox}_r + n\mathrm{Red}_s \rightleftharpoons p\mathrm{Red}_t + q\mathrm{Ox}_w \qquad (1)$$

which allows for the participation of polynuclear species. Ox_r and Red_t may be complexes of a metal (in two oxidation states M and M′) with a ligand, and equation (1) can be rewritten as

$$m\mathrm{M}_r\mathrm{L}_x + n\mathrm{Red}_s \rightleftharpoons p\mathrm{M}'_t\mathrm{L}_y + q\mathrm{Ox}_w \qquad (2)$$

where x and y may or may not be equal, depending on the nature of the metal ion and the ligand. One or both of these complexes may be coloured, which would make the system useful for spectrophotometric analysis. A further possibility is extraction of one of the species involved, which can increase the selectivity and sensitivity. The sensitivity will depend on several factors, such as the completeness of the redox and/or complexation reactions, the distribution coefficient if an extractable species is formed, and any solvent or other effects on the molar absorptivity of the species selected for measurement.

The iron(III)/phenanthroline system[3–6] is particularly useful, since the reduction product obtained from it is always ferroin, $[Fe(phen)_3]^{2+}$, which has a fairly high molar absorptivity, is stable, and can be extracted as an ion-association complex with perchlorate, iodide *etc.* as counter-ion.

EXPERIMENTAL

The spectrophotometric measurements were performed with a Beckman DU spectrophotometer and a Zeiss Specord M 40 instrument. The pH adjustments were made with dilute acid or ammonia solutions and controlled by use of an MV 870 pH-meter (VEB Präcitronic, Dresden). For measurement of electrode potentials a platinum-electrode/SCE combination and the MV 870 were used at 25°. All potentials became stable after 15 min.

Aqueous solutions of ionic strength 0.3 (Na_2SO_4) were used at room temperature for all measurements. The components were mixed in the following order: Fe(III), phen, sodium sulphate, pH adjuster, reductant. The solutions must be protected by an atmosphere of nitrogen.

Reagents

The parent 1*M* iron(III) solution was prepared by dissolving $Fe_2(SO_4)_3 \cdot x H_2O$ (*p.a.*, Riedel de Haën) in 0.1*M* sulphuric acid and

standardized by titration with 0.1*M* EDTA (tiron as indicator).

Fe^{2+} solutions were always freshly prepared from $(NH_4)_2Fe(SO_4)_2 \cdot 6H_2O$ (*p.a.*, UCB). The 0.01*M* 1,10-phenanthroline solution was made by dissolving the solid (*z.A.*, Chemapol) in 0.05*M* sulphuric acid. The degree of purity of the phen was checked by potentiometric titration of an aqueous solution with 0.1*M* hydrochloric acid (glass electrode). All the organic compounds tested were commercial products, the purity of which was checked by determination of the melting point or refractive index.

The system Fe^{3+}/phen

1,10-Phenanthroline is almost completely insensitive to oxidizing agents. Both its nitrogen atoms can be protonated, resulting in the following protolytic equilibria:[7]

$$H_2phen^{2+} \rightleftharpoons Hphen^+ + H^+ (pK_{a1} = 1.9)$$

$$Hphen^+ \rightleftharpoons phen + H^+ (pK_{a2} = 4.96)$$

In aqueous solutions Fe^{3+} and phen can form different chelates. Oxidation of the red iron(II) chelate results in the blue complex $[Fe(phen)_3]^{3+}$ ($\log \beta_3 = 14.1$).[8] The direct reaction of iron(III) and phen leads to a binuclear yellow-brown compound. The blue chelate slowly changes into the yellow-brown form, probably because steric repulsion takes place in the trichelate.[9]

According to Anderegg[10] the yellow-brown solution contains different species, with the ratio Fe:phen = 2:4. Other work[11] with dilute solutions ($c_{Fe} = 10^{-3}M$) has shown that formation of the complex is complete at pH 3–4 in presence of excess of the ligand ($c_{phen}/c_{Fe} \geq 3$). The species $[Fe_2(OH)_2(phen)_4]^{4+}$, $[Fe_2(OH)O(phen)_4]^{3+}$ and $[Fe_2O_2(phen)_4]^{2+}$ were identified, and have hydroxo or oxo bridges between the metal ions.

It is scarcely necessary to emphasize that the blue chelate is not suitable for photometric determination, because of its low kinetic stability. However, the yellow-brown dimer shows good stability at room temperature. When higher temperatures, which may be needed in the application of redox reactions, are used, the system Fe^{3+}/phen in the pH range 2–9 ($c_{Fe} = 10^{-3}M$, heated for 1 hr at 60°) shows the following behaviour after cooling to room temperature.

In the interval from pH 3.2 to 4.2 a precipitate is formed in the clear solutions, which is soluble in methanol or hydrochloric acid to give a yellow solution containing iron(III) and phenanthroline. It is supposed that a polymeric Fe^{3+}–phen product is formed. This effect does not occur in more dilute solutions, with $c_{Fe} = 10^{-4}M$. Therefore use of lower reagent concentrations is more suitable in practical applications.

The system Fe^{2+}/phen

The very stable covalent chelate $[Fe(phen)_3]^{2+}$ ($\log \beta_3 = 21.3$)[8] exists in the system Fe^{2+}/phen. As spectrophotometric and electrophoretic examinations have shown, the orange-red complex (ferroin) is stable in water in the pH range 2–9 and also in water–methanol (1:1 v/v) mixtures. Ferroin exhibits typical charge-transfer absorption by intramolecular electron-exchange:

$$[Fe(II)(phen)_3]^{2+} \rightleftharpoons [Fe(III)(phen)_2(phen)^-]^{2+}$$

The effect is based on electron transfer from an occupied level of Fe(II) to the unoccupied orbital of the ligand. As a result there are maxima at 450 and 490 nm and a main band at $\lambda_{max} = 510$ nm. From repeated measurements the molar absorptivity at 510 nm is found to be $\epsilon = (1.119 \pm 0.009) \times 10^4$ $l \cdot mole^{-1} \cdot cm^{-1}$ (*P* 0.95; 100 replicates).

For its practical application it is advantageous that the complex gives not only high sensitivity, but also has very good kinetic stability, its solutions being stable for some months and not affected by heating.

There is also the possibility of extracting the chelate as an ion-association complex, into an appropriate organic solvent:[12]

$$[Fe(phen)_3]^{2+}_{aq} + 2R^-_{aq} \rightleftharpoons \{[Fe(phen)_3]^{2+} \cdot 2R^-\}_{org}$$

where R^- is a colourless counter-ion such as ClO_4^-, I^-, CN^-. In this way the sensitivity can be further increased. Extended research work[13] has shown that perchlorate in combination with EDTA as a sequestering agent and nitrobenzene as the solvent is very suitable, because the interference of excess of iron(III) can be eliminated.

Electrode potentials in the Fe^{3+}/Fe^{2+}/phen system

The orange-red Fe^{2+} complex, when used as a redox indicator (ferroin), is oxidized to the blue Fe^{3+} chelate:

$$[Fe(phen)_3]^{2+} \rightleftharpoons [Fe(phen)_3]^{3+} + e^- \qquad E^0 \sim 1.0 \text{ V}$$

Because of the instability of the blue product, this reaction is of no importance for photometric determination. On the other hand, the electrode potentials for the brown-yellow forms $[Fe_2O_2(phen)_4]^{i+2+}$ $(i = 0, 1, 2)$ have not been known up to now. Therefore these potentials and their dependence on pH were determined. The results are shown in Fig. 1. As can be seen, the system Fe^{3+}/Fe^{2+}/phen acts as an oxidizing agent, and the higher potential of 0.85 V (compared with that of 0.77 V for the system Fe^{3+}/Fe^{2+}) has its cause in the high stability of the iron(II) chelate $[Fe(phen)_3]^{2+}$. It can also be seen that the redox potential can be influenced by the pH over a wide range. The following iron(III) species are mainly involved in this behaviour:

pH 2.0 $[Fe_2(OH)_2(phen)_4]^{4+}$; Fe^{3+}

pH 3.0 $[Fe_2O(OH)(phen)_4]^{3+}$; $Fe(OH)_2^+$

pH 4.0 $[Fe_2O(OH)(phen)_4]^{3+}$; $Fe(OH)_2^+$

pH 5.0 $[Fe_2O(OH)(phen)_4]^{3+}$; $Fe(OH)_2^+$

pH 6.0 $[Fe_2O_2(phen)_4]^{2+}$; $Fe(OH)_2^+$

With increasing pH more and more protolytic (and also polynuclear) forms of iron(III) appear in addition to the iron chelates, so the real potential decreases with increasing pH. At pH 4 only one species of the iron(III) complex exists and the redox equilibrium can be written as

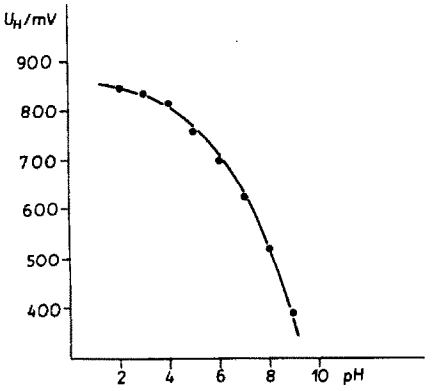

Fig. 1. Conditional potentials (U_H) of the system Fe^{3+}/Fe^{2+}/phen as a function of pH. $[Fe^{3+}] = [Fe^{2+}] = 10^{-3}M$; $c_{phen}/c_{Fe} = 5$; temperature = 25°; (Na_2SO_4).

Reactions with the Fe^{3+}/phen system

For reactions with this system the analyte A must be a reducing agent.

$$[Fe_2(OH)_2(phen)_4]^{4+} + 2phen + A \rightleftharpoons 2[Fe(phen)_3]^{2+} + 2OH^- + A^*$$

(A* = oxidation product of A)

The identification of the type of reaction results from the experimental examination of the colour reaction by measuring λ_{max} after reaching the equilibrium of system S and comparison with a solution of known composition (system C).

Starting system, S	System for comparison, C	
(Fe^{3+}, phen, A)	(Fe^{2+}, phen)	$\lambda_{max}(S) = \lambda_{max}(C)$ redox reaction
(Fe^{3+}, phen, A)	(Fe^{2+}, phen)	$\lambda_{max}(S) \neq \lambda_{max}(C)$ complex formation
(Fe^{3+}, phen, A)	(Fe^{2+}, A/phen)	$\lambda_{max}(S) = \lambda_{max}(C)$ formation of a binary complex
(Fe^{3+}, phen, A)	(Fe^{2+}, A/phen)	$\lambda_{max}(S) \neq \lambda_{max}(C)$ formation of a ternary complex

$$2[Fe(phen)_3]^{2+} + 2H_2O \rightleftharpoons [Fe_2O(OH)(phen)_4]^{3+} + 2Hphen^+ + H^+ + 2e^- \qquad (E = 0.82\ V)$$

This shows that the Fe^{3+}/phen reagent system is suitable for photometric determination and that some selectivity will arise because of the medium oxidation potential.

For practical application is was necessary to find out which experimental factors significantly affect the reaction. With the aid of the multifactor design due to Plackett and Burman[14] and pyrocatechol as a model, the absorbance was used as an output (2 parameter levels, 4 variables and 3 dummy variables). Table 1 gives the corresponding formalism, and the parameter

Table 1. Variables of the design matrix[14] for reaction of iron(III), 1,10-phenanthroline and pyrocatechol

Influencing factor	Variables	Low level (−)	High level (+)
pH	x_A	3.0	7.0
$[Na_2SO_4]$, M	x_B	0.01	0.1
Time, hr	x_C	1	3
[phen], M	x_D	5×10^{-4}	1×10^{-3}

levels. The measured absorbances between 0.134 and 0.220 resulting from the individual experiments (λ 510 nm; 1-cm cells; $c_{Fe} = 10^{-4}M$; $c_{Pyr} = 5 \times 10^{-6}M$) gave the following values for the estimated extent, W_i, of the influence[15] of the factors examined:

$$|W_A| = 0.035 > W^*$$

$$|W_B| = 0.003 < W^*$$

$$|W_C| = 0.045 > W^*$$

$$|W_D| = 0.014 < W^*$$

$$W^* = 0.016$$

The calculated values W_i are significant only if they are greater than the standard deviation, and a factor has a valid influence if $W_i \geqslant W^* = t_{(0.99,f)}s$.[15] The values of W_i and W^* shown above indicate that only pH (x_A) and time (x_C) significantly influence the system. The concentration of phen is without influence if at least a 5-fold excess relative to iron(III) is used. Likewise the concentration of sodium sulphate up to an ionic strength of 0.3 is without effect.

Further experiments made it plain that these reactions generally need some hours to reach equilibrium. We suppose that the reactions run by an inner-sphere mechanism, since it has been reported that iron(III) complexes with 1,10-phenanthroline and oxalate[16] occur as a typical transition state. These compounds are destroyed by the action of light or heat by an intramolecular redox reaction, forming carbon dioxide and $[Fe(phen)_3]^{2+}$. With pyrocatechol (H_2R) a mixed-ligand complex also exists in weakly alkaline solution (pH_{max} 9.3):[17]

$$Fe^{3+} + 2HR^- + \text{phen} \rightleftharpoons [Fe(phen)R_2]^- + 2H^+.$$

Because many organic compounds are reducing agents, we tested a selection of them. As the reaction is kinetically hindered, the reaction rate must be increased by use of a higher temperature. The conditions used were $c_{Fe} = 10^{-4}M$; $c_{phen}:c_{Fe} = 10$; $c_A:c_{Fe} = 0.1$; pH = 2–9; temperature 60°.

As expected, hydrocarbons (n-heptane, cyclohexane, benzene), alcohols (ethanol, benzyl alcohol, glycerol), carboxylic acids (acetic, oxalic, benzoic), ethers (diethyl, dioxan) and aliphatic amines (ethylenediamine, triethanolamine, triethylamine) do not react with Fe^{3+}/phen. It is unexpected, however, that aldehydes (formaldehyde, acetaldehyde, benzaldehyde) and ketones (acetone, isobutyl methyl ketone) also give no colour reaction. Phenols react only if their OH-groups are free; their esters or ethers (anisole) do not react. The reaction behaviour of monophenolic compounds is strongly dependent on the nature of any substituents. Phenols, cresols, xylenols and methoxyphenols undergo colour reactions, but nitro- (4-nitrophenol, 2,4-dinitrophenol, picric acid) and halogen-substituted compounds (2-chlorophenol, 4-chlorophenol) as well as other phenols substituted with groups with a $-I$ effect (salicylic acid, salicylaldehyde, methyl p-hydroxybenzoate) do not react. In the case of polyphenols the reactions are positive for all types of compounds (diphenols, triphenols, substituted compounds). This is also valid for dyes (Eriochrome Black T, Bromopyrogallol Red, PAR) with aromatic OH-groups. However, these reactions do not have better sensitivity. It is of interest that compounds with quasi-aromatic OH-groups (kojic acid, meconic acid) do not react. Naphthols (1-naphthol, 2-naphthol, 2,3-dihydroxynaphthalene, chromotropic acid) form intensely coloured products.

Aliphatic enols (acetylacetone, acetoacetic ester) can act as reducing agents, because of the keto–enol tautomerism. Acetylacetone gives only a weak colour reaction, as a result of the low concentration of the enol form. Acetoacetic ester hardly reacts at all because the equilibrium is even more in favour of the ketone. Ascorbic acid, as an enediol, shows an intense colour reaction, which occurs even at room temperature. Aromatic amines exhibit reactions similar to those of the phenols, but pyridine and quinoline do not react. Reactions can be observed with phenylenediamine, aminophenols and also monoamines (aniline, 1-naphthylamine) and their derivatives, such as diphenylamine or benzidine. There is no reaction with aminobenzoic acids, again showing the strong influence of substituents with a $-I$ effect. Compounds containing thiol groups

(thioethanol, thiophenol, toluene-3,4-dithiol) give orange-red reaction products, without heating. Moreover, kinetically hindered reactions are observed with many inorganic reductants and these reactions are also activated by increasing the temperature.

The following inorganic species react: SO_3^{2-}, $S_2O_5^{2-}$, $S_2O_3^{2-}$, $S_2O_4^{2-}$, S^{2-}, $Fe(CN)_6^{4-}$, I^-, NO_2^-, NH_2OH, N_2H_4. In this connection it must be mentioned that anions which are not reducing agents will not react.

Another possibility for the application of the redox system Fe^{3+}/Fe^{2+}/phen is based on the reaction of Fe^{2+}/phen with an oxidative analyte. Unlike the reactions discussed above, here the iron(II) complex reacts with the analyte and the intensity of its colour decreases. As the reactions with Ce(IV) or ClO^- show, the blue complex $[Fe(phen)_3]^{3+}$ appears as an intermediate compound, and then changes to the yellow-brown chelate of iron(III). These reactions likewise depend on pH and time. This type of reaction makes it possible to determine H_2O_2, $S_2O_8^{2-}$, Cl_2, ClO^-, Br_2, BrO_3^-, IO_4^-. However, NO_3^-, NO_2^- and ClO_4^- and (remarkably) also ClO_3^- and IO_3^- do not react in this way. Note, however, that NO_2^- gives the reduction reaction as noted above.

APPLICATION OF REDOX REACTIONS IN SPECTROPHOTOMETRY—II*

DETECTION AND SPECTROPHOTOMETRIC DETERMINATION OF PHENOLIC COMPOUNDS WITH THE IRON(III)/1,10-PHENANTHROLINE COMPLEX

S. KOCH, G. ACKERMANN and P. LINDNER
Bergakademie Freiberg, Fachbereich Chemie, 0-9200 Freiberg, Germany

(*Received* 6 *March* 1990. *Revised* 5 *November* 1991. *Accepted* 20 *November* 1991)

Summary—To test the utility of the iron(III)/1,10-phenanthroline reagent system for the determination of organic compounds, its reaction with phenolic compounds has been characterized. By a redox reaction the reagent forms the chelate $[Fe(phen)_3]^{2+}$, which is extractable as ion-association complexes. Determinations based on these complexes are very sensitive.

Redox reactions are frequently used in spectrophotometric determinations,[1] particularly those in which coloured reaction products are formed. The Fe^{3+}/1,10-phenanthroline (Fe^{3+}/phen) system is a valuable reagent for analytes with reducing properties, because the final product is the intensely coloured and extractable chelate $[Fe(phen)_3]^{2+}$.[2]

Because phenols are more or less strong reducing agents, they give deeply coloured compounds with this reagent system, but only a few publications deal with this type of reaction.[3–5]

The aim of this paper is to report the detection and spectrophotometric determination of a variety of phenols with Fe^{3+}/phen.

EXPERIMENTAL

Apparatus

A Beckman DU spectrophotometer and Zeiss M 40 and UR 20 spectrophotometers were used.

To increase the reaction rate, samples were kept for 1 hr in a thermostat at 60°. The pH was adjusted with dilute sulphuric acid or ammonia solution and checked with an MV 870 pH-meter (VEB Präcitronic, Dresden).

Reagents

All solutions were prepared on the day of use. A 1*M* iron(III) solution in 0.1*M* sulphuric acid was prepared from $Fe_2(SO_4)_3 \cdot xH_2O$ (*p.a.*, Riedel de Haën) and standardized by EDTA titration with tiron as indicator. 1,10-Phenanthroline (*z.A.*, Chemapol) was used for preparation of a 0.01*M* solution in 0.1*M* sulphuric acid. The purity of the phen was checked by potentiometric titration of an aqueous solution with 0.1*M* hydrochloric acid. All phenols were obtained commercially. Demineralized water was additionally purified by dissolving potassium permanganate in it and distilling.

RESULTS AND DISCUSSION

Reactions in the system iron(III)/1,10-phenanthroline/analyte

The system Fe^{3+}/Fe^{2+}/phen has pH-dependent positive electrode potentials. With a reducing agent A as an analyte, the reaction scheme is:[2]

$$[Fe_2(OH)_2(phyen)_4]^{4+} + 2phen + A \rightleftharpoons 2[Fe(phen)_3]^{2+} + 2OH^- + A_{ox},$$

where A_{ox} is the oxidized form of the analyte A.

Other forms of the binuclear Fe^{3+}/phen complex can also appear, depending on the reaction conditions, *e.g.*, $[Fe_2O_2H_i(phen)_4]^{i+2}$ ($i = 0, 1$). The orange-red chelate $[Fe(phen)_3]^{2+}$ (λ_{max} 510 nm, $\epsilon_{510} = 1.12 \times 10^4$ $l.mole^{-1}.cm^{-1}$ is well known as a very stable complex cation.

Phenols can react with the system Fe^{3+}/phen, especially in a weakly acidic medium. These reactions are influenced by various parameters. Examination by a multifactor design[2] has shown

*Part I—*Talanta*, 1992, **39**, 687.

there is a significant influence of the pH value and reaction time, but not of the concentration of 1,10-phenanthroline provided that there is a 5-fold excess relative to iron(III). At room temperature the final state is reached only after several hours because of kinetic hindrance. An inner-sphere mechanism is assumed, because ternary iron(III) complexes could be detected in systems containing excess of the ligand. In an earlier work[6] the following blue species were detected:

$$[Fe(phen)(catechol)_2]^-$$

$$[Fe(phen)(tiron)_2]^{5-}$$

$$[Fe(phen)(gallic\ acid)_2]^{3-}$$

The oxidation products A_{ox} are quinonoid compounds that have not yet been fully characterized. According to textbooks of organic chemistry the oxidation of phenols leads to reaction products which are very seldom of uniform composition. Radicals arise as intermediates, and can react to form ring compounds by different ways of dimerization.

In the present work the Fe^{3+}/phen system was used to oxidize phenols at pH 4.0 and 60° and the oxidation products were extracted with diethyl ether. After evaporation of the ether the residue was dried under reduced pressure over anhydrous calcium chloride and then examined by infrared spectroscopy.

The following products could be identified: *p*-benzoquinone from phenol or hydroquinone; *o*-benzoquinone from pyrocatechol; *o*- and *p*-benzoquinone from pyrogallol and phloroglucinol. Condensed aromatic ring systems could also be detected, besides the benzoquinones.

Extraction of the $[Fe(phen)_3]^{2+}$ chelate

The sensitivity of the basic reaction can be increased by extraction of the coloured complex ion. With perchlorate as a counter-ion we have:

$$[Fe(phen)_3]^{2+}_{(aq)} + 2ClO^-_{4(aq)} \rightleftharpoons [Fe(phen)_3]^{2+}\cdot(ClO^-_4)_{2(org)}$$

As shown earlier,[7] extraction of this with nitrobenzene in the presence of EDTA is possible in the pH range 3–9. The EDTA (H_2Y^{2-}) is used to suppress the reaction of the excess of iron(III) with 1,10-phenanthroline and perchlorate to form a yellow-brown product that would also be extractable:

$$[Fe_2O(OH)(phen)_4]^{3+} + 2H_2Y^{2-} + 3H^+ \rightleftharpoons 2FeY^- + 4Hphen^+ + 2H_2O$$

The ion-pair of the iron(II) complex with perchlorate has maximum absorbance at 515 nm and a molar absorptivity in nitrobenzene of 1.25×10^4 l.mole^{-1}.cm^{-1} at that wavelength.

The redox systems were characterized by the mole-ratio method.[8] For the system

$$m\,Fe^{3+} + n\,Red \rightleftharpoons p\,Fe^{2+} + q\,Ox$$

the absorbance (A) was determined with c_{Fe}, pH, ionic strength and λ constant, and increasing concentrations of Red. From the breakpoint of the function $A = f(c_{Red}/c_{Fe})$ the ratio n/m was obtained and from this value the smallest values of the coefficients. The number of electrons z_A exchanged during the reaction can be derived simply as $z_A = mz_{Fe}$, and since $z_{Fe} = 1$, it follows that $z_A = m$.

Statistical characterization

The apparent molar absorptivities were calculated in the normal way and the relative standard deviation was obtained from 16 measurements of solutions with medium concentration ($A \sim 0.7$). The calibration function $A = bc + a$, where c is the analyte concentration, was calculated by linear regression with 6 degrees of freedom, and the detection limit according to Kaiser and Specker,[9] as the concentration corresponding to a signal equal to $a + 3s_a$, where s_a is the standard deviation of the intercept. Because the sensitivity of photometric measurements is best in the interval $0.1 < A < 1.5$, the range of application was defined as $(a + 0.1) < A < (a + 1.5)$.

Detection reactions were characterized by the dilution limit D, defined as

$$D = \frac{\text{limit of perceptibility } (\mu g)}{\text{volume of test sample (ml)} \times 10^6}$$

Determination without extraction

In a 50-ml standard flask place 10 ml of Fe^{3+}/phen reagent ($10^{-3}M$ Fe^{3+}, $10^{-2}M$ phen, pH 4.0) followed by 5 ml of $1M$ acetate buffer (pH 4) and up to 25 ml of analyte solution, and dilute to the mark with water. Heat the closed flask for 1 hr in a thermostat at 60°, cool to room temperature, and measure the absorbance at 510 nm in 1-cm cells, against water.

*c expressed as μg/50 ml.

Determination with extraction

Prepare the samples as given above, but with only 1 ml of Fe^{3+}/phen reagent. After cooling, transfer the solution to a 100-ml separatory funnel, add 1 ml of 0.05M EDTA and 1 ml of 1M sodium perchlorate and immediately extract with 5.0 ml of nitrobenzene, shaking the mixture for 30 sec. Separate the extract, dry it with 2 g of anhydrous sodium sulphate, and measure the absorbance at 515 nm in 1-cm cells, against nitrobenzene.

Detection

In a semimicro test-tube place 1 ml of Fe^{3+}/phen reagent ($10^{-4}M$ Fe^{3+}, $10^{-3}M$ phen, pH 4.0) followed by 5 drops of 1M acetate buffer (pH 4) and some drops of sample solution. Heat the test-tube for about 30 sec in a boiling water-bath and compare with a reagent blank. For use of the extraction method, add to the cooled solution 3 drops of 0.05M EDTA, 3 drops of 1M sodium perchlorate and 5 drops of nitrobenzene, and shake the tube. Compare the colour of the organic phase with that of a reagent blank.

CONCLUSIONS

As shown in Tables 1 and 2, the Fe^{3+}/phen system is a valuable reagent for the detection and determination of phenolic compounds,

Table 2. Extraction-photometric determination of phenols with Fe^{3+}/phen as a reagent ($\lambda = 515$ nm)

*Conditional molar absorptivity in nitrobenzene, assuming that the extraction coefficient is 1.00.

†c expressed as μg/50 ml.

especially by the extraction method. Only aromatic amines, enediols and aliphatic or aromatic thiol groups will react similarly and can interfere with the detection or determination of phenols.[2] However, there is practically no selectivity for phenols themselves. Only nitrophenols, halogen-substituted phenols and other phenols containing substituents with a negative induction effect do not react with the reagent. Polyhydroxy phenols and naphthols give positive reactions.

It is possible to detect (with and without extraction) phenol (p*D* 7.0; 6.3), *o*-cresol (p*D* 6.8; 5.9), *m*-cresol (p*D* 6.4; 5.8) and *p*-cresol (6.4; 5.7), but determination of these compounds is not possible, because of non-linearity of the function $A = f(c)$.

The following conditional molar absorptivities ($l.mole^{-1}.cm^{-1}$) (two-fold excess of reagent, $c_A = 5 \times 10^{-5} M$) were calculated: phenol, 4.8×10^4; *o*-cresol, 1.6×10^4; *m*-cresol 5.2×10^4; *p*-cresol 1.8×10^4.

The results demonstrate that the procedures are very sensitive for the detection and determination of single species. The small selectivity within the groups makes it possible to determine the sum of compounds giving similar molar absorptivities, because λ_{max} and pH are the same for all the compounds discussed here. As a standard substance, phloroglucinol (which gives a medium number of exchanged electrons) can be recommended.

The semiquantitative determination of a mixture of compounds is possible and is based on the additivity of the absorbances. A test with phloroglucinol, pyrocatechol, hydroquinone, 2,3-dihydroxynaphthalene and 1,2-aminophenol at levels giving $A \sim 0.1$ per compound showed the following total absorbances (measured; calculated):

without extraction	0.63; 0.62
with extraction	0.62; 0.62

o-HYDROXYACETOPHENONE THIOSEMICARBAZONE AS A REAGENT FOR THE RAPID SPECTROPHOTOMETRIC DETERMINATION OF PALLADIUM

G. V. RAMANA MURTHY* and T. SREENIVASULU REDDY
Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515003, India

(*Received* 22 *August* 1989. *Revised* 25 *September* 1991. *Accepted* 28 *October* 1991)

Summary—*o*-Hydroxyacetophenone thiosemicarbazone has been synthesized and employed as a new reagent for the spectrophotometric determination of palladium(II), which forms two complex species with it in aqueous dimethylformamide at pH 6.0, these having 1:1 and 1:2 metal–ligand ratios. The Job and molar-ratio plots have an unusual shape that is due to the stepwise conversion of the 1:1 complex into the 1:2 species. The molar absorptivity at 370 nm is 9×10^3 l.mole^{-1}.cm^{-1}. Beer's law is obeyed over the range 0.42–10.6 μg/ml palladium.

Derivatives of hydroxyacetophenone have been extensively developed as analytical reagents.[1–8] Earlier we reported the use of *o*-hydroxyacetophenone thiosemicarbazone (HAPT) as a spectrophotometric reagent for the determination of copper,[9] cobalt[10] and nickel,[11] and now report its application to determination of palladium. Most of the spectrophotometric methods using thiosemicarbazones suffer from low sensitivity, the need for heating or extraction, and poor selectivity.[12–20] The proposed method based on HPAT is free from these drawbacks.

Although the proposed method does not provide any significant improvement in sensitivity over existing methods, a very interesting feature is the unusual shape of the Job and molar-ratio plots used to characterize the complexation reaction. In both cases there is a minimum in the absorbance between the maxima corresponding to 1:1 and 1:2 metal:ligand ratios. Similar behaviour in Job plots has been reported by others.[21–24]

EXPERIMENTAL

Apparatus

A Beckmann DU-2 spectrophotometer and an Elico LI-120 pH-meter were employed.

Reagents

Analytical-reagent grade chemicals and doubly distilled water were used.

A stock solution of palladium(II) was prepared by dissolving 1.773 g of palladous chloride in distilled water and diluting to volume in a 100-ml standard flask, standardized,[25] and further diluted as required.

A 0.2*M* acetic acid–sodium acetate buffer (pH 6.0) was used.

Preparation of the reagent

Thiosemicarbazide and a few drops of glacial acetic acid were dissolved in the minimum amount of water and an equimolar amount of *o*-hydroxyacetophenone was dissolved in the minimum of ethanol, then the solutions were mixed. The mixture was refluxed for 3 hr on a boiling water-bath. The hot solution was filtered under suction and cooled. Yellow crystals of HAPT were obtained and were recrystallized from ethanol (yield 65%, m.p. 183–186°). A stock solution (0.05*M*) was prepared by dissolving 0.5352 g of the reagent in 50 ml of dimethylformamide (DMF). It was stable for a day.

Elemental analysis and spectral characteristics of the reagent

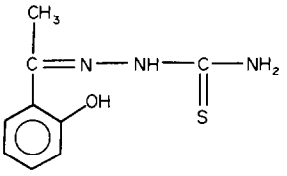
Analysis gave C 51.0%, H 5.2%, N 20.0%; $C_9H_{11}N_3OS$ requires C 51.65%, H 5.24%, N 20.08%.

The infrared spectrum was obtained (KBr discs) and bands were assigned to the stretching vibrations of NH–NH_2 at 3330–2950 cm^{-1}, >C=N at 1630 cm^{-1} and >C=S at 1050, 850 cm^{-1}.

The proton NMR spectrum was obtained in d_6-DMSO with tetramethylsilane as reference.

*Present address: 17/84-A, T.V. Street, Nellore 524001, India.

The peaks were assigned as follows: (δ) 2.5, (3H, singlet —CH_3), 3.59 (2H, singlet —NH_2), 5.74 (1 H, singlet —NH); 7.8 (multiplet, C_6H_6).



HAPT

HAPT is soluble in dimethylformamide (20 g/l.) and dimethylsulphoxide (12 g/l.) and sparingly soluble in methanol, water, chloroform, carbon tetrachloride and cyclohexanone.

Reactions with metal ions

No visible colour reactions were observed with 25 cations tested, except for palladium, copper, iron, cobalt, nickel, vanadium, silver, gold and platinum. The photometric characteristics of the complexes of these metal ions in solution are given in Table 1.

Recommended procedure

For calibration, to each of a set of 25-ml standard flasks containing 12.5 ml of pH 6.0 buffer, 3 ml of DMF and 2 ml of 0.05*M* reagent, add appropriate volumes of $5 \times 10^{-4}M$ palladium(II) solution to cover the range up to 10 μg/ml palladium, and dilute to the mark with distilled water. Read the absorbance at 370 nm against a reagent blank. Analyse samples in the same way.

RESULTS AND DISCUSSION

Absorption spectra and effect of pH

The complex formed between Pd(II) and HAPT has maximum absorbance at 370 nm (Fig. 1) and a plot of absorbance *vs.* pH shows that the absorbance remains constant in the pH range 5.0–9.0. Use of pH 6.0 is recommended. The absorbance of the complex remains stable for one day. The system obeys Beer's law over the range 0.4–10.6 μg/ml palladium, and the optimum range (Ringbom plot) is 1.1–9.5 μg/ml. The molar absorptivity is 9.0×10^3 l.mole^{-1}.cm^{-1}.

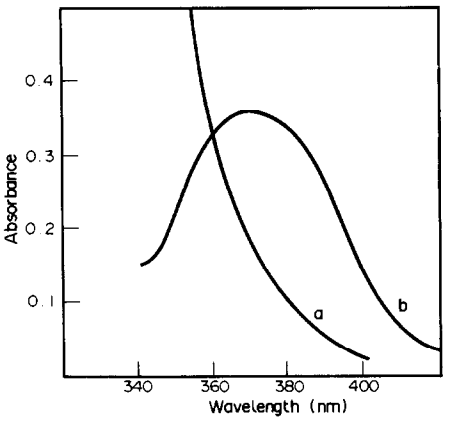


Fig. 1. Absorption spectra (a) HAPT *vs.* buffer blank; (b) Pd-HAPT system *vs.* reagent blank. [Pd(II)] $4 \times 10^{-5}M$; [HAPT] $1 \times 10^{-3}M$; pH 6.0.

Effect of DMF concentration

The Pd(II)–HAPT complex is soluble in DMF, and 14% v/v DMF in water is required to keep the complex in solution. At lower DMF concentration the solution is turbid.

Effect of reagent concentration

The molar-ratio plot showed that a fivefold ratio of HAPT to palladium is sufficient for full colour development, but a tenfold molar ratio is recommended.

In addition to this, the molar-ratio plot indicated that 1:1 and 1:2 metal:ligand complexes were formed successively, but there was a marked decrease in absorbance between the corresponding intersections on the plot (Fig. 2).

Table 1. Characteristics of metal ion–HAPT complexes

Cation	pH	λ_{max}, *nm*	Molar absorptivity, 10^3 *l.mole*$^{-1}$*.cm*$^{-1}$	M:L	Beer's law range, *ppm*	Optimum range (Ringbom plot), *ppm*	Stability constant

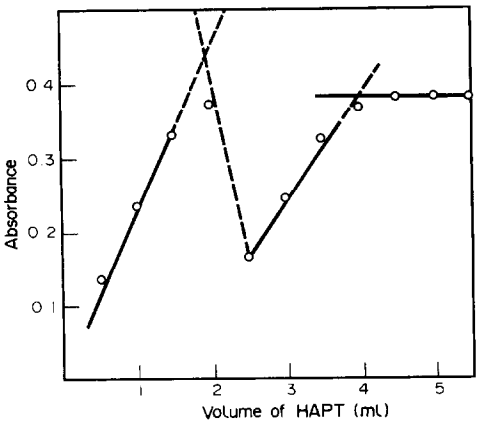

Fig. 2. Molar ratio plot. [Pd(II)] = [HAPT] = $5 \times 10^{-4}M$; pH 6.0. Pd(II) solution 2 ml; total volume 25 ml; blank 12.5 ml of buffer + 2.5 ml of DMF.

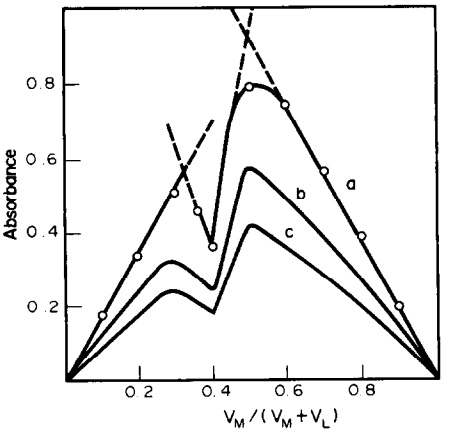

Fig. 3. Job plots: (a) at 370 nm, $5 \times 10^{-4}M$ reactants; (b) at 370 nm, $4 \times 10^{-4}M$ reactants; (c) at 380 nm, $3 \times 10^{-4}M$ reactants; blank 12.5 ml of buffer + 2.5 ml of DMF.

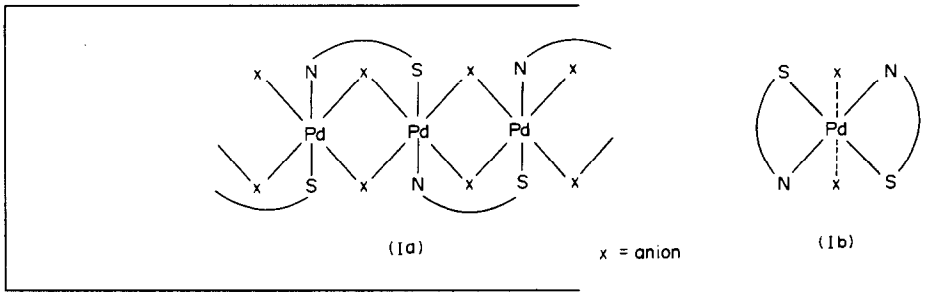
Formation of more than one complex was confirmed by the Vosburgh and Cooper method.[26]

A Job plot was also anomalous, having two maxima corresponding to Pd:HAPT ratios of 1:1 and 1:2, with a sharp decrease in absorbance between them (Fig. 3). The position of the maxima and minima did not change with variation of either the wavelength or the concentration used.

It is interesting (and unusual) that the molar absorptivity of both complexes is almost the same. From this behaviour it is evident that a drastic reorganization of the structure of the complex takes place in conversion of the 1:1 into the 1:2 (metal:ligand) complex. A possibility for this was proposed by Rao *et al.*[24] for the Pd(II) complexes with 5,6-dimethyl-1,3-indanedione-2-oxime.

The shape of the molar-ratio plot and Job curves presented in Figs 2 and 3 suggests that two complexes with compositions corresponding to 1:1 and 1:2 metal:ligand are formed under the experimental conditions. The minimum between the two maxima in the Job curve not only indicates that considerable reorganization is involved as the ligand:metal ratio is increased, but also that this reorganization does not take place smoothly and immediately. By analogy with the work of Campbell and Grzeskowiak on the copper complexes of some thiosemicarbazides,[27] we consider that our results could be accounted for by postulating formation of a polymeric 1:1 type complex with both an anionic bridge and a thiosemicarbazone bridge between neighbouring palladium ions (structure Ia, below), and depolymerization of this in presence of excess of HAPT, to form a 1:2 square coplanar complex with two loosely attached anions (structure Ib, below).



Infrared spectral data

The infrared spectral data in Table 2 allow some conclusions to be drawn about the bonding sites in the Pd–HAPT complex. The band at 1630 cm^{-1} is shifted to lower frequency (1585 cm^{-1}), indicating the participation of the azomethine nitrogen atom in co-ordination.[29,30] A sharp band at 1050 cm^{-1} due to the >C=S band in the ligand shifts to lower frequency in the complex, suggesting co-ordination of the sulphur atom of the ligand.[28,31] Absence of the band due to the S—H stretching mode at 2570 cm^{-1} suggests that in the solid state the

ligand remains in thioketo form.[33] Based on the infrared spectral investigations, the structure of the solid Pd–HAPT complex is assumed to be that shown as Ib above.

Effect of foreign ions

Various amounts of foreign ions were added to a fixed amount of palladium(II) (80 μg) and the recommended procedure for the spectrophotometric determination was followed. The amounts (mg) at which various ions did not cause more than $\pm 2\%$ change in the absorbance are given below.

Ascorbic acid (53); tartrate (44); nitrate (37); phosphate (29); citrate (28), iodide (19), perchlorate (15), sulphate (14), oxalate (13), bromide (12), EDTA (11), chloride (11), thiocyanate (8.7), thiourea (7.6), fluoride (5.7), U(VI) (3.6), Th(IV) (3.5), W(VI) (2.8), Pb(II) (2.1), Cd(II) (1.7), Mn (0.83), Ce(IV) (0.70), Mo(VI) (0.30), Al(III) (0.27), Zn(II) (0.20), Os(VIII) (0.010). Cu(II), Co(II), Ni(II), Cr(III), V(V), V(IV), Pt(IV), Au(III) (0.95, 0.88, 0.88, 0.78, 0.76, 0.76, 0.33, 0.22 mg respectively) could be masked with 11 mg of EDTA. Fe(III) (0.11 mg) was masked with 19 mg of phosphate. Ag(I) and Sn(II) interfere, forming a turbidity.

Application to synthetic mixtures

The method was applied to the determination of Pd(II) in certain synthetic mixtures corresponding to its alloys. Phosphate and EDTA were added to mask iron and copper, cobalt, nickel, vanadium, platinum and gold. Ag(I) was separated by precipitation as silver chloride. The complete data are presented in Table 3.

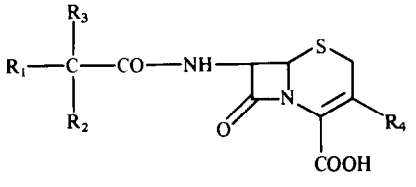
SPECTROPHOTOMETRIC DETERMINATION OF CEPHALEXIN IN DOSAGE FORMS WITH IMIDAZOLE REAGENT

A. A. ALWARTHAN, S. ABDEL FATTAH and N. M. ZAHRAN
Chemistry Department, College of Science, King Saud University, P.O. Box 2455, Riyadh-11451, Saudi Arabia

(*Received* 18 *March* 1991. *Revised* 1 *August* 1991. *Accepted* 16 *September* 1991)

Summary—A simple spectrophotometric method is proposed for the determination of cephalexin. The method involves acetylation of cephalexin with acetic anhydride in aqueous solution at pH 11.5 to yield α-acetamidocephalexin and subsequent measurement at 335 nm of α-acetamidocephalexin mercuric mercaptide. The method characterizes a newly developed, sensitive procedure for the determination of cephalexin in different pharmaceutical preparations. The effect of several reaction conditions were investigated. Beer's law was obeyed over the concentration range 30–340 μg/ml. The results compare favourably with those obtained by the official B.P. 1980 method.

Cephalosporins are a series of antibiotics containing a β-lactam ring fused to a six-membered ring with a sulphur atom.



They have antibacterial action against Gram-positive and Gram-negative bacteria. Cephalexin, a potent cephalosporin, exhibits a broad spectrum of antibiotic activity.[1] Several analytical procedures are available in the literature for the analysis of cephaloxin, *viz.* spectrophotometric,[2–6] titrimetric with potassium iodate,[7,8] fluorimetric,[9] polarographic,[10] chromatographic,[11] and iodometric methods.[12]

The aim of this paper was to develop a simple and reproducible spectrophotometric procedure for determining cephalexin monohydrate in alkaline aqueous solution, using imidazole reagent containing mercuric chloride.

EXPERIMENTAL

Apparatus

A Varian Model DMS 100 spectrophotometer interfaced with a Varian Model DS 15 Data station and a Hewlett–Packard Model 82905 B Printer was used for all absorbance measurements. Matched sets of 10-mm silica cells were used throughout.

Materials

Pure drug sample was kindly provided by Chemical Industries Development, Giza, Egypt. Dosage forms were obtained from local sources. Several formulations were used:

(A) Cephalexid, 250 mg of cephalexin per capsule (Chemical Industries Development, Giza, Egypt).
(B) Ibilex, 250 mg of cephalexin per capsule (Ibi Instituto Biochemico Italiano Giovanni Lorenzini S.P.A., Milano, Italy).
(C) Keflex, 250 mg of cephalexin per capsule (Eli Lilly and Company Ltd., Basingstoke, England).
(D) Keflex, 500 mg of cephalexin per tablet (Eli Lilly and Company Ltd., Basingstoke, England).
(E) Keflex granules, 250 mg of cephalexin per packet (Eli Lilly and Company Ltd., Basingstoke, England).
(F) Ospexin, cephalexin suspension, 250 mg of cephalexin per 5 ml (Biochemie GmbH, Vienna, Austria).

Reagents

The reagents used were all of analytical or pharmaceutical grade. Distilled demineralized water was used throughout.

Cephalexin solution. A stock solution of $9.18 \times 10^{-4} M$ was prepared by dissolving 0.3354 g in 2 ml of 0.1*M* sodium hydroxide and then diluting one litre with water.

Imidazole reagent. A 1.2*M* aqueous imidazole solution containing $10^{-3}M$ mercuric chloride with pH adjusted to 6.8.

*Acetic anhydride solution, 0.2*M. Acetic anhydride (1.0 ml) diluted to 50 ml with acetonitrile.

*Borate buffer, 0.1*M. Boric acid (1.24 g) dissolved in 10.6 ml of 1*M* sodium hydroxide and diluted to 200 ml with distilled water to give a solution with pH 11.5.

Analysis of authentic samples

An aliquot of cephalexin (34 μg/ml–350 μg/ml) was transferred to a 25-ml standard flask. Then 0.5 ml of the borate buffer, 0.03 ml of acetic anhydride solution and 2 ml of imidazole reagent were added and the volume was completed to the mark. The mixture of the solutions was heated at 60° for 55 min. Then the solution was cooled to room temperature and the absorbance was measured at 335 nm against a blank prepared with all the reagents but no cephalexin. The calibration curve was obtained by applying the same procedure, using standard cephalexin solutions.

Analysis of dosage forms

Capsules and granules. The contents of ten capsules or three granule packets were weighed and powdered. An amount of powder equivalent to 20 mg of the active constituent was weighed accurately and transferred into a 100-ml calibrated flask. It was shaken with 50 ml of distilled water and then diluted to volume with distilled water. An aliquot of this solution giving an analyte concentration of 200 μg/ml was transferred into a 50-ml calibrated flask and analysed as for authentic samples.

Tablets. Ten tablets were weighed and powdered. An amount of powder equivalent to 20 mg of the active constituent was weighed accurately and transferred into a 100-ml calibrated flask. It was dissolved in 50 ml of distilled water and then diluted to volume with distilled water. The solution was filtered through a Whatman No. 1 filter paper. The first 15 ml of filtrate was discarded. An aliquot of this solution to give an analyte concentration of 200 μg/ml was transferred into a 50-ml calibrated flask and analysed as for authentic samples.

Suspension. The contents of a well mixed suspension were filtered through dry filter paper. An aliquot of this suspension equivalent to 200 μg/ml was pipetted into a 100-ml calibrated flask and analysed as for authentic samples.

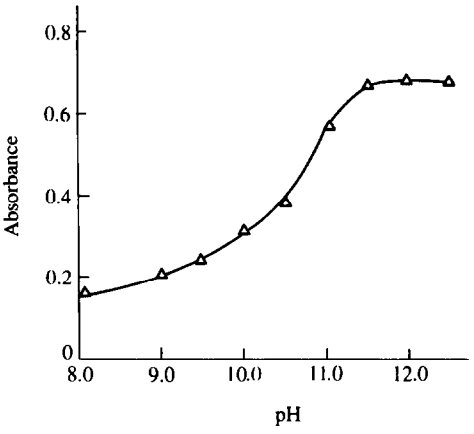


Fig. 1. Effect of pH on the absorbance of the drug complex.

RESULTS AND DISCUSSION

Several parameters such as pH, acetic anhydride concentration, temperature, heating time and the volume of imidazole reagent were optimized to achieve high sensitivity, low blank reading and high stability.

Effect of pH

Cephalexin has a similar chemical structure to ampicillin. Bundgaard found that ampicillin undergoes an imidazole-catalysed rearrangement into the corresponding penicillenic acid which yields the corresponding stable mercuric mercaptides in the presence of mercuric chloride at pH 6.8.[13] Therefore, in order to get the best medium for the quantitative determination of cephalexin in aqueous solution, different borate buffer solutions, with different pHs were prepared. The absorbance readings were maximum at pH 11.0–12.5 as shown in Fig. 1. A solution of boric acid adjusted to pH 11.5 with sodium hydroxide was used in the calibration measurements.

Effect of acetic anhydride concentration

Different amounts of acetic anhydride were added keeping other conditions constant. As shown in Table 1, 30 μl of 0.2*M* acetic anhydride is sufficient for complete acetylation of the cephalexin amino group.

Effect of imidazole concentration

The effect of imidazole was similarly investigated by taking various amounts of imidazole. It was observed that 2 ml of imidazole gave maximum absorbance in its reaction with cephalexin, as shown in Table 2.

Table 1. Effect of acetic anhydride concentration

Cephalexin	1 ml of 31 μg/ml solution
Borate buffer	0.5 ml
Acetic anhydride	x ml
Imidazole reagent	2 ml
λ_{max}	335 ml
Acetic anhydride added, *ml*	Absorbance
0.01	0.75
0.02	0.87
0.03	1.25
0.04	1.25
0.05	1.25

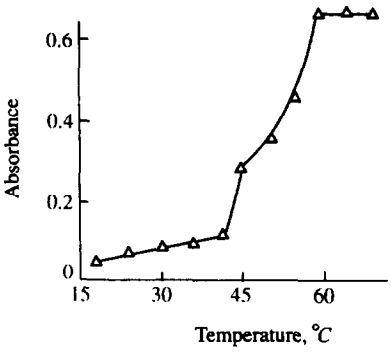

Fig. 2. Effect of temperature on the absorbance of the drug complex.

Effect of temperature

The reaction between cephalexin and the aqueous imidazole solution to form a product with a measurable absorbance is temperature dependent. Therefore, the effect of temperature on the formation of the product was studied in the range 18–70°. It was found that the absorbance increased slowly during heating up to 55°. However, a significant increase was observed at 60° above which the absorbance remained constant as shown in Fig. 2.

Effect of heating time

The effect of heating time on the formation of the product was studied at the optimal temperature (60°). The absorbance was found to increase with time reaching its maximal value after 55 min as shown in Fig. 3.

The proposed method exposes the β-lactam compound (cephalexin) to rather harsh conditions before derivatization with imidazole/$HgCl_2$ reagent. Therefore, to study how much of the cephalexin originally present was eventually used for quantification, the imidazole/$HgCl_2$ reagent was added to the solution of cephalexin together with the other reagents required, at 5-min intervals from 0–60 min. The results obtained are shown in Fig. 4. They indicate that if such harsh conditions have destroyed the β-lactam (cephalexin), the imidazole/$HgCl_2$ reagent would not couple with the degraded cephalexin and the absorbance would be zero.

Table 2. Effect of imidazole concentration

Cephalexin	1 ml of 31 μg/ml solution
Borate buffer	0.5 ml
Acetic anhydride	0.03 ml
Imidazole reagent	x ml
λ_{max}	335 ml
Imidazole added, *ml*	Absorbance
0.5	0.75
1.0	1.15
1.5	1.25
2.0	1.50
2.5	1.50
3.0	1.50

Using the above described optimum parameters, a calibration graph correlating the absorbance versus concentrations was found to be linear with slope 0.19 and correlation coefficient 0.999. Beer's law was obeyed over the range 30–340 μg/ml. The regression equation, calculated from the calibration graph, was $A = 0.009 + 0.19C$ where A = absorbance and C = concentration (μg/ml). To test its validity, the method was applied to authentic samples of cephalexin. The results given in Table 3 show that the method is accurate and precise.

The method was applied to some dosage forms containing cephalexin. The performance of the recommended method was assessed by calculation of the t-values. A mean value of $t = 0.877$ was obtained in a student's t-test,[13] showing the absence of any systematic error in the method; the corresponding tabulated t-value for five degrees of freedom and for a 95% confidence level is 2.571. Therefore, it can be

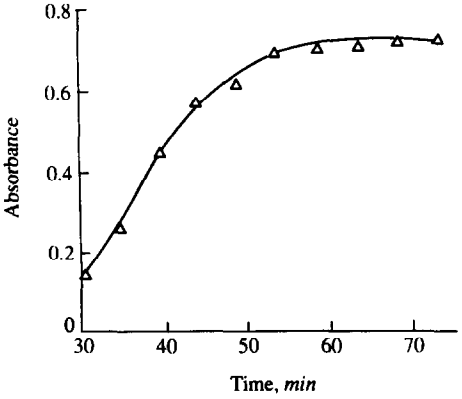

Fig. 3. Effect of heating time on colour formation of the drug product.

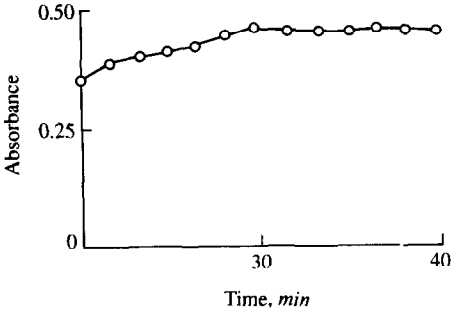

Fig. 4. The effect of cephalexin derivatization by the imidazole/$HgCl_2$ reagent (at pH 11.5 and 60°) on its quantitative determination.

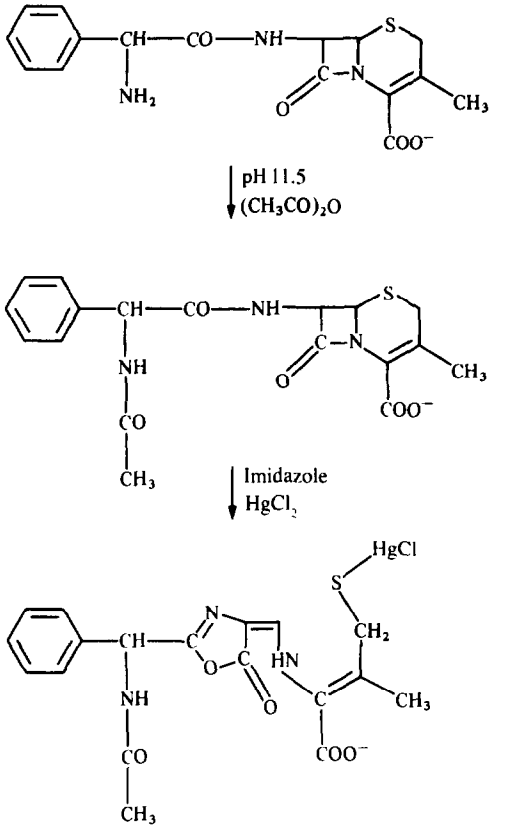
concluded that there is no significant difference between the proposed method and the official one. Table 4 gives the results of these applications. However, the present method has the advantage of ease of operation, convenience, small sample/reagent consumption, and can be used as a stability indicating method.

Preliminary studies have shown that the present method can be automated with an Autoanalyzer system or flow-injection analysis, which may have useful application in routine or research laboratories. This procedure will be reported later when more results are available.

The method of the imidazole and mercury(II) reaction for determination of cephalosporines and penicillins is favoured currently in many laboratories,[14] because imidazole reacts with the intact β-lactam compound and hence can be used as a stability indicating method. However, it has the disadvantage of using mercury(II) which is a potential chemical hazard. This method is general for all cephalosporins containing the β-lactam ring fused to a six-membered ring with sulphur atom. But the method dose differentiate between the intact molecule and the degraded one.

The quantitative determination of cephalexin, using the procedure mentioned previously, is similar to that for penicillin.[15] Therefore, the reaction of cephalexin can be represented by the proposed mechanism as shown in the following scheme:



Proposed mechanism of the reaction between cephalexin and imidazole reagent.

Table 3. Analysis of authentic sample of cephalexin by the proposed and official method*

THREE SIMPLE SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF SULPHINPYRAZONE

C. S. P. SASTRY,* A. SAILAJA, T. THIRUPATHI RAO and D. MURALI KRISHNA

Foods and Drugs Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530 003, India

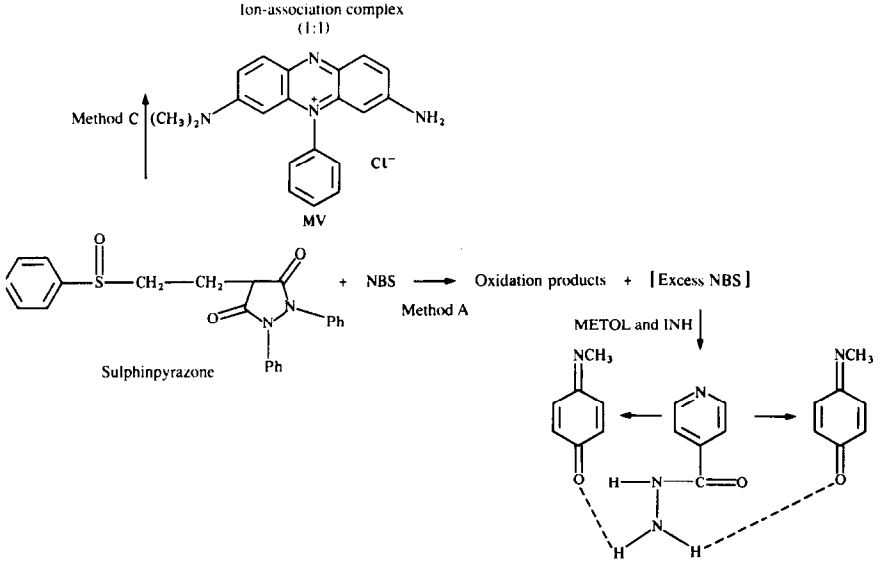
(*Received* 24 *June* 1991. *Accepted* 29 *August* 1991)

Summary—Three simple and sensitive spectrophotometric methods for the determination of sulphinpyrazone (SP) in bulk samples and pharmaceutical formulations are described. They are based on the oxidation of sulphinpyrazone with excess *N*-bromosuccinimide (NBS) and determination of the unconsumed NBS with metol–isonicotinic acid hydrazide (method A, λ_{max}: 620 nm); by the reduction of Folin–Ciocalteu reagent (method B, λ_{max} 770 nm); or by the formation of a chloroform-soluble, coloured ion-association complex between the drug and Methylene Violet (MV) at pH 7.0 (method C, λ_{max} 545 nm).

Sulphinpyrazone is chemically known as 3,5-pyrazolidine dione, 1,2-diphenyl-4-[2-(phenyl sulphinyl) ethyl]. Its structure is given in Scheme 1. It is widely used as a uricosuric agent and reduces elevated concentrations of uric acid in the blood and causes the slow depletion of urate deposits in tissues. It is used in the treatment of recurrent and chronic gout and is official in U.S.P.[1] and B.P.[2] Reported methods include a single titrimetric[3] and two visible spectrophotometric[4,5] methods besides a few GLC[6,7] and HPLC[8,9] methods. The first visible spectrophotometric method with *p*-dimethylaminocinnamaldehyde as the chromogenic agent requires a preliminary treatment of the drug with acetic acid and hydrochloric acid. The second method with 2,2′-diphenyl-1-picrylhydrazyl is not satisfactory for microgram quantities.

Sulphinpyrazone exhibits acidic character and reducing properties due to the presence of sulphoxide and enolic hydroxyl groups. These have not been exploited so far for its estimation. Three sensitive visible spectrophotometric methods have been developed based on

*Author for correspondence.



Scheme 1

these properties. *N*-Bromosuccinimide (NBS) contains unstably bound bromine and is used for brominations and dehydrogenations in organic compounds. Sastry *et al.*[10] suggested a procedure for determining isonicotinic acid hydrazide (INH) by treatment with *p*-*N*-methyl aminophenol sulphate (MAP, metol) and oxidant. In method A of the present study, SP was treated with standard NBS in excess. The consumed NBS corresponding to SP was obtained by estimating excess NBS spectrophotometrically with metol and INH and deducting it from the NBS initially taken (*i.e.*, blank). Folin–Ciocalteu reagent in the presence of alkali has been utilized as a chromogenic agent for the determination of a number of drugs.[11] The basic dye, methylene violet, has been used for the determination of drugs which are acidic in nature.[12] This basic dye was used for the determination of SP. All three methods have been applied to bulk samples and pharmaceutical preparations.

EXPERIMENTAL

Apparatus

A Systronics model 106 spectrophotometer with 1-cm matched glass cells was used for all the absorbance measurements. An Elico-digital model LI-120 pH meter was used for pH measurements.

Reagents

All solutions were prepared in doubly distilled water. Freshly prepared aqueous solutions of 0.8% metol (*p*-*N*-methyl aminophenol, Loba-Chemie), 0.045% NBS (*N*-Bromosuccinimide, Loba-Chemie, standardized iodometrically), 0.1% INH (isonicotinic acid hydrazide, Wilson Labs) and 1% acetic acid (BDH) were prepared.

A 10% (w/v) sodium carbonate (BDH) aqueous solution and commercially available 2*N* Folin–Ciocalteu (Loba-Chemie) reagent were used.

A 0.068% (w/v) aqueous methylene violet solution (Gurr, MV; C.I. No. 50210) was prepared. A buffer solution (pH 7.0) was obtained by mixing 390 ml of 0.067*M* potassium hydrogen phosphate (Merck) and 610 ml of 0.067*M* disodium hydrogen phosphate (Merck).

Standard drug solution. A 1-mg/ml solution of sulphinpyrazone was prepared in 0.01*N* sodium hydroxide. The working solutions (methods A, 100 μg/ml; B, 50 μg/ml; C, 10 μg/ml) were obtained by further dilution of the stock solution with distilled water.

All chemicals used were of analytical or pharmacopoeial grade.

Analysis of bulk samples

Method A. Aliquots of the standard drug solution (0.75–4.0 ml, 100 μg/ml) were transferred into a series of 25-ml graduated test tubes and the total volume in each tube was brought to 4 ml with distilled water. Then 2 ml of NBS was added to each and the test tubes were kept aside for 15 min at room temperature (25–30°). Next 15 ml of acetic acid and 1 ml of metol were added and the solutions were mixed thoroughly. After 2 min, 1 ml of INH was added. The solutions were made up to the mark with methanol. The absorbances were measured at 620 nm after 15 min and before 25 min against distilled water. A blank experiment was also carried out, omitting the drug. The decrease in the absorbance corresponding to sulphinpyrazone was obtained by subtracting the absorbance of the drug solution from the blank. The amount of sulphinpyrazone was computed from the standard calibration curve.

Method B. Aliquots of the drug solution (0.75–5.0 ml, 50 μg/ml) were transferred into a series of 25-ml graduated test tubes. The total volume in each test tube was brought to 5.0 ml with distilled water. A 2.5-ml portion of Folin–Ciocalteu reagent and 7 ml of sodium carbonate were added and the mixture kept aside for 40 min. Then the solutions were made up to 25 ml with distilled water and the absorbances measured at 770 nm immediately against a reagent blank prepared in a similar manner. The coloured species was stable for eight hours. The amount of drug was computed from the calibration graph.

Method C. Aliquots of the standard drug solution (1.0–5.0 ml, 10 μg/ml) were placed in a series of 125-ml separating funnels. Then 10 ml of buffer (pH 7.0) and 1 ml of MV solution were added to each separating funnel. The total volume of aqueous layer in each separating funnel was brought to 16 ml with distilled water. A 10-ml portion of chloroform was added to each and the contents were shaken for 1 min. The absorbance of the separated chloroform layer was measured at 545 nm against a reagent blank within the stability period (1 min–1 hr). The amount of drug was calculated from its calibration graph.

NBS: $1.52 \times 10^{-4}M$, Metol: $9.3 \times 10^{-4}M$, INH: $2.92 \times 10^{-4}M$; Sulphinpyrazone: $7.42 \times 10^{-4}M$, MV: $2.32 \times 10^{-3}M$.

Analysis of pharmaceutical preparations

As the tablets and capsules were not available in the local market, we prepared our own according to the literature method.[13,14] An amount of the powdered tablet or capsule content equivalent to 100 mg was treated with 100 ml of $0.01N$ sodium hydroxide and the insoluble residue was filtered to obtain a stock solution of 1 mg/ml. The stock solutions were further diluted with distilled water to provide working solutions as in the case of standard drug solutions and were analysed by the three different procedures.

RESULTS AND DISCUSSION

The absorption spectra of the reaction products in methods A, B and C show characteristic λ_{max} values (Figs. 1 and 2). The reaction conditions were established by variation of one parameter at a time. Method A involves two stages:—oxidation of SP by NBS (first stage) and estimation of unconsumed NBS with metol–INH reagent (second stage). In the first stage for the oxidation of sulphinpyrazone, use of 1.5–2.5 ml of NBS and a waiting period of 10–30 min were found necessary. In the second stage, 12–18 ml of acetic acid, 0.5–1.5 ml of metol solution and 0.5–1.5 ml of INH solution were found optimal. The intermittent waiting period prior to the addition of INH was 1–3 min.

In method B, 2.20–2.80 ml of Folin–Ciocalteu reagent and 6–8 ml of sodium carbonate were found to give maximum colour intensity. The order of addition however was found not to have a significant effect. Sodium hydroxide instead of sodium carbonate did not give a positive test.

In method C, in order to establish the optimum pH range, sulphinpyrazone was allowed to react with MV in aqueous solutions buffered to pH 4.0–7.5 and the complex formed was extracted into chloroform for measurement. Constant absorbances were obtained over the pH range 6.8–7.2 in phosphate buffer. Hence a pH of 7.0 was used. A 0.75–1.20 ml-portion of MV solution was found to be optimal. Shaking times of 0.5–4.0 min produced constant absorbance, hence a shaking time of 1.0 min was selected for use. A ratio of 1.6:1 of aqueous to chloroform phases was required for efficient extraction of the coloured species.

Analytical data

The Beer's law limits, molar absorptivity, regression equation, and correlation coefficient obtained by linear least squares treatment of the results are given in Table 1. The precision and accuracy were found by analysis of six separate samples containing known amounts of the drug (300 μg in method A, 200 μg in method B, 30 μg in method C) and the results are summarized in Table 1. The relative standard deviation, and % range of error at 95% confidence level are also given in Table 1.

The values obtained by the proposed and reference methods for pharmaceutical prep-

*$Y = m + nC$ where C is the concentration (μg/ml).
†Six replicate samples.

arations are compared in Table 2 and are in good agreement. These results were compared statistically by the F-test and found not to differ significantly. The results of the recovery experiments by the proposed methods are also listed in Table 2. The commonly used excipients and additives in the formulations of sulphinpyrazone such as starch, lactose, talc, stearic acid, boric acid, gelatin, magnesium carbonate and sodium lauryl sulphate were found not to interfere in the analysis.

The proposed methods are simple and sensitive and can be used for the routine determination of sulphinpyrazone.

Chemistry of the coloured species

Method A is based on the oxidation of sulphinpyrazone by excess NBS to form oxidation products (probably a mixture, but reproducible under the proposed experimental conditions, each mole of drug consuming 3.83 moles of NBS), and the unreacted NBS was determined with metol–INH. The coloured complex may be regarded as a charge-transfer type shown in scheme 1, presumed to be taking place involving electron transfer from the highest occupied molecular orbital of INH to the lowest empty molecular orbital (π^*) of the two adjacent *p-N*-methylbenzoquinonemonoimine (formed *in situ* from metol and NBS) molecules as in the metol, iodine and INH reaction.[10]

The colour formation by the F–C reagent in the presence of sulphinpyrazone may be explained based on analogy with the literature.[15] The mixed acids in the FC preparation are the final chromogens and involve the following chemical species:

$$3H_2O.P_2O_5.13WO_3.5MoO_3.10H_2O$$

and

$$3H_2O.P_2O_5.14WO_3.4MoO_3.10H_2O.$$

Sulphinpyrazone probably affects the reduction of 1, 2 or 3 oxygen atoms from tungstate and/or molybdate thereby producing one or more of several possible reduced species which have a characteristic blue colour (770 nm).

Sulphinpyrazone—being acidic—forms an ion-association complex with the basic dye Methylene Violet (MV C.I. No. 50210) which is extractable into chloroform from the aqueous phase. The stoichiometric ratio of the drug to MV was determined with the slope-ratio method[16] and found to be 1:1 (ion-pair).

INFLUENCE OF MEDIUM POLARITY UPON SELECTIVITY AND EFFICIENCY OF ALKALI METAL CATION SORPTION BY POLYETHER CARBOXYLIC ACID RESINS

TAKASHI HAYASHITA, JOUNG HAE LEE,* JONG CHAN LEE, JAN KRZYKAWSKI and RICHARD A BARTSCH†

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, U S A

(*Received* 23 *July* 1991 *Revised* 12 *September* 1991 *Accepted* 20 *September* 1991)

Summary—The influence of medium polarity upon competitive sorption of alkali–metal cations from aqueous and aqueous methanolic solutions by the polymethacrylic acid resin Amberlite CG-50, two acyclic polyether carboxylic acid resins, and six *sym*-(alkyl)dibenzo-16-crown-5-oxyacetic acid resins has been investigated Addition of methanol was found to strongly depress the selective Li^+ sorption of CG-50 and one of the acyclic polyether carboxylic acid resins Enhancement of metal ion-crown ether interactions as the percentage of methanol in the medium was increased accentuates the Na^+ sorption selectivity for the lariat ether carboxylic acid resins The highest Na^+ sorption selectivity was obtained for *sym*-(alkyl)-dibenzo-16-crown-5-oxyacetic acid resins with ethyl and propyl groups in 80% methanol–20% water

Macrocyclic polyethers (crown ethers) are superior ligands for complexation of alkali–metal cations.[1] Attachment of a side arm with one or more potential coordination sites to a crown ether gives a lariat ether for which the efficiency and selectivity of alkali–metal cation complexation may be altered.[2] Incorporation of crown and lariat ether units into resin matrices should provide chelating resins which can be used for selective separation of alkali–metal cations from solution.

Recently we prepared acyclic polyether carboxylic acid resin **2** and lariat ether carboxylic acid resins **3–8** (Fig. 1) which are a new type of ion-exchange resin with both ion-exchange and polyether binding sites for metal ions.[3,4] For competitive sorption of alkali metal cations from aqueous solutions by these resins, the sorption efficiency and selectivity were influenced by: (1) the pH of the aqueous sample solution; (2) whether the polyether unit was acyclic or cyclic; (3) conformational positioning of the carboxylic acid group with respect to the cyclic polyether unit in resins **3–8**; and (4) the length of the alkyl group chain in resins **4–8**.[3–5] The highest sorption efficiencies and Na^+ selectivities were noted for *sym*-(alkyl)-dibenzo-16-crown-5-oxyacetic acid resins **4–6** which have methyl, ethyl, and propyl alkyl groups, respectively. For the lariat ether units in **4–6**, the carboxylic acid group of the side arm is positioned over the polyether cavity when the alkyl group points away from the polar polyether ring. Such preorganization of the binding site[6] produces high loading of the resins and enhanced Na^+ sorption selectivity. The presence of longer alkyl groups makes the resins more hydrophobic which decreases the effective ion-exchange capacity.[4] Thus not only the steric configuration of the binding site but also the micro-environment of the resin was found to play an important role in metal ion sorption.

The polarity of the sample medium should also affect the micro-environment of the resin. Metal ion-crown ether interactions generally increase as the polarity of the solution is diminished,[7] which might increase the sorption selectivity and efficiency of a polyether carboxylic acid resin. To investigate this possibility, the competitive alkali metal cation sorption behavior of Amberlite CG-50, a commercial polymethacrylic acid resin, the previously reported and new acyclic polyether carboxylic acid resins **2** and **1**, respectively, and lariat ether carboxylic acid resins **3–8** in aqueous and aqueous methanolic solutions, are now compared.

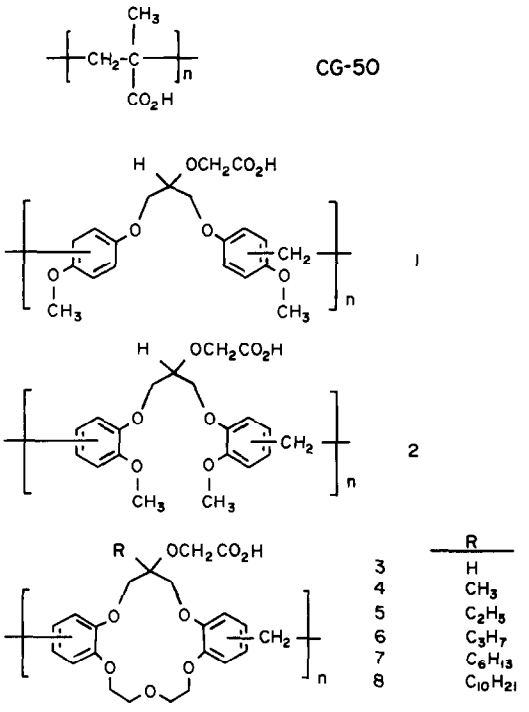

Fig 1 Structures of carboxylic acid resins that were utilized in this study

EXPERIMENTAL

Apparatus

The apparatus was the same as that utilized in the previous study.[3] To prevent metal contamination, all glassware was soaked in 5% nitric acid solution for 24 hr then rinsed with distilled, demineralized water before use.

Reagents

Resin **2** from 1,3-di(*o*-methoxyphenoxy)-2-(oxyacetoxy)propane, resin **3** from *sym*-dibenzo-16-crown-5-oxyacetic acid, and resins **4–8** from *sym*-(alkyl)dibenzo-16-crown-5-oxyacetic acids were prepared by condensation polymerization of the dibenzo polyether carboxylic acid monomers with formaldehyde in formic acid as described previously in detail.[3,5] Unless specified otherwise, reagent grade compounds and solvents were obtained from chemical suppliers and used as receivers. Stock aqueous solutions of alkali metal chlorides and hydroxides (1.00*M* and 0.50*M* each of lithium hydroxide, sodium chloride, potassium chloride, rubidium chloride and cesium chloride) were stored in polyethylene bottles. Sample solutions were prepared by diluting these solutions with water and methanol. Purified water was prepared by passing distilled water through three Barnstead D8922 combination cartridges in series.

*Preparation of 1,3-di(*p*-methoxyphenoxy)-2-propanol*

By the procedure reported for the synthesis of 1,3-di(*o*-methoxyphenoxy)-2-propanol[3] but replacing *o*-methoxyphenol by *p*-methoxyphenol, the title compound (mp 99–101°) was synthesized in 54% yield. IR (deposit on sodium chloride plate from $CDCl_3$ solution) 3417 (OH), 1233, 1107 (CO) cm^{-1}. ^1H NMR ($CDCl_3$) δ 2.83 (s, 1), 3.95 (s, 6), 3.94–4.08 (m, 4), 4.24–4.36 (pen, 1), 6.82–6.89 (m, 8). Analysis calculated for $C_{17}H_{20}O_5$: C, 67.09; H, 6.62. Found: C, 67.28; H, 6.70.

*Preparation of 1,3-di(*p*-methoxyphenoxy)-2-(oxyacetoxy)propane*

With the procedure reported for the synthesis of 1,3-di(*o*-methoxyphenoxy)-2-(oxyacetoxy)-propane,[3] but replacing 1,3-di(*o*-methoxyphenoxy)-2-propanol with 1,3-di(*p*-methoxyphenoxy)-2-propanol, the title compound was prepared in 84% yield as a yellow liquid. IR (neat) 3213 (OH), 1760 (C=O), 1226, 1038 (CO) cm^{-1}. ^1H NMR ($CDCl_3$) δ 3.68 (s, 6), 4.06 (s, 5), 4.34 (s, 2), 6.76–6.77 (m, 8). Analysis calculated for $C_{19}H_{22}O_7$: C, 62.97; H, 6.12. Found: C, 62.87; H, 6.15.

*Preparation of 1,3-di(*p*-methoxyphenoxy)-2-(oxyacetoxy)propane resin* **1**

Resin **1** was synthesized by condensation polymerization of 1,3-di(*p*-methoxyphenoxy)-2-(oxyacetoxy)propane with formaldehyde in formic acid by the reported general method[3] in 61% yield. IR (KBr) 3448 (COOH), 1740 (C=O), 1207, 1028 cm^{-1}. Analysis calculated for a hydrate of the partially crosslinked general structure given in reference 3: C, 63.84; H, 5.93. Found: C, 63.74; H, 5.72.

Procedure

A resin (0.050 g) and 5.00 ml of an aqueous or aqueous methanolic solution containing 0.10*M* (each) lithium hydroxide, sodium chloride, potassium chloride, rubidium chloride and cesium chloride was shaken for 3.0 hr in a 30-ml separating funnel at room temperature (21–23°) with a Burrell Model 25 wrist-action shaker. The aqueous phase was filtered with a sintered glass funnel (15 ml, medium porosity). The measured equilibrium pH of the aqueous phase was in the range 12.5–12.9. The resin was washed with 100 ml of distilled, demineralized water and dried. Of the dried resin, a 0.020 g

sample was shaken with 5.0 ml of 0.10*M* hydrochloric acid for 1.0 hour to strip the alkali–metal cations from the resin into an aqueous solution for analysis with a Dionex Model 2000i ion chromatograph.

RESULTS AND DISCUSSION

Competitive sorption of alkali–metal cations by Amberlite CG-50 and acyclic polyether carboxylic acid resins 1 and 2

In earlier work, Amberlite CG-50, a commercially available polymethacrylic acid, and acyclic polyether carboxylic acid resin **2** were used as model systems for interpreting the competitive sorption of alkali–metal cations from aqueous solutions by lariat ether carboxylic acid resins **3**–**8**.[3–5] The acyclic polyether carboxylic acid resin **1** has now been prepared to serve as an additional model compound. Resin **1** is a structural isomer of resin **2** in which the *para*-positioned methoxy groups can no longer form the pseudo-cyclic arrangement of the four alkyl aryl ether polyether oxygens that is possible in resin **2**.

To probe the effect of medium polarity upon alkali–metal cation sorption by Amberlite CG-50 and acyclic polyether carboxylic acid resins **1** and **2**, each resin was shaken with an aqueous or aqueous methanolic solution (10, 20, 40, 60 and 80 volume percent of methanol) which was 0.10*M* in each of the five alkali–metal cations as the chlorides and hydroxides. The mixture was filtered and the equilibrium pH of the filtrate was measured and found to be in the range 12.5–12.9. For these weakly acidic ion exchange resins, maximum alkali–metal cation sorption would be expected under such alkaline conditions.[3] The filtered resin was thoroughly washed with distilled demineralized water and dried. A portion of the dried resin was shaken with 0.10*M* hydrochloric acid to strip the metal ion species from the resin for analysis by ion chromatography.

Although the general sorption selectivity ordering for cation-exchange resins is $Cs^+ > Rb^+ > K^+ > Na^+ > Li^+$,[8] carboxylic acid resins exhibit a reversed ordering under alkaline conditions due to strong ion-associative interaction of carboxylate groups with alkali–metal cations of smaller ionic dimensions.[9,10] Data for the competitive sorption of alkali–metal cations by CG-50 and acyclic polyether carboxylic acid resins **1** and **2** are presented in Figs. 2 and 3(a) and (b), respectively.

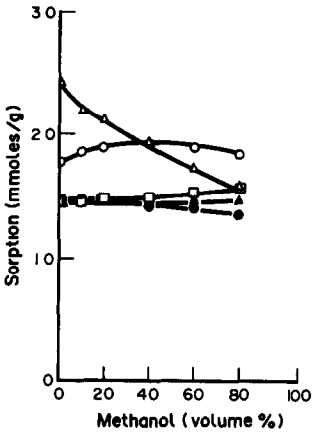

Fig. 2. Competitive sorption of alkali–metal cations by Amberlite CG-50 *vs.* the methanol percentage in the aqueous methanolic solvent at pH 12.5–12.9. (△) Li^+ (○) Na^+ (□) K^+ (▲) Rb^+ (●) Cs^+.

For CG-50, Li^+ sorption decreases linearly as the volume percentage of methanol increases (Fig. 2). On the other hand, only minor changes in sorption for the other four alkali–metal cations are noted as the medium is systematically varied from water to 80% methanol–20% water. Thus the pronounced Li^+ sorption selectivity for CG-50 in water changes to equal sorption propensity for Li^+ and Na^+ in 40% methanol–60% water. When the methanol content of the medium is increased even further, CG-50 exhibits modest sorption selectivity for Na^+.

A similar competitive sorption profile is observed for acyclic polyether carboxylic acid resin **1** [Fig. 3(a)] and the resin exhibits Li^+ sorption selectivity from aqueous solution. However, the diminution of Li^+ sorption with increasing methanol content of the medium is not as severe for **1** as that for CG-50 and the decrease in Li^+

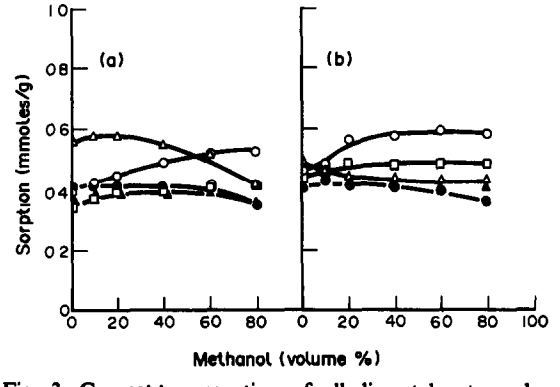

Fig. 3 Competitive sorption of alkali–metal cations by acyclic polyether carboxylic acid resins (a) **1** and (b) **2** *vs.* the methanol percentage in the aqueous methanolic solvent at pH 12.5–12.9. (△) Li^+ (○) Na^+ (□) K^+ (▲) Rb^+ (●) Cs^+

sorption is offset by an enhancement of Na^+ sorption.

For acyclic polyether carboxylic acid resin **2**, the sorption selectivity for Li^+ from water is slight and the decrease in Li^+ sorption with enhanced methanol content in the medium is much smaller than that observed for CG-50 or resin **1**. Resin **2** becomes Na^+ selective for alkali–metal cation sorption from 20% methanol–80% water.

Diminution of Li^+ sorption upon addition of methanol to the medium is in the order CG-50 > resin **1** > resin **2** which suggests that Li^+ solvation at the binding site is an important factor. For CG-50 the binding site is only the carboxylate ion so highly hydrated Li^+ is probably involved and association of the cation and anion may occur through one of the solvating water molecules.[9] In resin **1**, the binding site, which contains three ether oxygens and the carboxylate ion, is much more hydrophilic and interactions of Li^+ with one or more ether oxygens replace some of the solvating water molecules. This trend continues on going to resin **2** for which the binding site possesses five ether oxygens (if the polyether framework adopts a pseudo-cyclic conformation) and the carboxylate anion. Thus the binding site in resin **2** becomes even more hydrophilic which further diminished the need for solvating water molecules and reduces the sensitivity of Li^+ sorption to added methanol in the medium. The similar sorption profiles for acyclic polyether carboxylic acid resin **2** and lariat ether carboxylic acid resin **3** [Fig. 4(a)] suggests that the four alkyl aryl oxygens in the former do indeed adopt a pseudo-cyclic arrangement.

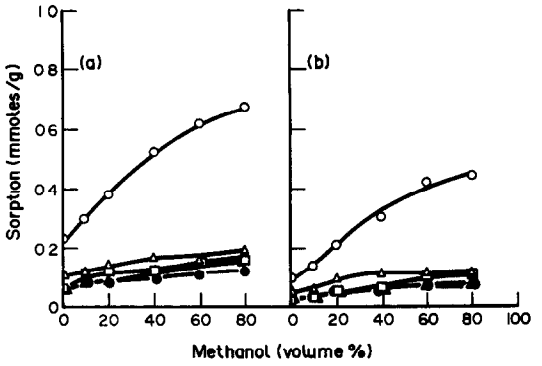

Fig 5 Competitive sorption of alkali–metal cations by lariat ether carboxylic acid resins (a) **7** and (b) **8** *vs.* the methanol percentage in the aqueous methanolic solvent at pH 12 5–12 9· (△) Li^+ (○) Na^+ (□) K^+ (▲) Rb^+ (●) Cs^+.

Competitive sorption of alkali–metal cations by cyclic polyether carboxylic acid resins 3–8

The influence of methanol concentration in the medium upon competitive sorption of alkali–metal cations by lariat ether carboxylic acid resins **3–6** is shown in Figs. 4(a)–(d), respectively. Sorption selectivity for Na^+ would be predicted for the 16-crown-5 ring size and is observed for all four resins. Also for all four resins, the Na^+ sorption selectivity increases when the medium is changed from water to aqueous methanol. Such enhancements in Na^+ sorption selectivity are reasonable in view of the two-to-three log unit increases in stability constants for metal ion–crown ether interactions when the solvent is changed from water to methanol.[7]

Compared with lariat ether carboxylic acid resin **3** (Fig. 4(a)] attachment of methyl, ethyl and propyl groups to the polyether ring carbons that bear the sidearms in resins **4–6** [Figs. 4(b)–(d)], respectively, substantially enhances the Na^+ sorption selectivity in water. As proposed earlier, this is attributed to conformational positioning of the pendent carboxylic acid function over the cyclic polyether ring when an alkyl group is introduced.[3] Such preorganization of the bind site[6] enhances sorption

Table 1 Alkali-metal cation loadings for polyether carboxylic acid resins 1–8

Resin	Alkyl chain	Ion-exchange capacity,* *mmoles/g*	Percent metal ion loading for different methanol contents of the medium, % 0†	40†	80†

‡An acyclic polyether carboxylic acid resin

selectivity. The increased Na^+ sorption selectivity of resins **4–6** over that of resin **3** in water is further accentuated in aqueous methanol. This is consistent with enhanced metal ion–cyclic polyether interactions in aqueous methanol. The highest Na^+ sorption selectivity was observed in 80% methanol–20% water for resins **5** and **6** in which the positioning alkyl groups are ethyl and propyl.

For lariat ether carboxylic acid resins **7** and **8** which have much longer alkyl groups, the sorption profiles are considerably different than those for resins **4–6**. Compared with the sorption of alkali–metal cations from aqueous solutions by lariat ether carboxylic acid resins **4–6** [Figs. 4(b)–(d)], the sorption efficiencies for resins **7** and **8** are much lower [Figs. 5(a), (b)]. This is attributed to the longer alkyl groups of resins **7** and **8** which enhance the hydrophobicity of the resins and hinder penetration of the aqueous solution into the resins and also diminishes effective interactions between the metal cations and the binding sites.[4] For resins **7** and **8**, the addition of methanol to the medium produces a much larger enhancement in Na^+ sorption selectivity and efficiency than was observed with resins **4–6**. The markedly enhanced Na^+ sorption for **7** and **8** is consistent with better penetration of the alkali–metal cation solution into the resins for the aqueous methanolic solvent.

The total alkali–metal cation loadings for polyether carboxylic acid resins **1–8** for water, 40% methanol–60% water, and 80% methanol–20% water are compared in Table 1. The loading is defined as the total sorption, as calculated from total alkali–metal cation concentration in the stripping solution, divided by the ion-exchange capacity for the resin, as calculated from the elemental analysis data.[3,4] For acyclic and cyclic polyether carboxylic acid resins **1–6**, the percent loading observed for aqueous solutions increases by 4–10% in the aqueous methanolic media. In contrast, resins **7** and **8** exhibit 2.7 and 3.7-fold increases in loading percentages for a change of medium from water to 80% methanol–20% water. Thus the reduced efficiency for alkali–metal cation sorption from water which results from the presence of long alkyl groups in *sym*-(alkyl)dibenzo-16-crown-5-oxyacetic acid resins may be partially overcome by decreasing the polarity of the medium to improve penetration of the alkali–metal cation solution into the resin matrix.

CONCLUSIONS

This study demonstrates that competitive sorption of alkali–metal cations by polyether carboxylic acids **1–8** is influenced by the polarity of the medium from which the alkali–metal cations are sorbed. Similarity of alkali–metal cation sorption behavior for acyclic polyether carboxylic acid resin **2** and lariat ether carboxylic acid resin **3** suggests a pseudo-cyclic conformation for the former. The enhanced Na^+ sorption selectivity of *sym*-(alkyl)dibenzo-16-crown-5-oxyacetic acid resins **4–6** over resin **3**, which does not possess a side arm-positioning alkyl group, is further increased as the medium polarity is diminished to promote greater metal ion–crown ether interactions. The low alkali–metal cation sorption from water by hydrophobic lariat ether resins **7** and **8** is markedly improved when the polarity of the medium is lowered.

Summary—In this work the reaction of cysteine (H_2Q) with 2,6-dichlorophenolindophenol (D) is studied kinetically in the pH range 2 5–9.0. Taking into consideration the distribution diagrams for the species H_3Q^+, H_2Q, HQ^-, Q^{2-} for cysteine and DH_2^+, DH, D^- for 2,6-dichlorophenolindophenol the reaction rate constants k_i for all possible combinations of the reacting species were determined. The maximum reactivity appears at pH 6 88 with an overall reaction constant $k = 306$ l.mole^{-1}.sec^{-1} at 22° The effect of the concentrations of the reagents and the ionic strength on the reaction rate is also given. From Arrhenius plots an activation energy $E_a = 8.1$ kcal/mole was calculated. Working curves for the determination of cysteine in aqueous solutions are also presented applying the reaction rate method Finally the paper includes important analytical information for the calculation of the errors due to interference of cysteine by the kinetic determination of ascorbic acid, using its reaction with 2,6-dichlorophenolindophenol

The reaction of ascorbic acid with 2,6-dichlorophenol–indophenol (DCPI) has been used in a series of analytical methods, both equilibrium and kinetic, for the determination of ascorbic acid in several food and biological samples.[1–4]

An important source of error in the determination of ascorbic acid, especially in equilibrium methods, is the reaction of DCPI with concomitant reducing species such as sulphites (common preservatives in fruit juices), reducing amino acids (*e.g.*, cysteine) and metal ions of lower oxidation state (*e.g.*, Fe^{2+} and Sn^{2+}). Because these species generally react with DCPI more slowly than ascorbic acid, they pose a more serious interference to equilibrium methods than to kinetic methods. However, under certain conditions the rate of reaction with DCPI can be comparable to that for ascorbic acid, causing a serious interference with kinetic methods also.[5]

Cysteine was chosen for this study because of its use in the preparation of tissue extracts for the determination of ascorbic acid. Cysteine is added to reduce concomitant dehydroascorbic acid to ascorbic acid. Samples treated in this manner contain more ascorbic acid than untreated samples as determined by titration with DCPI. Some investigators disagree as to the actual basis for the measured increase as excess cysteine can also react with DCPI. Further complicating the determination of ascorbic acid, cysteine is similar to ascorbic acid with respect to reduction of DCPI.

In addition to its use in sample treatment, cysteine is important as it often coexists with ascorbic acid in natural products.

Previous investigators found that cysteine at any equimolar concentration with ascorbic acid increased the result by 7–9%, and at a 10:1 molar concentration by 40–50%. The interference of cysteine in the determination of ascorbic acid depends on the pH of the reaction mixture.[6] Although slow, the reaction of cysteine with DCPI may also interfere with the determination of ascorbic acid by kinetic methods.[1,7] This is due to changes in first- or pseudo-first-order rate constants of both reactions because of variations in experimental conditions, such as pH, ionic strength, *etc.* Therefore for both equilibrium-based analyses and reaction rate methods for ascorbic acid, it is important to have a complete understanding of the reaction of 2,6-dichlorophenolindophenol with cysteine.

EXPERIMENTAL

Apparatus

The experimental apparatus consists of a single beam stopped-flow spectrophotometer (SFS), equipped with a logarithmic photometric unit and a storage oscilloscope. Data acquisition was accomplished with an IBM Data Acquisition and Control Adapter (IBM corporation, Boca Raton, FL) and an IBM-compatible personal computer. Data acquisition software was written in Microscoft QuickBASIC and Macroassembler (Microsoft, Redmond, WA), and uses the computer's interrupt system for rapid data acquisition.[8] The software allows the collection of 2500 points from the reaction curve, the measurements of the slopes at any point of the curve and the constant k_{ob}, applying the infinite time method, *e.g.*, graphical presentation of $\ln(A_t - A_\infty) = f(t)$.[9] The system is also connected with a printer and a plotter.

A pHM83 Autocal pHmeter (Radiometer, Denmark) was used for pH measurements.

Reagents

Buffer solutions. The buffer solutions used were based on 0.1*M* potassium hydrogenphthalate and either 0.1*M* hydrochloric acid or 0.1*M* sodium hydroxide for the pH-range 2.5–6.0, on 0.1*M* potassium dihydrogenphosphate and 0.1*M* sodium hydroxide for the pH-range 6.0–8.0 and on 0.025*M* borax and either 0.1*M* hydrochloric acid or 0.1*M* sodium hydroxide for the pH-range 8.0–10.0. For the entire pH-range the ionic strength was kept almost constant, $I = 0.05$, by carefully adjusting the ratio as well as the absolute concentrations of the buffer reagents. As it is state in the paragraph "Effect of Ionic Strength", there is a small effect on the reaction rate.

2,6-Dichlorophenolindophenol (DCPI). A stock solution, $7.5 \times 10^{-4}M$ in DCPI (Sigma, U.S.A.), containing 210 mg/l. $NaHCO_3$, was prepared. This solution was standarized by titration with freshly prepared ascorbic acid solution and stored in a refrigerator. Working solutions of different concentrations in DCPI were prepared from this stock solution daily by diluting with a $NaHCO_3$ solution of the above concentration. The concentration of the DCPI-solution was spectrophotometrically verified at 522 nm (isosbestic point of DCPI), where the molar absorptivity is 8600 $l.mole^{-1}\ cm^{-1}$.[10]

Cysteine. Working solutions of cysteine (Sigma, U.S.A.), were prepared daily by diluting an aqueous stock solution ($5.0 \times 10^{-2}M$ in cysteine) with the working buffer solution. The stock solution kept refrigerated in amber bottles was stable for at least one week.

Procedure

The stopped-flow spectrophotometer was calibrated for zero and 100% transmittance with the solution of cysteine in the observation cell. The concentration of the reactants was adjusted to create pseudo first-order conditions in respect to DCPI. The stopped-flow apparatus was flushed several times to remove bubbles from the system and the observation cell. The reaction was repeated until the trace observed on the oscilloscope was reproducible. Data from the next run were collected and evaluated with the computer. The number of the collected points and the interval between them was adjusted according to the total reaction time. The software allows the probing of a maximum of 2500 points on the reaction curve, which was observed on the monitor's screen as absorbance *vs.* time. The software, except the initial rate, $(dA/dt)_{in}$, also allows the measurement of the reaction rate $(dA/dt)_t$ at any point of the curve and also the calculation of the observed reaction rate constant, k_{ob}.

In all the experiments the concentrations given in the figures and the tables are the initial concentrations of the reagents in the observation cell.

All solutions and the cell compartment were kept at $22.0 \pm 0.1°$ via a circulating thermostat.

RESULTS AND DISCUSSION

Effect of pH

Figure 1 shows the dependence of the second-order reaction rate constant k on pH.

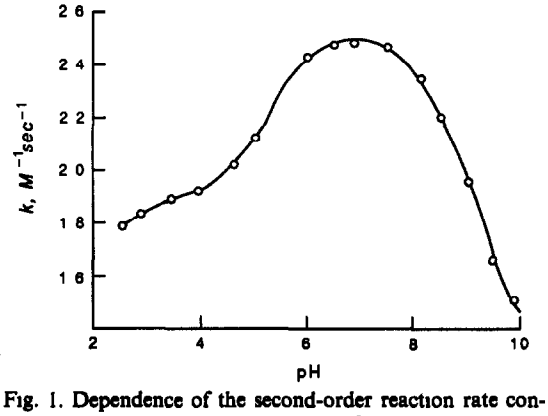

Fig. 1. Dependence of the second-order reaction rate constant on pH. $[DCPI]_o = 2.95 \times 10^{-5}M$, $[Cys]_o = 5.00 \times 10^{-4}M$, $t = 22.0 \pm 0.1°$.

Table 1. Effect of concentrations of the reacting reagents in k_{ob} pH = 6.88, $t = 22.0 \pm 0.1°$. The parameters k and k_j are means calculated from individual experiments and from regression analysis, respectively

$[DCPI]_o$, M	(1) 9.83×10^{-6}		(2) 1.97×10^{-5}		(3) 2.95×10^{-5}		Mean value	
$[Q]_o$, M	k_{ob}, sec^{-1}	k, $l.mole^{-1}\ sec^{-1}$	k_{ob}, sec^{-1}	k, $l.mole^{-1}\ sec^{-1}$	k_{ob}, sec^{-1}	k, $l.mole^{-1}\ sec^{-1}$	$k \pm s_k$, $l.mole^{-1}.sec^{-1}$

8.0×10^{-4}	0.236	295	0.233	291	0.229	286	291 ± 11	C
10.0×10^{-4}	0.288	288	0.287	287	0.285	285	287 ± 4	D
Mean value, $\bar{k} \pm s_{\bar{k}}$, $l.mole^{-1}\ sec^{-1}$		292 ± 7		287 ± 5		286 ± 2		
$k_j \pm s_b$, $l.mole^{-1}.sec^{-1}$		289 ± 37		290 ± 7		284 ± 6		

The second order reaction rate constant was calculated by dividing the value of the observed reaction rate constant k_{ob} by the concentration of the reductant.

Effect of concentration of the reacting substances

The effect of the concentration of the reacting substances on k_{ob} is shown in Table 1. In this table k_j denotes the value of the second-order reaction rate constant calculated by regression analysis of the equation $k_{ob} = kC_q$, where C_q is the initial (analytical) concentration of cysteine.

From Table 1 it is evident that:
(1) The values of k_{ob} show a linear dependence on the initial concentration of cysteine by constant concentration of DCPI (columns 1, 2, 3)
(2) At constant concentrations of cysteine the k_{ob} values remain constant within the limits of the experimental error (lines A, B, C and D).

The evaluation of the experimental data, shown in Table 1, proves that the reduction of DCPI by cysteine is a first order reaction with respect to each of the reagents and second order in all.

Effect of ionic strength

The ionic strength was varied with different concentrations of sodium sulphate. The increase of k seems to be about 6% for the range of ionic strength from 0.05 to 0.55 ionic strength.

For pH 6.88, the dependence of ln k on the ionic strength is linear in the range 0.05–3.00 ionic strength and the regression equation is: $\ln k = 5.68 + 0.121\ [I]$ with a correlation coefficient of 0.9997. This behaviour of the system is consistent with the fact that at this pH the reaction takes place mainly between H_2Q and D^- species which are already at their maximum concentrations. There are also some minor contributions to the reaction from the couples HQ^-/D^- and H_2Q/DH with rate constants $k_9 = 45.3$ $l.mole^{-1}.sec^{-1}$ and $k_5 = 78.5$ $l.mole^{-1}.sec^{-1}$, respectively. An increase in the dissociation constants with increasing ionic strength might also be responsible for the increase of the reaction rate. Such an effect of the ionic strength is more significant on the k_{Q3}.

Effect of temperature

The effect of the temperature on k_{ob} of the reaction was studied under the following experimental conditions: $[DCPI]_o = 1.97 \times 10^{-5} M$, $[Cysteine]_o = 6.00 \times 10^{-4} M$, pH = 6.88 and temperature 21.0–46.0°.

Treatment and evaluation of the experimental data plotting the logarithmic form of the Arrhenius equation gave a straight line with slope $(= -E_a/2.303R)$ of -1762.75 and an activation energy $E_a = 8.1$ kcal/mole.

The dependence of the reaction rate constant k on pH can be explained, at least qualitatively, by assuming the following mechanism:

In aqueous solutions, cysteine exists as a mixture of four species: H_3Q^+, H_2Q, HQ^- and Q^{2-} with ionization constants:[11] $K_{Q1} = 0.011$, $K_{Q2} = 4.365 \times 10^{-9}$ and $K_{Q3} = 5.248 \times 10^{-11}$. The oxidant DCPI exists in three forms: DH_2^+, DH and D^- with ionization constants:[12] $K_{D1} = 0.3$ and $K_{D2} = 2.69 \times 10^{-6}$.

From the distribution diagrams of DCPI and cysteine, shown in Fig. 2 and the fact that decolourization of DCPI occurs over a wide range of pH values, it is logical to conclude that the total reaction is a summation of partial reactions between the various forms of the two reagents in all possible combinations. Table 2 shows the probable partial reactions between the forms of the reducing and the oxidizing agents.

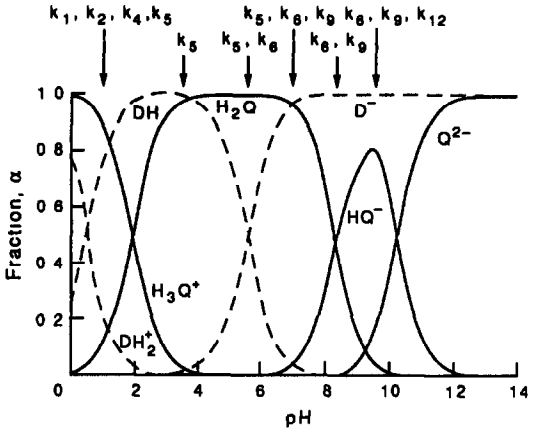

Fig. 2. Distribution diagrams for mixtures of species resulting from DCPI (DH_2^+, DH, D^-) and cysteine (H_3Q^+, H_2Q, HQ^-, Q^{2-}) *vs* pH

The reaction between DCPI (D) and cyteine (Q) has the general form:

$$D_{ox} + Q_r \xrightarrow{k} D_r + Q_{ox} \quad (3)$$

where the subscripts ox and r denote the oxidized and the reduced forms of the DCPI and cysteine respectively. The reduced form of DCPI is the leuco-compound of the dye and the oxidized form of cysteine is cystine.

The rate constant of the entire reaction is calculated, considering the partial parallel reactions, which take place at any pH. For instance at pH = 5 only two reactions take place:

$$DH + H_2Q \xrightarrow{k_5} \text{Products} \quad (4)$$

$$D^- + H_2Q \xrightarrow{k_6} \text{Products} \quad (5)$$

For these parallel reactions, rate equation (6) is valid:

$$-\left(\frac{dC_d}{dt}\right) = k_5[DH][H_2Q] + k_6[D^-][H_2Q] \quad (6)$$

The concentration [DH], [H_2Q] and [D^-] can be calculated with equations (7), (8) and (9):

$$\alpha_1' = \frac{[DH]}{C_d} = \frac{K_{D1}[H^+]}{[H^+]^2 + K_{D1}[H^+] + K_{D1}K_{D2}} \quad (7)$$

$$\alpha_2' = \frac{[D^-]}{C_d} = \frac{K_{D1}K_{D2}}{[H^+]^2 + K_{D1}[H^+] + K_{D1}K_{D2}} \quad (8)$$

$$\alpha_1 = \frac{[H_2Q]}{C_q} = \frac{K_{Q1}[H^+]^2}{[H^+]^3 + K_{Q1}[H^+]^2 + K_{Q1}K_{Q2}[H^+] + K_{Q1}K_{Q2}K_{Q3}} \quad (9)$$

Table 2. Possible combinations of reactions between species of cysteine and DCPI with the corresponding reaction rate constant

D\Q	H_3Q^+	H_2Q	HQ^-	Q^{2-}
DH_2^+	k_1	k_4	–	–
DH	k_2	k_5	–	–
D^-	–	k_5	k_9	k_{12}

where α_1', α_2' and α_1 are the distribution coefficients for DH, D^- and H_2Q respectively. C_d and C_q are the initial (analytical) concentrations of DCPI and cysteine, respectively.

Substitution of equations (7)–(9) to equation (6) gives equation (10):

$$-\left(\frac{dC_d}{dt}\right) = (k_5\alpha_1'\alpha_1 + k_6\alpha_2'\alpha_1)C_d.C_q \quad (10)$$

Since $C_q \gg C_d$, the equation (10) gives:

$$-\left(\frac{dC_d}{dt}\right) = k_{ob}c_d \quad (11)$$

where: $k_{ob} = (k_5\alpha_1'\alpha_1 + k_6\alpha_2'\alpha_1)C_q$

Dividing the k_{ob} values by C_q the reaction rate constant k is given by equation (12):

$$k = \frac{k_{ob}}{C_q} = k_5\alpha_1'\alpha_1 + k_6\alpha_2'\alpha_1 \quad (12)$$

Substitution of equations (7)–(9) into equation (12) yields:

$$k = \frac{k_5 + k_6\dfrac{K_{D2}}{[H^+]}}{\left(1 + \dfrac{[H^+]}{K_{Q1}} + \dfrac{K_{Q2}}{[H^+]} + \dfrac{K_{Q2}K_{Q3}}{[H^+]^2}\right)\left(1 + \dfrac{[H^+]}{K_{D1}} + \dfrac{K_{D2}}{[H^+]}\right)} \quad (13)$$

Applying similar arguments and considering all possible parallel reactions between the forms of the reducing and the oxidizing agent, equation (14) is produced whose graphical presentation is the solid line of Fig. 1.

Table 3 Second-order reaction rate constants k for different combinations of reacting species of the DCPI and cysteine $t = 22.0 \pm 0.1°$

k_1	k_2	k_5	k_6	k_9	k_{12}
k_1, $l.mole^{-1}.sec^{-1}$	4.9	78.5	336.0	45.3	1.4

$$k = \frac{k_1\frac{[H^+]^2}{K_{Q1}K_{D1}} + k_2\frac{[H^+]}{K_{Q1}} + k_4\frac{[H^+]}{K_{D1}} + k_5 + k_6\frac{K_{D2}}{[H^+]} + k_9\frac{K_{Q2}K_{D2}}{[H^+]^2} + k_{12}\frac{K_{Q2}K_{Q3}K_{D2}}{[H^+]^3}}{\left(1+\frac{[H^+]}{K_{Q1}}+\frac{K_{Q2}}{[H^+]}+\frac{K_{Q2}K_{Q3}}{[H^+]^2}\right)\left(1+\frac{[H^+]}{K_{D1}}+\frac{K_{D2}}{[H^+]}\right)} \quad (14)$$

The values of k_i ($i = 1, 2, \ldots$), calculated on the basis of equation (14), are presented in Table 3.

An attempt was made to differentiate equation (14) and calculate the pH at the maximum value of the reaction rate constant, k_{max}. In order to simplify equation (14), all the terms which include the partial constants k_1, k_2, k_4 and k_{12} are eliminated because their contribution in the reaction is negligible in the pH range 6–8. This is evident if one refers to the distribution diagrams of Fig. 2 and Table 3. As a second approximation the terms $[H^+]/K_{Q1}$, $K_{Q2}K_{Q3}/[H^+]^2$ and $[H^+]/K_{D1}$ from the denominator of equation (14) can also be eliminated as very small compared to 1 for pH's 6–8. After these approximations equation (14) becomes:

$$k = \frac{k_5[H^+]^2 + k_6K_{D2}[H^+] + k_9K_{Q2}K_{D2}}{[H^+]^2 + [H^+](K_{Q2}+K_{D2}) + K_{Q2}K_{D2}} \quad (15)$$

The derivative of equation (15) is given by equation (16). The denominator of equation (16) is always positive. Getting the numerator equal to zero, $[H^+]_{max}$ and k_{max} can be calculated. The results are $[H^+]_{max} = 1.16 \times 10^{-7}$ or pH = 6.94 and $k_{max} = 315$ l.mole^{-1}.sec^{-1}.

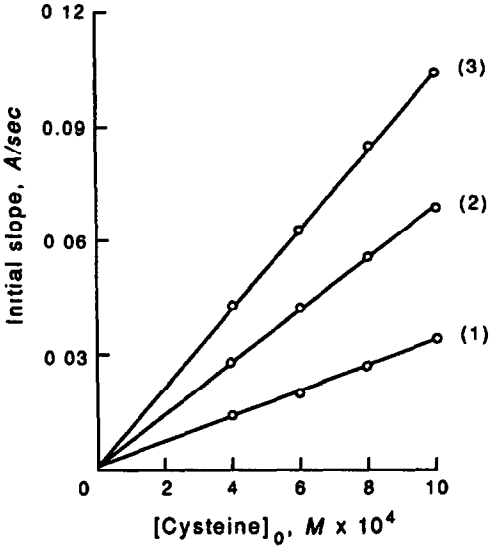

Fig 3. Working curves for the determination of cysteine pH = 6 88, $t = 22.0 \pm 0\,1°$. (1) [DCPI] = $9.83 \times 10^{-6}M$, $y = 3 \times 10^{-4} + (34 \pm 4).x$, $r = 0.9993$. (2) [DCPI] = $1\,97 \times 10^{-5}M$, $y = 1 \times 10^{-3} + (68 \pm 7).x$, $r = 0.9994$. (3) [DCPI] = $2.95 \times 10^{-5}M$, $y = 2 \times 10^{-3} + (103 \pm 8)$ x, $r = 0.9996$

$R_A = (dA/dt)_{in}$ are very reproducible as one can conclude from the quality and the statistics of the regression equations given in Fig. 3.

$$k = \frac{\{k_5K_{Q2} + k_5K_{D2} - k_6K_{D2}\}[H^+]^2 + \{2k_5K_{Q2}K_{D2} - 2k_9K_{Q2}K_{D2}\}[H^+] - K_{Q2}K_{D2}\{k_6K_{D2} - k_9K_{Q2} - k_9K_{D2}\}}{\{[H^+]^2 + (K_{Q2}+K_{D2})[H^+] + K_{Q2}K_{D2}\}^2} \quad (16)$$

Analytical application

The procedure described above can be applied to the kinetic determination of cysteine in aqueous solutions. The measurements were taken at pH = 6.88, which is the pH of maximum reaction rate constant according to the findings already presented.

The reaction rate measured as initial slope of the reaction curve is proportional to the concentration of cysteine. The working curves are linear for the range 1.0×10^{-4}–$1.0 \times 10^{-3}M$ for the concentration of DCPI 1.0×10^{-5} to $3.0 \times 10^{-5}M$. This range can be lowered to $10^{-5}M$ of cysteine if the concentration of DCPI is accordingly adjusted. The slopes

Although many equilibrium methods exist for the determination of cysteine, the kinetic method[13] in some cases offers additional advantages: (i) it is fast, (ii) it provides the possibility to differentiate intereferences which, depending on pH, react either faster or slower with DCPI, (iii) it can avoid intereferences due to turbidity and background absorbances of coloured solutions containing substances not reacting with DCPI.

Table 4 demonstrates the effect of cysteine on the kinetic determination of ascorbic acid (AA). The error introduced by the determination of ascorbic acid in samples containing cysteine in different ratios might be very serious depending on the working pH-range. By pH's in the range

*Calculated considering cysteine interference
†k_{obAA} taken from reference,[7] k_{obQ} from this work

6–7 the error is significantly high, while for pH < 4 it is relatively small. This can be explained by considering the curve of Fig. 1 and the known dependence of the reaction of ascorbic acid and DCPI on the pH, published in our previous work.[7]

From the experimental results of this work and also data given in previous publications,[7] it is possible to determine simultaneously the concentrations of both reductants in mixtures. It can be done by measuring either the initial rates (R_A, R'_A) or by calculating the observed reaction rate constants (k_{ob}, k'_{ob}) from the reaction curves of two experiments performed at two pH's (pH, pH'). This can be done applying equations [17(a)] and [17(b)] or the couple [18(a)] and [18(b)].

$$k_{ob} = k_{AA} C_{AA} + k_c C_q \qquad [17(a)]$$

$$k'_{ob} = k'_{AA} C_{AA} + k'_c C_q \qquad [17(b)]$$

$$R_A = (k_{AA} C_{AA} + k_c C_q) C_d \qquad [18(a)]$$

$$R'_A = (k'_{AA} C_{AA} + k'_c C_q) C_d \qquad [18(b)]$$

In these equations k_{AA}, k'_{AA} are the values of the second order reaction rate constants, for DCPI + ascorbic acid reaction[7] and k_c, k'_c are the values of the second order reaction rate constants for the DCPI + cysteine reaction, given in this work, for the two pH's.

The parameters k_{ob}, k'_{ob}, R_A, R'_A are experimentally available. C_d is the concentration of 2,6-dichlorophenolindophenol and C_{AA}, C_q are the unknown concentrations of ascorbic acid and the cysteine, respectively.

The validity of this technique was verified experimentally in our laboratory with artificial mixtures of ascorbic acid and cysteine.

CONTINUOUS AUTOMATIC DETERMINATION OF AMMONIA BY USING AN INTEGRATED SEPARATION/DETECTION UNIT

MIGUEL DE LA TORRE, M. D. LUQUE DE CASTRO and MIGUEL VALCARCEL
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(*Received* 31 *July* 1991 *Revised* 2 *December* 1991 *Accepted* 16 *December* 1991)

Summary—An automatic continuous-flow photometric method for the determination of ammonia is proposed It is based on the Berthelot reaction, the product of which is temporarily immobilized on a suitable support (Sephadex QAE) located in the flow-cell The retained product is eluted after measurement by a cationic surfactant contained in the carrier solution. The method allows the determination of the analyte between 0 4 and 20 0 μg/ml, with an RSD of 0 8%, at a sampling frequency of 13/hr The determination limit can be reduced by a factor of ten by using a flow-cell with a two-fold longer path length, but the sampling frequency is also reduced as a result The method was applied to the determination of this analyte in agricultural samples (plants and soils) and compared with standard methods for these types of samples

Ammonia (or ammonium ion) is commonly determined in areas of social interest (clinical, environmental, industrial, *etc.*), hence the large number of methods developed for its determination, which rely on a variety of principles.

There are a number of papers describing the flow injection determination of ammonia with or without use of gas-diffusion units.[1-3] Recently, several flow systems in which reaction, retention and detection are integrated have been described.[4,5] They can be considered as an alternative to conventional probe-type sensors.

Sensor design and characterization is an area of great current interest.[6,7] Several types of sensor based on the basic nature of this ammonia have also been described for the determination of this analyte; photometric and fluorimetric acid–base indicators have been most often used for this purpose.

Probe-type sensors making use of optical fibres and a colorimetric indicator (*p*-nitrophenol) were used by Arnold and Osteer[8] to build a photometric sensor from disposable pipette tips. A similar principle (in this case bromothymol blue immobilized on a hydrophylic matrix) but with reflectance measurements, was used by Caglar and Narayanaswamy to build another sensor for this analyte.[9] A fluorimetric indicator and optical fibre as transmitter have also been employed by Smock *et al.*[10] to construct a probe for the determination of ammonia in blood, and by Wolfbeis and Posch,[11] who designed a similar device which they gave no practical application.

The continuous-type sensors for ammonia designed so far have been used for the determination of urea; all of them entail the use of an enzyme (urease) and the quantitation of ammonia as a product of the catalysed reaction. All these devices are optosensors involving measurements based on the presence of a colorimetric indicator.[12-14] The selectivity of the determinations was improved by using a gas-diffusion unit to ensure the exclusive presence of compounds occurring in the sample, which were converted into gases in the acceptor stream in contact with the indicator. In all cases, the use of integrated microconduits allowed sample and reagent consumption to be dramatically decreased. Units such as timers or active interfaces to a microcomputer were coupled to the configuration to implement the stopped-flow mode for the calculation of kinetic parameters and equilibrium constants.[12] An enzymatic sensor for this analyte based on a different principle was reported by Shiono *et al.*,[15] who used a field-effect transistor onto whose gates the enzyme (urease) was immobilized. It provided quite satisfactory results in flow systems.

Some few ammonia sensors based on non-reversible (ninhydrin reagent),[16,17] and reversible (oxazyne dye)[18] derivatizing reactions have so far been reported. The flow-through sensor system proposed herein is based on the reaction

between the analyte and the phenol/hypochlorite mixture (Berthelot reaction). The product is retained (transient retention) on a suitable support located in the flow-cell and is rapidly eluted after the measurements. Its functioning was optimized by using a flow injection system, which allowed the development of a method for the determination of ammonia that was applied to agricultural samples (plants and soils) with excellent results.

EXPERIMENTAL

Instruments and apparatus

A Philips PU 8620 UV/Vis–NIR spectrophotometer equipped with a Radiometer REC 80 recorder and 138 OS, 178.52QS, 178.12QS and 137 OS Hellma flow-cells[19] was used. A Gilson Minipuls-2 peristaltic pump, a Tecator TM III chemifold and a Selecta S-380 thermostat were also used.

Reagents

Phenol solution. A 50-g amount of phenol with 120 g of sodium hydroxide and 100 ml of ethanol were diluted up to one litre with distilled water.

Hypochlorite solution. A 400-ml volume of ClO^-, as sodium salt, of 60 g/l + 20 g of borax + 20 g of sodium hydroxide diluted up to one litre with distilled water.

Carrier/eluent solution. A 7.7075-g amount of dodecyltrimethylammonium bromide diluted up to 250 ml with distilled water. Standard aqueous solution of ammonia (1 g/l.) prepared from $(NH_4)_2SO_4$.

All reagents were of analytical grade.

Sample pretreatment

Plant samples (Kjeldahl distillation). Dried sample (1 g) was introduced into a digestor tube and 1 g of catalyst (potassium sulphate and metal selenium 20:1) + 15 ml of concentrated sulphuric acid were added to digest the sample at 420° for one hour. After cooling, distilled water was added to two-thirds of the tube digestor height and together with some pieces of Zn dust. Then, the tube was fitted to the distillation device and 50 ml of 40% sodium hydroxide was added. The distillation process was continued up to consumption of about 150 ml. The distillate was collected into 50 ml of 2% boric acid, after which the sample was ready for introduction into the FIA system.

Soil samples (solid–liquid extraction). Sample (20 g) was introduced into an Erlenmeyer flask and mixed with 100 ml of 2*M* potassium chloride. After stirring for one hour, the mixture was filtered and the filtrate was stored at 4° until the determination.

Standard methods

Plant samples. Acid–base titration with bromocresol green/methyl red as indicator.

Soil samples. A 5-ml portion of the filtrate was mixed with 1 ml of 10^{-2} *M* EDTA in a 25-ml standard flask, then 2 ml of phenol–nitroprusside and 4 ml of buffer hypochlorite were added and the flask was made up to volume and immersed in a water bath kept at 40°, for 30 min. After allowing it to cool to room temperature for 40 min the absorbance was measured at 636 nm.

Calibration curves run with standards treated like samples were obtained.

Flow-cell packing

The outlet of the flow cell was packed with glass-wool and a small fragment of the Technicon filter to retain the support in the flow cell. The cell itself was packed with support up to 8 mm from the bottom, so that the light beam passed through the upper part of the packed material, which required a period of 5 min with solution flowing through the cell for proper packing. Otherwise, the baseline absorbance increased slightly with time, probably because the solid support became increasingly compacted.

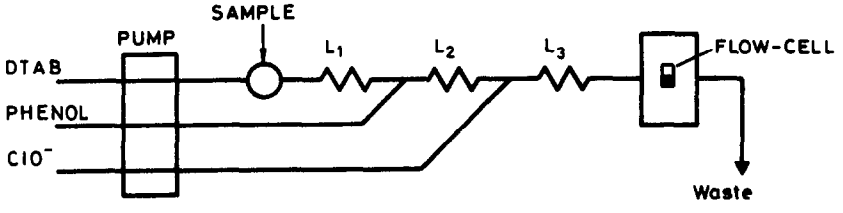

Fig. 1 Scheme of the FIA configuration used for the development of a flow-through sensor for the determination of ammonia (for details see text).

Manifold and procedure

Figure 1 depicts the FIA manifold used. A 0.1*M* solution of surfactant acted as carrier, into which 300 μl of sample was injected and then merged successively with streams of phenol (50 g/l) and hypochlorite (24 g/l); the dye developed along reactor L_3. On passage through the flow-cell, the reaction product was retained on the support and concentrated during the interval over which the sample was passed through it. Elution was effected while the surfactant/carrier solution was circulated again through the flow-cell. A FIA peak was obtained, its height was used to calculate the concentration of the analyte by comparing it with the calibration curve obtained under the same working conditions. A blank was also processed under the same working conditions. The difference between the FIA peak of the sample and that of the blank gave the analytical signal.

RESULTS AND DISCUSSION

Preliminary studies

The conventional absorption spectra of the reaction product were recorded at different times from sample/reagent mixing. A small bathochromic shift of the maxima at 360 and 625 nm was observed during the time period. FIA absorption spectra of the product obtained by using the manifold described in the Experimental section were recorded successively and compared with the blank (injection of distilled water with an ionic strength similar to that of the sample). A slight bathochromic shift of the maxima relating to the above values at an identical time was observed when the product was retained in the flow-cell. This phenomenon has also been observed in other flow-through systems of the same type.[19] A wavelength of 644 nm was selected for measurements in studying variables. This value was modified when the variables determining the residence time (reactor length and flow-rate) were optimized. The injection of a blank yielded a positive signal reflecting a change in the support compactness; hence this value must be subtracted from the sample peak to obtain the net value of the analytical signal. Other FIA configurations such as merging zones with simultaneous injection of the sample and phenol, hypochlorite or both, and a two-channel configuration, were tested with the aim of decreasing the elution time. However, both provided worse results than the original.

Study of variables

The univariate method was followed to optimize variables characteristic of the retention/detection unit, chemical, FIA variables and temperature.

Hellma 138 OS, 178.52QS, 178.12QS and 137 OS model cells were assayed. The first provided the best results because of its small inner cavity and hence smaller amount of non-irradiated resin and higher analyte concentration in the light path. The path of the cell (1.0 mm) provided good sensitivity with not too high a background absorbance from the support. Its inner volume was 20 μl. Special cells made by Hellma, similar to the 138 OS model but with longer path-lengths allowed the sensitivity to be doubled by increasing the slope of the calibration curve and decreasing the determination limit, but to the detriment of the sampling frequency, which was dramatically decreased.

After assaying different types of Sephadex supports, Sephadex QAE was found to be most suitable because of its non-polar aromatic nature. The anionic character of the product to be retained avoided the use of cationic exchangers (Sephadex SP and CM). Strong (Sephadex QAE) and weak (Sephadex DEAE) basic exchangers provide good analytical signals and elution times (twice longer for Sephadex DEAE than that of QAE type). Other exchangers assayed (XAD type: XAD 2, XAD 4 and XAD 8) in which the absence of charged groups allowed the derivatized product to be weakly retained and rapidly eluted, were highly absorbant, approaching the detector saturation.

The level of the support in the flow-cell was a key variable to the sensitivity of the method. This level must always be above the light path (the higher the level, the lower the sensitivity because the maximum retention occurred at the solid–liquid interface). The most appropriate height was 8 mm.

The chemical variables to be optimized were phenol and hypochlorite concentration, ethanol content, ionic strength, pH, eluent and presence of catalysts.

Increasing hypochlorite concentrations resulted in increasing the analytical signal; nevertheless, concentrations above 24 g/l. degraded the resin, which lost some retention capacity and increased in compactness. Phenol concentrations above 50 g/l. posed the same problems.

The presence of ethanol up to 10% improved the analytical signal by stabilizing the reaction product; above this content the signal decreased again.

The influence of the ionic strength, a key to the resin compactness, was eliminated by the high reagent concentrations and confluence points used, which ensured a constant and homogeneous ionic strength in the stream reaching the detector.

The optimum pH values of the different solutions were 12.4 and 12.2 for phenol and hypochlorite, respectively, and were adjusted with sodium hydroxide and borax/sodium hydroxide buffer. The presence of the buffer in the hypochlorite solution made the sample pH insensitive.

Of the different ways assayed to elute the product retained in the flow-cell, namely use of bulky counterions, pH changes, use of organic solvents and surfactants, the last was the most effective because very acidic media and high organic solvent contents resulted in resin degradation, while bulky counterions had appreciable effect. The best results were obtained with cationic surfactants; the three assayed (cetylpyridine chloride CPC-, cetyltrimethylammonium bromide -CTAB- and dodecyltrimethylammonium bromide -DTAB-) resulted in no appreciable differences. The last was chosen and used at an optimum concentration of 0.1*M*.

The influence on the derivatizing reaction of several catalysts described in the literature (acetone,[20] manganese,[21] nitroprusside and ferrocyanide[22]) was studied. Samples containing these compounds were measured and compared with others in the absence of catalyst. Positive results were obtained only in the presence of nitroprusside, but the values of the analytical signal were of the same order as those obtained in the presence of ethanol under the working conditions, thus, the last was preferred.

Increasing temperatures resulted in slightly increasing signals up to 35°, above which the signals decreased. This last, which contradicts literature reports,[23] must be a result of the effect of this variable on the retention equilibrium.

The variables characteristic of the FIA system were the reactor lengths, flow-rate and injected volume.

The evolution of the reaction depended on the order of sample/reagent mixing and was contradictory to the behaviour of the conventional method.[23] Reactor L_1 had no influence on the reaction. The first step took place at reactor L_2, but a length of 100 cm was enough because this step was very fast. The slow rate of the second step called for an optimum length of 450 cm for L_3. The resulting dispersion did not affect the analytical signal thanks to the features of the sensor (*in situ* concentration).[19]

The signal increased as the flow-rate decreased, but the dependence of the sampling frequency on the flow-rate led us to choose 0.8 ml/min as a compromise. At the residence time obtained under these conditions, the absorption maximum also appeared at 640 nm.

Large sample volumes saturated the support with the reaction product, while small volumes resulted in poor sensitivity. A volume of 300 μl was found to be optimum.

Features of the method

The calibration curve was linear between 0.4 and 20.0 μg/ml and conformed to the equation $y = 0\,032 + 3.82 \times 10^{-3}x$, where y is the peak height after subtracting the blank and x is the ammonia concentration in μg/ml. The regression coefficient was 0.998.

The reproducibility ($\pm 0.8\%$) of the method was studied on 11 samples containing 6 μg/ml and injected in triplicate.

The sampling frequency achieved under the working conditions was 13/hr.

The sensitivity of the method was increased by over one order of magnitude by using a flow-cell similar to the Hellma 138 OS, but with a path length of 2 mm; this involved a longer elution time as a result of the larger amount of support in the flow-cell, so the sampling frequency was roughly halved.

Application of the sensor to the determination of ammonia in agricultural samples

The applicability of the proposed method was tested by assaying two types of agricultural sample (plants and soils) requiring different pretreatments. These, and the conventional method required to compare the analyte concentration found by the proposed method were commented on in the Experimental section. Different calibration curves were run for each type of sample because of the different media required in the pretreatment step; these resulted in slightly different slopes.

The results found for the plant samples by the proposed and conventional methods, the dilution required and the study of the analyte recovery are summarized in Table 1, while Table 2 lists the concentrations found for soil

Table 1. Determination of ammonia in plants

STUDY ON SELECTIVE QUANTITATIVE DETERMINATION OF BARIUM BY SULPHONAZO III IN COMPLEX MATRICES

F MANNA, F CHIMENTI, A. BOLASCO and A. FULVI
Department of Chemical and Technological Studies of Biologically Active Substances, University of Rome "La Sapienza", 00185 Rome, Italy

(*Received* 5 *September* 1991 *Revised* 24 *October* 1991 *Accepted* 25 *October* 1991)

Summary—Selective quantitative determination of barium by commercially available Sulphonazo III was studied in complex matrices The application of two more promising methods was tried, but interferences derived from cations and anions present in natural waters and waste waters made them unuseful

Many authors studied the stability of some complexes of alkaline-earth metals and their application to the colorimetric determination of barium and strontium.[1-6] The most promising of complexing agents for their analysis was the 2,7-bis-(2′-sulphophenylazo)-1,8-dihydroxy-3,6-naphthalenedisulphonic acid (Sulphonazo III).

Budesinsky and Vrzalova[1] first reported conditions under which barium might be determined colorimetrically by Sulphonazo III although no analytical data were given. Later, since Sulphonazo III had become commercially available, Kemp and Williams[4] attempted to use this in direct simultaneous method for barium and strontium determination in the presence of other cations masked by chelons EGTA [ethylen glicol bis(amino-ethyl ether)-*N*,*N*′-tetracetic acid] and CDTA (trans-1,2-diamino-cycloexane-*N*,*N*′-tetracetic acid). They gave analytical data relative only to synthetic matrices.

Since a simple direct colorimetric method for detection of barium and strontium is not available, we decided to study the application of previous methods to the analysis of natural and waste waters, utilizing the commercially available Sulphonazo III, without further purification.

EXPERIMENTAL

Apparatus

A Perkin–Elmer spectrophotometer model 552 with 1-cm quartz cells was used for UV spectra; IR spectra were registered on a Perkin–Elmer spectrophotometer model 297, and NMR spectra on a Varian EM-390 instrument, using TMS as internal standard. The pH control was carried out by a Metrohm apparatus model E512.

Sulphonazo III

The IR and NMR spectra of the synthetic product and of commercial Sulphonazo III were identical and confirmed their structures:

IR, KBr (cm^{-1}): 1580 (C—N=); 3400–3500 (OH).
NMR ($CDCl_3$) ppm: 17.20 (s, 2 H, 2 OH); 8.20 (d, 2 H, H6′); 7.90 (d, 2 H, H3′); 7.80–7.30 (m, 6 H, H4, H5, H4′, H5′).

Hexamine/nitric acid buffer was prepared in accordance with Budesinsky.[1]

Effect of pH on Sulphonazo III and its complexes

Desired values of pH (2.5, 7.5, 9.1, 10.7, 11.3) potentiometrically controlled were obtained by dilution of 0.1*M* nitric acid and 0.1*M* potassium hydroxide.

Solutions for spectrophotometric measurements were prepared by mixing 5 ml of nitric acid or potassium hydroxide, 5 ml of $10^{-3}M$ Sulphonazo III and 5 ml of $3.2 \times 10^{-4}M$ barium or interfering ions [calcium(II), magnesium(II) and strontium(II)] solutions; nitrates were used.

Variations of Sulphonazo III concentrations

Volumes of 5 ml of nitric acid (pH 6.8 or 2.4) and 5 ml of 10^{-6}, 10^{-5}, 10^{-4}, 10^{-3},

$10^{-2}M$ Sulphonazo III solutions were added to 5 ml of $3.2 \times 10^{-4}M$ barium stock solution [$Ba(NO_3)_2$].

Calibration curve

A 1-ml volume of $0.1M$ nitric acid and 10 ml of $10^{-4}M$ Sulphonazo III were added to 10 ml of barium solutions containing 1, 2, 3, 4 and 5 mg/l. barium nitrate [0.7, 1.4, 2.1, 2.9 and 3.6×10^{-2}mM]. Absorbance values were measured at 641 nm and were respectively 0.075, 0.146, 0.225, 0.285, 0.353.

Effect of chloride and acetate

Mixtures of barium and interfering ions were prepared by dilution of a barium nitrate stock solution (Ba^{2+} 50 mg/l.) with sodium acetate and sodium chloride solutions at a suitable concentration. Nitric acid ($0.1M$, 1 ml) and 10 ml of $10^{-4}M$ Sulphonazo III were added to 10 ml of barium/chloride or barium/acetate mixtures.

Interfering cations

First tests were carried out using solutions containing 5 mg/l. barium and interfering cation, obtained by dilution of 50 mg/l. cation nitrate stock solution; 1 ml of $0.1M$ nitric acid and 10 ml of $10^{-4}M$ Sulphonazo III were added to 10 ml of barium/interfering ions solutions. Another test was carried out on equimolar $3.6 \times 10^{-5}M$ solutions of barium and interfering cations obtained by dilution of $3.6 \times 10^{-3}M$ standard solutions.

Effect of EDTA

A 1-ml volume of $0.1M$ nitric acid and 10 ml of $10^{-4}M$ Sulphonazo III were added to 10 ml of $3.6 \times 10^{-5}M$ cation and EDTA solution.

Internal standard

A calibration curve was prepared by adding different amounts of barium nitrate to natural waters and waste waters in order to have final solution concentrations from 1 to 5 mg/l. ($0.7–3.6 \times 10^{-2}$mM) of barium ion. A 1-ml volume of $0.1M$ nitric acid and 10 ml of $10^{-4}M$ Sulphonazo III were added to 10 ml of barium solution.

The EGTA–CDTA method was performed in accordance with Kemp[4] and the same procedure was used to the internal standard method. A blank solution was constituted of drinking water containing appropriate amounts of barium and strontium.

RESULTS AND DISCUSSION

The control of experimental conditions reported by Budesinsky at pH 2.4 showed a shift of the maximum absorption value of the commercial Sulphonazo III we used from 550 nm to 580 nm, in agreement with Kemp and Williams.[4] Thus Sulphonazo III was synthesized according to the method reported by Budesinsky and Vrzalova[1] and compared with a commercially available product, the compounds were identical and showed a maximum absorption value at 580 nm.

Furthermore the pH 2.4 hexamine/nitric acid buffer showed a slow and continuous variation of pH during the time derived from dissociation of hexamine, together with a decrease of complex absorbance; therefore a solution of nitric acid of suitable concentration was used in order to obtain the desired pH value.

The absorption spectrum of Sulphonazo III did not vary with pH, while its complex with barium had a maximum absorption value at 640 nm in alkaline medium. The shift could have been useful for increasing the sensitivity of the method, but interferences of calcium also increased at pH 9–10.

A $10^{-3}M$ concentration of Sulphonazo III determined a shift of the maximum absorption of the barium complex to 659 nm accompanied by rapid variations of absorbances (few hours), while a $10^{-4}M$ solution was the most suitable for its stability and sensitivity.

Unlike Budesinsky's statement, some cations and anions commonly present in superficial and waste waters interfered; strontium(II), lead(II) and copper(II) caused an increase of absorbance while sodium(I), potassium(I) and calcium(II) its decrease. Cadmium(II), iron(III), zinc(II), chromium(III) and magnesium(II) did not interfere up to 40 mg/l. Chlorides decreased the absorbance of the barium/Sulphonazo III complex at concentrations of 25 mg/l., while nitrates and acetates didn't interfere.

Addition of EDTA, suggested by Budesinsky to eliminate interferences at pH 2.4, binded only lead(II) and calcium(II), leaving other interactions practically unchanged (Fig. 1).

The internal standard method applied, using drinking and waste water, gave an increase in

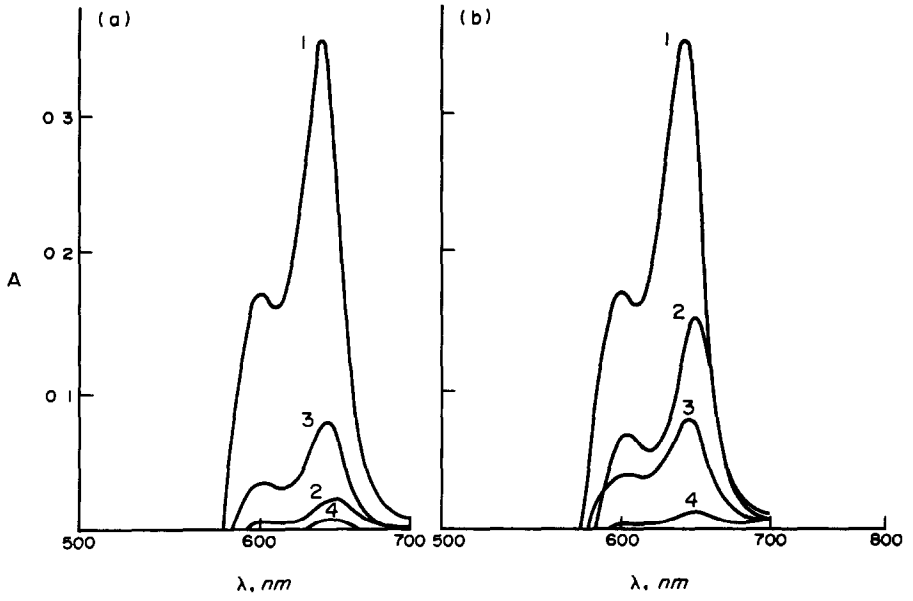

Fig 1 Effect of EDTA on Sulphonazo III complex formation with Ba(II), Sr(II), Ca(II), Pb(II) (a) = with EDTA $3\,6 \times 10^{-5}M$ $C_{Me} = 3\,6 \times 10^{-5}M$, $C_R = 1 \times 10^{-4}M$, $l = 1$ cm (1) Ba(II), (2) Pb(II), (3) Sr(II), (4) Ca(II), (b) = without EDTA

absorbances relative to lower barium concentrations producing a levelling of values between 0.38 and 0.50 units which made this method useless. It was therefore impossible to apply Budesinsky's method to the analysis of complex matrices (Fig. 2).

The more promising method of Kemp and Williams[4] was therefore tested, using commercially available Sulphonazo III without further purification, that didn't show any difference with that used by Kemp.

We noted that concentrations of barium and strontium standards ($0.5–10 \times 10^{-5}M$) were in contrast with values used for experimental measurements. They were required to be in the range $0.5–10 \times 10^{-4}M$ to give final concentrations after dilution of $0.5–10 \times 10^{-5}M$.

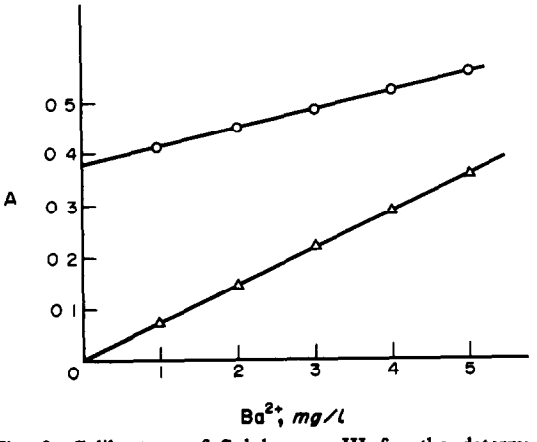

Fig. 2. Calibration of Sulphonazo III for the determination of barium. $C_R = 1 \times 10^{-4}M$; $l = 1$ cm, △ = water; ○ = internal standard by using drinking water

CONCLUSIONS

The determination of barium and strontium in drinking water showed continuous and rapid variations of absorbances, and a positive interference of other cations. The internal standard method was also used but the Beer–Lambert Law was not obeyed (Fig. 3) so a calibration curve could not be constructed Low sensitivity and interferences also made this method unsuitable for use.

The best method of determination of barium, found by Kragten,[7] is direct photo-

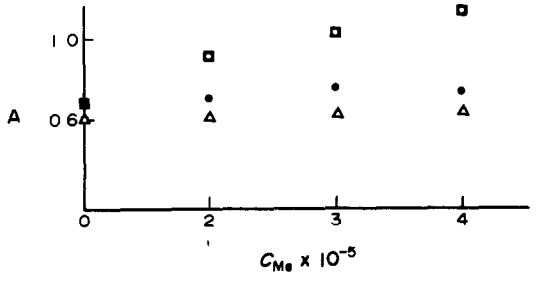

Fig 3 Calibration of Sulphonazo III for determination of barium and strontium by the internal standard method (drinking water). $C_{Ba} = (0–4) \times 10^{-5}M$ and $C_{Sr} = 1 \times 10^{-5}M$; $C_{Sr} = (0–4) \times 10^{-5}M$ and $C_{Ba} = 1 \times 10^{-5}M$; $C_R = 1 \times 10^{-4}M$; $l = 1$ cm. ○ = Ba(CDTA); □ = Ba(EGTA); △ = Sr(CDTA); ● = Sr(EGTA).

metric titration with sulphate with an automatic titrator (which ensures reproducibility) after adding propylalcohol 3-fold, to lower the solubility product of barium sulphate. The precipitate deviates from the stoichiometry for about 2–3%, but the results are even so reproducible. The titration takes about 15 min to perform.

There are hardly any interfering ions at pH 3.5 where the titration is performed. Sulphonazo III is the best indicator in these cases.

BOOK REVIEWS

Non-Chromatographic Continuous Separation Techniques: M. VALCÁRCEL and M D. LUQUE DE CASTRO, The Royal Society of Chemistry, Cambridge, 1991. Pages xii + 290. £42 50.

As the authors proclaim on page 8 of their book, "analytical separation techniques play a transcendental role in today's analytical chemistry" According to the philosopher Kant, transcendental refers to what is beyond experience, or cannot be experienced, and what is a perogative for having experience. It is quite clearly the aim of the authors to provide the reader with the necessary experience to exploit analytical separations intelligently and diligently. While these techniques can be classified according to a number of criteria, "they can basically be divided into two broad groups according to whether or not a flow of one of the two phases is used to facilitate the differential displacement of the mixture (sample) components", *i.e*, Static Separation Techniques (discrete or batch types) and Dynamic Separation Techniques It is the latter of these· *i e*, "continuous non-chromatographic separation techniques using a detector—usually optical or electrochemical—connected on-line to the separation system", that is covered in this text

The book is divided into five Chapters, and Chapter 1 introduces the reader to the subject matter The next three chapters describe non-chromatographic continuous separation techniques grouped, as the authors have opted, according to the type of interface across which mass transfer takes place Thus, Chapter 2 deals with gas–liquid systems (direct introduction of gas samples, gas diffusion, hydride generation, vaporization), while Chapter 3 discusses the two most commonly used liquid–liquid systems, namely dialysis and extraction. Chapter 4 is devoted to the wide variety of non-chromatographic separations involving solid–liquid interfaces (sorption, precipitation, electrochemical stripping and leaching) Finally, Chapter 5 provides an overall evaluation of the techniques dealt with in the preceding three Chapters and a brief description of two recent techniques of increasing interest, *i e*, field flow fractionation and capillary electrophoresis

The book might equally well have been called the execution of non-chromatographic continuous separation techniques by flow injection analysis (FIA), because the examples given are overwhelmingly dominated by FIA (although this term has not managed to find its way into the subject index). This should not be considered as a negative remark On the contrary, this reviewer was pleasantly surprised to observe the ramifications that FIA has had on modern analytical chemistry It is at the same time a distinct asset for the book because the authors are well known experts in FIA They are prolific writers of scientific papers on FIA—in particular on its use in various separation techniques—and they are the authors of one of the early FIA monographs Hence the book contains many FIA references (notably to the authors' own publications). However, it is also characterized by much recycling from previous FIA monographs and has obviously presented Valcárcel and Luque de Castro with a golden opportunity to update their earlier FIA monograph in a new wrapping.

In the first Chapter of their book, the authors have made a very good dissection of the anatomy of the Analytical Process, pointing out, that although it comprises several links (preliminary operations such as sampling, sample preservation and appropriate treatment, signal measurement and transducing; and data handling and treatment), there is, nevertheless, a widespread tendency to underestimate the preliminary operations, which although often trivial, time consuming, complex and requiring dedication from the operator, in fact, might be the potential sources of major errors in the analytical chain. Therefore, the first stage of the analytical process decisively influences its precision, accuracy, sensitivity, selectivity, rapidity and cost The authors have succeeded very well in emphasising these points in the many practical examples in their book, and if only for this reason the book is well worth consulting It is commendedly very detailed in its many descriptions, and should therefore also serve as a useful handbook for practical chemists. In this context, it is interesting to consult the Preface where the authors write, that the intent with their book "is neither for use as a monograph nor as a textbook, but as something in between" Obviously they have succeeded in reaching that goal. If I should point to a negative aspect of the book, then it is to the language (as in the opening phrase of this review). It is obvious that the authors have written their manuscript in their mother tongue (Spanish) and then used a translation editor to produce the English version It is somewhat doubtful if that person was a trained analytical chemist, because in addition to making the general language somewhat bombastic, he has at places construed some rather startling expressions. Yet it does make the reading entertaining.

E. H. HANSEN

Advances in Steroid Analysis '90: S GÖRÖG and E HEFTMANN (editors), Akadémiai Kiadó, Budapest, 1991 Pages xiii + 493. £36.00.

This book presents the proceedings of the 4th symposium on the analysis of steroids held at Pécs, Hungary, 24–26 April, 1990 and a total of 62 papers from authors in 16 different countries is included. The quality of binding and the variation in print size and intensity of the multi-authored compilation do not do justice to the high quality of a number of contributions.

The papers are arranged under five headings receptor binding studies, immunoassays, chromatography, spectroscopy, clinical studies and finally, miscellaneous. The link between all these is provided by the subject index but only the names of the various steroids are listed. The papers are compact, normally about seven pages long, and contain references.

E. H. HANSEN

Advances in Steroid Analysis '90: S GÖRÖG and E HEFTMANN (editors), Akadémiai Kiadó, Budapest, 1991 Pages xiii + 493. £36.00.

This book presents the proceedings of the 4th symposium on the analysis of steroids held at Pécs, Hungary, 24–26 April, 1990 and a total of 62 papers from authors in 16 different countries is included. The quality of binding and the variation in print size and intensity of the multi-authored compilation do not do justice to the high quality of a number of contributions.

The papers are arranged under five headings receptor binding studies, immunoassays, chromatography, spectroscopy, clinical studies and finally, miscellaneous. The link between all these is provided by the subject index but only the names of the various steroids are listed. The papers are compact, normally about seven pages long, and contain references.

The contribution by Duax and Griffin on the stereochemical aspects of receptor binding of steroids provides a good introduction to the receptor binding section (66 pages) The immunoassay section (49 pages) is subdivided into radioimmunoassay, enzyme immunoassay and other immunoassays and an interesting paper by Meyer on the combination of HPLC and EIA for multi-residue screening of anabolic steroids and stilbenes is included in this section The chromatography section (152 pages) contains 18 papers covering the techniques of GC, HPLC, GC–MS, HPLC–MS, and TLC. The paper by Shackleton on GC–MS and HPLC–MS in clinical steroid analysis is the largest single contribution in the book Some of the contributions span two or more of the section headings such that their location in the book is a little arbitrary The spectroscopy section (53 pages) is subdivided into mass spectroscopy, other spectroscopic methods (NMR, optical rotation, colorimetry), and complex application of spectroscopic techniques The latter part includes a contribution from the main editor (Görög) and others on the analysis of impurities in ethynodiol acetate. Clinical studies occupies a large section of the book (138 pages) and covers biosynthesis and metabolism, diagnosis, and other studies. Many analytical methods mentioned in previous papers are again included in this section The final miscellaneous section contains just two papers, one concerns thermal methods and the other is a polarographic study Practising steroid chemists will no doubt add this book to the previous work on steroid analysis by Gorog.

Electroanalytical Chemistry, Volume 17: A J Bard (editor), Dekker, New York 1991 Pages xii + 393 $145 00 (US and Canada), $174 00 (elsewhere)

This collection of reviews is concerned not with the analytical capability of electrochemistry, but with applications of analytical techniques to electrochemical problems. *Applications of the Quartz Crystal Microbalance to Electrochemistry* by D. A Buttry (85 pages) has many interesting things to say on electro-deposition and should be useful to those contemplating the use of piezoelectric detectors in the liquid phase Figure 13, however, purports to show a shift in frequency decreasing with time, t, but increasing with $t^{1/2}$, while values at $t = 1$ are unequal. *Optical Second Harmonic Generation as an* in situ *Probe of Electrochemical Interfaces* by G. L Richmond (94 pages) describes the applications to monolayer films on metals and makes it clear that the technique is still in its early stages. I certainly would have needed a longer and more basic introduction to SHG itself before I derived much from this review. The title *New Developments in Electrochemical Mass Spectroscopy* by B Bittins-Cattaneo, E Cattaneo, P Konigshoven and W Vielstich (40 pages) involves a misnomer. This application examines the MS of gases evolved at electrodes, which yields insights into absorptive as well as redox processes Although applications so far are not numerous, this is an interesting chapter *Carbon Electrodes: Structural Effects on Electron Transfer Kinetics* by R L McCreery (152 pages) summarizes a great deal of background structural information for users of carbon electrodes in voltammetry and should be a favourite with graduate students Overall, this is a source-book for researchers in electrochemistry rather than a text for analysts It is worth its place on the library shelf, but will not attract many individual purchasers

D Midgley

Mass Spectrometry: E Constantin and A Schnell, Ellis Horwood, Chichester, 1990 Pages 184 £39 95.

This book is an English translation of the book originally published in French in 1986 As can be judged from a few references, some updating has been carried out.

It is a concise book containing information on the principles of mass spectrometry, practical aspects and a limited number of applications Several chapters contain selected lists of references and collected together at the end of the book there are additional lists of references and a general bibliography as well as a subject index There are many figures, some more relevant and informative than others

There are times when the book appears to be too concise, almost appearing like a catalogue It probably attempts to cover too many features in too few pages For many readers, further information will be required and other sources will have to be consulted For an organic/analytical chemist, for example, too little information is given on fragmentation pathways, there are already various spectroscopy books which cover this aspect really well and these will be preferentially consulted

As a general book, it has value but it is difficult to see it having many personal buyers However, it should have a place in many institutional libraries

Mass Spectrometry: E Constantin and A Schnell, Ellis Horwood, Chichester, 1990 Pages 184 £39 95.

This book is an English translation of the book originally published in French in 1986 As can be judged from a few references, some updating has been carried out.

It is a concise book containing information on the principles of mass spectrometry, practical aspects and a limited number of applications Several chapters contain selected lists of references and collected together at the end of the book there are additional lists of references and a general bibliography as well as a subject index There are many figures, some more relevant and informative than others

There are times when the book appears to be too concise, almost appearing like a catalogue It probably attempts to cover too many features in too few pages For many readers, further information will be required and other sources will have to be consulted For an organic/analytical chemist, for example, too little information is given on fragmentation pathways, there are already various spectroscopy books which cover this aspect really well and these will be preferentially consulted

As a general book, it has value but it is difficult to see it having many personal buyers However, it should have a place in many institutional libraries

Modern NMR Techniques and Their Application in Chemistry: A I Popov and K Hallenga (editors), Dekker, New York, 1991. Pages x + 665. $135.00 (US and Canada), $162.00 (elsewhere)

This book contains ten chapters written by nine scientists from Europe and North America. The chapters are on (1) NMR properties of Nuclei, (2) Fourier-Transform NMR: Theoretical and Practical Aspects, (3) Solid State NMR of Spin-$\frac{1}{2}$ Nuclei, (4) Solid State NMR of Quadrupolar Nuclei, (5) Quantitative Chemical Analysis by NMR, (6) Structural Determination of Organic Compounds, (7) Structural Determination of Inorganic Compounds, (8) Equilibria Studies in Solutions, (9) Reaction Kinetics and Exchange and (10) Two-Dimensional NMR Studies.

The contribution by Duax and Griffin on the stereochemical aspects of receptor binding of steroids provides a good introduction to the receptor binding section (66 pages) The immunoassay section (49 pages) is subdivided into radioimmunoassay, enzyme immunoassay and other immunoassays and an interesting paper by Meyer on the combination of HPLC and EIA for multi-residue screening of anabolic steroids and stilbenes is included in this section The chromatography section (152 pages) contains 18 papers covering the techniques of GC, HPLC, GC–MS, HPLC–MS, and TLC. The paper by Shackleton on GC–MS and HPLC–MS in clinical steroid analysis is the largest single contribution in the book Some of the contributions span two or more of the section headings such that their location in the book is a little arbitrary The spectroscopy section (53 pages) is subdivided into mass spectroscopy, other spectroscopic methods (NMR, optical rotation, colorimetry), and complex application of spectroscopic techniques The latter part includes a contribution from the main editor (Görög) and others on the analysis of impurities in ethynodiol acetate. Clinical studies occupies a large section of the book (138 pages) and covers biosynthesis and metabolism, diagnosis, and other studies. Many analytical methods mentioned in previous papers are again included in this section The final miscellaneous section contains just two papers, one concerns thermal methods and the other is a polarographic study Practising steroid chemists will no doubt add this book to the previous work on steroid analysis by Gorog.

P J Cox

Electroanalytical Chemistry, Volume 17: A J Bard (editor), Dekker, New York 1991 Pages xii + 393 $145 00 (US and Canada), $174 00 (elsewhere)

This collection of reviews is concerned not with the analytical capability of electrochemistry, but with applications of analytical techniques to electrochemical problems. *Applications of the Quartz Crystal Microbalance to Electrochemistry* by D. A Buttry (85 pages) has many interesting things to say on electro-deposition and should be useful to those contemplating the use of piezoelectric detectors in the liquid phase Figure 13, however, purports to show a shift in frequency decreasing with time, t, but increasing with $t^{1/2}$, while values at $t = 1$ are unequal. *Optical Second Harmonic Generation as an* in situ *Probe of Electrochemical Interfaces* by G. L Richmond (94 pages) describes the applications to monolayer films on metals and makes it clear that the technique is still in its early stages. I certainly would have needed a longer and more basic introduction to SHG itself before I derived much from this review. The title *New Developments in Electrochemical Mass Spectroscopy* by B Bittins-Cattaneo, E Cattaneo, P Konigshoven and W Vielstich (40 pages) involves a misnomer. This application examines the MS of gases evolved at electrodes, which yields insights into absorptive as well as redox processes Although applications so far are not numerous, this is an interesting chapter *Carbon Electrodes: Structural Effects on Electron Transfer Kinetics* by R L McCreery (152 pages) summarizes a great deal of background structural information for users of carbon electrodes in voltammetry and should be a favourite with graduate students Overall, this is a source-book for researchers in electrochemistry rather than a text for analysts It is worth its place on the library shelf, but will not attract many individual purchasers

Modern NMR Techniques and Their Application in Chemistry: A I Popov and K Hallenga (editors), Dekker, New York, 1991. Pages x + 665. $135.00 (US and Canada), $162.00 (elsewhere)

This book contains ten chapters written by nine scientists from Europe and North America. The chapters are on (1) NMR properties of Nuclei, (2) Fourier-Transform NMR: Theoretical and Practical Aspects, (3) Solid State NMR of Spin-$\frac{1}{2}$ Nuclei, (4) Solid State NMR of Quadrupolar Nuclei, (5) Quantitative Chemical Analysis by NMR, (6) Structural Determination of Organic Compounds, (7) Structural Determination of Inorganic Compounds, (8) Equilibria Studies in Solutions, (9) Reaction Kinetics and Exchange and (10) Two-Dimensional NMR Studies.

Thus all aspects of NMR spectroscopy are covered. solution and solid state, theory and practice, 1D and 2D, *etc.*

The preface indicates that the book is intended to complement existing books written by specialists for specialists and it is for those chemists who require NMR as a tool and who need to discover what advances have been made in the last decade This reviewer is just that target. However, my clear impressions of this book are that the book was written by experts and it surely needs a specialist to find it an easy and joyful read Everything is there. all the maths, for example, for Fourier transform NMR and for solid state NMR of quadrupolar nuclei, is remorselessly presented with no concessions at all for the non-mathematically inclined. To follow such detail is probably too much for the average chemist who just wants to use the NMR technique

There is clearly much useful information in the book and to persevere with it will be rewarding. However, the difficulties many readers may experience in attempting to follow the great detail classifies the book as somewhat reader-unfriendly. The book as a whole, and not just the contents, was not attractive to this reviewer. Some of the Figures are badly reproduced (*e.g*, Figure 3 on page 576)

The book has a place in a chemistry library due to the importance of NMR but scope remains for a book more sympathetic to the average chemist

J L. WARDELL

Wood and Cellulose Chemistry: D N-N HON and N SHIRAISHI (editors), Dekker, New York, 1991. Pages viii + 1020 $195 00 (US and Canada) $234.00 (elsewhere).

There are many books on wood and cellulose chemistry but this massive one is a very welcome and worthy newcomer. It has the features one would wish but also incorporates much work of Japanese origin. This is quickly recognized to rectify imbalances of reportage in other texts Japan is at the forefront of investigations of the chemistry of wood and its utilization The majority of the contributors are Japanese but there are also several Americans

The text is divided into three substantial sections, namely, I, Structure and Chemistry, II, Degradation, and III, Modification and Utilization In the first section after an introductory chapter on chemical composition and distribution there are others on cellulose, hemicelluloses, extractives and lignin, and others on the chemistry of bark and the characterization of wood and its components. The second section deals with colour and discoloration of woods, before dealing in separate chapters with various factors affecting the degradation of wood and its components including chemical, photochemical and pyrolytic degradations and enzymatic, microbial and biomimetic degradation of lignin and biodegradation of cellulosic materials. The last section has chapters on chemical modification of wood, chemical modification of cellulose, characterization of chemically modified cellulose, wood plasticization, wood–polymer composites, adhesion and adhesives and utilization of wood and cellulose for chemicals and energy

The text is comprehensive, highly detailed, up-to-date, well-written, and supported by extensive, and attractively presented and clear, tables and figures Future authors will be indebted to the ease of access the volume provides to work (and workers) they might easily have overlooked Japanese reportage is not at the expense of reportage of other work which is incorporated seamlessly into a splendid text The editors and contributors are to be congratulated on providing a stimulating and desirable addition to the works already available.

K. C B WILKIE

Factor Analysis in Chemistry, 2nd Ed.: E R MALINOWSKI, Wiley, Chichester, 1991 Pages xii + 350. £43 70.

The ideas of principal component and factor analysis were first proposed by the great statistician Pearson as early as 1901, but it was not until sixty years later that it was introduced into analytical chemistry by Malinowski as part of his doctorate The first edition of this book followed in 1980, and it proved to be a milestone in the acceptance of the method by the chemical community It was a timely publication coinciding as it did with the advent of the personal computer, and the increasing sophistication of analytical instruments under computer control producing large amounts of data that needed factor analysis to extract and interpet the underlying physical chemistry

Since the book is an established classic, it is the additions and amendments to the second edition that will be of interest to many people. Much of the text remains the same, especially chapters 7–10 which deal with chemical applications, there are, for example, only 19 references post 1980 out of a total of 157 in these chapters which is something of a disappointment. However, the earlier sections do include a considerable number of new techniques with practical examples in a later chapter. The new methods include autocorrelation techniques, statistical methods for target testing, and errors in the factor loadings, *etc* These are listed in full in the Preface, so anyone who has the first edition can easily decide for themselves whether to invest over £43 on a new copy

The approach remains clear and readable, with mathematics limited, in general, to matrix methods in a way that never becomes indigestible, there is always adequate discussion and illustration of what the underlying mathematics means. Couple this with a host of chemical examples and you have a book that remains indispensable for those working with factor analysis

C. J. GILMORE

TWO-COLOR LASER DESORPTION MASS SPECTROMETRY USING A SINGLE LASER

JEFFREY R. APPLING* and D. DANELLE BLAND
Department of Chemistry, University of Kentucky, Lexington, KY 40506, U.S.A.

(*Received* 17 *October* 1991. *Revised* 19 *November* 1991. *Accepted* 19 *November* 1991)

Summary—A Nd:YAG laser has been used to perform IR desorption of analytes followed by UV ionization, all within the same laser pulse. At moderate laser powers, mass spectra recorded using this method are dominated by molecular ions.

In recent years there have been important advances in mass spectrometric techniques,[1,2] many of which were largely motivated by the need for analysis of non-volatile and high molecular weight compounds. These methods include[2] SIMS, field desorption, fast atom[3] and ion bombardment,[4,5] plasma desorption,[6] and laser desorption.[1,7] Laser desorption mass spectrometry (LDMS) has proven itself to be one of the most powerful methods, especially when used in the matrix-assisted format.[7–10] Another LDMS strategy[1,11,12] relies on the use of two lasers for separate desorption and ionization. A distinct advantage is gained by desorbing intact neutral molecules (with infrared radiation for example) for subsequent ionization and detection. The present work was prompted by the desire to simplify this two-color desorption/ionization approach through the use of a single laser. Employing a Nd:YAG laser, we have successfully performed IR desorption of analytes detected with UV ionization within the same laser pulse.

Use of a single laser wavelength for sample vaporization and ionization often leads to indiscriminant destruction of analytes due to the power densities necessary to bring about the ionization process. Ion intensities depend greatly on the matrix,[9] which can make relative and absolute quantitation difficult. This is especially true for organic species that tend to fragment easily under conditions that promote ionization. In addition, substrate materials can contribute ions which may cause a serious interference problem. Infrared laser pulses are useful for desorption due to their ability to remove surface molecules with less fragmentation[13] than shorter wavelengths. Conditions which do not generate surface ions will still produce large amounts of neutral molecules.[14,15] This can be put to advantage by using a separate ionization scheme to detect ejected species. UV laser pulses can provide a convenient "soft" ionizaton for these molecules.

To accomplish this two-color desorption/ionizaton with a single laser we use a frequency-quadrupled Nd:YAG laser which has a fundamental IR output at 1064 nm. Coincident pulses of 1064 nm, frequency-doubled 532 nm, and frequency-quadrupled 266 nm light are filtered to eliminate the visible radiation. The remaining IR and UV pulses are passed through a short focal length lens prior to interaction with a sample target inside a time-of-flight mass spectrometer. Since focal length depends upon wavelength, this lens causes a spatial separation of the IR and UV laser beams. Thus we are able to position the UV focus above the target surface to intercept analyte molecules desorbed from the substrate by the IR laser pulse.

EXPERIMENTAL

The schematic diagram presented in Fig. 1 shows the arrangement of our home-built linear time-of-flight (TOF) mass spectrometer, detection electronics, and laser source. The spectrometer is composed of modular 40-mm Kwik Flange (KF-40) vacuum fittings (MDC) pumped by a 110 l./sec turbomolecular pump (Balzers). The detector is a single 18-mm microchannel plate (Varian VUW-8960) mounted

*Author for correspondence.

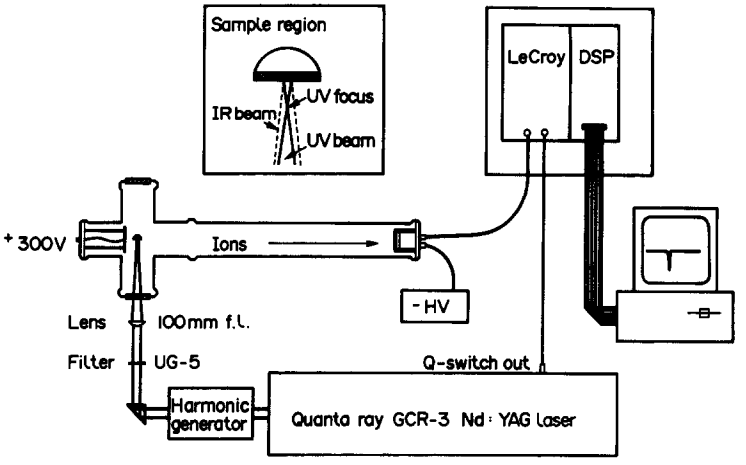

Fig. 1. Schematic of laser desorption time-of-flight system.

on a KF-40 flange outfitted with Safety High Voltage (SHV) feedthroughs (Insulator Seal, Inc.). A repeller plate biased at +300 V is used to push ions into the flight tube. Ions created above the target surface travel approximately 50 cm before they strike the detector.

The laser used for these preliminary experiments was a Quanta-Ray GCR-3 Nd:YAG laser equipped with a harmonic generator to produce doubled and guadrupled laser frequencies. The visible 532-nm (doubled) light was rejected with a UG-5 Schott glass filter, which also attenuates the IR (about 70%) and UV (about 20%) beams. The IR and UV pulses, with a temporal width of 9 nsec, are focused through the same 100-mm focal length fused silica lens mounted on a positioning stage outside the vacuum chamber. The IR and UV focal points are approximately 1 cm apart under these conditions. The inset of Fig. 1 shows the relative positions of the IR and UV focii as they would be during a surface analysis. In practice, the UV focus is first positioned directly on the surface creating large signals from substrate ions, then the lens is backed away from the target until these substrate ions disappear. The lens is then moved laterally to probe a fresh part of the target surface.

Ion signals were preamplified (SRS model SR445) before input into a 200-MHz transient digitizer (LeCroy TR8828C) for time characterization. The digitizer is contained in a CAMAC crate (Kinetic Systems) interfaced to a personal computer via a DSP 6001 crate controller. Data acquisition is accomplished with custom software. The Q-switch output of the laser is used to trigger the digitizer, and spectra can be collected from single or multiple laser shots.

RESULTS AND DISCUSSION

Figure 2 shows the sequential removal of glutamic acid from a target one laser shot at a time, with a constant lens position. Each trace corresponds to the mass spectrum (near the molecular ion) acquired from individual laser shots. The laser was fired manually about every 45 sec. The target substrate is a 5 mm × 5 mm × 2 mm section of a flat natural pyrite crystal face (origin unknown), which is known to be pure iron(II) sulfide from analysis by Rutherford Backscattering. This target is identical to those used in our current study[16] of adsorption of organic molecules to metal sulfide surfaces. In this case, the glutamic acid was simply deposited on the target by evaporation of one droplet of 20m*M* aqueous solution. We estimate a coverage of approximately 500 ng/cm^2 on the surface. A single shot mass spectrum shows the molecular ion only, as depicted in Fig. 3. These results indicate that the IR pulse desorbs glutamic acid molecules intact for ionization by the UV pulse.

Unfortunately, the spectra in Fig. 2 corresponding to the first three laser shots are just outside the dynamic range of the digitizer, so they appear to have the same ion intensity. But subsequent laser shots clearly show a decreasing surface concentration until no analyte is left (the twelfth laser shot yielded no ions). The glutamic acid was localized to a very small area on the surface, as expected for a dried droplet of solution. Preliminary work[16] with pyrite exposed to solutions of cysteine and serine show uniform coverage indicative of surface adsorption.

Mass spectra collected in this fashion are dependent on laser power. The laser was

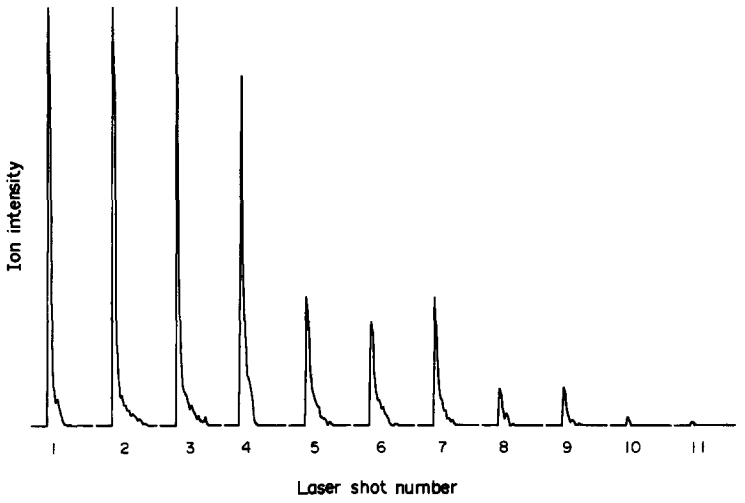

Fig. 2. Sequential removal of glutamic acid from a natural pyrite target. Each spectrum is collected after a single laser shot.

operated with the oscillator flashlamps only. For the spectra in Figs. 2 and 3, the pulse energies for the IR and UV pulses were about 50 and 1 mJ, respectively, before passing through the filter. After attenuation by the filter the energy ratio was reduced to about 20:1. Significantly higher laser powers remove material at a given target position in a few laser shots, and mass spectra are dominated by fragment ions. To obtain spectra of molecular ions, the laser energy was adjusted just above a lower threshold for ion production.

Under the conditions outlined above, only absorbed analyte molecules are observed to ionize; no surface substrate ions are detected. This leads to the conclusion that the IR pulse desorbs analytes under conditions of low irradiance[17] ($\approx 10^5$–10^6 W/cm^2). High heating rates at the surface[18] cause the release of intact molecules[17] in a plume that can be intercepted by the focused UV pulse. Thus molecular ions dominate the mass spectrum generated by the IR/UV pulse combination.

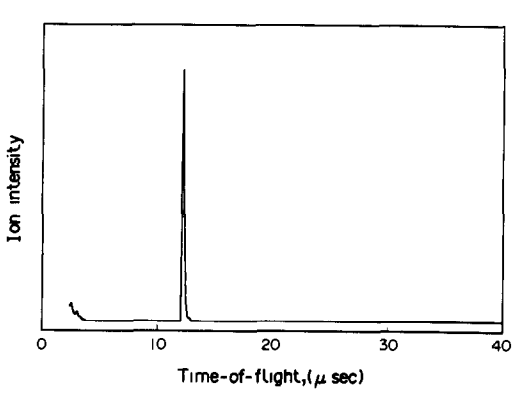

Fig. 3. Time-of-flight mass spectrum of glutamic acid absorbed to pyrite substrate. The feature at early time is the tail of an intense peak created when scattered laser light reaches the detector. This tail obscures ion signals for masses less than 10 amu.

The UV beam expands enough before it strikes the surface so that it does not generate surface ions or destroy analyte molecules to a great extent. When the "focal point" is pulled back from the surface to eliminate surface ionization, the focal volume is positioned about 1 mm above the target. Success of this method requires that analytes desorbed by the head of the IR pulse have enough time to move into the UV ionization region. This feature will limit the maximum mass of analyte which can be detected, since massive molecules will take too long to move away from the surface to be ionized within the 9 nsec laser pulse. We intend to explore these upper mass limit capabilities for our system.

CONCLUSIONS

A single Nd:YAG laser with a pulse duration of 9 nsec can be used to desorb and ionize surface-deposited molecules with little or no fragmentation. This is accomplished by positioning the spatially separated focii of the IR and UV laser beams so that the UV focus is just above a target surface, and the IR beam strikes the target under conditions of low irradiance. The main advantages of this method lie in the simplicity of the laser and optical system needed to perform two-color laser surface analyses. It seems possible that low-cost modifications

could allow incorporation of this technique into current commercial laser microprobe mass analyzers which use Nd:YAG laser sources.

NEW COMPUTATIONAL APPROACH FOR THE SIMULTANEOUS PHOTOMETRIC DETERMINATION OF CATALYSTS AND ACTIVATORS

ANDREU CLADERA, ARTURO CARO, ENRIQUE GÓMEZ, JOSÉ MANUEL ESTELA and VÍCTOR CERDÀ*
Departamento de Química, Facultad de Ciencias, Universidad de las Islas Baleares, E-07071 Palma de Mallorca, Spain

(*Received* 2 *September* 1991. *Revised* 28 *October* 1991. *Accepted* 5 *November* 1991)

Summary—A new method for the simultaneous kinetic determination of catalysts and activators was developed on the basis of a mathematical model. The parameters and variables are optimized from experimental data obtained by application of a multiple standard-addition method and use of the Gauss–Newton and Simplex method, both of which provide identical results. The proposed method was applied to the simultaneous photometric determination of Mn(II) and Pb(II) on the basis of their catalytic and activating effects, respectively, on the oxidation of Tiron by hydrogen peroxide. Data were both acquired and processed with the aid of software developed by the authors. The linear determination range achieved was 1.00–5.00 ng/ml Mn(II) and 200–800 ng/ml Pb(II). Experimental readings were made at 450 nm with a fibre optics detector. The most serious interference with the method was posed by Cr(III).

Catalytic reactions can be accelerated by using a variety of substances known as "activators". These are usually organic compounds[1,2] and, less often, metal ions.[3,4] As a rule, activators, which enhance the effect of the catalysts, are determined with lower sensitivity than catalysts.[5]

Despite the wide use of kinetic spectrophotometric methods for the catalytic determination of metals on account of their high sensitivity, few of them rely on activating effects for determination purposes.[6] Thus, activating effects have so far only been used in general to increase the sensitivity—and, occasionally, the selectivity—of catalyst determinations. No simultaneous determination of both types of substance, however, appears to have been attempted to date.

In previous work involving the kinetic thermometric determination of Mn(II) based on its catalytic effect on the oxidation of Tiron by hydrogen peroxide[7] we found Pb(II) to exert an activating effect on the analytical reaction. This led us to develop a simultaneous kinetic photometric determination taking advantage of both effects.

The problem was addressed by developing a new mathematical model based on a multiple standard-addition method. Thus, a general mathematical expression accounting for the potential non-catalytic effect, the Mn(II)-catalysed reaction and the activating effect of Pb(II) was used as starting point. The different parameters and variables included in the equation were calculated from experimental data that were processed by two different optimization methods (Gauss-Newton and Simplex) in order to compare the results obtained.

Both the acquisition of kinetic data, which was effected by using the initial-rate method, and the calculation of the parameters and variables in the starting mathematical expression were performed with the aid of software developed by the authors.[8,9]

The results obtained showed that the proposed simultaneous determination is an alternative to, for example, thermometric determinations on account of its higher sample throughput—the slope of the kinetic curve can be obtained in less than 30sec.

THEORY

The catalytic effect and the activating action of chemical substances can be exploited for the simultaneous determination of catalysts and activators. This requires the use of a mathematical equation relating the rates of the two reactions with the concentrations of the two analytes. The parameters involved in such an equation can be optimized by several

*Author for correspondence.

mathematical methods, for instance the Gauss–Newton or Simplex method.

The starting equation for development of the mathematical method was as follows:

$$v = A + (B + C[Y])[X]$$

where parameter A represents the contribution of the potential uncatalysed reaction, coefficient B is related to the exclusively catalytic process of X, and C denotes the activating effect of Y.

Therefore, by applying the multiple standard addition method, the above equation can be written as:

$$v = A + (B + C\{[X]_i + [X]_x\})([Y]_i + [Y]_x)$$

where subscript i denotes the known concentrations of each substance added to the sample or the determinations, and subscript x denotes the unknown concentrations in the sample to be determined.

The optimization will thus be made via a function U dependent on the three parameters and the two variables such that the expression

$$U(A, B, C, [Y]_x, [X]_x) = \Sigma(v_{exp} - v_{calc})^2$$

takes a minimum value.

We addressed the problem by first calculating the three parameters A, B and C from solutions of known catalyst and activator concentrations and then optimizing the two variables that yielded the analyte concentrations by a method resembling that of standard additions but involving two components rather than one. The determination could in principle also be performed by simultaneously calculating all five unknowns; however, this procedure yielded poor results.

The problem was resolved mathematically by using two different algorithms in order to compare the results obtained, namely:

—the Gauss–Newton method, which is based on the development of the partial derivative matrix of the function until a minimum condition is met.

—the Simplex method, which requires no prior knowledge of the function relating the different variables to be optimized, so it involves a much larger number of iterations than do differential methods. This is a result of the foundation of the smoothing procedure, yet poses no hindrance thanks to the high computational power of current computers. On the other hand, inasmuch as the optimization procedure is based on a mathematical model, it calls for no additional experimental work, but only for the parameters to be fitted to the model. The Simplex method was applied in its simple unidirectional advance variant, with contraction and no quadratic interpolation.

A more detailed description of the most common optimization procedures is provided elsewhere.[10]

EXPERIMENTAL

*Apparatus and software**

The measuring set-up used consisted of a Metrohm 662 fibre optics photometric detector connected via an RS232C interface to a PC computer for data acquisition and processing by means of the program FIBER, a magnetic stirrer, a reaction cell that was thermostated by means of a cryostat, and a Crison microBur 2031 autoburette furnished with an RS232C interface and controlled by the computer for addition of reagents to the cell.

Kinetic data were acquired by using the program FIBER.[8] Once the solution was homogenized, the program plotted the measured absorbances against time and then calculated the slope of the resulting kinetic curve. The reaction rates obtained on addition of different amounts of Mn(II) or Pb(II) were processed in order to optimize the parameters of the mathematical equation and determine the concentration of the two analytes by using the following programs:[9]

—GKCAL.EXE and GKAD.EXE to optimize parameters and variables, respectively, by the Gauss–Newton method.

—SIMKINCA.EXE and SIMKINAD.EXE to optimize parameters and variables, respectively, by the Simplex method.

Reagents

All reagents used were pro-analysis reagent-grade chemicals and distilled water was employed throughout. The solutions used were as follows:

0.1M Tiron (sodium pyrocatechol-3,5-disulphonate), prepared from the corresponding monohydrate salt (Merck).

0.05M 1,10-phenanthroline, made from its hydrochloride (BDH Chemicals Ltd).

*The software used can be obtianed on request from SCIWARE, Banco de Programas, Departamento de Química, Universidad de las Islas Baleares, E-07071 Palma de Mallorca, Spain.

0.1*M* borax buffer of pH 9.7, made from $Na_2B_4O_7 \cdot 10H_2O$ (Merck).

1000 mg/l. Mn(II) standard, prepared from $MnSO_4 \cdot H_2O$ (Merck).

1000 mg/l. Pb(II) standard, prepared from $Pb(NO_3)_2$ (Panreac).

1.5*M* H_2O_2, made from a 30% solution (Probus) titrated with $KMnO_4$.

Procedure

In a 50-ml standard flask place in the following order: 1 ml of 0.1*M* Tiron, 1 ml of 0.05*M* 1,10-phenanthroline, 10 ml of 0.1*M* borax buffer of pH 9.7, *x* ml of sample containing Mn(II) and Pb(II) in amounts providing concentrations in the ranges 1–5 ng/ml Mn(II) and 200–800 ng/ml Pb(II) on dilution to the mark. Next, pour the solution into a thermostated cell at 20 ± 0.1°. Once the temperature has stabilized, have the autoburette inject 1 ml of 1.5*M* hydrogen peroxide and obtain the corresponding kinetic curve by monitoring the absorbance at 450 nm, which yields the initial slope. The data thus obtained are subsequently processed by the optimization software in order to calculate the concentrations of the two metal ions.

RESULTS AND DISCUSSION

To demonstrate the capacity of the proposed method we have used the catalytic and activating effects of Mn(II) and Pb(II), respectively, on the oxidation of Tiron by hydrogen peroxide.[7] The simultaneous determination of both ions will be addressed by photometric monitoring at 450 nm.

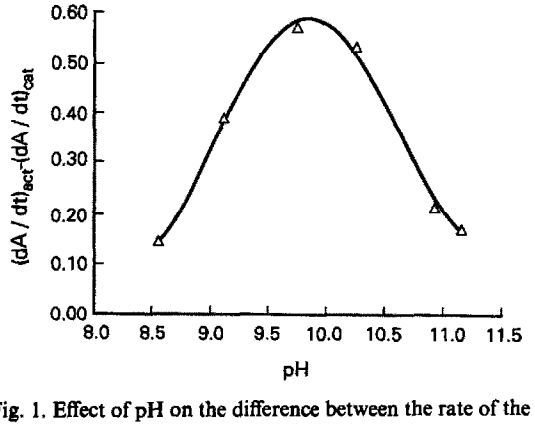

Fig. 1. Effect of pH on the difference between the rate of the activated and catalysed reaction. T = 20°. [Mn(II)] = 10 ng/ml, [Pb(II)] = 1 μg/ml, [1,10-phen] = $10^{-3}M$, [Tiron] = $2 \times 10^{-3}M$, $[H_2O_2] = 0.09M$, λ = 450 nm.

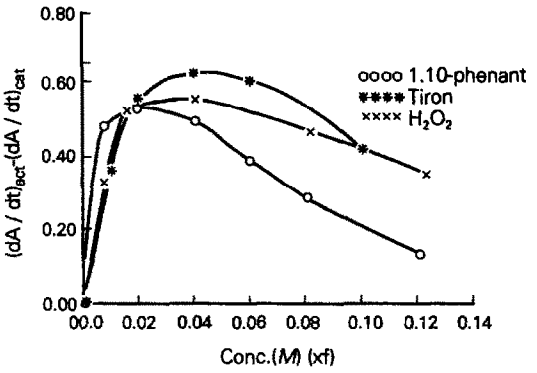

Fig. 2. Effect of the concentrations of 1,10-phenanthroline (f = 40, [Tiron] = $2 \times 10^{-3}M$; $[H_2O_2] = 0.09M$), Tiron (f = 10, [1,10-phen] = $10^{-3}M$; $[H_2O_2] = 0.09M$) and H_2O_2 (f = 1, [1,10-phen] = $10^{-3}M$; [Tiron] = $2 \times 10^{-3}M$) on the difference between the rate of the activated and catalysed reaction. T = 20°, [Mn(II) = 10 ng/ml, [Pb(II)] = 1 μg/ml, pH 9.7, λ = 450 nm.

Optimization of experimental variables

The variation of the rates of the catalysed and activated reaction (dA/dt) as a function of the temperature has been studied over the range 10–30°. Both rates increase with increasing temperature throughout the range studied; however, the increase is more gradual between 10 and 20°, the latter of which was chosen for subsequent experiments on account of its ready achievement in the laboratory environment.

Reactant concentrations and the reaction medium were optimized for the greatest difference in absorbance between the catalysed and activated reaction. Thus, the influence of pH was studied by using borax buffers of pH between 8.5 and 11.2. As can be seen in Fig. 1, the maximum difference between the two signals was obtained at pH 9.7.

Figure 2 shows the differences between the rates of the catalysed and activated reaction obtained at various 1,10-phenanthroline, Tiron and hydrogen peroxide concentrations, the optimal values of which were found to be 10^{-3}, 2×10^{-3} and 0.03*M*, respectively.

Once the optimal working conditions had been established, the linear determination range for each element in the presence of the other was calculated. The results obtained showed the slope of the kinetic curves to be linearly related to the catalyst concentration over the range 1–5 ng/ml Mn(II) in the presence of activator concentrations between 200–800 ng/ml Pb(II). Over these linear ranges, the theoretical equation can be applied.

Table 1. Results obtained in the simultaneous determination of Mn(II) and Pb(II) by the proposed method in synthetic mixtures

Sample	Added, ng/ml Mn(II)	Added, ng/ml Pb(II)	Gauss–Newton, ng/ml Mn(II)	Gauss–Newton, ng/ml Pb(II)	Simplex, ng/ml Mn(II)	Simplex, ng/ml Pb(II)
1	1.0	400	1.00	397	1.00	398
2	3.0	500	2.97	500	2.98	498
3	2.5	300	2.55	294	2.51	307

Simultaneous determination of Mn(II) and Pb(II)

The proposed method was applied to the determination of the two metal ions in several synthetic mixtures containing Mn(II) and Pb(II) concentrations in the linear ranges. The results obtained are summarized in Table 1. As can be seen, the results obtained are quite consistent with the reference concentrations.

Next, as an example, we develop the mathematical treatment for the first mixture.

Gauss–Newton method

Table 2 lists the contents of the results file used for the calculation of the parameters relating the rates of reaction involved in the photometric method with the concentrations of catalyst and activator by using standard mixtures.

Once A, B and C (-0.268, 0.900 and 0.136) were determined, the data file was used to obtain the Mn(II) and Pb(II) concentrations in the first mixture of Table 1. From this in turn the result file was obtained (Table 3). Then, by using the same parameter values, the second and third mixtures of Table 1 were resolved in the same way.

A, B and $C = -0.268$, 0.900 and 0.136.

Simplex method

Table 2 lists the content of the results file used for the determination of parameters *A*, *B* and *C*, which were found to be −0.268, 0.900 and 0.136, respectively, *i.e.*, identical to those obtained by the Gauss–Newton method.

These values were subsequently used to construct the data entry file for calculation of the Mn(II) and Pb(II) concentrations. After a smoothing process the results given in Table 3 were obtained. As can be seen, the catalyst and activator concentrations found were virtually identical to those provided by the Gauss–Newton method.

Selectivity

A study of potential interferents revealed Cr(III) to pose the most serious problems; in fact, this ion resulted in an increase in the reaction rate at concentrations above 10 ng/ml in the presence of 3 ng/ml Mn(II) and 800 ng/ml Pb(II). Iron(III) was found to interfere at concentrations above 200 ng/ml, while the effect of Mg(II), Zn(II) and Co(II) was only felt above 400 ng/ml. On the other hand, such metals as Cu(II), Ca(II), Al(III), Ni(II) and Cd(II) only interfered at concentrations over 600 times higher that of Mn(II). None of the commoner anions (chloride, nitrate, sulphate and phosphate) had any appreciable effect on the reaction rate at concentrations up to 100 μg/ml.

CONCLUSIONS

The proposed kinetic method based on experimental data obtained by multiple standard–additions proved to be a useful alternative for the simultaneous determination of catalysts and activators.

The approach is potentially applicable to other chemical systems for the determination of catalyst–activator and catalyst–inhibitor pairs on the basis of a virtually identical theoretical foundation.

ADSORPTION MECHANISM OF POLYLYSINE ON HYDROXYAPATITE AND ITS EFFECT ON DISSOLUTION PROPERTIES OF HYDROXYAPATITE

HIDEJI TANAKA,* YOUKO NUNO, SHINOBU IRIE and SHIGERU SHIMOMURA

Laboratory of Pharmaceutical Analytical Chemistry, Faculty of Pharmaceutical Sciences, The University of Tokushima, Sho-machi 1-78-1, Tokushima 770, Japan

(*Received* 20 *September* 1991. *Revised* 13 *December* 1991. *Accepted* 14 *December* 1991)

Summary—Adsorbed amounts of poly-L-lysine (pLys) and bromide ion on hydroxyapatite (HAp) from aqueous solutions of poly-L-lysine hydrobromide, and amounts of calcium and phosphate ions liberated concurrently from HAp during the adsorption of pLys were determined at 25°. The pLys was adsorbed on HAp by the mechanism of ion-exchange between its amino groups and calcium ions of HAp. The released amount of calcium ion increased, therefore, with the adsorbed amount of pLys. On the other hand, the released amount of phosphate ion first decreased and then increased after attaining a minimum with the equilibrium concentration of pLys. The analysis using an equilibrium dialysis method revealed that the released phosphate ions were mainly in the bound state to the amino groups of pLys remaining in the solution, and that the concentrations of calcium and phosphate ions free from both HAp and pLys were restricted by each other under the law of the solubility product of HAp. The first decrease in the released amount of phosphate ion was concluded to be attributed primarily to the increase in the released amount of calcium ion because pLys remaining in the solution was little in this region. When sodium hydroxide was added to the solution, the adsorbed amount of pLys increased and then slightly decreased with the equilibrium pH of the solution due to the increase or decrease of the electrostatic attractive force between the adsorbate and the adsorbent. However, conformational change in pLys around pH 10 seemed to have little effect on the adsorption.

Hydroxyapatite (HAp), a basic calcium phosphate which has the chemical formula $Ca_{10}(PO_4)_6(OH)_2$, is the most stable phase of calcium phosphates under ordinary conditions.[1,2] This has been widely used for chromatographic separations of proteins, nucleic acids, enzymes, and so on, since Tiselius *et al.* introduced it as a packing material for liquid chromatography in 1950's.[3] Today, many commercial HAp-columns for high performance liquid chromatography are on the market.

In the studies on HAp-column chromatography, the factors governing interactions between proteins and HAp have been investigated, and some mechanisms, such as specific or non-specific complex formation between functional groups of protein and calcium or phosphate ions of HAp and as ion-exchange between the groups and the ions, were proposed.[4–7] However, detailed mechanism of the adsorption is still unknown because complexity of conformation and diversity of side chains of proteins make the elucidation of the mechanism difficult.

On the other hand, HAp is known to dissolve slightly in aqueous media. This behaviour is complicated and, in spite of many studies,[8–12] not elucidated entirely, mainly because HAp exists in the form of very small crystallites and its physicochemical properties depend on the surface state.[13] The dissolution properties of HAp seem important in connection with the durability of HAp-columns.

Poly-L-lysine (pLys) is a typical homopolypeptide, the molecular structure of which has been studied extensively. In the present study, the interactions between pLys and HAp are investigated by using an equilibrium dialysis technique. The adsorbed amount of pLys on HAp and the amounts of calcium and phosphate ions liberated from HAp are determined, and the results are discussed taking into account ion-exchange between calcium ions of HAp and amino groups of adsorbed pLys, binding of phosphate ions to the groups of pLys in solution, and the solubility product of HAp.

EXPERIMENTAL

Reagents

Hydroxyapatite was synthesized according to the method of Avnimelech *et al.*[14] The calcium/phosphorus ratio was 10.38/6, and the point of zero charge (PZC) determined by pH titration was 6.70. The specific surface area determined by the BET procedure at 77 K with nitrogen gas as an adsorbate was 29.0 m^2/g. Poly-L-lysine hydrobromide (pLysHBr) was purchased from Sigma Chemical Co., and its viscosity average molecular weight assessed by the supplier was 21,500. The standardization of a stock solution of the pLysHBr was performed by the colloidal titration method[15] for amino group of pLys, using a standard solution of potassium polyvinyl sulphate (Wako Pure Chemical Industries, Ltd.) with Toluidine Blue indicator, and by the mercuric thiocyanate method[16,17] for bromide ion. Water was demineralized with a Milli-QSP water purification system (Millipore Co.).

Apparatus

A Nippon Jarrel-Ash ICAP-750N multichannel inductively coupled plasma atomic emission spectrometer was used. The nebulizer used was a conventional cross-flow type and argon gas flow-rates were 0.5 (carrier), 0.6 (auxiliary) and 16 (coolant) l l./min. A Hitachi 330 spectrophotometer, Hitachi 650 spectrofluorometer, Jasco J-600 spectropolarimeter and Horiba F-11 pH meter were also used for the analyses described below.

Procedure

The adsorption experiment was carried out by suspending HAp (1 g) to aqueous solutions of pLysHBr (50 ml) at 25° for 5 days. After filtration with a Millipore filter with a pore size of 0.1 μm, the filtrates were analysed.

The dialysis experiment was carried out as follows: HAp (0.6 g) was suspended in pLysHBr solutions (30 ml). A dialysis bag (Visking Company, type 36/32) containing water (20 ml) was immersed in each suspension. After 5 days, the dialysis bags were taken out and the concentrations of the ions in the inner solutions were determined. The suspensions remaining in the vessels were filtered through the Millipore filters, and the filtrates were analysed.

The concentration of pLys was determined by fluorometry at 475 nm with excitation at 335 nm, using *o*-phthalaldehyde and 2-mercaptoethanol according to the method of Roch.[18] The reaction was performed at pH 9.0 by using sodium dihydrogen phosphate–potassium hydroxide buffer. Hereafter, the concentration of pLys is given in terms of molarity of the lysine residue of pLys. The concentration of bromide ion was determined by spectrophotometry at 458 nm, using mercuric thiocyanate and ferric nitrate.[16,17]

The concentrations of calcium and phosphate species in solution were determined by inductively coupled plasma atomic emission spectrometry (ICP–AES) at 393.4 and 214.9 nm, respectively. Working standards were prepared from 1,000 mg/l. standards (Kanto Chemical Co.) by mixing and diluting them with 1% nitric acid. It was confirmed that pLys up to 5m*M* does not interfere with the determination. For the determination of phosphate in the solutions inside the dialysis bags, where the phosphate level was very low (around 0.01m*M*) and pLys was absent, spectrometry at 720 nm using ammonium molybdate and stannous chloride[19] was adopted instead of ICP–AES.

Circular dichroism (CD) spectra of the pLys solutions in the range of 200–250 nm were measured at various pH values on the spectropolarimeter. Solutions of pLys in the three forms (*i.e.*, random coil, α-helix and β-sheet) were prepared according to the method of Greenfield *et al.*[20,21]

RESULTS AND DISCUSSION

Adsorption of pLys on HAp and concurrent release of calcium and phosphate ions from HAp

The adsorbed amounts of pLys and bromide ion (X_{pLys} and X_{Br}) on HAp from aqueous solutions of pLysHBr are shown in Fig. 1 as a function of the equilibrium concentration of pLys (C_{pLys}), where both amounts increased with C_{pLys}, and X_{pLys} was larger than X_{Br}.

It was found that calcium and phosphate ions were released from HAp incongruently (non-constant in the calcium/phosphorus ratio) during the adsorption of pLys on HAp. The equilibrium concentrations of calcium and phosphate ions in the solutions were plotted against C_{pLys} in Fig. 2(a). The equilibrium concentration of calcium ion (C_{Ca}) increased and that of phosphate ion (C_{Pi}) decreased with C_{pLys}. However, the latter increased after attaining a minimum when C_{pLys} became high. Figure 2(b) shows the relationship between the

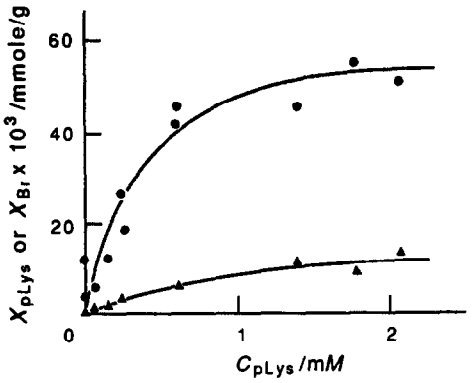

Fig. 1. Adsorbed amounts of pLys and bromide ion on HAp from aqueous solutions of pLysHBr as a function of equilibrium concentration of pLys. No buffering solutions were used in order to avoid the effect of buffering agents on the properties of the adsorbate and the adsorbent. The closed circles and closed triangles correspond to X_{pLys} and X_{Br}, respectively.

Concentrations in m*M*.

equilibrium pH of the solutions and C_{pLys}, where the pH had the similar tendency to C_{Pi}.

Migration of released ions through dialyzing membrane

From the outer suspension in contact with the dialysis bag containing water, some of the bromide ions (added as pLysHBr) and some of the calcium and phosphate ions (released from HAp) migrated into the inside of the bag to reach membrane equilibrium. The equilibrium values of the dialysis experiment are listed in Table 1; initial concentration of pLys was 2.31 (A) or 3.08 m*M* (B). The concentrations of anionic species in the outer solution were higher than those in the inner solution, whereas the concentration of calcium ion in the outer solution were lower than that in the inner solution. Equilibrium pH of the outer solution was higher than that of the inner solution.

Effect of pH on adsorption of pLys on HAp

Figure 3(A) shows the adsorbed amounts of pLys and bromide ion on HAp as a function of the equilibrium pH. Initial concentration of pLys was kept constant at 2.89 m*M* and pH was adjusted by addition of sodium hydroxide. The X_{pLys} (closed circles) increased with the pH and then decreased slightly after attaining a

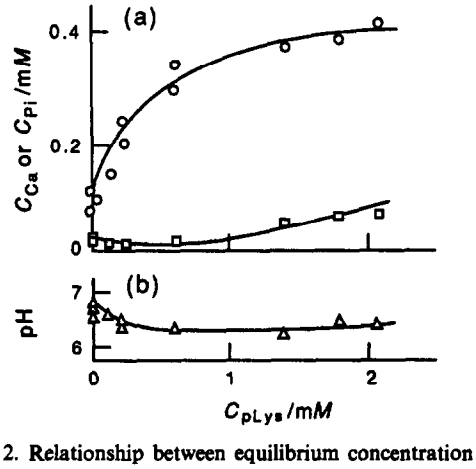

Fig. 2. Relationship between equilibrium concentration of pLys and concentrations of calcium and phosphate ions released from HAp (a), and equilibrium pH of solution (b). The experimental condition was the same as that in Fig. 1. The open circles and open squares correspond to C_{Ca} and C_{Pi}, respectively.

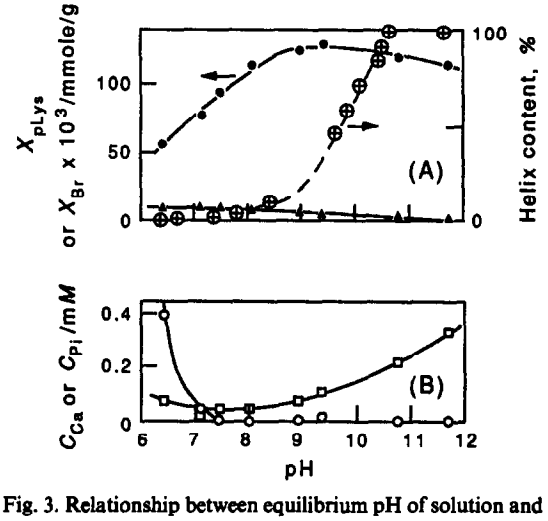

Fig. 3. Relationship between equilibrium pH of solution and adsorbed amounts of pLys and bromide ion on HAp (A), and equilibrium concentrations of calcium and phosphate ions released from HAp (B). All the symbols are the same as those in Figs. 1 and 2. The dotted line on ⊕ in Fig. 3(A) shows the helix content (%) in pLys.

maximum around pH 9.5. On the other hand, X_{Br} (closed triangles) was low and decreased monotonously with the pH. Figure 3(B) shows the equilibrium concentrations of calcium and phosphate ions (C_{Ca} and C_{Pi}) as a function of the equilibrium pH. It shows that C_{Ca} decreased monotonously, and C_{Pi} increased after attaining a minimum with the pH. This dissolution property of HAp in basic media was discussed before.[22]

In aqueous solution of calcium phosphates, the chemical species of Ca^{2+}, PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4, $CaHPO_4$ and $CaH_2PO_4^+$ are formed through protonation of phosphate ion and through complex formation between calcium and phosphate ions.[23] Moreover, in the presence of pLys, a part of anionic species of phosphate is considered to be bound to amino groups of pLys. The concentration of calcium species determined by the ICP–AES is, therefore, the sum of the concentrations of Ca^{2+}, $CaHPO_4$ and $CaH_2PO_4^+$; the concentration of phosphate species determined simultaneously is the sum of the concentrations of PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^-$, H_3PO_4, $CaHPO_4$, $CaH_2PO_4^+$ and phosphate which is bound to pLys in solution.

The concentrations and activities of chemical species in the solutions inside the dialysis bags can be calculated from the data shown in Table 1 using the first, second and third dissociation constants of phosphoric acid (K_1, K_2 and K_3, respectively) and the formation constants of $CaHPO_4$ and $CaH_2PO_4^+$ (K_x and K_y, respectively).[24] The obtained values were listed in the middle part of Table 2, where brackets and parentheses mean concentration and activity, respectively. The numerical values used were as follows: K_1 7.08×10^{-3}, K_2 6.31×10^{-8}, K_3 4.17×10^{-13},[25] K_x 244 and K_y 8.20.[24] The activity coefficient for each ion (γ) was calculated through the Debye–Hückel equation;

$$\log\gamma = -Az^2I^{\frac{1}{2}}/(1 + Ba^\circ I^{\frac{1}{2}}) \qquad (1)$$

where z is the valency of the ion, I is the ionic strength of the medium, A and B are constants ($A = 0.515$ and $B = 0.329$ at 25° for aqueous solution),[26] and a° is an ion size parameter (H^+ 9, OH^- 3.5, $H_2PO_4^-$ 4.25, HPO_4^{2-} 4, PO_4^{3-} 4, Ca^{2+} 6, Br^- 3 and $CaH_2PO_4^+$ 4.25).[27] The values of $-\log(Ca^{2+})^{10}(PO_4^{3-})^6(OH^-)^2$ were found to be 122.1 and 120.1 for initial concentrations of pLys of 2.31 and 3.08 mM, respectively. These values were in agreement with the literature values of the solubility product (K_{sp}) of HAp (108–125).[28] This result means that the concentrations of calcium and phosphate ions in the inner solutions were limited by each other under the law of the K_{sp} of HAp.

Table 2. Equilibrium values in solutions inside and outside dialysis bag calculated from data listed in Table 1. The symbol Y means the amount of phosphate or bromide ion which is bound to pLys in the solution per lysine residue of pLys: $Y_{Pi} = [Pi]_b^\circ/C_{pLys}$, $Y_{Br} = [Br^-]_b^\circ/C_{pLys}$. Initial concentrations: (A) pLys 2.31, Br^- 1.98 mM; (B) pLys 3.08, Br^- 2.64 mM

Concentrations in mM.

When membrane equilibrium is attained, the K_{sp} of HAp are equal on both sides of the membrane, under the assumption that the standard chemical potential of HAp on both sides of the membrane are the same. Therefore, even in the outer solutions containing pLys, the activities of calcium and phosphate ions were mutually restricted under the law of the K_{sp} of HAp. It was concluded that the released phosphate ions in the outer solution exist mainly in the bound state to the amino groups of pLys in the solution. On the other hand, adsorbed pLys expels calcium ion from HAp through the ion-exchange between positively charged amino groups of pLys and calcium ions of HAp to keep electroneutrality of the surface phase. The concomitant increase of C_{Ca} and C_{Pi} shown in Fig. 2(A) were attributed to these facts. The tendency of C_{Pi} to decrease with an increase in C_{Ca} was observed only in the region of low C_{pLys}, where the amount of phosphate ions which were bound to pLys in the solution phase was little.

Taking the Donnan's membrane equilibrium into account, the concentrations of anions, *i.e.*, phosphate and bromide ions, free from both pLys and HAp in the outer solution ($[Pi]_f^\circ$ and $[Br^-]_f^\circ$) can be evaluated from the

following equations;

$$[Pi]_f^o = [H_3PO_4]_f^o + [H_2PO_4^-]_f^o + [HPO_4^{2-}]_f^o + [PO_4^{3-}]_f^o + [CaHPO_4]_f^o + [CaH_2PO_4^+]_f^o \quad (2)$$

$$= [H_3PO_4]^i + [([H_2PO_4^-]^i)^2[Ca^{2+}]^i/[Ca^{2+}]^o]^{\frac{1}{2}} + [HPO_4^{2-}]^i[Ca^{2+}]^i/[Ca^{2+}]^o + [([PO_4^{3-}]^i)^2([Ca^{2+}]^i)^3/([Ca^{2+}]^o)^3]^{\frac{1}{2}} + [CaHPO_4]^i + [CaH_2PO_4^+]^i[H^+]^o/[H^+]^i \quad (2')$$

and

$$[Br^-]_f^o = [([Br^-]^i)^2[Ca^{2+}]^i/[Ca^{2+}]^o]^{\frac{1}{2}} \quad (3)$$

where the subscript "f" means "free", and the superscripts "i" and "o" mean "inside" and "outside", respectively. It was assumed that the activity coefficients for uni- and bivalent ions and the concentrations of neutral species, *i.e.*, H_3PO_4 and $CaHPO_4$, were equal on both sides of the dialysis membrane, and that the cationic species did not interact with pLys. Accordingly, the concentrations of phosphate and bromide ions which were bound to pLys in the outer solution are obtained;

$$[Pi]_b^o = C_{Pi}^o - [Pi]_f^o \quad (4)$$

and

$$[Br^-]_b^o = C_{Br}^o - [Br^-]_f^o \quad (5)$$

The calculated values were listed in the bottom part of Table 2. It shows that phosphate ions in the outer solution exist mostly in the bound state as presumed above.

When the solution pH becomes higher than the PZC of HAp (6.7), the electrostatic attraction between the cationic pLys and the negatively charged HAp surface increases. Thus, X_{pLys} increased with the pH. However, when the pH further increases, pLys comes to lose its positive charges and the conformational change between random coil (at lower pH) and α-helix (at higher pH) occurs in pLys. The dotted line in Fig. 3(A) shows the helix content, estimated from the CD-spectra of the pLys solutions according to the procedure of Greenfield *et al.*[21] It shows that the helix content increased sharply in the range of pH 9–11. However, no pronounced change in X_{pLys} was observed in this region. It was concluded, therefore, that the conformational change of pLys in this region does not give a significant effect on the adsorption of pLys.

In general, as for the adsorption of highly solvated polymers on an impenetrable surface, a fraction of the molecules is actually attached to the sorbent surface, and the remainder dangles in solution.[29] Therefore, the following model explaining the phenomena found in the present study was considered as shown in Fig. 4. A fraction of adsorbed pLys which was actually attached to HAp (c) released calcium ions from HAp (d) by the mechanism of ion-exchange. Co-adsorbed bromide ions were captured by the amino groups of the remaining fraction of adsorbed pLys (b), because the affinity of bromide ion to HAp is very low.[30] In addition to the ion-exchange mechanism, calcium ions were released from HAp through the dissolution of HAp (e). On the other hand, phosphate ions were released only through the dissolution (e). Most of these phosphate ions protonated (g) and/or were bound to pLys in the solution phase (i). Some released phosphate ions formed complexes with calcium ions (h). The dissolution of HAp and the protonation of phosphate ions (g) increased the concentration of hydroxide ion in solution (e) and (f). The similar tendency between the shape of curves of C_{Pi} and (pH) in

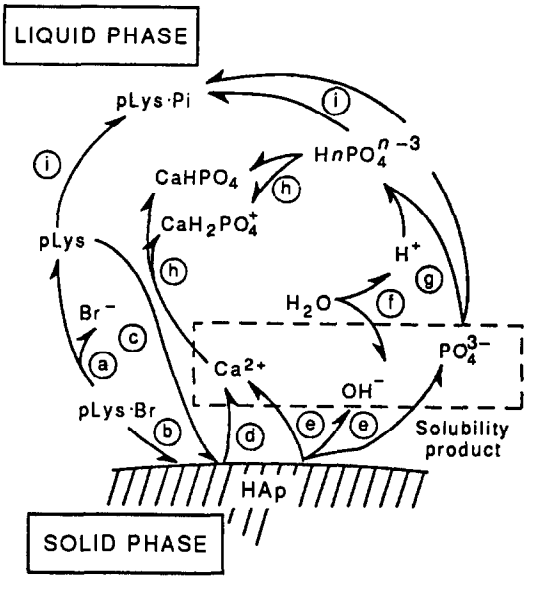

Fig. 4. Scheme of interactions occurring between pLysHBr and HAp. (a) Liberation of bromide ion from pLys, (b) co-adsorption of pLys and bromide ion on HAp, (c) ion-exchange adsorption of pLys on HAp, (d) release of calcium ion through ion-exchange with adsorbed pLys, (e) dissolution of HAp, (f) dissociation of water, (g) protonation of phosphate ion, (h) complex formation between calcium and phosphate ions, (i) counterion binding of phosphate to pLys. For simplicity, arrows are expressed only for the direction of mass transfer or reaction mainly occurs in the course of adsorption of pLys on HAp.

Fig. 2 is attributed to this fact. The concentrations of Ca^{2+}, OH^- and PO_4^{3-} were limited by each other under the restriction of the K_{sp} of HAp (enclosed with the dotted line). Therefore, the release of phosphate ions through the dissolution of HAp (e) was suppressed by the excess release of calcium ions through the ion-exchange (d) when the equilibrium concentration of pLys in solution was low. These facts were responsible for the marked incongruent dissolution properties of HAp in the presence of pLys.

It is known that the constituent ions of HAp having the same sign of electric charge as that of the adsorbed polymeric ions are released from HAp during their adsorption.[31,32] On the other hand, little attention is paid to the behaviour of the constituent ions having a counter-charge to the adsorbate. One of the exceptions is a report of Juriaanse *et al.*[33] They found that not only calcium ions but also phosphate ions were released from HAp in the presence of pLys and poly-L-ornithine; not only phosphate ions but also calcium ions were released in the presence of poly-L-asparaginate. Although they did not refer to it, initial decrease in the released amount of the counter-charge ions, such as that shown in Fig. 2(a), was seen in their reported data. These facts suggest that the dissolution tendency of HAp found in the present study is not specific for the case of adsorption of pLys but is common to those of other cationic peptides, and that the behaviour of phosphate and calcium ions changed place with each other according to the sign of the electric charge of the adsorbed polymeric ions. The results obtained in the present study are, therefore, important as a basis for understanding the interaction between charged polymers and HAp.

DIFFERENTIAL PULSE POLAROGRAPHIC STUDY OF THE HYDROLYSIS OF ENDOSULFAN AND ENDOSULFAN SULPHATE IN EMULSIFIED MEDIUM. APPLICATION TO THE DETERMINATION OF BINARY MIXTURES OF ORGANOCHLORINE PESTICIDES

A. J. Reviejo, J. M. Pingarron* and L. M. Polo

Department of Analytical Chemistry, Faculty of Chemistry, Complutense University of Madrid, 28040 Madrid, Spain

(*Received* 4 *November* 1991. *Revised* 19 *December* 1991. *Accepted* 3 *January* 1992)

Summary—Hydrolysis reactions of endosulfan and endosulfan sulphate in the emulsified medium formed with ethyl acetate and a mixture of the two surfactants Hyamine 2389 and Triton X-405 are studied by differential pulse polarography. Besides the heptachlor–endosulfan sulphate pair, whose peak potentials are sufficiently different at pH 8.0 to allow their simultaneous determination, the organochlorine pesticide binary mixtures endosulfan–endosulfan sulphate, dieldrin–endosulfan and dieldrin–endosulfan sulphate can be determined based on their hydrolysis reactions in basic medium and on their different reaction rates. The endosulfan–endosulfan sulphate pair can be determined by allowing the mixture to hydrolyse at pH 11.0 and measuring the endosulfandiol peak for the determination of endosulfan. The analysis of the mixture dieldrin–endosulfan is based on endosulfan hydrolysis at pH 12.0 in which dieldrin is not hydrolysed. Dieldrin and endosulfan sulphate can also be determined simultaneously in a 0.5*M* sodium hydroxide medium. When determining one pesticide in binary mixtures containing a $5.0 \times 10^{-6}M$ concentration of the other pesticide, the lower limits of the calibrations obtained were: endosulfan–endosulfan sulphate mixture, 4.0×10^{-6} and $1.0 \times 10^{-6}M$ respectively; heptachlor–endosulfan sulphate mixture, $2.0 \times 10^{-6}M$ for endosulfan sulphate; all other cases, $3.0 \times 10^{-6}M$.

The importance of organochlorine pesticides from a toxicological point of view is well established due to their bioaccumulative ability. These pesticides as well as their degradation products have been detected in foodstuffs, waters and soils.[1]

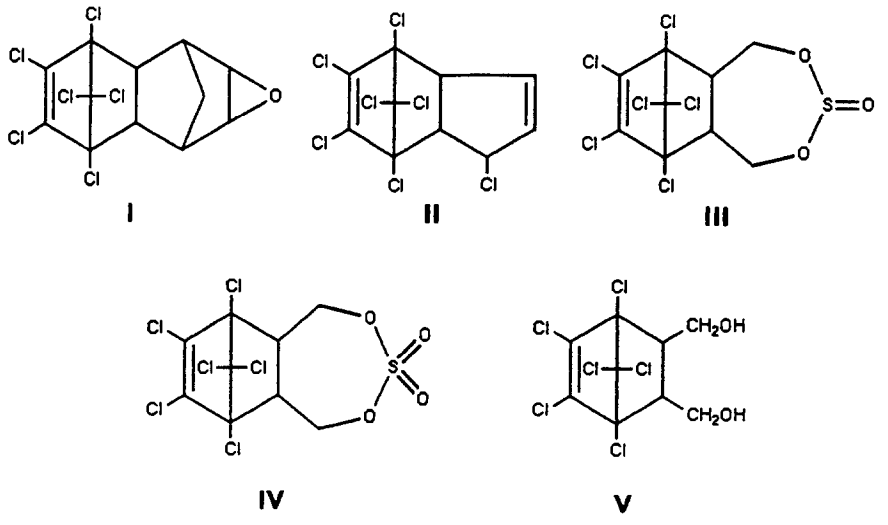
Further, electroanalysis in oil/water emulsified media has proved to be a useful technique because of the predominantly aqueous nature of these media, which offers some practical advantages.[2–5] Recently, we performed[6] a polarographic study of the cyclodiene organochlorine pesticides dieldrin (I), heptachlor (II), endosulfan (III) and endosulfan sulphate (IV) (all included in the E.P.A. list of priority pollutants) in the emulsified medium formed with ethyl acetate and a mixture of two surfactants, Hyamine 2389 and Triton X-405, as emulsifying agent. Our investigation of how the i_p and E_p values of each of the four pesticides were affected by the others showed that all except heptachlor and endosulfan sulphate interfere with each other. Therefore, the direct simultaneous determination of the components of binary mixtures, other than the mixture containing heptachlor and endosulfan sulphate, was not possible at the working pH used for their individual determination. Nevertheless, the possibility of using hydrolysis processes of endosulfan and endosulfan sulphate in basic medium was envisaged as a means of introducing differences which allow simultaneous determination of the components of binary mixtures containing endosulfan and/or endosulfan sulphate. In this paper, hydrolysis reactions of endosulfan and endosulfan sulphate in the above-mentioned emulsified medium are studied. Based on these reactions, the simultaneous determination of the components of some binary mixtures of these organochlorine pesticides is proposed. These mixtures could appear in samples of fruits and vegetables treated directly with commercial pesticide formulations.

EXPERIMENTAL

Apparatus

A Metrohm E626 Polarecord equipped with a Metrohm 663 VA polarographic stand was

*Author for correspondence.



Scheme 1.

used. A P-Selecta Ultrasons ultrasonic bath was also used.

Electrodes and electrochemical cell

A Metrohm 6.1246.020 multimode mercury electrode equipped with a Metrohm 6.1226.030 capillary tube, a Metrohm 6.0728.000 Ag/AgCl/KCl 3*M* reference electrode, a Metrohm 6.1247.000 glassy-carbon electrode (as counter electrode), and a double-walled Metrohm EA 876-20 cell were used.

Reagents and solutions

Heptachlor, endosulfan ($\alpha + \beta$) and endosulfan sulphate (Riedel de Haën), and dieldrin (Sigma) were used. Triton X-405 and Hyamine 2389 (Serva) were the surfactants used as emulsifying agents. The organic solvent was ethyl acetate (Carlo Erba). All chemicals used were of analytical-reagent grade and the water used was obtained from a Milli-Q (Millipore) system.

Stock solutions of each of the pesticides ($2.5 \times 10^{-3}M$) in ethyl acetate were prepared by weighing. More dilute standards were prepared by suitable dilution with the same organic solvent. Stock solutions of surfactants were 10% v/v and 5% v/v in aqueous solution for Triton X-405 and Hyamine 2389 respectively. Buffer solutions, used as supporting electrolyte, were a Britton–Robinson solution containing each component acid at 0.2*M*, a HPO_4^{2-}/NaOH solution 0.50*M* in monoacid phosphate and a 1.0*M* sodium hydroxide solution.

Procedure

To a 50-ml flask were added a suitable volume of the pesticide stock solution in ethyl acetate, sufficient ethyl acetate to obtain a final organic phase volume of 2.0 ml, 1.0 ml of the 10% Triton X-405 solution, 2.0 ml of the Hyamine 2389 solution, and 25.0 ml of the appropriate buffer solution in that order; the solution was diluted to the mark with water. After shaking for a few seconds, the flask was placed in the ultrasonic bath for 3 min.

The emulsion obtained was transferred to the electrochemical cell and deaerated by passing an argon stream through it for 20 min (or longer times). Differential pulse polarograms were registered at $20 \pm 1°$ while keeping an inert atmosphere in the cell. Experimental conditions were : scan rate, 10 mV/sec; pulse amplitude, -50 mV, and $t = 0.5$ sec.

RESULTS AND DISCUSSION

Hydrolysis of endosulfan and endosulfan sulphate in basic medium

Some knowledge is now available about the hydrolysis of endosulfan and endosulfan sulphate in basic medium to form endosulfandiol (V).[7,8] We have found that this compound is electroactive in the emulsified medium used, giving rise to a well defined reduction peak at potential values between -1.16 and -1.18 V.

The hydrolysis reaction of both pesticides, at a concentration of $5.0 \times 10^{-5}M$, was studied in the pH range 9.0–13.0 by measuring i_p values of endosulfan, endosulfan sulphate and endosulfandiol for hydrolysis times between 20 and 80 min. Figure 1(a) summarizes data for pH 9.0 and 10.0, whereas in Fig. 1(b) peak current values are plotted as a function of time for pH 11.0 and 12.0. At pH 9.0, endosulfan is slowly

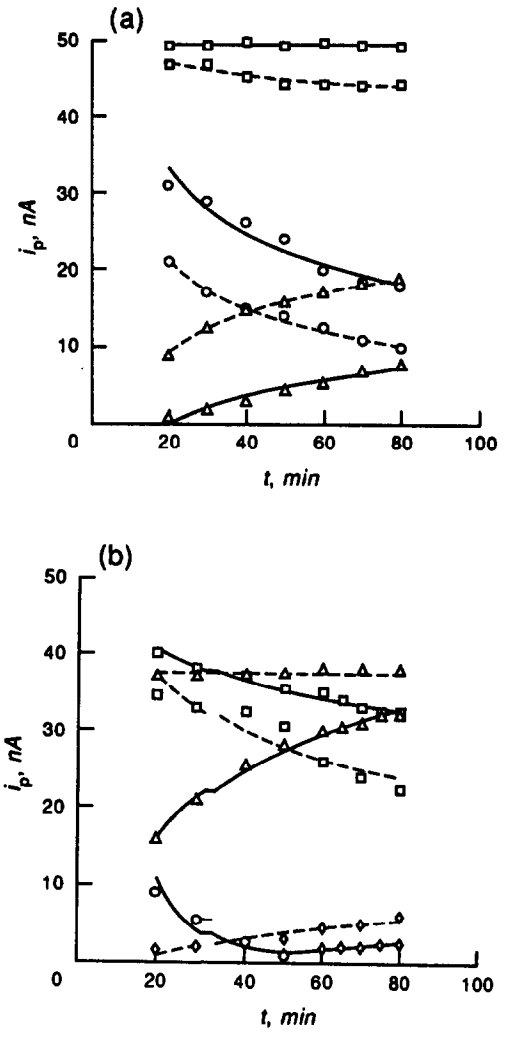


Fig. 1. Peak current as a function of time for $5.0 \times 10^{-5}M$ endosulfan and endosulfan sulphate in emulsified medium. (a) (——) pH 9.0; (-----) pH 10.0. (b) (———) pH 11.0; (– – – –) pH 12.0. (○) endosulfan; (□) endosulfan sulphate; (△) endosulfandiol (hydrolysis product of endosulfan); (◇) endosulfandiol (hydrolysis product of endosulfan sulphate). $\Delta E = -50$ mV; $v = 10$ mV/sec; $t = 0.5$ sec; 2.0 ml of ethyl acetate, 0.2% Triton X-405 + 0.2% Hyamine 2389.

hydrolysed (deaeration of the emulsion for 60 min gives an i_p value 35% lower than that obtained after 20 min deaeration) while endosulfan sulphate is practically unhydrolysed. At pH 10.0, the endosulfan hydrolysis rate is only slightly higher (i_p drop between 20 and 60 min is now 40%), and a very small decrease over time of the endosulfan sulphate peak current is observed (only 5% between 20 and 80 min), although it is not possible to yet see the endosulfandiol reduction peak [Fig. 2(A)]. At pH 11.0, the endosulfan peak [peak a of Fig. 2(B)] decreases sharply with time and practically disappears after 60 min, whereas the peak

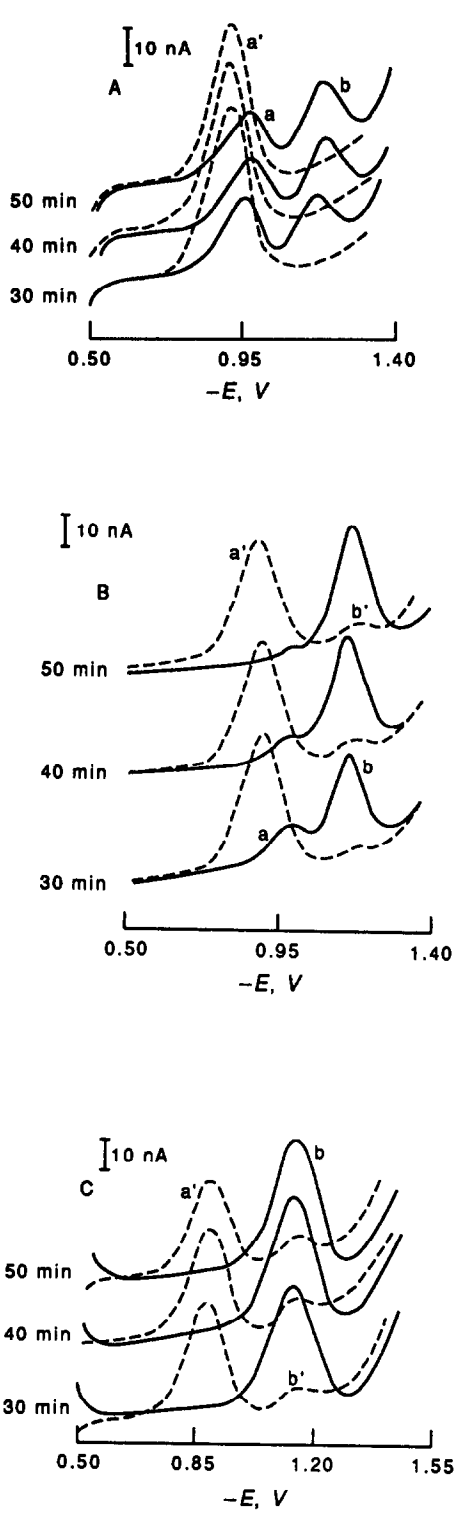

Fig. 2. Differential pulse polarograms of $5.0 \times 10^{-5}M$ endosulfan (solid line) and endosulfan sulphate (dashed line) in emulsified medium. (A) pH 10.0, (a) endosulfan, (b) endosulfandiol, (a′) endosulfan sulphate; (B) pH 11.0, (a) endosulfan, (b) endosulfandiol, (a′) endosulfan sulphate, (b′) endosulfandiol; (C) pH 12.0, (b) endosulfandiol, (a′) endosulfan sulphate, (b′) endosulfandiol; 2.0 ml of ethyl acetate, 0.2% Triton X-405 + 0.2% Hyamine 2389. $\Delta E = -50$ mV; $v = 10$ mV/sec; $t = 0.5$ sec.

corresponding to endosulfandiol [peak b of Fig. 2(B)] increases with time until reaching a practically constant value at 80 min. However, hydrolysis of endosulfan sulphate is still rather slow.

At pH 12.0, endosulfan is completely hydrolysed, even at 20 min, and only the endosulfandiol reduction peak is observed in the polarograms [Fig. 2(C)]. On the other hand, endosulfan sulphate is more quickly hydrolysed than at pH 11.0, and the polarograms show peaks of both endosulfan sulphate and endosulfandiol [Fig. 2(C)]. Finally, at pH 13.0, obtained in 0.1*M* sodium hydroxide, both pesticides are completely hydrolysed, although a hydrolysis time of at least 40 min is necessary to suppress the endosulfan sulphate peak.

Based on the above results, pH 11.0 was chosen to study the endosulfan–endosulfan sulphate mixture, as a compromise between a sufficiently rapid endosulfan hydrolysis and a sufficiently slow endosulfan sulphate hydrolysis; so a more detailed study of the hydrolysis reactions of these two pesticides at this pH value was carried out. Figure 3 shows ln $(i_p - i_{p\infty})$ versus time plots at 20° for endosulfan and endosulfan sulphate. Linear relationships were observed, indicating that the hydrolysis processes can be described by pseudo-first-order reactions. Apparent reaction rate constants obtained from the slopes of these plots were 7.4×10^{-2} and 8.5×10^{-3} sec^{-1} for endosulfan and endosulfan sulphate respectively.

The hydrolysis reactions of endosulfan and endosulfan sulphate were also studied at this pH value for a concentration level of $5.0 \times 10^{-6}M$

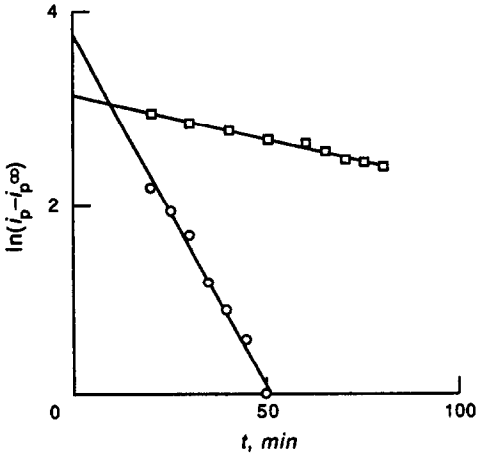

Fig. 3. Plots of $\ln(i_p - i_{p\infty})$ *vs.* time for the hydrolysis of endosulfan and endosulfan sulphate at pH 11.0 in emulsified medium. $5.0 \times 10^{-5}M$ (○) endosulfan; (□) endosulfan sulphate.

of both pesticides. Endosulfan hydrolysis is practically complete after 30 min, whereas the peak currents of endosulfandiol, coming from endosulfan, and of endosulfan sulphate (it is not possible to observe any endosulfandiol peak in this instance) remain practically constant between 30 and 80 min.

Kinetic curves of the hydrolysis of endosulfan and endosulfan sulphate mixtures at pH 11.0. The hydrolysis of endosulfan and endosulfan sulphate mixtures at pH 11.0 in the emulsified medium was studied. Figure 4 shows i_p values of the peaks of non-hydrolysed endosulfan and endosulfan sulphate and of endosulfandiol, formed as a hydrolysis product of both pesticides as a function of time for a fixed $5.0 \times 10^{-5}M$ endosulfan (*a*, *d*) or endosulfan sulphate (*c*, *b*) concentration when the endosulfan sulphate (*a*, *d*) or endosulfan (*b*, *c*) concentration is varied in the range 1.0×10^{-5}–$9.0 \times 10^{-5}M$. The curves obtained are fitted to equations of the type $i_p = -a + b \ln t$ (*b*, *d*) or $i_p = a\,t^{-b}$ (*a*, *c*). As can be observed, the decrease of the current with time for peak 1 is very similar for all the endosulfan sulphate concentrations studied [Fig. 4(a)], while peak currents are approximately the same after 80 min and practically coincident at 100 min when the endosulfan concentration is changed [Fig. 4(c)]. Furthermore, the endosulfandiol peak current is very similar for all endosulfan concentrations at short hydrolysis times, rising progressively faster with time as the endosulfan concentration increases [Fig. 4(b)]; when the endosulfan sulphate concentration is varied, i_p values tend to become the same at long hydrolysis times (100 min) [Fig. 4(d)].

All the above results led us to study the possibility of simultaneously determining the components of binary mixtures containing endosulfan and/or endosulfan sulphate. In order to accomplish this, calibration graphs for these components in the ranges 1.0×10^{-5}–$1.0 \times 10^{-4}M$ and 1.0×10^{-6}–$1.0 \times 10^{-5}M$ were prepared in the presence of the other mixture component at a constant concentration of $5.0 \times 10^{-5}M$ or $5.0 \times 10^{-6}M$ respectively.

Endosulfan–endosulfan sulphate mixture

Figure 4 suggests that both pesticides could probably be determined simultaneously at pH 11.0 by allowing the mixture to hydrolyse for 80–100 min, and then measuring the endosulfan sulphate peak for the determination of endosulfan sulphate and the endosulfandiol peak for the

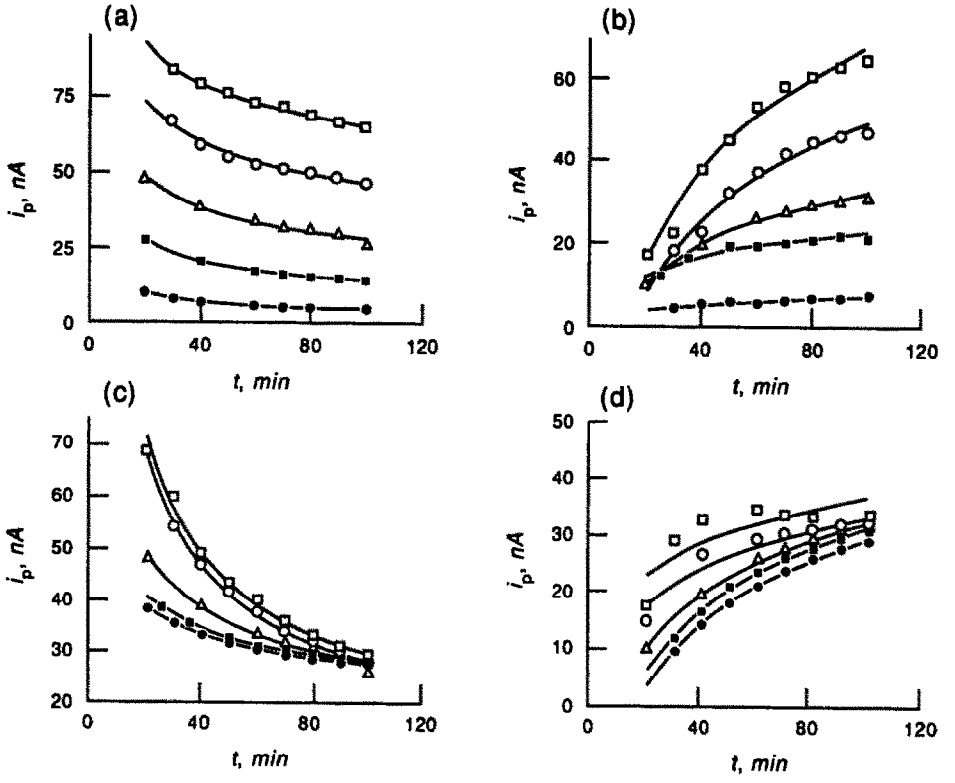

Fig. 4. Peak current as function of time of endosulfan and endosulfan sulphate mixtures at pH 11.0 in emulsified medium. (a) and (c), non-hydrolysed endosulfan and endosulfan sulphate peak current; (b) and (d) endosulfandiol peak current. (a, d), $5.0 \times 10^{-5}M$ endosulfan; (b, c), $5.0 \times 10^{-5}M$ endosulfan sulphate. (●) 1.0×10^{-5}, (■) 3.0×10^{-5}, (△) 5.0×10^{-5}, (○) 7.0×10^{-5} and (□) $9.0 \times 10^{-5}M$ endosulfan sulphate (a, d) or endosulfan (b, c).

determination of endosulfan. To confirm this, calibration graphs for endosulfan (via endosulfandiol) were obtained at 80 and 100 min keeping the endosulfan sulphate concentration constant. Linear calibrations were obtained for both hydrolysis times; the slopes and intercepts were quite similar (Table 1). Analogously, linear calibration graphs for endosulfan sulphate were obtained for the same hydrolysis times and keeping a constant endosulfan concentration; once more the slopes and intercepts were similar.

To obtain calibration graphs for both pesticides in the lower concentration range, keeping a constant concentration of the other pesticide of $5.0 \times 10^{-6}M$, it was enough to allow the mixture to hydrolyse for 30 min, as stated above. A linear calibration graph was obtained for endosulfan (via endosulfandiol) in the concentration range 4.0×10^{-6}–$1.0 \times 10^{-5}M$ (the

lower concentration is imposed by the proximity of the endosulfandiol peak to the medium reduction barrier), while the range of linearity for endosulfan sulphate was between 1.0×10^{-6} and $1.0 \times 10^{-5}M$; the characteristics of these calibration graphs are summarized in Table 1. In order to verify these results, the pesticides were simultaneously determined in mixtures containing 5.0×10^{-5} or $5.0 \times 10^{-6}M$ each of endosulfan and endosulfan sulphate. The results obtained from three determinations of each mixture yielded endosulfan sulphate contents of $(5.3 \pm 0.2) \times 10^{-5}M$ for a hydrolysis time of 80 min, and $(5.4 \pm 0.6) \times 10^{-6}M$ for a hydrolysis time of 30 min, while endosulfan concentrations were $(4.6 \pm 0.4) \times 10^{-5}M$ and $(4.7 \pm 0.6) \times 10^{-6}M$ respectively, the confidence intervals being calculated for a significance level of 0.05.

Dieldrin–endosulfan mixture

The analysis of this mixture is based on the observation that endosulfan, but not dieldrin, hydrolyses at pH 12.0. Indeed, at this pH value, endosulfan is practically completely hydrolysed after 20 min; however, dieldrin does not hydrolyse at all. Under these conditions, at pesticide concentrations of $5.0 \times 10^{-5}M$ the peak potential of the endosulfandiol formed (-1.18 V) is sufficiently different from the dieldrin peak potential (-0.98 V) to permit the simultaneous determination of the components of this mixture. A HPO_4^{2-}/NaOH mixture, $0.25M$ in monoacid phosphate, was used as buffer solution.

Calibration graphs for dieldrin and endosulfan (measuring the endosulfandiol peak current) at pH 12.0 were prepared in the presence of a constant concentration of endosulfan and dieldrin respectively, and were compared with those obtained in the absence of the latter. In the lower concentration range studied, the $5.0 \times 10^{-6}M$ endosulfan or dieldrin reduction peak prevents the accurate measurement of the dieldrin or endosulfan peak respectively for concentrations lower than $3.0 \times 10^{-6}M$.

The characteristics of the linear calibration graphs obtained are summarized in Table 2. These data show that the presence of endosulfan (actually endosulfandiol because endosulfan is completely hydrolysed at this pH value) affects the slope of the dieldrin calibration curves in both concentration ranges studied, and therefore the use of the standard additions method is necessary to determine dieldrin in the presence of endosulfan. However, the presence of dieldrin does not seem to significantly affect the slope in either concentration range when endosulfan (via endosulfandiol) is determined.

Dieldrin–endosulfan sulphate mixture

In order to carry out the simultaneous analysis of the components of this mixture it would be necessary to hydrolyse completely endosulfan sulphate to endosulfandiol in a sufficiently alkaline medium, without dieldrin undergoing hydrolysis in such a medium. As stated above, endosulfan sulphate hydrolysis is practically complete from pH 13.0, and therefore the analysis of this mixture was accomplished in $0.5M$ sodium hydroxide medium after deaerating the mixture for 30 min. Dieldrin peak potential and current values are the same as those obtained at pH 6.0,[6] thus confirming that this pesticide does not hydrolyse in that medium.

The possibility of obtaining calibrations for dieldrin and endosulfan sulphate (measuring the endosulfandiol peak) under the above-mentioned conditions was evaluated in the presence of either endosulfan sulphate or dieldrin. The characteristics of the calibration graphs obtained are summarized in Table 2, which also shows calibrations in this medium in the absence of endosulfan sulphate or dieldrin. The lowest concentration that can be accurately measured is $3.0 \times 10^{-6}M$ for both pesticides. The slopes of the dieldrin calibrations in the presence and absence of endosulfan sulphate suggest that the standard additions method must be used to determine dieldrin in the presence of endosulfan sulphate. Moreover, calibration graphs for dieldrin in the absence of endosulfan sulphate, in this $0.5M$ sodium hydroxide medium, have slopes very similar to those obtained at pH 6.0, which confirms that dieldrin does not undergo hydrolysis in the alkaline medium used. However, the slopes of the endosulfan sulphate calibration graphs (via endosulfandiol) in the presence and absence of dieldrin are not very different, which seems to indicate that dieldrin does not significantly influence the endosulfan sulphate calibrations.

Heptachlor-endosulfan sulphate mixture

As mentioned in the introduction, the direct simultaneous determination of the components of the heptachlor–endosulfan sulphate mixture should be possible. Indeed, the difference between the E_p values of the two pesticides at

	—	0.999	0.5 ± 0.3	10.1 ± 0.5

pH 8.0 in this emulsified medium is about 140 mV and polarograms of mixtures of these two pesticides showed two well-separated reduction peaks. In order to verify this simultaneous determination, heptachlor and endosulfan sulphate calibration graphs at pH 8.0 were prepared in the presence of the other pesticide, and were compared with those obtained in its absence.

In the lower concentration range studied, the endosulfan sulphate reduction peak prevents the accurate measurement of the heptachlor peak for concentrations lower than $3.0 \times 10^{-6}M$, and similarly, the $5.0 \times 10^{-6}M$ heptachlor reduction peak prevents the measurement of the endosulfan sulphate reduction peak at concentrations lower than $2.0 \times 10^{-6}M$.

Linear calibration graphs were obtained in all instances; their characteristics are summarized in Table 2. From these data it can be deduced that the simultaneous determination of heptachlor and endosulfan sulphate is possible, but the comparison of the calibration slopes obtained in the absence and in the presence of the other pesticide, in both concentration ranges studied, suggests the necessity of using the standard additions method to carry out the analysis of heptachlor in the presence of endosulfan sulphate and vice versa.

Other mixtures

Direct simultaneous determination of the components in the binary mixtures heptachlor–dieldrin and heptachlor–endosulfan is not possible. Separation methods need to be applied before polarographic determination. Similarly, mixtures of three of the pesticides studied and a mixture of all four cannot be

resolved directly, and separation methods also need to be applied before polarographic determination, as will be reported in a further paper. Nevertheless, from the above results it can be deduced that the determination of dieldrin is possible in the presence of endosulfan and endosulfan sulphate if a sufficiently basic working medium (0.5*M* sodium hydroxide) is used to achieve a complete hydrolysis of the last two pesticides. Likewise, the determination of endosulfan sulphate in the presence of heptachlor and endosulfan will be possible at pH 11.0, after allowing the practically complete hydrolysis of endosulfan.

CONCLUSIONS

Based on the hydrolysis of endosulfan and endosulfan sulphate in basic medium, and on their different hydrolysis rates, the simultaneous determination of the components of the organochlorine pesticide binary mixtures endosulfan–endosulfan sulphate, dieldrin–endosulfan and dieldrin–endosulfan sulphate is possible by dpp in emulsified medium. Endosulfan and endosulfan sulphate can be determined simultaneously at pH 11.0 by allowing the mixture to stand for 80–100 min, if concentration levels of both pesticides of about $10^{-5}M$ are involved, or for 30 min, if concentrations of about $10^{-6}M$ are involved, and then measuring the endosulfan sulphate peak to determine endosulfan sulphate and the endosulfandiol peak to determine endosulfan. The analysis of the mixture dieldrin–endosulfan can be achieved at pH 12.0 by allowing the endosulfan to hydrolyse completely (20 min) and then measuring the dieldrin and endosulfandiol peaks. Dieldrin and endosulfan sulphate can also be determined simultaneously in a 0.5*M* sodium hydroxide medium by allowing the endosulfan sulphate to hydrolyse completely (30 min) and measuring the dieldrin and endosulfandiol peaks. Also, the components of the mixture heptachlor–endosulfan sulphate can be determined directly at pH 8.0 in a Britton–Robinson buffer solution. The use of the standard additions method has been shown to be necessary in many cases to carry out analysis. Although this methodology does not attempt to be an alternative to gas chromatography for complex samples, it could be useful in some particular applications. Moreover, it is particularly interesting when the analytes can be extracted from the sample into organic solvents that are able to form emulsions.

FLOW INJECTION FLUORIMETRIC DETERMINATION OF THIAMINE AND COPPER BASED ON THE FORMATION OF THIOCHROME

T. PEREZ-RUIZ,* C. MARTINEZ-LOZANO, V. TOMAS and I. IBARRA
Department of Analytical Chemistry, Faculty of Sciences, University of Murcia, Murcia, Spain

(*Received* 14 *November* 1991. *Accepted* 2 *December* 1991)

Summary—The reaction, involving the oxidation of thiamine by copper(II) in basic solutions to fluorescent thiochrome, has been adapted to the determination of thiamine by flow-injection analysis. Linear calibration graphs are obtained between 0.30 and 6.02 μg/ml with a sampling rate of 50 samples/hr and a relative standard deviation of 0.53%. This reaction has also been adapted to the determination of copper(II) over the range 0.5–5.0 μg/ml. The applicability of both methods for determination of thiamine and copper is demonstrated by investigating the effect of potential interferences and by the analysis of real samples (pharmaceuticals for thiamine and ores and alloys for copper).

The thiamine (vitamin B_1) is a natural nutrient present in many foods and is also added as an essential nutrient. It has been used for the prevention and treatment of beriberi, neuralgia, *etc.* in medical doses or vitamin B_1 enriched foods or drinks. Since its discovery and isolation, several methods have been reported for determining this important compound, including microbiological methods, chromatography, direct molecular absorption spectroscopy, spectrofluorimetry, polarography, reaction-rate method and electrodes sensitive to vitamin B_1.[1–6]

The chemical methods most widely used involve the reaction between the vitamin and potassium hexacyanoferrate(III) in alkaline solution to form thiochrome (TC), which is then measured fluorimetrically;[2,7] this procedure is the official U.S.P. method[8] and has been automated by flow injection with fluorimetric[9] and chemiluminiscence detection.[10]

The oxidation of thiamine to fluorescent TC is always accompanied by the simultaneous formation of thiamine disulphide (TDS) a condensation product of two thiamine molecules. Oxidizing agents such as potassium permanganate, hydrogen peroxide and iodine favour the production of nonfluorescent TDS.[11]

However, the use of hexacyanoferrate(III) as oxidant in the thiochrome method suffers disadvantages since the yield of the reaction is about 67% and the extraction of TC is necessary in order to separate it from potassium hexacyanoferrate(III) which quenches the TC fluorescence.[12–13]

Apart from potassium hexacyanoferrate(III) other oxidizing agents have been used to oxidize thiamine such as cyanogen bromide,[14] copper(II),[15] mercury(II)[13,16,17] with a higher yield in thiochrome.

This paper describes a sensitive procedure for the determination of thiamine involving a simple FIA technique based on the oxidation of the vitamin to TC by Cu(II). The results of an extensive interference study and the application of the method to the determination of thiamine in multivitamin-mineral preparations are reported.

On the other hand, the reaction has also been applied to flow injection determination of copper. Many methods suitable for the determination of copper have been reported and some of these are based on flow injection analysis with the aim of developing fast, reliable and simple methods for routine analysis,[18] although the FIA methods with fluorimetric detection are scarce.[19–21] This paper reports a new fluorimetric flow injection method for the determination of copper with a reverse FIA mode (rFIA) based in the formation of thiochrome.

EXPERIMENTAL

Apparatus

A Perkin–Elmer model 3000 spectrofluorimeter connected to a Linseis 6512 recorder was

*Author for correspondence.

used as a detector with a Hellma 176.052 QS flow cell (inner volume 25 μl).

A Gilson Minipuls HP4 peristaltic pump, and an Omnifit injection valve were used. PTFE tubing of 0.5 mm i.d. was used for the mixing coil and for all connections.

Reagents

All chemicals used were analytical-reagent grade and doubly distilled water was used throughout.

Thiamine stock solution $10^{-3}M$ was prepared dissolving the solid (Sigma), previously dried, in water and adjust to pH 4 with hydrochloric acid. This solution was stable for months if kept refrigerated. Working solutions of vitamin B_1 were prepared daily and protected from light.

A stock solution of copper $10^{-2}M$ was prepared by dissolving copper nitrate (Merck) in distilled water and standardized by titration with EDTA. Working standard solutions were prepared from the stock solution by appropriate dilution with water.

Phosphate buffers prepared from $0.2M$ disodium or dipotassium hydrogen phosphate and sufficient $5M$ potassium hydroxide to give the desired pH. These buffers also contain NH_3 ($0.1M$) in order to hinder the Cu(II) precipitation.

Manifold

The manifold employed is shown in Fig. 1. The thiamine solution is introduced with the aid of an injection valve. The Cu(II) and the thiamine solution are mixed with the phosphate buffer solution in R_1. The reaction coil, R_2, is submerged in a water-bath, the temperature of which is adjustable. A timer, synchronized to the injection system allows the flow to be stopped for a given period of time.

Recommended procedure

Thiamine determination. The Cu(II) solution and the buffer solution were pumped at a rate of 2.8 and 0.9 ml/min respectively. A 185-μl sample, containing between 0.30 and 6.02 μg/ml of thiamine, was injected into the FIA manifold. The timer was programmed so that after 10 sec the flow stops for one minute and then the pump starts again. The TC fluorescence ($\lambda_{ex} = 370$ nm, $\lambda_{em} = 465$ nm) was measured and recorded.

Copper(II) determination. For copper(II) determination, good results were obtained between 0.5 and 5 μg/ml with the reverse FIA, using the same manifold shown in Fig. 1. The volume of thiamine injected was 185 μl.

Preparation of assay solutions

Tablets. Ten tablets are powered and an amount equivalent to one milligram of thiamine was weighed accurately and dissolved in *ca.* 100 ml of water. The solution was filtered through Whatman No. 1 filter-paper and the filtrate and two washings, each of 20 ml, were collected in a 1000-ml calibrated flask and diluted to volume with water.

Injections. An injection vial solution was shaken thoroughly and a volume equivalent to one milligram of thiamine is transferred into a 1000-ml calibrated flask and diluted to the mark with distilled water.

Ores and alloys. For analysis of copper in ores and alloys the sample (0.5–1.0 g) was digested with nitric acid and sulphuric acid. The residue was filtered off and washed filtrate and washing were combined, evaporated nearly to dryness, diluted with doubly distilled water and evaporated again to low volume to reduce the acidity. The solution is transferred into a 50-ml standard flask and diluted to volume with doubly distilled water.

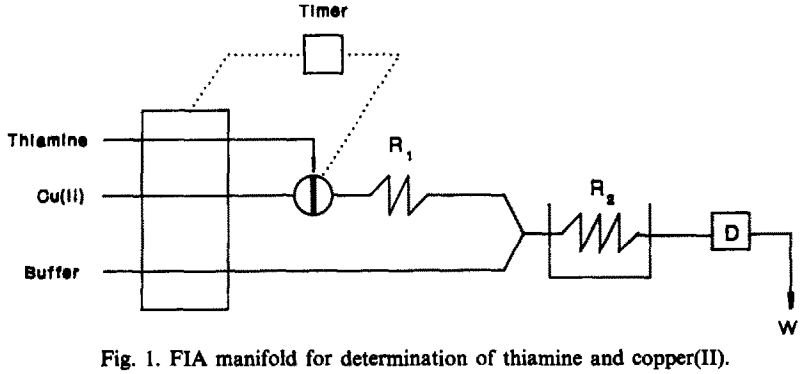

Fig. 1. FIA manifold for determination of thiamine and copper(II).

RESULTS AND DISCUSSION

When thiamine is oxidized by Cu(II) in a FIA system the largest yield of TC is obtained at a high Cu(II) concentration and in an alkaline medium. The time taken to reach equilibrium decreases with increasing Cu(II) and OH^- concentrations.

Optimization of variables

The investigation of the effect of the chemical and FIA variables on the fluorescence intensity were performed by altering each variable in turn, while keeping the others constant.

As the reaction rate is pH dependent (Fig. 2) the reaction mixture must be well buffered. The buffer solution selected was 0.2*M* in phosphate and 0.1*M* in ammonia because it provides a good buffering capacity at pH 12, precision in the measurements and avoided the precipitation of copper.

On the other hand, the order of addition of the reagents is critical. The thiamine must be mixed with Cu(II) before the addition of the buffer, in order to achieve that thiamine be stabilized by the formation of a complex with Cu(II), which can be easily oxidized to TC when the base is added.

The effect of copper(II) concentration was investigated (Fig. 3) and $5 \times 10^{-4}M$ was selected.

The influence of the temperature exerts the opposite effect, both on the reaction development (positive effect) and on the fluorescence emission (negative effect). The net effect is a decrease of the fluorescence intensity with increasing temperature. A temperature of 30° was selected to obtain an appropriate peak height.

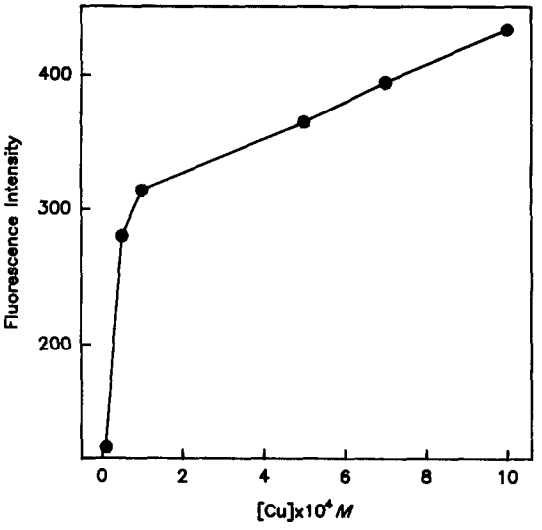

Fig. 3. Influence of pH on peak height other conditions as Fig. 2.

The influence of the flow-rate of each channel on the analytical signal was studied. Maximum peak height was obtained at flow-rates of 2.9 ml/min for the copper(II) line and 0.8 ml/min for the buffer line.

The effect of loop size and length of the coil R_2 is shown in Fig. 4. The optimum values for these variables are sample injection volume = 185 μl and reactor length $R_2 = 100$ cm. A 100-cm reaction coil R_1 was selected in order to ensure the formation of the complex thiamine–Cu(II) before merging with the buffer line.

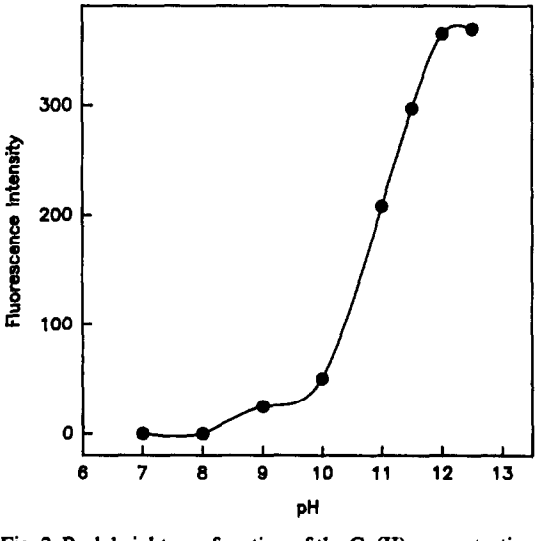

Fig. 2. Peak height as a function of the Cu(II) concentration. Sample volume 185 μl, $10^{-5}M$ thiamine, 0.2*M* phosphate buffer pH 12, flow-rate 2.8 ml/min and stop-time 1 min.

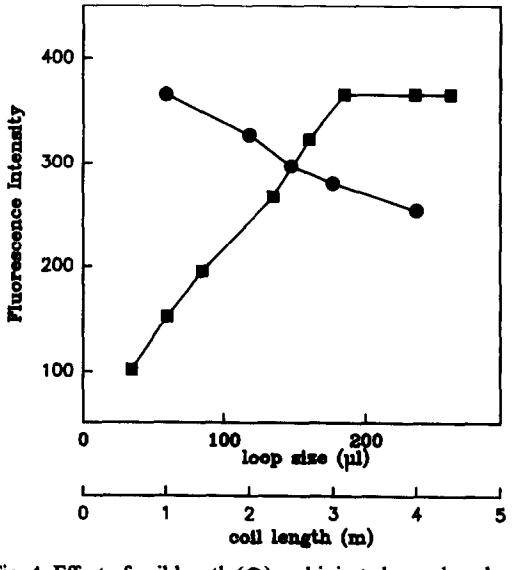

Fig. 4. Effect of coil length (●) and injected sample volume (■) on the peak height.

The peak height increased with increasing residence time because the oxidation of the thiamine to TC by Cu(II) is not very fast. The best results were obtained if the pump was stopped when the plug was located in the reaction coil R_2. After a given period of time the pump was triggered by a timer and the reaction zone was directed toward the detector. The timer was programmed so that after 10 sec the flow stops for one minute as a compromise between analytical signal and sampling rate.

Determination of thiamine

A series of standard solutions were injected in triplicate to test the linearity of the calibration graphs. The calibration graph was found to be linear from 0.30 to 6.02 μg/ml. The least-squares calibration equation was $I_F = 4.29 + 118C$ ($r = 0.9996$) where the concentration (C) was measured in μg/ml and the fluorescence intensity I_F in arbitrary units. The sampling rate is about 40 samples/hr. The statistical study performed on two series of 10 samples of 0.75 and 3.01 μg/ml of thiamine yielded a RSD of 0.54 and 0.52% respectively. The limit of detection was 0.17 μg/ml and the quantification limit was 0.23 μg/ml.

Interferences

An extensive interference study aimed at the determination of thiamine in vitamin-mineral preparations was performed. Samples containing a fixed concentration of thiamine (3 μg/ml) and various concentrations of the foreign substances were injected into the FIA system. A substance was considered not to interfere if the variation in the peak height of thiamine was less than $\pm 3\%$ in its presence. The results are shown in Table 1.

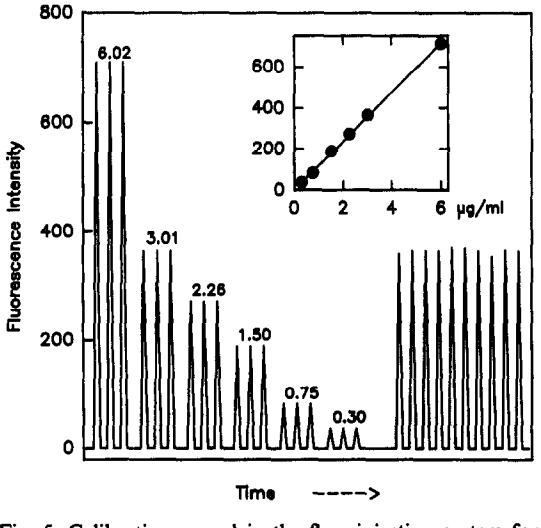

Fig. 5. Calibration record in the flow injection system for triplicate injections of 185 μl of thiamine standard solutions. Values on the peaks represent concentrations in μg/ml.

Analysis of pharmaceutical dosage forms

The proposed method was applied to the determination of thiamine in pharmaceutical dosage forms. Commercially available formulations were analysed and the results obtained are summarized in Table 2.

As can be seen for all the formulations, the assay results were in good agreement with the declared content.

Determination of copper

The oxidation of the thiamine to thiochrome by Cu(II) was also applied to the fluorimetric determination of copper using a reverse FIA mode.

Optimization of the flow system

Of all the FIA techniques tested the best results were obtained with the reverse mode

Table 2. Determination of thiamine in pharmaceutical preparations

Sample*	Source	Thiamine content, *mg*	Thiamine found, *mg*†	% Error
Benerva	Roche	100	103.8	3.3
Betabion	Merck	100	98.5	1.5
Nervobion	Merck	100	99.8	0.2

*Composition of samples. Benerva: thiamine, 100 mg; water, 1 g. Betabion: thiamine 100 mg; water 2 g. Nervobion: thiamine, 100 mg; pyridoxine, 100 mg; cyanocobalamine 1000 γ.
†Average of four determinations.

shown in Fig. 1, because it resulted in an increase in sensitivity and a decrease in the number and level of interferences. The optimum values for the variables are flow-rates of the buffer line of 0.5 ml/min and the sample line of 1 ml/min, injection volume of thiamine ($2 \times 10^{-5}M$) of 185 μl, and length of the first coil (R_1) of 100 cm and the second coil (R_2) of 200 cm.

The timer was programmed so that after 10 sec, when the sample zone was in the reactor R_2, the flow was stopped for 60 sec and the pump started again.

Calibration graph

Under the recommended conditions the peak height *vs.* copper concentration was linear in the range 0.5–5 μg/ml. The least-squares calibration equation was $I_F = 3 + 81.3C$ ($r = 0.9994$) where the concentration (C) is measured in μg/ml. The sampling rate is 35 samples/hr. The repeatability of the method is good; two standard solutions containing 2.54 and 1.27 μg/ml were injected 10 times and relative standard deviations of 0.644 and 0.371% were obtained respectively.

Interferences

An interference study aimed at the determination of copper in alloys and ores was performed. Samples containing a fixed concentration of Cu(II) (0.64 ppm) and various concentrations of foreign substances were analysed in the flow system. The results are shown in Table 3.

Copper determination in real samples

In order to check the validity of the proposed method, it has been applied satisfactorily to the determination of copper in real samples, alloys and ores certified by Gebr. Hoepfner of Hamburg. The results obtained are summarized in Table 4 and showed a good agreement with the certified values.

STUDIES ON THE EQUILIBRIA OF *o*-PHTHALIC AND PHOSPHORIC ACIDS IN MIXED DIMETHYL SULPHOXIDE–WATER MIXTURE

H. A. AZAB

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(*Received* 8 *July* 1991. *Revised* 18 *November* 1991. *Accepted* 29 *November* 1991)

Summary—The secondary dissociation constants of *o*-phthalic and phosphoric acids have been determined in 50% w/w dimethyl sulphoxide–water from reversible emf measurements of the cell of the type: Pt, H_2 (1 atm), M_2A (m), MHA (m), MCl, AgCl; Ag at different temperatures (288.15–308.15 K) and at different ionic strengths. To minimize the unsteadiness in potential measurements palladium-coated platinum electrodes have been used. The large set of such emf values has been analysed in terms of a multi-linear regression method recommended in recent IUPAC documents. The thermodynamic values $\Delta G°$, $\Delta H°$, $\Delta S°$ for the respective equilibria were estimated. The possibility of using these acids as a basis for some buffer solutions in 50% dimethyl sulphoxide (Me_2SO)-water mixture is discussed.

Many potentiometric equilibrium measurements have nevertheless, been made in mixed solvents on the basis of calibration with aqueous buffers.[1–5] The meter reading, pH(R), obtained in a partially aqueous or non-aqueous medium differs by an amount, δ, from the reading, pH*, obtained when the meter is standardized with appropriate standard pH* buffers. This method is not a procedure of high accuracy as the asymmetry potential of the glass electrode is likely to vary when the electrode is removed from the aqueous standardizing medium and then immersed in the solvent system in which measurement is to be made.[6] The study of the dissociation equilibria of phosphoric and *o*-phthalic acids in water[7–10] has permitted the combination of a series of standard aqueous buffer solutions. The standardization of pH* measurements in mixed solvents, needs similar studies regarding the dissociation equilibria of certain adequate electrolytes in these solvents.[11–17] In the present work the second-stage dissociation constants of phosphoric and *o*-phthalic acid in 50% w/w dimethyl sulphoxide (Me_2SO)–water mixture have been determined in continuation to work in the field of preparing standard buffer solutions.[10,18,19]

EXPERIMENTAL

All reagents used were of AnalaR(BDH) grade. All stock solutions were prepared in doubly-distilled air free conductivity water. 50% Dimethyl sulphoxide-water mixtures were prepared by mixing appropriate weights of analytical grade dimethyl sulphoxide, fractionally distilled before use, with conductivity water. Owing to the low solubility of dipotassium hydrogen phosphate in the given solvent, disodium hydrogen phosphate was used. *o*-Phthalic acid, potassium chloride, certified ULTREX Baker potassium hydrogen phthalate, before use, were dried at 110°. The potentiometric equilibrium measurements, using the electrochemical cell provided with a hydrogen electrode were carried out with an OP-208 Radelkis digital millivolt meter–pH meter accurate to $\pm 1 \times 10^{-4}$ V. To minimize the instability in potential measurements palladium-coated platinum electrodes have been used.[20]

The silver–silver chloride electrode was of the thermoelectrolytic type and was prepared in the laboratory.[21] It was immersed for 24 hr in a solution of pure hydrochloric acid (0.05*M*) and tested in a cell of the type:

$$(Pt)H_2/HCl(0.1M)/AgCl;\ Ag$$

whose emf must equal 0.3523 V; this corresponds to a standard potential of 0.2223 V of the Ag; AgCl, Cl^- ($a = 1$) electrode. Several electrodes were prepared and those were used whose potential did not differ by more than ± 0.0001 V from the standard value. The values of the standard potential of the Ag/AgCl electrode, ${}_sE°_{AgCl}$, in 50% dimethyl sulphoxide–

Table 1. Values of ${}_sE^\circ_{AgCl}$ in 50% dimethyl sulphoxide–water mixture at different temperatures

293.15	0.2206
298.15	0.2164
303.15	0.2121
308.15	0.2073

H_2O mixture at different temperatures (288.15–308.15 K) have been determined and are given in Table 1. Each measured emf value was corrected to 1 atm (101325 Pa) pressure of hydrogen from the barometic pressure and the vapor pressure of the solution, the latter being taken as the same as the vapor pressure of the solvent.[22–24] An average of about four independent cells were measured at each electrolyte molality and at each temperature. The large set of such emf values has been analysed in terms of a multilinear regression method recommended in recent IUPAC documents.[25]

RESULTS AND DISCUSSION

Electrochemical cell without liquid junction potential of the type:

$$\text{Pt; } H_2 \text{ (1 atm), } M_2A(m), \text{ MHA}(m), \text{ MCl}(m), \text{ AgCl; Ag} \quad (1)$$

has been used in the determination of pK_{a_2} values of *o*-phthalic and phosphoric acids in 50% w/w dimethyl sulphoxide–water mixture at different temperatures (288.15–308.15 K), where A^{2-}, represents the $C_6H_4(COO)_2^{2-}$ and HPO_4^{2-} anions and M^+ the Na^+ or K^+ cations.

The emf of cell (1) is given by:

$$E = {}_sE^\circ_{AgCl} - \frac{RT}{F}\ln a_{H^+} \cdot a_{Cl^-} \quad (2)$$

$$= {}_sE^\circ_{AgCl} - \frac{RT}{F}\ln a_{H^+} \cdot m_{Cl^-} \cdot \gamma_{Cl^-} \quad (3)$$

For the equilibrium under study

$$HA^- \rightleftharpoons A^{2-} + H^+$$

one can write

$$K_2 = \frac{a_{H^+} \cdot m_{A^{2-}} \cdot \gamma_{A^{2-}}}{m_{HA^-} \cdot \gamma_{HA^-}} \quad (4)$$

from equations (3) and (4):

$$E - {}_sE^\circ_{AgCl} = -\frac{RT}{F}\ln \times \left[K_2 \frac{m_{Cl^-} \cdot m_{HA^-}}{m_{A^{2-}}}\left(\frac{\gamma_{HA^-} \cdot \gamma_{Cl^-}}{\gamma_{A^{2-}}}\right)\right] \quad (5)$$

Taking the salt concentrations so that $m_{Cl^-} = m_{HA^-} = m_{A^{2-}} = m$, the relationship (5) takes the following form:

$$pK_{a2} - \log\left(\frac{\gamma_{Cl^-} \cdot \gamma_{HA^-}}{\gamma_{A^{2-}}}\right) = \frac{F(E - {}_sE^\circ_{AgCl})}{2.303RT} + \log m \quad (6)$$

The term containing the activity coefficients can be approximated at ionic strengths smaller than 0.1 by means of the Debye–Hückel equation:

$$\log\left(\frac{\gamma_{Cl^-} \cdot \gamma_{HA^-}}{\gamma_{A^{2-}}}\right) = \frac{2AI^{1/2}}{1 + Ba^\circ I^{1/2}} - \beta I \quad (7)$$

where A and B are the constants of the Debye–Hückel equation for the respective solvents which were derived for 50% w/w dimethylsulphoxide from the expressions given by Robinson and Stokes:[26]

$$A = (1.825 \times 10^6)/(\epsilon T)^{1/2} \text{ mole}^{-1/2} \text{ L}^{1/2} K^{1/2}, \quad (8)$$

$$B = 50.29/(\epsilon T)^{1/2} \text{ mole}^{-\frac{1}{2}} \text{ L}^{1/2} K^{1/2} \quad (9)$$

β is the salting out parameter and a° the "ion-size" parameter which has been assigned the widely used value of 4.4 A° in the present calculation. Electric permittivities (ϵ), necessary for the calculation of Debye–Hückel constants, for solvents containing Me_2SO were not available in the literature for temperatures other than 25°.[27–29] However, it was observed from the data of Akerlof[30] that the relationship between the log of the electric permittivity and temperature is linear and that the gradients of the lines for various organic solvents and their aqueous mixtures are essentially parallel. This provided an acceptable method of extrapolating the measured electric permittivities for Me_2SO–H_2O mixtures at 25°.[27–29] An equation for the least-squares regression line for the relationship between $\log \epsilon_{H_2O}$ and temperature was derived from the data given by Hamer.[31]

$$\log \epsilon = -0.00197t + 1.9431 \quad (10)$$

The Debye–Hückel constants for 50% w/w Me_2SO–H_2O mixtures at temperatures other

than 25° were calculated with electric permittivities estimated from the known difference between ϵ_{H_2O} and the electric permittivity for the mixed solvent at 25° by extrapolating the difference to different temperatures. Combination of equation (6) and (7) results:

$$pKa_2 + \beta I = \frac{(E - {}_sE^\circ_{AgCl})F}{2.303RT} + \log m + \frac{2AI^{1/2}}{1 + Ba^\circ I^{1/2}} \quad (11)$$

Representing graphically the right hand side of equation (11) versus concentration (m) one obtains a straight line intersecting the ordinates at pKa_2.

Seven cell solutions containing hydrochloric acid at molalities ranging from 0.05 to 0.005 m were tested for the emf measurements leading to the standard potential of the silver–silver chloride electrode. The standard potential E_m, on the molality scale was obtained by extrapolation of the function ($E^{\circ\prime}$) of the emf, E, to $m = 0$:

$$E^{\circ\prime} \equiv E^\circ_m - bm = E + 2k \log m - \frac{2kAm^{1/2}}{1 + Ba^\circ m^{1/2}} \quad (12)$$

This function is derived from the Nernst equation, where a Debye–Hückel expression has been included to approximate the mean activity coefficient of hydrochloric acid. The term k is written for $RT \ln 10/F$ and the Debye–Hückel constant A and B were calculated as mentioned above.

By using ${}_sE^\circ_{AgCl}$, we obtain the acidity function $P_s(a_H \cdot \gamma_{Cl})$ from the emf of the hydrogen–silver chloride cell (1) containing the standard solutions (with added chloride) in dimethyl sulphoxide–water medium.[32]

$$P_s(a_H \cdot \gamma_{Cl}) = \frac{(E - {}_sE^\circ_{AgCl})F}{2.303RT} + \log m_{Cl} \quad (13)$$

and then pa_{H^*} by the nonthermodynamic step

$$pa_{H^*} = P_s(a_H \cdot \gamma_{Cl}) + \log \gamma_s Cl \quad (14)$$

Data for the experimental measurements of the emf of cell (1) at different temperatures (288.15 – 308.15 K) and different ionic strengths are given in Tables 2 and 3 for both *o*-phthalic and phosphoric acid in 50% w/w dimethyl sulphoxide–water medium. As the concentration of the supporting electrolyte increased, the salting out effect is observed. This is because the activity coefficient of the

Table 2. Experimental data obtained by electrochemical cell (1) for $C_6H_4(COOK)_2(m) + HKC_6H_4(COO)_2(m) + KCl(m)$ in dimethyl sulphoxide–water mixture 50% w/w

acids have been calculated and are given in Table 6.

The need for reliable pH measurements at different temperatures in mixed solvents such as dimethyl sulphoxide (Me_2SO) and water has become increasingly apparent in the studies of the preservation of biological cells, tissues, and organs.[34,35] The data obtained in the present report can be used for preparing standard buffer solutions for p*a*H* measurements in 50% DMSO–water mixture at different temperatures (288.15–308.15 K) as shown in Tables 2 and 3.

ELECTROCHEMICAL STUDY OF SOLVENT EXTRACTION WITH 8-QUINOLINOLS AS COMPLEXING AGENT— I. DISTRIBUTION BEHAVIOR OF 8-QUINOLINOLS

SINRU LIN

Shanghai Institute of Metallurgy, Chinese Academy of Sciences, Shanghai 200050, China

HENRY FREISER

Strategic Metals Recovery Research Facility, University of Arizona, Tucson, AZ 85721, U.S.A.

(*Received* 31 *May* 1991. *Revised* 27 *November* 1991. *Accepted* 30 *November* 1991)

Summary—The distribution behavior of 8-quinolinols (HQ) in organic and acidic aqueous solutions (or alkaline solutions) was electrochemically examined by current scan polarography and chronopotentiometry. It follows from the results that the half wave potential of the observed polarographic waves, corresponding to the Faradaic transfer of quinolinolium ions (or oxinate ions) formed in the aqueous solution after distribution of quinolinols is dependent on the dissociation constant of H_2Q^+ (or HQ) and the pH of the aqueous solution, but independent of the distribution constant of 8-quinolinols.

Previous work on tervalent lanthanide ions extracted by 1,2-dichloroethane with 4-acyl-5-pyrazolones as chelating agent[1] demonstrated that powerful insights into the mechanisms of ion transfer processes in a solvent extraction system can be gained by electrochemical study of ITIES (interface of two immiscible electrolyte solutions). 8-Quinolinol has a hydrogen atom which can be replaced by a metal ion and a heterocyclic nitrogen which form a five-membered chelate ring with this metal ion, so it is one of the most useful and versatile chelating agents in metal ion extraction. This report is aimed at learning more about the distribution behavior of 8-quinolinol and some of its derivatives.

EXPERIMENTAL

Apparatus

Current scan polarography at the ascending water electrode (AWE), constant current chronopotentiometry and current reversal chronopotentiometry at the stationary water electrode (SWE) were employed. The electrolytic cell, apparatus and experimental procedures were described previously.[1–5]

Materials

The organic phase solvents used were nitrobenzene (NB) and 1,2-dichloroethane (DCE). Tetraheptylammonium tetraphenylborate (THA^+, TPB^-) was used as the supporting electrolyte in the organic phase.

8-Quinolinol (Eastman Kodak Co.) and its 2-methyl-, 5-chloro-, 5-nitro- and 5,7-dibromo-derivatives (Aldrich Chemical Company, Inc.) were used without further purification.

RESULTS AND DISCUSSION

A well-defined anodic wave at the AWE was obtained when 8-quinolinol (HQ) in NB was in contact with 1*M* magnesium sulphate solution with pH <4 (Fig. 1). The wave has the following characteristics:

(a) The limiting current (i_l) is proportional to the initial concentration of 8-quinolinol in NB and is essentially independent of the pH of the aqueous phase.

(b) The half-wave potential ($\Delta_0^a E_{1/2}$) is linearly dependent on the pH of the aqueous solution with a slope of 56 mV/pH (the experimental error for the half-wave potential is ± 4 mV).

(c) The variation of $\log[i/(i_l - i)]$ with $\Delta_0^a E$ is linear with a slope of 53 mV.

Hence, it can be seen from the characteristics that the limiting current is controlled by diffusion of 8-quinolinol in NB and that the cationic species, whose Faradaic transfer from the aqueous into the organic phase results in the wave, is singly charged. Constant current chronopotentiometry at the SWE was carried out to further test this interpretation (Fig. 2).

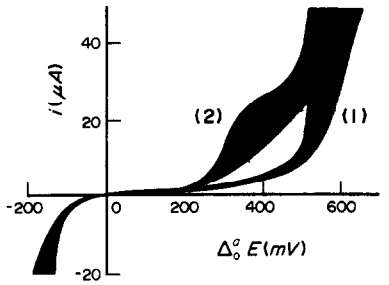

Fig. 1. Current scan polarograms of 8-quinolinol in nitrobenzene. Aqueous phase: 1*M* $MgSO_4$, pH 2.5. NB phase: (1) 20m*M* THA^+, TPB^-; (2) 20m*M* THA^+, TPB^- + 0.3m*M* 8-quinolinol.

It was found that the product of the applied current and the square root of transition time ($i\tau^{1/2}$) is independent of the applied current. The diffusion coefficient of 8-quinolinol in NB, evaluated from the data according to the Sand equation, was found to be $8.1(\pm 0.3) \times 10^{-6}$ cm^2/sec. Figure 3 shows the effect of the standing time (t_s) of the SWE on τ of the anodic chronopotentiometry (*i.e.*, before the electrolysis system is subjected to a controlled current, the SWE is allowed to stand in contact with the organic phase for a time t_s). It is seen that $\tau^{1/2}$ increases linearly with $t_s^{1/2}$, indicating that the singly charged cation accumulates in the aqueous phase during t_s. Inasmuch as the amount of the proton in the aqueous electrolyte remains constant, the cation transferring across the interface must be the 8-quinolinolium ion (H_2Q^+), which forms in the aqueous phase after HQ distributes there. When AWE and SWE experiments were repeated with HQ initially in the aqueous phase, waves with identical half-wave potentials to those of the previous experiments were obtained at the AWE, but with the

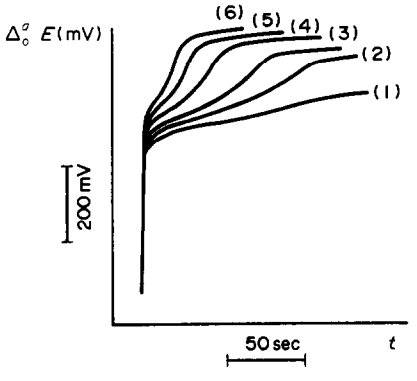

Fig. 2. Constant current chronopotentiograms at SWE. Aqueous phase: 1*M* $MgSO_4$, pH 2.5. NB phase: 20m*M* THA^+, TPB^- + 0.3m*M* 8-quinolinol. Current (μA): (1) 3, (2) 3.5, (3) 4, (4) 5, (5) 6, (6) 7. Surface area of SWE: 0.41 cm^2.

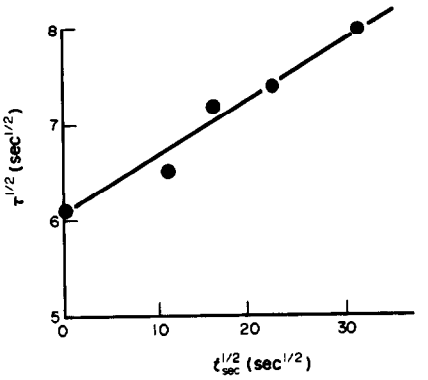

Fig. 3. Effect of standing time on transition time at SWE. Aqueous phase: 1*M* $MgSO_4$, pH 2.5. NB phase: 20m*M* THA^+, TPB^- + 0.3m*M* 8-quinolinol. Current: 5 μA. Surface area of SWE: 0.41 cm^2.

SWE no variation of τ with t_s was observed, entirely in keeping with the explanation of the transfer process given above.

Well-defined anodic waves were also observed when NB contained 2-methyl-8-quinolinol or 5-chloro-8-quinolinol, but no wave appeared when the organic phase contained 5-nitro- or 5,7-dibromo-quinolinol. The characteristics of the waves observed are the same as those of the 8-quinolinol wave, whereas the 2-methyl-8-quinolinolium wave appears at 40 mV less positive $\Delta_0^a E_{1/2}$ while the 5-chloro-8-quinolinolium wave is 75 mV more positive. The following discussion will give the explanation for the difference in $\Delta_0^a E_{1/2}$ among quinolinols.

As shown previously,[2,4] the half wave potential of the protonated wave can be expressed as follows:

$$\Delta_0^a E_{1/2,H_2Q^+} = \Delta_0^a E^0_{H_2Q^+} + \frac{RT}{2nF} \ln \frac{D_{HQ,O}}{D_{H_2Q^+,O}} + \frac{RT}{nF} \ln(K_{D,HQ} K_{a,H_2Q^+}) - \frac{RT}{nF} \ln H^+ \quad (1)$$

where $\Delta_0^a E^0$ is the standard potential difference, D the diffusion coefficient, $n = 1$, subscript 0 stands for the organic phase (none is used for aqueous phase),

$$K_{D,HQ} = \frac{[HQ]_0}{[HQ]} \quad (2)$$

$$K_{a,H_2Q^+} = \frac{[H^+][HQ]}{[H_2Q^+]} \quad (3)$$

As is known,

$$\Delta_0^a E^0_{H_2Q^+} = \frac{\Delta G^{0,a\to 0}_{tr,H_2Q^+}}{F} = -\frac{RT}{F} \ln K_{D,H_2Q^+} \quad (4)$$

Table 1. Comparison of observed and reported pK_a values

	I			II		
	$H_2Q^+ \overset{K_{a,H_2Q^+}}{\rightleftharpoons} H^+ + HQ$			$HQ \overset{K_{a,HQ}}{\rightleftharpoons} H^+ + Q^-$		
	$\Delta\Delta_0^a E_{1/2}$, mV	pK_a		$\Delta\Delta_0^a E_{1/2}$, mV	pK_a	
	Observed	Calculated*	Reported	Observed	Calculated*	Reported
8-Quinolinol			4.99[6]			9.66[6]
2-Methyl-8-quinolinol	−40	5.67	5.77[7]	37.5	9.02	10.04[7]
5-Chloro-8-quinolinol	76	3.72	3.68[8]	75	8.39	10.45[8]
5,7-Dibromo-8-quinolinol	/	/	2.6[9]	176	6.69	7.3[9]

*Calculated value with observed $\Delta\Delta_0^a E_{1/2}$ and equation (8).

$\Delta G_{tr,H_2Q^+}^{0,a\to 0}$ in equation (4) is the standard Gibbs energy of transfer of protonated quinolinols from the aqueous to the organic phase and

$$K_{D,H_2Q^+} = \frac{[H_2Q^+]_0}{[H_2Q^+]} \quad (5)$$

In the Yoshida and Freiser's report,[2] a comparison of a series of phenanthrolines indicates that the difference between $\ln K_D$ of neutral and protonated species is a constant factor, *i.e.*,

$$\ln K_{D,H_2Q^+} = \ln K_{D,HQ} - C \quad (6)$$

where C is a constant.

From equations (1), (4) and (6) we have the expression,

$$\Delta_0^a E_{1/2,H_2Q^+} = \frac{RT}{2F} \ln \frac{D_{HQ,O}}{D_{H_2Q^+,O}} + \frac{RT}{F} \ln K_{a,H_2Q^+} - \frac{RT}{F} \ln H^+ + \frac{RT}{F} C \quad (7)$$

The above equation indicates that if the difference between D_{HQ} and $D_{H_2Q^+}$ in the organic phase is negligible, $\Delta_0^a E_{1/2}$ of the wave for transfer of protonated 8-quinolinols is independent of their K_D values. It follows from equation (7) that if the organic solutions of 8-quinolinol and its derivatives are in contact with the aqueous solutions with the same pH, the difference in $\Delta_0^a E_{1/2}$ arises from the difference of their K_a values:

$$pK_{a,H_2Q^+}^d = pK_{a,H_2Q^+}^p - \frac{\Delta\Delta_0^a E_{1/2}}{59} \quad \text{(at 25°)} \quad (8)$$

where $\Delta\Delta_0^a E_{1/2}$ (in mV) $= \Delta_0^a E_{1/2}^d - \Delta_0^a E_{1/2}^p$, superscript d and p stand for derivative and parent, respectively. It can be seen from part I in Table 1 that the results observed coincide with those reported. Obviously, no protonated wave will be observed in 8-quinolinol systems under conditions in this work if the pK_{a,H_2Q^+} is smaller than about 3, because the wave shifts to such a positive value that it would be overlapped by the background current. 5-Nitro- and 5,7-dibromo-derivatives are such cases.

8-Quinolinols have an amphoteric nature. They form 8-quinolinolium ions with protons in acidic solutions and oxinate ions (Q^-) by deprotonation in alkaline solutions. Cathodic waves, which correspond to the Faradaic transfer of oxinate ions from the alkaline aqueous phase into the DCE phase, were observed (Fig. 4). For 8-quinolinol and its 2-methyl derivative, the well-defined cathodic wave can be observed when their DCE solutions are in contact with sodium hydroxide solution $\geqslant 0.1M$. For 5-chloro-8-quinolinol, the wave can be observed with sodium hydroxide solution $\geqslant 0.01M$ and for 5,7-dibromo-8-quinolinol with sodium hydroxide solution $\geqslant 10^{-4}M$ ($0.5M$ sodium sulphate as supporting electrolyte). The heights of these waves are proportional to the amount of 8-quinolinols in the DCE phase and independent of the sodium hydroxide amount in the aqueous phase. The half wave potentials of the waves shift by about 52 mV more positive with one decade increase in the sodium hydroxide concentration. The difference in $\Delta_0^a E_{1/2}$ between 8-quinolinol and its derivatives observed is

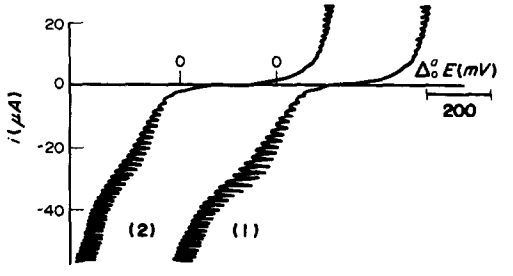

Fig. 4. Current scan polarograms of 5,7-dibromo- and 5-chloro-8-quinolinol in 1,2-dichloro-ethane. Aqueous phase: $1M$ NaOH. DCE phase: 10mM THA^+, TPB^- + (1) 0.3mM 5,7-dibromo-8-quinolinol; (2) 0.3mM 5-chloro-8-quinolinol.

listed in part II of Table 1. If the neutral and the deprotonated 8-quinolinols have the relationship expressed by equation (6) the $pK_{a,HQ}$ values of 8-quinolinols should decrease in the order from the parent to 2-methyl, 5-chloro and 5,7-dibromo derivatives according to their $\Delta_0^a E_{1/2}$ with equation (8), whereas the values reported in the references are not in keeping with the order. For the case of 5,7-dibromo-8-quinolinol, the $pK_{a,HQ}$ value elucidated from the difference in $\Delta_0^a E_{1/2}$ between it and its parent is in reasonable agreement with the value reported.[9] For the case of 5-chloro-8-quinolinol, the $pK_{a,HQ}$ value should be smaller than its parents, not greater as reported.[8] Because Cl is an electrophilic functional group, deprotonation becomes easier. Its illustration can be found in phenol and its chloro derivative. The negative logarithm dissociation constant reported for phenol is 9.10,[10] that for chloro-phenol is 8.78.[11] Obviously, the value 8.39 elucidated from the experimental $\Delta_0^a E_{1/2}$ for 5-chloro-8-quinolinol in this work and 7.47 reported[12] for 5,7-dichloro-8-quinolinol is reasonable. But, for the case of 2-methyl-8-quinolinol, the $pK_{a,HQ}$ value should be greater, not smaller, than that of its parent because of the methyl group being an electrophobic functional group. Alternatively, the $\Delta_0^a E_{1/2}$ for the 2-methyl case should be less positive than that for the 8-quinolinol case. Further work will be needed to investigate the cause of the unreasonable experimental value in the case of 2-methyl-8-quinolinol.

Acknowledgements—Most of the laboratory work was carried out in the laboratory of H. F. This research was partly supported by a grant from the Nature Science Foundation of China (No. 2880239).

A COMPARISON OF GRADIENT CAPACITY ANION CHROMATOGRAPHY USING MACROCYCLES D-2.2.2 AND D-2.2.1 IN CONSTANT OR VARIABLE TEMPERATURE MODE

JOHN D. LAMB* and ROBERT G. SMITH
Department of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A.

(*Received* 29 *October* 1991. *Revised* 9 *December* 1991. *Accepted* 9 *December* 1991)

Summary—The ability of macrocyclic ligands to complex alkali metal cations has been exploited to perform chromatographic separations of anions. Macrocycles adsorbed to reversed phase columns can complex eluent cations, thus generating anion exchange sites. Gradient separations of anions can be performed by changing the column capacity during the course of the separation, either by changing the eluent cation or by changing the column temperature. Gradient anion separations are performed by changing the eluent from sodium hydroxide to lithium hydroxide with the cryptand D-2.2.2, while similar anion separations are achieved with D-2.2.1 by a KOH–LiOH gradient. Since the complexation of cations by macrocycles is exothermic, increasing the column temperature decreases the anion column capacity, allowing temperature gradient separations. The experimentally measured ΔH values for D-2.2.1 are higher than for D-2.2.2, leading to steeper gradients and thus better separations with D-2.2.1.

Macrocyclic ligands, such as crown ethers and cryptands, have been noted for their ability to selectively complex cations. This unique complexing ability has been exploited in ion chromatography. The ability of the macrocycle to complex a given cation is related to the ability of the cation to fit into the central cavity of the macrocycle.[1] Those cations that fit most closely into the macrocyclic cavity are often most strongly bound, while those cations that are either too large or too small to fit well into the cavity are less strongly bound. Thus retention in macrocycle-based chromatographic columns is determined, in general, by the size of the cation, with those that most closely match the macrocyclic cavity being retained longer than those cations that do not fit as closely.[2,3]

Macrocycle-based columns have also been used to separate anions. The cation bound to the macrocycle must be closely associated with an anion in order to maintain electrical neutrality, since most macrocycles are uncharged. Anions that are more hydrophobic in nature allow stronger interaction in low dielectric media since the macrocycle is also generally hydrophobic. Therefore not only can cations in the presence of a common anion be separated, but also anions in the presence of a common cation.[4–8] While macrocycles are noted for their cation selectivity, anion separations have been achieved which are at least as interesting, if not more so, than separations of cations.

We have performed anion separations with macrocycle-based columns in an ion exchange mode rather than a ligand exchange mode by using an alkali metal hydroxide as eluent.[9] The alkali metal cation forms a positively charged complex with the macrocycle, creating the anion exchange site, while the OH^- serves to elute anions. We have performed gradient separations by decreasing the column anion exchange capacity during the course of the separation by two different methods. In the first, the identity of the cation in the eluent is changed from one with a high affinity for the macrocycle to one of a lower affinity, and thereby decreasing the number of cation-macrocycle complexes, reducing the column anion exchange capacity.[10] A second method of decreasing the column capacity is to raise the column temperature. Since most cation-macrocycle complexation reactions are exothermic, increasing the column temperature results in fewer cation-macrocycle complexes, with a decrease in ion exchange capacity.[11] These capacity gradient separations show advantages over conventional ion exchange gradient separations which are carried out by increasing the eluent strength. With

capacity gradients the eluent ionic strength is unchanged or changed very little, resulting in much greater baseline stability.

In this work, we compare anion separations in these two modes with two different macrocycles, the cryptands decyl-2.2.2 (D-2.2.2) and decyl-2.2.1/(D-2.2.1). Advantages of separations performed with each of these macrocycles are discussed.

EXPERIMENTAL

Materials

Reagent grade cryptands *n*-decyl-2.2.2 (D-2.2.2) and *n*-decyl-2.2.1 (D-2.2.1) whose structures are shown in Fig. 1, were obtained from EM Science (Gibbstown, NJ., U.S.A.). Reagent grade compounds were used in making standards and eluents. All water used in making eluents and standards was purified to 18 mΩ resistivity with a Milli-Q water purification system (Millipore) and eluents were degassed by sparging with helium.

Apparatus

All chromatography was performed on a Dionex 4000i Series ion chromatograph. Dionex anion micro membrane (AMMS) suppressors were used for eluent suppression prior to conductometric detection with a Dionex conductivity detector. Suppressant was 12.5m*M* sulphuric acid flowing at 3–5 ml/min. Columns used were Dionex MPIC NS-1 reversed phase columns. Temperature was controlled by either coiling one metre of tubing just prior to the column and placing the coiled tubing and column in a water jacket connected to a constant temperature bath circulating a 50:50 water:ethylene glycol mixture or by placing the coiled tubing in a Dionex column heater. The chromatograph was controlled and data collected on a personal computer with Dionex AI400 software.

Column preparation

The macrocycle-based columns were prepared in the manner previously described[9] by circulating a solution of the appropriate cryptand in a 60:40 methanol:water solution through the MPIC column for 12 hr.

RESULTS AND DISCUSSION

Macrocycle-based separation system

Macrocycles have been explored for use in separating both anions and cations in a ligand exchange mode at other laboratories. In our studies, however, we have focused on a method to separate anions on macrocycle-based columns by ion exchange rather than ligand exchange. This method has the advantages that anion retention is not a function of anion concentration or sample cation, drawbacks manifested when anions are separated in the ligand exchange mode. Anion exchange sites are formed by the complexation of cations with the neutral macrocycle. The resulting positively charged complex forms an anion exchange site, and the hydroxide counterion elutes the anions from the column.

Effect of eluent cation on column capacity

The number of exchange sites formed, and hence column capacity, is determined by the amount of ligand adsorbed on the column and the type and concentration of the cation in the

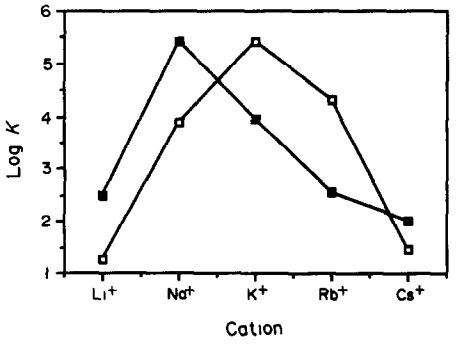

Fig. 2. Variation in log *K*, the formation constant for alkali metal complexes, in water for the cryptands 2.2.1 (■) and 2.2.2 (□) at 25° (from ref. 1).

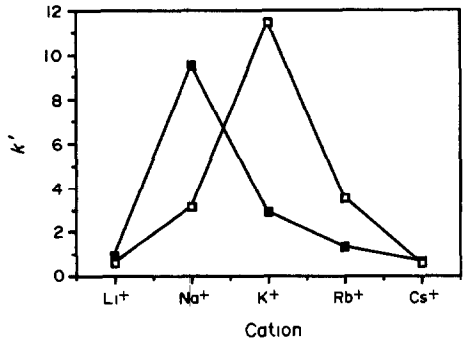

Fig. 3. Variation in Cl^- capacity factor, k', with eluent alkali metal cation (20mM), on D-2.2.2 (□) and D-2.2.1 (■) columns. The points for Cs^+ coincide.

eluent. Those cations that form the strongest complexes with the macrocycle, as measured by the binding constant, will generate more exchange sites than those cations that do not bind as strongly to the macrocycle. Column capacity is therefore a function of the binding constant for the reaction of the cation in the eluent with the macrocycle loaded on the column. Figure 2 plots the log of the binding constants for the cryptands 2.2.2 and 2.2.1 with the alkali metal cations. The cryptand 2.2.2 shows the highest binding with K^+, followed by Rb^+, Na^+, Cs^+ and Li^+. On the other hand 2.2.1, which has a smaller central cavity, shows the selectivity for Na^+, followed by K^+, Rb^+, Li^+ and Cs^+.

The dependence of anion retention on the eluent cation is illustrated by measuring the anion retention on the same column with different cations in the eluent. The retention of Cl^- on identical columns loaded with the same amount of D-2.2.2 and D-2.2.1 with different alkali metal cations in the eluent is demonstrated in Fig. 3. The eluent in each case was a 20mM alkali metal hydroxide. It is clear that the amount of retention is strongly related to the binding constant of the metal ion with the

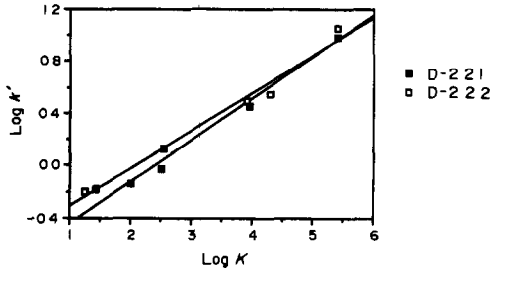

Fig. 4. Variation in log of the capacity factor (log k') for Cl^- versus log of the eluent cation binding constant in water (log K) for D-2.2.1 and D-2.2.2.

cryptand. The retention for the D-2.2.2 column follows the same order as the binding constants, with the K^+ eluent showing the most retention, followed by Rb^+, Na^+, Cs^+ and Li^+. The D-2.2.1 column retains anions most strongly with the Na^+ eluent, followed by K^+, Rb^+, Li^+ and Cs^+, respectively, in direct agreement with the order of the binding constants of these cations with 2.2.1. The relationship between the degree of anion retention and the strength of eluent cation binding to the column is shown in Fig. 4, in which the logarithm of the capacity factor of Cl^-, k', and the log of the cation-macrocycle binding constant are linearly related. This dependence of retention on eluent cation is most graphically demonstrated by Fig. 5, which shows the separation of a seven anion standard on the D-2.2.1 column with eluents composed of the different alkali metal hydroxides.

Cation capacity gradients

Gradient separations can be performed by changing the eluent cation from a cation with a higher affinity for the macrocycle to one with a lower affinity during the course of the

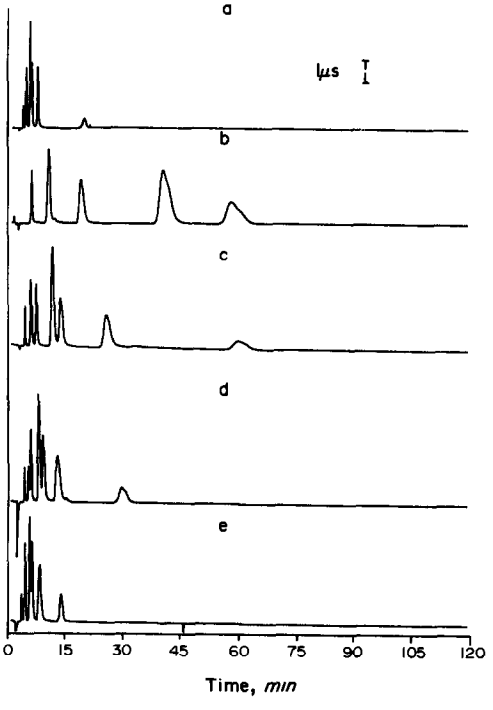

Fig. 5. Separation of 7 common anions on D-2.2.1 column in order of elution from left to right: 1 = F^-, 1.5 ppm; 2 = acetate, 10 ppm, 3 = Cl^-, 2.5 ppm; 4 = NO_2^-, 10 ppm; 5 = Br^-, 10 ppm; 6 = NO_3^-, 10 ppm; 7 = SO_4^{2-}, 10 ppm with different 20mM alkali metal hydroxide eluents: (a) Li^+ (b) Na^+ (c) K^+ (d) Rb^+ (e) Cs^+.

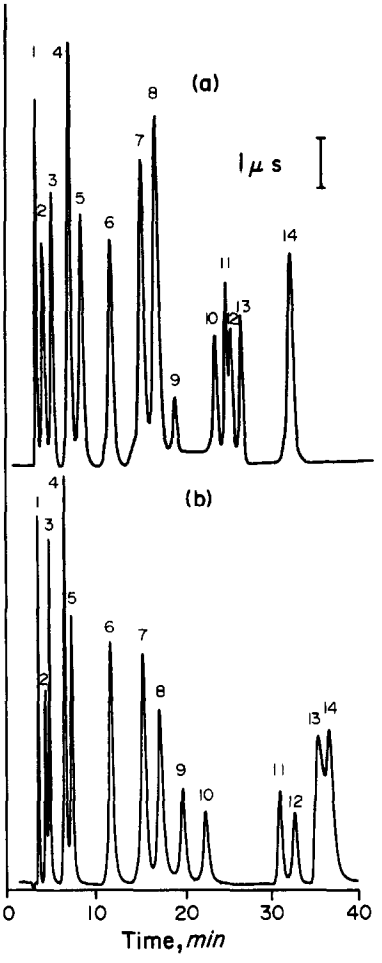

Fig. 6. Capacity gradient separation of 14 anions: 1 = F^-, 1.5 ppm; 2 = acetate, 10 ppm; 3 = Cl^-, 2.5 ppm; 4 = NO_2^-, 10 ppm; 5 = Br^-, 10 ppm; 6 = NO_3^-, 10 ppm; 7 = SO_4^{2-}, 10 ppm; 8 = oxalate, 10 ppm; 9 = CrO_4^{2-}, 10 ppm; 10 = I^-, 10 ppm; 11 = PO_4^{3-}, 10 ppm; 12 = phthalate, 10 ppm; 13 = citrate, 10 ppm; 14 = SCN^-, 10 ppm; on (a) D-2.2.2 column, with 30m*M* NaOH/30m*M* LiOH linear gradient for 20 min; (b) D-2.2.1 column, with 30m*M* KOH/30m*M* LiOH linear gradient for 20 min.

separation. The number of exchange sites decreases during the chromatogram as the higher binding cation is replaced by the cation with lower affinity and bleeds off the column. The resulting column has fewer exchange sites, and thus shows lower retention of anions.

The choice of cation combinations useful for capacity gradients is determined by the binding constants of the metal ions with the macrocycle, the rate at which the cations bleed from the column (*i.e.*, the cation complexation–decomplexation rate), and the background conductivity of the cation. For the D-2.2.2 column a successful gradient is achieved by changing the eluent from sodium hydroxide to lithium hydroxide as shown in Fig. 6(a). We are able to separate 14 anions in less than 40 min with a gradient from 30m*M* sodium hydroxide to 30m*M* lithium hydroxide. The potassium hydroxide eluent shows too much retention and bleeds from the column too slowly to make a good gradient. Rubidium and cesium cannot be used in the eluent as either the first or last cation because the background conductivity of these eluents is too high, resulting in unacceptable baseline drift. With D-2.2.1 column, a successful gradient is achieved with a potassium hydroxide to lithium hydroxide gradient. A gradient from 30m*M* potassium hydroxide to 30m*M* lithium hydroxide separates the 14 anion standard in just over 40 min, shown in Fig. 6(b). Sodium cannot be used as the first cation because it bleeds too slowly from the column, with the column capacity decreasing too slowly to be useful.

Both D-2.2.2 and D-2.2.1 columns can be used with gradients from one cation to another to separate a wide variety of anions. The resulting separations are similar, with the same elution order for all anions. However in comparing the two separations, we can see that the D-2.2.2 column is better suited for this type of gradient. In particular, the separation is achieved faster with the D-2.2.2 column. The binding constant of D-2.2.2 with Na^+ is close to that of D-2.2.1 with K^+, resulting in the same column capacity for the D-2.2.2 column with a sodium hydroxide eluent and the D-2.2.1 column with the potassium hydroxide eluent. The difference lies in the fact that the D-2.2.1 binds Li^+ better than D-2.2.2, resulting in higher column capacity at the end of the gradient, and thus more retention of longer retained peaks and a slower separation.

Effect of temperature on column capacity

Another method to change the column capacity during the course of a separation with a macrocycle-based column is to slowly increase the column temperature under isocratic eluent conditions. In conventional ion chromatography of both anions and cations the ion exchange reaction can be either exothermic or endothermic, depending on the ions involved. The ion exchange equilibrium can be shifted in either direction, resulting in either more or less retention, as the temperature is increased.

The complexation reaction of cations with macrocycles is generally exothermic. As the temperature is increased the equilibrium is shifted to form fewer cation–macrocycle complexes. The degree to which the equilibrium is

shifted, and hence the number of complexes formed, depends on the magnitude of the change in enthalpy for the complexation reaction. Since the retention of cations in macrocycle-based ion chromatography is based on the complexation–decomplexation reaction there should be less retention of cations at higher temperatures. For the separation of anions the situation is a little more complex. The column capacity is expected to be lower at elevated temperatures due to the decreased complexation and concomitantly fewer exchange sites. But since we are separating the anions by an ion exchange mechanism the retention behavior should also display the effect of temperature on conventional ion exchange.

The variation of capacity factors as a function of temperature is described by the equation:

$$\ln k' = -\frac{\Delta H}{RT} + \frac{\Delta S}{R} + \ln \varphi$$

where k' is the capacity factor, ΔH the enthalpy change for the reaction, R the molar gas constant, T the temperature at which the separation is carried out, ΔS the entropy change for the reaction, and φ the phase ratio for the column, a constant for a given column. Thus if we plot the capacity factor versus $1/T$ we should obtain a straight line with the slope $-\Delta H/R$, allowing us to obtain an estimate of ΔH for the reaction.

We measured the retention of both cations and anions on both D-2.2.2 and D-2.2.1 columns at varying temperatures. The columns were placed in a water jacket connected to a constant temperature bath to carefully regulate the temperature. For the cation separations a pure water eluent was used and the appropriate cation was injected while the column was maintained at the desired temperature by the constant temperature bath. Figure 6 shows the plot of the log of the capacity factor versus the reciprocal of the temperature, showing that the retention of all the alkali metal cations decreases significantly as the temperature is raised. From these plots we are able to calculate the ΔH for the cation retention reaction from the slopes of the lines obtained, the results of which are tabulated in Table 1. We see that the values are of the same order of magnitude for both the D-2.2.2 and D-2.2.1 columns. The significant difference between ΔH values measured for the macrocycle on the column and those for the parent compound in water is a clear indication that the cation reaction with column-bound macrocycle does not occur with the macrocycle portion floating free in the eluent, but must be involved in the extraction process.[11]

The anions were separated in a similar system, with a 20mM sodium hydroxide eluent used for the D-2.2.2 column and a 20mM potassium hydroxide eluent used for the D-2.2.1 column. The resulting plot of ln k' *vs.* $1/T$ in Fig. 7 shows that retention of all of the anions on both the D-2.2.2 and D-2.2.1 columns decreases with increasing temperature. The slopes of the lines obtained have a slightly higher value for the D-2.2.1 column than the D-2.2.2 column, indicating a larger negative value of ΔH for the retention reaction. This is demonstrated by the values for the enthalpy change tabulated in Table 1. The values for the ΔH's obtained under chromatographic conditions are lower than the reported values for the homogeneous solution complexation reactions.[1] The thermodynamic behaviour of these systems will be the subject of a future paper.

The separation of anions on the macrocycle column takes place mainly through an ion exchange mechanism. However if this were the only effect the temperature dependence of retention should be the same as for conventional ion exchange, with the retention of some anions increasing and others decreasing, as we have previously shown.[11] As demonstrated in Fig. 8 we see that the retention of all anions decreases. This decrease in retention for all anions can be

explained by measuring the column capacity as a function of temperature.

The column capacity was measured for the macrocycle columns at different temperatures by the following method. The column was equilibrated with the eluent, a 20mM sodium hydroxide eluent for the D-2.2.2 column and a 20mM potassium hydroxide eluent for the D-2.2.1 column. The column was switched out of line and the connecting tubing rinsed free of eluent by pure water. The column was switched back in line and the cations eluted from the column by 0.1M nitric acid and the column effluent was collected. The concentration of the eluent cation in the effluent was determined, and by knowing the original eluent concentration, the uptake of eluent cation by the column was calculated, taking into account the column dead volume and original eluent cation concentration to correct for the amount of cation in the column dead volume. This was done at temperatures ranging from 20–80° for both the D-2.2.2 and D-2.2.1 columns. By plotting the amount of eluent cation taken up by the column, and hence the column anion exchange capacity, versus the column temperature, shows that for both columns the exchange capacity decreases significantly with increasing temperature (Fig. 9). This effect outweighs the effect of the anion exchange reaction, explaining the decrease of retention for all anions with increasing temperature.

Temperature gradient separations

Temperature gradient separations on both cryptand columns were carried out by placing one metre of tubing immediately ahead of the column in a Dionex column heater. The temperature was then controlled by the Dionex

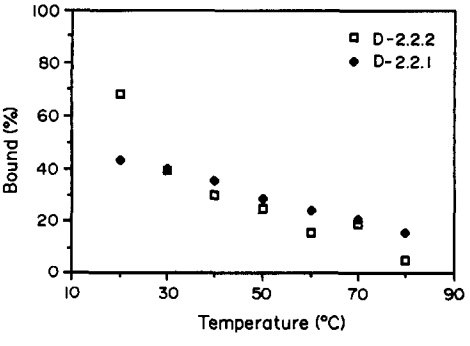

Fig. 9. Variation in column anion exchange capacity of D-2.2.2 and D-2.2.1 columns versus temperature expressed as percent of macrocycle sites containing bound sodium cations for D-2.2.2 column and potassium cations for D-2.2.1 column.

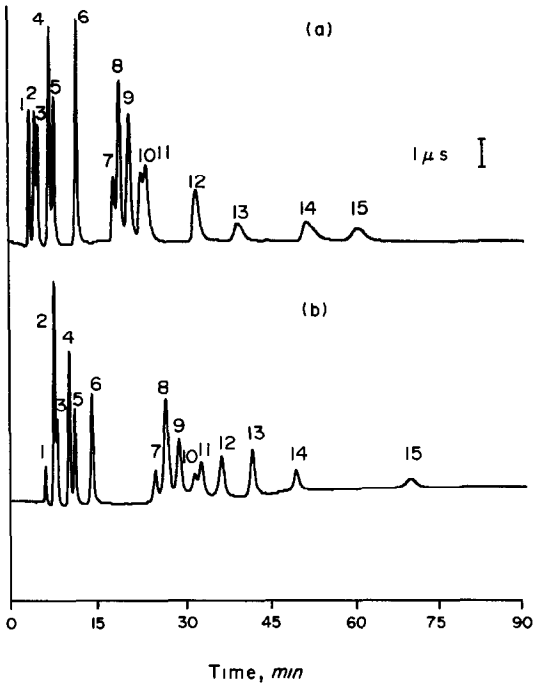

Fig. 10. Temperature gradient separation of 15 common anions: 1 = F^-, 1.5 ppm; 2 = acetate, 10 ppm; 3 = Cl^-, 2.5 ppm; 4 = NO_2^-, 10 ppm; 5 = Br^-, 10 ppm; 6 = NO_3^-, 10 ppm; 7 = I^-, 10 ppm; 8 = SO_4^{2-}, 10 ppm; 9 = oxalate, 10 ppm; 10 = CrO_4^{2-}, 10 ppm; 11 = MoO_4^-, 10 ppm; 12 = SCN^-, 10 ppm; 13 = ClO_4^-, 10 ppm; 14 = PO_4^{3-}, 10 ppm; 15 = phthalate, 10 ppm; with temperature gradient program starting at 30° and increasing to reach 80°, beginning at 5 min and ending at 30 min on (a) D-2.2.1 column with 20m*M* KOH eluent and (b) D-2.2.2 column with 20m*M* NaOH eluent.

AI400 software. The eluent for the D-2.2.2 column was 20m*M* sodium hydroxide and 20m*M* potassium hydroxide for the D-2.2.1 column, each at 1.0 ml/min. These cations were chosen for the respective eluents because they showed enough retention of anions to separate the early eluting peaks, yet would bleed off the column rapidly enough to allow a gradient separation. The temperature gradient program began at 30° and increased to 80°, beginning at five minutes and ending at 30 min. The resulting separations are shown in Fig. 10. The resulting chromatograms show good resolution of the earlier eluting peaks, while eluting strongly retained species in a reasonable time. It is interesting to note several changes in the elution order compared to the cation gradient system. With temperature gradient separations some late eluting species switch elution order, with strongly retained monovalent anions such as perchlorate and thiocyanate elution before polyvalent phosphate and phthalate. In temperature programming the baseline may be affected by the increase in mobile phase temperature since conductivity is a strong function of temperature. With suppressed conductivity detection the temperature of the eluent reaching the detector cell is kept constant by the cooling of the eluent in the suppressor by the room temperature regenerant, flowing 3–5 times faster than the eluent. The resulting baseline shows little perturbation due to the increase in the eluent temperature during temperature programmed elution.

Since the experimentally measured values for the enthalpy change for the retention of anions on the D-2.2.1 column are generally larger for the corresponding values for the D-2.2.2 column, we would expect to see a larger change in retention for the D-2.2.1 column. The separation of an anion standard does indeed show that for the D-2.2.1 column the separation is carried out slightly faster, with little or no loss of resolution, than for the D-2.2.2 column.

CONCLUSION

The ability to perform gradient separations of anions by dynamically altering the column capacity during the course of the separation has been demonstrated. Two different methods can be used to change the column capacity: changing the cation in the eluent and raising the column temperature. The macrocycle that is most effective is dependent on the method used. The capacity gradient by changing cation is more effective with D-2.2.2 than D-2.2.1 because D-2.2.2 binds lithium less strongly than D-2.2.1, allowing lower column capacity. Temperature gradients are more effective with D-2.2.1 because of the higher change in enthalpy, resulting in a greater shift in the complexation equilibrium to less cation-complex formation. Overall, cation gradient separations result in faster separations than temperature programmed separations. However temperature gradient separations show a more stable baseline and a different selectivity for some anions.

LIQUID FILM PERTRACTION—A LIQUID MEMBRANE PRECONCENTRATION TECHNIQUE

Z. LAZAROVA and L. BOYADZHIEV
Institute of Chemical Engineering, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria

(*Received* 11 *November* 1991. *Revised* 2 *January* 1992. *Accepted* 2 *January* 1992)

Summary—A new liquid membrane technique for preconcentration of trace components from aqueous solutions is proposed. This technique, known as liquid film pertraction (LFP), provides simple and stable continuous operation and high enrichment factors. Experiments are carried out with two types of model systems, preconcentrating copper(II) ions and aromatic amines (*m*-toluidine). In the first case the liquid membrane of C_{11}–C_{13} normal paraffins, contained commercial chelating extractant LIX 65N, but in the second one the membrane of liquid paraffins with no additives was used. The influence of flow-rates of donor and acceptor solutions were studied as well as the effect of the membrane circulation and the initial solute concentration in the treated donor solution. Applying the new LFP technique enrichment factors in the order of 10 were obtained.

Contemporary ecological problems cannot be solved, unless effective waste-free technologies are developed or novel effective techniques for trace analysis of various substances are established. To prepare suitable samples of industrial waste waters, physiological fluids, natural waters, *etc.*, generally selective extraction of a particular component from these solutions is required, combined with component enrichment in an appropriate liquid medium for subsequent analysis. Therefore, the use of a liquid membrane method for simultaneous selective extraction and preconcentration of various species, presents an attractive research problem. Compared to the classical solvent extraction, the liquid membrane separation ensures higher extent of recovery of the solutes from the initial dilute solutions. In particular, this feature becomes essential in cases where the distribution coefficient of the solute between the organic solvent and the aqueous phase, is in order of one or even less.[1]

The early results published confirmed the idea that the liquid membranes might be used as a suitable method for preconcentration of metal ions or organic compounds dissolved in aqueous effluents. A number of such studies have been employed and so called emulsion liquid membranes (ELM) for preconcentration of metals, as uranium, cerium, cobalt, manganese, strontium, *etc.*[2–4] Other authors preferred to use the supported liquid membranes (SLM) technique.[5–7] For example, Audunsson[8,9] used a *n*-undecane-impregnated PTFE membrane of 70% porosity for preconcentration of various amines from urine. Amines have been the subject also of other studies, focused on the mathematical modelling of the transfer processes in the above-mentioned ELM systems.[10–13] An attempt was also made to separate enantiomers and other isomers by means of aqueous membranes, supported on thin cellulose sheets.[14]

Our studies were directed towards selective recovery and preconcentration of metal ions as well as of organic compounds from their diluted aqueous solutions by means of another liquid membrane technique, namely liquid film pertraction (LFP).[15] Copper(II) ions and the aromatic amine *m*-toluidine were subject to preconcentration.

EXPERIMENTAL

Apparatus

Figure 1 represents the principle diagram of the LFP method. Both aqueous solutions—the donor solution F, initially containing the analyte, and the acceptor or the receiving one, R, where the extracted solute is concentrated, flew down along the hydrophilic surfaces of the solid supports 4 and 5 in the form of thin liquid films. The organic liquid, S, acting as a membrane, occupied the free space of the apparatus and was continuously recirculated in counter current with respect to both aqueous solutions F and R as shown in the figure.

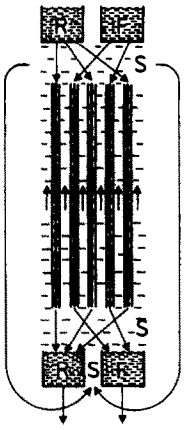

Fig. 1. Principal flow diagram of the LFP technique.

The experiments were carried out in a simple laboratory pertractor shown in Fig. 2. The device made of organic glass contained three vertical hydrophilic supports, the central one for the treated solution F and the other two supporting the acceptor liquid. These supports, intended for the aqueous solutions were made of regenerated porous cellulose sheets. The operational height of supports was 50 cm, the thickness—0.4 and 0.05 cm, respectively, and the distance in between—0.5 cm. The latter represents the real thickness of the membrane liquid layer.

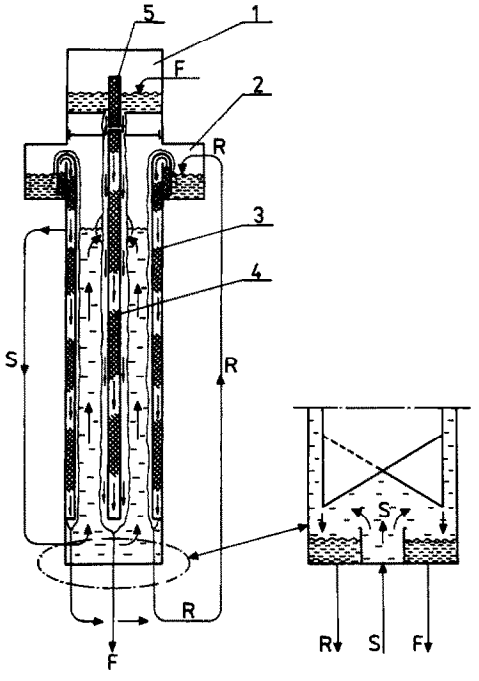

Fig. 2. Scheme of laboratory apparatus used in the experiments: 1. donor solution (F) compartment. 2. Acceptor solution (R) compartment. 3. Lateral hydrophylic supports for recirculating acceptor solution (R). 4. Central hydrophylic support for donor solution (F). 5. Disposable filter-distributor of donor liquid (F). Right: side view of bottom collectors for both aqueous solutions, explains the way the two liquids are separated.

The initial aqueous solutions F_0 and R_0 were fed into the appropriate feeding pertractor chambers by means of two peristaltic pumps, operated independently by means of timers in order for both solutions to be supplied periodically. This mode of liquid supply provides uniform horizontal distribution of the solutions and garantees their plug flow down the supports, especially when very low flow-rates, are used. When high concentration degree is needed, the acceptor solution R was recirculated in a close loop, too. The membrane liquid was set into motion by a magnetically-driven centrifugal pump, and its velocity in the device was measured and controlled.

Reagents and analytical methods

Copper ion preconcentration was carried out using a solution of the copper-selective chelating extractant LIX 65N (Henkel Corp.) in normal paraffins, as a liquid membrane. The active carrier in this commercial extractant is 2-hydroxy-5-nonyl benzophenone oxime. The oxime was used without special purification in concentrations of 5–20% (vol.) in a regular boiling point range of normal paraffins NORPAR 10/13 containing 0.1% *n*-nonane, 3.4% *n*-decane, 17.3% *n*-undecane, 45.7% *n*-dodecane, 33.2% *n*-tridecane and 0.4% *n*-tetradecane and higher *n*-paraffins. The paraffins were washed at least five times with large amounts of distilled water to remove any traces of ammonia or other water soluble impurities.

Regarding the preconcentration of *m*-toluidine, the organic membrane used was the above-mentioned hydrocarbon mixture without additives.

Model donor aqueous solutions were prepared by dissolving $CuSO_4.5H_2O$ (p.a. from KZ Co) or *m*-toluidine (pro synth., Merck) in distilled water. The donor solutions were not buffered. The acceptor solutions contained 1.5 or 1 *M* sulphuric acid (p.a. from KZ Co.).

The copper concentrations in the aqueous solutions were measured complexometrically by using EDTA.[16]

The amine concentration in the aqueous solution was measured by a UV–Vis spectrophotometer SPECORD(Carl Zeiss) at $\lambda = 287$ nm.[17] The pH-values were monitored with a LP-17 digital pH-meter. The experiments were carried out at 20°.

All concentrations in the sections to follow, are in ppm (w/v), and each point presents an average value obtained on the basis of three independent concentration measurements.

RESULTS AND DISCUSSION

The experimental studies were intended to evaluate the effects of the major concentration and flow variables upon the so-called enrichment factor EF, which was considered as a preconcentration efficient parameter. This parameter was defined as a ratio of final analyte concentration in the receiving solution R, to its initial concentration in the treated solution F, at steady state conditions. The steady state conditions were reached within 30 min–2 hr continuous operation, depending on the flow-rate (Q_F) of the donor solution and on the organic membrane circulation velocity Q_S.

The preconcentration of copper

The following three-liquid phase system was employed in the studies: aqueous solution of copper sulphate—solution of LIX 65N in the above-mentioned normal paraffins—3N sulphuric acid. The flow-rates of both solutions, F and R, were maintained constant, *i.e.*, $Q_F = 0.05$ cm^3/sec and $Q_R = 0.005$ cm^3/sec. The initial pH value of the donor liquid was 2.3. As well as the initial copper concentration which was varied between 50 and 1000 ppm, the other parameters relevant to the process were the concentration of LIX 65N in the paraffins [5 or 20% (vol.)] and the recirculation flow-rate of the membrane liquid, Q_S (0 to 3 cm^3/sec).

The effect of membrane recirculation intensity upon the EF value at 5 and 20% (vol.)

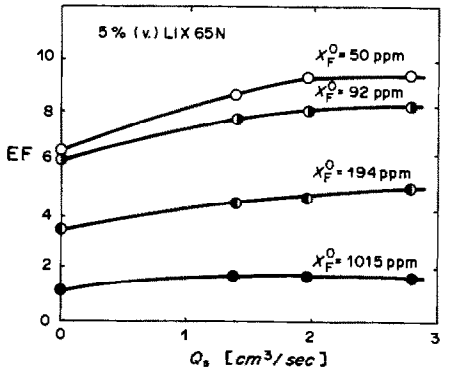

Fig. 3. Effect of recirculation flow-rate (Q_S) of the membrane liquid containing 5% (vol.) LIX 65N on the enrichment factor (EF) at various initial copper(II) concentrations in the donor solution (X_F^0).

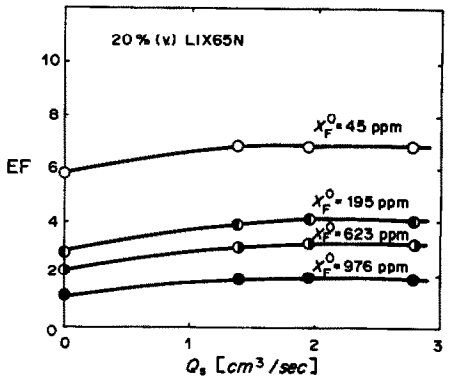

Fig. 4. Effect of recirculation flow-rate (Q_S) of the membrane liquid, containing 20% (vol.) of LIX 65N on enrichment factor (EF) at various initial copper(II) concentrations in the donor solution (X_F^0).

of LIX 65N in the membrane liquid, is shown in Figs. 3 and 4. Evidently, the rise of flow-rate Q_S, which increases the membrane mobility, resulted in a positive effect, particularly at the lowest copper concentrations. When the initial copper content in the treated solution exceeded 500 ppm, is only slightly affected by Q_S. By the donor solutions with relatively high copper concentration, copper transfer was hindered, which was likely to occur, due to the limited loading capacity of the carrier in the membrane liquid. The effect of copper content in the treated solution at mobile membrane phase, is illustrated in Fig. 5. As seen from the figure in the region exceeding 700 ppm, EF remained constant, regardless of oxime concentration in the membrane liquid, *i.e.*, there was no difference between the runs carrier with the membrane containing 5 and 20% active carrier. In contrast, at concentrations below 300 ppm, the lower the LIX 65N concentration was, the better the results were at constant initial copper

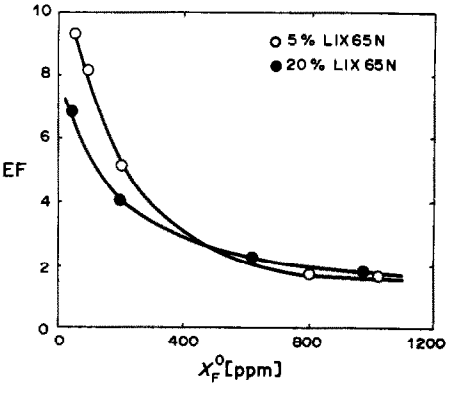

Fig. 5. Effect of initial copper(II) concentration in the donor solution on the enrichment factor (EF). $Q_S = 2.77$ cm^3/sec; $Q_F = 0.12$ cm^3/sec.

concentrations. As supported by the results obtained, the higher concentrations of the oxime in the paraffins results in a significant increase of membrane viscosity which slow down the rate of the mass transfer across the membrane layer.

From these results, it was concluded that the recirculation of the membrane liquid, applied for donor solutions with low initial copper concentrations, results in higher rates of extraction and more efficient preconcentration of the analyte in the receiving solution, R. For example, starting at 50 ppm by using a 5% LIX 65N solution in the membrane liquid, the EF rises, as shown in Fig. 3, from 6.46 (for immobile membrane) to 9.3 (for membrane circulation flow-rate of 2.77 cm^3/sec). The time required to reach a steady state in this case was 30 min. The enrichment factor obtained is close to the value reported by Cox *et al.*,[7] using LIX 64N as carrier.

It should be noted that, besides the enhancement of membrane phase circulation, two more variables facilitate achievement of higher EF. The first one is the change in the coefficient of copper distribution between membrane and donor liquids. Our previous experiments[18] as well as the results of other authors[19,20] have shown that this coefficient strongly depends on the donor solution pH value. Due to the equimolar counter diffusion of hydrogen ions from the receiving acidic solution R, the pH value of the donor liquid fell from 2.3 to 2. The higher the pH-value of solution F, the higher the copper distribution coefficient, and hence the higher the rate of copper transfer obtained. The second factor enhancing the enrichment factor is the recirculation of the receiving solution R which facilitates the transmembrane copper transport.

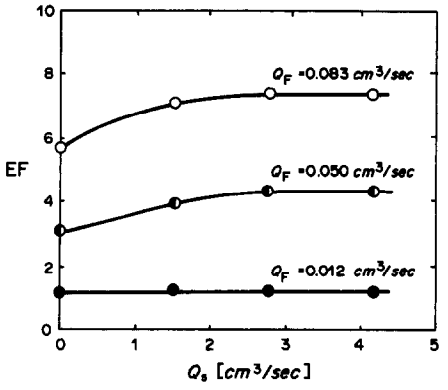

Fig. 7. Effect of membrane liquid circulation (Q_S) on the enrichment factor (EF) at various donor solution flow-rates (Q_F). $X_F^0 = 10$ ppm.

The preconcentration of m-*toluidine*

The second three-liquid-phase system used to study the LFP preconcentration technique was an aqueous solution of *m*-toluidine—NORPAR 10/13—2*N* sulphuric acid. The results obtained in the preconcentration of this aromatic amine are shown in Figs. 6–8. Figure 6 illustrates the effect of donor solution flow-rate (Q_F) on the enrichment factor at an initial *m*-toluidine concentration of 105 ppm. As seen from the figure, the increase of Q_F which also means a decrease of the mean residence time of the solution in the apparatus, also resulted in a rise of EF. However, this relationship was not linear, *e.g.*, the EF rise was accompanied by a fall in the efficiency of amine recovery. This fact has to be accounted for, since this is a major factor in the calculations of analyte preconcentration. Thus, at $Q_F = 0.012$ cm^3/sec, $Q_S = 1.76$ cm^3/sec the extraction efficiency was 95.3%, while a ten-fold increase of flow-rate Q_F shows EF = 8.97, but the efficiency falls to

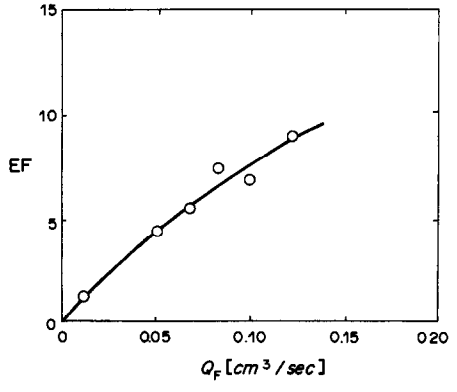

Fig. 6. Effect of donor solution flow-rate (Q_F) on the enrichment factor (EF). $X_F^0 = 105$ ppm; $Q_S = 1.76$ cm^3/sec.

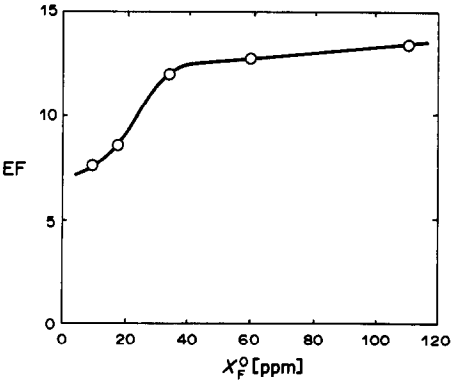

Fig. 8. Effect of initial concentration of *m*-toluidine in the treated (donor) solution (X_F^0) on the enrichment factor (EF). $Q_F = 0.083$ cm^3/sec; $Q_S = 1.76$ cm^3/sec.

71.4%. Obviously, an appropriate relationship between the flow-rate Q_F and the values of EF and E, has to be established.

Figure 7 shows the influence of the membrane flow-rate, Q_S on the value of EF at three donor solution flow-rates, Q_F. At the higher Q_F which, as already mentioned, leads to an increase in the EF the membrane circulation intensity exhibits some influence. At $Q_F = 0.083$, EF increased from 5.6, which corresponded to a quasistagnant membrane, to 7.4 at membrane circulation velocities exceeding 2.7 cm^3/sec. The circulation of membrane liquid showed no effect on the EF value at the lowest flow-rate level, *i.e.*, when $Q_F = 0.012$ cm^3/sec, it is likely that at this liquid film velocity the mass transfer resistance was located entirely in the donor solution F and any changes in membrane hydrodynamics did not influence the over-all mass transfer rate.

The effect of initial amine concentration on the enrichment factor EF, is shown in Fig. 8. It can be seen that for concentrations under 40 ppm, EF is affected significantly by the initial amount of amine in the donor solution: EF increased from 7.5, at an initial concentration of 10 ppm, to about 13.0, by the concentrations exceeding 35–40 ppm. The peculiar form of the curve is difficult to explain, but is very likely related to the dissociation of amine molecules in the donor solution and/or the amine solubility in the organic membrane.

CONCLUSION

The experiments carried out showed that the liquid film pertraction is an efficient liquid membrane technique for selective preconcentration of various solutes from their dilute aqueous solutions. Enrichment factors in the range of 5–15 were obtained. Additions of appropriate selective extractants to a neutral membrane of liquid paraffins provide good results in the case of copper preconcentration. For preconcentration of aromatic amines a membrane of liquid paraffins is quite suitable. In this case the enrichment factor depends strongly on amine solubility and dissociation in the treated aqueous solution.

SYNTHESIS AND CHARACTERIZATION OF A MACROPOROUS POLY(VINYL-AMINOACETONE) CHELATING RESIN FOR THE PRECONCENTRATION AND SEPARATION OF TRACES OF GOLD, PALLADIUM, RHODIUM AND RUTHENIUM

XIJUN CHANG,* XINGYIN LUO,* GUANGYAO ZHAN and ZHIXING SU

(*Received* 13 *August* 1991. *Revised* 20 *November* 1991. *Accepted* 20 *November* 1991)

Summary—An inductively coupled plasma atomic-emission spectrometry (ICP–AES) procedure is established with a new macroporous poly(vinyl-aminoacetone) chelating resin (PVAA) for preconcentration and separation of traces of Au(III), Pd(IV), Rh(III) and Ru(III) from sample solutions. The conditions of quantitative enrichment and desorption of these analytes from PVAA columns, including investigations of the stability, the regeneration capabilities and the adsorption capacities of that collector, are discussed. Moreover, interferences of foreign ions on the analytes are not observed and analysis of a real sample is performed with reliable results. Recoveries of these elements added to non-ferrous matrices are above 95% with relative standard deviations (RSD) between 2.0 and 4.0%.

A series of papers reported that polystyrene-based chelating resins are useful for preconcentration of trace elements.[1–7] Difficult syntheses of such resins, however, often lower their analytical value. Chang and co-workers have reported the syntheses of macroporous poly(vinyl-ethylenediamine), poly(vinyl-diethylenetriamine), poly(vinyl-propionamide oxime), and poly(vinyl-amidine thiocyanate-thiourea) chelating resins,[8–11] which were used to enrich different trace elements from various matrices with better effects than earlier resins.

In this paper, the synthesis of a macroporous resin with immobilized poly(vinyl-aminoacetone) chelating groups (PVAA) and its application for enrichment of noble metal ions is described. An ICP–AES procedure is established for the determination of traces of Au, Pd, Rh and Ru in real samples after preconcentration on PVAA. The acidity, the flow-rates, the performance, the adsorption capacity, and interferences of foreign ions on the separation of the analytes, as well as the conditions of desorbing these ions from the collector, are characterized. Moreover, the precision and the accuracy of the analytical procedure using this resin investigated by analysis of a real sample, with satisfactory results.

EXPERIMENTAL

Instrumentation and conditions

A Perkin–Elmer ICP/6500 inductively coupled plasma system equipped with a PE 7300 computer and RF power supply was operated according to standardized conditions (forward power 1100 W, viewing height 17 mm, Ar plasma gas flow 14 l./min, Ar auxiliary gas flow 0.4 l./min, Ar nebulizer gas flow 1.0 l./min, solution uptake rate 1.0 ml/min, wavelengths: Au 201.200 nm, Pd 229.651 nm, Rh 233.477 nm, and Ru 240.272 nm). Wavelengths were scanned in ascending order to determine Au, Pd, Rh and Ru with the ICP/6500 (integration time 10 sec, each). A Perkin–Elmer 577 Crafting Infra-red spectrometer was used to determine the structure of the PVAA resin.

To prepare the column, 0.3 g of chelating resin, soaked in high-purity water overnight, was loaded into a glass tube (15 cm long, inner diameter 0.4 cm, 0.15 cm at the lower end) enclosed with small cotton wads.

Reagents and standards

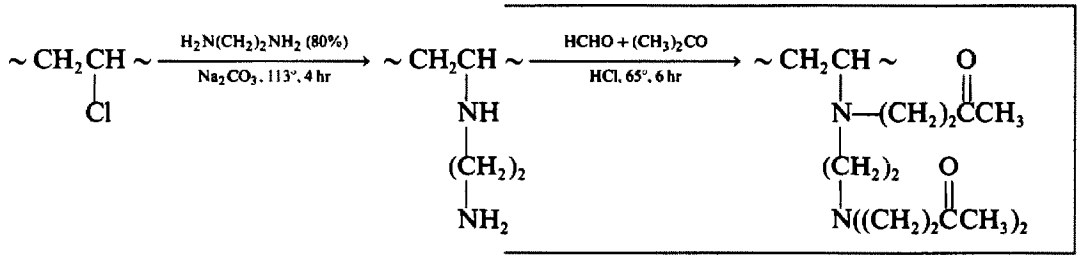
Reagents of high or analytical purity were used for all experiments. Stock solutions of 1 g/l. Au, Pd, Rh, Ru each were prepared by dissolving spectroscopically pure $HAuCl_4 \cdot 4H_2O$, $(NH_4)_2PdCl_6$, $(NH_4)_2RuCl_5$ and $Rh_2O_3 \cdot 5H_2O$ (Shanghai Reagent Station) in

diluted hydrochloric acid. They were diluted and mixed in 0.5*M* hydrochloric acid to 16 μg/ml Au and Ru and 12 μg/ml Pd and Rh to give standard stock solution.

Synthesis of chelating resin

A 10-g amount of spherical poly(vinyl chloride) particles of 0.32–1.3 mm diameter, 30 g of ethylenediamine and 1.5 g of sodium carbonate were mixed in a three-necked flask. After refluxing for 4 hr at 113°, the resin was washed with 400 ml of water until the resin was neutral and dried under an IR lamp. An aminated resin was obtained. Then 10 g of the aminated resin and 30 g of (1 + 1) acetone and formaldehyde were added to another three-necked flask and refluxed for 6 hr at 65°, and washed with water and dried as above. Synthesis of a new aminoacetone chelating resin was thus achieved. The aminoacetone functional group in the resin was verified through the IR spectrum shown in Fig. 1.

According to the Mannich reaction principle,[12] the synthesis reaction of PVAA chelating resin can be briefly expressed as follows:



The average pore diameter and pore volume of the synthesized resin determined by the mercury intrusion method[13] was 6500 Å and 0.51 cm^3/g, respectively. Its specific surface area measured by the Brunner Emmett Teller method[13] was 5.9 m^2/g. The nitrogen content of this resin determined by an elemental analyser (ARLO ERBR 1106) was 9.21%. Because cross linkage reactions of the resin occur simultaneously with the above reaction,[14] conjugated bonds were formed, so that the N-content of the resin cannot be further increased.[14]

Analytical procedures

Standard solutions of Au, Pd, Rh and Ru were prepared in high-purity vessels (200–500 ml samples). Subsequently, the pH was adjusted to an appropriate value with a Clark–Lubs buffer solution and the solution passed through the column under a controlled flow-rate (*e.g.*, 1.5 ml/min). After elution of the analytes from the column by 10 ml of mixed 6*M* hydrochloric acid and 3% $CS(NH_2)_2$ solution, traces of Au, Pd, Rh and Ru in the 10 ml of eluate were determined by ICP–AES.

Procedure for non-ferrous metal analysis

A 0.1000-g portion of a ferrous sample with Cu, Ni and Fe matrix from a smelter was weighed into a Ni-crucible and 0.8 g of (1 + 12) sodium nitrite and sodium hydroxide were added. The crucible was heated in a furnace for an hour at 600° and then cooled. The melted sample in the crucible was leached with 50 ml of boiling distilled water into a beaker and neutralized with 6*M* hydrochloric acid, and then the Clark–Lubs buffer solution of pH 6 was added. Thus, the sample solution was passed through the chelation column according to the above analytical procedures.

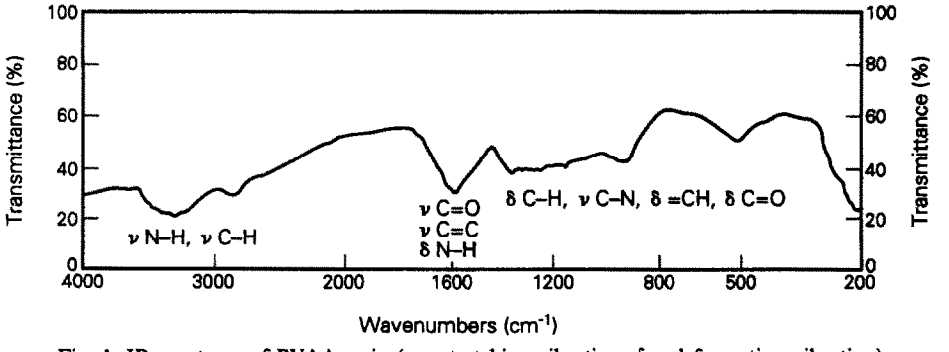


Fig. 1. IR spectrum of PVAA resin (ν = stretching vibration, δ = deformation vibration).

RESULTS AND DISCUSSION

Influence of pH value on quantitative enrichment

Appropriate solutions of Au, Pd, Rh and Ru (60–80 ng/ml each) were enriched by means of the column procedures described in the pH range 2–9. Traces of Au, Pd, Rh and Ru can be adsorbed quantitatively by the resin between pH 5–9 with recoveries in the range 92–100% (Fig. 2). A pH of 6 was selected as the optimum value for preconcentration.

On the basis of the column procedure, Pt(IV) and Ir(IV) (60–80 ng/ml each) in the pH range 5–9, Cr(III), Pb(II), Cu(II), V(V), and Y(III) (40–100 ng/ml each) in the pH range 7–9, and Ti(IV) (50 ng/ml) in the pH range 8–9 can also be adsorbed by the resin with recoveries of over 90%, while recoveries of Fe(III), In(III), Sn(IV) and Bi(III) (100–500 ng/ml each) adsorbed by the resin at pH 7 below can only reach 10–40%. The above ions do not interfere with the Au, Pd, Rh and Ru preconcentrations at pH 6. In addition, Na, K, Be, Mg, Ca, Ba, Ga(III), Tl(I), As(III), Cd(II), Co(II), B(III) and Ge (IV) (100–500 ng/ml each) are not adsorbed by the resin at pH <7. Accordingly, the resin separation of trace Au, Pd, Rh and Ru at pH 6 is not interfered with by these other ions.

Because Ag(I) can combine with chlorine ion in the solution to form a precipitate and Os(VIII) volatilizes easily at ordinary temperatures, these ions were not tested. When the above noble metal ions are in high acidity solution, their adsorption by the PVAA resin is not satisfactory.

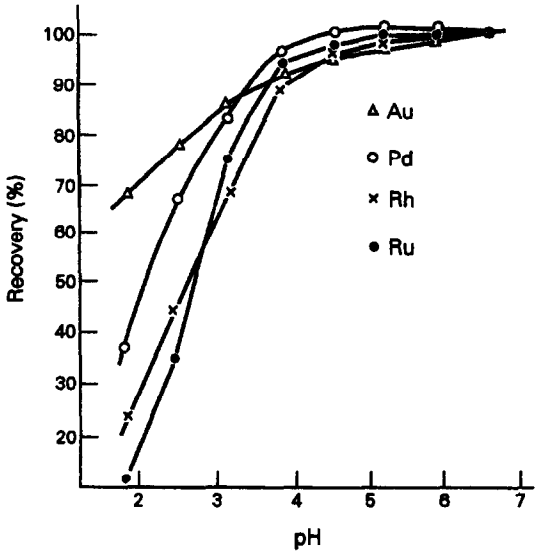

Fig. 2. Separation of Au, Pd, Rh and Ru by PVAA resin as a function of pH.

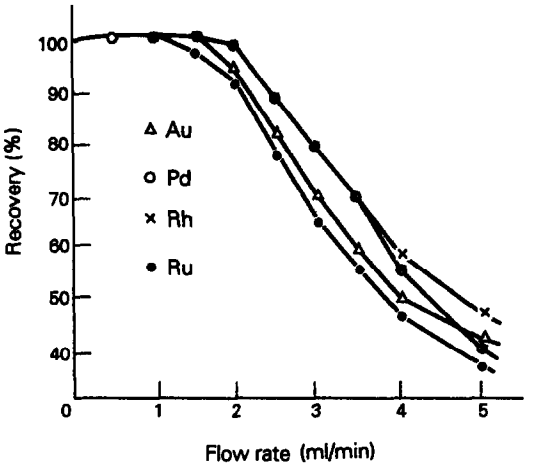

Fig. 3. Effect of collection on flow-rate on the recovery of Au, Pd, Rh and Ru by PVAA columns.

Flow-rates of separation

With the column procedure, the influence of the flow rate (0.5 to 6 ml/min) on the separation of Au, Pd, Rh, and Ru ions was investigated. As Fig. 3 shows these ions can be adsorbed quantitatively by the resin at flow-rates ≤ 2 ml/min. Based on this finding, the flow-rate during the following separation experiments was kept at 1.5 ml/min.

Conditions for quantitative desorption

Subsequent to their separation, Au, Pd, Rh and Ru ions were eluted from the columns by means of 10-ml mixture solutions (hydrochloric acid and thiourea) of different concentrations. The desorption flow-rate was kept at 3 ml/min. The results of this determination, presented in Figs. 4 and 5, reveal that Rh and Ru can be desorbed with $4M$ HCl + 3% $CS(NH_2)_2$ or $6M$ HCl + 1% $CS(NH_2)_2$ solution; Au can be desorbed with $6M$ HCl + 2% $CS(NH_2)_2$ solution; but desorption of Pd requires $6M$ HCl + 3%

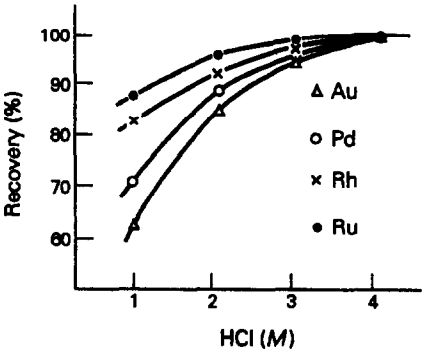

Fig. 4. Elution curves of Au, Pd, Rh and Ru as a function of HCl concentration [in 3% $CS(NH_2)_2$].

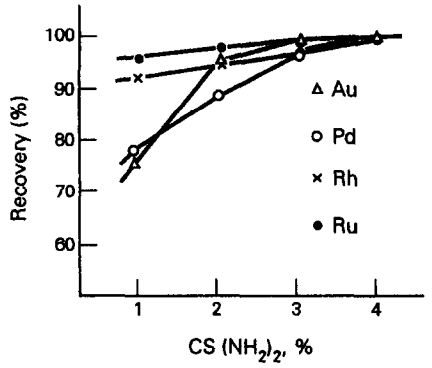

Fig. 5. Elution curves of Au, Pd, Rh and Ru as a function of $CS(NH_2)_2$ concentration (in 6*M* HCl).

$CS(NH_2)_2$ solution. The desorption recoveries were above 93%. Thus, 10 ml of 6*M* HCl + 3% $CS(NH_2)_2$ solution was selected for elution of analytes.

In separation experiments, we found that the elution of Pt ion from the resin requires 8*M* HCl + 8% $CS(NH_2)_2$ solution, while the elution of Ir ion requires 4% (1 + 1) $NaNO_2 + NH_4Cl$ solution (recoveries $\geq$90%). However, the quantitative elutions of Cr, Pb, Cu, V, Y and Ti ions from the resin require only 2–4*M* hydrochloric acid solution. Because the conditions of Pt and Ir ions eluted from the resin were different from Au, Pd, Rh and Ru ions, both ions were not investigated further in following experiments.

Resin stability, regeneration and capacity

After the chelating resin was treated with strong acids or concentrated bases, the adsorptions of Au, Pd, Rh and Ru ions were over 92%. The swelling rate of the resin was 28.3% (in 0.1*M* hydrochloric acid, 270 min).

When the resin was used repeatedly as described for the determination of Au, Pd, Rh and Ru ions up to seven times [after Au, Pd, Rh and Ru were desorbed from the resin each time with 6*M* HCl + 3% $CS(NH_2)_2$ solution, the resin column was washed with 1*M* sodium hydroxide solution and distilled water to neutrality, thus, a regeneration of the resin was reached], the adsorption efficiency was still above 95%. The saturated adsorption capacities of the PVAA resin for these elements were 124 mg/g for Au, 66.8 mg/g for Pd, 67.0 mg/g for Rh, and 45.5 mg/g for Ru.

Interferences of foreign ions

Standard solutions of 200 ml of Au, Pd, Rh and Ru ions (60–80 ng/ml each) containing different metal (Cu, Ni, Zn, Mn, Fe, Al, Ca, Mg) ions as interferents were analysed according to the combined ICP procedure. The results (recovery rates) summarized in Table 1 show that hundred-fold excesses of these foreign ions do not affect the recovery of the above analytes.

Precision and accuracy

The precision and accuracy of the combined ICP procedure were characterized by the analysis of standard solutions containing 64 ng/ml Au and Ru, each and 48 ng/ml Pd and Rh, each. Accordingly, the average values of 7 determinations were 62 ng/ml Au, 64 ng/ml Ru and 48 ng/ml Pd, Rh each, and the relative standard deviations (RSD) were 3.6% for Au, 2.0% for Ru, 2.7% for Pd and 3.3% for Rh. When the lowest analyte concentrations were 32 ng/ml Au, Ru each and 24 ng/ml Pd, Rh each, the RSD of these ions determined in accordance with the above analytical procedure were still between 2.0 and 4.0%.

Moreover, the accuracy of the combined procedure was checked by the analysis of an aqueous sample solution from a smelter nonferrous sample with about 0.5 mg/ml of Ni and Co metal matrix, using the standard addition method for calibration. The results listed in Table 2 reveal >95% recoveries for traces of Au, Pd, Rh and Ru, and show the analyte concentrations in the sample solution detected by the ICP procedure were 44 ng/ml for Au, 58 ng/ml for Pd, 33 ng/ml for Rh, and 20 ng/ml for Ru. When the analytical procedures were applied to the analysis of a ferrous sample solution with Cu, Ni and Fe metal matrix, the contents of Au, Pd, Rh and Ru determined by the proposed procedure in the real matrix were in

Table 1. Influence of foreign ions on the Au, Pd, Rh and Ru recovery

Interfering ions		Ca^{2+}	Mg^{2+}	Zn^{2+}	Ni^{2+}	Cu^{2+}	Mn^{2+}	Fe^{3+}	Al^{3+}
Conc. (10^3 ng/ml)		40	40	20	20	20	15	15	10

	Ru	106	106	98.5	103	92.0	95.6	100	100

*The concentration of Au and Ru was 80 ng/ml each, the concentration of Pd and Rh was 60 ng/ml each.

Table 2. Analytical results of real samples with non-ferrous matrix

	Solution sample				Control sample	
Elements	Conc. found *ng/ml*	Added, *ng/ml*	Sum found *ng/ml*	Recovery, %	Conc. found *ng/ml*	Expected (ETAAS) *ng/ml*
Au	44 ± 2	80	120 ± 4	95.0	163 ± 6	163
Pd	58 ± 2	60	120 ± 3	103	161 ± 4	161
Rh	33 ± 1	60	93 ± 3	100	50.5 ± 1.6	50.4
Ru	20 ± 1	80	98 ± 2	97.5	21.2 ± 0.4	21.1

good agreement with the analytical results measured by a ETAAS method (Table 2).

The above results demonstrate the reliability and feasibility of the proposed analytical procedure for the chelating adsorption for traces of Au, Pd, Rh and Ru in real sample solutions.

CONCLUSION

The macroporous PVAA chelating resin can be synthesized readily. It shows good chemical and mechanical stability. Separations of traces of Au, Pd, Rh and Ru from matrix elements by the new collector can be carried out applying a reliable column procedure. When combined with ICP–AES, the procedure offers considerable advantages in convenient operation, low interference, good precision and accuracy for the analytes Au, Pd, Rh and Ru.

BATCHWISE SEPARATION OF GALLIUM BY AN ANION EXCHANGE RESIN LOADED WITH A SULPHONATED AZO DYE

MARIA PESAVENTO, TERESA SOLDI and ANTONELLA PROFUMO
Dipartimento di Chimica Generale, Università di Pavia, V. Taramelli 12, 27100 Pavia, Italy

(*Received* 8 *July* 1991. *Revised* 21 *October* 1991. *Accepted* 21 *October* 1991)

Summary—Gallium(III) is sorbed by a strong base anion exchange resin loaded with a sulphonated azo-dye, T-azo-R [1-(tetrazolylazo)-2-hydroxynaphthalene-3,6-disulphonic acid], which is able to complex it in aqueous solution. As sorption takes place at acidities at which the hydrolysis of gallium is not negligible, it must be considered as concomitant equilibrium. The distribution equilibria depend on the amount of ligand sorbed, and on the volume, acidity and ionic composition of the aqueous solution, according to the Gibbs–Donnan model. The thermodynamic complexation constant in the resin phase can be calculated from the experimental distribution coefficients; the value of $\log K = -1.24(0.20)$ is in acceptable agreement with that in aqueous solution [$\log K = -0.75(0.33)$] which was also determined in the present investigation. Two equations deriving from the Gibbs–Donnan model are used for predicting the conditions for sorption and elution of gallium by a batch procedure, and for separating it from aluminium.

The possibility of predicting the distribution of heavy metal ions between aqueous solution and strong base anion exchange resin containing chelating sulphonated azo dyes has been shown in some previous papers.[1,2] To this purpose it is convenient to accept the model proposed by Boyd,[3] Gregor,[4] Helfferich[5,6] and more recently by Marinsky.[7] In that case, if the same standard and reference state are assumed for the solution and the resin phase, the activities of proton and metal ion inside the resin depend on the activities in aqueous solution, according to the Gibbs–Donnan equilibrium.

Let's suppose that the ion exchange takes place by the following reaction

$$\mathrm{M} + \overline{\mathrm{H}_x\mathrm{L}} \rightleftharpoons \overline{\mathrm{MH}_r\mathrm{L}} + q\mathrm{H} \qquad (1)$$

$$K_{ex} = \frac{\overline{[\mathrm{MH}_r\mathrm{L}]}[\mathrm{H}]^q}{[\mathrm{M}]\overline{[\mathrm{H}_x\mathrm{L}]}} \qquad (2)$$

where barred symbols indicate the species in the resin.

The fraction of the sorbed metal ion to the total ion (f) is given by the following equation

$$f = \frac{\overline{[\mathrm{MH}_r\mathrm{L}]}g}{[\mathrm{M}]_t V + \overline{[\mathrm{MH}_r\mathrm{L}]}g} = \frac{1}{1 + \dfrac{[\mathrm{H}]^q V Z_{\mathrm{M}} Z_{\mathrm{HxL}}}{K_{ex}\bar{c}_{\mathrm{L}} g}} \qquad (3)$$

where $Z_{\mathrm{M}} = [\mathrm{M}]_t/[\mathrm{M}]$ and $Z_{\mathrm{HxL}} = \bar{c}_{\mathrm{L}}/\overline{[\mathrm{H}_x\mathrm{L}]}$.

$[\mathrm{M}]_t$ indicates the total concentration of metal ion in the solution phase and $\bar{c}_{\mathrm{L}}$ the total concentration of the ligand not complexed in the resin. V is the volume of the aqueous solution (in cm^3) and g are the grams of water sorbed on the resin. All quantities in equation (3) are experimentally accessible by independent determination, or are evaluable. The exchange coefficients can also be evaluated on the basis of the model, as previously suggested,[3–7] and by estimating the activity coefficients of the ionic species involved by the Specific Interaction Theory (SIT).[8] The following equation is used:

$$\log K_{ex} = \log K\gamma_{\overline{\mathrm{HxL}}}/\gamma_{\overline{\mathrm{MHrL}}}\{\overline{\mathrm{Y}}\}^{(z-q)} + (z-q)\log[\mathrm{Y}] - \frac{0.51I^{1/2}}{1+1.5I^{1/2}} \times [z^2 + (z-q)z_{\mathrm{Y}}^2 - qz_{\mathrm{H}}^2] + [b(\mathrm{M},\mathrm{Y}) + (z-q)b(\mathrm{N},\mathrm{Y}) - qb(\mathrm{H},\mathrm{Y})]I \qquad (4)$$

where NY is the salt of the ionic medium, z is the charge of the metal ion and K is the thermodynamic complexation constant in aqueous solution. I is the ionic strength of the solution. Symbols between { } indicate activities, γ the activity coefficients and b the specific interaction coefficients defined by SIT.

In the case of chelating resins consisting of a strong base anion exchange resin containing a

sulphonated azo-dye at low concentration, predictions on sorption and elution of metal ions are easily done. First of all the chelating groups are introduced on the resin under very mild conditions, simply by ion exchange. Thus they keep the same molecular structure and chelating properties as in aqueous solution, where they are known in many cases, or can be determined by the usual equilibrium analysis methods. Moreover the activity of the counter ion Y in the resin phase is constant, since the number of counter ion moles substituted for the ligand is low, and the resin is rigid enough to have a constant water content. The activity of the counter ion in the resin phase has been evaluated in some previous work.[9]

The complexing properties of some azo-dyes with two metals of the Group IIIB, indium and aluminium, in aqueous solution have been previously investigated.[10,11] A very peculiar behaviour of the two metal ions has been observed. One of the ligands previously considered, which derives from R salt, T-azo-R [1-(tetrazolylazo)-2-hydroxynaphthalene-3,6-disulphonic acid], is a good ligand for indium,[10] while it does not complex aluminium[11] at all. On the contrary a ligand with similar structure, derived from Chromotropic acid, T-azo-C [2-(tetrazolylazo)-1,8-dihydroxynaphthalene-3,6-disulphonic acid], reacts only slightly with indium,[10] but is a good complexing agent for aluminium.[11] The same was observed also when comparing other derivatives of R salt and Chromotropic acid, and was to be expected since a peri-di-hydroxylic structure is required to form stable complexes with aluminium.

Nothing is known about the behaviour of these ligands with gallium, so this point had to be investigated before making any prediction. However some preliminary observations showed that gallium forms steady complexes with both the sulphonated azo dyes T-azo-R and T-azo-C in aqueous solution at pH values higher than about 2. It is expected that the same happens when the dyes are sorbed on AG MP-1.

The aim of the present investigation is to check the possibility of using the loaded resin for sorbing gallium from aqueous solution, and for separating it from aluminium.

As a matter of fact gallium is often obtained as a by-product in the aluminium metallurgical industries, since it is present in aluminium minerals as an impurity at different concentration levels, from 0.01 to 0.1%. Thus it is important to separate it for determination in the presence of large amounts of aluminium.

The hydrolysis of gallium had also to be studied because it is a concomitant equilibrium at the acidity at which the complexation in aqueous solution and the sorption on the loaded resin take place.

EXPERIMENTAL

Materials and apparatus

The sulphonated azo dyes T-azo-R [1-(tetrazolylazo)-2-hydroxynaphthalene-3,6-disulphonic acid] and T-azo-C [2-(tetrazolylazo)-1,8-dihydroxynaphthalene-3,6-disulphonic acid] were prepared and characterized by the previously reported methods.[12,13] Their standard solutions were prepared directly by weighing the solid.

The strong base resin AG MP-1 was obtained from Bio-Rad and converted to the nitrate form as previously described.[9] Its capacity for anions was 4.2 meq per g of dry resin and the water content was 1.42 g of water per g of dry resin, in agreement with that declared. It was then loaded with the sulphonated azo-dye according to the usual procedure.[2]

Gallium nitrate stock solution was prepared by dissolving the 99.999% pure metal obtained from Aldrich in a small excess of nitric acid diluted 1 to 1, by gentle heating and refluxing. The gallium concentration in the stock solution was determined both gravimetrically by precipitating the hydroxide with ammonia and weighing the oxide, and volumetrically with EDTA.[14] The acidity of the stock solution was determined by passing a known volume on a strong cation exchange resin (Dowex 50) in the hydrogen form, and titrating potentiometrically the protons in the solution. The protons exchanged for gallium were subtracted from the total acidity titrated. The excess acidity in the final solution was 0.12*M*. All other reagents were of analytical grade and triply distilled water was used.

Spectrophotometric determinations were made with a Varian Cary 3 UV–Vis spectrophotometer.

The acidity (pH) was measured potentiometrically by a Ross combined glass electrode (Orion 8102-SC). The potentiometric cell was standardized daily in proton concentration by the previously described standard addition method.[13] All measurements were made under a

small nitrogen overpressure in a temperature-controlled cell. The same was used for the potentiometric titrations.

Voltammetric determination of gallium

Gallium concentration was determined in the test solution and the amount of sorbed metal was estimated by difference from the total amount added; f was then calculated.

The determination of gallium in the test solution was done by analysing a known volume of clear solution. A very sensitive technique (anodic stripping voltammetry, D.P.) should be used to allow volumes of test solution as small as possible to be used. A polarograph AMEL Analyzer 433 was used, with Hg as indicator electrode, Ag/AgCl, saturated KCl as reference electrode and Pt wire as counter electrode. The supporting electrolyte was $0.1M$ sodium chloride and $8 \times 10^{-3}M$ hydrochloric acid. Other conditions were: pulse amplitude, 50 mV; scanning speed, 20 mV/sec; pre-electrolysis time, 60 sec; drop, a.u. = 20; stirring rate, 300 r.p.m. At these conditions E_p was -0.6 V, and the sensitivity was 0.04 μA/10 ppb Ga.

Separation of gallium traces from an aluminium solution

To 50 ml of sample containing aluminium and less than 0.01 mmole of gallium(III), 5 g of dry resin loaded with 1 mmole of T-azo-R were added. After one hour of stirring, the resin was separated by filtration on porous glass, washed with water, transferred to a beaker and stirred for one hour with 20 ml of $0.2M$ nitric acid to elute gallium(III).

RESULTS AND DISCUSSION

Hydrolysis of gallium

In order to correctly interpret the equilibria of gallium with the ligands considered here, both in aqueous solution and in the resin, its hydrolysis reactions must be exactly known. While a number of investigations on this subject have been reported,[15] it has never been studied at the conditions considered in the present study (sodium nitrate aqueous solutions, 25° and gallium concentrations lower than $1 \times 10^{-3}M$). The investigation was made by titrating solutions containing fixed concentrations of sodium nitrate, gallium and nitric acid, with standard sodium hydroxide. The mean number of hydroxyl ions bound per mole of gallium (n) was then calculated according to the following relationship, obtained from the mass equilibria

$$n = \frac{[H] - H}{c_{Ga}} \quad (5)$$

where H is the analytical concentration of protons, and c_{Ga} is the total concentration of gallium.

Some results obtained in $0.1M$ sodium nitrate aqueous solutions are reported in Fig. 1 as a function of pH. The curves obtained at different gallium concentrations coincide at low pH, but differ in less acidic solutions. This indicates that a mononuclear complex is first formed, which then reacts further to give one or more polynuclear hydroxo derivatives.

The final results were obtained by the program SUPERQUAD,[16] by considering all together the titrations at different gallium concentrations. Two hydroxo derivatives were detected, one with molar composition 1 to 1 (GaOH) and the other 5 to 15 [$Ga_5(OH)_{15}$]. Their formation constants are reported in Table 1, together with those obtained at other sodium nitrate concentrations.

The variations of the conditional hydrolysis constants with ionic strength were interpreted on the basis of the Specific Interaction Theory (SIT).[17] According to this the conditional constant of the hydrolysis equilibrium

$$m\mathrm{Ga} + n\mathrm{H_2O} \rightleftharpoons \mathrm{Ga}_m(\mathrm{OH})_n + n\mathrm{H} \quad (6)$$

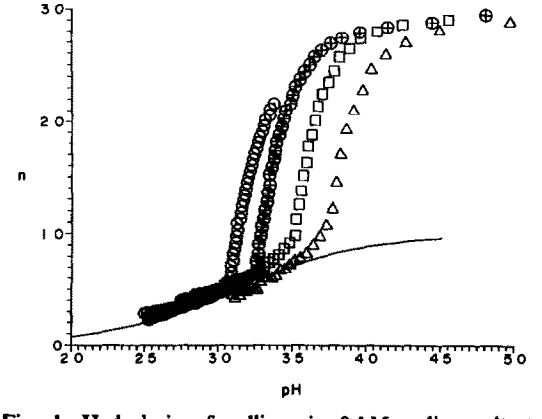

Fig. 1. Hydrolysis of gallium in $0.1M$ sodium nitrate T = 25°. Ordinates: mean number of hydroxyl ions bound per mole of gallium (n) ○ $c_{Ga} = 2.89 \times 10^{-3}M$; ⊕ $c_{Ga} = 9.84 \times 10^{-4}M$; □ $c_{Ga} = 2.45 \times 10^{-4}M$; △ $c_{Ga} = 7.44 \times 10^{-5}M$. The continuous line has been calculated for GaOH, with $\log K_{1,1} = -2.94$.

*Values obtained with SUPERQUAD, considering four titrations at the same time, respectively with $c_{Ga} = 7.44 \times 10^{-5}$, 2.45×10^{-4}, 9.84×10^{-4}, $2.89 \times 10^{-3} M$.

†Values obtained with SUPERQUAD, considering two titrations at the same time, one with $c_{Ga} = 2.998 \times 10^{-4} M$ and the other with $c_{Ga} = 2.099 \times 10^{-4} M$.

depends on the ionic strength of the solution as shown by the following relationship

$$\log K_{m,n} = \log K_{Tm,n} - \frac{0.51 I^{0.5}}{1 + 1.5 I^{0.5}} \times [m z_{Ga}^2 - z_{Gam(OH)_n^q}^2 - n z_H^2] + \{mb(Ga, Y) - b[Ga_m(OH)_n, Y] - nb(H, Y)\} I \quad (7)$$

$Z = m z_{Ga}^2 - z_{Gam(OH)_n}^2 - n z_H^2$ has a value of 4 and 30 respectively for the formation of GaOH and $Ga_5(OH)_{15}$.

The parameters $\log K_{Tm,n}$ and $B = mb(Ga, Y) - b[Ga_m(OH)_n, Y] - nb(H, Y)$ are evaluated by a least-squares method, assuming I as the independent variable and $\log K_{m,n} + 0.51 I^{0.5}(m z_{Ga}^2 - z_{Gam(OH)_n^q}^2 - n z_H^2)/(1 + 1.5 I^{0.5})$ as dependent variable. The following results were obtained (standard deviations are reported in brackets): $\log K_{T1,1} = -2.64(0.17)$; $\log K_{T5,15} = -32.99(0.82)$; B is not significantly different from 0. The values of $\log K_{Tm,n}$ calculated from the conditional constants at each ionic strength on the basis of equation 7, and $B = 0$, are shown in Table 1.

In order to verify that nitrate does not complex gallium, the hydrolysis was also studied in sodium perchlorate. The conditional hydrolysis constants of gallium in sodium perchlorate are: $\log K_{T1,1} = -2.78(0.10)$ and $\log K_{T5,15} = -33.06(0.35)$, and B is again not significantly different from 0. The agreement between the results obtained in sodium nitrate and in sodium perchlorate indicates that gallium is not complexed by the anions of the ionic media considered here.

Complexation of gallium in aqueous solution by T-azo-R and T-azo-C

The complex formation in sodium perchlorate aqueous solution was studied by molecular absorption spectrophotometry. The spectral characteristics of the complexes of gallium with the azo-dyes T-azo-R and T-azo-C are reported in Table 2. The complexation equilibrium and constant are

$$m\mathrm{Ga} + p\mathrm{H}_x\mathrm{L} \rightleftharpoons \mathrm{Ga}_m\mathrm{H}_r\mathrm{L}_p + q\mathrm{H}$$

$$K_{cm,p} = \frac{[\mathrm{Ga}_m\mathrm{H}_r\mathrm{L}_p][\mathrm{H}]^q}{[\mathrm{Ga}]^m[\mathrm{H}_x\mathrm{L}]^p} = K_{cTm,p} \frac{\gamma_{Ga}^m \gamma_{HxL}^p}{\gamma_{GamHrLp} \gamma_H^q} \quad (8)$$

$K_{cTm,p}$ is the thermodynamic complexation constant:

$$K_{cTm,p} = \frac{\{Ga_mH_rL_p\}\{H\}^q}{\{Ga\}^m\{H_xL\}^p} \quad (9)$$

The composition of the complex and the formation constants were determined by the spectrophotometric method previously described,[13] based on the following absorbance and mass balances:

$$A = \epsilon_{HxL}[H_xL] + \epsilon_{H_{x-1}L}[H_{x-1}L] + \epsilon_{GamHrLp}[Ga_mH_rL_p]$$

$$c_{Ga} = [Ga] + [GaOH] + [Ga_5(OH)_{15}] + [Ga_mH_rL_p]$$

$$c_L = [H_xL] + [H_{x-1}L] + [Ga_mH_rL_p] \quad (10)$$

It is important to take into account the formation of the hydroxo derivatives, considering that the complexes are formed at pH higher than about 2 (that with T-azo-R) and 3 (that with T-azo-C), at which hydrolysis is not negligible.

To set the value of p and m, two groups of experiments were performed at constant composition of the ionic medium (0.1M sodium perchlorate). In one of them the metal ion concentration was much higher than that of the ligand ($c_{Ga} \gg c_L$), and in the other the concentration of ligand was higher than that of metal ion ($c_L \gg c_{Ga}$). The calculations were performed at fixed wavelengths, corresponding to the maximum absorbance of the complexes, *i.e.*, 510 nm for T-azo-R and 580 nm for T-azo-C. In each case the diprotonated form of the ligand H_2L was considered to react.

The values $m = 1$, $p = 1$ and $q = 2$ were obtained in 0.1M sodium perchlorate for the complexation of gallium with T-azo-R both in excess of metal ion and of ligand. The formation constants $K_{cm,p}$ of the complex obtained in some independent experiments are reported in Table 3. The formation constants $K_{cm,p}$ obtained at other sodium perchlorate concentrations are reported in Table 4. They depend on the ionic strength I of the solution according to the following relation, derived from the Specific Interaction Theory[8]

$$K_{cm,p} = K_{cTm,p} - \frac{0.51I^{1/2}}{1 + 1.5I^{1/2}} \times (mz_M^2 + pz_{HxL}^2 - z_{MmHrL_p}^2 - qz_H^2) + [mb(M, Y) + pb(H_xL, N) - b(M_mH_rL_p, Y, N) - qb(H, Y)]I \quad (11)$$

The parameters of equation 11, $\log K_{cTm,p}$, $(mz_M^2 + pz_{HxL}^2 - z_{MmHrL_p}^2 - qz_H^2) = Z$, and $[mb(M, Y) + pb(H_xL, N) - b(M_mH_rL_p, Y, N) - qb(H, Y)] = B$, can be evaluated by a multiple linear regression procedure. Their values are reported in Table 4.

The complexation with T-azo-C takes place at an acidity only slightly lower than that with T-azo-R. This indicates that gallium has a behaviour intermediate between indium[10] and aluminium.[11] Also a polynuclear complex is

formed with T-azo-C in a large excess of metal ion. The equilibrium reactions and constants in 0.1M sodium perchlorate are reported in Table 3, and those at other ionic strengths in Table 4. In this case too the thermodynamic complexation constant, and Z and B were estimated by equation (11). Their values are reported in Table 4.

The expected[18] values of Z are 6 for the complexation of gallium with T-azo-R and T-azo-C (1 to 1 complexes) and 12 for the complexation with T-azo-C (2 to 1 complex) which are inside the found confidence limits (95%).

Sorption of gallium on AG MP-1 loaded with T-azo-R

If the sorption of a metal ion on a strong base anion exchange resin containing a chelating group H_xL takes place by equilibrium (1), the fraction of sorbed ion at the given condition can be estimated by means of equation (3), where K_{ex} can be estimated according to the Gibbs–Donnan model (equation 4), and considering that $\log \gamma_{\overline{H_xL}}/\gamma_{\overline{MHrL}} = 1$[1] and $\log\{\overline{NO_3}\}^{z-q} = -(z-q)0.71$.[9]

For instance the estimated value of $\log K_{ex}$ in a 0.5M sodium nitrate aqueous solution is −1.39 for a resin loaded with T-azo-R and −6.40 for a resin loaded with T-azo-C. The fraction f of metal ion sorbed at pH = 3, on a resin containing 0.1 mmoles of dye, from 25 ml of solution, which are typical conditions for a batch experiment, should be respectively 0.98 and 0.50. The hydrolysis constants are those in 0.5M aqueous solution, and are either experimentally found, or evaluated by equation (7). K_{a2} is the apparent protonation coefficient of the ligand in the resin, and can be evaluated from

$$\log K_{ax} = \log K_{axi}\gamma_{\overline{Hx-1L}}/\gamma_{\overline{HxL}}\{\overline{NO_3}\} + \log[NO_3] - \frac{0.51I^{1/2}}{1+1.5I^{1/2}}(z_{NO_3^-}^2 + z_H^2) + [b(NO_3, Na) + b(NO_3, H)]I \quad (12)$$

where again $\log \gamma_{\overline{Hx-1L}}/\gamma_{\overline{HxL}} = 1$ and $\log\{\overline{NO_3}\} = -0.71$,[9] and K_{axi} is the thermodynamic

protonation constant. The values of the apparent protonation coefficients in $0.5M$ solution are $\log K_{a2} = 2.95$ for T-azo-R and $\log K_{a2} = 4.15$ for T-azo-C.[18]

From the estimated values of f it seems preferable to investigate the sorption by the resin containing T-azo-R, because of its ability to quantitatively sorb the metal at pH lower than 3, at least under selected conditions. As a matter of fact at pH higher than about 3 gallium is sorbed not only through equilibrium 1, but also directly by the resin, as demonstrated by the data reported in Table 5, where the sorption of gallium on AG MP-1 not containing ligand is shown. The sorption of a cation on a strong base anion exchange resin is quite surprising, because cations are usually excluded from such resins, due to the existence of a potential difference (Donnan potential) between the resin and the solution phase.[7] However a similar behaviour was observed for aluminium.[2] An interpretation of the sorption by the resin AG MP-1 not containing anionic ligand will be given below. Moreover, the sorption of gallium by a resin containing T-azo-R is probably useful for separating gallium from aluminium because T-azo-R doesn't complex aluminium in aqueous solution. Thus the sorption properties of AG MP-1 loaded with T-azo-R have been extensively investigated. Some results are reported in Table 6, where the fraction f of gallium sorbed on AG MP-1 loaded with T-azo-R under different conditions is shown. Each experiment was performed at fixed volume and ionic strength of aqueous solution, with fixed amount of resin, sorbed ligand and total metal ion, and by changing the acidity which was then measured potentiometrically.

2.76	0.70	1.13	4.21			
3.06	0.68	1.25	7.40			

The value of f was determined at each pH as previously described.

The value of q was experimentally found by plotting $\log(1/f-1)/Z_M Z_{H_2L}$ *vs.* pH. Only the points at pH lower than 3 were taken into account, in order to consider only the sorption which takes place according to equation (1). Straight lines with slopes of about -2 were obtained in each case, so bearing out that the sorption reaction is the same as the complexation reaction in aqueous solution, as expected from the Gibbs–Donnan model. The values of $\log K_{ex}$ calculated at different ionic strengths are reported in Table 6, together with $\log K$ evaluated from equation (4) with $b(M,Y)+(z-q)b(N,Y)-qb(H,Y)=0$. The average value obtained is $-1.24(0.20)$, in acceptable agreement with the value $-0.75(0.33)$ found in aqueous solution. Thus also in the case of gallium, the convenience of the Gibbs–Donnan model for the prediction of sorption and elution from chelating resin is confirmed.

Sorption of gallium on AG MP-1 not loaded

The sorption of gallium on an unmodified anion exchange resin (see data in Table 5) can be explained as follows. It is known[1] that a small amount of weak acid groups are present in strong base anion exchange resins AG-1 and Dowex 1. It has been found by potentiometric titration that the resin AG MP-1 considered here is able to exchange 0.02 protons per g. This should also be the maximum capacity for metal ions. So 2.5 g of dry resin should be able to sorb 0.05 meq of metal ion. This is demonstrated by some saturation experiments of AG MP-1 anion exchange resin not loaded reported in Table 7.

The sorption mechanism could be

$$Ga + 3\overline{HX} \rightleftharpoons \overline{GaX_3} + 3H \qquad (13)$$

$$K_{exGa} = \frac{\overline{[GaX_3]}[H]^3}{[Ga]\overline{[HX]}^3} \qquad (14)$$

where X indicates the weak cation exchanging groups on the resin. In this case the fraction of gallium sorbed by the resin not loaded is given by

$$f = \frac{\overline{[GaX_3]}g}{[Ga]_t V + \overline{[GaX_3]}g} = \frac{1}{1+\dfrac{[H]^3 V Z_{Ga} Z_{HX^3}}{K_{exGa}\bar{c}_x^3 g}} \qquad (15)$$

By plotting $\log(1/f-1)/Z_{Ga}Z_{HX}$ *vs.* pH it is expected that a straight line with slope -3 is obtained. In practice from the data reported in Table 5 a straight line with slope $-2.33(0.10)$ was obtained, in acceptable agreement with the expected one.

Sorption and separation of gallium(III) traces from an aluminium solution

It is known[10] that in aqueous solution T-azo-R is not able to complex aluminium, which requires a peri-di-hydroxylic structure to form stable chelates with this kind of ligand. According to the Gibbs–Donnan model, the same would be valid when the ligand is sorbed on a strong base anion exchange resin. Thus it is to be expected that the separation of gallium from aluminium by using a resin loaded with T-azo-R is possible. This prediction was checked by considering a synthetic sample containing $0.1M$ $Al(NO_3)_3$ and gallium $1\times10^{-5}M$ (sample *l*). Reasonable conditions for a batch separation are those reported in the experimental section: 50 ml of sample treated with 5 g of dry resin AG MP-1 loaded with 1 mmole of T-azo-R. Higher concentrations of ligand can't be permanently held on the resin. Thus, to have a quantitative sorption of gallium by a unique batch treatment, a pH as high as 3 is required. At these conditions 98% gallium should be sorbed through equation (1), as calculated with $\log K\gamma_{\overline{HxL}}/\gamma_{\overline{MHrL}}\{NO_3\} = -1.24$, *i.e.*, the value actually found. Probably the sorption yield is even better because at this acidity gallium is also partly sorbed by equation (13). On the contrary aluminium is expected not to be sorbed at all. Another problem is the determination of the best conditions for elution, which can also be predicted by equations (3) and (4). A well-suited

Table 7. Sorption of gallium on the strong base anion exchange resin AG MP-1 from $0.06M$ $NaNO_3$. $V=25$ ml; pH = 4.20; 2.5 g of dry resin in nitrate form

Total concentration of gallium (M)	Conc. in solution (M)	mmoles of Ga sorbed per g of dry resin
4.57×10^{-4}	1.09×10^{-4}	3.48×10^{-3}
9.14×10^{-4}	1.28×10^{-4}	7.86×10^{-3}
12.19×10^{-4}	5.10×10^{-4}	7.09×10^{-3}

solution for eluting gallium is 0.2*M* nitric acid. Solutions at higher acidity can't be used, because nitrate at higher concentration can release the sulphonated azo-dye from the resin. The volume of eluting solution which must be used for a quantitative (99.3%) recovery of gallium by one batch treatment was 25 ml as calculated from equations (3) and (4). Based on the above considerations, the separation of gallium was performed as suggested in the experimental section. The concentration of gallium and aluminium were then determined in the eluting solution. Gallium was quantitatively recovered (99%), while the concentration of aluminium was below the limits of the spectrophotometric method employed.[2] The concentration of aluminium in sample *l* after treatment with the loaded resin was also determined spectrophotometrically and found to be unchanged. This demonstrates that gallium is completely separated from aluminium solution, as predicted on the basis of the Gibbs–Donnan model. However gallium cannot be preconcentrated by this method, because relatively large volumes of eluting solution are required for a quantitative recovery. The same loaded resin can be used many times without any loss of reagent.

THIN-LAYER CHROMATOGRAPHY OF LASER DYES AND DYE ANALOGS WITH CYCLODEXTRINS IN THE MOBILE PHASE

IEVA R. POLITZER,* KATHLEEN T. CRAGO, KEITH AMOS, KYRAN MITCHELL and TIFFANY HOLLIN
Department of Chemistry, Xavier University, New Orleans, Louisiana 70125, U.S.A.

(*Received* 19 *September* 1991. *Revised* 14 *November* 1991. *Accepted* 15 *November* 1991)

Summary—The addition of β-cyclodextrin and substituted hydroxyethyl and hydroxypropyl-β-cyclodextrins to aqueous urea-containing mobile phases, can be used to enhance the migration of various laser dyes on thin layer chromatography. Selected laser dyes from the coumarin, rhodamine and bimane families were examined, as well as a number of dye analogs. Silica gel, polyamide and C18 reverse phase plates were utilized. Overall, the substituted hydroxypropyl-β-cyclodextrins appeared to be the most effective for increasing dye migration.

Cyclodextrins (CDs) are cycloamylases which are known for their ability to form inclusion complexes with a wide range of guest molecules.[1] They are extensively used as stationary phase components in gas chromatography as well as stationary or mobile phase additives in liquid chromatography.[2–5] In contrast, there has been relatively little utilization of CDs in thin layer chromatography (TLC). The recent introduction of urea as a solubilizing agent for aqueous CD solutions, has opened the way for more extensive TLC applications.[6,7] Our earlier work has indicated probable inclusion complexation between certain laser dyes and CDs.[8–10] Thus, it seemed likely that the TLC characteristics of these laser dyes would also be affected by CDs in the mobile phase.

In this investigation, urea solubilized β-CD and the substituted hydroxyethyl and hydroxypropyl-β-CDs were used as aqueous mobile phase additives. Their effects were examined on the separation of selected laser dyes and dye analogs. Stationary phases for this TLC study included silica gel plates as well as polyamide and C18 reverse phase plates.

EXPERIMENTAL

Materials

Beta-cyclodextrin (Advanced Separation Technologies, Whippany, NJ), hydroxyethyl-β-cyclodextrins, hydroxypropyl-β-cyclodextrins, urea, 2,5-diphenyl oxazole, fluorescein, indole (Aldrich Chemical Co., Milwaukee, WI), ethanol, acetone, tert-butyl alcohol (Fisher Scientific Co., Raleigh, NC), coumarin laser dyes and rhodamine laser dyes (Eastman Kodak, Rochester, NY) were used as received without further purification. The bimanes were synthesized and purified as reported previously.[11] In-house demineralized water was used to prepare all aqueous solutions.

The thin layer chromatography plates employed included Whatman KC18F reverse phase (10 × 10 cm, 200 μ), Baker-flex polyamide 6-F (5 × 20 cm) and Baker-flex silica gel 1B-F (20 × 20 cm) plates. These plates were used as received.

Methods

The mobile phase solutions were patterned after those described by Hinze *et al.* and were prepared as follows. First, aqueous solutions of 4.0*M* urea were made. Next, appropriate amounts of various cyclodextrins were dissolved in the urea solutions to make the final solutions 0.1*M* for the respective cyclodextrin to be studied. Each mobile phase to be used with reverse phase C18 plates was also made 0.5*M* in sodium chloride and 5% v/v with tert-butyl alcohol. When necessary, the solutions were warmed gently (~50°) to dissolve the cyclodextrins and then allowed to cool to room temperature prior to use. Stock solutions of the different test solutes were generally prepared by dissolving 2.0 mg of the solid in 1.0 ml of methanol. A few microliters of these solute stock solutions were applied 2 cm from the lower edge of the plates.

Fig. 1. Structures of selected coumarin laser dyes.

Ascending thin layer chromatography was performed in 27 × 8 × 25 cm rectangular chambers which were lined with mobile phase-soaked filter paper. The final positions of the solutes were located under UV-Vis light (Mineralight UVSL-58). Most of these compounds moved as distinct spots thus facilitating determination of retardation factors.

RESULTS AND DISCUSSION

The ability of cyclodextrins (CDs) to modify the characteristics of selected laser dyes on thin layer chromatography (TLC) was examined. The β-cyclodextrin (β-CD) as well as hydroxyethyl and hydroxypropyl substituted cyclodextrins were individually added to the aqueous urea mobile phases. Commercially available polyamide, silica gel and reverse phase C18 plates served as solid supports. The retardation factor (R_f) values were obtained and compared for selected laser dyes from the coumarin, rhodamine and bimane families as well as for a number of other heterocycles. (R_f = Distance compound travels/distance solvent travels.) Corresponding capacity factor (k') values were calculated[12] by using the relationship $k' = (1 - R_f)/R_f$.

Coumarin laser dyes

Five coumarin laser dyes (C30, C314, C314T, C102 and C153) were examined (see Fig. 1). Using polyamide TLC plates, an aqueous solution of 4.0*M* urea was compared to aqueous solutions of urea with various added cyclodextrins in the mobile phase. In all cases, when β-CD, the substituted hydroxyethyl, or hydroxypropyl CDs were in the mobile phase, the R_f values of the dyes increased. As shown in Table 1, for the selected coumarins, the hydroxypropyl-β-CDs were overall the most effective agents for increasing R_f values on

polyamide plates. These coumarins have very similar R_f and k' values on silica gel TLC plates with ethanol as the mobile phase. Substitution of aqueous 4.0M urea as the mobile phase on the other hand, resulted in uniformly low R_f values. Aqueous solutions of urea and added CDs, however, led to a wide range of R_f and k' values and facilitated identification of the coumarins on silica gel plates. These results are summarized in Table 2.

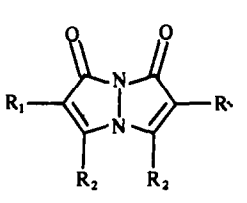
The coumarins listed above did not move at all on reverse phase C18 plates with a mobile phase consisting of aqueous 4.0M urea, 5% v/v t-butyl alcohol, 0.5M sodium chloride and 0.1M CD. The CDs examined here as mobile phase additives were β-CD and hydroxypropyl-β-CD (molecular substitution, MS = 0.9).

Bimane laser dyes

Five bimane dyes [syn- and anti-(Me,Me), syn and anti (Me,Cl), and syn-(Ph, Cl) bimane] were studied. Their structures are shown in Fig. 2. TLC was carried out on polyamide and reverse phase C18 plates as described above. The presence of β-CD or the substituted hydroxyethyl and hydroxypropyl CDs in the mobile phases did not make any significant difference in the R_f values obtained for these bimanes. All of the bimanes examined gave R_f values above 0.50 and k' values below 1 on silica gel plates with ethanol as the mobile phase. The R_f values were markedly decreased when aqueous 4.0M urea was substituted as the mobile phase. Addition of CDs, particularly hydroxypropyl-β-CD, to the urea mobile phase again elevated the R_f values, but not to the same levels as found with ethanol. The results with silica gel plates are shown in Table 3. As can be seen, using the urea-CD mobile phase may be useful in the separation of certain bimanes on silica gel plates.

Rhodamine laser dyes

The rhodamine laser dyes, Rh6G and RhB as well as sulforhodamine B and sulforhodamine 101 (see Fig. 3) were examined on polyamide TLC plates as described earlier. In all cases, except for sulforhodamine 101, the addition of CDs to the urea mobile phase increased the R_f values of the rhodamines. These results (R_f and k' values) are shown in Table 4. In contrast,



syn-(R_2, R_1) bimanes:

when reverse phase C18 plates were used, the introduction of β-CD or hydroxypropyl-β-CD (MS = 0.9) had very little effect on the R_f values.

When silica plates were used, the advantages of CDs in the mobile phase became particularly striking. The rhodamines examined exhibited very little migration on the silica gel plates with either acetone or aqueous urea as the mobile phase. However, upon addition of CDs, considerable elevation of the R_f values was obtained (see Table 5 for R_f and k' values). This could prove quite useful in the identification and/or separation of the rhodamine family members.

Fluorescein, a laser dye akin in structure to the rhodamines, qualitatively has similar TLC characteristics. Aqueous urea mobile phases did not promote any migration of this compound on the solid supports examined here. Upon addition of CDs however, fluorescein R_f values were increased. This was most pronounced with hydroxypropyl-β-CD (MS = 0.9), whereupon fluorescein R_f values of 0.19, 0.22 and 0.72 were obtained on polyamide, C18 and silica gel plates respectively. Hydroxypropyl-β-CDs were also the most effective aqueous mobile phase additives for the aromatic heterocycle, indole. Whereas no migration of indole was obtained in aqueous urea, R_f values of 0.42, 0.18 and 0.51 can be obtained (polyamide, C18 and silica gel plates respectively) upon addition of hydroxypropyl-β-CD (MS = 0.9) to the mobile phase.

As seen from the above, the addition of CDs and urea to aqueous mobile phases can be used to increase the migration of various laser dyes and dye analogs on TLC. Often, better separation or better selectivity is facilitated. Selectivity refers to the capability of a chromatographic system to distinguish between two compounds. The separation or selectivity factor, α, for two

solutes A and B, can be related to their capacity factor by the equation

$$\alpha = k'_B/k'_A$$

where B is the more strongly retained species and A is the less strongly held species. By this definition, α is always greater than unity. As α approaches 1, separation becomes difficult.[13,14] Tables 6 and 7 show capacity factors and selectivity factors for the various coumarin and rhodamine laser dyes when β-CD or the hydroxypropyl-β-CDs are added to the mobile

phase. In most cases, α is greater than 1. Capacity factors and selectivity factors are also shown for two sets of isomeric bimanes in Table 8. The selectivity factors reflect the better separation of the syn- and anti- (Me,Me) bimane isomers as contrasted to the syn- and anti- (Me, Cl) bimane isomers. Overall, the substituted hydroxypropyl-β-CDs appear to be the most effective in increasing the migration of coumarin, rhodamine and bimane laser dyes, especially on polyamide or silica gel plates. This achievement of good TLC separations on the commonly used silica gel plates by introduction of CDs in the mobile phase, may prove to be particularly useful.

(*Received* 28 *January* 1991. *Revised* 2 *July* 1991. *Accepted* 30 *August* 1991)

Summary—Any investigation for a better knowledge of precipitation/dissolution problems necessitates the availability of all the β formation constants of the uncharged soluble species (ion-pair). Several difficulties dealing with solubility measurements are briefly reviewed, especially related to phase structure variations, time-lag or supersaturation phenomena. Thanks to some thermodynamic considerations, the evolution of the uncharged soluble species with hydration and solid phase modifications can give a new explanation about the observed dispersion in literature values for some weakly soluble ionic compounds. When not given elsewhere, the evaluation of thermodynamic data of interest (formation constants, solubility product, *etc.*) is made possible according to given methods.

The application of conditional calculations, as introduced by Ringböm,[1] has permitted the development of rational use of computers to study the thermodynamics of electrolytic solutions. Two of us have shown, mainly as a pedagogical tool,[2] that computers easily allow all the equilibria between the ions in the solution to be taken into consideration, thus avoiding any approximation.

Hereafter, our intensive practical insights into industrial (*e.g.*, waste management, plating, *etc.*) and environmental (*e.g.*, geology, ecotoxicity, *etc.*) processes lead us to study the behaviour of weakly soluble compounds, for which the solubility product is a classical approach.

In this work, we want to study the solution equilibria of a weakly soluble compound ML in water:

$$\underset{\text{Saturated solution of } ML_{aq}}{ML_S} \Leftrightarrow \underset{}{ML^0_{aq}} \Leftrightarrow \underset{\text{Dissociation of } ML_{aq} \text{ in solution}}{M^+_{aq} + L^-_{aq}}$$

Most frequently, we only know the solubility product:

$$K_S = |M^+_{aq}||L^-_{aq}|$$

either from Gibbs energy calculations, or from solubility measurements. In both cases, the determination of K_S currently neglects the presence of the molecular form ML^0 in solution, so we can explain, in part, the apparent variability observed in the literature.

The first equilibrium is markedly dependent on the crystalline form of the solid ML; this is well known, and can also lead to some spread in the solubility data. An amorphous precipitate evolving to a crystalline form strongly diminishes the solubility, as is the case for numerous hydroxides or for calcium orthophosphate (with its apatite form). Much work on saturation time-lag gives evidence of a large body for new studies taking the nature of the intermediate form ML^0_{aq} into account.

Saturation

When we consider a solution of ML at a concentration below saturation, the second equilibrium can be characterized by the classical thermodynamic constant β,

$$\beta = |ML^0_{aq}|/|M^+_{aq}||L^-_{aq}|$$

(where $||$ stands for activities), depending only on temperature, pressure and ionic strength. If we progressively raise the ML concentration in water, the limiting solubility is obtained for a given value S of this concentration.

Therefore $\beta \Rightarrow S/|M^+_{aq}||L^-_{aq}|$ and with the solubility product: $\beta = S/K_S$.

*Author for correspondence.

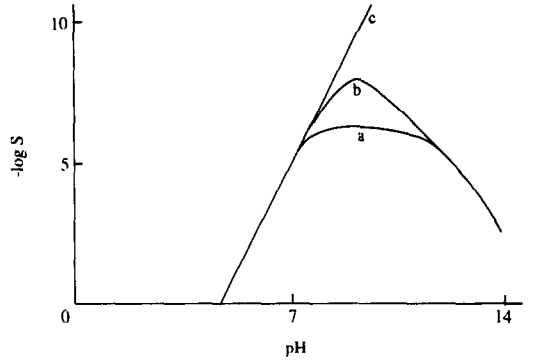

Fig. 1. Solubility in the Cu^{2+}–OH^- system; influence of the knowledge of various β formation constants (curves a, b, c: see text).

So, while β is a constant, every variation in the limiting solubility for the molecular form leads experimentally to a variation in the solubility product. Knowing β precisely is a very useful topic, as this allows us to calculate the ML^0 activity in a given solution from the measured values for M^+ and L^-

$$|ML^0| = \beta\,|M^+_{aq}|\,|L^-_{aq}|$$

As long as the solution maintains limpidity, we have either under-saturation if $|ML^0| < S$, or over-saturation if $|ML^0| > S$.

The importance of knowing both β and S becomes evident in the study of diluted solutions, or when dealing with the environmental hazards of toxic metallic salts. In these cases, we cannot systematically neglect the solubility of the molecular form in comparison with the very low concentrations in free ions.

As an example, we want to present here the results for the solubility calculations in a Cu^{2+}/OH^- solution, at an ionic strength $I = 0.15M$. In Fig. 1, curve (a) is the solubility of all metal species, taking into account the $\beta_{2,OH}$ formation constant of the weakly soluble hydroxide $Cu(OH)^0_2$:

$$S = [Cu^{2+}] + [CuOH^+] + [Cu(OH)^0_2] + [Cu(OH)^-_3] + [Cu(OH)^{2-}_4]$$

$$S = |Cu^{2+}|/\gamma_{2+} + |CuOH^+|/\gamma_+ + |Cu(OH)^0_2| + |Cu(OH)^-_3|/\gamma_- + |Cu(OH)^{2-}_4|/\gamma_{2-}$$

$$S = |Cu^{2+}|/\gamma_{2+} \times \{1 + \beta_{1,OH}|OH^-|/\gamma_+ + \beta_{2,OH}|OH^-|^2 + \beta_{3,OH}|OH^-|^3/\gamma_- + \beta_{4,OH}|OH^-|^4/\gamma_{2-}\}$$

[where [] stands for concentrations, || for activities, and γ_i for activity coefficients]. In such cases, for concentrations Ringböm introduces the conditional solubility product K'_S and the α coefficient, *i.e.*:

$$K'_S = [Cu^{2+}]_T[OH^-]^2 = \alpha_{Cu(OH)} \cdot K_S$$

(see ref. 1, p. 67).

However, in order to obtain the correct curve (a) for the total metal solubility from the conditional solubility product, it is important to take into account the presence of the $Cu(OH)^0_2$ species in the $\alpha_{Cu(OH)}$ term;[2] but the pertinent data were not available at the time of the publication by Ringböm.[1]

When we ignore the $\beta_{2,OH}$ value (which is most frequent for compounds other than hydroxides) we write only

$$S = [Cu^{2+}] + [CuOH^+] + [Cu(OH)^-_3] + [Cu(OH)^{2-}_4]$$

and the calculated solubility at pH = 9.5, for example, is 100 times smaller than the correct value [compare curves (a) and (b), Fig. 1].

In order to obtain a straightforward calculation, some authors consider the presence of free metallic ions only, obtaining:

$$S = [Cu^{2+}] = K_{S,Cu(OH)_2}/(|OH^-|^2\gamma_{Cu^{2+}})$$

which is presented as curve (c) in Fig. 1. The importance of such approximations is evident, and their consequences may be dramatic, particularly when dealing with a compound of ecotoxicological importance.

For two weakly soluble compounds under competition, one implicitly supposes that the more insoluble compound is also the more stable; this is not always true however. If we write for the two competing ligands L^- and X^- with the cation M^+:

$$ML_S + X^- \underset{(a)}{\Leftrightarrow} ML^0 + X^- \underset{(b)}{\Leftrightarrow} MX^0 + L^- \underset{(c)}{\Leftrightarrow} MX_S + L^-$$

the formation of the precipitate MX_S, even more insoluble than ML_S, depends on the evolution of the solution equilibrium (*b*), *i.e.*, on the β formation constants for ML^0 and MX^0, and of the dissolution/precipitation kinetics for equilibria (*a*) and (*c*).

This is the reason why we review, in the present article, some secondary phenomena and some thermodynamic considerations related to

the precipitate formation and to the use of β formation constants.

Supersaturation and difficulties in the determination of solubilities

In spite of an apparent facility, solubility determinations are not easy to obtain with sufficient precision,[3] as one has to successively prepare a saturated solution, separate it from the solid in excess and finally analyse this solution. All steps can lead to many uncertainties,[4] and only careful checking of the system gives useful data. Here we want to focus on the various phenomena leading to a spread in solubility data.

When the solute concentration is increased, the solution progressively goes from an unsaturated state to an oversaturated one (where the precipitate forms spontaneously), but an intermediate metastable step arises frequently. The current way studying a solid/solution equilibrium is to introduce the supersaturation ratio

$$\Omega = |M^+||X^-|/K_{S,MX}$$

The driving force for the formation of the precipitate is given by the Gibbs free energy on going from the supersaturated solution to equilibrium

$$\Delta G = -(RT/2)\ln \Omega$$

But the nucleation of crystals from aqueous solutions is not a straightforward process; it may be heterogeneous (crystallization is induced by foreign ions or by the reactor wall) or homogeneous, which requires high supersaturation ratios.[5] This nucleation phenomenon may be dependent on particle size; moreover, its time delay is generally inversely proportional to the concentration.[5-7] Afterwards, a diffusion process in the solution is necessary, in order to assure the growth of crystals; this heterogeneous equilibrium is also associated with some time-lag.

Analytical chemists are well aware of the different behaviour between fresh and aged precipitates,[8] when a very fine crystalline solid progressively converts to a more ordered phase. The particle size may also play a significant role in the conversion from one polymorphous form to another, such as in the case with the various hydrated forms; and due to the time-lag for the solid-state interconversion, it is not necessarily the most stable hydrate that is present, as shown later in this article.

The coexistence of different phases in equilibrium is also a frequent situation, especially in natural waters (and geological compounds therein),[4,9,10] and this can lead to solid solutions, either homogeneous or heterogeneous, where the activity of the solid phase under study is decreased.

Finally, the presence of other ions in the solution gives rise to several effects. First, an ionic strength effect, modifying the values of all thermodynamic constants (see hereafter); secondly, some complexes can be formed, either soluble or insoluble, whose formation constants have to be taken into consideration; thirdly, foreign ions frequently have a kinetic effect, either catalytic or inhibiting, on the precipitation rate.

According to the preceding considerations, it will not be astonishing to reach solubility product values in great variation, and it is not uncommon to have a 10-fold dispersion for K_S. In such a case, the classical treatment infers a $\sqrt{10}$ multiplication for the ion solubility (*i.e.*, $\times 3.16$); but when we are dealing with the ion pair, its concentration is multiplied by 10, which is very different.

It should be noted that when dissolution of a weakly soluble compound in excess of precipitant does not take place, this does not mean that complex formation is impossible: the value of β depends on the S/K_S ratio and even if S and K_S are very small, β may be high.

Solvation of ions

The solubility product can be obtained by a combination of tabulated Gibbs free energy data, according to the well-known relationship:

$$MS_S \Leftrightarrow M_h^+ + X_h^- \quad K_S = |M^+||X^-|/|MX|$$

$$\Delta G^0 = -RT \ln K_S$$

$$= \Delta G_f^0(M_h^+) + \Delta G_f^0(X_h^-) - \Delta G_f^0(MX_S)$$

where S is the solid form, and h the hydrated one.

In fact, the free energy for this reaction is the sum of two terms related to the separation of ions from the crystal (dissolution) and to their hydration:

$$\Delta G^0 = \Delta G_d^0 + \Delta G_h^0$$

Any modification into the solid (nature of the crystal lattice or of the amorphous form, particle dimension, *etc.*) leads to variations of these two terms and also of the solubility product.[11-13]

In such a model, we can write when various solid forms α, β, *etc.* are available:

$$M_h^+ + X_h^- \Leftrightarrow (MX_S)_\alpha \quad \Delta G_\alpha ; K_{S\alpha}$$

$$M_h^+ + X_h^- \Leftrightarrow (MX_S)_\beta \quad \Delta G_\beta ; K_{S\beta}$$

where

$$\Delta G_\alpha = \Delta G_d + \Delta G_{h(\alpha)}$$

$$\Delta G_\beta = \Delta G_d + \Delta G_{h(\beta)}$$

and the variations in K_S are related to modifications in the solid form.[11–13]

Free energies of formation ΔG_f^0 for the solid salts MX are sometimes difficult to obtain, due to the possibility of various crystalline or amorphous phases being present (see preceding paragraph). But the obtention of thermodynamic data for the formation of ions in solution is somewhat cumbersome, as we are concerned by (hypothetic) individual ions where solvation state is unknown; this can be resolved, in part, from a Born–Haber type formulation and some arbitrary partition.[14]

Two different conventions are used in thermochemical data compilations for ions in solution, each referring to the hydrated proton H_h^+; they concern either its standard formation

$$1/2H_{2g} \rightarrow H_h^+ \quad \Delta H_f^0(H_h^+) = \Delta G_f^0(H_h^+) = 0$$

or the hydration of the gaseous proton

$$H_g^+ \rightarrow H_h^+ \quad \Delta H_f^0(H_g^+) = \Delta G_f^0(H_g^+) = 0$$

In fact, solvent shells can be built up by the stepwise attachment of molecules to gas-phase ions. So, measurements of the thermochemistry of clustering reactions (in the gas phase) such as

$$M^+ \cdot (n-1)H_2O + H_2O \rightleftharpoons M^+ \cdot nH_2O$$

or

$$X^- \cdot (n'-1)H_2O + H_2O \rightleftharpoons X^- \cdot n'H_2O$$

allow an insight into ion-solvent interactions in the inner solvation shells, and constitute a useful step towards elucidation of the ion solvation in the condensed liquid phase. Such studies have been conducted recently, thanks to high-pressure or pulsed electron-beam mass spectrometry techniques.[15,16] Other determinations by emf measurements and calculations[17–19] lead to the admitted experimental values (in good accordance with the hypothesis of equality between these values):

$$\left.\begin{aligned} \Delta H_h^0(H_g^+) &= (-1100 \pm 10)\ \text{kJ/mole} \\ \Delta G_h^0(H_g^+) &= (-1060 \pm 10)\ \text{kJ/mole} \end{aligned}\right\} \text{ for } H_g^+ \rightarrow H_h^+$$

Although the conventional value is eliminated by subtraction during the calculation of ΔG^0, tabulated values should be examined with care before any discussion and use. On the other hand, some corrections or re-evaluations for the free energy of formation of any ion in solution can lead to solubility products with differences in several orders of magnitude from previous values: this is the case for metal sulphides, as recently detailed by Licht.[20]

Another complicating factor is the solvation of the ion-pair, while for the overall solubilization process of a weakly soluble ionic compound

$$MX_S \Leftrightarrow MX_h^0 \Leftrightarrow M_h^+ + X_h^-$$

we have to take into account the different behaviour of the solid MX (in its crystalline or amorphous form) and of MX in solution, *i.e.*, of the ion-pair MX^0 somewhat hydrated. When referring to the usual model for the solvation of an ionogen,[21] we propose to write here a series of equilibria such as

$$\underset{\text{ionic solid}}{M^+X_S^-} \Leftrightarrow \underset{\text{contact ion-pair}}{(M^+X^-)_h^0} \Leftrightarrow \underset{\text{solvent-separated ion-pair}}{(M^+//X^-)_h^0} \Leftrightarrow \underset{\text{free solvated ions}}{M_h^+ + X_h^-}$$

According to the analytical technique, the measured equilibrium constant (or any thermodynamic data) will refer to any combination of the intermediate data. Contact ion-pair and solvent-separated ion-pair are separated by an energy barrier corresponding to the formation of a hole between the ions, with a dimension compatible with the size of a solvent molecule to be introduced in between.

The ion-pair model is most understandable when introduced starting from a saturated solution; here we have to write a formation constant for the soluble species

$$M_h^+ + X_h^- \Leftrightarrow (M^+X^-)_h^0$$

$$\beta = \frac{|(M^+X^-)_h^0|}{|M_h^+||X_h^-|} = S/K_S$$

valid also after the beginning of precipitation. It implies that the solubility S for the (solvated) ion-pair depends on the K_S value, *i.e.*, on the final state of the solid form.

So they are limiting solubilities related to each form of ion-pair solvation; these species determine the nucleation type. The unsolvated (*i.e.*, totally dehydrated) ion-pair MX^0 will be the less soluble species. A dehydration

reaction is endothermal,[22] and the formation of an amorphous solid can be facilitated during the precipitation, as corresponding to a minimum in free energy.

It is possible that in solution the evolution of a hydrated species to another (such as various aggregates or various solvation steps) should be relatively small in comparison with the differences between the solid forms. With this hypothesis, we maintain a unique value for β which is in fact a conditional formation constant for all the MX species in the solution:

$$\beta' = |(M^+X^-)^0_h|_T / |M^+_h|\,|X^-_h|$$

$$\Delta G' = -RT \ln \beta'$$

The solution model becomes:

$$M^+_h + X^-_h \Leftrightarrow (M^+_h)_a(X^-_h)_a + (M^+_h)_b(X^-_h)_b + \cdots$$

$$\begin{array}{ccc} & \overset{\Delta G_a}{\updownarrow} & \left(\begin{array}{c}\\ \end{array}\right) \overset{\Delta G_b}{\updownarrow} \\ (MX_S)_\alpha & & (MX_S)_\beta \end{array}$$

and

$$\Delta G_\alpha = \Delta G_d + \Delta G_{h(\alpha)} = \Delta G' + \Delta G_a$$

$$\Delta G_\beta = \Delta G_d + \Delta G_{h(\beta)} = \Delta G' + \Delta G_b$$

With such a model, we can better understand the supersaturation phenomenon or the preferential formation of a given solid species, as the repartition of the species $(M^+_h)_a$, $(X^-_h)_a$, $(M^+_h)_b$, $(X^-_h)_b$, *etc.*, depends on the solution composition. Such polymorphic transformations due to successive dissolution/recrystallization processes have been characterized (with a time-lag of only some hours) in highly supersaturated calcium carbonate solutions at 50°.[23,24] When several morphological or crystalline forms of a solid co-exist, the form with the highest energy will dissolve first, and the measured solubility will correspond to the solubility of the most energetic form still undissolved. We can also explain how a solid form is transformed into another, in humid conditions[8,11] (dashed arrow in the preceding diagram): the authorized transformation is only $\alpha \Rightarrow \beta$ due to the ΔG criterion, but also with a solubility criterion. Starting from the β solid species, we can only solubilize $S_\beta < S_\alpha$ while $(M^+_h)_b$, $(X^-_h)_b$ and $(MX_S)_b$ are in equilibrium, and the system is not in saturation condition according to the α species. Bearing in mind this model of a series of equilibria between hydrated uncharged ion-pairs in solution, we can better explain some apparent contradictions, for example concerning the high phosphate content in waste waters *vs.* lake waters:[25–27] with a slow circulation flow, there is sufficient time for the precipitate to give a more stable species (see also the evolution of calcium carbonate[8,23,24] or calcium phosphate[11] crystalline forms in solution).

Moreover, according to the experimental techniques used for precipitation/dissolution studies, it becomes less easy to obtain $K_{S\alpha}$ with precision, as the transformation kinetics can interfere, and also the supersaturation ratio related to the species of interest.[6] Studying the dissolution on solid compound (of known structure) gives rise to K_S measured in good accordance from one study to another; this is not always the case when the corresponding solid is obtained through a precipitation reaction, while the operating conditions are not exactly the same, and while the solid structure may differ. Such a problem can explain some discrepancies between K_S or β values for calcium carbonate, for example;[10,28–31] this will be developed in a forthcoming article.

Choice/estimation of thermodynamic constants

The preceding discussion has focused on the importance of the knowledge of the β formation constant for a MX^0 uncharged soluble complex, in order to calculate the total solubility of a given metal in a given solution system.

Due to various IUPAC compilations,[32–35] we have a lot of critical data for inorganic (and also organic) ligands, with complex stability constants, solubility product, and other thermodynamic values. Other data are available, for many metal/ligand systems in the book by Kragten[35] and for hydroxide compounds in the book by Baes and Mesmer,[37] for example. Thanks to the recent developments of microinformatic treatment of electrochemical data concerning solubility equilibria, many teams are actually beginning to establish new β values for a lot of compounds, mainly of environmental interest.

However many data are missing or are sometimes contradictory; this is especially the case when dealing with weakly soluble compounds, for which the β formation constant is rarely known. In order to avoid any dubiousness in the speciation studies, we have to estimate this β value, which can be obtained from the solubility data and the $\beta = S/K_S$ relationship.

A method given by Clifford[38,39] can be used to extimate the unknown β or K_S value for a given compound: he observed a linear variation of

Table 1. Estimation of solubilities and formation constants for insoluble divalent metal sulphides, from the values for corresponding insoluble carbonates (as described in the text)

		Cd^{2+}	Cu^{2+}	Pb^{2+}	Zn^{2+}	Fe^{2+}
MCO_3	$\log \beta_1$ (lit.)	4.4	6.8	6.2	4.8	5.3
	pK_S (lit.)	12.5	9.6	12.8	10.7	10.2
MS	pK_S (lit.)	26.6	35.1	26.1	22.8	18.1
	$-\log S$ (lit.)	15.1	15.6	13.2	11.9	8.8
	$\log \beta_1$ (est.)	11.5	19.5	12.9	10.9	9.3

$-\log \beta$ or pK_S against the metal electronegativity (after some corrections). This author was consequently able to correct some inadequate data, and merely to predict the values when not yet determined, as applied to a lot of sulphides, hydroxides, carbonates, sulphates, *etc.* On the other hand, in a recent study concerning the simultaneous complexation of divalent heavy metallic cations by carbonate and sulphide ions,[40] we have proposed the hypothesis that for each precipitate of a given cation, the ratio of the solubility over the M^{2+} concentration is constant. That is

$$S_{MCO_3}/[M^{2+}] = F \quad (MCO_3 \text{ precipitate})$$

$$S_{MS}/[M^{2+}] = F \quad (MS \text{ precipitate})$$

As β formation constants for heavy metal carbonates are well known, this hypothesis allows us to estimate a value for the β formation constant of the corresponding sulphide.

From the tabulated values of β_1 and K_S for MCO_3, we can write

$$F = S_{MCO_3}/[M^{2+}] - \beta_{1,MCO_3}[K_{S,MCO_3}]^{1/2}$$

and hereafter

$$S_{MS} = F[K_{S,MS}]^{1/2}$$

and

$$\beta_{1,MS} = \beta_{1,MCO_3}[K_{S,MCO_3}]^{1/2}/[K_{S,MS}]^{1/2}$$

The estimated values (Table 1) are well in the range of the literature data, when available. If in error, they give a first approximation, and they have allowed us a good accordance between a speciation calculation and the substrate analysis.[40]

Another point of importance, in the use of the β constants within a speciation calculation, lies in the ionic strength correction. In fact, many compiled data are given for infinitely diluted solution ($I = 0$) or for some finite values (such as $I = 0.1$; 0.5 or $1M$); but the system under study can be at any other value, such as $0.04M$ for a given soil, $0.7M$ for seawater, *etc.*

The classical way for estimating the β value at a given ionic strength is from the activity coefficient correction, as given by the Debye–Hückel equation or any modification.[41,42] At low ionic strength, Linder and Murray have proposed[43] a useful approach, in order to estimate the value from only one or two data points, and their results are no more dispersed than other literature values.

In multicomponent systems with a speciation study, we frequently have to use an algorithmic method[40,42] in which a first estimated value of ionic strength (and of thermodynamic equilibrium constants) gives rise to a more precise value of any concentration for all the species in the system, and so a novel estimate for the ionic strength.

Another way to estimate the activity coefficients in a multicomponent system with an ionic strength up to $2M$ is the Pitzer equation,[44,45] which takes into account pairwise interactions between ions of opposite charge sign. Activity coefficients in salt mixtures can be estimated, in Pitzer's ion interaction treatment, through computer programs.[46] Due to a considerable effort in the determination and compilation of the empirical parameters, we are able to describe any system under study, even when somewhat cumbersome.[47]

Other models can be used in order to obtain ionic activity coefficients; this is the case of the mean spherical approximation, whose results in aqueous electrolyte mixtures[48] are also satisfactory when compared to experimental data.

TRACE DETERMINATION OF SULPHIDE AND SULPHUR DIOXIDE BY VAPOR MOLECULAR ABSORPTION SPECTROMETRY USING MAGNESIUM AND TELLURIUM HOLLOW CATHODE LAMPS

QINHAN JIN,* HANQI ZHANG, YIXIANG DUAN, AIMIN YU, XINWEI LIU and LISHUANG WANG
Department of Chemistry, Jilin University, Changchun, 130023, People's Republic of China

(*Received* 21 *August* 1991. *Revised* 22 *November* 1991. *Accepted* 23 *November* 1991)

Summary—A new method has been developed in this paper for determining sulphide and sulphur dioxide simultaneously. Two emission lines, 202.6 nm and 214.3 nm which are emitted from hollow cathode lamps (HCL) of magnesium and tellurium, respectively, were used as radiation sources for measurement of absorbances of H_2S at 202.6 nm and SO_2 at 214.3 nm or 202.6 nm. The detection limit for S^{2-} was shown to be 0.01 μg/ml and the detection limits for SO_2 with 202.6 nm and 214.3 nm lines were 0.05 and 0.2 μg/ml, respectively. The method has been employed to satisfactorily analyse practical samples.

Atomic absorption spectrometry (AAS) has been very successful for determining most metallic elements, but its use is limited for the determination of nonmetallic elements. This disadvantage arises from the following reasons:

(1) The most sensitive resonance lines of the nonmetallic elements are situated in the vacuum ultraviolet region (below 190 nm) and, therefore, they cannot be directly determined with the usual instruments covering the spectral range from 190 to 700 nm.

(2) There is a lack of appropriate hollow cathode lamps for the nonmetallic elements. Molecular absorption spectrometry (MAS) for determining sulphur-containing compounds has been reviewed.[1-2] Vapour molecular absorption spectrometry (VMAS) is one of the simplest methods in MAS. Winkler and Syty[3-5] used VMAS to determine sulphur dioxide and sulphide. They used a hydrogen hollow cathode lamp as a continuum source to determine SO_2 at 210 nm and the detection limit was 2 μg/ml. For sulphide, a deuterium arc lamp was used as the source and the detection limit was shown to be 1.2 μg/ml S^{2-} at 200 nm. In this paper, two emission lines, 202.6 nm and 214.3 nm, from hollow cathode lamps of magnesium and tellurium, respectively, were used as radiation sources to measure absorbance of H_2S at 202.6 nm and SO_2 at 214.3 nm or 202.6 nm. The detection limit for S^{2-} at 202.6 nm was shown to be 0.01 μg/ml. The detection limits for SO_2 were 0.05 μg/ml at 202.6 nm and 0.2 μg/ml at 214.3 nm, respectively. Thus detection limits are improved by 1–2 orders of magnitude.

*Author for correspondence.

EXPERIMENTAL

Apparatus

Absorption measurements were made with a Model WF5 atomic absorption spectrophotometer (Xintian Optical Fine Instrument Factory, P.R. China). The instrument was modified for cold vapour analysis by replacing the burner with a 15-cm long, 0.7-cm i.d. flow through glass absorption cell (Fig. 1). The SO_2 and H_2S evolution vessel (reaction cell) used is also shown in Fig. 1. The spectrophotometer was equipped with a recorder readout accessory and a strip-chart recorder. The hollow cathode lamps of magnesium and tellurium were used as sources of radiation. The lamps were operated at a current of 6 mA and the wavelengths selected were 202.6 nm for Mg HCL and 214.3 nm for Te HCL.

Reagents

Standard S^{2-} stock solution (1000 μg/ml). A 7.5-g amount of sodium sulphide $Na_2S.9H_2O$ was dissolved in dilute sodium hydroxide solution and diluted to 1000 ml with water.

Standard SO_2 stock solution (1000 μg/ml). A 1.97-g amount of sodium sulphite was dissolved in dilute sodium hydroxide solution and diluted to 1000 ml with water.

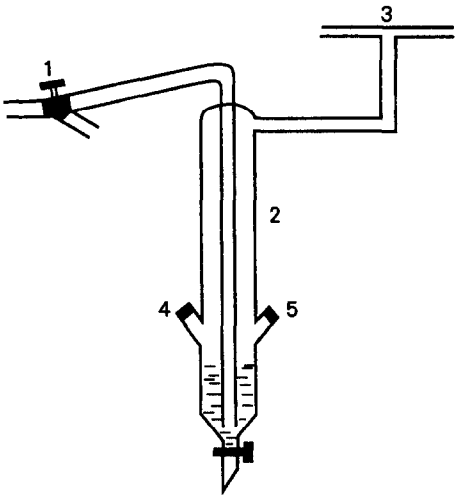

Fig. 1. Apparatus for SO_2 and H_2S evolution. 1. 3-way stopcock, 2. reaction cell, 3. absorption cell, 4. sample injection port, 5. reaction solution injection port.

The accurate concentrations of S^{2-}, and SO_2 were standardized by iodometry just before use. All reagents used were of superpure or analytical grade. Solutions were prepared with demineralized water.

Procedure

About 2 ml of 2*M* sulphuric acid was placed into the reaction cell. Either nitrogen or compressed air may serve as the carrier gas and generally the former was preferred to minimize the possibility of oxidation of SO_2 in the presence of moist air. The 3-way stopcock was adjusted to let the carrier gas flow into the air. The recorder was turned on and a base line was recorded. With the gas flow and the strip-chart recorder on, sample solution was injected into the side-arm of the reaction cell through the rubber septum with a syringe. After reaction for a certain time (defined as the reaction time) the 3-way stopcock was turned to let the carrier gas flow into the reaction cell and the absorption signal was recorded.

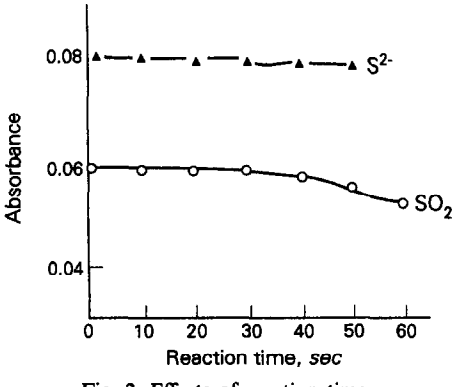

Fig. 2. Effects of reaction time.

RESULTS AND DISCUSSION

Optimization of operating conditions

Wavelength. The SO_2 and H_2S absorption spectra have been reported in the literature[4,5]. The absorption maximum of SO_2 and H_2S occurs at 210–220 nm and 194–200 nm, respectively. In this work, the absorption spectra of SO_2 and H_2S were obtained by using hollow cathode lamps of different elements as the radiation sources. The experimental results indicate that the absorption maxima of SO_2 and H_2S are all at about 200 nm.

In this paper, the hollow cathode lamps of magnesium and tellurium were used as radiation sources to measure the absorbance of H_2S at 202.6 nm and SO_2 at 202.6 nm or 214.3 nm.

Reaction conditions. The signal depends on a number of variables such as volume of solution, acid concentration, volume of sample solution and carrier gas flow rate. These parameters were investigated, and the results generally confirmed those of Syty.[4,5]

The successive injections of sample solutions into the same aliquot of reaction solution were proved to be unacceptable because of a decreasing trend in the resulting absorbance. It took about a few minutes per injection for the evolved gas to be flushed out of the reaction vessel and for the pen to return to the baseline. The lack of signal reproducibility and the time consumed per injection indicate also that successive injections of sample into the same aliquot of acid is not a desirable approach.

The time interval from the sample injection into the reaction cell to the carrier gas flow into the reaction cell was defined as the reaction time. The effect of reaction time on absorbance is shown in Fig. 2. It is evident that with an increase in the reaction time the absorbance remains constant when the reaction time is less than 30 sec, and decreases slightly above 30 sec. In our experiment, the carrier gas flows into the

Table 1. Operating condition

Mg-HCL	202.6 nm (for S^{2-} or SO_2)
Te-HCL	214.3 nm (for SO_2)
Current of HCL	6 mA
Reaction solution	2*M* H_2SO_4
Volume of reaction solution	2 ml
Volume of sample solution	3 ml
Reaction time	A few seconds
Carrier gas flow rate	200 ml/min

Table 2. Comparison of detection limits and linear ranges

Species	Radiation source	Wavelength, *nm*	Detection limit, *μg/ml*	Linear range, *μg/ml*	Reference
SO_2	Mg-HCl	202.6	0.05	0.2–80	This work
SO_2	Te-HCl	214.3	0.2	1–80	This work
SO_2	H_2-HCl	215.0	2	10–5000	4
SO_2	H_2-HCl	210.0	2	2.0–200	3
S^{2-}	Mg-HCl	202.6	0.01	0.05–6.0	This work
S^{2-}	D_2 arc lamp	200.0	1.2	1.2–400	5

Table 3. Measurement of absorptivity values for S^{2-} and SO_2

Species	Concentration, *μg/ml*	A_{203}	A_{214}	$a_{203}^{S^{2-}}$	$a_{214}^{S^{2-}}$	$a_{203}^{SO_2}$	$a_{214}^{SO_2}$
S^{2-}	0.72	0.048	0.015	0.067	0.021	—	—
SO_2	9.91	0.116	0.059	—	—	0.012	0.006

reaction cell immediately after sample injection into the reaction cell.

Based on these experimental results and those of Syty,[4,5] the optimum conditions selected for the method are summarized in Table 1.

Detection limits and linear range

The detection limits which are defined as the concentration of analyte which gives a signal twice the standard deviation of the blank signal, and linear ranges for S^{2-} and SO_2 are shown in Table 2. For comparison, the results obtained in the literature are also included. The method appears particularly attractive in view of its lower detection limits.

Interferences

The effects of eight diverse anions on the determination of S^{2-} (concentration of S^{2-} remains 0.93 μg/ml) at 202.6 nm were investigated. Cl^- (100-fold), Br^- (100), I^- (100), CO_3^{2-} (100), SCN^- (100), NO_3^- (100), NO_2^- (10) and CN^- (10), did not affect the determination of sulphide. When the SO_2 concentration remains at 9.9 μg/ml, the effect of concomitant anions on the determination of SO_2 at 214.3 nm were as follows: Cl^- (100-fold), Br^- (100), I^- (100) and NO_3^- (100) did not effect the determination of sulphur dioxide.

Simultaneous determination of S^{2-} and SO_2

The simultaneous determination of S^{2-} and SO_2 in the gas phase can be accomplished from measurements at two different wavelengths. In analogy to simultaneous spectrophotometric methods, two simultaneous equations may be written:

$$a_{203}^{S^{2-}} C_{S^{2-}} + a_{203}^{SO_2} C_{SO_2} = A_{203}$$

$$a_{214}^{S^{2-}} C_{S^{2-}} + a_{214}^{SO_2} C_{SO_2} = A_{214}$$

where a is the absorptivity of the component to be determined and C is its concentration in solution. To obtain the value of a the absorbances at 202.6 and 214.2 nm were measured when the sample solution only contained S^{2-} or SO_3. The results are listed in Table 3.

To examine the reliability of the method, certain amounts of standard S^{2-} and SO_2 were simultaneously added to a water sample and analysed according to the procedure described above. Results obtained are shown in Table 4. It is obvious from the results that the method can be satisfactorily employed for the simultaneous determination of sulphide and sulphur dioxide and for determination of either single component.

Table 4. Analytical results of spiked samples

	Quantity added, *μg/ml*		Absorbance		Quantity found, *μg/ml*	
Sample	SO_2	S^{2-}	202.6 nm	214.3 nm	SO_2	S^{2-}

CONCLUSIONS

By using two emission lines at 202.6 nm and 214.3 nm emitted from Mg and Te HCLs, respectively as radiation sources, the simultaneous determination of trace sulphide and sulphur dioxide is possible by vapour molecular absorption spectrometry. However, from the point of view of sensitivity the measurement of sulphide at 202.6 nm is not ideal because the maximum of the absorption spectrum of H_2S lies between 194.0 and 200,0 nm. It is therefore predictable that if a line source in this wavelength range, such as an Se electrodeless discharge lamp (196.0 nm), is available, the detection of sulphide will be improved. Since two line sources instead of a continuum radiation source were used in this method, it is also probable that a nondispersion absorption spectrometer would be suitable in this kind of cold vapour molecular absorption spectrometry.

SPECTROFLUORIMETRIC DETERMINATION OF MOLYBDENUM IN SOME REAL AND ENVIRONMENTAL SAMPLES

BIJOLI KANTI PAL,* K. ANAND SINGH and KHANA DUTTA
Analytical Chemistry Division, Jadavpur University, Calcutta-700 032, India

(*Received* 30 *August* 1991. *Accepted* 22 *October* 1991)

Summary—A very simple, highly-sensitive and selective quenchofluorimetric method for the rapid determination of molybdenum(VI) in aqueous media is described. The method is based on the instantaneous quenching action by the metal-ion upon the native fluorescence of bathophenanthrolinedisulphonate (4,7-diphenyl-1,10-phenanthrolinedisulphonate) solution [λ_{ex} (max) 288 nm; λ_{em} (max) 444.8 nm] in the optimum pH-range of 3.0–3.7 at room temperature (25 ± 5°). The fluorescence quenching is co-linear in the range of 0.01–1.0 ppm molybdenum. Large excesses of over 50 cations, anions and some common complexing agents were found to have no interference. Cu, Ni, Co, Fe and V can be tolerated only up to the corresponding amount of molybdenum. Interference from greater amounts can however be removed by a one-step ion-exchange separation process. The developed method was successfully tested over several standard alloys, synthetic mixtures of various compositions, factory effluents and in spiked environmental waters.

The industrial importance of molybdenum, its impact on the environment, its microessentiality, its adverse effects on living systems, and the assessment of existing fluorimetric methods for molybdenum(VI) have been discussed and reviewed recently by the authors.[1] We have previously described the bathophenanthroline method[1] in which an alcoholic solution of bathophenanthroline (4,7-diphenyl-1,10-phenanthroline) was used as the quenchofluorimetric reagent for trace analysis of molybdenum(VI) and which overcame many of the limitations of earlier methods.[2–5] The present method is a further improvement over the previous one prescribed from this laboratory.[1] Here emphasis has been given to the introducton of a sulphonate group to the bathophenanthroline ring to remove the water insolubility problem experienced with bathophenanthroline. The method has achieved two distinct advantages over the previous one by (i) using a new fairly water soluble fluorimetric reagent, bathophenanthrolinedisulphonate (4,7-diphenyl-1,10-phenanthrolinedisulphonate) and (ii) using buffer solution (sodium acetate-acetic acid buffer) for pH maintenance that makes the method much simpler and yields higher accuracy and reproducibility of results. The method is based on the instantaneous, virtually specific quenching action of molybdenum(VI) on the native fluorescence of bathophenanthrolinedisulphonate in slightly acidic media (pH 3–3.7) under the optimum experimental conditions. The standard deviation and relative standard deviation for 11 replicate determinations of 0.1 ppm molybdenum(VI) were found to be ±0.009 and 0.76%, respectively.

*Author for correspondence.

EXPERIMENTAL

Apparatus

A Shimadzu spectrofluorophotometer (Model RF-5000) fitted with a video accessory was used to record the uncorrected spectra and to measure the fluorescence intensity. A pH meter, Model pH 5651 (Electronic Corporation of India Ltd), was used to measure pH. A Hanovia U.V. lamp set was used for the qualitative visual study of fluorescence intensity changes.

Reagents

A $10^{-3}M$ solution of the reagent, bathophenanthrolinedisulphonate (4,7-diphenyl-1,10-phenanthrolinedisulphonate) (Loba-Chemie, Wien-Fischamend) was prepared by dissolving the requisite amount in demineralized water. From this stock solution, more dilute solutions

were prepared as and when needed. The reagent solution is very stable. A stock solution of 1000 ppm molybdenum(VI) was prepared by dissolving 0.1840 g of ammonium molybdate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (J. T. Baker), in 100 ml of demineralized water and subsequently standardized by EDTA titration.[6] More dilute solutions were prepared by appropriate dilution of aliquots from the stock solution with demineralized water. A 100-ml buffer solution of pH 3.5 was prepared by mixing 5 ml of 0.2*M* sodium acetate (Merck) and 95 ml of 0.2*M* acetic acid (Merck).

A large number of solutions of inorganic ions and complexing agents were prepared from their Analar grade or equivalent grade water soluble salts. In case of insoluble substances, special dissolution methods were adopted.[7] Doubly distilled demineralized water was used throughout the study.

General procedure

To a 10-ml standard flask containing 0.1–1 μg or 1–10 μg of molybdenum(VI) were added 0.5 ml or 1.5 ml of $10^{-4}M$ reagent bathophenanthrolinedisulphonate reagent, respectively, and 2 ml of sodium acetate–acetic acid buffer of pH 3.5. The volume was then made up with demineralized water, and the fluorescence intensity was measured against a reagent blank at 444.8 nm, using excitation at 288 nm. The fluorescence quenching due to molybdenum(VI) is achieved by subtracting the relative fluorescence intensity of the molybdenum–reagent system from that of the corresponding reagent blank solution.

RESULTS AND DISCUSSION

Spectral characteristics

The uncorrected excitation and emission spectra of the bathophenanthrolinedisulphonate solution are shown in Fig. 1. The wavelength maxima of excitation and of emission were found to occur at 288 nm and 444.8 nm, respectively.

Effect of pH

The effect of pH studies showed that the maximum and constant quenching occurred over the pH range 3.0–3.7.

Effect of buffer

Citric acid–disodium hydrogen phosphate buffer (pH 3.4) masked the quenching action

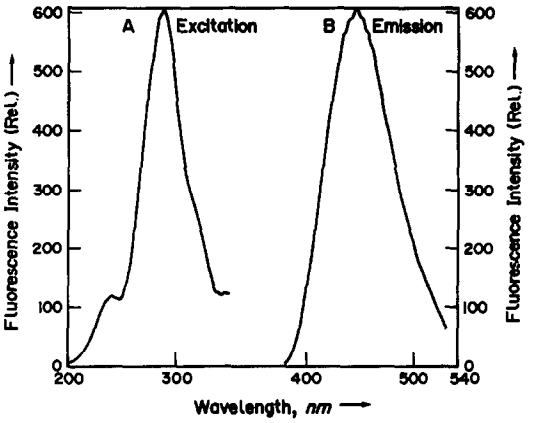

Fig. 1. Uncorrected excitation (A) and emission (B) spectra of bathophenanthrolinedisulphonate.

of molybdenum(VI) while potassium hydrogen phthalate–hydrochloric acid buffer (pH 3.18) quenched the fluorescence of the reagent solution. Up to 5 ml of sodium acetate–acetic acid buffer (pH 3.5) was added to the total 10-ml solution containing molybdenum(VI) and had no effect on the quenching intensity. Consequently, 2 ml of this buffer solution was added throughout the experiment.

Effect of time

The maximum quenching was reached immediately after making up the volume, and remained constant for 24 hr. Longer time periods were not studied.

Effect of metal concentration (calibration graph)

The fluorescence quenching intensity exhibited a linear dependance on the molybdenum(VI) concentrations over a wide range (10 ppb–1.0 ppm) distributed over two different molybdenum concentration ranges (10 ppb–0.10 ppm and 0.10–1.0 ppm) for convenience of fluorescence intensity measurement.

Interferences

Over 50 cations, anions and common complexing agents, in the presence of 0.10 ppm molybdenum(VI) were found to have no interference at all. Five thousand-fold excess each of oxalate, perchlorate, phosphate, sulphate, acetate, thiosulphate, thiocyanate, halides, H_2O_2, alkali and alkaline earth metals, Zr^{4+}, Hf^{4+}, Zn^{2+}, La^{3+}, Th^{4+} and Se^{4+} ions do not interfere. The amount mentioned is not the tolerance limit but the actual amount studied. However, for those ions whose tolerance limits have been studied, their tolerance ratios are mentioned in Table 1.

Cu^{2+}, Co^{2+}, Ni^{2+}, $Fe^{2+,3+}$ and V^{5+} interfere when present in amounts in excess of the molybdenum(VI). Interferences from these metal ions have been effectively removed by a short single-step ion-exchange separation process, using AG1-X8 (sulphate form, 100–200 mesh) anion exchanger as mentioned below.

Separation of interfering ions through anion exchanger

One gram of a strong base anion exchange resin, AG1-X8 (chloride form 100–200 mesh) resin was placed in a beaker and washed repeatedly with demineralized water to remove the fine particles. It was then immersed in demineralized water and kept overnight. Later, a small column (5 cm × 1 cm) was made with the resin supported over quartz wool in an all-glass column. The packed resin bed was washed with sufficient volume of 3M sulphuric acid to convert it into the sulphate form. The washing was discontinued when the eluate did not contain chloride (silver nitrate test solution). The resin was then washed with demineralized water to completely free it from sulphate ions (barium chloride test solution). A solution containing known amounts of molybdenum(VI) and other interfering ions was mixed with 1 ml of 30% hydrogen peroxide and diluted to 50 ml with demineralized water. It was then quantitatively passed through the conditioned resin column at a flow-rate of 1–2 ml/min. The resin bed was then washed with 50 ml of 1M ammonium sulphate–0.02M sulphuric acid. Molybdenum(VI) was finally eluted with 25 ml of 0.5M sodium chloride–0.5M sodium hydroxide at a flow-rate of 0.5 ml/min. The eluate was boiled for few minutes, cooled, neutralized with dilute sulphuric acid and finally diluted to 50 ml with demineralized water. From suitable aliquots, the molybdenum content was then determined fluorimetrically with bathophenanthrolinedisulphonate as described earlier, with the calibration graph being prepared from standard molybdenum(VI) solutions, also adsorbed on the resin bed and eluted identically. The results were very satisfactory. It is worth mentioning that the concentration of hydrogen peroxide is necessary to retain molybdenum(VI) on the column and there should be at least 0.3–6% peroxide in the final solution, particularly if iron(III) is present that acts as catalyst[8] for deterioration of the resin activity.

Applications

Molybdenum(VI) determination in synthetic mixture. Synthetic inorganic mixtures of different compositions were prepared. These were subjected to the ion-exchange separation process, eluted and diluted to a known volume as described earlier. From suitable aliquots, the molybdenum(VI) content was then determined fluorimetrically with bathophenanthroline-disulphonate as above. Results are shown in Table 2. Accurate recoveries were achieved in all solutions.

Molybdenum(VI) determination in certified reference materials

An accurately weighed 0.1-g portion of the sample was dissolved in 4 ml of a mixture (1:1) of concentrated HCl–HNO_3 with heating and was then diluted to 100 ml with demineralized water. Suitable aliquots of this sample solution with and without molybdenum(VI) spiking were processed through the anion exchange resin AG1-X8, eluted and diluted to a known volume as described earlier. Then, from suitable aliquots of the eluate, the molybdenum(VI) content was fluorimetrically determined as described before. The results are shown in Table 3. The certified molybdenum value in the alloy cast iron was obtained. Added molybdenum was accurately recovered from the other metals.

Molybdenum(VI) determination in environmental waters

Aliquots (50 ml) of filtered environmental water samples were mixed with 1 ml of concentrated sulphuric acid and 2 ml of concentrated nitric acid. The mixture was heated until SO_3 fumes were evolved and then cooled. The solution was treated with 2 ml of perchloric acid and again heated until SO_3 fumes were evolved. The resulting solution was cooled again and filtered (if necessary). The filtrate was neutralized with dilute ammonium hydroxide solution and made up to the mark with demineralized water in a 50-ml standard flask. Suitable aliquots of this solution with and without molybdenum(VI) spiking were subjected to the anion exchange AG1-X8, eluted and diluted to a known volume according to the earlier procedure. Then, from suitable aliquots, the molybdenum(VI) content was fluorimetrically determined. The results are shown in Table 4. The spiked quantities of molybdenum were accurately recovered.

Acknowledgements—The authors are grateful to Professor A. K. Majumdar for his keen interest and constant encouragement. One of us (K.A.S.) expresses his gratitude to the authorities of Jadavpur University for providing laboratory facilites, to the Manipur State Government for extending financial support and to Moriang College Authority for sanctioning study leave for conducting Ph.D. research here. The use of the COSIST instrument spectrofluorophotometer of this department is also acknowledged.

SIMULTANEOUS DETERMINATION OF ACETAMINOPHEN AND CAFFEINE IN TABLET PREPARATIONS BY PARTIAL LEAST-SQUARES MULTIVARIATE SPECTROPHOTOMETRIC CALIBRATION

ABDÜRREZZAK BOZDOĞAN, ALPER MERT ACAR and GÖNÜL KANDEMIR KUNT
Yildiz University, Department of Chemistry, Şişli, Istanbul, Turkey

(*Received* 25 *July* 1991. *Revised* 9 *December* 1991. *Accepted* 20 *December* 1991)

Summary—The use of partial least-squares spectrophotometric calibration for the simultaneous determination of analgesic tablets in a multicomponent formulation is presented. This method is applied to the determination of acetaminophen and caffeine in tablet preparations. The results show that these components in a molar ratio of about 21:1 in tablets have been determined simultaneously with high precision.

Ultraviolet visible spectrophotometry is an instrumental technique in wide use in pharmaceutical analysis on account of its rapidity, simplicity and applicability to the pharmacologically active species and their derivatives absorbing in that spectral zone. The quantitation methods traditionally used involve measuring the analyte absorbance at a given wavelength. However, the analyte of interest is often accompanied by other compounds absorbing in the same spectral region. In such cases, spectral overlap is often a serious limitation and requires resolution by using sample clean-up and separation procedures.[1,2] Thus, HPLC has become one of the analytical techniques most frequently used in pharmaceutical analysis.[3,4] But, these methods are expensive and time-consuming. In order to avoid these procedures, the simultaneous determination of active components in analgesic formulations has been performed by using instrumental approaches[2,5] or various numerical methods based on multiple regression and SIMPLEX.[6] However, the mathematical programs used for spectrophotometric multicomponent analysis are based on an ordinary multiple regression method.[7,8] The important limitations of these analyses based on multiple regression are due to deviations from linearity, interaction between components and severe overlap of spectral bands. To solve these problems, a partial least-squares (PLS) method has been developed and found that PLS methods are also better suited to calibration problems than multiple regression is.[7–9]

The interest in PLS calibration has been increased in recent years.[7,8] However, the potential of this method for the assay of active components in tablet preparations has not been studied in detail. Therefore, the present paper describes the use of the PLS method in the simultaneous spectrophotometric analysis of acetaminophen (AAP) and caffeine (CAF) in tablet preparations.

Partial least squares

The theory of the PLS method has been thoroughly discussed elsewhere.[7,10] Therefore, this presentation will be restricted to its application to the present work.

In this study, the absorbances measured in the selected wavelengths were used as X-variables. The corresponding acetaminophen and caffeine concentrations were used as Y-variables. Thus, for n samples, two matrices are formed, and their inter-relationship must be calculated. The model can then be used to analyse samples of unknown composition.

Calibration with use of the PLS method is done by decomposition of both the concentration and absorbance matrices into latent variables

$$Y = F_y L_y + E_y \quad (1)$$

$$X = F_x L_x + E_x \quad (2)$$

where F_y is the latent concentration matrix with n rows (mixtures) and d columns (number of dimensions), L_y represents the concentration

loading matrix with d rows and m columns (number of components), F_x is the nxd latent absorbance matrix, L_x is the dxp absorbance loading matrix (where p is the wavelength), and E_y and E_x are error matrices that have the same dimensions as the original concentration matrix (nxm) and absorbance matrix (nxp), respectively. Relating the latent variable matrix from equation (1) to that in equation (2), one obtains a diagonal regression matrix V according to

$$F_y = F_x \cdot V + E_e \quad (3)$$

where E_e is an error matrix. The matrix V is used in the prediction step for estimation of the unknown concentrations from the absorbance spectrum x_0 of the sample as follows,

$$y_0 = x_0(F_y'X)' \; VL_y \quad (4)$$

Here the matrices F_y,L_y and X are known from calibration.

EXPERIMENTAL

Apparatus and computations

A Philips Model PU 8740 UV–Vis scanning spectrophotometer was used for obtaining digitized absorbance. Computations were run on an IBM PC/2/30 computer. A computer program for PLS was written according to previous work.[7]

Reagents

The AAP, CAF and Vermidon tablets were supplied from İLTAS Tic. San. A.Ş. Redistilled water was used throughout the work.

Procedure

The calibration set was generated by a 5-level full factorial design[11,12] and thus 25 samples were used to construct the model. The levels selected for AAP are 11, 13, 15, 17, 19 μg/ml, and for CAF 0.3, 0.6, 0.9, 1.2, 1.5 μg/ml in this design. By this choice of design, possible interactions and non-linearities can be accounted for.

Calibration solutions were prepared by dissolving AAP and CAF in water. The absorbances were recorded in 1-cm cuvettes between 190 and 300 nm every 5 nm. In this way a signal concentration matrix which could be subjected to data analysis was obtained. The calibration samples were measured in random order so that experimental errors due to drift were not introduced. In analyzing the active components of Vermidon, 20 tablets were ground and mixed. The amount of the tablet mass equivalent to one tablet was dissolved in one litre of water. This solution was stirred for 30 min and then filtered.

RESULTS AND DISCUSSION

For this investigation, two substances found in analgesic pharmaceutical formulations were chosen, namely acetaminophen and caffein. In such formulations, if all components contribute similarly to the mixture absorbance, the results obtained by any procedure are usually satisfactory. However, significant errors occur when components contributing to a much lesser extent than the others are determined. This is a rather common situation in the analysis of pharmaceutical formulations.

As the above situation described, CAF was present at a much lower concentration than AAP in our formulation. The molar ratio of these components is about 1:21. Thus, the strongest absorbance was obtained from AAP in this mixture. In such cases, since the conventional calibration procedures cannot provide good quantitative determinations, a reliable computational method is required. Therefore, PLS method was applied to the resolution of mixtures of two components AAP and CAF in this study.

The correlation coefficients between the true and predicted concentrations found by two-factor PLS solution are 0.9992 and 0.9993 for calibration of AAP and CAF, respectively.

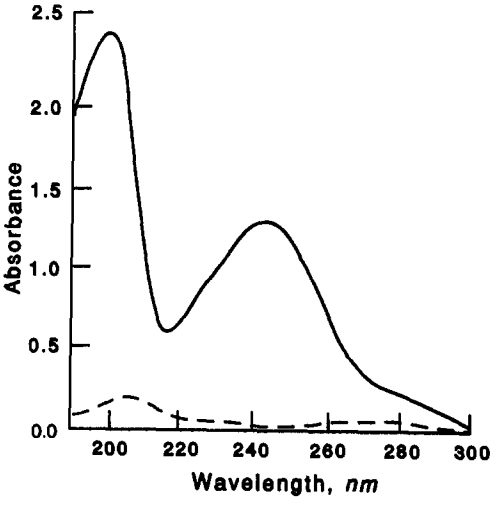

Fig. 1. Spectra of AAP (——) and CAF (– – –) at their nominal analytical concentrations.

Table 1. Determination of active components in Vermidon

Sample	% AAP	% CAF
1	98.5	100.2
2	100.2	100.5
3	99.6	100.3
4	100.2	100.6
5	100.1	100.5
6	100.5	100.6
7	100.1	100.6
8	99.9	100.5
9	98.0	99.6
10	99.8	100.5
Mean value	99.7	100.4
Standard deviation	0.8	0.3

Tablet analysis

Vermidon is available in tablets with nominal contents of 500 mg of AAP and 30 mg of CAF. The spectra of these active components at their nominal analytical concentrations are shown in Fig. 1. The results obtained by two-factor PLS solution in Vermidon analysis are listed in Table 1. In this table, values are reported as percentages of label contents.

CONCLUSION

As seen from the results, all two components AAP and CAF in analgesic formulations have been determined highly accurately by using the PLS method. This method demands calibration for developing the model to determine unknown concentrations of the components. For accurate resolution of the mixture, the calibration set must contain the same components and the same interferences as in the actual samples. Compared with other approaches, the PLS calibration has several advantages. In this method, the information from the calibration set is better used and the unidentified species in the mixture can be compensated. The method also has a much shorter computation time and gives lower prediction errors than other methods.

In order to investigate further the potential of the method, our work has been directed to analysing more complex pharmaceutical mixtures.

SPECTROPHOTOMETRIC STUDY OF THE COMPLEX FORMATION OF 3-(2-HYDROXYPHENYL)-2-MERCAPTOPROPENOIC ACID WITH Ni(II) AND Zn(II)

J. L. BELTRAN, G. CENTENO, A. IZQUIERDO and M. D. PRAT
Department of Analytical Chemistry, University of Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 13 *May* 1991. *Revised* 9 *December* 1991. *Accepted* 9 *December* 1991)

Summary—The dissociation and complex formation equilibria between Ni(II) and Zn(II) with 3-(2-hydroxyphenyl)-2-mercaptopropenoic acid, at 25° in aqueous 0.1 and 1.0*M* sodium perchlorate solutions, containing about 1% ethanol, have been studied spectrophotometrically. The data were connected directly from the spectrophotometer to an IBM-PC via a serial interface, using the DUMOD program (written in BASIC), described in the paper. The obtained spectra were treated by the factor analysis program NIPALS in order to determine the number of absorbing species and the experimental error. Dissociation constants of ligand (H_3L), and formation constants for the complexes Ni(HL), $Ni(HL)_2$, Zn(HL) and $Zn(HL)_2$ at 0.1 and 1.0*M* ionic strengths, refined by the SQUAD program, are reported.

The chelating ability of α-mercaptoacids is well known. Their reactivity and the structural arrangement of the oxygen and sulphur donor atoms lead to the formation of highly stable chelates with most of the common metal ions.

The coordination chemistry of these ligands with metal ions, mainly zinc(II) and nickel(II) has been widely investigated. A comparison of different α-mercaptoacids shows that the presence of an aryl group confers greater stability on the complexes formed,[1] and that 3-aryl-2-mercaptopropenoate complexes, with a conjugated double bond in the ligand molecule, are more stable than the corresponding 3-aryl-2-mercaptopropanoates.[2,3] Furthermore, whereas the complex formation between nickel(II) and 3-phenyl-2-mercaptopropanoic acid, and other α-mercaptoacids, leads to polynuclear complexes,[1,3–8] only monomeric species, ML and ML_2, are formed between 3-aryl-2-mercaptopropenoic acids and the divalent metal ions nickel, zinc, iron and cobalt.[2,3,9]

The metal complexing ability of these ligands makes them useful not only in analytical chemistry (as spectrophotometric reagents and masking agents), but also in biology. The interaction of heavy metals with biological systems frequently involves their bonding to mercapto groups of enzymes. Chelating agents that themselves contain mercapto groups can compete for metal ions with the biological binding sites and reverse the action of the metal ion. Thus, it was shown that 3-phenyl-2-mercaptopropenoic acid inhibits the metal-dependent enzymes, like alkaline phosphatase and carboxypeptidase,[10] and 3-(2-furyl)-2-mercaptopropenoic acid increases the serum zinc concentration may times.[11]

In previous potentiometric studies on the complex equilibria between some 3-aryl-2-mercaptopropenoic acids and metal ions, the formation constants with nickel(II) and zinc(II) ions have been reported;[2,3,9] however, the poor solubility of these ligands and their complexes in water requires the use of mixed solvents, such as ethanol–water of dioxane–water. In some cases, the formation constants of the systems studied have been applied to simulate their effect in the distribution of metal ions in biological systems,[12] despite the fact that the constants were determined in mixed solvents media.

In the present work, the complexes formed between 3-(2-hydroxyphenyl)-2-mercaptopropenoic acid (H_3L) with nickel(II) and zinc(II) ions have been studied by UV-Vis spectrophotometry, at two ionic strengths, 0.1 and 1.0*M* in sodium perchlorate, at 25°. Spectrophotometric measurements can be done at concentration levels at which the ligand and the complexes formed are soluble in water.

The determination of the number of absorbing species in solution was carried out by the NIPALS program,[13] based on the principal

component regression (PCR) algorithm NIPALS.[14] The protonation constants of ligand and the complex formation constants were determined using the SQUAD program.[15]

EXPERIMENTAL

Apparatus

The pH values were measured with a Radiometer PHM 84 pH-meter, with a G 202 B glass electrode and a K 801 Ag/AgCl reference electrode, the latter filled with saturated sodium chloride solution instead of saturated potassium chloride solution to prevent clogging of the electrode frit by precipitation of potassium perchlorate. Calibration of the electrode system at 0.1*M* ionic strength was done with buffer solutions at pH 4.008, 6.863 and 9.185 (at 25°) according to DIN 19266. The hydrogen ion concentration is calculated from the activity coefficient given by the Davies equation[16] (0.771 at 0.1*M* ionic strength and T = 25°). Hydrogen ion concentrations at $I = 1.0M$ were measured by calibrating the electrode system with standard perchloric acid solutions, with pCH = 2.000, 3.000 and 4.000, with ionic strength adjusted to 1.0*M* by addition of sodium perchlorate. The nernstian response of the electrode was also checked by Gran titrations.[17]

The temperature of the solutions was kept constant at 25 ± 0.2° with a Selecta model Tectron thermostatic bath.

Absorbance data were recorded on a Beckman DU-7 single beam spectrophotometer, with a 10-mm path length cell, connected to an IBM PC via a serial interface (RS-232-C). The program used for this purpose is commented on later.

Reagents

3-(2-Hydroxyphenyl)-2-mercaptopropenoic acid was synthesized as described previously,[18] and recrystallized from benzene. Its purity was periodically tested by iodometric titrations.[19] In all experiments freshly prepared aqueous solutions, containing less than 1% ethanol, were used.

Standard stock solutions of metals (about 0.05*M*) were prepared as their perchlorate salts. They were obtained by dissolving nickel carbonate and zinc oxide in perchloric acid (1:1), followed by evaporation and recrystallization from water. The nickel(II) and zinc(II) solutions were standardized gravimetrically with dimethylglyoxime, and volumetrically with EDTA, respectively.

The ionic strength of solutions (0.1 and 1.0*M*) was adjusted by the addition of sodium perchlorate solution (0.5 and 5.0*M*).

All reagents were of analytical grade.

Procedures

Aqueous solutions containing ligand, metal ion (when required), buffer solution, and sodium perchlorate to adjust the ionic strength to 0.1–1.0*M* were prepared as above. The solutions were thermostated in a waterbath at 25°. The absorbance was recorded at 5-nm intervals over the spectral range required (see Table 1), and the pH or pCH value was measured.

The residual absorbance error of the spectrophotometer [$S_{inst(A)}$] was 0.0023 absorbance units, as evaluated by the Werimont's procedure.[20]

In the determination of the protonation constants of ligand, buffer solutions covering the pH ranges given in Table 1 were prepared according to Perrin.[16] In the complex formation equilibria, the solutions of Ni(II) and Zn(II) were buffered with formic acid/sodium formiate and acetic acid/sodium acetate, respectively, with total concentration of formic or acetic acids about 0.002*M*, because of their low complex formation constants with Ni(II) and Zn(II).[21]

The upper limit of ligand and metal concentrations was set by the solubility of the ligand and metal complexes, as well as by the absorbance readings.

Spectral data acquisition: DUMOD program

To acquire the absorbance data from the Beckman DU-7 spectrophotometer on an IBM-PC computer, a BASIC program named DUMOD was developed. The program has been compiled with Microsoft Quick-Basic 4.0, and runs on an IBM-PC or compatible computer with an RS-232 serial interface, 256 Kbytes of memory, one diskette unit (360 or 720 Kbytes), and a CGA or Hercules graphics screen. The operating system must be MS-DOS 3.1 or later.

Table 1. Experimental conditions ($T = 25°$)

Equilibria	Spectral range (nm)	−log H range	C_L(μM)	C_M(μM)
Acid–base	250–450	1–12	100	—
Ni complexes	350–500	3.7–5.3	20–460	70–99
Zn complexes	250–450	3.2–5.7	10–170	25–70

The possible options of this program are:

(1) Recording of the data from the spectrophotometer. After this, the data are saved in an ASCII file.

(2) Draw the stored spectra on a HP-GL compatible plotter.

(3) Draw the spectra on the computer screen.

(4) List the directory of the disk.

Data treatment

The equilibria studied can be generalized as:

$$pL + qM + rH \rightleftharpoons L_pM_qH_r$$

and the overall formation constants are defined by:

$$\beta_{pqr} = [L_pM_qH_r]/[L]^p[M]^q[H]^r$$

where M, L and H are the free concentrations of metal ion, ligand and hydrogen ion. Charges are omitted for simplicity.

The experimental data were prior processed by using the NIPALS program[13] in order to determine the number of absorbing species in solution by factor analysis of absorbance matrices, as described by Kankare.[22] The program calculates the eigenvalues and the eigenvectors corresponding to an absorbance matrix, and recalculates the data array corresponding to k eigenvalues and eigenvectors, the values of k changing from 1 to 20. For each value of k, the standard deviation of absorbance values obtained in the reconstruction of the original data array as a function of the number of eigenvectors [$s_{k(A)}$] is calculated. The determination of the number of absorbing species is done by plotting $s_{k(A)}$ versus k.

Figure 1 shows the $s_{k(A)}$ values obtained in the protonation and complex equilibria, from the data corresponding to 1.0M ionic strength. As expected, four species are detected in the ligand protonation data, as it has three dissociation constants. In this case, $s_{4(A)} = 0.0016$, slightly under the instrumental error.

The treatment of data corresponding to Zn(II) complexes shows that at least three species are needed to explain the experimental data [$s_{3(A)} = 0.0018$, $s_{4(A)} = 0.0011$]. Taking into account that in the pH range studied, the ligand species H_3L and H_2L are predominant (less than 5% of the ligand is in the HL form), we conclude that two zinc complexes are formed.

The case of Ni(II) complexes is very different, as in the wavelength range studied the ligand absorption is low, and the absorption band in this range corresponds to the formation of nickel complexes. The values of $s_{2(A)} = 0.0021$ and $s_{3(A)} = 0.0009$ indicate that there are two principal species, and a third less important. From this, we can deduce that the two former species correspond to two Ni(II) complexes.

All the experimental data (protonation and complex equilibria) were processed later by the

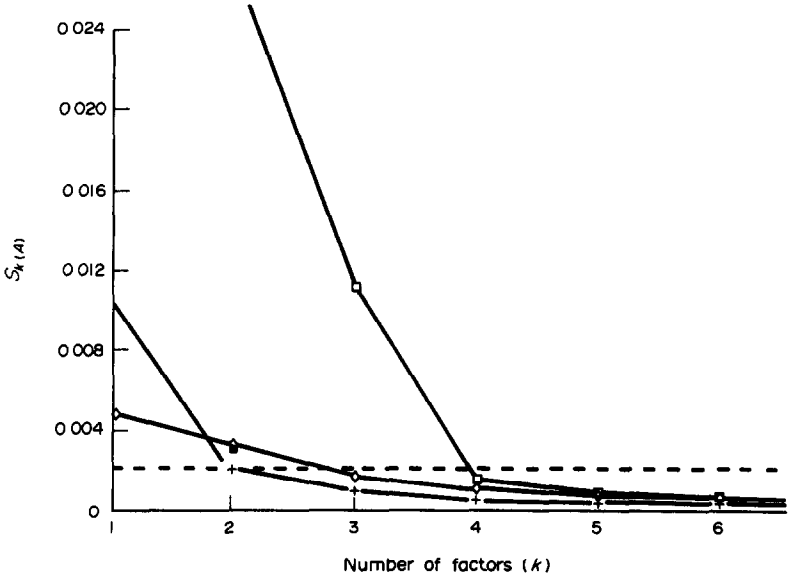

Fig. 1. Graphical determination of the number of absorbing species. Plot of the calculated standard deviation of absorbance matrix [$s_{k(A)}$] as estimated by factor analysis of the absorbance data matrix versus the number of factors (k) (from the data obtained at $I = 1.0M$). Dashed line indicates the instrumental error. Symbols are: (□): dissociation equilibra; (+): Ni(II) complexes; (◇): Zn(II) complexes.

Table 2. Calculated formation constants (at 25°, ionic strength adjusted with sodium perchlorate)

Equilibrium	$I = 0.1M$ log β ($\sigma_{\log\beta}$)	sdr*	$I = 1.0M$ log β ($\sigma_{\log\beta}$)	sdr*
$H^+ + L^{3-} \rightleftharpoons HL^{2-}$	11.54 (0.02)	0.0064	10.88 (0.01)	0.0048
$2H^+ + L^{3-} \rightleftharpoons H_2L^-$	18.45 (0.02)		17.74 (0.02)	
$3H^+ + L^{3-} \rightleftharpoons H_3L$	21.70 (0.02)		21.03 (0.02)	
$Ni^{2+} + HL^{2-} \rightleftharpoons Ni(HL)$	6.73 (0.01)	0.0058	6.97 (0.01)	0.0066
$Ni^{2+} + 2\,HL^{2-} \rightleftharpoons Ni(HL)_2$	13.91 (0.01)		14.41 (0.01)	
$Zn^{2+} + HL^{2} \rightleftharpoons Zn(HL)$	7.23 (0.02)	0.0057	7.43 (0.03)	0.0062
$Zn^{2+} + 2\,HL^{2-} \rightleftharpoons Zn(HL)_2$	13.63 (0.02)		13.81 (0.03)	

*sdr means the standard deviation of residuals, in absorbance units.

least-squares program SQUAD.[15] This program refines the equilibrium constants and calculates the unknown molar absorbances at the working wavelengths. The function minimized (U) is based on the residuals of absorbance values of the solutions:

$$U = \sum_{i=1}^{ns} \left[\sum_{j=1}^{nw} (A_{i,j,\text{exp}} - A_{i,j,\text{calc}})^2 \right]$$

Where ns and nw are the number of solutions and wavelengths, respectively. The results of the dissociation and complex formation constants are shown in Table 2.

RESULTS AND DISCUSSION

3-(2-Hydroxyphenyl)-2-mercaptopropenoic acid (H_3L) has three dissociation constants which can be assigned to the carboxylate, thiol and phenol groups. The spectral differences between the different species allow the determination of the three pK_a values. The protonation constants obtained, together with the standard deviations of the absorbance residuals are presented in Table 2.

In the complex formation studies we postulated that the hydroxyl group does not coordinate with the metal ions, because its high pK value, compared with those of mercapto and carboxylic groups. Moreover, since β-aryl-α-mercaptopropenoic acids do not form polynuclear complexes, we assumed that the predominant metal complexes were M(HL) and $M(HL)_2$. Figures 2 and 3 show some of the spectra obtained in the determination of complexation constants of the ligand with Ni(II) and Zn(II), and Table 2 summarizes the formation constants obtained. The greater standard deviation obtained in the formation constants of the zinc complexes could be due to the smaller spectral differences between the zinc complex and the ligand when we compare the nickel complexes.

The values of the ligand acidity constants show that the difference in the first dissociation (carboxylic group) at 0.1 and $1.0M$ ionic strength is negligible (within the experimental error). However, the dissociation of the mercapto group is favoured at the higher ionic strength (0.2 pK units lower), and the differences in the pK values of the hydroxyl group are still larger (0.7 units lower at $1.0M$ ionic strength).

As shown in Table 2, the Ni(II) complexes are more stable at higher ionic strength. The magnitude of the increments [0.25 units in log β for the Ni(HL) complex, and 0.5 units for the $Ni(HL)_2$ complex] correspond to the higher acidity of the mercapto group of the ligand at 1.0 ionic strength. The Zn(II) complexes are also more stable at the higher ionic strength, but the difference in the $Zn(HL)_2$ complex is less important.

The acquisition of spectral data by the DUMOD program proved to be reliable, simple and easy to use. Although the data can be collected from the spectrophotometer with the Beckman Data capture software (DC, also used in this work) or Beckman Data Leader package, the program DUMOD has several features that make it very useful when the absorbance data must be treated numerically after their acquisition.

For example, when the Beckman DC program is used to acquire the spectral data, it saves all the absorbance values (in our conditions, at 600 nm/min scanning speed, corresponding to an absorbance reading after every 0.5 nm) in a file in binary format (BSF: Beckman Standard Format). A file is needed for each recorded spectrum. However, if these data are used as input data for the least-squares SQUAD program, we have two more tasks: to translate the BSF files to ASCII files, and to take the absorbance values at the desired wavelength interval (*e.g.*, each 2, 5 or 10 nm). A BASIC program, also supplied by Beckman, was

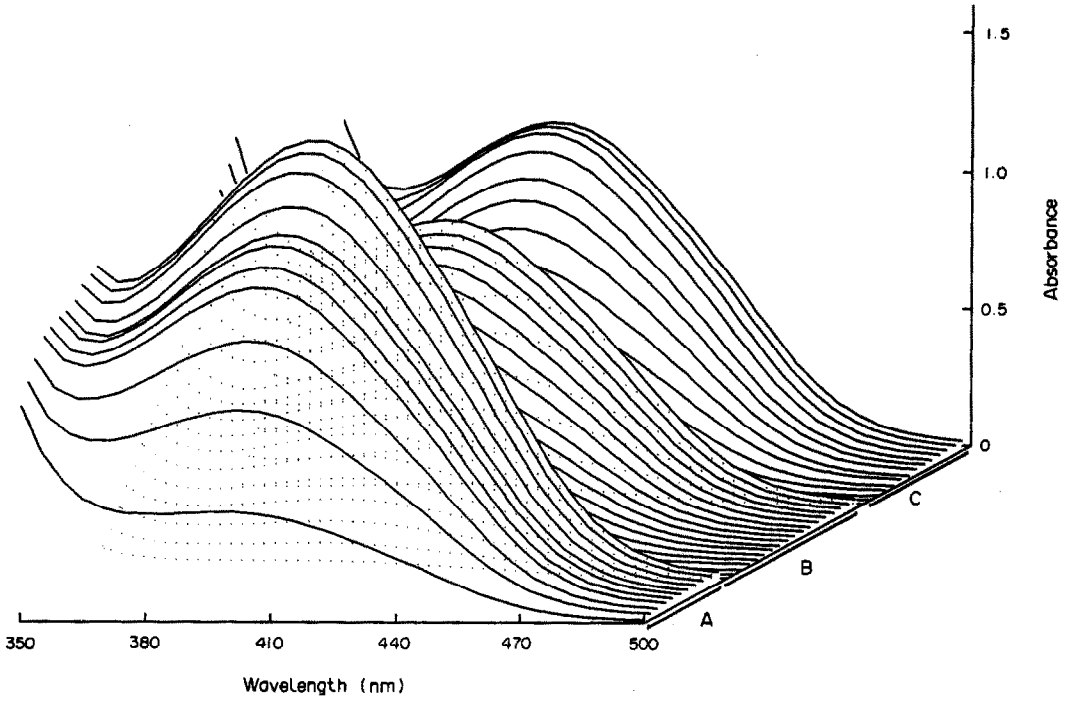

Fig. 2. Absorption spectra of the system Ni(II)–H_3L at $I = 1.0M$ in $NaClO_4$. The experimental conditions for these series are: (A) $C_M = 0.99 \times 10^{-4}M$, $C_L = 2.65 \times 10^{-4}M$; pH changed from 3.2 to 5.3. (B) $C_M = 7.07 \times 10^{-5}M$. The C_L/C_M ratio changes from 0.25/1 to 6.1/1; pH is maintained about 3.7. (C) $C_M = 7.07 \times 10^{-5}M$. The C_l/C_M ratio changes from 0.5/1 to 6.5/1. pH is maintained at about 4.7.

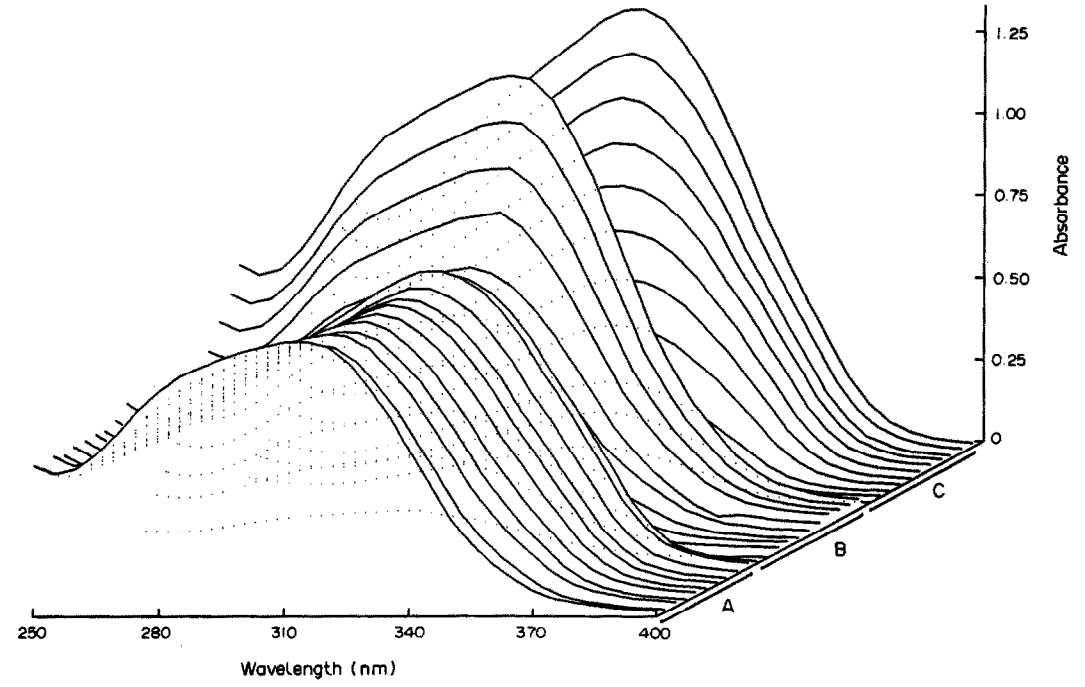

Fig. 3. Absorption spectra of the system Zn(II)–H_3L at $I = 1.0M$ in $NaClO_4$. The experimental conditions for these series are: (A) $C_M = 2.58 \times 10^{-5}M$, $C_L = 1.06 \times 10^{-4}M$; pH changed from 3.9 to 5.3. (B) $C_M = 2.58 \times 10^{-5}M$. The C_L/C_M ratio changes from 0.65/1 to 6.5/1; pH is maintained about 4.2. (C) $C_M = 2.58 \times 10^{-5}M$. The C_L/C_M ratio changes from 0.65/1 to 6.5/1; pH is maintained about 5.2.

adapted to do this work, but it is a tedious task when we need to transform 30–50 spectra for each system studied. More recently, the new Beckman Data Leader software can transform the BSF files to ASCII files directly, but the selection of the absorbances at the desired wavelengths remains an "a posteriori" task.

In the DUMOD program, these difficulties are overcome when the spectra are acquired in real time: they are stored directly in ASCII format, taking the absorbance values at wavelength intervals selected by the user, and all the spectra can be located in only one file. The number of the spectra in the file is limited only by the disk capacity. The arrangement of absorbance values in the data files obtained corresponds to the input data for the SQUAD program.

The task that remains for the user when the data are used as input for the program SQUAD is just the preparation of the head of the input (description of the system and the equilibria involved) and the typing of the concentrations of reactants, pH and pathlength in each spectrum. These tasks can be carried out directly with a PC text editor.

SPECTROPHOTOMETRIC DETERMINATION OF THE TOTAL AMOUNT OF RARE-EARTH ELEMENTS IN AGRICULTURAL SAMPLES WITH *p*-CHLORO-CHLOROPHOSPHONAZO*

SHIHE LI, SHENGQUAN LI† and YUEJUN ZHANG
Department of Basic Sciences, Shanxi Agricultural University, Taigu, People's Republic of China

(*Received* 3 *January* 1991. *Revised* 30 *May* 1991. *Accepted* 5 *June* 1991)

Summary—A simple, sensitive and accurate spectrophotometric method for determination of the total amount of rare-earth elements in agricultural samples with *p*-chloro-chlorophosphonazo [*p*CCPA, *i.e.*, 2-(4′-chloro-2′-phosphon-benzylazo)-7-(4″-chlorophenyl)-1,8-dihydroxynaphthalene-3,6-disulphonic acid] in sulphuric acid medium has been developed. The apparent molar absorptivity of RE*x*O*y* (the general formula of rare-earth oxides)–*p*CCPA complex is 8.17×10^4 l.mole^{-1}.cm^{-1} at 676 nm, and Beer's law is obeyed for the mixture of RE*x*O*y* in the range 0–12 μg/25 ml. The proposed method has been successfully applied to the determination of the total amount of rare-earth elements in soils, herbs, vegetables, dried stems of maize, water samples and rare-earth microelement fertilizer samples with satisfactory results.

Spectrophotometric methods for determination of the total amount of rare-earth elements in steels,[1-3] alloys,[3,4] rocks and minerals,[1,5] human hair[6] and water samples[1,7,8] have been reported. *p*-Chloro-chlorophosphonazo (*p*CCPA) has been shown to be a reliable colorimetric reagent for yttrium[9] and scandium.[10] To our knowledge no systematic spectrophotometric investigations concerning the determination of the total amount of rare-earth elements in agricultural samples with *p*CCPA in aqueous solutions have been published previously. Recently, more and more applications of rare-earths (mainly nitrate) in agriculture are being investigated.[11] Applications of the rare-earths in agriculture have been reported to increase crop yield by 10–20% over controls. For example, oil-bearing crops have increased by 11–15%, cottons by 2.6–23.6%, vegetables by 11%, water melons by 15–23%, grapes by 10–25%, *etc.*[11] The contents of rare-earth elements in soil range from 200 to 1500 μg/g (cerium being the richest element) and the amounts of rare-earth elements in plants depend on their type and on the relative amounts of rare-earths in the soil in which the plants grow. Obviously, it is important for convenient methods to be available for determining the amounts of rare earths in soils. In this paper, the proposed method for the determination of total amounts of rare-earths in agricultural samples is shown to be simple and accurate. In the presence of proper masking agents, the determination is free of interferences from major elements and other microelements in agricultural samples, without the need for preliminary separation steps.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade unless otherwise indicated. Demineralized water was used throughout.

*Standard solution of a single RE*xOy, *1 mg/ml.* Dissolve 0.1000 g of RE*x*O*y* (purity, 99.999%, Yue Long Chemical Plant, Shanghai) in 2 ml of hot hydrochloric acid (6*M*) with dropwise addition of hydrogen peroxide. Cool, add 0.5 ml of concentrated sulphuric acid, heat and evaporate until acid fumes appear, cool, then add 2 ml of water and 1–2 drops of hydrogen peroxide. Boil to remove residual hydrogen peroxide, cool and dilute to 100 ml with water.

*Standard solution of mixed RE*x*O*y, 1 mg/ml. Prepared by mixing 40 ml of 1 mg/ml CeO_2 solution, 30 ml of 1 mg/ml Y_2O_3 solution, 15 ml of 1 mg/ml La_2O_3 solution and 15 ml of 1 mg/ml

Nd_2O_3 solution. The stock solution is further diluted to 10 μg/ml as working solution.

p-Chloro-chlorophosphonazo (pCCPA) aqueous solution, 0.05% (w/v).

*Sulphuric acid, 1*M.

Masking agent solution. Prepared by mixing 40 ml of 0.1*M* EDTA, 20 ml of 0.5*M* NaF, 5 ml of 0.1*M* citric acid and 5 ml of 0.1*M* oxalic acid.

Apparatus

Absorption spectra were measured with a Hitachi Model 220 double beam UV-Vis spectrophotometer (Japan) and the absorbance measurements were performed on a Model 721 spectrophotometer (Shanghai). A Fei-Yue-Pai Model WL-5001 Microwave oven (Radio Plant 18 of Shanghai) and polytetrafluoroethylene pot (Plant 9759 of PLA, Wuxi, P. R. China) were used for treatment of samples.

Procedure

General. To an aliquot of standard solution or sample solution containing 0–12 μg of REx*O*y in a 25-ml calibrated flask, add 0.5–1.6 ml of masking agent (not needed for standard solution), 3 ml of 1*M* sulphuric acid, and 3 ml of 0.05% *p*CCPA solution, dilute to the mark with water and shake thoroughly. Leave at room temperature for 30 min. Measure the absorbance in a 2-cm cell at 676 nm against a reagent blank prepared similarly.

Treatment of sample. For the control mineral specimen, fuse 0.1000 g of specimen with 2 g of sodium hydroxide and 2 g of sodium peroxide at a temperature of 700° for 15 min, cool and add 100 ml of boiling water, 10 ml of triethanolamine-water (1:1 v/v) solution, 1 g of EGTA, and 2 ml of 5% (w/v) $MgCl_2$ solution, boil and filter. The precipitate is dissolved in 15 ml of concentrated hydrochloric acid, followed by 100 ml of hot water and 20 ml of concentrated ammonia. The mixture was filtered after cooling to room temperature, and the precipitate was dissolved with 15 ml of hydrochloric acid (6*M*, 80°) and washed with 25 ml of 1.2*M* hydrochloric acid (about 80°). The solution was made up to 100 ml after cooling.

For the agricultural samples (except water samples), weigh accurately 0.2000 g of sample that has been treated preliminarily (dried, crushed, ground and sifted). Transfer the sample to a polytetrafluoroethylene pot, add 2.0 ml of concentrated sulphuric acid, and 1 ml of 30% hydrogen peroxide. Screw the lid on the pot, then place the pot in a microwave oven, and digest the sample for 3 min (6 min for soil samples). The pot is cooled for 20 min after being taken out of the oven. Unscrew the lid and transfer the solution to a 25-ml standard flask, and dilute to the mark with water. Samples are also digested by weighing 0.5000–2.000 g (determined by the total amount of rare-earths in the sample) of sample treated preliminarily and placed in a Kjeldahl flask. Add 5–10 ml of concentrated sulphuric acid and leave at room temperature for about 12 hr. Boil for 5–10 min, cool a moment and add several drops of hydrogen peroxide, continue to boil for about 5 min, and follow the same process until the solution appears clear. Boil to remove residual hydrogen peroxide, cool, filter (if necessary), transfer the solution to a 100-ml standard flask and dilute to the mark with water.

Water samples were prepared by concentrating via evaporation (the final volume depended on the total amount of rare-earths).

RESULTS AND DISCUSSION

Absorption spectra

Figure 1 shows the absorption spectra of the REx*O*y–*p*CCPA complexes and the mixed REx*O*y–*p*CCPA complex. There are two strong absorption bands in the wavelength range of 560–760 nm. Maximum absorption of

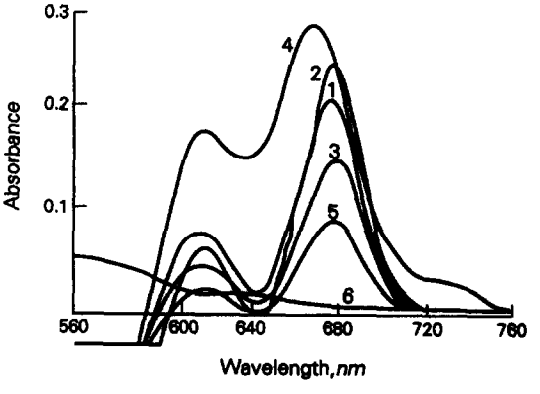

Fig. 1. Absorption spectra of complexes: 1, 10 μg La_2O_3/25 ml + *p*CCPA complex against reagent blank; 2, 12 μg CeO_2/25 ml + *p*CCPA complex against reagent blank; 3, 8 μg Nd_2O_3/25 ml + *p*CCPA complex against reagent blank; 4, 10 μg Y_2O_3/25 ml + *p*CCPA complex against reagent blank; 5, mixed REx*O*y (5 μg/25 ml) + *p*CCPA complex against reagent blank; 6, *p*CCPA against demineralized water.

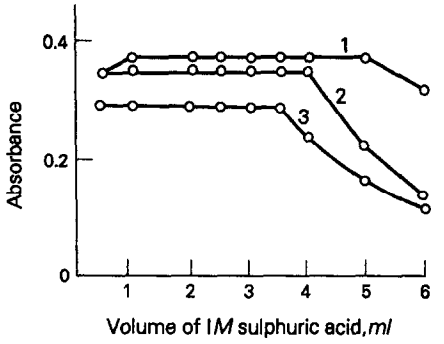

Fig. 2. Effect of acidity: 1, 10 μg CeO_2/25 ml; 10 μg La_2O_3/25 ml; 10 μg mixed REx*O*y/25 ml. Wavelength is 676 nm. 2, 10 μg Nd_2O_3/25 ml, 676 nm. 3, 5 μg Y_2O_3/25 ml (but at 667 nm).

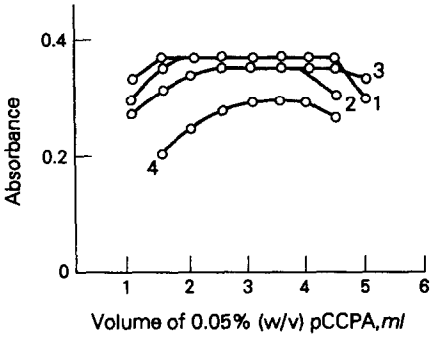

Fig. 3. Effect of *p*CCPA concentration: 1, 10 μg CeO_2/25 ml; 10 μg mixed REx*O*y/25 ml; 676 nm. 2, 10 μg La_2O_3/25 ml; 676 nm. 3, 10 μg Nd_2O_3/25 ml; 676 nm. 4, 5 μg Y_2O_3/25 ml, 667 nm.

the complexes of La, Ce, Pr, Nd, Sm and Eu with *p*CCPA and the mixed REx*O*y–*p*CCPA omplex is at 676 nm, but that of Gd, Tb, Dy, Er, Tm and Y with *p*CCPA is at 667 nm, measured against a reagent blank. Because the amounts of light rare-earths in agricultural samples are greater than those of heavy rare-earths, 676 nm was chosen as the measurement wavelength.

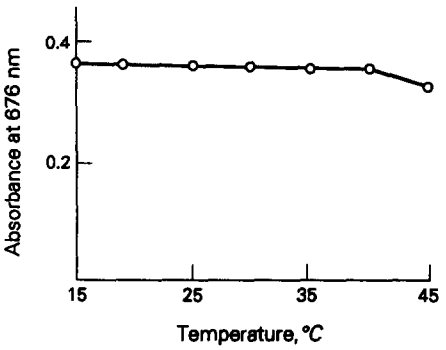

Fig. 4. Effect of temperature.

Effect of acidity

The effect of acidity on the absorbance of the complexes was studied with 1*M* sulphuric acid. The results obtained are shown in Fig. 2. The recommended amount of acid is 3 ml.

Effect of p*CCPA concentration*

The effect of *p*CCPA concentration on the absorbance of complexes was studied. The usable ranges are shown in Fig. 3. The recommended amount is 3.0 ml.

Effect of temperature

The influence of the temperature on the reaction of REx*O*y–*p*CCPA was studied by holding samples at different temperatures between 15 and 45°. The absorbance is not appreciably affected by changes in the temperature between 15 and 40° (Fig. 4).

Characteristics of the system

Table 1 shows some of the calibration and precision characteristics of the measurement system for different rare-earths. Table 2 gives the apparent molar absorptivities of REx*O*y–*p*CCPA complexes.

Table 1. Calibration and precision characteristics of the system

REx*O*y	L.R.E.*	*R*†	R.B.L.O.‡	S.D.	RSD, %

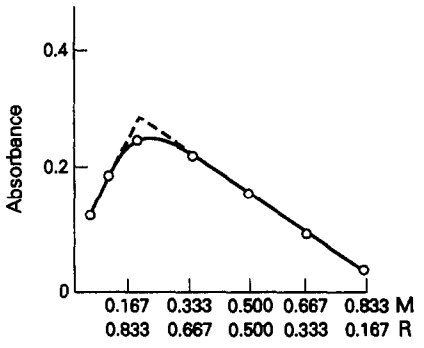

Fig. 5. Method of continuous variations. M: Mole fraction of RE; R: Mole fraction of *p*CCPA.

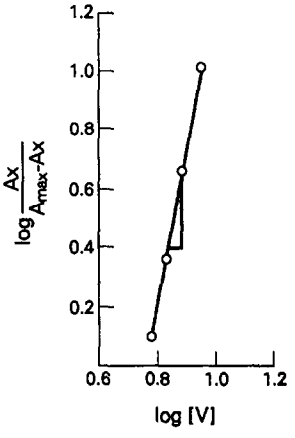

Fig. 6. Method of equilibrium shift. V: Volume of *p*CCPA; A: Absorbance.

Job's method of continuous variation and the method of equilibrium shift shows that the reaction ratio of RE (rare-earths) to *p*CCPA is 1:5 (Figs. 5 and 6).

Effect of reaction time

The reactions of La, Ce, and Nd with *p*CCPA are very rapid. The absorbance reached a maximum immediately after the solutions were made up to final volume. But the absorbance of the Y_2O_3–*p*CCPA complex reached its maximum 30 min after the solution was made up to final volume. The absorbances of all RE*x*O*y*–*p*CCPA complexes are stable for up to 3 hr.

Water sample I					3.28 (μg/l.)
Water sample II					35.01 (μg/l.)
RE-bearing microelement-fertilizer from Henan Province					39.8%

*All determined values given in Table 6 are averages of three separate determinations.

†The REExOy amount in a sample in 25 ml (*i.e.*, the value determined by the procedure described, but consideration must be given to both the range of Beer's law and the range of permissible acidity of the proposed method when the volume of a sample solution is decided).

‡The amount of rare-earths in the sample was obtained by converting the determined value to weight per gram of a given sample.

The stated levels of the species shown in Table 3 did not cause an error exceeding 5%.

The amounts of major elements and microelements in soils have a range of values. In order to show the selectivity of the proposed method for soil analysis, a comparison between the highest limits of the amounts of major elements and microelements in soils (statistical averages)[12] and the tolerance limits of diverse ions is given in Table 4.

It can be seen from Table 4 that the tolerance limits of diverse ions are by far, larger than the highest limits in soils. Therefore, the selectivity of the proposed method for soil analysis is satisfactory.

Accuracy and validity

In order to check the accuracy and the validity of the proposed method, control mineral specimens and various agricultural samples were analysed. The results are shown in Tables 5 and 6.

Acknowledgements—The authors are indebted to Professor Changsong Liu (the Department of Chemistry, Shanxi University, Taiyuan) and Professor Dingcheng Guo (the Department of Basic Sciences, Shanxi Agricultural University) for their help. We thank the Laboratory of the Geology Department of Shanxi Province for supplying the control mineral specimens.

SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF SELENIUM WITH CATALYTIC REDUCTION OF BROMATE BY HYDRAZINE IN HYDROCHLORIC ACID MEDIA

A. AFKHAMI, A. SAFAVI* and A. MASSOUMI
Department of Chemistry, College of Sciences, Shiraz University, Shiraz, Iran

(*Received* 7 *June* 1991. *Revised* 24 *September* 1991. *Accepted* 26 *September* 1991)

Summary—A method is presented for the determination of selenium, based on the catalytic effect of selenium(IV) on the reduction reaction of BrO_3^- by $N_2H_4 \cdot 2HCl$. The decolourization of Methyl Orange by the reaction products was used to monitor the reaction spectrophotometrically at 525 nm. This method is precise, highly sensitive, simple, rapid, widely applicable and selective for the determination of selenium(IV) and total selenium. The variables which affected the reaction rate were fully investigated and the optimum conditions were established. Selenium, as low as 1 ng/ml, can be determined by this method. The relative standard deviation of 20 ng of selenium was 0.94% ($N = 10$). The method was applied to the determination of Se(IV) in a health-care product.

Selenium is becoming increasingly important from a toxicological and physiological point of view.[1] Selenium is an essential micro-nutrient for animals although excesses have been known to cause toxicity. On the other hand selenium deficiency syndromes have also been reported. It has been reported that selenium acts as an antidote for mercury, cadmium, arsenic and other elements.[2]

On the basis of this background, the determination of micro amounts of selenium is becoming increasingly important. Determination of selenium as hydrogen selenide by atomic-absorption spectrometry is subject to many interferences[3] such as Ag, Cu, Ni, Pd, Pt, Rh, Ru and Sn, and it is necessary to ensure that the matrix being analysed does not interfere. An alternative method for determination of traces of selenium is based on the spectrophotometric or fluorimetric measurement of piazselenol formed by the reaction of selenium(IV) with diaminonaphthalene.[4–6] These methods are tedious, time consuming and the reagents used are toxic and relatively unstable.

Catalytic kinetic methods, which are simple, sensitive and selective for many elements,[7] have also been applied to the determination of this element, and some of them are described below. Selenium(IV) has been determined by using its catalytic effect on the reduction of methylene blue by sodium sulphide;[8] this method had a detection limit of 0.05 μg. Another catalytic method for the determination of selenium is based on the reduction of 1,4,6,11-tetraazanaphthacene by glyoxal and hypophosphorous acid and has a detection limit of 0.03 μg of Se.[9] This method suffers from a non-linear calibration and has the drawback of requiring a reagent that is not commercially available. A third method is based on the catalytic effect of selenium on the reduction of tetranitro blue tetrazolium by dithiothreitol.[10]

Recently, we reported a highly sensitive and selective method for the determination of selenium based on its catalytic effect on the reduction reaction of resazurin by sulphide.[11] This paper describes the development of a new method for the determination of selenium(IV) based on its catalytic effect on the reduction reaction of bromate by hydrazine dihydrochloride. This method which is very rapid, simple, highly selective and sensitive, uses only readily available reagents.

EXPERIMENTAL

Reagents

Demineralized triply-distilled water was used throughout. Selenite standard solutions were prepared by dissolving 1.40 g of selenium dioxide (Merck) in water and diluting to the

*Author for correspondence.

mark in a one-litre standard flask. This solution was standardized iodimetrically.[12] Working solutions were prepared by diluting the stock solution with water.

A 0.5*M* solution of hydrazine dihydrochloride was prepared by dissolving 13.12 g of $N_2H_4 \cdot 2HCl$ (BDH) in water and diluting to the mark in a 250-ml standard flask. Bromate (0.24*M*) was prepared by dissolving 10.02 g of potassium bromate (Merck) in water and diluting to the mark in a 250-ml standard flask.

Methyl Orange, 0.1% was prepared by dissolving 0.1 g of Methyl Orange (Merck) in water and diluting to the mark in a 100-ml standard flask.

A pH = 1 buffer solution (Merck) of glycine–hydrochloric acid was used.

Apparatus

A Perkin–Elmer model 35-spectrophotometer with a 1-cm glass cell was used for absorbance measurements.

Procedure

All the measurements were performed at 25.0 ± 0.1°.

Into a 10-ml standard flask introduce a suitable aliquot of the sample solution containing 0.05–8.0 μg of selenium(IV) and 1.5 ml of buffer solution. Add 2 ml of 0.5*M* hydrazine dihydrochloride followed by 0.2 ml of 0.1% methyl orange solution and 1 ml of 0.24*M* bromate, then dilute the solution to the mark with water and mix well. Transfer a portion of the solution to a glass cell within 30 sec and measure the absorbance at 525 nm. Find the initial reaction rate ($\Delta A/\Delta T$) during the first three minutes after starting the reaction.

RESULTS AND DISCUSSION

Selenium(IV) has a catalytic effect on the reduction reaction of bromate by hydrazine dihydrochloride. The steps involved in this reaction are:

$$2BrO_3^- + 10Cl^- + 12H^+ \rightleftharpoons Br_2 + 5Cl_2 + 6H_2O \text{ (slow)} \quad (1)$$

$$2Cl_2 + (N_2H_6)^{2+} \rightleftharpoons N_2 + 4Cl^- + 6H^+ \text{ (fast)} \quad (2)$$

$$2Br_2 + (N_2H_6)^{2+} \rightleftharpoons N_2 + 4Br^- + 6H^+ \text{ (fast)} \quad (3)$$

The first step of the reaction is slow and the second and third are fast. Selenium(IV) acts as a catalyst for the first step. The presence of hydrazine in the medium slows down step (1) which is fairly fast in its absence or when the medium is very acidic.[13] Methyl Orange reacts with the products of the reaction (bromine and chlorine) and is decolourized.

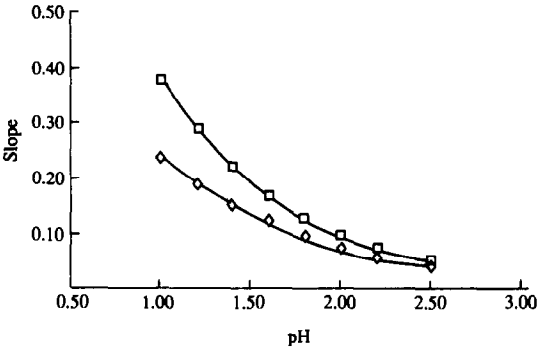

Fig. 1. Effect of pH on the rate of (■) catalysed and (●) uncatalysed reaction.

This reaction can be monitored spectrophotometrically by measuring the decrease in absorbance versus time for the first three minutes of the reaction.

Effects of variables

The graph of the decrease in absorbance versus time at 525 nm was linear during the first three minutes and the slope (tan α = dA/dt) was used as a measure of the initial reaction rate.

The reaction rate of both catalyzed and uncatalyzed reactions increased with decreasing pH. Figure 1 shows the influence on the catalyzed and uncatalyzed reaction of pH in the range 1.0–2.5.

Samples with pH lower than 1 were not tested because the rate of the uncatalyzed reaction is too fast at these pH values. Therefore, pH 1 was selected for routine works.

The influence of the concentrations of bromate and hydrazine dihydrochloride on the reaction rate was also studied. The reaction rate increases as the concentration of these two reagents is increased. On the other hand a high increase in the reaction rate causes perturbation in the absorbance reading by the appearance

Table 1. Accuracy and precision of the recommended procedure

Amount of Se(IV) taken, *ng/ml*	Relative error, %	Relative standard deviation, % ($n = 10$)
20	1.4	0.94
50	1.8	0.83
300	2.3	0.53
500	0.95	0.10

Table 2. Effect of diverse species on the determination of 0.5 μg/ml Se(IV)

Ion	Tolerance limit μg/ml
Th(IV), Se(VI), Pd(II), La(III),* Os(VIII), Co(II), Mn(II), Hg(II), Ce(IV),* Mo(VI), W(VI), Ce(III), K(I), Na(I), Tl(I), UO_2^{2+}, Zn(II), Ni(II), Fe(III),* Ca(II), Mg(II), As(V), Te(VI), As(III), Cd(II), Co(III), Al(III), PO_4^{3-}, CH_3OO^-, F^-, SO_4^{2-}, NO_3^-	100
I^-, IO_3^-, Br^-	30
Hg_2^{2+}, Cu^{2+}*	10
V^{3+}, Pd(II)†	2
EDTA	0.05*M*

*After addition of 0.5 ml of 0.1*M* EDTA.
†After addition of 1 ml of saturated dimethyl-glyoxime solution.

of nitrogen bubbles. Therefore the optimum concentration of these two reagents is the concentration at which the reaction has a high reaction rate and N_2 bubbling does not perturb the absorbance reading. These concentrations were found to be 0.10 and 0.024*M* for $N_2H_4 \cdot 2HCl$ and BrO_3^-, respectively.

Increasing temperature increased the reaction rate of both the catalyzed and uncatalyzed reactions, but at high temperatures N_2 gas bubbles are formed. For this reason and also for simplicity $25° \pm 0.1$ was selected for routine work.

Ionic strength up to 0.81*M* had no effect on the reaction rate.

Analytical parameters

The calibration graph was obtained under the experimental conditions chosen. A plot of initial reaction rates as a function of selenium(IV) concentration is linear in the range 5–800 ng/ml, with the equation:

$$\tan \alpha = 1.482 \times 10^{-4} C + 0.0806$$

with $r = 0.9994$, where C is the concentration of selenium(IV) in ng/ml.

The limit of detection, defined as the average of the blank value plus three times its standard deviation, was 1 ng/ml. Table 1 shows the accuracy and precision of the recommended procedure.

Effects of foreign species

The effects of various cations and anions on the determination of 0.5 μg/ml selenium(IV) were studied. The results are summarized in Table 2. The tolerance limit was defined as the concentration of added ion causing less than 3% relative error. Most ions did not interfere with the determination even when they are present at concentrations 200 times as great as that of selenium(IV).

Positive interferences were observed from lanthanum(III), copper(II), palladium(II), vanadium(III), tellerium(IV) and bromide because they could also catalyse the reaction. Negative interferences were observed from iodate and iodide, because they inhibit the indicator reaction. Hg_2^{2+} interferes by precipitation with the reagents. Iron(III) and cerium(IV) interfere by changing the colour of the solution probably by complexation with Methyl Orange. The interfering effect of copper(II) in concentrations less than 2 μg/ml and palladium(II) in concentrations less than 2 μg/ml can be removed by the addition of EDTA and dimethylglyoxime, respectively. However, higher concentrations of copper(II) can be removed by extracting its complex with dimethylglyoxime into chloroform, and higher concentrations of palladium(II) can be removed by extracting its complex with oxine into chloroform. The interfering effect of vanadium(III) can also be removed by extracting its complex with oxine into chloroform.

Determination of selenium in a health-care product

In order to test the described method, selenium was determined in a health-care product (a shampoo for the treatment of dandruff). Sample dissolution was carried out by the procedure described by Belarra *et al.*[14] Approximately 1 g of sample was weighed into a 100-ml Kjeldahl flask. Concentrated sulphuric acid (1 ml) was added and the mixture was heated to fuming for 15 min. The solution was allowed to cool and 5 ml of 30% w/v hydrogen peroxide was added. The mixture was boiled vigorously to eliminate excess of hydrogen peroxide and the flask was allowed to cool. The mixture was diluted to 1.0 litre with triply distilled water. A 0.5-ml volume of this solution was taken for determination of selenium(IV) as in the recommended procedure.

The results showed the presence of 13.45 ± 0.42 g/l. selenium ($n = 7$). (Manufacturer's value is given as 13.81 g/l. selenium as selenium sulfide.)

CONCLUSIONS

This method can be used to determine selenium as low as 1.0 ng/ml without the need for any preconcentration step. The method is very simple and more selective than the other kinetic methods reported previously or hydride generation atomic-absorption spectrometry which is subject to many interferences. Also, the limit of detection obtained by the proposed method (1.0 ng/ml) is lower than that obtained by hydride generation atomic-absorption spectroscopy (5 ng/ml).[3]

Since the method only responds to selenium(IV) species, the determination of selenium(IV) in the presence of selenium(VI) is possible.

TRIPHENYLTETRAZOLIUM CHLORIDE FOR DETERMINATION OF IODATE AND PERIODATE

M. KAMBUROVA
Department of Chemistry, Higher Institute of Agriculture, 4000 Plovdiv, Bulgaria

(*Received* 11 *February* 1991. *Revised* 11 *June* 1991. *Accepted* 14 *June* 1991)

Summary—Optimum conditions for complexation in the systems triphenyl-tetrazolium chloride-iodate-iodide-dichlorethane and triphenyltetrazolium chloride-periodate-iodide-dichlorethane were found. The molar absorptivity of the complex was 7.48×10^4 l. mole^{-1}. cm^{-1} for the iodate, and 9.09×10^4 l. mole^{-1}. cm^{-1} for the periodate. Beer's law is adhered to in the range of 0.04–0.7 μg/ml for iodate and 0.02–0.35 μg/ml for periodate. The influence of foreign ions was studied. Cr(VI), Hg(II) and $S_2O_3^{2-}$ interfere. The proposed method has been applied to analysis of iodate and periodate in fresh water.

There are a few methods for determination of iodates and periodate described in the literature.[1–5] The existing methods for spectrophotometric determination of these ions are, to some degree, unsatisfactory as the procedures require strict maintenance of the experimental conditions (*e.g.*, a strictly fixed pH, standing of the samples before the determination of the iodate or periodate and low stability of the compounds formed).

During our investigations we found that triphenyltetrazolium chloride (TTC), in acidic medium, reacted with iodate or periodate. The good solubility of the compounds obtained in organic solvents can be used in a determination of iodate or periodate and also in their isolation from other ions. This led to the development of an extraction spectrophotometric method for determination of iodate and periodate. The method we suggest is superior to some of the reported methods, in sensitivity,[1] stability of the complex obtained[2,3] and rapidity.[3]

EXPERIMENTAL

Apparatus

A Carl Zeiss VSU 2-P spectrophotometer (Jena, DDR) was used with 1-cm cuvettes, and measurement at 255 and 295 nm.

Reagents

2,3,5-Triphenyltetrazolium chloride (TTC), (Renal), $5 \times 10^{-4}M$ potassium iodate, *p.a.* $1 \times 10^{-5}M$, potassium periodate, *p.a.* $1 \times 10^{-5}M$, potassium iodide, *p.a.* $1 \times 10^{-3}M$ sulphuric acid, *p.a.* $-2M$ phosphoric acid, *p.a.* $-2M$ 1,2 dichlorethane, Merck.

Procedure

Determination of iodate. Aqueous solutions of the sample containing 0.4–7 μg of iodate are introduced into separating funnels. Portions of 3 ml of phopshoric acid $2M$, 0.4 ml of potassium codate $1 \times 10^{-3}M$ and 0.5 ml of $5 \times 10^{-4}M$ TTC are added. The volumes are brought up to 10 ml with distilled water and the solutions are extracted with 3 ml of $C_2H_4Cl_2$ for 15 sec. After phase separation, the organic phase is measured at 255 nm in a 1-cm cuvette. A blank containing no codate is run in parallel.

Determination of periodate. Aqueous solutions of the sample containing 0.2–3.5 μg of periodate are introduced into separating funnels. Portions of 0.5 ml of $2M$ sulphuric acid, 0.6 ml of $1 \times 10^{-3}M$ potassium iodate and 0.2 ml of $5.10^{-4}M$ TTC are added. The volumes are brought up to 10 ml with distilled water and the solutions extracted with 3 ml of $C_2H_4Cl_2$ for 15 sec. After phase separation, the organic phase is measured at 295 nm in a 1-cm cuvette. A blank is run in parallel as above.

RESULTS AND DISCUSSION

Optimization of conditions

The technique suggested for determination of iodate and periodate is based on their interaction, in acidic medium, with an excess of iodide ions which are oxidized to iodine. The complex anion obtained, I_3^-, is extracted as an

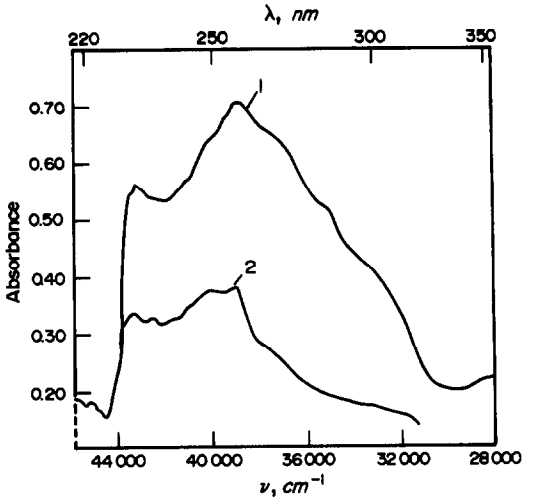

Fig. 1. Absorption spectra in $C_2H_4Cl_2$ of: 1-ion-association complex of TTC with IO_3^-, 2-TTC in phosphoric acid solutions; $C_{IO_3^-} = 8 \times 10^{-6}M$, $C_{TTC} = 2.5 \times 10^{-5}M$.

ion association complex with triphenyltetrazolium chloride. The solubility of the associates in the following organic solvents was investigated: chloroform, dichlorethane, benzene, nitrobenzene, tetrachloromethane. The associates showed highest solubility in dichlorethane. The absorption spectra of the ion-pair in dichlorethane which triphenyltetrazolium chloride formed with iodate and periodate are shown in Figs. 1 and 2. The associate formed from TTC and iodate has a maximum absorption at $\lambda = 255$ nm and the associate from TTC and periodate has two maxima, at $\lambda = 255$ nm and 295 nm. The determination of the periodate was carried out at 295 nm because the absorption of TTC is lower.

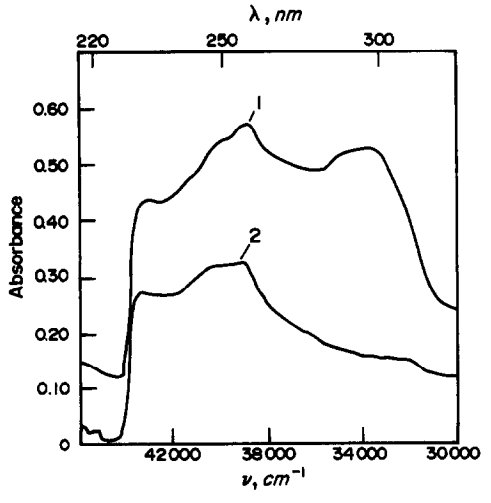

Fig. 2. Absorption spectra in $C_2H_4Cl_2$ of: 1-ion-association complex of TTC with IO_4^-, 2-TTC in sulphuric acid solutions; $C_{IO_4^-} = 8 \times 10^{-6}M$, $C_{TTC} = 2.5 \times 10^{-5}M$.

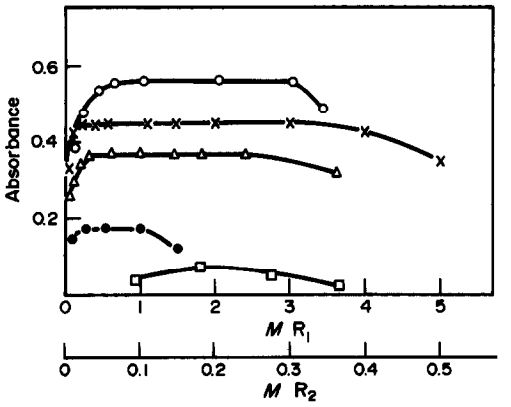

Fig. 3. Investigation of the acidity influence on the extraction of IO_3^- with TTC; R_1: (○) H_3PO_4, (×) H_2SO_4, (△) HCl, (●) HNO_3; R_2: (□) $HClO_4$; $C_{IO_3^-} = 3 \times 10^{-6}M$, $C_{TTC} = 1 \times 10^{-5}M$.

To optimize the reaction conditions we studied the effect of the type of the mineral acid and its concentration upon the interaction of TTC and iodate or periodate. The effect of the phosphoric, sulphuric, hydrochloric, nitric and perchloric acids upon the extraction equilibrium was studied. The experimental data (Fig. 3) showed that the maximum absorption for the iodate was obtained with the phosphoric acid in the range of 0.6–3M. Maximum extraction of periodate was reached in sulphuric acid medium (Fig. 4), with the maximum absorption in the range 1×10^{-1}–0.1M sulphuric acid. In both cases the experimental data showed that it is possible to work in a rather wide range of pH values.

The effect of triphenyltetrazolium chloride concentration upon the determination of iodates and periodates was studied. The absorbance increased with an increase in the TTC concentration. At an aqueous phase acidity of 0.6M phosphoric acid, the maximum extraction

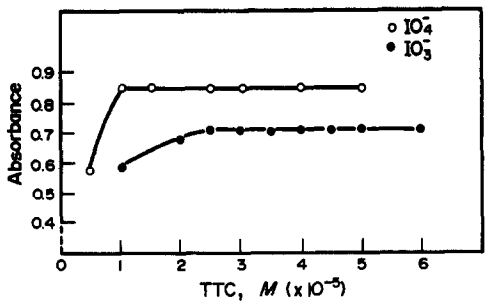

Fig. 5. Dependence of the light absorption change on the concentration of TTC; $C_{IO_3^-} = 0.7\ \mu g/ml$, $C_{IO_4^-} = 0.35\ \mu g/ml$.

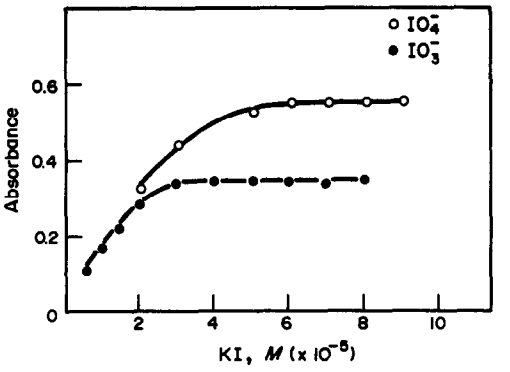

Fig. 6. Dependence of the light absorption change on the concentration of KI; $C_{IO_3^-} = 3 \times 10^{-6}M$, $C_{IO_4^-} = 1 \times 10^{-6}M$, $C_{TTC} = 1.10^{-5}M$.

of the iodate was reached at a concentration of TTC $\geqslant 2.5 \times 10^{-5}M$ (Fig. 5). At an acidity of the aqueous phase of $0.1M$ sulphuric acid, the maximum extraction of periodate was reached at a concentration of TTC $\geqslant 1 \times 10^{-5}M$.

The formation of ion-pairs between TTC and iodate or periodate largely depends on the concentration of potassium iodide. In order to shift the equilibrium towards formation of the ion-pairs, the concentration of iodide ions should be high. For the extraction of $3 \times 10^{-6}M$ iodate, the concentration of KI should be $\geqslant 3 \times 10^{-5}M$, and for the extraction of $1 \times 10^{-6}M$ periodate, the concentration of KI should be $\geqslant 6 \times 10^{-5}M$ (Fig. 6).

Photometric characteristics

In the presence of phosphoric acid, Beer's law is adhered to in the range 0.04–0.7 μg/ml iodate. The molar absorptivity at 255 nm is 7.84×10^4 $l.mole^{-1}.cm^{-1}$. The relative standard deviation

Table 1. Effect of foreign ions $C_{IO_3^-} = 0.2\ \mu g$; $C_{H_3PO_4} = 0.6M$ $C_{TTC} = 2 \times 10^{-5}M$; $C_{IO_4^-} = 0.2\ \mu g$; $C_{H_2SO_4} = 0.1M$ $C_{TTC} = 2 \times 10^{-5}M$

	0.15	−1.1	0.4

*Relative error.
†Relative standard deviation.

(10 determinations with 0.5 μg of iodate, 95% confidence level) of the method is +0.35%. The Sandell sensitivity index[6] is 2.22×10^{-3} μg/cm². The absorbance of the organic phase is maximum and stable for seven days.

Beer's law is obeyed between 0.02 and 0.35 μg/ml periodate in sulphuric acid medium. The molar absorptivity at 295 nm is 9.09×10^4 l.mole^{-1}.cm^{-1}. The relative standard deviation (10 determinations with 0.5 μg of periodate, 95% confidence level) of the method is ±0.27%. The Sandell sensitivity index is 2.10×10^{-3} μg/cm². The ion-pair is stable for seven days.

Effects of foreign ions

The effect of some ions upon the extraction equilibrium in the determination of 0.2 μg of iodate and periodate was studied. The concentration limit of the foreign ions as well as the top ratio with iodate and periodate is given in Table 1. Most of the ions studied do not interfere even when in high concentration. No masking reagents were used. Only Cr(VI), Hg(II) and $S_2O_3^{2-}$ showed interfering action. The results in Table 1 show that the formation reaction of the ion-pair of TTC with periodate is more selective than the reaction between TTC and iodate.

Determination of iodate-iodine and periodate-iodine in fresh waters

Methods for determination of iodate and periodate based on the experimental data were developed. The experiment was carried out using artificial fresh water containing 10 mg/l. sodium, calcium, chloride, sulphate and bicarbonate, together with 200 μg/l. of iodate and periodate.

Add 3 ml of 2*M* phosphonic acid, 0.4 ml of 1×10^{-3} potassium iodate 0.5 ml of $5.10^{-4}M$ for determination of iodide–iodine, and 0.5 ml of 2*M* sulphuric acid, 0.6 ml of $1 \times 10^{-3}M$ potassium iodide, 0.2 ml of $5 \times 10^{-4}M$ TTC for determination of periodate–iodine in the sample of fresh water. Then dilute to 50 ml with distilled water. Extract with 3 ml of $C_2H_4Cl_2$ for 15 sec. Measure at $\lambda = 255$ nm and 295 nm. A blank is run likewise.

The concentrations of iodate and periodate are determined by preconstructed standard curves. The results are given in Table 2.

Advantages of these methods is the good accuracy and the wide range of pH that can be used. Besides, no standing is needed before determining the ions. The associates obtained are very stable.

(*Received* 29 *April* 1991. *Revised* 6 *January* 1992. *Accepted* 8 *January* 1992)

Summary—The construction and general performance characteristics of ion-selective membrane electrodes sensitive to BF_4^- and ClO_4^- anions, respectively, are described. All electrodes show near-Nernstian responses in the range 10^{-2}–$10^{-5}M$. The selectivity of the electrodes to a number of organic and inorganic anions are reported. The electrodes are useful in the potentiometric determination of a few pharmaceutical preparations. The method is simple, rapid and does not require prior sample pre-treatment.

Drug control quality is a branch of analytical chemistry that has a wide impact on public health, and so development of reliable quick and accurate methods for the active ingredient determination is welcomed.

Ion-selective membrane electrodes (ISMEs) development has seen spectacular achievements in the last few years, and, theoretically, it should be possible to construct such electrodes for any ionic species.

ISMEs are used extensively for quality control of various drugs and became a useful tool for solving analytical problems connected with complex pharmaceutical formulations.[1–7] Much effort is required in the development of a rapid, simple and sensitive method for the determination of a certain drug, as it may be found also in complex pharmaceutical preparations or in human fluids,[8] not only in pure form.

The paper describes the preparation and the characterization of two types of BF_4^--selective membrane electrodes and a ClO_4^--selective membrane electrode among those existing in the literature.[9–11] The electrodes use tricaprylmethylammonium cation as the counter-ion in the electroactive material of the membrane. One of the BF_4^--selective electrodes is based on the ion-pair complex dissolved in nitrobenzene ($5 \times 10^{-3}M$), (Electrode A), and the other on the same ion-pair complex embedded in a PVC matrix, (Electrode B). The ClO_4^--selective electrode is based on the ion-pair complex embedded in a PVC matrix (Electrode C). The electrodes exhibit useful analytical characteristics for the determination of some compounds of pharmaceutical interest, such as colidinium,[12] trimethylpyrylium and trimethylpyrydinium salts[13] and potassium perchlorate.

EXPERIMENTAL

Apparatus

A Präcitronic digital pH/mV-meter, model 870 MV (±0.01 mV precision) was used for all direct potentiometric measurements. The electrodes proposed were used in direct potentiometry in conjunction with an Orion 91-01 double junction reference electrode with saturated $Na_2B_4O_7$ solution in the outer compartment. The potentiometric titrations were performed with an automatic assembly, consisting of ABU 12 Autoburette, TTT 2 Titrator and SBR 2 c Recorder (Radiometer). The pH measurements were performed with a Radiometer G202 B glass electrode in combination with a Radiometer K401 calomel electrode.

Reagents and materials

All reagents were of analytical reagent grade. $NaBF_4$ and $KClO_4$ were supplied by Reactivul, while *n*-dodecanol was from Sigma. Other materials were: tricaprylmethylammonium chloride (Aliquat 336S), (General Mills Chemical Inc.); 2-nitrophenyloctylether (2-NPOE) (Fluka), and poly(vinylcholoride) (PVC) of high molecular mass (Aldrich). The pharmaceutical preparations were synthesized in our laboratory by one of us.[12,13] Standard solutions of sodium

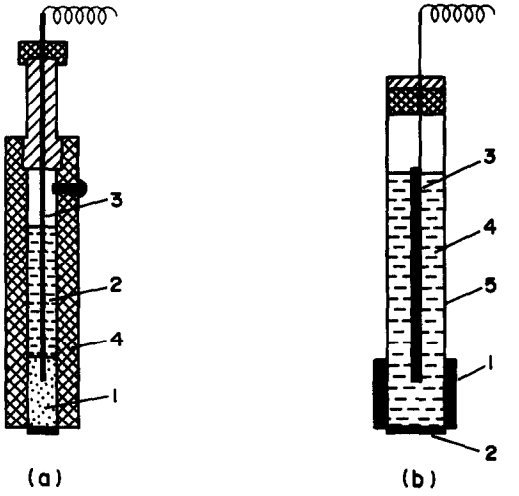

Fig. 1. The electrode design: (a) liquid membrane electrode. 1—graphite rod; 2—internal filling solution; 3—internal reference electrode; 4-electrode body. (b) PVC membrane electrode. 1—Tygon tube; 2—electroactive material; 3—internal reference electrode; 4—internal filling solution; 5—glass tube (electrode body).

tetrafluoroborate were prepared by serial dilution while keeping the pH constant at 2.7 (acetic acid/sodium hydroxide). Standard solutions of potassium perchlorate were prepared by serial dilution while keeping pH at a constant value of 6.4 with borax–KH_2PO_4 buffer.

Standard solution of sodium tetraphenylborate (NaTPB) ($5 \times 10^{-2}M$). An amount of 17.112 g of sodium tetraphenylboron was dissolved in distilled water and diluted to one litre. Potentiometric titration with $5 \times 10^{-2}M$ silver nitrate standard solution using an Ag_2S electrode as indicator was used to determine the solutions titre.

Procedures

Direct potentiometry. Standard solutions of 10^{-3}, 10^{-4}, 10^{-5} and $10^{-6}M$ concentrations were prepared by serial dilution of a $10^{-2}M$ potassium perchlorate solution. The electrodes were placed in the stirred standard solution in the order 10^{-6}–$10^{-2}M$. A plot of E (mV) against log[concentration] was recorded and the unknown concentration was determined from the calibration graph.

Potentiometric titration. The electrodes were placed in a sample solution (30–40 ml, concentration *ca.* $10^{-2}M$), then the sample was titrated with the $5 \times 10^{-2}M$ sodium tetraphenylborate standard solution. The end-point corresponds to the maximum slope on the E(mV) *vs.* volume titrant curve (1 ml of $5 \times 10^{-2}M$ tetraphenylborate solution is equivalent to 10.5 mg of 2,4,6-trimethylpyrylium tetrafluoroborate, 16.8 mg of colidinium tetrafluoroborate, 15.37 mg of 2,4,6-trimethylpyrydinium-*N*(acetoxiethyl) perchlorate and 17.04 mg of 2,4,6-trimethylpyrydinium-*N*(stearylamino) tetrafluoroborate, respectively).

Content uniformity assay of $KClO_4$ tablets. Ten individual tablets were placed in separate 100-ml standard flasks and dissolved by shaking with distilled water. The pH was kept constant at 6.4 with borax–KH_2PO_4 buffer and then the concentration was determined with a direct potentiometric method, as described above.

Electroactive materials

The quaternary ammonium cation, tricaprylmethylammonium (Aliquat 336S), is a well-known extracting agent and was used to obtain the ion-pair association complexes with the tetrafluoroborate and perchlorate anions respectively. Five grams of Aliquat 336S was mixed with 5.0 g of *n*-dodecanol and equilibrated with ten separate 10–15 ml aliquots of $0.1M$ $NaBF_4$ or $0.1M$ potassium chlorate, respectively. The organic phases were washed twice with distilled water until the reaction of chloride ion was negative, and then centrifugated until clear solutions were obtained.

Preparation of the electrodes

The BF_4^--selective membrane electrode (Electrode A), was prepared as described elsewhere[14,15] by impregnating the support material [a graphite rod 15 mm long, 6.5 mm diameter (6) attached to the end of a PTFE tube (1)], with a solution of ion-pair complex in nitrobenzene (2). The electrode was stored in the same electroactive material solution as the inner filling solution and was washed with distilled water after use. The BF_4^--selective membrane electrode (Electrode B) and the ClO_4^--selective membrane electrode (Electrode C) were prepared as described elsewhere.[16–18] The ion-pair complexes were embedded in a PVC matrix containing 2-NPOE as plasticizer. The membrane composition, selected to be one of the best among those studied, was 4% w/w electroactive material 64% w/w 2-NPOE and 32% w/w PVC. A disc (0.9 cm diameter) was cut from the membrane and fixed to the end of a 10-mm Tygon tube using a PVC–tetrahydrofuran solution as adhesive. The other end of the Tygon tube was fitted on to a glass tube to form the electrode body. A Ag/AgCl wire was then inserted and the electrode body was filled with a $10^{-3}M$ standard solution of $NaBF_4$ and $KClO_4$, respectively. The electrodes were stored in the air between the measurements and washed with distilled water after use. Figure 1 shows the electrode design for both types used in the present investigation.

RESULTS AND DISCUSSION

Electrode responses

The emf measurements were made with electrochemical cells of type (I):

X^--selective membrane electrode | X^- (C_{X^-}) pH constant | Ag/AgCl (I)

where $X^- = BF_4^-$ and ClO_4^- respectively, C_{X^-} is the anion concentration ranging from 10^{-1} to $10^{-6}M$ for the BF_4^--selective membrane electrodes and respectively from 10^{-2} to $10^{-6}M$ for the ClO_4^--selective membrane electrode. The emf of the cells of type (I) are given by:

$$E_{(A)} = E'_{o(A)} - 0.055 \log[BF_4^-] \quad \text{for electrode A} \qquad (1)$$

$$E_{(B)} = E'_{o(B)} - 0.061 \log[BF_4^-] \quad \text{for electrode B} \qquad (2)$$

$$E_{(C)} = E'_{o(C)} - 0.052 \log[ClO_4^-] \quad \text{for electrode C} \qquad (3)$$

where E_0' represents the conditional standard potentials for the electrodes A, B and C, respectively, under the conditions of use of cell (I) and 0.055, 0.061 and 0.052 represent the $dE/d[\log X^-]$, respectively. Figure 2 shows the electrode functions for the three electrodes.

The critical response characteristics for the electrodes are shown in Table 1. The calibration curves for the individual electrodes were found to be reproducible from day to day.

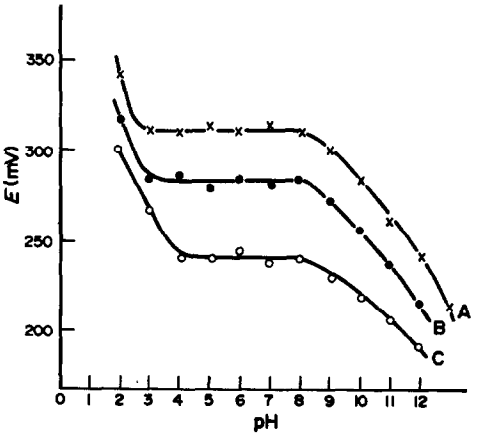

Fig. 3. The influence of pH on the response of the X^--selective membrane electrodes (A, B and C) in $10^{-3}M$ solutions.

Sulphate	$<10^{-4}$	$<10^{-4}$	$<10^{-4}$

*Except potassium perchlorate, all the other salts used were those containing Na^+ cation.

Influence of pH

The effect of pH on the potentials of the electrodes was examined by measuring the emf of the cell (I), in which the pH was varied by adding appropriate amounts of acetic acid/sodium hydroxide solution. At pH values between 3 and 8 no significant change in the membrane potential was observed for the BF_4^--selective membrane electrodes (A, B), while for the ClO_4^--selective membrane electrode the pH range was 4–8. At pH values higher than 8.0–8.5 the potential decreased slowly because of hydroxide anion interference (Fig. 3).

Response time

The response time of the electrodes was tested over the range used, the sequence of measurements was from low concentrations to high concentrations. The PVC matrix electrodes provide a stable emf reading, and the response time is a few seconds at higher concentrations (10^{-1}–$10^{-3}M$) and about 2–3 min in diluted solutions. The liquid membrane electrode also provides a stable emf reading, but the response time is 1–2 min even in concentrated solutions, and about 5 min in low concentration solutions.

The selectivity of the electrodes

Potentiometric selectivity coefficients for all the electrodes were evaluated by the mixed solution method and calculated as previously described.[19]

The results presented in Table 2 show that the tetrafluoroborate selective membrane electrode potentials are affected by the presence of perchlorate anions. If the BF_4^--selective membrane electrodes are exposed, even for a short period of time to perchlorate solution, these will displace BF_4^- ions from the ion-pair complex and become selective to ClO_4^-.

The data presented show good selectivity of the X-selective membrane ($X^- = BF_4^-$, ClO_4^-) over a number of potentially interfering ionic species.

Analytical applications

The electrodes proved useful for the assay of some compounds of pharmaceutical interest. The BF_4^--selective membrane electrodes were used for the potentiometric titration of some pharmacologically active compounds, such as 2,4,6-trimethylpyrylium tetrafluoroborate, colidinium tetrafluoroborate, 2,4,6-trimethylpyrydinium-*N*-(2-acetoxiethyl)perchlorate and

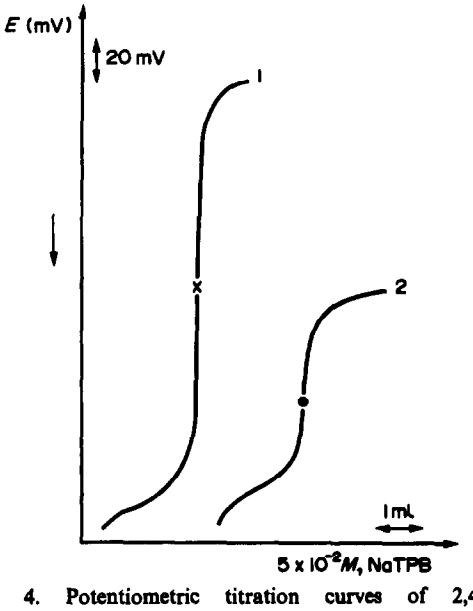

Fig. 4. Potentiometric titration curves of 2,4,6-trimethylpyrylium tetrafluoroborate using BF_4^--selective electrodes. 1—liquid membrane electrode (Electrode A); 2—PVC membrane electrode (Electrode B).

Table 3. Potentiometric determination of some pharmaceutical compounds used X^--selective membrane electrodes ($X^- = BF_4^-$ and ClO_4^-)

Pharmaceutical compound	Formula	Found (%) (standard deviation for Liquid-membrane electrode	Found (%) (standard deviation for PVC matrix membrane electrode
Potassium perchlorate	Drug-substance	—	98.4 (SD = 1.4; $n = 5$
	Tablets 0.05 g $KClO_4$	—	99.6 (SD = 1.3; $n = 5$
2,4,6-Trimethylpyrylium tetrafluoroborate		100.4 (SD = 1.1; $n = 5$)	100.8 (SD − 2.0; $n = 5$)
Colidinium tetrafluoroborate		103.1 (SD = 3.8; $n = 5$)	98.5 (SD = 1.0; $n = 3$)
2,4,6-Trimethylpyrydinium N(2-acetoxiethyl) perchlorate		98.6 (SD = 2.3; $n = 5$)	98.1 (SD = 1.9; $n = 3$)
2,4,6-Trimethypyrydinium N(stearylamino) tetrafluoroborate		97.6 (SD = 2.5; $n = 3$)	98.4 (SD = 1.5; $n = 3$)

2,4,6-trimethylpyrydinium-*N*(stearylamino) tetrafluoroborate, respectively, using NaTPB as titrant. The reaction is based on the property of tetraphenylborate ion to form more insoluble products with the above mentioned organic cations, the potential jumps around the equivalence point are high enough for accurate evaluation of the equivalence volumes. Two potentiometric titration curves for the quantitative determination of 2,4,6-trimethylpyrylium tetrafluoroborate are presented in Fig. 4 (curve 2 is displaced for clarity).

The ClO_4^--selective membrane electrode was used for the quantitative determination of potassium perchlorate both as raw material for drug formulations and tablets.

The Table 3 presents the results obtained by using X^--selective membrane electrodes for the analytical determination of the mentioned products of pharmaceutical interest.

CONCLUSIONS

The X^--selective membrane electrodes prepared and characterized present a linear response in the range 10^{-2}–$10^{-5}M$ with a near-Nernstian response slope and good reproducibility. They can be applied with good results for the potentiometric determination of some pharmaceutical compounds and formulations.

(*Received* 30 *March* 1990. *Revised* 9 *December* 1991. *Accepted* 18 *December* 1991)

Summary—A titrimetric method for determination of sulfide and of sulphur in steels with chloranilic acid by biamperometric and automatic potentiometric end-point detection is described. The construction of the sensor for potentiometric indication is also described. The results obtained agree with those of the iodine–thiosulfate method and with the certified values for the steels.

Determination of sulfide in various natural and manufactured materials is important. As the critical quantities of sulfide are generally small (trace level), sufficiently sensitive methods must be used. Classical titrimetry uses iodine or potassium hexacyanoferrate(III) as the titrant.[1] The Methylene Blue method[2] is most often used for spectrophotometric determination.

The instrumental techniques for rapid determination of sulfur in steels and alloys involve oxidation to sulfur dioxide in a current of oxygen and determination of this product by gas chromatography, spectrophotometry, coulometry or conductimetry.[3]

Sulfide has also been determined by an automatic potentiometric procedure[4] and in MnS and FeS inclusions in steels by absorbing in alkali the hydrogen sulfide evolved on acidification, followed by voltammetric analysis of the solution.[5]

Recently, potentiometric titration, with ion-selective indicator electrodes, has been used for sulfur determination in air and steel samples[6] and in sulfur, polysulfide and thiosulfate mixtures.[7]

Chloranilic acid (2,5-dichloro-3,6-dihydroxy-*p*-benzoquinone) forms sparingly soluble complexes with metal ions such as Pb(II), Bi(III), Hg(II) and Hg(I), and has been used in precipitation titrations with biamperometric indication for the determination of these ions and for phosphate determination.[8–12]

This paper describes an indirect method for determining sulfide in sulfide solutions and sulfur in steels. It is based on the classical evolution procedure,[13] with absorption of hydrogen sulfide in excess of standard hydroxoplumbate(II) solution, the surplus Pb(II) being determined by titration with chloranilic acid. Biamperometric and automatic potentiometric indication is used for end-point detection, the first giving high accuracy, and the second considerably shortening the determination time. The detector is a solid-state ion-selective electrode, constructed by impregnating graphite with lead chloranilate by a procedure similar to that described by Hassan and Habib.[14]

EXPERIMENTAL

Apparatus

Biamperometric measurements were made by use of a conventional polarization source, with a digital voltmeter and microammeter. A potential difference of 1.00 V was applied across the electrodes. A twin Metrohm (60308000) electrode was used as current sensor. The titrant was added from a 10-ml Metrohm E 485 buret. The sample solution was stirred with a Metrohm G 1514-220 magnetic stirrer.

The potentiometric measurements were made with an Orion ionalyzer Model 701 and Orion Automatic Titrator (Automatic System 960), by using the graphite–lead chloranilate electrode in conjunction with a double-junction reference electrode (Orion 90-02). When the Orion Ionalyzer was used, the reagent was added with a Metrohm EA485 multiburet.

In the determination of sulfur in steels, the basic equipment for the evolution method[13] was used, modified by replacing the absorption flask with a long glass tube (400 mm × 7 mm) with delivery tube penetrating far enough into the absorption solution to avoid loss of hydrogen sulfide (Fig. 1).

Reagents

All reagents used were of analytical grade. Doubly distilled water was used throughout.

No differences in behavior were found between commercially available chloranilic acid and a product purified by recrystallization or sublimation.[15,16]

Chloranilic acid solutions in distilled water were standardized by amperometric titration with standard lead(II) solution.[17] The stock solution was stored in a darkened container at 1–5°. Periodic checks showed that the solutions could be preserved in this way for a long period of time.

Lead chloranilate was prepared by modification of a method for the preparation of barium chloranilate,[18] 1000 ml of 0.1*M* lead nitrate were placed in a 2000-ml beaker and 0.01*M* chloranilic acid was added from a separating funnel at a rate of 40–60 drops/min, with continual magnetic stirring. The precipitate was left in contact with the supernatant liquid overnight, then centrifuged and washed with water until the purple-red color of the chloranilic acid had disappeared. The product was dried in a vacuum oven at 120° for 12 hr.

Preparation of the lead chloranilate electrode

Two spectrographic graphite rods (30 mm × 50 mm) were treated as follows: (*a*) a suspension of lead chloranilate in glacial acetic acid was drawn into one of the rods by suction (Electrode I). (*b*) 0.01*M* lead nitrate solution was first drawn into the other rod by suction, followed by 0.01*M* chloranilic acid to form a precipitate inside the pores and channels of the graphite. Both rods were then dried in a vacuum oven at 120° overnight.

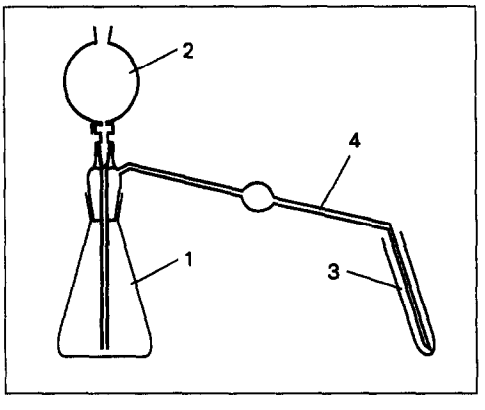

Fig. 1. Apparatus for determination of sulfur by a modification of the evolution method. (1) 250-ml Erlenmeyer flask; (2) 100-ml separatory funnel; (3) 50-ml collector tube; (4) delivery tube.

The rods were inserted into glass tubes, with 20 mm of the rod exposed to constitute the active surface. The ends of the rods within the tubes were connected to a copper wire (1 mm o.d.) for external contact. The surface between the glass and the graphite was insulated with a waterproof material (SILOC®).

Procedures

Determination of sulfide. Fifty milliliters of ~0.001*M* sodium sulfide solution were added to a mixture of 10 ml of 0.01*M* lead nitrate treated with enough 2*M* sodium hydroxide to turn all the Pb(II) into hydroxoplumbate(II) (pH 13), and the mixture was stirred magnetically for 15 min. The precipitate was filtered off on a medium texture paper, and washed 3 or 4 times with small quantities of 0.3*M* sodium hydroxide. The filtrate and washings were evaporated to ~30 ml, cooled, adjusted to 0.1*M* acidity with 4*M* nitric acid, and titrated with 0.01*M* chloranilic acid.

Since aqueous sulfide solutions are unstable, all the samples were treated with the hydroxoplumbate(II) solution at the same time.

Sulfur in steels. A sample (between 1 and 2.5 g in weight, depending on the sulfur content) was placed in the Erlenmeyer flask and 100 ml of 6*M* hydrochloric acid (3*M* acid for the higher sample weights) were added from a separating funnel. The absorption tube was loaded with 5–10 ml (depending on the amount of sulfur) of 0.01*M* lead nitrate, distilled water, and enough 2*M* sodium hydroxide to give pH 13 (total volume ~30 ml).

The Erlenmeyer flask was heated gently and the hydrogen sulfide evolved was absorbed in the hydroxoplumbate(II) solution. When dissolution of the steel was complete, the delivery tube was disconnected and rinsed with 2 or 3 small volumes of 0.3*M* sodium hydroxide. The sulphide was then titrated as described above.

RESULTS AND DISCUSSION

Lead chloranilate electrodes

Potential drift and response time. It was observed that in manual titrations the electrode

attained a stable potential in 5–10 min. Reagents were added every 30 sec throughout the titration, except near the end-point, where additions were made every 2 min since stable potential values were attained in this time. The total time for each titration was 20 min. The behavior of the electrode in a standard titration is shown in Fig. 2. Both electrodes tested gave a large potential break at the end-point, but electrode I gave the larger and therefore was used for further tests.

Effect of acidity. The optimum acidity range was 0.01*M* nitric acid, in agreement with that observed in titrations with biamperometric indication.[8] At acid concentrations higher than 0.1*M* the solubility of lead chloranilate increases considerably, but when the acid concentration is lower than 0.01*M* the electrochemical reaction of chloranilate is inhibited by the poor buffer capacity at the electrode–solution interface.[19] The sensitivity of the electrode to changes in acid concentration is shown in Fig. 3.

Range of determinable concentrations. The sensor gave a good response in the range from $3 \times 10^{-3}M$ to $1 \times 10^{-4}M$ lead (II). For concentrations lower than $1 \times 10^{-4}M$ the end-point potential break is much reduced, and the solubility of chloranilic acid becomes the limiting factor for determining lead concentrations higher than $3 \times 10^{-3}M$.

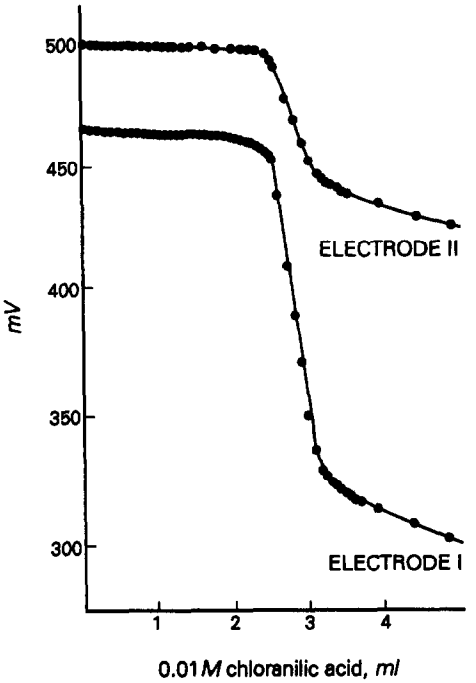

Fig. 2. Response of electrodes I and II in the titration of 25 ml of ~0.0010*M* lead(II) with chloranilic acid at pH = 1.0.

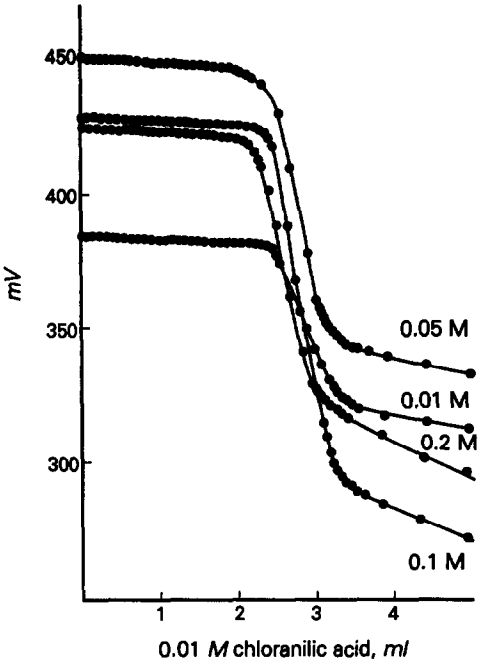

Fig. 3. Titrations of 25 ml of ~0.0010*M* lead(II) with chloranilic acid at various nitric acid concentrations, with use of electrode I.

Accuracy and precision. Twelve titrations of ~0.001*M* lead nitrate in 0.1*M* nitric acid with 0.01*M* chloranilic acid gave a mean of 0.207 g/l. lead, with a standard deviation of 0.0007 g/l. The relative error was estimated by comparison of the values obtained by potentiometric indication with those corresponding to the average of three titrations performed with biamperometric indication, and was about 2%.

The behavior of the sensor in automatic titrations was checked with nine repetitive analyses of another lead nitrate solution; the mean found was 0.223 g/l.lead, standard deviation 0.008 g/l. Titration with biamperometric indication gave 0.219 g/l. (mean of three titrations).

Analysis of sulfide solutions. Table 1 shows the results of six replicate biamperometric and automatic potentiometric titrations of 25 ml of nominally 0.030 g/l. sodium sulfide solution with 0.01*M* chloranilic acid and of titrations by the iodine–thiosulfate method recommended by Budd and Bewick[2] for standardization of sodium sulfide solutions in the Methylene Blue method.

The displacement reaction between mercury chloranilate and sulfide, used by Hoffmann for absorptiometric sulfide determination,[20] were found not to be suitable for titrations.

The pH of the Pb(II) solution was chosen as ~13 because at a pH lower than 7 sulfide was

only partially retained, and between pH 7 and 12.5 lead hydroxide is precipitated.

Steel analyses

Three certified samples from the "Instituto de Pesquisas Tecnologicas" (IPT), San Pablo, Brazil: IPT No. 43 (AISI 1132), IPT No. 14A (AISI 1040) and IPT No. 37 grey iron were analyzed for sulfur content. The results are shown in Table 2.

It was verified that the optimum weight of sample for steels containing about 0.1% of sulfur was about 1 g. With higher weights of sample (*e.g.*, 2.5 g), the evolution of hydrogen sulfide was very fast, causing considerable losses. Also, prolonged heating was necessary to complete the dissolution, and some hydrochloric acid distilled into the absorption tube. Lower weights of sample allowed more dilute acid (3*M*) to be used, which considerably reduced this risk.

When the sulfur content is lower, as in the IPT standards 14A and 37, it is more convenient to use higher weights of sample (2–2.5 g) in order to decrease the amount of lead chloranilate precipitate, which disturbs the end-point location by either detection mode.

The procedure proposed shows several advantages over the classical evolution method. (*a*) It is more exact and precise since it diminishes the risk of hydrochloric acid distilling into the absorption solution (because it requires a lower weight of sample, which also reduces the dissolution time). (*b*) The electrochemical behavior of chloranilic acid at $E = 1.00$ V allows amperometric curves to be obtained with a great number of points in both branches (Fig. 4). This means that the determination of the end-point can be made more accurate by applying the least-squares method. (*c*) When automatic potentiometric titration is used, the time required for the determination is mainly that consumed in the dissolution of the sample and conditioning of the solution for the titration. (*d*) The potentiometric sensor developed is strong, very low in cost, easily manufactured, long-lasting and very easily reactivated. Its optimum acidity range allows it to be used in solutions where the use of other sensors, such as the Orion 94-82-00 lead electrode,[21] is impossible.

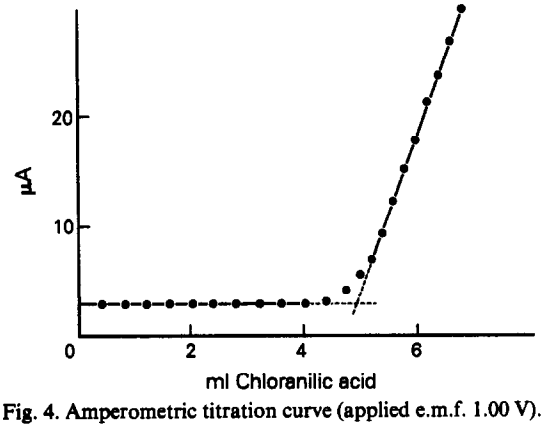

Fig. 4. Amperometric titration curve (applied e.m.f. 1.00 V).

ION-EXCHANGER PHASE PHOTOACOUSTIC SPECTROMETRY FOR TRACE ANALYSIS OF METAL IONS

SUNAO YAMADA and KAZUHISA YOSHIMURA

Chemistry Laboratory, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810, Japan

(*Received* 1 *July* 1991. *Revised* 16 *December* 1991. *Accepted* 17 *December* 1991)

Summary—Laser-induced photoacoustic spectroscopy has been applied to the determination of chromate, uranyl, and Cr(VI) and Fe(II) ions as coloured complexes that were sorbed on ion-exchanger beads. A simple photoacoustic cell has been constructed; it consisted of a fused silica glass tube and an attached cylindrical piezoelectric transducer. A pulsed laser light at 532 or 355 nm irradiated the ion-exchanger beads that had been collected in the glass tube of the cell. Since a sample material was effectively concentrated on the ion exchanger, the sensitivity was much higher than that in the corresponding photoacoustic spectrometry in a solution state. The lowest detection limit was 0.21 ng/ml Fe for Fe(II)–DPPS (4,7-diphenyl-1,10-phenanthrolinedisulphonate) complex sorbed on QAE-Sephadex gel. Analytical characteristics of the present method are described.

Although photoacoustic spectroscopy (PAS) is a well characterized quantitative spectroscopic technique for homogeneous samples, its real utility must appear in applications to heterogeneous samples such as opaque solids and powders. The use of lasers as excitation light sources has greatly improved the sensitivity[1] and expanded the applicability such as for the study of a single microparticle,[2,3] because of their high photon flux, monochromaticity, and excellent spatial and temporal coherence.

Ion-exchanger phase absorptiometry[4] is very sensitive and practical for the determination of trace amounts of various kinds of inorganic analytes;[5,6] this technique is based on the direct measurement of light absorption by metal complexes pre-concentrated on an ion exchanger. Since PAS is based on light absorption, it must be possible to detect such metal complexes sorbed on an ion exchanger. In fact, PAS has been recently applied to the determination of some metal ions complexed on modified silica gel[7] and phosphate as molybdenum blue adsorbed on anion-exchanger beads,[8] but the sensitivities were at most μg/ml levels and analytical procedures seemed to be somewhat complicated and time-consuming.

From these viewpoints, we have first applied laser-induced PAS (LIPAS) for the determination of some metal ion species sorbed on ion exchangers. A simple photoacoustic cell with a fused silica glass tube and an attached cylindrical piezoelectric transducer was constructed, and a pulsed laser light was used. Basic characteristics of the present system and its analytical applications are presented.

EXPERIMENTAL

Apparatus

The block diagram of the experimental apparatus is shown in Fig. 1. A Nd:YAG laser (Continuum YG660B-10S; pulse duration, 4–6 nsec; repetition rate, 5 Hz) was used as an excitation light source; a 532-nm (second harmonic) or 355-nm (third harmonic) laser light passed through an aperture (4 mm in diameter) and irradiated the cell. Pulse-to-pulse intensity fluctuations of the 532-nm and the 355-nm light are nominally 3.5 and 4%, respectively. The laser pulse energy was varied with the use of appropriate neutral density filters (Sigma Koki MANY-25-5—50) and glass filters. It was monitored and measured with a photodiode (Hamamatsu S1722 or S1336) and an oscilloscope (Iwatsu SS-6122); the photodiode output was calibrated with a calorimeter (Photon Control Model 25V-Vis). The resultant pulsed photoacoustic signal was amplified with an amplifier (NF P61, 100 kHz, gain 100) and then averaged over 16 laser pulses with a digital storage oscilloscope (Iwatsu DS-6411).

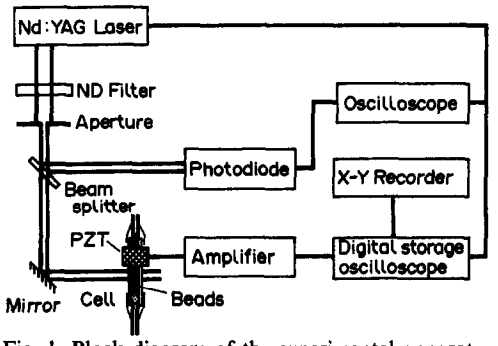

Fig. 1. Block diagram of the experimental apparatus.

Its output was recorded with an X–Y recorder (Graphtec WX1100).

Photoacoustic cell

Figure 2(a) shows the photoacoustic cell compartment. The pulsed photoacoustic signal was detected with a cylindrical piezoelectric transducer (PZT) (Tokin NPM, NR; 7 mm o.d., 5 mm i.d., 7 mm in length); it was attached to a fused silica glass tube (4 mm o.d., 1.5 mm i.d., 38 mm in length) via a brass cylinder. A silver paste (Dojindo) was used to fix the brass cylinder with the glass tube and to electrically grind the inside of the PZT through the brass cylinder and an aluminium body which provided electrical shielding. The outside terminal of the PZT detected the signal. A washer was used to fit the PZT tightly in the aluminium body. A poly(tetrafluoroethylene) (PTFE) sheet (0.1 mm in thickness) was inserted between the bottom of the PZT and the washer for electrical insulation [Fig. 2(a)]. A PTFE tube (2 mm o.d., 1 mm i.d.) was connected in each end of the glass tube with a thermally shrinkable PTFE tube. A polypropylene filter tip (1.5 mm in diameter, 3 mm in length) was placed at the bottom of the glass tube. The glass tube and PTFE tubes were also fixed inside the aluminium body with an epoxy adhesive. Then, the cell was attached on a micrometer-driven translation stage in order to adjust the distance between the laser beam and the PZT.

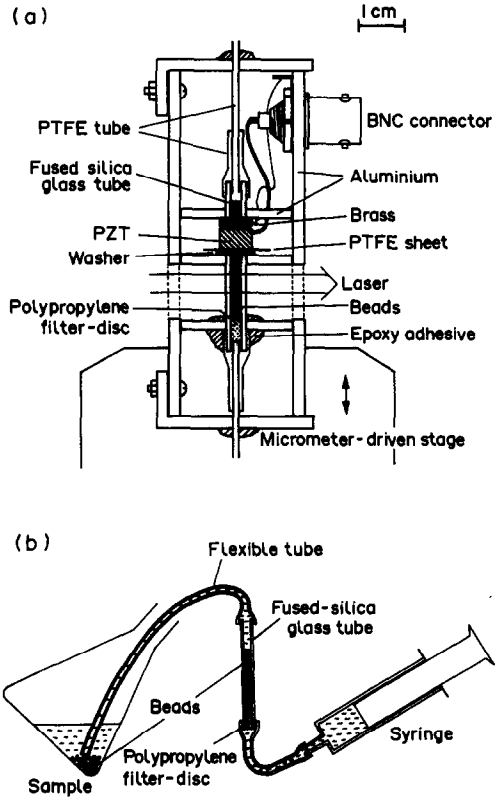

Fig. 2. Schematic diagram of the photoacoustic cell (a) and sample introduction (b): PZT, piezoelectric transducer.

Chemicals

All chemicals used were of analytical grade. Water, purified with a Milli-Q SP reagent water system (Millipore), was used for the dilution of samples and reagents.

Ion exchangers of analytical grade were purchased from Bio-Rad, and crosslinked dextran-type ion exchangers from Pharmacia.

Sample preparation

For chromate (CrO_4^{2-}), to a 20-ml solution containing 0.4–40 μg of chromium (as chromate) was added 0.104 ml of QAE-Sephadex A-25 gel (in the chloride form).

For the chromium(VI)–1,5-diphenylcarbazide [Cr(VI)–DPC] system, to a 20-ml solution containing 0.04–2 μg of chromium (as chromate) were added 1 ml of 0.5*M* sulphuric acid, 1 ml of 0.01% (w/v) acetone solution of DPC (Kishida Chemicals), and then 0.104 ml of AG 50W-X2 (100–200 mesh) in the hydrogen form.

For the iron(II)–1,10-phenanthroline [Fe(II)-PHEN] complex, to a 20- ml solution containing 0.1—5 μg of iron were added 2 ml of a solution containing hydroxylammonium chloride [2.5% (w/v)], acetate (0.2*M*, pH 4.8) and PHEN [0.1% (w/v), Wako Pure Chemicals], and then 0.104 ml of AG 50W-X2 or SP-Sephadex C-25 (40-120 μm, in the hydrogen form).

For iron(II)–4,7-diphenyl-1,10-phenanthroline–disulphonate [Fe(II)-DPPS] complex, to a 20-ml solution containing 0.05–5 μg of iron were added 2 ml of a solution containing hydroxylammonium chloride [2.5% (w/v)], acetate (0.2 *M*, pH 4.8) and DPPS [0.1% (w/v), Dojindo], and then 0.104 ml of AG 1-X2

(100–200 mesh, in the chloride form) or QAE-Sephadex A-25.

For uranyl (UO_2^{2+}), to a 20-ml solution containing 10–200 μg of uranium (as uranyl chloride) was added 0.104 ml of SP-Sephadex C-25.

Procedure for signal measurements

The mixture of a sample solution and an ion exchanger was stirred for 20 min in a flask. In order to evaluate the amount (height) of the collected beads in the glass tube of the cell, we have prepared another fused-silica glass tube (1.5 mm i.d., 60 mm in length); its one end had a polypropylene filter tip, and a disposable syringe was connected to this end via a flexible tube, while the other end had a flexible tube to collect the beads. The beads were once collected in this glass tube using the syringe, and the height of the collected beads was measured. Then, the beads were transferred into the glass tube of the cell by connecting the flexible tube with the PTFE tube of the cell [Fig. 2(b)]. The cell was filled with water in all measurements.

In the presence of air bubbles in the cell, both intensity and waveform of the signal varied drastically and irregularly, probably because of complicated travel routes of sound; in other words, the presence or absence of air bubbles could be confirmed from signal waveform. In the absence of air bubbles, the signal was stable and reproducible.

For analytical studies, the height of the collected beads was 20 mm, and the distance (L) between the center of the laser beam and that of the PZT was maintained constant at 10.5 mm. One of the largest peak-to-peak heights (Δh) of positive and negative excursions that were observed in the $\sim$19–$\sim$23 μsec region of the photoacoustic signal waveform was used for calibration (*vide infra*).

RESULTS AND DISCUSSION

Characterization of the cell

Shida *et al.*[8] applied PAS to the determination of phosphate as molybdenum blue species sorbed on an anion exchanger. They measured the photoacoustic signal of 10 mg of beads that were placed in a PAS cell for each sample. However, there seems to be considerable room to improve more conveniently and sensitively for practical use of ion-exchanger phase spectrometry with photoacoustic detection.

In ion-exchanger phase absorptiometry, the volume ratio, V/v, defined as the ratio of the volume of the sample solution (V) to that of the ion exchanger (v), profoundly affects the detection sensitivity, since the sample is effectively concentrated on ion-exchanger beads;[4,5] the larger the volume ratio, the higher the sensitivity. Therefore, the cell volume should be as small as possible. In addition, it is desirable that the ion-exchanger beads can be collected easily in the cell and removed easily from it. From these viewpoints, we have designed the cell as shown in Fig. 2(a).

In order to investigate the characteristics of the photoacoustic cell, Fe(II)–DPPS complex sorbed on QAE-Sephadex gel was used as a test sample. The pulsed photoacoustic signal is obtained at various distances of the laser beam from the PZT along the glass tube, as shown in Fig. 3; the beads were collected for about 20 mm in height (*vide infra*). Similar photoacoustic cells consisting of glass tubes and PZTs have been

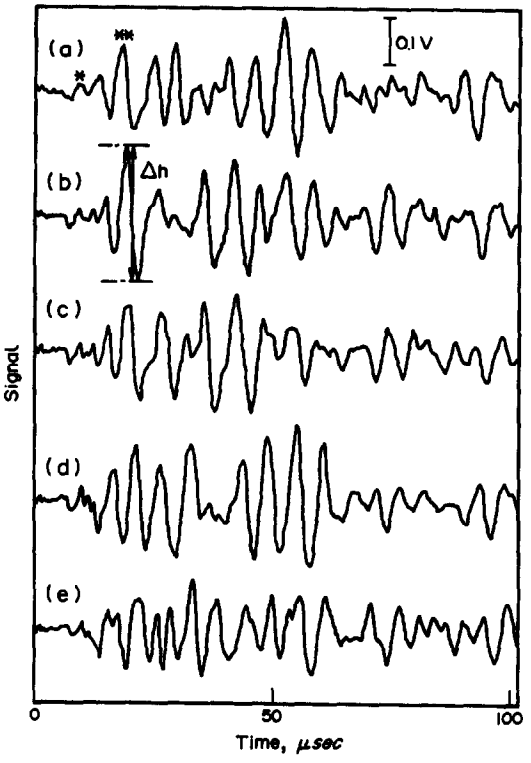

Fig. 3. Typical waveforms of the photoacoustic signals for Fe(II)–DPPS complex, when the height of the beads was about 20 mm. Distance L between the center of the laser beam and that of the PZT: (a) 8.5; (b) 10.5; (c) 11.5; (d) 13.5; (e) 15.5 mm (see Fig. 4). Sample solution: 20 ml, 0.2 μg/ml Fe; ion exchanger: QAE-Sephadex A-25, 0.104 ml. The first and the third positive excursions are marked by * and ** in the waveform (a). The peak-to-peak height of the large excursion shown by Δh in the waveform (b) was used for evaluating the signal intensity. The laser pulse energy at 532 nm is 5.5 mJ.

reported.[9-11] Rowlen *et al.*[11] carefully investigated and analysed the waveform of the photoacoustic signal, with the cell consisting of a fused silica glass tube (6 mm o.d., 1 mm i.d., 19.3 or 26.7 cm in length) and a cylindrical PZT attached on it; the signal was very complicated due to electrical and mechanical ringing, damping, acoustic reflections in the cell, and so on. This must also be the case in this study. However, detailed assignments of the signal waveform is not the aim in this study.

Although the signal waveform was affected by the distance L, the amplitude of the largest excursions did not differ substantially (Figs. 3 and 4). The first weak positive excursion [marked by * in the waveform (a)] was observed even in the absence of the beads and its delay time from the laser flash did not change; it was not observed when the laser did not irradiate the cell. Thus, it may arise from some mechanical vibration of the cell due to laser irradiation. On the other hand, the delay time of the third positive excursion [marked by ** in the waveform (a)] clearly changed with L; the relationship between L and the delay time was linear with a slope of 1.45×10^3 m/sec. The corresponding value for Fe(II)–DPPS complex in 95% ethanol solution was 1.11×10^3 m/sec; it agreed well with the literature value of 1.24×10^3 m/sec for the velocity of sound in ethanol at 18°.[12] The velocity of sound in distilled water at 18° is 1.52×10^3 m/sec.[12] These facts strongly suggest that the third positive excursion is due to the sound which is produced from the sample and arrives at the PZT via transport through the solvent, water.

A set (positive and negative) of large excursions was observed around 20 μsec after the laser flash when the distance L was about 10 mm, as was seen in Fig. 3(b) (L = 10.5 mm). The peak-to-peak height, Δh shown in Fig. 3(b), was used for evaluating the intensity of the photoacoustic signal.

Figure 4 shows the relationship between the packed amount (height) of the beads in the tube of the cell and the signal intensity Δh. The signal waveform was insensitive but the signal intensity was sensitive to the packed amount of beads. The Δh value was large when the height of the beads lay between the laser irradiation position and the PZT; it became ~20% smaller when the beads were collected over the position of the PZT, but it was roughly constant even when the beads were collected further. For practical convenience, therefore, all analytical measurements were carried out with the height of the collected beads at about 20 mm, slightly above the position of the PZT.

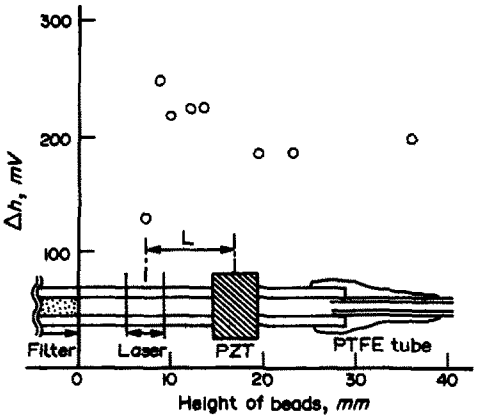

Fig. 4. Effect of the packed amount (height) of beads in the glass tube of the cell on Δh for Fe(II)–PHEN complex. Sample solution: 25 ml, 0.2 μg/ml Fe; ion exchanger: QAE-Sephadex A-25, 0.104 ml. L: 10 mm. The laser pulse energy at 532 nm is 2.5 mJ, and other conditions are identical to those of Fig. 3. The abscissa shows the height of the beads collected in the tube from the top of the filter. Positions of the laser beam and the PZT are shown schematically, and the distance L is also shown.

Sensitivity and detection limit

For low light absorption conditions where the absorbed power is small, the intensity of photoacoustic signal, I_{PAS}, can be approximately expressed as:[13]

$$I_{PAS} = kI_0\epsilon Cl.\beta, \quad (1)$$

where I_0 is the excitation intensity, ϵ the absorptivity of a sample, l. the light path, C the sample concentration, β a measure of the conversion efficiency of absorbed power to heat by radiationless processes, and k an instrumental proportionality constant. In the measurement of the photoacoustic signal for the ion-exchanger phase that is prepared with v ml of ion-exchanger beads and V ml of solution containing C_0 M of a sample, equation (1) can be rewritten as:

$$I_{PAS} = kI_0C_0\bar{\epsilon}\bar{l}\bar{\beta}(V/v)\{1 + V/(vD)\}^{-1}, \quad (2)$$

where D is the distribution ratio of the sample between the ion exchanger and the solution, and $\bar{\epsilon}$, $\bar{l}$. and $\bar{\beta}$ stand for the corresponding terms for the ion-exchanger phase.[14] Under the condition of $V \ll vD$, equation (2) can be simplified to:

$$I_{PAS} = kI_0C_0(V/v)\bar{\epsilon}\bar{l}.\bar{\beta}. \quad (3)$$

In this study, the signal intensity was linear to the laser pulse energy (~0.5–~5 mJ). Thus, the signal obtained under the identical condition should be proportional to C_0 and the volume ratio V/v.

For each system examined, a calibration graph was obtained by plotting the Δh value versus the concentration of the analyte, giving a straight line at least within the concentration range studied. The sensitivity, defined as the concentration giving 100 mV of Δh, and the detection limit, defined as the concentration giving the photoacoustic signal equal to three times the standard deviation of the blank signal, were summarized in Table 1.

The sensitivities of Fe(II)–PHEN and Fe(II)–DPPS for the ion-exchanger phase were compared with those for the solution state (Table 1). The D values for these species exceeded 10^4. As the sample species in 20 ml of a solution was concentrated on 0.104 ml of the ion exchanger, the volume ratio was 190. Thus, the sensitivity in the ion-exchanger phase can be expected to be 190 times greater than that in the solution state. Table 1 shows that the expected sensitivities could be obtained by using ion exchangers for both complexes.

For the Fe(II)–PHEN complex, variation of the volume of the sample solution from 10 to 200 ml resulted in a proportional increase in the signal. Thus, much higher sensitivities will be achieved by employing larger volumes of sample solution, that is, larger volume ratios.

The molar absorptivity for each sample species at the excitation wavelength is also shown in Table 1. The larger the molar absorptivity, the higher the sensitivity, as can be expected from equation (3).

The polystyrene-type ion exchanger has a larger D value than the dextran-type one; but the former has considerable absorptivity at 355 nm and causes a high background in the absorptiometry.[15] It was also the case in this study. In addition, laser irradiation at 532 nm caused some unexpected cracking in the resin beads. The dextran-type ion exchanger, on the other hand, showed no such problems at 532 nm.

In the previous ion-exchanger phase absorptiometry where $V/v = 1200$, the detection limits were 0.11 ng/ml Cr for the Cr(VI)–DPC system[16] and 0.9 ng/ml of Fe for Fe(II)–PHEN complex.[17] In the present study where the V/v value was 190, the corresponding detection limits with AG 50W-X2 ion exchanger were 0.58 and 4.7 ng/ml, respectively. Thus, the present method is as sensitive as the absorptiometry.

In the Cr(VI)–DPC system, the Cr(III)–diphenylcarbazone complex mainly forms by redox reaction and this complex is sorbed on the cation-exchanger beads. As shown in Fig. 5, the photoacoustic signal of this complex sorbed on AG 50W-X2 decreased with proceeding laser irradiation, indicating decomposition by light absorption. In the present method, however, the signal could be obtained very quickly (within 3 sec), and the signal obtained by the first run was linear with respect to the concentration of Cr(VI). Thus, the present method can also be useful for such an unstable analyte.

In this paper, we have demonstrated that LIPAS was very useful for highly sensitive

Table 1. Sensitivity and detection limit*

ion–exchanger phase spectrometry; direct measurement of the ion exchanger by LIPAS enabled detection sensitivity at ng/ml levels or lower. Application of the present system to flow analysis is quite attractive and will appears in our companion paper.[18]

APPLICATION OF ION-EXCHANGER PHASE PHOTOACOUSTIC SPECTROSCOPY TO FLOW ANALYSIS OF TRACE AMOUNTS OF IRON IN WATER

KAZUHISA YOSHIMURA and SUNAO YAMADA

Chemistry Laboratory, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810, Japan

(*Received* 1 *July* 1991. *Revised* 16 *December* 1991. *Accepted* 17 *December* 1991)

Summary—Ion-exchanger phase photoacoustic spectroscopy has been applied to the flow analysis of trace amounts of iron in water. The reaction product of iron(II) with 4,7-diphenyl-1,10-phenanthroline-disulphonate, introduced into a carrier solution stream in the flow system, was concentrated on a small amount of QAE-Sephadex gel settled in a fused silica glass tube (1.5 mm i.d.) of a photoacoustic cell. The photoacoustic signal produced by pulsed laser irradiation of the gel beads at 532 nm was detected by a cylindrical piezoelectric transducer which was attached outside the glass tube. When 3.7 ml of a sample solution was introduced into the flow system, the sensitivity of this method was 590 times higher than that of the corresponding solution photoacoustic spectrometry and the detection limit of iron was 0.33 ng/ml. Because the coloured complex was desorbed from the cell with a desorbing agent solution, the present method could afford repeated analyses of natural water samples containing iron at ng/ml levels without any preconcentration procedures.

Photoacoustic spectroscopy (PAS) is one of the most useful spectroscopic techniques for quantitative analysis in a condensed phase. Laser-induced PAS (LIPAS) has been especially sensitive and useful for the detection in a small volume, because of high photon flux and excellent spatial coherence of the laser light. Thus, LIPAS has been employed as a detection method for liquid chromatography.[1–5]

On the other hand, ion-exchanger phase absorptiometry, a method based on the direct measurement of the absorption of light by metal complexes pre-concentrated on an ion-exchanger, is sensitive and practical for the determination of inorganic analytes in water,[6,7] and has been applied to flow analysis.[8,9] In this flow analysis method, a target element is exclusively concentrated in the ion-exchanger phase as coloured complex during absorptiometric measurement. Thus, it is not affected by the sample-zone colour dispersion (the dilution effect), which is unavoidable in conventional flow injection analysis. In addition, higher sensitivity can easily be attained by using a larger amount of water sample.

PAS (LIPAS) is also effective for the study of heterogeneous and/or opaque samples. Recently, PAS has been applied to the determination of metal ions complexed on modified silica gel[10] and of phosphate as molybdenum blue sorbed on anion-exchanger beads,[11] but the sensitivities were at most μg/ml levels and analytical procedures were somewhat complicated and time-consuming. As has been shown in our companion paper,[12] we have successfully applied LIPAS to the determination of some metal ions as their coloured complexes sorbed on ion-exchanger beads; a typical detection limit was 0.58 ng/ml of chromium(VI).

In this paper, we have extended the LIPAS measurements in ion-exchanger phase to flow analysis of iron in water. 4,7-Diphenyl-1,10-phenanthrolinedisulphonate (DPPS) was used as a colour forming agent.[13]

EXPERIMENTAL

Chemicals

All chemicals used were of analytical grade. Water was purified with a Milli-Q SP reagent water system (Millipore) and was used for the dilution of samples and reagents.

The standard iron(III) solution (1000 μg/ml) was supplied from Wako Pure Chemicals.

A buffer solution (pH 5.3) was prepared by dissolving 15.4 g of ammonium acetate with water, mixing it with 12.6 ml of acetic acid, and

then diluting the mixture with water to the total volume of 100 ml.

A hydroxylamine solution was prepared by dissolving 10 g of hydroxylammonium chloride with water, adjusting pH of the solution to 4.8 with ammonia, and diluting it to 100 ml with water. These two solutions were filtered through a 0.45-μm membrane filter-paper (Millipore).

A colouring reagent solution was prepared by dissolving 0.1 g of sodium salt of DPPS, supplied by Dojindo Laboratories, and 2.3 g of ammonium acetate in a mixture of 0.63 ml of acetic acid and 10 ml of the hydroxylamine solution, and then diluting it to 100 ml with water.

A carrier solution was prepared by diluting the mixture of 10 ml of the acetate buffer and 10 ml of the hydroxylamine solution to one litre with water and dissolving 1 mg of DPPS in the solution.

A desorbing agent solution was prepared by dissolving 80 g of ammonium nitrate into 250 ml of water, filtering the solution through a 0.45-μm membrane filter paper, and mixing the solution with 250 ml of ethyl alcohol. Dissolved gases were expelled from the solution for 3 hr with an ultrasonic bath.

QAE-Sephadex A-25, crosslinked dextran-type ion-exchanger gel, was purchased from Pharmacia.

Apparatus

The experimental apparatus is almost identical to that reported in our companion paper.[12] One of intense excursions in the photoacoustic signal waveform could be simultaneously integrated with a boxcar integrator (NF BX530-A) for evaluating its intensity. It was recorded on a strip-chart recorder (RDK R-02) set at 5 V in full scale.

The photoacoustic cell used for the batch colour development method was also employed for the present method. The QAE-Sephadex gel beads were settled in a fused silica glass tube (4 mm o.d., 1.5 mm i.d., 38 mm in length), with its height 5 mm from the top of the polypropylene filter tip. The upper and large parts of the beads were irradiated with the laser beam (4 mm in diameter) [Fig. 1(a)], since the analyte was preferentially concentrated from the top of the packed beads.

Flow diagram

Figure 1(b) shows the schematic diagram of the flow analysis system. The carrier solution was pumped by a Sanuki pump, Model DMX-2000. A sample solution (3.7 ml) and a desorbing agent (1 ml of the alcoholic solution of ammonium acetate) were introduced into the flow system by means of respective six-way valves with PTFE [poly(tetrafluoroethylene)] tube loops. All tubings were made of PTFE (2 mm o.d., 1 mm i.d.). The flow rate was maintained constant at 1.3 ml/min. The solution flowed into the flow-through cell from its top.

Iron present in the carrier solution as an impurity should be eliminated. Thus, the carrier solution was on-line purified: the carrier solution containing a small amount of DPPS was passed through a PTFE tube (3 mm in diameter, 10 cm in length) packed with AG 1-X2 (100–200 mesh) in the acetate form.[14]

Procedure for determination of water-soluble (total) iron in fresh water

When a natural water was sampled, 0.1 ml of concentrated hydrochloric acid was added per 50 ml of sample immediately after filtration through a 0.45-μm cellulose nitrate membrane filter by using a disposable polyethylene syringe and a filter unit (Advantec Dismic-25). The sample solutions were stored in polyethylene containers.

To a 5-ml sample solution containing 5–500 ng of iron, 1 ml of the colouring agent solution was added and then the solution was diluted to 10 ml with water. A 3.7-ml aliquot of the solution was introduced into the flow system. The photoacoustic signal was continuously monitored; the signal waveform was measured if necessary, while the signal intensity was monitored with time to obtain a signal development profile. After the signal development was completed, about 1 ml of the desorbing solution was introduced into the stream by means of the other six-way rotary valve to regenerate the ion exchanger in the cell. A calibration graph was obtained by plotting the signal intensity increase from the background level at 4.5 min after sample introduction versus the concentration of iron, and the iron concentrations of water samples were determined by means of this graph.

RESULTS AND DISCUSSION

Selection of colouring agent for iron

DPPS is soluble in water and forms a water-soluble 3:1 complex with iron(II) in the pH range 3–7.[13] We chose DPPS as a colouring

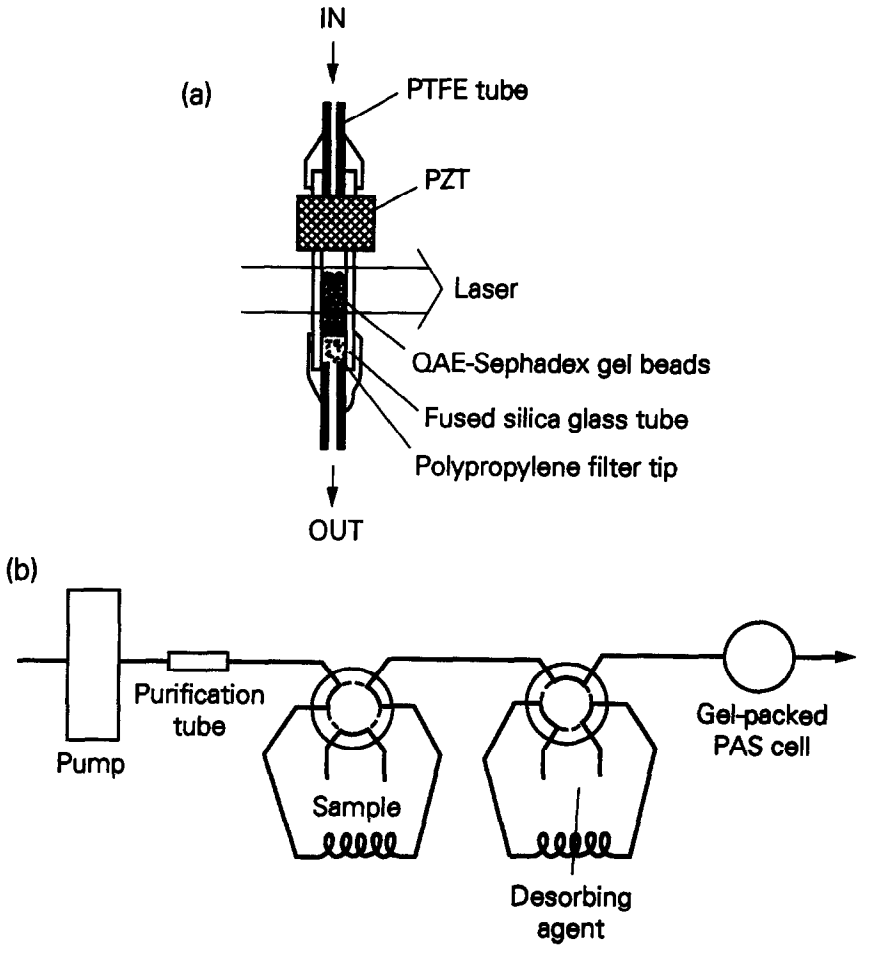

Fig. 1. (a) Schematic diagram of the ion-exchanger phase photoacoustic cell for flow analysis, showing the positions of the laser beam and the beads. (b) Schematic diagram of the flow analysis system. Flow-rate: 1.3 ml/min.

agent for iron, because its molar absorptivity at 532 nm was 2.4×10^4 l. mole^{-1}. cm^{-1}, much higher than that of 1,10-phenanthroline (7.6×10^3 l. mole^{-1}. cm^{-1}). In addition, the coloured complex can be easily sorbed on a dextran-type anion exchanger due to its highly negative charge (−4).

Photoacoustic signal

A typical waveform of the photoacoustic signal for Fe(II)–DPPS complex is shown in Fig. 2. The signal is complicated due to electrical and mechanical fluctuations, acoustic reflections in the cell, and so on, as in the case of similar PAS studies[2,5] but the analysis of the waveform is not the aim of the present study. Some negative drift of baseline of the waveform was observed only when the solution flowed through the cell, lasting for about 60 μsec after the laser flash. This baseline drift was almost unchanged at a constant flow-rate and caused no significant problems for the measurements.

Signal development profiles were investigated for several excursions, and the detection at the largest positive excursion showed the best result;

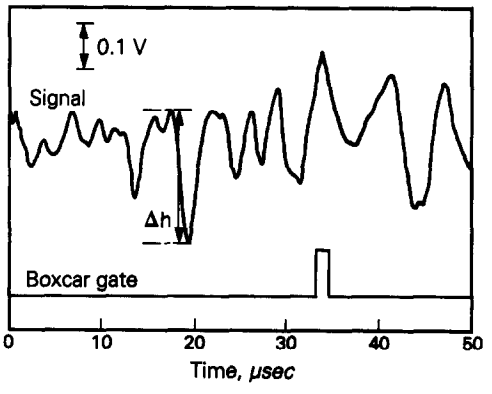

Fig. 2. A typical photoacoustic signal waveform for 7.5 ng/ml of Fe. Sample volume, 3.7 ml. The position and the duration of the boxcar gate is also shown.

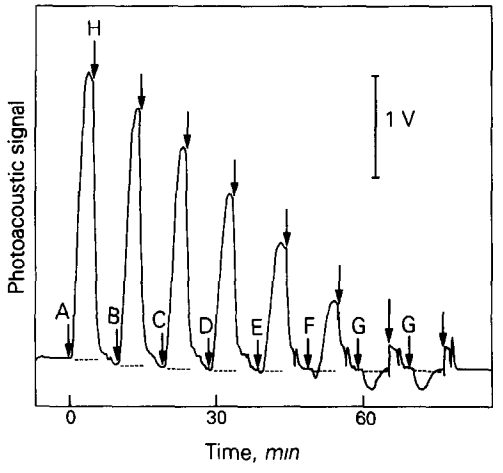

Fig. 3. Development profiles of the photoacoustic signals for Fe(II)–DPPS complex. Sample volume, 3.7 ml: A, 15.0; B, 12.5; C, 10.0; D, 7.5; E, 5.0; F, 2.5 ng/ml Fe; G, blank; H, desorbing agent. The solution was introduced at a position shown by an arrow. Dashed lines are assumed baselines.

thus, the boxcar gate was adjusted at this excursion, as shown in Fig. 2.

Chemical and flow variables

Concentration of reagents. In ion-exchanger phase absorptiometry, the present reagent system has already been employed and successfully applied to iron analysis of highly purified water for electronic industries.[14] The final concentrations of reagents employed were similar to those in the previous work: 0.01% DPPS, 0.1% hydroxylammonium chloride, 0.02*M* acetic acid, and 0.02*M* ammonium acetate.

Standing time of colour development. At least 5 min after mixing the reagents, colour development was completed and a constant signal was obtained.

Flow rate. Lower flow-rates required a longer measurement time, while higher flow-rates increased in the inner pressure of the flow system. The flow-rate should, therefore, be compromised and maintained constant in the range 1.0–1.5 ml/min.

Flow analysis

Figure 3 shows typical signal development profiles for iron(II)–DPPS complex sorbed on QAE-Sephadex gel. By introducing 15 ng/ml Fe for the Fe–DPPS complex at the position A, the signal developed with time because Fe(II)–DPPS complex was continuously concentrated on the beads. In the case of the reagent blank, which was introduced at the position G in Fig. 3, the signal showed some negative baseline drift probably due to the composition difference between the carrier solution and a sample solution. After the development was completed, the desorbing agent was introduced at the position H. Then, the signal dropped rather steeply; the sample could be completely desorbed within a few minutes.

The calibration graph for iron was obtained by plotting the signal height from the baseline in Fig. 3 versus the corresponding iron concentration. The graph was slightly convex. The detection limit, defined as the concentration giving the signal height equal to three times the standard deviation of the blank height, was 0.33 ng/ml (Table 1). The detection limit for the corresponding ion-exchanger phase absorptiometry was 0.2 ng/ml (the sample volume introduced into the flow system was 4.8 ml).[14] The sensitivity of the present method is almost comparable to the absorptiometry.

Enhancement of sensitivity

As discussed in our companion paper,[12] for a system with large distribution ratio of coloured species between ion-exchanger and solution, the sensitivity of ion-exchanger phase spectrometry is proportional to the volume ratio, V/v, where v is the volume of the ion-exchanger in ml and V is the sample volume in ml.

Table 1. Comparison of sensitivity and detection limit of PAS for iron in some media*

§The concentration giving an intensity equal to three times the standard deviation of the background intensity (95% confidence).

‖The amount of ion exchanger collected in the cell: batch, 0.104 ml; flow, 0.009 ml.

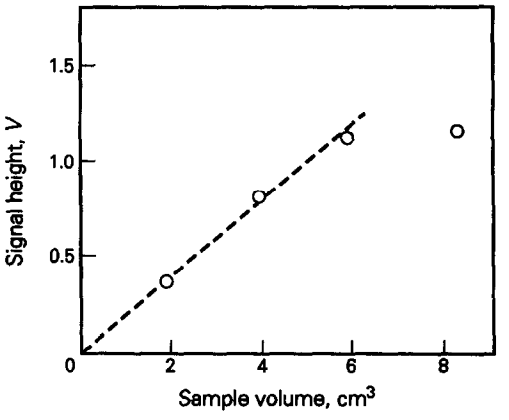

Fig. 4. Effect of sample volume on the signal intensity. Fe concentration: 5 ng/ml.

The sensitivity, defined as the concentration giving 100 mV of Δh (the peak-to-peak height of the signal waveform in the 17–20 μsec region as shown in Fig. 2) was compared with those for the corresponding batch systems; the results are summarized in Table 1.

In our batch system,[12] the iron–DPPS complex in 20 ml of the solution is completely sorbed on 0.104 ml of the ion-exchanger, and therefore the sensitivity was expected to be improved 190 times over that of the corresponding solution PAS because $V/v = 190$.

In the present flow method, the laser beam (4 mm in diameter) is expected to strike less than 0.007 ml of the ion exchanger beads and almost all of the analyte introduced into the flow system was used for measurements. On the other hand, the batch system required 0.104 ml of the ion-exchanger beads for collecting the beads from the equilibrated solution and packing them into the tube in the cell,[12] and the laser beam irradiated only 1/15 of the beads added in the sample solution. Therefore, the flow system improves the sensitivity by about 15-fold over the batch system, provided that other measurement conditions are identical. The observed sensitivity was enhanced by a factor of about three, because the sample volumes used were 3.7 ml for the flow system and 20 ml for the batch system. Above all, the amounts of iron giving the same signal intensity were almost identical in all cases, as shown in Table 1.

The sensitivity can also be improved by increasing the volume of sample solution. The effect of sample volume on the photoacoustic signal is shown in Fig. 4. The signal developed proportionally to the sample volume up to about 5 ml.

Effect of foreign ions

Although some transition metals react with DPPS, giving coloured (*e.g.*, nickel, cobalt and copper) or colourless (*e.g.*, zinc) complexes, at least the comparable amounts of these metal ions with that of iron do not interfere with the determination.[13] The concentration levels found in river waters are 200–400, 0.3–2.5, 1.5–7 and 4–20 ng/ml for iron, nickel, copper and zinc, respectively:[15] in general, iron is most abundant among transition metal ions in natural water. Therefore, the presence of these metals that occur in river water are generally tolerable, and the present method can be applied to the analysis of iron in river water without any pre-treatments for those metals.

The validity of the present method for the determination of trace amounts of iron in river waters has been examined; the recovery test for a river water sample was performed by adding known amounts of iron(III) (Table 2). The recovery of iron was almost quantitative. Another examination has also been done; the analytical value obtained by the present method was compared with that by atomic-absorption spectroscopy. The sample solution (No. 4 in Table 3) was carefully concentrated up to 1/20 in volume by evaporation of water in a PTFE vessel. The concentration of iron in the solution was determined by using a calibration curve prepared at similar electrolyte concentrations to those in the sample solution. The analytical value (13.7 ng/ml) for the sample water determined by atomic-absorption spectrometry was in fairly good agreement with that (12.6 ng/ml) determined by the present method.

The presence of a large amount of a background electrolyte such as sodium chloride resulted in both a volume contraction of the ion-exchanger beads and a decrease in the

distribution ratio of the iron complex. In such cases, the iron concentration should be evaluated by means of a calibration graph prepared at electrolyte concentrations similar to those in the sample solution.

Determination of water-soluble (total) iron in river water

The present method was applied to the determination of the total amounts of water-soluble iron species in river waters. After filtration of water samples through a 0.45-μm membrane filter, pH values of filtered samples were adjusted to 1.5 by adding concentrated hydrochloric acid, and the samples were stored in polyethylene vessels; under this condition the loss of iron is negligible.[16] Analytical values of iron at eight sites of Shintate River (Kasuya, Fukuoka) are summarized in Table 3. The contents of the water-soluble (total) iron were in the range of 2.2–12.6 ng/ml. The contents in two tributary streams (Nos 4 and 5), where trees were cut down over the catchment basins, were somewhat high.

The precision was investigated with a sample solution (No. 1 in Table 3). For three determinations, the analytical value was 3.34 ± 0.32 ng/ml (90% confidence).

By using the present method, six water samples containing water-soluble (total) iron [iron(II) and (III)] at concentrations of ng/ml levels could be analyzed within one hour; such a highly sensitive detection was impossible in conventional flow-injection analysis without any preconcentration procedure. It may be possible to determine the contents of iron in different oxidation states with the use of citrate as a masking agent for iron(III).[17]

CONCLUSION

We have demonstrated in these two back-to-back papers that LIPAS is quite applicable either for the batch or flow method of ion-exchanger phase spectrometry. A smart combination of ion-exchange concentration and direct measurement of the ion exchanger by LIPAS enabled the detection sensitivity at ng/ml levels or lower.

Compared with ion-exchanger phase absorptiometry, the present cell compartment is very simple. A fused silica tube packed with a small amount of ion-exchanger beads is combined only with a piezoelectric transducer attached on it. In addition, room light and scattered light do not affect the sensitivity and reproducibility in this method. A system with higher molar absorptivity at an excitation wavelength and larger distribution ratio will certainly improve the analytical sensitivity even for smaller sample volumes.

Summary—Free chlorine in water can be determined by acidifying the water sample, purging it with nitrogen and determining the chlorine present in the nitrogen stream with a gold porous electrode. The current response of gold porous electrode is related to the concentration of free chlorine by using a calibration curve. This pneumatoamperometric method gives results fully comparable to the standard *o*-toluidine photometric method used for water supplies. It is uninfluenced by the presence of other dissolved oxidants and requires only one milliliter of sample.

Our previous paper[1] dealt with the possibility of the pneumatoamperometric determination of trace amounts of oxidants and the total dissolved chlorine in water. The method involved the reaction of various oxidants with iodine. A stream of nitrogen transported the iodine vapors to a gold porous electrode, AuGPE. The current at the AuGPE corresponded to the total amount of the test oxidants.

Pneumatoamperometry is also suitable for the determination of free chlorine (hydrochlorite) because chlorine can be purged rapidly from an acidified solution. The equilibrium,

$$HClO + H^+ + Cl^- = Cl_2 + H_2O \qquad (1)$$

shifts to the right on acidification and on purging with nitrogen, molecular chlorine enters the gas phase. The chlorine/nitrogen mixture impinges on the AuGPE which is held at a potential where chlorine reduces to chloride ion. This reduction causes a cathodic current at potentials between +0.2 to −0.2 V. The results we report below show that this chlorine determination is rapid, sufficiently sensitive, and simple to perform. The method's analytical accuracy for determination of chlorine in waters is comparable to presently used standard methods.[2,3] The pneumatoamperometric method satisfies the analytical requirements of water supply establishments and possesses certain advantages over the standard methods which are discussed below.

EXPERIMENTAL

Reagents

All the reagents we used were of p.a. purity. The water used for the preparation of standard solutions and synthetic chlorine-containing water samples was distilled twice from a glass apparatus. The chlorine demand was compensated by adding 200–250 μg of Cl_2 per liter of water and then exposing the water to sunlight for 4–5 days. Nitrogen (99.5%) purged this water for at least two hours prior to use. The water then exhibited no reaction with *o*-toluidine reagent. A pressure cylinder supplied the 99.5% nitrogen which was not further purified. The chlorine stock solution (*ca.* $10^{-2}M$) was prepared by saturating the distilled water with gaseous chlorine of the kind used for water supply purposes.[4] The stock solution was stored in a dark glass bottle at laboratory temperature and standardized by iodometric titration.

Apparatus

The AuGPE was prepared by stretching a porous Teflon membrane, vacuum-coated

*Authors for correspondence.

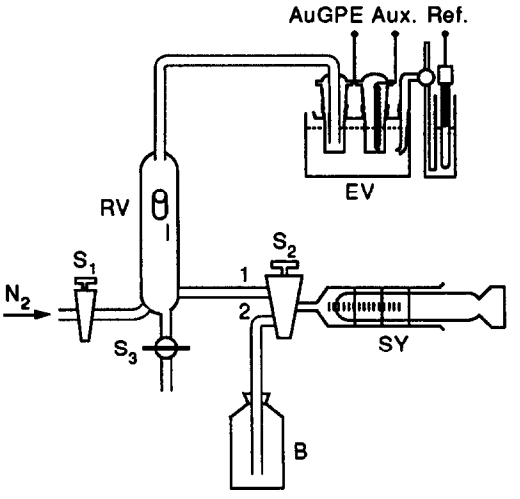

Fig. 1. Diagram of the pneumatoamperometric apparatus for determination of chlorine in water. S1 and S3 are on–off stopcocks, S2 is a two-way stopcock with positions 1 and 2, B is a vessel containing $5M$ H_2SO_4, SY is a syringe, RV is the reaction vessel, I is the port for sample injection and is sealed with a rubber septum, EV is the electrolysis vessel, Aux is the auxiliary electrode, Ref is reference electrode, AuGPE is the gold porous electrode.

with gold (thickness, 650 $\mu g/cm^2$) over the glass portion of a gas electrode. Electrical contact to the porous gold was made by the method of Gifford and Bruckenstein.[5] The electrolysis vessel contained $1M$ sulfuric acid as the supporting electrolyte. Either an operational amplifier potentiostat,[1,4] or a PA 3 polarographic analyzer was used with a TZ 4100 line recorder (all from Laboratorní Přístroje, Czechoslovakia). A saturated calomel electrode (SCE) was used as the reference electrode and all potentials are reported with respect to it.

Figure 1 depicts the pneumatoamperometric apparatus used. Chlorine is liberated in the reaction vessel, RV, which has an inlet, I, sealed by a rubber septum. Stopcock S1 introduces nitrogen into the vessel. Stopcock S3 serves as the solution outlet. If stopcock S2 is in position 2, the acid solution can be aspirated from vessel B into syringe SY. In position 1 of stopcock 2, acid can be injected into RV to shift reaction (1) to the right. The evolved chlorine reaches the AuGPE placed in electrolysis vessel EV, which also contains a reference SCE electrode and a counter electrode.

Procedure

Step 1. Open stopcock S1 and introduce nitrogen into the apparatus at a flow-rate of 0.5 l./min.

Step 2. Turn the potentiostat on and set the working electrode potential to 0 V. Wait until the rate of the residual current decrease becomes 10 nA/min. Then prepolarize the AuGPE by a step potential change to +1.25 V and scan the AuGPE between +1.25 V and 0 V at a rate of 100 mV/sec three times, stopping at 0 V.

Step 3. Set stopcock S2 to position 2. Aspirate 1 ml of $5M$ sulfuric acid into syringe SY. Turn S2 to position 1 to transfer the acid to the empty RV and close S2. Wait for the residual current to stabilize (*ca.* 5 min).

Step 4. Inject 0.1 ml of a solution containing 1.0 to 1.5 mg Cl_2/l. through the septum sealing opening I using a syringe. This is to preoxidize any reducing impurities in the sulfuric acid. Wait until the residual current stabilizes (*ca.* 2 min) and then inject a one-ml water sample to be analyzed for Cl_2 content through the septum using a syringe. Record the peak current response.

Step 5. Wait until the electrode current reattains a stable residual value and then drain the solution out of RV through stopcock S3.

The AuGPE should be stored dry if intervals between the measurements are greater than one day. The electrode activity and response stability of a new AuGPE, or of one that has been stored dry for a long period, should be determined by making three to five measurements with a standard chlorine solution.

RESULTS AND DISCUSSION

Effect of the electrode potential

Voltammograms obtained with a gold ring disk electrode (AuRDE) show that the limiting reduction current for chlorine (or hypochlorous acid) starts at *ca.* +0.2 V.

Currents for chlorine reduction at the AuGPE are poorly reproducible at potentials more negative than −0.2 V, and so the potential, 0 V, was used for all pneumatoamperometric measurements.

Effect of cyclic prepolarization

The AuGPE current response for chlorine reduction is poorly reproducible under conditions of long term constant applied potential within the region, +0.2 to −0.2 V. When the time between the determinations was longer than one hour, the next determination yielded *ca.* 20% lower current peak as compared to the peak found for an immediately performed replicate determination. Reproducible, 20% higher

values were reattained by performing four replicate determinations in rapid succession. This undesirable behavior can be eliminated by cyclic prepolarizaton before each measurement.

We tested the effect of varying the polarization interval from 0 to +1.5 to 0 to +0.7 V, varying the polarization rate from 5 to 500 mV/sec and using step potential changes. The reproducibility of the results is poorer for polarization intervals narrower than 0 to +0.9 or wider than 0 to +1.3 V. Cyclic prepolarization at a uniform scan rate leads to a gradual increase in the current peak height. Stepping the potential to a positive value and scanning back to 0 V produced the best reproducibility. Higher potential scan rates causes the residual current to stabilize faster. Three potential step/scan cycles produced optimal results.

The prepolarization procedure we finally used consisted of three repetitions of stepping the potential from 0 to +1.25 V and scanning it back to 0 V at a rate of 100 mV/sec. This procedure stabilized the residual current within 4–5 min and the current remains stable (±5%) for at least 15 min. Then the procedure must be repeated.

Effect of sulfuric acid concentration in the reaction vessel

One-milliliter water samples containing 0.41 μg of Cl_2 were injected into one milliliter of sulfuric acid whose initial concentration was varied from 0.1 to 5*M*. Figure 2 shows that the current peak height increases with the concentration of the acid. Acid concentrations higher than 5*M* (final 2.5*M*) were impractical.

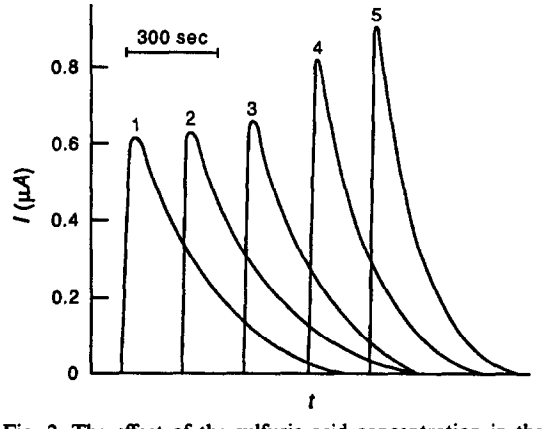

Fig. 2. The effect of the sulfuric acid concentration in the reaction vessel on the AuGPE current response. $E_{AuGPE} = 0$ V, flow-rate of $N_2 = 0.5$ l./min., $[Cl_2] = 0.41$ mg/l., 1 ml of $H_2SO_4 + 1$ ml of sample, H_2SO_4 concentration: 1—0.1, 2—0.5, 3—1, 4—2.5, 5—5*M*.

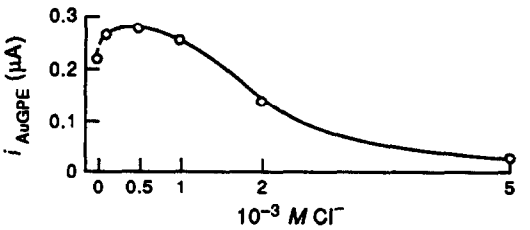

Fig. 3. The effect of the chloride concentration in the sample on the AuGPE current response. $E_{AuGPE} = 0$ V, flow-rate of $N_2 = 0.5$ l./min., $[Cl_2] = 0.28$ mg/l., 1 ml of 5*M* $H_2SO_4 + 1$ ml of sample.

The effect of chloride in the reaction vessel

Figure 3 illustrates the effect of changing the chloride ion concentration. The current peak height increases by *ca.* 20% on adding a small amount of chloride. The maximum current response occurs at *ca.* $5 \times 10^{-4}M$ Cl^- and the current peak height is nearly one-tenth of the maximum value at a concentration of $5 \times 10^{-3}M$ Cl^-. The time required to purge chlorine from the sample decreases substantially at higher chloride ion concentrations.

Most water standards permit concentrations of 100 mg Cl^-/l. (*i.e.*, *ca.* $3 \times 10^{-3}M$). Hence we adapted our method to a chloride concentration of $1.5 \times 10^{-3}M$ (52 mg Cl^-/l.) in our samples to minimize the influence of chloride that might be present initially, and obtained a calibration curve. A new calibration curve would have to be determined for samples with higher chloride contents. As the concentration of chloride is often routinely determined in water samples, a

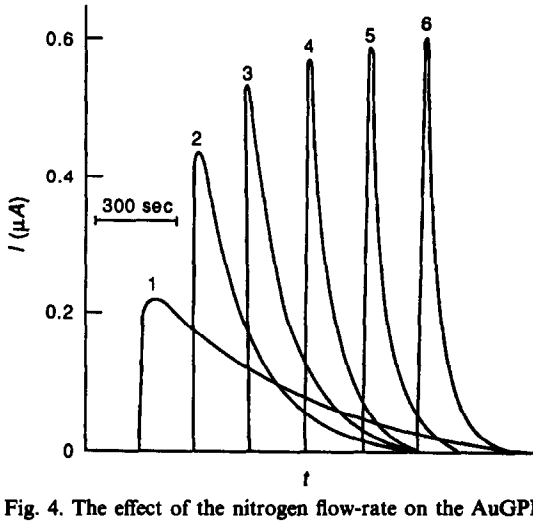

Fig. 4. The effect of the nitrogen flow-rate on the AuGPE current response. $E_{AuGPE} = 0$ V, $[Cl_2] = 0.45$ mg/l., 1 ml of 5*M* $H_2SO_4 + 1$ ml of sample, $[Cl^-] = 1.5 \times 10^{-3}M$. N_2 flow-rate (l./min): 1—0.1, 2—0.3, 3—0.5, 4—0.8, 5—1.0, 6—1.5.

correction factor could be incorporated in the procedure or the chloride content of calibration standards adjusted accordingly. A standard additions calibration would also eliminate the influence of chloride.

The influence of nitrogen flow rate

Figure 4 shows how the purging gas flow-rate affects the current peak height. The shape of the current–time response is the expected one, but the peak current value is higher. We selected a nitrogen flow-rate of 0.5 l. N_2/min for practical analyses.

The concentration dependence

We determined the dependence of peak current height on chlorine concentration in the range 0.06–0.90 mg Cl_2/l. All these test samples contained $1.5 \times 10^{-3}M$ chloride ion. Two procedures were employed. First, a one-milliliter water sample was added to one milliliter of $5M$ sulfuric acid and the peak current accompanying gas purging was recorded (Fig. 5, lower curve). Secondly, to eliminate the effect of trace reductants that might be present in the sulfuric acid, 0.1 ml of a solution containing 1.0–1.5 mg Cl_2/l. was added to 1 ml of $5M$ sulfuric acid. The mixture was bubbled with nitrogen to attain a constant residual current (*ca.* 2 min). Only then did we add a 1.0-ml water sample and record the peak current (Fig. 5, upper curve).

The peak current height–chlorine concentration responses were not linear. The character of the curvature is the same in both the above procedures and is qualitatively identical with the shape of the voltammetric response reported by Pungor *et al.*[7]

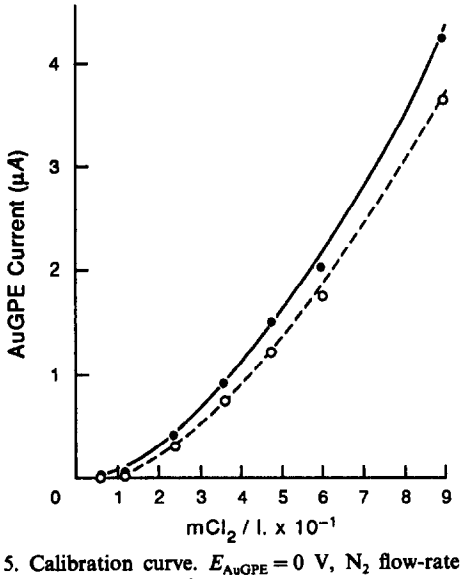

Fig. 5. Calibration curve. $E_{AuGPE} = 0$ V, N_2 flow-rate 0.5 l./min., $[Cl^-] = 1.5 \times 10^{-3}M$. (○) 1 ml of $5M$ H_2SO_4 + 1 ml of sample; (●) 1 ml of $5M$ H_2SO_4 + 0.1 ml of a solution containing 1 mg Cl_2 per liter, 1-ml sample after 2 min.

The effect of any formation of chloramines, of the matrix, and of organic impurities can be excluded, as the same curve shape was obtained for water treated by standing with chlorine, followed by bubbling out the chlorine and then distilling in a quartz apparatus.

Adding chlorine to the sulfuric acid before adding the water sample (the second procedure) is advantageous in the determination of very low chlorine concentrations. The second procedure yields higher peak currents than the first one. For a chlorine concentration of 0.06 mg/l. the peak current is higher by 275% and for a concentration of 0.120 mg/l. it is higher by *ca.* 100% (the lowest two points in Fig. 5). The differences in the results obtained by the two procedures can be attributed to the presence of traces of reductants in the sulfuric acid equivalent to *ca.* 0.12 mg/l. chlorine. Reducing impurities have the greatest relative influence when determining low chlorine concentrations.

The curvature in the current–concentration response at low chlorine concentrations may be due to kinetics. The ratio $(Cl_2)/(HClO)$ during purging is constant and independent of total dissolved Cl_2 because both the hydronium and chloride ion concentrations are constant ($2.5M$ $H_2SO_4 + 1.5 \times 10^{-3}M$ Cl^{-1}). The instantaneous equilibrium concentration of Cl_2 in the flowing N_2 would be proportional to the dissolved Cl_2 concentration if equilibrium existed, and no curvature in the current concentration response would occur. This is not the case however. The curvature of the concentration plot suggests, as one possibility, that the partitioning of $(Cl_2)_{aqueous}$ to the gas phase becomes rate-determining.

The effect of the electrolyte composition

The gold porous, reference and auxiliary electrodes are immersed in $1M$ sulphuric acid supporting electrolyte. The sulfuric acid concentration has no significant effect on the peak current response for the reduction of chlorine. The current only increases slightly with the concentration of the acid. The presence of chloride ions in the sulfuric acid supporting electrolyte significantly increases the peak currents for chlorine reduction. We observed as much as a 20-fold increase, but this sensitivity increase was accompanied by poorer reproducibility. Also,

the sensitivity decreases and the AuGPE residual current increases with time. The electrode lifetime in chloride-containing solutions is limited to a few weeks after which time the current response suddenly drops to zero.

Effect of oxidizing agents

While strong oxidants are not likely to be present, we tested our procedure in the presence of MnO_4^- (1.0 and 2.0 × $10^{-5}M$), Fe^{3+} (1.0 and 2.0 × $10^{-5}M$) and NO_3^- (1.0 and 2.0 × $10^{-3}M$) in solutions containing 0.30 mg Cl^-/l. and 0.28 mg Cl_2/l., and noted no effect on the pneumatoamperometric response. The photometric response, on the other hand, was nearly doubled and tripled in the presence of the MnO_4^-.

Reproducibility

Figure 6 illustrates the reproducibility of the measurements on the same water sample. Replicate measurements on two different water samples gave the following results: for a water sample containing 0.275 mg Cl_2/l., the estimate of the standard deviation was 0.003 mg Cl_2/l. (7 measurements); the corresponding value for the sample containing 0.520 mg Cl_2/l. was 0.007 mg Cl_2/l. (7 measurements).

Practical water samples

Chlorine was determined in water samples using the pneumatoamperometric method (described in the Procedure) and the results were compared with those obtained by the *o*-toluidine photometric method.[3] The sensitivity of the pneumatoamperometric method does not differ appreciably from the *o*-toluidine photometric method. As can be seen from Table 1, our pneumatoamperometric method yields higher values than the photometric technique. One possible explanation for the difference may lie in the observation that the literature does not contain any evidence that the reaction between *o*-toluidine and chlorine is stoichiometric. The Czechoslovak standard[3] merely recommends that this reaction be carried out at a pH of 1.2, and that the *o*-toluidine: chlorine ratio be at least 3:1. Lower ratios lead to decomposition of the oxidized form of *o*-toluidine. American standards recommend that the *o*-toluidine reagent: chlorine ratio be 8:1 in the analysis of potable waters. Thus complete agreement about the chemical reagent conditions for the photometric method does not exist. The *o*-toluidine method has, in fact, been replaced in more recent

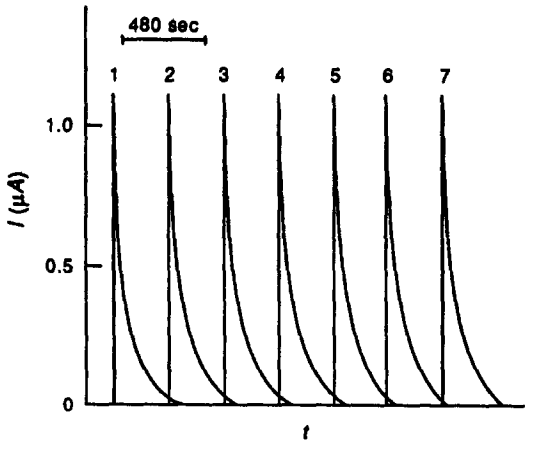

Fig. 6. Measuring reproducibility with the AuGPE. $E_{AuGPE} = 0$ V, N_2 flow-rate = 0.5 l./min., $[Cl^-] = 1.5 \times 10^{-3}M$, 1 ml $5M$ H_2SO_4 + 0.1 ml of solution containing 1 mg Cl_2 per litre, followed by 1 ml sample after 2 min. $[Cl_2] = 0.63$ mg/l., $s_x = 0.0035$ mg Cl_2/l. at the 95% confidence level.

*Sampling at the farthest location in the water supply system.
†Sampling in the middle of the water supply system.
‡Sampling at the beginning of the water supply system.

editions of Standard Methods, although it is still the standard in Czechoslovakia for the moment. We, unfortunately, do not have access to the reagents needed to carry out the supposedly more accurate DPD or FACB methods. Because of the known limitations of the *o*-toluidine method, the comparisons in Table 1 at least demonstrate reasonable agreement.

A second reason for discrepancies between the two methods may be that the photometric determination is performed in open vessels at pH = 1.3 while stirring the sample. The distribution diagram for the various forms of dissolved chlorine shows that molecular chlorine exists in water under these conditions. Some of this molecular chloride could volatilize and lead to less than quantitative recovery of dissolved chlorine. Finally, it is not clear how the presence of dissolved organic substances will affect the photometric procedure.

We believe that the pneumatoamperometric method is free of these type of problems. We use a closed system and inject samples into it. The chlorine in the sample is purged with a flowing gas stream and the chlorine is detected by electroreduction to chloride ion. This procedure is inherently less subject to complications arising from the presence of other species in the water sample.

We found that the time of analysis is similar for the two methods. A simple, dedicated analyzer for free chlorine in water based on this pneumatoamperometric method is being designed.

CONCLUSIONS

The pneumatoamperometric method for determination of free chlorine in water supplies gives precision and, we believe, accuracy fully comparable to the standard *o*-toluidine photometric method. The pneumatoamperometric method has two advantages as compared to the *o*-toluidine method. First, smaller samples suffice and secondly, dissolved oxidants do not interfere as they do in the optical method. A standard additions procedure would alleviate chloride dependence. While we have been unable to compare these preliminary results against a more accurate method, our method can certainly serve as a simple screening procedure requiring no sample treatment/reactions, and for monitoring threshold levels of Cl_2 (to establish if Cl_2 is above a minimum level).

STUDY OF THE TRANSPORT OF SILVER ACROSS A SUPPORTED LIQUID MEMBRANE CONTAINING SULPHIDE PODAND

ELWIRA LACHOWICZ

Department of Analytical Chemistry, Warsaw University of Technology, Noakowskiego 3, 00-664 Warsaw, Poland

(*Received* 26 *August* 1991. *Revised* 4 *December* 1991. *Accepted* 4 *December* 1991)

Summary—The transport of silver through a supported liquid membrane saturated with a polydentate neutral ionophore 1,12-di-thienyl-2,5,8,11-tetrathiadodecane in *m*-chlorotoluene has been studied. Thiosulphate was used as the stripping solution. The influence of the feed solution composition, the type of a microporous polypropylene Celgard support, the ratio of feed/receiving solution volume, and the initial Ag concentration on the rate of transport of silver was examined. Transport of Ag is selective towards Cu(II), Pb and Zn, but these cations affected the rate of the Ag flux.

Supported liquid membranes (SLMs) are the subject of widespread investigation[1–16] as a potential method of separation and preconcentration for both technical and analytical purposes.

A micro-porous polymer support with immobilized organic solution of ionophore is interposed between sample (feed) solution and receiving solution. A continuous transport of ions across that membrane occurs due to simultaneously arising processes of extraction and back-extraction.

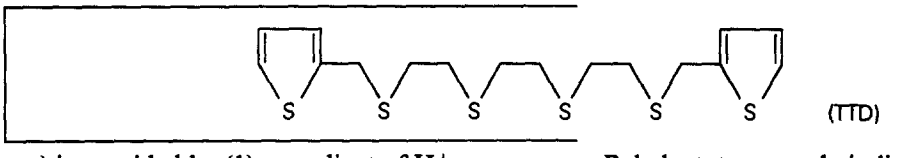
A complexing reagent incorporated into the organic phase acts as the carrier for metal ions and first of all its selectivity towards the desired ions determines the overall selectivity of the process. A very small volume of reagent solution enables the use of ionophores of higher cost. A driving force for active "up-hill" transport of ions (against their concentration gradient) is provided by (1) a gradient of H^+ concentration or (2) by complexing or redox reaction of target ions in a receiving phase.

Danesi *et al.*[10] listed the factors favourable to forming stable SLMs: a low solubility of organic liquid in water, a low difference of the ionic strength between feed and stripping solutions, a high organic/water interfacial tension, small pore radii and low hydrophobicity of a polymer support. The latter three points were also stressed by Takeuchi *et al.*[11]

Izatt and co-workers[4,5] confirmed that the time stability of SLM depends on the boiling point and solubility of the solvent in water.

Among recently published papers on SLMs were studies on the transport of Li,[14] K,[13] alkali metal and alkaline earth cations[4] across a membrane that contained crown ethers, Cu(I)[15] or Cu(II)[9] across a membrane with a thioeter or a mixture of oximes respectively, Zn(II) ions through SLM with incorporated dithizone[8] or bis-(2,4,4-trimethylpentyl)phosphinic acid,[7] rare earth cations[12] with use of some β-diketones as carriers, and uranium(VI) with TOPO.[16]

The present paper is a continuation of our studies on a solvent extraction of metal ions with the sulphide podand (open-chain analog of thiocrown) 1,12-di-2-thienyl-2,5,8,11-tetrathiadodecane (TTD).



(TTD)

Polydentate open-chain ligands, so-called podands according to the Weber and Vögtle classification,[17] form similar crown ethers and cryptands, the host-guest complexes. TTD, being a neutral all-sulphur ligand reacts selectively with metal ions classified as "soft" in Pearson's HSAB approach.[18] Studies on extraction of Ag,[19,20] Pd and Au[21] by TTD solution in 1,2-dichloroethane, 4-methylpentanone

(MIBK) or chloroform were presented previously. Recently it was found by Chayama and Sekido[22] that the acyclic tetrathio ethers show a higher extractability than the corresponding cyclic tetrathio ethers.

In the present study the transport of Ag ions across a liquid membrane with immobilized TTD will be presented. The effect of a composition of a sample solution, a type of polymeric membrane and other conditions of process on a rate of up-hill transport, as well as a selectivity problem will be discussed.

EXPERIMENTAL

Reagents

1,12-Di-2-thienyl-2,5,8,11-tetrathiadodecane (TTD) was synthesized as described previously[19] and used as 0.1M solution in m-chlorotoluene. A stock $10^{-2}M$ solution of silver was prepared from silver nitrate dissolved in water with nitric acid. Other reagents used were all of analytical purity.

Apparatus

A Thermo Jarrell-Ash S11 atomic-absorption spectrometer was used for determination of Ag (328.1 nm), Cu (324.7 nm), Zn (213.8 nm) and Pb (217.0 nm).

Membrane cell

The apparatus used followed the device described by Cox and Bhatnagar.[8] Experiments were carried out in the device including a glass container for a feed solution, a Teflon tube (i.d. 40 mm) closed at one end with microporous membrane fixed with a Teflon screw-nut (Fig. 1). The feed solution (500 ml) was stirred with a magnetic stirring bar. A volume of receiving solution (0.1M thisulphate) was 50 ml unless otherwise stated. In some experiments with 50 ml of receiving solution, this solution was stirred by a second (paddle) stirrer.

The 0.1M (unless otherwise stated) solution of TTD in m-chlorotoluene was pipetted onto a membrane. A volume of 2–3 drops was sufficient to saturate the membrane.

Samples of 2 ml from the feed phase or 1 ml from the receiving solution were transferred to calibration flasks of appropriate volume and diluted with water to the mark. Concentration of Ag as well as Cu, Zn and Pb ions was determined by AAS method.

Results are expressed as the enrichment coefficient $c_{r,t}/c_{f,0}$ *i.e.*, the ratio of the concentration of silver in the receiving phase at the time t, $c_{r,t}$ to the initial concentration of silver in the feed solution, $c_{f,0}$.

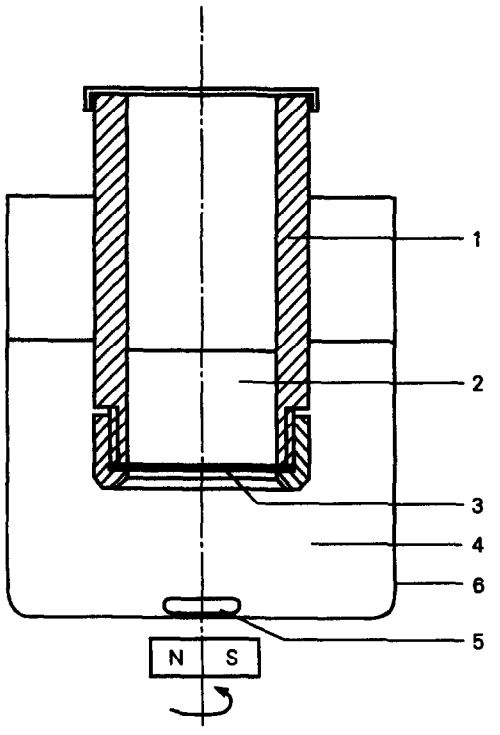


Fig. 1. Diagram of membrane cell. 1—Teflon tube; 2—receiving phase; 3—SLM; 4—feed phase; 5—stirring bar; 6—glass container.

A value of flux of ion J (in M cm^{-2} hr^{-1}) calculated as the amount of moles transferred across the 1-cm^2 area of SLM during one (first) hour of experiment will also be used, mainly for comparison of transport of various cations.

Membranes

Four hydrophobic polypropylene Celgard membranes (kindly supplied by the Hoechst Celanese Corporation) were tested: the Celgard 2400 and 2500 membranes as well as their laminates on a polypropylene nonwoven web: Celgard 4410 and 4510 respectively. The laminate variants exhibit an improved strength, toughness and tear-resistance, but also an increased thickness over a basic membrane. The properties of membranes are shown in Table 1.

The area of contact of membrane and solution was 12.5 cm^2.

RESULTS AND DISCUSSION

Dependence of Ag flux on composition of feed solution

Silver ions were extracted[19] with a high selectivity and efficiency from solutions of pH 1–6 in

Table 1. Celgard microporous polypropylene membranes

Type	Porosity, %	Effective pore size, μm	Average thickness, μm
2400	38	0.05	25 ± 2.5
2500	45	0.075	25 ± 2.5
4410	38	0.05	175 ± 75
4510	45	0.075	175 ± 75

the presence of ClO_4^-, and from HNO_3, $HClO_4$ or $HNO_3 + HClO_4$ solutions by TTD in 1,2-dichloroethane or MIBK. The value of log D (log of the distribution coefficient of Ag between the organic and water phases) ranged from 1.8 to 2.2. The complex cation Ag–TTD$^+$ was transferred into an organic phase as an ion pair with ClO_4^- or NO_3^- acting as the counter ion.

Here, the transport of Ag from various media into 0.1M thiosulphate, used as the stripping solution, was examined. Thiosulphate medium was chosen (log $K = 8.82$ for complexation with Ag[23]) to facilitate the release of silver in the receiver and eliminate an overall rate controlling stage from the stripping process. Experiments were carried out with the Celgard 4410 membrane. Results are shown in Fig. 2.

The transport of silver occurs in acetic buffer (with the presence of ClO_4^-) and in acidic media. As follows from experiments at pH 4.7, the increase in sodium perchlorate concentration and the increase in the concentration of TTD was profitable for Ag transport. Using a concentration much higher than 0.1M TTD was not feasible because 0.2M TTD solution is close to saturation. The flux of Ag from 0.1M perchloric acid is higher than that from 0.1M nitric acid. Similarly, the extraction of Ag from perchloric acid solution has been characterized by higher D values[19] than in the case of nitric acid. The effect of an anion on the rate of transport of a cation complex of a metal ion with a neutral crown ether as an ionophore was discussed by Lamb *et al.*[24] on the basis of anion hydration reaction. They showed that anions with small Gibbs free energies of hydration (ClO_4^- has the smallest among the presented group) allowed faster transport of metal cation.

The medium 0.1M $HNO_3 + 0.05M$ $HClO_4$ has been chosen in this study because of a better balance (in comparison to 0.1M $HClO_4$) of Ag in both aqueous phases during long-time experiments.

Comparison of microporous membranes

The experiments carried out for the four polypropylene supports point out the differences among them. The curves in Fig. 3 present the mean values of two transport experiments for each of the membranes. Range is ±10%. The mean values of Ag transport expressed in $10^{-8}M$ cm^{-2} hr^{-1} are as follows: 35.6 and 12.4 for Celgard 2500 and Celgard 2400 and 18.6 and 13.0 for their laminates respectively.

As follows from this comparison the addition of a polypropylene web diminishes the rate of transport for a membrane of higher porosity, but, in the range of error, has no influence on lower porosity support. In the case of Celgard 4510—laminated membrane of higher porosity—the silver flux is still better than for Celgard

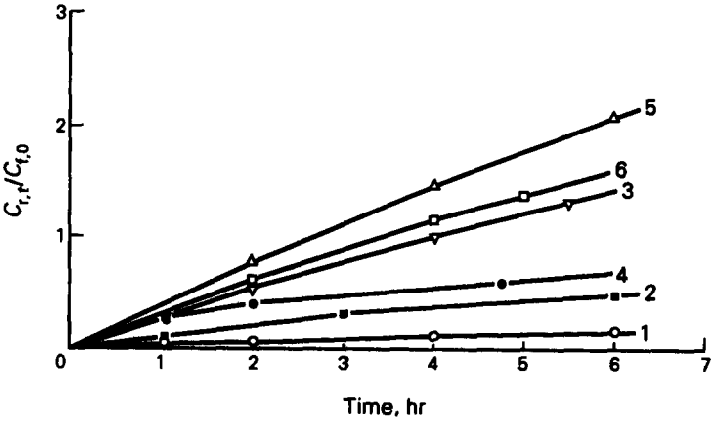

Fig. 2. Effect of the composition of feed solution on transport of silver through the liquid membrane supported on Celgard 4410. Composition of feed solution and TTD concentration in *m*-chlorotoluene: 1—pH 4.7, 0.002M $NaClO_4$; 0.01M TTD; 2—pH 4.7, 0.02M $NaClO_4$; 0.01M TTD; 3—pH 4.7, 0.05M $NaClO_4$; 0.1M TTD; 4—0.1M HNO_3; 0.1M TTD; 5—0.1M $HClO_4$; 0.1M TTD; 6—0.1M $HNO_3 + 0.05M$ $HClO_4$; 0.1M TTD. Feed solution: 500 ml, $10^{-4}M$ Ag. Receiving solution: 50 ml 0.1M $Na_2S_2O_3$, both phases stirred.

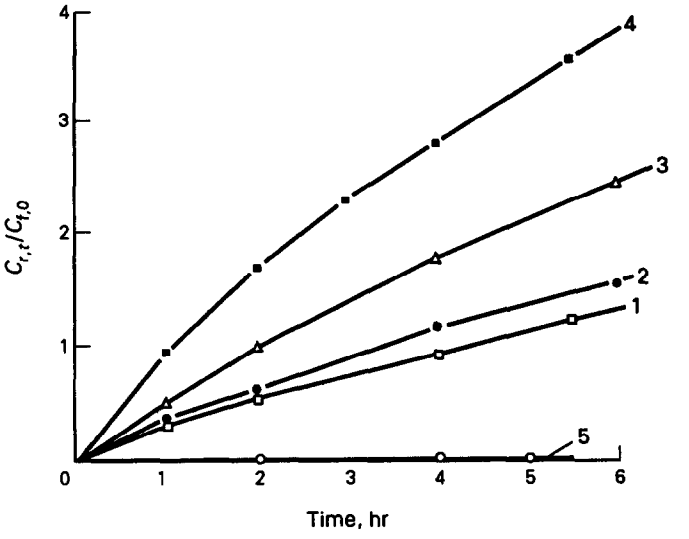

Fig. 3. Transport of silver ions from 0.1*M* HNO_3 + 0.05*M* $HClO_4$ solution across various Celgard membranes saturated with 0.1*M* TTD in *m*-chlorotoluene. 1—Celgard 2400; 2—Celgard 4410; 3—Celgard 4510; 4—Celgard 2500; 5—Celgard 2500 saturated with *m*-chlorotoluene (without TTD). Other conditions as for Fig. 2.

2400. Further investigations will be carried out for Celgard 2500 membranes. A blank experiment carried out for Celgard 2500 support saturated with *m*-chlorotoluene only (without ionophore) demonstrated no Ag transport (Fig. 3, curve 5).

Effect of stirring

In preliminary tests it was noticed that the rate of transport of Ag during a rest time (without stirring) was only *ca.* 5-fold lower than when both aqueous phases were stirred. Therefore the stirring in the receiver was abandoned. Next, the influence of the rate of stirring of the feed solution was investigated. For given compositions of both solutions the over-all transport rate seems to be limited by diffusion in the very thin organic layer and therefore increase in beyond gentle stirring contributes to the damage of the liquid membrane, as observed by partial loss of transparency and a diminishing of the Ag flux.

Transport of silver from solutions containing zinc, copper(II) and lead ions

It has been demonstrated previously[19,21] that TTD does not extract Cu(II), Pb or Zn, but besides silver, it forms extractable complexes also with mercury(II), palladium, gold and copper(I).

Transport of silver in the presence of another cation [Cu(II), Pb or Zn] or the mixture of four cations was examined. Results are presented in Table 2. Experiments were carried out for five hours. After that time a concentration of interfering cations in the stripping solution was negligible. It indicates that the "up-hill" transport of Ag is very selective relative to Cu(II), Pb and Zn ions.

The flux of silver is greater in a single cation system than in a binary or multi-cation system. This diminishing effect is more distinct for Zn and Pb than for Cu(II) ions. The flux of silver in the presence of 10-fold higher concentration of Cu(II), Zn or Pb equals respectively 83, 73, and 70% of that value for Ag transport in similar conditions, but without interferents.

In the literature, the opposing effects of a second cation in the bulk membrane[25,26] and the up-hill SLM[7-9] transport are reported. In the

Table 2. Transport of silver from a mixture with Cu, Zn and Pb

	Ions in source solutions				
Flux $J \times 10^8$ ($M cm^{-2} hr^{-1}$)	Ag	Ag +Cu(II)	Ag +Zn	Ag +Pb	Ag +Cu(II) +Zn + Pb*
Flux of silver	35.6	29.6	26.0	24.8	29.6
Flux of interfering ion	—	<0.05	<0.05	<0.05	<0.01 for each interferent

Source solution: 500 ml, 0.01*M* HNO_3 + 0.05*M* $HClO_4$, $10^{-4}M$ Ag, $10^{-3}M$ Cu(II) or Zn or Pb, optimum rate of stirring.

Receiving solution: 50 ml of 0.1*M* $Na_2S_2O_3$, unstirred.

Celgard 2500 membrane with 0.1*M* TTD in *m*-chlorotoluene.

*$10^{-4}M$ Cu(II), Zn, Pb.

case of an ionophore reacting with both cations, the flux of the target cation in the presence of a second cation was unchanged[7] or lower[8] than in a single-cation system. For ligands selective towards the first cation, the diminishing effect of the second cation was reported [Cd influence on Pd transport[25] with sulphur substituted macrocycles, Fe(III) effect on Cu(II) transport[9] with LIX 64], but small increasing effects[25] were also found. The reduction of Ag flux noticed in this study is difficult to explain because the copper(II), zinc(II) and lead(II) ions are not extracted or complexed by TTD, and their concentration is too low to produce a considerable change in the redox potential of the feed phase or in an ion strength. Therefore, surface phenomena rather than competition in complexation with the ionophore are probably responsible for the effect.

Dependence of silver accumulation on time and feed/receiving volume ratio

The time-dependence of Ag transport from Ag + Cu(II) + Zn + Pb mixture at 10:1 (curve 1) and 100:1 (curve 2) feed/receiving volume ratios is shown in Fig. 4. The shapes of both curves are very similar despite *ca.* 10-fold higher concentration of Ag in the 5-ml receiving solution (Fig. 4, curve 2). It indicates that the back-extraction reaction in the receiver does not control the overall rate of transport. After 24 hr equilibrium was not reached but the membrane was still working. The majority of Ag was removed selectively and concentrated in the receiver.

The dependence of silver accumulation in a receiving solution after a 24-hr experiment on the volume of the receiving phase is presented in Fig. 5. The enrichment coefficient of silver (curve 1 in Fig. 5) is almost inversely proportional to the volume of the stripping solution, so the amount of Ag (Fig. 5, curve 2) is, over a wide range, independent of the feed/receiving volume relation. For the highest volume ratio (500 ml:3 ml), the ratio of concentrations between the receiving and the feed solutions after a 24-hr process is 1.4 mg/ml to 1.4 μg/ml, *i.e.*, 10^3. The amount of silver selectively transferred during a 24-hr period into receivers of 3–50 ml volume ranges from 85 to 95% of the initial Ag. The highest enrichment coefficient obtained was equal to about 140 (for a 3-ml receiver).

Effect of initial silver concentration

The relation between an initial concentration of an analyte in a feed solution and its concentration response, after a fixed time of preconcentration, in a compartment separated by a liquid membrane, was investigated experimentally for uranium[16] and zinc[7] as well as being considered theoretically.[13]

The effect of the initial concentration on the value of the enrichment coefficient obtained

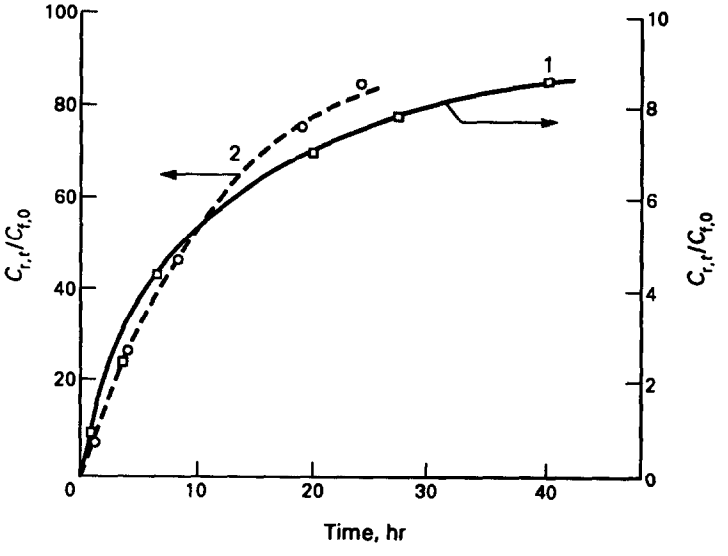

Fig. 4. Enrichment coefficient for Ag transport from Ag + Cu(II) + Zn + Pb mixture *vs.* time at two feed/receiving volume ratios. Feed solution: 500 ml, 0.1*M* HNO_3 + 0.05*M* $HClO_4$, 10^{-4}*M* Ag, stirred with optimum rate. Celgard 2500, 0.1*M* TTD in *m*-chlorotoluene. Curve 1—10^{-4}*M* Cu(II), Zn, Pb, in feed phase; 50 ml receiving phase (unstirred). Curve 2—10^{-3}*M* Cu(II), Zn, Pb in feed phase; 5 ml receiving phase (unstirred).

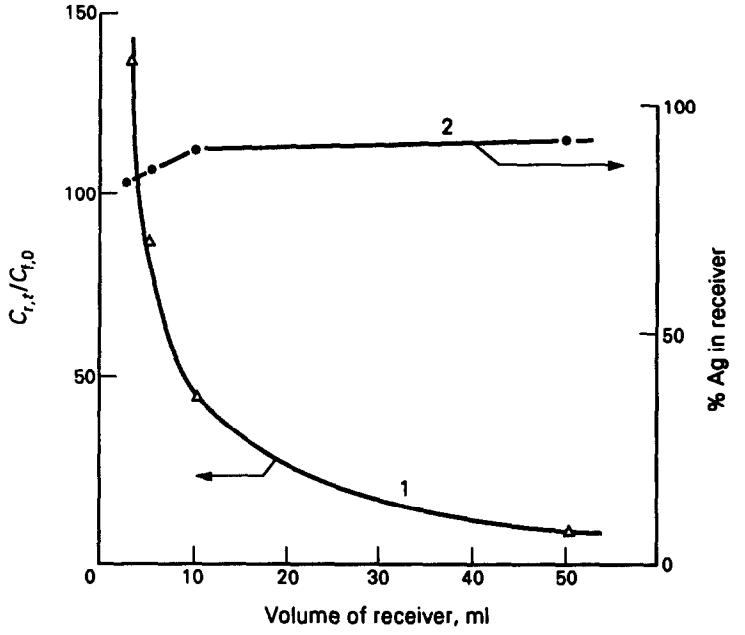

Fig. 5. Enrichment coefficient (curve 1) and amount of silver (curve 2) transferred to the receiver as a function of volume of receiving phase, 24 hours experiment. Feed solution: 500 ml, 0.1*M* HNO_3 + 0.05*M* $HClO_4$, 10^{-4}*M* Ag, 10^{-3}*M* Cu(II), Zn, Pb, stirred with optimum rate. Receiving solution: 0.1*M* $Na_2S_2O_3$ (unstirred), Celgard 2500, 0.1*M* TTD in *m*-chlorotoluene.

after a one-hour experiment is presented in Table 3. The ratio of sample to receiver volumes equals 100:1. In the range 10^{-6}–10^{-4}*M* Ag, the enrichment coefficient remains practically constant. A similar conclusion was drawn in the study of transport of zinc[7] and uranium[16] in the same concentration range.

CONCLUSION

The flux of silver through the SLM containing sulphide podand (1) depends on the composition of feed solution in a similar way to the distribution coefficient does in solvent extraction,[19] (2) increases in the sequence of membranes: Celgard 2400, Celgard 4410 < Celgard 4510 < Celgard 2500 and the rise of flux between Celgard 2400 and 2500 is higher than the ratio of their porosity, (3) is proportional to the initial Ag concentration, (4) is, over a wide range, independent of the stripping solution volume, (5) is selective towards Cu(II), Zn and Pb ions in 10-fold higher concentrations but (6) is diminished in their presence.

The highest observed concentration gradient between receiving and exhausted source phase was 1000, and the best enrichment factor equaled 140. The membrane with podand in *m*-chlorotoluene is stable for *ca.* 4 days.

(*Received* 3 *June* 1991. *Revised* 2 *December* 1991. *Accepted* 4 *December* 1991)

Summary—Microdialysis probes have been tested to evaluate the influence of flow-rate, probe dimensions and temperature when used as sampling systems inserted subcutaneously for *in vivo* monitoring of glucose. The probe was coupled with a glucose biosensor obtained from a thin layer electrochemical cell generally used as detector for liquid chromatography. Glucose oxidase was immobilized on a nylon net membrane and it was placed over an acetate cellulose membrane into the cell in contact with the platinum anode.

Microdialysis is a new sampling technique for *in vivo* analysis and continuous monitoring.[1–3] The technique has been mainly developed for measurement of neurotransmitters in the brain and coupled to liquid chromatography to identify specific compounds.[4–6]

The *in vivo* continuous measurement of glucose is a challenge for developing a wearable artificial pancreas.

Needle shaped glucose biosensors have been developed for *in vivo* analysis and have been inserted subcutaneously or in the bloodstream of anaesthetized animals. The technique has been developed in a few laboratories[7–13] and several problems have arisen.

The production of useful biosensors is low (only 20–50% of sensors produced are useful); the biosensors have only been inserted in anaesthetized animals because any movement affects the output signal; the biosensors should be sterilized which impairs the enzyme activity; there is a marked variation in the sensitivity when biosensors are implanted *in vivo*;[8–10] this can only be controlled with an *in vivo* calibration of the device, which can only be done indirectly.[12]

There is also a potential health hazard. To leave a needle in the human body is considered a low risk if the site is subcutaneous, medium risk if intraperitoneal and high risk if it is placed directly into the blood stream.

However diabetics need a continuous glucose control and the dream of a closed loop artificial pancreas where the continuous output of a glucose biosensor drives the insulin infusion into a diabetic patient is a challenge for many research teams.

In this paper we show a complete apparatus suitable for *in vivo* glucose monitoring obtained by coupling a microdialysis probe and a glucose biosensor in a thin layer flow cell configuration. The system could be easily miniaturized for the development of a wearable glucose monitor.

The principle is outlined as follows: a physiological buffer is pumped at constant flow (10–30 μl/min) into a thin dialysis fiber with diameter of 200 μm (the microdialysis probe) placed subcutaneously (or in the bloodstream); the buffer equilibrates with the subcutaneous liquid (or with blood), then flows into a thin layer cell provided with a glucose biosensor which continuously monitors the glucose value. As microdialysis probe we compared *in vitro* a commercial probe and a single sterilized thin dialysis hollow fiber.

The system has several advantages over the insertion of a bioprobe-needle into the body; the sensitivity of the biosensor can be checked regularly, the hollow fiber used as microdialysis probe can be easily sterilized, it can be inserted

*Author for correspondence.

in animals and humans while awake; the overall process of the *in vivo* implantation can be controlled much more and processes such as inflammation and clotting (when inserted in bloodstream) can easily be followed and eliminated.

Preliminary experiments with a hollow fiber sterilized on animals and humans are discussed.

EXPERIMENTAL

Materials and apparatus

Glucose oxidase (GOD, E.C.1.1.3.4, from Aspergillus Niger, type VII, 132,000 U/g) was obtained from Sigma.

A GOD immobilized-nylon net membrane was prepared as previously reported.[14]

The glucose solution was prepared with β-$D(+)$glucose from Farmitalia Carlo Erba (Milano, Italy), allowed to equilibrate overnight and suitably diluted.

The buffer solution, Dulbecco's physiological buffer (pH = 7.4), was prepared in doubly distilled water.

All chemicals were analytical grade.

Cellulose acetate (53% acetyl) and polyvinyl acetate of high molecular weight were obtained from Farmitalia Carlo Erba (Milano, Italy). For casting the cellulose membrane a precision gauge tool (from Precision Gage and Tool Co., Dayton, OH, U.S.A.) was used. This membrane, with about 100 Dalton MWCO, was prepared as previously reported.[15-17]

Peristaltic pump, Minipuls 3, for flow analysis was from Gilson (France). Thermostat model F3 was from Haake.

Rheodyne valve (U.S.A.) Model 7125 was used as injection valve.

A complete thin-layer transducer cell for LCEC (liquid chromatography/electrochemistry) was obtained from BAS (BioAnalytical Systems, IN, U.S.A.). A LC-4B Amperometric detector from BAS was connected to an Amel Model 868 recorder.

The CMA/10 Microdialysis probe (fitted with a polycarbonate–polyether co-polymeric membrane, i.d. 400 μm, wall thickness 60 μm and molecular cut-off approximately 20,000 Dalton) was obtained from Carnegie Medicine (Stockholm, Sweden).

The hollow fiber Filtral 12 AN 69 HF polyacrylonitril sodium metalil sulphonate (i.d. 200 μm and molecular cut-off approximately 35,000 Daltons) was obtained from Hospal Industie (Meyziev, France).

Silicone tubing (i.d. 0.300 mm, o.d. 0.630 mm, wall thickness 0.165 mm) from A-M Systems and Teflon tubing (i.d. 0.330 mm, o.d. 0.482 mm, wall thickness 0.152 mm) from Firie (Genova, Italy) were used to connect hollow fibers to the flow-system.

Assembling of the sensor

A complete thin-layer transducer cell includes three separate electrodes: the working electrode (platinum disk with diameter of 3 mm), the reference (Ag/AgCl) and the auxiliary electrode (stainless steel). Figure 1 shows the assembly of the sensor.

A thin (20 μm) membrane of cellulose acetate was stretched over the entire plastic block where the electrode area was located; it removes the electrochemical interferences (uric acid, ascorbate, *etc.*) with its nominal MWCO of 100;[15-17] this figure is obtained as a rough number and mainly means that ascorbic and uric acids do not reach the electrode surface while hydrogen peroxide passes through easily. A dialysis membrane with a nominal claimed MWCO of 100

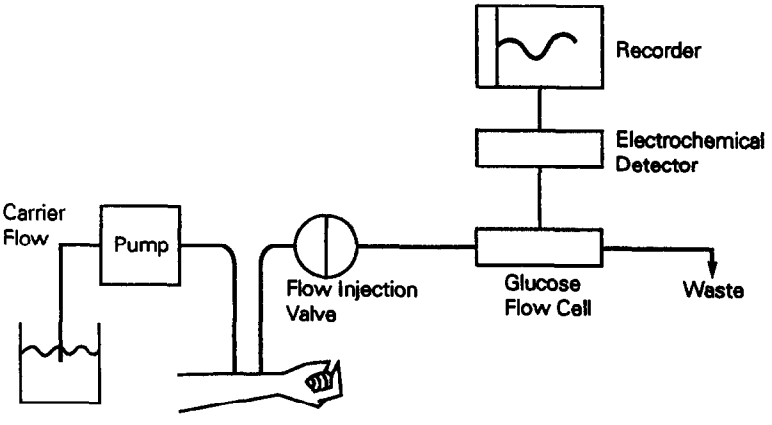

Fig. 1. Schematic diagram of the thin layer cell.

recently became commercially available from Spectrum Med. Ind. (CA, U.S.A.). Unfortunately this last membrane cannot be used, because it shows high interferences from uric and ascorbic acids, common substances in blood and subcutaneous liquid.

A nylon net (thickness 100 μm, with diameter of 6 mm) with the immobilized glucose oxidase enzyme was placed over the electrode area. Then a gasket is put on the half cell before assembling the cell. The upper half of the cell contains two ports to insert the inlet and outlet tubing.

The microdialysis probe is connected to the inlet tubing, the outlet is connected to the reference electrode and then to waste.

Procedures

The flow system for *in vitro* experiments is shown in Fig. 2. The peristaltic pump drives carrier solution through the microdialysis probe immersed in glucose standard solutions at constant rate. A steady-state current is obtained.

The standard solutions where the microdialysis probe was immersed were manually changed.

The CMA/10 probe was used as received. The hollow fiber probe (200 μm) was connected to the Teflon tubes of the flow system. *In vivo* experiments have been performed only with a sterilized hollow fiber.

To place the microdialysis hollow fiber subcutaneously a sterilized needle was inserted transcutaneously through the skin for about one centimeter and the needle tip was pulled out. Then the sterilized fiber was inserted from the needle tip and the needle taken out leaving the hollow fiber under the skin. The fiber was connected to Teflon tubes and fixed with epoxy glue.

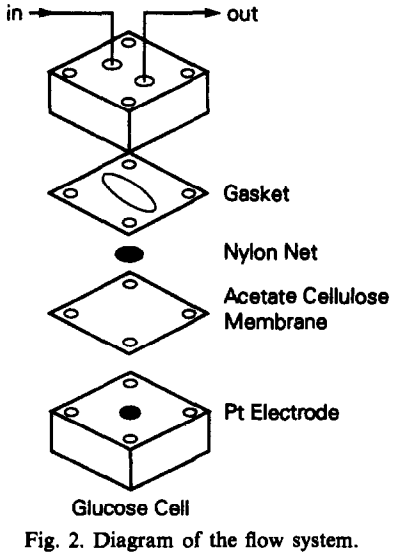

Fig. 2. Diagram of the flow system.

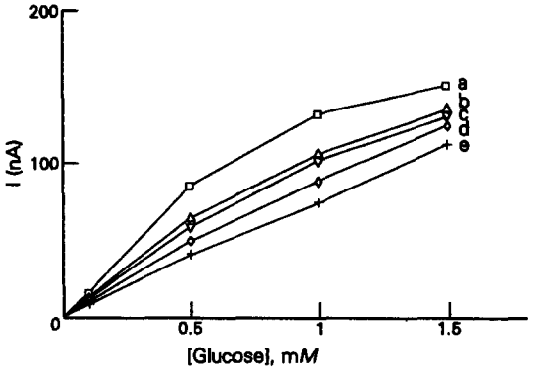

Fig. 3. Calibration curves of glucose biosensor at different flow-rates (without the microdialysis probe). (a) = 10 μl/min, (b) = 20 μl/min, (c) = 30 μl/min, (d) = 40 μl/min, (e) = 50 μl/min. Room temperature.

For checking variations in sensitivity during the experiments, a flow injection system was used. A Rheodyne injection valve with a 20-μl sample loop was introduced into the flow system just after the microdialysis probe. A glucose standard buffered solution filled the loop of the injection valve and flowed through the glucose biosensor.

Then we obtained a current profile similar to a peak. The dispersion coefficient of the apparatus was 1.1.

These peaks demonstrate the high reproducibility in "*in vitro*" experiments.

RESULTS AND DISCUSSION

In vitro *experiments*

Typical calibration curves for the glucose flow cell, without the microdialysis probe, at different flow-rates are shown in Fig. 3.

When the flow-rate is increased the linear range of the calibration curve increases and the current values decrease. This is a common experience with a glucose biosensor with hydrogen peroxide detection in a flow cell. The logical explanation is that hydrogen peroxide reaching the electrode surface decreases by increasing the flow-rate. This is due partly to a lower conversion of glucose and partly to a lower fraction of hydrogen peroxide reaching the electrode surface. Calibration curves obtained with hydrogen peroxide standards show a parallel variation with the flow-rate.

The non-linearity of the calibration curve at a concentration higher than about 1mM is

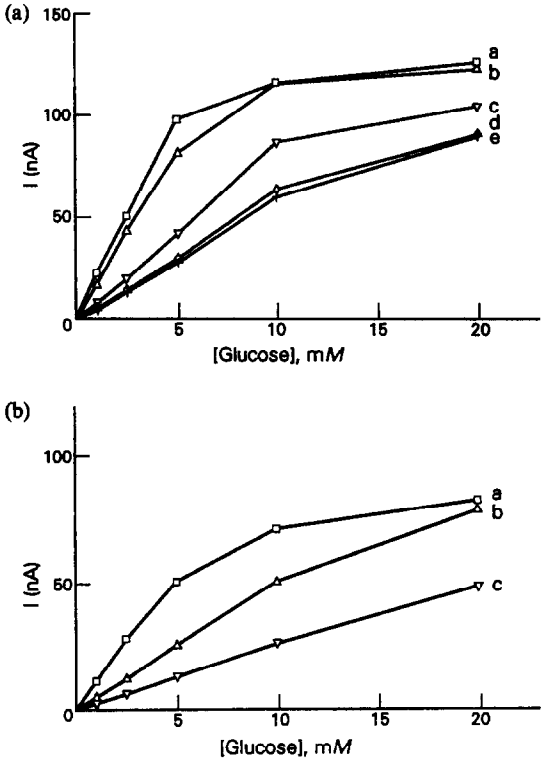

Fig. 4. Calibration curves of glucose with the microdialysis probe at different flow-rates. (a) CMA/10, length = 10 mm, $T = 37°$; (a) = 10 μl/min, (b) = 20 μl/min, (c) = 30 μl/min, (d) = 40 μl/min, (e) = 50 μl/min; (b) Hollow fiber, length = 20 mm, $T = 37°$; (a) = 10 μl/min, (b) = 30 μl/min, (c) = 50 μl/min.

mainly due to depletion of molecular oxygen, a cofactor in the glucose oxidase reaction.[18]

In Fig. 4(a) and 4(b) calibration curves are shown where the glucose biosensor is coupled with a microdialysis probe (CMA/10 and hollow fiber).

The upper limit of concentration attained in this case (20mM) is much higher and due to the limited diffusion of glucose through the microdialysis probe and reaching the glucose biosensor.

Besides this effect we observe a flow-rate influence as in Fig. 3, but in this case the diffusion rate through the microdialysis probe also affects the results.

It is interesting to notice how the two microdialysis probes show similar results in spite of the different materials and the different geometries (Carnegie length 10 mm and diameter of 400 μm, hollow fiber length 20 mm and diameter of 200 μm).

In Fig. 5 the length of the microdialysis probe (hollow fiber) was varied and the linearity range and the current values are greatly affected by this parameter. This is shown for the hollow fiber microdialysis probe, but similar results were obtained with the commercial probe.

To obtain a linear calibration curve up to 20mM (the high value for glucose in blood for diabetes) we chose a hollow fiber one centimeter long and a flow-rate of 30 μl/min. This flow is feasible for a wearable instrument, since it corresponds to less than 50 ml/day which can be stored easily.

In Fig. 6 dynamic curves are reported for the hollow fiber. The system, microdialysis and biosensor, shows such a fast response and recovery that it was difficult to forecast; only a few seconds are necessary to reach a stable current value corresponding to a defined concentration. The reproducibility of the current is very high, it was evaluated in several experiments as less than 5% over 10 consecutive assays.

Delay time was greatly reduced by using narrow bore tubing (Teflon tube 0.3 mm) between the microdialysis probe and the glucose biosensor (under 50 μl of volume).

The influence of temperature on the dialysis probe was evaluated. At 37° the current is about 30% higher and the linearity range is slightly reduced; this reflects the variation of the diffusion coefficient of the glucose through the microdialysis probe.

The stability of the signal with a hollow fiber during a ten-hour period was followed *in vitro*. Fluctuations smaller than 15% were generally obtained due to random variations in the experimental parameters.

Glucose biosensor is known to be stable during such interval of time, so it is not the primary source of fluctuation.

In vivo *experiments*

Fast response and recovery, simple apparatus and procedures have allowed the proposed

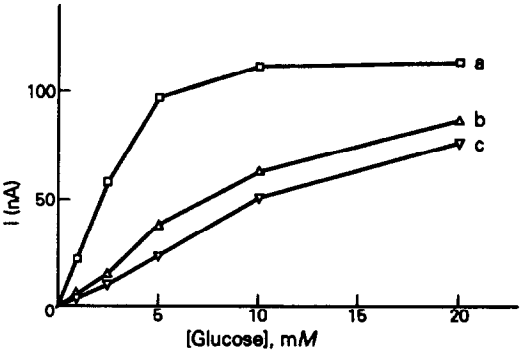

Fig. 5. Calibration curves of glucose with different membrane length microdialysis probes. Flow-rate = 30 μl/min, $T = 37°$, (a) = 40 mm, (b) = 20 mm, (c) = 10 mm.

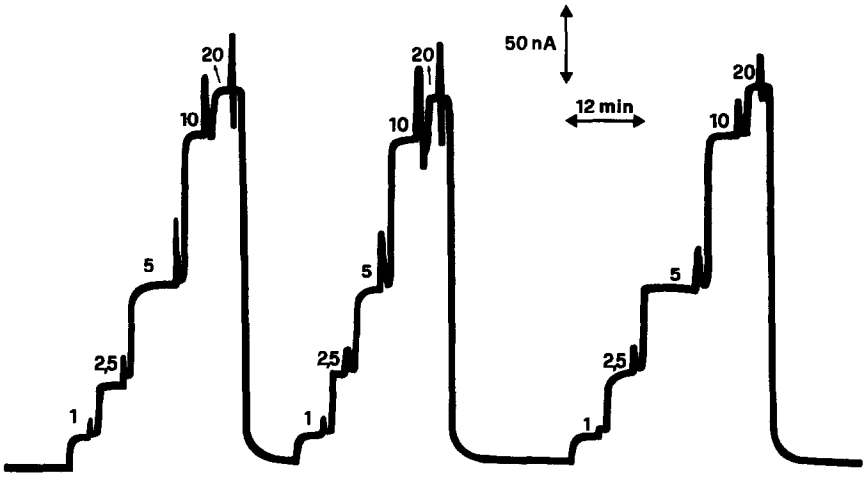

Fig. 6. Response time of the hollow fiber as microdialysis probe. Flow-rate = 30 μl/min, room temperature, membrane length = 20 mm.

method to be directly applied in *in vivo* experiments.

The fiber can be sterilized, it is rugged and easily handled and the material is reported to be highly biocompatible.[19]

Figure 7(a) shows preliminary results obtained monitoring glucose by sampling with a hollow fiber inserted subcutaneously in a rabbit [Fig. 7(a)] and in a human volunteer [Fig. 7(b)] during a glucose load experiment.

The stability of the signal before the glucose load shows how the removal of glucose by the probe does not disturb the physiological process. After a glucose load the current increases and then decreases following normal behavior. The variation of sensitivity was checked

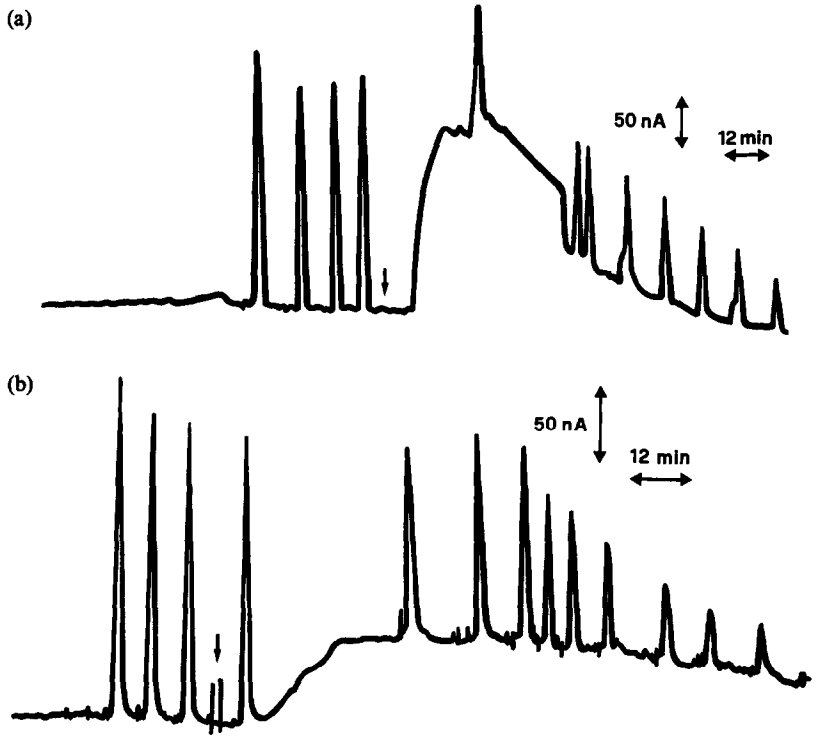

Fig. 7. *In vivo* experiments during glucose loading. Hollow fiber as microdialysis probe, flow-rate = 30 μl/min, membrane length = 10 mm; (a) rabbit weight 2.5 kg, fasting, unanesthetized (intravenous glucose loading = 3.5 g glucose). (b) On a human volunteer (oral loading = 70 g). The arrow shows the glucose administration. The peaks show the monitoring of sensitivity variation. The glucose standard solution was 1m*M*.

regularly by the flow injection apparatus described. A sharp decrease of the sensitivity is evident after about two hours in both experiments [Fig. 7(a) and (b)]. This effect was not previously detected.[20] If the microdialysis probe was disconnected and buffer as carrier was pumped through the cell, the glucose biosensor recovered the initial sensitivity in 15–30 min. We think an unknown substance is produced in the physiological liquid, probably in response to the fiber introduction. We believe it is released as a consequence of an inflammatory reaction and is able to diffuse through the hollow fiber and interfere with the enzyme or the electrode reaction.

This sensitivity variation can explain why the attempts to measure glucose *in vivo* by directly inserting needle glucose biosensors in blood or inserting subcutaneously fail more or less rapidly and it may explain the variations in sensitivity (slope of response *i vs.* concentration of glucose) reported in literature.[8–10] It is the first time that this phenomenon was followed during an *in vivo* experiment.

The problem of tissue reaction was reported recently in a few cases[10] to explain the high failure of subcutaneous glucose monitoring.

We are trying now to identify this compound and to use a suitable microdialysis fiber to overcome this problem.

However we did not notice this effect when the probe was inserted into the bloodstream; in this case normal behaviour was obtained and the output was related to the glucose concentration. Other experiments are now planned with clinicians for inserting the probes *in vivo* to obtain more data on this interesting effect.

CONCLUSIONS

The system shown is suitable for measuring glucose *in vivo* by coupling microdialysis with a glucose biosensor in the form of a thin layer cell. The system follows rapidly the variations of glucose concentration at the site where the "probe" is inserted. Preliminary results obtained placing the probe subcutaneously revealed the formation of an interferent species for the glucose oxidase enzyme or for the electrode. Such species are considered the result of an inflammatory reaction and it can explain the failure of experiments reported so far with the subcutaneous insertion of needle glucose biosensors.[8–10]

However, the same effect was not detected when the probe was placed in the bloodstream. We can explain it with the vascularized nature of the bloodstream but more *in vivo* experiments will clarify the nature of this effect.

RELIABLE AND FACILE METHOD FOR PREPARATION OF SOLVENTLESS BILAYER LIPID MEMBRANES FOR ELECTROANALYTICAL INVESTIGATIONS

DIMITRIOS P. NIKOLELIS* and ULRICH J. KRULL†

Chemical Sensors Group, Department of Chemistry, Erindale Campus, University of Toronto, 3359 Mississauga Road North, Mississauga, Ontario, Canada L5L 1C6

(*Received* 25 *October* 1991. *Revised* 2 *December* 1991. *Accepted* 4 *December* 1991)

Summary—Bilayer lipid membranes continue to be of interest as elements for development and investigation of chemically-modified electrodes and biosensors, yet also continue to be difficult to prepare and replicate with precision. A simplified and reliable technique for the rapid formation of solventless bilayer lipid membranes is described, and the method has been shown to produce membranes which nominally vary by only 5–10% with respect to ion conductivity. Methods for rapid physical and chemical characterization of these membranes for establishment of reproducibility and quality are given.

Perturbation of the structure and electrostatic fields of artificial bilayer lipid membranes (BLMs) caused by a selective binding event of a "receptor" with a ligand (analyte) can be monitored electrochemically as changes in transmembrane conductivity. This strategy for the development of chemically-selective sensors has as the main advantage an increased sensitivity which is derived from an intrinsic amplification process.[1] Other favorable features of these membranes are fast response times, small size, a wide range of concentration level determination, flexibility for application of a wide variety of selective "receptors", and reversibility for continuous signal generation.

The perpetual problem faced by the sensor specialists has been the difficulty of preparation of BLMs with a lifetime that is sufficient for completion of electrochemical experiments. Planar BLMs are formed by the "brush" technique and the folding method. The former systems which retain the hydrocarbon solvent are referred to as "black lipid films" and the latter as "solventless" or "solvent-free" bilayers because they do not contain significant quantities of residual solvent. Retention of solvent reduces precision in electroanalytical experimentation and makes the use of solventless BLMs preferable. This technical note describes a method for the formation of solventless BLMs, which in our experience can provide BLMs suitable for experimentation in a period of minutes with a 90% success rate. Methods for physicochemical characterization of these membranes are also presented and a comparison of electrochemical properties with black lipid films and natural membranes are made.

EXPERIMENTAL

Reagents and apparatus

A number of different lipids can be used for the formation of stable BLMs.[2,3] The common feature among these lipids is that they usually have a head group of high polarity and two hydrophobic acyl chains. Egg phosphatidylcholine (PC) is commonly employed to form BLMs, and stearic acid, dipalmitoylphosphatidic acid (DPPA) and dipalmitoylphosphatidylserine (DPPS) can be used in a mixture with egg PC to prepare negatively charged membranes. Control of ion transport across BLMs can be made by chemical modification of interfacial regions between phase domains[4] or by adjustment of the amount of the negatively charged lipid in a membrane.[5]

Planar BLMs separate two aqueous phases and each side of the BLM must be in contact with an electrolyte solution (*e.g.*, 0.1*M* potassium chloride). Such a solution provides the inorganic ions desired for electrochemical studies and assists electrostatic stabilization of the structure of a membrane.

†Author for correspondence.

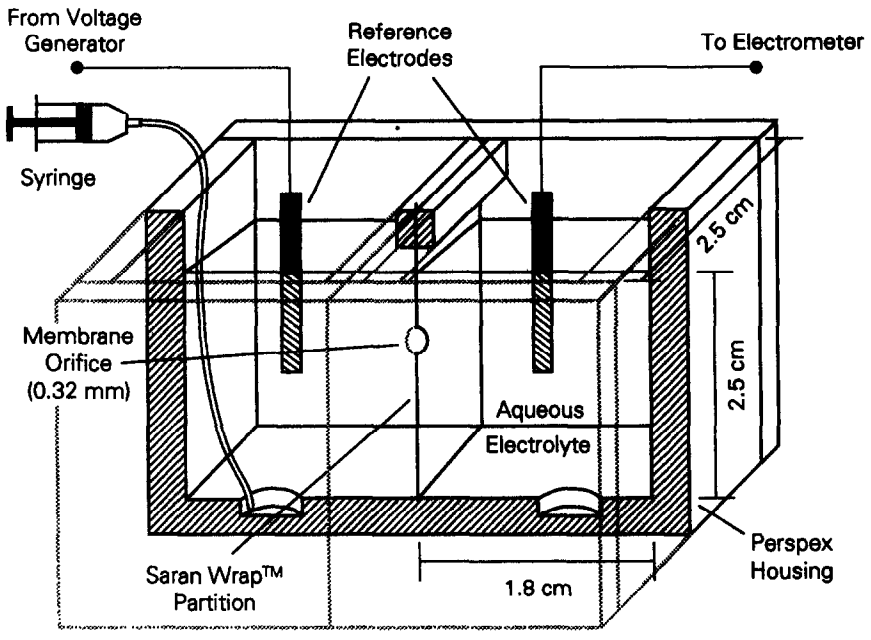

Fig. 1. Basic electrochemical cell used for the study of BLM. Gentle stirring (2.5 rpsec) can be done by a magnetic flea in the small well(s) (0.9 cm diameter) at the bottom of each chamber.

Simple apparatus for the formation of membranes consists of two chambers separated by a thin plastic sheet. Before the chambers are used, they should be hydrated and rinsed several times with purified water. The plastic sheet contains a small aperture in which the membrane is formed (Fig. 1). We have found that Saran Wrap® about 10 μm thick provides excellent results, and that a thicker partition results in membrane instability (although partitions of 25-μm thickness have been reported in the literature[2]). A paper cutter is used to shape the Saran Wrap® partition to the desired size, and care should be exercised to avoid contamination of the plastic partition with residue from one's fingers. The plastic sheet should extend beyond the limits of the edges of the chambers so that no ion current leakage can occur around this barrier. For the same reason the chambers should be clamped tightly together, but must not pinch or stretch the plastic sheet at points where the corners of the chambers meet. The aperture in the film can be made by punching with a perforation tool similar to the one described previously[6] (Fig. 2). The size of the aperture is critical for preparation of stable membranes. The protocol required for the formation of solvent-free bilayers is that such membranes should not have areas larger than 0.1 mm^2 otherwise they are unstable.[7] We have found that circular apertures of 0.32 mm diameter give BLMs with excellent stability over 4 hr, with lifetimes extending up to 24 hr, while BLMs formed in holes with diameters of about 0.6 mm last only about 1–5 min. The hole should be inspected visually with a microscope to measure the diameter and to ensure that the aperture is circular, and free of edge defects and irregularities.

A simple circuit that is commonly used for the measurement of the ion current through a BLM consists of a voltage reference source (VRS) and an electrometer with an input resistance much higher ($>10^{14}$ Ω) than the membrane resistance ($\sim 10^{10}$ Ω). An external DC potential of about 25 mV is applied across the BLM between a pair of reference electrodes (*e.g.*, Ag/AgCl or calomel) from the power supply to provide the driving force for ion transport across the membrane. The applied DC potential is small to restrict any substantial electrochemical reaction from occurring in the electrodes and also to avoid electroconstriction and membrane bulging. The electrochemical cell and electrometer should be shielded from external electromagnetic interference in a grounded copper screen Faraday cage.

Procedures

The formation of BLMs by the folding method was introduced by Takagi[8] and refined by Montal and Mueller.[9] The technique was based on the transfer of two opposing

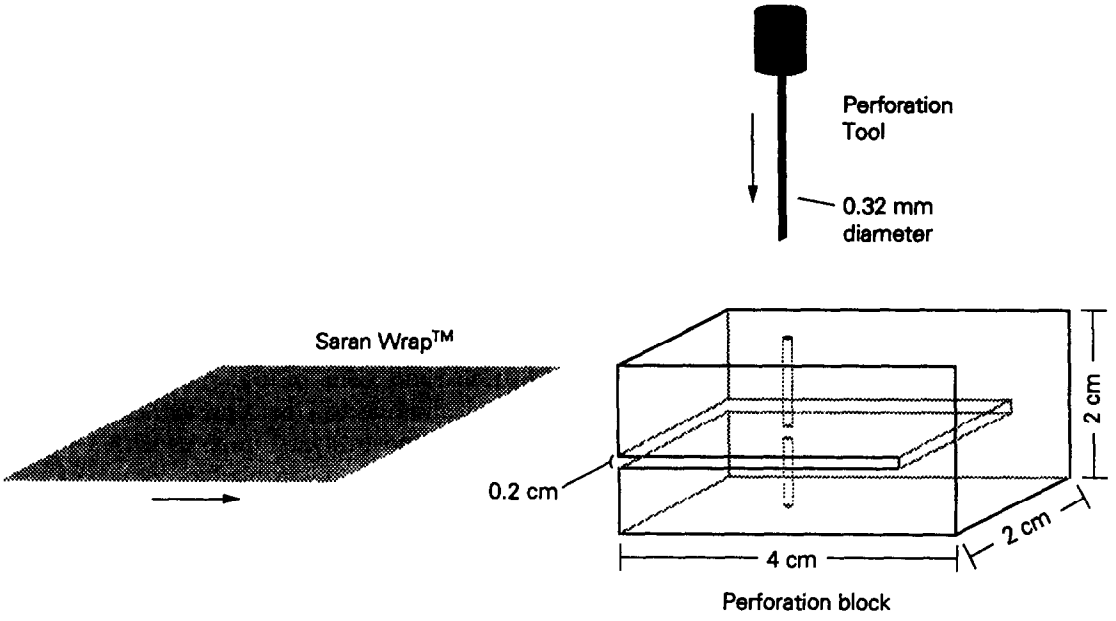

Fig. 2. The perforation tool used to punch an aperture in the Saran Wrap® sheet in which the bilayer is formed. Two stainless-steel plates were fixed at a common joint, and a hole (0.32 mm) was drilled through the plates. The punch was a steel rod which was sharpened. The Saran Wrap® sheet was clamped between the plates and a firm and fast movement was used to push the punch through the film so that the plastic did not warp or pinch.

monolayers at an air–water interface of a Teflon trough into a Teflon sheet by using the Langmuir–Blodgett dip casting technique. A simplified version of this method was later described for the formation of solventless bilayers.[2,10] Two Teflon chambers with a volume of about 2 ml each, an air–water interface of about 1 cm^2 each, and separated by a plastic septum were used instead of the Langmuir–Blodgett trough. The amount of the lipid used was in excess of the quantity to form a monolayer (5–10 μl of 0.1–1% w/v of lipid solution in *n*-hexane in each compartment), but the multilayer that was formed thinned to a bilayer structure. We have found that polymethylmethacrylate blocks with a volume of about 10 ml and an air–water interface of about 3 cm^2 for each cell can be used instead of the Teflon chambers. The lipid concentration can be less than that described previously to form stable membranes (0.02% w/v) with a substantially reduced torus volume.

For the formation of a membrane, the lipid solution (5–10 μl) is added dropwise to the water surface in one cell compartment. The drops are applied to the water surface near the partition and surface impurities are swept away from the partition as the lipid solution spreads at the air–water interface. Over a period of a few seconds the electrolyte level in one solution compartment is manually adjusted and is brought below the aperture level and then raised again with a 10-ml disposable syringe (with plastic tubing at the end). An amount of about

Table 1. Comparison of electrochemical properties of artificial BLMs and natural cell membranes

Property	Black lipid films	Solventless BLMs	Cell membranes

Membrane specific capacity ($\mu F/cm^{-2}$)	0.45 ± 0.05	0.9 ± 0.1	1.0 ± 0.2
Thickness of hydrocarbon region obtained from			
(a) Capacitance data	42 Å	22 Å	16–24 Å
(b) X-ray data	—	29 Å	28–35 Å
Increase of membrane conductance caused by the addition of 0.1 μM levels of Gramicidin	10^3	10^3	$<10^3$

2 ml of electrolyte solution is taken out from the cell compartment with the syringe. A flow-rate of about 3 ml/sec is used when the electrolyte solution is injected back to the chamber.

The formation of the membrane can be checked by monitoring the ion current through the aperture. In the unusual event that the first attempt for formation of a membrane is not successful, then an additional 5 to 10 μl of *n*-hexane can be spread across the air–water interface and the procedure for membrane formation can be repeated. The formation of a membrane takes only a few seconds, and many membranes can be formed by this technique in a short period of time, although each membrane requires about 5–10 min to fully stabilize before quantitative measurements can begin. This arrangement for membrane formation provides stable BLMs which last for periods of more than 4 hr, and in most cases the formation of BLMs is immediately successful. Pretreatment of the aperture with petroleum jelly or squalene is unnecessary and does not facilitate the formation of BLMs.[10]

The electrical capacitance of a membrane can be measured by applying a voltage step of 25 mV through the reference electrodes across the membrane. The time constant, τ, of current versus time is measured and the membrane capacitance, C_m, is calculated from the equation:

$$C_m = \tau J_0 / V \qquad (1)$$

where J_0 is the current extrapolated at zero time, and V the applied voltage. The capacitance of a membrane can also be measured directly with a lock-in amplifier by applying a sinusoidal waveform to the reference electrodes and observing the out-of-phase component of charge flow.

RESULTS AND DISCUSSION

Any BLMs used for electroanalytical experimentation must first be characterized to demonstrate the existence of the BLM structure, and to establish reproducibility. Specific capacitance is often used as the primary criterion mainly for characterization of membranes. In fact a few studies have been reported that involve capacitance measurements to detect selective binding interactions.[11] The specific capacitance of these solventless BLMs is almost twice the magnitude observed for black lipid films (0.9 ± 0.1 $\mu F/cm^2$) and approaches the corresponding value for natural cell membranes (Table 1). The values of specific capacitance can be used to estimate the hydrocarbon thickness, d, of a membrane using the equation:

$$C_m = \epsilon_0 \epsilon / d \qquad (2)$$

(ϵ_0, the permittivity of free space is 8.85×10^{-2} F/cm^2, and ϵ the dielectric constant of the hydrocarbon core of the membrane is 2.1). The membrane can be represented as a large capacitor (polar layers) in series with a smaller capacitor (the hydrophobic core of the membrane), and d is therefore almost equal to the thickness of the hydrocarbon layer of the membrane. The values of specific capacitance and apparent thickness for solvent-free membranes as compared with black lipid films indicate a decrease of the membrane thickness for the hydrocarbon region of the solventless BLMs and exclusion of the hydrocarbon solvent. Using PC as a lipid the apparent thickness for solventless BLMs was found to be about 25 Å.[4]

The specific resistance of the solventless BLMs and the black lipid films is similar ($\sim 10^8$ Ω/cm^2) and cannot be used to differentiate between the two structures. The membrane resistance can be calculated from the inverse of the slope of current–voltage recordings obtained when applying a linear ramp of voltage with time. The sweep-rate should be such that there is no substantial contribution of the capacitive current. Resistance can also be calculated from the steady-state values of current when applying voltage increments of about 20 mV. The linearity between current and voltage extends to about 400 mV (dielectric breakdown of these membranes).

Chemical characterization of the bimolecular thickness of solventless BLMs can be derived from addition of gramicidin (A, B or C) at concentration levels of about 0.1μM. This peptide transports cations through the membrane by formation of ion-channels and the conductance increases many fold as shown in Table 1. Gramicidin does not induce conductance changes if the membrane is thicker than one bilayer.[9]

CONSTRUCTION AND PERFORMANCE OF PROBE-TYPE CELLS CONNECTED IN A SERIES ASSEMBLY

MA WANLI

Research Institute for Material Protection, Wuhan Institute of Technology, Wuhan 430070, People's Republic of China

(*Received* 5 *February* 1991. *Revised* 24 *July* 1991. *Accepted* 26 *July* 1991)

Summary—Construction of a newly improved cells connected in series (CCS) assembly is introduced. The random error model presented by previous investigators has been revised. The assembly was so designed that it can be used in conventional ion-selective electrode measurements, but resulted in multiplied response thus enhancing the precision and accuracy of potentiometric analyses.

The CCS (cells connected in series) assemblies, proposed by Stepak[1,2] and Suzuki,[3] show promise in significantly enhancing the precision and accuracy of potentiometric analyses. Yet, their practical application is limited owing to the fact that they require rather large volumes of sample solution and are inconvenient to use. Although a microsized container may be used for each cell, filling each container with sample still remains a time-consuming and troublesome process. The resistance of the electrode membrane is far greater than that of the sample solution, so any attempt to test with all indicating and reference electrodes inserted in one beaker will prove futile. Therefore, separate cells must be employed. To make further improvements, other routes were tried. The construction of a CCS assembly which can be used like a conventional single electrode is described in this paper.

EXPERIMENTAL

Reagents

Demineralized doubly distilled water and A. R. grade chemicals were used throughout unless otherwise stated. Quinine hydrochloride was Chinese pharmacopoeia quality (>99%). Mono- and di-protonated quinine–tetraphenylborate (TPB) ion-pair complexes were prepared by mixing quinine hydrochloride and tetraphenylborate sodium solutions at pH = 2.0 and 6.0, respectively, in stoichiometric ratios.

Construction of the CCS assembly

The assembly mold was constructed as shown in Fig. 1.

The bottom cylinder, on which five square holes were uniformly bored, was actually made of two 5-mm diameter perspex plates. In each hole, a pair of indicating and reference electrodes were oppositely arranged to construct an independent unit. Together with a ready made perspex rod, the three parts were affixed with 10% perspex–acetone solution. The mold surface was coated with a thin layer of wax (melting point 90°) with an area left for the heads of the indicating and reference electrodes. The usual electrode membranes were then prepared separately by applying electroactive material dropwise[4] onto each silver disc. The membrane contained 30% (w/w) poly(vinyl chloride) (PVC) and 70% dibutyl-*o*-phthalate (DOP, in which about 5m*M* mono- or di-protonated quinine-TPB ion-pair complex was dissolved). A 0.1 potassium chloride solution was used for filling all Ag/AgCl reference electrodes; the loss of solution from the exits of their conduits can be compensated with an injector. When in use, the outlet wires of the required number of cells were connected in series. In case any unit had a defect, it was left out and a new one used instead. When the electrode membranes needed to be restored, the old membranes were scraped off and new ones were prepared by the same procedure.

EMF measurement

The sensing part of the assembly was immersed in the sample solution with stirring. After 20 sec, it was lifted above the water surface, and the samples in the different cells were separated due to the hydrophobicity of the wax. The output potential was monitored with

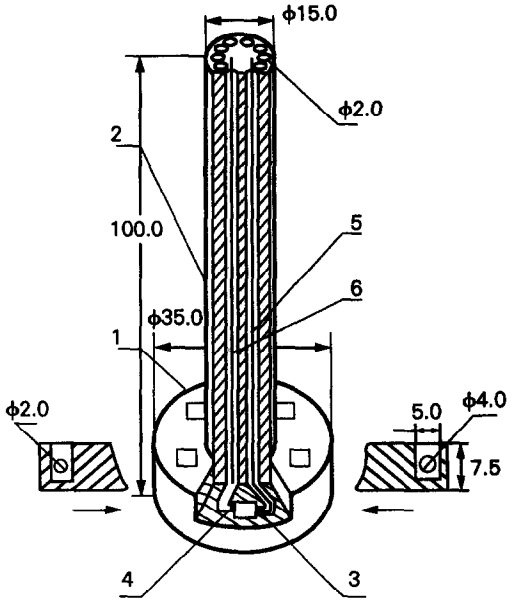

Fig. 1. The CCS assembly mold (units in mm). 1—perspex plate; 2—perspex rod; 3—silver disc, on which the electrode membrane was supported; 4—porous material, obtained from damaged Model 217 saturated calomel electrode (Shanghai, China); 5—shielded copper wire, bent to contact the silver disc; 6—Ag/AgCl wire, 0.5 mm in diameter.

an Orion 980 Digital Ion Analyser. After testing, the sample solutions can be easily cleaned by inserting a piece of rolled-up filter paper to each cell. The assembly was then ready for the next sample. The testing process of the proposed CCS assembly, as described, is almost the same as that of a conventional single electrode, except the recording of the potential was performed after the assembly had been lifted out of the solution. The assembly can also be applied for microsample testing. The sample could be added with a dropper; no more than two drops were needed for each cell. Calibration graphs for the assembly were obtained for

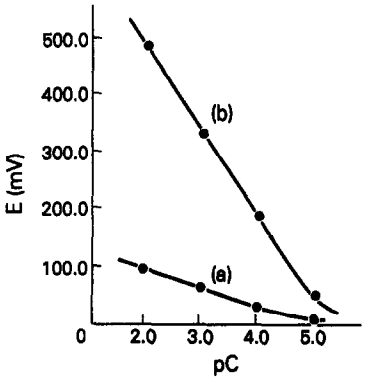

Fig. 2. Calibration curves for the CCS assembly with (a) $n = 1$ and (b) $n = 5$ at pH = 2.0.

Table 1. Experimental results: response slope (S_n), membrane resistance (R_n) and detection limit (pC_{lim})

pH	n	1	2	3	4	5
2.0	S_n	29.3	58.0	88.2	115.4	146.2
	R_n	15.1	31.6	44.5	62.0	78.3

	pC_{lim}	4.3	4.3	4.5	4.4	

ionic strength $I = 0.5$, pH = 2.0 and 6.0 buffered[5] solutions containing quinine in concentrations ranging from 10^{-5} to $10^{-2}M$, respectively.

RESULTS AND DISCUSSION

Performance of the CCS assembly

The calibration curves obtained with $n = 1$ and 5 at pH = 2.0 are demonstrated in Fig. 2, where n is the number of cells. The response slope, membrane resistance and detection limit are summarized in Table 1. The proposed CCS assembly resulted in an increased response slope, indicating that the output signal for a given concentration variation (sensitivity) can be amplified. The detection limit and selectivity coefficient (Table 2) remained the same as for the conventional electrode. When as many as five cells were connected in series, the multiplication of membrane resistance had no obvious influence on electrode behaviour.

Random error model

The measurement of potential is the major source of random error in potentiometry. Each connected unit contributes its potential (E_i) independently of the whole circuit (E), and each unit is also an independent source of random error. If one assumes that E_i is normally distributed around its true value (μ_i) with variance

Table 2. Selectivity coefficients obtained by both the CCS assembly ($n = 4$) and conventional PVC membrane electrode ($n = 1$). pH = 6.0, mixed solution method

pH	n	1	2	3	4	5
	$S_E^{(n)}$	0.95	1.21	1.52	1.56	1.73
2.0	$S_{pC}^{(n)} \times 10^2$	1.91	1.22	1.01	0.79	0.69
	F	1.00	0.41	0.28	0.17	0.13
	$S_E^{(n)}$	1.06	1.50	1.34	1.89	
6.0	$S_{pC}^{(n)} \times 10^2$	1.66	1.61	0.70	0.67	
	F	1.00	0.49	0.18	0.16	

*$F_{(0.025)9,9} = 0.248$[6].
$S_E^{(n)}$—standard deviation of measured potential.
$S_{pC}^{(n)}$—standard deviation of pC determination.
F—F-analysis, comparing the precisions of pC determination results obtained by the CCS assembly with $n = 1$ and $n = n$, respectively.

(d_i), $N(\mu_i, d_i)$, then upon the convolution principle of normal distribution,[6]

$$E = \sum_{i=1}^{n} E_i = N\left[\sum_{i=1}^{n} \mu_i, \left(\sum_{i=1}^{n} d_i^2\right)^{1/2}\right] \quad (1)$$

For all units made under the same conditions, assume $d_1 = d_2 = \cdots = d_n$, then

$$\frac{S_E^{(n)}}{S_E^{(1)}} = \frac{\left(\sum_{i=1}^{n} d_i^2\right)^{1/2}}{d_i} = \sqrt{n} \quad (2)$$

The standard deviations of determination (S_x) and of the measured potential (S_E) are related by

$$\frac{S_x^{(1)}}{S_x^{(n)}} = n\frac{S_E^{(1)}}{S_E^{(n)}} \quad (3)$$

Comparing with equation (2) yields

$$\frac{S_x^{(1)}}{S_x^{(n)}} = \sqrt{n} \quad (4)$$

Note that the assumption made by Parczewski and Stepak,[2] that $S_E^{(n)}$ does not depend on n, is invalid.

For $S_E^{(n)}[=\sqrt{n}S_E^{(1)}] > S_E^{(1)}$, it was demonstrated experimentally that, unlike a conventional single electrode whose potential can usually stabilize to within 1.0 mV, the data fluctuated on the digital frame in a certain range (about 4 mV for $n = 5$ in our experiment). The potential finally recorded was the value which appeared most often, this usually occurred at the centre of the potential fluctuation range, and

Table 4. Deviation analysis for simulated samples ($N = 1000$)

n	1	2	3	4	5
$S_E^{(n)}$	1.00	1.42	1.73	1.96	2.23

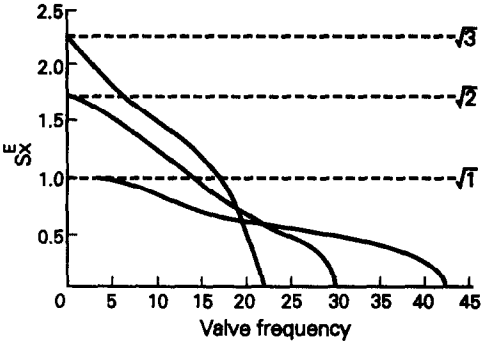

Fig. 3. Filtering tendencies for $n = 1$, 3 and 5.

is where the true value in a normal distribution exists. Therefore, a filtering process occurred when the data were recorded. With more cells connected in series, the resulting wider potential fluctuation range allowed easier estimation of the midpoint range (true value). The improved precision was actually better than when calculated with equation (4).

Model verifications

Experimental results. The experimental result obtained by Parczewski and Stepak[2] [$S_x^{(1)}/S_x^{(n)}$ approaches $\sqrt{n}$] has already proved the validity of equation (4). It largely originates from the cumulative effect of random errors and not by the appearance of new error sources.

Here we offer another example for further verification. Summarized in Table 3 is the deviation analysis result for replicate determinations on the sample pC = 3.0 at pH = 2.0 and 6.0, respectively. All the tested ratios of $S_E^{(n)}$ to $S_E^{(1)}$ are found to be approximately equal to or less than $\sqrt{n}$, indicating that the determination precision has been enhanced $\sqrt{n}$ times or more. According to the density function of normal distribution, the dispersion degree of the random errors will be reduced with improved precision. Thus the accuracy of a single determination will also be statistically enhanced. F-Analysis demonstrates that, when $n \geqslant 3$ for

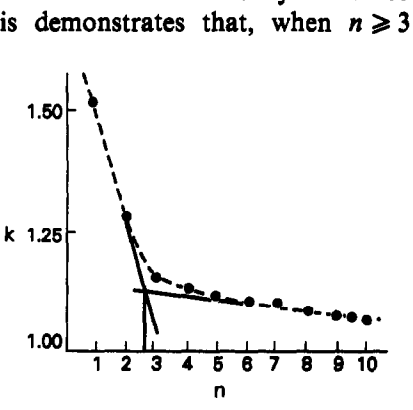

Fig. 4. Standard deviation decrease (k) *vs.* no. of cells (n).

Table 5. Recovery of quinine hydrochloride tested both with the CCS assembly (pH = 2.0, $n = 4$; pH = 6.0, $n = 3$) and with the conventional single electrode

	pH = 2.0 Found and % Recovery				pH = 6.0 Found and % Recovery			
Added *mg/ml*	CCS		Conv.		CCS		Conv.	
3.970	3.969	100.0	3.962	99.8	3.970	100.0	3.954	99.5
1.191	1.189	99.8	1.211	101.7	1.190	99.9	1.210	101.6
0.397	0.395	99.5	0.388	97.7	0.394	99.2	0.395	99.5
0.119	0.120	100.8	0.123	103.4	0.120	100.8	0.122	94.1
0.0397	0.0398	100.3	0.0389	98.0	0.0392	98.7	0.0403	101.5
0.0119	0.0119	100.0	0.0122	102.5	0.0120	100.8	0.0122	102.5

pH = 6.0 or $n \geqslant 4$ for pH = 2.0, this kind of enhancement is significant at $\alpha = 0.05$.

To achieve a full appreciation of what this means, more samples are needed which should be obtained under ideal conditions.

Monte Carlo simulation. The random errors of a definite cell are assumed normally distributed with a standard deviation of 1.0 around its mathematical expectation 0.0, $N(0.0, 1.0)$. At a given moment, this equals $(E_i - \mu_i)_t$. The momentary potential deviation of the assembly can be calculated by summing up the errors generated by all the cells connected at the moment.

$$\Delta E_t = \sum_{i=1}^{n} (E_i - \mu_i)_t \qquad (5)$$

Table 4 shows the computer simulation results with 1000 samples for $n = 1, 2, \ldots, 5$, respectively.

Obviously, the $S_E^{(n)}/S_E^{(1)}$ approaches $\sqrt{n}$ as expected, and also, the potential variation range grows wider with increasing n.

To observe the filtering effect, all the generated samples have been accurate to 0.1 mV and their frequencies counted. By increasing the valve frequency in steps, the samples whose frequencies are less than the valve value will be gradually filtered off. The random errors of the samples left are then analysed and the results are shown in Fig. 3.

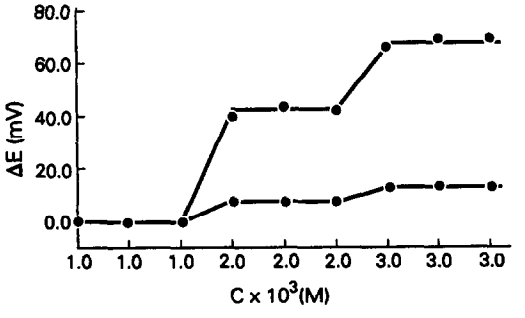

Fig. 5. Step potential signal monitored by both the CCS ($n = 5$) assembly and the conventional single electrode when the concentration of quinine changes stepwise from $1.0 \times 10^{-3}M$ to $2.0 \times 10^{-3}M$ to $3.0 \times 10^{-3}M$, pH = 2.0.

Higher precision is obtained as more lower-frequency samples are filtered off. The efficiency of this kind of improvement increases with the number of cells connected. However, the cells cannot be added infinitely. Apart from the consideration that connecting too many cells may generate a potential exceeding the maximum determination range of the employed instrument, the standard deviation reduction (k) with one extra cell

$$k = \frac{S_x^{(n)}}{S_x^{(n+1)}} = \sqrt{\frac{n+1}{n}} \qquad (6)$$

becomes negligible when n reaches a certain level. As shown in Fig. 4 the improvement becomes small at $n > 2$–3, *i.e.*, 3 or 4 cells would be appropriate.

Application

Shown in Table 5 are the results for the determination of quinine hydrochloride obtained by both the CCS assembly and a corresponding conventional PVC membrane electrode through repetitive measurements (three repetitions). It is obvious that those obtained with the proposed CCS assembly show improved precision and accuracy. It cannot be denied that, through repetitive measurements, conventional single electrodes can also provide accurate data. However, single electrode measurements may have deviations up to 5%. For the proposed CCS assembly, the deviation is scarcely more than 1%, which is the result of the significant enhancement of the precision of determination. From Table 5, $F_{(\text{CCS, Conventional})} = 0.061$ $(F_{0.025,11,11} = 0.288)$[6] can be calculated.

The assembly can also be used for process monitoring. A slight potential change which might be missed when testing with a conventional single electrode can be expanded when testing with the proposed CCS assembly. Figure 5 illustrates the relative response changes.

The system is particularly useful for multivalent ions, for which the response slope is small for corresponding single electrodes.

LETTER TO THE EDITORS

SIRS,

It has been drawn to our attention that in our paper on further developments of the RAMESES algorithm,[1] after commenting on the potential for error from the representation of species such as $Al(OH)_3$ by "AlH_{-3}", ironically we ourselves failed to realize the consequences of this notation when we were using the log β values given in the literature for the test systems[2,3] selected, primarily because no explanation was given there. In particular, we failed to recognize that the values reported corresponded to what in IUPAC nomenclature[4,5] would be log $^*\beta$ values, and hence should have been corrected by the addition of $-n \log K_w$ (where K_w is the ion product for water) to convert log $^*\beta$ for a species designated MLH_{-n} into log β for the corresponding species $ML(OH)_n$. For example, the log β value we used for $[Cu_2(cit)_2OH^{3-}]$ in System II should have been 25.87 instead of 11.90. The result was that the log β values reported for System II,[2,3] and program ES4EC,[2] were mistakenly criticized by us, and we unreservedly apologize to Professor Sammartano and his co-workers for any trouble or embarrassment caused them in consequence. We take this opportunity to say that a similar error arose in our computation[6] for other systems tested where such a notational difficulty was present, but we should add that there were no previous results published which might have alerted us to the problem.

However, after making the necessary corrections to the log β values and recalculating for System II with RAMESES, we still found discrepancies between our results and those reported by De Robertis *et al.*[2] The reason for these differences was eventually traced to a printer's error in that paper, where the list of constants for System II, on p. 391, included the species $[CuNi(cit)H_{-2}]$, and this was the species we had used in our calculation. However, this species *should* have been $[CuNi(cit)_2H_{-2}]$, as is shown by examination of the footnotes to Table 4 in that paper and correction of a further printer's error for species (18), where Cu had been omitted from the formula. It may also be noted that species (12) should have been $[Cu_2(cit)H_{-1}]$, not $[Cu(cit)H_{-1}]$; we made a similar error in proof-reading ourselves in our own paper,[1] where a species was given as (10) $[Ca_2(cit)_2OH_2^{4-}]$ instead of $[Cu_2(cit)_2(OH)_2^{4-}]$. Recalculation for System II with the correct formula gives good agreement with the results reported by De Robertis *et al.*[2] and excellent agreement with an independent calculation with program EQCAL.[7] Figure 1 shows the extraordinarily and unexpectedly large effect of this apparently trivial error, on the proper distribution of the species concerned.

We believe that confusion may have arisen in the past because of the nature of the various computer programs developed for such calculations, most of which use $[H^+]$ as a variable but exclude $[OH^-]$, though some allow use of $[OH^-]$ instead. It may be noted that RAMESES handles $[H^+]$ and $[OH^-]$ together directly, because the dissociation of water is used as an explicit equilibrium, essential for proper accounting and charge balance. If, as appears to be the case, the notation under discussion has arisen from program limitations, it is seen to be entirely unnecessary. Whether these other programs may be modified is unknown. Even so, RAMESES handles negative stoichiometry coefficients without difficulty, and we have rerun each of the relevant systems in that style and obtained results identical to those achieved with what we regard as the more realistic convention.

The definition of $^*\beta$ was given in the first[4] and subsequent editions of "Stability Constants of Metal Ion Complexes" and again in the IUPAC Information Bulletin.[5] A clear explanation is given by Sillén in a review[8] and an illustration has been given by Dyrssen *et al.*[9] The notion of treating addition of OH^- as equivalent to abstraction of H^+ from H_2O dates back to about 1954, when it appeared in a footnote to a paper by Sillén,[10] and was used in a paper by Hietanen and Sillén.[11] The first use of the H_{-n} notation seems to be about 1961, though with β instead of $^*\beta$.[12] Its use is implied in the Appendix to the description of MINIQUAD (example 3, where $^*\beta$ is called β'),[13]

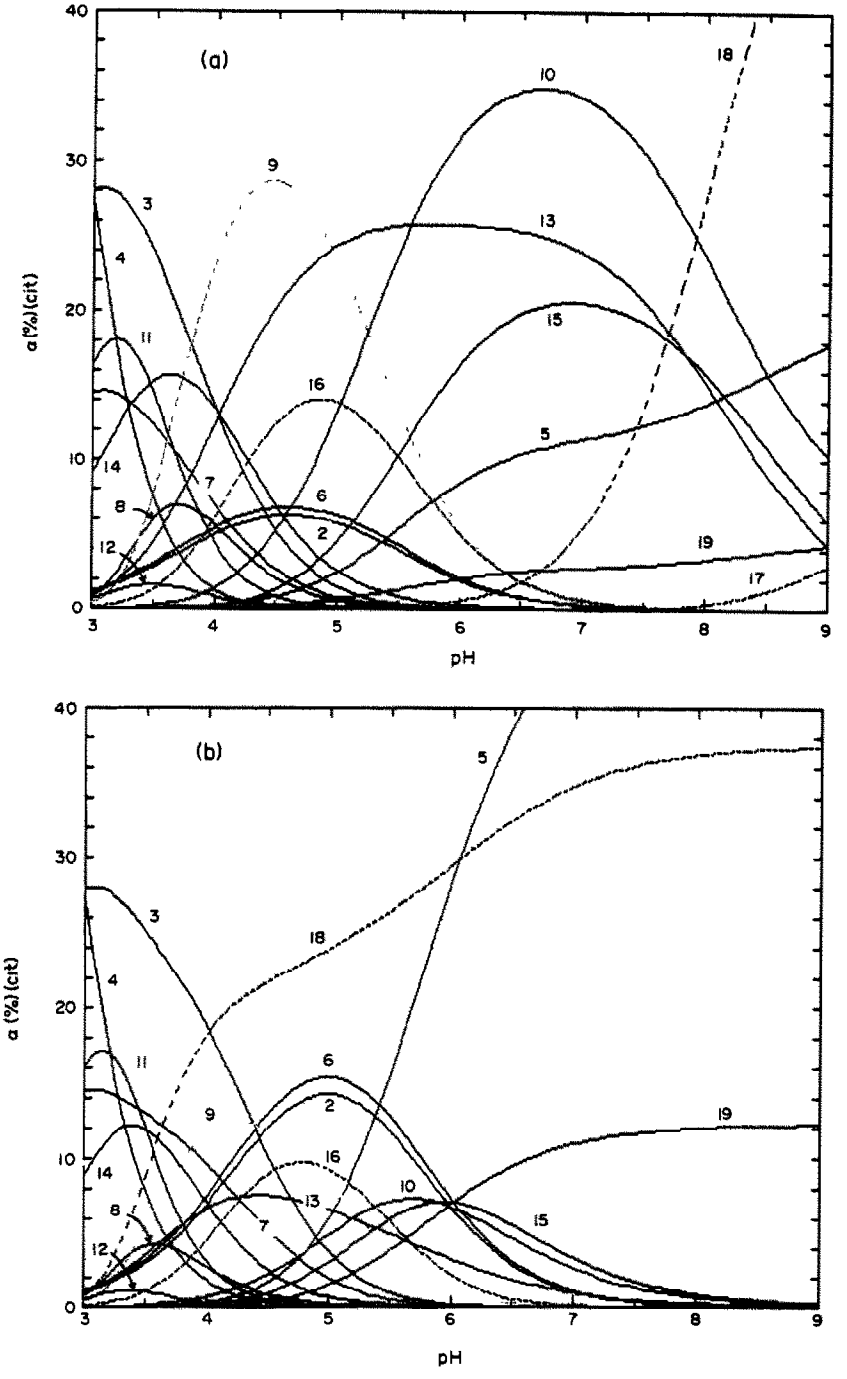

Fig. 1. The species distribution for System II, calculated by RAMESES with (a) species (18) taken correctly as $CuNi(cit)_2H_{-2}$; (b) species (18) taken incorrectly, as $CuNi(cit)H_{-2}$. The correctly calculated distribution is in good agreement with that reported by de Robertis *et al.*[2] The species are (2) [H(cit)]; (3) [H_2(cit)]; (4) [H_3(cit)]; (5) [K(cit)]; (6) [K(cit)H]; (7) [K(cit)H_2]; (8) [$Cu_2(cit)_2$]; (9) [$Cu_2(cit)_2H_{-1}$]; (10) [$Cu_2(cit)_2H_{-2}$]; (11) [Cu(cit)H]; (12) [$Cu_2(cit)H_{-1}$]; (13) [Ni(cit)]; (14) [Ni(cit)H]; (15) [$Ni(cit)_2$]; (16) [$Ni(cit)_2H$]; (17) [$Ni(cit)_2H_{-2}$]; (18) [$CuNi(cit)_2H_{-2}$]; (19) [cit] (this species was not shown in Fig. 2 in reference 2). α (%) (cit) indicates the citrate content of a species, calculated as a percentage of total citrate.

and an explicit use can be found in 1979 (with β instead of $^*\beta$).[14] A further trap for the unwary is that in the case of polynuclear hydroxo complexes, such as $Fe_3(OH)_4^{5+}$, the subscript used to identify β in tabular material generally has the number of hydroxide ions (or number of hydrogen ions "released") given *first*, *e.g.*, β_{43} in the example quoted.

We hope that this letter will help to prevent confusion and error in the future, and make amends for any in the past. Nevertheless, the fact of the existence of such an error and the large number of programs for computation of species distribution leads us to wonder whether a suite of validation examples should be assembled and a "Round Robin" conducted to compare results. We would be happy to act as convenors for such an exercise, which should ultimately be to everyone's benefit. Potential participants are invited to write to us to express an interest in the first instance.

We should like to thank Dr R. A. Chalmers and Dr M. R. Masson of the University of Aberdeen for help with the historical aspect of this letter and the EQCAL calculation, respectively.

BOOK REVIEWS

Analysis of Substances in the Gaseous Phase: E. SMOLKOVA-KEULEMANSOVA and L. FELTL, in Comprehensive Analytical Chemistry, Volume XXVIII, G. Svehla (editor), Elsevier, Amsterdam, 1991. Dfl 400.00.

This book has been a great disappointment to me. Books on gas analysis are few and far between, and the subject is rarely dealt with in modern analytical textbooks, yet it is a field of analytical chemistry which occupies many workers, both in plant control and in environmental monitoring. A glance at the glossy trade journals shows how many manufacturers are vying for their share of the market for dedicated gas analysers as well as for gas chromatographs, infrared spectrometers and mass spectrometers. And yet, in spite of the publisher's claim that this volume "provides a comprehensive description of the state of the art," I find it distinctly weak on the modern instrumental techniques.

A short chapter on "Qualitative and semi-quantitative methods" deals only with chemical detector tubes. This would be a very slow and expensive way of dealing with an unknown gas. I would first record the infrared absorption spectrum, surely the most powerful technique for identification, and would then measure the gas density to get the molecular weight. Gas density is mentioned briefly (later on) only as the basis of certain on-line gas analysers.

Infrared spectrometry is dismissed, along with UV and visible techniques, in a brief 12 pages, most of it is taken up with a general account of dispersive spectrometers and general spectrophotometry. Bolometers and pneumatic detectors are listed as components for IR instruments, but none of the modern semiconductor detectors, nor the pyro-electric capacitative detectors, ideal for small portable instruments with modulated light sources, are mentioned. FT-IR has apparently not been discovered yet, which is a pity when it is capable of giving good quantitative performance over several orders of magnitude down to ppm concentrations when used with a variable long-path cell.

A discussion of mass spectrometry for gas analysis need not dwell on the theory of deflection of ions, but should give help on the type of inlet system to be purchased for gas analysis. To dismiss the possibilities as "cold" (relevant), "hot" (irrelevant for gases) and chromatographic (very rare for gas analysis) is to demonstrate a lack of appreciation of the real problems. The choice between membrane, ceramic and jet inlet systems is rather important, and depends on the type of sample, the analyte, and the type of pumping system used. Sample flow systems with membranes are excellent for trace organic vapours in air but are, for example, useless for trace permanent gases such as O_2 in high-purity argon.

The authors are clearly more at home when dealing with gas chromatography, though here again the introductory section could have been shortened to advantage. The merits of flow control versus pressure control for carrier gas are compared, but the authors do not point out that one cannot combine flow control with a gas sampling valve, which is the usual sample introduction device for gas samples, because it takes too long for the loop to be filled up with carrier gas, resulting in severe peak broadening. Later, in a section on columns, PLOT columns are mentioned, but nowhere are we told what types are now available, and what impressive separations can be achieved (such as the argon–oxygen separation at room temperature, or light hydrocarbon analysis for many isomers). Mention is made of graphitised carbon black, which is useful for polar organic molecules, but it is not clear to me what steroid analysis (Fig. 10.45) has to do with gas analysis. Under detectors we are given a wrong cross reference to 9.3.4 for the flame photometric detector, and there (in 9.3.3) we find a statement that the response is *linear* to sulphur compounds, when it is well documented that the relationship is a square law one due to the emission originating from the S_2 molecule.

So, do we perhaps get a good account of the widely used chemical methods of gas analysis, based on pumping through selective absorbents followed by selective colour chemistry? I am afraid the answer is no. This section is a mere four pages long and does not even give a comparison of the performance of different methods for the determination of SO_2, surely the most widely determined air pollutant.

The topic of standards for the calibration of gas analysers is an important one, and also a difficult one. It is therefore a pity that we are told that gases "cannot be weighed simply. . ." because this *is* the only way to make accurate gas mixtures of non-reactive gases. And we are neither told about making mixtures by pressure nor the problems of non-ideality.

So, what does fill these pages? There are twenty pages on classical volumetric methods including drawings of the apparatus of Orsat, Hempel and Gooderham, and a great many pages of background material to the instrumental techniques. What a pity to waste this opportunity to produce a book for which there is a real need. There are plenty of people struggling with the real problems of gas analysis who would welcome a book with a good account of the modern methods and solutions to some of their difficulties. This book will probably be of little assistance to them and they will have to look elsewhere or wait patiently.

I. L. MARR

Wilson and Wilson's Comprehensive Analytical Chemistry Volume XXIV—Energy dispersive X-ray Fluorescence Analysis: B. DZUNIKOWSKI, Elsevier, Amsterdam, 1989. Pages xx + 431. Dfl 420.00.

The aim of this book is to "present in a concise manner the physical principles and some technical aspects of EDXRFA and to survey its various applications". In this aim the book seems to succeed, with a very practical vein running throughits entire length.

Bolometers and pneumatic detectors are listed as components for IR instruments, but none of the modern semiconductor detectors, nor the pyro-electric capacitative detectors, ideal for small portable instruments with modulated light sources, are mentioned. FT-IR has apparently not been discovered yet, which is a pity when it is capable of giving good quantitative performance over several orders of magnitude down to ppm concentrations when used with a variable long-path cell.

A discussion of mass spectrometry for gas analysis need not dwell on the theory of deflection of ions, but should give help on the type of inlet system to be purchased for gas analysis. To dismiss the possibilities as "cold" (relevant), "hot" (irrelevant for gases) and chromatographic (very rare for gas analysis) is to demonstrate a lack of appreciation of the real problems. The choice between membrane, ceramic and jet inlet systems is rather important, and depends on the type of sample, the analyte, and the type of pumping system used. Sample flow systems with membranes are excellent for trace organic vapours in air but are, for example, useless for trace permanent gases such as O_2 in high-purity argon.

The authors are clearly more at home when dealing with gas chromatography, though here again the introductory section could have been shortened to advantage. The merits of flow control versus pressure control for carrier gas are compared, but the authors do not point out that one cannot combine flow control with a gas sampling valve, which is the usual sample introduction device for gas samples, because it takes too long for the loop to be filled up with carrier gas, resulting in severe peak broadening. Later, in a section on columns, PLOT columns are mentioned, but nowhere are we told what types are now available, and what impressive separations can be achieved (such as the argon–oxygen separation at room temperature, or light hydrocarbon analysis for many isomers). Mention is made of graphitised carbon black, which is useful for polar organic molecules, but it is not clear to me what steroid analysis (Fig. 10.45) has to do with gas analysis. Under detectors we are given a wrong cross reference to 9.3.4 for the flame photometric detector, and there (in 9.3.3) we find a statement that the response is *linear* to sulphur compounds, when it is well documented that the relationship is a square law one due to the emission originating from the S_2 molecule.

So, do we perhaps get a good account of the widely used chemical methods of gas analysis, based on pumping through selective absorbents followed by selective colour chemistry? I am afraid the answer is no. This section is a mere four pages long and does not even give a comparison of the performance of different methods for the determination of SO_2, surely the most widely determined air pollutant.

The topic of standards for the calibration of gas analysers is an important one, and also a difficult one. It is therefore a pity that we are told that gases "cannot be weighed simply. . ." because this *is* the only way to make accurate gas mixtures of non-reactive gases. And we are neither told about making mixtures by pressure nor the problems of non-ideality.

So, what does fill these pages? There are twenty pages on classical volumetric methods including drawings of the apparatus of Orsat, Hempel and Gooderham, and a great many pages of background material to the instrumental techniques. What a pity to waste this opportunity to produce a book for which there is a real need. There are plenty of people struggling with the real problems of gas analysis who would welcome a book with a good account of the modern methods and solutions to some of their difficulties. This book will probably be of little assistance to them and they will have to look elsewhere or wait patiently.

I. L. MARR

Wilson and Wilson's Comprehensive Analytical Chemistry Volume XXIV—Energy dispersive X-ray Fluorescence Analysis: B. DZUNIKOWSKI, Elsevier, Amsterdam, 1989. Pages xx + 431. Dfl 420.00.

The aim of this book is to "present in a concise manner the physical principles and some technical aspects of EDXRFA and to survey its various applications". In this aim the book seems to succeed, with a very practical vein running throughits entire length.

The physical principles underlying the technique are covered first, with treatments of the basic ideas of atomic spectroscopy and the generation of primary (incident) and secondary (sample) radiation. I found the references in these early chapters to experimental evidence, supporting the assertions made, somewhat sketchy and they could possibly have been augmented with more diagrams relating to the examples cited to prove the postulated ideas.

The practical basics concerned with production and detection of the relevant radiations continued with descriptions of X-ray sources and typical EDXRFA spectrometers. At this stage a significant amount of theoretical background was hinted at, but I found this section contained too much unsubstantiated theory—merely quoting equations without derivation can be confusing. Doubtless reference to the bibliography would fill in these gaps but I did find it rather disconcerting. While one appreciates the scope of the work as a practical guide, some derivations, in an Appendix say, would have been welcome. One further point regarding this—I found the free flow of interchange between computational/theoretical discussion and extremely practical considerations of techniques somewhat off-putting. This tended to interrupt the flow for the systematic reader.

After the introduction of the basics, a further comprehensive series of techniques used in actual measurements are discussed, eventually evolving into a discussion of the computational techniques used in modern analysis.

It was slightly disconcerting to read the book and find that the precise definition of what constitutes the energy-dispersive technique and the consequent distinction between wavelength ($d\theta/d\lambda$) and energy (dV/dE) dispersive techniques does not emerge explicitly until Chapter 5. More seriously, having covered almost half of the book I found myself wondering about questions of sensitivity of the technique, and how precise in absolute terms these measurements are, since there is no account of these given early in the work.

The last 1/3 of the book is devoted to an account of some practical applications, including at last an indication of the vital facts regarding the sensitivity of the technique (in fact typically 10^{-3}% in careful quantitative analyses). The examples given rounded off the discussion, indicating the highly practical nature of EDXRFA in geology, processing control and in trace analysis, including the important field of air pollutants, among others. In the latter section (Chapter 13) there is finally a justification given for EDXRFA, when it is said that it is advantageous because of its "rapidity, possibility of simultaneous detection of several elements and satisfactory detection and determination limits"; again a point it would have been good to know at an earlier stage.

In general, I found the layout of the book not terribly clear, but as a 'dip-in' reference and bibliographic text, the information is clearly all there. It is a practical book, leaning heavily away from detailed, in depth discussions of theory, as opposed to discussions of basics, which are well covered. My main criticism of the book is the lack of an introductory chapter to capture the imagination, define the problem, give a short account of the achievements and limitations of the technique and put the succeeding discussions rather more into context. This would certainly induce more enthusiasm in the reader for finding out what EDXRFA can do and how it does it.

C. C. WILSON

Standardization Within Analytical Chemistry: P. KIVALO, Akadémiai Kiadó, Budapest, 1989. Pages 155 + appendices. US$36.00.

As a scientific discipline, analytical chemistry is a branch of metrology. As Lord Kelvin pointed out, "... when you can measure what you are speaking about and express it in numbers, you know something about it." The expression of analytical information in numbers unfortunately cannot always be referred uniquely to the basic physical constants. For this reason it is often necessary to specify in detail how the measurement is to be performed. Uniform procedures are essential if the highest reliability and repeatability are to be attained. The requisite definitions, procedures, and calculations are collectively embodied in the standardization for each particular measurement.

This book discusses in detail the several aspects of standardization and the steps in their development. Standard methods or techniques are based on sound scientific principles. Nevertheless, standardized or test methods for specific purposes or commercial products must often take into account the individual characteristics of the material to be analysed in order to ensure quality control and fitness for the intended purpose. In these instances, "pure" analytical chemistry becomes "applied" analytical chemistry in the development of protocols and certified reference materials. This process, the domain of numerous national and international standardizing bodies, is traced with logic and clarity in the seven chapters of the book.

Following an introduction, the history of analytical chemistry and the development of metrology are reviewed briefly. In chapters 3 and 4, the reader is introduced to early international standardization efforts, especially through ISO and IEC (of which Lord Kelvin was the first president), and the International Union of Pure and Applied Chemistry (IUPAC). Chapter 5, at 53 pages the longest of the book, is devoted to such matters as terminology, sampling and quality assurance, collaborative studies, and standard reference materials. The latter subject may merit more attention than it receives in the few pages allotted to it. Reference standards are currently available in a variety of forms, and they may be certified for composition or for many different properties critical to special analytical problems. The short final chapters discuss legal aspects and future trends in standardization.

Especially commendable is the inclusion, among the appendices, of the 49-page ISO Guide 2-1986, "General terms and their definitions concerning standardization and related activities." Terms relating to all aspects of standardization are defined in English, French, and Russian, while the equivalent terms in German, Spanish, Italian, Dutch and Swedish are listed.

This book is recommended to all who are concerned with the development, nature, and application of analytical standards.

R. G. BATES

The physical principles underlying the technique are covered first, with treatments of the basic ideas of atomic spectroscopy and the generation of primary (incident) and secondary (sample) radiation. I found the references in these early chapters to experimental evidence, supporting the assertions made, somewhat sketchy and they could possibly have been augmented with more diagrams relating to the examples cited to prove the postulated ideas.

R. G. BATES

The Kirk-Othmer Encyclopedia of Chemical Technology: Volume 1, Fourth Edition. A to Alkaloids. J. I. KROSCHWITS, M. HOWE-GRANT, M. BICKFORD and L. GRAY (editors), Wiley-Interscience, Chichester, 1991. Pages xxxii + 1087. £135.00.

Volume one of the fourth edition of this *Encyclopedia* covers topics in alphabetical order ranging from ablative materials to alkaloids. The volumes in the previous third edition were published between the years 1978 to 1984 and hence I expect it will be some considerable time before all volumes in this new edition appear. All the articles in the new work are reported to have been rewritten and updated with many new subjects added.

Contributions to the first volume have been made by 65 authors (nearly all from the U.S.A.) and 33 topics have been covered. The more dominant topics include (1) acrylamide, acrylic ester and acrylonitrile polymers, (2) adsorption (gas and liquid), (3) air conditioning and pollution and (4) alcohols. In this volume and those planned for future publication about one-half of all the articles are concerned with chemical substances. Many cross references for these substances are given and CAS registry numbers together with formula follow the names of compounds. The preamble to this volume also mentions an index for many common names, for some systematic names and for trade names. Presumably this index will appear at a later date. Substances described in volume one include acetaldehyde, acetic acid, acetone, acetylene, adipic acid, aldehydes and alkali and chlorine products. Related compounds are also mentioned, in particular, acetic acid derivatives such as acetamide, acetic anhydride, acetyl chloride, dimethylacetamide and halogenated derivatives.

The industrial significance of chemical substances is emphasized and there are numerous flow diagrams of industrial processes and tables of physical properties. The headings for topics that might be expected to appear between two existing articles are quoted, e.g., as follows: ACACIA. See DIURETICS; GUMS. This implies, intriguingly, that articles such as ACACIA are dealt with in volumes not yet published.

An encyclopaedia should be comprehensive, informative and easy to read and I certainly found that to be true of this volume. The articles are well written and numerous up-to-date references are quoted. Much information such as annual production figures and government regulations are specific to the U.S.A. Although emphasis is on technology there are also examples of some slightly more theoretical concepts such as the electronic configurations of the actinides and reaction paths to adipic acid. There is a scarcity of spectroscopic data in this first volume. I enjoyed reading about the current use of alcohol fuels (especially in Brazil), the concise but competent section on aerosols, the various types and use of abrasive materials and the final section on alkaloids which contains much structural chemistry. Other important articles are concerned with absorption, adhesives and aeration.

This volume certainly whets the appetite for what is to follow. The *Encyclopaedia* should prove to be a major work and should be well received. Volume one is refreshingly up-to-date and well produced. I eagerly await future volumes.

P. J. COX

pH Measurement: H. GALSTER, Verlag Chemie, Weinheim, 1991. Pages xvii + 356. £58.00.

One of the most commonly measured parameters in the chemical laboratory must surely be pH, and yet it is generally true that the simpler a procedure the less one thinks about it. Interlaboratory comparisons of pH measurement on river waters have revealed how great the discrepancies can be, and anyone running teaching experiments will be well aware of the difficulties of obtaining compatible data sets from groups of students using different pH meters. As more laboratories introduce quality assurance procedures and are obliged to think about the quality of their pH measurements, there will be an increasing demand for a reference source which answers the many questions to which disagreeing results give rise.

This very thorough treatise will provide a great many answers, not just for the inexperienced, but for those who think they already know a little about pH measurement. Perhaps, you will argue, most of the 350 pages will be only for the specialist. Perhaps you will be proved wrong, for I found the greater part of this volume to be of very practical relevance, combining the accounts of the troublesome phenomena associated with glass electrodes and the discussions of the underlying theory which can explain the effects. "The existence of two pH scales (the BS and the NBS/IEC/DIN) with definitions that are fundamentally different is not only unnecessary, it also adds to the difficulty of understanding the already complex basis of pH values..." For peace of mind stemming from a lack of conflicting data, use the single-standard BS pH scale and have faith in your pH electrode and meter. For peace of mind stemming from confidence in the quality of your results, however, read this book and be prepared to get involved in a lot of checking of your buffers, electrodes and even the meter itself.

The eight chapters deal with Fundamentals, pH scales, pH measurement cells, (including detailed discussions of glass electrodes, theory, use and care in handling) pH meters, Other pH measurement methods, Experimental procedures, (including pH measurement in aqueous solutions, non-aqueous solutions, and titrations), Process pH measurement and pH control. The book has a large number of clear illustrations, a substantial bibliography and a detailed index. However, I must disagree with the claim of the publishers on the back cover: "A book written by an expert for experts..." It is certainly written by an expert, and has been translated into very easily readable English, but it is a book for every laboratory where pH is measured, and that must mean, for a very wide readership indeed. I have enjoyed reading this book, and recommend it strongly.

I. L. MARR

Applications of Fluorescence in Immunoassays: I. A. HEMMILÄ, Wiley-Interscience, New York, 1991. Pages xi + 343. £67.00.

This is another book in the Wiley Chemical Analysis Series. It is an ideal reference text for those beginning or already involved in this area.

The first seven chapters give essential up-to-date background information on such assay methods. Particularly commendable are the chapters on instrumentation and photoluminescent probes—these cover every currently used instrument and probe together with their applications.

I. L. MARR

Applications of Fluorescence in Immunoassays: I. A. HEMMILÄ, Wiley-Interscience, New York, 1991. Pages xi + 343. £67.00.

This is another book in the Wiley Chemical Analysis Series. It is an ideal reference text for those beginning or already involved in this area.

The first seven chapters give essential up-to-date background information on such assay methods. Particularly commendable are the chapters on instrumentation and photoluminescent probes—these cover every currently used instrument and probe together with their applications.

The high standard of information is maintained in the subsequent chapters on FIA and ELFIA. Possible future developments are reviewed and make for thought-provoking reading.

Presentation is of a high standard throughout. The liberal use of tables to augment the information given in the text makes for ease of reference, *e.g.*, the requirement for an immunoassay kit based on a particular method. The text is also well referenced (over 1900 references are given) and current to 1990.

This unique book represents a fund of information for those who have an interest in fluorescence and immunoassaays.

R. R. MOODY

Chromatography Today: C. F. POOLE and S. K. POOLE, Elsevier, Amsterdam. 1991. Pages ix + 1026. Dfl. 295.00 (Hardback), Dfl. 150.00 (Paperback).

Those with a little knowledge of chromatography will find this book an ideal source of information for both updating and expanding their understanding of modern chromatographic systems.

The frequent use of tables to summarize or extend the information given in the text and the very extensive list of references given at the end of every Chapter makes the book a very useful reference source for any chromatographer. The book covers in some detail the fundamental relationships of chromatography, GC, HPLC, TLC and Supercritical Fluid Chromatography.

The authors succeed in showing that an understanding of the theory of the separation procedures involved and the apparatus used will aid in the selection of a chromatographic system and its optimization for a particular separation. The book also contains a valuable Chapter detailing the many methods available for sample preparation prior to chromatography (860 references). Identification of separated components may require the use of "hyphenated systems", *e.g.*, GC–Mass spectrometry.

The final Chapter clearly shows how such systems work, the options available and the difficulties that will be encountered. The quality of the presentation and the accuracy of the text is of uniformly high standard throughout. This up-to-date textbook will be a welcome addition to the chromatography section of any library.

R. R. MOODY

Cation Binding by Macrocycles: Y. INOUE and G. W. GOKEL (editors), Dekker, New York, 1990. Pages x + 761. $150.00 (US and Canada), $180.00 (elsewhere).

This book's eighteen chapters by a total of 20 authors give a comprehensive review of the chemistry of the interactions of cationic species with crown ethers and related compounds. The aspects covered include thermodynamics, equilibrium constants, kinetics and mechanism, crystallography, ion-selective electrodes, chromoionophores, and the reactions of various types of macrocycles (natural and synthetic) with various different groups of metal ions; and methods for studying all of these. The book is nicely produced, amply illustrated, and well referenced. I am sure that it will become compulsory reading for workers in the field, and will be particularly useful for those starting research in this area.

ANALYTICAL AND MECHANISTIC ASPECTS OF THE ROOM-TEMPERATURE FLUORESCENCE AND PHOSPHORESCENCE OF BENZO(*f*)QUINOLINE ADSORBED ON SILICA GEL CHROMATOPLATES WITH HUMIDIFIED GASES

LINDA A. CITTA and ROBERT J. HURTUBISE*
Chemistry Department, University of Wyoming, Laramie, Wyoming 82071, U.S.A.

(*Received* 24 *September* 1991. *Accepted* 19 *December* 1991)

Summary—The solid-matrix room-temperature fluorescence and room-temperature phosphorescence properties of benzo(*f*)quinoline adsorbed on silica gel chromatoplates were investigated over a wide range of humidities in N_2, air and O_2. Both neutral and acidic conditions were used and even at the highest relative humidity used, 93% relative humidity, the room-temperature fluorescence and phosphorescence intensities from benzo(*f*)quinoline were not totally quenched. However, in all experiments, the room-temperature phosphorescence was much more sensitive to humidity quenching than the room-temperature fluorescence. The results gave rather detailed information on quenching of the room-temperature fluorescence and phosphorescence in the different gases at a variety of humidities. It was possible to calculate the contribution to the percent decrease in luminescence due to moisture or a quenching gas. Thus, a more detailed assessment could be made about the quenching of moisture and individual quenching gases on the solid-matrix fluorescence and phosphorescence.

Room-temperature phosphorescence (RTP) and room-temperature fluorescence (RTF) from compounds adsorbed on solid matrices are important analytical techniques.[1–4] In most cases, the RTP intensity can be greatly reduced by the presence of moisture,[5–13] and it is usually necessary to dry the sample to observe appreciable RTP emission. Schulman and Parker[13] investigated the effects of dry and humidified argon and oxygen on the RTP of sodium 4-biphenylcarboxylate adsorbed on filter paper. This study involved a detailed investigation of the effects of moisture and oxygen on RTP with a silica gel chromatoplate as the solid matrix. The RTP of *p*-aminobenzoic acid adsorbed on sodium acetate was noted by von Wandruszka and Hurtubise[14] to be quite insensitive to moisture in the atmosphere. Limited studies have been reported on the effects of different gases on phosphorescence[7,15,16] and fluorescence.[16–19] Ramasamy *et al.*[20] have noted that higher quantum yields for RTF and RTP were obtained for *p*-aminobenzoic acid adsorbed on sodium acetate and 4-phenylphenol adsorbed on poly(acrylic acid)–sodium bromide with nitrogen present compared to the samples in the presence of air. McAleese *et al.*[21] reported that for relative humidities of 60% or less, samples adsorbed on sodium citrate impregnated filter paper appeared to be insensitive to immediate moisture and oxygen quenching as compared to similar samples adsorbed on filter paper and then spotted with water in place of sodium citrate. For relative humidities greater than 60%, the insensitivity to oxygen and moisture was not observed. Contrary to the usual results of optimal RTP with the presence of little or no moisture, Dalterio and Hurtubise[22] found enhanced RTP for 4-phenylphenol when a sizeable amount of water was present in the poly(acrylic acid)–salt matrix. They also noted that α-naphthoflavone adsorbed on a 1% poly(acrylic acid)–sodium bromide mixture gave the same RTP intensity as the initial intensity after seven days of exposure to atmospheric humidity. Recently, Citta and Hurtubise[23] have reported the effects of moisture, N_2, air and O_2 on the RTF and RTP of several compounds adsorbed on filter paper. In earlier work silica gel chromatoplates with a polyacrylate binder were shown to induce strong RTF and RTP signals from several compounds, and the chromatoplates were very easy to manipulate.[1,4,16] However, there have been no

*Author for correspondence.

reports on the influence of moisture and gases on the RTF and RTP signals of the compounds adsorbed on chromatoplates. This paper reports the effects of humidified N_2, air and O_2 on the RTF of benzo(f)quinoline and the RTF and RTP of B(f)QH$^+$ (B = benzo, Q = quinoline) adsorbed on silica gel chromatoplates which contained a polyacrylate binder. Also, a system designed to measure RTP and RTF intensities under humidified conditions is described.

EXPERIMENTAL

Apparatus

A Schoeffel spectrodensitometer was used to obtain the RTP and RTF intensity measurements. Details of the instrument have been described previously.[16] A polyethylene glove bag was fitted and secured to enclose the sample compartment of the densitometer. The polyethylene glove bag was used to provide a controlled environmental chamber to contain an atmosphere of the dry or the humidified gas. A digital hygrometer (Model 3309-50, Cole-Parmer) was used to measure the percent relative humidity (% RH) and the temperature inside the glove bag chamber. Several precautions were taken for the control of temperature inside the glove bag chamber. The lamp housing and illumination tube of the densitometer were wrapped with insulation material. A polystyrene foam cup with a vacuum line attachment was fitted over the monochromator to draw heat away, and a container of dry ice was placed in the sample compartment of the densitometer but outside the glove bag chamber to prevent the stage of the densitometer from warming up.

For dry air, compressed gas was allowed to flow through an activated charcoal purifier and through Drierite. Air was humidified by passing the air at 820 ml/min through three gas wash bottles each containing 500 ml of an aqueous sulfuric acid solution. A glass U-tube packed with glass wool was used to trap any sulfuric acid aerosol. To obtain a desired humidity inside the glove bag chamber, appropriate concentrations of aqueous sulfuric acid solutions had to be used.[24,25]

Reagents

Ethanol was purified by distillation. Prior to use, aluminum backed silica gel chromatoplates (EM Science, Cherry Hill, NJ) were developed in ethanol three times to collect impurities at one end. Benzo(f)quinoline (Aldrich) was used as received.

Procedures

Humidity experiments. Silica gel chromatoplates were dried at 190° for 30 min before use. Afterwards, the silica gel chromatoplate was placed inside a desiccator and transferred to a polyethylene glove bag which contained an atmosphere of dry nitrogen. Dry nitrogen was passed through an oxygen trap, activated charcoal, and Drierite before the gas filled the polyethylene glove bag. Inside the polyethylene glove bag, the sample solutions were spotted (1 μl) in duplicate on the silica gel chromatoplates. Benzo(f)quinoline (100 ng) was adsorbed on the silica gel chromatoplate either from ethanol, 0.1M hydrobromic acid–ethanol, or 0.1M hydrochloric acid–ethanol solutions. After spotting, the chromatoplate was allowed to dry inside the polyethylene glove bag for 5 min, and it was then transferred to an oven to dry for 15 min at 105°. The silica gel chromatoplate was removed from the oven and placed on the stage of the densitometer which was enclosed by the glove bag chamber and allowed to cool under an atmosphere of dry gas (0% RH).

Intensity measurements for the samples under the atmosphere of the dry gas were obtained after the samples had been inside the glove bag chamber for at least 10 min. After the measurements were obtained in the dry gas, the humidified gas was allowed to flow into the glove bag chamber, and the atmosphere with the desired humidity was reached after approximately 90 min. For each humidity investigated, measurements were obtained at 10-min intervals over a 70–120-min time span of exposure of the sample to humidified gas. There was little or no change in the emission intensities over this length of time. The emission intensities reported in this work were obtained after the 90-min exposure time, and the reproducibility from run to run was very good. For example, for the RTF of B(f)QH$^+$ the average intensity ratio for three runs gave 0.72 ± 0.17 at the 95% confidence level.

The system developed was a dynamic one in that the gas was allowed to continuously flow into the glove bag chamber, and the gas was not directly passed over the face of the sample. Thus, the sample was exposed to a surrounding atmosphere of the dry or humidified gas.

Excitation and emission wavelengths. The following excitation and emission wavelengths were used: RTP of B(*f*)Q with 0.1*M* hydrochloric acid–ethanol and 0.1*M* hydrobromic acid–ethanol, 370 nm, 510 nm; RTF of B(*f*)Q with 0.1*M* hydrochloric acid–ethanol and 0.1*M* hydrobromic acid–ethanol, 370 nm, 430 nm; RTF of B(*f*)Q with ethanol, 360 nm, 430 nm.

RESULTS AND DISCUSSION

Experimental considerations

It is known that silica gel absorbs moisture in varying degrees.[26] Ford and Hurtubise[27] found enhanced phosphorescence when samples adsorbed on silica gel were reheated. The increase in RTP was attributed to the loss of water adsorbed on the silica gel surface. In this work, to ensure each chromatoplate contained very small amounts of moisture, the silica gel chromatoplates were dried for 30 min at 190°.

With a flow-rate of 820 ml/min, the relative humidity inside the glove bag chamber did not reach the static humidity expected for the aqueous sulfuric acid solutions used in the gas wash bottles.[24,25] Lassen[28] found that a flow-rate of no more than 400 ml/min passing through the gas wash bottles would yield the same humidity as the static humidity associated with the concentration of sulfuric acid inside the wash bottles. The glove bag chamber enclosed a large area of the sample compartment due to the size of the chopper accessory.[16] Thus, a flow-rate of 350 ml/min into the glove bag chamber took about three hours for the system to come close to the desired humidity. However, a flow-rate of 820 ml/min required 90 min to reach a stable humidity inside the glove bag chamber. By experimentation, aqueous solutions with the appropriate concentration of sulfuric acid were found which gave the desired humidities inside the glove bag chamber. With this system, it was not possible to reach a relative humidity of 100% inside the chamber. The maximum relative humidity possible inside the glove bag chamber with air was 93%. To reach this humidity, the gas wash bottles which contained the aqueous sulfuric acid solution had to be heated in a water bath to 45°.

The phosphoroscope assembly was used when both RTP and RTF intensities were obtained. For RTP measurements, the chopper was in the position as described by Ford and Hurtubise.[16] The assembly had to be moved to a different position for RTF measurements so the chopper did not block the source radiation to the sample or the emission from the sample to the detector. The rotating chopper was needed for proper mixing of the humidified atmosphere inside the glove bag chamber. RTF measurements obtained without the mixing of the atmosphere by the chopper resulted in very nonreproducible data, whereas with the chopper turned on, quite reproducible results were obtained. Since the chopper was turned on for RTP measurements, there was no difficulty with the reproducibility of the results.

Effects of humidity on RTP and RTF in air

The RTP properties of several aromatic nitrogen heterocycles adsorbed on silica gel have been investigated.[29–31] Ford and Hurtubise[29] and Ramasamy and Hurtubise[32,33] have explored the various interactions responsible for the RTP of nitrogen heterocycles adsorbed on solid surfaces. Therefore, for analytical purposes, it was considered important to study the effects of humidified air on the RTP and RTF of B(*f*)Q as a model compound adsorbed on silica gel chromatoplates.

For the RTP of B(*f*)QH$^+$ in air, the average relative intensity ratios decreased as % RH increased. The average RTP ratio values of B(*f*)QH$^+$ adsorbed as a hydrobromic acid solution at a given humidity were much smaller than the average ratio values for RTP of B(*f*)QH$^+$ adsorbed as a hydrochloric acid solution (Fig. 1). Also, the RTP of B(*f*)Q with hydrobromic acid was more sensitive to humidified air than the RTP of B(*f*)Q with hydrochloric acid. In Fig. 1 for B(*f*)Q with hydrobromic acid, there was a dramatic

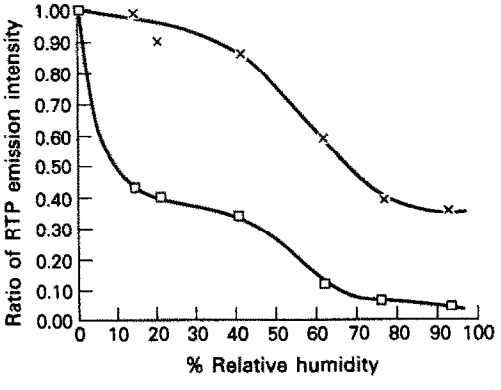

Fig. 1. Ratio of the RTP emission intensity in air at a given humidity to the RTP emission intensity in dry air for 100 ng of B(*f*)QH$^+$ adsorbed on EM silica gel chromatoplates from ethanol/0.1*M* HCl (×) and ethanol/0.1*M* HBr (□) solutions as a function of % relative humidity.

reduction in RTP over the humidity range 0–93% RH; however, the RTP signal was not totally quenched. The decrease in RTP was largest between 0 and 20% RH. From 20 to 40% RH there was a small change in the RTP ratio values for B(f)Q with hydrobromic acid. As shown in Fig. 1, another significant decrease in the RTP ratio values was observed between 40 and 60% RH. Between 60 and 93% RH, the decrease in RTP for B(f)Q with hydrobromic acid was relatively small. For B(f)Q with hydrochloric acid, there was a more gradual decrease in RTP (Fig. 1). A rapid decrease in RTP for B(f)Q with hydrochloric acid was observed between 40 and 75% RH. The change in the RTP intensity ratio values for B(f)Q with hydrochloric acid between 75 and 93% RH was small. Again it was observed that the RTP signal remained quite evident in air at 93% RH. For the RTP of B(f)Q with hydrochloric and hydrobromic acids, there was a relatively slow change in the ratio of RTP values from 20 to 40% RH.

Figure 2 gives the average ratio of the RTF peak height in air at a given humidity to the RTF peak height in dry air versus relative humidity at 90 min. The average ratio values for RTF of B(f)Q with hydrochloric acid followed a linear relationship over the humidity range of 0–93% RH (correlation coefficient = −0.973). After the initial drop in the RTF ratio values for B(f)Q adsorbed with ethanol from 0 to 20% RH in Fig. 2, the RTF values remained relatively constant over the humidity range of 20–60% RH. The RTF ratio values for B(f)Q from 40 to 93% can be fitted to a linear relationship with a correlation coefficient of −0.974. The RTF for B(f)Q with hydrobromic acid gave unusual results in that the ratio values at 20, 40 and 93% RH were greater than the ratio value of 1.00 for dry air.

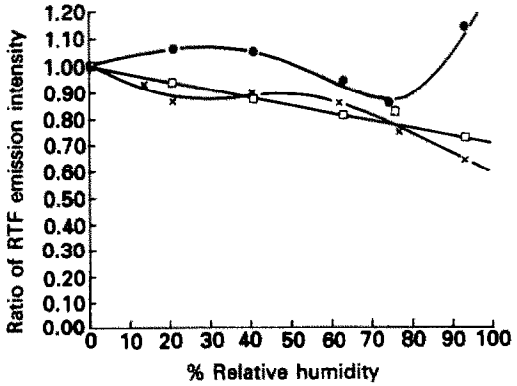

Fig. 2. Ratio of the RTF emission intensity in air at a given humidity to the RTF emission intensity in dry air for 100 ng of B(f)Q adsorbed on EM silica gel chromatoplates from ethanol (×), and 100 ng B(f)QH$^+$ from HBr (●) and from ethanol/0.1M HCl (□) solutions as a function of % relative humidity.

As discussed, the RTF of B(f)Q was not affected by the humidified air as much as the RTP of B(f)Q. This is most likely related to the shorter lifetime of RTF as compared to RTP. For B(f)Q with hydrochloric acid, the relative decrease in the RTF and RTP ratio values from 0 to 40% RH was almost the same. Thus, it appears that humidified air has a similar effect on RTF and RTP over this humidity range. After 40% RH, the reduction in the relative intensity ratio values was more dramatic for RTP of B(f)Q with hydrochloric acid than for RTF of B(f)Q with hydrochloric acid (see Figs. 1 and 2).

For the RTP of B(f)QH$^+$ adsorbed with hydrochloric acid under an atmosphere of air, a range of 0–20% RH would be most useful analytically. Due to the dramatic decrease in RTP intensity for B(f)Q with hydrobromic acid in the 0–20% RH region, it would be important to keep the chromatoplate very dry during the measurement step. However, the emission intensity in the humidity range 20–40% RH offers a relatively constant RTP signal for analytical work. For the RTF of B(f)Q with hydrochloric acid, there was a relatively constant rate of decrease in emission intensity over the humidity range 0–93% RH. The RTF signal was still quite strong even with air at 93% RH. However, the optimum humidity range for intense signals appears to be from 0 to 40% RH.

RTF and RTP intensities relative to dry nitrogen at different humidities in different gases

The RTF intensities relative to dry nitrogen for B(f)Q adsorbed with hydrochloric acid were obtained in nitrogen and oxygen at different humidities. The RTP intensities relative to dry N_2 were obtained in N_2, air and O_2. By comparing the data in this fashion, direct comparisons could be made between the effects of humidity and different gases on the RTF and RTP signals for B(f)QH$^+$ adsorbed on the chromatoplate. Figure 3 gives graphs for the effects of nitrogen and oxygen on the RTF of B(f)QH$^+$ at different humidities. It was assumed that N_2 had no effect on the RTF signals. As indicated in Fig. 3, the RTF signals decreased by about 22% from 0 to 20% RH and

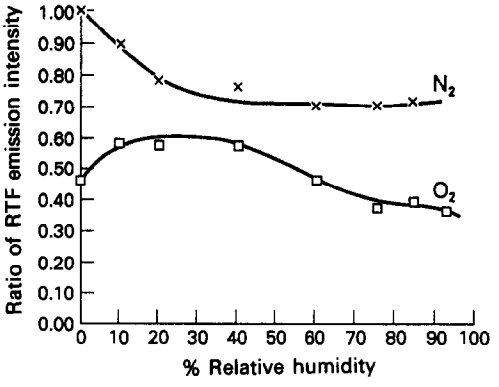

Fig. 3. Ratio of the RTF emission intensity relative to dry N_2 for 100 ng of B(*f*)QH$^+$ adsorbed on EM silica gel chromatoplates from ethanol/0.1*M* HCl as a function of % relative humidity. N_2(×), O_2(□).

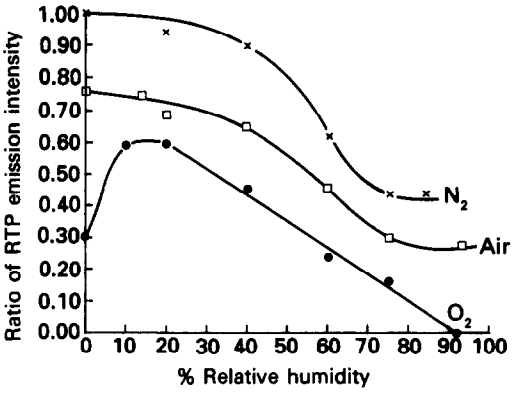

Fig. 4. Ratio of the RTP emission intensity relative to dry N_2 for 100 ng of B(*f*)QH$^+$ adsorbed on EM silica gel chromatoplates from ethanol/0.1*M* HCl as a function of % relative humidity. N_2(×), air (□), O_2(●).

then level off after a 30% decrease in RTF. With O_2 under dry conditions, the RTF signal was less than half the signal obtained under dry conditions with N_2 (Fig. 3). As shown in Fig. 3, the RTF signals increase from 10 to 40% relative humidity in the presence of O_2, decrease from 40 to 75% relative humidity and finally level off from 75 to 92% relative humidity. The type of graph obtained with O_2 indicated a somewhat complicated interaction of the gas and moisture with the fluorophor. The graph obtained with N_2 implies that fluorophor molecules near the surface are quenched by moisture in the approximate range of 0–20% relative humidity and the solid matrix provides considerable protection of B(*f*)QH$^+$ molecules buried in the three dimensional matrix of the chromatoplate.

Figure 4 shows the RTP intensities in three different gases as a function of % RH for B(*f*)QH$^+$ adsorbed from a hydrochloric acid solution. In N_2 the RTP signals were the strongest and in air the general shape of the curve is the same as that obtained for N_2, but there is a global shift to lower RTP intensities. This shift to lower intensities is due to the presence of O_2 in the air. In Fig. 4, the RTP intensities in the presence of O_2 increased from 0 to 20% relative humidity and then showed a linear decrease in RTP intensities from 20 to 92% relative humidity. At 92% relative humidity the RTP signal was zero. Because the RTP signals remained in the presence of N_2 at 84% relative humidity and in the presence of air at 92% relative humidity, then a fraction of the phosphor molecules were very well protected by the solid matrix under these conditions. In order to sort out the contributions from moisture and the quenching gases, it was necessary to determine the percentage contributions from moisture and a quenching gas. These aspects are discussed in the next section.

Percentage contribution to luminescence quenching from moisture and quenching gases

In earlier work, Schulman and Parker[13] discussed equations that are useful in determining the various quenching contributions of moisture and gases to the RTP of model compounds adsorbed on filter paper. Recently, Citta and Hurtubise[23] reported a somewhat modified version of the Schulman and Parker equations for use with filter paper. These equations were used in this work and are listed in Table 1. The equations give the percent decrease in luminescence signals and permit a more quantitative evaluation of the effects of moisture and gases

Table 1. Equations used to distinguish the contribution to quenching due to moisture and the gases

% Decrease due to H_2O:	$\frac{I^0_{N_2} - I_{N_2}}{I^0_{N_2}} \times 100$
% Decrease due to H_2O + air:	$\frac{I^0_{N_2} - I_{Air}}{I^0_{N_2}} \times 100$
% Decrease due to air:	$\frac{I_{N_2} - I_{Air}}{I^0_{N_2}} \times 100$
% Decrease due to $H_2O + O_2$:	$\frac{I^0_{N_2} - I_{O_2}}{I^0_{N_2}} \times 100$
% Decrease due to O_2:	$\frac{I_{N_2} - I_{O_2}}{I^0_{N_2}} \times 100$

$I^0_{N_2}$ Intensity in dry N_2.
I_{N_2} Intensity in N_2 at a given humidity.
I_{Air} Intensity in air at a given humidity.
I_{O_2} Intesnity in O_2 at a given humidity.

on the solid-matrix luminescence intensity. Figure 5 shows the % decrease in RTF for B(f)QH$^+$ in the presence of both H_2O and O_2 and two graphs that represent individual contributions from H_2O and O_2. With both H_2O and O_2 present, the % decrease in RTF is between 42 and 64% over the entire range of humidity investigated. For O_2 from 0 to 20% relative humidity, the percent decrease in RTF actually becomes less than with dry O_2, whereas the RTF decrease becomes greater compared to dry N_2. At relative humidities greater than 20%, the contributions to the percent decrease in RTF for H_2O and O_2 are about the same.

Figure 6 gives several graphs for the % decrease in RTP versus % RH for B(f)QH$^+$ adsorbed on a silica gel chromatoplate. The graph for % RTP decreases with H_2O and O_2 shows a drop in the % RTP decrease from 0 to 20% relative humidity. The graph becomes linear from 20 to 94% relative humidity. A similar graph for the same model compound on filter paper gave a linear relationship over the entire range of humidity investigated.[23] In Fig. 6, the plot for % RTP decrease with water shows that the % decrease is linear from 0 to 40% relative humidity, but with only an overall % decrease in RTP of 10%. Then from 40 to 75% relative humidity, the slope of the curve is much greater and a maximum of 56% decrease in RTP occurs. Finally the curve levels off at 75% relative humidity and remains constant to the maximum % relative humidity (84%). In similar relative humidity work by Citta and Hurtubise[23] with B(f)QH$^+$ adsorbed on filter paper, the shape of the H_2O curve gave a dramatic rise in %RTP decrease to about 40% relative humidity

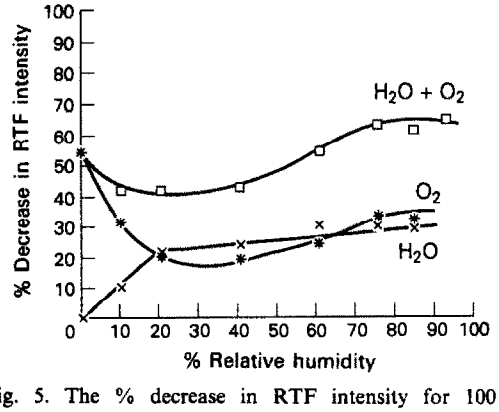

Fig. 5. The % decrease in RTF intensity for 100 ng B(f)QH$^+$ adsorbed on EM silica gel chromatoplates from ethanol/0.1M HCl due to moisture and O_2. □ = % Decrease due to H_2O and O_2; ● = Calculated % decrease due to O_2; × = Calculated % decrease due to H_2O.

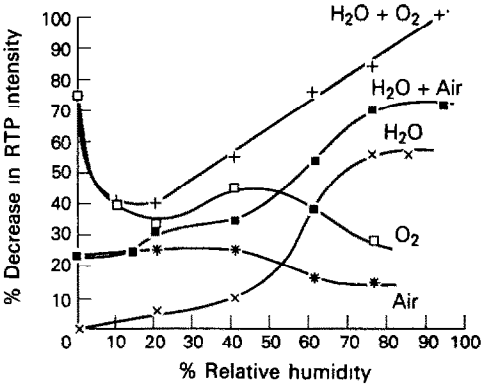

Fig. 6. The percent decrease in RTP intensity for 100 ng of B(f)QH$^+$ adsorbed on EM silica gel chromatoplates from ethanol/0.1M HCl due to moisture and gases. + = % Decrease due to H_2O and O_2; ■ = % decrease due to H_2O and air; × = % decrease due to H_2O; □ = calculated % decrease due to O_2; ● = calculated % decrease due to air.

and then the curve showed a gradual rise as the humidity increased beyond 40% relative humidity.

In Fig. 6, the % decrease in RTP due to O_2 shows that the quenching effects from O_2 decrease with increasing % relative humidity, and the quenching effects are roughly constant from 20% relative humidity and beyond. Interestingly, with filter paper and B(f)QH$^+$ a similar graph was obtained for O_2.[23] Finally in Fig. 6, the % decrease in RTP due to air remained essentially constant from 0 to 40% relative humidity and then decreased somewhat beyond 40% humidity. B(f)QH$^+$ adsorbed on filter showed a similar trend.[23]

Analytical and mechanistic aspects related to the decrease in RTF and RTP signals

It is clear from the results presented that RTF is much less affected by moisture and gas quenching than is RTP. This is most likely related to the much shorter lifetime of the excited singlet state relative to the lifetime of the excited triplet state. Because a substantial amount of RTF signal remained at high humidity and in the presence of pure oxygen (Figs. 3 and 5), then the matrix offered considerable protection of the fluorophor. Also, in the presence of air and high moisture content (Fig. 2), and nitrogen and high moisture (Fig. 3), a substantial amount of the fluorescence remained. The mechanistic aspects of the RTF of B(f)QH$^+$ obtained on dry EM silica gel chromatoplates were discussed by Ford and Hurtubise.[29] Because the chromatoplates contain a polyacrylate binder, the acid solution

deposited on the chromatoplate converts the polyacrylate salt to the acid form of the polymer. Thus, both silanol groups and carboxyl groups would interact with B(*f*)QH$^+$.[29] Because B(*f*)QH$^+$ in the singlet state would interact with both silanol groups and carboxyl groups, it is not possible to give a detailed interaction mechanism for the fluorophor in the presence of moisture and quenching gases without carrying out additional experiments such as fluorescence lifetime measurements.

The RTP signals were much more sensitive to environmental conditions than were the RTF signals (Figs. 1, 4 and 6). As considered earlier by Ford and Hurtubise,[29] the polymer binder in the chromatoplates was essential for RTP, and silica gel without the polyacrylate binder was an inefficient matrix for obtaining RTP. In fact, the acid form of the polymer binder was primarily responsible for inducing RTP from B(*f*)QH$^+$ adsorbed on the chromatoplate, and the silanol groups in the silica gel were not highly important in obtaining strong RTP signals. However, if one assumes that the binder is homogeneously dispersed in the silica gel matrix then the changes in the RTP signals should be a function of the adsorption of moisture by the matrix. Rassi *et al.*[34] have reported a detailed water adsorption isotherm for LiChrosorb SI 60 (Merck) from 0 to 100% relative humidity. Their isotherm has the same shape and characteristics as the water adsorption isotherm for silica gel 60 provided in the technical bulletin by Merck for the silica gel 60 chromatoplates. The isotherm given by Rassi *et al.*[34] shows that from 0 to 40% relative humidity there is a relatively flat region and the weight percent increase in water is less than 10%. In Fig. 6, the % decrease in RTP as a function of relative humidity in N_2 or in air shows the same trend over this humidity range. Namely, there is very little decrease in RTP as the humidity changes from 0 to 40% relative humidity. Rassi *et al.*[34] showed that beyond 50% relative humidity there was a dramatic increase in the moisture uptake by silica gel. In Fig. 6, the % decrease in RTP shows the same trend for B(*f*)QH$^+$ in N_2. The only major difference between the % decrease RTP curve in Fig. 6 and the water isotherm reported by Rassi *et al.*[34] is that in Fig. 6 the % decrease in RTP reaches an approximate plateau near 75% relative humidity in N_2 and air. Unger[35] has explained the large increase in moisture uptake in silica beyond 50% relative humidity to capillary condensation of water vapor in the pores of the silica. Based on our RTP results and the results reported by Rassi *et al.*,[34] it appears that the phosphor molecules near the surface of silica are quenched in the range of approximately 0–40% relative humidity and then from 50% relative humidity to about 75% relative humidity, where capillary condensation occurs, the phosphor molecules in the pores are quenched. Because a fraction of the phosphor molecules are not quenched beyond 75% relative humidity, then they are most likely in pores that are not available to water. The previous description for the RTP change with % relative humidity is obviously an over simplification because polyacrylic acid is dispersed throughout the silica gel and plays a very important role in obtaining RTP. Based on the RTP results obtained in this work, it would seem that the polyacrylic acid is not only homogeneously distributed in the silica gel matrix but the carboxyl functionality can penetrate into the pores of the silica gel and interact with B(*f*)QH$^+$ which is one of the main factors in permitting RTP to be observed from B(*f*)QH$^+$ adsorbed on silica gel.

CONCLUSIONS

The effects of moisture and quenching gases on solid-matrix luminescence are very important.[1,2,5] The silica gel chromatoplates used in this work were shown previously to give very good reproducibility and low limits of detection for RTF and RTP.[16,27,29] The results from this work will permit analysts to determine, in general, the conditions needed for optimal RTF and RTP with the silica gel chromatoplates. An important conclusion is that RTF was not affected much by quenching gases and moisture. In addition, the RTP signals were obtained in some cases even in very high humidity in N_2 and air. The same conclusions were reached by similar experiments with filter paper.[23] The results are also important mechanistically in solid-matrix luminescence because so little work has been done in the area of the effects of quenching gases and moisture in solid-matrix luminescence. For example, the particular correlation found between the water adsorption isotherm for silica gel and the decrease in RTP in N_2 for B(*f*)QH$^+$ with humidity would be important in mechanistic studies and in practical applications.

Summary—The use of high-performance liquid chromatography to determine the concentrations of metal-binding proteins (MBP) in freshwater mussels has been evaluated. Initial use of dilute buffers (*e.g.*, 10m*M* TRIS, pH 7 or 8), to minimize competition between the buffer and the metal-cytosolic ligand complexes, proved unacceptable; high losses of low molecular weight marker proteins occurred during chromatographic separation, presumably as a result of adsorption to the gel-permeation column packing. Losses were more dependent on salt than pH; satisfactory recoveries were obtained in the pH range 6–8 with 10m*M* buffer solutions and 100m*M* added electrolyte (NaCl; KCl). Competition experiments performed with commercial metallothionein (pre-labelled with ^{109}Cd) and fresh mussel cytosol extract demonstrated that no appreciable metal exchange occurred during the 20-min pre-equilibration or the subsequent chromatographic separation step. With ^{203}Hg-labelled metallothionein occasional losses were noted, however, appreciable loss of the radioisotope ranging from 50 to 58% did occur with ^{65}Zn-labelled metallothionein during the chromatographic separation step. These results, particularly for Zn indicate that the recovery of metals after separation using this chromatographic method may vary, even for metals sharing similar chemical properties.

Freshwater and marine mussels have been proposed as biomonitors for metal pollution in the aquatic environment.[1,2] In addition to their documented ability to bioaccumulate metals from the environment, these organisms are also able to carry out the *de novo* synthesis of low molecular weight, heat stable proteins containing a high cysteine content. Often referred to as metallothioneins, or more generally as metal-binding proteins (MBP), these molecules have a high affinity for certain "soft" cations. The presence of MBP is not restricted to bivalves and their occurrence has been reported in mammals,[3] fish,[4] echinoderms,[5] crustaceans,[6] insects[7] and phytoplankton.[8]

Several reports propose the use of MBP as a specific biochemical indicator of sublethal metal exposure and suggest that from an ecotoxicological point of view, an elevated MBP level in an organism may indicate chronic metal exposure long before any deleterious effects occur.[9,10] It should be noted, however, that basal levels of MBP may well be present in organisms that have not been exposed to excessive metal levels, given that MBP have been implicated in normal metal metabolism.[11]

In recent years, different methodologies have evolved to estimate the concentration of MBP in the different tissues of aquatic invertebrates. Techniques such as polarography,[12] immunoassays[13,14] and metal saturation assays[15,16] have found support for the quantification of MBP in aquatic invertebrates, particularly in marine species. The use of gel-filtration chromatography, coupled with post-column metal detection by such means as inductively coupled plasma atomic emission spectroscopy (ICP–AES)[17,18] or 4-(2-pyridylazo)-resorcinol (PAR) derivatization,[19] has also been advocated as a sensitive, quick technique for the separation and detection of MBP and their respective bound metals.[20] This technique has the advantage that chromatographic separation of a cytosol extract produces the whole protein profile. This approach, together with metal analyses of the different eluate fractions collected after chromatographic separation, has been used by many investigators to determine the distribution of metals among the different cytosolic ligands (ML′, ML″, *etc.*) and thus to detect metal "spillover" from the low molecular weight MBP to the high molecular weight (presumably

*Present address: Regional Marine Pollution Emergency Response Centre for the Mediterranean Sea, Manoel Island, Malta.

enzymatic) sites. However, as pointed out in the review by Winge and Brouwer,[21] potential problems do exist with this approach, notably with respect to possible dissociation of ML metal–ligand complexes during the chromatographic step and possible metal ion or ML interactions with column walls and/or packing; the potential influence of these reactions on HPLC results does not seem to be widely appreciated.

The objectives of the present study were thus to investigate the use of gel-permeation HPLC to determine MBP concentrations in freshwater invertebrates; we identify possible problems that may arise when using this method and suggest suitable conditions for the separation and detection of cytosolic proteins.

EXPERIMENTAL

To evaluate the extent of protein–column interactions, and to identify a suitable eluant that would minimize their importance, a range of the molecular weight standards was used: dextran (2×10^6), bovine albumin (66,000), egg albumin (45,000), carbonic anhydrase (29,000), chymotrypsinogen (25,000), myoglobin (17,000), ribonuclease a (13,700), cytochrome c (12,400), aprotinin (6500), vitamin B_{12} (1355) and trytophan (204). All standards were obtained from Sigma Chemical Co., St. Louis, MO, U.S.A. and were used at a concentration of 1 mg/ml. Each standard was first scanned for its UV absorption in the wavelength range 200–300 nm (Varian DMS 2000 spectrophotometer); to calibrate the high performance liquid chromatography (Waters 600 HPLC), the absorption was then measured in the HPLC detector at two predetermined wavelengths (254 and 280 nm) without the analytical column attached. Following this calibration procedure, the entire chromatographic set-up was reassembled with a gel-permeation column (TSK gel SW2000, 30×0.75 cm) and pre-column (TSK 7.5×0.75 cm) and used for elution of the marker molecules.

To determine the optimum buffer conditions, various eluant solutions were tested (all solutions contained 0.03% NaN_3): 10m*M* TRIS–HCl, pH 8.0; 10m*M* TRIS–HCl, pH 7.0; 100m*M* TRIS–HCl, pH 7.0; 200m*M* TRIS–HCl, pH 7.0; 10m*M* TRIS–HCl, 100m*M* NaCl, pH 7.0; 10m*M* MES, pH 6.0; 10m*M* MES, 100m*M* NaCl, pH 6.0; 100m*M* K_2HPO_4, 100m*M* KCl, pH 7.0. [TRIS = tris(hydroxymethyloamino)methane; MES = 2-(*N*-morpholino)-ethane sulphonic acid.] In all these cases the HPLC was operated in an isocratic mode with a flow-rate of 0.5 ml/min, at room temperature (22°) and with a pressure cut-off of 2075 kPa. In addition, each eluant was degassed with helium before use and periodically degassed during HPLC operation.

In a second investigation ligand competition experiments were performed in triplicate to determine if interaction and exchange can occur between metal bound to MBP and other proteins during the chromatographic separation step. A degassed solution of commercially available horse kidney or rabbit liver metallothionein (Sigma Chemical Co., St. Louis, MO, U.S.A.) was spiked with ^{203}Hg (NEN DuPont Canada Ltd., Toronto; initial specific activity 12 mCi/mg Hg) and left to stand for 15–20 min at room temperature under a nitrogen atmosphere. Unbound mercury was removed by the addition of hemolysed blood.[22] The resulting mixture was heated in a boiling water bath for 3–4 min, cooled and centrifuged at 10,000 *g* for 10 min. The supernatant was filtered by positive pressure through a 0.4-μm polycarbonate filter (Nucleopore). The hemolysate addition, heating, centrifugation and filtration steps yielded a clear mercury-radiolabelled metallothionein solution (final concentration 1 mg/ml), from which an aliquot was taken and the amount of radioactivity determined (LKB Wallac model 1282 gamma counter). An equivalent aliquot was injected into the HPLC system using a 10m*M* TRIS–HCl, 100m*M* NaCl, 0.03% NaN_3, pH 7.0 solution as the eluant buffer. Eluate fractions were collected and the radioactivity in each was determined by gamma counting. Additional radiolabelled metallothionein aliquots were taken and incubated separately with a solution of bovine albumin, egg albumin or vitamin B_{12} for 20 min at room temperature. These calibration markers were used to simulate the metal stripping properties of a high molecular cytosol fraction (egg/bovine albumin) and a low molecular cytosol fraction (vitamin B_{12}) respectively. In this context it should be noted that egg albumin has been used as a scavenger of unbound metal during the quantification of MBP by metal saturation methods.[23] To avoid the procedural artifacts of metal redistribution shown to take place when chemical agents are used to maintain buffers under reducing conditions,[24,25] the competition experiments were

performed under a nitrogen atmosphere in a glove bag. After the 20-min equilibration period, aliquots of these mixtures were taken for counting and an equivalent volume was injected into the HPLC; fractions were collected and counted as before.

A similar competition experiment was performed, also in triplicate, with cytosol mussel extract instead of the model cytosol components. To prepare the cytosolic extract, adult freshwater mussels, *Anodonta grandis*, of uniform size (7 to 8 cm) were collected from Lac St. Joseph, Quebec, Canada. Prior to dissection, the animals were kept in chlorine-free tap-water for 24 hr to depurate. The excised soft tissue was stored at −40° until use. The soluble fraction of the tissue was prepared by mechanical homogenization of the soft-tissue (Brinkman tissue grinder, model CH-6010) in an equal volume of ice-cold TRIS–HCl buffer (25m*M*, pH 7.2) under a nitrogen atmosphere. The homogenate was centrifuged at 170,000 *g* for 60 min at 2°. The supernatant (*ca.* 75 mg of organic matter/ml) was then incubated for 20 min at room temperature with an equivalent volume of the solution of ^{203}Hg-labelled metallothionein under a nitrogen atmosphere. A 100-μl aliquot was counted whilst an equivalent volume was injected into the HPLC and, as above, fractions were collected and counted for radioactivity. Similar combination experiments were performed with metallothionein that had been radiolabelled with ^{65}Zn or ^{109}Cd. Each set of competition or exchange experiments was performed with the same mussel cytosol extract.

RESULTS AND DISCUSSION

Results for the elution experiments designed to test the ability of the different buffers to elute the molecular weight markers from the analytical column are presented in Table 1. All markers exhibited UV absorption in the range 200–300 nm and thus, if eluted, would be readily detected by the HPLC 254/280 nm dual wavelength detector. All markers with molecular weights higher than the upper molecular weight cut-off of the analytical column (30,000) were quantitatively eluted, irrespective of the concentration or type of buffer used for elution, implying that no interaction of these proteins with the column lining took place. The results in Table 1 also show that the highest concentration of TRIS–HCl (200m*M*) was as efficient in eluting the protein markers as was the phosphate buffer or a low concentration (10m*M*) of TRIS–HCl or MES with the addition of salt (NaCl, 100m*M*). Difficulties in the elution of some proteins in the molecular working range of the column arose when low buffer concentrations were used with no added electrolyte. Thus, for example, whereas myoglobin was eluted with the lowest TRIS–HCl concentration, only the highest concentration of TRIS–HCl or a low concentration of TRIS–HCl with the addition of sodium chloride (100m*M*) was successful in eluting cytochrome c. Successful elution of molecular markers such as chymotrypsinogen, ribonuclease a and aprotinin also required high concentrations of either the eluant buffer or an added electrolyte.

The results in Table 1 would suggest that adsorption of the marker molecules to the column is more salt- than pH-dependent, since the introduction of 100m*M* sodium chloride to 10m*M* solutions of either TRIS–HCl or MES buffers in the pH range 6–8 was sufficient to ensure successful elution. The only marker to exhibit appreciable pH sensitivity was myoglobin, the elution of which at pH 6 was slower than at pH 7 or 8, possibly as a result of changes in the hydrodynamic radius of the myoglobin molecule at the lower pH.

The retention of certain molecular weight markers on the column in the presence of low ionic strength eluants is probably the result of interactions between highly charged marker molecules and silanol groups remaining on the surface of the gel-permeation support.[26] The high salt concentration effectively suppressed the residual silanol activity of the column packing, thereby limiting protein-column interaction. The original choice of a low concentration of TRIS–HCl, as utilized in the work of Suzuki and his co-workers,[27–29] was designed to limit the metal-complexing ability of the TRIS–HCl eluant since it has been demonstrated that at high concentrations this buffer may remove metals from proteins.[30] To minimize such re-equilibration is critical for a true study of the *in vivo* distribution of metals bound to different cytosolic ligands. Furthermore, the utilization of a mobile phase of relatively low ionic strength reduces the corrosion of internal metallic surfaces within the stainless steel components of commercially available chromatography systems.[31] On the other hand, as has been shown here, the use of a low concentration of TRIS–HCl can lead to a low recovery or no recovery at all of certain proteins. Clearly, as a

result of an inappropriate choice of eluant, key information regarding the presence of certain proteins with their associated metals might be lost during the chromatographic step, due to the retention of the metal–protein complex on the column. In all subsequent runs we used an eluate composition (10m*M* TRIS–HCl, 100m*M* NaCl, 0.03% NaN_3, pH 7) designed to minimize competition between the buffer and the cytosolic ligands in solution, and to reduce chemical interactions between the ligands and the chromatographic gel.

A typical HPLC elution profile following a competition experiment involving mussel cytosol and radiolabelled metal bound to commercial metallothionein is shown in Fig. 1, while results for the recoveries of radiolabelled metal bound to metallothionein are presented in Table 2. In excess of 96% of the ^{109}Cd was recovered with the metallothionein fraction

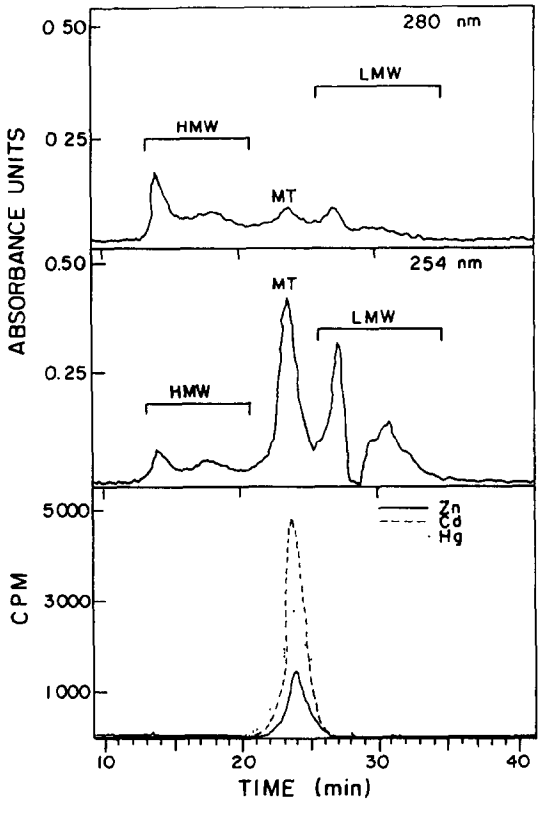

Fig. 1. Representation of an elution profile obtained by gel-permeation HPLC after a competition experiment involving mussel cytosol extract and radiolabelled metal initially bound to commercial metallothionein. Upper graphs—UV absorbance at 280 nm and 254 nm (HMW = high molecular weight fraction; MT = metallothionein fraction; LMW = low molecular weight fraction). Lower graph—typical ^{109}Cd, ^{203}Hg and ^{65}Zn profiles (cpm) with peaks corresponding to metallothionein.

after chromatographic separation, either when radiolabelled cadmium metallothionein was chromatographed on its own or when incubation with a mussel cystosol extract took place prior to chromatographic separation. Recovery of ^{203}Hg-labelled metallothionein was also quantitative when it was chromatographed alone. However, occasional recovery problems did arise when the radiolabelled mercury metallothionein preparation included other ligands. The results indicate very little exchange of the ^{203}Hg between the metallothionein and the other ligands, *i.e.*, the relative distribution of ^{203}Hg among the three molecular weight fractions remains unchanged in the eluate. Note that as expected a control injection of inorganic $^{203}HgCl_2$ gave 0% recovery.

The results for the recovery of radiolabelled zinc bound to metallothionein also show that very little ^{65}Zn exchange took place between the metallothionein and the other cytosolic ligands, *i.e.*, the relative distribution of ^{65}Zn among the three molecular weight fractions remains unchanged. However, in this case recovery of the metal was consistently low, ranging from 52 to 58% of the total zinc activity injected. Another subtle difference between these results and those obtained for mercury was that problems of recovery of radiolabelled zinc bound to metallothionein were evident even when such a preparation was injected in absence of other cytosolic ligands.

It should be noted that the loss of radioisotope (^{203}Hg, ^{65}Zn) during the HPLC separation does not necessarily imply that the metallothionein itself was lost to the column; metal exchange between the radiolabelled metallothionein and cold metal present in the HPLC system would yield the same results. Such a mechanism for loss of radiolabel seems unlikely for Hg, but may have occurred with Zn (an omnipresent metal). However, even if such exchange did occur, it does not weaken our argument. In fact, our central thesis is that metal-metallothionein complexes originally present in cytosol extracts may be labile during HPLC separation; loss of radiolabel by exchange with cold metal demonstrates just such lability.

In conclusion, these results show that problems may arise in the separation of metal-binding proteins by HPLC, as suggested by Winge and Brouwer.[21] In recent years, numerous studies have been undertaken to isolate MBP by HPLC. In many instances, 4 to 5 molecular

markers have been used for calibration of the steric exclusion gel-permeation column. In view of the results of this study, it would seem more appropriate to use a whole range of (protein) markers for calibration to ensure that minimal protein–column interaction takes place during chromatographic separation. It is also recommended that the justification for a particular eluant buffer be included in future research communications so as to help in the standardization of the HPLC method by research laboratories, if this approach is to be used for determining metallothionein concentrations and/or metal spillover as indices of sublethal metal stress. Furthermore, researchers should be aware that metal complexes originally present in cytosol extracts may be labile during HPLC separation; in the present study, such lability has been clearly demonstrated for one of the metals (Zn). If the distribution of a metal among various cytosolic ligands is to be used as an indication of metal spillover, it is strongly recommended that the stability of the cytosolic metal complexes during the HPLC separation step be tested.

DETERMINATION OF ABSORPTION EFFICIENCIES OF CARBON DIOXIDE ABSORBENTS BY GAS CHROMATOGRAPHY

WU LIXIN* and HE HUANNAN
Shanghai Institute of Metallurgy, Academia Sinica, Shanghai, 200050, P.R. China

(*Received* 7 *May* 1991. *Revised* 2 *April* 1992. *Accepted* 4 *April* 1992)

Summary—An HP-5880A gas chromatograph equipped with FID has been used to determine the efficiency of various CO_2 absorbents and some molecular sieves. Temperature, the CO_2 concentration in the absorbed gas mixture and space velocity of the gas mixture have effects on the absorption efficiency to different degrees, but temperature is a controlling factor. It has been established that in gas analysis the systematic errors arising from CO_2 impurities in the carrier gas are negligible when CO_2 is absorbed by carbon dioxide absorbents. Three methods for eliminating blank error are presented. The differential volume method through preconcentrating at the same time but at different flow-rates (DVMST) is proposed as the best method in preconcentration analysis. With the preconcentration technique, the minimum detectable level for CO_2 in a 10-litre sample is around 0.3 ppb(v/v).

Carbon dioxide absorbents are extensively used not only in analysis and purification of gases but also in the chemical and food industries, clinics, spacecraft and submarines, *etc.* There have been many reports about the absorption mechanism and absorption efficiencies of carbon dioxide absorbents.[1–7] Gootjes and Lagerweij[8] have investigated the dust content, flow resistance, colourshift and CO_2 absorption capacity of six brands of CO_2 absorbents under the same clinical conditions. However, a detailed report on the CO_2 residues that pass through carbon dioxide absorbents and effects on the absorption efficiencies has not been recorded yet, as far as we know. Herein, the CO_2 residue represents the residual (unabsorbed) carbon dioxide amount (ppb, v/v) of a gas mixture that passed through the carbon dioxide absorbent. Although gas chromatography with TCD has been generally used to determine residual carbon dioxide, unsatisfactory sensitivity means that the amount of CO_2 which passes through CO_2 absorbents (especially for those used in gas analysis) cannot be determined. The residues were therefore mostly reported as being no larger than a fixed value (*e.g.*, 0.01%, 5 ppm,[9] *etc.*). In order to demonstrate the main performances of the CO_2 absorbent prepared in our laboratory and other commercial products, to find out whether the residues will produce systematic errors in gas analysis, it is necessary to study the residues and effects on the residues of factors such as temperature, velocity, *etc.* Since zeolite molecular sieves have good adsorption to carbon dioxide, the CO_2 residues of gas mixtures adsorbed by zeolite molecular sieves are also determined in this paper.

Gas chromatography is the most effective method for trace gas analysis. To determine trace amounts of carbon dioxide, the gas is generally transformed to methane and then detected by a flame ionization detector (FID). If a preconcentration technique is used, the detection limit can be reduced to 10^{-10}–10^{-11} v/v.[10] In this work, an HP-5880A GC equipped with FID and combined with a preconcentration technique is used to determine the CO_2 residues that pass through CO_2 absorbents and zeolite molecular sieves.

It is well known that the accuracy of trace gas analysis is affected if a blank is too large or uncertain. The blank is mainly from impurities of carrier gas and gas penetration from the atmosphere. In preconcentration analysis, the blank will become more serious because of its accumulation. In order to minimize the analytical error, we aim to improve the preconcentration method and propose three calculation methods which make the results more accurate.

EXPERIMENTAL

Apparatus and chromatographic conditions

The experimental system is shown in Fig. 1. A gas mixture containing CO_2 passes through CO_2 absorbent and desiccant. After absorption by the CO_2 absorbent, the gas mixture is preconcentrated in the preconcentration column.

An HP-5880A GC (Hewlett Packard Co., U.S.A.) equipped with FID is used. The chromatographic conditions are as follows: stainless steel chromatographic column ($\frac{1}{8}$ inch × 800 mm) packed with carbon molecular sieve "601" (Shanghai Reagent Factory), 40–60 mesh; oven temperature 60°; injection temperature 150°; detector temperature 200°; carrier gas, hydrogen 56 ml/min; air 440 ml/min; nitrogen 24 ml/min; reduced nickel catalyst tube, $\phi 3 \times 150$ mm, 380–400°.

Recovery efficiency of CO_2 preconcentration

As shown in Fig. 1, the reference gases are injected in two ways. One is injected directly from injection port 15, the other is injected from injection port 9 and transported to the preconcentration column (−196°) by ultra pure hydrogen at different flow-rates. The ultra pure hydrogen was released from a hydrogen storage cylinder. Its CO_2 impurities are so little that CO_2 cannot be detected even if two litres of hydrogen are concentrated. Therefore, the peak areas in Table 1 do not require deduction of contributions from CO_2 impurities of ultra pure hydrogen. It can be seen from Table 1 that the preconcentration of carbon dioxide is complete when the flow-rate of the preconcentrated gases ranges from 400 to 800 ml/min. The recovery efficiency can reach 96.9% even when the flow-rate is 1000 ml/min.

Calibration curve

The standard reference gas (0.957% CO_2 in hydrogen) is injected in different amounts by micro syringe. The volume injected is plotted *vs.* CO_2 peak area (Fig. 2). The calibration curve is a straight line passing through the origin.

Table 1. The recovery efficiency of CO_2 preconcentration

Method of injection	Flow-rate of ultra pure hydrogen, *ml/min*	CO_2 Peak area	Recovery efficiency of preconcentration %
Direct injection*		2211.32	
2 litre†	400	Undetectable	
Preconcentration injection*	400	2210.82	99.98
	600	2210.14	99.94
	800	2167.05	98.00
	1000	2142.74	96.90

*40 μl of reference gas (0.957% CO_2) is injected by micro syringe.
†The preconcentration volume of ultra pure hydrogen, no extra gases are injected.

Analysis process

As shown in Fig. 1, the sample gas is concentrated at a constant flow-rate. When a given amount of sample is concentrated, the sampling valve V_1 is turned to the "ON" position and the Dewar vessel containing liquid nitrogen is removed. After 10 sec a hot water bath at 80° is put around the preconcentration column and the "START RUN" key is pressed. The chromatograph then runs automatically.

Minimum detectable level

According to the minimum peak area detected by the integrator, the minimum detectable level for CO_2 with a 10-litre sample is around 0.3 ppb (v/v).

RESULTS AND DISCUSSION

Absorption efficiencies of various CO_2 absorbents under different conditions

Carbon dioxide residues which passed through some CO_2 absorbents and molecular sieves. Some brands of CO_2 absorbents and zeolite molecular sieves are packed in an absorbing tube (15 mm i.d. × 100 mm) respectively. A gas mixture (4.2% CO_2 in hydrogen) is passed through the tube at a rate of 400 ml/min at a temperature of 25°. After CO_2 in the gas mixture is absorbed by the absorbent, the residual CO_2 portion is determined by chromatographic detection. The results are summarized in Table 2.

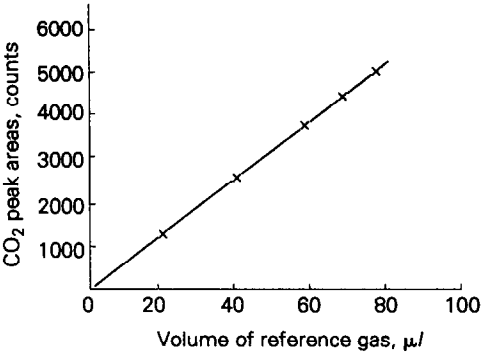

Fig. 2. Calibration curve for measurement of CO_2.

It can be seen from Table 2 that the residues that passed through HP-1 CO_2 Absorbent and Soda Asbestos are the lowest. All of the absorbents used for gas analysis (HP-1 Absorbent, Soda Asbestos, Ascarite II and Carbosorb AS) can absorb CO_2 completely. The residual CO_2 can be lower to ppb levels. Molecular sieves also have very good adsorption for CO_2, but their adsorptions are closely related to their degrees of activation. Due to their poor selectivity, molecular sieves are not widely used as CO_2 absorbents in gas analysis.

Effect of temperature on the residues. The CO_2 residues that passed through some absorbents and molecular sieves at different temperatures are listed in Table 3. The experimental conditions are as follows: gas mixture, 4.2% CO_2 in hydrogen; flow-rate, 400 ml/min; absorbing tube, 15 mm i.d. × 100 mm.

Table 2. CO_2 residues which passed through some CO_2 absorbents and molecular sieves

Absorbents	Number of determinations	Average of CO_2 residues, *ppb(v/v)*	Relative standard deviation, %
HP-1 CO_2 absorbent (our laboratory)	6	3.3	3.0
Soda asbestos (E. Merck Co., Germany)	3	3.5	4.4
Ascarite II (LECO Co., USA)	4	11.9	4.4
Carbosorb AS (B.D.H. Co., England)	4	7.2	3.3
Soda lime (Shanghai Reagent Factory, China)	4	365	3.1
5A Molecular sieve* (Linde Co., Germany)	3	240	4.8
10x Molecular sieve* (Karlsruhe Co., Germany)	3	123	4.6
13x Molecular sieve* (Schuchardt Co., Germany)	4	63.9	3.1

*Molecular sieves are activated at 500–550° in a furnace for 15 hr. Pure hydrogen is passed through the activated molecular sieves at 150 ml/min for 1–2 hr before analysing.

Table 3. Effect of temperature on the residues [units of ppb(v/v)]

Temperature, °C	0	25	50	75	95
HP-1 CO_2 absorbent	2.3	3.3	7.1	16.1	25.8
Soda asbestos	2.6	3.5	6.8	14.2	24.2
Ascarite II	5.7	11.9	—	31.8	—
Carbosorb AS	3.1	7.2	15.3	—	—
5A Molecular sieve	54.0	240	1400	—	—
10x Molecular sieve	42.7	123	—	—	—
13x Molecular sieve	12.8	63.9	—	—	—

Table 3 shows that CO_2 residues passing through CO_2 absorbents and molecular sieves will increase when the temperature increases because it is a thermopositive process. However, compared with CO_2 absorbents, molecular sieves are more sensitive to temperature change due to its characteristics of physical adsorption. They can make CO_2 residues as low as those of CO_2 chemical absorption at low temperature, which is very useful in gas separation and purification.

Effect of space velocity on the residues. When a gas mixture (4.2% CO_2 in hydrogen) is passed through the absorbents at different space velocities, their results are listed in Table 4. Herein, the space velocity means the number of volumes of gases that pass through one unit volume of the absorbent in unit time. The calculation method is: flow-rate of gas (ml/hr) divided by volume of the absorbent (ml).

In Table 4 the residues are lower at the space velocity of 18000 hr^{-1} because of incomplete preconcentration, since the flow-rate of the preconcentrated gas is over 1000 ml/min at that time. It can be concluded that the residues do not increase when the space velocity of the absorbed gas mixture ranges from 1500 to 18000 hr^{-1}. This demonstrates that the absorbents absorb CO_2 completely and rapidly.

Effect of CO_2 concentration of absorbed gases on the residues. In Table 5 it can be seen that the residues will increase slightly if the CO_2 concentration of the absorbed gas mixture is higher. As we know, when the absorbed gas containing high-concentration CO_2 passes through the absorbent, particularly at high space velocity, large amounts of heat may be released in very

Table 4. Effect of space velocity on the residues [units of ppb(v/v)]

Space velocity, hr^{-1}	1500	5200	13000	18000
HP-1 CO_2 absorbent	4.3	4.5	4.3	4.2
Soda asbestos	4.1	4.3	—	4.2

Table 5. Effect of CO_2 concentration of absorbed gas mixture on the residues [units of ppb(v/v)]

CO_2 concentration of absorbed gases (%)	4.2	10	16
HP-1 CO_2 absorbent	4.5	4.9	5.7
Soda asbestos	4.2	4.4	5.5

short time periods owing to intense reaction. The heat will be carried to the upside of the absorbing tube with gas flow and the temperature of the absorbent rises. Hence, the absorption efficiency of the absorbent will be decreased.

The residues absorbed by CO_2 absorbents in analogous gas analysis experiment. In practical gas analysis (*e.g.*, determination of carbon and oxygen in metals) carbon and oxygen are generally released in the form of CO_2. Since carbon/oxygen reacts with oxygen/carbon rapidly, the concentration distribution of released carbon dioxide is peak-like. The concentration of carbon dioxide may be very high at the top of the peak. The question arises as to whether such large amounts of carbon dioxide passing through the absorbent give a breakthrough of CO_2. In order to imitate the above situation, pure carbon dioxide is injected from injection port 3 (see Fig. 1) when gas mixture passes through the absorbent (gas mixture, 4.2% CO_2 in hydrogen; flow-rate, 400 ml/min; temperature, 25°).

It can be seen from Table 6 that a small amount of gas mixture containing high-concentration CO_2 does not cause the residues to increase. Compared with the amounts of released carbon dioxide, the residues are very slight. Accordingly, it can be concluded that the systematic error from the residual CO_2 in gases are negligible if they are absorbed by the absorbent in gas analysis. However, when the reagent only remains 2 cm in height, a breakthrough of CO_2 will occur.

Residues absorbed by CO_2 absorbents in gas purification. In order to investigate the absorbent's efficiency in absorbing micro amounts of carbon dioxide, pure hydrogen containing 2.3 ppm CO_2 impurities is used as absorbed gas.

Table 6. The CO_2 residues absorbed by CO_2 absorbents in analogous gas analysis [units of ppb(v/v)]

Height of unabsorbed absorbent (*cm*)		7–9		2
Amounts of pure CO_2 injected (*ml*)	0	30	50	30
Ascarite II	11.9	11.8	12.1	51
HP-1 CO_2 absorbent	3.5	—	4.0	63

When the pure hydrogen is purified by HP-1 CO_2 Absorbent, its CO_2 impurities can be reduced to 3.8 ppb (temperature, 28°; flow-rate, 800 ml/min).

Comparison of preconcentration methods for eliminating blank error

Preconcentration sampling is one of the most important means for measuring trace impurities in gases by GC. Compared with direct sampling, however, preconcentration sampling will naturally introduce a problem from the blank. The impurities of carrier gas, sample gas and penetration from outside will become obvious in trace gas analysis because of time accumulation and violent temperature changes in preconcentrating processes. The blank cannot generally be neglected and may sometimes lead to the wrong conclusion. Previously, eliminating blank error has been mainly done by deducting the measured blank value. In our view however, the method has at least two disadvantages: (1) In the blank test, an ultra pure gas which is assumed as absolutely pure is usually used in place of the sample gas in order to determine the blank value, but because the ultra pure gas will not be absolutely pure, the calculated blank must contain a new blank which comes from the impurities of the absolutely pure gas. (2) Since the experimental conditions in practical analysis are not always the same as those used in the blank test, the practical blank may change during long experimental processes. Considering the above situation, we present three methods for improving preconcentration sampling:

(1) Differential Volume Method through preconcentrating at the same flow-rate but different times (DVMSF);

(2) Differential Time Method through preconcentrating the same volume at different flow-rates (DTMSV) and

(3) Differential Volume Method through preconcentrating at the same time but different flow-rates (DVMST).

DVMSF can eliminate the blank error which comes from the impurities of carrier gas and sample gas, while DTMSV can eliminate the blank error which comes from CO_2 penetration from the atmosphere. DVMST which actually combines DVMSF with DTMSV can eliminate the above two errors.

As we know, at the very beginning of preconcentration, parts of the sample gas will be trapped in the preconcentration column with dramatic fall in temperature, but these parts cannot be included in the preconcentration volume because their volume is not known exactly, which will give a "sample gas blank". After preconcentration, there are a few seconds before desorbing the trapped gas with hot water in order to get good quality peaks. But during this time the impurities of carrier gas are trapped due to the very low temperature column, which will bring a "carrier gas blank". But, if sample gas flow-rate and release time are the same, the above two blanks are unchangeable whenever the preconcentration volumes are different. So we can use the DVMSF method to deduct the blank. The calculation formulae are as follows:

$$C_x = \frac{V_s \cdot C_s}{A_s} \cdot \frac{(A_2 - A_1)}{(V_2 - V_1)} \times 10^3$$

where C_x is the concentration of sample gas (ppb); V_s, C_s, A_s are the volume (ml), concentration (%) and peak areas of standard reference gas; V_2, V_1, A_2, A_1 are the preconcentration volume (litre) and corresponding peak areas at the same flow-rate but different preconcentration time.

Another blank, the "penetration blank", is more influential in trace gas analysis. It is very difficult to prevent air from penetrating into the analytical system completely. Although the amounts of air are very small, the amounts of CO_2 in air intruded are very large in comparison with the analysed gas in the trace analysis. If those parts penetrated from atmosphere are not deduced in experiment a large error will be produced, and a wrong conclusion may sometimes result. Since the penetration blank is equal at the same preconcentration time, we can use DVMST method to eliminate this blank error. The calculation formulae are as follows:

$$k = \frac{A_2 - A_1}{t_2 - t_1} \quad A_1' = A_1 - kt_1 \quad A_2' = A_2 - kt_2$$

where k is the correction factor; t_2, t_1, A_2, A_1 are the preconcentration time ($t_2 > t_1$) and corresponding peak areas at the same preconcentration volume but different flow-rate; A_1', A_2' are the corrected peak areas of A_1, A_2 respectively. Then the results can be calculated according to the routine peak area method (PAM), *i.e.*,

$$C_x = \frac{V_s \cdot C_s}{A_s} \cdot \frac{A_1'}{V_1} \quad \text{or} \quad C_x = \frac{V_s \cdot C_s}{A_s} \cdot \frac{A_2'}{V_2}$$

In order to obtain a convenient and effective method for eliminating the blank error, the DVMST method is proposed to be the best.

Table 7. Comparison of some preconcentration methods

Group	No. of experiment	Preconcentration: Time, *min*	Flow, *ml/min*	Volume, *litres*	Peak areas: CO_2	Corrected by DTMSV	CO_2 residues, ppb: PAM	DVMSF	DTMSV + PAM	DTMSV + DVMSF	DVMST
1	1	24.2	200	5.0	381.88	109.18	12.4		3.6	3.1	3.0
	2	24.1	400	10.0	473.52	202.40	7.7	7.2	3.3	(2–1)	(2–1)
	3	11.4	400	5.0	237.60	110.17	7.7	(4–2)	3.6	3.2	
	4	34.3	400	15.0	689.40	303.98	7.5	7.4 (4–3)*	3.3	3.1 (4–3)	
2	5	6.6	400	3.0	74.00	69.70	3.3	3.2	3.1	3.0	
	6	16.9	400	7.6	182.25	171.24	3.2	(6–5)	3.0	(6–5)	
	7	5.4	400	2.5	60.46	56.88	3.3	3.2	3.1	3.0	
	8	11.4	200	2.5	64.31	56.88	3.5	(6–7)	3.1	(6–7)	

*(4–3) means that the result is calculated from the difference of volumes and peak areas of Experiments No. 4 and No. 3 according to DVMSF method. Others are on the analogy of this.

The method has taken both sides of gas blank and penetration blank into consideration. Its calculation formula is identical with DVMSF's except some used symbols have different meaning, where V_2, V_1, A_2, A_1 are the preconcentration volumes (litre) and corresponding peak areas at the same preconcentration time but different flow-rate.

Table 7 summarizes the calculation results of some preconcentration methods. In Table 7, both Group 1 and 2 are the results of determining CO_2 residue that passed through HP-1 CO_2 Absorbent. In order to illustrate the superiority of the proposed methods, we let air penetrate into the analytical system in Group 1 quite seriously on purpose. It can be seen that the results calculated by DVMSF are a bit lower than those calculated by PAM as a result of deducting sample gas blank and carrier gas blank. When the penetration of CO_2 is serious, the results should be calculated by DTMSV or DVMST, otherwise, its accuracy will be very poor although its precision is satisfactory. It can also be seen that the results of DVMST are nearly equal to those of DTMSV + DVMSF; the results of DVMST and DTMSV in Group 1 are also identical with those of Group 2 where the penetration of CO_2 is slight. This proves our proposed methods to be correct and efficient.

Compared to the deduction method for blanks measured in the blank test, DVMST and DTMSV have the following advantages: (1) they can deduct the blank error without doing a blank test; (2) the analytical precision is better because only the flow-rate of the sample gas changes during the entire process; (3) the blank correction is dynamic, independent, and the corrected results are not affected by changes in the blank during experiments; (4) the blank change can be seen clearly and timely, which allows the measures to reduce the system blank to be taken purposefully. These methods will become more efficient in determining trace amounts of oxygen or nitrogen.

CONCLUSION

An HP-5880A gas chromatograph equipped with FID has been used to determine the CO_2 residues that passed through CO_2 absorbents produced by our laboratory, E. Merck Co., B.D.H. Co., LECO Co. and molecular sieves, such as 5A, 10x, 13x. In combination with preconcentration technique, the minimum detectable level for CO_2 with a 10-litre sample is around 0.3 ppb (v/v).

The results demonstrate that the CO_2 residue that passed through HP-1 CO_2 Absorbent (prepared in our laboratory) and Soda Asbestos (produced by E. Merck Co.) is the lowest (3–4 ppb at room temperature). Temperature, CO_2 concentration of absorbed gas mixture, space velocity have effects on the residues in different degrees, but temperature is a controlling factor. The residues will increase with rising temperature. The systematic errors coming from the residual CO_2 in gases are negligible when they are absorbed by CO_2 absorbents in gas analysis.

Blank problems in preconcentration techniques are discussed. Three methods for eliminating blank error are presented: differential volume method through preconcentrating at the same flow-rate but different times (DVMSF), differential time method through preconcentrating the same volume at different flow-rates (DTMSV), and differential volume method

through preconcentrating at the same time but different flowrates (DVMST). DVMST is proposed to be the best method in preconcentration analysis for its convenience and accuracy.

DETERMINATION OF TOTAL SELENIUM IN WATER BY ATOMIC-ABSORPTION SPECTROMETRY AFTER HYDRIDE GENERATION AND PRECONCENTRATION IN A COLD TRAP SYSTEM

ULF ÖRNEMARK,* JEAN PETTERSSON and ÅKE OLIN
University of Uppsala, Department of Analytical Chemistry, P.O. Box 531, S-751 21 Uppsala, Sweden

(*Received* 28 *October* 1991. *Revised* 4 *February* 1992. *Accepted* 4 *February* 1992)

Summary—A cold trap system for the determination of selenium by hydride generation–atomic absorption spectrometry (HG–AAS) is described. For a 30-ml sample the limit of detection is <2 ng/l. and the precision is better than 4% at the 30 ng/l. level. A number of digestion procedures for the destruction of organic matter prior to the determination of total dissolved selenium in water has been tested and compared. Concordant results were obtained except for oxidation by peroxodisulphate in strongly acidic solutions with a high content of organic material. The selenium concentrations found were in agreement with those obtained by HG–AAS after preconcentration by evaporation and dry ashing with the magnesium nitrate–nitric acid–hydrochloric acid method.

Hydride generation, followed by collection of the hydride in a cold trap, is used as a preconcentration step in the determination of several elements occurring in the low ng/l. range in natural waters. Since the work by Holak[1] in 1969 more than 80 papers have described trap systems for the determination of antimony, arsenic, bismuth, germanium, lead, selenium,[2–8] tellurium and tin. Selective hydride generation is possible since optimum conditions for hydride formation vary between the elements and between oxidation states of the same element. In addition to the usual information on speciation provided by the different reactivity of oxidation states, further information can be obtained by the cold trap technique by subjecting the contents of the trap to selective vaporization[9,10] or separation on a chromatographic column.[10]

There are difficulties connected with the cold trap technique due to the limited stability of the hydrides. Proper choice and pretreatment of the materials in the apparatus are essential. Volatile concomitants already present in the sample or formed during the hydride generation will also collect in the trap, and the amounts may reach levels that interfere with the determination of the analyte. Removal of such interferents by chemical sorbents[1,9] in the gas stream is not always possible due to decomposition of the hydride on the sorbent. It is therefore not surprising that the technique has been most frequently applied to the determination of arsenic, selenium, tin, antimony and germanium, which form the most stable hydrides.

In the present work a cold trap system assembled for the determination of selenium will be described. This element is present as selenite, selenate or organic selenium in natural waters. Great variations have been reported for the relative amounts of the three fractions.[11–13] The concentrations are low and for most Swedish surface and ground waters the total selenium concentration is <200 ng/l.[14] This concentration is close to the detection limit of the hydride generation–atomic absorption spectrometric (HG–AAS) method without preconcentration.[15] Thus the addition of a preconcentration step is needed for a study of these waters. A determination of total selenium requires that organic forms are transformed to inorganic selenium. Wet digestion with nitric acid or mixtures of this acid with other oxidizing agents,[16–18] permanganate,[19] peroxodisulphate,[20] and ultraviolet irradiation[21] have been used for this purpose. We here report the results from a comparative study of destruction methods for dissolved organics in water for use in the determination of total selenium by HG–AAS combined with a cold trap. The efficiency of the method to transform various forms of organic selenium to inorganic forms was also studied.

EXPERIMENTAL

Apparatus

The hydride generation and cold trap system shown in Fig. 1 consisted of a peristaltic pump (Minipuls 2, Gilson Medical Electronics, France) with PVC-tubings and four U-tubes in series. Solutions were transported through 0.5-mm PTFE-tubing and T-connections (Kabi-Pharmacia, Sweden) were used for mixing solutions and introduction of the carrier gas (N_2). The U-tubes were made of borosilicate glass (length 300 mm, inner diameter 16 mm, wall thickness 1 mm), silanized, connected by latex tubing and closed with silicone stoppers. The first tube served as a gas–liquid separator and the next two as water vapour traps. The latter were immersed in a cooling bath (Model D8-GH, Haake, Germany) containing ethanol at $-15°$. The selenium hydride was trapped at liquid nitrogen temperature by a plug of silanized quartz wool (50 mg) on the outlet side of the fourth U-tube. The flow of carrier gas was 550 ml/min and the flow of tetrahydroborate solution and sample were 5.6 and 12 ml/min, respectively.

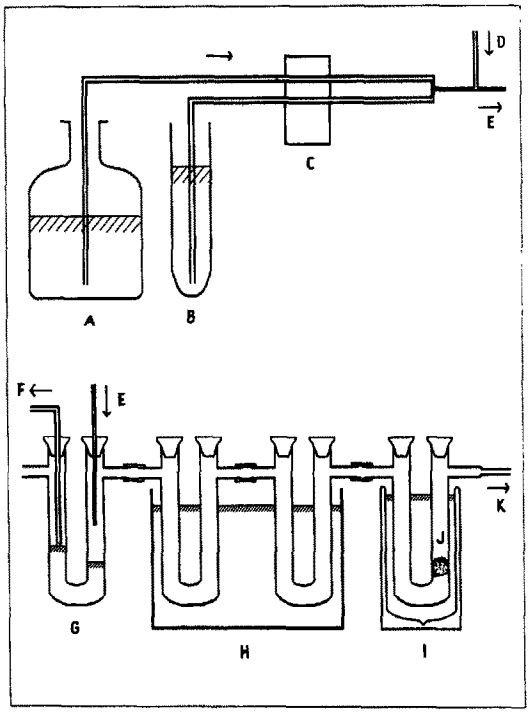

Fig. 1. Apparatus to generate, dry and collect hydrogen selenide. (A) Sodium tetrahydroborate, (B) acidified sample, (C) peristaltic pump, (D) carrier gas inlet, (E) to gas–liquid separator, (F) to waste, (G) gas–liquid separator, (H) water vapour traps, (I) hydride trap, (J) silanized quartz wool, (K) to quartz furnace.

The atomic-absorption measurements were made with a Perkin–Elmer 3100 double beam spectrometer. It was modified to hold the Perkin–Elmer MHS-20 oven with the quartz cuvette kept at 800°. The electrodeless discharge lamp (Perkin–Elmer) was operated at 7.6 W. The wavelength was 196.0 nm and the spectral band-width 0.7 nm. The deuterium background corrector of the instrument could not be used with our EDL power supply.

Determinations in the 1–10 ng Se/ml range were carried out on the flow-injection instrumentation described by Pettersson *et al.*[22]

Digestions and reductions of selenate to selenite were carried out in test tubes of borosilicate glass placed in a temperature controlled aluminium block[22] or in beakers on a hot plate. UV-irradiation was performed in 60-ml closed quartz tubes with the equipment described by Gustavsson *et al.*[23]

Chemicals

All chemicals were of analytical grade from Merck unless otherwise stated. Demineralized distilled water passed through a Millipore 3 filter cartridge system was used throughout.

A stock solution of selenium(IV), 1 g/l., was prepared from an ampoule of selenium dioxide in dilute nitric acid and its concentration was checked by an amperometric titration with thiosulphate after addition of a large excess of iodide (T. A. Bengtsson, unpublished method). The stock solution of selenium(VI), 1 g/l., was prepared by dissolving sodium selenate decahydrate (BDH) in water containing 2 ml/l. of concentrated nitric acid. Its concentration was checked against a selenium(IV) standard solution. Standard solutions of selenium(IV) and (VI) were prepared by dilution of stock solutions and contained 2 ml/l. of concentrated hydrochloric acid.

The organoselenium compounds studied were:

(A) 4,4-bis-(hydroxymethyl)-1,2-diselenolane[24]
(B) Se-benzyl-*N*-acetylselenocysteine methyl ester[25]
(C) 1,2-diselenane-3,6-dicarboxylic acid[24]
(D) seleno-DL-methionine, 99% (Sigma)
(E) seleno-DL-cystine, 90% (Sigma)
(F) trimethylselenonium iodide, 99.999% (TRI Chemical Lab., Kanagawa, Japan)

Compounds (A)–(E) were analyzed for selenium after wet digestion according to a variation of Gould's method[26] using a 10:1 (v/v)

mixture of concentrated sulphuric acid and fuming nitric acid and the amperometric titration method mentioned above. Test solutions in 0.01*M* hydrochloric acid of the organoselenium compounds, corresponding to 15 μg Se/l., were used in the experiments.

Tetrahydroborate solution, (0.5% w/v), was prepared by adding 2.5 g of sodium tetrahydroborate, 0.5 g of sodium hydroxide and 0.5 g of barium hydroxide octahydrate to 500 ml of water. After agitation, the solution was filtered through a membrane filter (0.45 μm, Millipore).

Solutions of sodium hydroxide, 5% (w/v), potassium peroxodisulphate, 2%, and potassium permanganate, 1%, were all prepared by dissolution in water.

Nitrogen used as carrier gas in the cold trap system was passed through a stainless steel column (300 × 23 nm) containing soda lime pellets to remove traces of carbon dioxide.

Water samples

The drinking water is a mixture of ground water and infiltrated surface water. At most 0.5 mg/l. of sodium hypochlorite is added at the water works. The lake water, which contained 24 mg C/l., was collected as surface water from lake Lafssjön, north of Uppsala. Both waters were filtered through a membrane filter (0.45 μm, Millipore), acidified to pH 2 with hydrochloric acid and stored in polyethylene bottles in a refrigerator.

Cleaning procedures

When first used, glassware was soaked for 12 hr in a 2% alkaline detergent (RBS-25, LabKemi, Sweden), rinsed with water, then leached for 24 hr in 4*M* nitric acid and finally rinsed with water. Glassware used in the cold trap system was, in addition, leached in 0.1*M* hydrochloric acid. Between uses utensils were soaked for a few hours in 4*M* nitric acid. The latex tubing was cleaned with the same acid and PVC tubing with 1*M* hydrochloric acid for a few hours and then rinsed with water and dried.

Conditioning of the glass used in the cold trap system involved cleaning and deactivation of the surface by silanization. The cleaned U-tubes were dried at 110° for 1 hr, soaked in a 5% dimethyldichlorosilane (Macherey-Nagel, Germany) solution in toluene for 2 hr, rinsed with small portions of toluene followed by methanol and dried at 100° for 1 hr. The U-tubes were then assembled and subjected to a continuous flow of 2–3 ml/min of nitrogen when not in use.

Pretreatment of water samples

In each of the following procedures (a)–(d), 150 ml of water were digested in a 250-ml glass beaker covered with a watch glass. In the reduction step 60 ml of concentrated hydrochloric acid were added in (b)–(e) and in (a) from the beginning. After digestion and reduction the sample was transferred to a 250-ml standard flask and diluted to volume with water.

(a) Peroxodisulphate in 3*M* hydrochloric acid; mix water, hydrochloric acid and peroxodisulphate solution (10 ml for lake water and 1.5 ml for tap water) and boil gently for 1 hr.

(b) Peroxodisulphate at pH 2; mix water and peroxodisulphate solution (10 ml for lake water and 1.5 ml for tap water) and boil gently for 0.5 hr. Add hydrochloric acid and continue boiling for 1 hr.

(c) Peroxodisulphate in alkaline medium; mix water, peroxodisulphate and sodium hydroxide solution (10 and 12 ml, respectively, for lake water and 1.5 and 7 ml for tap water) and boil gently for 0.5 hr. Add hydrochloric acid and continue boiling for 1 hr.

(d) Permanganate at pH 2; mix water and 5 ml of permanganate solution and boil gently for 0.5 hr. Add hydrochloric acid and continue boiling for 1 hr.

(e) UV-irradiation; to three quartz tubes add 50 ml of water, 50 μl of hydrogen peroxide and 1 ml of 6*M* hydrochloric acid. Irradiate for 3 hr at 600 W. Transfer to a 250-ml glass beaker, add hydrochloric acid and boil gently for 1 hr.

(f) Magnesium nitrate–nitric acid–hydrochloric acid; mix 200 ml of water, 1 ml of 6*M* hydrochloric acid, 5 ml of concentrated nitric acid and 2 g of magnesium nitrate hexahydrate in a 250-ml glass beaker. Evaporate to about 10 ml. Transfer to a 50-ml digestion tube, dilute to 20 ml and apply the following temperature programme to the aluminium block: 135°—3 hr, 175°—3 hr, 225°—2 hr, 300°—1 hr and 500°—5 hr. Cool and dissolve the residue in 10 ml of 6*M* hydrochloric acid. Heat at boiling temperature for 1 hr, cool and dilute to 25 ml.

Pretreatment of organoselenium compounds

Each of the organoselenium compounds (A)–(F) were subjected to the decomposition–reduction pretreatments (a)–(f) above. Digestions and reductions were carried out on 10-ml samples in open 50-ml digestion tubes placed in an aluminium block and in (e) as described for water samples. The samples contained 150 ng of selenium. The following reagent volumes were added: (a) 5 ml of concentrated hydrochloric acid and 0.3 ml of peroxodisulphate, (b) 0.3 ml of peroxodisulphate, (c) 0.7 ml of sodium hydroxide and 0.3 ml of peroxodisulphate, (d) 0.5 ml of permanganate, (e) 20 μl of hydrogen peroxide and 1 ml of 1*M* hydrochloric acid, (f) as for water samples. After addition of the reagents the samples were diluted to 20 ml. In the reduction step in (b)–(e) 5 ml of concentrated hydrochloric acid was added. The reaction times stated above were used.

The reduced samples were diluted to 50 ml corresponding to a selenium concentration of 3 μg/l. Selenium was determined by the flow-injection apparatus.[22]

Selenium determination

Adjust the acidity of a 30-ml sample containing not more than 5 ng of selenium to 1*M* with hydrochloric acid. Immerse the hydride trap into the liquid nitrogen. After 30 sec turn on the peristaltic pump. When the sample has been consumed, rinse the sample container and tubing with 1*M* hydrochloric acid. Turn off the pump 3 min after the start, wait for 10 sec and replace the liquid nitrogen with cold ethanol (−15°). Initiate the reading cycle of the spectrometer. Don't remove the ethanol bath until the whole selenium peak has been measured.

Prior to the next determination, remove the water vapour in the hydride trap by heating the trap with a heat gun.

RESULTS AND DISCUSSION

Cold trap system

The cold trap system was composed of silanized,[27] open-ended U-tubes with silicon rubber stoppers. They were connected by short lengths of latex rubber, which made our system flexible and easy to handle. When the traps were connected by teflon joints with viton rubber seals high blanks were observed, which disappeared when these connections were replaced by latex rubber. An all-glass system, except for the connection to the quartz furnace, failed to give acceptable precision. We believe that this was due to lack of oxygen, since oxygen is necessary for the atomization process in the heated cuvette.[5] With latex tubings enough oxygen was added to the carrier gas by diffusion through the walls. In order to protect silanized surfaces from moisture when the apparatus was not in use, the system was continuously flushed with a few ml of nitrogen per minute. The silanization of the gas–liquid separator deteriorated somewhat after a few weeks in use but the shape of the absorbance peak, precision and sensitivity were unaffected. However, as a precaution the equipment was resilanized after about 300 determinations.

Silanized quartz wool in the hydride trap proved satisfactory and a small plug, about 50 mg, placed on the outlet side of the trap was sufficient to collect all hydrogen selenide. A bigger piece of wool resulted in broader peaks.

Ambient air or water of room temperature was used initially to warm the trap and desorb the hydride. The peak height precision obtained with water was better than with air. However, a drift in baseline occurred during desorption. This observation was suspected to be caused by small amounts of water, which had escaped the water trap, collected in the hydride trap and subsequently been released in the desorption step. This problem disappeared when desorption was made with ethanol at −15°, which apparently held back any water present in the trap.

About 10 mg of water were transferred per minute from the gas–liquid separator to the cold trap system during the hydride generation. With two water traps about 95% of the water was removed. The remaining 5% of water, which condensed in the hydride trap, could easily be removed by heating the hydride trap for 15 sec with a heat gun between determinations. A layer of ice was gradually built up at the inlet of the first water trap. It was removed by raising the trap from the cooling bath for a short time. This was done 2 or 3 times a day. It was not necessary to empty the trap until the end of a day's measurements because of the big volume of the water trap. The second water trap needed no attention.

Several variations of the hydride trap were tried mainly to minimize the dead volume between the trapping zone and the quartz furnace. A V-shaped trap,[28] where only the knee was

filled with quartz wool and cooled, resulted in sharper peaks and the sensitivity almost doubled. However, peak height precision was poor. Peak splitting often occurred and the peak shape depended on the way the quartz wool was placed in the trap indicating that the desorption of the hydride from the trap was non-uniform. An obvious way to reduce the dead volume is to diminish the dimensions of the equipment following the plug of quartz wool. However, in the flow system there is a fairly delicate balance between the pressures built up in the various parts. If the dimensions of the outlet are made smaller, pressures must be increased on the inlet side. The increase in inlet pressure, when the diameter of the outlet was reduced, caused malfunction of the gas–liquid separator. Hence an equipment with fairly large inner diameters was chosen as a compromise between sensitivity and precision on one hand and ease of handling on the other.

Hydride generation, interferences and analytical performance

A sample input of 12 ml/min was used, which represented the maximum capacity of the peristaltic pump. The optimal concentration of sodium tetrahydroborate was found to be 0.5% (w/v) and the solution was stabilized by addition of sodium hydroxide. This solution contained carbonate which was released in the acid hydride generation step. The carbon dioxide was transported along with the hydrogen selenide and interfered with the selenium determination. Several experiments were performed in which test solutions with and without additions of carbonate were processed in the apparatus. The absorbance signal increased in all cases where carbonate had been deliberately added. Furthermore, the ratio between peak height and peak area changed from the value obtained with carbonate-free solutions. Addition of barium hydroxide to the tetrahydroborate solution followed by filtration through a membrane filter,[3] reduced the blank to about 75 pg of selenium. We believe that most of the reduction in the blank was due to removal of carbonate. No selenium could be detected in the precipitated barium carbonate.

The sensitivity increased with the hydrochloric acid concentration in the range 1–4*M*. Since the increase was only about 20%, 1*M* acid was chosen in order to prolong the life-time of the silanization and reduce corrosion.

The measured absorbance diminished with the time elapsed between hydride generation and desorption due to depletion of hydrogen in the carrier gas.[5] The decrease was about 40% during the first minute. It is therefore necessary to desorb the hydride at a short and fixed time after the hydride generation has ended.

In the determination of selenium by hydride generation the severe interference from nitrite[29] and the potential interference from nitrate[7] are well-known. Since both ions are present in natural waters, their influence on the performance of our system was investigated. The interferences increased with the concentration of hydrochloric acid in the sample. For samples containing 1*M* acid, as used here, normal nitrate concentrations in natural waters[30] do not interfere, but preservation of water samples by addition of nitric acid to pH 2 could not be used. Nitrite was found to interfere in 1*M* hydrochloric acid when the concentration exceeded 5μM, which leaves some margin to natural concentration levels.[31] At least part of the interference could be caused by nitrogen oxides. Trapped selenium was exposed for 1 min to the gases from hydride generation of blank solutions containing nitrate or nitrite in 4*M* hydrochloric acid. The absorbance signal decreased by 50% for 5μM nitrite and 20% for 0.2*M* nitrate.

Hypochlorite was found not to interfere at the concentrations added to potable water, <0.5 mg/l.

The calibration graph was linear below 5 ng of selenium or 0.17 μg/l. for the standard sample volume of 30 ml. The correlation coefficient was 0.999 or better. Absorbance was proportional to the sample volume at least up to 250 ml at 10 ng/l. Some loss in recovery was indicated for lower concentrations. Thus the recovery of 1 ng of selenium started to drop when the sample volume exceeded 100 ml and was about 75% at 200 ml. The shapes of the absorbance signals for various amounts of selenium are shown in Fig. 2. A frequency of 10 samples/hour could be analysed.

The sensitivity (average and standard deviation) calculated from calibration curves obtained during a period of three months ($n = 24$) was $26.7(1.4)10^{-3}$/ng Se for peak height and $99.2(5.3)10^{-3}$ s/ng Se for peak area. For repetitive measurements ($n = 3$) the precision was better than 4% for 1 ng of selenium. The limit of detection (3σ) estimated from the

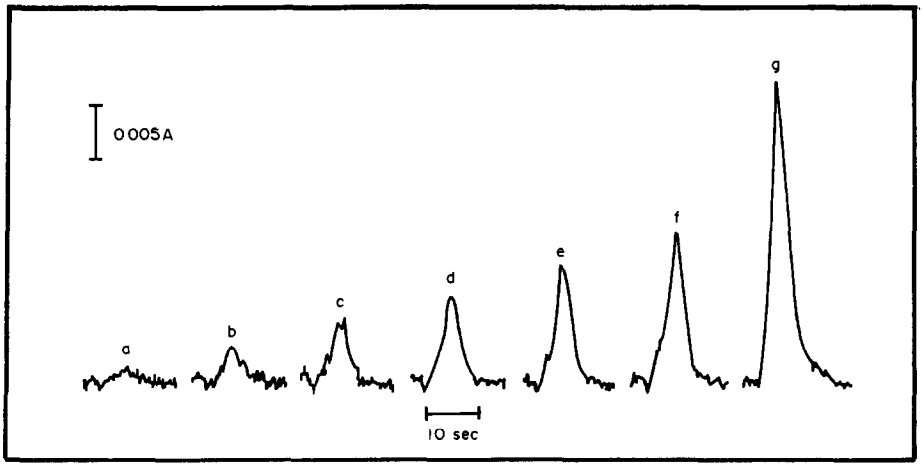

Fig. 2. Traces of selenium recorded after preconcentration from a sample volume of 30 ml in the cold trap system. (a) blank, (b) 100 pg Se, (c) 200 pg Se, (d) 300 pg Se, (e) 400 pg Se, (f) 500 pg Se, (g) 1000 pg Se.

standard deviation of the blank was 50 pg or <2 ng/l. selenium for a 30-ml sample.

Decomposition methods

In most methods for the determination of total selenium, organic selenium must be transformed to selenite. This transformation starts with a decomposition of the organoselenium compounds. The decomposition will also destroy organic matter that may interfere with the hydride generation[6,32] or the reduction of selenium(VI) to selenium(IV).[33] As discussed in the introductory part, a number of oxidizing agents have been used for destruction of organic material in water. Comparisons between the efficiencies of various destruction methods in conjunction with determination of selenium have been rather few,[16,34] and this work reports for the first time a comparative study of a range of methods. Wet digestion methods involving nitric acid were excluded. Although such methods[35] have been demonstrated to completely decompose selenium compounds they require addition of perchloric acid and evaporation of the sample. The interference caused by nitrogen oxides in our apparatus further detracted from the use of nitric acid.

The destruction methods (a)–(f) described in the experimental part were applied to the organic selenium compounds (A)–(F) and two water samples, one with high and one with a low organic matter content. The organic compounds represent the following bonding arrangements around the selenium atom: -C-Se-C- (B), (D); -C-Se-Se-C- (A), (C), (E); C_3-Se (F). The organic selenium in water may be present in proteins and peptides as selenoamino acids, notably selenomethionine, bound to humic substances, alkylselenides, alkyldiselenides and selenonium ions.[4,13] The various forms of organoselenium are thus represented in our selection of test compounds.

The results for the organoselenium compounds are presented in Table 1. The recoveries were quantitative for most compounds and destruction methods with the notable exception of the trimethylselenonium ion, which is known to be difficult to destruct.[35] The low result obtained with methods (a), (d) and (e) were not due to loss of selenium, since treatment by method (c)

of aliquots of the digests from these methods resulted in quantitative recovery of selenium. The low figure obtained for (A) treated with peroxodisulphate in 3*M* hydrochloric acid is significant.

The analytical results were evaluated with the method of standard additions. The slopes of the graphs did not differ from the slope of the calibration graph obtained with standards, which indicated that interferences from the chemicals used were absent.

The results from the water samples are collected in Table 2. For drinking water no difference was observed between the digestion methods, whereas for the lake water the results with method (a) were low. Apparently the rate of decomposition of peroxodisulphate increases faster with acidity than the rate of oxidation of organic material.[36] The sample remained slightly yellow in method (a), whereas the yellow colour of the humic substances disappeared in methods (b) and (c). A better recovery could probably have been achieved by increasing the peroxodisulphate concentration, but then the blank would also increase. The concentration of hydrochloric acid in (a) has been chosen so that the decomposition of the organic material and the reduction of selenium(VI) to selenium(IV) should proceed concurrently. The method is thus attractive but our results indicate that it should be used with caution.

It is gratifying that the preconcentration by evaporation used in method (f) yielded the same result as the cold trap system. We also tried to use the magnesium nitrate–nitric acid–hydrochloric acid method without preconcentration. However, it did not work in conjunction with the cold trap system. The reason for this could not be definitely established, but the interferences were similar to those found in the presence of nitrate indicating that some undecomposed nitrate remained.

CONCLUSIONS

The results indicate that methods (b) and (c), which use peroxodisulphate at pH 2 or higher, are the most efficient of the methods studied here for the destruction of organic selenium compounds in water. They decomposed all test objects including the very resistant trimethylselenonium ion. This substance was not decomposed by permanganate or oxidative UV-irradition, although they both decomposed the other test objects. Hence methods (b) and (c) can be recommended for water samples. Excess peroxodisulphate does not interfere in the reduction of Se(VI) to Se(IV) since it is rapidly decomposed in boiling 3*M* hydrochloric acid and the blank is low. The recommendation does not imply that methods (b) and (c) can cope with all types of water samples. As a check, evaporation and destruction with a mixture of nitric, perchloric and sulphuric acid or the magnesium nitrate–nitric acid–hydrochloric acid method can be used. Of these methods the latter is recommended since it does not involve perchloric acid.

(*Received* 26 *September* 1991. *Revised* 17 *January* 1992. *Accepted* 19 *January* 1992)

Summary—It could be shown that the pre- or double peaks which are frequently observed in the determination of tin by hydride generation atomic-absorption spectrometry are not due to reagent contamination or memory effects. Rather they originate from the silica material used to make the quartz tube atomizer. At elevated temperatures the tin diffuses to the surface and it can be volatilized and atomized only in the presence of hydrogen. The height of the pre-peak depends, among other things, on the time for which the quartz tube atomizer has been at a high temperature without hydrogen. The pre-peaks disappear when argon with 10% (v/v) hydrogen is used as the purge gas. In flow injection the pre-peaks can be separated in time from the analytical signal by using a program in which hydrogen is generated by reaction of sodium tetrahydroborate reductant solution with the acid carrier prior to the injection of the sample. Also investigated was the influence of the acid and sodium tetrahydroborate concentration on sensitivity and freedom from interferences. Best results were obtained when a saturated boric acid solution containing 0.1*M* hydrochloric acid was used for standards, samples and carrier solution, and a 0.4% (m/v) sodium tetrahydroborate solution with 0.05% (m/v) sodium hydroxide as the reductant. Under these conditions tin could be determined accurately in the range 0.008–0.1% in low alloy steel standard reference materials, with matrix-free standard solutions for calibration.

A sometimes confusing diversity of design approaches has been described in the literature for hydride generation (HG) and atomization systems since the introducton of this technique by Holak[1] in 1969 for use in atomic absorption spectrometry (AAS). Batch systems were used more frequently for HG AAS, but continuous flow and more recently also flow injection (FI) systems have been described as well. In addition to the various designs of HG systems, a number of methods with different reagents and reagent concentrations are reported in the literature. These details have to be considered very carefully in comparing published data because they could significantly influence not only sensitivity and peak shapes but also interferences in HG AAS.[2–5]

Tin is among those elements which are not too frequently determined by HG AAS. One of the reasons for that might be that the above-described variabilities have a particularly strong influence on this element. Among the difficulties described repeatedly in the literature are high blank values,[6–10] memory effects[8,10] and particularly the strong dependence of the sensitivity of tin from the acid content of the solution.[2,8,10–13] Åström[14] was the first to use FI for HG AAS in 1982, the number of publications in this field, however, remained scarce over the following years, and no application of this technique to the determination of tin has been reported until only recently. In an evaluation of the first commercially available accessory for FI HG AAS[15] we have investigated the influence of acid, sodium tetrahydroborate and sodium hydroxide concentration on the sensitivity for tin, however, the procedure was not optimized for this element. Fang *et al.*[16] found it very difficult to control the acid concentration to the extent which was necessary for a reliable determination of tin in canned food. They therefore used an on-line ion-exchange separation to modify the sample matrix and achieve optimized and reproducible conditions for HG.

The scope of this work was to optimize the parameters for the determination of tin in a way that an automatic and reliable determination of this element could be carried out with FI HG AAS. In order to achieve this goal we firstly investigated the reasons for the sporadic

pre-peaks and searched for methods for their elimination. Secondly we wanted to optimize the analytical parameters such as acid and reductant concentration and composition in order to obtain a reproducible sensitivity and a high freedom from interferences. The determination of tin in low alloy steel standard reference materials was chosen in order to test the ruggedness of the proposed procedure.

EXPERIMENTAL

Instrumentation

Most of the investigations were carried out with Perkin–Elmer Models 4000 and 2100 atomic-absorption spectrometers, equipped with a Perkin–Elmer FIAS-200 flow injection accessory and an AS-90 autosampler. A hollow cathode lamp, operated at 30 mA, was used as the light source, the wavelength was set to 224.6 nm and the slit width was 0.7 nm. The signals obtained with the Model 2100 were printed with an Epson EX-800 printer, whereas a recorder Model 56 was used with the Model 4000. For some of the measurements a Perkin–Elmer Model MHS-20 batch hydride system was used and the Model 4000 was equipped with a Perkin–Elmer data station 3600, an electrodeless discharge lamp for tin, operated at 8 W, and the wavelength at 286.3 nm was used. The signals obtained with this system were plotted with a Hewlett–Packard data plotter Model 7225 A.

The FIAS-200 flow injection accessory has been described in detail elsewhere.[15] The operating parameters are summarized in Table 1. Somewhat different conditions were used for some of the experiments and will be described in the Results and Discussion section. For investigating the origin of the pre-peaks the set-up shown in Fig. 1 was used which allowed the controlled addition of a second gas to the purge gas for the quartz tube atomizer (QTA). In this case hydrogen was added with a flow-rate of 34 ml/min to the argon carrier gas which was flowing at 230 ml/min.

The data reported in this work have been collected in part over a period of several years with different instruments and particularly with several different QTAs. It has been found that the sensitivity for tin may change significantly (up to a factor of 2) for different QTAs, possibly

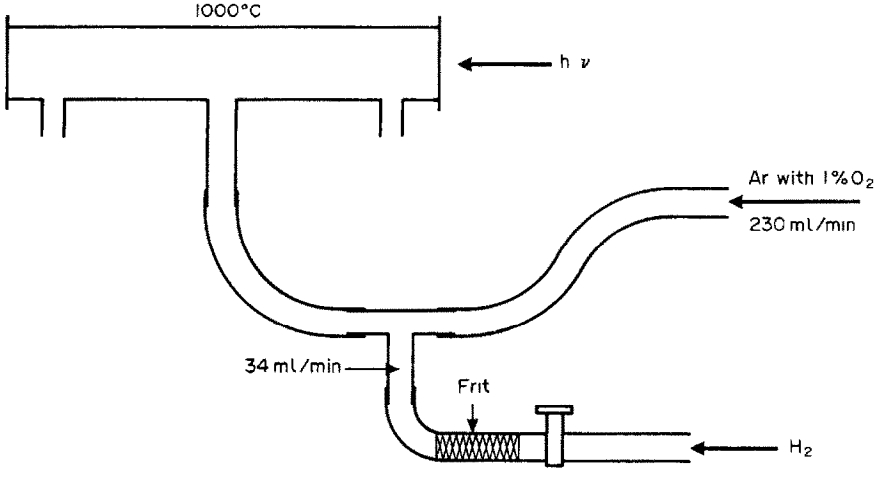

Fig. 1. Experimental set-up for the controlled addition of a second gas (hydrogen) to the purge gas (argon) of the QTA.

depending on the content of trace transition metals, such as copper and nickel, in the silica material. Concentrations in the order of 1 μg/g of these elements could be detected with ICP–MS. Differences in sensitivity for tin in the various figures should therefore not be over-interpreted. However, because we were aware of this problem, care was taken that all data within one set of experiments were obtained with the same QTA so that results remained comparable.

Reagents

All reagents, except for sodium tetrahydroborate (for which no purity was given) were of analytical reagent grade and obtained from Merck (Darmstadt, Germany).

Carrier solution. Saturated boric acid solution containing 0.1*M* hydrochloric acid. Standard and sample solutions were diluted with the same acid mixture.

Reduction solution. Prepared by dissolving 0.4 g of sodium tetrahydroborate (Riedel-de Haen, Seelze, Germany) in 100 ml of water and adding 0.05 g of sodium hydroxide.

Carrier gas. Argon 5.0 (99.9990%) was obtained from Sauerstoffwerk Friedrichshafen (Germany). Argon Sl (99% Ar + 1% O_2) was obtained from Linde (Germany). The mixtures 98% Ar + 1% H_2 + 1% O_2 and 89% Ar + 10% H_2 + 1% O_2 were custom-made by Sauerstoffwerk Friedrichshafen.

Samples and sample preparation

NBS standard reference materials Nos. 361, 362, 363 and 364 (low alloy steel) from the National Institute of Standards and Technology (Gaithersburg, MD, U.S.A). The steel sample (0.5 g) was placed in a 250-ml standard flask, 12 ml *aqua regia* was added, heated slowly to 90° and held at this temperature for 2–3 hr. After cooling to room temperature the digest was diluted to the mark with demineralized water. A 500-μl portion of this solution was transferred to a 50-ml standard flask and diluted to volume with the saturated boric acid–0.1*M* hydrochloric acid mixture. For higher concentrations of tin (*ca.* 0.1%) this solution was further diluted with the acid mixture.

RESULTS AND DISCUSSION

In batch systems for HG AAS, pre-peaks could be observed quite frequently, but their size and height was very variable and unpredictable. Nothing has been done until now to investigate the source of these pre-peaks. An additional problem, which confused the situation, was that these pre-peaks typically disappeared in the analyte signal when, as usual, a recorder was used for signal evaluation. It is quite likely that the high and variable blank values, the memory and carry-over effects frequently reported in the literature for this element were, at least in part, such pre-peaks. Only with the high time resolution and distortion-free registration of the signal shown in Fig. 2, could the pre-peak clearly be distinguished from the actual analytical signal. With this high time resolution it also became obvious that the pre-peak and the analytical signal reached their maxima at distinctly different points in time. However, when an ordinary recorder was used, these differences became less apparent, and the risk for a misinterpretation increased. This could eventually lead to errors, particularly if an automatic peak height readout was used for signal evaluation.

In FI HG AAS these pre-peaks could be observed as well as is shown in Fig. 3, and these peaks could also be very much different in height. With this technique, however, the pre-peaks appeared only before the first signal of a sequence of measurements, provided that hydrogen was generated continuously, *i.e.*, the acid carrier and the tetrahydroborate solution were pumped permanently. Because of this

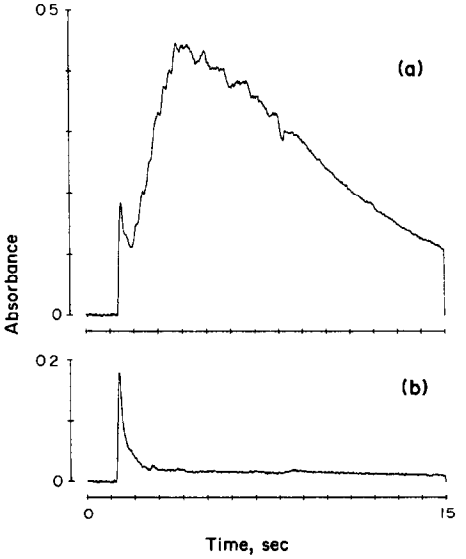

Fig. 2. Determination of tin using a batch HG AA system with high time resolution of the signal. *A.* 100 ng of Sn with pre-peak. *B.* Pre-peak which was misinterpreted as a blank.

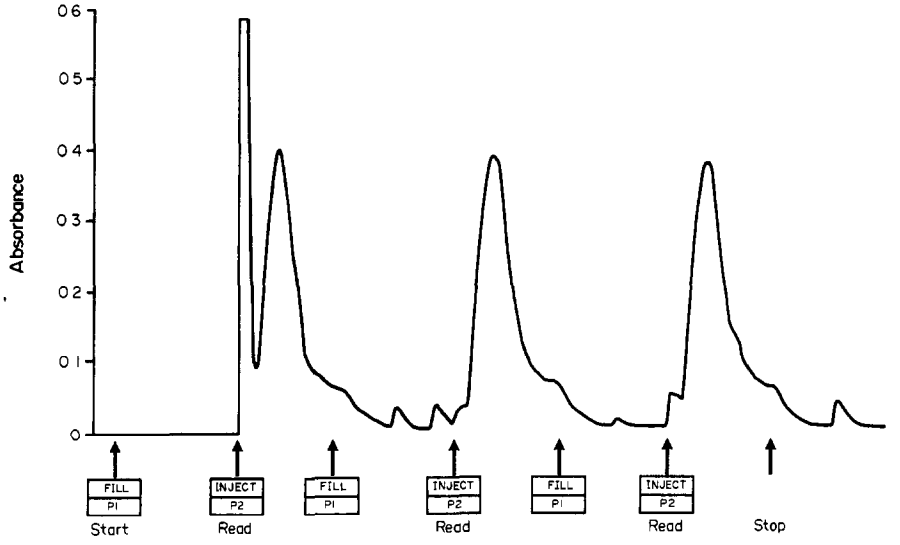

Fig. 3. Determination of 5 ng of Sn using FI HG AAS. Reductant flow and sample injection are initiated at the same time.

interconnection between the generation of hydrogen, which became apparent in all the experiments, it proved very easy to separate the pre-peak in time from the analytical peak in FI HG AAS. The pre-peak appeared right in front of the analytical signal only if the pump for sodium tetrahydroborate was activated together with the rotation of the valve, *i.e.*, introducton of the sample into the carrier stream. This was done in Fig. 3, and this is also the situation in all batch systems where the generation of hydrogen and reduction of the analyte element to the gaseous hydride are initiated at the same time by adding the tetrahydroborate to the acid sample solution. The pre-peak could be shifted at will in FI HG AAS simply by activating the pump for sodium tetrahydroborate prior to the injection of the sample or standard into the carrier stream as is shown in Fig. 4. This way the pre-peak could easily be generated early enough so that it would not appear in the time frame for signal recording. While this was an elegant means to circumvent the source of error inherent in these pre-peaks, it did not answer the question for their origin, except that they were associated with the generation of hydrogen.

This question was, however, of particular interest because, with the knowledge of their origin, it might have been possible to find better ways to avoid or eliminate the pre-peaks rather than to shift them only in time. First of all we found that these signals were generated when, after turning on the FI accessory, carrier and sodium tetrahydroborate solution were mixed and the hydrogen reached the heated QTA. As can be seen in Fig. 5 using continuous registration, a sharp signal was generated at the

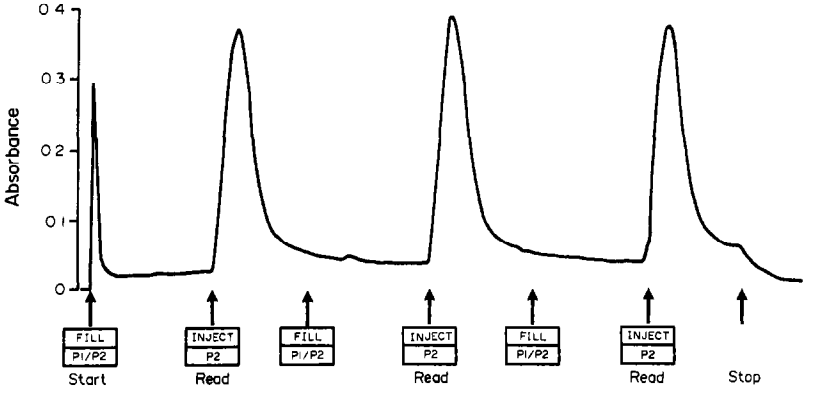

Fig. 4. Determination of 5 ng of Sn using FI HG AAS. Reductant flow is started 10 sec prior to sample injection (program in Table 1).

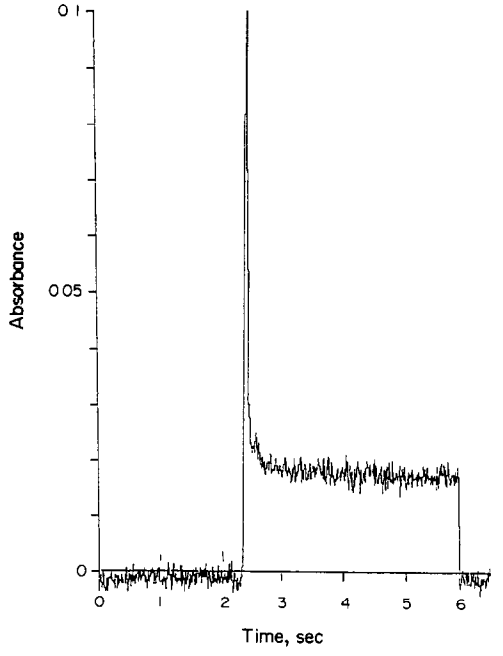

Fig. 5. Pre-peak and "blank" signal for tin recorded upon initiation of carrier and reductant flow and, hence, the generation of hydrogen. (AA spectrometer model 2100).

moment when hydrogen entered the QTA, which decreased at a slightly slower rate and finally reached a stable value. Similar to a "blank", this signal persisted at its elevated level until the reagent pump was turned off and hydrogen generation ceased. The absorbance of this continuous signal depended on the QTA temperature. In addition it was characteristic for a given QTA, but could be significantly different for different QTAs. The height of this continuous signal could not be influenced by the use of a background corrector, and the same was actually true for the sharp early peak which was generated at the appearance of hydrogen in the QTA. The height of this signal, however, depended also from the length of time for which the QTA was at a high temperature but without hydrogen flowing through.

The fact that neither the pre-peak nor the following continuous signal were influenced by background correction indicated already that these signals were due to tin atomic absorption. This was further supported by measurements at three resonance lines of different sensitivity for tin at 224.6 nm, 286.3 nm and 270.7 nm. At the same time we investigated systematically the previously mentioned influence of the length of time for which the QTA was left without hydrogen. For that purpose we used the modified set-up which was shown in Fig. 1 and which permitted the controlled addition of hydrogen to the purge gas. With this arrangement the experiment also became independent of any chemical reaction for hydrogen generation and hence from any possible side-effects caused by the reagents.

The QTA was heated to 900° and flushed continuously with argon. After various time periods of flushing with argon, hydrogen was admixed to the purge gas and the absorbance of the resulting pre-peak recorded. Figure 6 shows the dependence of the peak absorbance from the time without hydrogen for the three analytical lines for tin. The ratio of the reciprocal sensitivities of 1:1.9:2.4 obtained for the three lines corresponded quite reasonably with the characteristic concentration reported for these lines.[17] In addition the relation between the peak absorbance and the time without hydrogen was linear for times between 1 and 4 min.

All this essentially confirmed that the pre-peak and the following continuous absorbance were real absorbance signals caused by tin atoms. The experiments with pure gases with no chemical reaction going on in parallel have shown in addition that these peaks could not be caused by any contamination in the reagents. Finally, a memory-effect or carry-over could be excluded as a possible explanation because the signals were equally observed in "virgin" QTAs which have never come into contact with tin, and all efforts to clean the QTAs with various acids, including 40% (m/v) hydrofluoric acid, did not influence the height of the observed signals substantially. The only

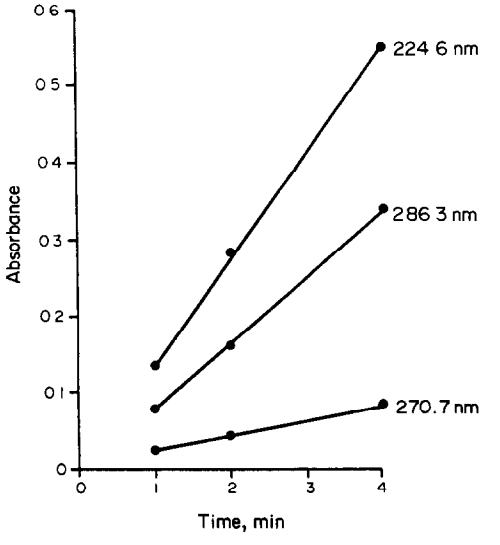

Fig. 6. Influence of the time without hydrogen on the absorbance of the pre-peak for tin at three different wavelengths.

significant influence, as already mentioned, came from the QTA itself, *i.e.*, the magnitude of the signals was different for different QTAs and was somehow typical for each QTA investigated.

In order to gain more information on that phenomenon we broke two quartz tube atomizers, dissolved some pieces in hydrofluoric acid and analysed them with ICP–MS. Among a few other elements we also found tin in a concentration around 0.5–1 μg/g in the solid silica material. If we assume a weight of approximately 20 g for the heated portion of the quartz tube, this means that some 10 μg of Sn was contained in that part of the atomizer. This was a mass of tin which was at least four orders of magnitude higher than that necessary to generate an analytical signal of about 0.1 absorbance units.

This leads to the assumption that the signals were caused by "endogenous" tin, *i.e.*, an impurity which was present in the silica material and which was continuously diffusing to the surface at temperatures typically used for HG AAS. In the absence of hydrogen the tin species remained at the surface of the QTA and accumulated with time. As soon as hydrogen was introduced, however, tin was volatilized and atomized readily. This process of diffusion of tin out of the silica material and its volatilization and atomization was going on continuously in the presence of a flow of hydrogen, producing the steady-state signal observed in these experiments (see Fig. 5). It is not very likely that this volatilization and atomization of tin was the work of molecular hydrogen, and it appears much more plausible that hydrogen radicals take part in the mechanism. Similar volatilization and atomization from the condensed phase has been observed earlier for arsenic, antimony and other volatile hydride forming elements[18–21] and has been associated with a mechanism in which hydrogen radicals were involved as the active species.

The dependence of the height of the pre-peaks from the temperature of the QTA is shown in Fig. 7. The highest signals were obtained between 800° and 900° with the sensitivity falling off to lower and to higher temperatures. The latter was in contrast to experiments with stannane where the sensitivity for tin increased with increasing temperature up to 1000° when argon was the purge gas, and the signal was independent of the temperature between 700° and 1000° when argon with 1% oxygen was used. No

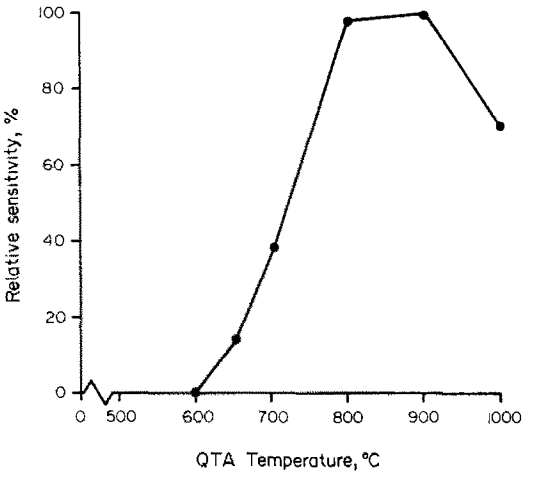

Fig. 7. Influence of QTA temperature on the relative height of the pre-peak for tin.

explanation can be given for this different behaviour at this point in time, it could be assumed, however, that it resulted from the different tin species under consideration and/or the differences in the atomization mechanisms. The diffusion of the tin species, most probably an oxide, out of the silica material, the rate of which is undoubtedly temperature dependent, must certainly also be taken into account.

As contamination of the silica material has been shown to be the source of the pre-peaks and the "blank" signals for tin, the question arises if and how these signals could be removed or avoided. The most obvious way would undoubtedly be to produce the QTAs from "tin-free" silica. However, no such material could be obtained until now. It has been mentioned earlier that all attempts to clean the QTAs with various acids, including 40% (m/v) hydrofluoric acid, had no long-term effect on the pre-peaks or blank signals. This confirmed that the tin species was diffusing from the depth of the material to the surface, *i.e.*, from parts which were not reached by acid cleaning. Experiments in which the QTAs were heated for extended periods of time in the presence of hydrogen were equally unsuccessful for the same reason.

Finally we investigated the use of various gas mixtures as carrier gases to see if at least the pre-peaks could be eliminated this way. The results of these experiments are shown in Fig. 8. When argon containing 1% (v/v) oxygen was used as the carrier gas, the sensitivity for tin was increased by about 35% over that in pure argon at a QTA temperature of 900°. This was in agreement with earlier experiments.[18] The

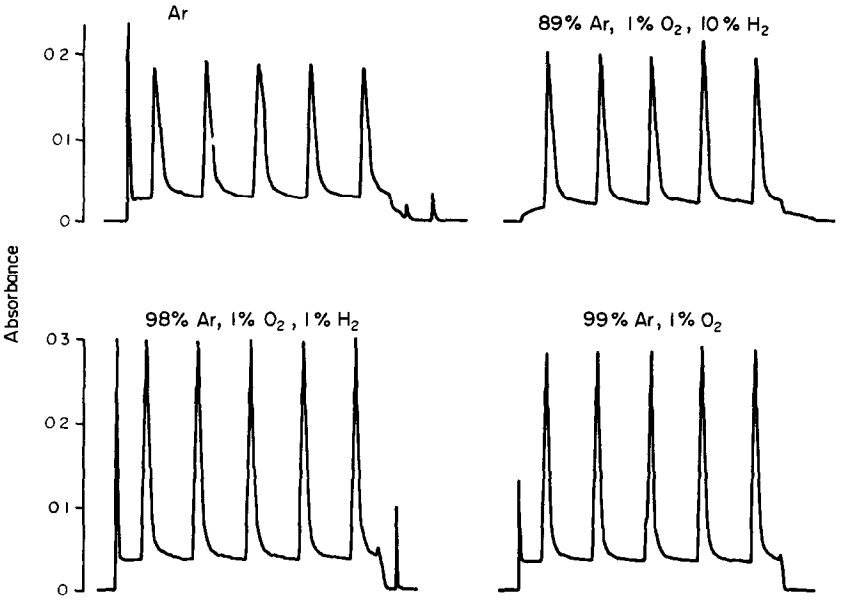

Fig. 8. Influence of oxygen and hydrogen concentration in argon purge gas on pre-peaks and signals for 5 ng of tin.

presence of oxygen, however, had no influence on the pre-peaks which was as expected because tin could only be atomized in the presence of hydrogen radicals. When a mixture of 98% Ar, 1% O_2 and 1% H_2 was used as the purge gas, the sensitivity for tin was highest, but the pre-peaks could not be eliminated. This only succeeded with a mixture of 89% Ar, 1% O_2 and as much as 10% H_2. With this carrier gas, however, the sensitivity for tin was reduced again approximately to the level obtained in pure argon. This means that the enhancing effect of oxygen was apparently offset by the excess of hydrogen.

It is obvious that these investigations were more of academic than of practical use because a mixture of 89% Ar, 1% O_2 and 10% H_2 is not likely to be used in any routine application. It is interesting, however, to realize that a fairly high concentration of 10% H_2 was required in the purge gas to avoid the pre-peaks, *i.e.*, to remove the tin which is continuously diffusing out of the silica material. As expected, the blank signal *i.e.*, the continously elevated level of tin, could not be avoided by any of the gas mixtures. Tin diffuses out of the silica material continuously and is hence atomized permanently in the presence of hydrogen which develops in the reaction of sodium tetrahydroborate with the acid carrier. For routine purposes the simplest approach to avoid errors due to the pre-peaks appears to be the separation in time by an early generation of hydrogen prior to sample injection. This can obviously be only used in FI HG AAS but not in batch systems. If highest sensitivity is to be obtained the use of argon containing 1% of oxygen may be of advantage and was used for most of our investigations.

Finally, in order to apply the determination of tin by FI HG AAS routinely, it was necessary to optimize carrier and reagent composition and concentration, and it is well documented in the literature that the acid concentration is most critical in the determination of tin. Fang *et al.*[16] have actually found that the effects of acidity were further enhanced in the FI mode, compared to batch HG AAS. The situation seemed to be particularly hopeless for hydrochloric and sulphuric acids for which virtually no stable region of influence on sensitivity could be found. The use of boric acid together with the strong acids which was successfully applied in the batch mode,[2] produced no improvement in the performance of FI HG AAS. This was somewhat in contrast to preliminary results obtained in our laboratory,[15] in which a stable signal for tin was obtained in 0.05–0.2*M* nitric and hydrochloric acids, added to saturated boric acid solution. It has to be kept in mind, however, that the influence of acids on the tin signal also depends on the concentration of the sodium tetrahydroborate solution and on the amount of sodium hydroxide in that solution.[15] Hence it was not really surprising that our results were different from those of Fang *et al.*[16]

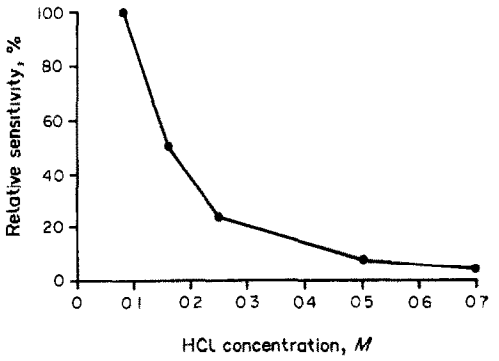

Fig. 9. Influence of hydrochloric acid concentrations in saturated boric acid solution on the sensitivity for tin.

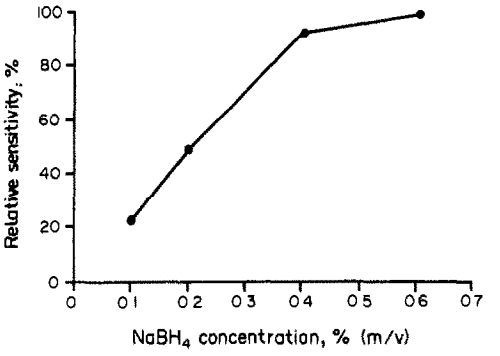

Fig. 10. Influence of sodium tetrahydroborate concentration on the sensitivity for tin.

as they were using a 0.2% (m/v) sodium tetrahydroborate solution containing 0.01*M* (0.03% m/v) sodium hydroxide whereas we used 1% (m/v) sodium tetrahydroborate with 0.5% (m/v) sodium hydroxide. As the influence of the acids was obviously correlated to the concentration of the other reagents, we decided to carry out the optimization procedure one more time.

In agreement with previous results obtained with batch systems[2] as well as with FI HG AAS[15] we could confirm that a saturated boric acid solution had a releasing effect on the influence of strong acids, such as hydrochloric acid, on the tin signal. The sensitivity for tin increased very significantly with decreasing hydrochloric acid concentration, as can be seen in Fig. 9. For concentrations lower than 0.1*M* hydrochloric acid, however, the sensitivity increase was marginal and the signals were no longer reliable, *i.e.*, we observed occasionally a sudden drop in sensitivity and a significant decrease in precision. As hydrolysis of tin(IV) has been reported to be rapid in solutions of low acidity, producing insoluble hydrolysis products which polymerize and are difficult to redissolve,[22] the highest tolerable acid concentration resulting in good sensitivity and a reliable signal for tin, *i.e.*, 0.1*M* was used throughout.

The influence of the tetrahydroborate concentration on the tin signal in 0.1*M* hydrochloric acid/saturated boric acid solution is shown in Fig. 10. The sensitivity clearly increased up to a sodium tetrahydroborate concentraton of 0.4% (m/v). The sodium hydroxide concentration was found to have only a very minor effect on the tin signal in the range between 0.05 and 1% (m/v) as long as the hydrochloric acid concentration did not exceed 0.1*M*. It was therefore kept at its lowest level of 0.05% (m/v).

The tetrahydroborate concentration did not only have an influence on the sensitivity of tin but also on the freedom from interferences when tin was determined in low alloy steel. It can be seen in Fig. 11 that the slope of the curve for tin added to a steel sample was different from that

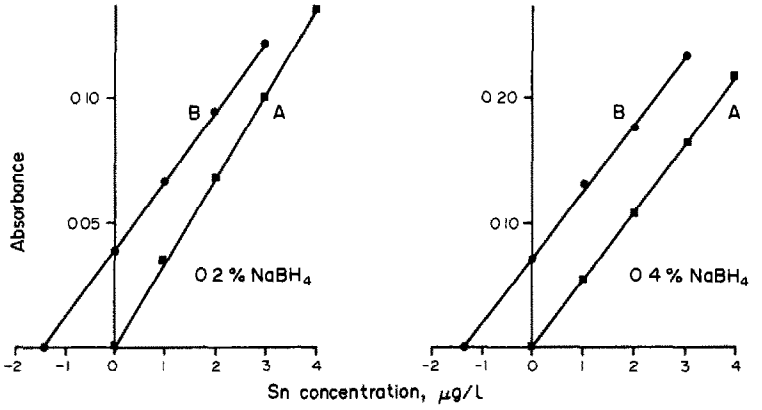

Fig. 11. Influence of sodium tetrahydroborate concentration on matrix interferences in the determination of tin in steel. *A*. Calibration curve established with matrix-free reference solutions. *B*. Tin added to acid steel digests.

Table 2. Determination of tin in NIST standard reference materials low alloy steels

	Concentration of tin (% in steel)	
SRM	Certified	Found ($n = 5$)
NIST 361	0.010 ± 0.001	0.009 ± 0.0001
NIST 362	0.016 ± 0.001	0.017 ± 0.001
NIST 363	0.104 ± 0.005	0.101 ± 0.004
NIST 364	0.008 ± 0.001	0.007 ± 0.0002

for matrix-free standards when 0.2% (m/v) sodium tetrahydroborate was used as the reductant, whereas the slopes were essentially identical with 0.4% (m/v) sodium tetrahydroborate. The results for the determination of tin in four low alloy steel Standard Reference Materials using 0.1*M* hydrochloric acid in saturated boric acid as the carrier and the diluent for standards and samples, and 0.4% (m/v) sodium tetrahydroborate with 0.05% (m/v) sodium hydroxide as the reductant are summarized in Table 2. The agreement of the results in the range of 0.008–0.1% tin in steel, obtained by direct calibration against matrix-free reference solutions, with the certified values is good, indicating an interference-free determination.

CONCLUSION

The pre-peaks in the determination of tin, which have previously been confused with blank values, memory effects and carry-over, originate from volatilization and atomization of tin from the silica material in the presence of hydrogen, most probably via hydrogen radicals. In batch systems these pre-peaks are difficult to separate from the analytical signal and may well cause errors in signal evaluation. In FI HG AAS these pre-peaks can be separated very easily in time and hence be removed from the time frame used for signal evaluation. The results of this study further support the hydrogen radical theory of atomization in heated quartz tube atomizers.

STUDIES ON SOME CADMIUM MIXED LIGAND COMPLEXES USING DIFFERENTIAL PULSE POLAROGRAPHY

M. I. ISMAIL

Department of Chemistry, Faculty of Science, University of Ain Shams, Cairo, Egypt

(*Received* 5 *November* 1991. *Revised* 15 *January* 1992. *Accepted* 27 *January* 1992)

Summary—Differential pulse polarography was used to study the mixed ligand complexes of imidazole and some dicarboxylate anions namely, oxalate, tartrate and malonate with Cd(II) at constant ionic strength ($\mu = 1$, $NaNO_3$) at $25 \pm 0.1°$. It has been found that the reduction of complexes is reversible and diffusion-controlled. Three mixed complexes are formed with malonate (or oxalate) whereas four mixed complexes are formed with tartrate. The overall stability constants for each system were calculated and discussed.

Mixed ligand complexes of metal ions, especially those playing an important role in various biological processes, have been studied extensively in recent years.[1–3] The physico-chemical properties of one of the important nitrogen containing heterocyclic compounds, namely, imidazole and its metal complexes have attracted increasing attention. It has been reported that a large number of imidazole derivatives possess diverse pharmacological effects, including anti-inflammatory, antimicrobial, antimalarial and antitumor activities.[4–6] The presence of imidazole in the histidyl residue of proteins provides a potential binding site for metal ions.[6]

The overall formation constants of Cd(II)–imidazole complexes have been the subject of several investigations. For instance, Li *et al.*[7] have studied polarographically the compositions and stability constants of simple complexes of Cd(II) with imidazole in aqueous and alcoholic media. The results revealed the formation of three complexes with stability constants; $\log \beta_2 = 5.0$, $\log \beta_3 = 6.3$ and $\log \beta_4 = 7.5$. However, the method employed by these authors was reported to be inaccurate.[8] Tanford and Wagner[9] have studied the same system potentiometrically, where the formation of four successive complexes was indicated with stability constants: $\log \beta_1 = 2.8$, $\log \beta_2 = 2.1$, $\log \beta_3 = 1.6$ and $\log \beta_4 = 1.1$. In this work, it was stated that the site of binding in the imidazole molecule is the pyridine nitrogen rather than the pyrrole nitrogen. On the other hand, the polarographic study of the Cd(II)–imidazole system provided by Shivhare and Singh[10,11] also revealed the formation of four complexes with stability constants $\log \beta_1 = 2.7$, $\log \beta_2 = 4.0$, $\log \beta_3 = 5.3$ and $\log \beta_4 = 7.0$ these differ considerably from those reported by Tanford and Wagner.[9]

In other work of Shivhare *et al.*,[12] concerning the stability constants of the Cd(II)-imidazole–malonate system from dc-polarography, the formation of three mixed complexes was observed with overall stability constants $\log \beta_{11} = 4.0$, $\log \beta_{12} = 4.4$ and $\log \beta_{21} = 5.9$. The recent polarographic study of the Cd(II)–1-methylimidazole–oxalate system by Gamal *et al.*[13] indicated the formation of three mixed complexes. Although the ligands used in the latter two systems were quite different, the stability constants of the three mixed complexes recorded by Gamal *et al.*[13] were identical to those given by Shivhare *et al.*,[12] *viz.*, $\log \beta_{11} = 4.0$, $\log \beta_{12} = 4.4$ and $\log \beta_{21} = 5.9$. In our opinion, these data,[13] seem to be unreliable. The uncertainty originates from the values reported for the stability constants in the simple Cd(II)–oxalate system (namely, $\log \beta_1 = 1.0$, $\log \beta_2 = 2.6$ and $\log \beta_3 = 3.6$), which are markedly different from those recommended earlier[14–16] for this system under the same experimental conditions: $\log \beta_1 = 2.7 \pm 0.2$, $\log \beta_2 = 4.2 \pm 0.1$ and $\log \beta_3 = 5.1 \pm 0.1$.

Accordingly, in view of the conflicting results reported in the literature regarding the number of complexes formed and the values of their stability constants, it became of special importance to undertake further study using differential pulse-(dp-) polarography on simple

complexes of Cd(II) with imidazole as well as on mixed complexes in the presence of some dicarboxylate anions (namely oxalate, tartrate and malonate). This technique offers a considerable advantage as compared to dc-polarography.[17] The dp-polarography gives more accurate measurements of $\Delta E_{1/2}$-values, leading most probably to proper calculation of the stability constants of the complexes under study.

EXPERIMENTAL

Chemicals and solutions

All chemicals used were analytical grade (BDH) and their solutions were prepared in demineralized water. Imidazole (Im), potassium malonate (Mal), potassium tartrate (Tart) and potassium oxalate (Ox) were used as ligands. A surfactant was not used as maximum suppressor.

Apparatus and working procedure

A polarographic analyser PAR Model 174A with PAR/GE Model 303A static mercury drop electrode as working electrode, saturated Ag/AgCl as reference electrode and platinum as counter electrode were used for dp-polarography. The polarograms were recorded on a Houston Omingraphic Model RE0089 X–Y recorder. A potential pulse of 50 mV was used throughout the dp-polarographic measurements. The dc-polarograms were recorded with a Sargent Welch polarograph Model XVI. The characteristics of the capillary in 0.1M potassium chloride at open-circuit was $m = 1.68$ mg/sec, $t = 4.76$ sec at $h = 45$ cm. All measurements were made at $25 \pm 0.1°$ and an ionic strength was maintained constant using 1M sodium nitrate as supporting electrolyte. The concentration of Cd^{2+} ions throughout the study was $1 \times 10^{-4}M$. Purified nitrogen gas was used for removing the dissolved oxygen.

Theoretical considerations

The stability constants of polarographically reversible systems may be determined through dp-polarography by using the Deford–Hume equation[18] as modified by Heath and Hefter.[17] This equation can be expressed as,

$$F_0(X) = \text{antilog}\left[\frac{0.4343nF}{RT}\Delta E_p + \log\frac{(I_p)_s}{(I_p)_c}\right]. \quad (1)$$

where, $F_0(X)$ represents the experimentally measured right-hand side of the equation, ΔE_p $[=(E_p)_s - (E_p)_c]$ is the shift in the peak potential due to complexation, I_p is the peak current of the dp-wave and the subscripts s and c refer to the free and complex ions, respectively.

Schaap and McMasters[14] developed a logical extension of the Deford–Hume method by applying the latter to cases where metal ions coordinate simultaneously with two different ligand species (X, Y) in the solution. Thus, the $F_0(X)$ function in equation (1) may be extended to give a new function, $F_{00}(X, Y)$ expressed in the following form,

$$F_{00}(X, Y) = \text{antilog}\left[\frac{0.4343nF}{RT}\Delta E_p + \log\frac{(I_p)_s}{(I_p)_c}\right]. \quad (2)$$

It has been reported[17] that for a reversible diffusion-controlled process, the peak potential (E_p) obtained from dp-polarography is related to the half-wave potential ($E_{1/2}$) of dc-polarography as follows:

$$E_p = E_{1/2} - \frac{\Delta E}{2}$$

where, ΔE is the magnitude of the pulse amplitude.

From Leden's approach,[19]

$$F_{00}(X, Y) = A + B[X] + C[X]^2 + D[X]^3. \quad (3)$$

The original graphical method[18] may be applied to F_{00} if the activity of one of the ligands (Y) is held constant while that of the other one (X) is varied. The intercept of the F_{00} axis in the plot of F_{00} *vs.* [X] gives A. Consequently,

$$F_{10} = \frac{F_{00} - A}{[X]} = B + C[X] + D[X]^2$$

By a similar plotting of F_{10} *vs.* [X], B is obtained and then C and D are obtained by iteration.

From the knowledge of C, the mixed stability constants β_{21} may be calculated. In order to determine β_{11} and β_{12}, B must be evaluated at two different concentrations of Y.

RESULTS AND DISCUSSION

The dp-polarography of imidazole does not show any reduction peaks within the normally available potential range. This lack of redox activity is not likely associated with the aromatic nature of the five-membered system of imidazole ring existing in a large number of

resonance forms[20] as confirmed by their stability towards chemical reduction.[21] On the other hand, Cd(II) exhibits one reduction peak (E_p) at −0.511 V representing the uptake of two electrons.

The stability constants of simple complexes of Cd(II) with imidazole (Im), oxalate (Ox), tartrate (Tart) and malonate (Mal) were determined separately prior to the study of the mixed ligand systems. Identical conditions were maintained for both the simple and the mixed systems. The Deford–Hume equation[18] as modified by Heath and Hefter[17] (equation 1) was applied to determine the stability constant of the simple complexes using dp-polarography. Table 1 includes the values of the stability constants of the simple complexes, and they are in good agreement with the previously reported values,[10,12,14,15]

   $\log K_M = 0.40$, $\log K_S = 0.099$

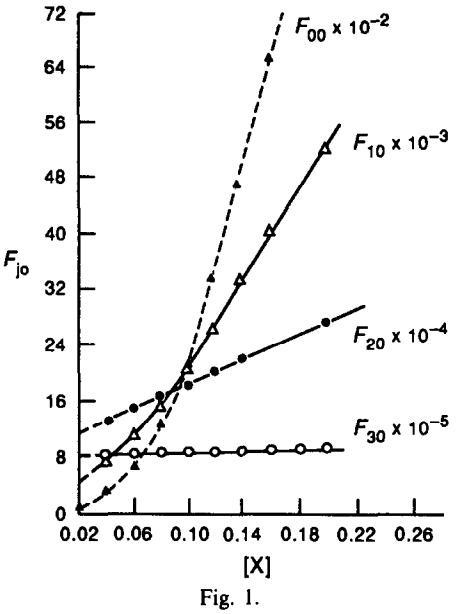

Fig. 1.

taking into consideration the differences in experimental conditions. As shown in Table 1, Cd(II) forms four successive complexes with (Im), three complexes with each of (Ox) and (Mal), and only one with (Tart).

As reported by several researchers,[22,23] a value of 62 mV is assigned for the half-peak width of the dp-polarographic reversible two-electron reduction step with a pulse of 50 mV. In the present work, the dp-polarograms of Cd(II) in nitrate medium showed half-peak widths of 62 ± 1 mV for both simple and mixed complexes, indicating the reversibility of the reduction process. Further confirmation was provided by using dc-polarography under the same conditions as the dp-polarography. The slopes of the linear plots of $\log i/i_l - i$ *vs.* E were 31 ± 1 mV, indicating a high degree of reversibility. Moreover, the plots of the limiting current (i_l) of the dc-waves against $h^{1/2}$ of the mercury column were linear, supporting the conclusion that reduction of the simple and mixed complexes is diffusion-controlled.

For mixed ligand systems, the concentration of imidazole was varied between 0.02 and 0.2*M*, keeping the concentration of dicarboxylate ions constant at either 0.1 or 0.2*M*. The stability constants of the mixed ligand complexes (Table 2), were evaluated using the Schaap and McMasters method[14] [equation (2)]. Figures 1 and 2 represent the plotting of F_{jo} function *vs.* [X] for the Cd(II)–imidazole–malonate system as a representative example for the studied systems. It is evident that three mixed complexes

13. $[Cd(Mal)_3]^{4-} + Im$	$\rightleftharpoons$	$[Cd(Im)(Mal)_2]^{2-} + Mal^{2-}$	0.85

are formed with imidazole and malonate (or oxalate), whereas four mixed complexes are formed with tartrate. Theoretical estimation of the stability constants of the mixed complexes under study was performed, using the Watters and DeWitt method.[24] The theoretical values seem to be less than those observed by about $10^{0.6 \pm 0.07}$. The higher experimental values may be derived from the cooperative effects of the electrostatic forces and steric effects[14,25,26] between the different kinds of ligands.

From the values of the stability constants for the simple and mixed complexes (*cf.* Tables 1 and 2), the affinity of Cd^{2+} ions toward the dicarboxylate ligands follow the order: Ox (5.2) >Tart (6.8) >Mal (8.0). The values given in parentheses are the overall basicity constants of the ligands.[27] Apparently, the observed stability constants do not necessarily follow the order of basicity for the ligands. The enhanced stabilization of the tartrate complexes as compared to those of malonate is probably due to the fact that one of the hydroxo groups of tartrate is coordinating the metal ion, whereas the stabilization of oxalate complexes over those of malonate (or tartrate) is mainly attributed to the differences in the chlelate ring size. The mixing constants,[28] namely $\log K_M = \log \beta_{11}^{-1/2} (\log \beta_{02} + \log \beta_{20})$ and the stabilization constants[29] namely, $\log K_s = \log K_M - \log 2$, for each system were also evaluated. The obtained positive values of $\log K_M$ and $\log K_S$ suggests that the ternary complexes are more stable than the binary ones. Moreover, the equilibrium constants were calculated for the Cd(II)–imidazole–malonate system as a representative example (Table 3). Inspection of these values confirms that the tendency of the imidazole ligand to add to the complexes is stronger than that of the dicarboxylate ions; this may be linked with the weaker nature of the dicarboxylate ligands.

ANALYSIS OF ACROLEIN AND ACRYLONITRILE IN AQUEOUS SOLUTION BY MEMBRANE INTRODUCTION MASS SPECTROMETRY

TARUN K. CHOUDHURY, TAPIO KOTIAHO* and R. GRAHAM COOKS†
Department of Chemistry, Purdue University, West Lafayette, Indiana 47907, U.S.A.

(*Received* 2 *December* 1991. *Revised* 16 *January* 1992. *Accepted* 23 *January* 1992)

Summary—Acrolein and acrylonitrile can be quantified directly at low levels in aqueous solution using membrane introduction mass spectrometry. Electron impact was used to generate positively charged ions and electron capture of the O-(2,3,4,5,6-pentafluorobenzyl)hydroxyl amine (PFBOA) derivative was used to generate negatively charged ions of acrolein in aqueous solutions. The origins of all ions in the mass spectra and product MS/MS spectra recorded using both ionization methods were assigned and a reaction scheme is given which accounts for the fragmentation of the PFBOA derivative. Detection limits were measured using multiple reaction monitoring in both the methods. With electron capture detection, acrolein could be detected without preconcentration at 10 ppb levels. Electron impact ionization and multiple reaction monitoring both allowed the measurement of acrylonitrile at levels as low as 10 ppb.

Acrolein and acrylonitrile are on the US EPA priority list of pollutants because of their toxicity. Acrolein has been reported to have severe biological effects on humans and other mammals. Short term (1–5 min) inhalation exposure to low concentrations (low ppm) of acrolein causes moderate to severe nasal and eye irritation as well as lacrymation, and exposure to higher concentrations (~150 ppm) for 10 min or longer can be fatal.[1] Acrylonitrile is reported to be carcinogenic.[1] Inhalation exposure to ppm levels of this compound for a few hours causes effects which range from slight transitory to fatal effects in animals.[1] There is therefore an obvious need to make correct qualitative and quantitative measurements of these compounds in water. This task is made difficult by the fact that the compounds are water soluble so that the usual procedure of extraction into an organic solvent is not applicable.

The methods generally used for the determination of acrolein are spectrophotometry,[2] fluorometry,[3,4] liquid chromatography,[5,6] gas chromatography with electron capture detection,[7,8] and HPLC with fluorescence detection.[9] Cohen and Altshuller[2] derivatized acrolein with 4-hexylresorcinol in ethyl alcohol prior to spectrophotometric determination at the low ppm levels. The fluorometric method of Suzuki and Imai[3] and that of Alarcon[4] allows the measurement of acrolein at low ppb levels but suffers from a lack of specificity. Similar detection limits were observed with liquid chromatography when used with appropriate methods of detection.[5,6] For example, application of HPLC in combination with fluorescence detection, allowed the low ppb level measurement of acrolein.[9] Detection limits of acrolein at and even below the ppb level were obtained by Nishikawa *et al.*[7,8] by bromination of the O-methyloxime derivative followed by electron capture detection.

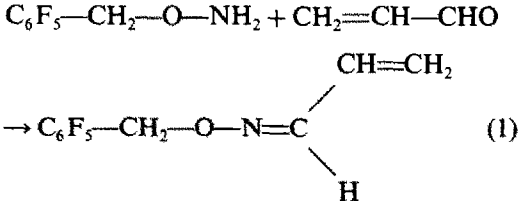
Most of the methods[10–15] used for the detection of acrylonitrile involve purge and trap preconcentration, followed by detection with gas chromatography (GC) or gas-chromatography–mass spectrometry (GC–MS). Ramstad and Nicholson[10] used a combination of steam distillation, elevated temperature purge and trap of the distillate and detection by gas chromatography/flame ionization in order to detect sub ppb levels of acrylonitrile in aqueous solutions. In EPA priority pollutant method 603,[11] which was developed for the measurement of acrolein and acrylonitrile, an inert gas bubbled through the water sample in a heated purge cell transfers the analyte into the vapor phase where it is swept through a sorbent and trapped. The trap is subsequently heated and

*On leave from Technical Research Center of Finland, Chemical Laboratory, Biologinkuja 7, 02150 Espoo, Finland.
†Author for correspondence.

flushed with helium in order to desorb and carry the analyte to the GC for separation and detection with a flame ionization detector. This method can be applied to detect acrolein and acrylonitrile in the sub ppb to low ppb range, depending upon the interference of the sample matrix. The EPA method 624[12] uses an ambient temperature purge cell, a packed column, and a quadrupole mass spectrometer as a detector. This method suffers from the fact that purging at room temperature is not highly efficient. The "modified 624" method,[15] using a purge and trap capillary GC–MS, allows identification and quantification of acrylonitrile to low ppb levels. Trussell *et al.*[14] isolated acrolein and acrylonitrile by purging with helium and cryotrapping in a capillary column. The analytes were then desorbed from the trap by heating before they were injected into the mass spectrometer where they were analyzed by electron ionization down to sub ppb levels. Though there are many methods for the measurement of acrolein and acrylonitrile, there is still a need for a direct, simple and more reliable analytical method for the analysis of these compounds in drinking water.

Membrane introduction mass spectrometry (MIMS), which eliminates the solvent reduction or analyte preconcentration step, might provide the basis for such a method. MIMS is a technique for the introduction of volatile organic compounds from an aqueous solution into the ion source of a mass spectrometer, and is currently undergoing rapid development.[16] The selective permeation of low molecular weight volatile compounds makes possible the qualitative and quantitative detection of these compounds at very low levels and a wide variety of applications has been reported.[16–39] The development of the flow-through technique,[30–33] which allows the sample to flow through the membrane within the ion source of the mass spectrometer, is particularly valuable for continuous on-line monitoring. This technique has proved to be valuable in detecting trace amounts of volatile compounds in aqueous solutions[33,34] and in monitoring organic and biochemical reactions.[35–39] The "flow-over" method, which uses a helium-purged hollow fiber membrane in which aqueous sample flows continuously over the surface of the membrane and the flow of helium through the interior sweeps analytes into the ion source of the mass spectrometer, has also shown low detection limits.[29]

The present study reports the application of MIMS for the detection of acrolein and acrylonitrile in aqueous solution. Since acrolein contains a carbonyl group, it can be derivatized with O-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine (PFBOA) to the corresponding oxime according to equation (1). This reaction can be performed in aqueous solution and since the derivative contains 5 fluorine atoms, it can be readily detected by electron capture using negative ion chemical ionization mass spectrometry.



Ionization by electron capture facilitates qualitative and quantitative detection of many organic molecules compared to their ionization by positive ion EI or CI methods[40] because of the remarkable improvements in selectivity and sensitivity achieved by examining negative ions.[40–42] For example, this technique has been successfully applied to the analysis of drugs and drug metabolites in biological samples.[42,43] PFBOA derivatization followed by electron capture has previously been applied to the detection of low ppb levels of C_1–C_7 aldehydes.[44] This paper also reports the application of MIMS for sample introduction and subsequent electron impact mass spectrometry for qualitative and quantitative measurements of low concentrations of acrylonitrile in aqueous solution.

EXPERIMENTAL

An experimental arrangement reported previously,[33–36] which allows the introduction of sample into the mass spectrometer using a membrane introduction probe is shown in Fig. 1. The

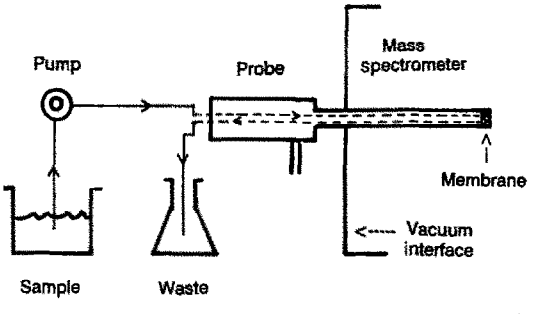


Fig. 1. Schematic diagram of the membrane introduction apparatus used in this study (taken from ref. 44).

dimethylvinyl silicone polymer membrane (ASTM: VMQ Dow Corning, Midland, MI) used for these experiments was 0.01 inches thick. In order to control the temperature of the membrane independently of the ion source, the probe is provided with a programmable temperature control device which was used to set the membrane temperature at 70° throughout the experiment. A stream of methanol and water in the ratio of 1:1 was continuously supplied to the membrane with a peristaltic pump (model 7618-30: Ismatic, Switzerland) and sample plugs of 0.2-ml volume were injected into the stream at intervals via a six-port liquid injector. The only purpose of using methanol in the mixture was to keep the sample introduction system clean. A Finnigan 4500 TSQ mass spectrometer (Finnigan Corporation, San Jose, CA) operated with an INCOS data system was used for all the measurements. The mass spectrometer was operated under both electron impact (EI) and chemical ionization (CI) conditions using an electron energy of 70 eV. The source pressure was 0.5 Torr for the CI experiments. The ion source was maintained at a temperature of 190°. Both full mass spectra and MS/MS product spectra were recorded. In order to record the MS/MS product ion spectra, a 20-eV collision energy was chosen and argon, typically at 1 m Torr was used as a collision gas in the second quadrupole. In order to establish detection limits, multiple reaction monitoring experiments were performed.

Acrolein (97% pure) and acrylonitrile (<99% pure) were supplied by Aldrich Chemical Company, Milwaukee, Wisconsin. Stock solutions (100 ppm) of acrolein and acrylonitrile were prepared by dissolving the appropriate quantity of the compounds in water. A series of dilutions was made to yield solutions with concentrations in the range of 1 ppb–10 ppm. PFBOA, supplied by Aldrich Chemical Company (Milwaukee, WI) was 99% pure. A solution (1 mg/ml) of O-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride was prepared by dissolving the appropriate quantity of the compound in water. The PFBOA derivative of acrolein was prepared following the method of Glaze *et al.*[45] To 5 ml of acrolein solution, 2 drops of 0.1*M* $Na_2S_2O_3$ solution and 0.5 ml of the PFBOA solution were added and the mixture was allowed to stand for a few minutes. The product was liberated by addition of a drop of concentrated sulphuric acid before the sample was injected into the membrane introduction probe via a six-port liquid injection system. Mass spectra for acrylonitrile were recorded by using elecron ionization. For acrolein, mass spectra were collected using electron ionization or negative ion chemical ionization for the PFBOA derivative using isobutane as the reagent gas.

RESULTS AND DISCUSSION

The electron ionization (EI) mass spectrum of an aqueous solution (100 ppm) of acrolein, recorded using the membrane introduction probe, is presented in Fig. 2(a). For comparison, an EI spectrum of pure acrolein, is presented in Fig. 2(b). Though there are differences in relative abundances of ions m/z 25–29 due to the transmission of air through the membrane, the presence of the characteristic ion signals for acrolein in Fig. 2(b) confirms that membrane introduction mass spectrometry can be used for the detection of acrolein in aqueous solutions. The spectrum shows a discernible molecular ion signal at m/z 56. The peak $(M + 1)^+$ at m/z 57 must be the result of an ion-molecule reaction occurring in the ion source and is presumed to be due to the protonated molecule $CH_2{=}CHCHOH^+$. The $(M - 1)^+$ ion at m/z 55 could be due to H_2 loss from protonated acrolein[46] and/or to the formation of

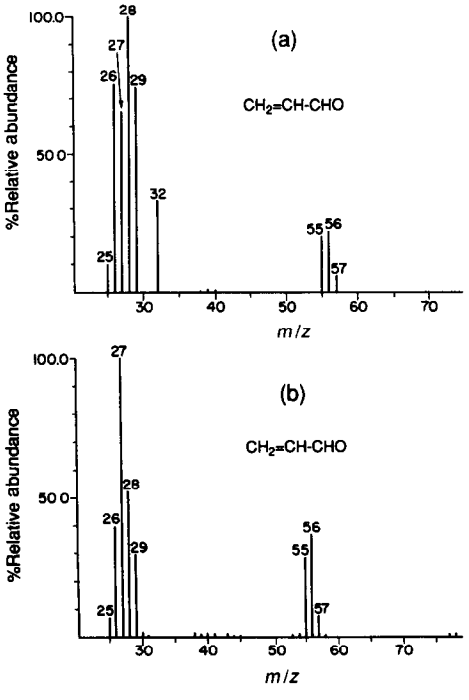

Fig. 2. (a) EI mass spectrum of a solution containing 100 ppm of acrolein recorded using membrane introduction probe, (b) EI mass spectrum of pure acrylonitrile.

CH_2=$CHCO^+$ as a result of fragmentation of the radical cation.[47] The presence of this ion in the MS/MS spectrum of $M^{+\cdot}$ (see below) favors at least some contribution from the latter mechanism. The large abundance of $(M-1)^+$ relative to $M^{+\cdot}$ is characteristic of aliphatic aldehydes.[48] The relative abundances of ions m/z 26, 27, 28 and 29 are much higher than that of the molecular ion. The origin of the peaks at m/z 26, 27, 28 and 29 were also confirmed by the MS/MS product spectrum of the acrolein molecular ion. The spectrum, which is shown in Fig. 3, is very simple indeed. The product ion peak at m/z 28 is assigned to the formation of the $C_2H_4^+$ ion according to equation (2) since thermochemical data[49] show this set of products to be favored over the complementary pair. The production of HCO^+ according to

$$CH_2{=}CHCHO^+ \rightarrow C_2H_4^+ + CO \qquad (2)$$

$$CH_2{=}CHCHO^+ \rightarrow C_2H_3 + HCO^+ \qquad (3)$$

equation (3), accounts for the appearance of the peak at m/z 29. The peak $(M—CHO)^+$ produced by the cleavage of the C—C bond adjacent to the C=O group is also unique in the fragmentation of low molecular weight aliphatic aldehydes.[48] In the present mass spectrum, this ion occurs in low abundance at m/z 27. The ion signals at m/z 26 and 25 in the mass spectrum (Fig. 2) are due to the formation of $C_2H_2^+$ and C_2H^+ respectively.

The detection limit of acrolein, studied by electron ionization and multiple reaction monitoring, was measured to be 50 ppb (S/N = 2). In this multiple reaction monitoring experiment, the ion at m/z 56 was selected in the first quadrupole and the products m/z 28, 29 and 56 were monitored. Since earlier results on C_1–C_7 aldehydes proved that significantly lower detection limits can be obtained by using negative ion chemical ionization for PFBOA derivatives of aldehydes,[44] this method was also applied for acrolein. Figure 4 shows the negative ion chemical ionization mass spectrum of the PFBOA derivative of acrolein. The mass spectrum is similar to those of C_1–C_7 aldehydes reported earlier.[44] The intensity of the molecular ion peak (M^-) of the derivative at m/z 251 is very low compared to the fragment at m/z 231 which is due to the elimination of HF from the molecular anion. Such an elimination of a ring fluorine probably leads to the formation of a cyclic product. The origin of the ion m/z 231 is confirmed by examining the product MS/MS spectrum of m/z 251 shown in Fig. 5. The peak at m/z 201 is proposed to be due to the elimination of NO· from $(M—HF)^-$ and the origin of this peak was confirmed by recording the product MS/MS spectrum of m/z 231. In addition to these peaks, the electron capture mass spectrum of the PFBOA derivative of acrolein contains the peaks m/z 178, 181 and 197. The peaks at m/z 181 and 197 are due to the formation of pentafluorobenzyl anion $(C_6F_5CH_2^-)$ and pentafluorobenzyloxy anion $(C_6F_5CH_2O^-)$ respectively, both originating from the derivatizing agent. The ion at m/z 178

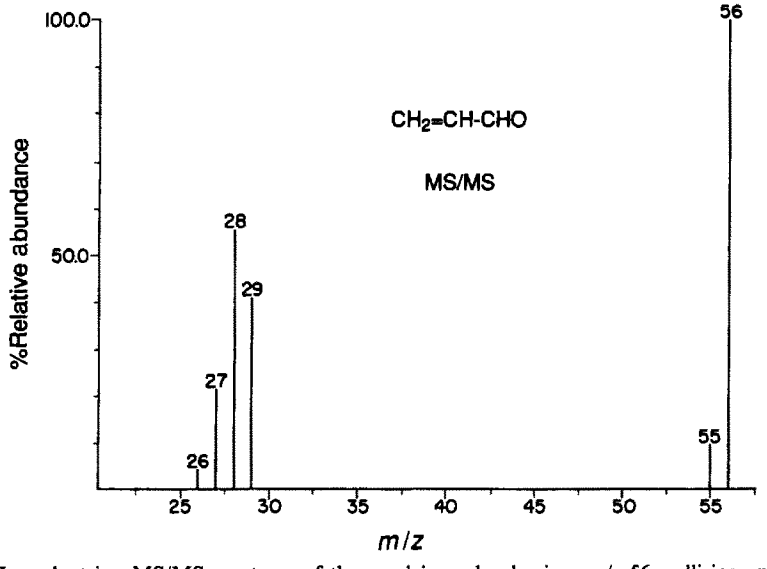

Fig. 3. EI product ion MS/MS spectrum of the acrolein molecular ion, m/z 56; collision energy 20 eV and collision gas (argon) pressure 0.5 mTorr.

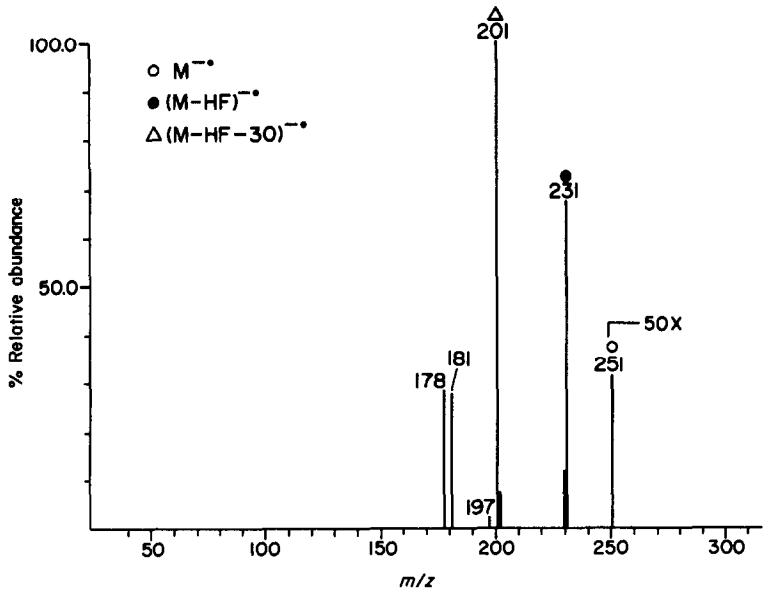

Fig. 4. Negative ion chemical ionization mass spectrum of the PFBOA derivative of acrolein (100 ppm solution).

is due to successive loss of HF and CH_2=CH—CN from the molecular ion. The appearance of the signal at m/z 162 in the product MS/MS spectrum (Fig. 5) can be rationalized as being due to the elimination of CH_2=CHCNO from the cyclic species formed by elimination of HF from the molecular ion $M^{-\cdot}$. In summary, the fragmentation pattern of the PFBOA derivative of acrolein is similar to that of other aldehydes studied earlier,[44] and can be explained with the help of reaction scheme 1.

The mass spectrometer was operated in the multiple reaction monitoring mode to measure the lowest level at which the PFBOA derivative of acrolein could be detected by electron capture negative ion chemical ionization. To do this the ion at m/z 231 was selected using the first quadrupole and the ions at m/z 231 and 201 were monitored. The detection limit for acrolein by derivatization followed by electron capture detection was found to be 10 ppb with S/N = 3/1 and the calibration curve was found to be linear from the detection limit up to at least 100 ppb.

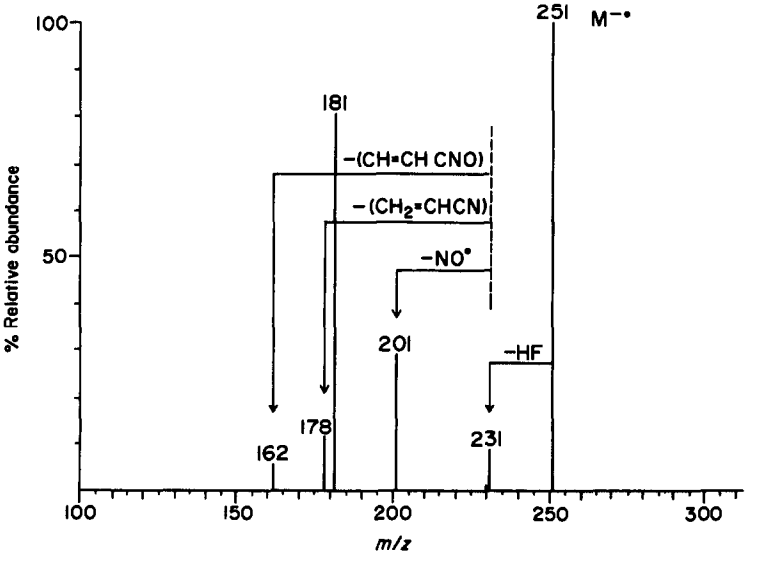

Fig. 5. Product ion MS/MS spectrum of the molecular anion of PFBOA derivative of acrolein; collision energy 20 eV and collision gas (argon) pressure 1 mTorr.

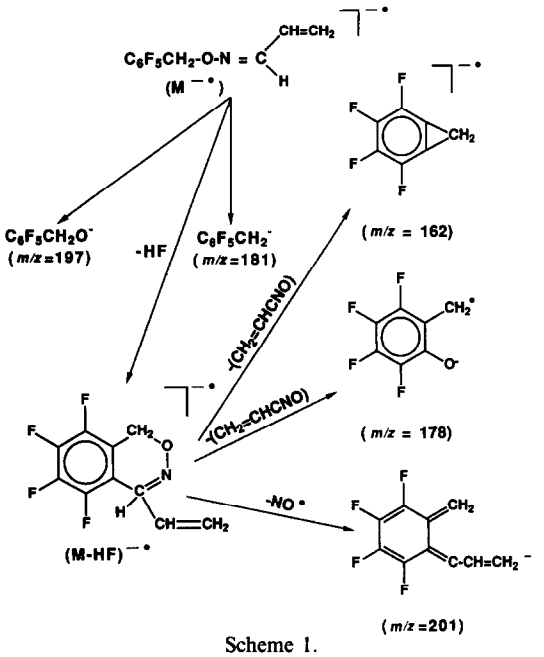

Scheme 1.

The EI mass spectrum of acrylonitrile is shown in Fig. 6. Comparison with the mass spectrum available in the literature[50] shows the presence of characteristic fragment ions. In addition, signals are observed at m/z 32 due to oxygen and, (at least in part) at m/z 28 due to nitrogen. The molecular ion shows a strong signal at m/z 53. The $(M+1)^+$ ion at m/z 54 under EI conditions is characteristic of aliphatic nitriles and is due to the formation of $CH_2{=}CHCNH^+$ as a result of an ion-molecule reaction involving abstraction of a hydrogen atom.[48] The $(M-1)^+$ peak at m/z 52, which may be in part the result of an ion/molecule reaction, is also diagnostic of aliphatic nitriles.[48] The $(M-2)^+$ peak at m/z 51 is due to formation of $HC{\equiv}CCN^+$. The EI MS/MS product spectrum of acrylonitrile is shown in Fig. 7. The product ion at m/z 52 is due to the loss of the alpha hydrogen atom from the molecular ion. The signal at m/z 27 is due to the formation of $C_2H_3^+$ and/or HCN, m/z 26 to CN^+ and $C_2H_2^+$ and m/z 25 to C_2H^+.

Multiple reaction monitoring was applied in order to establish the detection limit of acrylonitrile in aqueous solution. The molecular ion, m/z 53, was selected in the first quadrupole and the ions m/z 25, 26, 27, 52 and 53 were monitored. The detection limit for acrylonitrile was found to be 10 ppb with a S/N ratio of 2/1 and the calibration curve was found to be linear from the detection limit up to 100 ppb. The dynamic range over which detection of acrolein and acrylonitrile is linear is evident from the calibration curves shown in Fig. 8.

CONCLUSIONS

The present work demonstrates the capability of membrane introduction mass spectrometry to allow qualitative and quantitative measurements to be made on acrolein and acrylonitrile present in low concentrations in aqueous solution. Both electron ionization of underivatized acrolein and electron capture of the PFBOA derivative of acrolein were applied to measure the detection limits. Electron capture detection

of the derivatized acrolein gave better signal intensity and a lower detection limit than did electron impact. The most intense ion signal in the negative ion chemical ionization spectrum was due to the ion m/z 231 which is generated by the elimination of HF from the molecular ion $M^{-\cdot}$. The fragmentation pattern of the molecular ion of the PFBOA derivative of acrolein is analogous to that of aliphatic aldehydes examined previously. For acrylonitrile, electron ionization experiments were conducted in order to determine the lowest level of detection. For both acrolein and acrylonitrile, detection limits were measured by using the mass spectrometer in the multiple reaction monitoring mode. The calibration curves were found to be linear up to 100 ppb.

A SIMPLE DIFFERENTIAL TITRATOR FOR AUTOMATIC POTENTIOMETRIC TITRATION AT ZERO CURRENT, WITH TWO IDENTICAL INDICATOR ELECTRODES

A. ARREBOLA RAMIREZ and C. JIMENEZ LINARES
Department of Analytical Chemistry, Faculty of Sciences, University of Granada, 18071 Granada, Spain

(*Received* 21 *March* 1990. *Revised* 23 *December* 1991. *Accepted* 31 *January* 1992)

Summary—A simple differential titrator for automatic potentiometric titration at zero current, with two identical indicator electrodes, is described. The autoburette is a normal microburette connected to one tube of a peristaltic pump, and the differentiating system is a closed-flow circuit in a second tube of the pump, this tube containing two electrodes 5 cm apart. The apparatus has been applied to the determination of halides and sulphide–disulphide mixtures, with electrodes coated with an appropriate silver salt.

Most commercially available automatic titrators are differential, that is to say, they record the slope of the titration curve, $E = f(V)$, directly. MacInnes *et al.*[1-4] were the first to develop a simple experimental device for differential titrations using two identical indicator electrodes, but the measurements were not continuous and the differential curve could not be obtained automatically. Baker and Müller[5] showed that an electronic pulse amplifier can be used for the purposes of differential titration and can also be easily adapted to obtain automatic results. Later, Malmstadt and Fett[6] extended Baker and Müller's principle to develop an automatic differential titrator that responds to the second derivative of the titration curve and stops the flow of titrant when this second derivative is zero. Nowadays, titrators incorporate a microprocessor to store the experimental data and calculate the results by whatever method is required, *e.g.*, differential titration, Gran titration,[7,8] addition techniques, and so on.

Here we describe a differential titration method which can be put into practice with a simple instrument, the components of which are readily available in any analytical laboratory.

EXPERIMENTAL

Reagents

All chemicals used were of analytical reagent grade. Silver nitrate was dried at 110° and an appropriate amount was dissolved in demineralized water to give a 0.1*M* solution. Solutions of sodium chloride, potassium bromide and potassium iodide in demineralized water were standardized by potentiometric titration with the silver nitrate solution, and their concentrations were found to be 0.0996, 0.1000 and 0.0996*M*, respectively. A solution of hydrogen sulphide in demineralized water was standardized iodimetrically; its concentration was $4.86 \times 10^{-3}M$. Sulphuric acid (5*N*) and 1*M* potassium nitrate were prepared.

Apparatus

Two silver wires (2.5 cm long and 0.8 mm in diameter) were inserted into a silicone-rubber tube (2 mm in diameter) with a distance of 5 cm between them. They were then electro-oxidized in 0.1*M* solutions of potassium chloride, potassium bromide, potassium iodide or ammonium hydrogen sulphide (as appropriate) to form a precipitate layer.

The difference in potential between the two electrodes was measured with a Metrohm E 536 potentiometer, incorporating a graphic recorder.

An Eyela MP3 peristaltic pump with two tubes, and a 5-ml microburette were used.

Experimental device

The components of the experimental device are shown in Fig. 1. A microburette, connected to the pump by a silicone-rubber tube (1 mm internal diameter), supplies a constant flow of titrant, measured by observing the volume released over a given time. The differentiating system is a closed-flow circuit made up of the titration vessel and a silicone-rubber tube with

the two electrodes inserted close to the junction with the titration vessel.

Recommended procedure

Twenty ml of 5*N* sulphuric acid or 5 ml of 1*M* potassium nitrate solution are added to a measured volume of the solution to be titrated and the mixture is diluted accurately to 80 ml with demineralized water. This solution is then stirred at a high enough speed to ensure rapid and efficient mixing in the titration vessel. The closed-flow circuit is connected to the pump and the pump is switched on for about a minute. The tube connected to the microburette is introduced into the titration vessel and the titration begun, the pump and the recorder being switched on simultaneously. The titrant flow (ϕ) must be determined either before or after the titration. Alternatively, the titrant flow need not be measured if the pump and recorder are stopped simultaneously and a reading is taken of the volume of titrant added. When the titration is complete, the titration vessel is emptied and rinsed and the closed-flow loop is emptied by starting the pump, and then rinsed by pumping water through it for 2–3 min, and again emptied. The system is then ready for the next sample.

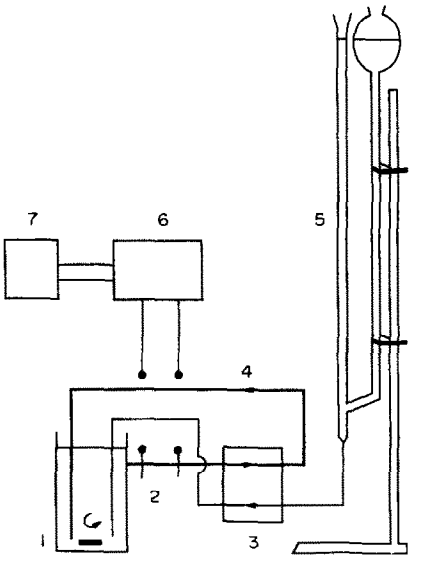

Fig. 1. Differential potentiometric titrator: 1, titration vessel; 2, electrodes; 3, peristaltic pump; 4, closed-flow circuit; 5, microburette; 6, potentiometer; 7, graphic recorder.

THEORY

The normal way of finding the end-point of a potentiometric titration is to measure the e.m.f. (E) as a function of the volume (V) of titrant added, and to take the end-point as the value of V at which $\Delta E/\Delta V = f(V)$ [or $\Delta E = f(V)$ since ΔV is small and constant]. With the experimental device described here, the potentials of the two electrodes represent two consecutive points on the titration curve, corresponding to addition of an increment ΔV of titrant, ΔV being the volume of titrant added in the time it takes for the solution to traverse the distance between the electrodes. Thus a linear concentration gradient is established in the closed-flow circuit tube, and the recorder will continuously give the function $\Delta E = f(V)$; the constant value for ΔV can be altered by changing the distance between the electrodes. A similar effect can be obtained by changing the concentration of the titrant. The speed of the pump does not influence the value of ΔV, but it does affect the time needed to carry out the titration, and also the probability that the potential of the electrodes will be a stable equilibrium potential. It should be emphasized here that, as no reference electrode is used, there is no liquid-junction potential. The end-point is indicated by the sharp maximum or minimum that appears on the derivative curve when the "front" of the fully titrated solution reaches the mid-point between the electrodes.

This experimental system involves two determinate errors, both of which can be easily evaluated and corrected for. The first is the time (t_0) which the solution to be titrated takes to cover the distance (l_0) between the beginning of the closed-flow circuit and the mid-point between the electrodes; t_0 can be measured and subtracted from the time (t_2) taken to reach the maximum (or minimum) on the titration curve. The second error is due to the volume of solution (V_1) contained in the length of tubing (l_1) between the mid-point between the electrodes and the end of the circuit, which still contains some unreacted titrand and will need a certain volume of titrant (ϕt_1) to reach the end-point.

At time t_2 (corresponding to the apparent end-point) there is a slight overtitration of the solution in the titration vessel and length l_0 of the circuit loop, and an undertitration of the solution in the rest of the loop. If the length of the loop is adjusted so that these two effects just cancel, t_2 will be the true titration time.

If V_0 is the initial total volume in the titration vessel before the loop has been filled and f is the

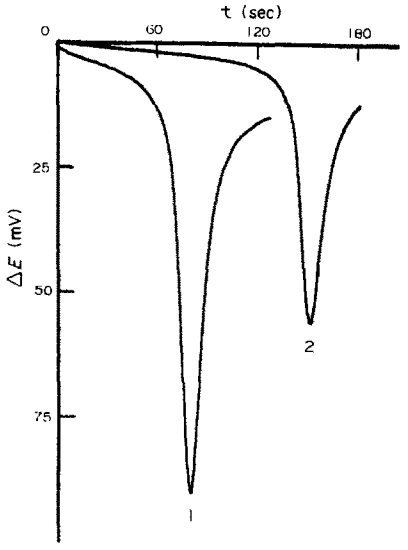

Fig. 2. Titration of 2 ml of 0.1*M* chloride with 0.1*M* silver nitrate (curve 1) or 0.05*M* silver nitrate (curve 2).

fraction of V_1 that is still untitrated, it can be shown that

$$t_1 = \frac{fV_1(t_2 - t_0)}{V_0 + \phi t_2 - fV_1} \quad (1)$$

If we operate so that $V_0 \gg \phi t_2 - fV_1$, this expression may be simplified to

$$t_1 = fV_1(t_2 - t_0)/V_0 \quad (2)$$

It can also be shown that if $t_2 - t_0$ is equal to $nl_1 t_0/l_0$, the value of f at the exit end of the loop is $1/n$. Since $f = 0$ at the mid-point between the electrodes at time t_2, and there is a linear titrand concentration gradient along the loop, the mean value of f is $1/2n$.

By combination of these equations we obtain

$$t_1 = l_1 V_1 t_0 / 2l_0 V_0 \quad (3)$$

and t_2 will be the true titration time if the circuit is designed so that $l_1 V_1 = 2l_0 V_0$ or

$$l_1 = \sqrt{2V_0 l_0/\pi r^2} \quad (4)$$

where r is the inner radius of the circuit tubing. For example, if $l_0 = 3.5$ cm, $V_0 = 80.0$ ml and $r = 0.1$ cm, l_1 must be 133.5 cm.

As this is an approximation, based on equation (3), the error of the titration will not be strictly zero, but nonetheless will be very small. Equation (3) can be made more exact by substituting $V_0 + \phi t_2 - fV_1$, yielding

$$t_1 = \frac{l_1 V_1 t_0}{2l_0(V_0 + \phi t_2 - fV_1)} = \frac{V_0 t_0}{V_0 + \phi t_2 - fV_1} \quad (5)$$

which allows calculation of the difference $t_1 - t_0$ and the relative error, on the basis of the equations

$$t_1 - t_0 = -\frac{(\phi t_2 - fV_1)t_0}{V_0 + \phi t_2 - fV_1} \quad (6)$$

$$\text{Error (\%)} = \frac{100(\phi t_2 - fV_1)t_0}{t_2(V_0 + \phi t_2 - fV_1)} \simeq \frac{100\phi t_0}{V_0} \quad (7)$$

For $V_0 = 80.0$ ml, $\phi = 30$ μl/sec and $t_0 = 1.4$ sec, the error will not exceed 0.05%.

An alternative development of the theory is given in the Appendix.

RESULTS AND DISCUSSION

Titration curves

The curves obtained on titrating, by the recommended procedure, 2 ml of 0.1*M* chloride with standard silver solutions are shown in Fig. 2. Both curves show a minimum corresponding to the end-point of the titration. Analogous curves are obtained in titrations of bromide, iodide and sulphide with silver.

Figure 3 shows the curve obtained on titrating a mixture of sulphide and disulphide with silver. This curve has two minima, the first due

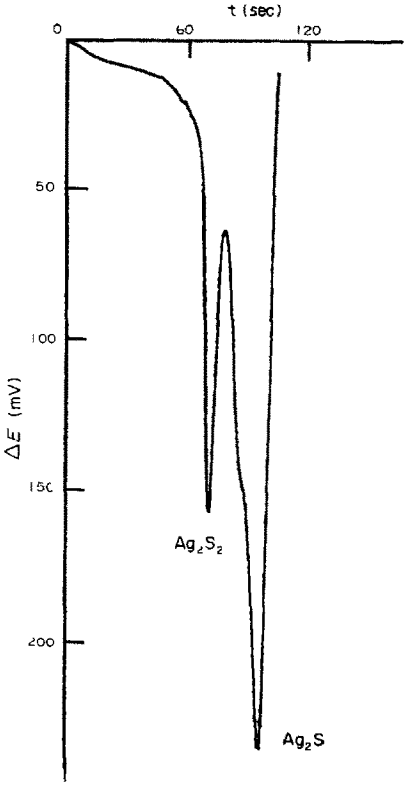

Fig. 3. Titration of a sulphide and disulphide mixture with 0.1*M* silver nitrate.

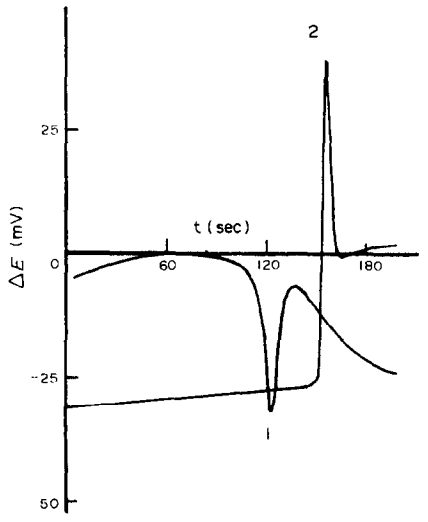

Fig. 4. Titration of ferrous iron with dichromate, using two platinum electrodes (curve 1), and the inverse titration (curve 2).

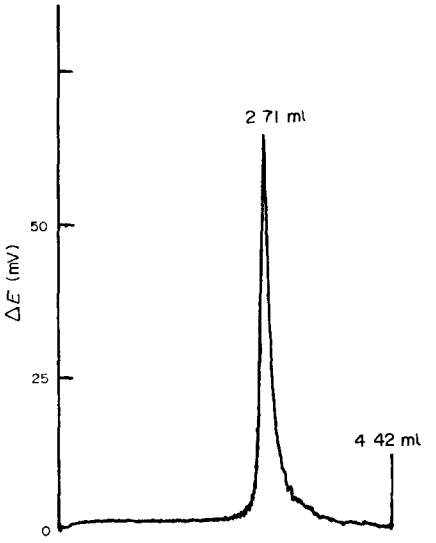

Fig. 5. Titration curve of 2 ml of 0.1*N* sulphuric acid with 0.075*N* sodium hydroxide, using two platinum electrodes.

to precipitation of Ag_2S_2 and the second to precipitation of Ag_2S, since the second peak is displaced when an H_2S solution is added to the sample.

The proposed method can be applied to other types of potentiometric titrations, such as acid–base, oxidation–reduction, *etc.*, by use of the appropriate electrodes. Thus, Fig. 4 shows the curves obtained on titrating 5 ml of 0.04*N* ferrous solution with 0.05*N* dichromate solution (curve 1), and 4 ml of 0.05*N* dichromate with approximately 0.04*N* ferrous solution (curve 2). The curve corresponding to the titration of 2 ml of 0.1*N* sulphuric acid with 0.075*N* sodium hydroxide is represented in Fig. 5. In this last titration, the pump and recorder were stopped simultaneously and the titrant volume added was read.

Precision of the method

We checked the precision of the method by titrating several Cl^-, Br^-, I^- and S^{2-} solutions with 0.1*M* Ag^+ solution. The results obtained (averages of ten determinations) are given in Table 1.

The precision obtainable with this simple titration device is comparable to that with conventional titrators. Thus, titration of 2 ml of a 0.1*M* chloride solution, with use of the Metrohm E 536 automatic titrator, gave a precision of 1.2%, whereas with our device we obtained a value of 1.4%.

Precision of flow measurement

Flow-measurement precision was determined from ten experiments, in which the volumes released by the microburette (between 2000 and 4000 μl) and the corresponding times were measured. The mean $\pm$ standard deviation was 26.36 ± 0.07 μl/sec.

Applications

The proposed method has been applied to determination of the chloride content of drinking water (200 ml) and two samples of wine

Table 1. Precision of the method

(50 ml), and to determination of the sulphide and disulphide concentrations of an ammonium hydrogen sulphide solution. The phosphate content of a sample of $Na_2HPO_4 \cdot 12H_2O$ was determined according to the following procedure: a measured volume of sample, containing less than 0.4 meq of phosphate, was transferred to the titration vessel, 4.00 ml of 0.1*M* silver nitrate solution and 5 ml of 1*M* potassium nitrate solution were added and the mixture was diluted accurately to 80 ml with demineralized water and neutralized. The excess of silver was titrated with 0.1*M* sodium chloride.

The results obtained (averages of six determinations) are given in Table 2.

Conclusions

This automatic differential titrator is a simple instrument with components (a potentiometer, a graphic recorder, a peristaltic pump with two tubes and a microburette) which are readily available in any analytical laboratory. Its cost is approximately a fifth of that of a commercial automatic differential titrator. In addition, the development of cheap and easily manufactured new coated wire[9] and tubular[10] microelectrodes considerably extends the field of application of the proposed method.

APPENDIX

At time $t_2 - t_0$ all the solution in the titration vessel has been titrated and the solution in the circuit loop has a titrand concentration gradient from zero at the entrance, to the titration vessel concentration at time $t_2 - t_0 - t_l$, at the exit, where t_l is the time taken for liquid to traverse the whole loop. During the time between $t_2 - t_0 - t_l$ and $t_2 - t_0$, $t_l \phi C$ μeq of titrant (concentration C μeq/μl) will have been added to the system, and divided between the titration vessel and the loop. To a first approximation, the fraction added to the titration vessel will be

$$t_l \phi C[V_0 - \tfrac{1}{2}V_l + (t_2 - t_0 - t_l)\phi]/[V_0 + (t_2 - t_0 - t_l)\phi]$$

where V_l is the *total* volume of the loop, and this fraction must have been equal to the amount of untitrated titrand present in the titration vesel at time $t_2 - t_0 - t_l$. Hence the titration vessel concentration of free titrand at that time was

$$t_l \phi C[V_0 - \tfrac{1}{2}V_l + (t_2 - t_0 - t_l)\phi]/$$
$$[V_0 + (t_2 - t_0 - t_l)\phi][V_0 - V_l + (t_2 - t_0 - t_l)\phi]$$

and this will therefore be the concentration at the exit of the loop at time $t_2 - t_0$. The loop therefore contains

$$V_l t_l \phi C[V_0 - \tfrac{1}{2}V_l + (t_2 - t_0 - t_l)\phi]/$$
$$2[V_0 + (t_2 - t_0 - t_l)\phi][V_0 - V_l + (t_2 - t_0 - t_l)\phi]$$

μeq of titrand still untitrated, and if t_2 is to be the true titration time, this must be equal to the $t_0 \phi C$ μeq of titrant to be added in time t_0. We therefore have

$$V_l t_l[V_0 - \tfrac{1}{2}V_l + (t_2 - t_0 - t_l)\phi]$$
$$= 2t_0[V_0 + (t_2 - t_0 - t_l)\phi][V_0 - V_l + (t_2 - t_0 - t_l)\phi]$$

Expanding, putting $V_l = (l_o + l_1)\pi = \pi x$, and $t_l = x/v$ wehre v is the linear velocity of the liquid in the loop, gives, after rearrangement:

$$\left(\frac{\pi^2}{2} + \frac{\phi\pi}{v}\right)x^3 - \left[\pi V_0 + (t_2 - t_0)\phi\pi - 2t_0\phi\left(\pi + \frac{\phi}{v}\right)\right]x^2$$
$$-2t_0(\pi v + 2\phi)[V_0 + (t_2 - t_0)\phi]x$$
$$+2t_0[V_0^2 v + 2V_0(t_2 - t_0)\phi v + (t_2 - t_0)^2\phi^2 v] = 0$$

This cubic equation contains one variable besides x, namely t_2, but that is to be expected because t_2 depends on the origial sample concentration, and determines the degree of dilution during the titration.

Substitution of $V_0 = 8.0 \times 10^4$ μl, $l_0 = 35$ mm, $t_0 = 1.4$ sec, $v = 25$ mm/sec and $t_2 - t_0 = 100$ sec gives

$$8.704713x^3 - 2.603875 \times 10^5 x^2$$
$$-3.219685 \times 10^7 x + 5.22430 \times 10^{11} = 0$$

which yields

$$x = l_0 + l_1 = 1387 \text{ mm, or } l_1 = 135.2 \text{ cm.}$$

For $t_2 - t_0 = 50$ sec, the equation is

$$8.704713x^3 - 2.556751x^2$$
$$-3.161479 \times 10^7 x + 5.050575 \times 10^{11} = 0$$

which yields

$$x = l_0 + l_1 = 1381 \text{ mm, or } l_1 = 134.6 \text{ cm.}$$

These values are in good agreement with the value of 133.5 cm for l_1, as deduced from the approximate equation (4). It is obvious from the terms in the cubic equation that V_0 is the most critical factor, and the initial dilution to this volume should be as accurate as possible. A tall and narrow titration vessel (marked accurately to indicate capacity V_0) is to be preferred, provided that its dimensions are also suitable for ensuring the fastest possible mixing.

SOME NEW ALGORITHMS APPLICABLE TO POTENTIOMETRIC TITRATION IN ACID–BASE SYSTEMS

TADEUSZ MICHAŁOWSKI

Department of Analytical Chemistry, Faculty of Chemistry, Jagiellonian University, 30-060 Kraków, Poland

(*Received* 6 *January* 1988. *Revised* 7 *January* 1992. *Accepted* 28 *January* 1992)

Summary—The paper describes some regression equations adaptable for determination of parameters such as concentrations, equilibrium constants and hydrogen-ion activity coefficients in systems comprising hydrolysable salts of type MeB_u and monoprotic and polyprotic acids or their salts. These equations are based on the charge and mass balances. Two unconventional types of regression equations are applied: (*i*) Padé functions $W = G_1(h)/G_2(h)$ relating the sum (W) of V_0 ml of titrand and V ml of titrant, $W = V_0 + V$, to polynomial functions $G_1(h)$ and $G_2(h)$ of the hydrogen-ion activity, h, and (*ii*) functions of the type $1/W = \phi(h)$, based on the Simms titration constants involved. The latter functions are notable for determination of acids and/or their salts in mixtures. The regression equations are developed for systems at constant ionic strength. The parameters of the system can be calculated by means of the computer program MINUITS. Other possibilities of the method, *e.g.*, application to mixed complexes and extraction systems, are also presented.

Potentiometric acid–base titration is the most common and straightforward method for the determination of acids. The mathematical methods used for interpretation of the titration data have been reviewed, *e.g.*, by Anfält and Jagner[1] and by Michałowski.[2] The methods are applied for acids (or bases) that are readily soluble over a wide pH range. Much less attention has been paid to theoretical considerations of mixtures of salts of MeB_u type formed by a hydrolysable cation Me^{+u} and the anion of a strong acid HB. Owing to formation of hydroxo-complexes, the Me^{+u} ions can be treated as acids. On the other hand, the hydroxide $Me(OH)_u$ which is insoluble in water over a defined pH range, can be treated as an analogue, from the opposite side of the pH scale, of a slightly soluble acid (*e.g.*, H_2SiO_3).

An aqueous solution of pure MeB_u contains protons originating from hydrolysis or dismutation.[3] Solutions of the commercial salt, however, may contain free strong acid (HB) or base (MOH) resulting from the preparation procedure. Neglect of the free acid or base leads to very dubious values for any equilibrium constants determined with such a solution. A detailed discussion concerning free acid/base has been made by von Barsewisch and Hasty[4] and Michałowski.[5]

A method described below has been developed to distinguish between the hydrolytic effect of the Me ions and the protolytic effect(s) caused by the presence of acids, bases or salts. It provides both analytical and physicochemical data, namely concentrations, equilibrium constants and the hydrogen-ion activity coefficient. The concentrations and physicochemical data form a set of internal parameters for a non-linear regression equation. The method can also be applied for determination of equilibrium constants in liquid–liquid extraction systems or in mixed or non-aqueous solvent systems.

The method presented here is based on semi-empirical regression equations obtained from the charge and concentration balances for unconventionally prepared titrand + titrant systems in which the sample solution is present in both the titrand and the titrant.[6,7] It is assumed that the titrand and titrant form a single phase (which may also be in equilibrium with an immiscible liquid phase) throughout the titration. The values of the internal parameters of the system are obtained by fitting an appropriate regression equation to the experimental points (V_j, pH_j) of a pH-titration performed according to a well-established optimization program run on a computer. The method has the following advantages.[8–11]

(1) Precise definition of the free acid or base terms and the possibility of distinguishing their effects from those resulting from hydrolysis and complexation reactions.

(2) The regression equations are relatively simple and have similar forms for all

applications; these features are very convenient for programming.

(3) It is easy to keep the ionic strength constant during the titration without prior knowledge of the composition of the sample.

(4) The similarity in composition of titrand and titrant practically eliminates any effect of change in dielectric constant during the titration.[12]

(5) Precipitation of basic salts or hydroxides can be avoided.

Such advantages are not offered by other systems based on use of computer programs;[13–20] in particular, TITRA[18] and TITAN[19,20] cannot be recommended for systems containing hydrolysable salts; the algorithms applied there are related to direct titration of mixture of acids with NaOH as titrant. Moreover, the form of the regression functions based on mass and charge balances is not convenient for computation because the response function in the regression equations contains unknown parameters, namely the hydrogen-ion activity coefficient and the ionic product for water (K_w). This makes the optimization procedure complex in its form and length; *e.g.*, TITAN[20] has about 1400 statements. In contrast, the optimization procedure in the method described here has only about 70 statements (not including the number of statements for entering the MINUITS optimization procedure[21] applied).

GENERAL ASSUMPTIONS

Composition of the sample

The following general composition is assumed:

$$Me^{(s)}B_{u_s}(s = 1, \ldots, P_{Me}) + HB + M_{m_t}H_{n_t - m_t}L^{(t)} \quad (t = 1, \ldots, P_L) \quad (1)$$

or

$$Me^{(s)}B_{u_s}(s = 1, \ldots, P_{Me}) + MOH + M_{m_t}H_{n_t - m_t}L^{(t)} \quad (t = 1, \ldots, P_L) \quad (2)$$

where $Me^{(s)}$, with charge $+u_s$, is a hydrolysable cation of the s-th kind, B^- the anion of a strong acid HB, M^+ a non-hydrolysable cation of a strong base MOH, $H_{n_t}L^{(t)}$ a weak acid of the t-th kind ($t = 1, \ldots, P_L$; $m_t = 0, \ldots, n_t$) forming the species $H_jL^{(t)}$ with charge $-n_t + j$ in solution ($j = 0, \ldots, q_t$; $q_t \geq n_t$). The molar concentrations of $Me^{(s)}B_{u_s}$, $M_{m_t}H_{n_t - m_t}L^{(t)}$, HB and MOH are denoted by $C_{0(s)}$, $C_{L(t)}$, C_a and C_b, respectively.

Titrand and titrant composition (example)

The titrand and titrant are prepared in standard flasks, of volume V_f. To do this, equal volumes (V^*) of the sample are placed in both flasks, then one of them is treated with volume V_B ml of C mole/l. HB solution or with V_M ml of C mole/l. MOH solution. Then, after addition of volumes V_{MB} and V'_{MB} of a solution (concentration C_1) of the non-hydrolysable salt MB, both solutions are made up to the mark with distilled water, see Table 1, system 4.

The presence of HB (C mole/l.) or MOH (C mole/l.) in the titrand or titrant ensures an appreciable pH change during the titration and this will be greater when the buffer capacity of the titrant is much greater than that of the titrand.

The isomolarity condition

The condition for constant ionic strength during the titration is expressed by the equation

$$C_1 V_{MB} = C_1 V'_{MB} + CV_B \quad (3)$$

for systems where HB is added, or

$$C_1 V_{MB} = C_1 V'_{MB} + CV_M \quad (4)$$

for systems where MOH is added; *e.g.*, equation (4) is the isomolarity condition for the system discussed in the example of titrand and titrant composition, see above. The presence of strong acid or strong base in one of the solutions is compensated by the corresponding surplus of MB in the other. This surplus can easily be calculated from $V_{MB} - V'_{MB} = CV_B/C_1$ or $V_{MB} - V'_{MB} = CV_M/C_1$.

Admissible complexes

In the mathematical models for the titrand + titrant systems containing the sample, represented by equations (1) or (2), the following types of soluble complexes are assumed:

Type 1:

$$[Me_{i_s}^{(s)}]M_\alpha H_\eta B_\beta L^{(t)} + [Me_{i_s}^{(s)}]M_\alpha B_\beta \quad (5)$$

Type 2:

$$[Me_{i_s}^{(s)}]M_\alpha H_\eta (OH)_\lambda B_\beta L^{(t)} + [Me_{i_s}^{(s)}]M_\alpha (OH)_\lambda B_\beta \quad (6)$$

where

$$[Me_{i_s}^{(s)}] = Me_{i_1}^{(1)} \ldots Me_{i_{P_{Me}}}^{(P_{Me})} \quad (7)$$

Complexes containing more than one $L^{(t)}$ ligand are not allowed in the model, nor are mixed

ligand complexes, *e.g.*, those containing two different ligands $L^{(t_1)}$, $L^{(t_2)}$. In the case of type 1 complexes, soluble hydroxo-complexes are neglected in the defined pH-interval.

As can be seen from literature data,[22,23] the exclusion of mixed-ligand complexes is justifiable for systems containing mixtures of chelating agents such as EDTA and citric or tartaric acid.

Relative contents of components of the system

Let us consider a titrand + titrant system containing a sample, as represented by equation (1) or (2). If the analytical concentrations $c_{Me(s)}$, c_M and c_B of $Me^{(s)}$, M and B in these solutions are much greater than the analytical concentrations $c_{L(t)}$ of the species containing $L^{(t)}$, *i.e.*,

$$c_{Me(s)} \gg c_{L(t)}, \quad c_M \gg c_{L(t)}, \quad c_B \gg c_{L(t)} \tag{8}$$

then, writing

$$\rho = \eta - \lambda \tag{9}$$

we can assume that the quantities [see equations (32), (36), (37)]:

$$P_{\eta t} = \sum_{t,\alpha,\beta} K^{(t)}_{(i_s)\alpha\eta\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[B]^{\beta} \tag{10}$$

$$Q_{\rho t} = \sum_{t,\alpha,\beta} K^{(t)}_{(i_s)\alpha\eta,\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[B]^{\beta} \tag{11}$$

$$R_{\lambda} = \sum_{t,\alpha,\beta} K_{(i_s)\alpha\lambda\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[B]^{\beta} \tag{12}$$

remain constant during the titration.

Constancy of dielectric constant

This condition is ensured by the similar composition of the titrand and titrant. The quantity of HB or MOH, *i.e.*, $C_a V_B$ or $C_b V_M$, is small in comparison with that of the salt MB.

pH-titration

The total volume after addition of V_j ml ($j = 1, 2, \ldots, N$) of titrant to V_0 ml of titrant is

$$W_j = V_0 + V_j \tag{13}$$

Let pH_j be the pH measured after addition of V_j ml of titrant. The pair (V_j,pH_j) defines this experimental point. The pH is defined as the negative logarithm of the hydrogen-ion activity (h)

$$pH = -\log h \tag{14}$$

so

$$h = f[H] \tag{15}$$

where f is the hydrogen-ion activity coefficient.

PROTON BALANCES AND THEIR TRANSFORMATIONS

Let us assume the existence of soluble complexes as given in equation (5). Defining the concentrations of the corresponding complexes by

$$c^{(t)}_{(i_s)\alpha\eta\beta} \ (t = 1, \ldots, P_L) \text{ and } c_{(i_s)\alpha\beta}$$

respectively and assuming the sample composition given by equation (1), we can write the balances related to the titrand + titrant system 4 in Table 1 as follows:

$$\sum_{t,s,i,\alpha,\eta,\beta} (i_s u_s + \alpha + \eta - \beta - n_t) c^{(t)}_{(i_s)\alpha\eta\beta} + \sum_{s,i,\alpha,\beta} (i_s u_s + \alpha - \beta) c_{(i_s)\alpha\beta} + [H] - [OH] = 0 \tag{16}$$

$$\sum_{t,i,\alpha,\eta,\beta} i_s c^{(t)}_{(i_s)\alpha\eta\beta} + \sum_{i,\alpha,\beta} i_s c_{(i_s)\alpha\beta} = dC_{0(s)} \tag{17}$$

$$\sum_{s,i,\alpha,\eta,\beta} c^{(t)}_{(i_s)\alpha\eta\beta} = dC_{L(t)} \tag{18}$$

$$\sum_{t,s,i,\alpha,\eta,\beta} \beta c^{(t)}_{(i_s)\alpha\eta\beta} + \sum_{s,i,\alpha,\beta} \beta c_{(i_s)\alpha\beta} = d \sum_s u_s c_{0(s)} + dC_a + C_i V_{MB}/V_f - b_M/W \tag{19}$$

$$\sum_{t,s,i,\alpha,\eta,\beta} \alpha c^{(t)}_{(i_s)\alpha\eta\beta} + \sum_{s,i,\alpha,\beta} \alpha c_{(i_s)\alpha\beta} = d \sum_t m_t C_{L(t)} + C_i V_{MB}/V_f \tag{20}$$

where:

$$(i_s) = i_1 \ldots i_{pMe} \tag{21}$$

$$d = V^*/V_f \tag{22}$$

$$b_M = CV_M V_0/V_f \tag{23}$$

$$W = V_0 + V \tag{13(a)}$$

(some of the parameters i_s can be equal to zero). The concentrations of the corresponding complexes can be expressed by the equations:

$$c^{(t)}_{(i_s)\alpha\eta\beta} = K^{(t)}_{(i_s)\alpha\eta\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[H]^{\eta}[B]^{\beta}[L^{(t)}] \tag{24}$$

$$c_{(i_s)\alpha\beta} = K_{(i_s)\alpha\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[B]^{\beta} \tag{25}$$

If a complex characterized by a given set of parameters

$$(i_1, \ldots, i_{pMe}, \alpha, \eta, \beta) \text{ or } (i_1, \ldots, i_{pMe}, \alpha, \beta)$$

does not exist, the corresponding equilibrium constants

$$K^{(t)}_{(i_s)\alpha\eta\beta} \text{ or } K_{(i_s)\alpha\beta}$$

will be equal to zero.

Linear combination of equations (16)–(20) gives the proton balance

$$\sum_{t,s,i,\alpha,\eta,\beta} \eta c^{(t)}_{(i_s)\alpha\eta\beta} + [H] - [OH] = d\left[\sum_t (n_t - m_t)C_{L(t)} + C_a\right] - b_M/W \quad (26)$$

Under analogous conditions, but with hydroxo-complexes present as in equation (6), at concentrations denoted by

$$c^{(t)}_{(i_s)\alpha\eta\lambda\beta} \quad \text{and} \quad c_{(i_s)\alpha\lambda\beta}$$

respectively, the proton balance is

$$\sum_{t,s,i,\alpha,\eta,\lambda,\beta} \rho c^{(t)}_{(i_s)\alpha\eta\lambda\beta} - \sum_{s,i,\alpha,\lambda,\beta} \lambda c_{(i_s)\alpha\lambda\beta} + [H] - [OH] = d\left[\sum_t (n_t - m_t)C_{L(t)} + C_a\right] - b_M/W \quad (27)$$

The concentrations of the corresponding complexes are given by [see equation (9)]:

$$c^{(t)}_{(i_s)\alpha\eta\lambda\beta} = K^{(t)}_{(i_s)\alpha\eta\lambda\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[H]^{\rho}[B]^{\beta} \quad (28)$$

$$c_{(i_s)\alpha\lambda\beta} = K_{(i_s)\alpha\lambda\beta} \prod_s [Me^{(s)}]^{i_s}[M]^{\alpha}[H]^{-\lambda}[B]^{\beta} \quad (29)$$

In systems with polyprotic acids $H_{n_t}L^{(t)}$ or their salts $M_{m_t}H_{n_t-m_t}L^{(t)}$ it is often the case that some species are present at such low concentrations that they can be omitted in the corresponding balances, which makes the regression equation simpler. For example, in aqueous solutions of orthophosphoric acid at pH < 4, the concentrations of PO_4^{-3} and HPO_4^{-2} can be omitted from the charge and concentration balances and the η values in the summations will be $\eta_1 = 2$ (the number of protons in $H_2PO_4^-$) and $\eta_2 = 3$ (the number of protons in H_3PO_4). Analogously, we can denote by $\eta_1 t$ and $\eta_2 t$ the lower (infimum, abbr. inf) and upper (supremum, sup) values of η for complexes containing a ligand form $L^{(t)}$:

$$\eta_1 t = \inf_t \{\eta\} \quad \text{and} \quad \eta_2 t = \sup_t \{\eta\} \quad (30)$$

The Bjerrum function then has the form

$$\bar{n}_t = \sum_{s,i,\alpha,\eta,\beta} \eta c^{(t)}_{(i_s)\alpha\eta\beta} \Big/ \sum_{s,i,\alpha,\eta,\beta} c^{(t)}_{(i_s)\alpha\eta\beta} = \sum_{s,i,\alpha,\eta,\beta} \eta c^{(t)}_{(i_s)\alpha\eta\beta}/dC_{L(t)} \quad (31)$$

$$= \sum_{\eta=\eta_1 t}^{\eta_2 t} \eta x_{\eta t}[H]^{\eta} \Big/ \sum_{\eta=\eta_1 t}^{\eta_2 t} x_{\eta t}[H]^{\eta} \quad [31(a)]$$

where

$$x_{\eta t} = P_{\eta t}/P_{\eta_2 t} \quad (32)$$

and $P_{\eta_2 t}$ is the $P_{\eta t}$ value [see equation (9)] related to $\eta t = \eta_2 t$.

Putting (31) into (26) gives, after transformation,

$$1/W = -\left[\sum_{t=1}^{P_L} (m_t + q_t - n_t)C_{L(t)} - C_a\right]\Big/a_M - (h/f - K_w f/h)b_M + \sum_{t=1}^{P_L} (q_t - \bar{n}_t)C_{L(t)}/a_M \quad (33)$$

where f and h are defined in equation (15), q_t is the maximal number of protons co-ordinated to the form $L^{(t)}$, and

$$a_M = b_M/d \quad (34)$$

$$k_w = [H][OH] \quad (35)$$

The proton balance for hydroxo-complexes [(27)] can be transformed into

$$1/W = -\left[\sum_{t=1}^{P_L} (m_t + q_t - n_t)C_{L(t)} - C_L\right]\Big/a_M - (h/f - K_w f/h)b_M + \sum_{\lambda=1}^{\Lambda} \lambda R_\lambda (h/f)^{-\lambda}/b_M + \sum_{t=1}^{P_L} (q_t - \bar{n}'_t)C_{L(t)}/a_M \quad (36)$$

where:

$$\bar{n}'_t = \sum_{s,i,\alpha,\eta,\lambda,\beta} \rho c^{(t)}_{(i_s)\alpha\eta\lambda\beta}/dC_{L(t)} = \sum_{\rho=\rho_1 t}^{\rho_2 t} \rho Q_{\rho t}[H]^{\rho} \Big/ \sum_{\rho=\rho_1 t}^{\rho_2 t} Q_{\rho t}[H]^{\rho} \quad (37)$$

$$= \sum_{\rho=\rho_1 t}^{\rho_2 t} \rho y_{\rho t}[H]^{\rho} \Big/ \sum_{\rho=\rho_1 t}^{\rho_2 t} y_{\rho t}[H]^{\rho} \quad [37(a)]$$

$$\rho_1 t = \inf_t \{\rho\}, \ \rho_2 t = \sup_t \{\rho\} \quad (38)$$

$$\Lambda = \sup \{\lambda\} \quad (39)$$

$$y_{\rho t} = Q_{\rho t}/Q_{\rho_2 t} \quad (40)$$

Here $Q_{\rho_2 t}$ is the $Q_{\rho t}$ value [see equation (11)] corresponding to $\rho t = \rho_2 t$ and Λ is related to the number of OH-groups in the complexes of $Me^{(s)}_{i_s}M_\alpha(OH)_\lambda B_\beta$ type, [see equation (6)].

The proton balance related to titrand + titrant systems can be presented in the general forms:

$$d\sum_{t=1}^{P_L} \bar{n}_t C_{L(t)} + [H] - [OH] = F \quad (41)$$

$$d\sum_{t=1}^{P_L}\bar{n}_t' C_{L(t)} - \sum_{\lambda=1}^{A}\lambda R_\lambda [H]^{-\lambda} + [H] - [OH] = F \quad (42)$$

In Table 1, the samples corresponding to equations (1) and (2) are called Sample I and Sample II, respectively. The expressions for J_a and J_b are:

$$J_a = \sum_{t=1}^{P_L}(n_t - m_t)C_{L(t)} + C_a \quad (43)$$

$$J_b = \sum_{t=1}^{P_L}(n_t - m_t)C_{L(t)} - C_b \quad (44)$$

Note that the corresponding expressions for F become identical on substitution of $-b_M$ for b_B and/or $-C_b$ for C_a. Moreover, the form of the F-expressions for the systems containing HB or MOH in the titrand differ from those for the systems with these species in the titrant.

With $F = dJ_a - b_M/V_0 + b_M/W$ (system 3 in Table 1) and rearrangement, equation (41) becomes

$$1/W = 1/V_0 + \left[\sum_{t=1}^{P_L}(m_t + q_t - n_t)C_{L(t)} - C_a\right]\Big/a_M - (h/f - K_w f/h)/b_M - \sum_{t=1}^{P_L}(q_t - \bar{n}_t)C_{L(t)}/a_M \quad (45)$$

The substitutions $-b_B$ for b_M, $-a_B$ for a_M, $-C_b$ for C_a in (45), where $a_B = b_B/d$, lead to the equation

$$1/W = 1/V_0 - \left[\sum_{t=1}^{P_L}(m_t + q_t - n_t)C_{L(t)} + C_b\right]\Big/a_B + (h/f - K_w f/h)/b_B + \sum_{t=1}^{P_L}(q_t - \bar{n}_t)C_{L(t)}/a_B \quad (46)$$

for system 5 in Table 1.

Making the same substitutions in (33) leads to

$$1/W = \left[\sum_{t=1}^{P_L}(m_t + q_t - n_t)C_{L(t)} + C_b\right]\Big/a_B + (h/f - K_w f/h)/b_B - \sum_{t=1}^{P_L}(q_t - \bar{n}_t)C_{L(t)}/a_B \quad (47)$$

for system 6 in Table 1.

For systems with $P_{Me} \geqslant 1$, the experimental points (V_j,pH_j) are chosen, as a rule, such that $[H] \gg [OH]$. This enables [OH] to be omitted from the proton balances; the same effect is attained by putting $K_w = 0$ in the regression equations.

REGRESSION EQUATIONS

Padé type

Regression equations of the Padé type will be applied, in this paper, to titrand and titrant systems where $P_L = 1$ and $P_{Me} \geqslant 0$ in the sample. In this case, the notation may be simplified by omitting qualifying index t in equations (9), (10), (30), (38) and (40) and replacing $L^{(t)}$ by L. Then:

$$x_\eta = \begin{cases} P_\eta/P_{\eta_2} \text{ for } \eta = \eta_1, \ldots, \eta_2 - 1 \\ 1 \text{ for } \eta = \eta_2 \\ 0 \text{ for other } \eta \text{ values} \end{cases} \quad (48)$$

$$y_\rho = \begin{cases} Q_\rho/Q_{\rho_2} \text{ for } \rho = \rho_1, \ldots, \rho_2 - 1 \\ 1 \text{ for } \rho = \rho_2 \\ 0 \text{ for other } \rho \text{ values} \end{cases} \quad (49)$$

$$J_a = (n - m)C_L + C_a \quad (50)$$

$$J_b = (n - m)C_L - C_b \quad (51)$$

Equations (31a), (41), (37a) and (42) then become, respectively:

$$\bar{n} = \sum_{\eta=\eta_1}^{\eta_2}\eta x_\eta [H]^\eta \Big/ \sum_{\eta=\eta_1}^{\eta_2} x_\eta [H]^\eta \quad (52)$$

$$dC_L\bar{n} + [H] - [OH] = F \quad (53)$$

Table 1. Composition of titrand (D) and titrant (T) for different isomolar systems and the corresponding expressions for F [equations (41), (42)]: $b_B = CV_0V_B/V_f$, $b_M = CV_0V_M/V_f$, $d = V^*/V_f$

8	—	—	V^*	V^*	—	—	V_M	—	V'_{MB}	V_{MB}	$dJ_b - b_M/W$

$$\bar{n}' = \sum_{\rho=\rho_1}^{\rho_2} \rho y_\rho [\mathrm{H}]^\rho \Big/ \sum_{\rho=\rho_1}^{\rho_2} y_\rho [\mathrm{H}]^\rho \tag{54}$$

$$dC_\mathrm{L}\bar{n}' - \sum_{\lambda=1}^{\Lambda} \lambda \mathrm{R}_\lambda [\mathrm{H}]^{-\lambda} + [\mathrm{H}] - [\mathrm{OH}] = F \tag{55}$$

The expressions for F are those presented in Table 1, but $\mathrm{J_a}$ and $\mathrm{J_b}$ are defined by equations (50) and (51).

Example 1. Let us take system 1 in Table 1 as an example. From equations (52) and (53):

$$b_\mathrm{B}/W \sum_{\eta=\eta_1}^{\eta_2} x_\eta [\mathrm{H}]^{\eta+1} = K_\mathrm{w} \sum_{\eta=\eta_1}^{\eta_2} x_\eta [\mathrm{H}]^\eta + \sum_{\eta=\eta_1}^{\eta_2} (d\mathrm{J_a} + b_\mathrm{B}/V_0 - \eta dC_\mathrm{L}) x_\eta [\mathrm{H}]^{\eta+1} - \sum_{\eta=\eta_1}^{\eta_2} x_\eta [\mathrm{H}]^{\eta+2} \tag{56}$$

Multiplying both sides of (56) by f^{η_2+2}/h^{η_1} and setting

$$\eta_2 - \eta_1 = \mathrm{p} \quad \text{and} \quad \eta = \eta_1 + \mathrm{i} \tag{57}$$

we have $\mathrm{i} = 0$ for $\eta = \eta_1$ and $\mathrm{i} = \mathrm{p}$ for $\eta = \eta_2$, so

$$b_\mathrm{B}/W \sum_{\mathrm{i}=0}^{\mathrm{p}} x_{\eta_1+\mathrm{i}} f^{\mathrm{p}+1-\mathrm{i}} h^{\mathrm{i}+1} = K_\mathrm{w} \sum_{\mathrm{i}=0}^{\mathrm{p}} x_{\eta_1+\mathrm{i}} f^{\mathrm{p}+2-\mathrm{i}} h^{\mathrm{i}} + \sum_{\mathrm{i}=0}^{\mathrm{p}} [d\mathrm{J_a} + b_\mathrm{B}/V_0 - (\eta_1 + \mathrm{i})dC_\mathrm{L}] \times x_{\eta_1+\mathrm{i}} f^{\mathrm{p}+1-\mathrm{i}} h^{\mathrm{i}+1} - \sum_{\mathrm{i}=0}^{\mathrm{p}} x_{\eta_1+\mathrm{i}} f^{\mathrm{p}-\mathrm{i}} h^{\mathrm{i}+2} \tag{58}$$

From (48), $x_{\eta_2+1} = x_{\eta_1-1} = x_{\eta_1-2} = 0$, and finally

$$W = \sum_{\mathrm{i}=0}^{\mathrm{p}} A_\mathrm{i} h^{\mathrm{i}+1} \Big/ \left[\sum_{\mathrm{i}=0}^{\mathrm{p}+1} B_\mathrm{i} h^\mathrm{i} - h^{\mathrm{p}+2} \right] \tag{59}$$

where:

$$A_\mathrm{i} = b_\mathrm{B} x_{\eta_1+\mathrm{i}} f^{\mathrm{p}+1-\mathrm{i}} \tag{60}$$

$$B_\mathrm{i} = \{K_\mathrm{w} x_{\eta_1+\mathrm{i}} + d[(\mathrm{n} - \mathrm{m} - \eta_1 + 1 - \mathrm{i})C_\mathrm{L} + C_\mathrm{a} + a_\mathrm{B}/V_0] x_{\eta_1-1+\mathrm{i}} - x_{\eta_1-2+\mathrm{i}}\} f^{\mathrm{p}+2-\mathrm{i}} \tag{61}$$

Substituting $-b_\mathrm{M}$ for b_B, and $-a_\mathrm{M}$ for a_B, in equations (60) and (61), we obtain the expressions for A_i and B_i for system 3 in Table 1. Particular cases of the expressions have been published elsewhere.[9,10]

Example 2. For system 4 in Table 1, at $[\mathrm{H}] \gg [\mathrm{OH}]$, from equations (52) and (53) we have

$$b_\mathrm{M}/W \sum_{\eta=\eta_1}^{\eta_2} x_\eta [\mathrm{H}]^\eta = \sum_{\eta=\eta_1}^{\eta_2} d(\mathrm{J_a} - \eta C_\mathrm{L}) x_\eta [\mathrm{H}]^\eta - \sum_{\eta=\eta_1}^{\eta_2} x_\eta [\mathrm{H}]^{\eta+1} \tag{62}$$

Multiplying both sides of equation (62) by f^{η_2+1}/h^{η_1} and rearranging gives

$$W = \sum_{\mathrm{i}=0}^{\mathrm{p}} A_\mathrm{i} h^\mathrm{i} \Big/ \left[\sum_{\mathrm{i}=0}^{\mathrm{p}} B_\mathrm{i} h^\mathrm{i} - h^{\mathrm{p}+1} \right] \tag{63}$$

where:

$$A_\mathrm{i} = b_\mathrm{M} x_{\eta_1+\mathrm{i}} f^{\mathrm{p}+1-\mathrm{i}} \tag{64}$$

$$B_\mathrm{i} = \{d[(\mathrm{n} - \mathrm{m} - \eta_1 - \mathrm{i})C_\mathrm{L} + C_\mathrm{a}] x_{\eta_1+\mathrm{i}} - x_{\eta_1-1+\mathrm{i}}\} f^{\mathrm{p}+1-\mathrm{i}} \tag{65}$$

Particular cases of equations (63)–(65) have been discussed elsewhere.[8,11]

Example 3. For system 4 in Table 1, from equations (54) and (55) we obtain, at $[\mathrm{H}] \gg [\mathrm{OH}]$,

$$b_\mathrm{M}/W \sum_{\rho=\rho_1}^{\rho_2} y_\rho [\mathrm{H}]^{\rho+\Lambda} = \sum_{\rho=\rho_1}^{\rho_2} d(\mathrm{J_a} - \rho C_\mathrm{L}) y_\rho [\mathrm{H}]^{\rho+\Lambda} + \sum_{\lambda=1}^{\Lambda} \lambda \mathrm{R}_\lambda [\mathrm{H}]^{\Lambda-\lambda} \sum_{\rho=\rho_1}^{\rho_2} y_\rho [\mathrm{H}]^\rho - \sum_{\rho=\rho_1}^{\rho_2} y_\rho [\mathrm{H}]^{\rho+\Lambda+1} \tag{66}$$

Multiplication of both sides of (66) by $f^{\eta_2+\Lambda+1}/h^{\rho_1}$ and further rearrangement leads to

$$W = \sum_{\mathrm{i}=\Lambda}^{\omega+\Lambda} A_\mathrm{i} h^\mathrm{i} / g(h) \tag{67}$$

where $\omega = \rho_2 - \rho_1$ and

$$A_\mathrm{i} = b_\mathrm{M} y_{\rho_1-\Lambda+\mathrm{i}} f^{\omega+\Lambda+1-\mathrm{i}} \tag{68}$$

$$g(h) = \sum_{\mathrm{i}=\Lambda}^{\omega+\Lambda} d[(\mathrm{n} - \mathrm{m} - \rho_1 + \Lambda - \mathrm{i})C_\mathrm{L} + C_\mathrm{a}] \times y_{\rho_1-\Lambda+\mathrm{i}} f^{\omega+\Lambda+1-\mathrm{i}} h^\mathrm{i} + \sum_{\lambda=1}^{\Lambda} \lambda \mathrm{R}_\lambda \sum_{\mathrm{i}=\Lambda-\lambda}^{\omega+\Lambda-\lambda} + y_{\rho_1-\Lambda+\lambda+\mathrm{i}} f^{\omega+\Lambda+1-\mathrm{i}} h^\mathrm{i} - \sum_{\mathrm{i}=\Lambda+1}^{\omega+\Lambda} y_{\rho_1-\Lambda-1+\mathrm{i}} f^{\omega+\Lambda+1-\mathrm{i}} h^\mathrm{i} - h^{\omega+\Lambda+1} \tag{69}$$

The regression equations presented above [equations (59), (63), (67)] are examples of functions of the Padé type (also called Padé approximants[24] or PADE W functions[9]). These functions can be presented in the general form

$$W = G_1(h)/G_2(h) \tag{70}$$

where $G_1(h)$ and $G_2(h)$ are polynomials of the hydrogen-ion activity, and the degree of

polynomial $G_2(h)$ is higher than that of polynomial $G_1(h)$. It should be noted that all components of $G_1(h)$ are of the same sign. Then the reciprocal

$$1/W = G_2(h)/G_1(h) \qquad (71)$$

has no singular points for positive values of f and x_η (or y_ρ). Equation (71) expresses the PADE $1/W$ function.[9]

The class of Padé functions is a subset of the set of rational functions.

Equations with Simms constants[25]

The differences $q_t - \bar{n}_t$ [equation (33)] and $q_t - \bar{n}'_t$ [equation (36)] can be expressed by means of the Simms titration constants[2,18–20,25–28] g_{tv} and g'_{tv} according to

$$q_t - \bar{n}_t = q_t - p_t - \eta_1 t + \sum_{v=1}^{p_t} g_{tv}/(h/f + g_{tv}) \qquad (72)$$

$$q_t - \bar{n}'_t = q_t - \omega_t - \rho_1 t + \sum_{v=1}^{\omega_t} g'_{tv}/(h/f + g'_{tv}) \qquad (73)$$

where

$$p_t = \eta_2 t - \eta_1 t \quad \text{and} \quad \omega_t = \rho_2 t - \rho_1 t \qquad (74)$$

{*cf.* equations [31(a)] and [37(a)]}. Substituting (72) into (33) or (73) into (36), we obtain examples of the SIMMS $1/W$ functions.[9]

In particular, if $\eta_1 t = 0, \eta_2 t = q_t$, *i.e.*, $p_t = q_t$, then from (72)

$$q_t - \bar{n}_t = \sum_{v=1}^{q_t} g_{tv}/(h/f + g_{tv}) \qquad (75)$$

If equations (52) and (57) are applied

$$q - \bar{n} = q - p - \eta_1 + \sum_{v=1}^{p} g_v/(h/f + g_v) \qquad (76)$$

At $\eta_1 = 0, \eta_2 = q$, *i.e.*, $p = q$, equation (76) leads to

$$q - \bar{n} = \sum_{v=1}^{q} g_v/(h/f + g_v) \qquad (77)$$

The Simms constants g_v [equation (76)] are involved with x_η [equation (52)] in a set of p symmetrical equations, similar to ones quoted elsewhere:[9]

$$\begin{aligned}
x_{k_1+p-1} &= g_1 + g_2 + \ldots + g_p \\
x_{k_1+p-2} &= \sum_{i=1}^{p-1} \sum_{j=i+1}^{p} g_i g_j \\
x_{k_1+p-3} &= \sum_{i=1}^{p-2} \sum_{j=i+1}^{p-1} \sum_{k=j+1}^{p} g_i g_j g_k \\
&\ldots\ldots\ldots\ldots\ldots\ldots\ldots \\
x_{k_1} &= g_1 g_2 \ldots g_p
\end{aligned} \qquad (78)$$

APPLICATIONS

Determination of free acid (or base) and hydrolysable cation in the mixture

The titrand + titrant systems presented above are characterized by a high concentration of Me-ions [equation(8)] in comparison with a weak acid H_nL or its salt, acting as buffering agent there.

This section discusses titrand + titrant systems containing a hydrolysable salt, MeB_u, and a strong acid, HB, or strong base, MOH, in the sample tested, at comparable and rather low concentrations: $c_0 = dC_0$, $c_a = dC_a$ or $c_b = dC_b$, respectively, where d is expressed by equation (22). Such systems, prepared according to system 1 in Table 1, have already been examined by Gordienko and Sidorenko,[6] who used a graphical method based on an equation obtained on the assumption that only one hydroxo-complex, $MeOH^{+u-1}$, is formed in the solution.

In comparison with the system described by the conditions in (8), the system discussed here has the requirements:

$$c_L = 0, c_M \gg c_{Me}, c_B \gg c_{Me} \qquad (79)$$

The forms of the regression equations become relatively simple if the hydroxo-complexes formed are only of $MeM_\alpha(OH)_\lambda B_\beta$ type, *i.e.*, mononuclear with respect to Me. This restriction can sometimes apply to dilute solutions of certain metal ions.

Let us consider system 1 in Table 1, containing MeB_u and HB at concentrations C_0 and C_a, respectively. At [H] ≫ [OH], the PADE W function then has the form

$$W = \sum_{i=0}^{\Lambda} A_i h^i \Big/ \left[\sum_{i=0}^{\Lambda} B_i h^i - h^{\Lambda+1} \right] \qquad (80)$$

where Λ is defined by equation (39), and

$$A_i = b_B x_{\Lambda-i} f^{\Lambda+1-i} \qquad (81)$$

$$B = \{d[C_a + (\Lambda - i)C_0 + a_B/V_0] \times x_{\Lambda-i} - x_{\Lambda+1-i}\} f^{\Lambda+1-i} \qquad (82)$$

$$x_\lambda = \begin{cases} 1 \text{ for } \lambda = 0 \\ R_\lambda/R_0 \text{ for } \lambda = 1, \ldots, \Lambda \\ 0 \text{ for other } \lambda \text{ values} \end{cases} \qquad (83)$$

$$R_\lambda = \sum_{\alpha,\beta} K_{\alpha\lambda\beta}[M]^\alpha[B]^\beta \qquad (84)$$

$$[MeM_\alpha(OH)_\lambda B_\beta] = K_{\alpha\lambda\beta}[Me][M]^\alpha[H]^{-\lambda}[B]^\beta \qquad (85)$$

For a sample consisting of a salt $MeO_m(OH)_v B_{u-2m-v}$ and a strong acid HB, the regression function and A_i are defined by equations (80) and (81), and

$$B_i = \{d[(A - 2m - v - i)C_0 + C_a + a_B/V_0]x_{A+1-i} - x_{A+1-i}\} f^{A+1-i}$$

Determination of equilibrium constants

The method can be applied to determination of the stability constants of mixed metal complexes of $M_\mu M'_\nu H_\eta L$ type in aqueous media and the equilibrium constants of complexes of H_2LB type in extraction systems.

Stability constants of $M_\mu M'_\nu H_\eta L$ *complexes.* Let us assume that (*a*) $M_\mu M'_\nu H_\eta L$ complexes are formed by anionic forms of the weak acid H_nL and non-hydrolysable singly-charged cations M and M′; (*b*) q = n, *i.e.*, H_nL is the most highly protonated form of L; (*c*) H_nL forms no complexes in the system; (*d*) the pH interval covered by the experimental points (V_j,pH_j) comprises the predominance ranges of all species with different degree of protonation. The last assumption requires some supplementary experimental conditions, *e.g.*, addition of the proper quantities of strong acid, HB, particularly when a salt $M_mH_{n-m}L$ of the weak acid is used.

The titrand and titrant compositions are the same as for system 3 in Table 1, with the addition of $V_{M'B}$ ml of a solution of M′B (concentration C_2). The isomolarity condition is still expressed by equation (4).

The system is then described by the regression equation

$$W = \sum_{i=0}^{n} A_i h^{i+1} \Big/ \left[\sum_{i=0}^{n+1} B_i h^i - h^{n+2}\right] \quad (86)$$

where

$$A_i = -b_M x_i f^{n+1-i} \quad (87)$$

$$B_i = \{K_w x_i + d[(n - m + 1 - i)C_L + C_a - a_M/V_0]x_{i-1} - x_{i-2}\} f^{n+2-i} \quad (88)$$

[*cf.* equations (59)–(61)] and

$$x_\eta = \begin{cases} P_\eta/P_n \text{ for } \eta = 0, \ldots, n-1 \\ 1 \text{ for } \eta = n \\ 0 \text{ for other } \eta \text{ values} \end{cases} \quad (89)$$

$$P_\eta = \sum_{\mu,\nu} K_{\mu\nu\eta}[M]^\mu[M']^\nu \quad (90)$$

$$[M_\mu M'_\nu H_\eta L] = K_{\mu\nu\eta}[M]^\mu[M']^\nu[H]^\eta[L]$$

and, on the basis of assumption (*b*),

$$P_n = K_{00n} \quad (91)$$

From (89)–(91) we have

$$x_\eta = \sum_{\mu,\nu} \frac{K_{\mu\nu\eta}}{K_{00n}}[M]^\mu[M']^\nu = \frac{K_{00\eta}}{K_{00n}} + \frac{K_{10\eta}}{K_{00n}}[M] + \frac{K_{01\eta}}{K_{00n}}[M'] + \cdots \quad (92)$$

where $\eta = 0, \ldots, n-1$, $K_{000} = 1$. Determination of $K_{\mu\nu\eta}/K_{00n}$ for N^* different values of the fraction $n_M/n_{M'}$ with $n_M + n_{M'}$ constant (n_X = number of mmoles of component X) leads to determination of the stability constants $K_{\mu\nu\eta}$. For

$$\mu + \nu + \eta \leqslant n \quad (93)$$

it is required that

$$N^* \geqslant \binom{n+2}{2} + 1$$

The equilibrium constant given by $K_{\mu\nu\eta}/K_{00n}$ corresponds to the reaction

$$\mu M + \nu M' + H_nL = M_\mu M'_\nu H_\eta L + (n - \eta)H$$

Determination of equilibrium constants in extraction system. The literature[29,30] gives some data indicating the existence of neutral complexes of H_2LB type in solvents such as isoamyl alcohol, methyl isobutyl ketone, butyl acetate, *etc.*, which suggests that they are also present in the aqueous phase in an extraction system.

Let $W = V_0 + V$ and W_{org} denote, respectively, the volumes of the aqueous and organic phases in the system obtained by addition of V ml of titrant to volume V_0 of titrand, in equilibrium with W_{org} ml of an organic solvent immiscible with water. Let HL be a weak acid forming ionic species H_2L^+ and L^- in solution (*e.g.*, 8-hydroxyquinoline). Let H_2L^+ and L^- form the ion-association complexes H_2LY and ML with anion Y^- of a strong acid HY or a cation M^+, respectively. In acidic media, with $[H] \gg [OH]$, the method implies the following equilibria in the system in question:

$$HL + H^+ \rightleftharpoons H_2L^+$$

$$H_2L^+ + Y^- \rightleftharpoons H_2LY$$

$$H_2LY \rightleftharpoons H_2LY_{org}$$

$$HL \rightleftharpoons HL_{org}$$

expressed by the equilibrium constants:

$$k_1 = [H_2L]/([H][HL]) \quad (94)$$

$$K_Y = [H_2LY]/([H_2L][Y]) \quad (95)$$

$$P_Y = [H_2LY]_{org}/[H_2LY] \quad (96)$$

$$P_{HL} = [HL]_{org}/[HL] \quad (97)$$

where changes are omitted for simplicity.

The compositions and preparation of the titrand and titrant are as follows.

	Titrand	Titrant
$HL(C_L) + HB(C_a)$	V^*	V^*
$HB(C)$	—	V_B
$MB(C_1)$	V_{MB}	V'_{MB}
$MD(C_2)$	V_{MD}	V_{MD}
H_2O	$V_f - V^* - V_{MB} - V_{MD}$	$V_f - V^* - V_B - V'_{MB} - V_{MD}$

V_{MB} and V'_{MB} fulfil equation (3). Because the pH measurements are made at different concentrations of species B, it is necessary to add a second salt of a strong acid in sufficient amount to make the number of mmoles of Y (where Y = B or D) constant, so that the ionic strength also remains constant.

The balances related to the systems are expressed by the equations

$$[H_2L] + [HL] + [L] + [H_2LB] + [L_2LD] + [ML] + ([H_2LB]_{org} + [H_2LD]_{org} + [HL]_{org} + [ML]_{org})W_{org}/W = dC_L \quad (98)$$

$$[B] + [H_2LB] + [H_2LB]_{org} W_{org}/W = dC_a + C_1 V_{MB}/V_f \quad (99)$$

$$[D] + [H_2LD] + [H_2LD]_{org} W_{org}/W = C_2 V_{MD}/V_f \quad (100)$$

$$[M] + [ML] + [ML]_{org} W_{org}/W = C_1 V_{MB}/V_f + C_2 V_{MD}/V_f - b_B/V_0 + b_B/W \quad (101)$$

$$[H_2L] + [M] + [H] = [OH] + [B] + [D] + [L] \quad (102)$$

Combination of equations (98)–(102) yields

$$[H] - [OH] = d(C_a - C_L) + b_B/V_0 - b_B/W + [HL] + [HL]_{org} W_{org}/W + 2([L] + [ML] + [ML]_{org} W_{org}/W) \quad (103)$$

In acidic media, the concentrations [OH], [L], [ML], $[ML]_{org}$ can be omitted in equations (98) and (103). Then equation (103) simplifies to

$$W[H] = \theta W - b_B + [HL](P + W) \quad (104)$$

where

$$\theta = d(C_a - C_L) + b_B/V_0$$

$$P = P_{HL} W_{org} \quad (105)$$

From equations (94)–(96), with Y = B and D,

$$[H_2L] = k_1[H][HL] \quad (106)$$

$$[H_2LY] = k_1 K_Y [Y][H][HL] \quad (107)$$

$$[H_2LY]_{org} = k_1 K_Y P_Y [Y][H][HL] \quad (108)$$

Substitution of (97) and (105)–(108) into the simplified form of (98) gives

$$[HL] = \frac{dC_L W}{P + W + Q[H] + RW[H]} \quad (109)$$

where

$$Q = k_1 W_{org}(K_B P_B[B] + K_D P_D[D]) \quad (110)$$

$$R = k_1(1 + K_B[B] + K_D[D]) \quad (111)$$

Combining (104) and (109) and the hydrogen-ion activity (h) leads to

$$W^2h^2 = A_1 + A_2h + A_3W + A_4Wh + A_5W^2 + A_6W^2h + A_7Wh^2 \quad (112)$$

where

$$A_1 = -b_B x_2 f^2$$

$$A_2 = -b_B x_3 f$$

$$A_3 = [(\theta + dC_L)x_2 - b_B x_1]f^2$$

$$A_4 = (\theta x_3 - x_2 - b_B)f$$

$$A_5 = (\theta + dC_L)x_1 f^2$$

$$A_6 = (\theta - x_1)f$$

$$A_7 = -x_3$$

in which $x_1 = 1/R$, $x_2 = P/R$, $x_3 = Q/R$.

Equations (110) and (111) can then be presented in the forms

$$Q = d_1[B] + d_2[D] \quad (113)$$

$$R = b_0 + b_1[B] + b_2[D] \quad (114)$$

where $b_0 = k_1$; $b_1 = k_1K_B$; $b_2 = k_1k_D$; $d_1 = k_1K_BP_B$; $d_2 = k_1K_DP_D$.

Equation (112) can be converted into

$$T_2W^2 + T_1W + T_0 = 0 \quad (115)$$

where

$$T_0 = A_1 + A_2h$$

$$T_1 = A_3 + A_4h + A_7h^2$$

$$T_2 = A_5 + A_6h - h^2$$

From equation (115) we obtain two equivalent functions

$$W = [(T_1^2 - 4T_0T_2)^{1/2} - T_1]/(2T_2) \quad (116)$$

$$1/W = -[(T_1^2 - 4T_0T_2)^{1/2} + T_1]/(2T_0) \quad (117)$$

$1/W$ is always positive, because T_0 is always < 0.

The method proposed enables finding of all the equilibrium constants related to the extraction system. In particular, it is possible to determine the partition constants P_Y [equation (96)] of complexes of H_2LY type between the organic and aqueous phases. This possibility is not offered by the method presented by Kuz'min *et al.*[29] Moreover, that method needs use of several other (pH-metric, spectrophotometric, titrimetric) techniques. As a result, only the fraction $P'_B = [H_2LB]_{org}/[H_2L]$, corresponding to incomplete reaction, was obtained there. The P'_B value thus obtained depends on the concentration of B^- ions, according to the formula $P'_B = K_B P_B[B]$ [see equations (95) and (96)].

The solubility of the neutral form (HL) of the weak acids discussed above is rather low. Higher concentrations of HL in such titrand + titrant systems are ensured by dissolution of the corresponding organic acid in an organic phase. If the concentrations of HL in the titrant and in the organic phase are identical and equal to c_L, then the sum $c_L V + c_L W_{org} = c_L W + c_L(W_{org} - V_0)$, expressing the total content (in mmole) of L in the system, will be equal to $c_L W$ for $W_{org} = V_0$ [compare with equation (98)].

To avoid any volume changes resulting from mutual solubility of the organic phase and electrolyte solution, the phases should be mutually saturated before addition of HL in preparation of the titrand and titrant. The titrand, titrant and their mixtures (at any stage of titration) should all be at the same temperature.

FURTHER DETAILS

Definitions of free acid and free base

The free acid can be defined as the concentration of hydrogen ions resulting from the presence of a strong acid HB and a weak acid, base or salt in the sample. The free base can be defined as the proton deficiency resulting from the presence of a strong base MOH.[9]

As examples, let us consider any titrand + titrant system, *e.g.*, system 3 in Table 1, with (*a*) $M_mH_{n-m}L$ (concentration C_L) + HB (concentration C_a), and (*b*) $M_mH_{n-m}L(C_L)$ + MOH(C_b). The corresponding proton balances are

$$(a) \quad [H] - [OH] = d[(n - \bar{n} - m)C_L + C_a] - b_M/V_0 + b_M/W \quad (118)$$

$$(b) \quad [H] - [OH] = d[(n - \bar{n} - m)C_L - C_b] - b_M/V_0 + b_M/W \quad (119)$$

The proton balances relating to the systems containing two-component mixtures: (*c*) $M_mH_{n-m}L$ $[C_L(1)] + M_{m-1}H_{n-m+1}L$ $[C_L(2)]$ and (*d*) $M_mH_{n-m}L$ $[C_L(1)] + M_{m+1}H_{n-m-1}L$ $[C_L(3)]$ are

$$(c) \quad [H] - [OH] = d[(n - \bar{n} - m)C_L(1) + (n - \bar{n} - m + 1)C_L(2)] - b_M/V_0 + b_M/W \quad (120)$$

$$(d) \quad [H] - [OH] = d[(n - \bar{n} - m)C_L(1) + (n - \bar{n} - m - 1)C_L(3)] - b_M/V_0 + b_M/W \quad (121)$$

From comparison of equations (118) with (120), and of (119) with (121) we have

$$C_a = C_L(2) \quad \text{when } C_L(1) + C_L(2) = C_L$$

$$C_b = C_L(3) \quad \text{when } C_L(1) + C_L(3) = C_L$$

respectively. Thus a system composed of $M_mH_{n-m}L$ ($m \leqslant n - 1$) and MOH as contamination ($C_b < C_L$) is equivalent to the mixture composed of $M_mH_{n-m}L$ and $M_{m+1}H_{n-m-1}L$.

Contamination with carbon dioxide

Solutions stored in badly sealed flasks, or exposed to the atmosphere, will contain some carbon dioxide.[31,32] The presence of this species can be taken into account in the corresponding regression equations presented in the sections on proton balances and their transformations.

Standardization

The method has already been applied for standardization of sodium hydroxide solution against commercial potassium hydrogen phthalate.[9]

Optimization procedure

Determination of the internal parameters of the non-linear regression equations is based on multiparametric curve-fitting. The degree of approximation of the Padé W function to the

titration data (V_j, pH_j) can be expressed as the sum of the squares of the residuals

$$SS = \sum_{j=1}^{N} (W_j - W_{j,calc})^2 = \sum_{j=1}^{N} (V_j - V_{j,calc})^2 \quad (122)$$

where $W_{j,calc}$ is the W-value calculated from the corresponding regression equation at pH_j, and $V_{j,calc} = W_{j,calc} - V_0$ [see equation (13)].

If the Padé $1/W$ function is used, the criterion of fit will be

$$SS1 = V_0^4 \sum_{j=1}^{N} (1/W_j - 1/W_{j,calc})^2 \quad (123)$$

The aim is to find the set of internal parameters corresponding to minimal values of SS or SS1. The factor V_0^4 in equation (123) makes these minimal values comparable in magnitude.

The optimized values of the internal parameters are sometimes the basis for further calculations, *e.g.*, in the determination of equilibrium constants in extraction systems. From the algorithms presented in that section, the following search procedure may be used for determining the equilibrium constants.

(1) Determination of parameters $(x_1, x_2, x_3) = (x_{1i}, x_{2i}, x_{3i})$ for the i-th ratio $n_D^{(i)}/n_B^{(i)}$ at constant $n_B^{(i)} + n_B^{(i)}$; $i = 1, \ldots, T$; $T \geqslant 4$, according to the curve-fitting method applied. The (x_{1i}, x_{2i}, x_{3i}) values are the basis for calculation of $(P, Q, R) = (P_i, Q_i, R_i)$, from $P = x_2/x_1$; $Q = x_3/x_1$; $R = 1/x_1$.

(2) d_1 and d_2 in equation (113) (at $T-2$ degrees of freedom) and b_0, b_1 and b_2 in equation (114) (at $T-3$ degrees of freedom) can be evaluated according to the least-squares method and then k_1, K_B, K_D, P_B and P_D are calculated [see definitions after equation (114)].

(3) The parameters $P_{HL}[=x_2/(x_1 W_{org})]$, C_L, C_a and f can be found from the results of one titration, at a given value of the fraction $n_D^{(i)}/n_B^{(i)}$. The C_a value can be treated as resulting from contamination of HL by a strong acid HB. If HL is contaminated with a strong base, MOH (C_b), then C_a is negative and $C_b = -C_a$.

Note that the equilibrium constants of complexes of ML type, predominating in alkaline media, can be found from titrations performed in isomolar systems containing two different non-hydrolysable salts, MB and M′B.

FACTORS INFLUENCING PERFORMANCE IN THE RAPID SEPARATION OF AFLATOXINS BY MICELLAR ELECTROKINETIC CAPILLARY CHROMATOGRAPHY

RODERIC O. COLE, RICKY D. HOLLAND and MICHAEL J. SEPANIAK*
Department of Chemistry, The University of Tennessee, Knoxville, TN 37996-1600, U.S.A.

(*Received* 23 *January* 1992. *Accepted* 28 *January* 1992)

Summary—Micellar electrokinetic capillary chromatography (MECC) is applied to the high-speed analysis of aflatoxins. Baseline separation of the four common aflatoxins G_1, G_2, B_1 and B_2, is accomplished in less than 30 sec. Small (25 μm) internal diameter capillaries are found to be critical in maintaining high efficiency under rapid MECC separation conditions. Van Deemter-like plots are generated in order to study the effects of capillary diameter and organic solvent on efficiency under high electric field conditions. Other experimental parameters affecting efficiency are investigated, including buffer concentration, surfactant concentration, and detector time constant. Simple on-column laser-based fluorescence detection, employing helium-cadmium laser radiation at 325 nm for excitation, allows for limits of detection in the range of 0.05–0.9 femtomoles injected for underivatized aflatoxins. Considerations important in the analysis of aflatoxins in real matrices are presented.

It is well established that capillary electrokinetic separation techniques such as capillary zone electrophoresis (CZE) and micellar electrokinetic capillary chromatography (MECC) are capable of highly efficient separations of minute amounts of many classes of compounds.[1-3] The MECC technique addresses the separation of neutral molecules and offers additional selectivity, relative to CZE, for charged analytes via analyte-specific interactions with the micellar phase. In principle, experimental conditions can be adjusted to facilitate rapid capillary electrokinetic separations. In a unique recent report, extremely rapid (2 second) separations of fluorescently derivatized amino acids were demonstrated.[4,5] Very small capillary columns (*ca.* 10 μm i.d.) and a unique photoinjection system were employed. This system, while permitting rapid separations, is thus far limited to molecules labeled with fluorescein isothiocyanate (FITC). Rapid (<one minute) separations are demonstrated herein using capillary electrokinetic methods with conventional injection and detection instrumentation.

Rapid separations are particularly desirable in situations where large numbers of samples are to be analyzed. As applications for MECC and CZE increase, analyses requiring high sample throughput are inevitable. Rapid separations require top performance from the chromatographic system employed. Conventional HPLC approaches generally employ short (~3 cm) columns packed with small (~3 μm) particles. The combination of high flow-rate and short column provides for short elution times, while the small particle diameters provide relatively efficient mass transfer, even for moderately high flow-rates. Adversely, extremely high flow-rates can degrade efficiency resulting in loss of resolution and, due to the use of very small column packing material, produce very high column pressure drops that often result in settling of the packing bed.

In situations where highly efficient liquid phase separations of neutral molecules are required, MECC can be very effective.[6,7] Unlike hydrostatically-pumped open tubular systems, MECC is not limited by mobile phase resistance to mass transfer.[8] High efficiency in the former separation technique is only achieved if solutes rapidly diffuse radially across the parabolic flow profile of the mobile phase, thereby averaging the velocity differences encountered. The large flow-rates needed for rapid separations exacerbate the mass transfer problem. Electroosmotic pumping produces a relatively flat ("plug-like") flow profile,[8] minimizing the need for rapid radial diffusion in CZE and MECC. Moreover, the micelles in MECC are somewhat analogous to conventional packed column particles. The

*Author for correspondence.

small size of micelles (~40 Å in diameter for sodium dodecyl sulfate) and close, uniform (electrostatic) packing produces an ideal packing bed and further contributes to the high separation performance of MECC. MECC has been used to separate a variety of compounds including vitamins,[9] amino acids,[10] polyaromatic hydrocarbons,[11] and pharmaceutical compounds.[12-16]

One potentially important application of high speed separations is the analysis of mycotoxins, particularly aflatoxins. Aflatoxins are extremely toxic metabolites of fungi such as *Aspergillus Flavus*. These fungi occur in a variety of foodstuffs intended for both livestock and human consumption. Peanuts, corn, grain, rice, soybeans, and oats have all been found to support aflatoxin production.[17] Aflatoxins pose significant health risk even at low concentrations (ppb) and are generally found to target the liver.[18] Thus, analyses of aflatoxins are of utmost importance in assuring safe food supplies, but are challenging due to the presence of the toxins at trace levels in complex matrices. Moreover, the nonuniform distribution of aflatoxin in contaminated unprocessed commodities can result in a need for very high sample throughput (see ref. 17, p. 104). Conventional methods for aflatoxin analysis are numerous and include thin layer chromatography, HPLC, and immunochemical methods.[19]

The focus of the work reported herein is the optimization of rapid, sensitive separations in MECC as applied to aflatoxin separations. Experimental factors which maximize efficiency and minimize analysis time are investigated. Under the constraint of rapid separation, new experimental considerations for attaining high efficiency are revealed. Laser-based fluorescence detection is employed and exhibits injected concentration detection limits in the 20–100 ppb range. Illustrations involving the analysis of aflatoxins in corn samples are presented.

EXPERIMENTAL

Apparatus

Two laser-based fluorescence detection schemes were employed in this work. The instrumentation used for studies of analysis speed and efficiency has been recently described in detail,[20] and employs a monochromator/filter combination to isolate the desired emission wavelength (450 nm, FWHM = 6 nm). An alternate system was used for the determination of detection limits in an attempt to collect a wider portion of the emission spectrum and to increase transmission of signal to the photomultiplier tube. This was particularly important in this work due to the poor condition of the laser that was employed (see below). Fluorescence emission was collected at 90° with an f/2 lens and focused onto a 2-mm slit, placed in the center of a light-tight 2 inch cube that contained inlet and outlet apertures. The desired wavelength range was isolated with a bandpass filter (452 nm, FWHM = 20 nm) that is placed in the inlet aperture of the spatial filter cube (Oriel Corp., Stratford, CT, U.S.A.). Fluorescence excitation was provided by a helium–cadmium laser (Liconix Model 4230 NB, Sunnyvale, CA, U.S.A.) at 325 nm. Laser power ranged from 3–5 mW. Chromatograms were recorded with Varian Models 4270 and 4400 integrators (Palo Alto, CA, U.S.A.). Capillaries of 50 and 25 μm internal diameter (i.d.) were purchased from Polymicro Technologies (Phoenix, AZ, U.S.A.). Fluorescence spectra were obtained with a Spectrovision DA-10 spectrofluorimeter. Specific spectral acquisition conditions are given where appropriate.

Chemicals

Aflatoxin standards, sodium dodecyl sulfate (SDS), and Bile Salts were purchased from Sigma Chemical Co. (St. Louis, MO, U.S.A.). All water and solvents used were of HPLC grade and were obtained from Baxter Healthcare Corp. (Stone Mountain, GA, U.S.A.). *Aspergillus Favus* spores were obtained from Northern Regional Research Laboratories (Peoria, IL, U.S.A.). Corn meal was obtained from a middle Indiana dairy farm.

Procedures

Chromatography. Capillary columns were rinsed with 0.01*M* sodium hydroxide for approximately 10 min before filling with mobile phase. The system was allowed to equilibrate for 10–15 min using an applied voltage of 20 kV prior to injection of sample. Applied voltages during chromatographic runs ranged from 8 to 36 kV. Efficiency studies were performed using hydrostatic injection, 7 seconds at a height differential of 10 cm. Chromatograms for standard solutions and corn meal extracts were obtained using electroinjection, 2 kV for 30 sec. Capillaries used in the work were 40 cm in length, and 35 cm to detection window, unless otherwise noted.

Efficiency calculations. Plate numbers were calculated by using the relationship

$$N = 2\pi\left(\frac{t_R h}{A}\right)^2$$

where N is number of theoretical plates, h is peak height counts, A is peak area counts and t_R is retention time.[7] It is essential to note that for some integrators area and height count response factors may not be equivalent and appropriate conversion factors need to be included in the equation. Plate height, H, is calculated as the capillary length to the detection zone divided by N.

Sample preparation. Standards were prepared by adding one milliliter of HPLC grade acetonitrile to one milligram solid aflatoxin and making appropriate dilutions with mobile phase. Stock acetonitrile solutions were stored in the dark at approximately 0°. Corn inoculated with *Aspergillus Flavus* spores were extracted with two 100-ml portions of chloroform as previously described,[21] with the exception that the dry residue was dissolved in HPLC grade acetonitrile. Further clean-up of this solution was provided by the solid phase extraction (SPE) procedure described below.

Corn meal samples (approximately 50 g) were extracted with 100 ml of an 80/20 (v/v) methanol/water solution. One ml of this solution was diluted to 5.0 ml with 0.5% (v/v) aqueous acetic acid and subjected to the following SPE sample clean-up procedures: 3.0-ml SPE tubes containing 40 μm of LC-CN (Supelco, Bellefonte, PA) bonded phase were preconditioned with 2.0 ml 0.5% (v/v) aqueous acetic acid followed by a one-minute drying time with air passing through the tube via aspiration. The 5.0 ml of diluted extracted sample was placed on the column. The sample was washed by passing 0.5 ml of 20% (v/v) tetrahydrofuran in 0.5% (v/v) aqueous acetic acid followed by 2.0 ml of HPLC grade hexane. After a drying period of 2 min, the SPE tube was washed with 3.0 ml of 25% (v/v) tetrahydrofuran in hexane followed by a one-minute wash. The aflatoxins were eluted from the SPE tube with two 2.0-ml portions of CH_2Cl_2/tetrahydrofuran (99:1). The elution solvent was evaporated and the remaining residue dissolved in 200 μL acetonitrile. 50 μL of this solution was diluted with 200 μL mobile phase prior to injection. Further details concerning this SPE procedure can be found in product literature available from Supelco.

Safety precautions

The extremely toxic nature of aflatoxin demands the utmost in attention to safety precautions. Gloves were worn at all times when preparing or handling solutions. Standards were dissolved in an appropriate solvent and transferred via syringe. All working areas and equipment were wiped down with a 5% solution of NaOCl (bleach) to form considerably less toxic derivatives, and all waste solutions were made approximately 5% in NaOCl.

RESULTS AND DISCUSSION

Optimization of analysis time and efficiency

Several experimental parameters influence efficiency and analysis time in MECC. Most directly, the voltage applied across the capillary is the primary factor in determining the velocity of the mobile phase and, consequently, separation time. Figure 1 illustrates the inverse relationship between capillary void time, t_0, (*i.e.*, length of capillary to the detection zone divided by electroosmotic flow velocity), and the elution time of aflatoxin B_1, (*i.e.*, total aflatoxin separation time) on applied field. When this data is used to plot applied voltage versus flow-rate, positive deviations from the normal linear relationship are observed at high fields. This is not surprising, because decreases in mobile phase viscosity (hence increases in electrophoretic mobilities) are expected at large applied voltages, as

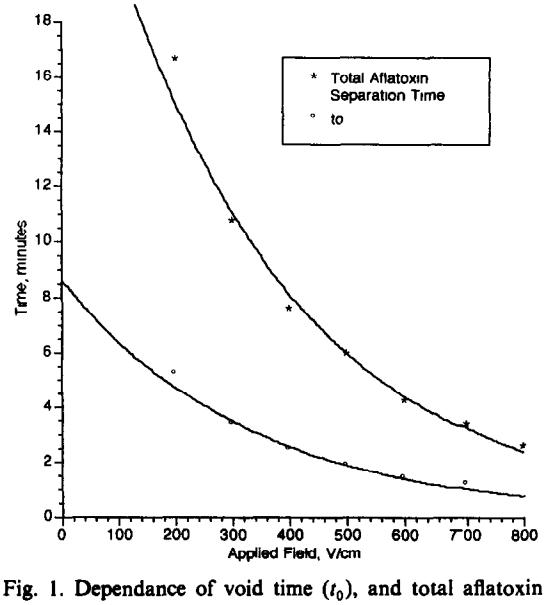

Fig. 1. Dependance of void time (t_0), and total aflatoxin separation time on applied field. Mobile phase composition: 0.05*M* SDS, 0.01*M* Na_2HPO_4, 0.006*M* $Na_2B_4O_7$. t_0 marked by methanol system peak.

the ability of the capillary to dissipate Joule heat is exceeded and its temperature increases.[1] However, the practical ramifications of this behavior in rapid MECC separations are interesting. In our laboratory, we have often observed that several minutes into separations performed at the highest fields expressed in Fig. 1, the system breaks down due to degassing or boiling of the mobile phase. The rapid separations of aflatoxins shown later in this work occur before the onset of this problem and, in fact, analysis times are even shorter than predicted based on extrapolations from low field separations. Presumably in the most common CZE/MECC arrangement (capillary in air), several minutes may be required to reach complete thermal equilibrium, following the initial application of voltage. It is possible that the temperature of the mobile phase increases during the course of the rapid separations presented herein. Thus, thermostated CZE/MECC systems and measures to correct for temperature related changes in retention time,[22] may be especially important in obtaining reproducible rapid separations with these techniques.

Efficiency in MECC is also dependant on mobile phase velocity, as well as factors such as buffer and surfactant concentration, column diameter, and detector time constant. An experimental parameter that is key to achieving rapid separations in MECC is the i.d. of the capillaries employed. The use of small diameter capillaries (i.d. <50 μm) permits the application of high field strengths while maintaining high efficiency. This is illustrated, along with the effects of other parameters, in Table 1. Note that the efficiency data in the table is reported in number of theoretical plates/minute to give a better idea of the temporal performance of the technique. Retention times for aflatoxin G_1 are less than 5 min. The "standard conditions" used in this work for the table were as follows: buffer composed of 0.01M Na_2HPO_4 and 0.006M $Na_2B_4O_7$, surfactant concentration of 0.05M SDS or sodium deoxycholate (NaDC), capillary 25 μm i.d. by 50 cm long (40 cm to detection zone), field strength of 600 V/cm, and a detector time constant that was limited by the 60 Hz acquisition rate of the integrator employed. Narrowbore capillaries effectively dissipate heat, resulting in less distortion of the flat flow profile and better efficiency (see below). In our studies, the use of 50 μm i.d. capillaries limited maximum applied fields to roughly 300–400 V/cm due to higher conductivity and poorer heat dissipation than the 25-μm i.d. capillaries. Application of fields exceeding this value to capillaries with i.d. ≥ 50 μm generally resulted in degradation of efficiency or complete breakdown of the system.

Figure 2 contains plots of applied field *vs.* efficiency (plate height) using both 50- and 25-μm i.d. capillaries. The plots are computer generated best fits to data obtained from single injections of aflatoxin G_1. Van Deemter-like plots such as these can be helpful in studying band broadening mechanisms in MECC.[6] At lower fields, efficiency is degraded due to the onset of problems with longitudinal diffusion. Long capillary residence times provide the solute bands with significant opportunity to disperse along the axis of the capillary due to molecular diffusion. As field strength is increased, residence time in the capillary decreases, and an optimum value of field strength is observed (see Fig. 2). Efficiency begins to degrade at higher fields due to increased resistance to mass transfer[6] and, more importantly, increased thermal load. This not only produces a general increase in temperature as discussed above, but can also result in radial temperature gradients in the capillary. The temperature gradient can cause band dispersion due to a distortion of the flat flow profile of electroosmotic flow.[23] Radial variances in phase ratio, due to the temperature dependence of critical micelle concentration (CMC), and partition coefficient can also lead to band dispersion. Since

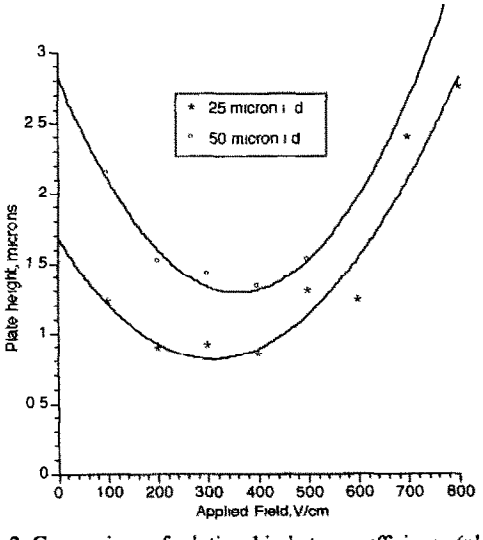

Fig. 2. Comparison of relationship between efficiency (plate height) and applied field for 50 and 25 μm i.d. capillaries. Mobile phase composition: 0.05M SDS, 0.01M Na_2HPO_4, 0.006M $Na_2B_4O_7$. Data for aflatoxin G_1.

temperatures may be changing rapidly during the early stages of electrophoretic runs (see discussion above), these problems may be more severe for rapid separations. Use of smaller diameter capillaries allows greater potentials to be applied without critical losses in efficiency. As illustrated in Fig. 2, the optimized plate height is significantly lower and the working range of applied field is much wider for the 25-μm i.d. capillary. The optimum value of applied field is roughly the same for the two capillaries. However, since different silica surface composition and different thermal properties may be involved, it should not be inferred that the two capillaries have similar optimums in terms of linear flow velocities. The use of smaller i.d. capillaries is clearly very important when performing high-speed MECC separations.

Further evidence of the importance of Joule heating as a source of band dispersion is given by the buffer concentration data in Table 1. At higher salt concentrations, current passing through the capillary is greater, and the resulting large thermal load results in band dispersion. Dramatic losses in efficiency are observed for both surfactant systems when the buffer concentration is increased above the standard conditions case. Working at a relatively low buffer concentration is thus essential for maximizing efficiency.

Surfactant concentration is perhaps the most fundamental adjustable mobile phase parameter in MECC. The working range of surfactant concentration in MECC is bounded at the lower end by the surfactant CMC and at the upper end by the creation of the thermal problems cited above. At the low end of this concentration range micelle-monomer exchange kinetics are such that the adverse effects of micelle polydispersity are generally observed.[3,6,7] Increasing the surfactant concentration counteracts this effect and efficiency improves as indicated in the table.[24] Reducing the standard conditions surfactant concentration by half reduces the efficiency with NaDC by nearly 70%, while SDS shows a 20% reduction. The difference in the magnitude of the reduction of efficiency between the two surfactants may be attributed to the fact that the bile salt has a higher CMC than the SDS. In all of our work, efficiency in MECC degrades dramatically when the surfactant concentration is reduced to values near the CMC.

Efficiency may also be affected by injection and detection conditions and instrumentation.[7,25] Efficient, rapid separations necessarily have very small temporal peak variances that require rapid data acquisition and fast detector time constants. Table 1 also shows the effect of time constant on efficiency for aflatoxin G_1. As a consequence of the short time constants that are needed to maintain efficiency in high-speed MECC, baseline noise and limits of detection are increased. Trade-offs between efficiency and detection time constant, as well as injection plug length, must thus be reached.

Retention control also plays an important role in achieving high-speed separations. Optimizing capacity factors in terms of resolution and analysis time can be critical. Poorly retained solutes elute quickly but may not be well-separated and strongly retained solutes tend to coelute at the micelle migration time. The optimum capacity factor, k', in MECC falls in the range of 1–5.[2] In our laboratory, two approaches are commonly used to control and optimize separations. First, organic modifiers

such as methanol, acetonitrile, and 2-propanol are added to the mobile phase. These solvents have the effects of decreasing mobile phase polarity and extending the elution range.[6,26,27] In some cases, k' is reduced to more optimal values. In addition to reducing mobile phase polarity, organic solvents generally reduce conductivity, which can improve efficiency at high fields.[26,27] Figure 3 contains plots of applied field *vs.* plate height for SDS mobile phases containing 0 and 10% (v/v) acetonitrile. The minimum values of plate height are approximately equal, but plate height does not increase at high fields as sharply for the mixed aqueous–organic mobile phase. Under these conditions, a wider range of (higher) fields can be applied without significant loss of efficiency. This effect is the result of a decrease in dielectric constant of the mobile phase upon addition of the acetonitrile to the mobile phase, which reduces the conductivity of the mobile phase and, hence, the current that is passed at a given voltage. Decreases in mobile phase polarity with the addition of organic solvents generally reduce k' values, causing solutes to spend more time in the faster moving mobile phase. While reduction of electroosmotic flow and a concomitant extension of elution range is often observed upon addition of organic solvent to the mobile phase, the reduction of solute k' often dominates and solutes elute more quickly.[28] However, it should be noted that, depending on the nature and concentration of the organic solvent, electroosmotic flow may be reduced to a point where analysis time is increased, sometimes dramatically.[26]

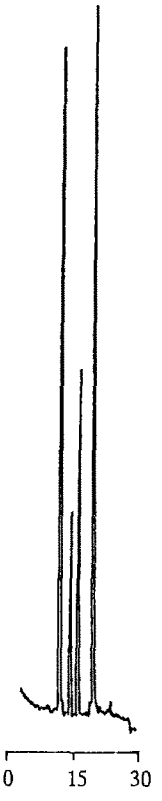

Fig. 4. High-speed separation of aflatoxin standards. Mobile phase composition: 0.05*M* NaDC, 0.01*M* Na_2HPO_4, 0.006*M* $Na_2B_4O_7$, 5% Acetonitrile. Applied voltage 36 kV. Elution order is G_2, G_1, B_2, B_1.

The second approach to control capacity involves the use of bile salt surfactants.[11,24] These naturally-occurring surfactants are based on a hydroxy-substituted steroidal backbone and are more polar in nature than the conventional *n*-alkyl variety.[11,24] Hence, they retain moderately to highly hydrophobic solutes less (k' values are generally closer to the optimum range). They have found use in MECC for chiral separations,[14,16,24,29,30] and for the separation of hydrophobic molecules.[11,31] Figure 4 shows the separation of the four common aflatoxins with a bile salt micellar phase, using conditions that have been optimized in terms of overall resolution and analysis time.

Detection

The very small i.d. capillaries that are essential for rapid MECC separations exacerbate problems with attaining adequate detection sensitivity. In order to preserve the integrity of the narrow solute bands, on-column detection is generally employed. Absorbance detection is

limited in small i.d. capillaries due to very short optical pathlengths, low throughput, and large levels of stray light.[32] Laser-based fluorescence detection schemes offer high sensitivity as well as compatibility with capillaries of diminutive dimensions.[3,9,20,33] Aflatoxins readily absorb the 325-nm output of helium–cadmium lasers and exhibit native fluorescence, allowing sensitive laser-based detection to be employed.[34] Fluorescence detection in MECC can be influenced by the type of pseudostationary phase employed, since emission wavelengths and intensities are often affected.[28] Association of solute with micelles often enhances fluorescence emission.[35] The spectroscopic behavior of the aflatoxins in different solvents or micelle solutions is shown in Table 2. This data illustrates the importance of considering both the spectroscopic characteristics and the chromatographic properties of the micellar phase in MECC. The varied spectroscopic nature of each individual aflatoxin indicates that multichannel detection might be advantageous, both in terms of identification and increased sensitivity.[33]

The absence of inner filter related curvature of calibration plots for laser fluorometric detection in narrow-bore capillaries is well established.[28] Thus, linearity was not evaluated in this work. However, short response plots were constructed from single injections of three standard solutions that all yielded S/N (peak height/baseline noise) of less than 25. Extrapolation of the plots to a S/N of 3 yielded the limits of detection (LODs) shown in Table 3. The electroinjection procedure used to obtain this data (see Experimental section) resulted in an injection volume of approximately 2 nl. An internal standard was added to correct for variations in detector response. While these concentration LODs are not as low as previous reports,[34] the weakly fluorescent G_1 and B_1 were quantitated without prior conversion to more fluorescent derivatives. The use of chemical derivitization techniques can result in the formation of highly fluorescent derivatives, leading to improved limits of detection.[36] Moreover, the laser used in this work, due to an ageing plasma tube, suffered from low output power and sporadic changes in both power and mode structure. Relatively large amounts of baseline drift and noise were observed, adversely affecting detectability and reproducibility.

In general, optical detection in capillary separations exhibits somewhat higher concentration LODs than when applied to conventional analytical scale separation techniques. Conversely, because of the very small volumes involved with capillary separations, absolute LODs can be extremely low and far superior. Although sophisticated signal acquisition and processing was required, recent reports of "zeptomole" absolute LODs for laser fluorometric detection in CZE illustrate this capability.[37,38]

Analysis of corn samples

Aflatoxins are sometimes present in foodstuffs at ppb levels, requiring extraction and concentration. Figure 5(a) shows the chromatogram resulting from the solid-phase extraction of an Indiana corn meal sample that was spiked at the 16 ppm (w/w) level. Since ultimate speed was not sought in this separation, a SDS micelle system was used. No detectable levels of aflatoxins were found in the unspiked sample. Based on the procedure used and the S/N of the spiked sample, the LOD in the corn meal is estimated to be about one ppm. However, it is

Table 3. Limits of detection for aflatoxins in MECC*

Aflatoxin	Injected concentration, *M*	Amount injected, femtomoles
G_2	2.85×10^{-8}	0.06
G_1	4.36×10^{-7}	0.9
B_2	2.64×10^{-8}	0.05
B_1	1.26×10^{-7}	0.2

*Limits of Detection based on S/N = 3; SDS mobile phase used.

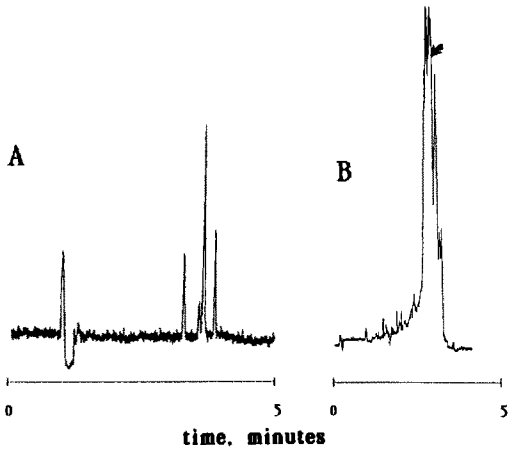

Fig. 5. Chromatograms of spiked (16 ppm w/w) corn meal extract (A) and artificially innoculated corn extract (B). Mobile phase composition: 0.05*M* SDS, 0.01*M* Na_2HPO_4, 0.006*M* $Na_2B_4O_7$, 10% v/v Acetonitrile. Applied voltage 20 kV. Arrow denotes expected retention of B_1.

expected that the LOD could be lowered by orders of magnitude via simple modifications of the sample work-up procedure. For example, only 1% of the initial extract was subjected to the SPE procedure and the sample was ultimately taken-up in 200 μl of solvent, while multiple injections from solutions with volumes of less than 10 μl can be routinely accomplished with this technique.

Considering the cooler climate from which it was obtained, it was not expected that the corn meal would contain aflatoxins. Aflatoxin production is most favored under conditions of high humidity and temperature;[17,18] contamination is thus more of a problem in southern climates. To assure the presence of aflatoxins in a complex sample matrix, *Aspergillus Flavus* spores were introduced onto a sample of moist corn kernels and allowed to grow for two weeks at 28°. Figure 5(b) shows the chromatogram of an extract of this sample obtained as described previously. The more complex sample matrix clearly illustrates the need for thorough sample clean-up, as aflatoxin peaks (see arrow for approximate retention time of B_1) are not clearly resolved from extraneous fluorescent compounds in the sample. However, if a more selective detection scheme was employed, it might be possible to discern individual aflatoxin peaks in such a mixture. Possible detection schemes include multichannel or time resolved detection.[32,39] Although not pursued in this work, it should be possible to reoptimize the separation to accommodate the more complex sample. The use of longer capillaries to increase plate numbers and/or the incorporation of alcoholic solvents in the mobile phase to significantly increase the elution range could provide the necessary resolution (albeit at the expense of analysis time).

CONCLUSIONS

MECC offers a viable method of rapid aflatoxin analysis, and for other compounds requiring routine monitoring. Separation times in the order of tens of seconds are readily achieved if experimental parameters are optimized, and provide the opportunity for large sample throughput via the simultaneous work-up of numerous samples. Significant samples include foodstuff extracts and pharmaceutical formulations. In addition, separations involving enantiomers may well lend themselves to high-speed MECC separation using bile salt surfactant systems. Detection still remains a limiting factor in applications of rapid MECC and CZE methods, but improvements in laser sources and the development of sensitive alternate schemes will increase the applicability of these techniques.

(*Received* 20 *November* 1991. *Accepted* 25 *January* 1992)

Summary—Electrochemical reduction of nicergoline was studied at different pH and concentrations using differential pulse polarography and linear sweep voltammetry. Both techniques reveal that the reduction process occurs with strong adsorption of the product. Nicergoline is an excellent model for the previously developed theory related to the effects of strong adsorption of electroactive species in voltammetry. At concentrations below 0.1m*M*, the adsorption prepeak is linearly dependent on nicergoline concentration. This peak was used to develop a new differential pulse polarographic method for the determination of the drug in pharmaceutical dosage forms. The method is simple and not time-consuming because nitrogen purging of samples and previous separation of the excipients were not needed. A comparative UV spectrophotometric assay was applied. Recovery data and composite and uniformity content studies for both methods are reported.

Nicergoline[8β]-10-methoxy-1,6-dimethylergoline-8-methanol-5-bromo-3-pyridine carboxylate (ester) (Fig. 1), is a drug with vasoactive properties due to its alpha-adrenergic blocking activity, which causes peripheral and central vasodilation. In different tests, the drug has proved to have cerebral-anti-ischemic action, also exhibiting platelet antiaggregating and disaggregating actions.[1,2]

Several clinical studies[3,4] have demonstrated that nicergoline was effective in lowering total peripheral resistance and normalized blood pressure without producing reflex tachycardia and concluded that the drug was useful in the early phases of acute myocardial infarction, due to its lowering of myocardial oxygen consumption.

Biotransformation of nicergoline both in man and animals demonstrated extensive metabolism in all species tested, the main metabolites being 1,6-dimethyl-8β-hydroxymethyl-10-alpha-methoxyergoline and 8β-hydroxymethyl-10-alpha-methoxy-6-methylergoline, as well as their glucuronides, all of which were excreted by the kidneys.[5,6] Therefore, the most important routes of chemical transformation in man appear to be hydrolysis of the ester linkage and *N*-demethylation.

To our knowledge, no analytical assays for nicergoline have appeared in the literature. Electrochemical methods have become very competitive from the analytical point of view because of sophisticated developments in electronics, three-electrodes systems, pulse voltammetry, *etc.* Modern polarography and voltammetry show important advantages in pharmaceutical analyses. Several reviews and papers related to the electrochemical determination of drugs in pharmaceutical forms have been published recently.[7,8]

This paper reports the electrochemical behaviour of nicergoline and the development of a novel method to determine the drug in dosage forms (injectable and tablets). For comparative purposes, a UV spectrophotometric assay was also used.

EXPERIMENTAL

Reagents and materials

Drug. Nicergoline was obtained from Chile Laboratories, Santiago, Chile (100% chromatographically pure, 99.8% activity).

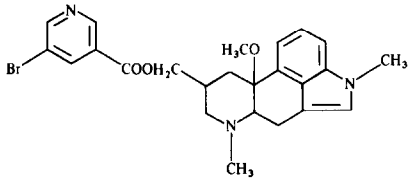

Fig. 1. Chemical structure of nicergoline.

Buffer solutions. To study the effect of pH on the electrochemical behaviour of the drug, 0.04*M* Britton Robinson buffer with a pH range between pH 2.0 and 9.0 was used. The ionic strength was kept constant at 0.3*M* with potassium chloride. For analytical determinations, 0.1*M* hydrochloric acid was selected as the supporting electrolyte. All other reagents were analytical grade.

Drug solutions. (a) Standard stock solutions were prepared by weighing Nicergoline and dissolving in 0.1*M* hydrochloric acid to obtain a concentration of $1 \times 10^{-3}M$. Solutions for the calibration curves were individually prepared by diluting the standard solution with 0.1*M* hydrochloric acid to obtain solutions which varied from 2×10^{-5} to $1 \times 10^{-4}M$. The narrow range is due to the adsorption nature of the polarographic peaks.

(b) Sample solutions. Samples were dissolved in 0.1*M* hydrochloric acid to give solutions about $8 \times 10^{-5}M$ nicergoline.

(c) Synthetic samples for recovery studies were prepared according to the manufacturer's batch formulas for 10 mg of nicergoline tablets. The solutions were directly assayed by polarography. However, for UV spectrophotometric determinations, they were previously filtered.

(d) Composite studies. Eleven tablets were finely ground and aliquots equivalent to a tablet average weight (0.1038 g) were dissolved and diluted to 250 ml with 0.1*M* hydrochloric acid to obtain final concentrations about $8 \times 10^{-5}M$. For the spectrophotometric studies, the above solutions were filtered.

Apparatus

Differential pulse polarography (DPP) was performed with a PARC 174 A polarographic analyzer equipped with a Metrohm polarographic stand, model E 554, containing a 5-ml constant-temperature cell with a three electrode system. The working electrode was a dropping mercury electrode, the reference electrode a saturated calomel electrode (SCE) and the auxiliary electrode a platinum foil.

The following polarographic conditions were used for measurements: potential range, −0.5–1.2 V; current range, 2–10 μA full scale; scan rate, 2 mV/sec; pulse modulation, 100 mV p.p.; drop time, 1 sec. The temperature of the experiments was kept constant at 25 ± 1° and samples were purged with pure nitrogen for 10 min, unless otherwise stated. Polarograms were recorded on a Hewlett–Packard 7004 B X–Y recorder.

Linear sweep and cyclic voltammetry experiments were carried out in a Inelecsa assembly similar to that previously described.[9] The working electrode was a hanging mercury drop electrode (hmde), Metrohm model EA-290, with a saturated calomel electrode as the reference electrode and a platinum wire as the auxiliary electrode. Controlled potential coulometric measurements and large scale electrolysis were performed with the same equipment and electrodes as was previously reported.[10]

Spectrophotometric measurements were carried out with a Perkin–Elmer model 550 spectrophotometer in 1-cm quartz cells. Spectra were run between 200 and 400 nm, and quantitative sample measurements were made at 275 nm using 0.1*M* hydrochloric acid as a blank.

RESULTS AND DISCUSSION

Preliminary experiments showed that the polarographic behaviour of nicergoline markedly depends on the concentration of the solutions at constant drop time. At concentrations below 0.1m*M*, we observe only one peak with a peak potential at approximately −700 mV in 0.1*M* hydrochloric acid.

The behaviour of this peak with the nicergoline concentration is illustrated in Fig. 2. As can be seen, its height is linearly dependent on concentration up to 0.1m*M*. Above 0.1m*M*, the height of this peak remains unchanged, but a second peak with a peak potential at approximately −1000 mV appears. The height of this second peak also increases with the increasing of nicergoline concentration [Fig. 3].

The above behaviour is essentially the same as described by Laviron[11] for the case of strong adsorption of the product by classical polarography. In our case, the first peak is an adsorption prepeak corresponding to the general process:

$$Ox + ne \rightarrow [Red]_{ads} \quad (1)$$

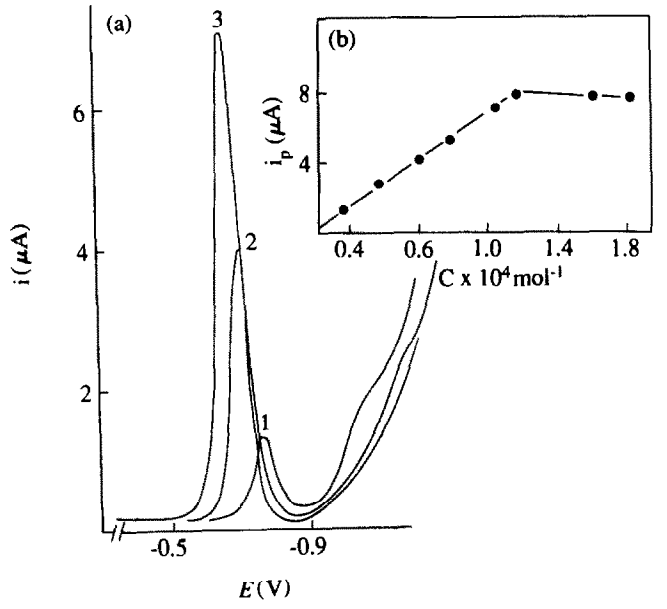

Fig. 2. (a) Some differential pulse polarograms of nicergoline at low concentrations (1) 0.02mM (2) 0.062mM; (3) 0.1mM. (b) Relationship between peak current and concentration for the prepeak.

At sufficiently high nicergoline concentrations [>0.1mM], a compact film of adsorbed product is formed and the reduction of nicergoline will occur now through the film, originating a second peak (diffusion peak) at more negative potentials due to the general process:

$$\mathrm{Ox} + ne \rightarrow \mathrm{Red} \qquad (2)$$

Linear sweep voltammetry (LSV) was also used to confirm the above described behaviour. Linear sweep voltamperograms of nicergoline exhibit two peaks: an adsorption peak (I) and a normal diffusion peak (II) (Figs. 4 and 5). The former appears at less negative potentials than the latter.

The dependence of voltamperograms on scan rate and on nicergoline concentrations was studied. As the scan rate increases, the ratio of the adsorption peak to the diffusion peak increases (Fig. 4). As the bulk concentration of nicergoline is increased, a relative decrease in the height of the adsorption peak and an anodic shift in its

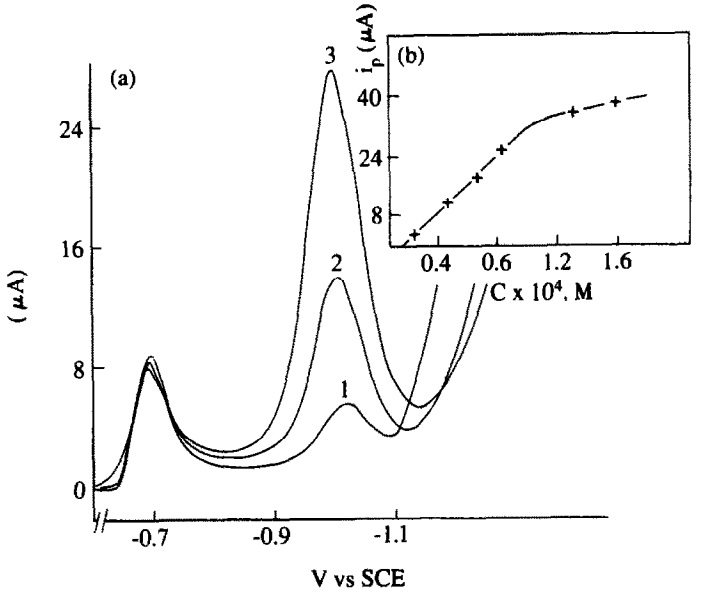

Fig. 3. (a) Differential pulse polarograms of nicergoline solutions at high concentrations: (1) 0.24mM; (2) 0.45mM; (3) 0.65mM.

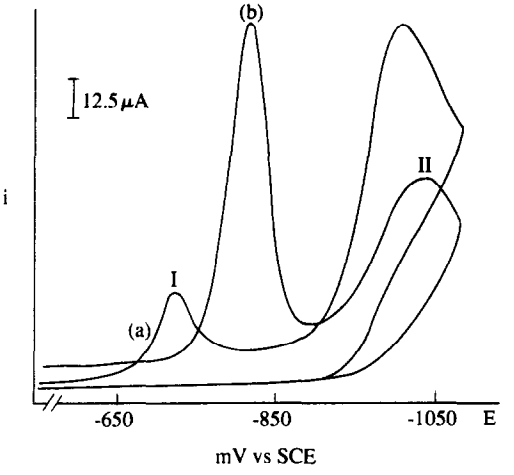

Fig. 4. Linear sweep cyclic voltamperograms of 1.0m*M* nicergoline at two different sweep rates: (a) 0.5 V/sec; (b) 25 V/sec.

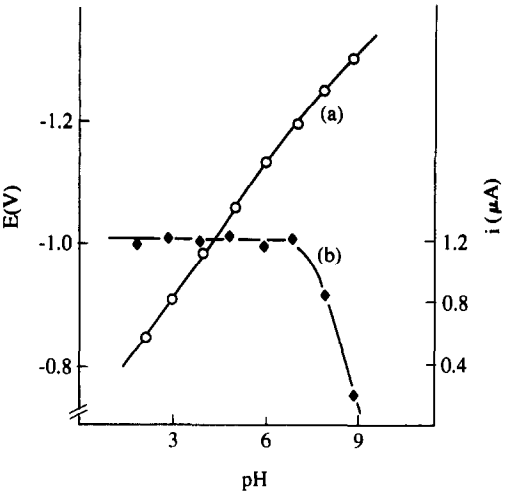

Fig. 6. D.p. polarographic variation with the pH of: (a) potential (*E*p) and (b) peak current.

potential is observed. The behaviour is shown in Fig. 5 (all other parameters were kept constant).

The above voltammetric response is completely consistent with a process where the electrode reaction involves the strong adsorption of the product. Nicergoline is shown to be an excellent model for the previously developed theory related to the effects of adsorption of electroactive species in voltammetry.[12]

Since the first pulse polarographic peak of nicergoline at concentrations below 0.1m*M* is limited by diffusion and is governed by the Ilkovic equation, we preferred it for a more thorough study and for quantitative analysis. For higher concentrations, the second peak

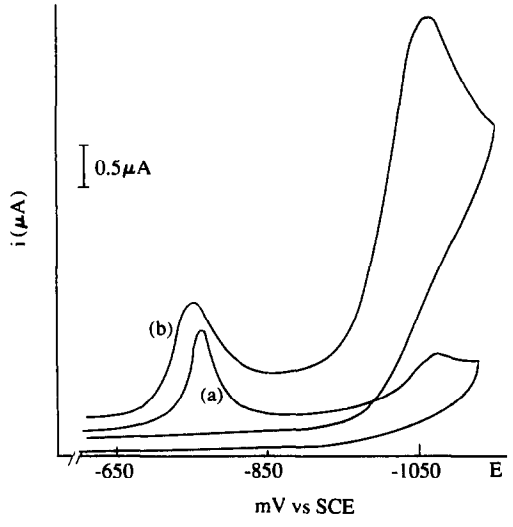

Fig. 5. Linear sweep cyclic voltamperograms of nicergoline at two different concentrations: (a) 0.1m*M*; (b) 0.5m*M*. Sweep rate: 0.5 V/sec.

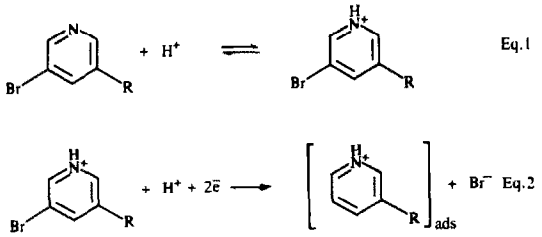
may be used, although its intercept is not at the origin; the sum of the two peak currents should actually give a curve through the origin.

The peak potential of the first peak was strongly dependent on pH solutions. Between pH 1.0 and 6.5, a linear dependence was obtained with a slope of 0.071 V/pH. A second linear dependence was also found above pH 7.0, with a slope of 0.057 V/pH. This behaviour is shown in Fig. 6. The peak currents are nearly constant in the pH range between pH 1.0 and 7.0. However, above pH 7.0 a sharp decrease is observed, and the peak practically disappears at pH values higher than 9.0.

From the *E*p/pH plot, we have obtained a polarographic pK_a of 6.4. The dependence of the *i*p/pH curve shows a behaviour in accord with a process in which a proton transfer precedes the electroreduction of the acidic form, *e.g.*, the protonation of the pyridine nitrogen to form the electroactive species. At pH values higher than pK_a, the proton transfer is slow and the process appears to be kinetic controlled.

UV spectrophotometric studies at different pH values also permit us to obtain a pK_a value [pK_{UV} = 4.9]. A comparison of polarographic and spectrophotometric pK's shows a higher value of the former. This apparent discrepancy may be due to the kinetic character of the polarographic system, in which the equilibrium is established in a period comparable to that of a drop-life, resulting in a pK_a greater than the equilibrium pK.[13]

Considering the above dependences on nicergoline concentration and pH, we postulate the



mechanism summarized in Scheme 1 for nicergoline concentrations below which a compact film of product is formed (approximately <0.1 mM).

The first step is the chemical proton transfer reaction in order to form the electroactive protonated nicergoline, being the non-protonated electroinactive nicergoline. This step proceeds fast at pH values less than pK values, producing an independence between the limiting current and pH. At more alkaline pH values than pK, this step proceeds slowly, with a decrease in the limiting current with increasing pH values. In order to verify the occurrence of the second step, we have carried out controlled potential electrolysis and Br- was identified in the electrolyzed solution.[14] Furthermore, previous works related to halogenopyridines agree with this proposed mechanism.[15-19]

Nicergoline exhibits a well-defined polarogram in 0.1M hydrochloric acid with a peak potential between -700 and -650 mV *vs.* SCE, which was used for analytical determination of the drug in pharmaceutical dosage forms.

This peak was diffusion-controlled and the peak current exhibited a linear dependence in the concentration range between 4×10^{-6} and $1 \times 10^{-4}M$. However, for the analytical assay of nicergoline, a working range between 2×10^{-5} and $1 \times 10^{-4}M$ was chosen. The calibration curve is described by the following regression equation:

$$ip\ (\mu A) = 69{,}774\ C(M) - 0.268$$

with a correlation coefficient of 0.9995 for $n = 10$, where ip is the peak current and C is the molar concentration of nicergoline. The detection limit was $1 \times 10^{-6}M$. With the purpose of developing a rapid analytical method, we have studied the effect of not purging the nicergoline solutions with nitrogen prior to polarographic measurements. Our results indicate that previous purging was not essential because calibration curves without purging were similar

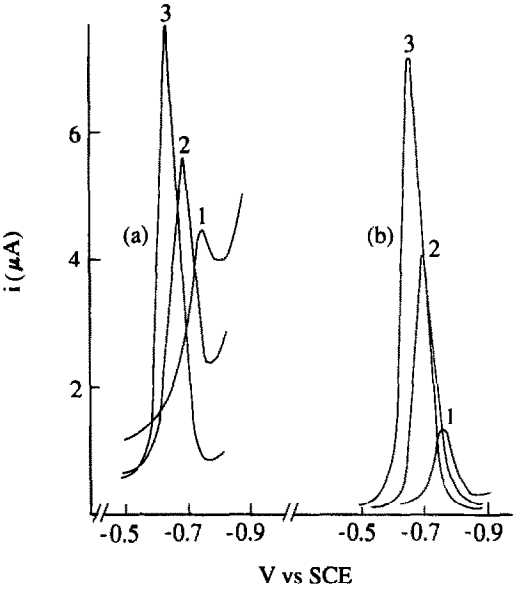


Fig. 7. Comparison of some differential pulse polarograms of nicergoline (b) with nitrogen purging (a) and without purging, at three different concentrations (1) 0.02mM; (2) 0.062mM; (3) 0.1mM.

(slope comparisons through a Student t-test were not significantly different, $p > 0.01$). However, the detection limit in the case with no-purging was about $9 \times 10^{-6}M$ (Fig. 7). The presence of oxygen produces a sloping baseline, but this effect is reduced as the concentration of nicergoline is increased. This fact can be interpreted as an inhibition of the reduction wave of the oxygen due to strong adsorption of the product on the mercury electrode. In conclusion, the purging of the nicergoline solutions with nitrogen is not needed for the quantitative determination of either the pure drug or dosage

*Nicergoline tablets, Chile Laboratories, Santiago, Chile. Declared amount: 10 mg of nicergoline.

†Sermion, Carlo Erba Laboratories, Santiago, Chile. Lyophilyzed injectable powder, declared 4 mg of nicergoline.

Composite analyses of tablets containing declared amounts of 10 mg of nicergoline show mean values of 9.58 and 10.61 mg for the polarographic and spectrophotometric determinations ($n = 10$), with a SD of 0.064 and 0.065, respectively (Table 2).

Individual dosage form assays of both tablets and injectables are shown in Table 3. It can be concluded that the polarographic determination developed here represents a good analytical alternative, because sample preparation is easy and the method is rapid. The present method is recommended for the quantitative determination of nicergoline in dosage forms and uniformity content tests.

ELECTROCHEMICAL STUDY OF METHYLCOBALAMIN

DETERMINATION OF THE REDUCTION POTENTIAL FOR A QUASIREVERSIBLE SYSTEM WITH A FAST FOLLOWING REACTION

QINGDONG HUANG and DAVID K. GOSSER, JR*

Department of Chemistry, City College of the City University of New York, New York, NY 10031, U.S.A.

(*Received* 2 *December* 1991. *Accepted* 9 *January* 1992)

Summary—The reductive electrochemistry of methylocobalamin in nonaqueous solution is typical of many electrochemical mechanisms in that the initial electron transfer at the electrode is followed by a fast chemical reaction. The rate constant of the following chemical step, methyl radical cleavage, was measured by double potential step chronoamperometry to be 590 sec^{-1} in a solvent mixture (DMF 40%, methanol 60%, at −30°). The cyclic voltammetric response in the slow scan-rate regime was analyzed by the simulation-fitting program CVFIT to extract the remaining parameters of the electrode reaction–chemical reaction mechanism: the formal reduction potential ($E^{0\prime} = -1.529 \pm 0.004$ V), the standard heterogeneous rate-constant ($k^0 = 0.012 \pm 0.002$ cm/sec), and the transfer coefficient ($\alpha = 0.78 \pm 0.02$). This method of analysis allows for the rigorous determination of reduction potentials under conditions where the cyclic voltammetric response appears irreversible (no reverse peak is observed). A detailed analysis of the actual reversibility of the system and its effect on the apparent transfer coefficient is presented.

Vitamin B_{12}, the antipernicious-anemia factor, is a group of organometallic compounds which are among the most complex of the naturally occurring compounds.[1] Methylcobalamin, an important member in the B_{12} family, is involved in the methyl group transfer reaction as a coenzyme.[2] In general, the involvement of vitamin B_{12} compounds in a variety of metabolic neurological diseases is a major reason for the thorough understanding of their chemistry and biochemistry, particularly of their redox chemistry. The nature of the cobalt-carbon bond is a fundamental concern, both from the point of view of basic chemistry and as an aid in understanding the function of the coenzyme in protein substrates. The electrochemistry of vitamin B_{12} species has been reviewed by Lexa and Saveant.[3] Since it is a cobalt coordination compound where the cobalt ion can have three different formal oxidation states, redox chemistry is expected to play an important role in their enzymatic reactions.

The reduction of methylcobalamin is typical of many electrochemical reactions in that the electron transfer is followed by a fast and irreversible chemical reaction. In such systems the determination of the formal reduction potential $E^{0\prime}$ by cyclic voltammetry (CV) is problematical. No reverse wave is obtained at slow scan-rates. At a fast scan-rate[4] data are distorted by iR drop (the error in potential control due to the uncompensated solution resistance) and capacitive current that prevents a precise analysis of the CV wave shape. Also for the case of slow electron transfer, the range of scan-rate will be limited. We present here a detailed cyclic voltammetric study in the slow scan-rate regime. Analysis by CV simulation and simplex curve fitting, combined with double potential step chronoamperometry (DPSC), allows for the determination of $E^{0\prime}$ within a few millivolts. Even with the combination of sluggish charge transfer and fast following chemical reaction for this mechanism, which results in apparently irreversible cyclic voltamperograms, the thermodynamic and kinetic parameters can be determined by careful data analysis.

The mechanism of the reductive electrochemistry of methylcobalamin was suggested by Lexa and Saveant using rapid sweep CV in 50 : 50% ratio of DMF and 1-propanol.[4] They were able to show the existence of one electron adduct and estimated the rate constant for the following chemical reaction k_{chem} as 1200 sec^{-1}

*Author for correspondence.

at $-30°$ and the formal reduction potential to be $E^{0'} = -1.6$ V. Spectroelectrochemical experiments have confirmed that the product formed by exhaustive reduction is [Co(I)]cobalamin,[5-7] the vitamin B_{12s}. The electrode process has been shown one electron overall because of the results of controlled potential coulometry. Gas chromatography–mass spectrometry has indicated that ethane is greater than 97% of the cleavage product of the methylcobalamin reduction.[7] Based on these results, the mechanism in Scheme 1 was put forward. Such a mechanism where a chemical reaction follows electron transfer near the electrode is termed as an EC (electrode reaction–chemical reaction) mechanism. This mechanism was further studied through a combination of CV and potential step experiments by Kim and Birke.[8] It is apparent that this mechanism might actually be understood as a sequence of steps more complicated than that shown in Scheme 1. For instance, the timing of the base-on to base-off transition is not resolved. However, our present analysis considers only the rate of the overall reaction.

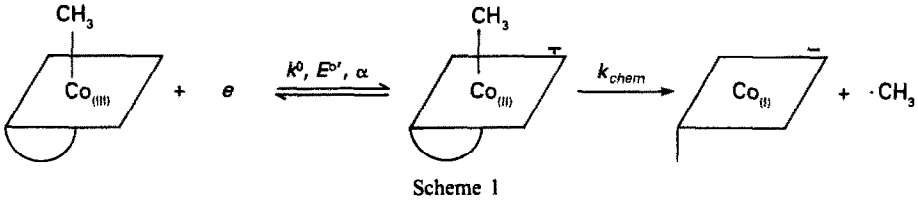
Our goal in pursuing this work was to fully characterize this EC mechanism by CV simulation analysis using the program CVFIT.[9] A complete characterization of the EC mechanism requires the determination of E^0, k^0, α and k_{chem}, where $E^{0'}$, k^0 and α are the kinetic parameters of the Butler–Volmer equation and k_{chem} influences the concentration of the reducing products in the same equation.[10]

In order to characterize the electrochemical properties of a system by simulation and fitting analysis, a working electrode that gives facile charge transfer is essential. Methylcobalamin usually shows adsorption on common electrode materials. When a mercury electrode was used in DMF with ethanol or 1-propanol solvent mixture, some interfacial adsorption was noticeable even though the results were better than that obtained with a gold or vitreous carbon disk electrode.[4] Reduction of alkylcobalamins on mercury in the presence of ethanol leads to the formation of the corresponding alkylmercury compounds.[11] We examined the electrode responses of methylcobalamin at a number of electrodes in order to find a system which would be amenable to a rigorous simulation analysis. Platinum and silver electrodes had poor characteristics. Glassy carbon was better, but the performance deteriorated quickly with time. A silver amalgam electrode was found to have the best electrode response. It is very stable and its surface does not need to be repolished during the experimental period. This electrode is suitable for the present experiments with methylcobalamin and other alkylcobalamins utilizing a low temperature cell where frequent electrode treatment is inconvenient.

EXPERIMENTAL

The reference electrode was an Ag/AgCl electrode with ethanol solvent saturated by lithium chloride (ultrapure grade, Alfa) at $-85°$, the lowest temperature the temperature control system could reach. The cell temperature was controlled by a Multicool temperature bath controller (FTS Systems). The temperature was monitored near the working electrode with an Omega temperature probe. The solvent was a mixture of DMF (Burdick Jackson Laboratories, Inc.) and methanol (Fisher Scientific) in the ratio 40 : 60%. The DMF was dried over type 3A molecular sieves (Alfa). The supporting electrolyte was TBAF (tetrabutylammonium fluoroborate, Fisher Scientific) in 0.30M and the concentration of methylcobalamin (Sigma) was 2.0mM for CV. Experiments were performed by a BAS-100A electrochemical analyzer. The experimental results were transferred to a PC-XT computer, then converted and analyzed.

The working electrodes were silver amalgam electrodes with diameters of 0.25 and 1.60 mm, which were made from silver wire. The original silver electrode was polished with fine aluminum oxide powders (0.05 μm) and put into an electrochemical cell in which there was a drop of liquid mercury on the bottle immersed by nitric



Scheme 1

acid solution at pH 1.5. Using an aqueous Ag/AgCl electrode as reference electrode and a platinum wire as auxiliary electrode, a potential of -1.0 V was applied. This potential reduced hydrogen ions in solution and produced hydrogen gas at the silver working electrode where the surface was activated. After 3 min, the silver electrode was contacted with the mercury in the cell while still holding the same potential. A film of mercury was formed on the surface of the silver electrode. This electrode was rinsed with demineralized distilled water several times and then was immersed in the same type of water for 50 min. The electrode was polished with aluminum oxide powder again and finally washed with demineralized distilled water followed by DMF–methanol solvent.

Several solvent mixtures with different ratios of DMF and methanol were tested. Since there is limited solubility for methylcobalamin in DMF and a higher freezing point compared with methanol, we avoided using a high ratio of DMF. On the other hand, methanol has lower dielectric constant compared with DMF, which causes higher resistance particularly at low temperatures. Experiments showed no significant difference in CV for the reduction of methylcobalamin from ratio 25 : 75% to 75 : 25% for DMF with methanol, ethanol and 1-propanol and so on, except that the rate of the following chemical reaction was sensitive to the exact solvent mixture.[12] These solvent mixtures were not frozen as low as $-85°$. The nitrogen, which was saturated by the same ratio of components and pre-cooled through a U-tube immersed in the cooling system, was used to purge solvent until the initial background current was minimized. CV results of methylcobalamin, by a silver amalgam electrode of 1.6 mm diameter, were background subtracted with data taken under the same experimental conditions but only using solvent and electrolyte. The DPSC experiments for the chemical reaction rate k_{chem} were carried out with time resolution (100 μsec) by a silver amalgam electrode of 0.25 mm diameter.

The CVFIT program includes the correction of iR drop in CV. For this iR correction, uncompensated resistance was analyzed by potential step chronoamperometry. The initial potential was set to the same as the initial potential in CV experiments, and then a step of -50 mV to the initial potential was applied. This step potential was applied for 1 or 2 msec. Since the procedure did not involve faradaic current, the current response follows the relationship

$$i_t = \frac{\Delta E}{R} \exp\left(\frac{-t}{RC_{dl}}\right) \tag{1}$$

where i_t is the response current, ΔE is the potential step applied, R is resistance, C_{dl} is the capacitance of the double layer and t is the time. A plot of t *vs.* $\ln(i_t)$ extrapolated to zero time was used to find the resistance from the intercept.[13]

RESULTS AND DISCUSSION

The rate constant of the following chemical reaction was determined by DPSC and later used as a fixed parameter in the simulation and fitting analysis. The DPSC results were fitted by the theoretical curve developed by Schwarz and Shain.[14] The first few points of data due to double layer charging current were ignored. The usable time window was confirmed by the Cottrell equation[10] where constancy of $it^{1/2}$ was observed. The cathodic current was fitted first within time $0 < t \leqslant \tau$, where τ is the period of pulse applied. It follows the relation

$$i_c = nFAC_0^* \sqrt{\frac{D_0}{\pi t}} \tag{2}$$

where n is the number of electrons involved in the charge transfer, F is the Faraday constant, A is the area of the electrode, C_0^* is the bulk concentration of methylcobalamin and D_0 is the diffusion coefficient. Then k_{chem} was adjusted when the same parameters (n, A, C_0^* and D_0) were kept within time $\tau < t \leqslant 2\tau$ until the anodic current could be fitted by the relation

$$i_a = nFAC_0^* D_0^{1/2} \left[\frac{\phi}{\sqrt{\pi(t-\tau)}} - \frac{1}{\sqrt{\pi t}}\right] \tag{3}$$

where

$$\phi = e^{-k_{chem}\tau/2} I_0\left(\frac{k_{chem}\tau}{2}\right) + 2\, e^{-k_{chem}\tau/2} \times e^{-k_{chem}(t-\tau)} \sum_{n=1}^{\infty} I_n\left(\frac{k_{chem}\tau}{2}\right) \times \frac{\int_0^{k_{chem}(t-\tau)} \cdots \int_0^{\lambda_2} \lambda_1^n e^{\lambda_1} d\lambda_1 \cdots d\lambda_n}{[k_{chem}(t-\tau)]^n} \tag{4}$$

and $I_n(k_{chem}\tau/2)$ represents the modified Bessel functions. Three terms of the infinite series

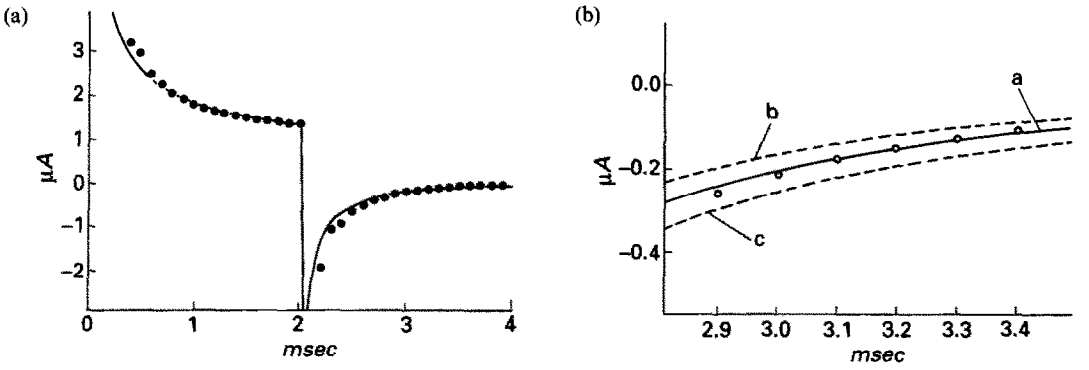


Fig. 1. Double potential step chronoamperometry experiment and fitting result of methylcobalamin in solvent mixture DMF (40%) and methanol (60%) at −30°. Silver amalgam electrode (0.25 mm in diameter), methylcobalamin = 1mM, TBAF = 0.30M. The initial potential was −1.35V, the step potential −1.60V and the final potential back to −1.35V. (a) Result fitted by $k_{chem} = 590$ sec^{-1}, the solid points are experimental results. (b) Detail of the fitting with an error range, where the data close to noise background (at the end of the time period) are ignored. The hollow points are experimental results. Curves a with $k_{chem} = 590$ sec^{-1}, b with 690 sec^{-1} and c with 490 sec^{-1}.

were used. The results are shown in Fig. 1 in which (a) is a general experimental and fitting result and (b) is a detail with the error range indicated. The k_{chem} results were also checked by the measured current ratios $-i_a/i_c$ with the working curve data.[14] All results fall within 5–15% of an average value.

CV with a resolution of one millivolt per point was carried out at −30° with the silver amalgam working electrode. The cyclic voltamperograms at scan-rates 50, 100 and 300 mV/sec are shown in Fig. 2. These voltamperograms are characterized by a cathodic wave showing a well-defined current maximum but no anodic

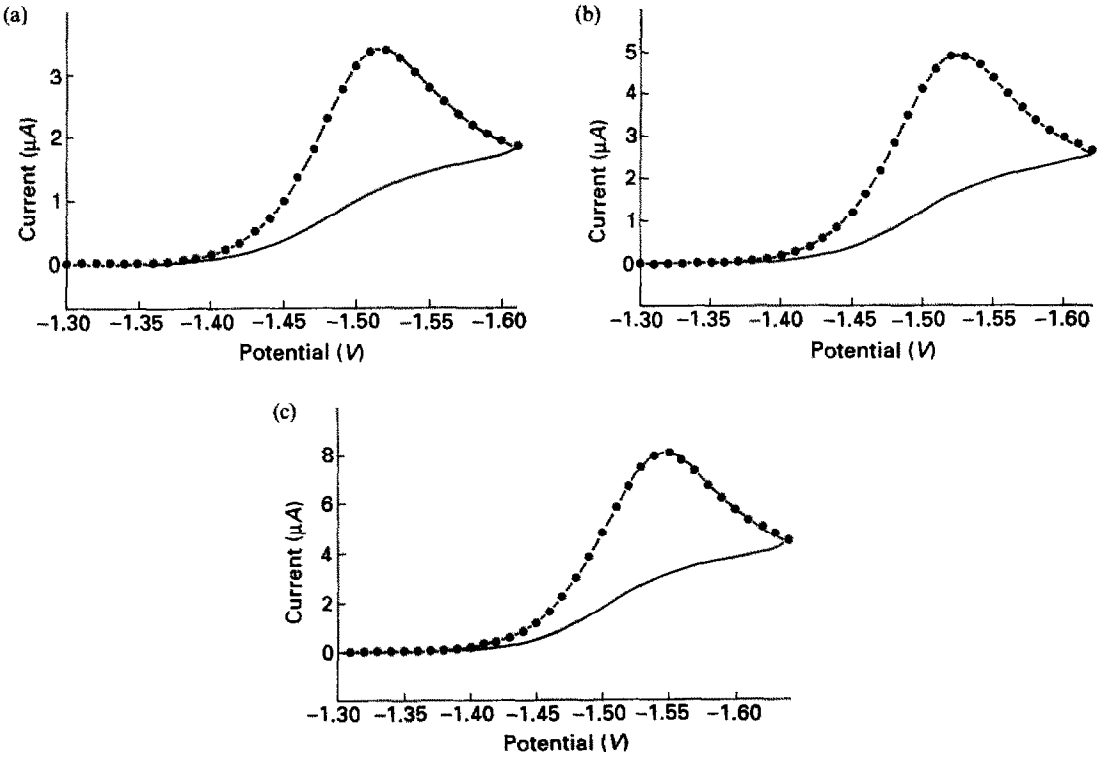

Fig. 2. Cyclic voltamperograms of 2.0mM methylcobalamin in a solvent mixture of DMF (40%) and methanol (60%) at −30°. The supporting electrolyte is TBAF in 0.30M and the working electrode is a silver amalgam electrode in diameter 1.6 mm. The simulation-fitting results of parameter are shown in Table 1. Solid lines are experimental data and solid dots are the simulation-fitting results. Scan rates: (a) 50 mV/sec; (b) 100 mV/sec and (c) 300 mV/sec.

wave on the reserve scan. The digital simulation and fitting results from CVFIT program are also shown on the same voltamperograms. The input parameters of the program included diffusion coefficient D_0, the rate of the following chemical reaction k_{chem}, the resistance R, and experimental condition including scan-range and scan-rate. First guess parameters were provided for the formal reduction potential $E^{0'}$, the standard heterogeneous charge transfer constant k^0, the transfer coefficient α, and a proportionality constant that includes small errors in concentration of methylcobalamin and the electrode area. The program CVFIT utilized Nelder and Mead's modified simplex minimizing procedure to find the best fit between the experimental and simulation results by adjusting these guesses in the simulation process.[9,15,16] (The diffusion coefficient used at $-30°$ was measured by DPSC in the time window of constancy $it^{1/2}$ and checked by CV.) The iR drop was corrected by adding each experimental point of current multiplied with the measured solution resistance to the applied potential, then the calibrated potential (E) was used through equation (5) in simulation:[17]

$$E = E_{applied} + iR \tag{5}$$

The errors are estimated by summation of the square of the difference between experiment and simulation-fitting current for corresponding potentials:

$$\chi^2 = \sum_{j=1}^{n} W_j[\text{current}_j(\text{measured}) - \text{current}_j(\text{theory})]^2 \tag{6}$$

where the weighting factor W_j is set to one in the case of constant variance.

The formal reduction potentials, the heterogeneous rate constants and the transfer coefficients obtained through simulation-fitting are listed in Table 1. The constancy of the reduction potential and other fitted parameters for repeat experiments and the experiments at three different scan-rates provides strong evidence that the values obtained are not spurious or the result of the location of fortuitous local minimum in the fitting procedure. In addition, the $E^{0'}$ value is in agreement with the less precise value (-1.6 V *vs.* SCE) obtained by Lexa and Saveant in the similar experimental condition with fast scan-rate.[4]

In order to estimate the error of the $E^{0'}$ measurement which is caused by the error in the measurement of the following chemical reaction k_{chem}, a series of CV simulations with different scan-rates and k_{chem} were performed. It was found that the deviation in k_{chem} would not affect $E^{0'}$ measurement in our electrochemical system. At a scan-rate of 300 mv/sec, the peak potential shift is less than one millivolt as k_{chem} changes from 490 to 690 sec^{-1}; and the shift is 1 mV in the same k_{chem} change range at the scan-rate 50 mV/sec.

It has been suggested that the reduction potential can be estimated at slow scan-rates by assuming electron transfer reversibility and applying the formula for the kinetic shift due to the following chemical reaction under such circumstances:[10,18]

$$E^{0'} = E_p + 0.780\frac{RT}{nF} - \frac{RT}{2nF}\ln\left(\frac{RT}{nF}\frac{k_{chem}}{v}\right) \tag{7}$$

where E_p is the peak potential in CV and v is the scan-rate. Application of this formula to our system even at the slowest scan-rate (50 mV/sec) leads to an error in the reduction potential of 30 mV compared to that obtained by the more rigorous method presented here (± 4 mV).

From the simulation and fitting results, we obtained α equal to 0.78. A value of $\alpha > 0.5$ indicates that the structure of the transition state for reduction is close to the reactant.[10] Our results ($\alpha = 0.78$) support the mechanism in Scheme 1 where the transition state $[B^{\bullet}_{12a}]^-$ is

Table 1. Simulation-fitting results for methylcobalamin electrochemical parameters at $-30°$. The iteration indicates the simplex iteration times. The resistance measured and used in CVFIT program is 1650 Ω

expected to have a similar structure to the reactant B_{12a}.

Although the cyclic voltamperograms appear irreversible, analysis of the data showed this is not entirely the case (otherwise we could not expect to obtain a reliable $E^{0\prime}$).* In order to understand this more fully we carried out a study of the reversibility of the system. The electrochemical current corresponds to the difference between the rate of the forward electron transfer $k_f[B_{12a}]$ and its rate $k_b[B^{\bullet}_{12a}]^-$ for the reverse process. However, with a following chemical reaction, the reversibility of the system will be influenced. If the following chemical reaction-rate is much faster than the rate of the reverse electron transfer, the rate of the forward electron transfer will become rate limiting. Under these circumstances, the electrochemical process is totally irreversible. If the rate of the forward electron transfer is not completely rate limiting, the system is described as quasi-reversible. In general the reversibility of an EC mechanism depends on the heterogeneous kinetics, the homogeneous kinetics and the scan-rate. The reversibility factor f_r, introduced by Klingler and Kochi,[19] describes the reversibility of the system. It is a continuous function of the electrode kinetics varying smoothly from $f_r = 1$ for Nernstian behavior to $f_r = 0$ for total irreversibility. It can also be applied to estimate the error range for the transfer coefficient α. The reversibility factor f_r for the methylcobalamin system is described as

$$f_r \frac{[B_{12a}]_0}{[B^{\bullet}_{12a}]_0^-} = \exp\left[\frac{nF}{RT}(E - E^{0\prime})\right] \qquad (8)$$

where $[B_{12a}]_0$ and $[B^{\bullet}_{12a}]_0^-$ are the corresponding concentrations on the electrode surface in Scheme 1. These concentrations can be obtained from the digital simulation by extrapolating the concentrations in the first few spatial grid points of the simulation to the electrode surface. The variation of the reversibility factor f_r as the function of the heterogeneous charge transfer constant is shown in Fig. 3. The reversibility factors f_r were evaluated at the corresponding peak potential. The results demonstrate that electrode reversibility is actually a continuum, with total irreversibility merely being one limiting extreme. For the value of the chemical rate constant in our system ($k_{chem} = 590$ sec^{-1}), the reversibility factors have a maximum value of $f_r = 0.73$ as the heterogenous rate increases. We are particularly interested in the reversibility under the conditions of our experiments. The CV simulations for methylcobalamin at $-30°$ result in reversibility factors $f_r = 0.18$ at scan-rate 300 mV/sec and $f_r = 0.21$ at 50 mV/sec. Both of them are close to the root of the curve, but they are not completely irreversible even though the cyclic voltamperograms appear "irreversible".

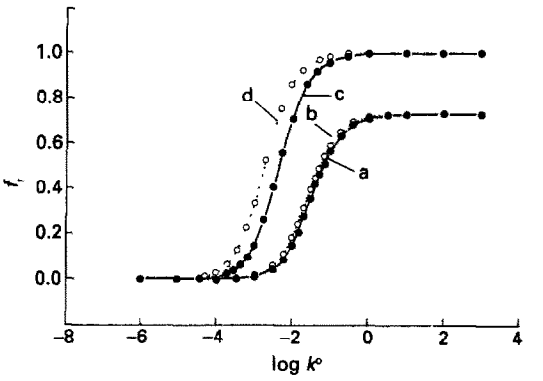

Fig. 3. The relationship of the reversibility factor f_r and the heterogeneous charge transfer constant k^0. The concentrations of the electroactive species in the electrode surface were evaluated at the peaks of cyclic voltamperogram by digital simulation with $E^0 = -1.529$ V, $\alpha = 0.78$, $D_0 = 1.8 \times 10^{-6}$ cm^2/sec at $-30°$. The reversibility factor f_r was calculated through equation (8). (a) 300 mV/sec and $k_{chem} = 590$ sec^{-1}, (b) 50 mV/sec and $k_{chem} = 590$ sec^{-1}, (c) 300 mV/sec and $k_{chem} = 0$ sec^{-1}, (d) 50 mV/sec and $k_{chem} = 0$ sec^{-1}.

The charge transfer coefficient α is an important electrochemical parameter. For a totally irreversible system, α is given by [10,19]

$$\alpha = \frac{1.857RT}{nF}\frac{1}{|E_p - E_{p/2}|} \qquad (9)$$

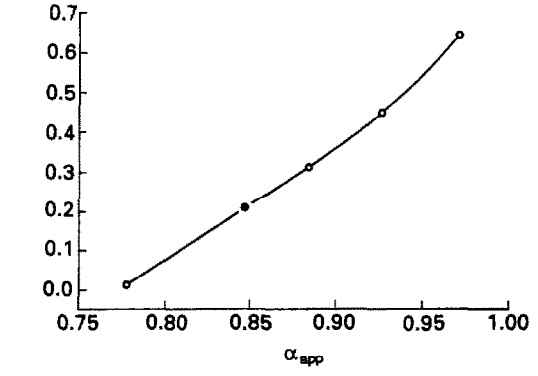

Fig. 4. The relationship of the reversibility factor f_r and the apparent transfer coefficient α_{app}. The solid point represents the simulation and fitting result of Fig. 2(a), estimated through equation (9).

*An examination of the Butler–Volmer equation suggests that both forward and reverse processes must be occurring in order to separate the three terms $E^{0\prime}$, k^0 and α.

Table 2. Various measurements of α. The values of α_{app} are measured from experimental results through equation (9). The values of $\alpha_{app,corr}$ are the experimental results measured through equation (9) and corrected through equation (10). The values of α_{fit} are measured from simulation-fitting of the cyclic voltamperograms with input $E^{0\prime} = -1.529$ V, $k^0 = 0.012$ cm/sec, $D_0 = 1.8 \times 10^{-6}$ cm^2/sec and $k_{chem} = 590$ sec^{-1} at $-30°$

Rate, mV/sec	α_{app}	$\alpha_{app,corr}$	α_{fit}	f_r
300	0.72	0.80	0.76	0.18
	0.71	0.80		
	0.71	0.80		
	0.71	0.80		
100	0.76	0.83	0.80	0.20
	0.78	0.84		
	0.78	0.84		
	0.78	0.84		
50	0.81	0.85	0.77	0.21
	0.81	0.86		
	0.81	0.86		
	0.81	0.86		

where $E_{p/2}$ is the potential of half peak. We expect that α_{app} obtained in this manner will be a reasonable value even though the system is not totally irreversible. Klingler and Kochi's results[19] and our digital simulation data also show the influence of f_r to α_{app} values by equation (9); the larger α_{app} value will have the smaller error if a system has similar irreversibility. Since $\alpha = 0.78$ in this system, we expect a small error estimating α_{app} through equation (9) if f_r is in the foot area of the curves *a* and *b* in Fig. 3. The small error in potentials used in equation (9) due to *iR* drop also results in errors of α_{app} values. We introduce *iR* correction into equation (9) in the following way:

$$E_p - E_p/2 = (E_p - i_p R)_{exp} - (E_{p/2} - i_{p/2} R)_{exp}$$
$$= (E_p - E_{p/2} - \tfrac{1}{2} i_p R)_{exp} \quad (10)$$

where i_p is the peak current and $i_{p/2}$ is the half wave height peak current. The values of $\alpha_{app,corr}$ from measurements after *iR* correction through equation (10) in cyclic voltamperograms are listed in Table 2. These results are consistent with the α values obtained by simulation. Figure 4 shows the influence of f_r to α values by estimation calculated from simulation and through equation (10). The error is also consistent with the experimental measurements. The reason for slightly larger values in $\alpha_{app,corr}$ than that in α_{fit} is that the system is not completely irreversible or f_r is not small enough.

MICELLAR CATALYSIS IN KINETIC METHODS OF ANALYSIS: IMPROVEMENT OF SPECTROPHOTOMETRIC CATALYTIC DETERMINATION OF COPPER

Mª Loreto Lunar, Soledad Rubio and Dolores Perez-Bendito
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(*Received* 7 *October* 1991. *Revised* 20 *January* 1992. *Accepted* 10 *February* 1992)

Summary—The combined effects of micellar and chemical catalysis were studied with a view to improving the features of catalytic kinetic determinations. For this purpose we chose the reaction between *N,N*-dimethyl-*p*-phenylenediamine (DPD) and *N,N*-dimethylaniline (DA) to form Bindschedler's Green leuco base, which is oxidized by hydrogen peroxide in a reaction catalysed by Cu(II). This reaction was found to be accelerated by anionic sodium dodecylsulphate (SDS) and cationic dodecyltrimethylammonium bromide (DTAB) micelles. Several advantages were gained in relation to the analytical features of the kinetic photometric determination of Cu(II) when the reaction was developed in the presence of micelles compared to that occurring in an aqueous medium. Such advantages include a lower detection limit, higher sensitivity, precision and solubility of DPD and DA, and substantially increased selectivity in some cases. A detailed study of the parameters which influence both reactions is reported. Some observations on the effect of SDS and DTAB on the reaction are also commented on.

The fact that micelles accelerate chemical reactions is being increasingly frequently exploited to improve determinations of substrates[1–3] and catalysts[4–6] by using kinetic methods. Micellar catalysis has been rationalized in terms of favourable reagent distribution and/or changes in the apparent dissociation constants of ionizable functional groups. Various quantitative kinetic treatments have been developed to assess the intrinsic reactivity of substances in micelles.[7–12]

The analytical features of kinetic methods can be enhanced by confining the chemical reaction in micelles. Thus, sensitivity can be greatly augmented as a direct result of the increased effective concentration of reactants on the micellar surface. Enhanced selectivity with respect to some interferent ions has also been reported.[2,6] It is very difficult however to predict the potential advantages that micelles can provide in relation to this analytical feature because of a number of factors affecting the behaviour of foreign ions in micellar media. The use of micelles as catalysts can also shorten analysis times, increase sample throughputs and make assays more convenient and less expensive. In this context, there are some examples in the literature in which the reaction time of photometric[13] and fluorimetric[14] methods has been reduced from 90–120 min to only 1–5 min.

The greater experimental convenience that can be achieved if kinetic measurements are made in an appropriate micellar medium is particularly desirable for those methods permitting the analyte to be determined with a high sensitivity but suffering from drawbacks such as the involvement of different consecutive reactions that must occur under different experimental conditions and/or long reaction times. This paper reports an example of this type of application of micelles. A previously reported[15] sensitive catalytic method for the spectrophotometric determination of Cu(II) was selected. It is based on the reaction between *N,N*-dimethyl-*p*-phenylenediamine (DPD) and *N,N*-dimethylaniline (DA) to yield Bindschedler's Green leuco base (BGL), which is oxidized by hydrogen peroxide to a colored compound ($\lambda = 730$ nm). Copper(II) catalyses this oxidation, which allows its determination between 0.2 and 2 ng/ml with good selectivity. However, the working curve is not linear and preparation of the samples involves two steps, each of which takes about ten minutes. Also, it is necessary to quench the reaction by placing the vessel in ice cold water and measure the absorbance within 20 min. In addition, solubility problems must be considered when DPD and DA concentrations in the reaction medium are increased above 1×10^{-4} and $1.5 \times 10^{-2} M$, re-

spectively. As shown below, implementation of this method in the presence of micelles is much more convenient.

EXPERIMENTAL

Apparatus

Kinetic measurements were made on a Hewlett–Packard 8452 A diode array spectrophotometer furnished with 1-cm quartz and glass cells. The temperature of the cell compartment was kept at constant temperature by circulating water through it. Kinetic data were collected and processed by a Hewlett–Packard Vectra E/S 12 computer interfaced to a ThinkJet printer.

Reagents

All reagents used were of analytical grade and were employed as supplied. Doubly distilled water was used throughout. A stock Cu(II) solution was prepared by dissolving 1.000 g of Cu metal (Merck) in 15 ml of concentrated nitric acid and diluting up to one litre with 1:1 nitric acid. Working solutions ($1.57 \times 10^{-5}M$) were prepared daily by dilution with doubly distilled water. A $3.39 \times 10^{-3}M$ solution of *N,N*-dimethyl-*p*-phenylendiamine (DPD) (Aldrich) was prepared daily in 1:1 ethanol water. A $0.28M$ *N,N*-dimethylaniline (DA) (Aldrich) solution in ethanol was also prepared. Hydrogen peroxide solution ($2.0\,M$) was prepared daily. Buffer solutions of pH 6.0, 7.0 and 7.8 were made by mixing disodium hydrogen phosphate dihydrate and ammonia (final concentrations in the mixture 0.1 and $1.07M$) with the appropriate volume of $2M$ hydrochloric acid. Aqueous dodecyltrimethylammonium bromide (DTAB) (Sigma) ($1.62 \times 10^{-1}M$) and sodium dodecylsulphate (SDS) (Aldrich) ($6.94 \times 10^{-2}M$) solutions were also prepared. Solutions of the other surfactants tested, *viz.* cetylpyridinium chloride (CPC) (Serva), sodium dioctyl sulphosuccinate (Aerosol OT) (Aldrich), Triton X-100 (Serva), cetyltrimethylammonium bromide (CTAB) (Serva) and *N*-dodecyl-*N,N*-dimethylammonium-3-propanesulphonate (SB-12, sulphobetaine) (Serva) were prepared in a similar way. Less readily soluble surfactants were dissolved with warming.

Procedures for the kinetic photometric determination of copper(II)

In the presence of SDS. To a 10-ml standard flask are added, in sequence, 0.30 ml of $3.39 \times 10^{-3}M$ DPD, 0.50 ml of $0.28M$ DA, 1.5 ml of ammonia–phosphate buffer (pH 7.8), 2 ml of $6.94 \times 10^{-2}M$ SDS, 1.0 ml of $2M$ hydrogen peroxide and appropriate volumes of Cu(II) standard solution ($1.57 \times 10^{-5}M$) to obtain a final concentration between 1.5 and 5 ng/ml. The stopclock is then started and the solution is diluted to the mark with water. An aliquot of the reaction mixture is transferred to a cell kept at $50 \pm 0.1°$ and the absorbance at 730 nm is recorded as a function of time. Measurements are performed exactly 45 sec after the stopclock is started. Absorbance–time data are collected over an interval of *ca.* 1 min. The reaction rate is calculated by a linear least-squares fit of the data using the kinetics module of the HP 89531 A UV/Vis operating software. A blank solution containing no Cu(II) and prepared similarly is also measured and the resulting reaction rate subtracted from that yielded by the samples.

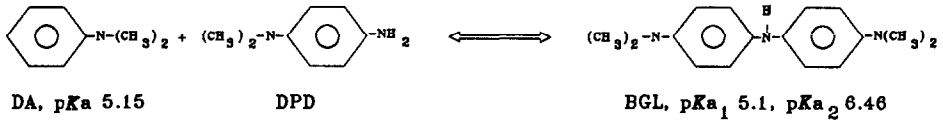
In the presence of DTAB. The procedure and reactant concentrations used to prepare the sample and blank solutions used in the presence of DTAB are identical with those given above, except that 0.35 ml of $3.39 \times 10^{-3}M$ DPD, 1.5 ml of $1.62 \times 10^{-1}M$ DTAB and 1.5 ml of ammonia–phosphate buffer (pH 7) solutions are added instead of the DPD, SDS and buffer solutions, respectively. The final concentration of Cu(II) must be between 1 and 6 ng/ml.

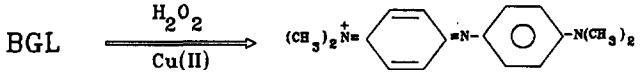
RESULTS AND DISCUSSION

Copper(II) ion catalyses the oxidation of the Bindschedler's Green leuco base (BGL) by hydrogen peroxide. The reagent is formed *in situ* by reaction of DPD and DA. According to Kawashima *et al.*,[15] *in situ* formation is compulsory since high reagent blank readings are obtained if commercially available BGL is used, probably because of the oxidation and/or decomposition products of BGL formed during its storage. Since the proposed experimental procedure requires about 25 min to obtain each measurement, with time control at 10 and 20 min we tested the possibility of making the assay more convenient and reducing the analysis time by carrying out the reaction in an appropriate micellar medium.

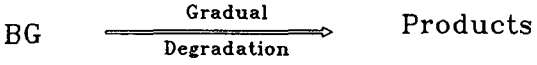
Selection of the micellar system

In order to choose an appropriate micellar system to increase the rate of this reaction, one must take into account the type of charge the reactants bear since the accelerating effect of





BG, pKa 3.27



Scheme 1.

micelles arises essentially from electrostatic and hydrophobic interactions between the reactants and the micellar surface. The simplified scheme of the overall reaction and the dissociation constant of hydrogen ions at the dimethylamino groups as reported in the literature are shown in scheme 1.

No data were found for the dissociation constants of DPD. Because of the different reactions involved and the changes that the micelles can induce in the acid constants of the reactants it was quite difficult to predict which type of micelle would increase the rate of the overall reaction at the pH values (6–8) tested. Thus, surfactants of different nature [cationic (DTAB, CPC, CTAB), anionic (SDS, Aerosol OT), nonionic (Triton X-100) and zwitterionic (SB-12)] were tested. Since it is rather difficult to determine the exact critical micelle concentration (cmc) of surfactants in dynamic systems where species are consumed and produced as a function of time hence the cmc value may change throughout the reaction, we assayed surfactant concentrations over a wide range encompassing their cmc in water in order to ensure that micelles of each tested surfactant were obtained under the experimental conditions used. The assays were carried out by mixing all ingredients involved in the reaction according to the procedure described in the Experimental section and monitoring the overall reaction by measuring the rate of formation of BG at 730 nm. The cationic surfactants DTAB, CPC and CTAB, and the anionic surfactant SDS increased both the rate and the final absorbance of the recorded kinetic curves. Aerosol OT and Triton X-100 had no influence on the reaction and SB-12 decreased its rate. The most significant catalytic effect was exerted by DTAB and SDS, so, they were chosen for subsequent experiments. Figure 1 shows the kinetic curves obtained for both surfactants compared to that obtained in an aqueous medium. Although the acceleration of the reaction rate induced by both surfactants was similar, the shape of the resulting kinetic curves was rather different (BG is more stable in SDS than it is in DTAB micelles) and it seems logical to think that both surfactants act on the reaction in a different way. As shown in Fig. 1, the reaction also developed in an aqueous medium, but the sensitivity for the determination of Cu(II) was smaller compared to that obtained in the above described procedure[15] in which reagents are mixed in two steps.

The influence of the concentration of SDS and DTAB on the reaction rate is shown in Fig. 2 for the uncatalysed and Cu(II)-catalysed reaction. Both surfactants enhance the accelerating

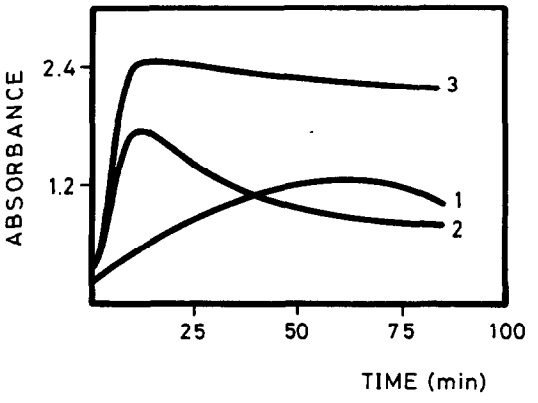


Fig. 1. Absorbance-time kinetic curves for the reaction in an aqueous (1), DTAB (2) and SDS (3) medium. $[DA]=6\times10^{-3}M$, $[DPD]=5\times10^{-5}M$, $[H_2O_2]=0.2M$, [Cu(II)]=4 ng/ml, pH = 6, T = 30°. Procedure as described under Experimental.

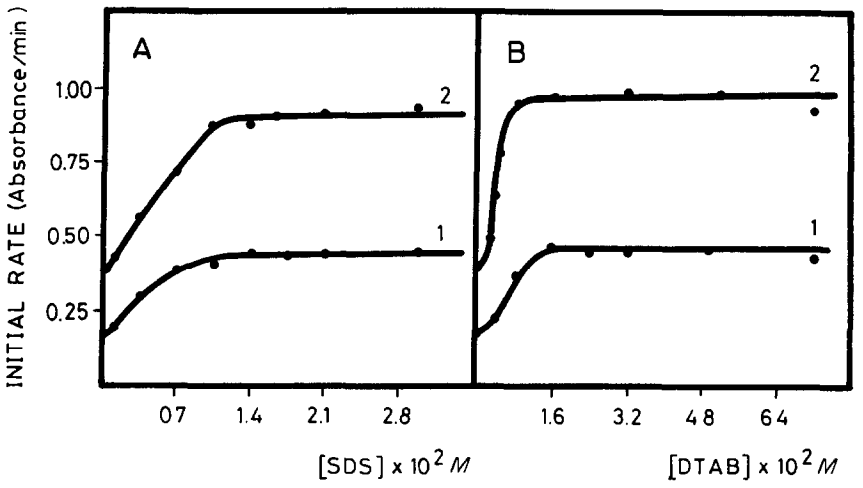

Fig. 2. Influence of the concentration of SDS (curves A) and DTAB (curves B) on the rate of the uncatalysed (curves 1) and Cu(II)-catalysed (curves 2, 4 ng/ml) BGL oxidation reaction. Solutions were prepared as described under Experimental.

effect of the catalyst, as can be inferred from the Fig. 2 by comparing the reaction rate increments of curves 1 and 2 at the SDS concentrations 0 and $1.4 \times 10^{-2}M$ and at the DTAB concentrations 0 and $2.5 \times 10^{-2}M$. Therefore, the kinetic determination of Cu(II) in the presence of these surfactants will be more sensitive compared to that developed in the aqueous medium.

Effect of DTAB and SDS on the reaction

In order to study the action of DTAB and SDS on the Cu(II)-catalysed DPD–DA–hydrogen peroxide reaction we must first consider the net changes that these surfactants induce on the reaction features. The observed alterations were as follows (Fig. 1):

Acceleration of the formation of the oxidation product, which is monitored at 730 nm.
Modification of the maximal absorbance obtained from the kinetic curves recorded.
Variation of the rate of degradation of BG.

Since the overall reaction includes at least three consecutive reactions (see Scheme 1) and, on the other hand, BG and BGL were not commercially available from major chemical manufacturers, it was very difficult to establish the real action of each surfactant on the studied reaction. However, several experiments (described below) permitted us to shed some light on the observed alterations to the reaction features caused by the presence of SDS and DTAB.

DA and DPD-micelles interaction. Reagent–micelle interactions can often be made evident by shifts in the absorption spectrum of the reagent when this is dissolved in the micelle. If no spectral shifts are observed, then other methods such as solubilization, separation, cmc depressions induced by the solute, *etc*, can be used. To determine whether there is any interaction between DA, DPD with SDS or DTAB several experiments were done.

DA–micelle interaction was shown to occur by recording the spectra of $6 \times 10^{-3}M$ DA at pH 7 and 7.8 in aqueous and in DTAB- and SDS-micellar media. The pH values used did not influence the spectral features of DA. SDS and DTAB modified the DA spectrum by introducing a shoulder at about 310 nm (Fig. 3). Because cationic (DTAB) and anionic (SDS) micelles had the same effect, and taking into account the p*K*a value of DA in the aqueous medium (5.15), it is logical to think that DA is uncharged in the reaction medium and that hydrophobic interactions are determinant for the DA–DTAB and DA–SDS association. The identical behaviour of both surfactants is not difficult to understand if one considers that SDS and DTAB are made up of the same hydrophobic chain.

DPD–micelle interaction was difficult to evidence spectrophotometrically at the DPD concentrations used in the reaction medium (about 100-fold lower than that of DA) since DPD only absorbs in the UV region where SDS and DTAB also absorb. In order to study this interaction we used solubilization methods

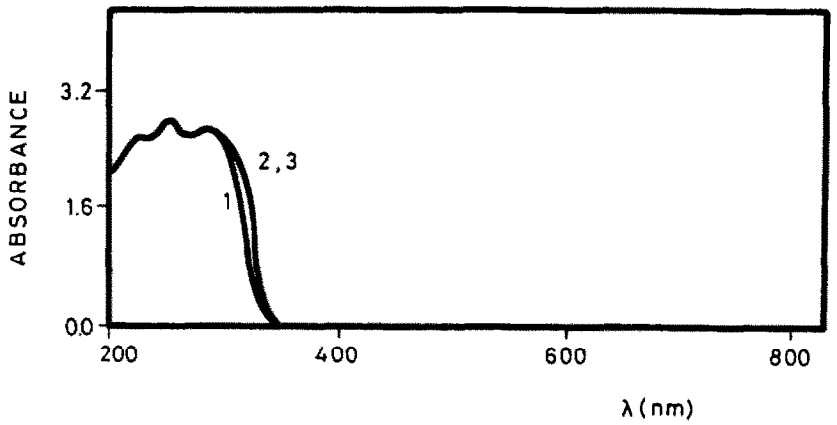

Fig. 3. Absorption spectra of $6 \times 10^{-3}M$ DA in an aqueous medium (1) and in DTAB (2) and SDS (3) micelles.

based on the enhancement of the solubility of some solutes by the presence of micelles. Qualitative experiments were carried out by assaying the solubilization of DPD $5.87 \times 10^{-4}M$ in the three media, namely: water, DTAB and SDS micelles. The reagent was only completely dissolved in SDS micelles. Saturated solutions were obtained in water and DTAB, although more reagent was dissolved in DTAB micelles. Since all solutions obtained were coloured we used the spectrophotometric technique to compare the amount of reagent dissolved after separation of no solubilized reagent. Figure 4 shows the results obtained. DTAB (curve 2) does not substantially alter the spectral features of DPD in the aqueous medium (curve 1), although a greater absorbance is obtained as a result of the greater solubilization of DPD in the micellar medium. In addition to significantly increased solubility of DPD, SDS causes a long shift in the spectral features of this reagent (curve 3). This experiment was also done at pH 7 and 7.8 and identical results were obtained. The divergent behaviour in the presence of SDS and DTAB seems to indicate a different mechanism for the solubilization of DPD in both micelles. Thus, the dimethylamino group is likely to be uncharged at the working pH used and DPD can associate to DTAB through it. The amino group, however, may bear a positive charge through which SDS can bond strongly to DPD.

Since both DA and DPD were concentrated on or within SDS and DTAB, real micellar catalysis occurred. This explains why the order of addition of reactants in determining Cu(II) must be such that the surfactant is added with DA and DPD to obtain the maximum possible signal.

Bindschedler's Green-micelles interaction. The interaction of BG with SDS and DTAB can shed some light on the alteration of the maximal absorbance in the kinetic curves obtained and/or the rate of degradation of BG in both micellar media (Fig. 1).

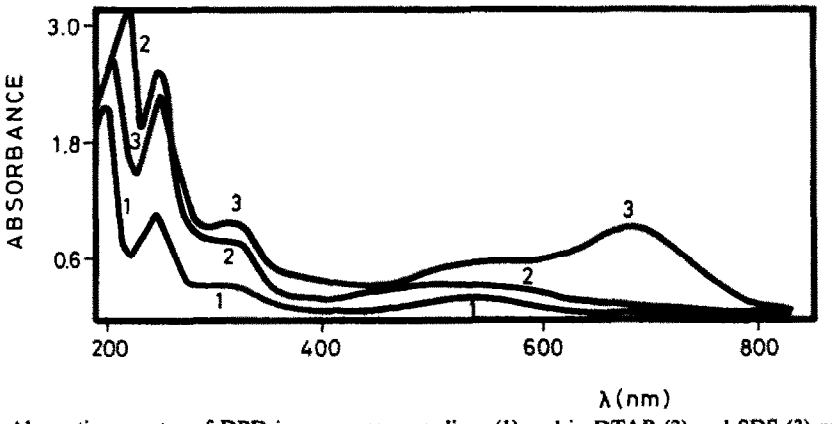

Fig. 4. Absorption spectra of DPD in an aqueous medium (1) and in DTAB (2) and SDS (3) micelles. For the DPD concentrations used, see text.

Micelles are known to increase the molar absorptivity of compounds, which result in increased final absorbances and apparently increased reaction rates if reaction development is monitored via the formation or disappearance of the compound. In order to clarify this point several experiments were done in which the potential sensitization of BG by SDS and DTAB was investigated. The experiments were carried out by mixing all reaction ingredients according to the procedure described in the Experimental section, but adding no SDS or DTAB. Once the reaction was complete, SDS or DTAB was added and both the absorbance obtained after the addition of surfactant and its evolution with time for about one hour was observed. This evolution was compared with that obtained in the absence of surfactant and is shown in Fig. 5, from which some important conclusions can be drawn. The absorbance of BG is not altered when SDS or DTAB is added (compare the absorbance at time zero in Fig. 5), so no sensitization of BG by these micelles occurs.

SDS substantially increases the stability of BG (curve 3, Fig. 5) with respect to the aqueous medium (curve 1, Fig. 5). DTAB does not influence the rate of degradation of BG (curve 2), so the apparently greater instability in this micellar medium (Fig. 1) is probably a direct result of the greater rate of formation of BG. Other variables such as temperature, reagent concentrations, *etc.*, also influence the rate of degradation of BG, probably because of similar causes. This instability is not improved by addition of non ionic surfactants such as Brij 35 or Triton X-100.

The stabilization of BG in the SDS micellar medium is logical if one considers that this reaction product is positively charged (see scheme 1), so it can bond tightly to anionic micelles. The BG–SDS micelles interaction does not modify the spectral features of BG.

Study of the optimum reaction conditions

The effect of the different variables affecting the reaction rate was studied in the presence and absence of SDS or DTAB. Blank reactions involving no Cu(II) were also examined. The optimum conditions resulted in a maximum initial rate, which corresponded to pseudo-zero-order concentrations. Hence, the initial reaction rate was not affected by small variations in the concentrations.

Figure 6(A) shows the variation in the initial rate as a function of pH for the Cu(II) (curve 1), DTAB–Cu(II) (curve 2) and SDS–Cu(II)-catalysed (curve 3) reactions. The initial rates yielded by the blanks [without Cu(II)] were subtracted prior to plotting. Since the reaction practically does not occur in the absence of ammonia, the net effect of the pH could not be determined. This variable was studied by keeping the buffer concentration constant and changing the pH by adding sodium hydroxide or hydrochloric acid. As shown in Fig. 6(A), the surfactants studied shift the optimum pH range at which the reaction takes place. The shift is not directly related to changes in the ionization constant of the reactants as both the anionic and the cationic surfactant resulted in an effect of the same sign. The pH was adjusted with an ammonia–phosphate buffer. The reaction rate increased with the ammonia concentration, at

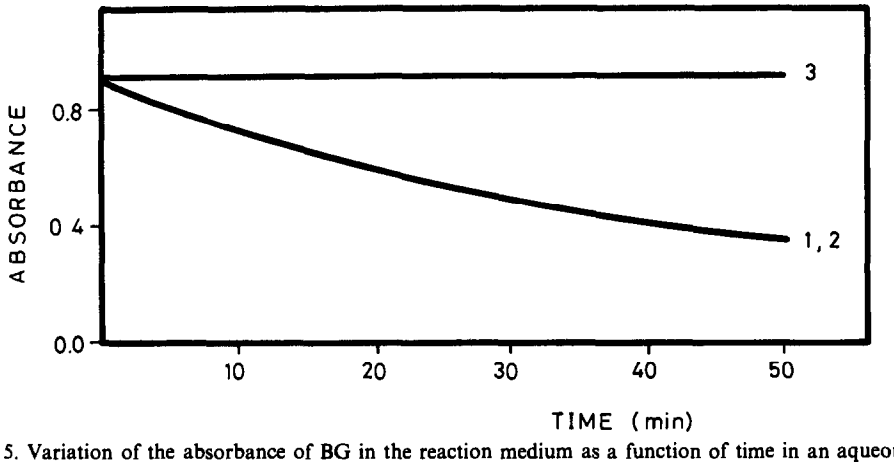

Fig. 5. Variation of the absorbance of BG in the reaction medium as a function of time in an aqueous medium (1) and in DTAB (2) and SDS (3) micelles.

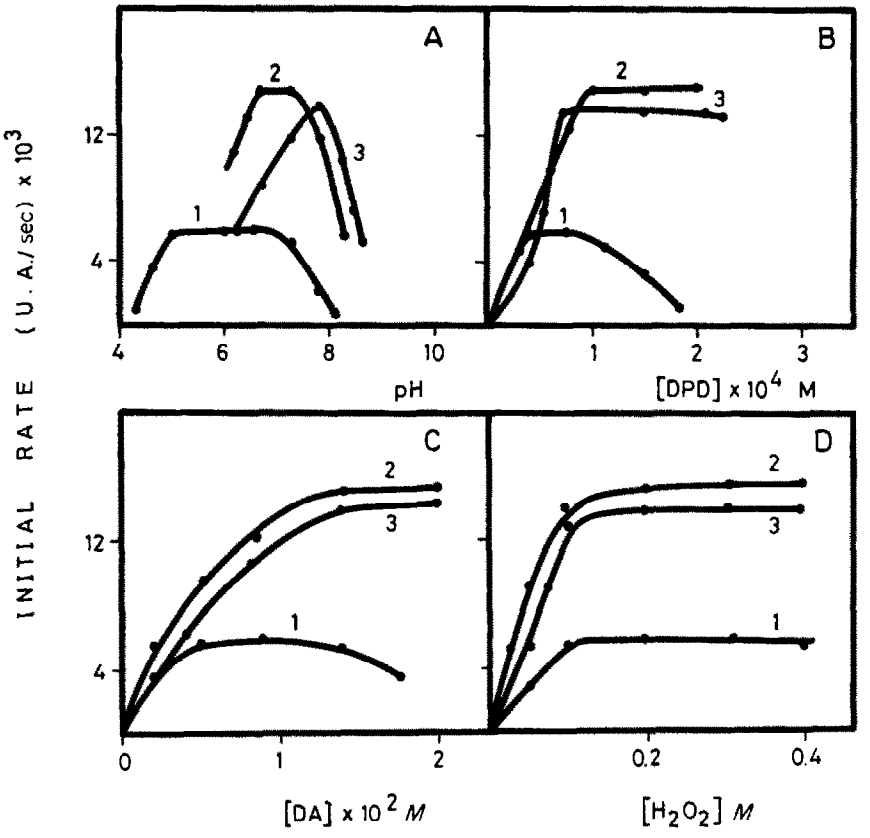

Fig. 6. Influence of (A) pH and the concentration of (B) DPD, (C) DA and (D) hydrogen peroxidse on the rate of the Cu(II) (curve 1), Cu(II)–DTAB (curve 2) and Cu(II)–SDS-catalysed (curve 3) DPD–DA–H_2O_2 reaction. Temperature = 50°.

least up to 0.65*M*. However, buffer concentrations higher than 0.2*M* resulted in irreproducible kinetic curves, so 0.16*M* was selected as optimal. The influence of the phosphate concentration on the different systems was studied over the 1×10^{-3}–$1 \times 10^{-1}M$ range. The reaction rate remained virtually constant and maximum between 1×10^{-2} and $2 \times 10^{-2}M$ phosphate.

The dependence of Cu(II)-catalysed reactions [curve 1, Figure 3(B)] on the DPD concentration is rather different from that shown by the Cu(II)–DTAB and Cu(II)–SDS-catalysed reactions [Fig. 6(B), curves 2 and 3, respectively] at DPD concentrations higher than about $8 \times 10^{-5}M$. This is probably due to the insolubilization of the reagent in the aqueous reaction medium above this concentration. Something similar occurs at DA concentrations above $1.5 \times 10^{-2}M$ [Fig. 6(C)]. Micelles solubilize both reagents.

Figure 6(D) shows the variation in the initial rate with the hydrogen peroxide concentration for the different reactions. This initial rate was found to depend linearly on the hydrogen peroxide concentration up to about 0.1*M*, above which it rapidly dropped to zero order. A 0.2*M* hydrogen peroxide concentration was selected in order to ensure maximum sensitivity.

The temperature influenced both the rate of formation and that of degradation of BG. The instability of this oxidation product increased with the temperature as shown in Fig. 7 [(A), (B) and (C)] in some kinetic curves recorded for the three studied systems. The dependence of the initial rate of Cu(II)-[Fig. 7(A′)] and Cu(II)–SDS-catalysed [Fig. 7(B′)] reactions on the temperature was similar. The optimum interval was between 40 and 60°. This dependence was more critical for the Cu(II)–DTAB-catalysed reaction [Fig. 7(C′)].

Increasing ionic strengths, which were adjusted with sodium chloride and potassium nitrate, resulted in slightly increased rates for all the systems studied up to 1*M*. Since the presence of an electrolyte in an aqueous solution decreases the cmc of anionic and cationic surfactants,[16] the reaction medium contained enough micelles when the effect of the electrolytes on the

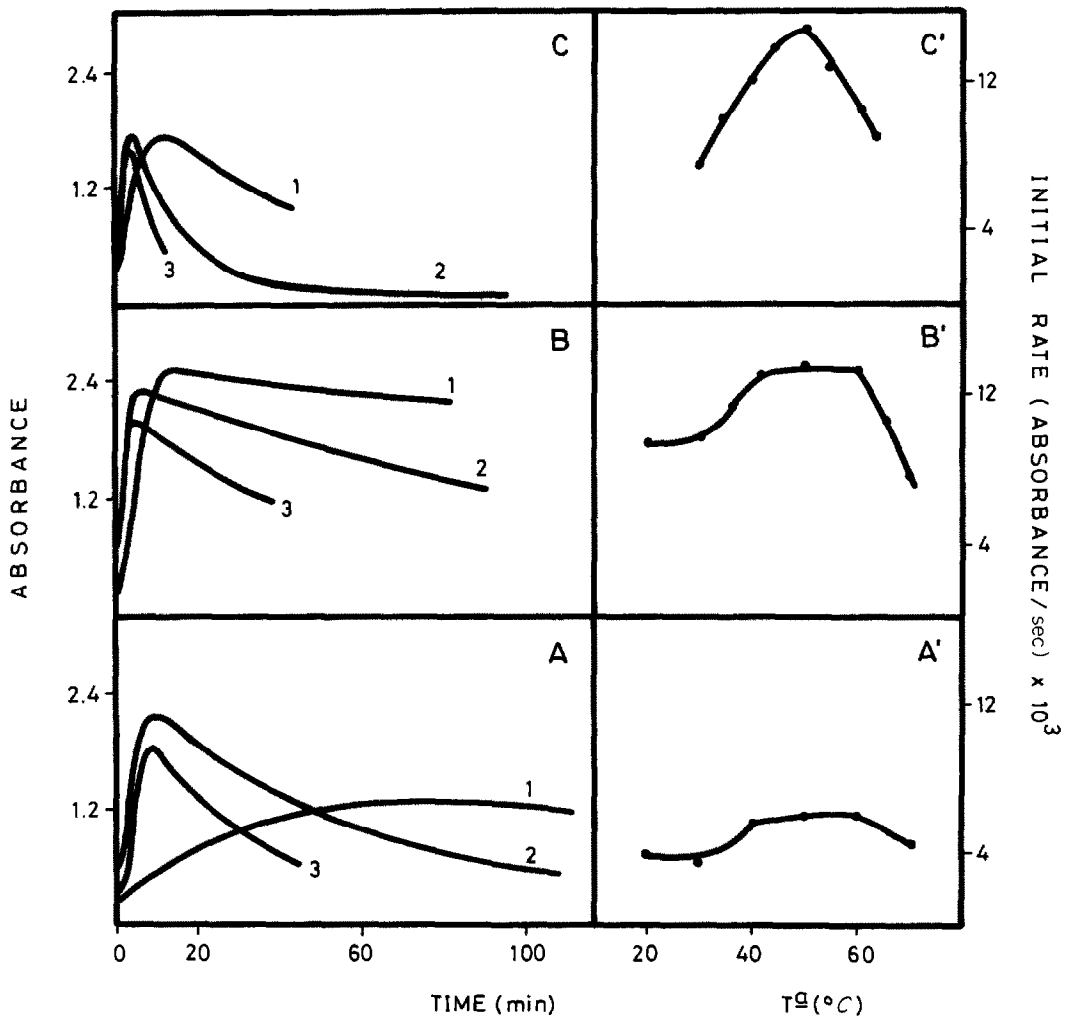

Fig. 7. Influence of the temperature on the profile of the kinetic curves (A, B, C) and initial rate (A', B', C') of the Cu(II) (A, A'), Cu(II)–SDS (B, B') and Cu(II)–DTAB-catalysed (C, C') BGL oxidation reactions. Temperature: curve 1, 30°; curve 2, 50° and curve 3, 60°.

initial rate was tested. Such an effect was similar for all the systems studied (with and without surfactants), so it cannot be attributed to changes in the cmc of the surfactants.

The ethanol concentration had hardly any effect on the reaction rate up to 20%. Higher contents of this solvent decreased the initial rate of all the reactions, particularly that of the Cu(II)–SDS-catalysed reaction. This behaviour is consistent with the common effect of short-chain polar compounds such as ethanol on the cmc of ionic surfactants. Low bulk phase concentrations of these compounds slightly depress the cmc,[17] so the fact that ethanol does not influence the initial rate of the reactions considered up to a concentration of 20% is quite logical. However, at high bulk phase concentrations, ethanol may increase the cmc, probably by decreasing the cohesive energy density of the water, thus increasing the solubility of the monomeric form of the surfactant,[18] or by reducing the dielectric constant of the aqueous phase, thereby increasing mutual repulsion of the ionic heads in the micelle.[19] This increase in the cmc value may diminish the initial rate of the reaction (Fig. 2).

Several orders of addition of reactants were assayed. The order in which Cu(II) and the surfactant were added to the solution was crucial. Optimum results were obtained when the surfactant was mixed with DPD, DA and the buffer and then hydrogen peroxide and Cu(II) were added to the mixture. If Cu(II) was added at the beginning or the surfactant was added at the end, the reaction rate was dramatically decreased.

Analytical features

Calibration graphs for the determination of Cu(II) in the SDS and DTAB micellar media were run under the optimal conditions given in the Experimental section. Their figures of merit are summarized in Table 1, which also includes such analytical features as the detection limit and precision. The same analytical features for the kinetic method, using no surfactant, are also included for contrast. All determined parameters are quite similar for both micellar media. Some advantages over the kinetic method, using no surfactant, include higher sensitivity and precision, and a lower detection limit. The standard errors of the estimates and the correlation coefficients suggest very good linearity, which is quite an advantage over the equilibrium method,[15] in which the calibration graph is not linear.

Since the proposed procedures involve taking measurements when the reaction has hardly developed, the calibration graphs obtained did not allow the determination of Cu(II) concentrations lower than 0.8 ng/ml. The equilibrium method,[15] in which the reaction is allowed to go to completion permits the determination of Cu(II) between 0.2 and 2 ng/ml.

The kinetic procedure is simpler than the equilibrium procedure since it features a shorter analysis time (3 min *vs.* about 25 min) and makes the assay more convenient (the equilibrium procedure involve two steps, each of which takes 10 min, and requires immersing the sample in an ice water bath).

In order to determine whether the micellar media resulted in increased selectivity towards Cu(II), the effect of various ions on the BGL-hydrogen peroxide system in the presence of DTAB and SDS was studied. Table 2 summarizes the results obtained including the type of error (negative, positive, precipitation, *etc.*) caused by the various ions. The maximal tested ion concentration was 100 and 400 μg/ml, respectively, for typical cations and anions, *i.e.*, 50.000 and 200.000 times the concentration of Cu(II). The tolerated concentrations of these ions in the equilibrium method[15] are also included for contrast. No data for the type of error were reported in this reference. Since kinetic methods are often more selective than equilibrium methods, we also studied the tolerated concentrations of the same ions by the kinetic method using no surfactant in order to determine whether increased or decreased selectivity resulted from the kinetic methodology or the micelles used. The results obtained are also included in Table 2. A substantial increase in the selectivity was achieved by the kinetic method compared to the equilibrium method. Micelles provide a further improvement over the kinetic method in the absence of surfactant for ions such as Mn(II), Cd(II), Hg(II), Pb(II), Ni(II), Zn(II), Cr(VI), Mo(VI) and Co(II). Two ions [V(V) and ClO_4^-] and five ions [Ca(II), W(V), Fe(III), Br^- and I^-] are tolerated at lower

concentrations when DTAB or SDS are added, respectively, to the reaction medium compared to the kinetic method using no surfactant. The only instance of lower selectivity in a kinetic method is that of ClO_4^- in the presence of DTAB, and is a result of the precipitation of a quaternary ammonium perchlorate salt that is scarcely soluble in water.[20] There is no clear correlation between the ionic charge of the micelles and the type of error caused by the various ions. On the other hand, since the exact effect of DTAB and SDS on the reaction studied could not be determined accurately as noted earlier, the enhanced or decreased selectivity resulting from the presence of the various ions cannot be accounted for plausibly.

CONCLUSIONS

The features of some analytical kinetic methods can be improved by developing the reactions involved in micellar media. Thus, we have shown the determination of Cu(II) based on its catalytic effect on the BG-hydrogen peroxide reaction to be more sensitive, precise and somewhat more selective in this type of medium. Further research is required in order to establish the advantages with which micellar media can endow kinetic methods of analysis, but previously reported results[4,6] show that real advantages are to be expected for some reactions.

AUTOMATIC KINETIC DETERMINATION OF OXAZEPAM BY THE CONTINUOUS ADDITION OF REAGENT TECHNIQUE

MANUEL CARMONA, MANUEL SILVA and DOLORES PEREZ-BENDITO
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(*Received* 22 *October* 1991. *Revised* 27 *January* 1992. *Accepted* 27 *January* 1992)

Summary—An automatic continuous-addition-of-reagent method for the routine determination of oxazepam based on the formation of a coupling product between diazotized 2-amine-5-chlorobenzophenone (the hydrolysis product of oxazepam) and 1-naphthol in a basic medium is proposed. The reaction is developed by continuously adding basic 1-naphthol to a reaction vessel containing the other ingredients and is monitored spectrophotometrically at 530 nm. The results obtained show the proposed kinetic method to surpass the performance of its conventional equilibrium counterpart as it permits distinguishing the intact drug from its hydrolytic degradation product and is suitable for the determination of oxazepam in dosage forms and urine samples.

Benzodiazepines make a major class of sedative-hypnotic drugs of wide use in the treatment of anxiety and insomnia. They are also the most frequently encountered in cases of drug overdose.[1] The detection and rapid determination of benzodiazepines in various biological and non-biological specimens is therefore of paramount importance in a number of clinical, forensic and pharmaceutical applications. Oxazepam, a 1,4-benzodiazepine derivative of this type, is widely employed as an antidepressant.

Analytical methods currently available for the determination of benzodiazepines in various matrices include gas chromatography[2] and high-performance liquid chromatography procedures[3] that take just a few minutes to complete. In addition, the thermal instability of some of these drugs—particularly oxazepam—complicates their gas chromatography and HPLC analyses for this compound often require careful selection of the mobile phase. As far as the determination of oxazepam is concerned, official pharmacopeias[4,5] recommended a spectrophotometric assay for assaying this drug in dosage form. The spectrophotometric methods used for this purpose are generally based on the acid hydrolysis of this compound, which is followed by ring opening, and the subsequent determination of the benzophenone thus obtained. In fact, oxazepam and other benzodiazepines have been determined in binary mixtures by UV-Vis spectrophotometry using micellar media[6] or by fourth-derivative spectrophotometric techniques after separation by HPLC.[7] In other methods, benzophenone is diazotized with nitrous acid and then coupled with a chromogenic reagent such as *N*-(1-naphthyl)ethylenediamine, Bratton–Marshall reaction,[8,9] or 1-naphthol.[10,11]

A new method for the kinetic determination of oxazepam is presented in this paper. It is based on the rate of coupling between 1-naphthol and diazotized benzophenone obtained from the acid hydrolysis of this drug. This automatic kinetic method is substantially simpler, faster and more sensitive than its equilibrium counterpart and relies on the continuous-addition-of-reagent (CAR) technique.[12] It is quite inexpensive to implement and lends itself readily to routine analyses for benzodiazepines. It has been previously used in various application fields with good results.[13]

EXPERIMENTAL

Reagents

The reagents used were of analytical-reagent grade and distilled water and ethanol were used to prepare the solutions. The oxazepam solution (200 μg/ml) was prepared by dissolving 200.0 mg of the drug (Sigma Chemical Co.) in one litre of ethanol. More dilute solutions were prepared as needed. The coupling reagent solution for the CAR procedure was prepared by mixing 5.0 ml of $3.47 \times 10^{-2}M$ 1-naphthol in 2:3 v/v ethanol/water and 20 ml of $7.5M$

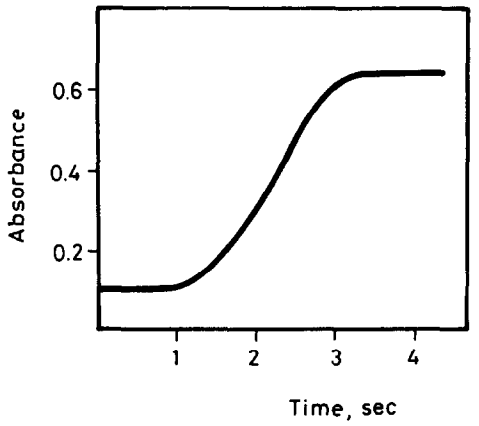

Fig. 1. Typical response curve obtained in the CAR determination of 1.5 μg/ml oxazepam by using the proposed reaction. (For experimental conditions, see Procedure.)

sodium hydroxide in a 50-ml standard flask and diluting to the mark with 2:3 v/v ethanol/water. A $1.45 \times 10^{-2}M$ sodium nitrite solution was also used.

Apparatus

All measurements were made by using a CAR system described elsewhere,[12] which consists essentially of an automatic burette (Mettler DL40), a fan stirrer, a photometric detector (Mettler DK18), an immersion probe (Mettler DK181) for measuring the absorbance in the visible region and a data acquisition and processing unit consisting of a Hewlett–Packard 98561AE computer and a 16-bit Hewlett–Packard analog-to-digital converter provided with a program for the determination of the reaction rate written by the authors. A Radiometer PHM62 pH-meter was also used.

Procedures

Kinetic determination of oxazepam. A volume of standard oxazepam solution (9–220 μg) of up to 10 ml was mixed with the same volume of 6*M* hydrochloric acid in a 100-ml reaction vessel and allowed to stand in a boiling water-bath for one hour. Once the solution was cool, 0.6 ml of $1.45 \times 10^{-2}M$ sodium nitrite solution was added and the mixture was accurately diluted to 60 ml with distilled water. The reaction was developed by continuously adding the coupling reagent solution at a rate of 35 ml/min with stirring at 200 rpm. The reaction was monitored at 530 nm and kinetic data (absorbance *vs.* time) were collected at a rate of 30 msec per point and subsequently processed by the computer. The reaction rate was measured in about 1.0 sec and each sample was assayed in triplicate.

Preparation and analysis of pharmaceutical and clinical samples

Pharmaceutical samples. To prepare the commercial pharmaceutical samples for analyses, a given number of tablets or capsules was ground to a fine powder. The accurately weighed sample was then stirred with 50 ml of ethanol (one portion of 20 ml and two portions of 15 ml) until dissolution was complete. If a residue was formed, it was filtered off and washed with portions of ethanol, and the filtrate and washings were hydrolysed as described above, the final solution being diluted to 100-ml in a standard flask containing ethanol. In all cases appropriate aliquots of these solutions were analysed for oxazepam by the above-described procedure.

Extraction of human urine samples. After collection, the human urine samples (approximate volume 25 ml) were spiked with various known amounts of oxazepam (50 to 450 μg) from the stock solution, pH adjusted to *ca.* 10 with sodium hydroxide and filtered. Next, each filtrate was shaken with 25 ml of methylene chloride in a 100-ml separating funnel for 5 min. The resulting organic extract was evaporated to almost dryness and the resulting residue was dissolved in 30 ml of ethanol and hydrolysed as described above. The remaining solution was diluted with distilled water in a 50-ml standard flask and 20-ml aliquots were used to analyse for oxazepam by using the above-described procedure.

RESULTS AND DISCUSSION

Acidic solutions of diazotized 2-amine-5-chlorobenzophenone (the hydrolysis product of oxazepam) react with basic 1-naphthol added from the autoburette of the CAR system to yield a red coupling product. Since this reaction is time-dependent and very fast, oxazepam must be determined by the continuous-addition-of-reagent technique by monitoring the reaction rate spectrophotometrically at 530 nm (absorption maximum of the coupling product formed). A typical absorbance *vs.* time plot for an oxazepam concentration of 1.5 μg/ml is shown in Fig. 1.

As stated in the literature, the acid hydrolysis of benzodiazepines to benzophenones is carried

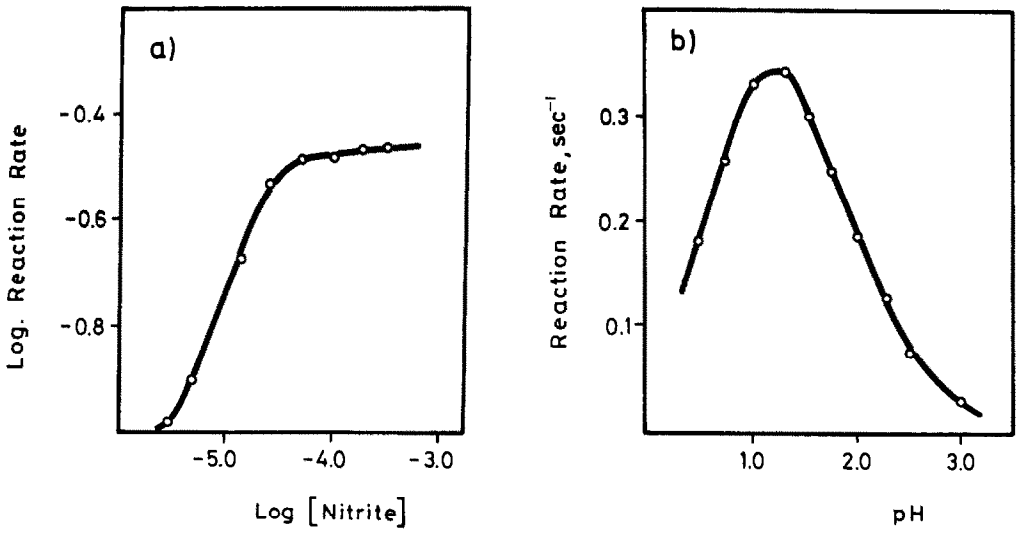

Fig. 2. Effect of (a) the sodium nitrite concentration and (b) pH on the kinetic determination of 1.5 μg/ml oxazepam. (For experimental conditions, see Procedure.)

out with hydrochloric acid at high temperatures.[6,14–19] In our method, oxazepam is quantitatively (99.5%) hydrolysed to 2-amine-5-chlorobenzophenone with 6*M* hydrochloric acid at 100° in a boiling water-bath for 1 hr. Thus, a kinetic study of the influence on the rate of the coupling reaction was performed in order to develop a kinetic method for the determination of the drug.

Optimization of experimental variables

Chemical and instrumental variables were optimized in order to maximize the sensitivity and precision of the proposed kinetic method. In short, stock 2-amine-5-chlorobenzophenone solutions were used and each variable was changed in turn while keeping all other constant. In this case, a 1.0-μg/ml benzophenone solution was equivalent to one containing 1.24 μg/ml oxazepam.

The influence of the sodium nitrite concentration was assessed over a wide range (2.42×10^{-6}–$2.90 \times 10^{-4}M$). The absorbance *vs.* time curves obtained show an increase in the reaction rate with increase in the diazotizing agent concentration up to $4.84 \times 10^{-5}M$, above which it remains virtually constant. This dependency shown in Fig. 2(a) (a log–log plot) arises from the wide concentration range studied. A concentration of $1.45 \times 10^{-4}M$ (0.6 ml of a $1.45 \times 10^{-2}M$ solution), which lay on the plateau, was selected. The influence of pH is closely related to the former variable since the true diazotizing agent for benzophenone is

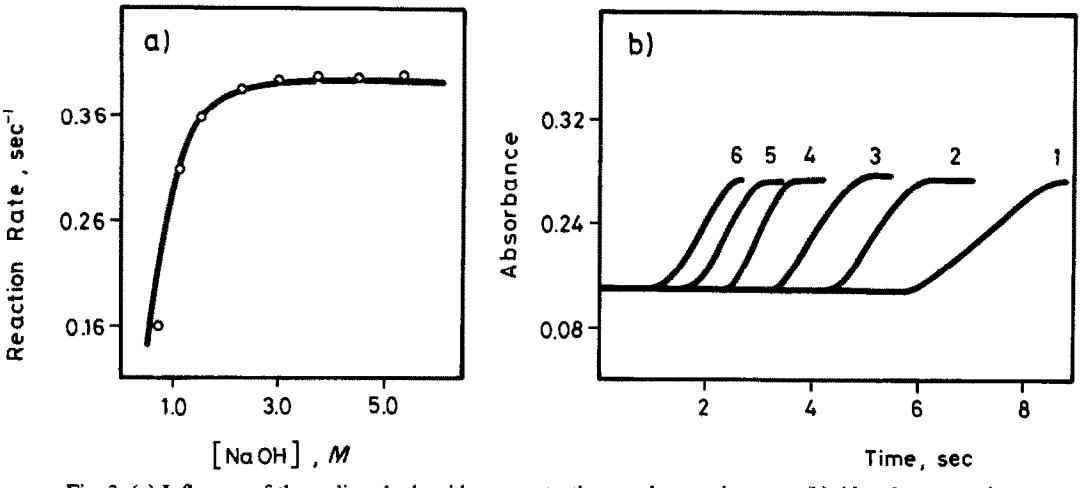

Fig. 3. (a) Influence of the sodium hydroxide concentration on the reaction rate. (b) Absorbance *vs.* time curves recorded at different NaOH concentrations: 1, 0.75; 2, 1.125; 3, 1.50; 4, 2.25; 5, 3.0 and 6, 3.75–5.25*M*. Oxazepam concentration, 1.5 μg/ml. (For experimental conditions, see Procedure.)

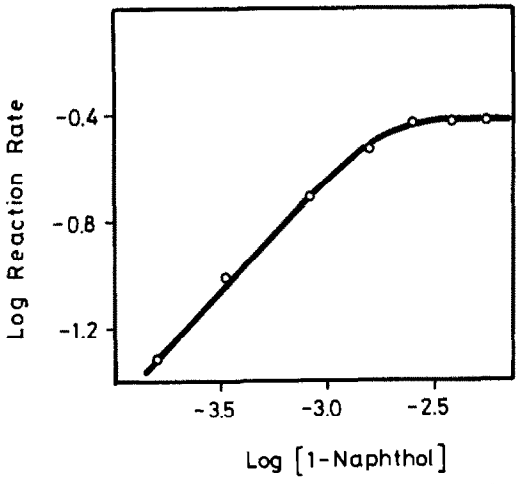

Fig. 4. Variation of the reaction rate as a function of the 1-naphthol concentration. Oxazepam concentration, 1.5 μg/ml. (For experimental conditions, see Procedure.)

nitrous acid. Thus, the effect of pH was studied between 0.5 and 3.0 [Fig. 2(b)]. The plot of the reaction rate *vs.* pH shows maximum dependency at about pH 1.25, above which it decreases. Taking into account this dependency, a pH of 1.30 (nitrous acid is not dissociated) was selected for use in the kinetic determination of oxazepam. At this pH, not only the reaction rate, but also the final absorbance was maximal.

The effect of the sodium hydroxide concentration in the reagent solution added from the autoburette was also tested in the range 0.75–5.25*M*; as shown in Fig. 3(a), the reaction rate increases sharply with an increase in this variable up to 1.5*M*, above which it remains virtually constant. Continuous addition of this chemical to the reaction vessel has two distinct effects: first, it neutralizes the acid present in the reaction vessel, which is required for the diazotizing reaction to develop; then it provides the basic medium needed for the coupling reaction with 1-naphthol. Therefore, the kinetic curves obtained in this study show a pseudo-induction period which is proportional to the sodium hydroxide concentration added from the autoburette, as shown in Fig. 3(b). Taking into account this behaviour, a concentration of 3.0*M* (20 ml of 7.5*M* sodium hydroxide in a final volume of 50 ml) was chosen for subsequent experiments. The concentration of 1-naphthol was varied over the range 1.38×10^{-4}–$5.52 \times 10^{-3}M$ in order to investigate its effect on the reaction rate (Fig. 4), which increased with increase in the concentration of this reagent up to about $2.08 \times 10^{-3}M$, above which it remained constant. A concentration of $3.47 \times 10^{-3}M$ (5 ml of $3.47 \times 10^{-2}M$ 1-naphthol in a final volume of 50 ml), which resulted in a maximal reproducibility and sensitivity, was selected.

Table 1. Influence of other benzodiazepines on the kinetic determination of 0.8 μg/ml oxazepam

Benzodiazepine added	Tolerance ratio
Flurazepam, chlotiazepam, loprazolam, lormetazepam, alprazolam	100
Diazepam*	50
Nitrazepam, chlordiazepoxide, lorazepam, bromazepam	<1

*Maximum ratio assayed owing to its solubility.

The rate of addition of the coupling reagent, the initial volume of the sample solution and the stirring speed are the three instrumental variables which exert an appreciable effect on the kinetic curves. The rate of addition of the alkaline 1-naphthol solution was studied in the range 5–35 ml/min. The reaction rate remained virtually constant throughout this interval, although as with the effect of sodium hydroxide, a pseudo-induction period (the length of which was inversely proportional to the rate of addition) was also observed. Thus, a rate of 35 ml/min was selected for further experiments. The influence of the initial sample volume (between 60–100 ml) and the stirring speed (50–300 rpm) on the reaction rate was also examined. The values advocated under Procedure were chosen as optimal.

Kinetic determination of oxazepam

Quantification of the drug was achieved by plotting the reaction rate against its concentration. Linear correlation ($r = 0.9995$, $n = 8$) over the concentration range 0.15–3.65 μg/ml was obtained. A representative calibration graph for oxazepam provided the following linear regression equation:

$$\text{Reaction rate} = 0.023 + 0.216\ [\text{Oxazepam}]$$

where the drug concentration is expressed in μg/ml. The detection limit of the proposed kinetic procedure was determined by calculating the minimum concentration of drug that could be detected. A concentration of 40 ng/ml oxazepam gave rise to a response (reaction rate) that was three times the standard deviation of the reaction rate for 20 determintions on a sample containing a low analyte concentration.[20] The precision (RSD = 1.26%) was confirmed by analysing 11 replicate samples each containing 1.0 μg/ml of oxazepam in the

Table 2. Analysis of synthetic mixtures of oxazepam and its hydrolysis product

3.20	0.40	3.15	1.6	0.40	0.0

reaction vessel. The sampling rate, as determined for triplicate runs on the same sample, was about 60 samples/hr.

A study of interferences was made in order to determine the tolerance to other benzodiazepines in the kinetic determination of 0.8 μg/ml of oxazepam. The tolerated limits for the foreign compounds were taken as the largest amounts yielding an error less than ±3% in the reaction rate measurements. As can be seen in Table 1, the proposed method is quite selective. The most serious interferences arise from other benzodiazepines or hydrolysis products of these including a primary amine group in their structures.

The acid-induced degradation product of oxazepam, 2-amine-5-chlorobenzophenone, is obviously a major interferent for the proposed method; however, its perturbation can be avoided by simultaneously determining oxazepam and its hydrolysis product using one hydrolysed and another unhydrolysed sample aliquot. Laboratory-prepared mixtures of oxazepam and its degradation product were thus assayed. Table 2 lists the results obtained; the analysis of oxazepam/benzophenone mixtures was feasible over the weight ratio range from 1:8 to 8:1 (maximum relative error, ±5%). These results are quite satisfactory and confirm that the proposed method allows the resolution of this mixture at lower degrees of hydrolysis of oxazepam in the sample (about to 10%). The average of the results from 11 samples each containing 1.0 μg/ml oxazepam and hydrolysis product yielded an overall relative standard deviation of 1.5% for the method.

Applications

In order to check the applicability of the proposed method we used it to analyse for oxazepam in pharmaceutical and urine samples. The pharmaceutical samples were treated as described above, and in order to detect potential matrix effects from other components, the recoveries of oxazepam added to these samples were also determined. Table 3 shows the results obtained in the determination of oxazepam in such samples, which are consistent with the nominal values of this drug given by the manufacturers (the recoveries ranged from 93.1 to 100.7%, with an average of 96.5%). These results show the good performance of the proposed method for the kinetic determination of oxazepam.

The analysis for oxazepam in urine samples is of great clinical significance since this drug is the main urinary metabolite of several benzodiazepines such as chlordiazepoxide, diazepam, halazepam, medazepam, *etc.*[21] Therefore, its determination in this type of sample can be used

18.00	17.05, 17.45	95.8

as a bulk analysis of these drugs or for the quantitative analysis of a given drug when only one benzodiazepine is present. Different urine samples were analysed by pretreating them as described under Experimental. The samples were spiked with 2–18 μg/ml oxazepam (Table 4) and the average recovery found, 96.5 ± 1.2%, shows the reliability of the proposed kinetic method for the determination of this drug in this type of sample. Finally, it is worth noting that this method can be used to determine smaller amounts of oxazepam in urine samples if these are used entirely for this analysis after the pretreatment. Thus, if 50 ml of urine are treated and then diluted to 60 ml in the reaction vessel to determine its oxazepam content by the proposed CAR method, the minimum amount of oxazepam that can be determined in this case is about 50 ng/ml, taking into account the detection limit of the proposed kinetic method.

CONCLUSIONS

Oxazepam was assayed in dosage forms and urine samples by using the continuous-addition-of-reagent technique. The method used for this purpose is simple, rapid, precise and more sensitive than the corresponding equilibrium approach in which the determination is feasible over the range 2–160 μg/ml.[10,11] The present method can be applied to quality control testing and drug stability monitoring as a good alternative to other methods available for the determination of this drug.

STUDIES ON COMPLEXATION EQUILIBRIA BETWEEN WATER-SOLUBLE HYDRAZONES WHICH CONSIST OF 5-NITRO-2-PYRIDYLHYDRAZINE AND HETEROCYCLIC KETONES AND DIVALENT METAL IONS

HAJIME ISHII,* MITSURU YAMAGUCHI† and TSUGIKATSU ODASHIMA
Institute for Chemical Reaction Science, Tohoku University, Katahira, Aoba-ku, Sendai, 980 Japan

(*Received* 14 *October* 1991. *Revised* 31 *December* 1991. *Accepted* 2 *January* 1992)

Summary—Complexation equilibria between five water-soluble hydrazones which consist of 5-nitro-2-pyridylhydrazine and heterocyclic ketones and divalent metal ions have been studied spectrophotometrically. Equilibrium constants of the complexation reactions and overall formation constants of the resultant complexes have been determined and species of the complexes clarified.

In earlier works[1–3] various water-soluble hydrazones which consist of 5-nitro-2-pyridylhydrazine and various heterocyclic ketones having one or two sulpho groups in their molecules were synthesized in order to develop highly sensitive and/or selective reagents for metals. Among them α-(5-nitro-2-pyridyl)-hydrazono-α-(2-pyridyl)-3-toluenesulphonic acid (NPHPTS),[1] α-(5-nitro-2-pyridyl)hydrazono-α-(2-quinolyl)-3-toluenesulphonic acid (NPHQTS),[2] α-(2-benzothiazolyl)-α-(5-nitro-2-pyridyl)hydrazono-3-toluenesulphonic acid (BTNPHTS),[2] α-(2-benzimidazolyl)-α-(5-nitro-2-pyridyl)hydrazono-3-toluene-sulphonic acid (BINPHTS)[2] and disulphonated (2-benzimidazolyl) (phenyl)methanone 5-nitro-2-pyridylhydrazone (DSBINPH)[3] were found to be very useful as highly sensitive spectrophotometric reagents for metals, some of them being applied to the determination of traces of cobalt[1,4] and nickel.[3,5] In this work complexation equilibria between the above-mentioned five hydrazones and metal ions including cadmium(II), cobalt(II), copper(II), iron(II), palladium(II) and zinc(II) have been investigated spectrophotometrically in detail in order to more fully understand these complexation reactions.

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade and all solutions were prepared with distilled, demineralized water, unless stated otherwise.

Standard solutions of cadmium(II), cobalt(II), copper(II), iron(II), palladium(II) and zinc(II) (about 0.5 mg/ml) were prepared by first dissolving their nitrates salts in 0.01*M* perchloric acid and then standardizing by EDTA titration. Working solutions were prepared by dilution of these solutions with water.

Hydrazone solutions, 5.0×10^{-4} or $1.0 \times 10^{-3}M$ were prepared by dissolving each hydrazone synthesized as in earlier works[1–3] in water or 0.01*M* sodium hydroxide solution. These solutions were further diluted with water if necessary.

Buffer solutions were the same as described in a previous paper.[3]

RESULTS AND DISCUSSION

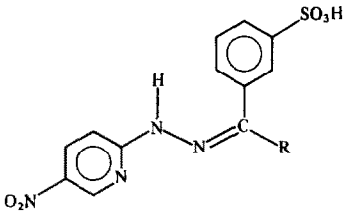
Acid dissociation constants of hydrazones

As is apparent from their structures, the five hydrazones studied in this work exist in solution in any of the following forms, depending upon the acidity or pH:

$$H_{b-i+4}L^{(i-4)-} \overset{K_{ai}}{\rightleftharpoons} H_{b-i+3}L^{(i-3)-} + H^+ \quad (1)$$

$$K_{ai} = \frac{[H_{b-i+3}L^{(i-3)-}][H^+]}{[H_{b-i+4}L^{(i-4)-}]} \quad (i = 1, 2, \ldots, 7) \quad (2)$$

Table 1. Acid dissociation constants of hydrazones



Hydrazone	R	pK_{a3}	pK_{a4}	pK_{a5}	pK_{a6}	pK_{a7}	Reference
NPHPTS		0.72	4.37	11.49			1
NPHQTS		0.70	4.38	11.54			2
BTNPHTS		<0.80	1.32	10.74			2
BINPHTS		0.70	3.58	10.61	12.61		2
DSBINPH			0.70	3.37	10.20	12.72	3

Here H_bL represents the neutral species of the hydrazones, b denotes the number of their dissociable protons ($b = 2$ for NPHPTS, NPHQTS and BTNPHTS, $b = 3$ for BINPHTS and $b = 4$ for DSBINPH) and K_{ai} is the acid dissociation constant. The pK_{ai} values of the hydrazones, which were already determined in earlier works,[1-3] are necessary for the calculation of the formation constants and are summarized in Table 1. Here K_{a3}, K_{a4}, K_{a5} and K_{a6} of the four hydrazones except DSBINPH may be assigned to the deprotonations from the protonated pyridine–nitrogens in the hydrazine and aldehyde moieties, the secondary amino group and the imino group in the benzimidazole moiety, respectively. In the case of DSBINPH, K_{a4}, K_{a5}, K_{a6} and K_{a7} correspond with the above-mentioned assignment, respectively. The values of pK_{a1}, pK_{a2} and pK_{a3} of DSBINPH and those of pK_{a1} and pK_{a2} of the other four hydrazones, which correspond to the deprotonations from the sulpho group and C = N nitrogen, were not determined because these deprotonations are complete in less acidic solutions than those studied.

Effect of pH on complexation and absorption spectra of complexes

The effect of pH on the formation of divalent-metal complexes of the hydrazones was investigated, with absorption spectra of the complexes formed under the optimum conditions. The results are summarized in Table 2 along with the complex compositions determined by the continuous variation method.

Complexation equilibria

In the analysis of complexation equilibria the method of Sommer and Langova[6] was referred to.

In general, the complexation equilibrium between the specified hydrazone and the divalent-metal ion, M^{2+}, may be expressed as

Table 2. Optimal pH ranges for complexation and characteristics of complexes

Complex	Optimal pH range	Absorption maximum, *nm*	Apparent molar absorptivity, $M^{-1}\,cm^{-1}$	Composition (M:L)

[a, b, c] Measured in earlier works.[3–5]

$$M^{2+} + nH_{b-i+4}L^{(i-4)-} \underset{}{\overset{K_{eq}}{\rightleftharpoons}} M(H_{b-i+4}L)_{n-m}(H_{b-i+3}L)_m^{Z-} + mH^+ \quad (3)$$

$$K_{eq} = \frac{[M(H_{b-i+4}L)_{n-m}(H_{b-i+3}L)_m^{Z-}][H^+]^m}{[M^{2+}][H_{b-i+4}L^{(i-4)-}]^n} \quad (4)$$

where $Z = n(i-4) + m - 2$ and K_{eq} is the equilibrium constant. If the initial concentration of the ligand, C_L, is much higher than that of the metal ion, C_M, and the acid dissociation of the ligand is taken into consideration, equation (4) can be approximated as

$$K_{eq} = \frac{x[H^+]^m}{(C_M - x)\left(\frac{C_L[H^+]}{K_{ai} + [H^+]}\right)^n} \quad (5)$$

where x is the equilibrium concentration of the complex formed. On the other hand, as the system obeys Beer's law additively over the wavelength range of interest, equation (6) can be deduced

$$A = \epsilon_L(C_L - nx) + \epsilon_C x \quad (6)$$

where ϵ_L and ϵ_C are apparent molar absorptivities of the ligand and the complex at a specified wavelength, respectively, and A is the absorbance of the solution containing the metal

ion and the ligand. When the absorbance of the solution is measured against a reagent blank, from equations (5) and (6), equation (7) can finally be obtained:

$$\frac{C_M}{A} = \frac{1}{\epsilon_C - n\epsilon_L} + \frac{[H^+]^m}{(\epsilon_C - n\epsilon_L)C_L^n K_{eq}} \times \left(1 + \frac{K_{ai}}{[H^+]}\right)^n \quad (7)$$

Equation (7) means that either the plot of C_M/A *versus* $1/C_L^n$ at constant values of C_M and $[H^+]$ or the plot of C_M/A *versus* $[H^+]^m\{1 + (K_{ai}/[H^+])\}^n$ at constant values of C_M and C_L should give a straight line, provided that the values of n and/or m were correctly assumed. The value of K_{eq} can be calculated from the intercept and the slope of either line.

When the hydrazone exists as one species under experimental conditions, the pH value of the solution is much smaller than the pK_{ai} value of the hydrazone. So the value of $K_{ai}/[H^+]$ becomes negligibly small. Therefore, equation (7) can be simplified to give equation (8):

$$\frac{C_M}{A} = \frac{1}{\epsilon_C - n\epsilon_L} + \frac{[H^+]^m}{(\epsilon_C - n\epsilon_L)C_L^n K_{eq}} \quad (8)$$

Also in this case the value of K_{eq} can be calculated from the intercept and the slope of either a plot of C_M/A *versus* $1/C_L^n$ or C_M/A *versus* $[H^+]^m$ in the same way as in the case of equation (7).

The overall formation constant, β_n, of the complex formed by

$$M^{2+} + (n-m)H_{b-i+4}L^{(i-4)-} + mH_{b-i+3}L^{(i-3)-} \rightleftharpoons M(H_{b-i+4}L)_{n-m}(H_{b-i+3}L)^{Z-} \quad (9)$$

is given by

$$\beta_n = \frac{[M(H_{b-i+4}L)_{n-m}(H_{b-i+3}L)_m^{Z-}]}{[M^{2+}][H_{b-i+4}L^{(i-4)-}]^{n-m}[H_{b-i+3}L^{(i-3)-}]^m} \quad (10)$$

and can be calculated from the values of K_{eq} and K_{ai} as follows:

$$\beta_n = K_{eq}/K_{ai}^m \quad (11)$$

In the case of palladium(II), the metal ion forms a 1:1 complex with each hydrazone and in the presence of a large excess of chloride ion over palladium(II) it forms a mixed ligand complex with each hydrazone and chloride ion, so the complexation equilibrium may be expressed as

$$Pd^{2+} + H_{b-i+4}L^{(i-4)-} + qCl^- \overset{K_{eq}}{\rightleftharpoons} Pd(H_{b-i+4-m}L)Cl_q^{Z-} + mH^+ \quad (12)$$

$$K_{eq} = \frac{[Pd(H_{b-i+4-m}L)Cl_q^{Z-}][H^+]^m}{[Pd^{2+}][H_{b-i+4}L^{(i-4)-}][Cl^-]^q} \quad (13)$$

Here $Z = i + m + q - 6$. In analogy with the derivation of equation (7), equation (14) can finally be obtained:

$$\frac{C_{Pd}}{A} = \frac{1}{\epsilon_C - \epsilon_L} + \frac{[H^+]^m}{(\epsilon_C - \epsilon_L)C_L K_{eq} C_{Cl}^q} \times \left(1 + \frac{K_{ai}}{[H^+]}\right) \quad (14)$$

where C_{Cl} is the initial concentration of chloride ion. The values of m and q can be determined by closely examining the linearity of plots of C_{Pd}/A *versus* $[H^+]^m\{1 + (K_{ai}/[H^+])\}$ and C_{Pd}/A *versus* $1/C_{Cl}^q$, respectively, the value of K_{eq} being calculated from the intercept and the slope of either line.

The overall formation constant, β, of the complex can be calculated from equation (15):

$$\beta = \frac{[Pd(H_{b-i+4-m}L)Cl_q^{Z-}]}{[Pd^{2+}][H_{b-i+4-m}L^{(i-4+m)-}][Cl^-]^q} = \frac{K_{eq}}{K_{ai}K_{a(i+1)}\cdots K_{a(i+m-1)}} \quad (15)$$

Cadmium(II) complexes

Cadmium(II) forms 1:2 (metal:ligand) complexes with all the hydrazones in weakly alkaline solutions as described already. Since each hydrazone exists as one species under the experimental conditions adopted, plots of C_{Cd}/A *vs.* $1/C_L^n$ and C_{Cd}/A *vs.* $[H^+]^m$ based on equation (8) were prepared for each cadmium(II)–hydrazone system. Both plots gave straight lines when it was assumed $n = 2$ and $m = 1$ in every system. An example of each plot is shown in Figs. 1 and 2. These results indicate that the complexation reactions proceed according to equations (16)–(18). With NPHPTS, NPHQTS and BTNPHTS:

$$Cd^{2+} + 2HL^- \rightleftharpoons Cd(HL)L^- + H^+ \quad (16)$$

with BINPHTS:

$$Cd^{2+} + 2H_2L^- \rightleftharpoons Cd(H_2L)(HL)^- + H^+ \quad (17)$$

and with DSBINPH:

$$Cd^{2+} + 2H_2L^{2-} \rightleftharpoons Cd(H_2L)(HL)^{3-} + H^+ \quad (18)$$

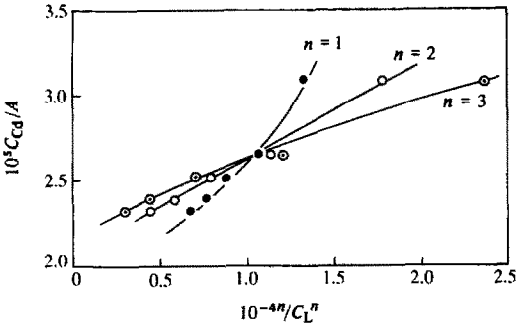

Fig. 1. Plots of C_{Cd}/A *versus* $1/C_L^n$ for the formation of the cadmium(II)–BINPHTS complex. C_{Cd}, $3.58 \times 10^{-6}M$; pH, 7.4; ionic strength, 0.2 ($NaClO_4$); wavelength, 495 nm; temperature, $25 \pm 0.1°$; standing time, 30 min.

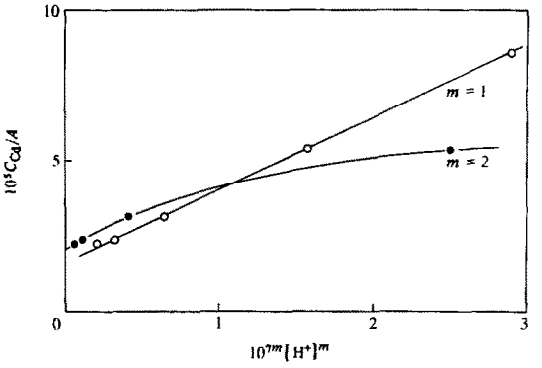

Fig. 2. Plots of C_{Cd}/A *versus* $[H^+]^m$ for the formation of the cadmium(II)–BINPHTS complex. C_{Cd}, $3.58 \times 10^{-6}M$; C_L, $1.74 \times 10^{-4}M$. Other conditions are the same as for Fig. 1.

The log K_{eq} value calculated from the intercept and the slope of each plot and the log β_2 value for each complex calculated by equation (11) are given in Table 3.

Copper(II) complexes

Copper (II) forms 1:1 complexes with all the hydrazones in weakly acidic solutions and, in addition, 1:2 complexes with NPHPTS and NPHQTS in weakly alkaline solutions. As two species of each hydrazone exist in acidic solutions where the 1:1 complex is formed, plots of C_{Cu}/A *vs.* $1/C_L^n$ and C_{Cu}/A *vs.* $[H^+]^m\{1+(K_{ai}/[H^+])\}^n$ based on equation (7) were prepared for each copper(II)–hydrazone system in the study of the formation equilibrium of the 1:1 complex. These plots gave straight lines when it was assumed $n = 1$ and $m = 1$ in every system. An example is shown in Fig. 3. These results indicate that the complexation reactions proceed according to equations (19)–(22).

With NPHPTS and NPHQTS:

$$Cu^{2+} + H_2L \rightleftharpoons Cu(HL)^+ + H^+ \quad (19)$$

and with BTNPHTS, BINPHTS and DSBINPH:

$$Cu^{2+} + HL^- \rightleftharpoons CuL + H^+ \quad (20)$$

$$Cu^{2+} + H_3L \rightleftharpoons Cu(H_2L)^+ + H^+ \quad (21)$$

and

$$Cu^{2+} + H_3L^- \rightleftharpoons Cu(H_2L) + H^+ \quad (22)$$

respectively. In the study of the formation equilibria of the 1:2 complexes formed with NPHPTS and NPHQTS in weakly alkaline solutions, plots of C_{Cu}/A *vs.* $1/C_L^n$ and C_{Cu}/A *vs.* $[H^+]^m$ gave straight lines when it was assumed $n = 2$ and $m = 1$ similarly to the case of the formation equilibria of cadmium(II) complexes described above. These results indicate that the complexation reactions with both hydrazones proceed according to equation (23):

$$Cu^{2+} + 2HL^- \rightleftharpoons Cu(HL)L^- + H^+ \quad (23)$$

Calculated values of log K_{eq}, log β_1 and log β_2 in each system are given in Table 3. The β_1 value of the BTNPHTS complex is remarkably larger than those of the other hydrazone complexes. The reason is as follows: as is clear from the pK_{a4} value of BTNPHTS, the species of BTNPHTS which reacts with copper(II) around pH 3 where the experiment was performed is HL^- but not H_2L, which is different from the species in the cases of NPHPTS and NPHQTS, and is as shown in equation (20). So, the K_{a5} value was used for the calculation of the β_1 value of the BTNPHTS complex, which makes the log β_1 value of the BTNPHTS complex remarkably large.

Palladium(II) complexes

Palladium(II) forms 1:1 complexes with all the hydrazones in acidic solutions. In the presence of a large excess of chloride ion, it forms a mixed ligand complex with each hydrazone and chloride ion. So, plots of C_{Pd}/A *vs.* $1/C_{Cl}^q$ and C_{Pd}/A *vs.* $[H^+]^m\{1+(K_{ai}/[H^+])\}$ based on equation (14) were prepared for each system except for the Pd(II)–NPHQTS–Cl system, their linearity being closely examined. In the Pd(II)–NPHQTS–Cl system, the complex was precipitated because of its low solubility, so its complexation equilibrium was not studied. The results revealed that $m = 2$ and $q = 1$ in every system except for the Pd(II)–BTNPHTS-Cl system in which $m = 1$ and $q = 2$, indicating that the complexation reactions with NPHPTS,

Table 3. Equilibrium constants, overall formation constants and species of complexes

Temperature: $25 \pm 0.1°$, Ionic strength: 0.2 ($NaClO_4$).

[a] Measured in aqueous 10% v/v 1,4-dioxane solutions.

[b,c] Determined in earlier works.[3,5]

[d] Shows the overall formation constant, β, of the mixed ligand complex.

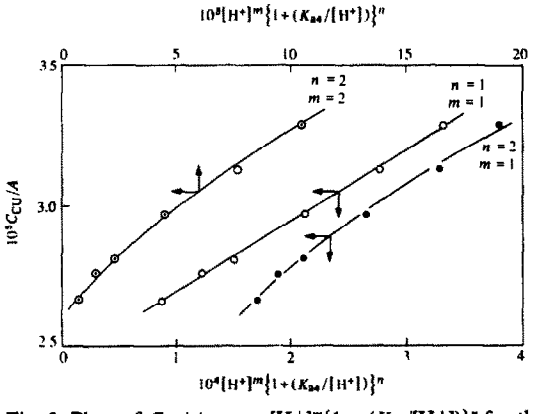

Fig. 3. Plots of C_{Cu}/A *versus* $[H^+]^m\{1+(K_{a4}/[H^+])\}^n$ for the formation of the copper(II)–NPHPTS complex. C_{Cu}, $6.33 \times 10^{-6}M$; C_L, $1.92 \times 10^{-4}M$; wavelength, 487 nm. Other conditions are the same as for Fig. 1.

BTNPHTS, BINPHTS and DSBINPH proceed according to equations (24)–(27), respectively:

$$Pd^{2+} + H_3L^+ + Cl^- \rightleftharpoons Pd(HL)Cl + 2H^+ \quad (24)$$

$$Pd^{2+} + H_3L^+ + 2Cl^- \rightleftharpoons Pd(H_2L)Cl_2 + H^+ \quad (25)$$

$$Pd^{2+} + H_4L^+ + Cl^- \rightleftharpoons Pd(H_2L)Cl + 2H^+ \quad (26)$$

$$Pd^{2+} + H_4L + Cl^- \rightleftharpoons Pd(H_2L)Cl^- + 2H^+ \quad (27)$$

Calculated values of $\log K_{eq}$ and $\log \beta$ for each system are given in Table 3.

In the absence of chloride ions, the investigation of the complexation equilibria by the above-mentioned equilibrium-shift method could not be applied because the spectral change due to the complexation was very small. So, Hildebrand–Reilley's method[3,7] was applied here, in which the complexation equilibria were investigated in the presence of a large excess of palladium(II) over the ligand and chloride ion, the linearity of the plot of the left hand side of equation (28) *vs.* $\log[H^+]$ for each system having closely been examined.

$$\log \frac{A}{A_\infty - A} + \log\left(1 + \frac{K_{ai}}{[H^+]}\right) - \log C_{Pd} = \log K_{eq} - m \log[H^+] \quad (28)$$

Here A_∞ is the limiting absorbance when all of the ligand is complexed quantitatively with the metal ion at higher pH. This plot for each system gave a straight line with a slope of about -2. An example is shown in Fig. 4. These results indicate that the complexation reactions proceed according to equations (29)–(31):

With NPHPTS, NPHQTS and BTNPHTS

$$Pd^{2+} + H_3L^+ \rightleftharpoons Pd(HL)^+ + 2H^+ \quad (29)$$

with BINPHTS and DSBINPH

$$Pd^{2+} + H_4L^+ \rightleftharpoons Pd(H_2L)^+ + 2H^+ \quad (30)$$

and

$$Pd^{2+} + H_4L \rightleftharpoons Pd(H_2L) + 2H^+ \quad (31)$$

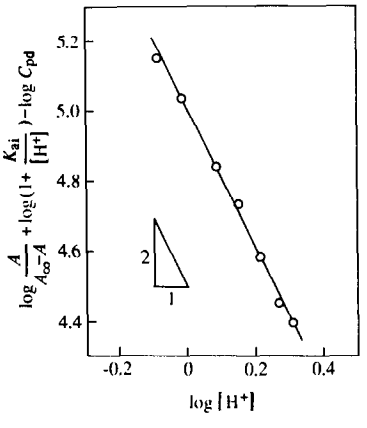

Fig. 4. Plot of $\log\{A/(A_\infty - A)\} + \log\{1 + (K_{ai}/[H^+])\} - \log C_{Pd}$ *versus* $\log[H^+]$ for the formation of the Pd(II)–DSBINPH complex. C_{Pd}, $6.43 \times 10^{-4} M$; C_L, $1.62 \times 10^{-5} M$; ionic strength, 2.0 ($NaClO_4$); wavelength, 520 nm. Other conditions are the same as for Fig. 1.

respectively. The value of $\log K_{eq}$ calculated from the intercept of each plot and that of $\log \beta_1$ of each complex obtained from equation (15) (in this case $q = 0$) are given in Table 3. The β_1 value of the BTNPHTS complex is considerably smaller than those of the other hydrazone complexes. The reason may be attributed to the large K_{a4} value of BTNPHTS, in other words, the weak basicity of the benzothiazole-nitrogen of BTNPHTS.

As is clear from the above results, the formation constant, β, of the Pd(II)–hydrazone–Cl complexes are larger than those, β_1, of the corresponding Pd(II)–hydrazone complexes. Incidentally, the formation constant of the Pd(II)–hydrazone–Cl complex when it was assumed to be formed by the reaction of the Pd(II)–hydrazone complex with chloride ion, β', is defined as equation (32) and is rewritten as equation (33) by using β_1 given by equation (34) and β already defined by equation (15) (in this case $m = 2$ and $q = 1$).

$$\beta' = \frac{[Pd(H_{b-t+2}L)Cl^{(t-3)-}]}{[Pd(H_{b-t+2}L)^{(t-4)-}][Cl^-]} \quad (32)$$

$$\beta' = \beta/\beta_1 \quad (33)$$

$$\beta_1 = \frac{[Pd(H_{b-t+2}L)^{(t-4)-}]}{[Pd^{2+}][H_{b-t+2}L^{(t-2)-}]} \quad (34)$$

The magnitude of the contribution of chloride ion to the Pd(II)–hydrazone–Cl complex may be estimated by using the value of β'. Calculated values of $\log \beta'$ for the complexes of NPHPTS, BINPHTS and DSBINPH were 3.15, 3.54 and 3.50, respectively, indicating that the β' value is independent of the kind of the hydrazone ligand.

Other metal complexes

Cobalt(II) forms 1:2 complexes with all the hydrazones in weakly acidic to alkaline solutions, the resultant cobalt(II) complexes being rapidly oxidized to the corresponding stable cobalt(III) complexes by dissolved oxygen. Both the formation of the cobalt(II) complexes and their oxidation to the tervalent complexes were very rapid and it was difficult to control the concentration of dissolved oxygen in solution, so the complexation equilibria of cobalt(II) with the hydrazones were not studied here.

Iron(II) forms 1:2 complexes with all the hydrazones in weakly acidic to neutral and/or alkaline solutions. Under experimental conditions for the study of formation equilibria of iron(II) complexes, two kinds of species must be

taken into consideration for each hydrazone, so plots of C_M/A *vs.* $1/C_L^n$ and C_M/A *vs.* $[H^+]^m\{1+(K_{ai}/[H^+])\}^n$ were investigated for each iron(II)–hydrazone system. Both plots gave straight lines when it was assumed $n=2$ and $m=1$ in every system except for the iron(II)–NPHPTS and iron(II)–BINPHTS systems. Calculated values of $\log K_{eq}$ and $\log \beta_2$ are summarized in Table 3 along with the species of the complex formed in each system. In the case of the iron(II)–NPHPTS and iron(II)–BINPHTS systems, mixtures of a 1:1 and a 1:2 complex are formed around pH 3 where the experiments were carried out (although stable 1:2 complexes were formed at higher pH), so values of K_{eq} and β_n of the NPHPTS and BINPHTS complexes could not be determined.

As for the formation equilibria between zinc(II) and the hydrazones, plots of C_M/A *vs.* $1/C_L^n$ and C_M/A *vs.* $[H^+]^m$ based on equation (8) were prepared for each system. Every plot gave a straight line when it was assumed $n=2$ and $m=1$. Calculated values of $\log K_{eq}$ and $\log \beta_2$ are summarized in Table 3 along with those for each nickel(II)–hydrazone complexes determined in earlier works.[3,5]

RAPID CHELATOMETRIC DETERMINATION OF BISMUTH, TITANIUM AND ALUMINIUM USING SEMI-XYLENOL ORANGE WITH VISUAL END-POINT INDICATION

MEDHAT ABD EL-HAMIED HAFEZ
Chemistry Department, Faculty of Science, Mansoura University, El-Mansoura, Egypt

(*Received* 13 *September* 1991. *Revised* 5 *March* 1992. *Accepted* 6 *March* 1992)

Summary—A rapid and simple general complexometric method was presented for the determination of bismuth, titanium and aluminium in laboratory synthesized alloys similar to those of some bauxites, clay, ilmenite, Portland cements and ceramic products. The precision and accuracy attainable in successive titrations of Bi^{3+}, Ti^{4+} and Al^{3+} with 0.01 and/or 0.001*M* solutions of disodium ethylenediaminetetraacetate (Na_2EDTA) and standard $ZnCl_2$ of the same concentration, using Semi-Xylenol Orange (SXO) as a metallochromic indicator with visual end-point indication were studied. For one aliquot Bi^{3+} was at first directly titrated at pH 1–2 (HNO_3) with Na_2EDTA using SXO as indicator in the presence of *L*-ascorbic acid to reduce Fe^{3+} to Fe^{2+}. At the bismuth end-point, an excess of Na_2EDTA was added, the pH was adjusted with hexamine buffer (pH 5) and the excess of Na_2EDTA was back-titrated with solution of standard zinc(II) chloride for both the simultaneous and consecutive titrations in the presence of (SXO) as indicator. For the simultaneous titration, fluoride was added to release the Na_2EDTA combined with both Al^{3+} and Ti^{4+}. For the consecutive titration, phosphate was added to release the Na_2EDTA combined with Ti^{4+} and then fluoride to release the Na_2EDTA combined with Al^{3+}. The interference of various anions and cations in the determination of Bi^{3+}, Ti^{4+} and Al^{3+} was studied. A comparison of the accuracy of both the simultaneous and consecutive titration was also carried out. The proposed methods were applied successfully to some real samples of bauxites, clay, ilmenite, Portland cements and ceramic products and the results were satisfactory.

Although Ti^{4+}, Al^{3+} and/or Bi^{3+} are common components of some clays, minerals, Portland cement and ceramic products, rapid and simple general methods for their analysis have encountered difficulties. The standard gravimetric methods are tedious and more time consuming. A comparatively small number of papers have dealt with the quantitative approach to the determination of $Ti^{4+} + Al^{3+}$ or $Ti^{4+} + Bi^{3+}$ or $Al^{3+} + Bi^{3+}$ ions.[1–7] It has been previously shown that the spectrophotometric indication of complexometric titrations using Semi-Xylenol Orange (SXO) as indicator gives very accurate and precise results at the microgram level.[8–11]

The aim of this work is to present a rapid and simple general complexometric method for the determination of Bi^{3+}, Ti^{4+} and Al^{3+} if present together by either two sample solutions (simultaneous titration) or a single aliquot solution (consecutive titration) with high precision and accuracy. At first artificial mixtures similar to those of some bauxites, clay, ilmenite, Portland cements and ceramic products were determined by visual end-point indication using SXO as a metallochromic indicator followed by an application of the proposed methods for real naturally occurring samples containing some of such metals. The problem of Ti^{4+} hydrolysis was avoided by using the very weak hexamine base solution to adjust the pH of the solution before the back-titration of Ti^{4+}. For the simultaneous titration, Ti^{4+} was separated as the hydroxide from Al^{3+} which was back-titrated with Na_2EDTA in one aliquot and then both Al^{3+} and Ti^{4+} were simultaneously determined in another sample, where Ti^{4+} was found by difference. For the consecutive titration no separation was required and both Ti^{4+} and Al^{3+} could be simply determined individually by firstly demasking quantitatively the Na_2EDTA equivalent to Ti^{4+} using $H_2PO_4^-$ ion[12] followed by the release of Na_2EDTA corresponding to Al^{3+} using F^- ion.[13,14]

EXPERIMENTAL

Reagents and solutions

A 0.01*M* solution of disodium ethylenediaminetetraacetate (Na_2EDTA) was prepared by dissolving the required mass of Na_2EDTA

(analytical-reagent grade, BDH, Poole, Dorset, UK) in bidistilled water and diluting to the necessary volume. Standard bismuth(III), titanium(IV) and aluminium(III) chloride solutions were prepared by dissolving high-purity (99.99%) bismuth, titanium and aluminium powdered metals (BDH) in boiling concentrated hydrochloric acid and diluting to the necessary volume with 0.3*M* hydrochloric acid. The Na_2EDTA solution ($\simeq 0.01M$) was standardized by the spectrophotometric titration of 0.001*M* Bi(III) chloride using Xylenol Orange as indicator in nitric acid solution (pH 1–1.5, 530 nm). All other salts were prepared by dissolving the calculated mass of each salt (BDH) in the required volume of bidistilled water. Zinc(II) solution was standardized by titration against standard Na_2EDTA solution using Xylenol Orange as indicator in hexamine buffer. The hexamine-HNO_3 buffer solution (1*M*) was prepared from analytical-reagent grade chemicals (BDH) by pH metric titration of 125 ml (2*M*) solution of hexamine against nitric acid (2*M*) until a pH of 5 was obtained and then the whole solution was completed to a total volume of 250 ml in a measuring flask using potassium nitrate solution (2*M*). Purified sample of indicator obtained by solvent-counter current separation[15,16] was used for preparing 0.01*M* solution of SXO (ammonium salt) in doubly distilled water.

Apparatus

A Beckman (Fullerton, CA, U.S.A.) digital pH meter with glass and saturated calomel electrodes calibrated on the operational pH scale with standard buffer solutions was used.

Decomposition of samples

The processes of crushing, grinding (200 mesh), decomposition by different fusion mixtures and dissolution of various real samples were carried out as described in literature.[17,18] For each sample $\simeq 0.5$ g was usually taken and dissolved after the described pretreatment into a 250-ml measuring flask. Silica must be completely separated in each case in the customary manner.[17,18]

RESULTS AND DISCUSSION

Simultaneous titration of Al^{3+} and Ti^{4+} with Bi^{3+} by visual end-point indication using SXO

Because of the importance of some of the three studied ions in many bauxites, clays, ilmenite, Portland cements and ceramic products, a rapid and simple complexometric method for the determination of the three ions with high precision and accuracy by visual titration using SXO as indicator would be helpful. Different series containing various proportions of Bi^{3+}, Ti^{4+} and Al^{3+} ions with constant concentraton of Fe^{3+} and Ca^{2+} ions were determined. The same procedure was applied for real naturally occurring samples. In one of such series (Series I), 5 ml of 0.01*M* of each of Bi^{3+}, Ti^{4+} and Al^{3+} solution were transferred into a conical flask containing 2 ml of Fe^{3+} solution (0.01*M*) and 8 ml of Ca^{2+} solution of the same concentration. A 2.5-ml volume of nitric acid (1*M*), 1 ml of *L*-ascorbic acid (1*M*) to reduce Fe^{3+} to Fe^{2+} and a few drops of SXO indicator to allow the end-point to be easily detected by the human eye were added to the ions to be determined. The whole solution was diluted by 80–100 ml of bidistilled water. The mixture was directly titrated against 0.01*M* Na_2EDTA until the colour changed from red to yellow; this step produces the Bi^{3+} ion. At the bismuth end-point an excess of 30 ml of Na_2EDTA was added, followed by 1*M* hexamine solution to a pH of $\simeq 5$ (pH test paper), and finally 2.5 ml of hexamine–HNO_3 buffer of pH 5 were added. The whole solution was boiled for 2–3 min, cooled to room temperature and then diluted to about 160–180 ml. A few drops of SXO solution were added, stirred and the excess of Na_2EDTA was back titrated against 0.01*M* standard zinc chloride solution until the colour changed from yellow to bright red.

For the simultaneous titration of both Al^{3+} and Ti^{4+}, 2 ml of 1*M* sodium fluoride were added to the latter end-point solution, boiled for 2–3 min, cooled and a few drops of SXO and 2.5 ml of hexamine–HNO_3 buffer (pH 5) were added. The whole solution was titrated again with 0.01*M* Zn(II) solution (this step gives $Al^{3+} + Ti^{4+}$). Another aliquot containing the same concentration of the studied cations was taken and Ti^{4+} was completely quantitatively precipitated together with Bi^{3+}, Fe^{3+} and most of Ca^{2+} as the corresponding hydroxides by the dropwise addition of sodium hydroxide solution (1*M*) until a pH of $\simeq 13.5$ (pH test paper) was approached where Al^{3+} exists in solution as AlO_2^-. The latter solution was boiled for 5 min, cooled and the precipitate was separated by filtration, washed several times with bidistilled water. The precipitate was neglected. The pH of the filtrate was lowered to a value of 2 by nitric

acid (1*M*) where aluminium exists in solution as simple Al^{3+} ion, then raised to a value of $\simeq 5$ by hexamine solution (pH test paper) and then hexamine–HNO_3 buffer (pH 5) was added. Aluminium(III) was determined in the filtrate by adding an excess known volume of standard Na_2EDTA followed by back-titration with standard Zn^{2+} solution of the same concentration as Na_2EDTA using SXO as indicator and titanium was found by difference. Calcium does not react with Na_2EDTA at a pH of 5, so any traces of such ion present in the filtrate will not interfere with aluminium.[11]

The feasibility of the simultaneous titration of Al^{3+} and Ti^{4+} with Bi^{3+} was studied for different ratios of them with Fe^{3+} and Ca^{2+}. Eight series of simultaneous titrations were performed with molar ratios of $Bi^{3+}:Ti^{4+}:Al^{3+}$ ranging from 10:4:1 to 1:10:4 to 4:1:10, respectively. For each series constant concentration of both Fe^{3+} and Ca^{2+} was added. No difficulties were encountered in the end-point detection for all the three metals studied. The results of parallel determinations of the three ions using the simultaneous titration method of Ti^{4+} and Al^{3+} with Bi^{3+} are given in Table 1. The calculated results show that the determination of Bi^{3+} is more accurate than the determination of both of Ti^{4+} and Al^{3+}.

Consecutive titration of Al^{3+} and Ti^{4+} with Bi^{3+} by visual end-point indication using SXO

The same experimental procedures described for the determination of Bi^{3+} and of the back-titration of excess Na_2EDTA in the simultaneous titration of one of such series were also exactly adopted in the consecutive titration. A 2-ml volume of sodium dihydrogen phosphate 1*M* were added to the latter solution. The whole mixture was boiled for 2–3 min, cooled and then few drops of SXO and 2.5 ml of hexamine–HNO_3 buffer were added. The analyte solution mixture was titrated against standard zinc(II) chloride solution, until a yellow colour changed to bright red (this step gives Ti^{4+}). For the determination of Al^{3+}, 2 ml of 1*M* sodium fluoride were added to the Ti^{4+} end point solution. The latter solution was boiled for 3–5 min then few drops of SXO and hexamine buffer (2.5 ml) were added and the whole solution was titrated while hot versus standard zinc(II) chloride solution (this titration gives Al^{3+}).

Table 1. Statistical evaluation of eight series of simultaneous titrations of Ti^{4+} and Al^{3+} with Bi^{3+} by visual detection of the end-point using SXO as indicator (pH 1–2 for Bi^{3+} and 5 for Ti^{4+} and Al^{3+}) for all series $c_{Fe^{3+}} = 0.02mM$, $c_{Ca^{2+}} = 0.08mM$, $c_{Na_2EDTA} = c_{Zn^{2+}} = 0.01$ and/or $0.001M$

The same series used in the simultaneous titration method was investigated by the consecutive titration procedure for a meaningful comparison of the accuracy between the two methods.

The results of eight series of parallel determination of the three ions with constant concentration of Fe^{3+} and Ca^{2+} ions are given in Table 2. The obtained results show that the determination of Bi^{3+} is more accurate than the determination of both Ti^{4+} and Al^{3+}. Comparisons of the accuracy between the simultaneous and consecutive titration for the determination of Ti^{4+} and Al^{3+} (Tables 1 and 2) show that the simultaneous method gives more accurate results for Ti^{4+} than the consecutive one specially for the lower concentration of Ti^{4+}. For higher Ti^{4+} concentration the accuracy of the two methods are approximately the same. The accuracy of Al^{3+} determination is almost the same for both methods.

Interference of foreign species

The interference of different anions was studied. It was found that 50-fold excess of Cl^-, Br^-, I^-, NO_3^-, SO_4^{2-} and ClO_4^- slightly interfered. Even equal concentrations of F^-, PO_4^{3-} and tartarate ions interfered. It was found that Fe^{3+}, Ni^{2+}, Th^{4+}, Zr^{4+}, Zn^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+}, Sn^{2+}, Cu^{2+} and lanthanides interfered seriously when present at 1 or 2 fold excess of the titrated metals. The interfering effect of Fe^{3+} on Bi^{3+} determination could be removed by *L*-ascorbic acid. Fortunately all other interfering cations are rarely found in ceramic products and both Al^{3+} and Ti^{4+} minerals.

The success of the present methods depends on the fact that Ti^{4+} is not hydrolysed when the pH is controlled. The results obtained (Tables 1 and 2) show that those cations can be kept in solution at pH $\simeq$ 5. However, hydrolysis often occurs unless the pH is controlled by dropwise addition of a weak base such as hexamine. It was found that the use of strong base, without respect to its careful addition to the solution, causes the precipitation of titanium after the determination of Bi^{3+}. When solid hexamine was added, it was also found that it causes slight precipitation of Ti^{4+}. Once hydrolysis occurs, an irreversible precipitation of Ti^{4+} happens immediately. In all our previous work, it was found that hexamine solution was preferable to any other weak base and gives a sharper end-point with Semi-Xylenol Orange.[9-11] In the

†Titanium is found by difference in a second titration.

consecutive titration, sodium dihydrogen phosphate was used to release Na_2EDTA and determine selectively large amounts of Ti^{4+} in the presence of Al^{3+}. The other advantage of using this salt was that it didn't alter the pH of the solution (≃5). The white precipitate of titanium phosphate formed did not affect the colour change at the end-point. Because of the determination of Al^{3+} and Ti^{4+} combined or alone after Bi^{3+} is based on two titrations, the first being unrecorded ($Ti^{4+} + Al^{3+}$ + blank). The detection limit[19,20] of the two applied methods was 20.9 ppm for Bi^{3+}, 4.79 ppm for Ti^{4+} and 2.7 ppm for Al^{3+}.

Application of the proposed methods

The results of the determination of Bi^{3+}, Ti^{4+} and Al^{3+} in a series of naturally occurring samples containing some of these ions are shown in Tables 3 and 4. These results (average of ten determinations for three weighed samples) are in good agreement with the values obtained by the standard classical methods. The relative standard deviation as calculated from the range method[9] was found to be (0.15–1.95%) and (0.25–0.85%) for both simultaneous and consecutive titration respectively. From the obtained results, it is clear that the analytical determination of the three metal ions in different real samples is simple, reliable and can be applied with good reproducibility. It has been previously shown that SXO is preferable to Xylenol Orange (XO) for both visual and spectrophotometric titrations because of its high precision and accuracy, sensitivity, sharp end-point and formation

DETERMINATION OF CARBAMATE HERBICIDE ASULAM IN PEACHES FOLLOWING FLUORESCAMINE FLUORIGENIC LABELLING

F. GARCIA SANCHEZ, A. AGUILAR GALLARDO and C. CRUCES BLANCO
Department of Analytical Chemistry, Faculty of Sciences, The University, 29071-Málaga, Spain

(*Received* 18 *October* 1991. *Revised* 23 *January* 1992. *Accepted* 23 *January* 1992)

Summary—Because of the primary aminic character of asulam, it is readily labelled with fluorescamine. A study of the variables affecting the derivatization reaction has been made. Two analytical approaches, that is, direct, synchronous spectrofluorimetry have been tested, and they both show good analytical performances. The linear dynamic range of the synchronous approach is 0.043–0.214 μg/ml and the relative standard deviation is 1.6%. The methods have been applied to the determination of asulam residues in peaches with recoveries of 85–106%.

Asulam (methyl 4-aminobenzenesulphonylcarbamate) is a translocation herbicide, absorbed by leaves and roots causing slow chlorosis in susceptible plants. It interferes with cell division and expansion and is used to control the growth of grasses.[1]

The original method for asulam residues quantification[2] was based on a colorimetric reaction.[3] Analysis for asulam using HPLC in wheat flour was reported,[4] but the metabolites were not examined. Using HPLC reverse phase column,[5] asulam was determined in peaches fortified at the 0.1 μg/ml, together with its metabolites, sulphanilamide and acetylasulam. GLC was used for determination of asulam and acetylasulam after hydrolysis to sulphanilamide.[6] Similarly asulam is analysed in forage crops and animal tissue by HPLC after derivatization.[7] Determination of asulam in soils by isotachophoresis and liquid chromatography,[8] using UV and conductivity detection has also been reported. Thin-layer chromatography using fluorescamine as labelling reagent has been used to analyse soil samples for the herbicide.[9]

Because Asulam does not show native fluorescence, the technique of spectrofluorimetry has not been previously applied to its determination.

Udenfriend *et al.*,[10] introduce fluorescamine as a labelling reagent to determine primary amines; this is superior to dansyl chloride because both the reagent and its hydrolysis products are nonfluorescent and permit homogeneous fluorogenic labelling. Such an approach has proved its usefulness in numerous analytical applications for some 30 years.

This paper describes the use of the synchronous derivative technique to determine the fluorescent derivative of asulam herbicide. This method may be used for the quantitative analysis of asulam residues in peaches fortified at levels of ng/ml.

EXPERIMENTAL

Apparatus

Emission measurements were done with a luminescence spectrometer, Perkin–Elmer LS-5, (Perkin–Elmer, Beaconsfield, Buckinghamshire, U.K.), equipped with a xenon discharge lamp (9.9 W) pulsed at line frequency, monochromators F/3 Monk-Gillieson type, and 1 × 1-cm quartz cells. The spectrofluorometer was operated in the computer-controlled mode via the RS232C serial interface by a Perkin–Elmer Model 3600 data station microcomputer. Instrumental control and data collection were achieved by using the commercially available Perkin–Elmer computerized luminescence software (PECLSII). For graphical recording, an Epson FX-85 printer–plotter was connected to the spectrofluorometer. All fluorescence spectra are uncorrected because no significant wavelength shifts are observed when comparing with corrected spectra.

UV absorption spectra were recorded with a Shimadzu UV-240 Graphicord recording spectrophotometer. A rotary vacuum evaporator.

Reagents

Stock solutions of asulam (99% pure, Dr. S. Ehrenstofer), were prepared in ethanol at concentrations of 1.0 mg/ml. Working solutions at 100 μg/ml were prepared in ethanol.

The analytical-reagent-grade Fluorescamine (4-phenylspiro[furan-2(3H),1′-phtalan]-3,3′-dione) was obtained from Aldrich and was dissolved in acetone (1 mg/ml).

All solvents used were of analytical reagent grade (Merck) and only demineralized water was used in this work.

Procedures

General procedure. To a 10-ml standard flask add the volume of stock solution needed to obtain a final concentration of asulam between 0.042 and 2.14 μg/ml. Add 0.5 or 2.5 ml (low or high concentration range) of fluorescamine ($3.59 \times 10^{-3}M$) and 2 ml of buffer solution (phthalate/HCl, pH 3) and dilute to the mark with demineralized water. For normal spectrofluorimetry, measure fluorescence intensity at 498 nm, with excitation at 402 nm, against a reagent blank.

For synchronous spectrofluorimetry, prepare the samples exactly as above, record the spectrum at $\Delta\lambda = 96$ nm (corresponding to the Stokes shift) at a time constant of 2 sec and scan speed of 240 nm/min.

Extraction procedure. To chopped peaches (50 g), add 60 μl of standard ethanolic solution of asulam 1170 μg/ml, and blend at high speed for 5 min in 50 ml of acetone. The blended sample was filtered through a fritted glass Büchner (coarse porosity) under reduced pressure. Add to the filtrate 25 ml of saturated sodium chloride and 50 ml of methylene chloride, make up to 250 ml with demineralized water and transfer to a 500-ml separating funnel. The organic phase was concentrated just to dryness by using a rotary evaporator and the residue diluted with demineralized water to a final volume of 25 ml. Aliquots of this solution were then analysed according to the proposed analytical procedure.

RESULTS AND DISCUSSION

Optimization of the derivatization reaction

Fluorescamine (FC), itself non-fluorescent, reacts rapidly with primary aliphatic or aromatic amines to give highly fluorescent pyrrolinone derivatives and non-fluorescent hydrolysis products.[11]

The fluorescence spectra obtained when the reaction takes place in an aqueous solution of 2 μg/ml at pH 3 exhibit two excitation maxima at 325 and 402 nm and an emission band at 498 nm. In order to check that the excess of fluorescamine is hydrolysed and gives no fluorescence signal, a blank test was performed without asulam. No significant blank signal was found.

We examined the effect of the pH on derivative formation in the media and the relative fluorescence intensity of the asulam derivative. In the range pH 2.8–3.1, the variations were minimum, and pH values greater than 10 produce very little fluorescence. To maintain the pH, a set of buffers was assayed and significant differences were found. Figure 1 shows the results obtained from a 10-ml solution containing $3.6 \times 10^{-4}M$ of FC and 2 μg/ml of asulam. Two sets of data points are shown, one obtained by adjusting the pH by little additions of diluted solutions of sodium hydroxide or hydrochloric acid to the phthalate buffer of pH 3, and the other by using 2-ml aliquots of different buffer solutions.

To keep the optimum pH selected to carry out the derivatization reaction constant, several buffers of different composition may be possible. Experiments to test the influence of the nature of buffer in fluorescence signal show that it is a critical variable, since phthalate based

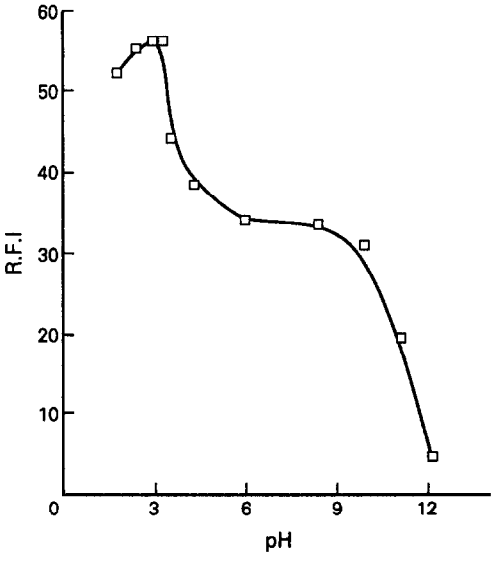

Fig. 1. Influence of pH on the fluorescence intensity of fluorescamine derivative of asulam. [Asulam] = $8.7 \times 10^{-8}M$; [FC] = $3.6 \times 10^{-4}M$. $\lambda_{exc} = 402$ nm, $\lambda_{em} = 498$ nm.

buffer gives twice the signal of glycine or citrate based buffer.

Also, buffer concentration affects the relative fluorescence intensity. A 1-ml portion of 0.05*M* phthalate buffer in an over-all volume of 10 ml produces a constant and maximum signal; higher concentrations of buffer depress the signal. This effect is due, probably, to changes in ionic strength and in the thermodynamic hydrolysis constant of FC. No changes have been found in the derivatization reaction on changing the addition order of the reactants, if we kept in mind that Asulam must be in the flask when buffer and FC are added.

The amount of FC used was found to influence the results. Approximately a 20-fold reagent excess is required to complete derivative formation.

The possibility of enhancing the sensitivity of the FC derivative by using different organic solvents to extract or dissolve the fluorophor was investigated. Derivative fluoresence was found to be strongest in the aqueous medium.

Synchronous derivative spectrofluorimetry

The most appropriate parameters to register synchronous derivative spectra for the procedure were selected. The contribution of this approach to the analytical methodology when the problem is the determination of an isolated compound, not a multicomponent fluorescent compound sample, is the improved sensitivity that may be attained. In this case, the limiting factor in the estimation of the detection limit is the blank signal and the associated standard deviation, and this figure can be significantly reduced since less contribution of the blank signals are observed, especially when the broad band blank spectra are obtained. In addition, the band narrowing effect that synchronous spectrofluorimetry applies, together with the sensitivity of the first derivative to narrowest spectral profiles, gives a gain in analytical sensitivity of the method. Also, in general, in the synchronous scanning the signal is stabilized and is less affected by random fluctuations, thus better precision in measurements can be obtained.

For simple analysis, the recommended scanning interval is the one that provides the highest intensity and the minimum peak half-width, which often corresponds to the Stokes shift. The derivative amplitude is normally taken as the vertical distance from peak to trough.

In this work, the best results were $\Delta\lambda = 96$ nm. The reduction of the peak half-width and the position of the synchronous maxima were calculated.[12] A reduction of $\Delta\lambda$ from 72 to 45 nm was observed. It is important to note that the effectiveness of derivative spectroscopy is a function of the bandwidth of the normal spectrum.

Analytical parameters

The calibration curves were recorded for both the direct and synchronous techniques. The linear dynamic ranges were from 0.043 to 2.14 μg/ml, were identical, that is while the correlation coefficients were 0.996 and 0.999, respectively ($n = 5$).

The precision of the methods determined by analyzing seven replicate of 64.2 ng/ml, was 6.2 and 1.6%, respectively.

Residue analysis of asulam in peaches

To check the usefulness and to compare two fluorimetric procedures proposed in the present work, known amounts of asulam were added to peach extracts and the samples were analysed as indicated under the general procedure.

Fruits were bought from the local market and their origin and previous treatment were unknown. The fruits were spiked with the herbicide at 0.14 μg/ml.

The results obtained for the analysis of the herbicide in peaches using direct and synchronous spectrofluorimetry are given in Table 1.

Recoveries obtained show that the synchronous technique fits the results with almost 100% efficiency with better precision than the direct approach. Because of its simplicity, the

Table 1. Recovery assay of Asulam in fortified peaches

THE DETERMINATION OF LEACHABLE URANIUM IN MARINE AND LACUSTRINE SEDIMENTS BY STEAM DIGESTION

DARRIN K. MANN,* THOMAS J. OATTS* and GEORGE T. F. WONG†
Dept. of Oceanography, Old Dominion University , Norfolk, VA 23529-0276, U.S.A.

(*Received* 31 *October* 1991. *Revised* 30 *January* 1992. *Accepted* 30 *January* 1992)

Summary—Uranium can be leached with a mixture of nitric and perchloric acids from 1 g of marine or lacustrine sediment in an autoclave at 275° and 2 atm in 4 hr. The leachate resulted from this steam digestion may then be analyzed for uranium by isotope dilution alpha spectrometry with a precision of about ±7%. In comparison to the conventional leaching scheme by wet digestion in an open beaker, this method is less time consuming, less labor intensive, requires the use of smaller amounts of acids while it yields data with comparable accuracy and precision. In the analysis of a set of samples collected from a variety of depositional environments, this method yielded results that were indistinguishable from those obtained by the conventional method.

The sedimentary geochemistry of uranium in aquatic environments has been studied extensively because it is a rather abundant and ubiquitous trace element with interesting geochemical properties and its longest-lived isotopes are also the ultimate parents of two decay series whose members have been used widely as tools for describing and quantifying the sedimentary processes.[1,2] The initial step in the determination of uranium in marine and lacustrine sediments usually involves a wet digestion of the sample in the presence of a yield tracer with some combination of nitric, hydrochloric, perchloric and/or hydrofluoric acids in an open beaker in order to solubilize the uranium from the solid phase for subsequent quantification.[3–8] The choice of the combination of acids used is determined by the expected phase association of the uranium in the sample.[4,8–11] The total amount of acid needed is relatively large, ranging from 50 to 200 ml.[3,9,10] The time for digestion is relatively long, ranging mostly between 24 and 48 hr. Frequent replenishment of the acids lost by evaporation during the process is often needed. As a result, more or less continuous attention must be given to this digestion step. Once the leaching process is complete, the leachate must be separated from the residual particulate material by filtration or centrifugation before it can be further processed.[1,12] The filtration of this highly acidic leachate-sediment slurry is somewhat cumbersome, potentially hazardous and thus must be handled with great care.

Recently, Nielsen and Hrudey[13] reported that trace metals in sewage and sludge may be determined by leaching them from the samples by steam digestion instead of wet digestion. We have adopted a modified version of this method for solubilizing uranium from lacustrine and marine sediments. The resulting method is simpler, less time consuming and less labor intensive and it yields results that are indistinguishable from those obtained by using the conventional method.

EXPERIMENTAL

Reagents and apparatus

All reagents used were of analytical grade.

A solution containing ^{236}U, with a specific acitivity of 11.27 dpm/ml, was prepared from $^{236}U_3O_8$ provided by the Oak Ridge National Laboratory (Batch 201DR2). This solution was standardized against a ^{238}U solution prepared from natural U_3O_8 supplied by the National Bureau of Standards (NBS SRM 950b).

An alpha counting system consisting of two Ortec Model 576 dual-detector alpha spectrometers, a Tracor Northern Model TN-1247 four

*Present Address: Martin Marietta Energy Systems, P.O. Box 2003, Oak Ridge, TN 37831-7458, U.S.A.
†Author for correspondence.

input multiplexor-router and a Model TN-7200 multichannel analyzer was used for alpha spectrometry.

Electroplating was carried out in teflon plating cells with platinum anodes similar to the one designed by Herada and Tsunogai[14] and modified by Anderson and Fleer.[4]

Procedures

Sample preparation for steam digestion. Transfer about 1 g of the dried, powdered and weighed sediment, 20 ml of 8*M* nitric acid, 1 ml of concentrated perchloric acid and 0.5 ml of the standardized ^{236}U solution into a 30-ml polysulfone centrifuge tube. Seal the centrifuge tube with a sealing cap. (Centrifuge tubes supplied by Nalgene are durable and relatively inexpensive. However, the caps that come with them may leak during centrifugation and they must be replaced with sealing caps.) Agitate the content in the tube with a vortex mixer for two minutes. Then, transfer the tube to an autoclave and incubate it for 4 hr at 275° and 2 atm. (Up to 60 samples may be digested simultaneously in a 12-l. autoclave.) Centrifuge it at 3000 rpm for 20 min and decant off the supernatant leachate. Wash the sediment twice with 10 ml of 2*M* hydrochloric acid and twice with 10 ml of demineralized water by resuspending the sediment in each washing with a vortex mixer for 2 min. Separate the sediment from the washings by centrifugation and combine the washings with the leachate.

Sample preparation for wet digestion. The method of Roe and Burnett[8] is followed. Transfer about 2–3 g of the dried, powdered and weighed sediment to a beaker together with 50 ml of concentrated nitric acid, 2 ml of concentrated perchloric acid and 0.5 ml of the standardized ^{236}U solution. Digest the mixture at about 80° for 24 hr. Separate the leachate from the sediments by filtration through a glass fiber filter. Wash the sediment 3 times with 15 ml of 2*M* hydrochloric acid and add the washings to the filtrate.

Purifying and electroplating uranium. The general scheme of Ku[3] and Anderson and Fleer[4] is used for the separation and determination of uranium in the leachate. Remove most of the iron from the solution by extracting it with diethyl ether. Convert the solution to 9.6*M* hydrochloric acid by evaporating it to near dryness and then diluting it with 9.6*M* hydrochloric acid. Separate uranium from most of the other matrix elements by passing the sample through an AG1 × 8 anion exchange resin column in the chloride form, equilibrated with 9.6*M* hydrochloric acid and with a bed volume of about 11 ml (1 cm diameter × 14 cm height), and then eluting the column by a serial gradient elution with 9.6*M* hydrochloric acid and then 0.1*M* hydrochloric acid in succession. Evaporate the fraction in 0.1*M* hydrochloric acid to near dryness and then dilute it with 8*N* nitric acid. Further separate uranium from other elements by passing the sample through an AG1 × 8 anion exchange resin column in the nitrate form, equilibrated with 8*N* nitric acid and with a bed volume of 6 ml (0.6-ml diameter × 20-cm height), and then eluting the column successively with 8*M* nitric acid, 9.6*M* hydrochloric acid and then 0.1*M* hydrochloric acid. Evaporate the fraction in 0.1*M* hydrochloric acid to near dryness. Dilute it with 1*M* nitric acid. Evaporate it to near dryness again and then dilute it with 0.1*M* nitric acid. Transfer the solution to the electroplating cell with washings of 2*M* ammonium chloride which has been adjusted to pH 2 with hydrochloric acid. Electroplate the uranium onto a silver disk for 3.5 hr at 0.8 amps and analyze for uranium by alpha spectrometry.

RESULTS AND DISCUSSION

Sub-samples of a single sample of marine sediment were digested by steam digestion for various amounts of time varying from 2 to 5 hr and then analyzed for the concentrations of ^{238}U and ^{234}U. Two to four sub-samples were analyzed at each time for digestion. Another four sub-samples were digested also by the conventional wet-digestion method in an open beaker and then analyzed for the uranium isotopes. The results are shown in Fig. 1 and Table 1.

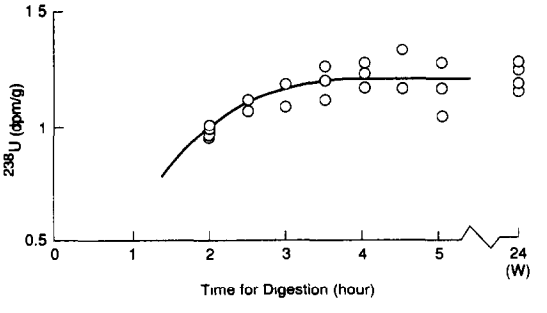

Fig. 1. The effect of the time for steam digestion on the recovery of ^{238}U in sediments from Tom's Cove, Virginia. (W) denotes the concentrations of ^{238}U determined by using the conventional wet digestion.

Table 1. Effect of time for digestion on the determination of uranium by steam digestion

Digestion method	Time for digestion, hr	Conc. in sub-samples 1	2	3	4	Avg.	S.D.,* %

Average (3.5 to 5 hr for digestion) = 1.12 ± 7%							

*Standard Deviation—1 sigma in %.

For a given time for digestion, steam digestion yielded highly precise results with precision ranging from ±2 to ±10% (1 standard deviation) for ^{238}U and ±2 to ±9% (1 standard deviation) for ^{234}U. (The uncertainty in the concentration of the ^{236}U yield tracer is not included in the calculation of the precision of the method. Any error from this source should have stayed constant throughout this study since the same tracer solution was used in all the analyses.) In most cases, the precision was better than ±5%. Between 2 and 3.5 hours of time for digestion, the concentration of ^{238}U increased with increasing time from 0.96 to 1.17 dpm/g. The concentration of ^{234}U followed a similar trend. Eleven sub-samples were digested for 3.5 to 5 hours. In this group of samples, the concentration of ^{238}U did not increase systematically with increasing time for digestion. The concentration ranged between 1.02 and 1.30 dpm/g with an average of 1.18 dpm/g ± 7% (1 standard deviation). These concentrations should be considered indistinguishable from each other within the analytical uncertainty of the analysis and the possible compositional variability among the sub-samples. We have adopted a time for digestion of 4 hours in order to insure that a constant recovery is reached. The concentration of ^{234}U and the activity ratio of $^{234}U/^{238}U$ in these samples ranged from 1.2 to 1.37 dpm/g with an average of 1.31 dpm/g ± 5%, and 1.04 to 1.25 with an average of 1.12 ± 7%, respectively. In comparison, by using the conventional wet digestion method, the concentration of ^{238}U, ^{234}U and the activity ratio of $^{234}U/^{238}U$ were 1.18 dpm/g ± 5%, 1.48 dpm/g ± 4% and 1.24 ± 7% respectively. The exact correspondence in the concentration of ^{238}U is probably fortuitous. However, the data do demonstrate clearly that the steam digestion can produce

data indistinguishable from those obtained by the conventional method.

The concentration of uranium in sediments collected from five different depositional environments was determined by using steam digestion and the conventional method of digestion. (Standard reference sediments that have been analyzed for leachable uranium are not yet available commercially for an intercalibration study.) These samples ranged from a fine grained sediment with a low organic content (<3% of weight loss on ignition at 550° or LOI) collected from a brackish environment to a highly organic sediment (>50% of LOI) collected from a fresh, black water lake. The results are shown in Table 2. The concentration of ^{238}U and ^{234}U ranged from 0.44 to 1.99 dpm/g and 0.74 to 2.5 dpm/g respectively. Although the chemical characteristics and the concentrations of ^{238}U and ^{234}U in these five samples of sediments varied considerably, both methods of digestion yielded results that are indistinguishable from each other when the analytical uncertainty of each method and the possibility of inhomogeneity among the sub-samples are taken into account. The differences in the concentrations of ^{238}U and ^{234}U as determined by these two methods were mostly less than 0.1 dpm/g. It is interesting to note that the largest percent difference in concentration was found in the most organic-rich sediment collected from Lake Drummond, where the LOI was about 58%, and steam digestion yielded the higher concentrations of ^{238}U and ^{234}U. This suggests that, with this type of sediment, the leaching of uranium with wet digestion may be less complete than with steam digestion. However, sediments with such a high organic content are not commonly found in the marine and lacustrine environments. The concentrations of ^{238}U are related to each other as follows:

$$U_s = (0.96 \pm 0.09)\quad U_w + (0.11 \pm 0.11)$$

$$\text{and}\quad r^2 = 0.98$$

where U_s and U_w are the concentrations of ^{238}U as measured by steam digestion and by the conventional digestion method respectively and r is the correlation coefficient (Fig. 2). The intercept of the line is indistinguishable from zero and the slope of the line is indistinguishable from unity suggesting that both methods yield identical results within analytical uncertainties.

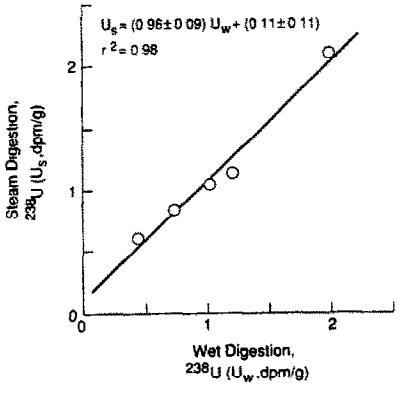

Fig. 2. The relationship between the concentration of ^{238}U determined by using steam digestion, U_s, and the conventional wet digestion, U_w. The best fit line and its equation are shown.

CONCLUSION

Steam digestion can greatly simplify the determination of uranium in lacustrine and marine sediments while yielding data with similar accuracy and precision as the conventional wet digestion method. The time for digestion is reduced from 24 to 4 hr. The amount of acid required can be reduced by up to a factor of ten. No special attention to the samples is required during the digestion. The

entire sample preparation may be carried out in a single centrifuge tube. Filtration may be circumvented. The resulting method is less time consuming and less labor intensive.

SPECTROPHOTOMETRIC AND VOLUMETRIC MOLYBDENUM DETERMINATION WITH 2,2′-BIQUINOXALYL

IRENA BARANOWSKA and KATARZYNA BARSZCZEWSKA
Department of Analytical and General Chemistry, Silesian Technical University 44-100 Gliwice, Poland

(*Received* 7 *June* 1991. *Revised* 12 *February* 1992. *Accepted* 12 *February* 1992)

Summary—Volumetric and spectrophotometric methods for molybdenum determination based on reaction with 2,2′-biquinoxalyl (2,2′-BQx) in concentrated hydrochloric acid media have been developed. Absorption spectra of the 1,1′-dihydro 2,2′-biquinoxalylene complex shows the most intensive absorption band at 685 nm with molar absorptivity $\epsilon = 3.3 \times 10^4$ l.mole^{-1}.cm^{-1}. The compound is characterized by good durability to high temperatures and concentrated acid media. The mentioned indicator gives distinct colour changes at the titration end-point. The spectrophotometric method for molybdenum determination is based on the use of the difference in absorbance between the oxidized and reduced forms of 2,2′-BQx. The indicator is reduced with Sn(II) and then part of it is reoxided as a result of addition of Mo(VI). The difference in absorbance between the blank determination and molybdenum sample increases linearily in the concentration range 0.2–2.0 μg Mo/cm^3. 2,2′-Biquinoxalyl was used as an indicator in the volumetric method for the determination of molybdenum concentrations in steel alloy. The interfering ions Fe(III) and Cr(III) are easily eliminated as the precipitate of hydroxides. The mineral acids, hydrochloric sulphuric and perchloric acids, have been tested as reaction media.

Raw-materials used for the preparation of molybdenum are characterized by large variations in their quantitative compositions. Amounts of molybdenum are in the range of: 20–90% in molybdenum ores; 50–80% in ferromolybden and 0.005–0.1% in copper ores. Such wide concentration ranges require large ranges of applicability when considering methods.

The aim of this work was to examine the usefulness of 2,2′-biquinoxalyl (2,2′-BQx) for the spectrophotometric and volumetric (stannometric) determination of molybdenum, and to verify this method on real samples.

The "Analysen Testprobe" Nr 4.4/7 (Head Office of Measures DDR Prüfdienstelle 301 Magdeburg) containing 2.28% of molybdenum was used as the standard sample. Previous works[1–6] show, that the 2,2′-BQx is a useful spectrophotometric reagent for the determination of strong reducing and oxidizing agents. It has also been applied as the redox indicator in volumetric methods.

On the basis of previous investigations with other metals it was assumed that optimum conditions were: a medium of 6*M* hydrocholoric acid, 3*M* sulphuric acid and a temperature of 80°.

The redox potential of the 2,2′-BQx$_{OX}$/2,2′-BQx$_{RED}$ system, which is equal to 0.4 V,[1] shows that separation of preliminary chromium, iron and other oxidants is necessary during stannometric molybdenum determination when 2,2′-BQx is used as indicator.

In this work, separation of heavy metals in the form of precipitates of their hydroxides, as recommended by Polish Standard PN-82/H-04207, was applied.

EXPERIMENTAL

Reagents and apparatus

*Molybdenum standard solution, 0.1*M *in 6*M *hydrochloric acid.* Dissolve 12.3556 g of $(NH_4)_6Mo_7O_{24}.4H_2O$ in 50 ml of concentrated hydrochloric acid and dilute to 100 ml with water. From this solution prepare the $2 \times 10^{-5}M$ concentrated solution by appropriate dilution.

*Stannous chloride standard solution, 0.5*M. Dissolve 112.8150 g of $SnCl_2.2H_2O$ in one litre of 6*M* hydrochloric acid. Less concentrated solutions (8×10^{-4} and $2.5 \times 10^{-4}M$) were made by appropriate dilution of the standard solution with deoxidized hydrochloric acid just before measurement.

2,2′-BQx (own synthesis by ref. 7). Appropriate weighed amounts of 2,2′-BQx were dissolved in concentrated hydrochloric acid.

Table 1. The results of molybdenum determination by the volumetric method

Mo taken, *mg*	$V_{Sn/Mo}$, *ml*	V_{KBrO_3}, *ml*	Mo found, *mg*	
	2.70	6.70	34.71	
33.56	2.70	6.10	31.60	$\bar{m}_{Mo} = 32.94$
	2.75	6.16	32.50	$s = 1.60$
	5.65	6.18	67.01	
	5.75	6.38	70.40	
	5.60	6.20	66.63	
67.12	5.60	6.30	67.70	$\bar{m}_{Mo} = 67.28$
	5.75	5.94	65.54	
	5.75	5.94	65.54	$s = 1.69$
	5.35	6.64	68.17	
	11.35	6.24	135.91	
	11.50	5.94	131.09	
134.24	11.49	5.90	130.09	$\bar{m}_{Mo} = 133.92$
	10.50	6.80	137.02	
	9.70	7.28	135.51	$s = 3.11$

The results were calculated by the equation

$$m_{Mo} = 1.919 . V_{Sn/Mo} . V_{KBrO_3} \text{ (mg)}$$

*Potassium bromate standard solution (1/6 $KBrO_3$) = 0.1*M. A weighed amount of $KBrO_3$ was dissolved in one litre of water. A Specol spectrophotometer (Zeiss Jena) with 10-mm cells was used for all measurements.

Volumetric molybdenum determination in the alloy

A known volume of molybdenum standard solution (5, 10 or 20 ml) was transferred into a 300-ml conical flask. Then 150 ml of 3*M* sulphuric acid was added. The sample prepared in this way was heated to 80°.

The sample was titrated with *ca.* 0.1*M* Sn(II) solution until it changed from yellow to dark-green. The end-point of the titration was indicated by the unchanging dark-green colour of the sample. Volume of 0.2 ml of 0.1% indicator solution was added to each sample. The concentration of stannous chloride was determined bromometrically immediately.

In order to check the reproducibility of the method three series of samples with known amounts of molybdenum were analysed. The average and standard deviation were calculated and the results are shown in Table 1.

Sample preparation. The alloy was ground in a boron carbide mortar and sieve. The powder ($\phi = 0.15$ mm) was solubilized.

Sample solubilization. About 2.5 g of the powdered sample was put into a quartz crucible. A 20-ml amount of a mixture of concentrated nitric and sulphuric acids (1 : 1) was added and the content was heated to obtain a moist residue. The procedure was repeated until the sample was completely solubilized. Then 5 ml of concentrated sulphuric acid was added to completely remove nitric oxides.

Separation of interfering ions. The contents of the crucible were cooled and 75 ml of water were added. The mixture was then boiled and the hot solution containing precipitated silica was filtered. Chromic and ferric hydroxides were precipitated from the filtrate with 30% sodium hydrochloride. The solution was decanted and the precipitated hydroxides were vacuum filtered. The precipitate was washed twice with 25 ml of sodium hydroxide. If the solution has just been prepared no coprecipitation will be observed. The clear filtrate (pH 10) was neutralized with sulphuric acid to pH 7. Sulphuric acid was then added to a final concentration of 3*M*. Then 0.2 ml of 0.1% 2,2′-BQx solution was added to the (80°) sample and titrated with Sn(II) solution. The concentration of the tin(II) chloride solution was determined bromometrically immediately. Results are shown in Table 2.

Spectrophotometric molybdenum determination

Ordinary method. Hydrochloric acid (30 ml, 6*M*) and 10 ml of 1×10^{-4}*M* 2,2′-BQx solution were added to each of six 50-ml measuring flasks. Samples were deoxidized with nitrogen, after which, 1 ml of 8×10^{-4} stannous chloride was added.

The reaction of Sn(II) with 2,2′-BQx leads to formation of 1,1′-dihydro 2,2′-biquinoxalylene. The molar absorptivity of this compound equals 3.3×10^4 l.mole^{-1}.cm^{-1} at the most intensive absorption band, with λ_{max} at 685 nm.

Maximum absorbance was attained after one hour, and 2, 4, 5, 6 and 7 ml of ammonium molybdate were then added. Samples were diluted to 50 ml with 1 : 1 hydrochloric acid. The difference in absorbance between the reagent blank and samples containing molybdenum was measured after 10 min. The results are given in Table 3. The analytical curve was given by the equation

$$\Delta A = 0.17c + 6.9 \times 10^{-3}$$

Table 2. Determination of molybdenum in the alloy sample with the volumetric method

Sample, *g*	Mo content, *mg*	%	Mo found, *mg*	%	
2.6047	59.40		56.40	2.16	
2.3289	53.10		54.08	2.37	
2.3962	54.63	2.28	55.79	2.33	$\bar{m}_{Mo} = 2.28\%$
2.4172	54.95		54.55	2.26	
2.2678	51.71		52.08	2.30	

Table 3. Absorbance variation according to the range of molybdenum sample taken (ordinary method)

	1	2	3	4	5	6
2,2′-BQx ml $1 \times 10^{-4}M$	10	10	10	10	10	10
Sn(II) (ml) $8 \times 10^{-4}M$	1	1	1	1	1	1
Mo $2 \times 10^{-5}M$ (ml)	—	2	4	5	6	7
Mo (μg)	—	26.86	53.72	67.16	80.59	94.02
Mo (μg/ml)	—	0.53	1.07	1.34	1.61	1.88
Absorbance	0.53	0.43	0.33	0.30	0.25	0.19
$\Delta A(1-n)$	—	0.10	0.20	0.23	0.28	0.34

where ΔA is the difference in absorbance and c is the concentration of molybdenum (μg/ml).

Ultimate precision method. Volumes of 30 ml of $6M$ hydrochloric acid were transferred to seven 50-ml measuring flasks. Then 10 ml of $1.5 \times 10^{-4}M$ 2,2′-BQx solution was added to six of them while 3 ml of the same solution was added into the remaining flask. In order to secure complete reduction of 2,2′-BQx, an excess of Sn(II) was added to the first and second flasks and 5 ml of $2.5 \times 10^{-4}M$ Sn(II) was added to the other five flasks. When the solutions obtained maximum absorbance, 1, 2, 4 and 5 ml portions of $2 \times 10^{-5}M$ ammonium molybdate were added to each flask. Samples, where the excess Sn(II) in relation to 2,2′-BQx had been added, were used as the standard solutions for 0 and 100% transmittance adjustment. In this way, an extended (T_r) scale of transmittance was obtained. In this manner tranmittances of the other samples were measured. The transmittances of standard solutions were measured on the ordinary scale (T_z). Transmittances on the extended scale (T_r) were reduced to transmittances on the ordinary scale (T_z) and then to absorbance. Differences in absorbance between the reagent blank and samples with molybdenum were calculated and the results are presented in Table 4.

The analytical curve was given by the equation

$$\Delta A = 0.15c + 0.025$$

where ΔA is the difference in absorbance and c is the concentraton of molybdenum (μg/ml).

RESULTS AND DISCUSSION

Stannometric molybdenum determination with 2,2′-BQx as the indicator was verified for amounts of 30–140 mg in $3M$ sulphuric acid. Solutions of hydrochloric and perchloric acids are inferior media in which to carry out the reaction.

The distinctive feature of an efficient indicator is a colour change that can be visible after adding the first excessive drop of titrant at the end-point of titration, carried on in 80°, 2,2′-BQx reacts with strong reducers in concentrated mineral acid medium. The product of reaction is blue 1,1′-dihydro 2,2′-biquinoxalylene, the molar absorptivity of this compound is 3.3×10^4 l.mole^{-1}.cm^{-1} (λ_{max} at 685 nm). Introduction of molybdenum is connected with reoxidation of biquinoxalyl and discharge of them.

The described spectrophotometric method was studied for molybdenum determination in the range 0.2–2.0 μg Mo/ml. This method is an alternative to coulometric titration[8] which enables determination of an amount of molybdenum not lower than 70 μg/ml. It is also competitive to the catalytic method.[9] The latter method is based on the observation of the

Summary—The complexation reactions between murexide and Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} ions have been studied spectrophotometrically in dimethylsulphoxide solution at 25°. The stoichiometry of the complexes was found to be 1:1. The stability constants of the complexes were determined, and found to follow the Irving–Williams rule for the cations of the first transition series. In dimethylsulphoxide solution, the complexes are much more stable than those in aqueous solution.

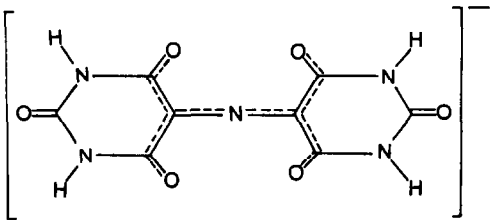
Murexide, the ammonium salt of purpuric acid (**I**), is frequently used as a complexing agent for a large number of metal ions, including the divalent ions of the first transition series, in aqueous solution over a wide range of experimental conditions.[1–5] It is known as a convenient ligand for the quantitative determination of metal ion concentrations in aqueous solution with visible spectrophotometry.[6,7] The equilibrium between various metal ions and metallochromic indicator murexide has been used to determine the stability constants of metal–ligand equilibria by monitoring spectrophotometrically the displacement of metal–murexide equilibrium due to metal–ligand binding.[8–11] Some of the metal–ligand equilibria involve biologically important macromolecules as ligands.[11]

However, the stability constants of murexide complexes with most metal ions are not very large in aqueous solutions[2–5] which possibly cause some limitations in the use of murexide as a chromogenic indicator. Since, in the complexation reactions, the ligand must compete with solvent molecules for cations, use of solvents of lower dielectric constant and solvating ability than water[12] is expected to lead to greater stability of the corresponding murexide complexes.

It was of interest to us to study the effect of solvent properties on the thermodynamics of the metal ion–murexide complexes. We have already reported some results obtained from the study of murexide complexes with a number of metal ions in non-aqueous[13,14] and mixed solvent.[15] In this paper we report a spectrophotometric study of the murexide complexes with Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} ions in dimethylsulphoxide solution at 25°.

EXPERIMENTAL

Reagent grade $CoCl_2.6H_2O$, $NiCl_2.6H_2O$, $CuCl_2.2H_2O$ and $Cd(NO_3)_2.4H_2O$ (all from Merck) were completely dehydrated by heating in an oven of proper temperature[16] until a predetermined weight was reached. The resulting water free solid salts were stored over phosphorus pentoxide under vacuum before use. Reagent grade zinc chloride, lead nitrate (both



I

*Author for correspondence.

from Merck), tetraethylammonium perchlorate (TEAP, Fluka) and murexide (Merck) were of the highest purity available and used without further purification except for vacuum drying over phosphorus pentoxide for 72 hr. Spectroscopic grade dimethylsulphoxide (DMSO, Merck) was used as received. All spectra were obtained with a Model 2100 Shimadzu UV–Vis spectrophotometer at $25 \pm 1°$.

The formation constants of 1:1 complexes between murexide and the metal ions used were determined by the absorbance measurements, at λ_{max} of each complex, of solutions in which varying concentration of metal ions (2.0×10^{-4}–$1.0 \times 10^{-3} M$) were added to a fixed concentration of murexide ($2.0 \times 10^{-5} M$) in DMSO. The ionic strength of all solutions was kept constant at $0.1 M$ with TEAP. All solutions were neutral and, hence, the ligand existed in its monovalent form, Mu^-, throughout.[2,13,14,17] Attainment of equilibrium was checked by the observation of no further change in the spectra after several hours.

When a metal ion, M^{2+}, reacts with murexide, Mu^-, to form a 1:1 complex, the formation constant is given as

$$K_f = \frac{[MMu]}{[M][Mu]} \quad (1)$$

(the charges are omitted for simplicity). The total concentration of Mu, C_{Mu}, and the absorbance at λ_{max} of the complex, A, are expressed as

$$C_{Mu} = [MMu] + [Mu] \quad (2)$$

$$A = \epsilon_{MMu}[MMu] + \epsilon_{Mu}[Mu] \quad (3)$$

where ϵ_{MMu} and ϵ_{Mu} are the molar absorptivities of complexed and free murexide, respectively.

By substitution of equation (1) into equations (2) and (3) we obtain

$$C_{Mu} = (K_f[M] + 1)[Mu] \quad (4)$$

$$A = (\epsilon_{MMu} K_f[M] + \epsilon_{Mu})[Mu] \quad (5)$$

Dividing equation (5) by (4) gives

$$\frac{A}{C_{Mu}} = \frac{\epsilon_{MMu} K_f[M] + \epsilon_{Mu}}{K_f[M] + 1} \quad (6)$$

By considering $[M] = C_M - [MMu] \approx C_M$ (since $C_M \gg C_{Mu}$) and $A_o = \epsilon_{Mu} C_{Mu}$ and rearrangement of equation (6) we have

$$AK_f C_M + A = \epsilon_{MMu} K_f C_M + A_o \quad (7)$$

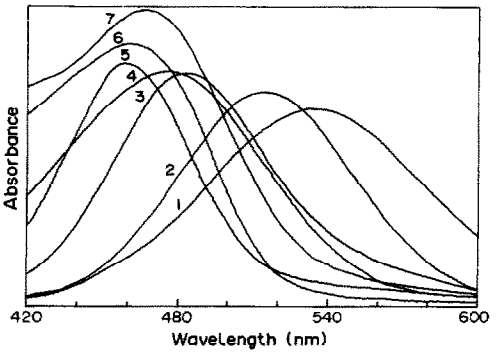


Fig. 1. Visible region spectra of murexide and its metal complexes in DMSO: 1, murexide; 2, Pb^{2+}; 3, Cd^{2+}; 4, Cu^{2+}; 5, Zn^{2+}; 6, Ni^{2+}; 7, Co^{2+}.

Dividing equation (7) by A_o and its rearrangement gives

$$(A/A_o - 1)/C_M = \epsilon_{MMu}/\epsilon_{Mu} K_f - K_f A/A_o \quad (8)$$

According to equation (8), there is a linear relation between $(A/A_o - 1)/C_m$ and A_o/A (Fig. 3). From the intercept of the line, the formation constant of the murexide complex could be obtained.

RESULTS AND DISCUSSION

The visible spectra of murexide and its complexes with the metal ions used in DMSO solution are shown in Fig. 1. All the complexes are distinguished by a strong and ion specific blue-shift, the reasons for which are discussed elsewhere.[13,14] The stoichiometry of the complexes was examined by the mole ratio method,[18,19] and found to be 1:1 in all cases. Some of the resulting absorbance–mole ratio plots are shown in Fig. 2. As can be seen, each plot consists of two straight lines, the intersections of which determines the stoichiometry of the complex (Table 1).

The complexation equilibria between murexide and the metal ions were studied

Table 1. Log K_f of different metal ion–murexide complexes in DMSO and water

Solvent	Cation	λ_{max} nm	Stoichiometry, (Mu^-/M^{2+})	log K_f
DMSO	Murexide	533	—	—
	Co^{2+}	475	1.02	4.56 ± 0.03
	Ni^{2+}	461	1.01	5.45 ± 0.05
	Cu^{2+}	477	0.96	5.65 ± 0.03
	Zn^{2+}	460	0.97	4.27 ± 0.04
	Cd^{2+}	483	1.02	4.63 ± 0.03
	Pb^{2+}	515	1.11	4.52 ± 0.03
H_2O	Murexide	522	—	—
	Co^{2+}	470	1	2.48
	Ni^{2+}	460	1	3.38
	Cu^{2+}	478	1	4.36
	Zn^{2+}	452	1	3.00
	Cd^{2+}	483	1	4.15
	Pb^{2+}	502	1	4.40

spectrophotometrically, by using solutions containing the ligand and the metals of the concentrations, $C_M \gg C_{Mu}$. The absorbance at the peak of each murexide complex (Table 1) was observed to increase with increasing concentration of each cation. The experimental results obtained showed the linear relations between $(A/A_o - 1)/C_m$ and A/A_o, according to equation (8), for all the metal ions used which were independent of C_{Mu}. The corresponding plot for Zn^{2+} ion is shown in Fig. 3. From the slopes of the lines, the formation constants of the murexide complexes were obtained. All calculated formation constants of the resulting 1:1 complexes along with the corresponding λ_{max} values and their stoichiometries are presented in Table 1. The corresponding reported values in aqueous solution[2] are also included for comparison.

From Table 1, it is immediately obvious that the solvent plays an important role in the complexation reactions. The resulting complexes in DMSO are much more stable (up to about 2 orders of magnitude for cobalt, nickel and copper complexes) than those in aqueous solution. There is actually an inverse relationship between the solvating ability of the solvent, as expressed by the Gutmann donicity number,[12] and the stability of the complexes. Water is a solvent of higher solvating ability (DN = 33)[20] than DMSO (DN = 29.8)[12] and, hence, can compete more effectively with murexide for the cations. Thus, it is reasonable to expect an increase in the formation constants when changing the reaction medium from water to DMSO. A similar solvent effect has already been reported.[9,10,13,14,21]

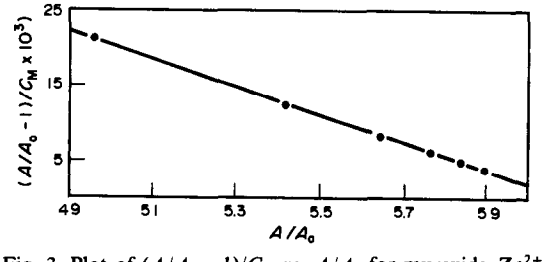

Fig. 3. Plot of $(A/A_o - 1)/C_M$ *vs.* A/A_o for murexide–Zn^{2+} system in DMSO.

Moreover, the lower dielectric constant of DMSO (46.7) in comparison with that of water (78.5) would also cause the electrostatic contributions to the bond formation between the two charged partners (*i.e.*, M^{2+} and Mu^-) to increase in DMSO solution.

The data in Table 1 show that the sequence of stability of the murexide complexes with the cations of the first transition series (*i.e.*, $Co^{2+} < Ni^{2+} < Cu^{2+} < Zn^{2+}$) follows the Irving–Williams order,[22] which generally holds for the equilibrium constants of transition metals. However, among cations Zn^{2+}, Cd^{2+} and Pb^{2+}, cadmium–murexide complex in DMSO solution shows the highest stability, this is probably due to the proper size of Cd^{2+} ion which could favour a suitable spatial fit with flexible donating atoms of the ligand (bridging nitrogen atom and neighbouring oxygen atoms).[14] Cadmium ion has about the same ionic size as Na^+ and Ca^{2+} ions[16] which has been shown to form the most stable murexide complexes among alkali and alkaline earth ions, respectively.[2,13,14]

BOOK REVIEW

Nucleotide Analogues as Antiviral Agents: J. C. MARTIN (ed.), American Chemical Society, Washington, DC, 1989. Pages viii + 190. $44.95 (US and Canada), $53.95 (elsewhere).

The introduction of acyclovir into clinical practice a decade ago revealed a tantalizing glimpse of a revolution in the treatment of viral diseases, which has yet to be realized. Largely as a result of the vast commitment to AIDS research and recent advances in molecular biology, the prospect of other selective antivirals, with low toxicity, becoming available seems closer, and the next few years promises some exciting developments.

The appearance of this book, in the ACS Symposium Series, is therefore welcome and timely, representing a useful reference source for all who are engaged in antiviral research. The twelve chapters, each by subject leaders, review latest developments in the synthesis of novel antiviral agents together with notes on structure-activity relationships, mode of action and host cell toxicity. Whilst there is an emphasis on activity against HIV and the herpes group of viruses, effects against some other viruses are also documented.

An earlier chapter discusses the substrate requirements of viral-encoded thymidine kinase responsible for the activation of certain nucleosides effective against the herpes simplex virus. Four chapters describe strategies for the development of acyclonucleoside phosphonates which are resistant to degradation by cellular phosphorylases and circumvent the need for activation by viral kinases. Some of these analogues are highly effective against herpes and some other DNA viruses which lack thymidine kinase activity, whilst retaining a low level of toxicity to mammalian cells. Other derivatives investigated are inhibitors of reverse transcriptase and may find application in the treatment of HIV.

Other sections in this book describe the development of viral thymidine kinase inhibitors, nucleotide dimers related to azidothymidine, simple pyrophosphate inhibitors of viral nucleic acid polymerases, and many more.

The final chapter explores the activity of nuclease-resistant short-chain oligonucleotides which, in principal, can interfere with viral genetic expression by hybridization with viral nucleic acids. The authors cite several modified oligomers with promising antiviral activity which are being evaluated. This general approach may allow specific viral nucleotide sequences to be targeted whilst minimizing host cell toxicity, and is undoubtedly an area for future development.

INVESTIGATION OF FOLDING IN PROTAMINE BY FTIR

JOSEPH J. PESEK and FARIBA RAISI SHABARY
Department of Chemistry, San Jose State University, San Jose, CA 95192, U.S.A.

(*Received* 10 *February* 1992. *Revised* 19 *March* 1992. *Accepted* 22 *March* 1992)

Summary—The secondary structure of purified protamine, a non-specific DNA binding protein, was studied in solution at pH 4, 7 and 8 by FTIR. This permitted analysis of the folded form of the protein (acidic pH) as well as the folded conformers (neutral and basic pH). Hg^{2+} was utilized to probe the accessibility of the free thiol groups (cysteine residues). The SH groups form when disulfides, which play the major role in stabilizing the conformation of this protein, are broken. It was possible to observe different conformational states in protamine as a function of pH and the presence of Hg^{2+} via spectral changes primarily in the amide region. The results lead to the conclusion that protamine is not completely folded under conditions similar to those found *in vivo* (37°, neutral pH, phosphate buffer and high protein concentration).

Biochemical studies have revealed that DNA in most vertebrate sperm is associated with only one protein class, the protamines.[1] These proteins are small (approx. 5 kD) and extremely basic; 50% of the amino acids are arginine. Structural studies have shown that both the primary and secondary structure of protamine vary depending on the organism.[2] The secondary structure is controlled primarily by disulfide formation. The cysteine residues in mammalian species, initially present as free sulfhydryls when the proteins are deposited on DNA, are oxidized forming intra and intermolecular disulfide bonds that lock adjacent protamine molecules together around the DNA helix.

Previous results suggest that only the carboxyl and amino-terminal regions of protamine actually fold. This occurs in both the presence and absence of DNA. The central polyarginine sequence is believed to be the region of the molecule that binds to DNA. Kinetic pathways of unfolding and refolding are defined by the intermediate conformation states.[3] For a complex process like protein folding, there are often a large number of intermediate states.

FTIR is just beginning to develop as a powerful means of studying protein structure and function.[4] Early studies in solution[5–7] have generally involved high concentrations (> 100 mg/ml) and long path length cells (> 50 μm) using D_2O instead of H_2O as the solvent.[5,6,8] However, some of the earliest studies on proteins involved anhydrous films[9,10] in order to overcome the strong background absorbance of both H_2O and D_2O. A recent study[11] has shown that thin films in conjunction with ATR can be used to detect an enzyme–substrate intermediate at relatively low concentrations (2.5 mg/ml) in the original solution.

The vibrational spectra of proteins can be characterized by three amide bands:[12,13] Amide I between 1630–1680 cm^{-1}, Amide II near 1550 cm^{-1} and Amide III between 1230–1300 cm^{-1}. The positions of the Amide I and III bands can be used to estimate the relative populations of α-helix, β-sheet and random coil in a particular protein.[14–16] For cytochrome b_5 the FTIR data correlated well with other techniques[17] and for α-chymotrypsin the FTIR of the thin film was consistent with both the solution spectrum as well as crystallographic measurements.[11] Finally, it should be noted that other functional group vibrations can provide information about the structure of the protein. For protamine the thiol group is important since it controls the secondary structure as mentioned above. Several studies have focussed on the S–H stretch which usually occurs between 2400–2600 cm^{-1}. Reports concerning hemoglobin,[18–20] myosin[21] and chymopapain[22] among others have appeared in the literature. The object of this study was to determine if FTIR could monitor, through changes in the amide and/or the thiol regions, how both pH and the presence of a heavy metal, Hg^{2+}, affect the overall structure of protamine.

EXPERIMENTAL

Materials

Bull and hamster protamine were obtained from Dr. Rod Balhorn at Lawrence Livermore National Laboratory. The proteins were purified by HPLC and the purity was determined by gel electrophoresis. The proteins were obtained as lyophilized powders in the reduced form[1,2] and stored dry. All buffers and other chemicals used in the experiments were reagent grade or the highest purity available.

Instrumentation

FTIR spectra were obtained on a Perkin–Elmer Model 1800 spectrometer equipped with a DTGS detector. Data were collected and processed on a Perkin–Elmer 7000 computer using the CDS-5 applications program. Spectra were taken on the Perkin–Elmer Multiple Internal Reflectance Accessory using a germanium crystal. The Ge crystal was determined to be most impervious to etching and fogging by the protein/buffer solutions used in these experiments. In general 100 scans at 2 cm^{-1} resolution were used for most samples.

Sample preparation

Protamine was weighed on an analytical balance and dissolved in the appropriate 0.10*M* buffer solution (acetate for pH 4 and phosphate for pH 7 and 8). When used, $HgCl_2$ was added to the solution before additional buffer was added to make the final concentration of protamine 1m*M*. The solution was allowed to stand for 30 min before placing it in the ATR cell or before applying it to the Ge crystal for a thin film.

To make a thin film, a small aliquot of solution was placed on the crystal and gently dried with a stream of argon. Before the sample was completely dry, a second aliquot of sample was placed on the crystal and the drying process was continued. This process was repeated until a uniform layer was formed on the crystal surface. Development of such a protocol led to reproducible thin films and allowed for deposition of more sample than would be possible from higher concentration solutions due to protein aggregation. After the sample was prepared, the ATR accessory was placed in the sample chamber which was purged with dry nitrogen for 30 min before spectral acquisition.

RESULTS AND DISCUSSION

Initial experiments involved attempting to obtain spectra on typical solutions of protamine using the ATR accessory. It was determined that a concentration of at least 100 mg/ml was necessary in order to obtain a reasonable signal to noise ratio. At these concentrations aggregation and long term stability were a problem so that in general reproducible results were difficult to obtain. With these limitations in mind, it was decided to try the thin film method for studying the samples. Spectra obtained on thin film samples were essentially identical in spectral detail to those obtained in solution. This result is consistent with the data of an earlier study[11] in which the thin film and solution spectra were identical.

Figure 1 shows a partial spectrum of bull protamine in acetate buffer at pH 4. This portion of the spectrum has been examined because the sulfhydryl region is of interest for the protamines due to SH participation in the secondary structure. At pH 4 protamine should be completely unfolded with the thiol groups intact, *i.e.*, not oxidized to form disulfide linkages.[2] The frequencies of the absorbance are shifted to the low end of the normal range of the S–H stretching mode probably due to hydrogen bonding effects. However, eight separate bands can be identified at 2391, 2384, 2368, 2358, 2340, 2327, 2320 and 2312 cm^{-1}. This result is reasonable since previous studies have identified seven cysteine residues per bull protamine. Since these absorbances are not in the frequency range of water vapor, carbon dioxide or the buffer, they must be part of the protamine molecule. Careful spectral subtraction of both the background and the buffer also suggest that the peaks observed here are due to protamine vibrational absorption. Addition of Hg^{2+} to the original

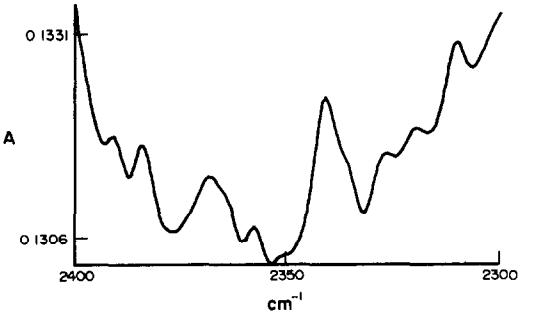

Fig. 1. Partial ATR FTIR difference spectrum (sulfhydryl region) of a thin film of protamine deposited on a germanium crystal from a pH 4 solution.

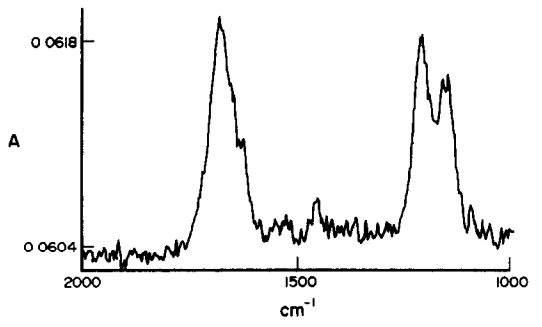

Fig. 2. Partial ATR FTIR difference spectrum (amide region) of a thin film of protamine deposited on a germanium crystal from a pH 4 solution.

protamine solution or raising the pH causes these bands to disappear. This is consistent with complexation of the thiols by Hg^{2+} and with formation of disulfide bridges in the folding process. The oxidant is thought to be oxygen but the mechanism is still under investigation. Lowering the pH will cause the protein to return to the unfolded state only if a reducing agent such as β-mercaptoethanol is present.

While the above data show that meaningful results can be obtained from the SH region of the spectrum, it is apparent from earlier studies that the amide region has the potential for providing more information about the overall structure of the molecule. Figure 2 shows a typical ATR thin film spectrum of protamine in the region encompassing the amide absorbances. These spectra can be used to determine the band positions shifts as a result of varying the pH or adding Hg^{2+}.

Table 1 is a summary of the data obtained from the various FTIR spectra. These results clearly show two readily identifiable trends. Both an increase in the pH and the addition of Hg^{2+} result in a shift of the Amide I from lower to higher frequency. The frequency range of various secondary structures for proteins has been assigned as follows: α-helix 1645–1660 cm^{-1}, β-sheet 1665–1680 cm^{-1} and disordered structure or random coil 1660–1670 cm^{-1}.[15,16] At pH 4, the Amide I peak is centered near 1655 cm^{-1} which is indicative of some α-helix component as well as perhaps a disordered or random coil contribution. This result is consistent with the reported nature of protamine which is thought to be completely unfolded at pH 4. Certainly a helical component in protamine would not be unusual since it has been shown to wrap around DNA in its initial state which mainly consists of free sulfhydryls. The existence of the free sulfhydryls at pH 4 has been confirmed by the data in the 2300–2400 cm^{-1} region. Addition of Hg^{2+} at pH 4 causes a substantial shift of the Amide I band to 1680 cm^{-1}. This indicates a major change in the secondary structure of protamine upon complexation with the metal ion. This could be a disruption of the helix component because hydrogen bonding is no longer available through the sulfhydryls, or it could involve some folding of the protein through sulfur–mercury–sulfur bridges. The β-sheet structure which might develop in the latter case can shift the Amide I band to 1680 cm^{-1} [15,16] but it can also have components as high as 1690 cm^{-1}.[17] Therefore, some combination of a random structure with a significant β-sheet component through S–Hg–S is the most likely configuration of protamine at pH 4 in the presence of mercury.

When the pH of the protamine solution is raised to 7, the Amide I band shifts to 1660 cm^{-1}. This is consistent with the known behavior of protamine which indicates increased folding of the molecule as free sulfhydryls are converted to disulfide linkages. This Amide I frequency is indicative of a greater β-sheet contribution to the structure which is expected when the two ends of the protein fold to form the disulfide bridges. Addition of Hg^{2+} causes a further shift in the Amide I band to 1675 cm^{-1}. This result is similar to that observed at lower pH indicating that additional changes in the secondary structure occur upon complexation with mercury. As mentioned above, these changes may involve the formation of S–Hg–S linkages or other types of interaction between mercury and another site (P–S–Hg···X–P) on the protein which results in a more β-sheet-like structure.

Raising the pH to 8 causes a further shift in the Amide I frequency to 1664 cm^{-1}. This result confirms that as the protein continues to undergo more folding the shift in the absorbance band will be to higher wave numbers. Addition of mercury shifts the Amide I to approximately the same value obtained at pH 7 indicating that the final structural state is somewhat similar at both pHs.

Table 1. Amide I frequencies of Protamine thin films

pH	Frequency (cm^{-1}) native	with Hg^{2+}
4	1655	1680
7	1660	1675
8	1664	1676

In summary, it appears that FTIR is a useful technique for studying the effects of both pH and external agents such as heavy metal ions on the secondary structure of proteins. In the case of protamine, the results obtained at various pH's can be correlated with those obtained from other techniques. This allows conclusions to be made about the structural effects when mercury is added to the system which have not been studied by other methods. In particular, protamine appears not to be completely folded under physiological conditions since further shifts in the Amide I band are observed when the pH is raised to 8.

ATOMIZATION EFFICIENCY OF A MASSMANN-TYPE GRAPHITE FURNACE

S. J. CATHUM

Centre for Analytical and Environmental Chemistry, Department of Chemistry, Carleton University, Ottawa, Ontario, Canada K1S 5B6

(*Received* 21 *January* 1992. *Revised* 7 *April* 1992. *Accepted* 9 *April* 1992)

Summary—The atomization efficiency of the Perkin–Elmer HGA-400 for the production and containment of atomic vapour has been determined for Al, Co, Au, Ni, Fe, Ag, Ga and Cu by a method developed under non-isothermal conditions. The method takes into account the residence time and the shape of the absorbance signal profile. It is based on the entire absorption signal profile rather than on any part of it. The uncertainty in the method arises from calculation of the rate constant of atom loss due to temperature gradient which has a pronounced effect on the "effective" length of the analysis path when the atomizer is operated under non-isothermal conditions. The average value of the atomization efficiency for the eight elements used for this study was found to be about 0.10.

The efficiency of the graphite furnace to produce and contain analyte atoms has been the subject of several studies.[1–5] Smets[5] has used a correction factor, β, given by the following equation,

$$\beta = \frac{\int_0^\infty R_{\text{form}}\,dt}{N_0} \qquad (1)$$

to account for the fraction of the total number of analyte atoms that enter the analysis volume during each stage of atomization, where R_{form} is the rate of atom formation, and N_0 is the total number of atoms introduced as sample. Note that $\int_0^\infty R_{\text{form}}\,dt$ is the number of vaporized atoms that enter the analysis volume during the time interval $0 \rightarrow \infty$, and N_0 is the total number of analyte atoms deposited in the graphite furnace assumed to be totally vaporized to the gas phase during the time interval $0 \rightarrow \infty$.

L'vov[6] has assumed a 100% atomization efficiency for the graphite furnace operated under STPF (stabilized temperature platform furnace) technique and deviations from this value include all the other factors which cause the theoretical and experimental values to differ. Sturgeon and Berman[2] have defined the efficiency of atomization, ϵ_a, for an electrothermal atomizer at the time the signal has attained its maximum value, as the ratio of the number of neutral analyte atoms, N_m, plus ionized analyte atoms, N_i, to the total number of analyte atoms introduced as sample, N_0, *i.e.*,

$$\epsilon_a = \left(\frac{N_m + N_i}{N_0}\right) \qquad (2)$$

This method requires existence of thermodynamic equilibria in the furnace during atomization. Falk and Tilch[3] have determined the atom number density within the atomizer using the following equation:

$$N_m = \left(\frac{(8.69 \times 10^7) A_m (T_m/M)^{0.5}}{l\gamma H(w, a) f \lambda_{21}}\right) \times \left(\frac{Z(T)}{\exp(-E_1/kT_m)}\right) \qquad (3)$$

where N_m is the atom number density within the atomizer, A_m is the peak-height absorbance, $Z(T)$ is the partition function at temperature T_m, the subscript m indicates that values of the subscripted terms are taken at the absorbance maximum, γ is a coefficient accounting for hyperfine splitting of the atomic line, $H(w, a)$ is the Voigt integral for the point of the absorption line contour at a distance of $w = 0.72a$ from the line center, f is the oscillator strength, λ_{21} is the wavelength of the absorption line, E_1 is the energy of the lower level involved, k is the Boltzmann constant and l and M are the atomizer tube length and the molar mass of the analyte atom, respectively. Determination of N_m

by using equation (3) introduces uncertainties in the terms used in the equation.[2] van den Broek and de Galan[1] have reported that the number of analyte atoms at the absorbance maximum, N_m, is given by:

$$N_m = N_0(\tau_R/\tau_s) \quad (4)$$

where N_0 is the total number of analyte atoms initially deposited and τ_R and τ_s are the overall time constants for the removal and the supply function, respectively. Chakrabarti *et al.*[7] have reported that for isothermal atomization in a graphite furnace the number of analyte atoms at the absorbance maximum, N_m, is given by equation (5),

$$N_m = N_0 \exp(-k_2 t_m) \quad (5)$$

where k_2 is a first-order rate constant for atom loss and t_m is the time at which the absorbance reaches its maximum value. L'vov *et al.*[8] has used fundamental constants to calculate the ratio of experimental to theoretical characteristic mass. In his 1990 paper,[6] L'vov revised his spectroscopic data published earlier in 1986[8] and he reported a value of 0.86 ± 0.10 for the ratio of experimental to theoretical characteristic mass using the STPF technique. The atomization efficiency by the method of L'vov is actually assumed 100% and deviations in the ratio must include all the factors which cause the theoretical and experimental values to differ.

Frech and Baxter[4] have defined the atomization efficiency as the ratio of the number of free analyte atoms present in the analysis volume to the number of atoms initially deposited in the graphite furnace. They have pointed out that it is not yet possible to count the number of free atoms produced directly, instead a measurable property of the atomic vapour must be related to this number using the necessary theoretical expression. The atomization efficiency by Frech and Baxter[4] is,

$$\epsilon_a = \frac{m_0(\text{calc})}{m_0(\text{exp})} \quad (6)$$

where m_0(calc) and m_0(exp) are the calculated and the experimental characteristic mass, respectively. To calculate, ϵ_a by equation (6) the graphite furnace must be operated under isothermal conditions (STPF). For the absolute analysis it was necessary to produce free analyte atoms in isothermal conditions and to measure integrated absorbance signals. To overcome the difficulty of obtaining isothermal atomization in the Massmann-type furnace L'vov[9] proposed the use of a platform to delay sample vaporization until the temperature of the graphite tube and the purging gas reaches a steady-state value. Slavin[10] has incorporated these suggestions together with a number of additional methodological and instrumental developments in the STPF technique. It would be useful to investigate the atomization efficiency of non-platform furnaces operated under non-isothermal conditions since tube wall atomization is still used in routine analysis and also in studying the mechanism of atomization. A low value of atomization efficiency, for instance, indicates formation of a non-absorbing species, which must be taken into account in proposing the mechanism of atomization.

The present work was undertaken in order to determine the atomization efficiency of the standard Perkin–Elmer HGA-400 operated under non-isothermal conditions.

THEORY

In the rapidly-heated graphite furnace used for this study, the number of analyte atoms present in the analysis volume at time t is determined by the release, and the transport of atoms into and their loss from the analysis volume.[11] The efficiency of the graphite furnace to produce and contain the analyte atomic vapour is governed by its ability to release neutral analyte atoms from the atomizer surface and to transport them into the analysis volume. Ideally, this process requires that the amount of analyte atoms released from the atomizer surface at any time of atomization should enter the analysis volume. In reality, however, some of the analyte atomic vapour formed may be lost during any stage of atomization by various atom loss processes, for example, loss by diffusion to the cooler ends of the atomizer and through the injection hole, by re-adsorption, by expulsion and by convection. It is also possible that analyte atoms are lost as non-absorbing molecular species, such as, oxides, carbides, chlorides *etc.*

The total number, $N(t)_g$, of analyte atoms including stable molecular species that have diffused to the gas phase at time t is given by the difference between the number of analyte atoms initially deposited in the graphite furnace, N_0, and that, $N(t)_w$, left unatomized on the graphite surface. Once atomization commences gaseous analyte atoms start to diffuse to the gas phase. It should be pointed out that not all of the

analyte atoms which are transported to the gas phase necessarily enter the analysis volume; a fraction of them may be lost. The loss of analyte atomic vapour from a Massmann-type atomizer (The Perkin–Elmer HGA-72), operated under non-isothermal conditions, has been estimated by van den Broek and de Galan[1] to be about 90% of the deposited atoms. Various authors have used a correction factor to account for the atom loss at each stage of the atom formation.[5,12–15] Note that, according to Smets,[5] $\beta N(t)_g$ represents the analyte atoms which are transported into the analysis volume at a given time t, and $N(t)_g$ is the total number of analyte atoms vaporized from the atomizer surface at time t, not necessarily as free atoms. Analyte vapour that diffuses to the atomizer cavity as a result of the increasing temperature of the graphite surface could be a mixture of free analyte atoms and molecular species. Existence of stable molecular species in the gas phase during atomization is acknowledged in the literature.[16] In the gas-interrupt mode of operation, diffusion out of the analysis volume is assumed to be the major loss process for atoms.[1,5,17,18] Under these conditions and taking the above definition for $N(t)_g$ into account, the number of analyte atoms, $N(t)_w$, which are left unatomized on the graphite surface is given by the following equation (see the Appendix):

$$N(t)_w = \frac{\langle k_2 \rangle}{Q\beta} \int_t^\infty A(t)\,dt \qquad (7)$$

where Q is a constant linking the number of gaseous analyte atoms in the atomizer with the measured absorbance signal, $A(t)$, *i.e.*, $A(t) = QN(t)_g$, and $\langle k_2 \rangle$ is the mean value of the rate constant of atom removal, k_2 taken over the indicated time interval, reported constant within 10%.[5] $\langle k_2 \rangle$ is assumed to be equal to k_2; hence, from now on k_2 will be used for $\langle k_2 \rangle$. Therefore, upon substituting equation (7) into the following equation for $N(t)_w$,

$$N(t)_w = N_0 - N(t)_g \qquad (8)$$

and rearranging terms one gets,

$$A(t) = QN_0 - \frac{k_2}{\beta} \int_t^\infty A(t)\,dt \qquad (9)$$

Equation (9) shows that a plot of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ should be linear with a slope $-k_2/\beta$ and intercept QN_0 equals a hypothetical absorbance pulse when 100% atomization is achieved. The measurements of the peak-height absorbance and the integrated absorbance are

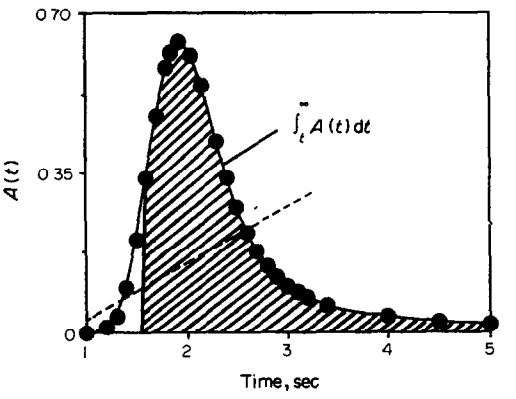

Fig. 1. Measurements of the peak-height absorbance, $A(t)$, against integrated absorbance, $\int_t^\infty A(t)\,dt$.

illustrated in Fig. 1. The shaded area represents the integrated absorbance over the indicated time interval. The temperature profile is also shown for reference. A peak-area program used to calculate the integrated absorbance was obtained from Nicolet Instrument Corporation, Madison, Wisconsin, U.S.A. At the leading edge, equation (9) shows that as $\int_t^\infty A(t)\,dt$ decreases $A(t)$ increases. This relationship between $A(t)$ and $\int_t^\infty A(t)\,dt$ as given by equation (9) should hold true starting from the initial time to t_m (defined as the time when the absorbance signal reaches its maximum). The value of k_2 can be obtained from an expression developed earlier by L'vov *et al.*,[8]

$$k_2 = \frac{8D}{l^2} \qquad (10)$$

where D is the concentration diffusion coefficient of the analyte element in Ar gas, which can be calculated by a formula given in the literature,[8,9] and l is the geometric length of the graphite tube (2.8 cm). The values of the parameters used for determining D can be found in the literature.[20] Since the length l used in equation (10) is greater than the "effective" length of the graphite tube because of the pronounced temperature gradient in the horizontal axis of the long tube (the Perkin–Elmer tube used in this study), the value of k_2 so obtained gives only an estimate of k_2.[21] The slope of the plot of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ then yields $-k_2/\beta$ from which β is obtained after differentiation from equation (10).

Atomization efficiency is defined in this paper[1–3,7] as the ratio of the number of neutral analyte atoms present in the analysis volume at

the time when the absorbance reaches its maximum to the total number of analyte atoms deposited in the graphite furnace,

$$\epsilon_a = \frac{N_m}{N_0} \tag{11}$$

where ϵ_a is the atomization efficiency and N_m is the number of analyte atoms present in the analysis volume at the time when the absorbance reaches its maximum. This definition of ϵ_a has been used by various authors.[1-4,7] Using the relationship between A_m and N_m (*i.e.*, $A_m = QN_m$, where Q is a proportionality constant), equation (11) may be re-written as:

$$\epsilon_a = \frac{A_m}{QN_0} \tag{12}$$

When the graphite furnace is operated in the gas-interrupt mode, the denominator of equation (12), may be expressed as follows[1,5,12,15] (see also the Appendix):

$$QN_0 = \frac{k_2}{\beta}\int_0^\infty A(t)\,dt \tag{13}$$

where β is as defined earlier. Substituting equation (13) into equation (12) yields the following equation,

$$\epsilon_a = \frac{\beta A_m}{k_2\int_0^\infty A(t)\,dt} \tag{14}$$

Here ϵ_a is the overall atomization efficiency determined when the graphite furnace is operated under the gas-interrupt mode. Equation (14) shows a linear relationship between ϵ_a and β. Hence, ϵ_a will increase when β increases, *i.e.*, if all the analyte atoms released from the atomizer surface are transported completely into the analysis volume ($\beta = 1$) and remain there for a relatively long time. Equation (14) also shows that ϵ_a is inversely proportional to the rate constant of atom loss, k_2 (which is inversely proportional to the residence time of analyte for a first-order loss process). Note that as k_2 is increased, for instance by forced convection, a low absorbance peak will result because of appreciable decrease in the residence time, which will also mean that ϵ_a will decrease. In order to increase ϵ_a, the experiment should be conducted in the gas-interrupt mode and using long graphite tubes (such as the Perkin–Elmer tubes) since these two factors will increase the residence time of analyte atoms which will result in a high value of ϵ_a.

EXPERIMENTAL

Apparatus

The Perkin–Elmer atomic absorption spectrophotometer model 503, modified to allow recording of the absorbance signal with a 20-msec time constant and equipped with a D_2-arc background corrector and HGA-400 atomizer was used. The graphite furnace was heated slowly with a laboratory-made power supply to lowest atomization temperatures. The temperatures used are somewhat low, this is to broaden the absorbance signal profiles to ease the measurement of the peak-height and integrated absorbance at different times. The temperature of the atomizer surface was measured with two automatic optical pyrometers (Ircon Inc., Skokie, IL, U.S.A.); high temperatures with a 1100 series pyrometer and low temperatures with a 300 series pyrometer. The standard Perkin–Elmer pyrolytically-coated graphite tubes (part No. B0091-504) were used. Signals were recorded with a Nicolet digital oscilloscope model 4094 (Nicolet Instrument Corporation, Madison, Wisconsin, U.S.A). The values of the integrated absorbance were measured at different times using a software package by Nicolet Instrument Corporation. Figure 1 shows how the peak-height absorbance, $A(t)$, was measured against the integrated absorbance, $\int_t^\infty A(t)\,dt$. Hollow-cathode lamps of cobalt (Perkin–Elmer), aluminum (EEL), copper, silver, iron, gold, nickel and gallium (the last six by Westinghouse) were operated at the lowest lamp current level still sufficient for reliable measurement of the absorbance signal. The spectral band width was set to 0.7 nm.

Standard solutions

Chemically pure metals or their salts were used to prepare stock solutions of standards. The stock solution of silver nitrate was prepared by dissolving an appropriate mass of silver nitrate in ultrapure water and diluting the solution to make the concentration 100 μg/ml. Stock solutions of cobalt and iron were prepared separately by dissolving each metal in nitric acid (ULTREX) by heating and then diluting the solution with ultrapure water to make the concentration 1000 μg/ml. Stock solutions of gallium and copper were prepared separately by dissolving each metal in nitric acid (ULTREX) by heating and then diluting the solutions with ultrapure water to make the concentrations 1000 μg/ml. The stock solution

Table 1. Experimental and instrumental parameters*

Element	Wavelength, nm	m_o(exp) (pg/0.0044)	Charring temperature, K	Atomization temperature, K
Al	309.3	26	1050	2700
Co	240.7	21	1090	2600
Cu	324.8	9	1000	2600
Ga	287.4	45	900	2600
Ag	328.1	9	800	2000
Fe	248.3	10	1080	2600
Au	242.8	16	1000	2400
Ni	232.0	16	1100	2600

*Spectral band width = 0.7 nm.

of aluminum was prepared by dissolving the metal in 20% (v/v) nitric acid (ULTREX) with heating; the solution was then diluted to 1000 μg/ml with ultrapure water. The stock solution of gold was prepared by dissolving an appropriate mass of the metal in *aqua regia* and diluting the solution to 1000 μg/ml with ultrapure water.

All test solutions were prepared daily by serial dilution of the stock solutions with ultrapure water just prior to determinations. Ultrapure water of resistivity 18.3 megaohm-cm was obtained direct from a Milli-Q2 water purification system (Millipore Co., Mississauga, Ontario, Canada).

Standard and test solutions were prepared to contain 1% (v/v) nitric acid (Ultrex, J. T. Baker Chemical Co.).

Argon gas

Argon gas (99.995% pure) was used both as sheath gas and as purge gas for the graphite furnace.

Procedure

In order to reach the maximum possible sensitivity for each analyte element, the lamp current of the light source was varied. The lowest lamp current which still gives sensitive and reliable absorbance signal profile was chosen for the analysis. In all cases, 10 μl of the test solution was injected into the graphite furnace with an Eppendorf micropipet fitted with disposable plastic tips. The absorbance signal and temperature profiles were recorded with a digital oscilloscope and stored on a floppy disc for later evaluation. In each case the blank signal was subtracted from the absorbance signal.

Experimental and instrumental parameters

Table 1 summarizes the experimental and instrumental parameters used.

RESULTS AND DISCUSSION

Table 2 summarizes the values of β for eight elements, Al, Co, Au, Ni, Fe, Ag, Ga and Cu, determined using the gas-interrupt mode of operation of the graphite furnace. The values of β ranged from 0.04 for Ga to 0.77 for Cu and had a precision of about 3% relative standard deviation calculated for three replicate determinations. Figures 2–9 show the plots of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ for Al, Co, Au, Ni, Fe, Ag, Ga and Cu. Slopes of the plots were calculated from linear regions using the least-squares method. As equation (9) predicts, β increases as the slope of the plot of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ decreases. Since the value of the slope is determined by the shape of the absorbance signal profile, the latter plays an important role in determining the value of β, as reported by van den Broek and de Galan.[1] To illustrate how the shape of the absorbance signal profile affects the value of β, plots of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ for Ga and Cu are shown in Figs. 8 and 9. The reason for taking these two plots of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ as an example as that Ga and Cu have equal values of k_2 (Table 2). Thus, if the β values of Ga and Cu differ from each other the only factor that should account for this difference is the slopes of the plots of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$ (Figs. 8 and 9), which are significantly different

Table 2. Set of data used in calculation of the atomization efficiency, ϵ_a

Element	D* (cm^2 sec^{-1})	k_2 (sec^{-1})	slope $(-k_2/\beta)$	β
Al	8.7	8.0	−36.0	0.25
Co	6.4	6.5	−20.2	0.32
Cu	6.9	7.0	−9.1	0.77
Ga	6.9	7.0	−156.0	0.04
Ag	3.4	3.5	−17.8	0.20
Fe	6.5	6.6	−36.0	0.18
Au	4.5	4.6	−14.4	0.32
Ni	6.8	6.9	−10.2	0.68

*The values of the parameters used in the calclation of D have been taken from Ref. 20.

(9.1 for Cu and 156 for Ga), and hence give different values of β (for equal values of k_2). This difference in the slopes makes the value of β for Cu (0.77) differ from that of Ga (0.04) by a factor of 19. For identical absorbance signal profiles [giving identical slopes of the plots of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$], the values of β should be equal, provided that k_2 values are equal.

Table 3 summarizes the values of the overall atomization efficiency, ϵ_a, for Al, Co, Au, Ni, Fe, Ag, Ga and Cu determined by using equation (14). The precision, calculated for three replicate determinations, is about 3% relative standard deviation, which reflects the combined reproducibility of the furnace thermal program and that of atom formation and loss. Our results for β and ϵ_a are different from L'vov[6] and Frech and Baxter.[4] Probably, the main reason for this difference is attributed to experimental conditions used in determination of the atomization efficiency. They used the STPF technique to produce free analyte atoms under isothermal conditions, we used a Massmann-type furnace operated under non-isothermal conditions to generate data for determination of the atomization efficiency. Certainly, different modes of atomization will result in different atom release processes (*i.e.*, different reaction paths) which will appreciably influence the value of the atomization efficiency. Another reason could be the response time of the measuring system (having a time constant 20 msec) which may decrease the sensitivity of the analyte element thereby altering the efficiency of atomization.

Turning now to an important aspect of the atomization efficiency, ϵ_a. In GFAAS, research is conducted mainly to improve the sensitivity and limit of detection of the analysis method. Thus, it would be useful to know whether or not there is any room for such an improvement. The value of ϵ_a shows that only a small fraction roughly about 10% of the total number of the deposited atoms are actually atomized, the rest are lost as non-absorbing species. This indicates that there is still some more research to be done on the graphite furnace to

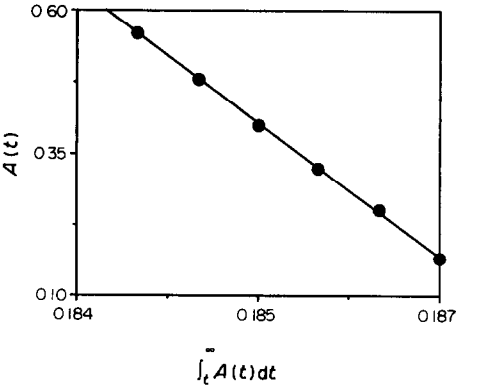

Fig. 8. Plot of peak-height absorbance, $A(t)$, *vs.* $\int_t^\infty A(t)\,dt$ for gallium (taken as the nitrate).

increase its efficiency. Most of the researchers[1-3,5,7] agree that a 100% efficient atomizer has not been yet achieved. As mentioned earlier, ϵ_a is inversely proportional to the rate constant of atom loss, k_2. Hence, ϵ_a can be increased by decreasing k_2, for example, by operating the atomizer in the gas-interrupt mode at low atomization temperatures. The effect of forced convection on the absorbance signal of most elements is obvious when the graphite furnace is operated in the gas-flow mode. The value of ϵ_a of a particular element should hold constant for a set of experimental conditions, such as, the inner gas flow rate and atomization temperature. The combination of these two factors and others play an important role in determining the residence time of the atomic vapour in the analysis volume, and ultimately the value of ϵ_a. Thus, in order to make the value of ϵ_a as a useful indicator for different atomizers all of experimental and instrumental parameters must be maintained unchanged. Another important experimental parameter which may have no effect on the calculation of the theoretical characteristic mass under isothermal conditions (*i.e.*, STPF conditions) but does have an effect on the shape of the absorbance signal recorded under non-isothermal conditions is the heating rate of the graphite furnace. This parameter must also be maintained constant if the atomization efficiency of different graphite furnaces needs to be compared. It is not difficult to fix the heating rate of the graphite furnace if the latter is heated slowly from a charring temperature to a predetermined atomization temperature.

From equation (14) the following observations on the values of β and ϵ_a are made. Since the $A_m/[k_2\int_0^\infty A(t)\,dt]$ values given in Table 3 are < 1 one would expect, according to equation (14), that the ϵ_a values to be less than the β values. As mentioned earlier, the β values have uncertainties originating from the use of equation (10) for calculating the first-order rate constant for atom dissipation, k_2. It is therefore reasonable to conclude that the ϵ_a values which are obtained by using β values have greater uncertainties than the β values. Hence, the ϵ_a

Table 3. Atomization efficiency, ϵ_a, calculated under non-isothermal conditions

Element	A_m	$\int_0^\infty A(t)\,dt$	$A_m/k_2\int_0^\infty A(t)\,dt$	ϵ_a
Al	0.230	1.769×10^{-1}	0.146	0.04
Co	0.520	5.508×10^{-1}	0.143	0.05
Cu	0.716	9.379×10^{-1}	0.109	0.08
Ga	0.530	1.868×10^{-1}	0.405	0.02
Ag	0.338	1.980×10^{-1}	0.488	0.10
Fe	0.401	3.259×10^{-1}	0.186	0.03
Au	0.350	9.649×10^{-2}	0.789	0.25
Ni	0.317	4.258×10^{-1}	0.108	0.07

values given in Table 3 should be considered only as a reasonable estimate of ϵ_a.

On the basis of the definition of β as the fraction of the total number of analyte atoms that have gone into the analysis volume at a given instant of atom formation and that of ϵ_a which is the ratio of the neutral analyte atoms that exist in the analysis volume to the total number of atoms initially deposited in the graphite furnace one would expect that ϵ_a is always less than β. The value of β represents a fraction of the total number of analyte gaseous species which are released from the graphite surface to the gas phase. To illustrate the definition of β, suppose that the total number of analyte atoms which are vaporized from the graphite surface at time t_1 is 10, and suppose that $\beta = 0.50$. The number of free atoms that will enter the analysis volume will be 5 atoms, the other 5 atoms will be lost as non-absorbing species or they may not get a chance to diffuse into the analysis volume. As the atomization proceeds more gaseous atoms will be released. Let us assume that at time t_2 the total number of analyte atoms vaporized from the surface becomes 20 atoms, the number of analyte atoms that will enter the analysis volume, in this case, are 10 atoms, the rest will be lost as non-absorbing species, and so forth. Thus, β remains constant during the entire duration of the absorbance signal, *i.e.*, at each stage of atom formation. This characteristic property of β made it possible to determine the activation energy by Smets equation[5] and calculate its value from the slope of the plot of $A(t)$ *vs.* $\int_t^\infty A(t)\,dt$. On the other hand, ϵ_a represents analyte atom population when the absorbance reaches its maximum. Notice the difference between the two definitions of β and ϵ_a, the latter is directly proportional to the former only at the absorbance maximum. Both of β and ϵ_a depend appreciably on the shape of the absorbance signal profile. This is clear if one carefully examines the magnitude of the slope, $-k_2/\beta$, and ϵ_a. The slope and ϵ_a are very sensitive to the shape of the absorbance signal and they should not change appreciably if all experimental and instrumental parameters are kept constant during absorbance measurements. Their values will be a characteristic property of a particular analyte element. The value of ϵ_a will be of prime importance for research workers since it represents the overall atomization efficiency of the graphite furnace to produce and contain the analyte atomic vapour under non-isothermal conditions. A value of less than one, for instance, means that the graphite furnace is not 100% efficient suggesting that more research can be done in order to increase the atomizer efficiency to its maximum.

Because β and ϵ_a imply a greater sensitivity for peak area and peak-height absorbance it is of interest to compare the signal to noise ratio, $(S/N)_{ht}$, which arises from peak-height measurements with that obtained by peak area, $(S/N)_{area}$, and show how these two modes of measurement influence the precision of β and ϵ_a. But first, let us mention the sources for the uncertainty in the measurement of the absorbance signal. Generally, absorbance signal consists of two components: a desirable component, which is related to the free analyte atoms, and an undesirable component, which is termed noise. The noise in the absorbance signals results from two distinct types: fundamental noise which arises from the motion of discrete charges in electrical circuits and cannot be completely eliminated, and excess noise which arises from imperfect instrumentation or non-ideal component behaviour and can in principle be reduced to insignificant levels. Assuming the noise is stationary white noise and keeping with a recent publication by Voigtman[22] the comparison of the two types of signal-to-noise ratios, mentioned above, can be made in the following manner. The $(S/N)_{ht}$ is computed from the following relationship:

$$\left(\frac{S}{N}\right)_{ht} \equiv \frac{A_m}{\sigma_{ind}} \qquad (15)$$

where A_m is the average peak-height absorbance and σ_{ind} is the relative standard deviation of the measurement. The expression for the $(S/N)_{area}$ is as follows:

$$\left(\frac{S}{N}\right)_{area} \equiv \frac{\frac{1}{t_{ind}}\int_t^\infty A(t)\,dt}{\sigma_{sum}} \qquad (16)$$

where t_{ind} is the integration time constant used by Voigtman,[22] equal to the time constant of the instrument (0.02 sec), and σ_{sum} is the relative standard deviation of the integrated absorbances (or peak areas). The ratio of signal-to-noise is then,

$$\frac{\left(\frac{S}{N}\right)_{ht}}{\left(\frac{S}{N}\right)_{area}} = \frac{A_m/\sigma_{ind}}{\frac{1}{\sigma_{sum}t_{ind}}\int_t^\infty A(t)\,dt} \qquad (17)$$

which is slightly rearranged to

$$\frac{\left(\frac{S}{N}\right)_{ht}}{\left(\frac{S}{N}\right)_{area}} = \frac{\sigma_{sum}}{\sigma_{ind}}\frac{A_m t_{ind}}{\int_t^\infty A(t)\,dt} \qquad (18)$$

But the 'sigma ratio' factor is given by the following equation:

$$\sigma_{sum} = \sigma_{ind}\left(\frac{t_{sum}}{t_{ind}}\right)^{0.5} \qquad (19)$$

where t_{sum} is the time over which the area is integrated, so equation (18) becomes

$$\frac{\left(\frac{S}{N}\right)_{ht}}{\left(\frac{S}{N}\right)_{area}} = (t_{sum}t_{ind})^{0.5}\frac{A_m}{\int_t^\infty A(t)\,dt} \qquad (20)$$

For copper, $t_{sum} = 4$ sec, and $t_{ind} = 0.02$ sec, $A_m = = 0.716$ (A.U.) and peak area $= 9.379 \times 10^{-1}$ (A.sec). Thus, with these numerical values the $(S/N)_{ht}/(S/N)_{area}$ is 0.22 which is substantially less than unity as predicted by Voigtman,[22] which also means that peak-height measurements may cause greater uncertainty in β and ϵ_a calculation relative to peak-area measurements.

APPENDIX

To show how equation (7) has been obtained the derivation of the Smets equation[5] has to be considered. To derive his equation Smets has used the following differential equations:

$$\frac{dN(t)_g}{dt} = R_{form} - R_{diss} \qquad (A1)$$

where $dN(t)_g/dt$ is the rate of change in the number of gaseous analyte atoms in the atomizer (assumed to be proportional to the rate of change of the number of atoms in the optical pathway), R_{form} is the rate of analyte atoms formation given by,

$$R_{form} = k_1 N(t)_w \qquad (A2)$$

where k_1 is a first-order rate constant and $N(t)_w$ is the number of analyte atoms left unatomized on the graphite surface; R_{diss} is the rate of atom dissipation given by[5]

$$R_{diss} = k_2 N(t)_g \qquad (A3)$$

Here k_2 is a first-order rate constant for atom dissipation.

Smets[5] has assumed that, for the strip heater (used by him), during all stages of atom formation, the rate of disappearance is approximately equal to the rate of atom formation [*i.e.*, $dN(t)_g/dt = 0$]. Other authors[23] have assumed that a local thermodynamic equilibrium between the analyte atomic vapour and the condensed phase prevails over the entire duration of the atom formation similar to

that prevailing during vaporization from a Langmuirian film. Under these conditions one gets for equation (A1),

$$R_{form} = R_{diss} \tag{A4}$$

At this stage one may address the following question: how can one account for the observed absorbance signal if an equilibrium is established during atom formation? To answer this question one has to fall back on the expression of the pressure equilibrium constant K_p which upon substituting equations (A2) and (A3) in equation (A4) yields,

$$K_p = p_{N_g} \tag{A5}$$

where K_p is equal to k_1/k_2 for elementary reactions. Since, K_p increases with temperature for endothermic reactions ($\ln K_p = -\Delta H°/RT + \Delta S°/R$), the pressure of the analyte atomic vapour will increase resulting in increased absorbance.

The integrated rate of atom formation, $\int_0^\infty R_{form}\,dt$, has been assumed[5] to be directly proportional to the number of analyte atoms, N_0, initially deposited in the graphite furnace as given by the following expression:

$$\int_0^\infty R_{form}\,dt = \beta N_0 \tag{A6}$$

Similarly,

$$\int_0^t R_{form}\,dt = \beta N(t)_g \tag{A7}$$

where β in equations (A6) and (A7) is the correction factor (constant) used by Smets to account for the analyte loss during all stages of atomization. According to equation (A7) the number of analyte atoms that will diffuse into the analysis volume during the indicated time interval is $\beta N(t)_g$ and that diffuses to the gas phase is $N(t)_g$. The next step in developing the above equation is to substitute equation (A4) into (A6) and (A7) for R_{form} and considering equation (A2) to get the following equations:

$$\langle k_2 \rangle \int_0^t N(t)_g\,dt = \beta N(t)_g \tag{A8}$$

$$\rangle k_2 \langle \int_0^t N(t)_g\,dt = \beta N_0 \tag{A9}$$

where $\langle k_2 \rangle$ and $\rangle k_2 \langle$ are the values of k_2 over the indicated time intervals (assumed to be constant within 10%[5]) as defined by the following two equations:[5]

$$\langle k_2 \rangle = \frac{\int_0^t k_2 N(t)_g\,dt}{\int_0^t N(t)_g\,dt} \tag{A10}$$

and

$$\rangle k_2 \langle = \frac{\int_0^\infty k_2 N(t)_g\,dt}{\int_0^\infty N(t)_g\,dt} \tag{A11}$$

Smelts[5] has further assumed that the number of analyte atoms, $N(t)_w$, left unatomized on the graphite surface is given by

$$N(t)_w = N_0 - N(t)_g \tag{A12}$$

where $N(t)_g$ is the total number of atoms in the gas phase and N_0 is the number of analyte atoms deposited in the graphite furnace. Therefore, upon substituting equations (A8) and (A9) in (A12) for N_0 and $N(t)_g$ one gets,

$$N(t)_w = \frac{1}{Q\beta}\left(\rangle k_2 \langle \int_0^\infty A(t)\,dt - \langle k_2 \rangle \int_0^t A(t)\,dt\right) \tag{A13}$$

where Q is a constant relating $A(t)$ to $N(t)g$. Setting $\langle k_2 \rangle = \rangle k_2 \langle = k_2$, yields,

$$N(t)_w = \frac{k_2}{Q\beta_1}\int_t^\infty A(t)\,dt \tag{A14}$$

which is equation (7) mentioned in Theory.

It is of interest to note that the Smets equation[5] is obtained as follows: Substituting equations (A2) and (A3) into (A4) and re-arranging terms one gets,

$$k_1 = k_2 \frac{N(t)}{N(t)_w} \tag{A15}$$

and then equation (A14) into (A15) to yield

$$k_1 = \frac{k_2 N(t)_g}{(k_2/\beta Q)\int_t^\infty A(t)\,dt} \tag{A16}$$

which, after setting $N(t)_g = A(t)/Q$ and cancellation of common term becomes

$$k_1 = \beta\left(\frac{A(t)}{\int_t^\infty A(t)\,dt}\right) \tag{A17}$$

SEQUENTIAL DETERMINATION OF IRON AND TITANIUM BY FLOW-INJECTION ANALYSIS

M. G. M. ANDRADE, S. L. C. FERREIRA, B. F. SANTOS and A. C. S. COSTA
Instituto de Química, Universidade Federal de Bahia Salvador, Bahia 40210, Brazil

(*Received* 8 *October* 1991. *Revised* 13 *February* 1992. *Accepted* 21 *February* 1992)

Summary—A flow-injection method has been developed for the sequential spectrophotometric determination of iron and titanium using 3,4 dihydroxybenzoic acid as chromogenic reagent. The system involves the sequential measurement of the absorbances of the complexes at 380 and 570 nm. The system is designed using a simultaneous injection of sample and reagent into separate carrier streams. The proposed method is characterized by a precision of about 2%, a sampling rate of about 50 samples per hour, and a reagent consumption of 200 μl (0.50% solution) per sample. It is relatively free of interferences and was used for the sequential determination of titanium and iron in rocks.

Flow-injection analysis (FIA) is a rapid and precise technique which has found wide application, especially in agricultural, environmental, geochemical, clinical and pharmaceutical analysis. The reaction between 3,4 dihydroxybenzoic acid (protocatechuic acid) or DHB with iron(III) and titanium(IV) allows the sequential determination of iron and titanium by flow injection, based on the additive property of the absorbances. Iron(III) reacts with this reagent, forming a complex with absorption maxima at 380 and 570 nm, and titanium(IV) forms a complex with an absorption peak at 380 nm. Considering these facts, a method is proposed in which the absorbances are measured at 380 and 570 nm. DHB is a good reagent for flow-injection analysis, because it is soluble in water (2 g/100 ml)[1] and does not absorb in the visible region of the spectrum. The reaction of iron(III) with DHB was studied by Hsieh and Liang[2] and of titanium(IV) with DHB by Sommer.[3] The 3,4 dihydroxybenzoic acid reagent has been used in the flow-injection analysis of manganese[4–6] and for conventional spectrophotometric determination of molybdenum,[7] vanadium,[8,9] cerium[10] and niobium.[11]

EXPERIMENTAL

Reagents

3,4 Dihydroxybenzoic acid solution. A 2.5-g amount was dissolved in 500 ml of water.

Standard iron(III) solution. Prepared from iron(III) sulfate heptahydrate and standardized gravimetrically.

Standard titanium(IV) solution.[12] Prepared by dissolving titanium(IV) oxide (0.20 g) in sulfuric acid (8 ml) and ammonium sulfate (3.2 g), heating and dilution with distilled water.

Buffer solution (pH 6.0). Prepared by dissolving 0.31 ml of acetic acid and 12.88 g of sodium acetate trihydrate in one litre of distilled water.

Apparatus

A Varian DMS 100 spectrophotometer equipped with an 8-μl flow cell, a Fisher 600 pH meter, a Micronal B332 peristaltic pump and an Intralab recorder were used.

Sample preparation

Weigh 0.2–0.3 g of dry material (110°), transfer to a Teflon beaker, and add a few mililiters of water so as to form a wet mixture. Add 1 ml of sulphuric acid (98%) and 10 ml of hydrofluoric acid (40%). Heat, on a hot plate, until almost dry.

Add an additional 1 ml of sulphuric acid and 10 ml of hydrofluoric acid and heat until white fumes. Add 5–10 ml of hydrochloric acid (37%) and transfer the contents of the beaker to a 250-ml glass beaker.

Boil to dissolve completely all the residue, cool to room temperature and transfer, with demineralized water, to a standard flask and dilute to volume.

Flow-injection analysis

Carrier solution C (buffer solution pH 6.0) is pumped into the analytical lines at a flow-rate of 3.50 ml/min with a peristaltic pump

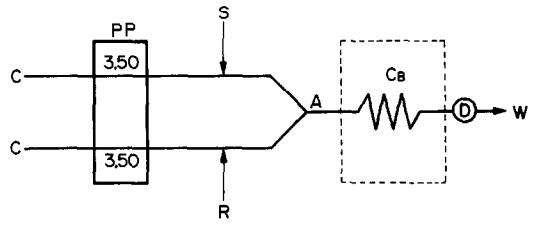

Fig. 1. Flow diagram: C carrier solution (buffer solution pH 6.0), PP peristaltic pump, S sample, R chromogenic reagent solution, A confluence point, CB mixing coil (0.5 mm i.d., 100 cm long), D detector—equipped with flow cell (volume 8 μl), W waste.

[Fig. 1]. The sample solution *S* (200 μl) and reagent solution *R* (200 μl) are introduced simultaneously into the carrier streams by a double proportional injector and the absorbance of the complex is monitored in the flow-through cell D at 380 nm for the titanium(IV)-complex and 380 and 570 nm for the iron(III)-complex, against the carrier solution as reference (baseline), separate injections are made for measurements at the two wavelengths. A narrow coil (100 cm long) is attached before the flow-through cell, as a back-pressure and mixing coil.

For calibration, similarly treated standard solutions are injected between the sample runs. The area or height of the absorbance peak can be used for calibration.

RESULTS AND DISCUSSION

The iron(III) reacts with DHB in the range pH 5.0–6.0 forming a complex with absorption maxima at 380 and 570 nm and molar absorptivities of 2.84×10^3 and 4.10×10^3 $l \cdot mole^{-1} \cdot cm^{-1}$, respectively. The titanium forms a complex with DHB in the pH range 4.0–6.0, with an absorption maximum at 380 and a molar absorptivity of 1.54×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ (Fig. 2). The DHB has an absorption peak at 280 nm and does not absorb in the visible spectrum. Considering these facts, the present method is proposed by measuring the absorbances at 380 and 570 nm, based on the additive property of the absorbances.

Optimization of flow system

Buffer concentration. The effect of the concentration of buffer solution was investigated from 0.100 to 1.000*M* acetate. Increasing the buffer to high concentrations increases the sensitivity but decreases the reproducibility. Concentrations below 0.100*M* are not recommended because the "buffering capacity" is low and the sample solutions are acid. The proposed system utilizes a dilute acetate solution, 0.100*M*, as the carrier stream.

Effect of pH. The effect of pH was investigated by using acetate buffer (0.100*M*) of various pH values as the carrier stream. Maximum absorbance is found between pH 5.5 and 6.0.

Flow rate. The effect of the flow-rate on the peak height was studied in the range of 2–4.5 ml/min, by injecting 200 μl each of iron standard and reagent solution. The maximum signal was obtained with a flow-rate of 3.50 ml/min for each stream.

Reagent and sample volume. The influence of the sample volume on the absorbance was investigated by injecting different volumes (50–300 μl) of iron and titanium standard solutions into the carrier stream at the recommended flow-rate and coil length, keeping the reagent volume at 200 μl. The injection volume has a significant effect, yielding increased peak height and reproducibility with increasing injection volume. However, increasing the injection volume widens the sample zone and lowers the sampling rate, so that 200 μl is taken as a compromise.

Length of coil. The effect of the length of the reaction coil was examined for various flow-rates. Coil lengths of 50, 100 and 150 cm were tested. Increasing the coil length lowered the peak height but improved the reproducibility. The optimum length was established as 100 cm.

Reagent concentration. The influence of the 3,4-dihidroxybenzoic acid concentration, ranging from 0.10 to 1.00%, was tested, using 200 μl of reagent and of sample. A calibration graph was obtained for each concentration of reagent with iron and titanium standards,

*Source of the certified sample.

ranging from 10.0 to 30.0 μg/ml; all measurements were performed in triplicate. The maximum and constant slope of the calibration curve was obtained above 0.40% reagent concentration, so 0.50% concentration was selected as optimal. A study was made with 200 μl of the reagent solution.

Calibration graph

A calibration graph was obtained at the optimum working conditions: reaction coil = 100 cm, flow-rates 3.50 ml/min, reagent concentration = 0.50%, volume injected = 200 μl and carrier stream = acetate buffer pH 6.0. The calibration graph was linear over the range 2–10 μg/ml for titanium and 10–40 μg/ml for iron.

Effect of foreign ions

The interference due to several anions and cations was studied in detail. In the flow-injection spectrophotometric determination of 2 ppm of iron(III) and 1 ppm of titanium(IV), V(V), Mo(VI), Ce(III), Nb(V), phosphate and tartrate ions interfered seriously. The following ions [when present in the amounts (in ppm) shown in brackets] do not interfere: Mn^{2+} (20), Hg^{2+} (4), Cu^{2+} (10), Co^{2+} (40), Al^{3+} (50), Ni^{2+} (60), Ca^{2+} (75), Mg^{2+} (75), Pb^{2+} (40), La^{3+} (40), Bi^{3+} (40), Sr^{2+} (40), SO_4^{2-} (200), CO_3^{2-} (40), Cl^- (200) and NO_3^- (200).

However, the proposed method can be conveniently applied for the simultaneous determination of iron(III) and titanium(IV) in silicate rocks that do not contain interferents such as vanadium(V), molybdenum(IV), cerium(III) and niobium(V), as illustrated below.

Determination of iron and titanium in synthetic samples and standard samples of rocks by flow-injection analysis

The flow-system proposed was used for the simultaneous determination of iron and titanium in several samples. The results in Table 1 show that the method can be used for determination of iron and titanium in several proportions.

The analysis of rocks revealed (Table 2) that the proposed method has satisfactory precision and can be used for determination

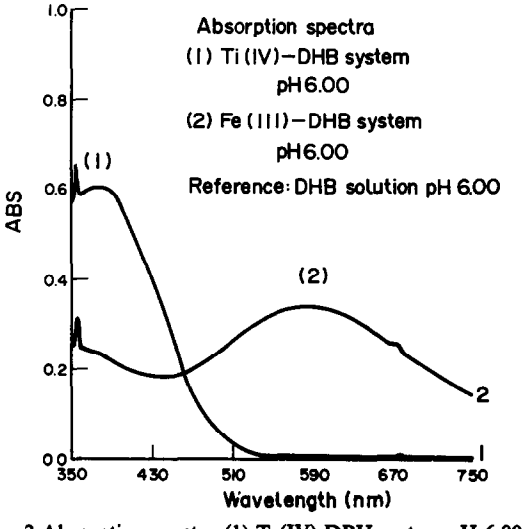

Fig. 2 Absorption spectra (1) T_i(IV)-DBH system pH 6.00 (2) Fe(III)-DHB system pH 6.00 reference: DHB solution pH 6.00.

of iron and titanium in rock samples with different composition (Table 3).

DHB does not show as high a sensitivity for iron as other reagents do but it is good for titanium. However, this presents a favorable situation for the sequential determination of these elements because, in large numbers of samples, the iron level is superior to that of titanium.

FLOW-INJECTION ANALYSIS OF SERUM UREA USING *o*-PHTHALALDEHYDE AND NAPHTHYLETHYLENEDIAMINE

D. NARINESINGH and A. POPE
Department of Chemistry, University of the West Indies, St Augustine, Trinidad, West Indies

T. T. NGO
BioProbe International, 14272 Franklin Ave., Tustin, California, CA 92680, U.S.A.

(*Received* 19 *September* 1991. *Revised* 17 *January* 1992. *Accepted* 24 *January* 1992)

Summary—An analytical procedure is developed for the determination of urea using flow injection analysis. The methodology is based on the color that develops (λ_{max}, 517 nm) when urea reacts with *o*-phthalaldehyde in the presence of naphthylethylenediamine under acidic conditions. Calibration curves are found to be linear up to 51 mg urea N/dl when the FIA manifold is operated at 42°, utilizing 90-μl samples and a flow-rate of 0.44 ml/min. By manual injection up to 40 samples can be analysed per hour. Recovery yields varied between 95–99%. The within day CV was 0.5–2.2% whereas the day to day CV was 2.1–3.9%. When applied to the analysis of urea in serum samples, excellent correlations (>0.998) are obtained when the FIA results are compared with those obtained for the same serum samples analysed by the free urease/Berthelot's and the hospital method (employing the Abbot Bichromatic Analyser). Interferences are observed with sulphur compounds such as sulphanilamide (>0.76 mg/dl) as well as with many amino acids but at relatively high concentrations (>21 mg/dl).

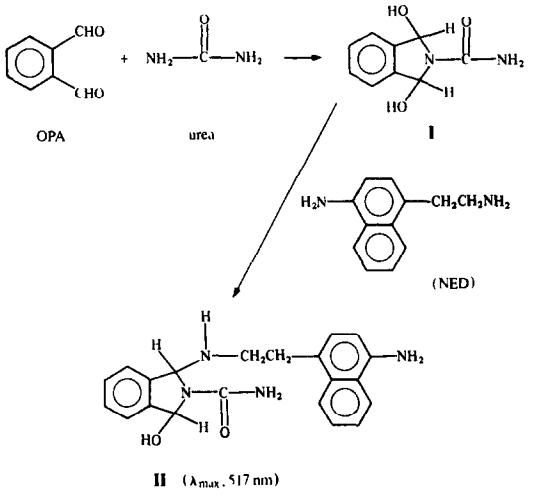
The quantitative determination of urea in biological fluids and soil samples are analyses that are routinely carried out in analytical laboratories. A wide variety of methodologies can and have been employed in such analyses. For example, there is the direct method in which the urea itself can be monitored by HPLC[1] or colorimetrically using diacetyl monoxime,[2,3] dimethylglyoxime,[4] *p*-dimethylaminobenzaldehyde[5] or *o*-phthalaldehyde in the presence of naphthylethylenediamine.[6–8] There are also enzyme based methods. These include the urease-glutamate dehydrogenase method[9] in which the nicotine adenine dinucleotide produced is monitored at λ_{340} and the urease hydrolysis method where the ammonia produced can be monitored either spectrophotometrically using Nessler's,[10] Berthelot's[11,12] or *o*-phthalaldehyde[13] reagents or potentiometrically using an ammonia gas sensing electrode.[14,15]

The diacetyl monoxime method is quite sensitive and very specific.[2,3] However, the color produced is unstable and a high incubation temperature (90°) is usually required. The methodologies based on urease hydrolysis are also highly specific and sensitive.[10–15]

However, these methods suffer from the disadvantages of urease inhibition, instability of reagents and possible contamination from environmental and/or endogenous ammonia.[10–15] Also some of these methods require sample pretreatment, expensive cofactors or relatively large reagent volumes.[9–11]

We now report on the development of a modified, improved method for the direct determination of urea in biological fluids employing *o*-phthalaldehyde (OPA) and naphthylethylenediamine (NED) as the colorimetric reagents for flow-injection analysis. This colorimetric method, using OPA and NED was first proposed by Jung *et al.*[16] and later modified by Lequang *et al.*[17] The reagents are stable and non-volatile and color development is very rapid (<3 min) at relatively low temperature (<40°), quite unlike diacetyl monoxime which requires an incubation temperature of about 90° for rapid color development.[2,3] These reaction characteristics make this method ideally suited for use in non-segmented continuous flow analyses such as FIA which is characterized by low reagent consumption, small sample volume requirement, high sample throughput (30–720 samples/hr) and high reproducibility.[18]

The coupling reactions which occur when urea reacts with OPA and NED are shown in Scheme 1. The chromogenic compound, **II**,



Scheme 1.

formed has a λ_{max} of around 517 nm but can be readily monitored over the wavelength range 480–520 nm. The extent of color development is directly proportional to the urea concentration.

EXPERIMENTAL

Materials

o-Phthalaldehyde (OPA) and Triton X-100 were purchased from Aldrich Chemical Company. Naphthylethylenediamine dihydrochloride (NED) and all other chemicals used were of analytical reagent grade and were obtained from BDH (Poole, U.K.). Serum samples were kindly provided by the Biochemistry Laboratory, Port of Spain General Hospital, Trinidad, West Indies.

Reagents

o-Phthalaldehyde reagent (OPA reagent). This reagent was prepared by first dissolving OPA (600 mg) in demineralized, distilled water (800 ml) containing concentrated sulphuric acid (1 ml) and Triton X-100 (7 g) and then making up to one litre with demineralized, distilled water.

Naphthylethylenediamine reagent (NED reagent). This reagent was prepared by first dissolving NED (600 mg) in demineralized, distilled water (600 ml) containing boric acid (5 g), concentrated sulphuric acid (224 ml) and Triton X-100 (7 g) and then making up to one litre with demineralized, distilled water.

These reagents when stored in amber colored bottles at 4° are stable for several years.[16]

The FIA manifold

The FIA manifold used in this study is shown in Fig. 1. Except for the pump tubing (polypropylene), PTFE tubing (0.50 mm, i.d.) was used throughout the manifold. The OPA and NED reagent streams were pumped through the FIA manifold via a peristaltic pump (Gilson Minipuls II, Surrey, U.K.). Samples of urea (90 μl) were injected into the OPA stream. Any urea–OPA–NED complex (II) formed was allowed to develop rapidly in a thermostated water bath maintained at 42° and monitored at 510 nm on a Pye-Unicam SP6-550 UV/VIS spectrophotometer equipped with a 10-μl flow cell and a strip chart recorder. The use of two separate reagent streams (Fig. 1) rather than one is recommended because of the instability of the mixed reagents upon standing.

RESULTS AND DISCUSSION

Optimization of the operating parameters

In the development of this FIA method as a viable alternative to the reported end point,[16] segmented continuous flow and kinetic methods for the direct determination of urea using NED and OPA as the colorimetric reagents several operating parameters had to be optimized in order to achieve high sensitivity, good repro-

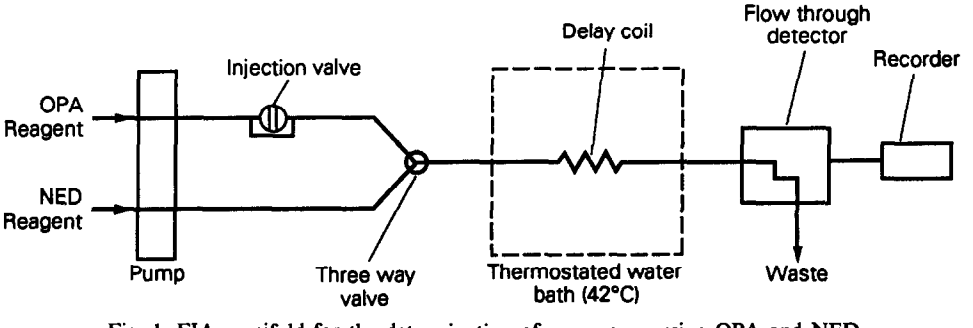


Fig. 1. FIA manifold for the determination of serum urea using OPA and NED.

ducibility, minimum interference and at the same time high sample throughput. The operating parameters that were optimized included temperature, flow-rate, sample injection volume and length of reaction coil. The effects of these various parameters on the sensitivity of the detection method are discussed below.

Temperature optimization

Jung *et al.*[16] reported in their studies that the rate of colored product formation is directly related to temperature only up to 40°, and that temperatures above 40° lead to color instability. However, in the present study it was observed that when a solution containing 3.8 mg urea N dl^{-1} was allowed to react with OPA and NED at various temperatures, the absorbance after any fixed reaction time interval (at least up to 10 min) was found to increase linearly up to 65° (Fig. 2). It was only at temperatures above 65° that product breakdown appears to take place. Also at such high temperatures (>65°) color development was observed when urea was added to OPA even in the absence of NED. Thus it should be possible to carry out analyses at temperatures below 65°. It should be noted that even if analyses were to be carried out at temperatures above 65°, then under FIA conditions this may prove not to be too critical as say in the endpoint or kinetic methods of Jung *et al.*[16] where precise timing would then be crucial. In FIA under any fixed set of operating conditions the time taken for the sample plug to travel from the point of injection to the point of detection is a constant. Thus it should be possible to obtain a high degree of precision even if there is product breakdown.

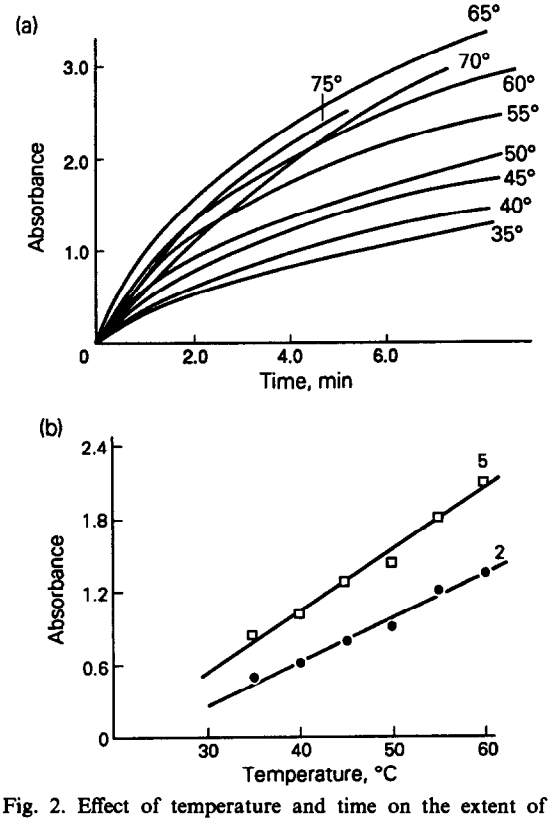

Fig. 2. Effect of temperature and time on the extent of color development of the urea–OPA–NED complex. Urea conc. = 3.8 mg N dl^{-1}. (a) Change in absorbance with time at various temperatures. (b) Absorbances at various fixed intervals and temperatures. The numbers on the graphs indicated the fixed time intervals (min) after which absorbances were measured at each temperature. Data taken from Fig. 2(a).

Typical calibration curves at selected temperatures gave the following linear regression equations ($r > 0.995$, $n = 7$):

$$29.5°\ \text{Abs} = 0.0041\ (\text{urea, mg N dl}^{-1}) + 0.0011$$
$$35.0°\ \text{Abs} = 0.0045\ (\text{urea, mg N dl}^{-1}) + 0.0028$$
$$42.0°\ \text{Abs} = 0.0080\ (\text{urea, mg N dl}^{-1}) + 0.0055$$

Flow-rate optimization

The flow-rates of both the OPA and NED reagent streams were varied by using pump tubings of varying internal diameters. It was found that maximum color development is achieved when a flow-rate ratio of 1:1 is used. Utilizing this optimized ratio and a reaction coil length of 59 cm, the overall effluent flow-rate was then varied over the range 0.26 to 0.88 ml/min. These results show that increasing effluent flow-rates results in decreased absorption intensities (peak heights). A flow-rate of 0.44 ml/min was eventually selected for use in all subsequent investigations since it provided a compromise between sample throughput and sensitivity.

Reaction coil length optimization

The effect of varying the reaction coil lengths (59, 119, 178 and 238 cm) were also investigated. The results show that with increasing reaction coil length (increased incubation time) there is a corresponding increase in absorption intensity. Use of longer reaction coils may lead to increased sensitivity but significantly increased reagent consumption and analysis time would be experienced. Also the dispersion coefficient was found to increase (1.72–1.85) as the total length of the tubing between the points of injection and detection increased. However, they

all fall into the dispersion category described as limited by Růžička and Hansen,[18] a condition which is desirable in the operation of any FIA system. A reaction coil length of 119 cm was eventually selected for urea serum analysis since it provided a compromise between sensitivity, dispersion and sample throughput rate.

Sample volume optimization

The influence of sample injection volume (90, 160 and 225 μl) was also investigated. The responses obtained for the 160 and 225-μl sample loop sizes were broad and large with sharp onset but relatively long peak decay times. With the 90-μl sample loop the peaks obtained were considerably narrower and sharper, with rapid onset and decay times and with peak heights being decreased only by about 14% (at 10 mg urea N dl^{-1} concentration) relative to the 225-μl injection volume. This increased sharpness of peaks coupled with an increase in sample throughput and a relatively small sample volume requirement led to the choice of the 90-μl loop size for all subsequent investigations.

Calibration graph, precision and detection limit

Utilizing the above compromised conditions for operating the FIA manifold (Fig. 1) calibration graphs were prepared and found to be linear over the concentration range up to 51 mg urea N dl^{-1}, curvature being observed at higher concentrations. More concentrated urea samples can be readily analysed by simply diluting so as to fall within the linear calibration range. A typical calibration curve is shown in Fig. 3.

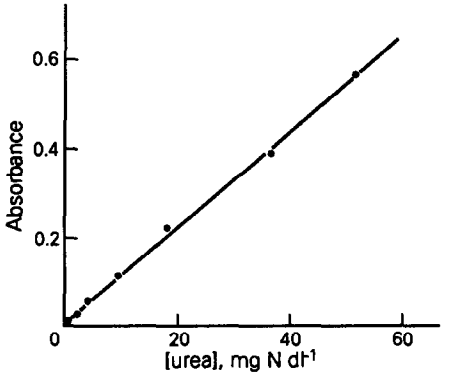

Fig. 3. Urea calibration graph under optimized compromise FIA conditions: T = 42°, flow-rate = 0.44 ml/min, sample volume = 90 μl; ratio of NED:OPA = 1:1; delay coil length = 119 cm.

The following least-squares regression equation ($r = 0.997$) was found to hold.

$$\text{Abs} = 0.107\ (\text{urea, mg N dl}^{-1}) + 0.0058$$

Urea concentrations as low as 1 mg urea N dl^{-1} can be detected at a flow-rate of 0.44 ml/min. Lower detection limits can be achieved at lower flow-rates.

The within-day coefficient of variations for the determination of a 3.0 and a 36.0 mg urea N dl^{-1} serum, obtained from 16 replicate analyses performed over a period of 6 hr were found to vary between 0.5 and 2.2%. The corresponding day to day coefficient of variation for the same 3.0 and 36.0 mg urea N dl^{-1} serum samples was found to vary between 2.1–3.9% indicating a high degree of precision of the method.

Interferences

There are many substances which are present in the blood stream and which will react with the OPA and NED reagents to produce a similar color to that obtained with urea. Comprehensive studies on the possible interferences by such substances have been reported.[16]

The present study shows that under the FIA conditions employed the amino acids, *L*-arginine, *L*-lysine, glycine and *D,L*-tryptophan and the serum protein albumin showed no interferences at least up to the concentrations specified in Table 1. These concentrations are higher than those normally found in the blood stream and hence should not interfere with urea analysis of samples. Similar non-interferences have been reported by Jung *et al.*[16] using the segmented continuous flow techniques of

Table 1. Concentration levels below which non-interference is observed for certain compounds in the reaction between urea, OPA and NED under FIA conditions

Substance	Non-interfering concentrations (mg/dl)*
L-Arginine	<3368.0

†Sulphanilamide	

*Concentrations below which no absorption is detected under FIA conditions.
†Interferences at levels as low as 0.76 mg/dl.

analysis. However, sulphanilamide was found to interfere significantly.

The latter gave the same amount of color per mole equivalent to about 25 moles of urea. This compares to the 15 and 9 mole equivalents observed by Jung *et al.*[16] using the segmented continuous flow and manual procedures respectively. These variations in urea color equivalents using the different analytical techniques can be accounted for as follows. The reaction between sulphur compounds and the OPA/ NED reagents is very fast and hence color development very rapid. However, the color fades rapidly with time. Hence the extent of interference will be dependent upon the time at which absorbance measurements are made. With the manual method reported by Jung *et al.*[16] absorbance measurements were made after an incubation time of 30 min. In contrast, in the present FIA system, the time taken for the sample plug to travel between the point of injection and the point of detection (incubation time) is only about 45 sec.

Analysis of urea in serum samples

In these analyses, triplicate samples of serum from hospitalized patients and containing both normal and abnormal urea levels (16–280 mg urea N dl^{-1}), appropriately diluted, were analysed for their urea content using the FIA manifold shown in Fig. 1. Simultaneously, independent analyses were carried out on these same serum samples for their urea content using free urease and Berthelot's reagent.[11,12]

The results were matched statistically and pair-data t-tests of the values indicate that there was a >99.9% probability that samples analysed for urea by the hospital (employing the Abbot Bichromatic Analyser) and FIA methods would yield similar results. This is reinforced by the plots of the values obtained for the same serum samples by these methods [Figs. 4(a) and (b)] and which give correlation coefficients >0.999.

Recovery studies

Samples of serum of known urea concentration were supplemented with urea to give final concentrations in the range 2–51 mg urea N dl^{-1} (normal range of urea nitrogen in blood). Analysis of these samples under FIA conditions, gave recoveries in the range 95–99% (Table 2).

CATALYTIC KINETIC DETERMINATION OF ULTRATRACE AMOUNTS OF NITRITE WITH DETECTION BY LINEAR SCAN VOLTAMMETRY AT A DME

JIANG ZHI-LIANG, QIN HAI-CUO and WU DA-QIANG
Department of Chemistry, Guangxi Normal University, Guilin, People's Republic of China

(*Received* 24 *September* 1991. *Revised* 25 *March* 1992. *Accepted* 25 *March* 1992)

Summary—Nitrite has a very strong catalytic effect on the bromate oxidation of Methyl Orange in dilute sulphuric acid medium. The oxidation product of methyl orange exhibits a well derivative voltammetric wave at −0.41 V *vs.* SCE in sodium hydroxide medium. The linear scan voltammetric behaviour for the product at a DME has been studied, and it was selected as indicator component for the indicator reaction. Based on these studies, a novel and highly sensitive and selective catalytic reaction–voltammetric method for nitrite is proposed. A detection limit of $2 \times 10^{-9}M$ and calibration graph from 4×10^{-9} to $4 \times 10^{-7}M$ nitrite are obtained. Nitrite in water samples was determined by this method, with satisfactory results.

Nitrite ion can react with amines and amides, and form nitrosamino compounds that cause cancer.[1,2] Its analysis in water is also important.[3] So the development of sensitive, selective and facile analytical methods for nitrite has important significance.

Several polarographic methods for the determination of nitrite have been reported.[4–10] But their sensitivity and/or selectivity are generally unsatisfactory. Recently Wang and Li have developed a 2.5th order differential electroanalytical method to determine nitrite as low as 5 ng/ml based on the diazo-reaction.[11] Catalytic kinetic methods for nitrite are rare.[12–15] A sensitive kinetic spectrophotometric method for nitrite has been presented, based on the nitrite induced catalysis of the reaction system Fe(III)–SCN^-–I^-. However, the analysis time is relatively long (24 min).[12] Recently, Zhang has proposed a catalytic spectrophotometric method for nitrite with a detection limit of 4 ng/ml, using the new indicator reaction of bromate and Janus green.[14] Catalytic methods with oscillopolarographic (linear scan voltammetry at the DME) detection is a sensitive means of catalytic kinetic analysis.[16–25] Catalytic reaction–oscillopolarographic methods for several metals have been reported.[16–30] Catalytic reaction–oscillopolarographic methods for inorganic anions are rare.[31] And no method for nitrite has been reported.

Methyl Orange is a commonly used indicator for acid–base titrations. It has been applied for the catalytic spectrophotometric determination of As,[32] Br,[33] Cr,[34] Fe,[35] I[33] and Ru.[36] However, it does not seem to have been used for the catalytic determination of nitrite. In preliminary experiments, we have found that nitrite considerably catalyses bromate oxidation of Methyl Orange in sulphuric acid medium, and the reaction product of Methyl Orange exhibits an oscillopolarographic wave at −0.41 V. In the present work, we investigated the new indicator reaction for nitrite by linear-sweep oscillopolarography. A very sensitive and selective catalytic reaction–oscillopolarographic method for nitrite is proposed. This method is the most sensitive oscillopolarographic measurement and the most sensitive catalytic method for nitrite reported.

EXPERIMENTAL

Apparatus

A model JP-2 single-sweep oscillopolarograph (Chendu Instrumental Factory) with a three-electrode system (DME as working electrode, SCE as reference electrode, and platinum electrode as auxiliary electrode) was used. A thermostat was used to control the temperature.

Reagents

A standard solution of nitrite ($1.000 \times 10^{-2}M$) was prepared from sodium nitrate.

Working solutions were prepared by dilution of the standard solution shortly before use. Solutions of potassium bromate (0.10*M*), Methyl Orange (MO, $1.00 \times 10^{-4}M$), sulphuric acid (0.10*M*) and sodium hydroxide (1.0*M*) were used.

Procedure

Into a 25-ml graduated test tube fitted with a glass stopper, a known volume of solution containing between 5×10^{-11} and 5×10^{-9} mole of nitrite, 0.50 ml of $1.00 \times 10^{-4}M$ MO, 1.0 ml of 0.10*M* sulphuric acid and 0.30 ml of 0.10*M* potassium bromate were placed, followed by dilution to 10 ml with double distilled water. The tube was kept in a thermostat bath (at $60 \pm 0.1°$). After 15 min the reaction was quenched by tap water-cooling. Then 2.5 ml of 1.0*M* soidum hydroxide solution was added while the tube was shaken vigorously. A portion of the solution was transferred into a polarographic cell and the second derivative peak current, $(I''_p)_{t,cs}$, was measured with scanning from -0.20 V in the positive direction. $(I''_p)_{t,un}$ for the uncatalysed reaction was measured in a similar way. The $\Delta(I''_p)$ $[=(I''_p)_{t,cs} - (I''_p)_{t,un}]$ values for a range of nitrite concentrations were plotted as a function of nitrite concentration to prepare a calibration graph.

RESULTS AND DISCUSSION

Oscillopolarographic behaviour of the reaction product for MO

The polarographic character of azo-compounds has been studied extensively. Pittoni[37] reported the reduction potential for MO. However, the application of MO in inorganic oscillopolarographic analysis does not seem to have been reported. Our experiments indicated that MO and its oxidation product (MO_{ox}) exhibit oscillopolarographic waves at -0.50 and -0.41 V in sodium hydroxide medium, respectively (Fig. 1). Using the reaction product as the indicator component in catalytic kinetic analysis, provides simplicity, rapidity and high selectivity. In this work, MO_{ox} was chosen as the indicator component, and its oscillopolarographic behaviour was investigated. The I''_p is maximum and constant when the sodium hydroxide concentration is 0.15–0.40*M*, and so 0.20*M* sodium hydroxide was selected for use. The influence of bromate and bromide ions on the wave in sodium hydroxide medium was considered, and no effect was observed.

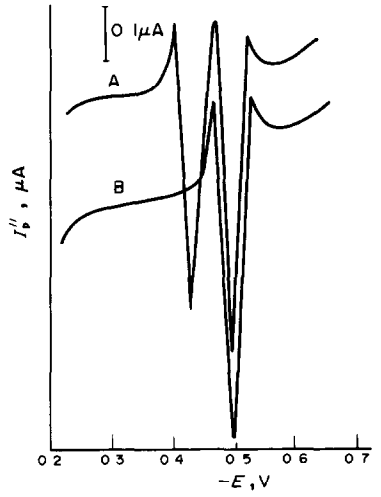

Fig. 1. The second derivative wave for MO and MO_{ox}. A: $4 \times 10^{-7}M$ NO_2^-; B: $0M$ NO_2^-. Other conditions as in procedure.

Under the conditions as in Fig. 2(A), the MO was completely oxidized to form MO_{ox} (that is, the solution is colourless). The electrocapillary curve is lower in the presence of MO_{ox} than in its absence, owing to adsorption of MO_{ox} on the surface of the DME, changing the surface tension of the mercury drop (Fig. 2). The anodic and cathodic waves are shown in Fig. 3, from which $-I_{pc}/I_{pa} = 1.82$ and $\Delta E = 30$ mV (under the conditions, the MO was completely oxidized to form MO_{ox}). The mean temperature coefficient is -1.05%/deg in the range of 15–35°. The I''_p decreases when Triton X-100, peregal O, polyvinyl alcohol and sodium dodecyl sulphonate are added. This confirms that the MO_{ox} has adsorption character.

The results demonstrate that the wave is an adsorption wave.

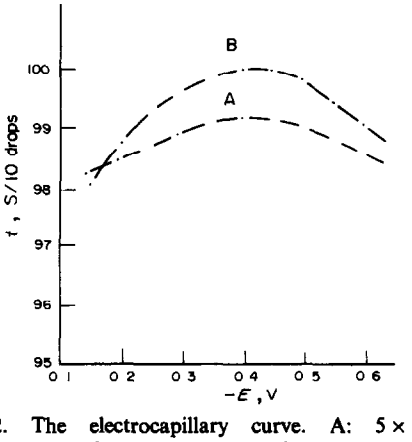

Fig. 2. The electrocapillary curve. A: $5 \times 10^{-6}M$ NO_2^-–$1.6 \times 10^{-6}M$ MO; B: $5 \times 10^{-6}M$ NO_2^-–$0M$ MO.

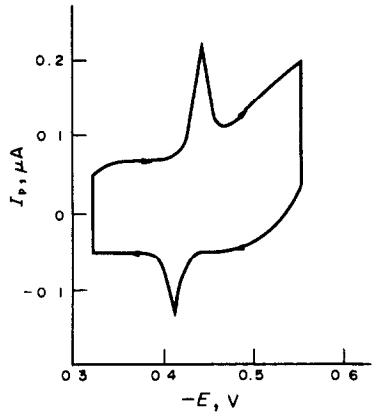

Fig. 3. Cathodic and anodic waves for the catalytic system containing $5 \times 10^{-6}M$ NO_2^- + $1.6 \times 10^{-6}M$ MO.

Principle for the catalytic determination of nitrite with oscillopolarographic detection

We first found that nitrite considerably catalysed the decolorization reaction between MO and bromate ion in dilute sulphuric acid medium at elevated temperature, and no catalytic action for nitrite occurs in sodium hydroxide media. MO_{ox} exhibits an oscillopolarographic wave at −0.41 V in sodium hydroxide medium. The reaction is very slow in sulphuric acid at room temperature. Hence, cooling by tap water or addition of sodium hydroxide can quench the reaction. The I_p'' remains constant for 120 min after quenching the reaction as in the procedure.

In the catalytic reaction solution, the catalysed and uncatalysed reactions occur simultaneously

$$MO + BrO_3^- \xrightarrow[\text{fast}]{H_2SO_4,\ 60°,\ \text{catalysed by } NO_2^-} MO_{ox} + Br^- \quad (1)$$

$$MO + BrO_3^- \xrightarrow[\text{slow}]{60°,\ H_2SO_4} MO_{ox} + Br^- \quad (2)$$

The rate equation for the catalytic reaction is

$$V_{cs} = [d(MO_{ox})/dt]_{cs} = k_c'(H_2SO_4)^a(BrO_3^-)^b(MO)^c(NO_2^-) + k_{un}'(H_2SO_4)^a(BrO_3^-)^b(MO)^c \quad (3)$$

where k_c' and k_{un}' are the rate constants of the catalytic and uncatalysed reactions respectively. And a, b and c are the reaction orders for H_2SO_4, BrO_3^- and MO respectively. Under the chosen conditions, the bromate, MO and sulphuric acid concentrations are greater than MO_{ox} concentration, and their concentrations held constant in the reaction process. Equation (3) can be expressed as

$$[d(MO_{ox})/dt]_{cs} = k_c(NO_2^-) + k_{un} \quad (4)$$

where k_c and k_{un} are the apparent rate constants of the catalytic and uncatalysed reactions, respectively. Integration of equation (4) gives

$$(MO_{ox})_{t,cs} = [k_c(NO_2^-) + k_{un}]t + B \quad (5)$$

where $B = (MO_{ox})_{0,cs}$, is the initial concentration of MO_{ox} in the catalytic reaction solution. When $(NO_2^-) = 0$, only the uncatalysed reaction takes place, and equation (5) has the form

$$(MO_{ox})_{t,un} = k_{un} \times t + B \quad (6)$$

where $(MO_{ox})_{t,un}$ is the concentration of MO_{ox} in the uncatalysed reaction solution at time t. Combining equations (5) and (6), we obtain

$$\Delta(MO_{ox}) = (MO_{ox})_{t,cs} - (MO_{ox})_{t,un} = k_c(NO_2^-)t \quad (7)$$

According to the Randel–Servick equation, $I_p'' = k'(MO_{ox})$, and equation (7) may be rewritten as

$$\Delta(I_p'') = (I_p'')_{t,cs} - (I_p'')_{t,un} = k(NO_2^-)t \quad (8)$$

where $k = k_c k'$. Equation (8) indicates that the $\Delta(I_p'')$ term is proportional to the NO_2^- concentration with the other variables and the reaction time and temperature held constant for the given system.

Effects of variables

The effects of the concentrations of sulphuric acid, potassium bromate and MO, reaction time

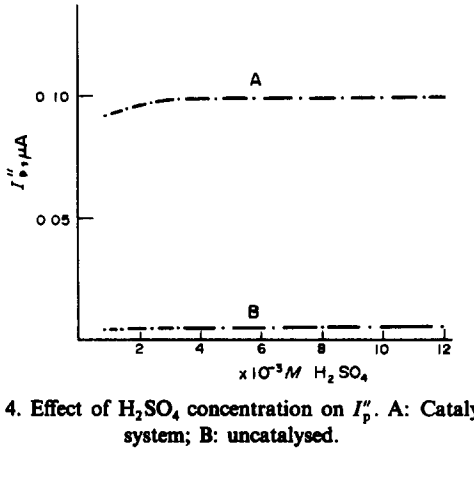

Fig. 4. Effect of H_2SO_4 concentration on I_p''. A: Catalytic system; B: uncatalysed.

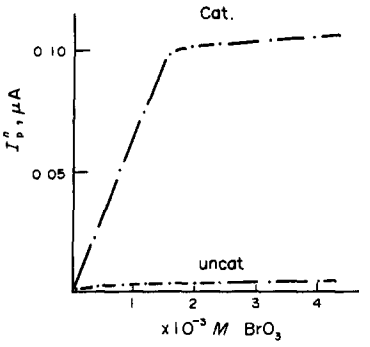

Fig. 5. Effect of BrO_3^- concentration on I_p''.

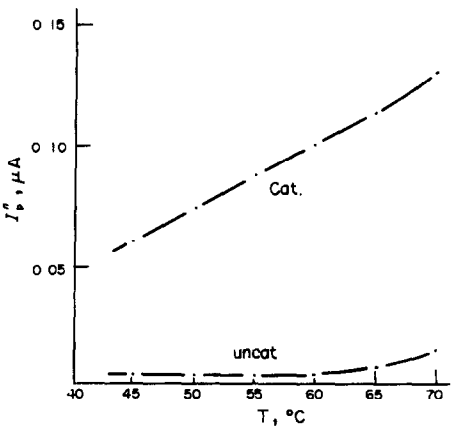

Fig. 7. Influence of temperature on I_p''.

and temperature on the $(I_p'')_{t,cs}$ and $(I_p'')_{t,un}$ were studied by the fixed-time procedure. A fixed-reaction time of 15 min was chosen, giving a good compromise between high sensitivity and analysis time. The relationship of I_p'' and sulphuric acid concentration is shown in Fig. 4. When the sulphuric acid concentration is 2.4×10^{-3}–$1.2 \times 10^{-2}M$, $(I_p'')_{t,cs}$ and $(I_p'')_{t,un}$ are constant, and $a = 0$. A concentration of $8.0 \times 10^{-3}M$ sulphuric acid was chosen. Figure 5 shows that the $(I_p'')_{t,cs}$ is proportional to bromate concentration at less than $1.6 \times 10^{-3}M$, and $b = 1$. And $(I_p'')_{t,cs}$ is stable when the concentration is more than $1.6 \times 10^{-3}M$, and $b = 0$. A $2.4 \times 10^{-3}M$ concentration of potassium bromate was selected for use. The effect of MO concentration on (I_p'') is indicated in Fig. 6, from which the order c is small and becomes zero at almost $2.5 \times 10^{-6}M$. A concentration of $4 \times 10^{-6}M$ was selected.

Under the selected conditions, $(I_p'')_{t,un}$ is very small, and can be considered negligible. Equation (8) may be rewritten as

$$k = (I_p'')_{t,cs}/(NO_2^-)t \ (A/M \cdot s) \qquad (9)$$

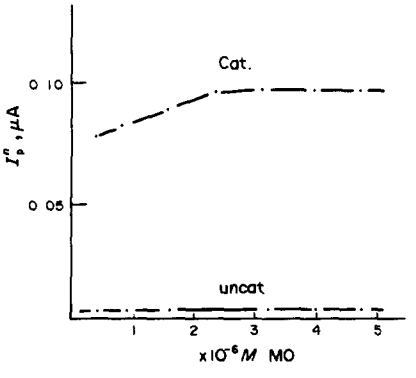

Fig. 6. Effect of MO concentration on I_p''.

The magnitude of $(I_p'')_{t,cs}$ increases with temperature (Fig. 7), and substituting the relevant data into (9), an apparent rate constant at different temperatures (45, 50, 55, and 60°) is obtained. Then according to the Arrhenius equation, an apparent activation energy $E_a = 51.7$ kJ/mole is obtained. The $(I_p'')_{t,cs}$ is very small when temperature is less than 30°. A temperature of 60° was chosen, giving a low blank value.

Effect of foreign ions

The effect of 38 foreign ions on the catalytic determination of $8 \times 10^{-8}M$ nitrite was examined. The results are shown in Table 1, and demonstrate that the catalytic method with oscillopolarographic detection has high selectivity. The tolerance limit is that multiple of the

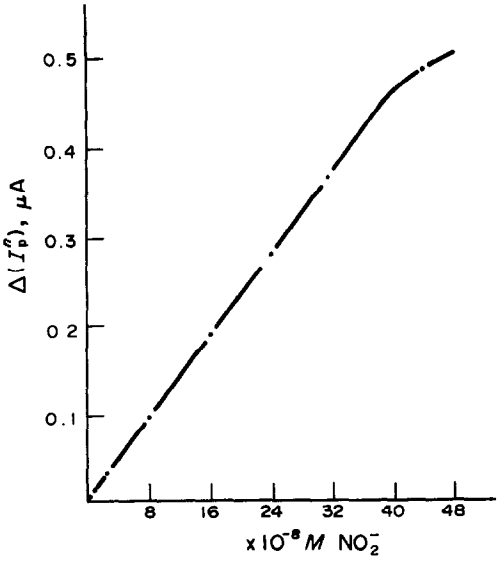

Fig. 8. Calibration graph for nitrite.

Table 1. Influence of foreign ions on determination of nitrite of $8 \times 10^{-8}M$

interference concentration relative to nitrate giving not more than $\pm 6\%$ error.

Calibration graph

Under the conditions as in the procedure, $\Delta(I_p'')$ is proportional to the nitrite concentration in the range 4×10^{-9}–$4 \times 10^{-7}M$. The detection limit [defined as the concentration for which $(I_p'')_{t,cs}$ is equal to $(I_p'')_{t,un} + 2\sigma$][38] is $2 \times 10^{-9}M$. The relative standard deviation for 2×10^{-8}, 8×10^{-8} and $1 \times 10^{-7}M$ was 5.3, 3.0 and 2.4%, respectively (10 determinations).

Analysis of samples

The catalytic method was applied to the direct determination of nitrite in water samples, which were also analysed by the Griess spectrometric method.[39] Recovery of standard additions of nitrite to the sample was also determined. The results given in Table 2 illustrate good recovery and accurate analysis when compared with the spectrophotometric method.

ADSORPTIVE STRIPPING VOLTAMMETRIC BEHAVIOUR OF COPPER COMPLEXES OF SOME HETEROCYCLIC AZO COMPOUNDS

PERCIO A. M. FARIAS,* SERGIO L. C. FERREIRA,† ANIY K. OHARA, MARGARIDA B. BASTOS and MAURICIO S. GOULART

Department of Chemistry, Pontifícia Universidade Católica, 22453 Rio de Janeiro, Brazil

(*Received* 27 *August* 1991. *Accepted* 25 *September* 1991)

Summary—Controlled adsorptive accumulation of copper complexed with TAN, TAC, TAR and TAM (heterocyclic azo-compounds) on a static mercury drop electrode provides the basis for the direct stripping measurement of this element in the nanomolar concentration level. The ligand TAN exhibited great sensitivity and better separation of the peak current of the ligand in relation to the complex. The reduction current of adsorbed complex ions of copper is measured by linear scan cathodic stripping voltammetry, preceded by a period of accumulation of a few minutes. The peak potential is at ~ -0.37 V vs. Ag/AgCl. Optimal experimental parameters were found to be a TAN concentration of $1 \times 10^{-5}M$, an accumulation potential of -0.22 V, and a solution pH of 3.7 (acetate buffer). The detection limit is $0.8nM$ after a 5-min accumulation with a stirred solution, and the response is linear up to 50 μg/l. Many common cations and anions do not interfere in the determination of copper. The interference of titanium is eliminated by addition of fluoride ion. Results are reported for a fresh water sample.

Heterocyclic azo-compounds are widely used in analytical chemistry for the spectrophotometric determination of many elements and as complexometric indicators.[1] Recently Farias and Ohara developed a sensitive method for the determination of uranium with the heterocyclic azo-compound 4-(2-pyridylazo)resorcinol (PAR) as the complexing agent, utilizing the cathodic adsorptive stripping voltammetry technique.[2] This new technique is a useful tool for measuring electroactive species that cannot be accumulated by electrolysis; for this purpose, a controlled adsorptive accumulation is used as an effective preconcentration step, prior to the voltammetric measurement of the surface species.[3,4]

Several methods have been reported in recent years for the determination of copper, using this new technique, with different reagents: catechol,[5–7] 8-hydroxyquinoline,[8] thiourea[9] and CSN^-.[10] These methods present advantages and disadvantages in relation to the sensitivity, selectivity and resolution of the adsorptive stripping current peak. For example, the disadvantage of using catechol to determine copper lies in its instability toward oxidation by dissolved oxygen; and lead and cadmium interfere when 8-hydroxyquinoline is used as the ligand.

The present paper describes preliminary experiments with various heterocyclic azo-compounds as complexing ligands in order to investigate their use for the determination of copper, using repetitive cyclic and adsorptive stripping voltammetry. The ligands studied were: 1-(2-thiazolylazo)-2-naphthol, TAN; 2-(2-thiazolylazo)-4-methylphenol, TAC; 4-(2-thiazolylazo)-resorcinol, TAR; and 2-(2-thiazolylazo)-5-dimethylaminophenol, TAM.

Similar adsorptive voltammetric behaviour of the copper complexes with these ligands was observed. Greater sensitivity and better separation of peak current of the complex from that of the ligand was obtained with TAN. The results of a detailed study into the optimal analytical conditions for the determination of copper using this ligand are also reported in this paper.

EXPERIMENTAL

Solutions and instrumentation

The EG&G Princeton Applied Research (PAR) model 303A static mercury drop electrode was employed with an Ag/AgCl (saturated potassium chloride reference electrode and a platinum wire auxiliary electrode and was

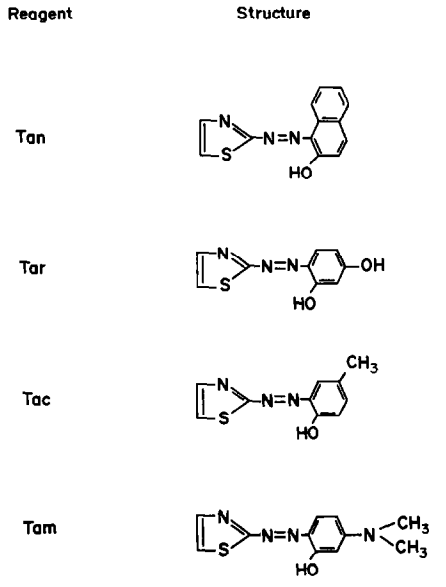

Fig. 1. Structural formula of the heterocyclic azo compounds used in the present study.

interfaced to the PAR 264 stripping analyzer, as recommended by the manufacturer. Instrument settings were as follows: medium drop size (surface area 0.016 cm^2); equilibrium time, 30 sec; potential scan rate, 100 mV/sec; filter 0.1 sec; DC stripping. Cyclic voltamperograms were obtained at 100 mV/sec. A PAR model RE 0089 X–Y recorder was used for the collection of experimental data. The sample cell was the PAR model 0057. Dissolved oxygen was removed from the test solutions by prepurified nitrogen. A magnetic stirrer (model 305) and a stirring bar (Nalgene cat no. 6600–0010) provided the convective transport during the accumulation step.

A 1000 mg/l. copper stock solution (Merck atomic-absorption standard) was used, and $2.0 \times 10^{-3}M$ TAN, TAC, TAR and TAM (Baker) stock solutions were prepared by dissolving the compounds in ethanol (Merck 99.5%). All solutions were prepared from water purified in a Milli-Q (Millipore) system, and analytical grade reagents.

Procedure

Ten milliliters of the supporting electrolyte solution [usually 2.0 ml of $0.25M$ acetate buffer (pH 3.7) + 8.0 ml of purified water] containing $1 \times 10^{-5}M$ of the heterocyclic azo compound was added to the cell and degassed with nitrogen for 8 min (and for 30 sec before each adsorptive stipping cycle). The preconcentration potential (usually 0.0 V) was applied to the electrode for a selected time (the length of the period of preconcentration depends on the copper concentration) while the solution was stirred. The stirring was then stopped, and after 30 sec the voltamperogram was recorded by applying a cathodic linear scan. The scan was terminated at −0.6 V, and the adsorptive stripping cycle was repeated using a new mercury drop. After the background stripping voltamperogram was obtained, aliquots of the copper standard were introduced. The entire procedure was automated, as controlled by the PAR 264 A

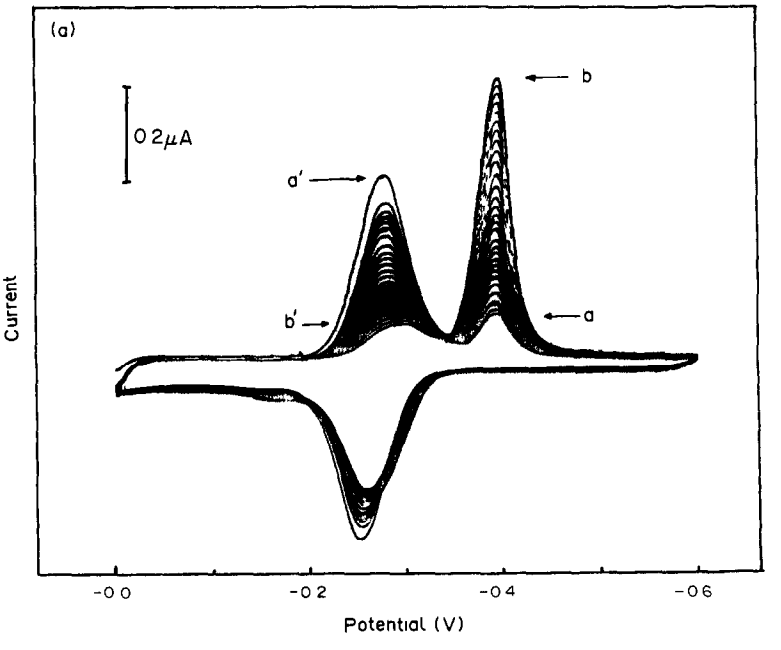

Fig. 2(a).

stripping analyzer. Throughout this operation, nitrogen was passed over the solution surface. All data were obtained at room temperature. UV-irradiation of the sample is recommended if the presence of organic surfactants is suspected.

RESULTS AND DISCUSSION

The structures of the ligands used in this study are represented in Fig. 1. Figure 2 shows repetitive cyclic voltamperograms for $1 \times 10^{-5}M$ of the studied heterocylcic azo compounds complexed with 40 μg/l. copper in an unstirred acetate buffer (pH 3.5) solution. The TAN ligand ($E_{pc} \sim -0.28$ V and $E_{pa} \sim 0.25$ V) and its complex with copper ($E_{pc} \sim -0.40$ V and no peak in the anodic branch) is represented in Fig. 2(A), which was plotted using repetitive scans for approximately 4.5 min with a scan rate of 100 mV/sec. The cathodic current of the complex gradually increases upon repetitive scanning (a–first and b–last scan) while that of the free ligand decreases (a′–first and b′–last scan). The peak current with the adsorbed complex at saturation is several times greater than that of the solution species alone (estimated from the first scan). A small variation of the potential and peak current is observed in the reverse or anodic repetitive. A 120-mV separation of the cathodic peak potentials between the ligand and the complex is better in relation to other heterocyclic azo compounds studied. Progressive increases of the complex peak currents were observed in similar experiments using TAC [Fig. 2(B)], TAR [Fig. 2(C)] and TAM [Fig. 2(D)]. In the case of TAC, a 65-mV separation of the cathodic peak potential between the ligand and the complex, and a 30-mV separation between the cathodic and anodic current peaks of the ligand, were observed. The TAR cyclic voltamperograms were characterized by a large first peak (at −0.30 V) in the forward, cathodic scan and small peaks (at −0.28 V) in the anodic branch. The TAR–copper peak current is separated from the free ligand by 50-mV. TAM exhibited weak complexation with copper. This effect is probably due to the presence of the dimethylamine group in the structure of the ligand.

The spontaneous adsorption process can be utilized as an effective preconcentration step prior to the voltammetric measurement. In this

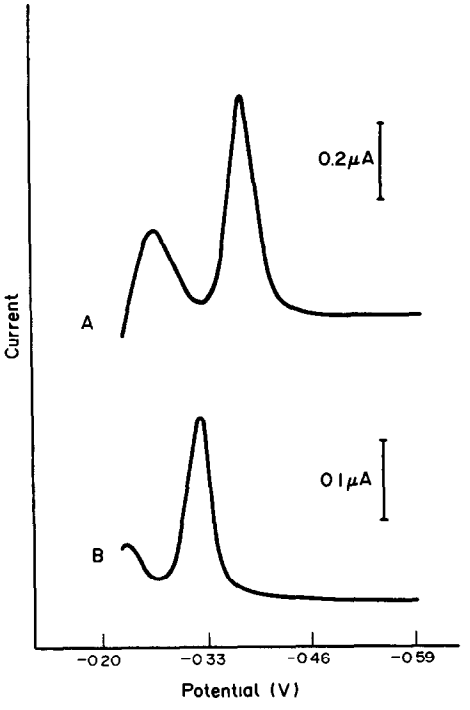

Fig. 3. Linear-scan (A) and differential-pulse (B) stripping voltamperograms for 20 μg/l. copper in a acetate buffer solution (2.0 ml of 0.25*M* acetate buffer (pH 3.4) + 8.0 ml of purified water) containing $1 \times 10^{-5}M$ TAN. Accumulation for one min at 0.22 V with stirring. Scan rate, 100 (A) and 10 (B) mV/sec; pulse amplitude (B), 25 mV; filter 0.15 (A); medium drop size and equil. time 30 sec.

way highly sensitive measurements of copper with heterocyclic azo compounds can be achieved by using the method of adsorptive stripping voltammetry.

Linear scan and differential pulse mode

Table 1 summarizes the characteristics of the stripping peaks of the heterocyclic azo compounds and their complexes with copper, in linear scan and differential pulse modes [potentials, E_{p1} (first peak), E_{p2} (second peak); currents, i_{p1}, i_{p2}; and half-widths, $b_{1/2}$ of 1, $b_{1/2}$ of 2). The TAN ligand exhibits the best efficiency in relation to sensitivity and resolution for development of a new and sensitive method to copper. Figure 3 compares linear-scan(A) and differential-pulse (B) stripping voltamperograms for 20 μg/l. copper, following 1-min accumulation. Both stripping modes exhibit significant peak current enhancements compared to direct voltammetric measurements. In particular, a considerable peak enhancement is obtained by the linear-scan mode. This mode offers good signal-to-background characteristics and greater speed, and thus is recommended for the determination of copper with the ligand TAN.

Effect of electrolyte

Among the various electrolytes (tartaric acid/sodium hydroxide, triethanolamine, citric acid/ammonium hydroxide and acetate buffer) examined for the adsorptive stripping study, best results were obtained in acetate buffer media. The effect of the electrolyte concentration on the adsorptive stripping response was evaluated and is represented in Fig. 4(A). The peak height of the complex Cu–TAN is constant when the concentration is increased from 0.050 to 0.090*M*.

Effect of pH

The peak potentials of the free ligand and of the Cu–TAN complex were also measured as a function of pH after an accumulation period of 60 sec at 0.0 V in acetate buffer (pH 3.0–5.0)

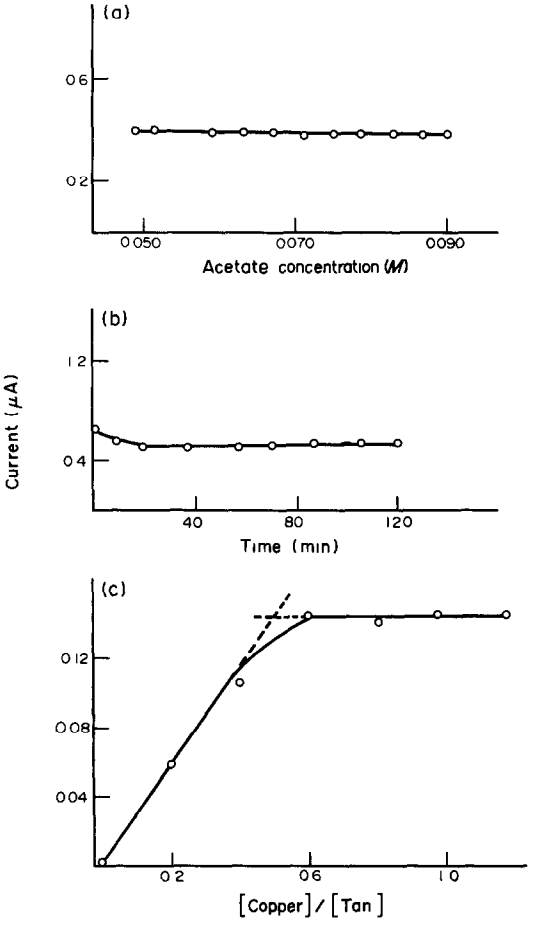

Fig. 4. Effects of acetate concentration (A), time study (B) and mole-ratio (C) on the stripping response for Cu–TAN complex. Conditions: electrolyte acetate buffer (1.0 ml of 0.50*M* [pH 3.5] + 9.0 ml of purified water) solution (B, C) containing copper and TAN; copper concentration 20 (A, B) and 1–12 (C) μg/l.; TAN concentration 1×10^{-5} (A, B) and 1.6×10^{-7} (C) *M*. Other conditions as Fig. 3(A).

containing $1 \times 10^{-5}M$ TAN and a 20 μg/l. addition of copper. It was found that the peak potentials shifted about 0.060 V/pH unit in the negative direction with increasing pH (Table 2).

Accumulation time and potential

The extent of preconcentration depends on the length of time over which the adsorption is allowed to proceed [Fig. 5(B)]. The longer the accumulation time, the more Cu-TAN complex is adsorbed and the larger the peak current. The peak increases almost linearly at first and then curves slightly toward the time axis. Such time-dependent profiles represent the corresponding adsorption isotherms because the peak current depends on the amount adsorbed. As in all types of stripping measurements, the choice of accumulation time requires a trade-off between sensitivity and speed. Forced convection during the accumulation period affects the resulting stripping response by increasing the rate of transport of Cu–TAN molecules to the surface. Such mass-transport control indicates a fast rate of adsorption.

The effect of the accumulation potential on the stripping peak current of the complex was examined over the +0.10 to −0.27 V range [20 μg/l. copper with one minute accumulation time, other conditions is in Fig. 5(A)]. The peak current remains essentially the same over the range from 0.0 to −0.15 V region; a small decrease in the peak is observed when the preconcentration

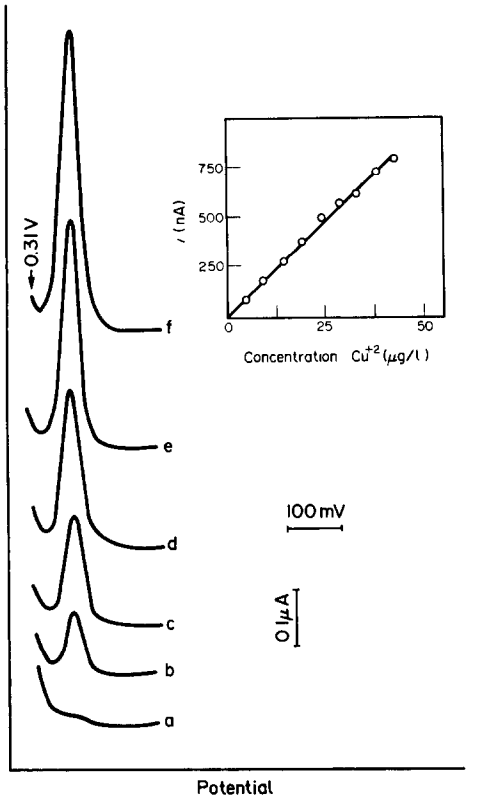

Fig. 7. Stripping voltammperogram obtained in the presence of TAN for increasing copper concentration, 5.0–29.0 μg/l. (b–f). Copper is absent in curve (a). Other conditions as 3A. Also shown is the resulting calibration plot (5.0–43.0 μg/l.).

potential varies from −0.0 to +0.10 V and from −0.20 to −0.27 V. For accumulation potentials less than −0.27 V, accentuated decrease in the complex stripping peak was also noted. The improved resolution obtained by a proper choice of the accumulation potential (at −0.22 V) reduces competition on the electrode surface by the free TAN.

Scan rate

Other conditions that affect the adsorptive response of the Cu–TAN complex are scan rate and stability. The effect of scan rate [Fig. 5(C)] on the stripping peak current of the complex was examined over the 10–500 mV/sec range; the peak increases linearly at first and then levels off. The half-width ($b_{1/2}$) of the peaks in this range varies from 29.1 to 100.8 mV. The complex is stable for at least 2 hr, as shown in Fig. 4(B), in which the solution was remeasured at time intervals. The composition of the complex was investigated by the adsorptive stripping voltammetry (Fig. 4C) technique. The TAN concentration ($1.6 \times 10^{-7}M$) was held constant and the concentration of copper was varied (0.16×10^{-7}–$1.89 \times 10^{-7}M$), and the current was plotted as a function of the molar ratio of ligand to metal ion in the solution. The ratio of ligand to metal ion at the "end point" ($0.8 \times 10^{-7}M$ copper $1.6 \times 10^{-7}M$ TAN) corresponds to the ratio in the complex, indicating that TAN/Cu in the complex is 2:1.

Analytical application

Figure 6 shows the relative slopes of calibration curves obtained for the linear adsorptive stripping voltammetry of copper with the heterocyclic azo compounds studied [correlation coefficients with corrected background: 0.9928 (A), 0.9974 (B), 0.9988 (C) and 0.9918 (D)]. The greatest advantage of the adsorptive stripping voltammetric measurements of copper complexed with TAN and other heterocyclic azo compounds is their inherent sensitivity. When TAN is used, the signal enhancement associated with the adsorptive preconcentration step results in significantly lower detection limits compared to those obtained by conventional voltammetric measurements. A detection limit of $8.3 \times 10^{-10}M$ was estimated from quantitiation of $3.2 \times 10^{-8}M$ copper after a 5-min accumulation (S/N = 2). Thus, 0.53 ng could be detected in the ten milliliters of solution used. Such detection limits compare favorably with those obtained in measurements of heavy metals by anodic stripping voltammetry.

In order for the adsorptive preconcentration step to possess significant analytical utility, it must exhibit a concentration dependence which is both well characterized and highly reproducible. Figure 7 shows linear scan voltammperograms obtained after successive standard additions of copper (5 to 29 μg/l.) in an electrolyte acetate buffer (pH 3.5) solution containing $1 \times 10^{-5}M$ of ligand TAN, after one minute of accumulation with stirring at −0.22 V. Well-defined stripping peaks were observed over this concentration range. The resulting calibration plot is also shown in Fig. 7. The stripping peak current increases linearly with the concentration. Least-squares analysis of this plot yielded a slope of 18.6 nA μg.$^{-1}$l.$^{-1}$ and 0.995 as correlation coefficient. In another experiment, solutions of increasing concentrations (0–12 μg/l.) also provided a linear response (same conditions as in Fig. 7). Deviations from linearity are expected at higher concentrations and/or when using longer preconcentration times. The high sensitivity of

Determination of copper (A) and copper with titanium (B) in the presence of fluoride: (a, a') acetate buffer (pH 3.5) solution containing $1 \times 10^{-5}M$ TAN with 20 μg/l. copper; (b) same as (a) after addition of 10 μg/ml F^-; (b') same as (a') after addition of 5 μg/ml titanium; (c) same as (b') after addition of 10 μg/ml F^-. Other conditions as in Fig. 3(A).

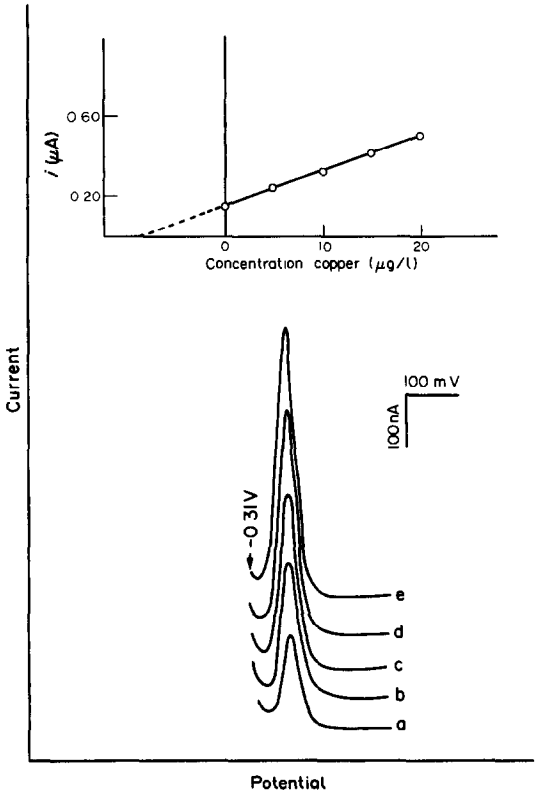

Fig. 9. Measurements of copper in fresh water from Carajás-Pará-Brazil (1.0 ml of fresh water + 2.0 ml of acetate buffer $0.5M$ + 7.0 ml of purified water + $1 \times 10^{-5}M$ TAN). (a) voltammperograms for the sample folowing 60 sec of preconcentration at −0.22 V; (b, c, d and e) same as (a) after addition of 5.0, 10.0, 15.0 and 20.0 μg/l. copper, respectively. Other conditions as in Fig. 3(A). Also shown is the resulting standard addition plot.

adsorptive stripping voltammetry is accompanied by good reproducibility of the results. This can be attributed to the reproducible area and self-cleaning control provided by the PAR 264 stripping analyzer (the use of a new drop of reproducible area in each run); as well as the stability of the formed complex Cu–TAN.

Interference studies

Interference from coexisting metal ions capable of forming complexes with TAN or depositing at the mercury electrode were evaluated. Ions tested at the 5 μg/ml level and found not to interfere in the determination of 20 μg/l. copper were Zn(II), Pb(II), Cd(II), Al(III), Ca(II), Mn(II), Sr(II), Ba(II), Co(II), Mg(II), Th(IV), In(III), Bi(III), U(VI), Cr(III), SO_4^{-2}, F^-, CO_3^{-2}, Br^-, $S_2O_3^{-2}$, NO_3^{-2} and Cl^-; CN^-, Fe(III) and Ni(II) do not interfere at the 2, 0.2 and 0.02 μg/ml respectively. The addition of 5 μg/ml V(V), Mo(II), Ti(IV), Fe(III) and Ni(II) resulted in drastic increase of the copper peak, and the appearance of new peaks for Fe(III) and Ni(II) at −0.41 V and ~ −0.39 V, respectively. The addition of $2 \times 10^{-6}M$ CDTA resulted in the dissapearence of the free ligand TAN. It was possible to eliminate the Ti(IV) interference by using F^- as masking agent. This effect is demonstrated in Fig. 8.

Determination of copper in environmental samples

The suitability of the method for the determination of copper in environmental samples is illustrated in Fig. 9. Four successive standard

additions to the "Carajás" fresh water (Pará, Brazil) samples result in well-defined adsorptive stripping peaks. The Cu–TAN peak in the original sample (Curve a) can thus be quantified based on the resulting standard addition plot (also shown in Fig. 9). These results were confirmed by differential pulse anodic stripping voltammetry (DPASV).

In conclusion, the present study describes an effective means for the determination of trace levels of copper. The use of TAN offers an attractive alternative to other ligands. It gives a similar detection limit but with reduced interference from several cations and anions, and a well-defined peak current shape. Each ligand may have an advantage over the others for certain applications. TAC, TAR and TAM present strong adsorption on the surface of the mercury electrode and potential complexation with adsorption of other important metals. We are also investigating the modification of the structure of heterocyclic azo compounds to further improve sensitivity and selectivity in the development of new analytical procedures.

Acknowledgements—The authors thank Dr. R. V. F. Bravo for critically reading this manuscript and Dr. A. L. R. Wagener for samples from Carajás (Pará, Brazil). Support of this research by SCT, CNPQ and CAPES of the Brazilian Government is gratefully acknowledged.

Summary—The voltammetric behavior of amaranth at a mercury thin film electrode on a silver substrate was studied in this paper. It was found that amaranth gave a sensitive reduction peak with the potential of −0.24 V at pH 4.0 in aqueous solution. The mercury thin film electrode on a silver substrate gave good reproducibility and useful life time. The peak currents depended linearly on the concentrations of amaranth from 0 to 100 ppb.

Amaranth, 1-(4′-sulfonyl-1′-azonaphthyl)-2-naphthanol-3,6-disulfonate, is one of the food colorants in widespread use in many countries. Some scientists have pointed out that amaranth might be causing abnormalities and toxicity for fetuses. Also, the carcinogenity cannot be ruled out. So the amounts of amaranth that can be added to foods are strictly limited by most countries using these colorants.

Most works on the determination of synthetic food colorants have usually involved thin-layer chromatographic methods, spectrophotometric methods,[1–6] high-performance liquid chromatographic methods,[6–11] although several other methods have also been described.[12–16]

Wang[17–18] and Luan[19] have determined the synthetic food colorants, tartrazine and ponceau 4R, at pH 9 by adsorptive stripping voltammetry on a hanging mercury drop electrode, respectively.

Using the hanging mercury drop electrode, Fogg and his co-workers[20–23] studied extensively the determination of a variety of synthetic food colorants by voltammetric methods and found that amaranth has a signal of detection at −620 mV (*vs.* SCE) at pH 10 buffer solution after accumulating 2 min at 400 mV. There was a linear relationship betweed the peak current and concentration of amaranth in the range 0–50 ppm. They suggested that amaranth can be determined directly at a hanging mercury drop electrode using the stripping voltammetric method in alkaline buffer solution. The sensitivity of determination should be much higher than HPLC and spectrophotometric methods.

In this paper, we studied the voltammetric behavior of amaranth on a mercury thin film electrode on a silver substrate under some different conditions. An advantage of this electrode relative to the hanging mercury drop electrode is that the mercury thin film electrode on a silver substrate is rigid and would not be deformed by a flowing fluid. It was found that amaranth has its most sensitive reducing signals at the mercury thin film electrode in buffer solutions at pH less than 7. The detection limits were in the ppb range. The mercury thin film electrode gave good reproducibility and usable life time. These cases showed that the mercury thin film electrode may be a convenient sensor combined with other instruments for monitoring synthetic food colorants.

EXPERIMENTAL

Equipment

A model AD-2 polarographic system was used for experiments with 3 electrodes consisting of the silver, platinum, and saturated calomel electrodes for experiments. The silver electrode was used as a substrate for coating a mercury thin film. The voltammetric signal was

*Author for correspondence.

recorded automatically by an autobalance chart recorder model XWX-1042. A model pH-S3 digital pH meter was used for measurement of pH. To ensure a high quality recording of the signal, a stabilized voltage source model WYJ-6C was used.

Reagents

Demineralized water was used throughout the study. Boric acid, phosphoric acid, glacial acetic acid, sodium hydroxide, sodium acetate, potassium chloride, nitric acid and mercury were all of reagent grade. Amaranth was biochemical reagent grade. A cylinder of highly purified nitrogen was used to remove the oxygen dissolved in sample solutions.

Procedure

Preparation of the Britton–Robinson buffer solution. A 2.7-g amount of boric acid, 2.3 ml of glacial acetic acid, and 2.7 ml of phosphoric acid were dissolved in demineralized water and diluted to one liter (pH of 1.90). The pH was then adjusted by 2*M* sodium hydroxide solution to values of 4.00, 6.00, 8.00 and 10.0, as required for study.

Preparation of stock solution of amaranth. A 0.0100-g amount of amaranth was weighed precisely and dissolved in a small amount of demineralized water, and then diluted to 100 ml. This stock solution (I) contained 100 ppm amaranth. A 5-ml solution of I was rediluted to 50 ml to obtain stock solution II containing 10 ppm amaranth. Both of these were kept in dark brown bottles at 4°.

Preparation of the mercury thin film electrode. A silver electrode (a silver rod of 1.0-cm length and 1.5 mm diameter) was de-oiled by acetone, the de-oiled electrode was treated with 10% nitric acid for 30 sec, and then washed thoroughly with demineralized water. The silver electrode was touched to a droplet of mercury weighing about 20–30 mg. The mercury spread on the surface of silver and formed a thin film of mercury.

The mercury thin film electrode was put into 0.5*M* potassium chloride solution. The solution was deaerated for 10 min by a stream of nitrogen.

Under the atmosphere of nitrogen, the potential was maintained at −1.80 V for 5 minutes, then swept to −1.0 V. This process was repeated for several times. The electrode was kept in demineralized water prior to use.

Experiment. An appropriate amount of stock solution (II) was injected with a microsyringe into a 2.5-ml Britton–Robinson buffer solution which had been adjusted to the required pH as mentioned. These solutions were diluted then to 25 ml.

In measurement, the compound was accumulated from a reproducibly stirred solution by adsorption at a mercury thin film electrode for a suitable fixed time before being determined in quiescent solution by means of a potential sweep. In this study, the order was: deoxygenation (for 10 min)—sample injection—accumulation (in a stirred solution)—solution quiescence—potential sweep.

Usually the quiescent time was 0.5 min, and the potential sweep was from 0.00 to −1.00 V.

RESULTS AND DISCUSSION

The effect of pH on peak potential and current

Figure 1 shows the curves of peak potential (V_p) and peak currents (i_p) versus pH at mercury thin film electrode in 100 ppb amaranth aqueous solution with one minute accumulation and 40 mV/sec of sweep rate.

Curve 1 shows that V_p shifted negatively as pH increased, and curve 2 indicates that i_p decreased with pH for pH > 4. The sensitivity at pH 8–10 was much less than at pH 2–4. Although the highest sensitivity occurred at pH 1.9 in these studies, it was not the optimum because the V_p (−0.10 V) at this pH was too close to the accumulation potential. The operating parameter in this work was selected as pH 4 ($V_p = -0.24$).

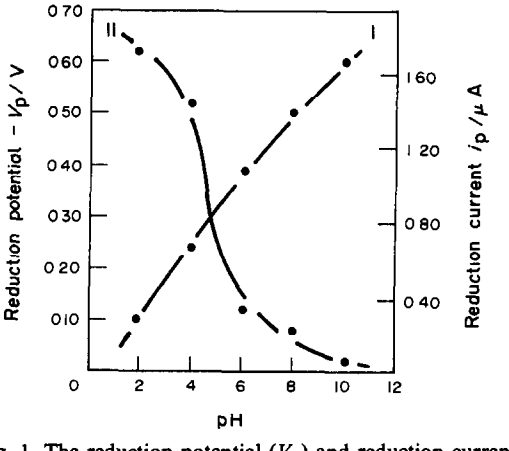

Fig. 1. The reduction potential (V_p) and reduction current (i_p) dependence on pH. Curve I: V_p *vs.* pH, Curve II: i_p *vs.* pH; Concentration of amaranth: 0.10 ppm; Accumulation potential: 0.0 V; Accumulation time: 1.0 min; Range of sweep: 0.1 → −1.0 V; Sweep rate: 40 mV/sec

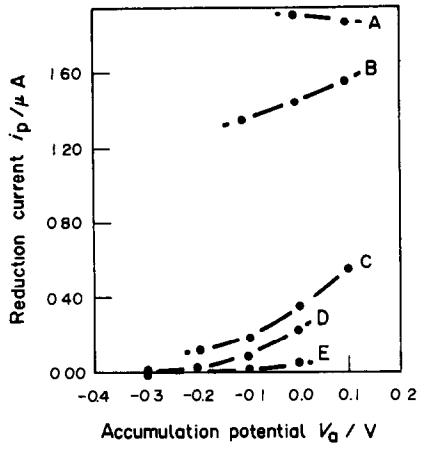

Fig. 2. The reduction current (i_p) dependence on accumulation potential (V_a) at different pH. Curve A: pH = 1.9 Curve B: pH = 4.0; Curve C: pH = 6.0 Curve D: pH = 8.0; Curve E: pH = 10.0 ; Concentration of amaranth: 0.10 ppm; Accumulation time: 1.0 min; Range of sweep: 0.0 → −1.0 V; Sweep rate: 40 mV/sec

The effect of accumulation potential on peak currents

Figure 2 shows the effect of accumulation potential on peak currents at different pH values. Obviously, the curves in Fig. 2 imply that the i_p increased with pH rather than accumulation potential. The accumulation potential has a relatively weak effect on i_p, also indicating that the process of accumulation was mainly the process of adsorption. To avoid occurrence of other reactions, 0.0 V was used as the accumulation potential.

The effect of accumulation time on the peak currents

The peak current dependence on the accumulation time (t_a) is shown in Fig. 3. It can be seen that peak currents increased linearly with t_a less than 2.5 min because amaranth adsorption

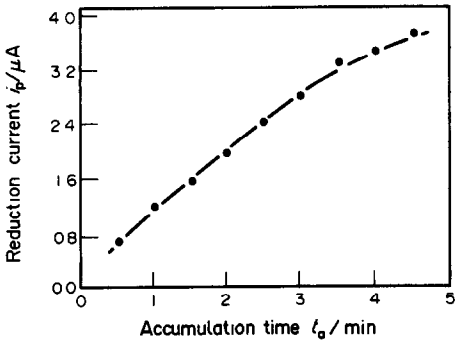

Fig. 3. The reduction current (i_p) dependence on accumulation time (t_a) at pH = 4.0. Concentration of amaranth: 0.10 ppm; Accumualtion time: 1.0 min; Range of sweep: 0.0 → −1.0 V; Sweep rate: 40 mV/sec

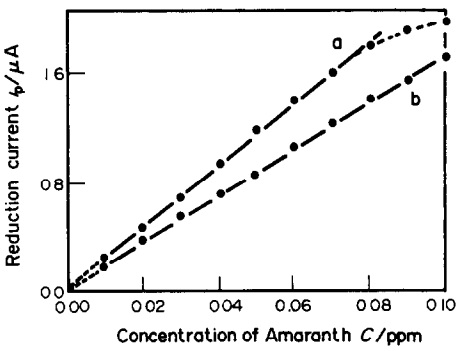

Fig. 4. The reduction current (i_p) dependence on concentration of amaranth (C) at pH = 1.9; Curve (a): Sweep rate: 40 Mv/sec, Accumulation time: 1.0 min. Curve (b): Sweep rate: 40 mV/sec, Accumulation time: 0.5 min. Range of sweep: 0.0 → −1.0 V; Sweep rate: 40 mV/sec.

was not saturated on the surface of the mercury thin film electrode. However, the adsorption tended to saturate when t_a was larger than 4 min, so it would not be available for increasing peak currents by prolonging accumulation time. Therefore, one minute t_a was adopted for this study.

The peak current dependence on concentration of amaranth

The sizes of peak currents obtained at various concentrations of amaranth at pH 1.9 are plotted in Fig. 4 for accumulation times of 1.0 and 0.5 min. Current was linearly proportional to concentration over the interval of 0–80 ppb for curve (a) as well as curve (b).

Figure 5 describes the peak current dependence on concentrations of amaranth at pH 4.0. The accumulation times of curve 1, 2 and 3 were 2.0, 1.0 and 1.0 min. Obviously, curves

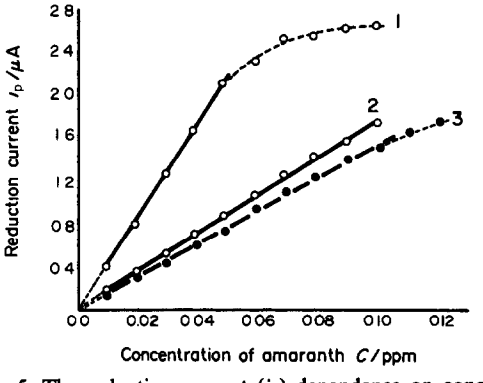

Fig. 5. The reduction current (i_p) dependence on concentration of amaranth (C) at pH = 4.0. Point ●: Data in Britton–Robinson buffer solution. Point ○: Data in HAc–NaAc buffer solution. Curve ①: Sweep rate 40 mV/sec, Accumulation time 2.0 min. Curve ②, ③: Sweep rate 40 mV/sec, Accumulation time 1.0 min. Accumulation potential: 0.0 V; Range of Sweep: 0.0 → −1.0 V.

2 and 3 exhibited linear dependence in the concentration interval 0–100 ppb. For curve 1, although the peak currents were higher in this interval, the linear region was limited to less than 50 ppb concentration. In this case, the sensitivity could be improved only by reducing the linear calibration range. This was one of the reasons for using an accumulation time of one minute in this study.

The useful life time of mercury thin film electrode and interferences

After fifty cycles of continuous potential sweeping, the peak currents still remained stable, with a coefficient of variation of 1% when the thin film electrode was used for 100 ppb amaranth solution at pH 4.0. This showed that the life time of this electrode was excellent.

No interferences were found in the presence of indigo carmine, tartrazine, or ponceau 4R at concentrations five times larger than that of amaranth. The determination was not interfered with by sugar, citric acid or benzoic acid.

CONCLUSION

Amaranth was detected with a sensitive voltammetric signal of amaranth at the mercury thin film electrode on silver substrate. The i_p at pH < 4 was much larger than that at pH > 4. Accumulation potential was a little effect on i_p. Appropriately prolonging the accumulation time is profitable for increasing the peak currents.

Suitable operating parameters are suggested as follows:

$$\text{pH} = 4.0 (V_p = -0.24\ \text{V}), \quad V_a = 0.0\ \text{V}$$

$$t_a = 1.0\ \text{min} \quad \text{sweep rate} = 40\ \text{MmV/sec}$$

Using these parameters, the peak currents increased linearly with the concentrations 0–100 ppb of amaranth. The mercury thin film electrode has good usable life time and reproducibility under these conditions.

SIMULTANEOUS DETERMINATION OF Cl^-, Br^-, I^- AND F^- WITH FLOW-INJECTION/ION-SELECTIVE ELECTRODE SYSTEMS

FADHIL M. NAJIB* and SHIREEN OTHMAN
Department of Chemistry, University of Salahaddin, Arbil, Iraq

(*Received* 20 *February* 1989. *Revised* 23 *September* 1991. *Accepted* 8 *November* 1991)

Summary—Flow-through ion-selective electrodes were constructed from compressed pellets (8–10 mm thick, 13 mm diameter, 10 tons/cm^2 pressure) of Ag_2S/AgX (X = Cl^-, Br^- or I^-) drilled longitudinally (1.5 mm diameter hole) to be suitable for use in flow-injection analysis. A column of AgCl (5.5 cm long, 2–3 mm i.d.) was included in the Cl^--electrode manifold to remove interferences from $10^{-4}M$ Br^- and $3 \times 10^{-5}M$ I^- and S^{2-}. A column of amalgamated lead (2–3 cm long, 2–3 mm i.d.) was used in the Br^--electrode manifold to remove interference from $2 \times 10^{-5}M$ I^-, $3 \times 10^{-5}M$ S^{2-} and $7 \times 10^{-4}M$ Cl^-. These columns and the addition of ascorbic acid were not required when I^- was determined with the iodide electrode. The carrier stream was $0.1M$ sodium perchlorate (pH 4) at a flow-rate of 0.5 ml/min. The sample pH could be 4–7. Simultaneous determination of Cl^- and I^-, Cl^-, I^- and Br^- and Cl^-, I^-, Br^- and F^- ions was possible with combinations of the corresponding electrodes and columns in series and/or parallel in specially designed manifolds. Calibration plots were linear, with almost theoretical slopes, down to $10^{-6}M$ I^-, $5 \times 10^{-6}M$ Br^-, $10^{-4}M$ Cl^- and $5 \times 10^{-6}M$ F^-, with precision better than 1%. Sampling rates for single-ion determinations were 72, 102, 90 and 80 per hr for the one-, two-, three- and four-electrode systems respectively. Determinations of these ions in water samples by the recommended procedure and by established batch methods showed no significant difference at the 95% confidence limits in a paired comparison t-test.

Ion-selective electrodes (ISEs) have been widely used as detectors in flow-injection analysis (FIA).[1–13] This combination of techniques can be extended by use of several electrodes in the same manifold for determination of a number of ions in the same sample. Few such application have been reported,[2,7,14] and none concerning the halides.

In the present work, home-made $AgCl/Ag_2S$, $AgBr/Ag_2S$ and AgI/Ag_2S membranes and a commercial fluoride-selective electrode were used, and mutual interferences between the halides were eliminated automatically within the manifold.

EXPERIMENTAL

Apparatus

A Desaga STA pump and an Omnifit injection valve with a 60-μl sample loop were used. All connecting tubes used in the manifold were 0.8 mm i.d. The commercial electrodes used were an Ingold 157205 F for fluoride, a Radiometer F 1012 Cl for chloride, an Orion 94-53 for iodide, and Orion 90-01 single-junction and 90-02 double-junction Ag/AgCl as references. Potentials were measured with an Orion 811 Ionalyzer, a Radiometer pH M62, and a Wissenchaftlich-Technische Werkstatten (Weilheim) model 410, and recorded with Philips PM 825 and Servograph REC 61 single-pen recorders and a Servogor 220 double-pen recorder.

Reagents

All chemicals were of analytical grade and ordinary distilled water was used for all preparations. Silver and mercuric sulphides were prepared[15] by adding $0.5M$ silver or mercuric nitrate dropwise to excess of $0.1M$ sodium sulphide. The precipitates were collected, washed first with dilute nitric acid, then distilled water and finally ethanol, and were dried at 50° for 12 hr.

Preparation of flow-through pellets

A weight of 6.5 g of a 1:1 molar ratio mixture of AgCl or AgBr with Ag_2S or 3:1 molar ratio

*Author for correspondence. Present address: Chemistry Department, College of Science, Babylon University, Hilla, P.O. Box 4, Iraq.

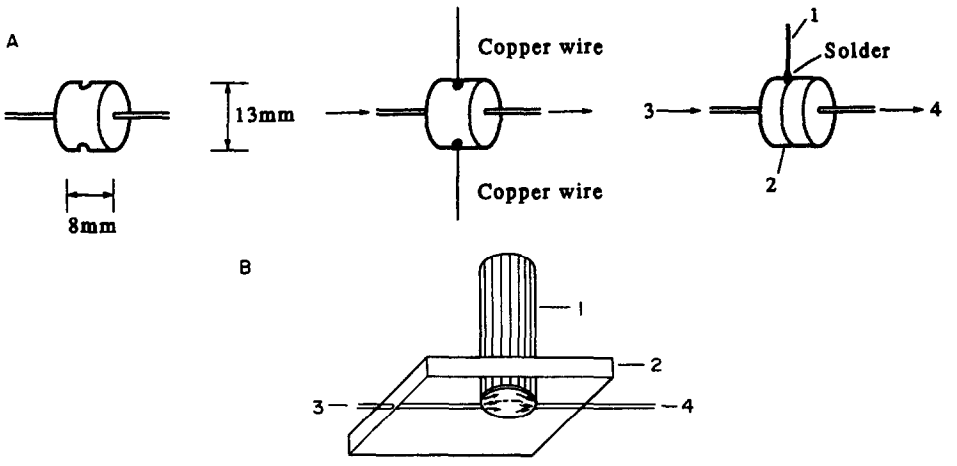

Fig. 1. Schematic diagram for A, flow-through pressed pellets of I^-, Br^- and Cl^- electrodes; 1, electrical conducting wire; 2, PVC tape; 3, inlet; 4 outlet; B, flow-through cell for F^--electrode; 1, commercial F^--electrode; 2, piece of Perspex; 3, inlet; 4, outlet.

mixture of AgI and Ag_2S was crushed to pass a 0.053-mm (300-mesh) sieve. The fine dry powder was pressed between two 13-mm diameter stainless-steel plates in a die-press under 10 tons/cm^2 pressure with continuous withdrawal of air before and during pressing, and left under pressure for 12 hr. The pellet thus obtained was about 8–10 mm long and 13 mm in diameter. It was drilled longitudinally to make a channel 1.5 mm in diameter. Electrical connection was made, as shown in Fig. 1A, by making another two holes of the same diameter and about 2–3 mm deep on opposite sides of the pellet. Two copper wire leads, 0.8 mm in diameter and about 5 cm long, were soldered into each hole. One wire was then bent round the pellet and soldered to the other, which was insulated and connected to the pH-meter by a properly screened wire lead. The electrode and wire lead were insulated with PVC tape, screened with thin aluminium foil and earthed. The flow-through cell for the fluoride electrode was made as follows. A piece of Perspex (2 × 2 cm, 6 mm thick) was drilled at the centre to accept a commercial fluoride electrode (Fig. 1B). The other surface of the plate was grooved on opposite sides of the central hole to accept two short Teflon tubes (0.8 mm i.d.). A piece of very thin nylon or PVC sheet was then glued over this surface and the electrode membrane surface was kept close to it to minimize the dead volume. A little flexibility in this cover helped to absorb any pulses produced during pressure build-up.

Preparation of interference suppressor columns

AgCl, AgBr and AgI columns. The salt was crushed to pass a 0.425-mm (36-mesh) sieve. The desired length of a 2-mm bore tube was filled with the salt and closed at both ends with glass wool. A silicone rubber tube was connected at each end with the aid of UHU-glue, and the tube was wrapped with black PVC tape to protect it from light. The column was placed in the manifold between the injection point and the chloride electrode.

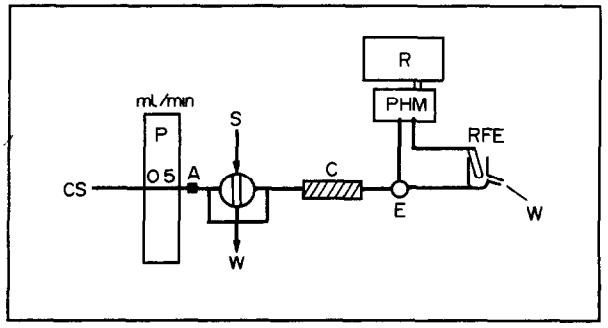

Fig. 2. Manifold for the determination of Br^- or Cl^-. CS, Carrier stream; P, pump; A; pulse suppressor; S, sample injection; C, interference suppressor column; E, flow-through detector; RFE, reference electrode; PHM, pH/mV-meter; R, chart recorder; W, waste.

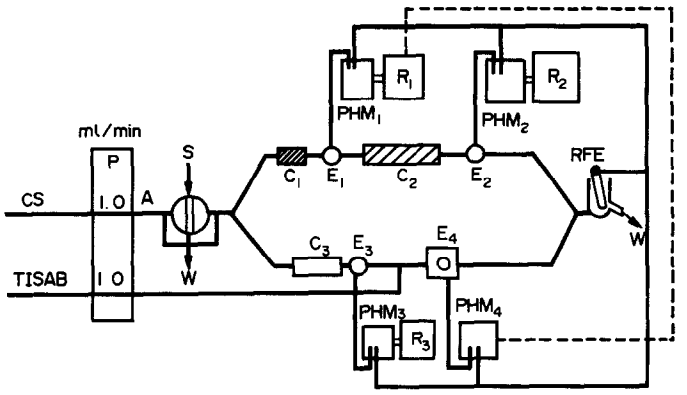

Fig. 3. Manifold used for simultaneous determination of I^-, Br^-, Cl^- F^-. E_1, E_2, E_3, E_4 are I^-, Cl^-, Br^- and F^- ISEs respectively; C_1, C_3, amalgamated-lead columns, 1.5 and 2.5 cm long, respectively; C_2, AgCl column; RFE, reference electrode; PHM, pH/mV-meter; S, sample injection; CS, carrier stream; P, pump; R, chart recorder; W, waste.

Lead or amalgamated lead columns. Granulated lead was passed through a 1-mm (16-mesh) sieve and treated with 1*M* hydrochloric acid in a small beaker for 1 min. The acid was then poured off and the lead was washed several times with water and packed into a short length of 2-mm bore glass tubing.

Lead that had been sieved and washed as above was amalgamated by stirring with 30 ml of 0.2*M* mercuric nitrate for 3 min. The liquid was poured off, and the lead was washed well with water, dried between two filter papers and packed in a glass tube (2 mm bore).

Manifolds

Figure 2 shows the manifold used for single measurements. The interference suppressor column (C) was used only with chloride and bromide electrodes, and was a column of AgCl (5.5 cm long, 2 mm diameter) when a Cl^--electrode was used, or an amalgamated lead column (2.5 cm long, 2 mm diameter) with a Br^--electrode. It was followed by the flow-through ISE (E) and a cell housing the Ag/AgCl single-junction reference electrode. The waste outlet of this cell was slightly higher than the inlet, to allow some carrier stream to remain in it for continuous electrical connection. The two electrodes were connected to the pH-meter and the electrode response was recorded.

Manifolds used for successive measurements

A manifold for consecutive Cl^- and I^- measurements was constructed with the two electrodes in series (line 1 in Fig. 3), the iodide electrode being placed first after the injection valve, followed by the AgCl interference-suppressor column, the chloride flow-through pellet, and the common reference electrode.

For successive determination of Cl^-, Br^- and I^-, or of Cl^-, Br^-, I and F^-, the bromide flow-through pellet and/or fluoride cell were added to this manifold (line 2 in Fig. 3) in parallel with the iodide and chloride detectors, the carrier stream being split by a Y-piece just after the injection point. The internal diameter of line 1 was 0.8 mm and that of line 2 was 0.5 mm; the angle between them was 90°. The two streams were recombined again by a Y-piece to pass through the common reference electrode. The bromide electrode was preceded by a lead-amalgam column, and the fluoride electrode, which followed it, needed an additional stream, connected by a T-piece just before the electrode, to carry TISAB III directly to the electrode.

Each electrode was connected to a separate pH-meter, each of which was connected to the common reference electrode. Each pH-meter was connected to a chart recorder, or a pair of pH-meters with the two channels of a double-pen chart recorder.

Obviously other electrode combinations can be used.

Procedure

A 0.1*M* sodium perchlorate solution (or sodium acetate if the Cl^--electrode is used alone) adjusted to pH 4 is used as the carrier stream and ionic strength adjuster (ISA). Its flow-rate at the waste outlet is adjusted to 0.5 ml/min. Standards containing from one to all four of the halides, as appropriate, in concentrations covering the sample ranges expected, are then injected after the samples.

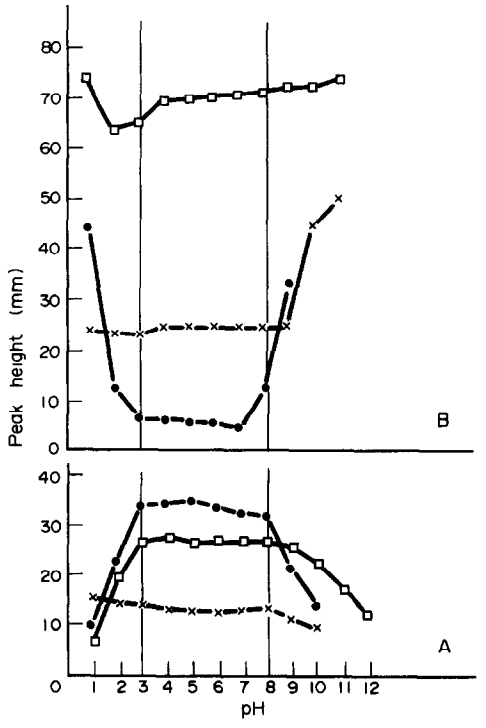

Fig. 4. Effect of pH on the response of the electrodes: A, pH of the carrier stream; B, pH of sample solutions with carrier stream at pH 4; ●, $10^{-5}M$ Cl^-; ×, $10^{-5}M$ Br^-; □, $10^{-5}M$ I^-.

The output of each electrode is recorded when the sample zone passes through the electrode. Average peak heights for the standards, measured from the base-line, are plotted *vs.* the logarithm of the analyte concentration to give the calibration graph. The concentration of each ion should not be less than $10^{-4}M$ for Cl^-, $5 \times 10^{-6}M$ for Br^-, $10^{-6}M$ for I^- and $5 \times 10^{-6}M$ for F^-.

RESULTS AND DISCUSSION

Optimization

The system was optimized for each electrode individually.

Carrier. The background electrolytes usually used in work with ISEs, such as KNO_3, $NaNO_3$, $NaClO_4$ and CH_3COONa, were examined at $0.1M$ concentration. They gave peak heights (mm) of 22, 33, 36 and 41 for $10^{-3}M$ Cl^-, 10, 16, 17 and 13 for $10^{-5}M$ Br^- and 20, 20, 20 and 15 for $10^{-6}M$ I^- respectively. Accordingly, sodium acetate solution was chosen as carrier for use with the chloride electrode, and sodium perchlorate solution for the bromide and iodide electrodes or for simultaneous use of all three electrodes.

pH. Figure 4 shows the effect of changing the pH of the carrier between 1 and 12, with constant sample pH, and of varying the sample pH from 1 to 12 with the carrier pH kept at 4, the optimum found from the first set of tests. The electrode response is practically constant when the sample pH is in the range 4–6 and the carrier pH is 4–6.

Flow-rate and response time. A flow-rate of 0.5 ml/min, measured at the outlet, gave the best sensitivity for all three electrodes. By using coloured solutions it was found that the sample zone remained in contact with the electrode for only 2.6 sec at this flow-rate, as shown in Table 1, which also shows that all three electrodes have practically Nernstian response at this flow-rate but not at 1 ml/min flow-rate.

When exposed to a continuous flow of sample solution, the electrodes gave the response times shown in Table 1, for reaching 50, 95 and 100% of the equilibrium signal (t_{50}, t_{95} and t_{eq}, respectively). The t_{95} values ranged between 9 and 30 sec, considerably longer than the contact time of 2.6 sec for a sample zone in the FIA system. This suggests that when FIA is used, it is not necessary for the electrode response to reach equilibrium, and a flow-rate of 0.5 ml/min would be optimal.

If the electrode response becomes sluggish and the slope decreases to about 50 mV/decade, the electrode can be reconditioned by passage of $10^{-3}M$ analyte solution for several hours, or in severe cases of contamination the channel can be redrilled to expose a new polished surface.

Table 1. Electrode characteristics

	Continuous flow of analyte as carrier stream				Injection of analyte into $NaClO_4$ carrier stream			
					Flow-rate 0.5 ml/min		Flow-rate 1 ml/min

Interferences

The very short contact time with the electrode means that interference will be reduced if the electrode response to the interferent is slower than that to the analyte. This can be seen in Table 2 which gives values of the selectivity coefficient (K_{ij}) of chloride, bromide and iodide electrodes and compares these with published data obtained from static procedures. In general, better selectivities were obtained in the FIA method except with the iodide electrode, which gave about 10- and 100-fold better selectivity for I^- in the static procedure, in the presence of the interfering ions Cl^- and Br^- respectively. The reason for this may be kinetic, as mentioned above, or the difference in the membrane compositions.

However, since the K_{ij} values were large in most cases (generally >1) the removal of these interferences became necessary, especially at low concentrations of the analyte.

Among the methods available for removing interference with a halide electrode by the other halides under static conditions,[16-19] that of Hara and Wakizaka,[19] employing a silver chloride suspension, seemed suitable for adaptation to column use.

In addition to the silver chloride column used to remove interference by Br^-, I^- and S^{2-} with the chloride electrode in the manifold, columns of silver bromide and iodide were examined and the results are shown in Table 3. The silver chloride column was the most effective in eliminating the interference caused by a mixture of $10^{-4}M$ Br^-, I^- and S^{2-} in calibration for chloride. Table 3 shows that this column gave better accuracies than the other two columns in the determination of chloride ion in model solutions of chloride, with and without interfering ions

Table 3. Evaluation of the suppressor columns for removal of the interference of $10^{-4}M$ $Br^- + 3 \times 10^{-5}M$ $I^- + 3 \times 10^{-5}M$ S^{2-} with the Cl^--electrode, and of $7 \times 10^{-4}M$ $Cl^- + 2 \times 10^{-5}M$ $I^- + 3 \times 10^{-5}M$ S^{2-} with the Br^--electrode

present. The reproducibility with all three columns was better than 0.8%.

None of the columns was suitable for use with the Br^--electrode, however, since they all remove some bromide. Consideration of solubility products suggested that a column of lead might solve this problem, but a trial showed that there was still some loss (Table 3). It was then thought that use of amalgamated lead might improve matters, and the results in Table 3 show that this column was quite effective for eliminating the effect of $10^{-3}M$ chloride, $3 \times 10^{-5}M$ sulphide and $2 \times 10^{-5}M$ iodide in calibration for bromide and analysis of synthetic samples. It was found that the effect was not due to lead alone, since a column of pure lead was much less effective. The reproducibility in this case was better than 0.5% with both columns.

The calibration graph for the fluoride-electrode was not subject to interference either with or without use of the column of amalgamated lead.

When the efficiency of the silver halide columns decreased, it was restored by passage of 10 ml of $0.2M$ silver nitrate at a rate of 0.5 ml/min, followed by washing with water until the washings were free from Ag^+.

The amalgamated lead column was regenerated by passage of 2 ml of 1% mercuric nitrate solution.

The mechanism by which the columns remove the interferences is not clear and needs further investigation. Some suppositions may be made, however. Hara *et al.* suggested that the mechanism is related to solubility and specific adsorption effects,[19] but which is predominant and why AgCl is more effective than AgBr and AgI is yet to be explained. There is, however, an important difference between their method and ours in that Hara *et al.* used a freshly made surfactant-stabilized colloidal suspension of silver chloride whereas we employ a column of comparatively large particle-size silver halide, and the resulting difference in surface area (and degree of adsorption of silver or chloride ions) will cause a difference in the behaviour of the two systems.

If ion-exchange is the sole mechanism, then an equivalent amount of chloride should be liberated from the AgCl column and cause a positive error, unless the chloride liberated is itself adsorbed on the column. In order to explain the results obtained for chloride in the absence of interferents but with use of the AgCl column, it would then be necessary to postulate that the chloride in the sample also gives an exchange reaction on the column and that this continues along the column with final release of chloride into the sample stream, so that a steady state is set up in the column. These two postulates seem to be self-contradictory. It seems

Table 4. Effect of interfering ions on the Cl^--electrode without and with an AgCl column, in absence and presence of a constant concentration of Cl^-

		Without column		With AgCl column

	e	120	+78	71	+38

*a = $10^{-7}M$ Br^- + $10^{-8}M$ I^- + $10^{-8}M$ S^{2-}.
b = $10^{-6}M$ Br^- + $10^{-7}M$ I^- + $10^{-7}M$ S^{2-}.
c = $10^{-5}M$ Br^- + $10^{-6}M$ I^- + $10^{-6}M$ S^{2-}.
d = $10^{-4}M$ Br^- + $10^{-5}M$ I^- + $10^{-5}M$ S^{2-}.
e = $10^{-3}M$ Br^- + $5 \times 10^{-4}M$ I^- + $5 \times 10^{-4}M$ S^{2-}.

more likely that adsorption of the interferent takes place on the surface of the column material. Although it cannot be ruled out that both mechanisms may be involved, it seems most probable that the adsorption mechanism would predominate. This view seems to be supported by the absolute values shown in Table 3 for the errors in determination of chloride with and without use of the suppressor columns. The magnitude of these errors is practically independent of the chloride concentration, and of whether a column is used. With interferents present, however, the results obtained without use of the columns are difficult to explain, since the positive errors are greater than can be accounted for by ion-exchange of interferent for chloride on the electrode surface, but less than those calculated from the K_{ij}^{pot} values, and are not constant in value. Presumably there is a complicated combination of effects arising from the kinetics of ion-exchange and adsorption on the electrode surface, the response rates of the electrode to different ions, and the concentration ratios of the analyte and interferents.

Table 4 gives additional information on the problem. When no chloride is present and no column is used, the electrode response increases with iodide concentration above $10^{-5}M$, quantitatively at concentrations higher than $5 \times 10^{-5}M$. When the AgCl column is used, however, the electrode response does not start until the iodide concentration is at least $10^{-4}M$, a tenfold improvement in interference tolerance. Similar behaviour is observed with mixtures of bromide, iodide and sulphide. At the $10^{-3}M$ chloride level, there is again a tenfold improvement in the interference tolerance.

It also appears from Table 3 that the efficiency of the three silver halide columns as interference suppressors is in the order AgCl > AgBr > AgI, as might be expected from the solubility products (and hence adsorption characteristics) of these three species. At chloride concentrations above $2 \times 10^{-4}M$, however, all three give fairly comparable performance. It is believed that if these columns are suitable for removal of interference by halides and sulphide, they will also be suitable for removal of other anions which form sparingly soluble silver salts at the pH used in the system. These ions and other metal ions which form precipitates or complexes with halides or sulphide were not considered further in the present work, since they are not present at significant levels in waters,[19] analysis of which formed the main application of the work.

It is believed that the working mechanism of the amalgamated lead column is adsorption on the mercury surface. Use of this column did not affect the determination of fluoride or change the slope of the calibration graph. The column has another advantage, which was discovered by accident during the work. It was found that when the iodide electrode or the AgCl column was used in the manifold, negative peaks appeared in the recording for low concentrations of iodide or chloride, respectively, but when the lead-amalgam column was used, no negative peaks were obtained. Further investigation showed that this column should be kept short (preferably 1.0, but not more than 1.5 cm). The reason for appearance of the negative peaks was not clear; the presence of silver ions is a possibility, but the matter was not pursued. In any case, the negative peaks do not affect the results for iodide or chloride.

At $10^{-6}M$ iodide concentration, the iodide electrode response was not affected by up to $10^{-3}M$ bromide, $10^{-5}M$ sulphide or $0.1M$ chloride. Although dissolved oxygen has been reported to affect the electrode,[20–22] and ascorbic acid has been used to eliminate this effect, it was found that the iodide electrode was not affected at iodide levels down to $10^{-6}M$.

Table 5. Conditions recommended for determination of Cl^-, Br^- and I^- with the ISE–FIA system

Electrode	Carrier stream	Flow-rate, *ml/min*	Sampling rate, *samples/hr*	Lowest level determined	Interfering ion tolerance at lowest analyte concentration

5	4.98	5.31	5.08	5.11	0.31	0.32	0.29	0.28	1.67	1.75	0.256	0.274
6	3.55	3.79	3.83	3.71	0.30	0.28	0.31	0.33	1.44	1.40	0.303	0.294
7	3.83	4.22	3.90	3.50	0.20	0.20	0.20	0.20	0.96	1.04	0.266	0.246
8	30.2	28.0	29.1	29.5	0.38	0.38	0.41	0.41	4.39	4.46	0.228	0.250

Because of the different circumstances for use of the fluoride electrode (pH, interferences, *etc.*) an additional line was added to the manifold, for introduction of TISAB III to adjust the pH and eliminate interferences by Al(III) and Fe(III).[23] The positioning of this line upstream of the fluoride electrode does not affect any of the other electrodes (Fig. 3). The iodide electrode must be placed before the AgCl column, since it is not affected by the other halides, and the AgCl would remove iodide if positioned before the iodide electrode. The fluoride electrode can be placed after the bromide electrode because its performance is not affected by the amalgamated lead column.

Table 5 gives the conditions for the determination of Cl^-, Br^- and I^- by the recomended procedure. Linear calibration plots were obtained for the ranges 10^{-4}–$10^{-2}M$ chloride, 5×10^{-6}–$10^{-3}M$ bromide and $10^{-6}M$–$10^{-4}M$ iodide.

Because of the delaying effects of the three- and four-electrode combinations in the manifolds, it is necessary to use different speeds of the pump to maintain a flow-rate of 0.5 ml/min at the output. Results obtained for simultaneous determination of the four halide ions in eight water samples, and comparisons with published values obtained by a batch method, are given in Table 6. Paired *t*-test comparison between each of the relevant methods showed no significant differences at the 95% confidence level. The reproducibility of the results was always better than 1%.

The excellent agreement shown in Table 6 indicates the efficiency of the procedure for analysis of water and similar samples. It also indicates the effectiveness of removal of interfering ions and that no other ions in the samples caused interference.

The sampling rates for single-ion determinations with one-, two-, three- and four-electrode combinations, were 72, 102, 90 and 80 samples/hr respectively. The highest sampling rate is obtained with the two-electrode combination, but in theory, could be increased even further by use of a parallel instead of a series arrangement.

PREPARATION AND APPLICATION OF SELENITE ION SELECTIVE ELECTRODE

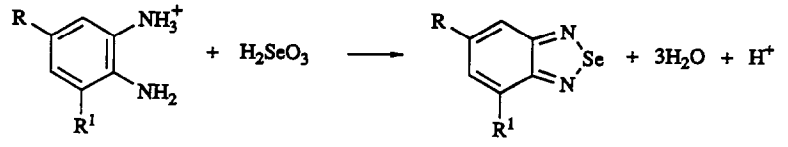
QIANTAO CAI,* YUELING JI, WENZHAO SHI and YAN LI
Department of Chemistry, Huazhong University of Science and Technology, Wuhan, 430074, People's Republic of China

(*Received* 1 *October* 1991. *Revised* 17 *January* 1992. *Accepted* 22 *January* 1992)

Summary—A new selenite ion selective electrode using 4,6-dibromopiaselenole as active material, PVC as membrane matrix and dibutyl phthalate as plasticizer has been developed. An analytically useful potential change occurs from about 10^{-6}–$10^{-1}M$ Se(IV), and the slope of the linear portion is −23.6 mV/10-fold change in Se(IV) concentration at a temperature of 21°. The electrode shows fairly good selectivity for selenite ion over other anions and has been used for the successful determination of total selenium in human hair.

The determination of selenium using ion selective electrodes has been reported, but most were indirect methods based on the catalytic effect of selenium on the reaction between picrate and sulphide, which is monitored with a picrate-selective electrode.[1–4] A selenium ion selective electrode used to determine trace Se(IV) directly has been described only by Malon and Christian,[5] in which the active ingredient in a liquid membrane consisting of a saturated solution of 3,3′-diaminobenzidine in hexane. Its linear response range is $\geqslant 10^{-4}M$ Se(IV) or above. Because the life-span of the electrode is shorter than one day and its potential readings as a function of Se(IV) concentration are easily affected by flowing pressure and mechanical stirring of the experimental solution, the application of the electrode to determining selenium is difficult.

Reaction of selenium(IV) with aromatic *o*-diamines to form corresponding derivatives of piaselenole is a special reaction and serves as the basis for the selective determination of small amounts of selenium by a variety of instrumental methodes,[6–8] such as spectrophotometry, fluorimetry, polarography, chromatography and voltammetry. The reaction is:



(R—R′–H⁺PD) (R—R′–PIS) (1)

where R and R′ represent the substituent groups, and the charge of the reactant species is dependent on the pH. The substance R—R′–PIS has the ability to enter into heterogeneous equilibrium with selenite ion, as described by equation (1), when dissolved in an organic solvent. When porous material such as poly(vinyl chloride) (PVC) is impregnated with suitable organic ionophore, it forms the basis of a membrane for an ion selective electrode. Ion selective electrodes offer certain advantages over other measurement techniques, such as their ability to measure activity non-destructively. After initial studies of the potential properties of the electrodes using several piaselenoles as active ingredients, such as 4,6-dibromopiaselenole (4,6-diBr–PIS),5-nitropiaselenole(5-NO_2–PIS) and 5,6-benzopiaselenole(5,6-B–PIS), the electrode using 4,6-diBr–PIS as active ingredients was selected for further investigation. We describe here an electrode for the measurement of selenium(IV) using 4,6-diBr-PIS as the active membrane constituent, PVC as the membrane matrix and dibutyl phthalate as the plasticizer or solvent, and its application.

EXPERIMENTAL

Apparatus

Potentiometric measurements were made *vs.* a SCE with a Digital Ionanalyzer, Model PXD-12 (China). A double-walled 20-ml beaker was used as the measuring cell. Water was circulated continuously through the measuring cell jacket with a pump kept at constant temperature. All measurements were taken under constant stirring with a magnetic stirring bar.

Reagent

Unless otherwise stated, all reagents were of analytical-reagent grade or guaranteed-reagent. All solutions were prepared with tri-distilled water from a quartz still. A stock $0.100M$ solution of selenium(IV) was prepared by dissolving elemental selenium in a small amount of nitric acid and diluting to 250 ml with water. Formate buffer solution was prepared by adjusting 10% (v/v) formic acid to the desired pH value 2.5 with ammonia solution. 1,2-Diamino-3,5-dibromobenzene (DBDA) was synthesized and purified as described.[9] A stock solution containing 0.5% (w/v) DBDA was prepared in aqueous ethanol(1 + 1).

Preparation of electrode

In a 50-ml beaker, milligram quantities of selenium(IV) and millilitre quantities of complexing agent (0.5% DBDA) solution were added, and the mixture was then made up to about 40 ml with pH 2.5 formate buffer solution. The solution was heated at 50° in a water bath for 30 min, cooled to room temperature and then transferred into a 125-ml separating funnel. After millilitre quantities of cyclohexane or toluene were added, the solution was vigorously shaken for 2 min, and the 4,6-diBr–PIS which formed was extracted. The extract was washed twice with 15 ml of hydrochloric acid ($2M$) and transferred into a flat-bottommed beaker after the phase separation. The flat-bottommed beaker was placed in an infrared drier to evaporate the solvent gently and then the active material (4,6-diBr–PIS) was obtained. A 100-mg portion of poly(vinyl chloride) was added to a flat-bottommed beaker about 4.2 cm in internal diameter, and was dissolved in 5 ml of tetrahydrofuran, and then 0.3 ml of dibutyl phthalate and an appropriate amount of 4,6-diBr–PIS were added. After the 4,6-diBr–PIS was dissolved, the solution was placed in an infrared drier to evaporate the tetrahydrofuran gently and formed a 0.3-mm thick and 14-cm^2 area of PVC active membrane. A disk of the membrane corresponding to the external diameter of a PVC tube was cut and mounted with forceps on the polished end. A small amount of PVC was dissolved in tetrahydrofuran and the solution used as an adhesive to seal the outer edge of the circular membrane to the end of the PVC tube. After setting for 3 hr, the tube was filled with an internal reference solution consisting of $0.1M$ sodium chloride and $0.1M$ Na_2SeO_3. A silver/silver chloride internal reference electrode was immersed in this solution. The PVC membrane electrode was conditioned by soaking it in the $10^{-5}M$ standard Se(IV) solution for several hr and then was washed with tri-distilled water before use until the potential readings were stable. All test solution contained $0.1M$ sodium sulphate used to control ionic strength.

RESULTS AND DISCUSSION

Composition of electrode membrane

In order to obtain an electrode with optimal characteristics, it is important to investigate the individual membrane constituents, since the limit of detection, selectivity and long-term stability are a function of the composition of the electrode membrane. On the basis of our studies, dibutyl phthalate (DBP) is a better plasticizer than dioctyl phthalate or diisooctyl sebacate and the optimal membrane composition was about 27% PVC, 71% DBP and 2% 4,6-diBr–PIS (wt/wt).

Principal properties of membrane electrode

With moderate stirring, the response time of the electrode is less than 90 sec at $\geqslant 10^{-4}M$ Se(IV), two minutes at $< 10^{-4}M$ Se(IV) and is prolonged at a Se(IV) concentration near its detection limit. As the stirring rate or temperature is increased, the response time will shorten. The thinner the membrane, the shorter the response time.

The potential readings at 1.0×10^{-6} to $1.0 \times 10^{-1}M$ Se(IV) were recorded five times over a period of one day at 2-hr intervals, and the relative standard deviations of potential readings thus calculated were less than 2 mV except at $1.0 \times 10^{-6}M$ Se(IV) (Table 1). Only a small drift of 1.5 mV in potential reading at $1.0 \times 10^{-3}M$ Se(IV) was observed during continuous measurements over two hours.

Table 1. Results of potential stability of the electrode at various $C_{Se(IV)}$

$C_{Se(IV)}$ (M)	1.0×10^{-1}	1.0×10^{-2}	1.0×10^{-3}	1.0×10^{-4}	1.0×10^{-5}	1.0×10^{-6}
Standard deviation of potential (mV)*	1.6	1.3	1.1	1.5	1.9	4.8

*$n = 5$

Table 2. The selectivity coefficients $K_{I,J}^{pot}$ of the electrode*

J	SO_4^{2-}	NO_3^-	Cl^-	MoO_4^{2-}	HPO_4^{2-}	TeO_3^{2-}	AsO_2^-	ClO_4^-	I^-	$C_6H_5CO_2^-$	$C_6H_4(CO_2^-)_2$
$K_{I,J}^{pot}$	4.6×10^{-6}	5.6×10^{-6}	5.6×10^{-6}	4.1×10^{-6}	5.1×10^{-6}	2.3×10^{-3}	7.8×10^{-4}	1.1×10^{-5}	1.0×10^{-5}	6.1×10^{-6}	7.5×10^{-6}

*Determine by separate solution method, pH = 10, I and J stand for selenite ion and interfering ion, respectively, $C_I = C_J = 1.0 \times 10^{-3} M$.

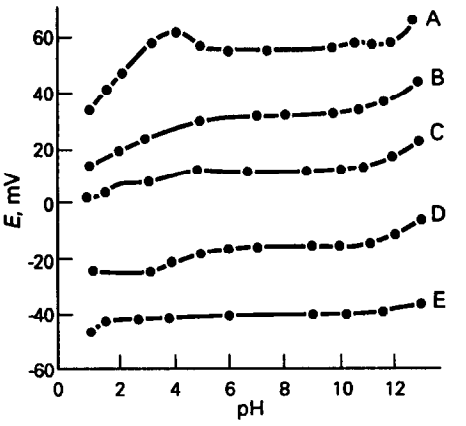

Fig. 1. Effect of pH on the potential readings at various Se(IV) concentrations (M): (A) 1.0×10^{-5}; (B) 1.0×10^{-4}; (C) 1.0×10^{-3}; (D) 1.0×10^{-2}; (E) 1.0×10^{-1}.

The life-span of the electrode is about one week if it is used for continuous measurements and can be extended to several months if stored dry.

The potential dependence on pH is summarized in Fig. 1. The potential reading remains unchanged within the pH range about 6–11 at various concentrations of Se(IV), the pH range becoming narrower as the concentration of Se(IV) decreases.

Potential readings as a function of selenium(IV) concentration are given in Fig. 2. An analytically useful change in the potential occurs from 3.2×10^{-6}–$1.0 \times 10^{-1} M$ Se(IV), and the slope of the linear portion is -23.6 mV/10-fold change of Se(IV) concentration at a temperature of 21°. The limit of detection for the electrode is $1.0 \times 10^{-6} M$ Se(IV).

The selectivity coefficient $K_{I,J}^{pot}$, where I and J stand for selenite ion and interfering ion, repectively, of the electrode for selenite ion with

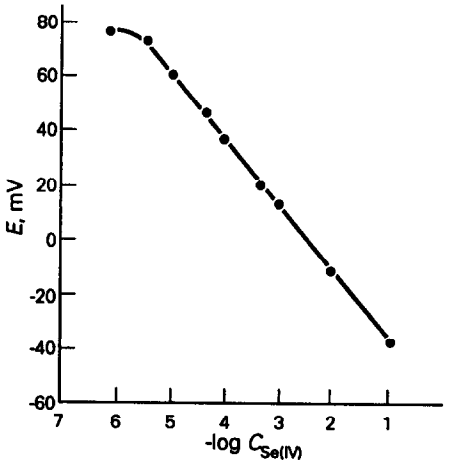

Fig. 2. Calibration curve for selenium(IV) pH = 10, $t = 21°$.

respect to more than ten anions have been determined using the separate solution method[10] at $C_I = C_J = 10^{-3}M$ and the same ionic strength (Table 2). All the value of $K_{I,J}^{pot}$ for most anions except AsO_2^- and TeO_3^{2-} are less than 1.0×10^{-5}, none of those ions interferes. As(II) or Te(IV), however, exerts slight interference if its concentration is sufficiently high, and the interference can be eliminated by means of extraction of these species, As(III) can be extracted with carbon tetrachloride from 8–12M hydrochloric acid solution, and Te(IV) can be extracted with methyl isobutylketone from 4–6M hydrochloric acid solution.[12]

In conclusion, the electrode exhibits fairly good selectivity for selenium(IV) over other ions, and practical long-term stability, response time, life-span and pH range, and can be used to determine trace Se(IV) directly.

Application of electrode to determining total selenium in hair

In this application, we use concentrated nitric acid (61%)–concentrated perchloric acid (70%) (5 + 1) to digest the sample, and hydrochloric acid as reductive and protective agent for Se(VI) and Se(IV), respectively, thus every species of Se in the sample can be converted into Se(IV).[11] In order to eliminate the effect of sample matrix on the response slope and give the same matrix concentration as for the sample solution, non-selenium hair sample solution was added to test standard solutions for the measurement of the calibration curve. Thus the experimental response slope (S) of the E *vs.* log $C_{Se(IV)}$ can be obtained from the calibration curve, and the S was used for the calculation of Se concentration in samples. The non-selenium hair sample solution was prepared by boiling the hair sample solution with hydrobromic acid.[13]

Table 3. The results for the determination of total selenium and recoveries in hair samples

Sample taken (g)	Selenium(IV) added (μg)	Selenium(IV) found (μg)	Recoveries (%)
0.500	0	0.150	
	2.00	2.15	100
	4.00	4.10	99

Table 4. Comparison of results obtained by this method and other methods

Method	This method	Fluorimetry[8]	Polarographic adsorption wave[7]
Se content of hair ($\mu g/g$)	0.300	0.348	0.330

After the extraction separation of Te(IV) with methyl isobutylketone, the total selenium in human hair and the recoveries of standard selenium added to human hair have been determined successfully by the standard addition method. Table 3 and Table 4 show that the recoveries of standard Se were fairly good and the result determined by this method is basically in agreement with the results obtained by either the fluorescence method[8] or polarographic adsorption wave method.[7] The Te was separated to assume no interference in unknown samples, since it exerts a slight interference at high concentrations (435 times greater than that of Se). This step can probably be avoided in many applications.

ADSORPTIVE–CATALYTIC STRIPPING MEASUREMENTS OF ULTRATRACE VANADIUM IN THE PRESENCE OF CUPFERRON AND BROMATE

JOSEPH WANG,* BAOMIN TIAN and JIANMIN LU
Department of Chemistry, New Mexico State University, Las Cruces, New Mexico 88003, U.S.A.

(*Received* 23 *January* 1992. *Accepted* 22 *February* 1992)

Summary—An extremely sensitive stripping voltammetric procedure for ultratrace measurements of vanadium is reported. The method is based on the interfacial accumulation of the vanadium–cupferron complex onto the hanging mercury drop electrode, followed by the catalytic reduction of the adsorbed complex in the presence of bromate. The dual amplification effect associated with these accumulation and catalytic processes results in a detection limit of $4.9 \times 10^{-12} M$ (0.25 ppt). The relative standard deviation (at 50 ppt) is 1.6%. The procedure is also very selective. Such coupling of catalytic and adsorptive collection processes holds great promise for the development of an ultrasensitive voltammetric procedure for other trace metals.

Because of the importance of vanadium and its extremely low levels in various matrices, an ultrasensitive method is required for its reliable quantitation. For example, atomic spectroscopic procedures for determining vanadium in seawater usually require laborious enrichment steps (coprecipitation, solvent extraction, *etc.*). Voltammetry has been shown useful for trace measurements of vanadium. Catalytic currents of vanadium complexes, in the presence of various oxidants, have permitted convenient polarographic determinations of nanomolar concentrations.[1,2] Adsorptive stripping procedures, based on the interfacial accumulation of vanadium complexes in catechol[3] or bromopyridylazo-diethylaminophenol,[4] have been exploited for measurements at the subnanomolar level.

This paper reports an extremely sensitive stripping voltammetric procedure for ultra-trace measurements of vanadium based on the coupling of catalytic and adsorption processes. The procedure relies on the catalytic response of the adsorbed vanadium–cupferron complex in the presence of bromate:

$$\mathrm{V(V)Cupf_{soln}} \xrightarrow{\text{accumulation}} \mathrm{V(V)Cupf_{surf}} \quad (1)$$

$$\mathrm{V(V)Cupf_{surf}} + e^- \rightarrow \mathrm{V(IV)Cupf_{surf}} \quad (2)$$

$$\mathrm{6V(IV)Cupf_{surf}} + \mathrm{BrO_3^-} + \mathrm{6H^+} \rightarrow \mathrm{6V(V)Cupf_{surf}} + \mathrm{Br^-} + \mathrm{3H_2O} \quad (3)$$

The dual current–magnifying effect associated with the adsorptive–catalytic stripping scheme offers remarkable sensitivity, with detection limit at the picomolar (sub–ppt) level, and high selectivity. Analogous procedures have been reported recently for measurements of picomolar levels of titanium,[5] molybdenum[6] and platinum.[7]

EXPERIMENTAL

Apparatus and reagents

An EG&G PAR voltammetric analyzer (Model 264A) was used in connection with the EG&G PAR Model 303 static mercury drop electrode. A medium-size hanging mercury drop electrode (HMDE), with an area of 0.016 cm^2, was employed. Data were displayed on an EG&G PAR Model 0073 X–Y recorder.

All solutions were prepared from doubly-distilled water. Stock solutions of vanadium [(1000 ppm) atomic adsorption standard, Aldrich] were diluted daily as required. The supporting electrolyte was $5 \times 10^{-3} M$ acetate buffer solution (of pH 4.8).

Procedures

The supporting electrolyte solution (10 ml), containing $2 \times 10^{-5} M$ cupferron and $6 \times 10^{-3} M$

*Author for correspondence.

sodium bromate, was pipetted into the cell, and purged with nitrogen for 8 min. The preconcentration potential (usually +0.1 V) was applied to a fresh mercury drop while the solution was stirred. Following the preconcentration period, the stirring was stopped, and after 15 sec the voltamperogram was recorded by applying a negative-going differential pulse scan (with 10 mV/sec scan rate and 25 mV amplitude). The scan was terminated at −0.5 V. Aliquots of the vanadium standards were introduced after recording the background voltamperograms. Throughout this operation, nitrogen was passed over the solution. All data were obtained at room temperature.

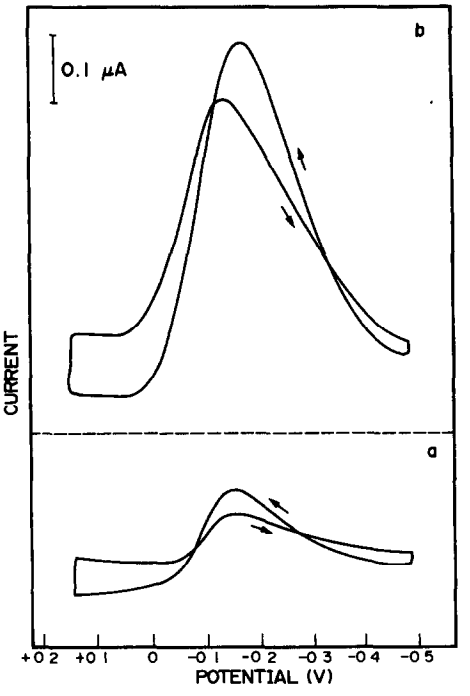

Fig. 1. Cyclic voltamperograms for 0.5 ppb vanadium following 0(a) and 120(b) sec stirring (400 rpm) at +0.15 V. Scan rate, 50 mV/sec; solution, acetate buffer (5m*M*, pH 4.8), containing $2 \times 10^{-5}M$ cupferron and $6 \times 10^{-3}M$ sodium bromate.

RESULTS AND DISCUSSION

Figure 1 shows cyclic voltamperograms for 0.5 ppb vanadium, in an acetate buffer solution containing $2 \times 10^{-5}M$ cupferron and $6 \times 10^{-3}M$ sodium bromate, after 0(a) and 120(b) sec accumulation at 0.15 V. One cathodic peak is observed at −0.14 V during the negative-going scan. Scanning in the reverse direction also exhibits a cathodic peak, indicative of a catalytic process. The response increases dramatically when an accumulation period precedes the potential scan [comparing (a) and (b)], indicating enhancement by adsorption. Subsequent scans resulted in a highly stable response, indicating that both forms of the complex remain adsorbed on the surface [equation (2)]. The fact that a defined and intense (μA) response is obtained in cyclic voltammetry for ppb concentrations indicates the remarkable sensitivity associated with the coupling of the catalytic and interfacial accumulation processes. Additional gains can be obtained in a differential pulse stripping operation, as illustrated below.

Figure 2 shows differential pulse voltamperograms for 50 ppt ($9.8 \times 10^{-10}M$) vanadium after different preconcentration times. A well-defined peak is observed at −0.09 V at this ultratrace level. The peak height increases with increasing

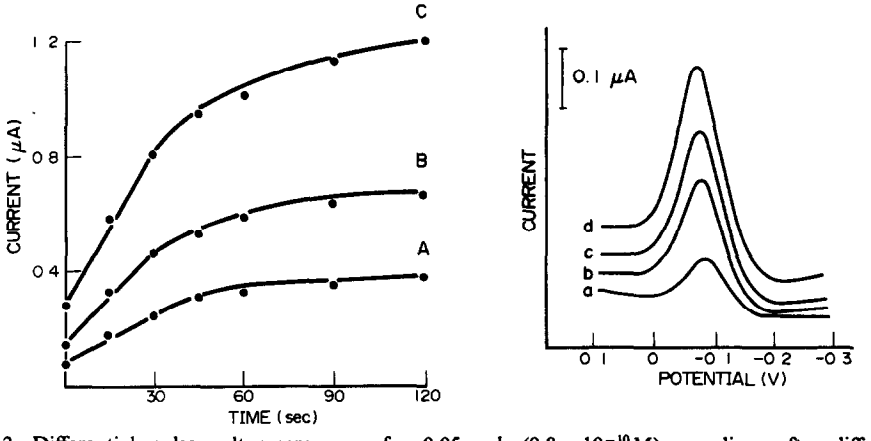

Fig. 2. Differential pulse voltamperograms for 0.05 ppb ($9.8 \times 10^{-10}M$) vanadium after different preconcentration times (a) 0 (b) 15, (c) 45, and (d) 90 sec, with 400 rpm stirring at +0.10 V. Also shown are current *vs.* preconcentration time plots for 0.05(A), 0.10(B) and 0.20(C) ppb vanadium. Differential pulse scan with 10 mV/sec rate 25 mV amplitude. Solution, as in Fig. 1.

preconcentration time, due to an enhancement of the vanadium–cupferron surface concentration. For example, with 90-sec preconcentration, there is a four-fold enhancement of the peak relative to that obtained without preconcentration [(*a*) *vs.* (d)]. Also shown in Fig. 2 are plots of peak current *vs.* preconcentration time for 50(A), 100(B) and 200(C) ppt. The current rises rapidly with time at first, and then more slowly.

The concentrations of the ligand and catalyst have a profound effect on the stripping current. For example, the stripping peak for 0.5 ppb vanadium increases rapidly with increasing cupferron concentration up to $1 \times 10^{-5}M$, and then more slowly [(Fig. (3)]. Similarly, as the bromate concentration increases, the vanadium response increases linearly at first and then more slowly [Fig. 3(B)]. The dependence of the stripping current on the preconcentration potential was examined over the range 0.0–0.2 V [Fig. 3(C)]. Only slight variations in the response are observed, with optimal accumulation around 0.05 V. The acetate buffer concentration also affects the response, with 5mM yielding the most favorable peak height and shape. The differential pulse waveform yielded significantly better signal-to-background characteristics than corresponding linear scan measurements, and was used throughout this work. Most subsequent work was thus performed in a 5mM acetate buffer solution (pH 4.8), containing $2 \times 10^{-5}M$ cupferron and $6 \times 10^{-3}M$ sodium bromate, using an accumulation potential of +0.10 V, and a differential pulse waveform.

Figure 4 shows stripping voltamperograms obtained for solutions of increasing vanadium concentrations (20–100 ppt) after a 15-sec preconcentration time. The very favorable signal-to-background characteristics permit convenient measurements of ppt concentrations. Calibration plots over a wide concentration range (10–200 ppt), obtained by using different preconcentration times, are also shown in Fig. 4.

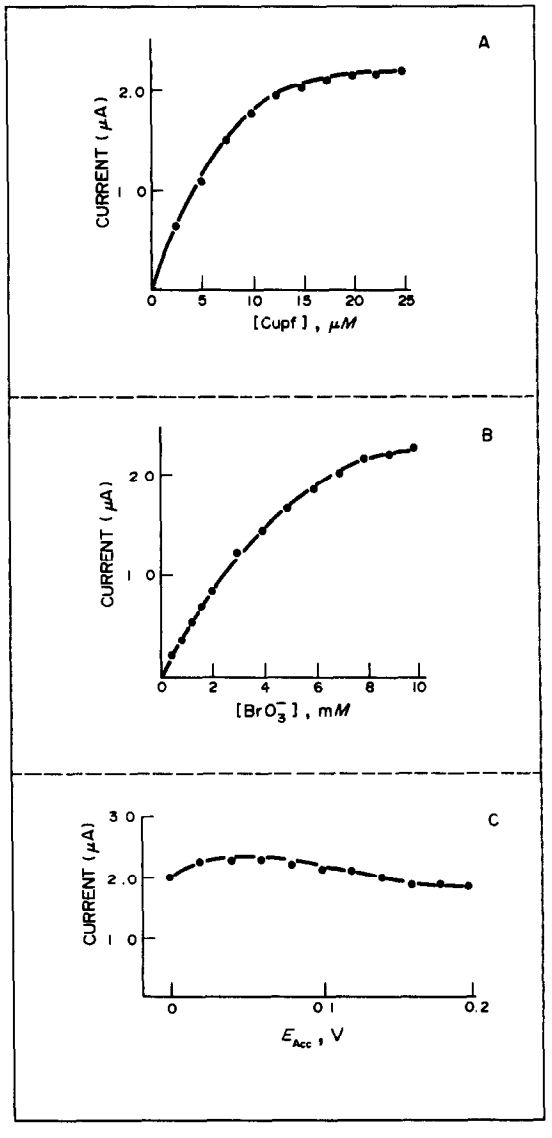

Fig. 3. Dependence of the stripping current for 0.5 ppb vanadium on the cupferron (A) and bromate (B) concentrations, as well as on the preconcentration potential (C). Preconcentration for 60 sec. Cupferron concentration: 5 × 10^{-5}(B) and 2 × 10^{-5}(C)M. Other conditions, as in Fig. 2.

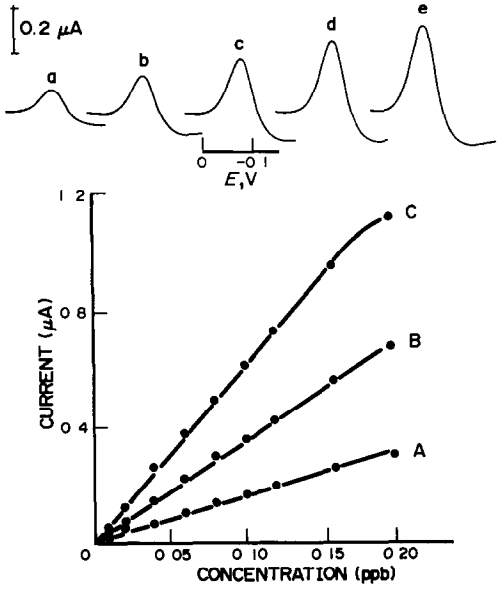

Fig. 4. Stripping voltamperograms obtained for solutions of increasing vanadium concentration over the range 20–100 ppt [(a)–(e)]. Preconcentration for 15 sec. Other conditions as for Fig. 2. Also shown are calibration plots for different preconcentration times: 0(A), 15(B), and 45(C) sec.

For 0- and 15-sec accumulation, the response is linear over the entire range [slope, 1.47(A) and 3.56(B) μA/ppt]. With 45-sec preconcentration, linearity prevails up to 150 ppt (slope of 5.99 μA/ppt). Such curvature is expected for a process that is limited by adsorption. The detection limit was estimated from measurements of 5 ppt ($9.8 \times 10^{-11} M$) vanadium following a 5-min accumulation [Fig. 5(a)]. The signal-to-noise characteristics of these data ($S/N = 3$) correspond to a detection limit of 0.25 ppt ($4.9 \times 10^{-12} M$). This value means that in the 10 ml of solution used, 2.5 pg can be detected. Such an extremely low value is attributed to the dual-amplification effect associated with the interfacial and catalytic processes. It is significantly lower than detection limits of previous polarographic and stripping schemes,[1-4] as well as of a recently reported[8] procedure using inductively coupled plasma atomic emission spectroscopy (0.25 ppb). Also, shown in Fig. 5(b) is the corresponding response using the catechol-based adsorptive stripping procedure.[3] Apparently, this scheme is not sensitive enough to allow convenient quantitation at the 5 ppt level. The precision was estimated from twenty repetitive measurements of 50 ppt vanadium (30-sec preconcentration). This series yielded a relative standard deviation of 1.6% (mean peak current of 54.0 nA, with a range of 53–55 nA). Hence, high precision is maintained despite the remarkably low concentration.

High selectivity is another attractive feature of the adsorptive–catalytic stripping procedure. The following metal ions were tested at the 5 ppb level and found not to interfere with the measurement of 50 ppt vanadium: Pb(II), Co(II), Mn(II), Bi(III), Cd(II), Cr(III), Ag(I), Hg(II), Zn(II), Ni(II), Ti(IV), Cu(II), Te(VI), As(III), Sb(III), Ga(III), Mo(VI), Sn(IV), U(VI), Fe(III), Pt(IV), TI(I), Zr(IV) and Ge(IV). Additional peaks were observed (at −0.60 V and −0.31 V) in the presence of titanium and copper, respectively, which did not affect the quantitation of vanadium. In contrast, surface-active organic materials, could compete for surface adsorption sites. For example, gelatin at 0.5 and 1.0 ppm resulted in 3 and 9% depressions, respectively, of the 0.5 ppb vanadium response (60 sec preconcentration). Depending on the nature of the sample, destruction of surfactants prior to the voltammetric analysis, *e.g.*, through u.v. irradiation, may be required. It is essential also to remove the dissolved oxygen due to a large overlapping peak.

In conclusion, this study demonstrates that the coupling of catalytic and adsorption processes can constitute the basis for an ultrasensitive voltammetric procedure for vanadium. The adsorptive-catalytic stripping procedure offers remarkably low (sub-ppt) detection limits and high selectivity, and should be suitable for *in situ* and on-line monitoring of vanadium. Compared to analogous catalytic–polarographic measurements,[1] the adsorptive accumulation results in a 2–3 orders of magnitude lowering of the detection limit. Such use of catalysis to greatly amplify the response of the accumulated complex should further expand the power and scope of stripping voltammetry.

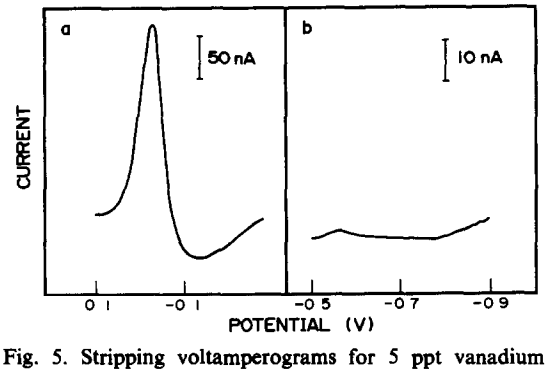

Fig. 5. Stripping voltamperograms for 5 ppt vanadium obtained in the presence of cupferron/bromate (a) and catechol (b). Preconcentration for 10 min (a) acetate buffer (2.5mM, pH 4.8) containing $1 \times 10^{-5} M$ cupferron and $2 \times 10^{-3} M$ sodium bromate, (b) $0.01 M$ Pipes buffer (pH 6.9), containing $2 \times 10^{-4} M$ catechol: preconcentration potential (b), −0.50 V. Other conditions, as in Fig. 2.

Modern Analytical Centre, China Pharmaceutical University, Nanjing, 210009, People's Republic of China

(*Received* 8 *August* 1991. *Revised* 13 *November* 1991. *Accepted* 16 *November* 1991)

Summary—A differential pulse polarographic method for the determination of trace amounts of selenium contained in Chinese herbal drugs is described. In the Na_2SO_3–KIO_3–NH_3–NH_4Cl medium (pH > 9) the selenium complex $Se(O)SO_3^{2-}$ gives a catalytic wave, the peak potential of the wave is −0.76 V *vs.* Ag/AgCl–KCl (1*M*), and the peak current is directly proportional to selenium in the range 0.01–1.0 μg per 0.5 g of sample (0.08–8 ng/ml). The recoveries of selenium added to the samples tested are between 95 and 105%. The method is simple, sensitive, accurate and rapid. The results are in good agreement with those found by a DAN (2,3-diamino-naphthalene) spectrofluorimetric method.

Selenium is one of the essential elements for humans and animals. In proper amounts, it can enhance our ability to protect against certain cancer and heart diseases. But too much selenium may cause neurosystem, skin and some other problems.[1] Increasing concerns about the significance and toxicity of selenium have led to extensive research in the biomedical realm and to the development of numerous analytical methods for its determination in various materials.[2,3] The selenium(IV)–Na_2SO_3–KIO_3 catalytic polarographic method provides a simple, sensitive and rapid approach to the determination of the element.[4] In this paper we propose a differential pulse polarographic method using this system and apply it to the determination of trace levels of selenium contained in Chinese herbal drugs. The results are compared with those measured by a spectrofluorimetric method.[5]

EXPERIMENTAL

Apparatus

The differential pulse polarograms were recorded with an F-78 type pulse polarograph (Fudan University, Shanghai, China), coupled with a YEW type 3066 chart recorder (Yokogawa Hokushin Electric, Tokyo, Japan), and with dropping mercury, platinum foil and Ag/AgCl–KCl (1*M*) electrode as working, counter and reference electrode, respectively. The fluorimetric data were measured by a MPF-4 spectrofluorimeter (Hitachi, Japan) with 10-mm quartz cells.

Reagents

All reagents used were of analytical grade and all aqueous solutions were prepared with quartz doubly distilled water.

Stock selenium solution (0.1000 mg/ml). Dissolve 10.00 mg of selenium powder (purity 99.99%) in 3 ml of concentrated nitric acid and 0.2 ml of concentrated perchloric acid. Place the solution in a boiling bath for 3 hours. Cool and then add 1.0 ml of concentrated hydrochloric acid, and again place the solution in the boiling bath for 5 min. Quantitatively transfer the solution to a 100-ml standard flask and dilute to the mark with water.

Selenium standard solution (0.1000 μg/ml). Pipette 1 ml of the stock solution to a one-litre standard flask and dilute to volume with 0.10*M* hydrochloric acid.

Digestion solution (H_2SO_4–$HClO_4$–Na_2MoO_4). Dissolve 2.5 g of $Na_2MoO_4 2H_2O$ in 50 ml of

*Author for correspondence.

water, then slowly add 67 ml of concentrated perchloric acid and 50 ml of concentrated sulphuric acid, and mix well.

Solutions for catalytic polarography. A 5.0% (w/v) solution of EDTA–2Na, a 1.3*M* solution of sodium sulphite (freshly prepared within two weeks), a NH_3–NH_4Cl buffer solution (dissolve 40.2 g of ammonium chloride in 50 ml of water and mix with 150 ml of ammonium hydroxide, pH 10.2), 0.20*M* potassium iodate and 0.10% (w/v) gelatin solution were used.

Analytical procedures

Sample treatment. The Chinese herbal drugs to be tested were first identified and then dried at 60° after which they were finely crushed and passed through 40 mesh sieves. The five kinds of Chinese herbal drugs tested are as follows:

Waterplantain	*Alisma orientalis* (Sam.) Juzep
Milkvetch	*Astraglus membranaceus* (Fisch.) Bge Var. mongholicus
Yam	*Dioscorea opposita* Thunb
Fig-tree	*Ficus carica* L.
Rehmannia	*Rehmannia glutinosa* Libosch

Sample digestion. Accurately weigh out about 0.5 g of sample and place in a 150-ml conical flask. Quantitatively add 5.00 ml of the digestion solution and put aside for about 12 hr. Then a small amount of water (2–5 ml) is added and it is placed on an electric burner (800 W) with an asbestos sheet or the equivalent for slow and even heating. Heat slowly until an intense reaction occurs in the solution and the perchloric acid starts to evaporate with white fumes, *i.e.*, the solution changes from muddy brown to colourless and then to greenish yellow; continue heating for a further minute. Let the solution cool and then add 5.0 ml of 6*M* hydrochloric acid and place in a boiling water bath for 15 min. Cool and quantitatively transfer the solution to a 50-ml standard flask and dilute with water to the mark.

Selenium determination. Pipette 10.00 ml of the prepared sample solution into a 25-ml standard flask and add 2.0 ml of 5.0% EDTA–2Na, 2.0 ml of 1.3*M* sodium sulphite, 5.0 ml of NH_3–NH_4Cl buffer, 2.00 ml of 0.20*M* potassium iodate and 2.00 ml of 0.10% gelatin solution in that order and mix thoroughly after each addition. Finally dilute with water to volume (pH 9.4). Purge oxygen from the solution with pure nitrogen. Record the cathodic sweeping differential pulse polarogram on the polarograph from −0.50 to −0.83 V [the catalytic wave P1 as shown in Fig. 1(a)]. The instrumental parameters are: sweep rate, $v = 2$ mV/sec, pulse period, $t = 0.5$ sec, pulse amplitude, $\Delta E = 20$ mV.

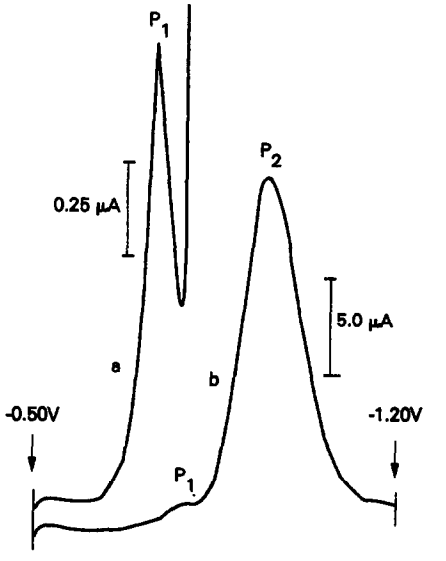

Fig. 1. Se(IV)–Na_2SO_3–KIO_3 cathodic sweeping differential pulse polarograms. Se concentration: 0.4 ng/ml, *i.e.*, 0.05 μg per sample. P1 catalytic wave, P2 reduction peak of IO_3^-.

RESULTS AND DISCUSSION

Catalytic wave mechanism

In acidic solution, selenium(IV) reacts with SO_3^{2-} to form the $Se(O)SO_3^{2-}$ complex, and then in the basic measurement solution (pH > 9) the reduction of the complex in a two-electron reversible mode at the dropping mercury electrode and the simultaneous reacting of the reduction product with the IO_3^- at the electrode surface produces a very sensitive polarographic catalytic wave P1. The peak potential of the wave is at −0.76 V versus Ag/AgCl–KCl (1*M*). The IO_3^- itself is reduced at a more negative potential, yielding a reduction peak P2 at −0.97 V [Fig. 1(b)]. The processes may be represented in the following equations:[4]

$$H_2SeO_3 + 3H_2SO_3 \xrightarrow{\{H^+\}} H_2Se(O)SO_3 + 2H_2SO_4 + H_2O$$

$$Se(O)SO_3^{2-} \xrightarrow[(+2e,\ \text{electrode process})]{\{OH^-\}} Se^{2-} + SO_3^{2-}$$

$$3SO_3^{2-} + 3Se^{2-} + IO^- + 3H_2O \xrightarrow[\text{(parallel chemical reaction)}]{\{OH^-\}} I^- + 6OH^- + 3Se(O)SO_3^{2-}$$

Thus the reagents must be added in accordance with the proposed procedures and the solution should be mixed well after each addition.

Experimental variables

The polarographic method measures selenium(IV), so a proper reductant should be added to the solution after the digestion to convert selenium(VI) to selenium(IV), while the selenium(IV) is not affected. Hydrochloric acid (6*M*) can quantitatively reduce selenium(VI) to selenium(IV) at 90°.[6] For this reason 5 ml of 6*M* hydrochloric acid was added to the digested sample solution, instead of hydroxylamine hydrochloride (NH_2OH-HCl) solution which has the ability to reduce selenium(IV) to elemental selenium.[7]

The peak current of the catalytic wave also has a linear relation with the concentration of potassium iodate. The presence of gelatin can strongly reduce the peak current of the catalytic wave, but in small amounts the gelatin makes the catalytic wave more stable and improves the linear range of the calibration curve while the effect on the limit of detection is negligible. Consequently, the potassium iodate and the gelatin solution must be quantitatively added to the system. Sodium sulphite in this system reacts with selenium(IV) and takes part in the electrode processes of the selenium. An excess of sodium sulphite has no obvious influence on the peak current of the catalytic wave. We found that 2.0 ml was an adequate amount for each of potassium iodate (0.2*M*), gelatin (0.10% w/v) and sodium sulphite (1.3*M*).

The instrumental parameters have great influence on the catalytic wave. The faster the sweep rate or the longer the pulse period, the smaller the catalytic wave peak current and the more asymmetric the wave. The larger the pulse amplitude, the larger the catalytic wave peak current and the more asymmetric the wave. Hence the sweep rate (v), pulse period (t) and pulse amplitude (ΔE) selected were 2 mV/sec, 0.5 sec and 20 mV, respectively.

Digestion solution selection

We tried HNO_3–$HClO_4$[8] and H_2SO_4–$HClO_4$–Na_2MoO_4[5] for the digestion of Chinese herbal drugs. The first method was very tedious and a severe selenium loss was observed, whereas the second one was very simple and easy to control with a sharp end-point of digestion. On approaching the end-point, the solution was a greenish yellow, and with further heating until the perchloric acid fumes diminished there was not significant selenium loss.

Interferences

Because the detection medium was an ammoniacal one with the presence of EDTA, the results of the interference tests showed that when the selenium level was 0.05 μg per sample, the presence of Cd, Co, Cr, Cu, Pb, Sn or Zn at 1,000 times as much as the selenium did not interfere with the determination. Therefore the selectivity of the method is very good.

Blank wave

Because the concentrated sulphuric acid contains a small amount of selenium and it is used

**t*(*F*, *n*) is the Student's *t*-Distribution value when *F* is 0.975 and the degree of freedom is *n*[9].
[a]0.10 μg of selenium added. [b]0.05 μg of selenium added.

as received, the blank solution also produces a small catalytic wave. However, when the digestion solution was quantitatively added and the blank determination was done in parallel, the blank wave did not appreciably influence the experimental results. The magnitude of the blank was equivalent to 0.08 μg of Se.

Calibration curve

We found that a linear current response was observed over the range from 0.01 to 1.0 μg of selenium with a limit of detection of 0.01 μg. The linear regression equation was:

$$i(\mu A) = 1.63 + 20.5 \times Se(\mu g),$$

$$r = 0.999 \ (n = 6).$$

The limit of detection was calculated from the following equation:

$$i(l) - i(m.b) > 2SD(b).$$

Where i(l) is the current response at the limit of detection, i(m.b) is the mean current response of the blank and SD(b) its standard deviation.

Application

The proposed differential pulse polarographic (DPP) method was used to determine trace levels of selenium contained in five kinds of Chinese herbal drugs. The results are shown in Table 1 (DPP). The good recoveries show that the method is accurate. From the significance test values included in Table 1, it can be seen that the results are in good agreement with those found by the DAN spectrofluorimetric method (FL) [Table 1 (FL)], except Waterplantain. But the DPP method is simpler and more rapid. It can be applied to selenium determination in a variety of samples.

MULTI-PURPOSE CAPILLARY ELECTROPHORESIS SYSTEM WITH CONCENTRATION GRADIENT DETECTION

JIAQI WU and JANUSZ PAWLISZYN*
Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada N2L 3G1

(*Received* 26 *December* 1991. *Revised* 11 *March* 1992. *Accepted* 15 *March* 1992)

Summary—A robust, inexpensive and versatile capillary electrophoresis (CE) system for routine and rapid analysis is reported, which consists of a rugged cartridge holding a 20-μm i.d. 15-cm long capillary, and an inexpensive, universal and sensitive concentration gradient detector. The design of the cartridge simplifies the sample introduction process and makes it possible to perform many separation modes, including moving boundary capillary electrophoresis (MBCE), capillary zone electrophoresis (CZE), capillary isotachophoresis (CITP) and capillary isoelectric focusing (CIEF), on the same system. This arrangement provides more information about a sample's components since analytes can be separated by different modes performed on the same CE system. The detector only consists of a low-power He–Ne laser, or laser diode, and a photodiode position sensor. Amino acids and proteins of 10^{-6}–$10^{-3}M$ concentration can be separated by different capillary electrophoretic modes, and detected directly by the detector. The universal detector shows particularly good sensitivity when applied to CE separation modes having self-concentration and focusing effects. Femtomoles of proteins were separated and detected with CIEF. In addition, a short and narrow capillary allows use of high electrical fields which facilitate rapid separations. Four amino acids at millimolar concentrations were fully separated and detected in less than 80 sec by the MBCE mode when a high electric field was applied. The physical size of the whole system is much smaller than that of conventional CE instruments with UV absorbance or fluorescence detector.

Capillary electrophoresis (CE) has become a fundamentally important separation method in bioanalytical chemistry.[1,2] Separation and detection of components in very small amounts of biological samples, in the order of pl–nl volumes, can be achieved with CE which are not possible with more conventional methods such as HPLC. Capillary electrophoresis is also a rapid analytical technique which achieves high resolution of sample components in a few minutes. In CE, many separation modes have been developed based on traditional electrophoretic techniques for different kinds of samples, such as capillary zone electrophoresis (CZE),[3] capillary isotachophoresis (CITP),[4] capillary isoelectric focusing (CIEF)[5] and moving boundary capillary electrophoresis (MBCE).[1] One of the most promising applications of CE is for routine quality and process control in pharmaceutical and biotechnology industries and clinical analysis. Capillary electrophoresis instruments for these applications should be versatile so that all CE separation modes can be performed with them in order to deal with different kinds of samples. In many cases, rapid separation and detection of samples, for example, in about 1 min, is required, because the feedback of the analysis data is essential for observing the effectiveness of a therapy, or adjusting drug doses in treatment of patients in hospital, and controlling process conditions in industrial manufacturing. Although CE is a relatively rapid separation method (separation of a mixture usually requires between 5 and 30 min with present commercial CE instruments), the speed is still slow relative to many requirements of routine analysis, and for monitoring the dynamics of the chemical system.[6] Also, for typical commercial CE instruments, the operators cannot change one separation mode into another mode because of instrument structure and capillary cartridge design.

For routine analysis, the most desirable detector is a universal type. Although conventional absorption spectrophotometric detectors can be considered as universal, they are not sensitive enough for CE with capillaries narrower than 50 μm, and they require an expensive monochromator. Fluorometric detectors not only need an expensive laser and photomultiplier but also

*Author for correspondence.

require fluorescent derivatization for most analytes.[7,8] The commercial CE instruments with such detectors are usually expensive and large devices.

A concentration gradient detector based on Schlieren optics is one of the promising universal detectors.[9] Use of modern optical equipment, such as lasers and silicon photodiodes, dramatically improves the detector, making it a sensitive sensor with a pl–nl detection volume.[9] As shown in Fig. 1, when the detector is used for detection in CE, a collimated probe laser beam, from a low power He–Ne laser or a diode laser, is focused directly onto the capillary. The direction of the beam is deflected when it encounters a refractive index gradient produced by migrating sample zones, and the deflection can be detected by a light beam position sensor. This deflection signal can be generated by any substance which has a refractive index different from that of the buffer. The deflection signal θ of the probe beam can be given as:[9]

$$\theta = \frac{L}{n}\frac{dn}{dx} = \frac{L}{n}\frac{dn}{dC}\frac{dC}{dx}, \quad (1)$$

where n is the refractive index of the solution in the capillary, L is the inner diameter of the capillary, and C is the concentration of the sample. In this equation, dn/dC is approximately a constant for a given solute, independent of absolute concentration.[9] Therefore, equation (1) shows a linear relationship between the amplitude of the deflection signal and the first derivative of the analyte concentration spatial distribution. Because of the high separation efficiency of CE, narrow sample zones are produced, which generate high concentration gradients along the capillary, and thereby give the concentration gradient detector good sensitivity.[9] Besides the universality property and good sensitivity, the detector is also an inexpensive sensor, which consists only of a low power He–He laser or a laser diode and a photodiode position sensor.[9]

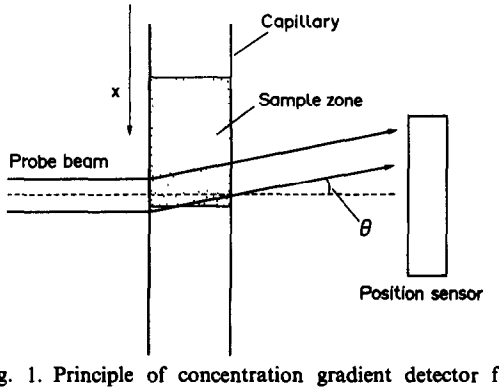

Fig. 1. Principle of concentration gradient detector for capillary electrophoresis.

In this report, the main focus is given to construction and performance of a rugged inexpensive and versatile capillary electrophoresis system consisting of a cartridge holding a short piece of capillary, which facilitates all modes of capillary electrophoretic separations with a single instrument.

EXPERIMENTAL

Chemicals

All chemicals were reagent grade, and solutions were prepared using deionized water. Buffers of 0.05*M*, 0.02*M* and 0.002*M* $H_2PO_3^-/H_3PO_4$ at pH 3 were used for amino acid and protein separations in CZE and MBCE modes. The samples were alanine, tryptophan, histidine and proline, which were dissolved in buffers. In the CITP mode, ammonium acetate (Aldrich) and tetraoctylammonium bromide were used as the leading electrolyte and tailing electrolyte, respectively. The samples used in CITP experiments were ethyltriphenylphosphonium bromide (Aldrich) and hexadecyl ammonium bromide (Sigma). For isoelectric focusing of proteins, 10m*M* phosphonic acid and 20m*M* sodium hydroxide were used as anolyte and catholyte, respectively.[10] Samples used in CIEF experiments included α-chymotrypsin (type II, Sigma), phosphorylase b (Sigma) and ovalbumin (grade V, Sigma). Samples for IEF were mixed with 2% ampholyte (Pharmalyte pH 3–10, Sigma) solution.[5] Solutions were filtered using 0.2-μm pore size cellulose acetate filters (Sartorius, Gottingen, Germany).

CE instrument and detector

A 20-μm i.d. and 350-μm o.d. fused silica capillary (Polymicro Technologies, Tucson, AZ) or a 25-μm i.d., 150-μm o.d. coated capillary (donated by Bio-Rad) was used for separations. For IEF and ITP separation modes, it is necessary that the capillary inner wall be coated with non-crosslinked acrylamide to eliminate electroosmosis.[11] The MBCE and CZE modes can be performed on either coated or uncoated capillaries. The total length of the capillary was about 15 cm. The cartridge which holds the capillary and the detection system are shown in Fig. 2. The capillary was fixed on the plexiglass

plate cartridge using epoxy glue, and its two ends were connected to two small buffer reservoirs made of polyethylene. The whole system was mounted on a vibration isolation table. The separations of samples were driven by a high voltage dc power supply (Spellman, Plainview, New York). The current passing through the capillary was monitored at the cathodic end of the capillary.

As shown in Fig. 2, the probe beam was a laser beam from a He–Ne laser (Uniphase, San Jose, CA, U.S.A.), and was focused by a 30-mm focal length lens directly into the capillary. The probe beam deflection was monitored by a position sensor consisting of a dual silicon photodiode with a differential amplifier.[9] The probe beam was arranged so that the far field intensity profile points to the centre between the two photodiodes placed close together in the position sensor. When irradiated uniformly, the photodiodes generate equal amounts of photocurrent. Upon encountering a concentration gradient inside the capillary, the probe beam is deflected by a refractive index gradient produced by the concentration gradient, and the amount of light reaching the two photodiodes is not equal. The difference in photocurrent associated with the two photodiodes corresponds to the magnitude of the deflection of the probe beam. The data were collected by an IBM DACA board, in a PC-AT personal computer, using the software ASYST™ (Asyst Software Technology Inc., Rochester, New York).

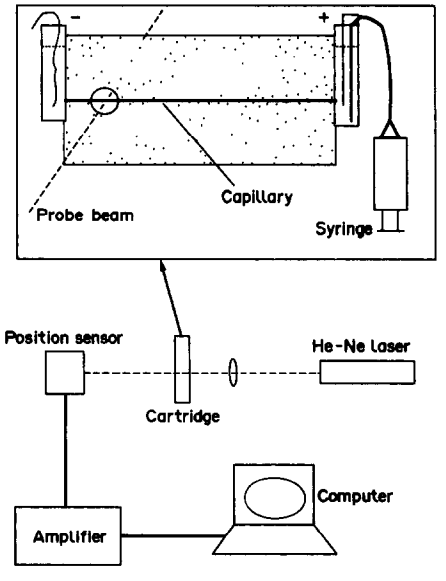

Fig. 2. Diagram of experimental set-up.

Operation of the CE system

In the MBCE mode, first, both reservoirs and the capillary were filled with buffer, and the high dc voltage was turned on. Then, as shown in Fig. 2, buffer in the reservoir of the anodic end was drawn off by a syringe and the reservoir was filled with sample solution. The separation began to occur immediately after the sample solution reached the separation capillary.[12]

In the CZE separation of amino acids, the capillary was filled with 0.05*M* phosphate buffer, and then a plug of sample was introduced into the capillary by the electrokinetic method, in which the reservoir at its anodic end was filled with sample solution, and the dc voltage was turned on. The plug length could be controlled by the introduction time and the voltage.[13] The introduction time was 3 sec. Then the reservoir was filled again with the buffer.

The field-amplified sample injection method[14] was also used in the CZE separation mode to increase the sensitivity of detection by the concentration gradient detector. In this injection method, first, the capillary was filled with 0.02*M* phosphate buffer. Then a plug of 0.002*M* phosphate buffer was hydrodynamically introduced into the anodic end of the capillary by filling the reservoir of this end with the 0.002*M* buffer. The plug length could be controlled by the introduction time and the height difference between solution levels in the two reservoirs.[13] After the introduction of a plug of low concentration buffer, the reservoir was filled with sample solution. The sample was introduced into the capillary by the electrokinetic method. The introduction time was typically 60–90 sec. Finally, the reservoir was filled with 0.02*M* phosphate buffer, and the dc voltage was applied again.

The hydrodynamic introduction method was also used in the CITP separation mode. The introduction time was 20 sec and the height difference between capillary ends was 10 cm. The IEF separation of proteins included two processes. In the focusing process, and 8 kV dc voltage was applied for 4–7 min, and current passing through the capillary was monitored to follow the focusing process. Then the focused proteins were removed from the capillary by a mobilization process. The mobilization process required exchanging catholyte with a solution containing 20m*M* sodium hydroxide and 80m*M* sodium chloride.[10] The dc voltage applied to the capillary during the mobilization was 10 kV. During the mobilization, the proteins moved

through the capillary in order of decreasing isoelectric point (pI). All experiments were repeated 2–3 times to assure reproducibility.

RESULTS AND DISCUSSION

CZE separations

When the CZE mode of separation is performed, three steps are required for the injection and separation of samples: filling the capillary with buffer; injecting the sample plug into one end of the capillary; and immersing the end again in the buffer. As described in the Experimental section, these steps can be completed on the CE cartridge by only operating the syringe which can be easily automated using a low pressure syringe pump. For the CE separation of the amino acid mixture in the CZE mode, for example, the four amino acids of proline, alanine, tryptophan and histidine, four zones are generated inside the capillary. These zones have a Gaussian concentration profile along the capillary, when the amino acids are fully separated.[2] When these zones migrate through the detection volume of the concentration gradient detector, beam deflection signals are produced. The shapes of the detected signals should be derivatives of Gaussian peaks for the separated amino acid zones since the signal magnitude is proportional to the first derivative of the concentration profile along the capillary as described by equation (1).[9] As expected, four derivative peaks are observed in the electropherogram shown in Fig. 3(a), which correspond to these four amino acids. Figure 3(b) shows the integral of the electropherogram in Fig. 3(a), which represents the actual refractive index trace along the capillary. The actual refractive index trace is subject to drift associated with temperature fluctuations inside the capillary. This low frequency noise can be effectively reduced by the derivative nature of the detector[9] as shown in Fig. 3(a), in which high signal peaks are generated only by narrow sample zones. The detection limit in Fig. 3(a) is estimated to be lower than 5m*M*, from the signal-to-noise ratio of Fig. 3(a). This low sensitivity is due to the widening of the sample zones and dilution effect during their migration in the capillary. The dilution factor is estimated to be about 2 in the separation shown in Fig. 3(a).[15] The concentration maximum of a peak decreases and its width increases with increasing retention time, because of the diffusion process. This results in a decrease of the concentration gradient at the zone boundaries.

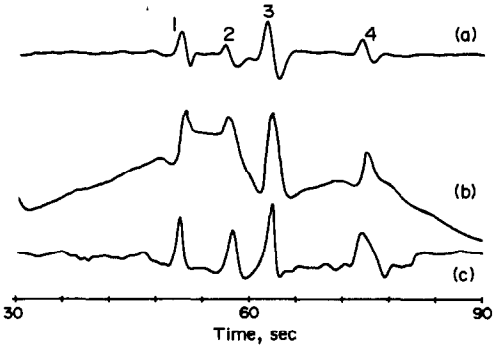

Fig. 3. (a) Electropherogram of four amino acids separated in the CZE mode: 10m*M* proline (peak 1), 10m*M* alanine (peak 2), 5m*M* tryptophan (peak 3) and 5m*M* histidine (peak 4); (b) Integral of electropherogram in (a); (c) electropherogram of four amino acids separated in the MBCE mode: 4m*M* proline (peak 1), 4m*M* alanine (peak 2), 2m*M* tryptophan (peak 3), and 2m*M* histidine (peak 4). Applied voltage is 12 kV.

MBCE separations

One method for reducing the dilution effect is by using the MBCE mode, in which the frontal injection method for the sample is employed. In the MBCE mode, sample components are not fully separated from one another to form discrete zones, rather they form boundaries since various sample components migrate with different velocities.[1] The concentration maximum in the capillary for each component is constant during the separation process. Concentration gradients are generated at the boundaries which can be detected by the concentration gradient detector.[12] Figure 3(c) shows the electropherogram of the four amino acids separated in the MBCE mode and detected by the concentration gradient detector. Four peaks are produced corresponding to the four amino acids in the injected sample. The results show high separation efficiency and high separation detection and speed because of the use of the narrow and short capillary. Four amino acids are fully separated in less than 80 sec. The number of theoretical plates for the tryptophan peak in Fig. 3(c) is estimated to be more than 2.5×10^4 for the 15-cm long capillary. High speed and high efficiency separation can be obtained by increasing the applied dc voltage, but overheating of the buffer solution inside the capillary is limiting.[6] These conditions can be achieved by using a narrow capillary which provides good heat dissipation.[2] In the above experiments, a 25-μm i.d., coated capillary was used, and the electric field applied to the capillary was 800

V/cm, which is higher than that typically employed with conventional CE, 200–400 V/cm. Under this applied voltage, the 25-μm i.d. capillary seems to provide enough heat dissipation.

The sample injection method is another factor affecting the separation efficiency. It is desirable to make an injection while the system is maintained at operating voltage, otherwise, the dispersion of the peak associated with diffusion of analytes during sample injection is unavoidable. The frontal injection method fulfills these requirements. The design of the cartridge facilitates use of the frontal injection method, in which the buffer in the reservoir at the anodic end of the capillary is removed and replaced by the sample by simply operating the syringe, while the high dc voltage is kept on. In this way, the dispersion of sample during injection is almost eliminated. The whole injection and separation process is simple and easily automated for the cartridge. For example, this can be accomplished by using two syringe pumps controlled by a PC computer.

The concentration gradient detection used is the best way for detecting moving boundaries in the MBCE mode[12] which are difficult to monitor by detectors based on concentration detection. Unlike most of the other separation modes, the concentration trace along the capillary in MBCE mode consists of "steps". In the above experiment, because of the lack of dilution of the sample during separation, and an efficient sample injection method, good sensitivity for the amino acid is obtained. The sensitivity is expected to be about two times higher than that of CZE mode which has a dilution factor of 2. Indeed the signal-to-noise ratio is about the same in Figs. 3(a) and 3(c), although the concentrations of analytes introduced to the system are about twice as high for CZE [Fig. 3(a)] compared to MBCE [Fig. 3(c)]. The detection limit is estimated to be about 1mM for these small molecular weight samples from the signal-to-noise level in Fig. 3(c). The design of the cartridge and use of the concentration gradient detector also allow for the use of a short capillary (for example, 3–15 cm long[9,12]), which provides high separation speed. The combination of MBCE operated with a narrow, short capillary, and the concentration gradient detector proved to be a good match, and MBCE performed on the proposed CE system was confirmed to be suitable for high speed separation and detection of biochemical samples, such as amino acids and sugars.[9,12]

Field-amplified injection

For detection of low concentration samples by the concentration gradient detector, on-column concentration and focusing techniques can be employed to achieve high sensitivity of detection without sacrificing resolution. These concentration and focusing techniques include field-amplified sample injection,[14] ITP,[4] and IEF.[5] Narrow sample zones or boundaries are created by these techniques. The sensitivity of the concentration gradient detector may be expressed as a function of the zone or boundary width, σ_x:[16]

$$\theta_{max} = \pm 0.24 \frac{L}{n} \frac{dn}{dC} \frac{C_0 l}{\sigma_x^2}, \qquad (2)$$

where σ_x is the standard deviation of the concentration distribution in the zone or boundary which is Gaussian, C_0 is the concentration of the injected sample and the l is the plug length of the injected sample. Equation (2) predicts that the sensitivity of the concentration gradient detector increases quickly with decreasing zone width, σ_x, and the concentration gradient detector is expected to have good sensitivity for the CE modes which have self-concentration and focusing properties.

The field-amplified sample injection process can be performed on the cartridge as described in the Experimental section. The four steps in the sample injection process can be completed by filling the reservoir at the anodic end of the capillary with different solutions with the syringe. Figure 4 shows the electropherogram of alanine and histidine separated in the CZE mode on a 20-μm i.d. capillary using the field-amplified injection technique. The wide band in the electropherogram behind the sample zones corresponds to the refractive index change caused by the plug of low concentration buffer injected before the injection of the sample. Since the sample is concentrated during the injection, amino acids of $10^{-4}M$ concentrations can be

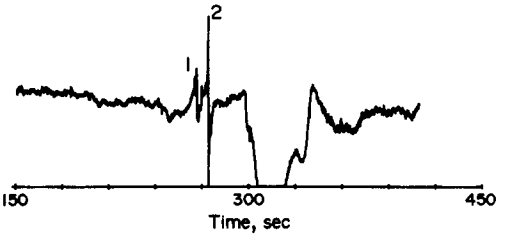

Fig. 4. Electropherogram of 0.5mM alanine (peak 1) and histidine (peak 2) introduced by zone injection with the field-amplified method. Applied voltage is 4 kV.

detected without any chemical derivatization. This sensitivity is about 10 times higher than that of the MBCE mode.

CITP separations

The CITP mode is another CE technique having self-concentration and focusing effects, which is suitable for detection of impurities in samples, such as pharmaceutical products.[17,18] In the ITP mode, the samples are injected as a plug between the leading and tailing electrolytes. During the course of the separation, each component of the sample becomes separated into a pure zone, stacked sequentially between the leading and tailing electrolytes, and migrates towards the detection end of the capillary. The zone width is proportional to the concentration of the component.[4] The zones remain narrow during the entire separation process because of self-sharpening and concentration effects.[4] Like the field-amplified injection, CITP can also be performed on the same CE cartridge. CITP separation of two small cations was performed on the CE system. For the separation of ethyltriphenylphosphonium and hexadecyl ammonium ions, three sharp boundaries should be formed between the leading electrolyte, samples and tailing electrolyte. Figure 5 shows three sharp peaks corresponding to the three boundaries. The injection concentration of the sample was 1m*M* in this experiment. The lengths of sample zones between the three peaks become shorter during the separation process because of the self-concentration effect.[4] The absolute amount of sample injected into the capillary can be estimated to be 10^2 fmoles from the sample volume, about 0.6 nl calculated from the 20-sec introduction time and the 10-cm height difference,[13] and the concentration of the sample

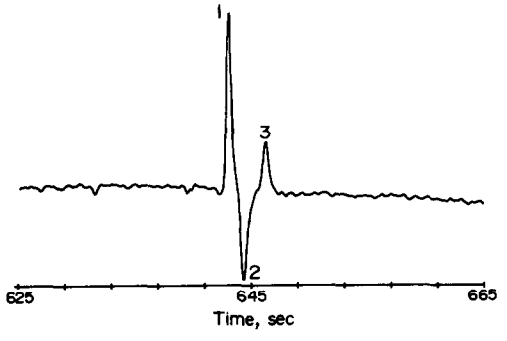

Fig. 5. Electropherogram of 1.0m*M* ethyltriphenylphosphonium ion (betweeen peaks 1 and 2) and 1.0m*M* hexadecyl ammonium ion (between peaks 2 and 3) separated in the ITP mode. The applied voltage is 7 kV.

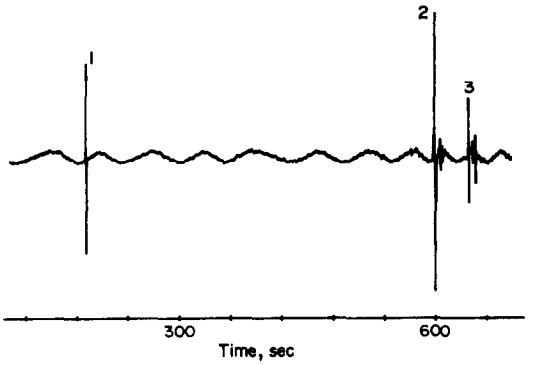

Fig. 6. Mobilization electropherogram of focused α-chymotrypsin (peak 1), phosphorylase b (peak 2) and ovalbumin (peak 3) in the CIEF mode with a 20-μm i.d. coated capillary. Concentrations of the samples are 0.3 mg/ml (0.1 mg/ml for ovalbumin), which correspond to 0.01m*M* α-chymotrypsin, 0.003m*M* phosphorylase b and 0.002m*M* ovalbumin. The focusing voltage is 8 kV, and focusing times is 4 min. The mobilization voltage is 10 kV.

1m*M*. More details about this application of the concentration gradient detector are given in Refs. 17 and 18.

CIEF separations

Capillary isoelectric focusing (CIEF) is a powerful technique for the separation of proteins, based on difference in isoelectric points. When a dc voltage is applied to two ends of a capillary filled with carrier ampholytes and protein samples, a pH gradient is established by isoelectric stacking of the ampholytes, arranged under the electric current in order of increasing pI from anode to cathode.[5] At the same time, proteins will also migrate to the point in the capillary where their pI values are equivalent to the pH, and migration ceases, creating discrete narrow zones. Zone broadening is eliminated in the CIEF, because of its focusing properties, which creates a high concentration gradient at the zone boundary. As predicted by equation (2), the concentration gradient detector is expected to be sensitive for CIEF. The configuration of the cartridge also makes the CE system a suitable instrument for performing CIEF. First, as shown in Fig. 2, the samples are placed in one of the reservoirs, and introduced into the capillary by pressure generated by a syringe. Then the two reservoirs are filled by syringe with anolyte and catholyte, respectively, and the high dc voltage was turned on.

Figure 6 shows a mobilization electropherogram of α-chymotrypsin, phosphorylase b and ovalbumin focused in a 20-μm i.d., coated

capillary. Sharp peaks are observed in the electropherogram, in which the zone width of ovalbumin is estimated to be 70 μm. This width already reaches the resolution limit of the detector, even when a focused laser beam is used as the probe beam. As predicted by equation (2), because of extremely narrow zones, the concentration gradient detector shows good sensitivity. The detection limit for the injected sample is at the $10^{-7}M$ level, which means that 1 fmole of absolute amounts of proteins inside the 20-μm i.d. capillary can be separated and detected by the system without chemical derivatization. It should be noted that the concentration gradient generated by the components of the carrier ampholytes can also be detected as broad variations in the baseline because of the universal nature of the detector as shown in Fig. 6. However, since these ampholytes only form wide bands in the capillary,[19,20] as mentioned above, the derivative nature of the detector makes the detector insensitive to these wide bands compared with narrow protein zones.

The above results illustrate that all four separation modes can be performed on the proposed CE cartridge. Highly efficient separation and sensitive, universal detection can be achieved by this system. It is straight forward to switch from one separation mode to another on the CE cartridge when analyzing an unknown sample. More information about the unknown sample can be obtained during this process since many electrophoretic techniques differ in their physical principles of operation. For example, the CZE separates samples based on differences in their mobilities, and the CIEF is based on isoelectric point differences. Figures 7 and 8 show electropherograms of ovalbumin separated by three separation modes. The ovalbumin was purified by the manufacturer with slab zone electrophoresis, which is based on mobility differences. As expected, when a pH 3 buffer is used, the electropherogram of the CZE in

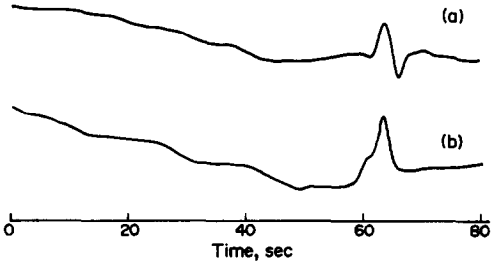

Fig. 7. (a) Electropherogram of ovalbumin (7 mg/ml) separated in the CZE mode; and (b) in the MBCE mode. Applied voltage is 12 kV.

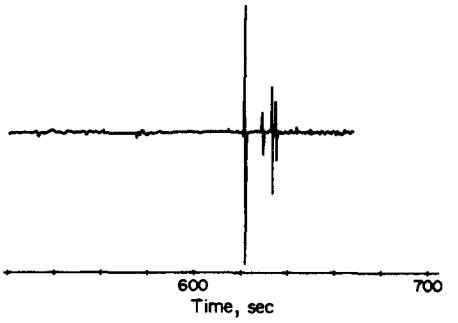

Fig. 8. Mobilization electropherogram of ovalbumin (1 mg/ml) separated in the CIEF mode. Conditions are the same as those of Fig. 6.

Fig. 7(a) only shows one peak. The electropherogram of the MBCE mode as shown in Fig. 7(b) also shows one peak since it is based on the same principle as that of the CZE. However, the electropherogram of the CIEF in Fig. 8 shows at least four peaks. The highest peak corresponds to ovalbumin, and other peaks can be attributed to impurities or minor components in the sample which have almost the same mobilities as that of ovalbumin, but different isoelectric points from ovalbumin. Separation of all those impurities or minor components may be achieved by the CZE or MBCE modes if the buffer's pH is adjusted so that it is in the range of pI's of the proteins. But for the unknown sample, it requires continuous adjustment of the buffer's pH value. By using the proposed CE system, the component information of the sample may be obtained by only switching between two separation modes.

This CE system is small and inexpensive, especially, when a diode laser is used as the probe beam source.[9] The design of the cartridge accommodates and allows for the convenient use of a short piece of capillary which results in rapid separations. The device can be constructed on a single substrate wafer since the majority of the components are silicone devices. In addition to industrial and clinical applications the system can be used as the pedagogical tool since it can built at a cost of just a few hundred dollars.

CHEMICALLY AMPLIFIED CURRENT RESPONSE OF VITAMIN C BASED ON THE CYCLIC REACTION BETWEEN L-ASCORBIC ACID AND DEHYDROASCORBIC ACID, USING DITHIOTHREITHOL AND ASCORBATE OXIDASE

SHUNICHI UCHIYAMA

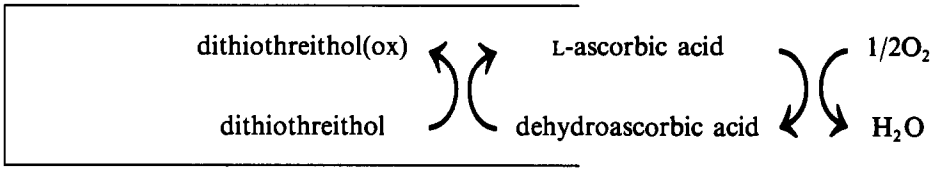
Department of Environmental Engineering, Saitama Institute of Technology, 1690 Fusaiji, Okabe, Saitama 369-02 Japan

(*Received* 19 *November* 1991. *Revised* 4 *March* 1992. *Accepted* 4 *March* 1992)

Summary—A cyclic reaction between the reduced and the oxidized forms of vitamin C takes place by combining the ascorbate oxidase reaction and the reduction of L-ascorbic acid to dehydroascorbic acid by dithiothreithol. L-Ascorbic acid is oxidized by the dissolved oxygen and its consumption is not compensated by the chemical regeneration of L-ascorbic acid from dehydroascorbic acid. The dissolved oxygen then continues to decrease during the cyclic reaction, consequently, the decrease of the reduction current of oxygen is amplified. The amplification factor of $5 \times 10^{-5}M$ L-ascorbic acid at $5 \times 10^{-3}M$ dithiothreithol and pH 7.5 was found to be 10.6 when enzyme activity is 0.64 units/ml and the reaction time is 10 min.

The electrochemical measurements of the reduced form of vitamin C (L-ascorbic acid) with high selectivity have been carried out by amperometric biosensors[1–5] or a coulometric method using ascorbate oxidase.[6] In most of these methods, the consumption of dissolved oxygen takes place in an enzymatic reaction and is detected by an oxygen electrode or the decrease of L-ascorbic acid measured by an enzymatic reaction electrochemically.

On the other hand, the oxidized form of vitamin C (dehydroascorbic acid) is electroinactive and has to be chemically reduced to L-ascorbic acid before detection. Dithiothreithol has been found to be an effective reducing agent of dehydroascorbic acid.[7–9] Ascorbate oxidase catalyses the oxidation of L-ascorbic acid to dehydroascorbic acid (DAA) and can drive the reaction in the opposite direction to that of the chemical reduction of L-ascorbic acid. By comparing both reactions, we can recognize that the consumed oxygen in the enzymatic reaction is not compensated for by the chemical reduction. Therefore, if dithiothreithol does not affect the enzyme activity of ascorbate oxidase, the cyclic reaction should take place and the consumption of the dissolved oxygen should continue until its concentration becomes zero. This cyclic reaction can be described by the following cyclic reaction scheme:



This scheme suggests that the enzymatic current response of L-ascorbic acid is amplified when L-ascorbic acid is added to the solution containing both ascorbate oxidase and dithiothreithol. The significant feature of this cycle is that dehydroascorbic acid is detected as well as L-ascorbic acid, although the response of dehydroascorbic acid begins later than that of L-ascorbic acid because of the reaction time needed to convert dehydroascorbic acid to L-ascorbic acid by dithiothreithol.

In this work, the amplification of the response current of vitamin C in this cycle has been evaluated and the effects of pH, concentration of dithiothreithol and enzyme activity on the amplification factors are described.

EXPERIMENTAL

Ascorbate oxidase (Toyo Jyozo Corp., 64.0 units/mg) solution (1 mg/ml) was prepared by dissolving ascorbate oxidase into 0.1*M* Tris buffer solution (pH 7.0) and this solution (100–500 μl) was added into the sample solutions before use. Dithiothreithol, L-ascorbic acid and dehydroascorbic acid used were all reagent grade chemicals. All experiments were done at room temperature.

Other agents for reducing dehydroascorbic acid to L-ascorbic acid exist, such as the reduced form of glutathione or homocysteine, but most of these compounds are not stable and are oxidized by oxygen. The stable compound, dithiothreithol, was then selected as a reducing agent for dehydroascorbic acid in the experiment.

The concentration of the dissolved oxygen in the sample solution was monitored by a Clark type oxygen electrode (Denki Kagaku Keiki Ltd) with a gold working electrode and a gas permeable membrane. The electrode potential of the working electrode was maintained by a potentiostat (Nikko Keisoku NPOT 2501) at −0.7 V *vs.* Ag–AgCl counter electrode and the reduction current of the oxygen was recorded by a pen recorder (Nippon Denshi Kagaku, Unicorder U-228).

The sample solutions (50 ml) were prepared by dissolving dithiothreithol and ascorbate oxidase into buffer solutions and were stirred by a magnetic stirrer throughout the experiment. If a small oxygen electrode is used, the sample solution volume can be reduced to several millilitres, and the large solution volume does not restrict the utility of the present method. After the background current of the dissolved oxygen in 0.1*M* Tris buffer solution reached a steady-state value (about 1.2 μA), vitamin C was added to this solution and the response current was recorded.

RESULTS AND DISCUSSION

The cyclic reaction of vitamin C results in a continuing decrease of the oxygen current, but the current response with L-ascorbic acid in the presence of enzyme without dithiothreithol reaches a limiting value as the L-ascorbic acid is depleted. The typical current responses (decreases) caused by L-ascorbic acid obtained in the presence of the enzyme solution with and without dithiothreithol are shown by lines (A) and (C), respectively, in Fig. 1. These results indicate that the current change in (A) is larger than 10 times at 10 min compared with that in (C), and support that the cyclic reaction of vitamin C takes place. A similar current response to (A) was obtained by $4.5 \times 10^{-5}M$ dehydroascorbic acid when dithiothreithol is contained in the enzyme solution as shown in (B) in Fig. 1. In this curve, a short time lag (T) was always observed because the change of current is begun after dehydroascorbic acid is reduced to L-ascorbic acid by dithiothreithol.

The current continues to increase up to almost zero because the cyclic reaction does not stop and the long reaction time required until the current reaches a steady state level after the sample addition. Measurement was carried out after 10 min and the RSD of 10 measurements after this time was 3.2%.

The response curves of $5 \times 10^{-5}M$ L-ascorbic acid, $3.4 \times 10^{-5}M$ DAA and a mixture of these solutions ($4.2 \times 10^{-5}M$ total vitamin C) indicated that the response curve of the mixture is between the other two curves and the total vitamin C can be detected when the sample solution contains both L-ascorbic acid and dehydroascorbic acid.

The amplified current response is pH dependent because the enzyme activity of ascorbate oxidase is decreased in acidic and alkaline media and the reduction rate of dehydroascorbic acid to L-ascorbic acid by dithiothreithol is decreased in acidic media. The effect of pH on the amplified current response of L-ascorbic acid is shown in Fig. 2. A significant variation was

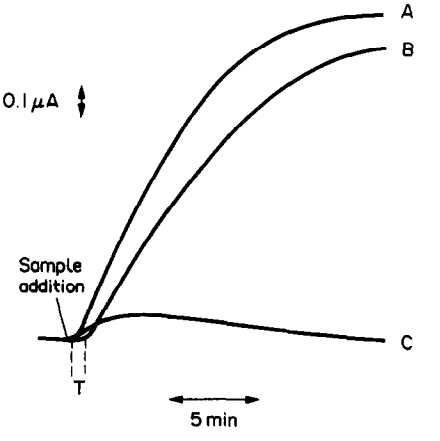


Fig. 1. Typical current responses of $5 \times 10^{-5}M$ L-ascorbic acid (*A*) and $4.5 \times 10^{-5}M$ dehydroascorbic acid (*B*) obtained by the enzyme solutions (pH 7.5) with $5 \times 10^{-3}M$ dithiothreithol and the current response of $5 \times 10^{-5}M$ L-ascorbic acid (*C*) obtained by the enzyme solution without dithiothreithol. Enzyme activity: 0.64 unit/ml.

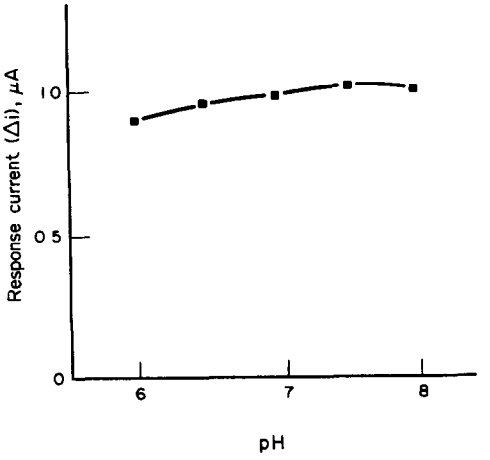

Fig. 2. Effect of pH on the current response of $5 \times 10^{-5}M$ L-ascorbic acid at reaction time 10 min.

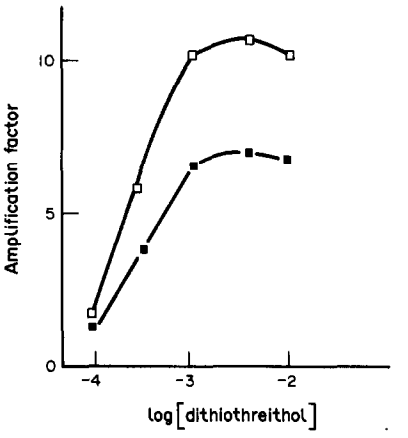

Fig. 4. Effect of the concentration of dithiothreithol on the amplification factor for $5 \times 10^{-5}M$ L-ascorbic acid at reaction times 5 min (■) and 10 min (□).

not observed in the pH range from 6 to 8, pH 7.5 was chosen throughout the experiment for maximum response.

The amplified current response is also dependent on the activity of enzyme and the effect is shown in Fig. 3. The amplified current was increased with increase in the amount of enzyme and 500 μl of enzyme (enzyme activity of the sample solution is 0.64 units/ml) was chosen for the remainder of the experiments.

The effect of the concentration of dithiothreithol on the amplified response of L-ascorbic acid at reaction times of 5 and 10 min are shown in Fig. 4. The current responses were increased by increasing the concentration of dithiothreithol but decreased slightly when the concentration was greater than $7 \times 10^{-3}M$. The decrease is because the consumption of the dissolved oxygen by the oxidation of dithiothreithol becomes important and the background current of the reduction of the dissolved oxygen is decreased. Then, the measurable current range becomes narrower, resulting in the reduction of the current response value. From the results described above, the measurement of L-ascorbic acid and dehydroascorbic acid were carried out under the conditions of pH 7.5, enzyme activity 0.64 units/ml and dithiothreithol $5 \times 10^{-3}M$.

When $5 \times 10^{-3}M$ L-ascorbic acid was added into the enzyme solution containing $5 \times 10^{-3}M$ dithiothreithol, the amplification factor obtained was 10.6 at 10 min reaction time. The relative standard deviation of this amplification factor ($n = 6$) was found to be 3.5%.

The amplified and non-amplified calibration curves of L-ascorbic acid are shown in Fig. 5. The latter was obtained from the peak current response values of each L-ascorbic acid concentration and in the case of the amplified calibration curve, while the former was obtained after a 10-min reaction time. These results indicate that a dynamic range is moved in

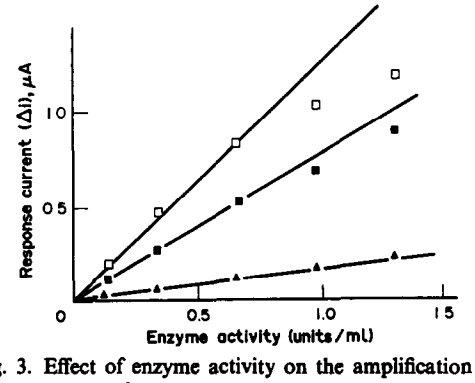

Fig. 3. Effect of enzyme activity on the amplification factors for $5 \times 10^{-5}M$ L-ascorbic acid at each reaction time: (▲) 1 min (■) 5 min (□) 10 min.

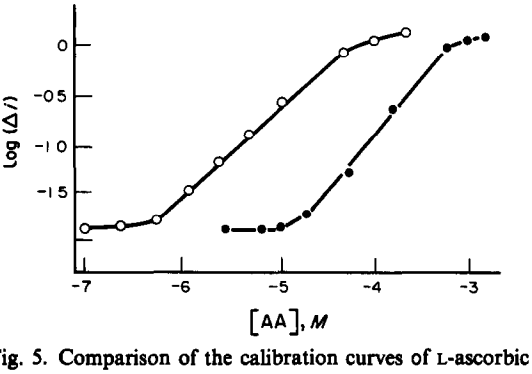

Fig. 5. Comparison of the calibration curves of L-ascorbic acid at reaction time 5 min obtained in the pH 7.5 buffer solution with (○) and without (●) $5 \times 10^{-3}M$ dithiothreithol.

parallel toward the lower concentration range ($7 \times 10^{-7}M$–$4 \times 10^{-5}M$) by more than one decade compared with that ($2 \times 10^{-5}M$–$7 \times 10^{-4}M$) obtained by buffer solution without dithiothreithol, and the detection limit was decreased by $2 \times 10^{-7}M$ from $8 \times 10^{-6}M$.

When reactants of dithiothreithol are contained in the sample solution, these would interfere because the concentration of dithiothreithol in an enzyme solution is decreased. But serious interference can be avoided by the dissolution of a large amount of dithiothreithol in the enzyme solution, or if large amounts of reactants consuming dithiothreithol are present, these reactants can be eliminated in advance by the addition of dithiothreithol into the sample solutions prior to measurement.

From the results, it can be expected that the sensitivity of an L-ascorbic acid sensor using immobilized ascorbate oxidase membrane would be significantly increased by using the described cyclic reaction of vitamin C and such a sensor system would be very effective for the measurement of not only L-ascorbic acid but also dehydroascorbic acid.

APPLICATION OF APCD/DIBK EXTRACTION SYSTEM IN STRONGLY ACIDIC MEDIA: DETERMINATION OF TRACES OF COPPER AND NICKEL IN TITANIUM METALS BY EXTRACTION–FLAME ATOMIC-ABSORPTION SPECTROMETRY

MASAHIKO MURAKAMI and TAKEO TAKADA

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171, Japan

(*Received* 6 *August* 1991. *Revised* 7 *April* 1992. *Accepted* 10 *April* 1992)

Summary—Extraction of nickel in strongly acidic solution (0.01 ~ 8*M* hydrochloric acid) with ammonium 1-pyrrolidinecarbodithioate (APCD) into di-isobutyl ketone (DIBK) has been studied, and the APCD/DIBK system has been applied to simultaneous extraction and flame atomic-absorption spectrometric determination of trace amounts of copper and nickel in titanium metal. Nickel could be extracted with copper from strongly acidic solution such as up to 5*M* hydrochloric acid with APCD/DIBK system. The extraction from such a strongly acidic media made it possible to extract nickel with copper, since it did not require the addition of a large amount of the masking agent which prevents the hydrolysis of the matrix titanium and also prevents the extraction of nickel. Thus, they could be extracted directly from the titanium metal sample digested by concentrated hydrochloric acid with a small amount of tetrafluorohydroboric acid. Effect of coexistence of a large amount (at least 0.2 g) of iron on the extraction of both elements could be prevented by keeping most of the matrix titanium as Ti(III). With the method described here, μg/g levels of copper and nickel in titanium metal could be rapidly determined with good precision and accuracy.

The solvent extraction of various elements with ammonium 1-pyrrolidinecarbodithioate (APCD) into isobutyl methyl ketone (IBMK) is most widely used for matrix separation and preconcentration prior to their determination by atomic-absorption spectometry (AAS). The application of the APCD/IBMK system has been studied for various elements and the conditions for their extraction with this system, such as a pH range of the system which can be used have also been investigated.[1–4] In these reports, most of the workers stated that the pH range of 2 ~ 11 had been considered as the standard procedure for extraction of metals with the APCD/IBMK system, although the APCD/$CHCl_3$ system can be used in a very low pH region (< 1); in early work it was reported that Cu(II), Sb(III), and Sn(II) can be quantitatively extracted into $CHCl_3$ with APCD even from 6*M* hydrochloric acid solution.[5] Although there are only a few reports that suggest the possibility for the use of the APCD/IBMK system in the very low pH region (< 1) or that mention the effect of hydrogen-ion concentration on the extraction of various elements,[6,7] in both reports, there is no positive intention to use this system in such a region.

However, it is expected that the extraction of elements from such a strongly acidic media has significant analytical advantages. Because it permits direct extraction of analytes from a solution of sample decomposed by concentrated mineral acid without any neutralization or pH adjustment, the time and labour needed for the analysis can be decreased, and the contamination by impurities contained in the reagent can be reduced. With this aim, we have systematically studied the extraction of copper(II) from strongly acidic solution (0.01–8*M* hydrochloric and nitric acids) with APCD, to apply this system to the extraction of some elements from very acidic solution.[8–11] We found that if di-isobutyl ketone (DIBK) is used as an alternative to IBMK and a large excess of the reagent is used, the decomposition of Cu(II)–PCD chelate in the extract can be effectively suppressed and copper can be quantitiatively extracted from up to 8*M* hydrochloric or 4*M* nitric acids.

We believe that a good case which demonstrates the excellent characteristics of the APCD/DIBK system in strongly acidic media is the analysis of some trace elements in a matrix which tends to be hydrolyzed in aqueous solution, such as titanium metal. In such a case, when the pH of the solution of the decomposed sample is adjusted to 2–11 for conventional extraction procedures, masking of the matrix by the use of a large amount of a reagent such as EDTA is required, in order to prevent the coprecipitation of traces caused by the precipitation of the matrix element due to its hydrolysis. However, besides being tedious, use of a large amount of the masking agent prevents the simultaneous extraction of some desired elements; for example, when EDTA is used as the masking agent in the ASTM method for the determination of copper in titanium metal,[12] some traces other than Cu(II) are masked and cannot be simultaneoulsy extracted with APCD. On the other hand, if the desired elements can be extracted from a solution of hydrochloric or nitric acids at a strength of at least $1 \sim 2M$, they can be extracted directly from such acidic sample solution without hydrolysis of the matrix and coprecipitation of analytes.

Hence, in this paper, we studied the extraction of nickel(II) from strongly acidic media (0.01–8M hydrochloric acid) with the APCD/DIBK system, and applied the APCD/DIBK extraction to the simultaneous extraction–AAS determination of trace amounts of copper and nickel in titanium metal, to demonstrate a validity of this system.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade. Water was redistilled from an all-glass apparatus. The standard stock solutions (1000 μg/ml) of copper and nickel were prepared from 99.99% pure metals of each element and their acidities were adjusted to 0.1M hydrochloric acid, respectively. The solution of iron(III) (Fe 0.4 mg/ml) was prepared from $FeCl_3.6H_2O$. All solvents were used without further purification.

Sample preparation

A 2-g portion of the titanium metal sample was transferred to a 200-ml conical flask, and 80 ml of concentrated hydrochloric acid and 2 ml of 42% tetrafluorohydroboric acid solution were added. The mixture was heated gently until the sample was dissolved. To prepare the "unoxidized" sample, the mixture was directly diluted to 100 ml with water. The "oxidized" sample was prepared by the dropwise addition of concentrated nitric acid until the purple colour of the mixture had completely disappeared, and it was boiled gently to expel oxides of nitrogen. After oxidation, it was diluted to 100 ml with water. The strength of acid of both sample solutions was about $5 \sim 6M$.

Extraction procedures

Optimum time and APCD concentration for Ni(II) extraction. A 20-ml portion of hydrochloric acid of desired concentration, and 2.5 ml of a 10-μg/ml nickel solution were transferred to a 100-ml separating funnel, and 10 ml of DIBK were added. Portions (2.5 ml) of different concentrations of APCD solution ($1.6 \times 10^{-3} \sim 8.0 \times 10^{-2}M$) were added to the mixture just before the extraction to avoid the decomposi tion of the reagent, and the mixture was mechanically shaken vigorously for different periods of time ($30 \sim 300$ sec). Immediately after the aqueous phase had been withdrawn, the extract was washed with water; 25 ml of water was added to the separating funnel and the mixture was mechanically shaken for 180 sec. The washed extract was filtered with dry filter paper.

Extraction of Cu and Ni in titanium metal. A 10-ml aliquot of the sample solution was transferred to a 100-ml separating funnel, and 10 ml of DIBK were added. In recovery tests, $0 \sim 0.3$ ml of a 10-μg/ml copper solution and $0 \sim 0.3$ ml of a 100-μg/ml nickel solution were also added to the titanium sample solution. To study the effect of iron on the recovery, 0.35 ml of a 100-μg copper solution and 0.15 ml of a 100-μg nickel solution (final amount of each element in the sample solution is 40-μg), and $0.1 \sim 5$ ml of 40-mg/ml iron(III) solution were added to the titanium sample solution; in this case, an appropriate volume of 10M hydrochloric acid was added to the mixture, to adjust the final acid concentration to 3M. A $1 \sim 10$ ml portion of $8 \times 10^{-2}M$ APCD was added to the mixture just before the extraction, and extraction was performed for 300 sec. Immediately after the aqueous phase had been drained off, the organic phase was washed with 25 ml of water and was filtered with dry filter paper.

Determination of Cu and Ni in titanium metal samples

The titanium strip (Nippon Mining Co, LTD, CP–Ti) was digested according to the above-

mentioned procedure for "unoxidized" sample preparation, and the extraction was done as mentioned above, with addition of 10 ml of $8 \times 10^{-2}M$ APCD.

For the high purity titanium standard TAS-104 (Japan Titanium Society), the sample preparation and the extraction were done as follows: a 1-g portion of the sample metal was transferred to a 100-ml conical flask, and 20 ml of concentrated hydrochloric acid and 0.5 ml of 42% tetrafluorohydroboric acid solution were added. The mixture was heated gently until the sample was dissolved. After the solution was cooled, 10 ml of water and 10 ml of DIBK was added to the flask. A 10-ml portion of $8 \times 10^{-2}M$ APCD solution was added to the mixture just before the extraction, and the mixture was extraced for 300 sec. To avoid a contamination and loss of the analytes, the extraction was directly performed in the flask. After the aqueous phase has been drained off with a 50-ml syringe, the organic phase was washed with 25 ml of water and filtered with dry filter paper.

Measurements

UV–Visible spectra of the extract were measured with a 10-mm quartz cell. For AAS measurements, an air-acetylene flame atomizer was used. The absorption line of 324.75 nm was used for copper. For nickel, the absorption line of 341.48 nm, which is not the most sensitive line, was selected since relatively large amounts of nickel were contained in the present titanium samples.

RESULTS AND DISCUSSION

Optimum time and APCD concentration for Ni(II) extraction

The shaking time and the reagent concentration needed for quantitative extraction of 25 μg of nickel from $0.01 \sim 8M$ hydrochloric acid with the APCD/DIBK system were studied.

Shaking time. The studies were performed in the range $0.01 \sim 5M$ hydrochloric acid with APCD at $8 \times 10^{-3}M$. In the whole range of acid concentrations, the nickel chelate could be quantitatively extracted into DIBK with shaking for $30 \sim 300$.

APCD concentration and acidity range. In the preceding paper,[11] it was observed that the limiting acidity of the quantitative extraction of the copper chelate was directly dependent on the concentration of the reagent added. Hence, the the acidity range of the nickel chelate extraction was studied with various concentrations of APCD. Figure 1 shows the percentage extraction of nickel chelate as a function of hydrochloric acid concentration of the aqueous phase, with $1.6 \times 10^{-4}M$, $3.2 \times 10^{-4}M$, and $8.0 \times 10^{-3}M$ of APCD. Similar to the copper extraction, the acidity range depends on the concentration of the reagent added. The limiting hydrochloric acid concentrations for quantitative extraction of the nickel chelate were taken as follows: $0.5M$ with $1.6 \times 10^{-4}M$ APCD (9.4-fold ratio to nickel), $1M$ with $3.2 \times 10^{-4}M$ (19-fold), and $5M$ with $8.0 \times 10^{-3}M$ APCD (470-fold).

Hence, the shaking time of $60 \sim 300$ sec and the reagent concentration of $8 \times 10^{-3}M$ or more were selected as the optimum conditions for the extraction of nickel from up to $5M$ hydrochloric acid solution. They are also taken as optimum for the simultaneous extraction of copper and nickel from such a medium, since copper could also be quantitatively extracted under the present conditions.[10,11]

Extraction of Cu and Ni in titanium metal

Effect of oxidation state of matrix titanium. Simultaneous extraction of copper and nickel contained in the titanium metal sample (Nippon Mining Co, LTD, heat No. 81475) with the APCD/DIBK system was examined. This titanium metal contains about 10 μg/g and 110 μg/g of copper and nickel, respectively, and also contains a relatively large amount (about 2.5 mg/g) of iron.

Figure 2 shows the percentage extraction of each element from a sample solution in which the matrix titanium was oxidized to Ti(IV)

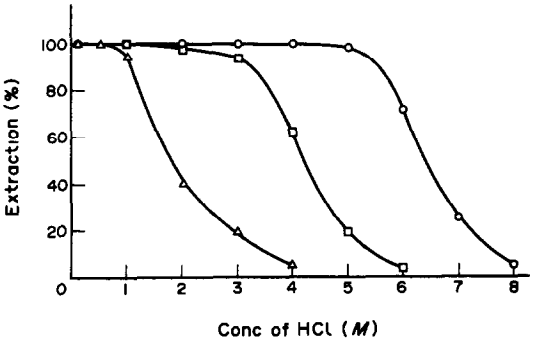

Fig. 1. Extraction range of Ni(II) with APCD/DIBK system in hydrochloric acid media: [APCD] $1.6 \times 10^{-4}M$(△), $3.2 \times 10^{-4}M$(□), $8.0 \times 10^{-3}M$(○); [Ni] $1.5 \times 10^{-5}M$; shaking time 180 sec.

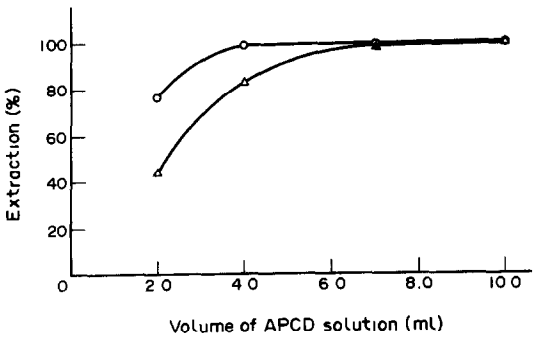

Fig. 2. Effect of volume of APCD solution on Cu and Ni extraction from the "oxidized" titanium sample: Cu(○), Ni(△); [APCD] $8.0 \times 10^{-2}M$; shaking time 300 sec.

according to the conventional sample preparation, as a function of the volume of $8 \times 10^{-2}M$ APCD solution. The strength of acid of the aqueous phase was about $2 \sim 3M$ with hydrochloric acid, during the extraction. The copper and nickel could be quantitatively extracted when 7 ml or more of the reagent was added. This suggests that the APCD/DIBK system has the obvious potential for the simultaneous extraction of some trace metals from samples requiring high acidity to prevent hydrolysis of the matrix element.

However, when nickel and copper were extracted from a sample solution in which the matrix titanium was oxidized to Ti(IV), considerable amounts of the iron chelate were also extracted. In the UV–Vis spectrum of the DIBK extract, characteristic absorption peaks of $Fe(PCD)_3$ were observed at 510 and 595 nm, and a large amount of iron was detected by AAS. There was concern that the co-existence of a large amount of iron would affect the extraction of copper and nickel due to consumption of the reagent. Although both elements could be quantitatively extracted in the above case, it may be assumed that the coexistence of iron affects the amount of available reagent; the amount of the reagent needed for the quantitative extraction of both elements is larger than that expected from the studies on the extraction conditions of copper and nickel.

It is known that some dithiocarbamato complexes of divalent iron were unstable,[13] and it was also reported that Fe(II) cannot be extracted from acidic solution (<pH 1) with diethylammonium diethyldithiocarbamate into $CHCl_3$.[14] Therefore, to avoid the chelation of iron it is preferable to keep the iron in the divalent state. Hence, we have tried to extract copper and nickel from a sample solution prepared by the procedure omitting oxidation of the titanium. In this "unoxidized" case, most of the titanium probably remains in the trivalent state, and it is expected that the iron is kept in the divalent state during the extraction since Ti(III) matrix acts as a reducing agent for iron.

Figure 3 shows the percentage extraction of each element in the "unoxidized" case, as a function of the volume of $8 \times 10^{-2}M$ APCD. In the "unoxidized" case, the volume of the APCD solution needed for complete extraction of each element was considerably less than that observed in the "oxidized" case (Fig. 2); the percentage extraction of copper and nickel were maximum when 1 and 4 ml of the reagent was added, respectively. In this case, the characteristic absorption spectrum of $Fe(PCD)_3$ was only slightly observed in the extract, and iron was not detected by AAS. These facts indicate that the chelation of large amounts of Fe(III) causes an increase in the amount of APCD needed for complete extraction of both elements, and that such an effect of iron can be suppressed provided that the matrix titanium is not oxidized to Ti(IV). We have therefore extracted the copper and nickel chelate from strongly acidic conditions without oxidation of matrix titanium.

Figure 3 also shows that adding 4 ml or more of $8 \times 10^{-2}M$ APCD is enough for the extraction of copper and nickel in the present sample, if titanium is not oxidized. However, in our previous studies it was found that the kinetic stability of the copper chelate in the extract, and therefore the limit of acidity for its extraction, could be increased by increasing the amount of APCD added.[10,11] Therefore, addition of 10 ml of APCD solution was selected for later studies.

Recoveries. To make sure of the effect of titanium matrix on the extraction–AAS deter-

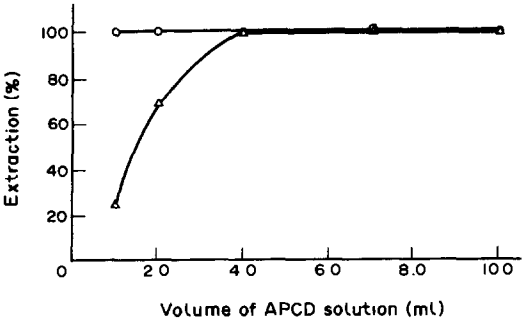

Fig. 3. Effect of volume of APCD solution on Cu and Ni extraction from the "unoxidized" titanium sample: Cu(○), Ni(△); [APCD] $8.0 \times 10^{-2}M$; shaking time 300 sec.

mination and the amounts of copper and nickel which can be extracted with the present condition, the recoveries of copper and nickel from the "unoxidized" titanium sample solution were studied. The studies were carried out by standard additions of each element to the sample solution during its preparation. The slopes and the linear ranges of the plots of AAS intensity against the added amount of each element were compared with those of working curves. The working curves were prepared by extracting the appropriate volume of the standard solutions of each element, in the absence of the titanium matrix.

The results are shown in Table 1. The slopes of the curves for each element agreed very closely with each other, indicating that both elements were satisfactorily recovered with this method. The linearity of the standard addition curves for each element remained throughout addition of 36 μg or more and 41 μg or more of copper and nickel, respectively. Since the present sample contains about 2 μg of copper and 22 μg of nickel, with the addition of 10 ml of the reagent solution, about 38 μg of copper and about 63 μg of nickel can be recovered from the sample solution containing about 0.2 g of titanium.

Effect of Fe. The effect of iron on the recoveries of copper and nickel were studied by adding various amounts of iron(III) ion to the above sample solution. In this study, the contents each of copper and nickel in the sample solution were adjusted to about 37 μg by addition of appropriate amounts of the standard solutions of each element. It is assumed that such an amount of both elements must be satisfactorily recovered with the present extraction, because it is approximately equivalent to the upper limit of the linear calibration of each element in this system; this is about 40 μg for both elements when the most sensitive absorption line of each element (324.75 nm for Cu and 232.00 nm for Ni) used.

Table 1. Slope and linear range of the standard addition plots and the working curve

Method	Slope (mm/μg)		Linear range (μ/g)	
	Cu	Ni*	Cu	Ni*
Std. add. plots ("unoxidized")	11.3	1.16	>38.2	>63.0
Working curve (no Ti contained)	11.1	1.18	≦40	≦65.0

*For AAS measurement of nickel, the absorption line of 341.48 nm was used.

Table 2. Determination of copper and nickel and titanium strip (CP–Ti) and standard sample of high purity titanium (TAS–104)

	CP–Ti		TAS–104	
	Cu	Ni	Cu	Ni
Certificate value (μg/g)	11	80	2*	28
Found (μg/g)	10.8	82.4	1.65	28.2
R.S.D. (%)	1.6	0.36	1.1	1.1

*This is the reference (non-certified) value.

The extraction of copper and nickel were not affected by the Fe(III) ions which were added in a 0.2-g weight, although extraction of considerable amounts of the iron chelate was observed. The copper and nickel chelates were stable at least for one week when the extract was kept in the light.

Therefore, it can be concluded that the amount of reagent is sufficient for the determination of copper and nickel by the proposed extraction-flame AAS. Hence, 10 ml of $8 \times 10^{-2}M$ APCD solution was selected for the determination of copper and nickel in titanium metal samples.

Determination of Cu and Ni in titanium metal samples

The method was applied to the simultaneous extraction–AAS determination of trace amounts of copper and nickel in titanium metal samples. The determination of both elements was carried out by the working curve method.

The results of five replicate analyses of both the titanium strip (Nippon Mining Co, CP–Ti) and the standard reference sample of high purity titanium (Japan Titanium Society, TAS–104) are shown in Table 2. As can be seen, the μg/g levels of copper and nickel in titanium metal can be determined by the present method, with good precision.

CONCLUSION

The APCD/DIBK system made its possible to extract both copper and nickel together directly from the strong hydrochloric acid solution (about $5M$) of digested titanium sample. In this case, the time required to prepare the sample solution could be reduced by about 50% or more. Furthermore, taking into consideration that copper and nickel can be simultaneously extracted from the same solution, further saving of time is achieved.

It was also found that co-extraction of iron can be avoided if the extraction of desired element is carried out in the strongly acidic medium under the existence of an appropriate reducing agent [not only Ti(III)] to keep iron in the Fe(II) state during the extraction. We believe this will be one of the significant advantages for the practical application of the APCD/DIBK system in the strongly acidic media.

Acknowledgement—The authors are grateful to Mr. Y. Tegawa, Nippon Mining Co., Ltd., for providing us with the samples of titanium.

(*Received* 24 *June* 1991. *Revised* 20 *February* 1992. *Accepted* 3 *March* 1992)

Summary—The partition constants of Cadion, *i.e.*, 1-(*p*-nitro-phenyl)-3-(*p'*-azobenzene)-triazene, of its complex with the methylmercuric ion, and of methylmercury chloride were determined in the system toluene/aqueous phase containing 40 vol.% methyl alcohol; they have the values of 4.3×10^3, 3.0×10^3, and 2.6 respectively. The reagent has an absorption maximum at 406 nm, whereas the methylmercury complex at 460 nm. The K_{HR} value corresponding to the $H^+ + R^- \rightleftharpoons HR$ equilibrium is $10^{10.85}$, HR being the reagent molecule and H belongs to the –NH– of the triazenic group (–N=N–NH–). The K_{ext} value corresponding to the equilibrium $H_3CHg^+ + (HR)_o \rightleftharpoons (H_3CHgR)_o + H^+$ is 1.0, where the "o" indicates the species present in the organic phase. The reagent/H_3CHg^+ combination ratio is 1/1. The formation constant of the methylmercury complex, K_{H_3CHgR}, which corresponds to the equilibrium $H_3CHg^+ + R^- \rightleftharpoons H_3CHgR$, has a value of $10^{10.8}$ as estimated by means of two different methods. The IR spectra allowed some conclusions to be drawn concerning the formation of the complex. The complex is stable up to 180°, and the reagent up to 140°. The molar absorptivity is of 3.46×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ and the H_3CHg^+ can be determined in the range 0.025–4 ppm. The determination is highly selective.

Methylmercury is one of the most toxic forms of mercury. In the environment, this compound can be formed from inorganic mercury by biological methylation; it then accumulates in living organisms by a series of processes taking place along the food chain.[1,2] This would account at least partially for the attention being paid to the chemistry of the complexes that methylmercury can form with a series of ligands[3–8] to the determination of methylmercury[9–13] and also to the study of the stability of the aqueous solutions containing this ion.[14–16]

The 1,3-diaryltriazenic derivatives have the property of forming very stable complexes with the mercury(II) and phenylmercury(I) ions, which can be extracted in organic solvents from a neutral or very slightly alkaline medium. Based on this property, sensitive and selective spectrophotometric methods of determining these ions with 1,3-diphenyltriazene[17,18] and 1-(*p*-nitro-phenyl)-3-(*p'*-azobenzene)-triazene (Cadion)[19,20] were proposed; these methods are neatly more selective than the method proposed originally with the latter of these two reagents,[22] in which the determinations have been made in a basic water–alcohol medium. The sensitivity, but particularly the high selectivity of these determination methods prompted us to investigate the equilibria involved in complexation and extraction, in order to establish the optimal conditions for the determination of methylmercury with Cadion.

The literature reports very few data on the reaction of methylmercury with organic reagents, especially with dithizone.[23,24] However, dithizone reacts with a large number of ions and its use for analysing methylmercury requires very pure reagents or their prior purification; moreover, the determination has poor selectivity, and the formed complex between the methylmercuric ion and dithizone is photosensitive. The reagent proposed by us does not show such disadvantages.

EXPERIMENTAL

Apparatus and reagents

The absorption spectra were recorded with the UV-Vis and 75IR Specord spectrophotometers, and the measurements at fixed wavelengths were carried out with the VSU 2G spectrometer, all these intruments being provided by Carl Zeiss Jena (Germany). The pH measurements were carried out with the MV85

*Author for correspondence.

pH-meter (Germany), whereas the thermograms were recorded with a system derivatograph (J. Paulik, F. Paulik and L. Erdey, Hungary).

All the used reagents were analytically pure. A 0.015% stock solution of 1-(*p*-nitrophenyl)-3-(*p'*-azobenzene)-triazene (Austranal) in methanol and 100 μg H_3CHg^+/ml of solution of methylmercury chloride (Merck) in water were prepared. The solution of methylmercury chloride was obtained by dissolving first the weighed amount of solid substance in 3 or 4 ml of acetone, then diluting with water. From these, solutions of necessary concentrations were obtained by dilution.

The working procedure

The following procedure was pursued in order to carry out the complexation and extraction studies. A 1-ml aliquot of 2*M* sodium acetate, the solution containing methylmercury chloride, distilled water, methanol, and the solution of the reagent were introduced into a 50-ml graduated cylinder provided with ground-glass stopper, so that the final volume was 10 ml and the methanol concentration was 40 vol.%. The solution was stirred for homogenization and then left to stand for 10 min. Toluene (5 ml) was added and the cylinder was stirred vigorously for one minute. After phase separation, an adequate amount of the organic phase was taken out with a dry pipette to fill up the spectrophotometer cell, and its absorbance was measured. In all cases 1-cm thick cells were used.

In order to draw the calibration curve and to determine methylmercury, the procedure described above was preserved, but 4 ml of reagent were introduced in all samples, and the absorbances were measured relative to a reference sample at 480 nm.

The complex of methylmercury with the investigated reagent was prepared as follows: stoichiometric amounts of methylmercury chloride and reagent, corresponding to a 1/1 combination ratio and calculated to yield 1 g of complex, were dissolved by heating in 10 ml and in 100 ml of acetone. The solution of methylmercury chloride was introduced over the hot solution of reagent, then 10 g of solid $H_3CCOONa \cdot 3H_2O$ were added, stirring until its complete dissolution. The solution was left to cool down, when at the bottom of the beaker a slightly coloured liquid phase separated, which contained most of the sodium acetate dissolved in its own crystallization water; the formed complex precipitated from acetone and separated at the interface between the two phases. The solution was filtered through a G4 sintered-glass filter, the precipitate was washed with hot water and then with a small amount of acetone; it was dried in an oven at 105°. The obtained solid complex was a microcrystalline structure and is red-violet in colour. The yield was 80%.

The partition constants of the reagent and of the complex were estimated on the basis of their solubilities in toluene and in an aqueous phase having identical composition to that used in the extraction studies. In order to do this, 50 ml of aqueous phase and 10 ml of toluene and reagent or solid methylmercury complex, taken in excess, were brought into contact in 100-ml separating funnels. The samples were stirred for 20 min, then the phases were separated and filtered. The reagent and the complex were extracted from their saturated aqueous phases by using volumes of toluene 2 and 10 times less, respectively for the reagent and the complex. The organic phases, which are saturated solutions of reagent and of complex, were diluted 1000 and 300 times, respectively. Absorbance measurements were made at the wavelengths of the absorption maxima of the reagent and of the complex. The partition constants were estimated from the values of the absorbances, taking into account the dilution.

The partition constant of methylmercury chloride between toluene and an aqueous phase having an identical composition to that used in the extraction studies was estimated similarly as for the partition constants of the reagent and the complex; finally, methylmercury was oxidized to Hg^{2+} and determined spectrophotometrically, with Cadion.[19]

RESULTS AND DISCUSSION

The absorption spectra of a $2.5 \times 10^{-5}M$ solution of reagent extracted in toluene (curve 1) and of a series of solutions containing the same amount of reagent and increasing amounts of methylmercuric ions (curves 2–6) are given in Fig. 1. As can be seen, the reagent has an absorption maximum at 406 nm (24,630 cm^{-1}), whereas the formed complex, at 460 nm (21,740 cm^{-1}). The spectra have a single isosbestic point, which suggests that a single complex is formed. However, the curve for the highest reagent concentration does not pass through the isosbestic point. This would indicate that some

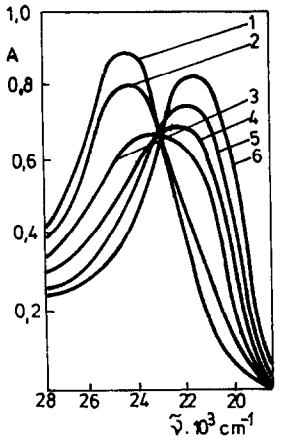

Fig. 1. The absorption spectra of the reagent and of the methylmercury complex, extracted in toluene: (1) reagent, $2.5 \times 10^{-5}M$; (2–6) the same concentration of reagent and increasing concentrations of CH_3Hg^+, with the following $[HR]/[H_3CHg^+]$ ratios: (2) 4/1; (3) 1/1; (4) 1/2; (5) 1/4 and (6) 1/8.

higher complex may also be formed. The difference between the absorbance of the complex and that of the reagent is maximum at 480 nm (20,830 cm^{-1}).

The influence of methyl alcohol concentration in the aqueous phase, of pH values of the aqueous phase, of phase stirring duration and of time on the absorbance of the complex extracted in toluene has been studied.

A variation of methyl alcohol concentration between 10–50 vol.% did not lead to a change in the absorbance of the methylmercury complex extracted in toluene. In general, the extraction studies were carried out in a medium of water–40 vol.% methanol.

Figure 2 shows the absorbance variation of the complex extracted in toluene as a function

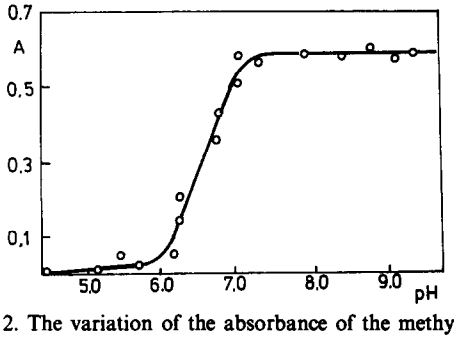

Fig. 2. The variation of the absorbance of the methylmercury complex extracted in toluene, as a function of the pH value of the aqueous phase. The concentration of the reagent in the organic phase = $2 \times 10^{-4}M$. The concentration of methylmercury chloride introduced initially in aqueous phase = $9.5 \times 10^{-6}M$.

of the pH. One can see that the absorbance remains constant for pH values larger than 7 in the aqueous phase, whereas the complex is extracted practically quantitatively in toluene. The pH-meter was calibrated with buffer solutions in 40 vol.% methyl alcohol, while the pH concept in this case has the same significance as that attributed to it in the book.[30] The reagent extraction in the organic phase as the non-dissociated form, HR, is practically not affected by the pH values within the 4.5–9 range.

One minute of vigorous stirring is quite enough for extracting the complex in toluene.

The complex absorbance remains constant for more than 2 hr provided that the organic extract is not submitted to very strong light.

The H_3CHg^+/reagent combination ratio, as well as both extraction and stability constants of the methylmercury complex (the latter by two different methods) were determined.

The H_3CHg^+/reagent combination ratio was determined by the spectrophotometric titration method and also using the method of continuous variations; it has the value of 1/1, in full agreement with the coordinative properties of methylmercury.[3,8]

The extraction constant of the complex was estimated from the influence of pH on the extraction yield (Fig. 2). It was considered that the extraction takes place according to the equilibrium:

$$H_3CHg^+ + (HR)_o \rightleftharpoons (H_3CHgR)_o + H^+ \quad (1)$$

where the "o" indicates the species present in the organic phase. The extraction constant is given by

$$K_{ext} = \frac{[H_3CHgR]_o[H^+]}{[H_3CHg^+][HR]_o} = D\frac{[H^+]}{[HR]_o} \quad (2)$$

where D is the partition ratio of mercury between the two phases and is equal to 1 at the pH of half-extraction. The half-extraction pH ($pH_{1/2}$) determined from Fig. 2 has the value 6.6. In the aqueous phase from which the extraction was made, methylmercury can however also be present as a complex with chloride, hydroxide and acetate ions, these having formation constants equal to $10^{5.25}$, $10^{9.37}$ (Refs. 3 and 4) and $10^{3.18}$ (Ref. 4), respectively. Taking account of the formation of these complexes, the concentration $[H_3CHg^+]$ of free methylmercury in the aqueous phase, at pH 6.6, will

have the value

$$[H_3CHg^+] = \frac{[H_3CHg^+]_t}{2} \times \frac{1}{1 + K_{H_3CHgOH}[OH^-] + K_{H_3CHgOOCH_3}[H_3CCOO^-]} \quad (3)$$

where $[H_3CHg^+]_t$ is the initial concentration of methylmercury ions introduced in the aqueous phase. (It was assumed that in the aqueous phase the species H_3CHgCl and the methylmercury complex of the reagent are practically absent). By estimating the value of $[H_3CHg^+]$ from equation (3) and substituting it in (2), it was found that $K_{ext} = 1.0$.

It is considered that the formation of the methylmercury complex in the aqueous phase takes place according to the equilibrium:

$$H_3CHg^+ + R^- \rightleftharpoons H_3CHgR \quad (4)$$

where R^- is the anion formed after the dissociation of the –NH– bond of the triazenic group (–N=N–NH–) of the reagent. The stability constant of the complex can be computed by means of the following relation:

$$K_{H_3CHgR} = \frac{[H_3CHgR]}{[H_3CHg^+][R^-]} = \frac{K_{HR} K_{ext} P_{HR}}{P_{H_3CHgR}} = 10^{11.0} \quad (5)$$

where

$$K_{HR} = \frac{[HR]}{[H^+][R^-]} = 10^{10.85}$$

and it corresponds to the equilibrium $H^+ + R^- \rightleftharpoons HR$, HR being the reagent molecule and H belongs to the –NH– of the triazenic group (–N=N–NH–). K_{HR} was determined from the influence of pH on the reagent's dissociation.

$$P_{HR} = \frac{[HR]_o}{[HR]} = 4.3 \times 10^3$$

and

$$P_{H_3CHgR} = \frac{[H_3CHgR]_o}{[H_3CHgR]} = 3.0 \times 10^3$$

are the partition constants of the reagent and the methylmercury complex, respectively, as determined from the solubility ratio. The "o" indicates the species present in the organic phase.

The stability constant of the methylmercury complex was also determined by a second method. This method is based upon the competing equilibria which occur when introducing a second ligand for the methylmercury ion. To this purpose, the Cl^- ion was used. The variation of the absorbance of the methylmercury complex extracted in toluene, as a function of the $[Cl^-]/[H_3CHg^+]$ ratio, is given in Fig. 3. From the data in this figure, one can infer that the competing equilibrium of the formation of the H_3CHgCl species is only to a little extent affected by the methyl alcohol in the aqueous phase. This leads to the conclusion that the constants of formation of the H_3CHgCl species are not appreciably modified under the influence

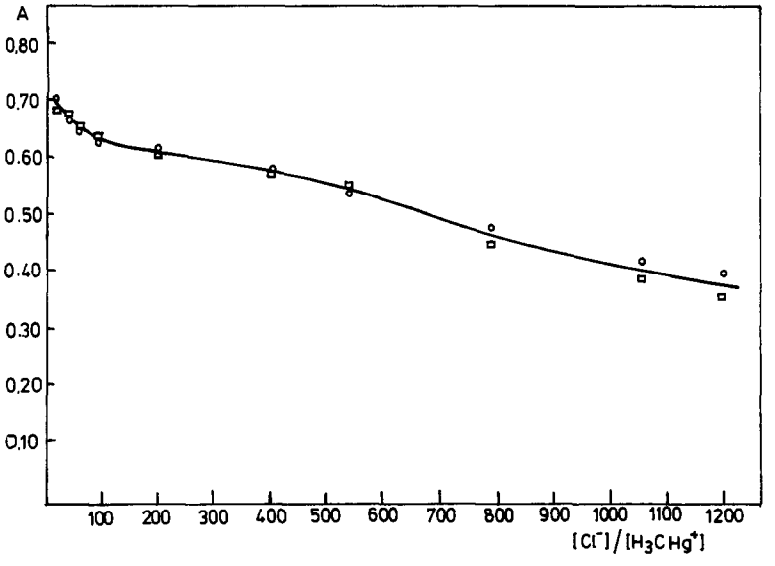

Fig. 3. The variation of the absorbance of the complex extracted in toluene as a function of the $[Cl^-]/[H_3CHg^+]$ ratio. The concentration of the reagent initially in the organic phase = $1.4 \times 10^{-4} M$; the concentration of methylmercury initially introduced in the aqueous phase = $2.0 \times 10^{-5} M$. In the presence of 40 vol.% of methyl alcohol (□) and in the absence of methyl alcohol (○). Equal volumes of the phases.

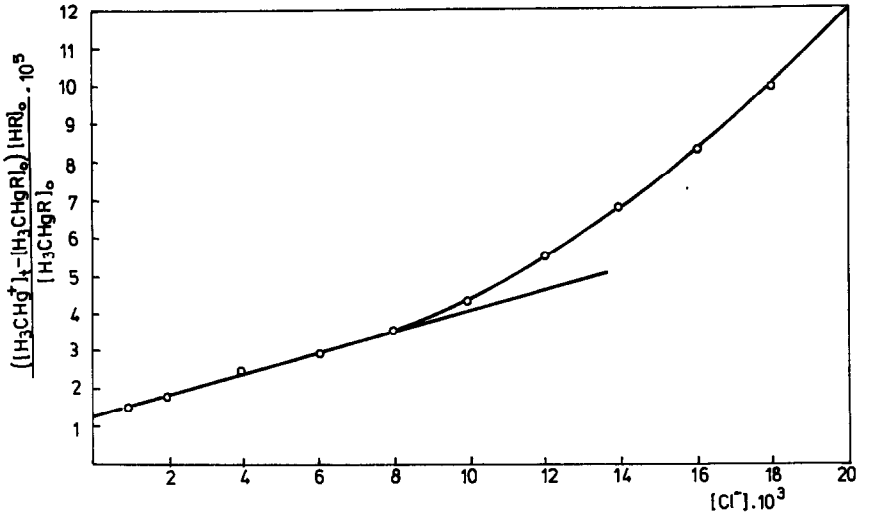

Fig. 4. The plot of $([H_3CHg^+]_t - [H_3CHgR]_o)\,[HR]_o/[H_3CHgR]_o$ as a function of $[Cl^-]$.

of methyl alcohol introduced in the aqueous phase, since the decrease in the methylmercury complex absorbance with studied reagent in Cl^- ion presence occurs similarly as much in presence as in absence of the methyl aclohol from the aqueous phase (Fig. 3).

The K_{H_3CHgR} value has been computed according to the following considerations. The sum of concentrations of all species (neglecting H_3CHgR) of the methylmercury in the aqueous phase is given by the relation:

$$[H_3CHg^+] + [H_3CHgCl] + [H_3CHgOH] = [H_3CHg^+]_t - [H_3CHgR]_o - 2.6[H_3CHgCl] \quad (6)$$

since the $[H_3CHgCl]_o/[H_3CHgCl]$ partition constant has the value of 2.6, as determined from the solubility ratio.

Substituting in (6) the values of $[H_3CHgCl]$ and $[H_3CHgOH]$ as functions of the stability constants of the corresponding complexes and taking account of the other determined quantities, one can write:

$$K_{H_3CHgR} = \frac{P_{HR} K_{HR} [H^+][H_3CHgR]_o}{P_{H_3CHgR}[HR]_o} \times \frac{1 + 3.6K_{H_3CHgCl}[Cl^-] + K_{H_3CHgOH}[OH^-]}{[H_3CHg^+]_t - [H_3CHgR]_o} \quad (7)$$

Rearranging equation (7) and plotting

$$\frac{([H_3CHg^+]_t - [H_3CHgR]_o)[HR]_o}{[H_3CHgR]_o}$$

against the concentration of the Cl^- ions, a straight line is obtained (Fig. 4) whose slope is

$$\frac{3.6P_{HR}K_{HR}[H^+]K_{H_3CHgCl}}{P_{H_3CHgR}\,K_{H_3CHgR}}$$

where all quantities are known, except the value of K_{H_3CHgR}, which can then be found. It may be seen that the plot in Fig. 4 is linear only on its first side, which corresponds to lower concentrations of Cl^- ions; for high Cl^- concentrations, the points no longer belong to the straight line, most likely because of the formation of higher complexes of H_3CHg^+ with Cl^- ions. For K_{H_3CHgR} the value of $10^{10.6}$ was found, which is close to the value determined by the previous method.

The IR spectra of the reagent and of the methylmercury complex, recorded in the range 4000–400 cm^{-1}, are given in Fig. 5. One can see that the bands located at 3260 and 1526 cm^{-1}, assigned, respectively, to the valence and bending vibrations of the -NH- bond of the triazenic group,[21] no longer appear in the spectrum of the complex; this indicates that the bonding between the H_3CHg^+ ion and the reagent's molecule is achieved by the replacement of the hydrogen atom of the triazenic group, which means, in fact, that the extraction and complexation equilibria represented by equations. (1) and (4) are correct.

The thermogravimetric (TG), differential thermal analysis (DTA) and differential thermogravimetric (DTG) curves for the reagent (curve 1) and its methylmercury complex (curve 2) are shown in Fig. 6. One can see that the reagent is stable up to 140°, and its methylmercury complex up to 180°; thus, the reagent could

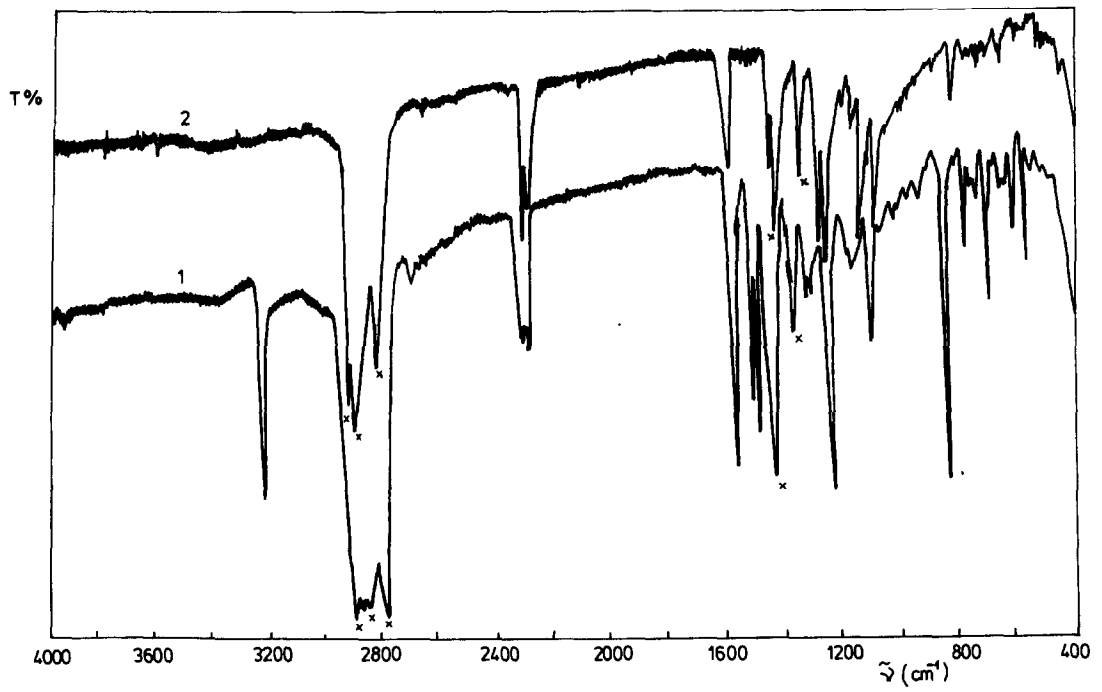

Fig. 5. The IR spectra of the reagent (1) and of the methylmercury complex (2). The samples were prepared as nujol mulls. The bands of nujol are marked by x on the spectra.

also be used for determining methylmercury gravimetrically.

Verification of the validity of Beer-Lambert's law

The procedure used was similar to that already described. The spectra obtained for the complex-containing solutions, recorded by using as reference a comparison sample, are given in Fig. 7; the variation of the absorbance as a function of concentration is also given. The value of the molar absorptivity is of 3.46×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$. By using 1-cm thickness cells, methylmercury can therefore be determined in the range 0.025–4 ppm.

Interferences

Based on the detailed study of the interferences occurring in the determination of mercury(II) with the considered reagent, described in Ref. 19, one can estimate that the errors which may affect the methylmercury determination are less than 3% for [ion]/[H_3CHg^+] ratios larger or equal to 1000 for the ions: Li^+, Na^+, K^+, Fe^{3+}, Co^{2+}, Ni^{2+}, Be^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}, Zn^{2+}, Cd^{2+}, Ga^{3+}, In^{3+}, Tl^+, UO_2^{2+}, Pb^{2+}, SO_4^{2+}, citrate and tartrate, larger or equal to 500 for the ions: Cu^{2+}, Bi^{3+}, Cr^{3+}, Mn^{2+} and CrO_4^{2-}, and larger or equal to 100 for the ions Rh^{3+}, Au^{3+}, Pd^{2+} and Pt^{4+}. The ions: Hg^{2+}, Hg_2^{2+}, Cl^-, Br^-, I^-, SCN^-, CN^- and S^{2-} do interfere, either by forming complexes with the reagent, or precipitating or complexing the methylmercuric ion. The Ag^+ ion interferes by forming a red complex with the reagent, but which can only be extracted with difficulty in toluene. Its interference can be eliminated by precipitation as silver(I) chloride, but the excess of Cl^- ions must be avoided. The interference of the Hg^{2+} and Hg_2^{2+} can be eliminated by their prior reduction with stannous chloride[9]. The H_3CHg^+ ion is stable under these conditions. The cations were introduced as nitrates, sulphates or acetates, and the anions as salts with alkali metals.

There are also other organomercuric compounds, such as $C_2H_5Hg^+$ and $C_6H_5Hg^+$, which react with Cadion with interferences. However, literature data[1,2] suggest that in samples in which methylmercury is usually determined (biological products, some foodstuffs) mercury is found only as inorganic compounds and as CH_3Hg^+. This is because methylmercury is a compound which forms even in living organisms from inorganic mercury.

We used cold-vapour atomic-absorption spectrometry as a reference method for comparing our results;[25] in this method reduction of

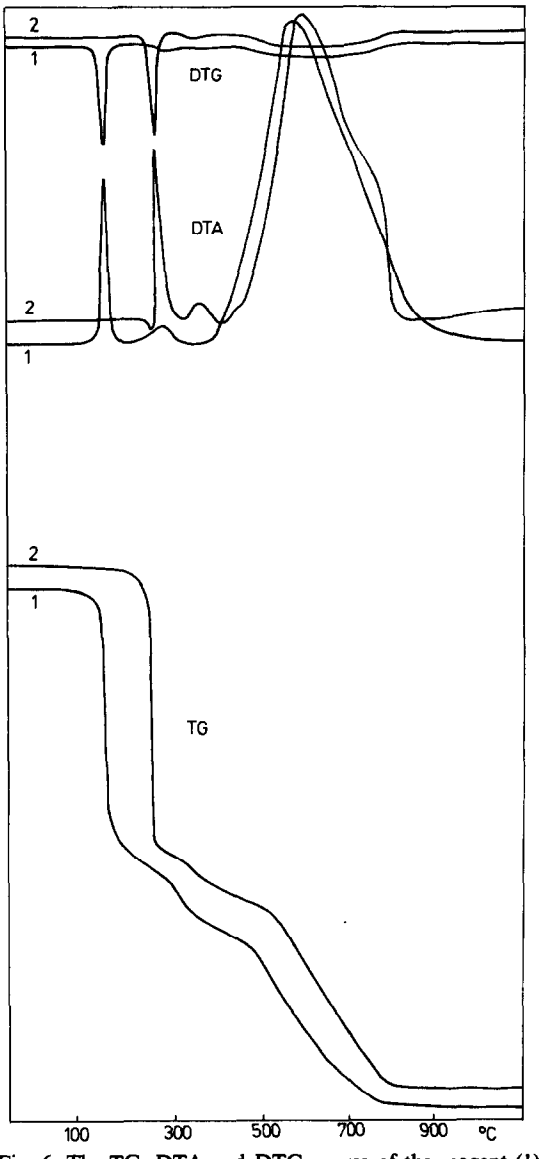

Fig. 6. The TG, DTA and DTG curves of the reagent (1) and of the methylmercury complex (2).

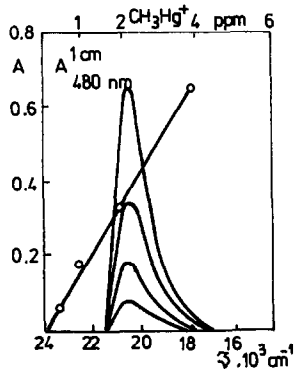

Fig. 7. The absorption spectra of the samples which contain the complex, vs. a reference sample, and the calibration curve used for determining methylmercury.

methylmercury is made with sodium borohydride. The results obtained by these methods are in good agreement.

CONCLUSIONS

The partition constants of the reagent, of its complex with the methylmercuric ion, and of methylmercury chloride were determined in the system toluene-aqueous phase containing 40 vol.% methyl alcohol. The optimum wavelength for carrying out the determinations were found based on the UV/Visible absorption spectra of the reagent and of its methylmercury complex. The extraction constant was determined from the half-extraction pH value and the formation constant of the methylmercury complex was estimated by two different methods, taking into account the main competing equilibria occurring in the aqueous phase and upon extraction. Based on the IR spectra and taking into account the value of the reagent/H_3CHg^+ combination ratio, the type of bonding of H_3CHg^+ ion to the reagent molecule could be determined. The range of thermal stability of the reagent and of the complex was established based on their derivatograms. The investigated reagent allows the determination of the methylmercuric ion with good sensitivity and high selectivity.

Even though the proposed method for determining methylmercury is less sensitive than the method based on the reduction of mercury and its determination by cold-vapour atomic absorption it has some advantages. Thus, a preliminary separation of methylmercury by extraction in benzene or toluene[26,27] could be carried out for typical samples (biological products, some foodstuffs). After separation, methylmercury can be determined directly in the organic phase by contacting it with an aqueous phase containing the reagent and then applying the described manner of analysis. The determination by atomic absorption is much more difficult in this case, since it requires the removal of the organic solvent (during which losses of mercury may occur) and the oxidation of methylmercury to inorganic mercury. The method of determining methylmercury described in this paper has been applied for determining this compound in seafish,[28] after its preliminary separation by distillation from the samples to be analyzed.[29]

Summary—Single-phase solutions ($1.72 \times 10^{-2} M$ in TTA) of water/ethanol/MIBK, when added to an excess of water, break down into two immiscible liquid layers and TTA complexes of Fe(III), Co(II), Ni(II), Cu(II) and Pb(II) are extracted into the organic layer. Quantitative extractions were obtained for the five metals and separations of Fe(III) from a 1000-fold excess of Co(II), Ni(II) or Pb(II) are obtained. The reactions of the metal ions with TTA were studied in the single-phase solutions before the extraction step, giving useful information as to their complexation behavior.

Several liquid–liquid extraction methods using the phenomenon of phase separation have appeared from time to time in the literature. The authors of these methods have made use of diverse physicochemical procedures in order to obtain phase separations.

The homogeneous extraction method of Murata and Ikeda,[1] in which a liquid phase of propylene carbonate coalesces with an aqueous phase at 80°, could extract Mo, after phase separation at room temperature, as an ion association complex.[2]

Workers have also studied the immiscibilization of some otherwise water-miscible solvents. By the use of the salting out effect, Matkovich and Christian[3] were able to separate an acetone phase, which is totally miscible with water, by saturating the aqueous phase with sucrose or any of a series of salts; Nagaosa[4] and Fujinaga and Nagosa[5] separated an acetonitrile phase, and verified the possibility of performing extractions of metal ions.

There is also the procedure of Fujinaga *et al.*[6] who used, instead of the salting out effect, the addition of a small volume of a third solvent to promote the separation of an immiscible ternary phase, made up almost entirely of the water-miscible solvent.

Finally, there is the single-phase technique in which an aqueous phase (A) is made totally miscible with an extractor solvent (B; *e.g.*, benzene, cyclohexane or MIBK), by the addition of a consolute solvent (C) such as acetone or ethanol. After preparing this single-phase solution, the homogeneous system is broken down by the addition of an excess of water, thus separating the solution into two liquid layers. Belcher *et al.*[7] made use of this extraction to obtain an organic phase containing the chelate of interest; nevertheless, they used the technique only in a preparative way, in order to obtain an organic extract for injection in a gas chromatograph. Our study, on the other hand, was primarily directed to the use of the process as an analytical technique.[8]

Although the last two cited techniques, the one of Fujinaga *et al.*[6] and the single-phase, seem to be similar, they are nevertheless quite different. In the former process, an auxiliary solvent must be empiricallly chosen and a volume phase diagram must be constructed[9] in order to determine the small volume of this solvent to be added to the one-phase, binary solution in order to separate the system into two well-defined phases, thus bringing about the extraction. In the single-phase technique a specific auxiliary solvent is not needed nor is it necessary to construct a (volume) phase

*Author for correspondence.

diagram. The system starts in the one-phase region of a ternary diagram, with a mixture of the three components, and by adding a large amount of water, we bring the system to the two-phase region where the extraction occurs. Therefore, the single-phase procedure is applicable to any three A, B and C solvents, defined as above.

To our knowledge, few practical applications[10] have been made for any of the extraction systems mentioned above, although a drastic difference in metal ion extraction is known to exist when they are compared to the conventional binary technique.

This paper reports a study of some practical applications for the single-phase method. From low-acidic single-phase solutions all five metals are extracted together into MIBK by the use of thenoyltrifluoroacetone (TTA), a fact that may be useful in group separations of metal ions, while from high-acidic single-phase solutions, iron(III) is separated from a 1000-fold excess of cobalt(II), nickel(II) and lead(II).

EXPERIMENTAL

Apparatus

A Zeiss atomic-absorption spectrophotometer model FMD-3 was used for the metal ion determinations and a UV–V Zeiss PMQ-II spectrophotometer was used for the photometric measurements with 10- and 50-mm quartz cells. Electrometric measurements were made with a Metrohm E-517 pH meter with a combined set of glass and calomel electrodes. A piston-microburette from Metrohn, using a 0.5000-ml tip, was used to deliver the metal ion solutions.

Reagents

Thenoyltrifluoroacetone, used without further purification, and methyl isobutyl ketone (MIBK) were analytical grade reagents from Carlo Erba.

The metal ion solutions were prepared from the pure metal (Baker), with the exception of cobalt which was prepared from cobalt(II) chloride, dried twice to fumes with nitric acid and standardized by titration with EDTA solution. All solutions contained *ca.* 2000 μg/ml of metal ion and have a pH near 1.

Metal ion cocktail solution. In a steam bath, 100-ml aliquots of the five metal ion solutions were evaporated to dryness and then transferred to a 100-ml standard flask. Enough nitric acid was added in order to make the pH *ca.* 1.

Phase titrations. Solutions (5 ml) of two miscible solvents, either MIBK/ethanol or water/ethanol, were titrated with the third solvent until the appearance of a turbidity, characteristic of the point of opalescence. These titrations were made at room temperature, since the objective was only to verify the position of the two regions of interest, namely those of the single-phase and of the system after phase separation.

Procedure to single-phase extraction. To 2 ml of water, the desired amount of the metal ion solution plus 10 drops of concentrated nitric acid were added, followed by the addition of 7.5 ml of ethanol and 5 ml of MIBK containing TTA. The acidity was adjusted to the desired value, first with concentrated and then with diluted ammonium hydroxide solutions while reading the pH_{sp} (see below) with a pH meter.

Single-phase solutions were always prepared by adding the solvents in the order given above, so as to have at all times a homogeneous solution.

In the extraction step, the prepared single-phase solution (a, in Fig. 1) was added through a filtration funnel (b), which had its bore reduced so as to deliver 30 ml of water in *ca.* 20 sec, to 80 ml of water in a pear-shaped separatoring funnel (c) that had its top removed at the point of its maximum circumference.

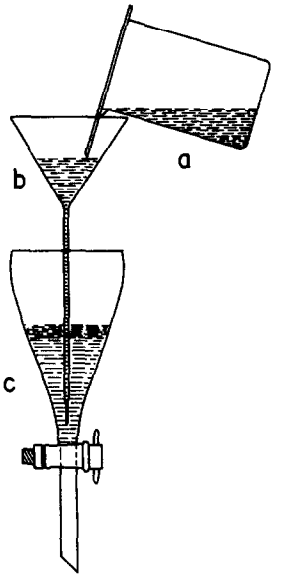

Fig. 1. Set-up for single-phase extractions. Single-phase solution in *a* is delivered through *b* into 80 ml of water at 40° (*c*).

In the successive extractions, after the initial one, 80 ml of water were poured into the funnel from a beaker with the help of a glass rod. The temperature of the separating water was always 40°.

RESULTS AND DISCUSSION

Acidity scale in single-phase solution

Many authors express the acidity of aquo-organic solutions for analytical purposes by nominal pH value. Thus, the pH readings of mixtures of water and acetone of high ionic strengths have been denoted by Matkovich and Christian as a nominal scale.[3] We will use the same procedure in this work but in order to avoid confusion, we shall designate this nominal pH scale as the pH_{sp}, which means that it refers exclusively to readings taken from the single-phase solutions.

Phase diagram of the water/ethanol/MIBK system

The results from the phase titrations were plotted on a ternary Roozeboom[11] diagram (Fig. 2). Point A in the diagram represents the single-phase solution we used in our work, and point B represents the two-phase region of the system after phase separation with water. Point A is well inside the one-phase region, so we can safely add aqueous acids or base solutions without the risk of starting an incipient phase separation. These results were obtained at room temperature, but separations of the single-phase solution with water at 30 and 40° also gave the same volume of the organic (MIBK) phase,

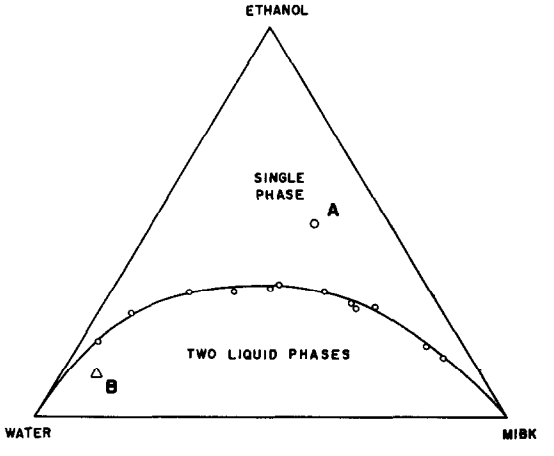

Fig. 2. Ternary phase-diagram for water/ethanol/methylisobutylketone. Point A: single-phase solution used in this work; point B: localization of the system after phase separation with water.

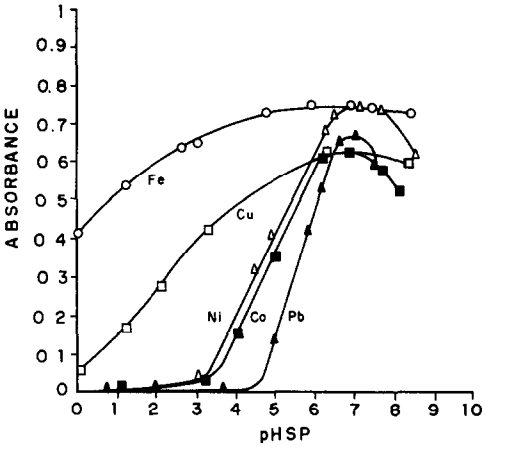

Fig. 3. Complexation curves of Fe, Cu, Ni, Co and Pb in single-phase solution. TTA: $1.72 \times 10^{-2}M$. Metal ions 500 μg each.

indicating that the system is not much affected by this change in temperature.

Complexation curves

An interesting feature of single-phase extractions is that we can normally follow the complexation of the metal ion in the single-phase solution by monitoring a suitable wavelength in which the complex is the only absorbing species. This permits one to study the complexation of each metal ion. To obtain these curves, a series of single-phase solutions with diverse pH_{sp} were prepared and their absorbances were measured in a spectrophotometer. The complexation curves of iron(III), cobalt(II), nickel(II), copper(II) and lead(II) (Fig. 3) show that iron is readily complexed at low acidities and that all complexation curves attain a maximum around pH_{sp} 5.5–7.

To construct the curves, absorbance readings in the range of 400–420 nm were used where the absorption of TTA is quite low and the metal ion complexes have their maximum. The TTA concentration in the single-phase solutions was $3.4 \times 10^{-2}M$. The complexation with TTA in single-phase solutions are very fast, a fact that has already been observed,[8] and specifically in the case of strongly coloured complexes like that of iron, it can be seen visually that as soon as a base is added to an acidic single-phase solution it becomes immediately coloured, the intensity depending, of course, on the amount of metal ion present.

Extraction curves

Extraction curves for the five metals studied are presented in Fig. 4. If we compare these

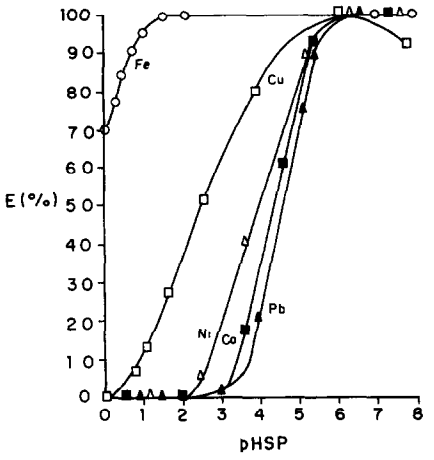

Fig. 4. Extraction curves of Fe, Cu, Ni, Co and Pb. SP solution separated with 80 ml of water at 40°. TTA: $1.72 \times 10^{-2}M$. Metal ions 500 μg each.

curves with the complexation curves, we can see some differences in behavior worth noting. Iron increases its complexation with TTA from pH_{sp} 0 up to pH_{sp} 5–6, while its extraction is already quantitiative at pH_{sp} 1.5. The extraction curve for copper lies between that of iron and those of the other metal ions and has its complexation decreased during the extraction step: its extraction is zero at pH_{sp} zero, while its absorbance at this pH_{sp} values is already more than 0.05. Around pH_{sp} 6, all metals are quantitatively extracted.

The behavior of these metals relative to MIBK and TTA, in the conventional, two-phase solvent extraction[12] and in the single-phase technique is similar: the order of extraction is about the same, Fe–Cu then Ni–Co and then Pb (in the conventional technique the pH of 50% extraction for each is respectively: 1.7–1.6, 3.3–3.8 and 4.0). The only important difference is that in single-phase extraction, the curve of Fe is quite far from that of Cu and also from those of Ni–Co, while in the conventional extraction they are much closer, those of Fe and Cu being almost superimposed.

Extractions

Successive extractions. After the initial single-phase extraction, the volume of the aqueous phase is very large (the phases were separated with 80 ml of water) so it would be time consuming to make a second extraction of the aqueous phase since one should reduce its volume to 2 ml again. Nevertheless, it is simple and in some cases advantageous to extract the organic phase again. If we add 7.5 ml of ethanol plus 2 ml of water, to this organic phase, and adjust the pH_{sp} to the same value as before, we have regenerated the single-phase solution. This new single-phase solution contains the metals extracted in the first organic layer, but now the metals are again dispersed in the single-phase solution, so that if we again perform a phase separation, it is proper to call it "a second single-phase extraction from the organic phase". This regeneration may be executed several times, as indicated in Fig. 5.

Performance of the successive extractions. If a metal A is highly extracted and another B poorly extracted, the application of the successive extractions on the organic phase will lead to purification of A from B. It was important to know whether these subsequent extractions, following a quantitative extraction, would still be quantitative. We have used Ni as a test, at a pH_{sp} of 6, and it was extracted consecutively four times, giving a total recovery of more than

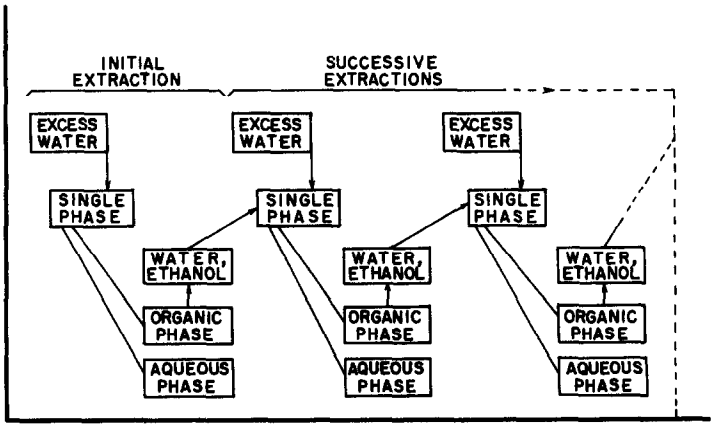

Fig. 5. Block diagram showing the procedure to perform the successive single-phase extractions from the organic phase.

Table 1. Single-phase extraction of metal ions as a function of the TTA concentration. Amount: 500 μg each

Acidity (pH_{sp})	TTA, M ($\times 10^3$)	E%				
		Fe	Co	Ni	Cu	Pb
1.5	34.5	>99	0.0	0.0	32	0.0
	17.2	>99	0.0	0.0	16	0.0
	3.45	>44	0.0	0.0	0.0	0.0
6.4	34.5	>99	>99	>99	>99	>99
	17.2	>99	>99	>99	>99	>99
	3.45	86	51	82	95	18

99.8%. This result justifies the use of the successive extractions from the organic phase in order to promote metal ion separations.

Extractions varying the TTA concentration. At pH_{sp} 6.4 and for TTA concentrations of 3.45×10^{-2} (I) and $1.72 \times 10^{-2}M$ (II) in the single-phase solution, all the studied metals are quantitatively extracted; the extraction being reduced only when the TTA concentration is ten times smaller (III) than I (Table 1).

When the pH_{sp} is lowered to 1.5, only iron continues to show quantitative results for TTA concentrations I and II and the extraction of the other metals is near zero, with the exception of copper which presents and intermediate extraction (16–32%); for the lowest TTA concentration, even iron is not quantitatively extracted (44%).

These results are confirmed when use is made of the cocktail solution employing TTA concentrations I and II; at pH_{sp} 1.5, iron is completely extracted, copper only partially (16–32%) and the other metals are not extracted, while at pH_{sp} 6.4, the extraction is quantitative for all metals.

Therefore, for Co(II), Ni(II) and Pb(II) in the range of a few hundred micrograms, Fe(III) is completely separated with just one single-phase extraction. Cu(II) can also be separated from Fe(III) if a series of four successive single-phase extractions from the organic phase is done after the initial one, its amount then being reduced to 0.2%.

Table 2. Separation of iron from a thousand-fold excess of Co, Ni or Pb with TTA by single-phase extractions (initial extraction followed by three more extractions from the organic phase). Fe: 100 μg. Co, Ni and Pb 100 mg each. TTA: $1.72 \times 10^{-2}M$. pH_{sp}: 2.1

Pair	E%			
	Fe	Co	Ni	Pb
Fe/Co	>99	<0.01	—	—
Fe/Ni	>99	—	<0.01	—
Fe/Pb	>99	—	—	<0.02

Separation of iron from large amounts of cobalt, nickel and lead. Table 2 shows the results for single-phase extractions of the pairs Fe/Co, Fe/Ni and Fe/Pb. They were made by taking 100 μg of Fe(III) and a thousand-fold excess (100 mg) of the other metals with a TTA concentration of $1.72 \times 10^{-2}M$ and a pH_{sp} value of 2.1. The initial single-phase extraction was followed by three additional successive single-phase extractions from the organic phase; the percent extraction of iron amounted to 99% while those of cobalt and nickel dropped to less than 0.01%, and that of lead to 0.02%.

CONCLUSION

One disadvantage of the method is that the single-phase solutions do not allow us to deal with concentrated solutions of any salt and that some species such as sulfates, phosphates and EDTA have a reduced solubility.

As to the applications, many colorimetric methods for the determination of iron call for a very reduced amount of Co and Ni as contaminants[13] and the single-phase technique could be used with advantage in such cases. The method is quite simple and fast. On the other hand, when extractions are done at high pH_{sp} values (around 6) it is possible to pass all the five studied metals to the MIBK phase, which may be interesting in the case where we want to extract a group of metal ions together. Studies are under way to verify how many other metal ions could be extracted together at this same pH_{sp}, and then to re-extract them selectively.

(*Received* 20 *January* 1992. *Revised* 23 *March* 1992. *Accepted* 3 *April* 1992)

Summary—We developed three analytical methods for the determination of carbohydrazide at different concentration levels. One involves the volumetric titration of the analyte with bromate ion and dead-stop end-point detection, and is applicable to concentrations above 10 mg/l., so it can be used for standardizing carbohydrazide solutions. A second, spectrophotometric method is based on the reduction of Fe(III) and measurement of the absorbance of the Fe(II)–ferrozine complex, and features an applicability range of 25–700 μg/l. carbohydrazide. The third method uses differential pulse polarography and the oxidation of carbohydrazide in a basic medium at a dropping mercury electrode to determine the analyte. This last method is the most sensitive of the three and also that offering the widest determination range: from 4 to 3000 μg/l. carbohydrazide.

Carbohydrazide is a hydrazine derivative that frequently replaces hydrazine as oxygen scavenger for all types of boiler. Its reaction with oxygen is similar to that of hydrazine, though somewhat more complex; in fact, the numerous intermediate steps involved in the deoxygenation of carbohydrazide result in higher reactivity and improved metal passivation. Unlike hydrazine, which is a suspected carcinogen, carbohydrazide is not toxic.

A literature scan revealed no analytical reports on carbohydrazide itself, and only a few papers on hydrazine providing some analytical information on carbohydrazide among a few derivatives of the parent compound.[1–4] There was thus an obvious need for methods allowing the determination of carbohydrazide not only at the high concentrations typically found in steam generation systems, but also at the lower concentrations encountered in boilers.[5,6]

In this work we determined carbohydrazide at different concentration levels by a titrimetric, a spectrophotometric and a differential pulse polarographic (DPP) method. The titrimetric method relies on the oxidation of the analyte by BrO_3^- with dead-stop end-point detection.[7] While using a coloured dye would seem appropriate, the fact that the analytical reaction is often slower than the indicator reaction in dilute solutions may result in the indicator being decomposed before the equivalence point is reached, thereby introducing a negative error in the determination. The spectrophotometric method is based on the reducing power of carbohyrazide, which yields the coloured complex Fe(II)–ferrozine with clearly higher sensitivity than other chromophores. Finally, the DPP method entails the oxidation of carbohydrazide at a dropping mercury electrode under conditions where the analyte is electroactive.

EXPERIMENTAL

Reagents

The solutions used in this work included the following: 0.1/6*M* potassium bromate, prepared by weighing from commercially available AR grade reagent (As_2O_3 can be used alternatively for standardization by biamperometric titration); 1 g/l. potassium bromide; 50 mg/l. iron (III), prepared by weighing from Merck iron (III) nitrate [$Fe(NO_3)_3 \cdot 9H_2O$]; aqueous 0.3% w/v ferrozine [3-(2-pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4-triazine]; and 1000 mg/l. stock carbohydrazide from Fluka, standardized with Merck AR grade $KBrO_3$.

All other chemicals used were Merck AR grade.

Apparatus

Biamperometric measurements were made with a Radiometer PHM29b pH-meter (polarization voltage 0–700 mV) furnished with a

*Author for correspondence.

Radiometer PP1311 dual platinum electrode. Spectrophotometric measurements were made on a Hewlett-Packard HP8451A diode array spectrophotometer. Finally, all polarographic measurements were made on a Metrohm Polarecord E506 instrument fitted with a VA E663 stand, also from Metrohm.

Procedure

Titrimetric determination. Once the polarization voltage of the pH-meter has been set to 50 mV, to 25 ml of the carbohydrazide solution are added 10 ml of potassium bromide and 4 ml of 6*M* hydrochloric acid, and the mixture is titrated with 0.1/6*M* potassium bromate. The end-point of the titration is signalled by a potential jump from 50 to *ca.* 300 mV. Very dilute carbohydrazide solutions are best titrated by using more dilute potassium bromate and adding 80–90% of the estimated titrant volume required at once and then continuing to add it more gradually in the vicinity of the equivalence point.

Spectrophotometric determination

A volume of 15 ml of the carbohydrazide stock solution, 2 ml of ferrozine and 2 ml of the Fe(III) solution are mixed and the pH of the mixture is adjusted to 1.6–1.9 with diluted sulphuric acid. Then, the mixture is heated in a water bath at 80–90° for 10 min and allowed to cool to room temperature, after which the pH is adjusted to 3.2 with sodium acetate and the mixture is finally transferred into a 25-ml standard flask. The absorbance of the mixed solution is measured at 562 nm against a blank containing all of the mixture ingredients except carbohydrazide.

The pertinent calibration graph is constructed by using carbohydrazide standards of known concentration.

Polarographic determination

The polarographic determination of hydrazide is carried out with an Ag/AgCl/KCl (3*M*) reference electrode and a platinum auxiliary electrode by using a drop time of 0.8 sec, a scan rate of 1.25 mV/sec and a pulse height of 70 mV.

The recording baseline is obtained by polarographing a solution of 25 ml of distilled water plus 2 ml of 0.5*M* sodium hydroxide between 0.4 and 0.1V after bubbling nitrogen through it for *ca.* 15 min. Then, the carbohydrazide solution is deoxygenated by passing N_2 for 5 min and the corresponding polarogram is recorded. A calibration graph is finally constructed by plotting the peak height against the concentration.

RESULTS AND DISCUSSION

Titrimetric determination

The chemical reactions involved in the redox titrimetric determination of carbohydrazide with bromate are as follows:

$$CO(NHNH_2)_2 + H_2O - 8e^- \rightleftarrows CO_2 + 2N_2 + 8H^+ \quad (1)$$

$$BrO_3^- + 6H^+ + 6e^- \rightleftarrows Br^- + 3H_2O \quad (2)$$

$$2Br^- - 2e^- \rightleftarrows Br_2 \quad (3)$$

Half-reactions (1) and (2) represent the titration process, while (3) corresponds to the end-point detection by the dead-stop end-point technique.

The process is quite slow for dilute carbohydrazide solutions, but can be expedited by initially adding 80–90% of the estimated titrant volume required and then continuing to add it dropwise at 20-sec intervals in the vicinity of the end-point.

The lower limit of determination of this method is 10 mg/l. carbohydrazide.

Table 1 lists the percent recoveries obtained in the titration of different analyte concentrations by using various titrant concentrations. As a rule, the method results in errors less than 2% for samples with concentrations of *ca.* 10 mg/l. As can be inferred from Table 1, the titrant solution should be very dilute—otherwise, the end-point is detected before the equivalence point and a negative error is introduced in the results. The influence of the titrant concentration decreases with increasing carbohydrazide concentration. Thus, recoveries from 25 mg/l. solutions of carbohydrazide are quite good whether 0.025/6 or 0.10/6*M* titrant is used.

Spectrophotometric determination

We optimized the conditions for the colorimetric determination of carbohydrazide by using

Table 1. Percent carbohydrazide recoveries obtained under different titration conditions

$[CO(NHNH_2)_2]$ *mg/l.*	$[KBrO_3]$ $M \times 6$	Number of titrations	Recovery %
100	0.1	6	100.7 ± 1.6
25	0.1	5	101.1 ± 2.2
25	0.025	9	98.2 ± 2.3
10	0.1	6	95.7 ± 4.2
10	0.025	4	98.9 ± 2.0

the univariate method to study the influence of the Fe(III) and ferrozine concentrations, temperature, reaction time and pH. The Fe(III) concentration was found not to alter the results provided the ion was in excess over carbohydrazide. We thus used Fe(III) solutions 100 times more concentrated than those of carbohydrazide and ferrozine solutions in 10-fold excesses over those of Fe(III). Beyond these concentrations the blank signal was too tall for practical purposes.

The temperature was found to have a marked effect on the reaction rate. We chose 80–90° as a compromise.

Under the above conditions, the reaction time had no appreciable effect after 5 min, so we chose 10 min as optimal.

Finally, the optimum pH for the reduction of Fe(III) was found to be 1.6–2.0. Since the maximum sensitivity to the complex was obtained at pH 3.2,[8] the pH of the medium was adjusted to this value with sodium acetate immediately after ferric ion was reduced.

The calibration graph obtained by plotting the absorbance at 562 nm of various carbohydrazide standards against their concentration conformed to the following equation

$$A = -0.0017(\pm 0.0049) + 6.08(\pm 0.13) \times 10^4 C$$

$$(r = 0.99993)$$

where C is expressed in M. Beer's law was obeyed over the range 25–700 μg/l. and the detection limit achieved was 10.7 μg/l.

We determined the molar absorptivity of the Fe(II)-ferrozine complex from the calibration curve obtained by reducing Fe(III) with hydroxylamine,[8] which was found to be $3.2(\pm 0.6) \times 10^4$ l.mol^{-1} cm^{-1}. Therefore, on the basis of reaction (1) as theoretical reference for the oxidation of carbohydrazide, the yield achieved was 24%. Improving the yield beyond this limit could only be accomplished at the expense of increased blank absorbance and hence of a higher the detection limit.

Polarographic determination

We carried out a preliminary study of the electroactivity of carbohydrazide at a dropping mercury electrode by recording a single oxidation wave in an alkaline medium. We used the differential pulse technique in order to ensure a high sensitivity. This provided two polarographic peaks at −0.304 and −0.230 V (Fig. 1). Only the height of the former was proportional to the analyte concentration at subtrace levels, so this peak was chosen for quantitation purposes.

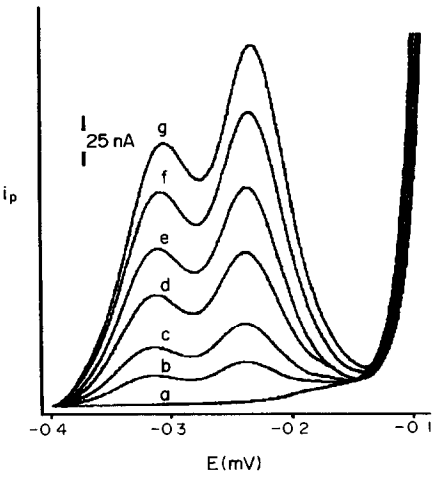

Fig. 1. Differential pulse polarograms of blank (a), 0.36 (b), 0.69 (c), 1.29 (d), 1.82 (e), 2.50 (f) and 3.08 (g) mg/l. solutions of carbohydrazide. Recording sensitivity = 2.50 nA/cm.

Figures 1 and 2 show the polarographic recordings obtained at various instrumental sensitivities from a series of calibration samples containing different amounts of carbohydrazide.

We studied the influence of the sodium hydroxide concentration and various instrumental parameters on the peak height. As far

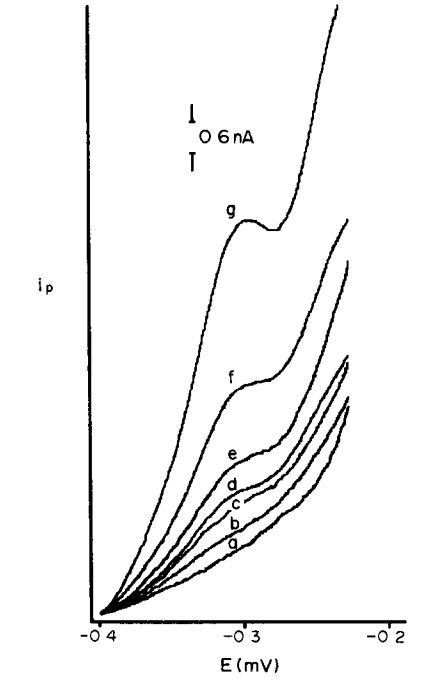

Fig. 2. Differential pulse polarograms of blank (a), 3.57 (b), 6.90 (c), 10.00 (d), 12.90 (e), 25.00 (f) and 51.35 (g) μg/l. solutions of carbohydrazide. Recording sensitivity = 0.06 nA/cm.

Table 2. Figures of merit of the polarographic calibration curves

Recording senstivity (nA/cm)	Concentration range (μg/l)	Regression equation $I_p = a + bC$ (I_p, nA; C, μg/l)	Regression coefficient	Regression standard deviation, $S_{y/x}$
0.06	3.6–51.4	$I_p = -0.075(\pm 0.174) + 0.120(\pm 0.007)C$	0.9993	0.09
0.10	37.2–82.0	$I_p = 0.048(\pm 1.096) + 0.110(\pm 0.018)C$	0.9998	0.09
0.15	100.0–235.0	$I_p = -0.181(\pm 1.529) + 0.106(\pm 0.009)C$	0.9999	0.11
2.50	360.0–3080	$I_p = -4.268(\pm 4.133) + 0.094(\pm 0.002)C$	0.9999	1.62

as the base concentration is concerned, the peak sensitivity increased with increasing concentration up to a maximum value. The scan rate influenced the baseline features, so the chosen working value was a compromise between smoothness and rapidity. Increasing pulse heights resulted in increased signal sensitivity up to a limit above which the resolving power started to decline. The optimal values of the different variables were given above.

Once the optimal working conditions were established, we ran a calibration graph for carbohydrazide concentrations between a few μg/l. and a few mg/l. Table 2 lists the equations and figures of merit of the four calibration curves obtained from the polarograms of 21 standards containing between 3.6 and 3080 mg/l. carbohydrazide. A random residual distribution was used in every case. The detection limit achieved[9] was 2.2 μg/l. As can be seen, the calibration curves were of a high quality and encompassed a few orders of magnitude in the concentration.

According to the reproducibility results obtained at the subtrace level, recordings made on different days or sensitivity scales resulted in small variations in the calibration curves, so standards and samples should be measured under similar instrumental conditions.

CONCLUSIONS

The results obtained in this work show the titrimetric determination of carbohydrazide with bromate ion and biamperometric end-point detection to be appropriate for the standardization of carbohydrazide solutions.

On the other hand, the proposed indirect spectrophotometric determination of carbohydrazide by reduction of Fe(III) and formation of the Fe(II)–ferrozine complex allows the analyte to be determined over the range 25–700 μg/l. In addition, the method is highly sensitive and provides high-quality calibrations despite the previous reduction involved.

Finally, the differential pulse polarographic method offers excellent features such as a very broad linear response range (between a few μg/l. and a few mg/l. at the recording sensitivities used in this work), which makes it applicable to samples with concentrations varying by up to 3 orders of magnitude or even more if a higher recording sensitivity is employed.

A NOVEL AND HIGHLY SENSITIVE CATALYTIC METHOD WITH OSCILLOPOLAROGRAPHIC DETECTION FOR THE DETERMINATION OF ULTRATRACE AMOUNTS OF IRIDIUM

JIANG ZHI-LIANG

Laboratory of Instrumental Analysis, Department of Chemistry, Guangxi Normal University, Guilin, People's Republic of China

(*Received* 5 *November* 1991. *Revised* 19 *March* 1992. *Accepted* 23 *March* 1992)

Summary—Iridium(IV) has a strong catalytic effect on the slow redox reaction between Malachite Green and periodate ion in pH 4.2 acetate buffer solution at 100°, and Malachite Green exhibits a sensitive single-sweep oscillopolarographic wave at −0.65 V *vs.* SCE. This provides the basis for a novel and highly sensitive and selective catalytic method with oscillopolarographic detection for iridium. The effect of pH, potassium periodate and Malachite Green concentrations, reaction temperature and reaction time and other variables are investigated. The detection limit is 8 ng/l. with a fixed-reaction time of 10 min. A linear calibration graph from 24 to 1600 ng/l. is obtained. Possible interferences by co-existing ions are examined.

Precious metals have many desirable properties, and have been widely applied to modern technological fields.[1] However, their content in the earth's shell is very low. It is important to develop highly sensitive and selective methods for the determination of precious metals.

Because of the stability of iridium compounds, polarographic methods are few and not completely satisfactory.[2,3] Ezerskaya *et al.*[4] have reported a polarographic method for the determination of $1–10 \times 10^{-7}M$ Ir with thiosemicarbazide. A procedure has been suggested for determining $5–50 \times 10^{-8}M$ Ir, based on the complex of Ir(III) with 2-furylmonooxime which exhibits a catalytic polarographic wave.[5] Bao *et al.*[6] have found that Ir(IV) exhibits a sensitive catalytic polarographic wave in a supporting electrolyte of $0.07M$ thiourea–$0.2M$ potassium iodide–$2M$ hydrochloric acid, with a detection limit of $5 \times 10^{-8}M$ Ir.

Catalytic methods for silver,[7] osmium[8,9] and ruthenium[10,11] with oscillopolarographic detection have been proposed. However, a catalytic method for iridium with oscillopolarographic detection does not seem to have been reported to date. To develop such a method, many catalytic reaction systems of Ir(IV)–potassium periodate–organic reagent were tested. The results demonstrate that some of the Ir(IV)–potassium periodate–triphenylmethane dyes and Ir(IV)–potassium periodate–azocompound systems can be utilized. In the present work, we studied the Ir(IV)–potassium periodate–Malachite Green system in detail by single-sweep oscillopolarography. A very sensitive and selective catalytic method with oscillopolarographic detection was developed for Ir, with a detection limit of 8 ng/l. and a determination range of 24–1600 ng/l. by the fixed-reaction time procedure.

EXPERIMENTAL

Apparatus

A model JP-2 single-sweep oscillopolarograph (Chendu Instrumental Factory) was used for the polarographic measurements. The settings on the JP-2 single-sweep oscillopolarograph were: dropping mercury period 7 sec; scanning rate 250 mV/sec; scanning potential range 500 mV in the negative direction; initial scanning potential −400 mV; I_p'' (second derivative weave); and a three-electrode system–DME, SCE, and platinum electrode. A model JY-501B thermostat and a pHS-2 pH meter were used.

Reagents

A standard solution of Ir(IV) (100 μg/ml) was prepared according to the following procedure: weigh out 22.94 mg $(NH_4)_2IrCl_6$ and place in a 250-ml beaker. Add about 20 ml of $5M$ hydrochloric acid solution, heat to dissolve, cool, then transfer to a 100-ml standard flask

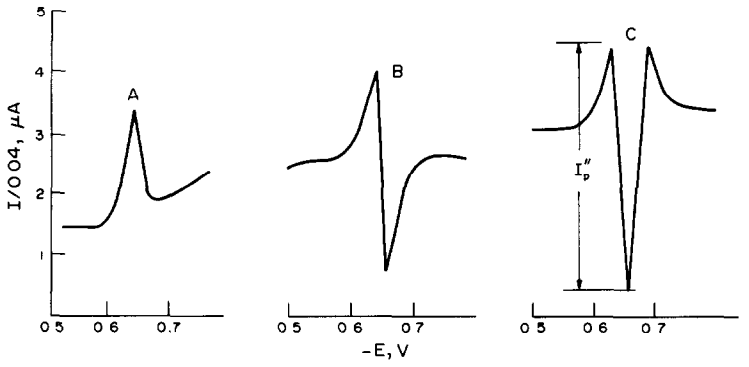

Fig. 1. The single-sweep oscillopolarographic wave of $8.00 \times 10^{-6}M$ Malachite Green in pH 4.2 of acetate buffer solution. A: Normal wave; B: First derivative; C: Second derivative.

and dilute to the mark with doubly distilled water. Prepare working solutions by dilution shortly before use.

A $1.00 \times 10^{-4}M$ Malachite Green solution and a $1.5 \times 10^{-2}M$ potassium periodate solution were prepared by dissolving the reagents in water. A pH 4.2 acetate buffer solution was used.

Procedure

Into a 25-ml graduated test-tube fitted wtih a glass stopper, 1.0 ml of pH 4.2 acetate buffer solution, 2.3 ml of $1.5 \times 10^{-2}M$ potassium periodate and 1.0 ml of $1.00 \times 10^{-4}M$ Malachite Green were added, and the solution was diluted accurately to 10 ml with water, then 2.5 ml of $0.10M$ ascorbic acid solution was added, and mixed well. A portion of the solution was transferred into a polarographic cell and the second derivative peak current $(I''_p)_i$ was measured. This represents current at reaction time zero.

Into a 25-ml graduated test-tube fitted with a glass stopper, 1.0 ml of 5.0 ng/ml Ir(V) solution, 1.0 ml of pH 4.2 buffer solution, 2.3 ml of $1.5 \times 10^{-2}M$ potassium iodate and 1.0 ml of $1.00 \times 10^{-4}M$ Malachite Green were transferred, and the solution was diluted accurately to 10 ml with water, and mixed well. The tube was placed in the boiling water bath (100°), while the stopwatch was started. After 10 min the reaction was quenched by cooling with tap-water, then 2.5 ml of $0.10M$ ascorbic acid solution was added, and mixed well. The second derivative peak current $(I''_p)_{cat}$ was measured. The log $[(I''_p)_i/(I''_p)_{cat}]$ value was obtained. The $(I''_p)_{uncat}$ for the uncatalysed (blank) reaction was measured in a similar manner. And the log$[(I''_p)_i/(I''_p)_{uncat}]$ (that is, blank value) was obtained.

The log $[(I''_p)_{uncat}/(I''_p)_{cat}]$ values for a range of Ir concentrations were plotted as a function of Ir concentration to prepare a calibration graph.

RESULTS AND DISCUSSIONS

The oscillopolarographic behaviour of Malachite Green

The oscillopolarographic behaviour for many organic compounds has been studied.[12] However their applications in inorganic oscillopolarographic analysis are few.[13-15] In the present work, the oscillopolarographic character of Malachite Green was investigated for the application of Malachite Green to the catalytic determination of iridium.

In pH 4.2 acetate buffer solution, Malachite Green exhibits a sensitive single-sweep oscillopolarographic wave at −0.65 V *vs.* SCE. Figure 1 shows the normal wave, first derivative wave and second derivative wave. The second derivative peak current is biggest, and was chosen for use, although at lower concentrations the signal-to-noise ratio will deteriorate. The I''_p is proportional to the Malachite Green concentration between 4×10^{-7} and $4 \times 10^{-5}M$. The electrocapillary curve is lower in the presence of $5.0 \times 10^{-6}M$ Malachite Green than in its absence, owing to adsorption of Malachite Green on the surface of the DME changing the surface tension of the mercury drop. No wave was observed when scanning in the positive direction. The mean temperature coefficient is −0.95%/deg in the range of 20–40°. The I''_p decreases substantially when the surfactants polyvinyl alcohol, cetyltrimethylammonium bromide, Triton X-10, Triton X-100 and sodium dodecyl sulphate are added.

The experiments show that IO_4^- and IO_3^- ions interfere with the oscillopolarographic

measurements of Malachite Green, because both exhibit waves near the Malachite Green wave. To eliminate the interferences, several reduction reagents were considered. The results demonstrate that ascorbic acid can mask the interferences and does not affect the oscillopolarographic measurements of Malachite Green.

Ir(IV)–KIO_4–Malachite Green catalytic reaction system

Many catalytic methods for Ir have been reported.[16] The use of Malachite Green for the catalytic determination of Ir has not been reported. We first found that Ir(IV) catalysed the slow decolourization reaction of Malachite Green and potassium periodate in pH 4.2 acetate buffer solution at 100°. Malachite Green concentration in the reaction system can be measured spectrophotometrically or oscillopolarographically. Our experiments show that oscillopolarography is more sensitive than spectrophotometry. Oscillography was chosen as the detection technique for Malachite Green.

In the catalytic reaction solution, the catalytic and uncatalysed reactions occur simultaneously.

$$IO_4^- + \text{Malachite Green} \xrightarrow[H^+,\ 100^\circ]{\text{Ir(IV) cat., fast}} IO_3^- + \text{Products} \quad (1)$$

$$IO_4^- + \text{Malachite Green} \xrightarrow[H^+,\ 100^\circ]{\text{slow}} IO_3^- + \text{Products} \quad (2)$$

Under the chosen conditions, the periodate concentration is greater than the Malachite Green concentration, and it is presumed that a pseudo first-order reaction (with respect to Malachite Green) occurs. The rate equation of the overall reaction is

$$V_{cat} = -\mathrm{d}[MG]/\mathrm{d}t = k_c[MG][Ir] + k_{un}[MG] \quad (3)$$

or

$$-\mathrm{d}[MG]/[MG] = (k_c[IR] + k_{un})\,\mathrm{d}t. \quad (4)$$

where k_c and k_{un} are the rate constants of the catalytic and uncatalysed reactions, respectively, for use of a fixed concentration of periodate and pH, and MG is Malachite Green. Since

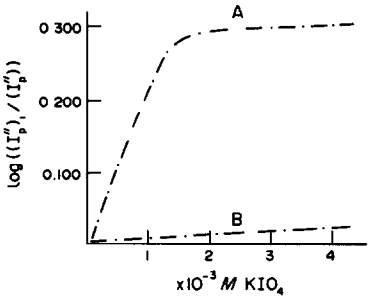

Fig. 2. Effect of KIO_4 concentration on $\log[(I''_p)_i/(I''_p)]$. A: Catalytic reaction (0.4 ng/ml Ir). B: Uncatalysed reaction. For other conditions see the procedure.

$I''_p = k'[MG]$, where k' is a constant, equation (4) may be rewritten as

$$-\mathrm{d}[(I''_p)_{cat}]/(I''_p)_{cat} = (k_c[Ir] + k_{un})\,\mathrm{d}t \quad (5)$$

Integration of equation (5) gives

$$\log[(I''_p)_i/(I''_p)_{cat}] = (k_c[Ir] + k_{un})t \quad (6)$$

where $(I''_p)_i$ and $(I''_p)_{cat}$ are the second derivative peak currents of Malachite Green in the catalytic reaction solution at time 0 and t min, respectively. When [Ir] = 0, only the uncatalysed reaction takes place, and equation (6) has the form

$$\log[(I''_p)_i/(I''_p)_{uncat}] = k_{un} \cdot t \quad (7)$$

where the $(I''_p)_{uncat}$ is the (I''_p) of MG in the uncatalysed reaction solution at time t min. Combining (6) and (7), we obtain

$$\log[(I''_p)_{uncat}/(I''_p)_{cat}] = k_c[Ir]t \quad (8)$$

Equation (8) shows that the logarithmic term is proporational to the Ir concentration, with the other variables held constant for the given system.

*Excess also has catalytic effect on the reaction.

Effects of variables

The effects of the concentrations of periodate and Malachite Green, pH, reaction temperature and time on $\log[(I''_p)_i/(I''_p)_{cat}]$ and $\log[(I''_p)_i/(I''_p)_{uncat}]$ were studied. In general the effect of each factor leads to higher $\log[(I''_p)_i/(I''_p)_{cat}]$ and lower $\log[(I''_p)_i/(I''_p)_{uncat}]$ which is to be recommended.

The reaction media tested were sulphuric acid, hydrochloric acid, perchloric acid and acetate buffer solution. The results show that pH 4.2 acetate buffer solution gives a bigger $\log[(I''_p)_i/(I''_p)_{cat}]$ value and a lower blank value than the others and was selected for use.

The effect of variation of the potassium periodate concentration on the logarithmic terms is shown in Fig. 2. The $\log[(I''_p)_i/(I''_p)_{uncat}]$ increases slowly with potassium periodate concentration; but that of the $\log[(I''_p)_i/(I''_p)_{cat}]$ increases substantially with potassium periodate concentration (less than $0.0013M$), and the logarithmic value reaches a limiting value not affected by potassium periodate concentration (more than about $1.5 \times 10^{-3}M$). A concentration of $2.76 \times 10^{-3}M$ potassium periodate, which gave the largest $\log[(I''_p)_i/(I''_p)_{cat}]$ value was chosen for use.

Figure 3 shows the relationship of the logarithmic terms and the Malachite Green concentration (i.e., the indicator species). The $\log[(I''_p)_i/(I''_p)_{cat}]$ decreases as the Malachite Green concentration increases as does the $\log[(I''_p)_i/(I''_p)_{uncat}]$ value for concentrations less than $6.4 \times 10^{-6}M$. A Malachite Green concentration of $8.00 \times 10^{-6}M$, which gives a lower blank, was chosen.

The relationship of logarithmic terms and reaction temperature is shown in Fig. 4. The $\log[(I''_p)_i/(I''_p)_{cat}]$ increases substantially with the reaction temperature, and the blank value increases slowly with the temperature. A temperature of 100°, which gives a higher sensitivity, was chosen. A fixed-reaction time of 10 min was selected for use, giving a good compromise between high sensitivity and short analysis time.

Effect of foreign ions

The influence of 31 foreign ions on the catalytic determination of 0.40 ng/ml Ir was examined. The results are summarized in Table 1. The tolerance limit is that giving not more than ±5% error. Most common ions do not interfere with the catalytic determination of Ir. The precious metal ions Rh(III) and Ru(III) also have catalytic effects on the redox reaction when exeeding their tolerence limits 4 and 20 times, respectively. Table 1 indicates that this catalytic method for iridium has good selectivity.

Calibration graph

The fixed-reaction time procedure under optimal experimental conditions gave a calibration

Table 2. Analysis of Ir in synthetic samples

Composition, μg/ml	Ir found, ng/ml	Mean value, ng/ml	RSD, %	Relative error, %
$0.001Ir^{4+}$–$1Pd^{2+}$–	0.960 0.960			
$1Pt^{4+}$–$0.5Au^{3+}$–	0.890 1.00	0.997	3.68	−0.30
$0.2Ag^-$–$0.1Os^{4+}$	1.04 1.04			
$0.001Ir^{4+}$–$1Fe^{3+}$–	1.00 1.00	1.02	1.52	+2.0
$0.5Cr^{6+}$–$0.5Hg^{2+}$–	1.02 1.02			
$0.2Ni^{2+}$–$5Si^{4+}$	1.02 1.04			

graph that was linear for iridium concentrations from 24 to 16000 ng/l. The relative standard deviation (RSD) of the $(I''_p)_{uncat}$ is 0.53%. The RSD of the method for 0.40 ng/ml and 0.80 ng/ml Ir was 3.6% and 2.4% (10 replication), respectively. The detection limit is 8 ng/l. The method is the most sensitive oscillopolarographic method for Ir and the most sensitive catalytic method at present.[2-6,16-18]

Analysis of synthetic sample

The method was directly applied to analysis of synthetic samples, with various mixtures of ions and good results were obtained (see Table 2).

(*Received* 26 *September* 1991. *Revised* 27 *March* 1992. *Accepted* 27 *March* 1992)

Summary—A spectrophotometric method for the determination of the intact clorazepate dipotassium in the presence of its degradation products is developed. It depends upon preliminary hydrolysis of clorazepate dipotassium—thus liberating its equivalent of *N*-desmethyldiazepam which is extracted, with benzene–methylene chloride (9:1). The extract is evaporated, the residue dissolved in methanol and its absorbance measured at about 315 nm. The procedure determines 0.4–1.6 mg of clorazepate dipotassium with an accuracy of $100.2 \pm 0.7\%$. The procedure is applied successfully for the determination of clorazepate dipotassium in bulk powder and in capsules; retaining its accuracy in the presence of up to 80% degradation. Determination of the different degradation products is also possible. Thus, *N*-desmethyl diazepam is determined after preliminary extraction with benzene–methylene chloride mixture, followed by TLC separation, 2-amino-5-chlorobenzophenone by directly applying the first derivative spectrophotometric technique, and glycine in the aqueous layer determined colorimetrically with ninhydrin reagent in the presence of pyridine.

Clorazepate dipotassium, 7-chloro-1,3-dihydro-2-oxo-5-phenyl-1H-1,4-benzodiazepine-3-carboxylic acid, dipotassium salt, degrades to *N*-desmethyldiazepam below pH 4 but is relatively stable at pH 7.4 and above.[1]

Several methods have been reported for the determination of clorazepate dipotassium, including fluorimetric,[2] colorimetric,[3] polarographic,[4] GLC,[5] TLC[6] and high performance liquid chromatographic procedures.[7]

The purpose of the present investigation is to develop a simple spectrophotometric method for the determination of only the intact clorazepate dipotassium in bulk powder and pharmaceutical preparations.

EXPERIMENTAL

Apparatus

The following apparatus was used: a UV/Vis spectrophotometer (Shimadzu UV-120); a Du.7 spectrophotometer Beckman; a UV short wavelength lamp (254 nm) and TLC plates (20 × 20 cm with 0.25 mm thickness silica gel GF 254, E Merck).

Reagents

All chemicals are of analytical grade. Clorazepate dipotassium, working standard was kindly supplied by the Nile pharmaceutical Co, Cairo, Egypt, and *N*-desmethyldiazepam, working standard, was kindly supplied by Arab Drug Co., Cairo, Egypt.

Other reagents used were: 2-amino-5-chlorobenzophenone (Aldrich); glycine (B.D.H.); dilute hydrochloric acid, about 2*N* aqueous solution; dilute sodium hydroxide, about 4*N* aqueous solution; benzene (A.R., Prolabo); methylene chloride (A.R., Prolabo); benzene–methylene chloride mixture (9:1); spectroscopic grade methanol (E. Merck); development system; heptane–chloroform–ethanol (50:50:5); citric acid–citrate buffer, pH 5;[8] ninhydrin–citrate reagent; 5% solution in citric acid–citrate buffer, pH 5; and pyridine; C.P. (E. Merck).

Procedure

Determination of clorazepate dipotassium via its quantitative degradation to N-desmethyldiazepam. Bulk Powder. Weigh, accurately, about 20–80 mg of clorazepate dipotassium, dissolve in 10 ml of water, add about 25 ml of dilute hydrochloric acid solution and leave each

*National Organization of Drug Control and Research.

at room temperature (18–22°) for 30–45 min. At the end of this interval, make alkaline with dilute sodium hydroxide solution, cool and extract with 3 × 20 ml portions of benzene–methylene chloride (9:1). Evaporate the combined extracts just to dryness, dissolve the residue in 20 ml of methanol, transfer into a 50-ml standard flask and complete to volume with methanol.

Transfer 1 ml of this solution, into a 10-ml standard flask, complete to the mark with methanol, and measure the absorbance at 315 nm against a blank prepared as for the test solution but without previous hydrolysis. This can be achieved by adding the same volume of dilute hydrochloric acid and dilute sodium hydroxide solutions together to the sample solution and completing as under "Bulk Powder", beginning with the words " . . . Cool and extract with 3 × 20-ml portions of benzene–methylene chloride (9:1) . . . ".

Calculate the concentration of clorazepate dipotassium in the sample from a calibration curve simultaneously prepared or from the A (1%, 1 cm) calculated to be 54.29 or from the following regression equation: $Y = 0.54x + 0.004$, $r = 0.998$ where Y is absorbance, X is concentration of the final solution in mg and r is the correlation coefficient.

Capsules. Evacuate the contents of 20 capsules, mix thoroughly, weigh, and calculate the average weight in each capsule. Transfer an accurate weight of the mixed sample, equivalent to about 20–80 mg of clorazepate dipotassium, shake with 10 ml of water, filter through a filter paper, add 25 ml of dilute hydrochloric acid solution to the filtrate and proceed as mentioned under Bulk Powder above, starting with the words " . . . allow to stand at room temperature for 30–45 min . . . ".

Determination of clorazepate dipotassium and its degradation products in laboratory prepared mixtures. Intact clorazepate dipotassium. Proceed as for Bulk Powder.

Degradation products. Weigh accurately about 20–80 mg of clorazepate dipotassium, dissolve in 10 ml of water and extract with 3 × 20-ml portions of benzene–methylene chloride (9:1). Combine the organic extracts together for the determination of *N*-desmethyldiazepam and 2-amino-5-chlorobenzophenone, and keep the aqueous layer for the determination of glycine.

Evaporate the combined organic extracts just to dryness and dissolve the residue in about 5 ml of methanol. Transfer, quantitatively, into a 10-ml standard flask, complete to volume with methanol and mix well (solution A). For *N*-desmethyldiazepam apply a band of 0.2 ml of the methanolic solution (above) onto a starting line on the silica gel glass plate and simultaneously apply on the same plate a parallel spot of a reference *N*-desmethyldiazepam methanolic solution. Develop with the developing solvent and mark the band corresponding to the spot of *N*-desmethyldiazepam under UV light (254 nm). Scratch, then extract, the band with 3 × 3 ml of methanol, passing the extracts through a filter paper moistened with methanol into a 10-ml standard flask and complete to volume with methanol. Measure the absorbance at 315 nm against a blank prepared by extraction of an area of silica gel equivalent to the sample spot. Calculate the concentration of the sample from a calibration curve simultaneously prepared from 0.2–1.2 mg of *N*-desmethyldiazepam, or from the *A* (1%, 1 cm) which amounts to 75.42, or from the following regression equation: $Y = 0.75x + 0.005$, $r = 1$.

For 2-amino-5-chlorobenzophenone transfer 5 ml of the methanolic solution A into a 25-ml standard flask and complete to volume with methanol. Introduce 1 ml of this solution into a 10-ml standard flask, complete to volume with methanol and record the corresponding first derivative curve against methanol as a blank. Measure the absolute trough amplitude at 362 nm as shown in Fig. 1. Calculate the concentration of the sample from a previously constructed curve using an authentic sample of 2-amino-5-chlorobenzophenone, or from the following regression equation $Y = 63.57x + 0.64$, $r = 0.999$, where Y is height in mm, X is concentration and r is correlation coefficient.

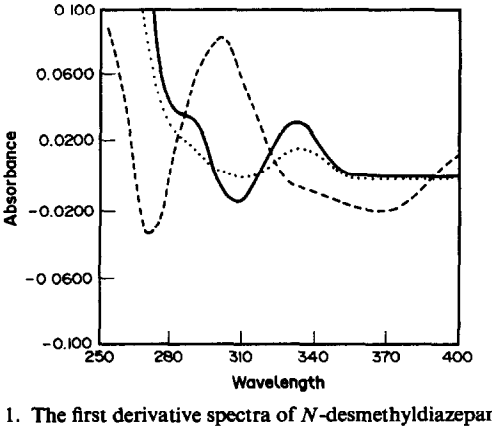

Fig. 1. The first derivative spectra of *N*-desmethyldiazepam (———), 2-mino-5-chlorobenzophene (– – –), and clorazepate dipotassium (· · ·), 0.15 mg/10 ml.

For determination of glycine[9] transfer the aqueous layer quantitatively into a 100-ml standard flask and complete to volume with citric acid–citrate buffer of pH 5 ± 0.2. Introduce 1 ml of the diluted solution into a 25-ml standard flask, add 4–4.5 ml of citrate buffer, 1 ml of ninhydrin reagent, 1 ml of pyridine and heat in a boiling water bath for 15–20 min. Complete to volume with water and measure the absorbance at 560 nm against a blank prepared simultaneously using 5 ml of citrate buffer. Calculate the concentration of glycine from a standard calibration curve, or from the A (1%, 1 cm) which was calculated to be 959.9 or from the following regression equation: $Y = 3.5x + 0.05$, $r = 0.959$ for glycine.

RESULTS AND DISCUSSION

Although clorazepate dipotassium is stable in alkaline medium, it is readily hydrolysed in acid medium. Upon standing at room temperature for half an hour in 2*N* hydrochloric acid it is completely degraded to *N*-desmethyldiazepam.[4] Under more drastic conditions, *i.e.*, heating with 6*N* hydrochloric acid at 100° for one hour, it is completely degraded yielding 2-amino-5-chlorobenzophenone and glycine.[10]

The proposed procedure depends upon the determination of clorazepate dipotassium via its degradation products, namely, *N*-desmethyldiazepam after hydrolysis with 2*N* hydrochloric acid for 30–45 min at room temperature (18–22°). The optimum conditions for quantitative hydrolysis of clorazepate dipotassium to *N*-desmethyldiazepam were studied and confirmed by TLC using silica gel glass plate GF 254 and heptane–chloroform–ethanol (50:50:5) as developing system, when only one spot corresponding to the *N*-desmethyldiazepam was detected under U.V. However, longer standing even at room temperature extends hydrolysis further to 2-amino-5-chlorobenzophenone and glycine; this has been evidenced by the formation of a precipitate of the benzophenone derivatives upon rendering the solution alkaline with 4*N* sodium hydroxide.

After hydrolysis, the solution was extracted with a mixture of benzene–methylene chloride (9:1), which extracted, not only the quantitatively produced *N*-desmethyldiazepam, but also any 2-amino-5-chlorobenzophenone and *N*-desmethyldiazepam, originally presented as degradation products. The absorption spectrum of an authentic sample of *N*-desmethyldiazepam was found to possess a maximum at about 315 nm as shown in Fig. 2. On the other hand, it overlaps with the spectral curves of 2-amino-5-chlorobenzophenone and clorazepate dipotassium (Fig. 2). Thus, to overcome interferences due to overlapping, a blank was done by extracting a similar amount of clorazepate dipotassium, with benzene–methylene chloride mixture, without preliminary hydrolysis. This would extract any *N*-desmethyldiazepam and 2-amino-5-chlorobenzophenone originally present as degradation products and would eliminate their interferences, it is only the *N*-desmethyldiazepam produced from the hydrolysis of the intact clorazepate dipotassium that is determined.

Different concentrations of an authentic sample of clorazepate dipotassium were analysed by the proposed procedure and the linear concentration–absorbance relationship is obtained.

To assess the efficiency of the proposed procedure, the degradation products, *N*-desmethyldiazepam, 2-amino-5-chlorobenzophenone and glycine were mixed with an authentic sample of clorazepate dipotassium in different ratios and analysed by the proposed procedures. It is obvious from the results in Table 1 that the presence of up to 80% degradation products does not affect the accuracy of the proposed procedure, while the reported procedure[11] gives much higher results.

Pharmacologically speaking, clorazepate dipotassium is the precursor of *N*-desmethyldiazepam; the latter being produced *in vivo* from the former[12] and is equally active. Yet, pharmaceutically speaking, formulation of partially degraded clorazepate dipotassium in a

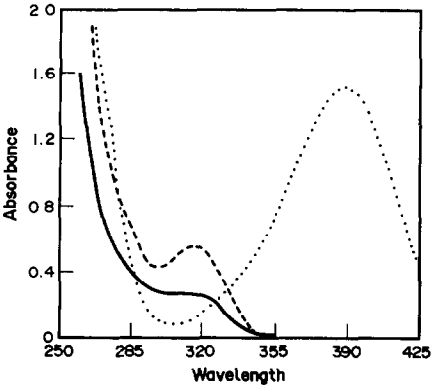

Fig. 2. Absorption spectra of clorazepate dipotassium (———), *N*-desmethyldiazepam (– – –), and 2-amino-5-chlorobenzophenone (· · ·), 6 mg/100 ml.

Table 1. Determination of mixtures of authentic samples and acid degradation products* by the proposed procedures and compendial method[11]

Mixtures, No.	Clorazeptate dipotassium Proposed procedure Found, %	Clorazeptate dipotassium Compendial method Found, %	*N*-Desmethyldiazepam Found, %	2-Amino-5-chloro-benzophenone Found, %	Glycine Found, %

*Five mixtures were prepared containing clorazepate dipotassium, *N*-desmethyldiazepam, 2-amino-5-chlorobenzophenone and glycine respectively:

1) 20:30:25:25
2) 30:25:30:15
3) 40:20:20:20
4) 50:15:15:20
5) 80:10: 5: 5

pharmaceutical preparation would result in an increase of the dose concentration; the molecular weight of clorazepate dipotassium being 408.9 and that of *N*-desmethyldiazepam being 270.7. On the other hand, a clorazepate stability-indicating method without simultaneous determination of its pharmacologically-active first degradation product *N*-desmethyldiazepam, would be inadequate. The presence of an undetermined amount of *N*-desmethyldiazepam would result in an overdose.

The proposed procedure was applied to determine the concentration of clorazepate dipotassium in its capsules and the results obtained are shown in Table 2. The accuracy of the procedure was assured by applying the standard addition technique. The results are shown in Table 2.

By applying the proposed procedure it is also possible to determine the different degradation products expected to be present with clorazepate dipotassium. *N*-desmethyldiazepam and amino-chlorobenzophenone were extracted from the aqueous solution of clorazepate dipotassium with benzene–methylene chloride mixture before hydrolysis. Due to the significant overlapping of the absorption spectra of *N*-desmethyldiazepam and aminochlorobenzo it

			C.V	±0.4%

was only possible to determine 2-amino-5-chlorobenzo-phenone in the presence of *N*-desmethyldiazepam by first derivative spectrophotometry (but not the reverse) as shown in Fig. 1. A linear relationship was found between the concentration of amino chlorobenzophenone and the trough amplitude over the range 0.1–0.7 mg/10 ml.

In order to determine *N*-desmethyldiazepam in the presence of 2-amino-5-chlorobenzophenone, it was inevitable to separate *N*-desmethyldiazepam by TLC before its determination.

Glycine, in the aqueous layer, was determined colorimetrically[9] by using ninhydrin in the presence of pyridine which has been found to accelerate the production of colour and stabilizes it for a longer period. The procedure was found to be applicable to the range 0.027–0.275 mg with an average accuracy of $99.9 \pm 0.3\%$.

The suggested procedures for the determination of degradation products were applied in the range 0.2–1.2 mg of *N*-desmethyldiazepam, with an average accuracy of $99.8 \pm 0.7\%$, and from 0.1–0.7 mg of 2-amino-5-chlorobenzophenone with an average accuracy of $100.2 \pm 0.2\%$.

Comparing the results of the proposed procedure with the compendial method,[11] it was found that the suggested procedure is more selective, since the nonaqueous procedure does not differentiate between the intact molecule and its degradation products.

(*Received* 2 *January* 1992. *Revised* 16 *March* 1992. *Accepted* 27 *March* 1992)

Summary—The construction of liquid membrane and PVC matrix-type cocainium ion selective electrodes and their use for direct potentiometry and potentiometric titration of cocaine are described. The ion-pair complexes of cocaine cation with reineckate and tetraphenylborate anions are either dissolved in nitrobenzene solvent or dispersed in a PVC matrix, with DOP or DBS plasticizer, and used as the ion-exchange membranes. The electrochemical response characteristics of electrodes incorporating these types of membranes are evaluated with regard to the effect of pH, foreign basic compounds, temperature and γ-radiation. The electrodes display a stable fast Nernstian response for 10^{-2}–$10^{-5}M$ cocainium cation over the pH range 3–7, the lower limit of detection being 1 μg/ml. Determination of as low as 20 μg/ml cocaine hydrochloride shows an average recovery of 98% and a mean standard deviation of $\pm$0.6%. The electrodes exhibit useful analytical characteristics for determining cocaine in some illicit powders. The results agree fairly well with those obtained by gas–liquid chromatography.

There has been an increasing world-wide availability and abuse of cocaine in recent years. This necessitates the development of suitable methods for determining cocaine in samples which are seized. The British and United States Pharmacopoeias give an assay method for cocaine hydrochloride based on the repeated extraction of cocaine base from an alkaline solution and subsequent non-aqueous titration.[1,2] This method besides being tedious, suffers from severe interference by various organic bases. Other techniques used for determining cocaine include polarimetry,[3] circular dichroism,[4] fluorescence polarization immunoassay,[5] nuclear magnetic resonance,[6] Fourier-transform infrared spectrometry,[7] gas–liquid chromatography,[8,9] gas chromatography–mass spectrometry,[10] high performance thin layer chromatography,[11] high pressure liquid chromatography,[12] and enzyme and radio immunoassays.[13] Many of these methods, however, require several time-consuming manipulation steps, sophisticated instruments and special training.

Ion selective membrane electrodes have been extensively used for monitoring various pharmaceutical preparations[14,15] and offer prospects for the determination of some illicit drugs.[16,17] However, little is known about the use of these sensors for determining cocaine. Potentiometric titrations of cocaine hydrochloride with silver(I),[18] picrate,[19] and tetraphenylborate[20] (TPB) ions have been described using chloride, picrate, and tetraphenylborate membrane electrodes, respectively. The methods are not selective for cocaine because the halides of various amines are similarly titrated. A coated wire membrane electrode for direct determination of cocaine based on the use of cocaine–dinonylnapthalene sulphonate ion-pair complex in poly (vinyl chloride) matrix has been suggested.[21] Selectivity data for this sensor have been evaluated for only three basic compounds and determination of cocaine in complex mixtures or illicit powders has not been tested.

The present work describes simple potentiometric sensors for the determination of cocaine in illicit powders. Electrodes with reineckate and tetraphenylborate ion pair complexes in liquid and poly (vinyl chloride) membranes have been prepared, characterized, compared and examined for determining cocaine. These electrodes display stable fast and linear response for 10^{-2}–$10^{-5}M$ cocaine hydrochloride over the pH

*Author for correspondence.

range 3–7 with minimum interference from many related basic compounds.

EXPERIMENTAL

Reagents

All the chemicals were of analytical reagent grade and doubly distilled water was used throughout. Sodium tetraphenylborate (NaTPB) and ammonium reineckate were obtained from Sigma (St. Louis, MO, U.S.A.). Poly (vinyl chloride) (PVC), dioctylphthalate (DOP), dibutyl sebacate (DBS) and tetrahydrofuran (THF) were obtained from Aldrich Chem. Comp., Inc., (Milwaukee, WI, U.S.A.). A Standard World Health Organization (WHO) cocaine hydrochloride sample of purity not less than 97% and different illicit cocaine powders of different origins were obtained through the Department of Narcotics, Criminal Laboratory, Ministry of Interior, Doha, Qatar.

A $10^{-2}M$ cocaine hydrochloride stock solution was prepared by dissolving 0.3398 g of pure cocaine hydrochloride in 100 ml of water. Dilute solutions (10^{-3}–$10^{-6}M$) were prepared fresh by appropriate dilution and kept in air-tight bottles. A standard $10^{-2}M$ NaTPB solution was prepared by dissolving 3.42 g in the minimum volume of water, followed by filtration and dilution to one litre. The solution was standardized by potentiometric titration with standard $10^{-2}M$ silver nitrate solution using an Orion Ag/Ag_2S membrane electrode (Model 94-16) for end-point detection.

Apparatus

All potentiometric measurements were carried out at $25 \pm 1°$ with an Orion pH/mV meter (Model SA 720) and cocaine membrane electrodes in conjunction with an Orion Ag/AgCl double junction reference electrode (Model 90-02) with 10% w/v potassium nitrate in the outer compartment. An Orion combination pH electrode (Model 91-02) was used for pH adjustments.

The electrical conductivities of the liquid membrane solutions were measured by means of a Tacussel conductivity cell (Type CM 0.05/G) and a Prolabo conductivity meter (Type CD 6N). A gamma cell 220 (Atomic Energy of Canada Ltd) was used for irradiation of the PVC membranes.

Gas–liquid chromatographic measurements were made using a Pye Unicam GLC instrument (Model 104) operated under the following conditions: column glass, 6 ft. × 1/4 in. i.d., packed with 3% OV-17 on Gas-Chrom Q (100–200 mesh), column temperature, 250°, injection temperature 270°, carrier gas, nitrogen at a flow-rate 25 ml/min; detector, flame ionization; and detector temperature 270°.

Cocaine ion-pair complexes

The ion association complexes of cocaine with tetraphenylborate and reineckate were prepared by mixing 10 ml of $10^{-2}M$ aqueous cocaine hydrochloride solution and 10 ml of $10^{-2}M$ of either sodium tetraphenylborate or ammonium reineckate. The precipitates were filtered off, washed with demineralized water, dried at room temperature and ground to fine powders. These complexes were used as electroactive materials in PVC and liquid membranes. Elemental analysis of the complexes gave C 78.7, H 6.6, N 2.2% for the cocaine–TPB ion-pair complex (C_{41} H_{42} P_4 NB, C 78.97, H 6.79, N 2.25%) and C 40.1, H. 4.7, N 16.1% for the cocaine–reineckate ion-pair complex (C_{21} H_{28} O_4 N_7 S_4 Cr, C 40.50, H. 4.53, N 15.74%).

Cocaine–PVC membrane electrodes

The membrane of the electrodes was prepared with the composition 2.0% cocaine ion pair complex, 28.3% PVC and 69.7% plasticizer (DOP or DBS). The master membrane was fabricated by dissolving 150 mg of powdered PVC, 370 mg of plasticizer and 10 mg of cocaine ion pair complex in 6 ml of THF. The solution was poured into a petridish (3 cm diameter and the solvent was evaporated at room temperature. Discs were cut from the membrane for the electrode assembly. The electrodes were constructed as previously described[15,22] with a mixed internal reference solution of sodium chloride ($2 \times 10^{-3}M$) and cocaine hydrochloride ($2 \times 10^{-3}M$).

Cocaine liquid membrane electrodes

An Orion liquid membrane electrode body (Model 92) was used in conjunction with an Orion porous membrane (92-81-04). The internal reference solution was a mixture of equal volumes of $2 \times 10^{-3}M$ sodium chloride and $2 \times 10^{-3}M$ cocaine hydrochloride. The liquid membrane was a solution of $5 \times 10^{-3}M$ ion association complex of cocaine in a nitrobenzene solvent. The liquid and PVC matrix membrane electrodes were preconditioned after preparation by soaking for at least 24 hr in

$5 \times 10^{-3}M$ aqueous cocaine hydrochloride solution and stored in the same solution when not in use.

Calibration of cocaine electrodes

The cocaine electrodes were calibrated by pipetting 5.0-ml portions of 10^{-2}–$10^{-5}M$ aqueous cocaine hydrochloride solutions into 100-ml beakers containing 45 ml of $0.1M$ potassium nitrate background. The cocaine electrode in conjunction with a double junction Ag/AgCl reference electrode was immersed in the solution. The emf readings were recorded after stabilization to ± 0.5 mV and plotted *vs.* log [cocaine. hydrochloride]. The calibration graph was used for subsequent measurement of cocaine in illicit powders.

Direct potentiometric determination of cocaine
