A portion of illicit cocaine powder (*ca.* 10 mg) was finely powdered and dissolved in doubly distilled demineralized water. The pH of the solution was adjusted to 4–5, the solution diluted with $0.1M$ potassium nitrate in a 25-ml calibration flask to the mark, shaken for 5 min and transferred to a 100-ml beaker. The cocaine membrane electrode in conjunction with an Orion double junction Ag/AgCl reference electrode was immersed in the test solution. The e.m.f. was recorded after stabilization to ± 0.5 mV and compared with the calibration graph. Alternatively, the standard known addition (spiking) technique was used by recording the e.m.f. before and after the addition of 2.50 ml of a standard aqueous $5 \times 10^{-3}M$ cocaine hydrochloride solution to the above test solution. The change in the potential readings was recorded and used for calculation of the cocaine content.

Potentiometric titration of cocaine

A 50-ml aliquot of aqueous cocaine hydrochloride solution (containing 3–20 mg) was pipetted into a 100-ml beaker. The cocaine and reference electrodes were immersed in the solution. The titration was performed with constant stirring using a standard $10^{-2}M$ NaTPB solution. The titration curves were recorded and the equivalence points calculated from the maximum slope ($\Delta E/\Delta V$). Alternatively, 3 to 6 aliquots of the titrant (0.5–1.0 ml each) were successively added and the potentials were recorded after each addition. The results were plotted on the Gran's plot paper (Orion 90-00-90) marking off the major divisions on the vertical axis in 5 mV. A blank experiment was carried out under identical conditions.

Gas liquid chromatographic determination of cocaine

An accurately weighed portion of illicit cocaine powder (*ca.* 20 mg) was finely powdered, dissolved in 5 ml of doubly distilled demineralized water and transferred to a 25-ml separating funnel. The solution was rendered slightly alkaline with $6M$ aqueous ammonia followed by addition of 5 ml of diethylether. The mixture was shaken for 5 min, centrifuged and the organic layer removed. The extraction was repeated 3 times, the organic phase was collected and evaporated on a water-bath. The residue was dissolved in 10 ml of chromatographic grade chloroform. After shaking, a 2–5 μl portion of the chloroform solution was injected on the GLC column. The peak heights for five replicate injections for each sample were recorded and their average value was compared with a standard calibration graph prepared for pure cocaine hydrochloride under similar conditions.

RESULTS AND DISCUSSION

Nature and composition of cocaine membranes

Cocaine cation reacts with tetraphenylborate and reineckate anions to form 1:1 water insoluble ion-association complexes. These complexes were tested as electroactive materials in liquid and poly (vinyl chloride) matrix (PVC) membranes responsive for cocaine. The typical cell used for potentiometric measurements was: Ag–AgCl/$10^{-3}M$ cocaine hydrochloride, $10^{-3}M$ sodium chloride//cocaine liquid or PVC membrane//Ag/AgCl reference electrode. The liquid membranes were prepared from $5 \times 10^{-3}M$ nitrobenzene solution of the complexes. Cocaine–tetraphenylborate and cocaine–reineckate liquid membranes displayed specific conductances of 13.8×10^{-6} ohm^{-1} cm^{-1} (1.35×10^{4} Ω) amd 18.7×10^{-6} ohm^{-1} cm^{-1} (1.0×10^{4} Ω), respectively. The PVC membranes were prepared by using casting solutions of the composition 28:2:70 w/w PVC, cocaine ion-association complex and dioctylphthalate (DOP) or dibutylsebacate (DBS) plasticizer, respectively.

Potential response of cocaine electrodes

The electrochemical response characteristics of liquid and PVC membrane electrodes were

evaluated according to IUPAC recommendations[23] and compared. Data collected over a period of 3 months from 5 different electrode assemblies for each membrane type are summarized in Table 1. The responses of all electrode systems at pH 5 are linear over the concentration range 10^{-2}–$10^{-5}M$ (Fig. 1). The slopes of the calibration plots are typically 53.5–63 mV/concentration decade. Deviation from the ideal Nernstian slope stems from the fact that the electrodes respond to the activity of cocainium ion rather than the concentration. The lower limit of detection, defined as the concentration of cocaine corresponding to the intersection of the extrapolated linear segments of the calibration graphs, ranges between $2 \times 10^{-5}M$ and $4.5 \times 10^{-6}M$ (1–6 ppm).

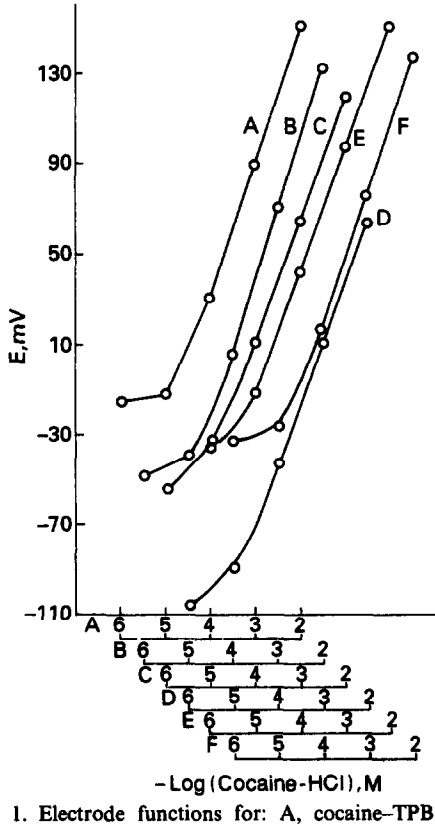

Fig. 1. Electrode functions for: A, cocaine–TPB liquid; B, cocaine–reineckate liquid; C, cocaine reineckate PVC (DOP); D, cocaine–TPB PVC (DOP); E, cocaine–TPB (DBS), and F, cocaine-reineckate PVC (DBS) membrane electrodes.

To check the pH dependence of the electrodes, potential–pH curves at various cocaine concentrations (10^{-2}–$10^{-4}M$) were constructed. For all electrodes, the potentials are stable and practically unaffected by pH fluctuations over the working pH range 3–7 (Table 1). Above pH 8, the potentials displayed by the electrode systems sharply decrease due to the formation of either a non-protonated cocaine base or cocaine-hydrolyzed products. On the other hand, the time required by the PVC matrix membrane electrodes to achieve steady potential readings within ±0.2 mV, after a rapid 10-fold increase in the concentration of $10^{-3}M$ cocaine hydrochloride, ranges from 0.5 to 1 min. Faster and more stable responses are obtained with the liquid membrane electrodes. Calibration curves for the PVC and liquid membrane electrodes are reasonably reproducible within ±1 mV from day to day. Ageing of the electrodes up to 8 weeks does not influence the response time, calibration slope and selectivity characteristics.

Effect of foreign compounds

The influence of 29 different inorganic and organic cations, including narcotics, anaesthetics, amides and amino acids, was investigated on the electrode response. Selectivity coefficients measured by the separate solutions method[15,23] using a $10^{-3}M$ concentration of both cocaine hydrochloride and the interferents are recorded in Table 2 as $-\log k^{pot}_{coc,B}$. The results reveal that the PVC matrix membrane electrodes are generally less susceptible to interference from many foreign compounds. The selectivity of TPB and reineckate based PVC membranes with DOP

plasticizer is generally better than those containing DBS plasticizer or liquid membranes. Narcotine and papaverine, however, are the most serious interferents with all membranes. These opium alkaloids are seldom associated with cocaine. On the other hand, interference from adulterants commonly added to cocaine samples illegally sold at the street level such as lactose, starch, inositol and mannitol on the response of the proposed electrode systems is negligible. Selectivity coefficient values measured for some interferents (*e.g.*, NH_4^+, K^+, Ca^{2+}, ephedrine, and alanine) by the mixed solutions method are very close to those obtained by the separate solutions method.

Effect of temperature

The potential response displayed by liquid and PVC cocaine membrane electrodes was monitored as a function of temperature of cocaine hydrochloride test solutions in the range 20–50°. All electrodes exhibit a slight gradual increase in their potentials as the temperature increases. The calibration graphs at different temperatures are essentially parallel. The temperature coefficients of the potentials are 0.5, 0.28 and 0.04 mV per degree for membranes consisting of PVC–DOP, PVC–DBS and nitrobenzene matrices, respectively. The limit of detection and response time do not significantly vary due to the change of temperature indicating reasonable thermal stability of the cocaine membranes up to 50°. These data show that the change of potentials due to the variation of temperature depends on the nature of the membrane solvent and is independent of the nature of the membrane ion pair complex.

Effect of γ radiation

The potential response of cocaine PVC matrix membranes was studied after exposure to various doses of cobalt-60 γ rays. Membranes incorporating the cocaine–TPB ion pair complex with either DOP or DBS plasticizer display a negative potential shift of ~3 mV upon increasing the radiation doses from 10^3 to 10^8 rad. Membranes containing cocaine reineckate ion pair complex with DOP or DBS plasticizer are significantly affected by γ radiation. Increasing the radiation doses from 10^3 to 10^8 rad is

associated by a positive potential shift (~25 mV) of the electrode response. All radiated membranes essentially exhibit the same calibration slope and linear response range as those displayed by the non-irradiated membranes. Contrary to the influence of temperature, variation of electrode potential due to the change of radiation doses depends on the nature of the membrane ion pair complex and is independent of the nature of the membrane solvent.

Determination of cocaine

The reliability of cocaine–TPB (DOP) membrane electrode for quantification of cocaine was assessed by determining 20–300 μg/ml standard cocaine hydrochloride (5 replicates each) at pH 5 using the standard addition method. The results depicted in Table 3 show an average recovery of 97.8% and a mean standard deviation of 0.5% ($n = 7$). Cocaine was also determined by potentiometric titration with standard sodium tetraphenylborate (NaTPB) using the same electrode system. Typical S-shape titration curve and linear Gran's plot are shown in Fig. 2. The S-shape titration curves (inflection break ~120 mV) are generated by addition of at least 20 increments of the titrant whereas Gran's plots are obtained by only 3–5 data points, before or after the equivalence point, on a semi-antilog paper.[15] The equivalence points are reproducibly and consistently obtained at points equivalent to the consumption of 1.00 ± 0.01 mole NaTPB per mole of cocaine ($n = 7$). The average recovery is 98.1% and the mean standard deviation being 0.3% (Table 3).

Cocaine in some real illicit samples from different sources was similarly determined by direct potentiometry. The results obtained are given in Table 4. A mean standard deviation of ±1.2% reveals reasonable precision of the electrode method for such complex mixtures. The accuracy of these data was evaluated by comparison with results obtained using gas–liquid chromatography (GLC). There is fairly good agreement between the results obtained by both techniques. The *t*-test reveals that the mean of 5 runs obtained for each sample by the electrode method as compared to the GLC method is not different at the 0.05 significant level. The *F*-test reveals no significant difference between means and variances of results obtained by the potentiometric and GLC methods. On the other hand, the uses of the Pharmacopoeial methods,[1,2]

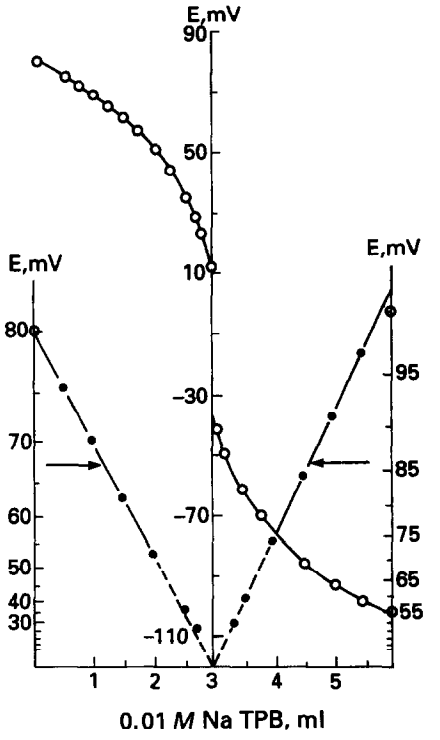

Fig. 2. Typical potentiometric titration curve (○) and Gran's plot (●) for 10.2 mg of cocaine hydrochloride with standard $10^{-2}M$ NaTPB using a cocaine–PVC membrane electrode (ion-pair complex: cocaine–TPB; plasticizer; DOP).

which involve treatment with alkalis and extraction in organic solvent followed by acid-base titration, are not suitable for the analysis of real cocaine illicit samples due to the presence of many interfering basic compounds. Without a prior separation, such compounds are extracted and titrated with the cocaine base.

In conclusion, the proposed potentiometric procedure for determination of cocaine involves little manipulation or pretreatment steps compared to other methods.[1,2,5,13] The proposed membrane electrode systems offer the advantages of simple design, fast response, good selectivity and applicability to real illicit cocaine powders.

Summary—A liquid membrane containing 4% di-2-ethylhexyl phosphoric acid and 5% sorbitan monooleate in kerosene is used in the form of an emulsion for the simultaneous extraction and concentration of cadmium and manganese from aqueous solutions. When 4% tri-n-octylamine is included in the membrane composition, only manganese is extracted while cadmium remains in the sample solution. The extracted elements in the concentrate are recovered by breaking the emulsion with n-butanol. Recoveries of cadmium and manganese range from 92–104% for 60-ml samples containing 2–9 μg of each element.

The accurate determination of trace elements such as cadmium, manganese, mercury, zinc and copper in natural waters is important because of the toxic properties of the elements. Very sensitive analytical methods based upon furnace atomic-absorption spectrometry, plasma source mass spectrometry and neutron activation analysis have been employed for direct measurements of trace elements in water. However, these expensive instruments are not readily available in many laboratories. Thus, techniques for the separation and preconcentration of trace elements are very valuable because the concentrate can be analyzed with other, less expensive instruments such as flame atomic-absorption spectrometers and UV/Vis spectrometers.

Liquid membranes in emulsion forms have proven useful as a means of extraction and concentration of trace elements in aqueous solutions. Li[1] patented a liquid membrane emulsion separation process. Industrial applications of liquid membrane emulsions have included the removal of elements such as copper from waste water[2] and the purification of brines. More recently, liquid membrane emulsions have been applied in analytical chemistry. Liquid membrane compositions and experimental conditions have been recommended for the quantitative extraction and concentration of rare earth elements,[3] manganese[4] and iron[5] in water.

In this report, new liquid membrane emulsions are described for the simultaneous extraction and concentration of cadmium and manganese in aqueous solution, and for the extraction of manganese from solutions containing both elements. The extracted elements are recovered from the emulsion rapidly and efficiently by chemical demulsification with n-butanol. The elements are determined by flame atomic-absorption spectrometry.

Principle of the method

A liquid membrane consists of an extraction reagent (or carrier), and a surfactant dissolved in kerosene. The kerosene solution is mixed with an acidic or a basic aqueous solution (internal phase or stripper) to form a stable water-in-oil emulsion. The droplets of internal phase of the emulsion are 1–10 μm in diameter. The emulsion is then mixed

*Author for correspondence.

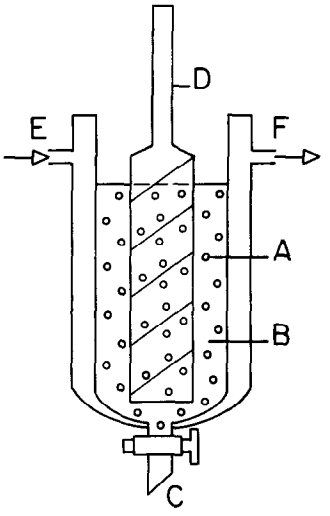

Fig. 1. Glass extraction vessel: A, liquid membrane; B, sample; C, drain; D, Stirrer; E, F, water in, out.

with an aqueous sample whose pH is adjusted in order to establish a pH gradient between the sample and the internal phase of the emulsion. The size of the kerosene droplets in this mixture range from 0.5–2 mm. While the phases are in contact, ions in the sample solution pass through the membrane and are concentrated in the internal phase of the emulsion. After the mixing is terminated, the phases separate and the emulsion is removed. The aqueous concentrate is recovered by means of chemical demulsification.

The extraction and concentration processes are illustrated in equation (1)

$$M^{2+}_{aq} + 2H_2A_{2_{org}} \underset{\text{stripping}}{\overset{\text{extraction}}{\rightleftharpoons}} M(HA_2)_{2_{org}} + 2H^{+}_{aq}$$

Cations (M^{2+}) in the aqueous solution react with the extraction agent (H_2A_2) in the kerosene. In this work, the extraction agent or carrier, di-2-ethylhexyl phosphoric acid, exists as a dimer. The cations enter the membrane in the form $M(HA_2)_2$. This is the extraction step. The complex diffuses to the surface of the membrane in contact with the internal aqueous phase. The metal ions pass into the aqueous phase. This is the concentration or stripping step shown in equation (1). The selectivity of the process depends upon the composition and physical properties of the membrane, and with the pH conditions of the sample and the internal aqueous phase. The pH gradient serves as the driving force. Because of the continuous transfer of M^{2+} ions from the sample to the internal phase, "multiple" extractions are achieved. This is contrasted with single extraction/stripping reactions in conventional extraction methods which must be repeated one at a time. Thus, extraction with a liquid membrane emulsion are highly efficient.

EXPERIMENTAL

Apparatus

The following equipment was used: Perkin–Elmer model 3030 atomic-absorption spectrometer; motor driven stirrers (ranges 0–600 rpm and 0–6000 rpm); pH meter; temperature controller; extractor shown in Fig. 1.

Reagents

Standard solutions of cadmium and manganese were prepared from reagent grade chemicals and distilled, demineralized water. Hydrochloric acid and n-butanol were reagent grade chemicals. Span 80 or sorbitan monooleate was obtained form Public Pharmacy Factory, Tianjing, P.R.C. D2EHPA or di-2-ethylhexyl phosphoric acid and TOA or tri-n-octylamine were obtained from the Organic Chemical Institute, Shanghai, P.R.C. Purified kerosene was used as the membrane solvent. Twenty percent (v/v) solutions of Span 80, D2EHPA and TOA in kerosene were used in this work.

Procedures

Preparation of liquid membrane emulsion. For the simultaneous extraction of cadmium and manganese, prepare the organic phase by combining 6 ml of Span 80 solution (surfactant), 4 ml of D2EHPA solution (carrier) and 90 ml of kerosene. Transfer 20 ml of the organic solution and 20 ml of 2*M* hydrochloric acid (internal aqueous phase) to a flask. Stir the contents at 2000–3000 rpm for 10 min to form the liquid membrane emulsion. For the extraction of manganese from samples containing both cadmium and manganese, combine 6 ml of Span 80 solution, 4 ml of D2EHPA solution, 5 ml of TOA (carrier) solution and 85 ml of kerosene. Transfer 20 ml of the organic solution and 20 ml of 2*M* hydrochloric acid to a flask. Form the liquid

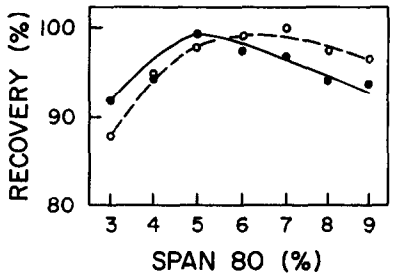

Fig. 2. Relationship between concentration of Span 80 and recovery of cadmium and manganese: ● cadmium; ○ manganese.

membrane emulsion by stirring as described previously.

Extraction of cadmium and manganese. Aqueous solutions contained 0.1 μg/ml of each cation. Adjust the pH of the sample solution to 5 by means of a sodium acetate–acetic acid buffer. Combine 60 ml of sample solution with 10 ml of liquid membrane emulsion in a flask. Stir the contents of 200–300 rpm for 10 min. Allow the phases to separate (1–2 min). Remove the liquid membrane emulsion and transfer it to a flask. Prepare a blank by treating 60 ml of pure water in the same manner as the sample.

Demulsification. Add 0.5–1 ml of n-butanol to the liquid membrane emulsion. After the phases have separated (2–5 min) remove the aqueous phase and measure its volume.

Determination of cations. Measure the concentrations of cadmium (wavelength 222.8 nm, 0.7 nm slit, 4 mA current) and manganese (279.5 nm wavelength, 0.2 nm slit, 10 mA current) in the separated aqueous phase by flame atomic-absorption spectrometry, using an acetylene : air ratio of 8 : 1. The recovery (R) of the cations from the sample was calculated by the following formula:

$$R\ (\%) = \frac{C_i V_i - C_{ib} V_{ib}}{C_e V_e}$$

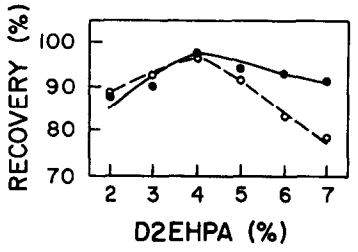

Fig. 3. Relationship between concentration of D2EHPA and recovery of cadmium and manganese: ● cadmium; ○ manganese.

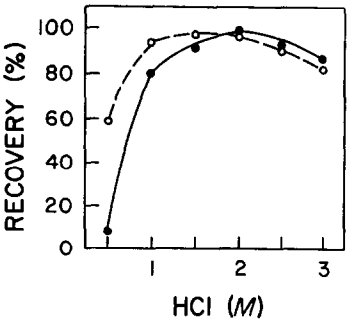

Fig. 4. Effect of acidity of stripping solution on the recovery of cadmium and manganese: ● cadmium; ○ manganese.

where C_i and V_i are the concentration of the cation in the stripping solution (internal aqueous phase of the membrane) and the volume of stripping solution, respectively. C_{ib} and V_{ib} are the corresponding concentration of ca ion and volume of stripping solution in the blank: C_e and V_e are the concentration of cation in the sample and the volume of the sample.

RESULTS AND DISCUSSION

Characteristics of the liquid membrane emulsion

Both the stability of the emulsion and the viscosity of the liquid membrane were altered by the proportion of surfactant in the organic phase. An increase in the concentration of Span 80 (surfactant) increased the stability of the emulsion. However the rate of transfer of the cations decreased. The relationship between the concentration of Span 80 in the organic phase and the recovery of the cations is shown in Fig. 2. A concentration of 5–6% by volume in the organic phase resulted in good recoveries of cations and rapid demulsifications. The effect of the concentration of D2EHPA (carrier) in the organic phase on the recovery of cadmium and manganese is shown in Fig. 3. The optimum concentration of carrier was 4% by volume. The relationship between the concentration of hydrochloric acid in the stripping solution and the recoveries of the cations is shown in Fig. 4. An acid concentration of 2M resulted in the best recoveries. There was a large decrease in the recovery of cadmium at a low acid concentration.

Sample solution

In order to establish a pH gradient between the sample solution and stripping solution and

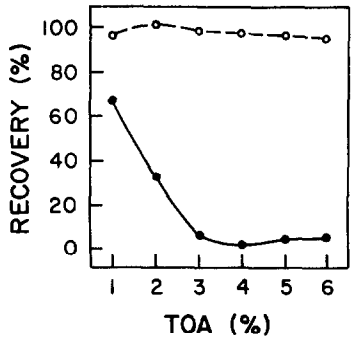

Fig. 5. Relationship between concentration of TOA and the recovery of cadmium and manganese: ● cadmium; ○ manganese.

thus ensure an efficient recovery of cations, the pH of the sample should be higher than 4. A pH of 5 was established by means of a sodium acetate–acetic acid buffer.

Analysis of samples

Samples containing known amounts of cadmium (7.2–1.6 μg) and manganese (5.7–8.5 μg) were extracted using the optimum conditions listed in the Procedures section for the simultaneous concentration of the two elements. Recoveries ranged from 92 to 104%. In the analysis of dilute solutions, it may be necessary to increase the concentrations of elements in the stripping solution to levels above those obtained from the treatment of a single sample with a liquid membrane emulsion. The same batch of liquid membrane emulsion (10 ml) can be used to treat several aliquots (60 ml) of sample solution. In order to describe the increases in concentration by means of the extraction of several aliquots of sample, the term enrichment multiple is used. It is defined as the ratio of the concentration of an analyte in the stripping solution of a liquid membrane emulsion to the initial concentration of the analyte in the sample solution. In this work, the same batch of liquid membrane emulsion was used to extract up to six aqueous samples containing 0.02 μg/ml cadmium and manganese. After each aliquot was extracted, the depleted sample solution was replaced by the same volume of fresh sample solution, and the extraction was repeated. The enrichment multiples increased with the number of extractions, as expected, from 10 for one extraction to *ca.* 50 for six extractions. The enrichment multiple increased by about 10 for 2 and 3 extractions and then about 5 for each subsequent extraction. Also four successive extractions yielded enrichment multiples of about 40 for each element without significant declines in recoveries. However, five and six successive extractions resulted in poor recoveries.

Separation of manganese from cadmium

The inclusion of TOA as a second carrier in the organic phase produced a liquid membrane which was used for the concentration of manganese, while cadmium was retained in the sample. The effects of increasing concentrations of TOA (in the presence of 4% D2EHPA) in the organic phase on the recoveries of both elements are shown in Fig. 5. As the proportion of TOA in the membrane increased from zero to 4%, the extraction of cadmium decreased until no cadmium passed through the liquid membrane. Recoveries of manganese from sample solutions containing 5–6 μg of manganese and 2–18 μg of cadmium ranged from 93 to 102%. Neither element was extracted from solutions by liquid membrane emulsions containing TOA as the sole extracting reagent. Thus, a liquid membrane containing both extracting reagents was selective in extracting manganese when both cadmium and manganese were present in the sample.

CONCLUSIONS

Cadmium and manganese in concentrations ranging from 0.03 to 0.15 μg/ml of each element in aqueous solution can be extracted and concentrated by means of a liquid membrane emulsion. Recoveries are in the range of 92–104%. A liquid membrane emulsion is also effective in the quantitative separation of manganese from cadmium. The procedures are rapid, and no expensive equipment other than an atomic-absorption spectrometer is required for the determination of these elements.

GENERATION OF AsH_3 FROM As(V) IN THE ABSENCE OF KI AS PREREDUCING AGENT: SPECIATION OF INORGANIC ARSENIC

A. LOPEZ, R. TORRALBA,* M. A. PALACIOS and C. CAMARA

(*Received* 16 *September* 1991. *Revised* 20 *February* 1992. *Accepted* 20 *February* 1992)

Summary—It is shown that the potassium iodide to the samples to reduce As(V) to As(III) is not essential when total inorganic arsenic is determined by molecular spectrophotometry (trapping AsH_3 in Ag–DDTC) or by atomic-absorption spectrometry (if Ar flow-rate and $NaBH_4$ addition rate are controlled in 6*M* hydrochloric acid medium). Furthermore, in the presence of low concentration of organic arsenic, a method is reported for the selective determination of inorganic As(III) and As(V), based on the use of citrate/citric acid medium to determine As(III) and hydrochloric acid to determine total inorganic As. As(V) is determined by the difference between total inorganic As and As(III). The interference level of organic arsenic species (monomethylarsenic acid and dimethylarsenic acid) in the determination of total inorganic arsenic and As(III) in 6*M* hydrochloric acid and citrate/citric acid medium respectively, is reported in the text. The developed method is applied to determine As(III) and As(V) in spiked, tap and waste waters and in lake sediments.

Hydride generation atomic-absorption spectrometry (HG–AAS) has been used for the determination of hydride forming elements in many kinds of sample analyses. Some of these elements can exist in various oxidation states, *e.g.*, As(III) and As(V).

The speciation of arsenic with respect to oxidation state is important from the points of view of bioavailability and toxicity, As(III) being more toxic than As(V).[1]

A great difference in sensitivity for these two oxidation states under the usual HG–AAS conditions (in batch and flow-injection analysis systems) has been reported.[2]

For the prereduction of pentavalent arsenic to the trivalent state before the hydride generation step, potassium iodide solution with or without ascorbic acid has gained acceptance as the most suitable reagent. However, some disadvantages are found.

(i) In samples treated with strong oxidizing acid or containing oxidizing agents (as Fe^{3+}), large amounts of I_2 are formed and a high potassium iodide concentration is needed. The presence of I_2 (or I_3^-) in the sample solution is objectionable for two reasons: (a) the I_2, a strongly absorbing agent, could be stripped from the solution prior to the addition of the sodium tetrahydroborate, changing the base line; and (b) loss of a volatile As(III)–iodine adduct in the generator can also be observed.[3]

(ii) Usually, ascorbic acid is also added to prevent the inevitable I^- oxidation by atmospheric oxygen.

(iii) The speed of As(V) reduction to As(III) even in very high acid concentration is sometimes very low and measurement is therefore time consuming (references and standard solutions must be treated in the same manner).

(iv) The most common derivatization method for arsenic speciation is hydride formation after separation of species by high pressure liquid chromatography or ion-chromatography. The analytical difficulties dealing with the potassium iodide prereduction step are difficult to avoid. Therefore, it would be highly desirable to find conditions where addition of potassium iodide is not required. The redox potential of the sodium tetrahydroborate solution is highly dependent on pH and some authors therefore propose combining suitable concentrations of $NaBH_4$ and hydrochloric acid to ensure rapid and efficient generation of the As(V) and As(III) hydride.[4]

In order to further characterize the conditions for the reduction of As(V) to AsH_3 without a potassium iodide prereduction step, we carried out experiments at the part per billion (ppb) and

*Author for correspondence.

part per million (ppm) arsenic level. For the ppm level, the reaction was followed by molecular visible spectrophotometry using silver–diethyl-dithiocarbamate (Ag–DDTC). The red chromophore formed in the determination of As with Ag–DDTC is a polynuclear dithiocarbamate complex containing silver metal and As(III) as central atoms.[5] This technique is in principle not affected by the possible slow kinetics of As(V) reduction by sodium tetrahydroborate. For the ppb level of As, the reaction was followed by hydride generation atomic-absorption spectrometry (HG–AAS).

EXPERIMENTAL

Apparatus

A Perkin–Elmer model 2380 atomic-absorption spectrometer equipped with an electrodeless discharge lamp operated at 8 W from an external power supply was used for all determinations.

A spectral band width of 0.7 nm was selected to isolate the 193.7–nm As line. The signals were recorded on a Perkin–Elmer model 56 recorded set at the 10-mV range.

A laboratory-made hydride system with three valves which allow control of the three Ar flows (purge, mixing and $NaBH_4$ addition), was used.[6]

Visible spectra were obtained with a HP8452 diode-array spectrophotometer. A domestic microwave oven (Balay Bahhm-III) with nine power settings (starting at 80 W and increasing by 80 W increments to 720 W) was used. The teflon–PFA vessels used for sample mineralization had a volume of approximately 150 ml and tight-fitting screw cap lids.

Chemicals

Stock solutions (1000 mg/l.) in As(III), As(V), monomethylarsenic acid (MMA) and dimethylarsenic acid (DMA) were prepared by dissolving the appropriate amount of ultrapure As_2O_3 (Merck), As_2O_5 (Aldrich), disodium salt of monomethylarsenic acid (Carlo Erba) and sodium salt of dimethylarsenic acid (Sigma) respectively; As(III) was dissolved in 20 ml of 1*M* sodium hydroxide, the solution was neutralized using 2*M* hydrochloric acid and finally diluted to one litre with 0.6*M* hydrochloric acid. As(V), MMA and DMA was prepared by dissolving the reagent in distilled water from a milli Q-system.

Sodium tetrahydroborate(III), Aldrich reagent-grade, was prepared as a 3% w/v solution in 0.1% sodium hydroxide.

Silver diethyldithiocarbamate solution was obtained by dissolving 0.5 g of Ag–DDTC in 100 ml of pyridine and stored in an amber bottle.

Buffer solutions for the pH range 2–5 were prepared from citric (40%) w/v, acetic (50%) w/v and tartaric acids (30%) w/v, and adjusted to the required pH with sodium hydroxide.

All other reagents were of analytical reagent grade.

Procedures

Sample aliquots containing about 10 μg of arsenic as As(III), As(V) or both in 2*M* hydrochloric acid (for molecular spectrophotometric method) or about 50 ng of arsenic as As(III) and As(V) or both in 6*M* hydrochloric acid (for the atomic-absorption method) and at pH 4.5 [for As(III) determination in both methods] were placed in a reaction flask and the following procedures were carried out.

Spectrophotometric method. The arsine generated at the μg level with 3 ml/min of $NaBH_4$ and 100 ml/min Ar flow was absorbed for 5 min in 3 ml of Ag–DDTC in pyridine. The molecular absorbance of the red complex formed was measured at 536 nm against its blank.

Atomic-absorption spectrometric method. Arsenic generated as arsine at the ng level with 3 ml/min of $NaBH_4$ and a 50-ml/min Ar flow was determined by measuring the absorbance as peak height at 193.7 nm using a quartz cell heated by an air–acetylene flame.

In both methods only peak height was possible with the equipment used, and thus peak height was therefore not compared with peak area.

Microwave oven mineralization. About 3 g of spiked waste-water (or 0.5 g of sediment) and 5 ml of 6*M* hydrochloric acid were placed in a teflon reactor. The samples were mineralized in the microwave oven in sets of three according to the following programme: 4 min at 40% P (280 W), 5 min at 30% P(210 W) and 10 min at 40% P (280 W).

Between each step, the samples were cooled in an ice bath, and depressurized in order to avoid overpressurization problems. The sample solution was made up to 25 ml with water and stored in plastic bottles until analysis.

RESULTS AND DISCUSSION

Effect of HCl concentration, Ar flow rate and $NaBH_4$ addition rate on the efficiency of arsine generation from As(III) and As(V)

The efficiency of reduction of arsenic species to arsine is highly dependent on pH and kinetics.[7]

When measurements were made by atomic-absorption spectrometry, the slow kinetics of the reduction reaction made it necessary to carefully control the $NaBH_4$ addition rate to the reaction flask in arsine generation as can be seen in Table 1. Thus, for both inorganic arsenic oxidation states, the analytical signal measured as peak height is clearly dependent on the $NaBH_4$ addition and Ar purge flow-rates. The peak height increases with increasing $NaBH_4$ flow-rate at constant purge flow-rate, the difference in sensitivity for As(III) and As(V) being about 35%. This difference may be attributed to the lower reaction rate between As(V) and $NaBH_4$. If the purge flow is decreased at constant $NaBH_4$ flow, it is possible to achieve identical, but lower, signal for the same concentration of As(III) and As(V). Thus, we conclude that the efficiency of the AsH_3 formation from As(III) and from As(V) is the same, when high $NaBH_4$ flow and low purge flow are used (3 ml/min of $NaBH_4$ and 50 ml/min Ar flow).

The addition of 2 ml of 1*M* potassium iodide to both As(III) and As(V) test solutions 15 min before hydride generation significantly increased the efficiency of AsH_3 formation, with similar signal intensities being measured for the two oxidation states (Table 1). However, if the signal was recorded as soon as the potassium iodide was added, the approx 35% difference in sensitivity achieved without addition of potassium iodide remained constant.

Experiments carried out in parallel using the molecular spectrophotometric method (8 μg of As), Fig. 1, clearly demonstrate that increasing the concentration of hydrochloric acid from 1 to 6*M* results in a marked decrease in the As(III) and As(V) absorbance signal. This decrease in the absorbance signal is not attributed to a difference in hydride efficiency generation but rather to competition (between arsine and hydrogen for the Ag–DDTC). No differences were observed between the two oxidation states between 2–6*M* hydrochloric acid. Table 2 shows that the slopes for As(III), As(V) and As(V) plus potassium iodide in 2*M* hydrochloric acid are identical after a 2-min arsine collection time in the Ag–DDTC solution.

Effect of different buffers

Different buffer solutions were used for AsH_3 generation in the molecular spectrophotometric method. The results, Fig. 2, show that in citric/citrate buffer at pH 4.5 it is possible to inhibit the reduction of As(V) to AsH_3 and hence to selectively obtain arsine from the As(III) oxidation state. These results agree with those obtained by the HG–AAS method (Fig. 3) in citric/citrate buffer. Thus, speciation of As(III) and As(V) can be carried out using this medium.

$n = 5$.

Similar results were obtained in acetic/acetate medium for the molecular spectrophotometric method but the sensitivity for As(III) was lower than in citric/citrate buffer. Other buffer solutions, such as tartaric/tartrate, resulted in a negligible As(V) signal at pH 4.5 (Fig. 2). The ability of citric/citrate medium to distinguish between As(III) and As(V) using the molecular spectrophotometric method can be seen in Fig. 4, where the calibration curve slope for As(V) is negligible. The same results were obtained by atomic-absorption spectrometry.

Effect of MMA and DMA on AsH_3 generation from As(III)

The interferent effect of different amounts of MMA and DMA on arsine generation from As(III) at the 60 ppb level using atomic-absorption spectrometric detection has been tested.

The presence of MMA in citrate/citric medium up to 180 ppb (maximum concentration assayed) does not interfere, whereas in 6*M* hydrochloric acid concentrations higher than 30 ppb interferes (60 ppb enhances the signal about 20%).

The interference level of DMA in citrate/citric medium is higher than MMA, in which 60 ppb is the maximum concentration allowed without interference (120 ppb enhances the absorbance by about 20%). On the contrary in 6*M* hydrochloric acid its interfering effect is significantly

lower than that of MMA (presence of 60 ppb produces an increase in absorbance by about 11%).

Application

Because of the difficulty in obtaining certified materials for As(III) and As(V), five synthetic samples for the molecular spectrophotometric method were prepared in 2*M* hydrochloric acid and pH 4.5 citric/citrate media, over a range of As(III)/As(V) ratios. Table 3 shows that the 2*M* hydrochloric acid medium, allowed the determination of total As independently of the oxidation state, while in citric/citrate at pH 4.5 only As(III) is determined. The concentration of As(V) can be calculated as the difference between total inorganic arsenic and As(III).

The proposed chemical method for differentiating inorganic As species was applied in both molecular spectrophotometry and atomic-absorption spectrometry. It can be used for As(III) and As(V) speciation when the presence of methylated arsenic compounds is not higher than 40% total arsenic. Thus, it can be useful for some environmental water samples in which methylated arsenic compounds are reported to be as high as 16–54% of the total arsenic.[8] As the As level content in tap water was too low to be detected, the developed method was applied to the speciation of As(III) and As(V) in spiked tap and waste (paper mill effluent) waters, and sediments. Spiked tap waters were analysed without any previous sample treatment, while spiked waste waters and sediments were treated with hydrochloric acid in a microwave oven as described in the procedure. Solid residue was discarded and only the supernatant was analysed.

When a known amount of As(III) and As(V) was added to waste water, all the arsenic was determined as As(V) and none as As(III). This fact can be attributed to the large amount of oxidant material in the matrix, which changed As(III) to As(V). The amount of As(III) measured in the sediment sample was about 85% of the total As (Soil 7-OIEA, RM). The amount of As(V) measured was negligible.

The presence of organic arsenic in sediments by molecular spectrometry was not detected as absorbance of the complex at 525 nm (maximum λ of Ag–DDTC-organic arsenic or/and As(V) complex[7]) was negligible. The 15% of the As that was unrecovered could be in the sediment attached to silicates not extracted by our procedure.

The analytical characteristics of both the atomic and molecular methods are included in Table 4.

Table 4. Analytical characteristics of atomic and molecular methods by hydride generation

	DL*	Linearity range	C.V.† Within run	C.V.† Between run	Recovery As(III)	Recovery As
AAS	0.5 ppb	0–100 ng	3%	5%	98 ± 3%	95 ± 6%
MAS	0.2 ppm	0–100 μg	3%	3%	98 ± 3%	98 ± 3%

$n = 10$.

AAS = atomic absorption spectrometry.

MAS = molecular absorption spectrometry.

*Calculated using the IUPAC recommendation (3σ).

†At the 8 ppm and 30 ppb levels.

CONCLUSIONS

We have demonstrated that in HG–AAS the addition of potassium iodide when the arsenic hydride is generated in 6*M* hydrochloric acid medium using adequate Ar flows and $NaBH_4$ is not necessary because identical signals for As(III) and As(V) can be obtained. This clarifies the controversial literature published on this topic.

The speciation of inorganic As(III) and As(V) in the absence of organic arsenic is possible by determining As(III) in citric/citrate media at pH 4.5 and total As in 2*M* and 6*M* hydrochloric acid for molecular and atomic methods respectively. As(V) is determined by the difference between total inorganic As and As(III).

Summary—A solid ion-pair compound produced from sodium 1,2-dihydroxybenzene-3,5-disulphonic acid (Tiron) and tetradecyldimethylbenzylammonium chloride(TDBA) supported on naphthalene in a simple glass-tipped funnel tube provides a simple adsorbent system for preconcentrating titanium from some alloys. Titanium reacts with Tiron to form a water-soluble coloured chelate anion which in turn forms a water-insoluble stable titanium/Tiron/TDBA complex with the ion-pair on the surface of naphthalene packed in a column. Titanium is quantitatively retained on the naphthalene in the presence of *L*-ascorbic acid and oxalic acid in the pH range 3.0–4.5 and at a flow-rate of 1 ml/min. The metal complex and naphthalene were dissolved from the column with 5 ml of dimethylformamide(DMF), and the absorbance of the solution was measured at 398 nm. A calibration graph was linear over the range 1–18 μg of titanium in 5 ml of the final DMF solution. The complex has a molar absorptivity of 1.39×10^4 l. mole^{-1}. cm^{-1} and a sensitivity of 3.44×10^{-3} μg/cm^2 for 0.001 absorbance. Eight replicate determinations for a sample containing 12 μg of titanium gave a mean absorbance of 0.697 with a relative standard deviation of 0.82%. The interference of various ions was studied and optimum conditions were developed for the determination of titanium in various aluminium and zinc alloys.

Numerous quaternary ammonium salts such as cetyltrimethylammonium chloride, trioctylmethylammonium chloride, and tetradecyldimethylbenzylammonium chloride(TDBA) have been widely used as the counter ions of anionic metal complexes or metal chelates in the solvent extraction–spectrophotometric determination of metals.[1,2] The use of high molecular weight amines provides high sensitivity and selectivity.

Tiron is a well-known chelating agent for the colorimetric determination of titanium,[3] molybdenum,[4] niobium,[5] vanadium,[6] *etc.* This reagent has two sulphonic acid groups and reacts with various metal ions to form anionic chelates. The metal chelate anions form water-insoluble complexes with quaternary ammonium salts like TDBA which can be extracted into nonaqueous solvents. Matsuo *et al.*[7] have reported the spectrometric determination of iron with SCN in the presence of TDBA. The sensitivity and selectivity of the method are greatly enhanced over the conventional thiocynate method and interference due to foreign ions is also diminished. However, some of the organic solvents are miscible with water to a certain extent, hence the degree of the concentration of the metal ion into the organic solvent is limited.

Recently some column methods have been reported for the preconcentration of metals with different adsorbents such as activated carbon,[8] thiol cotton,[9] green tea leaves,[10] chelating resin,[11] cellulose,[12] polythioether foam,[13] *etc.* Although some of these methods are fairly efficient, once prepared the adsorbents are not reuseable, unlike the material used in this procedure. Furthermore, introduction of a Chelex-100[14] and ion-exchange resin[15] minicolumn into a

*Author for correspondence.

flow-injection system increases the sensitivity to trace levels (ng/ml-pg/ml) thus allowing natural waters to be analysed.

Solvent extraction is a simple and convenient technique, but is inconvenient if emulsion forms or the solubility of the complex in the organic solvent is poor. These difficulties may be overcome by using molten naphthalene,[16] naphthalene adsorption[17] and benzophenone.[18] The only inconvenience of the methods are in the filtration and drying, which increase the number of the operation steps and thus make the method more time-consuming.

We have developed a new column method for the preconcentration of trace metals using various adsorbents supported on naphthalene.[19-21] In the present study, an efficient method has been described for the preconcentration of titanium with Tiron–TDBA adsorbed on naphthalene. The metal retained in the column is dissolved along with the naphthalene, and trace titanium is determined spectrophotometrically. The conditions have been optimized and the method has been used for the determination of titanium in standard aluminium and zinc alloys.

EXPERIMENTAL

Apparatus and reagents

A Hitachi Model 200-20 double beam spectrophotometer and a Toa-Dempa HM-5A pH meter were used. A funnel-tipped glass tube (60 × 6 mm i.d.) was used as a column. The column was plugged with coarse polypropylene fibres and then filled with the adsorbent to a height of 1.2–1.5 cm, compressed lightly with a flattened glass rod.

Standard titanium solution (3 μg/ml) was prepared by diluting 1000 ppm atomic-absorption standard titanium sulphate, $Ti(SO_4)_2$ solution with distilled water. Buffer solutions were prepared by mixing appropriate ratios of 0.5*M* acetic acid and 0.5*M* ammonium acetate solutions 0.5*M* aqueous ammonia and 0.5*M* ammonium acetate solutions, and 0.1*M* potassium dihydrogen phosphate and 0.1*M* disodium hydrogen phosphate solutions. TDBA, naphthalene, DMF, Tiron and all other reagents were of analytical reagent grade.

Preparation of Tiron/TDBA/naphthalene adsorbent

A solution of naphthalene was prepared by dissolving 20 g of naphthalene in 40 ml of acetone on a hotplate stirrer at 35°. This was transferred to 1400 ml of distilled water containing 3.5 g (0.0098 moles) of TDBA, with constant stirring at room temperature, and to it was added a 500-ml solution of Tiron (1.5 g, 0.0048 moles). The naphthalene mixture coprecipitate was stirred for a few hours and allowed to stand for one night. It was drained off by decantation and then the mixture was washed twice with distilled water in the same way. The slurry of naphthalene in water was stored in a bottle.

General procedure

To an aliquot of solution containing 1–18 μg of titanium were added 12 ml of distilled water, 0.7 ml of 1.0% *L*-ascorbic acid solution, 0.4 ml of 1.0% oxalic acid solution and 0.5 ml of the buffer (pH 4.0). The sample solution was passed through the column packed with naphthalene/Tiron/TDBA. The solid mass in the column was washed with a small volume of distilled water and then aspirated for *ca.* 30 sec, compressing the naphthalene material with a flat glass rod. This was dissolved from the column with 5 ml of DMF. The absorbance of this solution was measured at 398 nm with a spectrophotometer against the reagent blank.

RESULTS AND DISCUSSION

Retention characteristics of Tiron/TDBA

TDBA is used as a counter cation for the metal chelate anion. Tiron has two sulphonic acid groups capable of dissociation and it is considered to form an ion-pair (Tiron:TDBA = 1:2) with a quaternary ammonium cation as shown in the following reaction.

$$C_6H_2(OH)_2(SO_3^-)_2 + 2(R)_4N^+ = [C_6H_2(OH)_2(SO_3^-)_2][R_4N^+]_2$$

The experimental observation revealed that the ion-pair coprecipitated with naphthalene. The co-precipitated ion-pair forms a chelate ring between a metal ion and two OH groups, on the inactive surface of naphthalene. From the stoichiometry in the above reaction, the mole ratio of Tiron and TDBA should be 1:2. For the preparation of adsorbent, use of Tiron (1.5–2.0 g) and TDBA (2.5–4.0 g) for 25 g of naphthalene was quite adequate for the complete retention of metal ions. In the present work, 1.7 g of Tiron and 3.6 g of TDBA were used.

Various ion-pair reactions of Tiron with quaternary ammonium salts were examined.

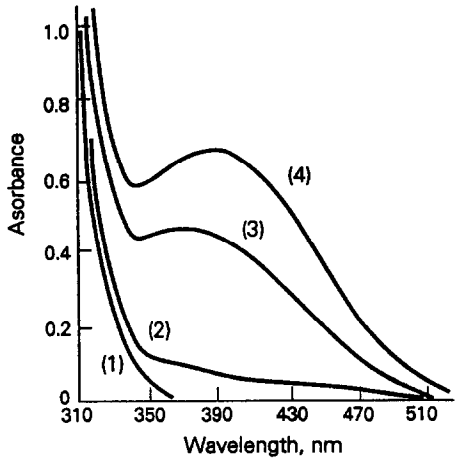

Fig. 1. Absorption spectra of the reagent blank and titanium complex in naphthalene–dimethylformamide solution. Ti: 12 μg, pH: 4.0, 1.0% *L*-ascorbic acid: 0.7 ml, 1.0% oxalic acid: 0.4 ml. Reference: water. (1) Reagent blank, with ascorbic acid and oxalic acid. (2) Titanium complex, without *L*-ascorbic acid and oxalic acid. (3) Titanium complex, with *L*-ascorbic acid. (4) Titanium complex, with *L*-ascorbic acid and oxalic acid.

Among the salts tested, cetylpyridinium chloride (CPC), cetyltrimethylammonium bromide (CTMA), trioctylmethylammonium chloride (TOMA) and TDBA formed ion-pairs with Tiron and coprecipitated with naphthalene. TDBA was recommended as a counter ion for Tiron because it is economical and available in high purity, and shows excellent retention characeristics for metal ions.

Absorption spectra

The absorption spectra of the reagent blank and the titanium/Tiron/TDBA complex in naphthalene–DMF solution were recorded against water (Fig. 1). The complex showed an absorption maximum at 398 nm in the presence of ascorbic acid and oxalic acid, and the absorption of the reagent blank is negligible at this wavelength. The complex showed absorption maxima at 375 and 398 nm in the presence of ascorbic acid and oxalic acid–ascorbic acid, respectively, whereas its absorption is very small in the absence of both acids. Thus, all absorbance measurements were made at 398 nm in subsequent works.

Effect of pH

Experiments were carried out by using 12 μg of titanium. The complex was quantitatively retained on this adsorbent in the pH range 3.0–4.5 (Fig. 2). The retention was incomplete at lower and higher pH values. The addition

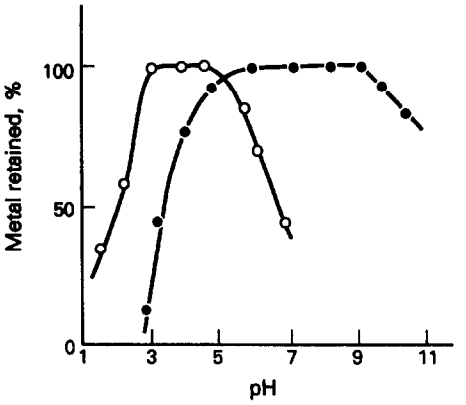

Fig. 2. Effect of pH. ○: Ti: 12 μg, 1.0% *L*-ascorbic acid: 0.7 ml, 1.0% oxalic acid: 0.4 ml. Wavelength: 398 nm. Fe: 15 μg, 0.5% potassium sodium tartrate: 1.0 ml. Wavelength: 248 nm (AAS method). Reference: reagent blank.

of 0.3–2.0 ml of the acetate buffer did not affect the retention of titanium and thus 0.5 ml was recommended in the present work.

Effect of L-*ascorbic acid and oxalic acid concentration*

Various amounts of ascorbic acid and oxalic acid were added to the solution containing 12 μg of titanium and the general procedure was followed. The results are given in Fig. 3. The absorbance of the complex increased with increasing amounts of 1% *L*-ascorbic acid and became constant with 0.6–1.0 ml of this solution. Keeping the *L*-ascorbic acid concentration (1.0%, 0.7 ml) constant, the absorbance remained constant over the range 0.2–1.0 ml of 1% oxalic acid. The absorbance of the complex was very small in the absence of both acids.

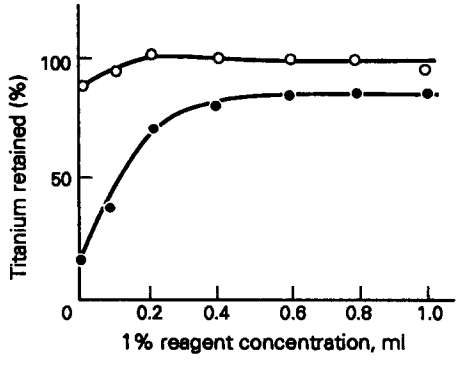

Fig. 3. Effect of reagent concentration. Ti: 12 μg, pH: 4.0, 1.0% *L*-ascorbic acid: 0.7 ml, 1.0% oxalic acid: 0.4 ml. Reference: reagent blank. ●: Varying *L*-ascorbic acid concentration; no oxalic acid. ○: Varying oxalic acid concentration, keeping *L*-ascorbic acid concentration (1.0%, 0.7 ml) constant.

Thus 0.7 ml of *L*-ascorbic acid and 0.4 ml of oxalic acid was used in further work.

Effect of flow-rate, standing time and aqueous volume

The flow-rate was examined from 0.5 to 10 ml/min under the optimum conditions. This range did not cause any effect on the absorbance. Thus, a flow-rate of 1 ml/min was selected. This rate is a natural rate of falling through the column. The colour of the complex in naphthalene–DMF solution was stable for 60 min. The volume of aqueous phase was varied from 15 to 150 ml. The absorbance remained constant when the aqueous phase volume did not exceed 80 ml. In subsequent work, 15 ml of the aqueous phase was used for convenience.

Choice of solvent

Different organic solvents were studied for dissolving the naphthalene/Ti/Tiron/TDBA complex from the column. Since the solid mass should be dissolved in a small volume of solvent, it is essential to select a solvent in which it has high solubility. The solid material was very soluble in DMF, methanol, ethanol, acetonitrile, 4-methyl-2-pentanone, dimethyl sulphoxide and acetone. The sensitivity and precision for measurement of the complex were the highest in DMF solution. Three millilitres of DMF were sufficient to dissolve the mixture, thus providing maximum sensitivity.

Beer's law, sensitivity and precision

Beer's law was obeyed over the concentration range 1–18 μg of titanium in 5 ml of DMF solution. The molar absorptivity of the complex was 1.39×10^4 l. mole^{-1}. cm^{-1} and the sensitivity was 3.44×10^{-3} μg/cm^2 for absorbance of 0.001. Eight replicate determinations containing 12 μg of titanium gave a mean absorbance of 0.697 with a relative standard deviation of 0.82%.

Effect of diverse ions

Different amounts of alkali metal salts of different anions and metal ion solutions were added individually to a solution containing 12 μg of titanium and the general procedure was applied. The tolerance limit was set as the amount which caused an error of $\pm 3\%$ in the recovery of 12 μg of titanium. The results are given in Tables 1 and 2. Among the salts examined, most of them could be tolerated up to 50 mg–1 g levels. KCN and EDTA interfered seriously. Anions like SCN^- and ClO^{4-} react with TDBA to form water-insoluble ion-pairs and cause errors in the determination. Larger amounts of Cl^- and ClO_4^- affect the determination, and thus for wet-ashing decomposition of practical samples, the samples must be completely evaporated to dryness on a water-bath to eliminate these ions. Most of the metal ions did not interfere in the determination of titanium at the one milligram level. W(VI), Cd(II), Cr(VI) and Pb(II) could be tolerated even in amounts of 20–40-fold more than titanium. The effects of

Table 1. Effect of diverse salts

*Mean of 4 determinations. 1.0% *L*-ascorbic acid (0.7 ml) and 1.0% oxalic acid (0.4 ml) were added. Masking agents were as follows: [a]$Na_2C_2O_4$ (50 mg), [b]$Na_2C_2O_4$ (50 mg), [c]KSCN (400 μg), [d]$Na_2C_2O_4$ (20 mg), [e]KSCN (400 μg). NIES: National Institute for Environmental studies (values in parentheses are approximate and not certified).

V(V), Pt(IV), Fe(II), Ag(I), Bi(III) and Pd(II) were greatly improved by using suitable masking agents, but Mo(VI) was not masked with the complexing agents described (Tables 1 and 2). The proposed method is quite selective and can be applied to the determination of titanium in standard aluminium and zinc alloys.

Analysis of alloys for titanium

The proposed method has been successfully applied to the determination of titanium in aluminium and zinc alloy. The results in Table 3 are in reasonable agreement with the certified values. For analysis of alloy samples, a 0.1-g mass of alloy was completely dissolved in 10 ml of *aqua regia* on a water-bath. The solution was evaporated to dryness to eliminate the excess acids. The residue was dissolved in a few drops of concentrated nitric acid and distilled water. The mixture was cooled and filtered through filter paper. The filtrate was diluted to 100 ml with distilled water in a standard flask. An aliquot (1–4 ml) of this sample was taken in a beaker and the general procedure applied.

CONCLUSION

A solid ion-pair compound produced from Tiron and TDBA on naphthalene provides a simple and rapid method for the preconcentration of trace titanium. The proposed method is the first attempt to separate titanium using the reaction of Ti/Tiron complex anion with the quaternary ammonium cation. Solvent extraction is difficult to separate metal ions in the presence of cationic surfactant due to the formation of emulsions in the two phases on shaking. In such cases, larger amounts of the salting-out agent must be added in the solution or both phases must be left to stand for a long time, thus making the method more tedious. The proposed method is free from these problems and needs only simple glassware such as funnel-tipped glass and small volume beakers. The sensitivity of the proposed method may be further improved by combination with an HPLC ultraviolet–visible flow detector.

KINETIC ANALYSIS OF SECOND ORDER REACTIONS USING UV–VIS SPECTROSCOPY

J. POLSTER

Lehrstuhl für Allgemeine Chemie und Biochemie der Technischen Universität München, D-8050 Freising-Weihenstephan, Germany

H. MAUSER

Institut für Physikalische und Theoretische Chemie der Universität Tübingen, Auf der Morgenstelle, D-7400 Tübingen, Germany

(*Received* 21 *November* 1991. *Revised* 6 *March* 1992. *Accepted* 6 *March* 1992)

Summary—A new method was recently developed for the spectroscopic kinetic analysis of reactions with two linearly independent concentration variables. Firstly, the results of this theory applied to experimental data are represented. For this investigation, reactions of the mechanism type

$$A + B \xrightarrow{k_1} C + D \text{ and } A + E \xrightarrow{k_2} F + G$$

were chosen since both reaction steps can be studied separately. The evaluation of the reaction system consisting of both reaction steps gives satisfactory results when the methods of "formal integration" and "singular value decomposition" (SVD) are used. Absorption coefficients of absorbing species are not needed for the evaluation. Only time dependent spectroscopic measuring values and initial concentrations are used in the presented practical example.

It has been demonstrated in a previous paper[1] that non-linear reaction systems with two linearly independent reaction steps can be analysed by spectroscopic methods. The following differential equations in matrix notation hold generally for the absorbances of those reactions:

$$\dot{\mathbf{A}} = \dot{\mathbf{A}}_0 + \mathbf{Z}\ \Delta\mathbf{A} + \mathbf{Y}\ \Delta\mathbf{A}^2$$
$$\mathbf{A} = \mathbf{Z}'(\mathbf{A} - \mathbf{A}_\infty) + \mathbf{Y}(\mathbf{A} - \mathbf{A}_\infty)^2 \qquad (1)$$

The vectors have the following meaning

$$\dot{\mathbf{A}} = \begin{pmatrix} \dot{A}_1 \\ \dot{A}_2 \end{pmatrix} \quad \dot{\mathbf{A}}_0 = \begin{pmatrix} \dot{A}_{01} \\ \dot{A}_{02} \end{pmatrix} \quad \Delta\mathbf{A} = \begin{pmatrix} A_1 - A_{01} \\ A_2 - A_{02} \end{pmatrix}$$

$$(\mathbf{A} - \mathbf{A}_\infty) = \begin{pmatrix} A_1 - A_{\infty 1} \\ A_2 - A_{\infty 2} \end{pmatrix} \quad \Delta\mathbf{A}^2 := \begin{pmatrix} \Delta A_1^2 \\ \Delta A_2^2 \\ \Delta A_1\, \Delta A_2 \end{pmatrix}$$

$$(\mathbf{A} - \mathbf{A}_\infty)^2 := \begin{pmatrix} (A_1 - A_{1\infty})^2 \\ (A_2 - A_{2\infty})^2 \\ (A_1 - A_{1\infty})(A_2 - A_{2\infty}) \end{pmatrix} \qquad (2)$$

and the following matrices are introduced

$$\mathbf{Z} := \mathbf{Q}\mathbf{k}\mathbf{Q}^{-1}, \quad \mathbf{Z}' := \mathbf{Q}\mathbf{k}'\mathbf{Q}^{-1} \quad \mathbf{Y} := \mathbf{Q}\mathbf{k}''\mathbf{P} \qquad (3)$$

The matrix **Q** transforms the two degrees of advancement X_1 and X_2 into the absorbance differences $(A_1 - A_{10})$ and $(A_2 - A_{20})$. The indices 1 and 2 indicate the two different measuring wavelengths of the observation light. These wavelengths have to be chosen in such a way that the matrix **Q** is regular. The matrices **k** and **k′** are the Jacobian matrices:

$$\mathbf{k} = \begin{pmatrix} \partial\dot{X}_1/\partial X_1 & \partial\dot{X}_1/\partial X_2 \\ \partial\dot{X}_2/\partial X_1 & \partial\dot{X}_2/\partial X_2 \end{pmatrix}_{t=0}$$

and

$$\mathbf{k}' = \begin{pmatrix} \partial\dot{X}_1/\partial X_1 & \partial\dot{X}_1/\partial X_2 \\ \partial\dot{X}_2/\partial X_1 & \partial\dot{X}_2/\partial X_2 \end{pmatrix}_{t\to\infty}.$$

The matrix **k″** is defined by

$$\mathbf{k}'' = \begin{pmatrix} \partial^2\dot{X}_1/\partial X_1^2 & \partial^2\dot{X}_1/\partial X_2^2 & 2\partial^2\dot{X}_1/\partial X_1\, \partial X_2 \\ \partial^2\dot{X}_2/\partial X_1^2 & \partial^2\dot{X}_2/\partial X_2^2 & 2\partial^2\dot{X}_2/\partial X_1\, \partial X_2 \end{pmatrix} \Big/ 2. \qquad (4)$$

The matrix **P** transforms the square elements of the degrees of advancement into the corresponding absorbance quantities.[2,3] This matrix

can be calculated by means of the elements of the matrix **Q**:

$$\mathbf{P} = \begin{pmatrix} Q_{22}^2 & Q_{12}^2 & -2Q_{22}Q_{12} \\ Q_{21}^2 & Q_{11}^2 & -2Q_{11}Q_{21} \\ -Q_{21}Q_{22} & -Q_{11}Q_{12} & Q_{11}Q_{22}+Q_{12}Q_{21} \end{pmatrix} \Big/ |\mathbf{Q}|^2 \tag{5}$$

$|\mathbf{Q}|$ is the determinant of **Q**.

The matrices of equation (4) obtain the information which characterize the single systems. Only the elements of the transformed matrices **Z**, **Z'** and **Y** can be obtained from spectroscopic measurements according to equation (1). The differential equation (1) written as a system of usual differential equations is:

$$\begin{aligned} \dot{A}_1 &= z_{01} + z_{11}\,\Delta A_1 + z_{12}\,\Delta A_2 + y_{11}\,\Delta A_1^2 \\ &\quad + y_{12}\,\Delta A_2^2 + y_{13}\,\Delta A_1\,\Delta A_2 \\ \dot{A}_2 &= z_{02} + z_{21}\,\Delta A_1 + z_{22}\,\Delta A_2 + y_{21}\,\Delta A_1^2 \\ &\quad + y_{22}\,\Delta A_2^2 + y_{23}\,\Delta A_1\,\Delta A_2 \end{aligned} \tag{6}$$

or

$$\begin{aligned} \dot{A}_1 &= z'_{11}(A_1 - A_{1\infty}) + z'_{12}(A_2 - A_{2\infty}) \\ &\quad + y_{11}(A_1 - A_{1\infty})^2 + y_{12}(A_2 - A_{2\infty})^2 \\ &\quad + y_{13}(A_1 - A_{1\infty})(A_2 - A_{2\infty}) \\ \dot{A}_2 &= z'_{21}(A_1 - A_{1\infty}) + z'_{22}(A_2 - A_{2\infty}) \\ &\quad + y_{21}(A_1 - A_{1\infty})^2 + y_{22}(A_2 - A_{2\infty})^2 \\ &\quad + y_{23}(A_1 - A_{1\infty})(A_2 - A_{2\infty}) \end{aligned} \tag{7}$$

The constants z_{ik} and y_{ik} or z'_{ik} and y_{ik} can be determined by means of an appropriate linear regression method when the absorbances A_1 and A_2 are measured as a function of time. These constants can be used for the kinetic analysis of the investigated reactions as shown in [1] and in the following examples.

Generally, a reaction mechanism cannot be proved by kinetic analysis of absorbance–time curves. It is only possible to show that the postulated mechanism (theory) does not contradict the experiment. If theory and experiment are inconsistent the theory has to be replaced. These facts can be expressed by Theorem 1:

Proving a reaction mechanism only by kinetic analysis is not possible.

Equation (1) is the basis of absorbance differential equations for about 100 different reaction mechanisms where at least one reaction is second order (all systems were theoretically studied in detail). It can be distinguished in suitable cases between different reaction mechanisms when the constants z_{ik} or z'_{ik} and y_{ik} are used as demonstrated by Mauser.[1]

A THEORETICAL EXAMPLE

Assuming that an investigated reaction runs according to the mechanism

$$A + B \xrightarrow{k_1} C \xrightarrow{k_2} D \tag{8}$$

the equations for **k**, **k'** and **k''** lead to

$$\mathbf{k} = \begin{pmatrix} -k_1(a_0+b_0) & 0 \\ k_2 & -k_2 \end{pmatrix},$$

$$\mathbf{k}' = \begin{pmatrix} -k_1(a_0-b_0) & 0 \\ k_2 & -k_2 \end{pmatrix},$$

$$\mathbf{k}'' = \begin{pmatrix} k_1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}. \tag{9}$$

It is true that the elements of the matrices **Z** and **k** are different as those of **Z'** and **k'** but the corresponding matrices are similar matrices, *i.e.*, they have the same rank, the same trace and therefore the same eigenvalues. The matrices **Y** and **k''** are equivalent matrices which have the same rank. From this it follows that for reaction (8) the rank of **Z** and **Z'** has to be two and the rank for **Y** is one. Furthermore it follows (S = trace of **Z**, D = determinant of **Z**)

$$\begin{aligned} S &= z_{11} + z_{22} = -k_1(a_0+b_0) - k_2, \\ D &= z_{11}z_{22} - z_{12}z_{21} = k_1k_2(a_0+b_0) \end{aligned} \tag{10}$$

These equations lead to

$$-S = k_1 + D/k_1 \tag{11}$$

Analogously, the following equations are true (S' = trace of **Z'**, D' = determinant of **Z'**)

$$\begin{aligned} S' &= z'_{11} + z'_{22} = -k_1(a_0-b_0) - k_2 \\ D' &= z'_{11}z'_{22} - z'_{12}z'_{21} = k_1k_2(a_0-b_0) \end{aligned} \tag{12}$$

and

$$-S' = k_1 + D'/k_1. \tag{13}$$

The existence of the equations (10)–(13) can be verified and their relations used for the determination of rate constants when various series of

measurements with different initial concentrations are carried out.

$$y_{11}/y_{12} = y_{21}/y_{22} = y(h) = (Q_{22}/Q_{12})^2 \quad (14)$$

$$y_{11}/y_{13} = y_{21}/y_{23} = y(h') = -Q_{22}/2Q_{12} \quad (15)$$

$$y_{12}/y_{13} = y_{22}/y_{23} = y(h'') = -Q_{12}/2Q_{22} \quad (16)$$

$$y_{11}/y_{21} = y_{12}/y_{22} = y_{13}/y_{23} = y(v) = Q_{11}/Q_{21} \quad (17)$$

The four quantities from $y(h)$ to $y(v)$, on the right hand side above, have close connections to the elements of the matrix **Q**. They indicate the directions of the axis X_1 and X_2 in the "absorbance (A)-diagram".[1-7] Experimental examples are given for evaluating this reaction type as a "quasilinear reaction" by Lachmann *et al.*[2,3] and Polster.[4]

The treated consecutive reaction mechanism A + B→C→D consists of one reaction step being of second order and one step of first order. This mechanism has to be distinguished from the system A→B→C where only reactions of first order take place. Both reaction systems lead to bent curves in the A-diagrams and to straight lines in the ADQ-diagrams.[1-4] Therefore, it is not possible to distinguish a priori between the system A + B→C→D and the system A→B→C. The situation is yet more complicated because of Theorem 2[8,9]

Two linear reactions the Jacobian matrices of which have the same rank cannot be distinguished alone by spectroscopic means.

For example, this means that the system A→B→C cannot be distinguished from the system A→B, C→D by spectroscopic kinetic analysis except by using additional information. However, the absorbance differential equations of linear systems[9] are completely different from those having at least one reaction step of second order [compare equation (1)]. This means that in practice "pure" linear reaction systems can be kinetically distinguished in most cases from those having reaction steps of second order. For example, the equation analogous to equation (10) holds for the system A→B→C or A→B, C→D[2,3,7,9]

$$S = z_{11} + z_{22} = -(k_1 + k_2)$$

and

$$D = z_{11}z_{22} - z_{12}z_{21} = k_1k_2$$

indicating that S and D are independent concentrations. S and D here are the trace and determinant of the matrix **Z** according to Lachmann *et al.*[2,3] and Mauser and Polster[9]

$$\dot{\mathbf{A}} = \mathbf{Z}(\mathbf{A} - \mathbf{A}_\infty)$$

is the basic equation for linear reaction systems.

Table 1. Results of evaluation according to equations (20) and (21) using different wavelength combinations λ_1/λ_2

Wavelengths *nm*	$k_1(20)$	$k_2(21)$	$k_2(20)$
370/350	(2.0)	0.39	–
370/330	2.89	0.34	0.39
370/310	2.81	(0.30)	–
350/330	2.85	0.35	0.39
350/310	2.78	(0.27)	–
330/310	2.82	(0.42)	–

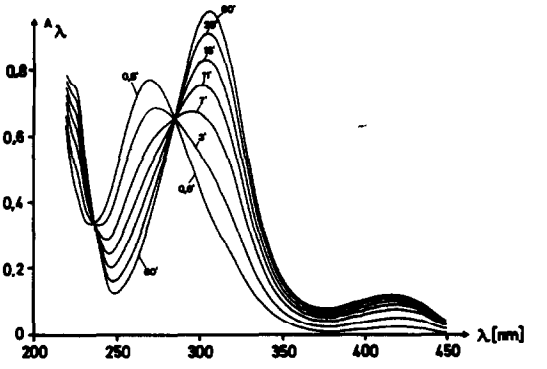

Fig. 1. Reaction spectra of the first reaction step: t-BOC-glycine p-nitrophenyl ester ($1 \times 10^{-4}M$) and n-butylamine ($6 \times 10^{-4}M$) in acetonitrile (25°). The reaction time is given.

A PRACTICAL EXAMPLE

Spectroscopically measured reaction systems can be analysed by means of the relations presented by Mauser.[1] However, a prerequisite is that methods can be found for determining the characteristic matrices with sufficient accu-

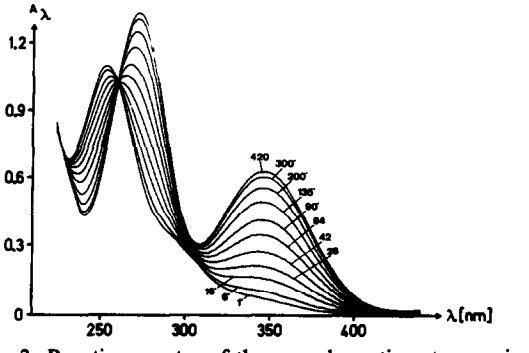

Fig. 2. Reaction spectra of the second reaction step: o-nitrophenyl acetate ($2 \times 10^{-4}M$) and n-butylamine ($6 \times 10^{-4}M$) in acetonitrile (25°). The reaction time is presented.

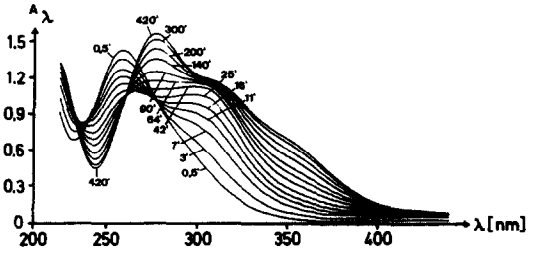

Fig. 3. Reaction spectra of the full reaction system (t-BOC-glycine *p*-nitrophenyl ester = $1 \times 10^{-4}M$, *o*-nitrophenyl acetate = $2 \times 10^{-4}M$, n-butylamine = $6 \times 10^{-4}M$; solvent = acetonitrile; 25°.

racy. At first glance it appears hopeless because six constants have to be determined simultaneously in each equation of (6) and in the case of equations (7) there are five constants for each equation. Firstly, in order to test the new method the following reactions were chosen:

$$\begin{aligned} A + B &\xrightarrow{k_1} C + D \\ A + E &\xrightarrow{k_2} F + G \end{aligned} \qquad (18)$$

The reactants are: A = n-butylamine; B = tert. butoxycarbonyl (t-BOC)-glycine *p*-nitrophenyl ester; C = t-BOC-glycine n-butylamide; D = *p*-nitrophenol; E = *o*-nitrophenyl acetate; F = *N*-acetyl-n-butylamide; G = *o*-nitrophenol. The solvent is acetonitrile (for UV-spectroscopy, Fluka). The experimental procedure has been described earlier.[2-6]

This reaction was chosen because both reaction steps can be studied separately in an easy way.[5,6] At first it was attempted to evaluate the spectroscopically measured values by the method of "formal integration".[2-7] Using common regression methods the results were totally unsatisfactory. Then the "singular value decomposition method" (SVD) developed in the seventies was applied for determining the constants of equations (6) on basis of the formal integration. Both FORTRAN and PASCAL programs were developed for this method.[10,11] Using the SVD method the results were encouraging. The matrix **k** has the form

$$\mathbf{k} = \begin{pmatrix} -k_1(a_0 + b_0) & -k_1 b_0 \\ -k_2 e_0 & -k_2(a_0 + e_0) \end{pmatrix} \qquad (19)$$

The determinant D and trace S were calculated from the computed values z_{ik} according to equation (10). The rate constants k_1 and k_2 can be determined from the equations

$$D = \text{determinant} = k_1 k_2 a_0 (a_0 + b_0 + e_0)$$

and

$$S = \text{trace} = -k_1(a_0 + b_0) - k_2(a_0 + c_0).$$

With the abbreviations of the known combinations of the initial concentrations

$$\sigma_1 = a_0(a_0 + b_0 + e_0)$$

$$\sigma_2 = a_0 + b_0,$$

$$\sigma_3 = a_0 + e_0,$$

it follows from the equations for D and S:

$$k_{1,2} = \frac{-\sigma_1 S \pm \sqrt{(\sigma_1 S)^2 - 4\sigma_1 \sigma_2 \sigma_3 D}}{2\sigma_1 \sigma_2} \qquad (20)$$

More accurate values for k_2 are obtained using the relationship

$$k_2 = D/k_1\sigma_1. \qquad (21)$$

The results of evaluation are presented in Table 1. The dimensions of k_1 and k_2 are

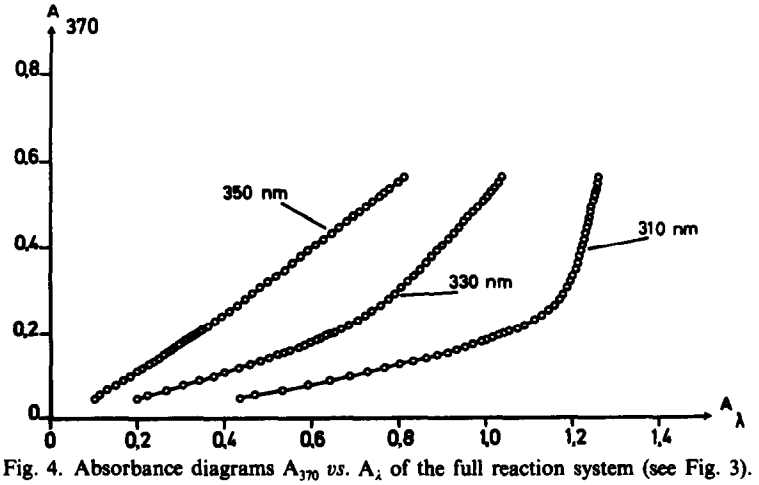

Fig. 4. Absorbance diagrams A_{370} *vs.* A_λ of the full reaction system (see Fig. 3).

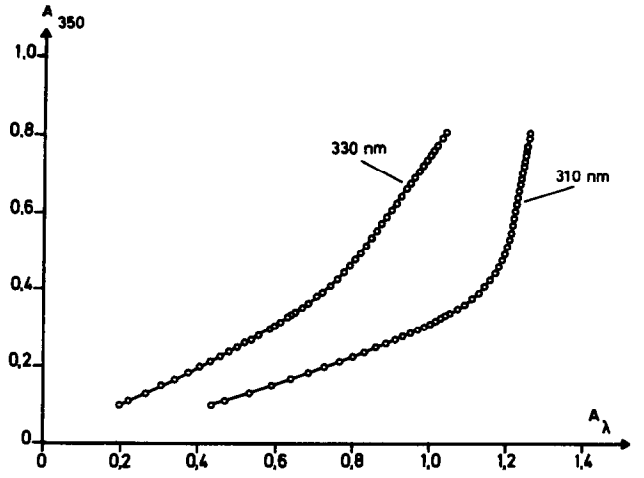

Fig. 5. Absorbance diagrams A_{350} *vs.* A_λ of the full reaction system (see Fig. 3).

$M^{-1}\,sec^{-1}$. The evaluation of the single reactions measured separately led to the values

$$k_1 = 2.86 \quad \text{and} \quad k_2 = 0.35$$

The 'reaction spectra'[2–7] of the first and second reaction step as well as of the full reaction system are presented in Figs. 1, 2 and 3. The A-diagrams for selected wavelength combinations are shown in Figs. 4 and 5. As Fig. 2 shows, the reactants of the second reaction step do not absorb strongly near 310 nm. Therefore, the quantities k_2 of this reaction determined by combining different wavelengths with 310 nm are relatively inaccurate (about 10–30%); these values are noted in the brackets in Table 1. It is astonishing that the k_i values calculated from the wavelength combination 370/350 nm are fairly reasonable though the corresponding A diagram shows only a weakly curved trend (see Fig. 4).

As shown by this practical example the knowledge of absorption coefficients is not a prerequisite for the application of the theory. During the reactions all or nearly all components may be absorbing. The only requirement for the evaluation is that enough components absorb, *i.e.*, that the single reactions of the system are individually registered spectroscopically. (Thus, in the case of the practical example it would be sufficient if only the components D and G were light absorbing.)

The practical procedure described here is typical for the analysis of about 100 different reaction systems obeying equation (1). The spectroscopically kinetic analysis involving reaction steps of second order is more complicated than that of systems consisting of only linear reactions. More constants have to be determined significantly in the case of reactions of second order at the same number of linearly independent reactions. However, it is possible to distinguish here between different reaction systems using consequently the criteria of equations (10)–(17) and other criteria described by Mauser.[1]

(*Received* 26 *September* 1990. *Revised* 27 *February* 1991. *Accepted* 1 *July* 1991)

Summary—The reaction between thiocarbamate herbicides and 2,6-dichlorobenzoquinone-*N*-chloroimine or 2,6-dibromobenzoquinone-*N*-chloroimine is suitable for the detection of these herbicides on thin-layer plates with high sensitivity. The reactions were followed by infrared, nuclear magnetic resonance and mass spectrometry. We have established the formation of 2,6-dichlorobenzoquinone-*S*-alkyl sulphenylimines. In the case of the bromo-derivative, halogen exchange and substitution on the quinone ring took place simultaneously leading to the formation of mixed halogenated 2,6-dihalo- and, in addition, 2,3,6-trihalobenzoquinone-*S*-alkyl sulphenylimines. The final product of the detection reaction, *i.e.*, 2,6-dichlorobenzoquinone-*S*-alkyl sulphenylimine was reacted with 2,6-dibromobenzoquinone-*N*-chloroimine where 2,6-dichloro-3-bromobenzoquinone-*S*-alkyl sulphenylimine formed as a consequence of the looser bromine–carbon linkage on the 2 and 6 positions of the quinone ring.

Gibbs[1,2] introduced the 2,6-dichlorobenzoquinone-*N*-chloroimine (**I**) and the 2,6-dibromobenzoquinone-*N*-chloroimine[3] (**II**) for the detection of phenols in alkaline solution, leading to the formation of indophenols.[4,5] This method was extended for the analysis of anilines, adrenalins and noradrenaline.[6–8]

The compounds **I** and **II** were supposed to react with thiophenols forming thioindophenols. Surprisingly, the products were 1,4-benzoquinone-4-aryl sulphenylimines[9] which could be converted by heat treatment into the expected thioindophenols. Thioketons, sulphur containing pesticides, alkyl-, and aryl heterocyclic mercapto compounds can also be detected by **I** and **II** in alkaline conditions.[10,11]

Cuzzoni and Pietra Lissi[12] studied the reaction of Gibbs reagents with alkyl and aryl disulphides pointing out the formation of sulphenylimines followed by Cl_2 evolution. In these reactions of **II**, anomalous mixed halogenated benzoquinone derivatives were observed.

More recently, sulphydryl groups were detected in histochemical studies by these reagents.[13] Analogously, glyoxaline-2-thiol gave also sulphenylimine derivatives[14] in the reaction with **I** or **II**.

Thiocarbamate herbicides can be visualized by different detection methods. Some of them are summarized in Table 1. Ninhydrine,[17] palladium chloride in acidic solution[18] detect these compounds with the same detection limit. Less sensitive is the reaction of 4-(dimethylamino)-benzaldehyde but *o*-toluidine–KI system[19] detects thiocarbamates with two orders of magnitude higher sensitivity than the former one. Insecticides are very effective inhibitors of acetylcholine esterases. Surprisingly, thiocarbamates have some inhibitory effect on these enzymes[19,20] but their detection limits are two or three orders of magnitude higher. NBD-Cl (4-chloro-7-nitrobenzo-2,1,3-oxadiazole)[21] can be used for fluorogenic labelling. This agent reacts with the amino part of the carbamates and thiocarbamates after hydrolysis, giving fluorescent spots on a non-fluorescent background.

Table 1. Sensitivity of the thin-layer chromatographic detection methods for thiocarabamate herbicides

Reagents	Sensitivity (μg/spot)	Ref.
Ninhydrine	2.0	17
$PdCl_2$ + HCl	2.0	18
4-(Dimethylamino)-benzaldehyde	10.0	19
o-Toluidine + KI	0.3	19
Bee head esterase + 2-naphthylacetate	1.0	20
Drosophyla esterase + 2-naphthylacetate	1.0	20
Horse serum esterase + 2-indoxylacetate	0.5 (Butylate)	19
NBD–Cl	0.1	21
I	0.05	15
II	0.05	15

In our previous works[15,16] Gibbs reagents (**I, II**) were reported as sensitive thiocarbamate (**III**) detecting agents (Table 1). These compounds gave yellow spots with **III** on the thin-layer chromatographic (TLC) plates in strong acidic conditions. We have extended this method for the quantitative determination of **III** by *in situ* densitometry.[22,23] The absorption maximum of the coloured spots obtained with **I** was constantly at 450 nm, but it was less reproducible when **II** was applied.

In order to understand this changing absorption maximum of the coloured spots, we investigated the colour reaction. We used the same conditions in the synthesis of the compounds responsible for the detection, as was used in the analytical procedure. The only difference was heat treatment of the plates at the nanogram range which completed the colour formation. The isolated coloured compounds were studied by infrared (IR) nuclear magnetic resonance (NMR) and mass (MS) spectrometry.

EXPERIMENTAL

Apparatus

Infrared spectra were taken with a Nicolet 170 SX FTIR spectrometer in carbon tetrachloride solution, in nujol and/or potassium bromide pellets. Solid state Raman spectra were recorded with a Cary 82 spectrometer with an argon ion laser (exciting line 514.5 nm).

^{1}H NMR spectra were measured with a Varian XL-100-15 FT spectrometer at 25°, and ^{13}C spectra at 50°, the chemical shifts (δ) are with reference to internal tetramethylsilane. The multiplicities of the carbon lines were determined by the attached proton test (APT) technique.[24]

The mass spectra were taken by an AEI–MS 902 spectrometer with the following settings: ion accelerating voltage 8 kV, ionizing voltage 8 kV, stop current 100 μA, direct introduction, 180°. All mass numbers are given in daltons calculated for ^{35}Cl and ^{79}Br isotopes, respectively.

For TLC detection, the TLC plates were dipped or sprayed with 1% solution of **I** or **II** in acetic acid (96%) and heated at 110° for 2–10 min after drying. The yellow spots of the thiocarbamates appeared against the white background.

Densitometric measurements were carried out with a Shimadzu CS-920 high speed scanner at the absorption maximum of 2,6-dichlorobenzoquinone-*S*-alkyl sulphenylimine (λ_{max} 450 nm) determined *in situ* on Silufol plates (Kavalier, Czechoslovakia).[22,23] When the detection was carried out by **II**, the λ_{max} value had to be determined *in situ* in each case separately, and was found to be between 450–455 nm.

Melting points (uncorrected) were determined with a Boetius micro melting point equipment.

Chemicals

2,6 - Dichlorobenzoquinone - *N* - chloroimine was purchased from Janssen Chimica (Beerse, Belgium) and 2,6-dibromobenzoquinone-*N*-chlorimine from Merck (Darmstadt, Germany). EPTC (*S*-ethyl dipropylthiocarbamate), butylate (*S*-ethyl diisobutylthiocarbamate), cycloate (*S*-ethyl cyclohexyl *N*-ethyl-thiocarbamate), pebulate (*S*-propyl butylethylthiocarbamate), vernolate (*S*-propyl dipropylthiocarbamate) were commercial products supplied by (Nitrokémia Fűzfőgyártelep, Hungary) and purified by distillation. Kieselgel 60 (0.063–0.040 mm) stationary phase and Kieselgel 60 TLC plates were purchased from Merck (Darmstadt, Germany) while Silufol F_{254} plates were from Kavalier (Votice, Czechoslovakia). Solvents were obtained from Reanal (Budapest, Hungary) and distilled from glass before use.

Reagents

2,6-Dichlorobenzoquinone-N-*chloroimine (I).* Purified by recrystallization from ethyl alcohol:[24] m.p. 67°. ^{13}C NMR ($CDCl_3$) 124.5 (C_3), 136.5 (C_2), 134.6 (C_5), 141.9 (C_6), 165.2 (C_4), 172.6 (C_1) ppm. Found C 34.22, H 0.94, Cl 50.56, N 6.65, $C_6H_2Cl_3NO$ requires C 34.24, H 0.96, Cl 50.54, N 6.66

2,6-dibromobenzoquinone-N-*chloroimine (II).* Purified by recrystallization from ethyl alcohol:

m.p. 79–80° (chromatographic purity). Found C 24.09, H 0.70, Cl 11.82, Br 53.35, N 4.67, $C_6H_2ClBr_2NO$ requires C 24.07, H 0.67, Cl 11.84, Br 53.38, N 4.68 ^{13}C NMR ($CDCl_3$) 128.8 (C_3), 127.6 (C_2), 134.3 (C_6), 138.7 (C_5), 166.0 (C_4) ppm; $^3J_{CH}(C_3)$ 5.9, $^1J_{CH}(C_3)$ 175.5, $^2J_{CH}(C_2)$ 5.4, $^2J_{CH}(C_6)$ 6.0, $^3J_{CH}(C_5)$ 5.5, $^1J_{CH}(C_5)$ 175.6 Hz.

Synthesis

*2,6-Dichlorobenzoquinone-S-ethyl sulphenylimine (IVa).** The solution of 1.0 g (5 mmoles) of 2,6-dichlorobenzoquinone-*N*-chloroimine (**I**) in 10 ml (96%) acetic acid was added dropwise to the stirred solution of 0.9 g (5 mmoles) of EPTC (**III**) in 10 ml of $CHCl_3$ at room temperature. In the slightly exothermic reaction gas evolved, a yellowish precipitate formed, and the pale yellow solution turned deep brownish–red. After 30 min the precipitate was filtered off and the filtrate was poured on ice. The organic layer was washed with 3 × 10 ml of water, 3 × 10 ml of 5% $NaHCO_3$, 3 × 10 ml of water, dried (with magnesium sulphate) and evaporated under reduced pressure. The residue was purified on a Florisil column (inner diameter 22 mm), deactivated by 5% w/w H_2O eluted with cyclohexane:ethylacetate (9:1). The elution was followed by TLC on Silufol F_{254} plates developed in xylene. Fractions, containing the compound which appeared on the TLC plate at R_f 0.35, were evaporated and the residue crystallized from cyclohexane, giving orange-red needles [1 g (84.75%), m.p. 82.5–83°]. Found: C 40.05, H 2.94, N 5.87, S 13.45, Cl 30.00, $C_8H_7Cl_2NOS$ requires C 39.95, H 2.90, N 5.63, S 13.29, Cl 30.10 IR (CCl_4) 3000–2800 (νCH_{aliph}, *S*-ethyl), 1665 ($\nu C{=}O$), 1559 ($\nu C{=}N$), 1277 ($=C_3H$ and $=C_5H$ in plane deformation), 1265 [(*S*)—CH_2 wagging], 1056 ($=C_3H$ and $=C_5H$ in plane deformation), 900 ($=C_3H$ and $=C_5H$ out of plane wagging) cm^{-1}. ^1H NMR ($CDCl_3$) 1.4(t), 3.1(q), 7.46(d) (overlapping doublets) $J_{3,5} = 2.5$ Hz (DMSO) 1.45(t), 3.36(q), 7.73(d) (overlapping doublets) ppm. $J_{3,5} = 2.5$ Hz. ^{13}C NMR ($CDCl_3$) 13.5(q), 35.9(t), 123.5 (C_3), 128.3 (C_3), 133.8 (C_6), 136.1 (C_5), 150.9 (C_4), 173.5 (C_1) ppm MS m/e (I%): 235 M(100), 207 M-C_2H_4(100), 179 M-C_2H_4—CO(9), 172 M-C_2H_4—Cl(20), 144 M-C_2H_4—Cl—CO(17), 60 C_2H_4S(20). When cycloate or butylate were reacted with **I** instead of EPTC, the same product **IVa** was isolated.

2,6-Dichlorobenzoquinone-S-propyl sulphenylimine (IVb).† Pebulate (**III**) (5 mmoles) was reacted with **I** (5 mmoles) according to the procedure described in **IVa**, giving the product **IVb**. R_f 0.39 (xylene, Kieselgel 60), 0.9 g (71.9%) m.p. 72–73°. Found C 43.10, H 3.78, N 5.53, S 12.86, Cl 28.37, $C_9H_9Cl_2NOS$ requires C 43.21, H 3.62, N 5.59, S 12.81, Cl 28.34 IR (CCl_4) 3000–3800 (νCH_{aliph}, *S*-propyl), 1660 ($\nu C{=}O$), 1559 ($\nu C{=}N$), 1276 ($=C_3H$ and $=C_5H$ in plane deformation), 1240 [(*S*)—CH_2 wagging], 1050 ($=C_3H$ and $=C_5H$ in plane deformation), 901 ($=C_3H$ and $=C_5H$ out of plane wagging) cm^{-1}. ^1H NMR ($CDCl_3$) 1.13(t), 1.86(m), 3.3(t), 7.46(d) (overlapping doublets) ppm, $J_{3,5} = 2.5$ Hz. ^{13}C NMR ($CDCl_3$) 12.90(q), 21.954(t), 43.961(t), 123.392(d), 136.062(d), 150.888(s), 173.3(s) ppm MS m/e (I%): 249 M(50), 207 M-C_3H_6(50), 202 M-CH_3S(20), 179 M-C_3H_6—CO(13), 172 M-C_3H_6—Cl(20), 144 M-C_3H_6Cl—CO(10), 74 C_3H_6S(90), 73 C_3H_5S(25), 43 C_3H_7(100). When vernolate was reacted with **I** instead of pebulate, the same product, **IVb**, was isolated.

2,6-Dibromobenzoquinone-S-ethyl sulphenylimine (Va). To the stirred and cooled solution of EPTC (5 mmoles) in 5 ml of chloroform, 1.45 g (5 mmol) **II** in 10 ml (96%) of acetic acid was added. After 30 min of stirring the precipitate was filtered off. The organic phase was poured on ice and washed with 3 × 10 ml of water, 3 × 10 ml of 5% $NaHCO_3$, 3 × 10 ml of water, dried on anhydrous magnesium sulphate and concentrated to 2 ml. This solution was checked by TLC. Two yellow spots were visible on Kieselgel 60 plates eluted with xylene. According to MS results the first one at R_f 0.58 was the mixture of **VIIa–IXa**, and the second one at R_f 0.31 contained the desirable **Va** but **VIa, VIIa** were also present (see later).

Preparative chromatographic separation of R_f 0.58 and R_f 0.31 was carried out by flash chromatography on a column (inner diameter 50 mm) packed with 300 g Kieselgel 60 (0.063–0.040 mm) under 0.2 bar overpressure, using xylene as an eluant. *Rf* 0.58 (**VIIa–IXa**), 0.3 g m.p. 101–103°, after crystallization from cyclohexane 0.2 g m.p. 105–106°; MS 2,3,6-tribromobenzoquinone-*S*-ethyl sulphenylimine (**VIIIa**) $C_8H_6Br_3NOS$ M = 401, 2-chloro-3,6-dibromobenzoquinone-*S*-ethyl sulphenylimine (**VIIIa**) $C_8H_6Br_2ClNOS$ M = 357 as main product, 2,6-dichloro-3-bromo-benzoquinone-

*"a" denotes the *S*-ethyl derivative.
†"b" denotes the *S*-propyl derivative.

S-ethyl sulphenylimine (**IXa**) $C_8H_6BrCl_2NOS$ M = 313. Each component exhibited fragment ions analogous to those of **IVA**. IR (CCl_4) 3000–2800 (νCH_{aliph}, *S*-ethyl), 1662 ($\nu C{=}O$), 1553 ($\nu C{=}N$), 1267 [(*S*)—CH_2 wagging] cm^{-1}. ^1H NMR ($CDCl_3$): 1.53(t), 3.36(q), 7.68 and 7.95(s) ppm (DMSO): 1.40(t), 3.36(q), 8.00 and 8.20(s) ppm

R_f 0.31. (**IVa–VIa**) 1.1 g m.p. 89–91°, crystallized from cyclohexane 0.96 g m.p. 91–91.5°; as minor component. MS 2,6-di bromobenzoquinone-*S*-ethyl sulphenylimine (**Va**) $C_8H_7Br_2NOS$ M = 323, 2-bromo-6-chlorobenzoquinone-*S*-ethyl sulphenylimine (**VIa**) $C_8H_7BrClNOS$ M = 279, 2,6-dichloro-benzoquinone-*S*-ethyl sulphenylimine (**IVa**) $C_8H_7Cl_2NOS$ M = 235. Each component exhibited fragment ions analogous to those of **IVa**. IR (CCl_4): 3000–2800 (νCH_{aliph}, *S*-ethyl), 1660 ($\nu C{=}O$), 1553 ($\nu C{=}N$), 1276 ($=C_3H$ and $=C_5H$ in plane deformation), 1267 [(*S*)—CH_2 wagging], 1057 ($=C_3H$ and $=C_5H$ in plane deformation), 903 ($=C_3H$ and $=C_5H$ out of plane wagging) cm^{-1} ^1H NMR: ($CDCl_3$) 1.53(t), 3.29(q), 7.43 and 7.76(d) (overlapping doublets) ppm $J_{3,5}$ = 2.5 Hz. (DMSO) 1.33(t) 3.4(q), 7.73 and 7.92(d) ppm. Densitometry of the separated **IVa–VIa** and **VIIa–IXa** was carried out on Silufol plates eluted with xylene and scanned 30 min after development. The ratio of **IVa–VIa** to **VIIa–IXa** was 3:1.

2,6-Dichloro-3-bromobenzoquinone-S-ethyl sulphenylimine (IXa). To the solution of 0.5 g (1.18 mmol) 2,6-dichloro-benzoquinone-*S*-ethyl sulphenylimine (**IVa**) in 5 ml of $CHCl_3$, 0.6 g (2 mmoles) **II** in 5 ml of 96% acetic acid was added and stirred for four hours. The precipitate was fitered off and recrystallized from 70% ethyl alcohol. According to the elemental analysis the precipitate was a mixed salt of ammonium chloride and ammonium bromide. After pouring the reaction mixture on iced water and extracting with chloroform, washing with $NaHCO_3$ (5%) and water, it was evaporated and purified by flash chromatography on Kiesegel 60 (0.063–0.040 mm) column eluted with xylene under 0.2 bar overpressure. 2,6-dibromo-, 2-bromo-6-chloro-, 2,6-dichlorobenzoquinone and unreacted **IVa** were separated from **IXa**. 0.1 g **IXa** m.p. 69–70° cafter crystallization from cyclohexane. IR 3000–2800 (νCH_{aliph}, *S*-ethyl), 1666 ($\nu C = O$), 1553 ($\nu C = N$) cm^{-1}. ^1H NMR ($CDCl_3$) 1.53(t), 3.33(q), 7.66(d) ppm. MS m/e (I%) $C_8H_6BrCl_2NOS$: 313 M(100); 285 M-C_2H_4(100).

Preparation of food extracts

Method A. Samples (100 g) with high water (>70%) and low sugar content (<5%) were extracted with acetonitrile (100 ml) in the presence of Hyflosupercel (10 g) in a high speed blender. After suction the remaining material was washed with acetonitrile (2 × 20 ml). The filtrate was partitioned with petroleum ether (100 ml). After 2 min of shaking, saturated sodium chloride solution (50 ml) and water (300 ml) was given to the mixture. After shaking and separation, the organic layer was washed with water (2 × 100 ml) dried on anhydrous sodium sulphate (15 g) and concentrated on a Kuderna-Danish evaporator. The obtained solution was cleaned on a Florisil column (20 g, 60–100 mesh), deactivated in 5% with water (w/w). The evaporated extract was eluted with 6 and 15% ether containing petroleum ether. The eluates were concentrated to 1 ml in Kuderna-Danish equipment and analysed by TLC.

Method B. High water (>70%) and 5–15% sugar containing samples (100 g) were extracted as given above but 25 ml of water was added before blending.

Deep frozen spinach and potato samples were analysed by method A and green pea and green bean samples by method B.[23]

RESULTS AND DISCUSSIONS

We studied the chemical reaction responsible for the detection of thiocarbamate herbicides (Fig. 1). The thiocarbamates (**III**) (EPTC, butylate, cycloate) reacted with the formation of the same derivative: 2,6-dichloro-benzoquinone-*S*-ethyl sulphenylimine (**IVa**), while pebulate and vernolate gave the *S*-propyl analogue (**IVb**) according to their IR, ^1H, ^{13}C NMR and mass spectra.

The highly pure **II** (controlled by elemental analysis, IR, NMR and MS) was reacted with **III** and an unexpected reaction was observed. In spite of the fact that, the product obtained in the reaction between **II** and **III** seemed to be chromatographically pure in several solvents and solvent systems having different polarity and selectivity (benzene, toluene, xylene, mesitylene, cyclohexane, cyclohexene and their mixtures),[22] the results of elemental analysis did not correspond to the expected 2,6-dibromobenzoquinone-*S*-alkyl sulphenylimine. The potentiometric halogen determination[26] gave evidence of the presence of chlorine and bromine in the product, suggesting the formation of a mixture.

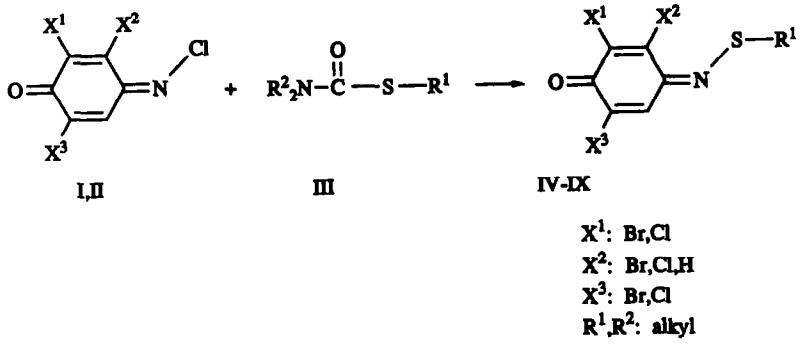

Fig. 1. Formation of halogen substituted benzoquinone-*S*-alkyl sulphenylimines in the detection process.

MS showed on the basis of the molecular ions that the separated materials were mixtures of dihalogenated (**IVa–VIa, IVb–VIb**) and trihalogenated (**VIIa–IXa, VIIb–IXb**) benzoquinone-*S*-alkyl sulphenylimines.

The molecular ions of the products undergo simultaneous fragmentation routes: cleavage of the mercapto group and elimination of ethylene or propylene, followed by the loss of the carbonyl group or a halogen atom (*cf.* mass spectral data of **IVa** and **IVb** in the experimental part). The molecular ions together with these fragment peaks enabled us to recognize the components of the mixture of **IVa–VIa, IVb–VIb, VIIa–IXa, VIIb–IXb**. Tetrahalogenated derivatives were never detected in the spectra of the above mixture.

As the MS analysis showed the reaction of **II** and **III** led not only to the formation of **Va** or **Vb**, but two simultaneous side reactions took place also: halogen exchange (**IV** and **VI**), and proton→halogen substitution (**VII–IX**) on the quinone ring.

The halogen exchange proceeds in the opposite direction of the Finkelstein reaction.[27] Earlier Cuzzoni and Pietra Lissi[12] found the formation of a mixture of dibromo-, dichloro- and Br,Cl-containing sulphenylimines, nevertheless the positions of these substituents were not established, furthermore no trihalogenated derivative was assumed. Presumably, this side reaction took place in that case as well.

In the literature there are some examples on halogen exchange in the unexpected direction: Lyons and Thompson[28] found the formation of 3,6-dichloronaphthoquinone from 3-bromo-6-chloronaphthoquinone in alcoholic hydrochloric acid solution; the same reaction took place with 3-bromo-6-methylnaphthoquinone, where the chloro atom entered at position 3. An ionic mechanism was assumed.

The halogen atoms attached to a quinone ring are exchangeable by fluorine as well: tetrachloro-1,4-benzoquinone can be transformed at high temperature to 6-fluoro-2,3,5-trichloro- and 3,6-difluoro-2,5-dichloro-1,4-benzoquinone.[29] Further on, the tetrabromo derivative can easily be transformed to a 2,6-di- or tetraiodo derivative.[30] Simultaneously Cl→Br, and H→Br substitutions are described on 2-chloro-1,4-naphthoquinone.[31] These few examples support that the Br→Cl exchange is not unprecedented, however, we have to verify that the halogen exchange on the quinone ring takes place at 2,6-position. This is supported by the results of ^{1}H, ^{13}C NMR and IR spectroscopy.

Because of the trigonal hybrid state of nitrogen in **II**, the chloroatom attached to nitrogen eliminates the equivalency of the protons at the 3 and 5 positions. Their signals can be assigned as doublets with the coupling constant $J_{3,5} = 2.5$ Hz[32,33]. The doublets of the protons at the 3 and 5 positions of the dihalogenated products (**Va, VIa** or **Vb,VIb**) were resolved in dimethyl sulphoxide. **IVa** was present only in a very small amount so it had no disturbing effect. The coupling constant was characteristic for the meta position. In the IR spectra of the dihalogenated compounds (**IVa, b–VIa,b**) the coupled in plane deformation vibrations of the protons at 3 and 5 positions showed changes. **I** and **IVa** have this vibration at 1277 cm^{-1}. In the spectrum of **II** this appeared at 1271 cm^{-1}, but after a short reaction time with **III** the product has it at 1265 cm^{-1}. After longer time a band appeared at 1277 cm^{-1} showing the formation of **IVa**.

In 30 min **I** or **II** reacted with **III** completely, but in the reaction of **II** trihalogenated benzoquinone sulphenylimine derivatives appeared (**VII–IX**). The ratio of di- and trihalogenated sulphenylimines was measured by *in situ* densit-

ometry and was found to be 3:1. The longer the reaction time the more **IVa,b**, **VIa,b** and **VIIa,b–IXa,b** formed simultaneously.

Steric hindrance of the *S*-propyl group on the 3 and 5 positions of the quinone ring causes the formation of **VIIb–IXb** in smaller quantities than that of **VIIa–IXa**. It should be remarked that the coupled deformation vibrations of the 3 and 5 protons disappeared from the IR spectra of **VIIa,b–IXa,b**. So we can establish that the bromine–carbon linkage on the quinone ring in the 2 and 6 positions is less stable than the chlorine–carbon one and therefore replacement of bromine by another halogen atom was observed. Spectroscopic data of this substitution reaction were supported by chemical reaction too.

We can study this substitution reaction separately from the formation of the sulphenylimine derivatives if the final product (**IVa**) of the reaction between **I** and **III** is reacted with **II**. On the basis of our results we expected the formation of 2,6-dichloro-3-bromo-benzoquinone-*S*-ethyl sulphenylimine (**IXa**) (Fig. 2) which was isolated.

Substitution took place only when the reaction was carried out for a longer time (several hours) while **II** suffered some decompositions leading to 2,6-dihalobenzoquinones.[34] These byproducts were identified by IR spectroscopy. The tetrahalogenated compound was never observed.

In the analysis of thiocarbamates, more reproducible results were obtained with the use of **I** than with **II**. The chemical investigations on the colour formation of **II** can explain this phenomenon. The thiocarbamate herbicide content of biological extracts was determined by densitometry with the application of the above discussed chemical colour detection method using reagent **I** on Silufol plates.[35] This detection was selective for the thiocarbamates in several biological samples. Figure 3 depicts a densitogram of deep frozen green peas extract where no interfering coextracts disturbed the quantitative determination.

(*Received* 27 *May* 1991. *Revised* 9 *March* 1992. *Accepted* 23 *March* 1992)

Summary—A highly sensitive spectrofluorimetric method for the determination of some drugs of the monosubstituted guanidine derivatives in laboratory made tablets, in spiked human serum and in urine samples is presented. The method is based on the reaction of guanethidine sulphate (I), guanoxan sulphate (II) and amiloride hydrochloride (III) with 9,10-phenanthraquinone (IV) to give highly fluorescent derivatives. The linearity ranges were found to be 0.06–0.96 μg/ml for (I) and (II) and 0.04–0.28 μg/ml for (III), with relative standard deviation less than 2%. Mean percentage recoveries for tablets were found to be 99.9 ± 1.3, 100.5 ± 1.1 and 100.0 ± 1.6 for I, II and III, respectively. For I and III the results are highly correlated with the B.P. methods. Using the synchronous fluorimetry, differentiation between I and II was possible. Chloroform, dichloromethane and ethyl acetate have been used to extract I, II and III, respectively from serum and urine at basic pH, followed by applying the proposed fluorimetric method. Percentage recoveries were found to be 95.7–102.2%. The limit of detection is 0.04 μg/ml for I and II and 0.02 μg/ml for III.

The fluorescence reaction of 9,10-phenanthraquinone as a very sensitive test for arginine and arginine-containing peptides was first introduced by Itano and Yamada.[1] The mechanism of the fluorescence reaction of benzylguanidine as monosubstituted guanidines with 9,10-phenanthraquinone was investigated.[2] Biguanides reacted similarly giving highly fluorescent products.[3]

Guanethidine and guanoxan sulphates have been widely used as antihypertensive agents. They exhibit marked neuron blocking effects in the treatment of moderate and severe hypertension. Several methods have been reported for their determination, including spectrophotometry,[4] oxidimetry,[5] complexometry,[6] colorimetry,[7–10] fluorimetry,[11–13] and high-performance liquid chromatography.[14–16] Amiloride hydrochloride is used as potassium-sparing diuretic in edema, renal and liver disorders. It interferes with the process of cationic exchange in the distal tubule by blocking the resorption of sodium ion and the secretion of potassium ion. It has been determined colorimetrically using sodium nitroprusside,[17] methylbenzothiazolin hydrazone[18] and *N*,*N*-dimethyl–phenylenediamine.[19] Second derivative spectrophotometric determination of amiloride hydrochloride in a two component mixture was described.[20] Methylguanidine and guanidine in physiological fluids have been determined by high-performance liquid chromatography with fluorescence detection[21] and determination[22] using their reaction with phenanthrene-9,10-dione. Guanethidine and guanoxan have been determined in biological fluids by gas chromatography after selective extraction procedures.[23]

The official methods[24] for the assay of the above-selected drugs are, (i) a colorimetric procedure using sodium nitroprusside and potassium hexacyanoferrate for guanethidine sulphate and (ii) a spectrophotometric measurement at 363 nm for amiloride hydrochloride using tributylorthophosphate as a solvent.

The present work deals with the determination of guanethidine sulphate, guanoxan sulphate and amiloride hydrochloride using the

condensation reaction of the guanidino group with 9,10-phenanthraquinone with the purpose of increasing sensitivity and selectivity. In urine and serum these drugs were first extracted according to the GC method[23] followed by applying the proposed fluorimetric method.

EXPERIMENTAL

Apparatus

All fluorimetric measurements were performed on a Perkin–Elmer Model 650-10S fluorescence spectrophotometer equipped with 1.0 × 1.0 cm quartz cells, a 150-W xenon lamp, excitation and emission grating monochromators and a Perkin–Elmer Model 56 recorder. The spectra were measured with the normal instrument gain and minimum ratio mode. The sensitivity ranges used were 0.1 and 0.3 according to the concentration level.

Reagents and samples

All reagents were of AnalaR grade, and were checked before use for the presence of fluorescent contaminants.

9,10-Phenanthraquinone reagent, 2 μg/ml in dimethylformamide, Gold label, free of anthraquinone, Aldrich Chemicals Co., Inc. The solution was kept in a refrigerator. Fresh solutions were prepared every week.

Authentic samples of guanethidine sulphate (Ciba–Geigy, Basle, Switzerland), guanoxan sulphate (Pfizer, Kent, England) and amiloride hydrochloride (Kahira Pharmaceuticals & Chemical Industries Co., Cairo, Egypt) were kindly donated by the manufacturer and were used without further purification.

Biological samples. Serum and urine specimens are collected from adult healthy volunteers who are not under medical treatment. The samples were first analysed by the proposed method to ensure that there is no interference from endogenous compounds.

Fluorimetric procedure

Preparation of calibration graphs. Prepare a solution containing 50 mg of either guanethidine sulphate, guanoxan sulphate or amiloride hydrochloride in 50 ml of distilled water. Place in a 25-ml calibrated flask, an appropriate volume of the drug solution (6–24 μl) for guanethidine sulphate and guanoxan sulphate and (2–8 μl) for amiloride hydrochloride so that the final content is between 6–24 μg for I and II and 2–8 μg for III. Add 2.5 ml of 9,10-phenanthraquinone reagent (2 μg/ml) and 0.25 ml of 1*M* sodium hydroxide solution. Allow the mixture to stand at room temperature for 45 min, then add 0.25 ml of concentrated hydrochloric acid. Make up to volume with distilled water and measure the fluorescence intensity. Correct the observed fluorescence by subtracting the fluorescence intensity measured using the same procedure on a reagent blank. Make the fluorimetric measurements using an excitation wavelength of 310 nm for I and II and 360 nm for III and an emission wavelength of 395 nm for I and II and 420 nm for III (Figs. 1 and 2).

Determination of Guanethidine sulphate, Guanoxan sulphate and Amiloride hydrochloride in laboratory prepared tablets. Weigh and powder 20 tablets. Weigh accurately a quantity of the powdered tablets equivalent to about 50 mg of each of the three drugs. Extract with three 10-ml portions of distilled water and filter (using Whatman No. 1) the combined extracts into a 50-ml calibrated flask. Complete to volume with distilled water. Apply the above procedure, using 20 μl of the final tablet solution for I and II and 5 μl of the final tablet solution for III beginning at "Add 2.5 ml of 9,10-phenanthraquinone...".

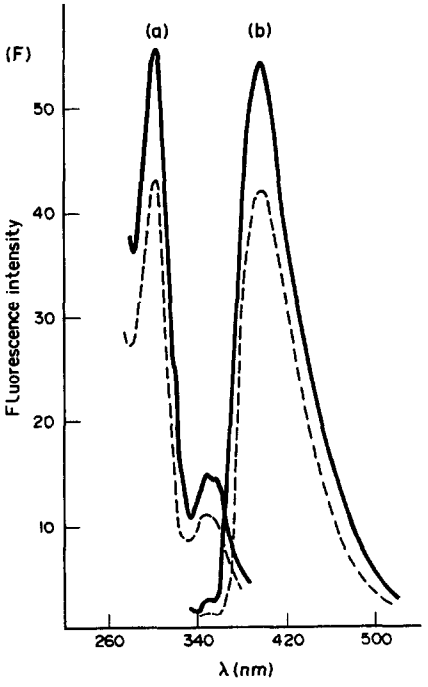

Fig. 1. (a) Excitation and (b) emission spectra of 9,10-phenanthraquinone derivatives of (——) guanethidine (0.60 μg/ml) and (– – –) guanoxan (0.36 μg/ml). (λ_{ex} = 310 nm, λ_{em} = 395 nm).

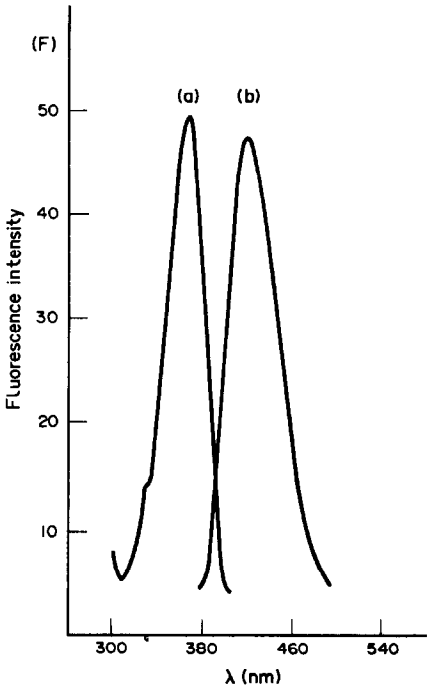

Fig. 2. (a) Excitation and (b) emission spectra of 9,10-phenanthraquinone derivatives of amiloride (0.16 μg/ml) (λ_{ex} = 360nm, λ_{em} = 420 nm).

Determination of the selected guanidino drugs in urine and serum. Adjust the pH of urine to 10.0 and of serum to 7.0. Place 5 ml of serum or urine in 50-ml stoppered shaking tube. Add a 6.0-ml aliquot of I and II and 2.0 ml of III. Add 20 ml of toluene in the case of urine and 20 ml diethyl ether in the case of serum, shake the tube for 10 min and centrifuge. Reject the organic layer. Add 0.5 ml of 50% sodium hydroxide, extract for 20 min using 30 ml of each of chloroform for I, dichloromethane for II and ethyl acetate for III. Centrifuge and remove the upper aqueous layer. Transfer the organic phase to another shaking tube containing 10 ml of 0.1*N* hydrochloric acid, shake the tube for 10 min and centrifuge. Transfer the aqueous layer to a 100-ml standard flask and complete to the mark with distilled water. Pipette 0.1–0.2 ml of this solution into a 25-ml standard flask, follow exactly as in "Calibration graphs above beginning at "Add 2.5 ml of 9,10-phenanthraquinone...". Calculate the concentration from a calibration graph prepared similarly using aqueous solutions in place of the urine and serum.

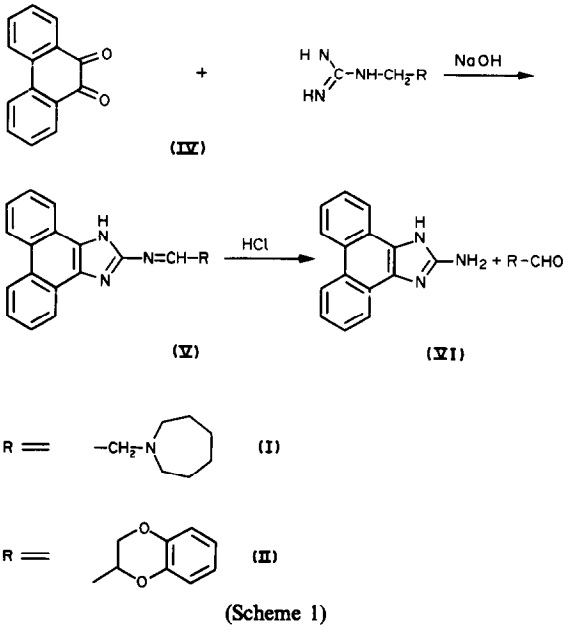
RESULTS AND DISCUSSION

9,10-Phenanthraquinone (IV) reacts with guanidino compounds in an alkaline medium to give an intermediate compound which can easily undergo hydrolysis in acid medium to give a fluorescent product and aldehyde.[2] Similarly, the reaction between guanethidine (I) and guanoxan (II) with IV can be explained to follow scheme I in the present work. The excitation and emission wavelengths of the fluorescent product (VI) were found to occur at 310 and 395 nm, respectively[13] (Fig. 1). These findings differ slightly from the previously reported wavelengths using simple guanidines.[2]

The reaction of 9,10-phenanthraquinone (IV) with amiloride (III) in alkaline medium is suggested to give another intermediate substance VII containing amide linkage. The latter (VII) cannot undergo hydrolysis in acid medium at room temperature. The excitation (360 nm) and emission (420 nm) wavelengths of the product (Fig. 2) were found to be completely different from those of compound VI. Moreover, the reaction product with amiloride was found to be 10 times more sensitive than VI (Table 1). Accordingly, we suggest that a further condensation of VII with another molecule of IV would occur to give a highly fluorescent compound VIII as shown in scheme 2.

Factors affecting the fluorimetric procedure

Influence of reagent concentration and reaction time. The effect of 9,10-phenanthraquinone concentration and reaction time selected for the recommended method was studied by carrying out the fluorimetric procedure using 0.72 μg/ml



(Scheme 1)

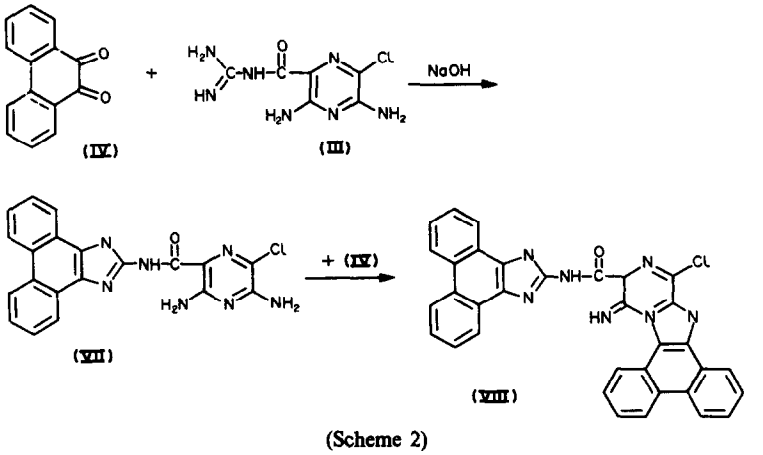
of I, 0.60 μg/ml of II and 0.12 μg/ml of III. Changing the concentration of 9,10-phenanthraquinone over the range 0.04–0.32 μg/ml showed that the optimum concentration to be used is 0.20 μg/ml. Maximum fluorescence intensity for all three was developed within 45 min and remained stable for 60 min at room temperature.

Effect of temperature, sodium hydroxide and hydrochloric acid concentrations. An experiment has been designed to study the effect of carrying out the reaction at 20° (room temperature), 40° and 60°. It was found that as the temperature increases, the fluorescence decreases with loss of sensitivity. Accordingly, the reaction was maintained at room temperature. The effect of sodium hydroxide and hydrochloric acid concentrations on the fluorescence intensity has been carried out separately. It was found that for maximum fluorescence intensity associated with a minimum blank reading, 1*M* sodium hydroxide and 10*M* hydrochloric acid solutions should be used.

Sensitivity, precision, limits of detection and accuracy of the procedure. Calibration graphs were constructed from five points covering the concentration ranges 0.24–0.96 μg/ml for I and II and 0.04–0.24 μg/ml for III using a sensitivity setting of 0.1. For the analysis in urine and serum, the concentration ranges for the linearities were prepared to be 0.06–0.36 μg/ml for I and II and 0.02–0.10 μg/ml for III using sensitivity setting at 0.3. Regression analysis indicated a linear relationship between fluorescence intensity and concentration (Table 1). The correlation coefficients were found to range between 0.9990 and 0.9997. Six replicate determinations at different concentration levels were carried out to test the precision of the method. The relative standard deviations were found to be less than 2%, indicating excellent reproducibility of the method. The limits of detection, where the fluorescence of the sample reading was double the blank reading, were found to be 0.04 μg/ml for I and II and 0.02 μg/ml for III. The accuracy of the procedure was tested by assaying the selected drugs in laboratory prepared tablets (prepared to contain 10 mg, 10 mg



(Scheme 2)

†Theoretical value: $t = 2.23$ at the 95% confidence level.
‡Theoretical value: $F = 5.05$ at the 95% confidence level.

and 5 mg per tablet, respectively) and in spiked human urine and serum. The mean percentage recoveries were found to be around 100.00% (mean of 5-replicates) for tablets (Table 2) and between 95.7–102.2% (mean of 5-replicates) for urine and serum (Tables 3 and 4).

The official methods (B.P. 1988) have been applied to assay the laboratory prepared tablets and the results were found to be in good agreement with the proposed fluorimetric method. The calculated t- and F-values did not exceed the theoretical values, indicating that there is no significant difference between the mean recoveries obtained by either method (Table 2).

Stability indicating assay. The fluorimetric method has been tested as a stability indicating assay of the studied guanidines. The effect of heating at 40, 50, 60 and 70° with 4*M* sodium hydroxide solution with subsequent fluorimetric determination has been carried out. Compounds I and II did not show any degradation indicating good stability. Rate of degradation of amiloride (III) in 4*M* sodium hydroxide solution at 40–70° using the fluorimetric method was found to be first order (Fig. 3). A typical Arrhenius plot was obtained for III with a degradation rate constant 0.000195 min^{-1} and $t_{1/2}$ of 59.26 hr. Degradation of III has been reported[25] to occur in the guanidine side chain. This is in good agreement with the fact that the proposed fluorimetric method can be considered a stability indicating assay.

The official B.P. method has been proven to be non-specific when applied to III in 4*M*

sodium hydroxide solution at 40–70°. Thus a solution of 1 mg %w/v of III after complete degradation was found to read 0.406 at the analytical wavelength used.

Differentiation between guanethidine and guanoxan has been carried out using synchronous fluorimetry.[26,27] Thus, by scanning the synchronous fluorescence of the reaction products at a starting excitation wavelength 220 nm with $\Delta\lambda = 40$ nm (*i.e.*, emission wavelength at 260 nm), II was found to exhibit a Gaussian band at 280, 320 nm (Fig. 4), whereas I did not show such a band.

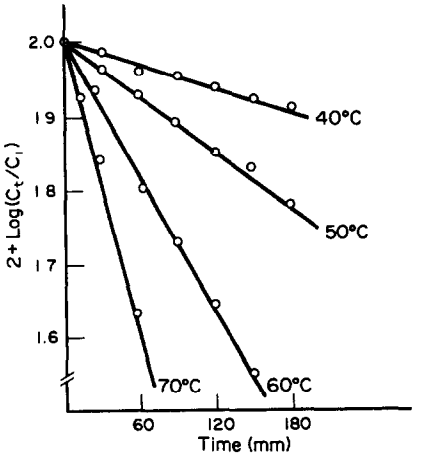

Fig. 3. Apparent first order degradation of amiloride hydrochloride in 4*M* sodium hydroxide solution at different temperatures. (C_1 = initial concentration, 0.16 μg/ml, C_t = remaining concentration in μg/ml after time, t).

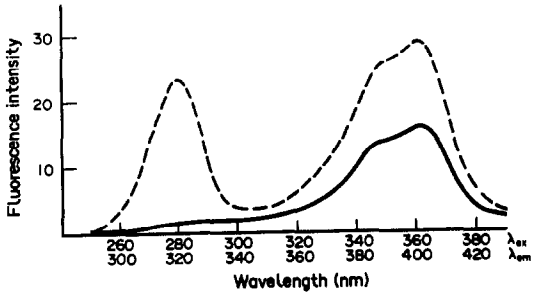

Fig. 4. Synchronous fluorescence spectra of 9,10-phenanthraquinone derivatives of 0.48 μg/ml guanethidine sulphate (——) and 0.48 μg/ml guanoxan sulphate (– – –).

In conclusion, the proposed spectrofluorimetric method, being simple, accurate, precise and highly sensitive is suitable for determination of the investigated drugs in dosage forms and in different biological fluids. In particular, the method is much simpler in technique than the GC method previously reported for biological fluids.[23] Furthermore the method can be used for the determination of amiloride hydrochloride in the presence of its degradation products, an advantage over the official method, and for the differentiation between guanethidine sulphate and guanoxan sulphate utilizing the synchronous spectrofluorimetry.

Acknowledgements—The authors wish to thank Ciba-Geigy Co., for providing guanethidine sulphate, Pfizer Co. for providing guanoxan sulphate and Kahira Co. for providing amiloride hydrochloride as pure authentic samples.

The authors also thank the Alexander von Humboldt foundation in Germany for the donation of the spectrofluorimeter.

(*Received* 12 *December* 1991. *Revised* 9 *April* 1992. *Accepted* 11 *April* 1992)

Summary—A simple procedure for selective sorption of tungsten is described. The method involves reduction of W(VI) to W(V) with tin(II) chloride (2%, w/v) at 8–9*M* hydrochloric acid, formation of the W(V)–SCN complex with 0.2*M* KSCN and its sorption on polyurethane foam within 20 min. The sorbed complex is then eluted with acidified acetone (1 ml of 1*M* hydrochloric acid and 8 ml of acetone) followed by addition of 1 ml of 0.1*M* KSCN to the eluent. The method has been applied to the spectrophotometric determination of tungsten in steels and silicates by measuring the absorbance of the eluted solution at 400 nm. Beer's law is obeyed for the range 0.1–12 μg W/ml. Other elements, *e.g.*, Co^{III} (50 μg/ml), Cu^{II} (10 μg/ml), Ti^{IV} (20 μg/ml), V^{V} (10 μg/ml) and Mo^{VI} (0.5 μg/ml) have no effect on the method. Interference of copper, up to 100 μg/ml has been eliminated by masking with thiourea and that due to molybdenum by prior separation with thioglycollic acid on PUF. The method has been verified with standard samples.

Thiocyanate has been used for several decades as a means of extracting W(V) into organic solvents.[1–6] After the pioneering work of Bowen,[7,8] Braun and Farag,[9–11] Chow and co-workers,[12–14] the use of polyurethane foam (PUF) has been established and found wide application in different separation procedures. Furthermore, the resilient character of PUF allows its use in a batch squeezing operation.[15] The resilient property combined with high retention capacity due to large surface area has made PUF preferred over conventional solvent and other extraction techniques for certain applications and the separation of elements by selective sorption on PUF has been the subject of various studies.

Systematic studies on the retention behaviour of W(VI) have been reported by Caletka *et al.*[16] using tracer techniques. They reported that the maximum sorption of W(VI) was reached at high hydrochloric acid concentration (4*M*). But till now hardly any method has been reported for the determination of small amounts of tungsten in silicates and other materials using the sorption technique with PUF. Moreover, the studies by Caletka *et al.*[16] possibly cannot be utilized for spectrophotometric determination of tungsten due to the poor colour sensitivity of the W(VI)–SCN complex in 4*M* hydrochloric acid.

However, available spectrophotometric methods[1–2,17–21] are based upon the formation of the yellow–green W(V)–SCN complex and its extraction with suitable solvents, but the retention behaviour of W(V) from HCl–SCN medium with PUF is yet to be studied. In the present work the parameters for quantitative sorption of W(V) from HCl–SCN medium with PUF were studied and established in order to develop a method for spectrophotometric determination of tungsten in silicates and steels.

EXPERIMENTAL

Apparatus and reagents

A Spectromom model 360 spectrophotometer was used. All reagents and chemicals were of analytical grade. Bidistilled water was used throughout.

Standard tungsten solution, 100 μg *W/ml*. A 0.08971-g amount of sodium tungstate,

$Na_2WO_4 \cdot 2H_2O$ (mol.wt 329.86) was dissolved in water and diluted to 500 ml in a calibrated flask. Working tungsten solutions (20 and 1 μg/ml) were prepared by diluting the above stock solution.

Potassium thiocyanate solution 2M. Iron (as impurity) was removed from a stock (2*M*) potassium thiocyanate solution by extracting with amyl alcohol. Working potassium thiocyanate solution (0.1*M*) was prepared by diluting the above solution.

Stannous chloride: 10% (w/v) in hydrochloric acid.

Preparation of foam chips

Polyether type polyurethane foam chips were cut from commercial 'U' foam sheet in the form of cylinders (6 mm diameter and 2 cm length, average weight 12 mg/chip), cleaned by soaking in 4*M* hydrochloric acid for 24 hr, washed thoroughly with distilled water and then refluxed with acetone in a Soxhlet apparatus for 6 hr. Washed foam chips were then air-dried at room temperature and stored in a dark coloured bottle.

Procedure

An aliquot of tungstate solution containing 1–120 μg of tungsten was transferred into a 50-ml beaker and evaporated on a water bath down to nearly 3 ml. Then 10 ml of hydrochloric acid followed by 4 ml of 10% (w/v) tin(II) chloride were added to the beaker. The solution was allowed to stand for 20 min for complete reduction of W(VI) to W(V). A 2-ml portion of 2*M* potassium thiocyanate was then added and the mixture diluted to 20 ml with water. Four pieces of foam chips were added to the solution and squeezed thoroughly with a glass plunger. The solutions were equilibrated with the foam chips from 20 min by squeezing every 5 min. The chips were removed from the solution and transferred into a 5-ml disposable syringe. The foam chips were thoroughly washed by squeezing 4 times with 4 ml of water. Finally the sorbed complex was eluted from the foam by washing 4 times with 2-ml portions of acidified acetone (1 ml of 1*M* hydrochloric acid 8 ml of acetone) into a 10-ml calibrated flask. A 1-ml portion of 0.1*M* potassium thiocyanate was added to each flask and diluted up to the mark with the acidified acetone added by the same syringe. The absorbance of the solution was measured at 400 nm within 45 min against a reagent blank.

RESULTS AND DISCUSSION

During preliminary studies, it was observed that the yellow–green complex of W(V)–SCN formed after reduction of W(VI) with tin(II) chloride in strong hydrochloric acid medium ($\sim$9*M*) in the presence of potassium thiocyanate could be sorbed on PUF within a short period of time. The sorbed complex on the foam matrix after washing with water using a syringe could also be eluted with acidified acetone, but not with acetone only. Further, it was observed that the eluted complex in acidified acetone medium could be stabilized by addition of small amounts of potassium thiocyanate solution. The absorption spectrum of the yellow–green W(V)–SCN complex in acetone–hydrochloric acid–potassium thiocyanate medium showed an absorption maximum at 400 nm at which the reagent blank did not absorb significantly. These observations lead to further investigations for establishing different parameters affecting the extraction of the W(V)–SCN complex on PUF, its quantitative elution and stability of the eluted complex, *i.e.*, acid concentration during extraction, time of reduction of W(VI) to W(V), concentration of stannous chloride and thiocyanate, time of equilibration and final acid and thiocyanate concentration in acetone medium.

Effect of reducing agent and hydrochloric acid concentration

The reduction of W(VI) with tin(II) chloride was found to be dependent on the hydrochloric acid concentration. Therefore, it was imperative to determine the optimum acid concentration for quantitative reduction of W(VI) to W(V) and subsequent sorption of the W(V)–SCN complex on PUF. The hydrochloric acid concentration was varied over a wide range of 1–9*M* hydrochloric acid and it was observed that a waiting time of 20 min was necessary for quantitative reduction of W(VI) to W(V) at 8–9*M* hydrochloric acid. The extent of formation as well as the sorption of the W(V)–SCN complex on PUF was found to be maximum in the acid range of 8–9*M* hydrochloric acid. However, the extent of sorption on PUF was found to decrease at acid concentration $<8M$. Therefore, the concentration of hydrochloric acid and time of reduction were maintained at 8–9*M* and 20 min for subsequent experiments.

The effects of the tin(II) chloride concentration on the reduction of W(VI) and on the sorption of the complex were also studied. The optimum

concentration of tin(II) chloride for achieving both was found to be 1%, and above this concentration, the further addition of the reducing agent up to 6% did not result in any change in the absorbance.

Effect of thiocyanate

The concentration of potassium thiocyanate was found to have a great influence on the formation and sorption of the W(V)–SCN complex on PUF. The formation as well as sorptions of the complex was found to be maximum at 0.2*M* potassium thiocyanate. But at concentration $>0.2M$ the sorption was found to decrease, probably due to the formation of unextractable species.

Effect of equilibration time

The sorption of the W(V)–SCN complex with PUF under the above mentioned conditions was found to be maximum after 20 min equilibration and no further sorption took place after that period (Fig. 1). The sorption of the W(V)–SCN complex was found to be more than 99% under the experimental conditions. But, in any case, equilibration time could not be extended beyond 30 min, as thiocyanate itself undergoes gradual decomposition in strong acid medium.[2] Gradual decomposition of PUF was also observed when it was subjected to strong acid ($>9M$) for more than one hour.

As reported by Caletka *et al.*[16,22] WO_2^{2+} is converted to WO^{4+} at high acidity but on reduction with tin(II) chloride this WO^{4+} is reduced to WO^{3+}. This reduced WO^{3+} reacts with SCN^- to form anionic species $[WO(SCN)_n]^{3-n}$ which are sorbed on PUF through a cation chelation mechanism.[13] According to this mechanism, complexation of cations, *e.g.*, K^+ or H_3O^+, takes place in the PUF cavities through ion-dipole interaction or hydrogen bonding or both.[14] Then the anionic species, *i.e.*, $[WO(SCN)_n]^{3-n}$, are extracted as counter ions to the captured cations in the PUF cavities.

Elution and stability of the eluted complex in acetone

It was observed during the study that the complex can only be quantitatively eluted from the foam matrix with acidified acetone, *i.e.*, acetone protonated with hydrochloric acid (8 ml of acetone +1 ml of 1*M* hydrochloric acid), which also established the anionic nature of the complex. The optimum acid concentration for quantitative elution and stability of the eluted complex was found to be 0.1*M* hydrochloric acid in acetone (Fig. 2). It can further be seen from Fig. 2 that below 0.1*M* hydrochloric acid, the elution of the complex from foam is not quantitative while at $>0.1M$ the complex tends to dissociate with time and yields lower absorbance values as obtained with 0.3, 0.6 and 1.2*M* acid concentrations.

The stability of the eluted complex can be increased further by the addition of fresh potassium thiocyanate solution to the eluted solution. Therefore, the concentration of

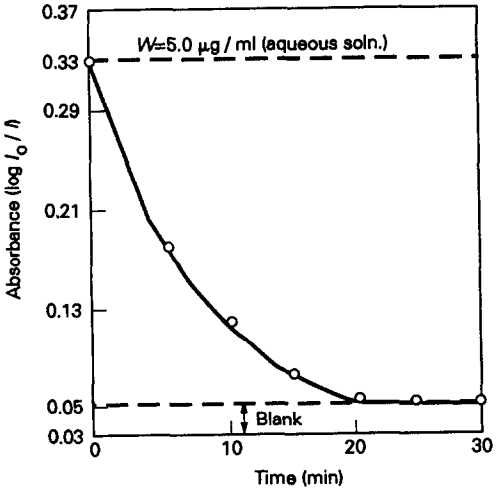

Fig. 1. Effect of time on the equilibration of W(V)–SCN complex with PUF at 8.5*M* HCl containing 2% $SnCl_2$ and 0.2*M* KSCN.

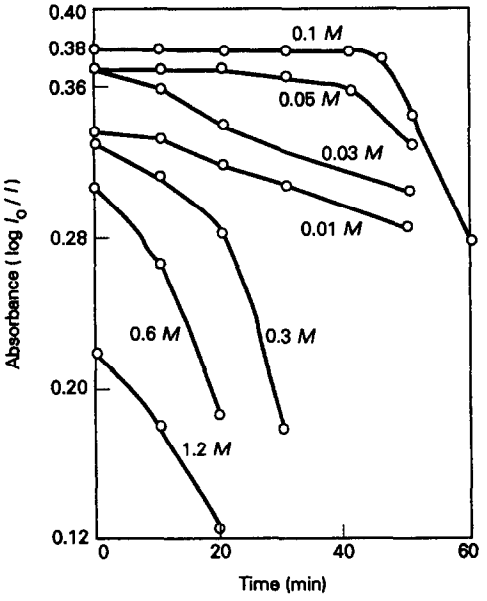

Fig. 2. Effect of HCl concentration in acetone on the quantitative elution and stability of the eluted W(V)–SCN complex.

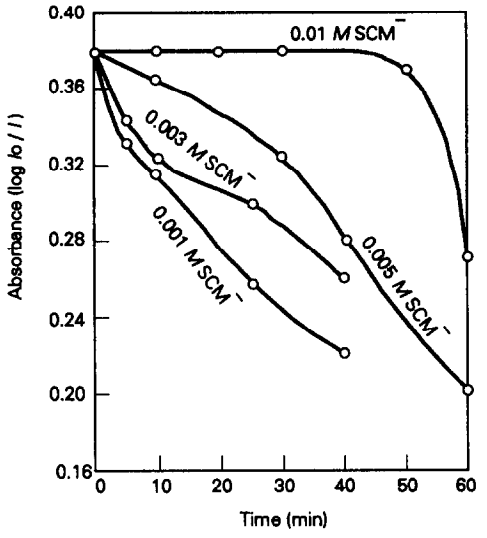

Fig. 3. Effect of KSCN concentration in acetone on the stability of W(V)–SCN complex after elution at 0.1*M* HCl.

potassium thiocyanate in the eluted solution was varied to establish its optimum concentration for stability of W–SCN complex. Figure 3 shows that the colour of the eluted complex is stable up to 45 min in 0.01*M* SCN^-. These observations suggested that a minimum concentration of 0.01*M* potassium thiocyanate was essential over the stoichiometric amount for increasing the stability of the colour in acetone–hydrochloric acid medium. However, a ratio between acetone:HCl:KSCN solution has to be maintained at 8:1:1 to avoid turbidity in the acetone–hydrochloric acid medium.

Validity of Beer's law

The effect of tungsten concentration was studied under the experimental conditions set up and Beer's law was found to be obeyed in the range 0.10–12 μg/ml tungsten. The molar extinction coefficient for W has been calculated to be 1.3×10^4 l. $mole^{-1}$. cm^{-1} at 400 nm. From the regression analysis of the calibration plot of absorbance against W concentration, the correlation coefficient was found to be 0.999. The Sandell's sensitivity was calculated to be 0.012 μg/cm against 0.001 absorbance.

Effect of foreign elements

The effect of diverse ions on the determination of 5 μg/ml W(V) was examined following the procedure and is presented in Table 1. The elements which remained in the solution along with tungsten after caustic soda separation, *e.g.*, Mo, V, Mn, Al and Zn, are of practical importance. But the elements Al, Mn and Zn did not interfere with the determination of tungsten. However, molybdenum could be tolerated only up to 0.5 μg/ml above which it interferes seriously by producing a positive error. The adverse effect of molybdenum (>0.5 μg/ml) could be eliminated by previously extracting its thiogycollate complex on PUF from 0.1*M* hydrochloric acid in the presence of oxalate,[23] and after sorption of the molybdenum, the acidity of the solution could be increased for sorption of tungsten by the given procedure. Vanadium up to 10 μg/ml did not interfere in the method. Further, the study (Table 1) indicates that copper up to 10 μg/ml, did not interfere in the determination of tungsten (5 μg/ml), but its adverse effect at higher concentration (up to 100 μg/ml) could be eliminated by masking with thiourea.

Table 1. Effect of foreign elements on the sorption of tungsten. Conditions: Tungsten (VI)—5 μg/ml, acid—8.5*N* HCl, $SnCl_2$—2% (w/v), KCNS—0.2*M*, sorbent—PUF, elutant—acidified acetone (8 ml acetone +1 ml 1*M* HCl), KCNS (in acetone medium)—0.01*M*

*In the presence of 0.1% thiourea (w/v).

Application of the method

The developed method was checked with indigenous plain carbon steel samples without tungsten spiked with known amounts of tungsten (Table 2). The method was then applied to the determination of tungsten in standard steel

Table 2. Determination of tungsten in stimulated steel solutions (results are averages of eight determinations)

Sample	Tungsten* added, %	Tungsten found, %	Standard deviation
Steel (1)	0.04	0.038	±0.0024
Steel (2)	0.10	0.098	±0.0031
Steel (3)	0.20	0.19	±0.022
Steel (4)	0.60	0.59	±0.015
Steel (5)	0.50	0.48	±0.008

*Calculated amount of tungsten were added to each steel sample during decomposition.

and silicate material samples after preparation of sample solution by following the procedures given below. Results are presented in Table 3.

Preparation of sample solution

Steel. A 0.1-g steel sample was decomposed with 10 ml of hydrochloric acid and 10 ml of nitric acid in a 200-ml glass beaker. The solution was evaporated on a water bath to near dryness. This process was thus repeated twice and evaporated to expel all the oxides of nitrogen. The residue was dissolved in 10 ml of hydrochloric acid (1 + 2) by boiling and poured into a 100-ml beaker containing 15 ml of hot 5*M* sodium hydroxide solution with stirring. It was then filtered through Whatman No. 41 filter paper. The residue was washed first with hot 1*M* sodium hydroxide and then with hot water. The filtrate was just acidified with dilute hydrochloric acid, transferred into a 100-ml calibrated flask, cooled and diluted up to the mark with water.

Silicates

A 0.1-g sample (dried at 110°) was placed in a PTFE basin and digested on a sand bath with 5 ml of nitric acid and 5 ml of HF to near dryness. The basin was cooled, a further 5 ml of nitric acid, 5 ml of HF and 1 ml of sulphuric acid (1 + 1) were added and the process repeated until fumes of SO_3 were evolved. The acid was almost driven off and the residue taken up in 10 ml of hydrochloric acid (1 + 2), boiled and poured into 15 ml of hot 5*M* sodium hydroxide solution, with stirring. It was then filtered through Whatman No. 41 filter paper. The residue was washed first with hot 1*N* sodium hydroxide and then with hot water. The filtrate was just acidified with dilute hydrochloric acid, transferred into a 100-ml calibrated flask, cooled and diluted up to the mark with water.

A 5-ml aliquot of the above sample solution was transferred to a 50-ml beaker and evaporated on a water bath almost to dryness. Then 2 ml of water were added and the determination procedure was applied.

Calibration

Standard tungstate working solutions (1–10 ml) containing 1–120 μg of W were added into 50-ml glass beakers and evaporated on a water bath to about 3 ml. The procedure for the determination of tungsten was then followed. The absorbance of each solution was obtained at 400 nm against a reagent blank and a calibration curve was plotted.

Calculation

The absorbance of the test solution was compared with the calibration curve and converted to the quantity of tungsten in μg, from which its concentration in the sample is calculated:

$$W = 2 \times 10^{-2} A / W\%$$

where A is the number of μg of W corresponding to the absorbance measured and the sample weight is in g.

RAPID AND SELECTIVE SPECTROPHOTOMETRIC DETERMINATION OF MANGANESE IN STEELS AND ALLOYS USING RESACETOPHENONE OXIME

C. KESAVA RAO, O. BABAIAH, V. KRISHNA REDDY and T. SREENIVASULU REDDY
Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515 003, India

(*Received* 11 *July* 1991. *Revised* 25 *September* 1991. *Accepted* 25 *September* 1991)

Summary—A sensitive spectrophotometric method is developed for the determination of manganese in aqueous medium. The metal ion forms a yellowish brown coloured complex with resacetophenone oxime (RPO) in ammonium chloride and ammonium hydroxide buffer of pH 10.5. The 1:1 complex shows maximum absorbance at 380 nm with a Beer's law range of 0.09–1.7 ppm. The molar absorptivity and the Sandell sensitivity are found as 2.5×10^4 l.mole^{-1}.cm^{-1} and 0.002 μg/cm^2, respectively. The stability constant of the complex calculated by Job's method is 7.5×10^5. The interfering effects of various cations and anions are studied. The present method is applied to the determination of manganese in some steel and alloy samples.

Oximes have found wide application as analytical reagents. They form the most selective class of reagents commonly employed as spectrophotometric reagents for a variety of metal ions.[1] Several methods using oxime reagents for the determination of manganese have been reported.[2] Among them, formaldoxime (stability constant = 1.12×10^4 at 455 nm)[3] is the most sensitive. The other oximes are generally insensitive, being suitable only for the determination in the mg/l. range. Among other methods, most of them are of the extraction type. In the present paper a simple, rapid and sensitive method is reported for the direct spectrophotometric determination of trace amounts of manganese in aqueous medium by complexing with 2,4-dihydroxy acetophenone oxime (resacetophenone oxime, RPO). The method is highly selective for the determination of manganese in steels in the presence of EDTA.

EXPERIMENTAL

Apparatus

An ELICO Digital spectrophotometer model CL-27 and a Philips Digital pH meter model PP9046 were used for absorbance and pH measurements respectively.

Reagents

Analytical reagent grade chemicals were used throughout without further purification. Standard manganese chloride (1 g/l. Mn) was prepared and standardized complexometrically.[4] Working solutions were prepared daily by diluting the stock solutions to appropriate concentrations.

Resacetophenone oxime was prepared using the reported procedure.[5] A stock solution (0.1*M*) in 40% aqueous methanol was used in the studies.

Buffer solutions

For the preparation of buffer solutions 2.0*M* ammonium hydroxide–2.0*M* ammonium chloride were uses.

Preparation of sample solutions

A 0.5-g sample was treated with 2 ml of concentrated nitric acid. When the reaction was almost over, the mixture was warmed on a hot plate to complete the dissolution. After the addition of 1 ml of concentrated sulphuric acid the mixture was evaporated until white fumes appear, then cooled and diluted to about 20 ml with 0.3*M* hydrochloric acid. The solution was heated almost to boiling and hydrogen sulphide was passed through it to precipitate copper. The copper sulphide was filtered off and washed and the filtrate was boiled to remove the dissolved hydrogen sulphide, and then evaporated to dryness. The residue was dissolved in distilled water and diluted to the required volume.

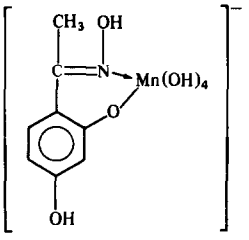
Procedure

In each of a set of different 25-ml standard flasks, 10 ml of buffer solution (pH 10.5),

various volumes of ($2 \times 10^{-4}M$) manganese solution, 4 ml of $2 \times 10^{-3}M$ RPO solution and 2.0 ml of $0.01M$ potassium persulphate were added and heated on a water bath for 10 min. The contents were cooled and made up to the mark with distilled water. The absorbance was measured at 380 nm against a reagent blank. A linear plot passing through the origin was obtained when absorbance was plotted against the amount of manganese.

RESULTS AND DISCUSSION

Manganese reacts with RPO in ammoniacal buffer medium to form a soluble yellowish brown coloured complex. The probable structure of the complex may be drawn as



The colour intensity increased with time and attained a constant value after about 5 days. The complex attains maximum and constant absorbance when it is heated on a water bath for 2 hr, as the manganese is air oxidized to Mn(IV). However, in the presence of 0.035% persulphate, the maximum absorbance could be attained when the reaction mixture is heated for 10 min.

Figure 1 shows the absorption spectra of the reagent and metal complex. The figure indicates that the reagent absorbance is small at 380 nm while the complex has maximum absorbance. Hence the studies are carried out at 380 nm. The complex shows maximum absorbance in the pH range 10.2–10.7. Hence further studies are made at pH 10.5. A 20-fold excess RPO is necessary to obtain maximum colour intensity. Beer's law is obeyed up to 1.7 ppm manganese. The practical range of determination of manganese obtained from Ringbom's method is 0.09–1.7 ppm. The complex has molar absorptivity of $2.0 \pm 0.5 \times 10^4$ $1.mole^{-1}.cm^{-1}$ at 380 nm. The Sandell's sensitivity is found to be 0.002 $\mu g/cm^2$. The relative standard deviation is 0.002 ppt. Comparing the mean determined values against the standard amount of manganese taken, the 't' value calculated (2.20) for 10 measurements is found to be less than the tabulated value (2.23) at the 95% confidence interval.

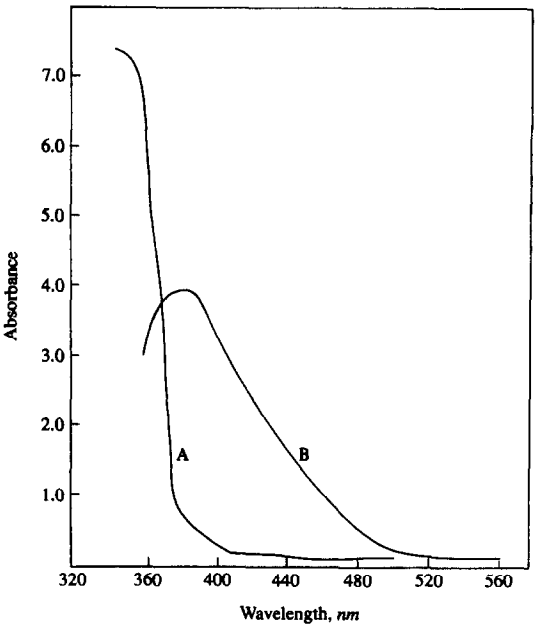


Fig. 1

The studies based on Job's continuous variation, mole ratio and slope ratio methods indicate a 1 : 1 complex formation between the metal and reagent. The stability of the complex calculated from Job's continuous method is 7.5×10^5.

The interference of various anions and cations normally found in association with manganese was studied. The amount of the diverse ion which brings about 2% variation in absorbance was taken as its tolerance limit.

In the determination of 0.9 ppm manganese, the tolerance limit (given in ppm) of various ions is as follows, EDTA (1600); thiosulphate (440); oxalate (350); tartrate (300); thiocyanate (300); iodide (135); nitrate (135); fluoride (130); carbonate (85); phosphate (70); thiourea (70); ascorbic acid (70); Zn(II) (700); Mo(VI) (700); V(V) (700); W(VI) (100); Cd(II) (100); Th(IV) (100); Pb(II) (86); Cr(VI) (60); Pd(II) (56); Ag(I) (30); Mg(II) (20); U(VI) (20); Ce(IV) (16); Pt(IV) (10); Hg(II) (8). In the presence of EDTA, Fe(III), Cu(II), Co(II) and Ni(II) are tolerable up to 210 ppm 25 ppm, 120 ppm and 120 ppm respectively. Hence in the presence of EDTA, the present method becomes highly selective for the determination of manganese.

Analysis of alloys and steel samples

Manganese present in various standard steel and alloy samples was determined by the present method.

Table 1. Analysis of alloy and steel samples

Sample	Composition (%)	Manganese Taken, *ppm*	Manganese Found,* *ppm*
BAS No. 180/2	Cu: 68.12, Fe: 0.68	0.140	0.141
	C: 0.04, Ni: 30.35	0.420	0.418
	Mn: 0.75, S: 0.006	0.630	0.629
BAS No. 179/2	Mn: 0.86, Cu: 58.5	0.165	0.166
	Ni: 0.56, Sn: 0.70	0.495	0.496
	Fe: 1.02, Si: 0.044	0.990	0.989
	Zn: 35.8, Pb: 0.35		
	Al: 2.22		
BCS No. 406	Mn: 0.53, Ni: 1.69	0.346	0.344
	Mo: 1.03, V: 0.02	0.965	0.963
	Cr: 2.12, Cu: 0.32	1.038	1.036

	Mo: 0.58, Ni: 2.55	0.352	0.351
	Cu: 0.088, Sn: 0.011	1.408	0.406
	Fe: 95.0		

*Average of six determinations.

A known aliquot of steel solution was transferred into a 25-ml standard flask containing 10 ml of buffer solution, 1 ml of reagent ($1 \times 10^{-3}M$), 2 ml of potassium persulphate ($1 \times 10^{-2}M$) and 1.5 ml of EDTA ($0.1M$) and made up to the mark with distilled water. After 10 min, the absorbance of the solution was measured at 380 nm. The amounts of manganese present were computed from the predetermined calibration plot. The results obtained are presented in Table 1.

For steel samples containing copper in amounts less than 25 times the manganese, prior separation with sulphide was not needed, as the copper could be masked with EDTA. In BAS No. 180/2 and BAS 179/2, sulphide precipitation was necessary.

Comparison with other reagents

Among the methods reported[2] using oximes, the present method is the most sensitive. It is also more highly sensitive than the most widely employed procedure based on the oxidation of Mn(II) to Mn(VII). Though the sensitivity is lower than those of other reagents such as PAR[6] or PAN,[7,8] the method has the advantage of higher selectivity in the presence of EDTA. Further, most of the more sensitive methods involve extraction.

SPECTROPHOTOMETRIC ASSAY OF ISOPROTURON AND METOXURON IN TECHNICAL GRADE AND FORMULATION SAMPLES USING 3-METHYLBENZOTHIOZOLIN-2-ONE HYDRAZONE HYDROCHLORIDE

K. RAMAKRISHNAM RAJU, T. N. PARTHASARATHY,* S. R. K. M. AKELLA and U. T. BHALERAO
Indian Institute of Chemical Technology, Hyderabad 500 007, India

(*Received* 9 *October* 1991. *Revised* 12 *February* 1992. *Accepted* 22 *February* 1992)

Summary—A spectrophotometric method for the assay of Isoproturon and Metoxuron in technical grade and formulation samples has been developed using the oxidative coupling reaction with 3-methylbenzothiozolin-2-one hydrazone hydrochloride (MBTH). The reaction variables have been optimized and the reaction mechanism is discussed. The method is simple, rapid and has been successfully applied for the assay of Isoproturon and Metoxuron in commercial grade technical and formulated samples. The percent relative standard deviation is found to be in the range 0.34–1.00 for Isoproturon and 0.33–0.57 for Metoxuron.

Isoproturon (IPN) and Metoxuron (MTN) belong to the phenylurea class of compounds, widely used as pre or post emergent herbicides for control of different weed species in cereals and carrots. Simple methods for their assay in technical grade and formulation samples are necessary for routine analysis and quality evaluation. The chemical[1] and GC[2] methods reported in the literature are time consuming and unsuitable for routine analysis. To overcome some of the difficulties we have reported a spectrophotometric method recently.[3] In search of more convenient methods, we have carried out further spectrophotometric investigations of the chromogenic reaction between these herbicides and 3-methylbenzothiozolin-2-one hydrazone hydrochloride (MBTH) based on oxidative coupling and application to technical grade and formulation samples and the results are presented here.

EXPERIMENTAL

Apparatus

Shimadzu Model UV-240 and 210 spectrophotometers, and matched 1.0-cm glass cells were used.

Reagents and materials

A 0.4% solution of MBTH (Loba Chemicals, Bombay, India) in water and a 0.1% solution of ceric ammonium sulphate in 10 and 6.5% sulphuric acid were prepared. All other chemicals used were of reagent grade.

IPN (99.65%) was supplied by Bharat Pulverizing Mills, Bombay, India and used as such. MTN supplied by Pesticides Division, IICT, Hyderabad, India, was used after recrystallisation in hot water and the purity was checked by HPLC (99.7%).

Standard herbicide solutions were prepared by dissolving about 20 mg (accurately weighed) in methanol, diluted to 100 ml with methanol and used as working solutions.

General procedure

Working sample solutions (1.0 ml) were transferred into 10-ml standard flasks. Portions of 5.0 and 2.0 ml of 0.1% ceric ammonium sulphate solution in 10 and 6.5% sulphuric acid respectively, were added for IPN and MTN and kept aside for 5 min, after which 2.5 ml and 3.5 ml of 0.4% MBTH reagent were added for IPN and MTN, respectively. The flasks were heated in a water bath at 60° for about 25 min for IPN and 4 min for MTN. After heating the flasks were removed from the water bath, cooled to room temperature and diluted to 10 ml with

*Author for correspondence.
†IICT Communication No. 2901.

water. The absorbances of these solutions were measured at 510 nm for IPN and 490 nm for MTN against a reagent blank.

Technical grade samples

About 20 mg of technical grade samples were weighed accurately and dissolved in 50 ml of methylene chloride, treated with 1*N* hydrochloric acid and the organic layer was evaporated.[1] The residue after evaporation was dissolved in 5.0 ml of methanol and diluted to 100 ml with this solvent. A 1.0-ml portion was subjected to analysis using the general procedure.

Formulation samples

About 40 and 30 mg of well mixed formulations of IPN and MTN, respectively, were weighed accurately and 50 ml of methylene chloride was added and the mixture centrifuged. The organic layer after treatment with 1*N* hydrochloric acid was evaporated. The residue was dissolved in methanol and 1.0 ml was subjected to analysis using the general procedure after dilution to 100 ml.

In the case of MTN, formulations were not available and hence synthetic formulations (80%) were prepared and analysed.

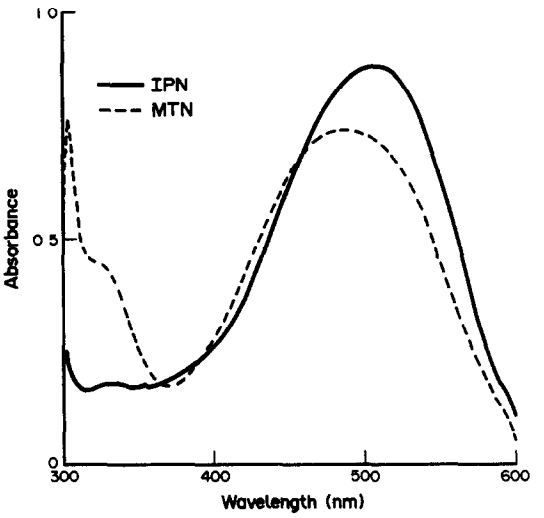

Fig. 1. Absorption spectra of IPN and MTN. —— IPN, --- MTN. 1.0 ml of 0.02% IPN + 5.0 ml of 0.1% ceric ammonium sulphate in 10% H_2SO_4 + 2.5 ml of 0.4% MBTH, against reagent blank. Heating at 60° for 25 min. 1.0 ml of 0.02% MTN + 2.0 ml of 0.1% ceric ammonium sulphate in 6.5% H_2SO_4 + 3.5 ml of 0.4% MBTH, against reagent blank. Heating at 60° for 4 min.

RESULTS AND DISCUSSION

Optimization of reaction variable

The absorption spectra of IPN and MTN are shown in Fig. 1. The reaction variables have been optimized by varying each profile, keeping others constant for obtaining maximum colour development as shown in Figs. 2–4. It is clear that 20 min (IPN), 3 min (MTN) reaction time in a water bath at 60°; 4.0 ml, 1.5 ml of 0.1% ceric ammonium sulphate in 10% (IPN) and 5% (MTN) sulphuric acid and 2.0 ml (IPN) 3.0 ml (MTN) of 0.4% MBTH reagent, respectively, were necessary for maximum colour development.

Beer's law precision and accuracy

The λ max, the molar absorptivities, Beer's law range, slopes, correlation coefficients, precision and accuracy of the method are given in Table 1. The colour is stable for more than two hours for IPN and one hour for MTN.

Reaction mechanism

Under acidic conditions the hydrolysed products of the corresponding amines of IPN (4-isopropyl-aniline) and MTN (3-chloro-4-methoxy aniline) coupled with MBTH in the presence of Ce(IV) to yield coloured oxidizing products, as reported in the literature.[4,5] As the *p*-position in both compounds is blocked, it is assumed that coupling would have taken place in the *o*-position (Scheme 1). The absorption maxima and low molar absorptivities also

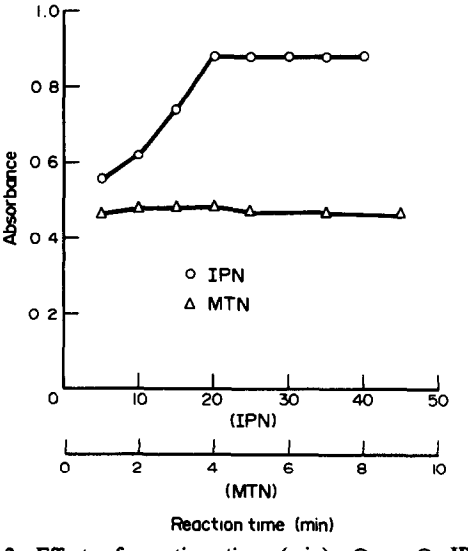

Fig. 2. Effect of reaction time (min). O——O IPN, Δ——Δ MTN. 1.0 ml of 0.02% IPN + 4.0 ml 0.1% ceric ammonium sulphate in 10% H_2SO_4 + 1.0 ml of 0.4% MBTH. Heating at 60°. 1.0 ml of 0.02% MTN + 2.0 ml 0.1% Ceric Ammonium Sulphate in 6.5% H_2SO_4 + 1.0 ml of 0.4%, MBTH. Heating at 60°.

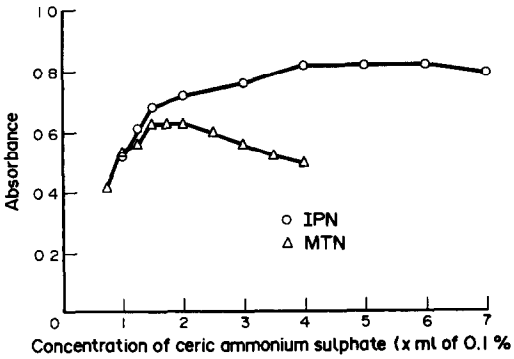

Fig. 3. Effect of ceric ammonium sulphate. O——O IPN, Δ——Δ MTN. 1.0 ml of 0.02% IPN + 1.0 ml of 0.4% MBTH + varying amounts of ceric ammonium sulphate in 10% H_2SO_4, heating at 60° for 25 min. 1.0 ml of 0.02% MTN + 3.5 ml of 0.4% MBTH + varying amounts of ceric ammonium sulphate in 6.5% H_2SO_4, heating at 60° for 4 min.

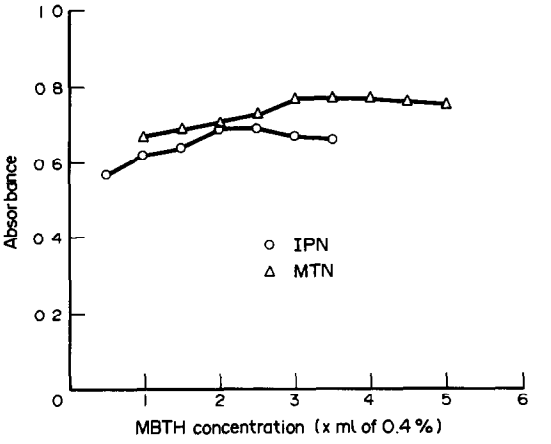

Fig. 4. Effect of MBTH concentration. O——O IPN Δ——Δ MTN. 1.0 ml of 0.02% IPN + 1.0 ml of 0.5% ceric ammonium sulphate in 10% H_2SO_4 + varying amounts of MBTH. Heating at 60° for 25 min. 1.0 ml of 0.02% MTN + 2.0 ml of 0.1% ceric ammonium sulphate in 6.5% H_2SO_4 + varying amounts of 0.4% MBTH. Heating at 60° for 4 min.

support this.[6] The slow reaction in the case of IPN (20 min) may be attributed to the out of plane arrangement of the bulky alkyl group in the *p*-position. However, in the case of MTN, the reaction is fast (3 min) which may be accounted for by the combined effects of Cl- and OMe-groups.

Interferences

Free amines which interfere with the method are removed by extracting into 1*N* hydrochloric acid. However, phenylurea derivatives if present cause interference.

Application

A number of technical grade and formulation samples of IPN and MTN have been subjected to analysis using the developed method and the results are shown in Tables 2 and 3. The percent relative standard deviations are in the range of 0.34–1.00 for IPN and 0.33–0.57 for MTN.

Formulation	78.00	78.79	101.01	0.50
(80%)	80.90	80.00	98.89	0.48
	80.80	80.12	99.16	0.57

Advantages

The method does not involve time consuming distillation and photodecomposition.[1] Further, the present method is superior to our earlier method[3] as analysis is faster and eliminates the hydrolysis step; but it is inferior with regard to sensitivity. Therefore, the method is simple, rapid and can be employed for routine analysis of technical grade and formulation samples of IPN and MTN.

Acknowledgements—The authors gratefully acknowledge Dr R. V. Venkataratnam and Dr M. Panduranga Rao for providing MTN samples and Dr B. S. N. Murthy for regression data. The authors also acknowledge Bharat Pulverising Mills, India for a gift of IPN samples.

SPECTROPHOTOMETRIC DETERMINATION OF AMPICILLIN AND ITS DOSAGE FORMS

M. B. DEVANI, ILA T. PATEL* and T. M. PATEL
Department of Pharmaceutical Chemistry, L. M. College of Pharmacy, Ahmedabad-380 009, India

(*Received* 15 *January* 1991. *Revised* 8 *January* 1992. *Accepted* 15 *January* 1992)

Summary—A new spectrophotometric procedure is described for the determination of ampicillin. The method is based on the reaction of ampicillin with acetylacetone–formaldehyde reagent to give a yellow coloured product having λ max at 400 nm. A variety of pharmaceutical dosage forms containing ampicillin are successfully analysed by the proposed procedure.

Several spectrophotometric methods for assay of ampicillin are cited in the literature.[1–8] The reported titrimetric procedures for estimation of ampicillin[9,10] are not satisfactory for microgram quantities. Acetylacetone–formaldehyde reagent has been found to be a valuable reagent for the determination of primary amines in the UV region. Csiba[4] has reacted ampicillin with acetylacetone and formaldehyde in acidic medium. The chromophore formed has λ max at 339 nm. This paper describes a modification of the acetylacetone–formaldehyde reagent method for colorimetric estimation of ampicillin, in which ampicillin is reacted with a buffered reagent (pH 4.3) to obtain an additional peak in the visible region at 400 nm. The procedure has been successfully applied to analyse a variety of pharmaceutical preparations of ampicillin.

EXPERIMENTAL

Apparatus

A Beckman Model-25 spectrophotometer with matched 1.0-cm quartz cells was used for absorbance measurements.

pH measurements were made on a Systronic digital pH meter Model-355, equipped with glass and calomel electrodes.

Reagents

All chemicals and reagents used were of analytical or pharmaceutical grade. All solutions were prepared in doubly distilled water.

The acetylacetone–formaldehyde reagent solution was prepared by mixing freshly distilled acetylacetone (7.8 ml), and formaldehyde (15.0 ml; 36% w/w) with sodium acetate (16.0 ml; 0.2*M*) and acetic acid (34.0 ml; 0.2*M*). After keeping the solution in a boiling water bath for 5 min, it was cooled to room temperature, the pH was adjusted to 4.3 and the solution was diluted with water to 100 ml. The reagent solution was prepared freshly.

Ampicillin solution (0.005*M*) was used as stock.

Procedure

Bulk samples. A portion of ampicillin solution (0.5–1.5 ml) was pipetted into a 25-ml standard flask. After addition of the reagent solution (4.0 ml), the reaction mixture was kept in a water bath at $35 \pm 1°$ for 30 min. The solution was then diluted to the mark with water and the absorbance measured at 400 nm against a reagent blank prepared in a similar manner. The drug concentration was read from the calibration graph prepared under identical conditions.

Pharmaceutical preparations. An amount of powdered tablet, capsule, injection, paediatric drops or oral suspension equivalent to 200 mg of ampicillin was extracted with water (four 15-ml portions). The combined extracts were collected in a 100-ml standard flask and the volume was made up to the mark with water. This solution was then analysed as above. The results were compared with the official method and are summarized in Table 1.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectrum of the reaction product from ampicillin and acetylacetone–formaldehyde reagent shows characteristic

†95% confidence limit.

The reaction conditions were established by variation of one parameter at a time. For the reaction, use of acetate buffer (pH 4.1–4.5) was found optimal. This compares with the pH range of 1.5–2 used by Csiba[4] for the UV method. The reaction time was established by increasing it in increments of 5 min, and it was found that 30 min is sufficient to yield maximum absorbance. The use of 3.0–5.0 ml of reagent solution and temperature $35 \pm 1°$ for the reaction was considered optimal. The final temperature after dilution was not critical.

Analytical data

The optical characteristics and figures of merit are given in Table 2. The values obtained by the proposed and official[11] methods for pharmaceutical preparations are compared in Table 1. Table 3 shows the results of recovery experiments.

*Mean of 5 determinations.
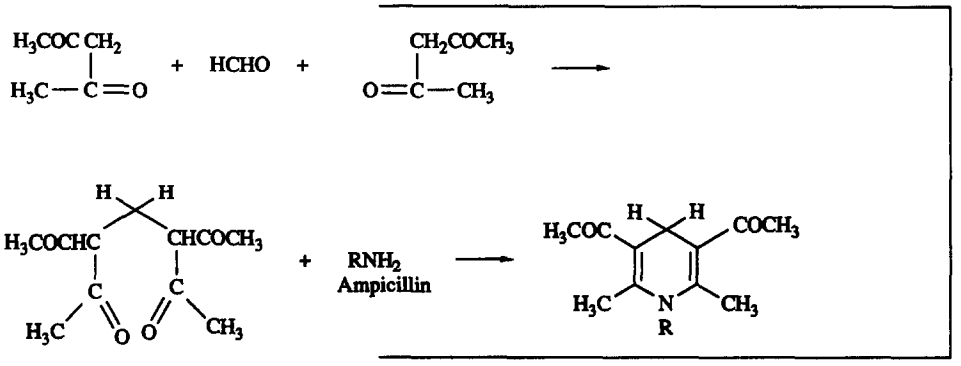
†Recovery of added amount, assuming label claims correct.

The present method has advantages over the pharmacopeial and other reported methods in terms of simplicity, sensitivity and freedom from interferences.

The chemistry of the colour reaction may be suggested on the basis of earlier reports[4] and our findings as follows:



Applications

The method was applied to the assay of ampicillin in drug formulations (commercial products randomly collected from local pharmacies). Typical results are given in Table 1 and show good agreement with those obtained by official methods.[11] The method can possibly be extended to the determination of other amino β-lactam penicillins, as described by Csiba.[4]

1-(4-NITROPHENYL)-3-(2-QUINOLYL) TRIAZENE AS AN EXTREMELY SENSITIVE REAGENT FOR SPECTROPHOTOMETRIC DETERMINATION OF MERCURY

CAO SHITI* and LI XU†
Changsha Research Institute of Mining and Metallurgy, Changsha, Hunan, 410012, People's Republic of China

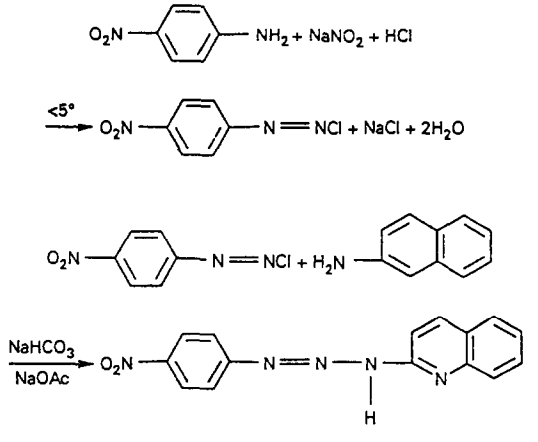
(*Received* 2 *December* 1988. *Revised* 17 *August* 1991. *Accepted* 1 *October* 1991)

Summary—1-(4-Nitrophenyl)-3-(2-quinolyl)triazene has been synthesized, and used as an extremely sensitive reagent for the spectrophotometric determination of mercury by the decrease in the absorbance of the reagent at 490 nm and pH 9.0–10.8 in the presence of cetylpyridinium bromide. Beer's law is obeyed over the range 0–120 ng/ml Hg(II), the apparent molar absorptivity being 1.0×10^6 l. mole^{-1}. cm^{-1}. The effect of 69 ionic species or compounds has been examined. Trace mercury in waste water has been determined satisfactorily.

4,4′-Dinitrodiazoaminobenzene (DNAAB),[1–6] 2,2′-dichloro-4,4′-dinitrodiazoaminobenzene (2,2′-diCl-DNAAB)[7–11] and 1-(4-nitrophenyl)-3-(2-pyridyl)triazene (NPPyT)[12] have been investigated as reagents for spectrophotometric determinations, and the use of triazenes in spectrophotometry has been reviewed.[13] In this paper the use of 1-(4-nitrophenyl)-3-(2-quinolyl)triazene (NPQT) as a spectrophotometric reagent for the determination of mercury(II) is reported.

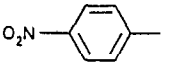
EXPERIMENTAL

Synthesis of NPQT

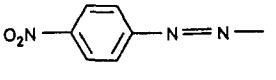


Concentrated hydrochloric acid (20 ml) and water (120 ml) were added to 4-nitroaniline (4.8 g) in a 500-ml flask and heated gently until the 4-nitroaniline dissolved. The solution was cooled in an ice-bath to below 5°, and a solution of 2.5 g of sodium nitrite in 20 ml of water (at <5°) was added with stirring. This solution was then mixed with a solution (cooled to <5°) of 5 g of 2-aminoquinoline in a mixture of 10 ml of concentrated hydrochloric acid and 20 ml of water. After half an hour sodium bicarbonate (30–40 g) was added in small portions, and after 24 hr about 40 g of sodium acetate was added with stirring until the pH of the solution rose to about 6. After another 24 hr the yellow solid was filtered off and dried in air. The crude product was recrystallized twice from ethanol, to yield bright yellow crystals, m.p. 216°.

The composition of NPQT was established from its low-resolution mass spectrum (Fig. 1) in which the molecular peak appears at m/z 293. The base peak at m/z 122 is due to



and the second most intense peak at m/z 150 is due to



*Author for correspondence.
†Present address: Zhuzhou Institute of Technology, Zhuzhou, Hunan, 412008, P.R.C.

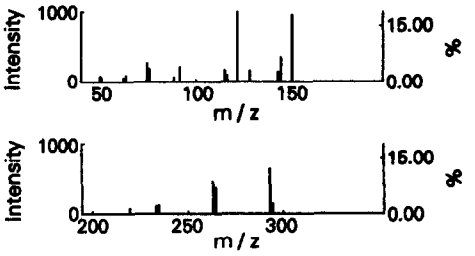


Fig. 1. Low-resolution mass spectrum of NPQT.

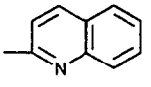
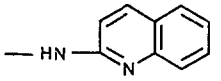
and the two weak peaks at m/z 128 and 143 are due to



and



respectively.

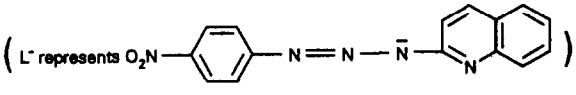
Analysis gave C 61.3%, H 3.8%, N 23.4%; $C_{15}H_{11}N_5O_2$ requires C 61.43%, H 3.78%, N 23.88%.

NPQT has good stability. It is sparingly soluble in water, but easily soluble in ethanol and in acids and alkalis. Its solution in alkaline aqueous alcohol is yellow and stable for at least a year.

In aqueous alcohol solution its dissociation equilibria are

$$H_2L^+ \underset{+H^+}{\overset{+OH^-}{\rightleftharpoons}} HL \underset{+H^+}{\overset{+OH^-}{\rightleftharpoons}} L^-$$

pH 1.5	pK_1 2.08	pH 2.5–11.5	pK_2 11.92	pH 12.5–14
yellow		greenish-yellow		orange



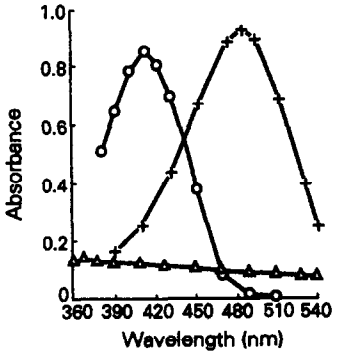


Fig. 2. Absorption curves of NPQT solution ($2.4 \times 10^{-5}M$) with HCl or / and NaOH present at pH 1.6 (○), 9.63 (△) and 14(+).

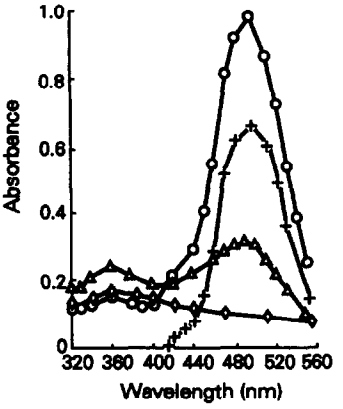

Fig. 3. Absorption spectra with $6.4 \times 10^{-7}M$ Hg(II)–NPQT (◇), NPQT–CPB (○) and NPQT–CPB–Hg(II) (△) solutions measured against H_2O and NPQT–CPB solution measured against NPQT–CPB–Hg(II) solution (+).

NPQT decomposes to give a greyish precipitate when the basicity of the solution is $>1M$ sodium hydroxide. The absorption spectra of NPQT at different pH values are shown in Fig. 2. The maximum absorption was at 412 and 481 nm at pH $\leqslant$ 1.5 and 12.5–14 respectively. There was no absorption maximum when the pH was 2.5–11.5.

RESULTS AND DISCUSSION

Spectrophotometric determination of Hg(II)

NPQT solution (1.5×10^{-4}M). In a 2-litre standard flask, dissolve 0.0898 g of NPQT in 1 litre of 95% ethanol and 5 ml of $2.5M$ sodium hydroxide, and dilute to the mark with water.

Standard mercury solution (5 mg/ml). Dissolve 6.891 g of mercuric chloride in 1 litre of 0.5% v/v hydrochloric acid. Prepare a working standard solution (1.0 μg/ml Hg) by diluting the stock solution with water just before use.

Buffer solution (pH 10.5). Prepare with $0.1M$ borax and $2.5M$ sodium hydroxide.

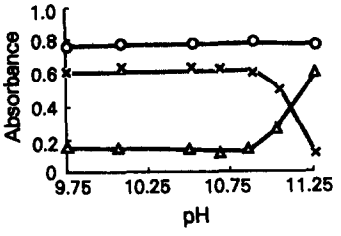

Fig. 4. Effect of pH on absorbance of NPQT–CPB (○) and NPQT–CPB–Hg(II) (△) solutions measured against H_2O and NPQT–CPB solution measured against NPQT–CPB–Hg(II) solution (+); (conditions as for Fig. 3).

*Determined with a mercury analyser.

Cetylpyridinium bromide (CPB) solution (5×10^{-3}M)

Procedure. In a 25-ml standard flask place 4.0 ml of the buffer solution, 3.5 ml of NPQT solution and a known volume of standard or sample solution (containing up to 3.0 μg of mercury), in that order, and mix. After 5 min add 5.0 ml of CPB solution and dilute to the mark with water. Prepare a reagent blank in the same way. Keep both solutions at 25° and after 15 min measure the absorbance of the reagent blank against the sample solution at 490 nm, in 1-cm cells.

The absorption spectra for the reagent and the complex system are shown in Fig. 3. NPQT itself has no absorption maximum in the visible spectrum at the pH used, but has a strong absorption peak at 490 nm in the presence of CPB (curve 1) and this is decreased by Hg(II) (curve 2) owing to formation of the Hg(II)–NPQT–CPB complex. The absorption maximum of the Hg(II)–NPQT–CPB complex is at 360 nm, and the apparent molar absorptivity for Hg(II) at this wavelength is 1.5×10^5 l.mole^{-1}.cm^{-1}, but the reagent blank is rather high. Moreover the sensitivity is considerably increased by use of the decrease in the reagent absorbance at 490 nm.

The absorbances of the reagent and the ternary complex vary slightly with the pH of the solution in the ranges 9.8–11.3 and 9.8–10.8 respectively (Fig. 4), but the difference between the two varies only slightly in the pH range 9.8–10.8. Therefore, pH 10.5 is chosen for the determination.

The absorbance of 25 ml of solution containing 1.6 μg of mercury is maximum and constant with 2.3–7.0 ml of $1.5 \times 10^{-4}M$ NPQT and 2–6 ml of buffer solution. The absorbance appears to be maximal with about 1.5 ml of $5 \times 10^{-3}M$ CPB and then decreases, but is constant with 3.5–5.5 ml of CPB solution. The absorbance of the reagent blank (measured against water) is constant for about 2 hr, but the absorbance for the mercury system (measured against water) increases slightly with time. However, the difference between them decreases by less than 5% per hr, so the spectrophotometric measurement should be made at a fixed time (in the range 15–45 min) after all the reagents have been added.

The absorbance for NPQT–CPB measured against water does not change with temperature, but that for Hg(II)–NPQT–CPB measured against water increases by about 34% when the temperature rises from 15° to 40°. Hence we recommend keeping the temperature at 25°.

Less than 3 ml of extra ethanol added together with the NPQT solution does not affect the sensitivity for the determination of mercury.

The effect of the temperature, time and other factors on the decrease of the absorbance of NPQT by mercury(II) is serious, so it is very important to control all conditions precisely in the determination of mercury. In particular, the sample and reference solutions have to be made up with as nearly as possible exactly the same amount of NPQT in each.

The calibration curve is constructed at 490 nm in the usual way, according to the general procedure. Beer's law is obeyed for 0–3 μg of Hg(II) in 25 ml of solution. The apparent molar absorptivity is 1.0×10^6 l.mole^{-1}.cm^{-1}. The method is one of the most sensitive spectrophotometric methods for mercury.

Effect of foreign ions

Cd(II), Ag(I), Cu(II) and Pd(II) behave like Hg(II), and cause positive interference, but 1 μg of Cd(II) or 3 μg of Cu(II) or Pd(II) can be tolerated if 1 mg of potassium bromide and 2 mg of citrate as masking agents are added for the determination of 1.6 μg of Hg(II). CNS^-, I^-, ClO_4^-, ascorbic acid, salicylic acid and $S_2O_3^{2-}$ interfere seriously and large amounts of EDTA, DCTA, $C_2O_4^{2-}$, F^-, NTA, tartrate, H_2O_2, $NH_2OH \cdot HCl$, $(NH_2OH)_2 \cdot H_2SO_4$ and thiourea interfere. Less than ±5% deviation in the determination of 1.6 μg of mercury(II) results from the following amounts (μg) of various ionic or molecular species: Na^+, K^+ (5000);

NH_4^+ (2000); V(V), Mn(II) (1000); Ba(II), Ca(II), Mg(II) (500); W(VI) (100); Ga(III), As(V), In(III), Sr(II), Cr(VI), Mo(VI), Al(III), Pt(II) (50); Ni(II), Co(II), Bi(III), Tl(III), Ge(IV), Sn(IV) (30); Zr(IV), Ti(IV), Fe(III), Au(III), Nb(V), Ta(V), Pb(II), Te(IV), lanthanides, Th(IV), Zn(II) (10); Rh(III) (5); Ir(III) (2); Sb(V) (1); Cl^-, SO_4^{2-}, $S_2O_7^{2-}$, TEA, citrate, PO_4^{3-} (20,000); tartrate, CO_3^{2-}, $S_2O_8^{2-}$, NO_3^- (2000); Br^-, NO_2^-, $C_2O_4^{2-}$, $CH_3CO_2^-$, H_2O_2 (1000); $NH_2OH \cdot HCl$, $(NH_2OH)_2 \cdot H_2SO_4$, thiourea (500); F^-, DCTA, NTA (100).

Determination of mercury in water

The mercury content of a waste water sample was determined by the proposed method (1 mg of potassium bromide and 2 mg of sodium citrate were added as masking reagents). The result was in reasonable agreement with that obtained with a mercury analyser. A mercury-free tap water was spiked with known amounts of mercury and analysed. The results are shown in Table 1.

BOOK REVIEWS

Dual Diagnosis in Substance Abuse: M. S. GOLD and A. E. SLABY (editors), Dekker, 1991. Pages x + 341. $89.75 (US and Canada), $103.00 (Elsewhere).

It has been a privilege for me as a psychiatrist to review this volume. The title is mildly misleading as not all patients will have only two diagnoses. However, if the title is designed to convey the occurrence of some substance misuse disorder with any other combination of diagnoses then the editors have succeeded in their task.

Three sections have been presented, namely an introduction, a section on clinical presentation of other diagnoses in substance misuse and a section on treatment. The chapters in these sections have been written by a number of physicians from the United States of America, some being better known than others, and two counsellors. Generally, these authors have presented their material well, though the editors have allowed some repetition across chapters. Unfortunately, the style in the chapter on "Diagnosing Dual Diagnosis Patients" is greatly at odds with that used throughout the rest of the volume. The authors have used quite a few unexplained initials and introduced jargon. Inclusion of case histories to illustrate the diagnostic criteria help to offset what might otherwise ruin this chapter completely.

For those who are looking for a word on the role and usefulness of chemical analysis, what a clinician wants and problems that might arise, there is not a whisper. There are at most three pages which mention thin-layer chromatography, gas chromatographic mass spectrometry, radio immunoassay and enzyme immunoassay in the chapter on pharmacotherapy. I respectfully suggest that while psychiatrists would find this book worth reading those who deal with chemical analysis might wish only to glance at the chapter on pharmacotherapy and read further only if wishing to have some background understanding of what is a complicated area in the substance misuse field.

A. D. T. ROBINSON

Instrumentation in Analytical Chemistry, volume 1: J. ZÝKA (editor), Ellis Horwood, 1991. Pages 368. £53.00.

This is volume one of a two-part work intended to provide students of analytical chemistry, industrial chemists and workers in other scientific fields with an up-to-date overview of a wide range of modern instrumental techniques. In recent years the pace of development in instrumentation, automation and computerisation and the increasingly diverse and complex nature of many contemporary analytical problems, some requiring an interdisciplinary approach, has made it difficult for students, industrialists, environmentalists, *etc.*, to keep fully abreast of such advances. The editor and authors have addressed this problem by planning two volumes of suitably condensed information on a variety of modern analytical techniques with extensive references to monographs and other specialised literature.

The sixteen chapters cover a quite diverse range of topics, *viz.*

1. Analytical isotachophoresis
2. Differential pulse polarography and voltammetry
3. Advances in ion-selective electrode potentiometry
4. Analytical measurements in flowing liquids
5. The use of computers in gas chromatography
6. The long-range detection of atoms, molecules and aerosols with lasers
7. New sources in optical emission spectrometry
8. Modern radioanalytical methods
9. Modern methods of decomposition of inorganic substances
10. Gas chromatography and headspace analysis
11. Inclusion compounds in chromatography
12. Chromatographic methods in the analysis of phenols
13. X-ray spectroscopy
14. Mössbauer spectroscopy
15. Neutron activation analysis
16. The analytical application of characteristic X-rays excited by charged particles (the PIXE method).

These are in the main well-structured and concisely written covering essential theory, instrumentation and practical applications. Diagrams are generally clear and long lists of more detailed and specialised references are given at the end of each chapter. Although some recent references are cited the number from the late eighties and nineties in many chapters is small and, coupled with the omission of such topics as radioimmunoassay and ICP-Mass spectrometry, this gives the book a somewhat dated feel. Nevertheless, the idea for this type of work is a good one but it must also be said that the choice of

These are in the main well-structured and concisely written covering essential theory, instrumentation and practical applications. Diagrams are generally clear and long lists of more detailed and specialised references are given at the end of each chapter. Although some recent references are cited the number from the late eighties and nineties in many chapters is small and, coupled with the omission of such topics as radioimmunoassay and ICP-Mass spectrometry, this gives the book a somewhat dated feel. Nevertheless, the idea for this type of work is a good one but it must also be said that the choice of

techniques (the chapter on phenols is all chromatography) is curious in that there is no apparent logic to it. Some of the techniques selected are in the mainstream of modern analytical chemistry whilst others are highly specialised and are likely to be of very little or no interest to many potential readers. Given the two-volume nature of the work, it might have been more prudent, and commercially adroit, to have grouped mainstream techniques in volume one and the more peripheral ones in volume two. The scope of the latter is as yet unknown but there are certainly many more widely-used techniques that could and should be covered.

Inevitably one must compare this book with the established and more detailed volumes on instrumental analysis several of which are up-dated frequently and are generally available in relatively cheap student editions. However, the attraction (but possibly the weakness) of this book is that it includes more diverse and esoteric techniques. It is not a book for the individual but will provide libraries with useful and reasonably up-to-date introductory material and a source of references to more detailed information.

D. KEALEY

The Important Peak Index of the Registry of Mass Spectral Data: Volumes 1–3. F. W. MCLAFFERTY and D. B. STAUFFER, Wiley-Interscience, New York, 1991. Pages: viii + 1352 (Volume 1), 1353–2708 (Volume 2) and 2709–4057 (Volume 3). £576.50.

This three-volume Index is derived from the "Registry of Mass Spectral Data", published in 1989, which contains spectra of over 115,000 different compounds of established structure.

With the proliferation of combined GC/MS and LC/MS instrumentation, reliable mass spectral data can now be routinely obtained on individual components of complex mixtures, without the need for isolation of the compounds themselves. This has generated an urgent need to identify the types of compounds which give rise to peaks at the masses found in the spectrum of a compound of unknown structure. Computer searching of MS databases does provide an efficient method for the matching of mass spectra, and recent advances have reduced costs in this area, but additional aids to interpretation are still required. One such adjunct is the widely used "Eight Peak Index" (RSC, 1983), which lists the most abundant peaks by m/z value. In this new Index, the peaks listed are chosen on the basis of their statistical importance, rather than just their abundance, according to a probability-based matching system. This more sophisticated system affords greater reliability in the matching of peaks for two main reasons (i) it eliminates all the commonly occurring low m/z peaks (which are usually the most abundant and the most infuriating) from the analysis, and (ii) it allows attention to be focussed upon those peaks which are of the greatest value in identifying an unknown compound. These innovations allow the number of possible structures to be narrowed down dramatically when higher m/z peaks are considered.

The probability of occurrence of ions in the Registry database has been tabulated in terms of the "uniqueness value" ("U") used in the probability based matching algorithm, U representing the log base 2 value for the probability that a reference will contain a peak of this m/z value of $\geqslant 1\%$ abundance. The "importance" rating of each peak for this Index is based upon the sum of the uniqueness and abundance values (U + A), thereby allowing ions of low to moderate abundance in the upper m/z range of a mass spectrum to be rated as highly as a base peak of low m/z value. As an aid, a one-line summary of approximate U and A values appears at the bottom of each page of the Index.

The Index has been found to be extremely useful in identifying aroma volatiles from various sources by GC/MS headspace analysis. The rating system provides a mechanism for allowing for the differences between mass spectra obtained with different instruments and conditions, particularly as abundance variability can sometimes be considerable. Of course it is not possible to identify new compounds using this Index, but its novel features ensure that existing compounds in the molecular weight range of an unknown can rapidly be identified and eliminated from consideration.

Each of these three volumes weighs no less than 5lb 5oz. Although the published price may seem high, it represents a rare bargain, for they are worth their weight in gold.

A. B. TURNER

Chromatographic Enantioseparation—methods and applications, 2nd edition: S. ALLENMARK, Ellis Horwood, 1991. Pages 282. £55.00.

The second edition of this book appears three years after the first. The original work was well received (for a review by J. L. Wardell see *Talanta*, 1989, **36**, No. 4) and the rapidly advancing field of chiral chromatography has provided the reason for this new edition. If you are new to this area of separation science and wish a good introductory text which also covers some recent work then this book is highly recommended. If you are an experienced practitioner in chromatography and have already purchased the first edition do you also buy this edition? If you wish to keep up to date then the answer must be "yes". However, a comparison with the first edition may be of interest.

The topics covered are essentially the same as in the first edition (the chapters have identical headings) but have been updated where necessary by reference to more recent literature. The most obvious difference between editions is the inclusion of additional experimental procedures for the synthesis of chiral sorbents. In particular, several techniques used for the binding of chiral selectors to silica are now presented. Chapter 10 on "future trends" is also of interest as the newly developed diode-laser-based micropolarimetric detectors (a "future trend" in the first edition) is now mentioned

TRIBUTE

THOMAS SUMMERS WEST—"Tom" to his many friends throughout the world—was born at Peterhead, Scotland, on 18th November 1927. When he was about six years old he moved with his parents to Portmahomack, a small fishing village on the Dornoch Firth. His father was a fisherman, indeed all his forebears were seafaring folk. In Portmahomack his primary education was at Tarbat Old Public School, after which he attended the nearby Tain Royal Academy.

In 1945 West entered the University of Aberdeen as a Highlands and Islands Bursary Scholar, graduating with first class honours in chemistry in 1949. He had been interested in analytical chemistry since his school days, and his future scientific path was confirmed while he was living at the YMCA in Aberdeen, where he met Ronald Belcher, Lecturer in Inorganic and Analytical Chemistry at the University. When Belcher moved with Prof. H. W. (now Sir Harry) Melville to the University of Birmingham in 1948, West followed in 1949. There he helped to form the nucleus of Belcher's Birmingham School of Analytical Chemistry. West duly received his Ph.D. (1952), was subsequently awarded a Senior DSIR Fellowship (1952–1955), and then became a Lecturer in Chemistry (1955–1963). His D.Sc. was conferred in 1962.

At Birmingham Belcher built up an international centre for microanalysis. West's early contribution to that was work on a quartz fibre torsion ultramicrobalance and on a system of ultramicro organic elemental and functional group methodology. With the award of his Ph.D, he started up his own group, pursuing an independent line of research into analytical chelate chemistry. Also, he did exploratory work on solvent extraction and polarography. A highlight was the specific chromogenic ternary complex reaction between fluoride, either of the first two members of the lanthanides and 3-dicarboxymethylaminomethyl-1,2-dihydroxyanthraquinone, and the interpretation of the mode of action of this only known positive colour reaction of the fluoride ion. It has subsequently replaced all other spectrophotometric reactions for fluoride. Another important discovery was the unique conditionally specific reaction between calcium and a new specially synthesized trishydroxytriazo clathrate cage dyestuff molecule.

West moved in 1962 to succeed Mr. L. S. Theobald as Reader in Analytical Chemistry at Imperial College of Science and Technology in London. There he found himself junior to Prof. F. C. Tomkins (Physical Chemistry and long-time Secretary of the Faraday Society), Prof. G. (later Sir Geoffrey) Wilkinson (Inorganic Chemistry and Nobel Laureate 1973), Prof. D. H. R. (later Sir Derek) Barton (Organic Chemistry and Nobel Laureate 1969), and Prof. R. M. Barrer (Head of Department and Physical Chemistry, renowned for his work on molecular sieve action and coincidentally Professor of Chemistry in West's final year at Aberdeen). Undeterred, and together with three young post-doctorates from Birmingham—Roy Dagnall, Bernard Fleet, and Gordon Kirkbright—he quickly set up a thriving team, and in 1965 was promoted to Professor of Analytical Chemistry. Over the course of some ten years, West established an international reputation for his analytical chemistry research work at IC.

This work was largely centred in analytical atomic and molecular absorption and fluorescence spectroscopy. In Australia Alan Walsh had opened a new era by demonstrating first an easy laboratory technique of atomic absorption spectrophotometry (AAS), and then showing its unique specificity for the determination of most metal ions. It was a far cry from classical analysis, but West in the U.K. and Jim Robinson in the U.S.A., another former Belcher student, made rapid advances in the new field. It proved to be very popular with West's students, extending AAS to pioneering studies in atomic spectroscopy by carbon rod electrothermal atomization, microwave-excited high intensity atomic line sources, low emissitivity separated flames, chemiluminescence in diffusion flames, atomic fluorescence spectroscopy, and atom trapping atomic absorption spectroscopy. He received widespread international recognition and awards.

In 1975 West returned to Scotland as Director of the Macaulay Institute for Soil Research at Aberdeen. The Institute's role was to evaluate the whole of Scotland's land and to determine how

best it might be used or developed. It carried out remote sensing and image processing, and used ESCA, photoacoustic and spectroscopic methods. The applied focus of the programme stimulated West to new experiments. He continued to evolve the technique of atom trapping atomic absorption spectroscopy, and made contributions to piezo-electric crystal sensor systems for minute traces of airborne pollutants and to the study of interfacial optical absorption and emission phenomena at platinum electrode surfaces under conditions of diffusion controlled electrolysis in aqueous solutions. Work on biosignificant and toxic trace elements in the soil–plant ecosystem and acidification phenomena led to his participation in the U.K. Royal Society's SWAP (Surface Water Acidification Programme) team together with the Royal Academies of Science in Norway and Sweden. His final years at MI were much taken up with the painful necessity, imposed by the Department of Agriculture and Fisheries for Scotland, to reduce the Institute staff by about 25% and with the battle to avoid closure of the Institute in Aberdeen for amalgamation with another Institute near Edinburgh. He was able to secure jobs elsewhere for all but a few, and mounted a campaign, mobilizing all the considerable scientific community in Aberdeen, members of Parliament and the House of Lords, plus a continuous stream of letters from some 200 former visitors from all over the world, who had worked at MI. In the end the civil service mandarins of the Scottish Office in Edinburgh were obliged to give way. Amalgamation took place on the Aberdeen site.

In the laboratory West was held in great affection and respect by his students. The ladies were much affected by his Scottish burr and good looks, although there is no record of them swooning or leaving poems behind at the end of a lecture. He is a committed internationalist, and always provided a warm welcome to students from abroad throughout his career. The sentiments of many are captured by Sameer Rahim, who writes "I found him a great-hearted and experienced head of the department, admired by everyone. I was very happy when told that I was lucky because Prof. West is your supervisor. He was very humanitarian: father, brother, and friend, especially to overseas students, who face special problems during their period of stay in Britain. Prof. West did his best to minimize such problems. When we visited his home, we found him an ideal family man, which helped him to be a great scientist. We were astonished to see a dish of Iraqi rice, and also learned that he was an expert in making tea."

At Birmingham he tolerated the brewing sub-industry of his students. Dai Rees, on loan from the Food Research Laboratory, set a high standard in this respect. Bob Close filled the laboratories with fermenting and exploding bottles, whose contents were usually deemed unspeakable and undrinkable. At IC West was not amused when, according to Godfrey Everett, some of his students caught a mouse, and it was incarcerated in a large round-bottomed flask with an ample supply of water, bedding, and food. He arrived earlier than usual the next day, and commented that his research laboratory "was not a menagerie". From then on mice and roosting pigeons were left in peace. He banned noisy radios, but supported ball-by-ball commentary through the cricket season. The social scene moved with members of his staff and former students, who set up Electrodeless Discharge Tubes (EDT) as a company to exploit inventions of the research team.

West encouraged open thinking and experimentation in new fields. In his Birmingham days, the analytical team had one of the very few spectrophotometers owned by the Department of Chemistry. West encouraged the use of all the techniques scattered throughout the Department. As he put it "All those other fellows (organic and physical chemists) are basically stuck with one set of apparatus or one measurement technique. In analytical chemistry we can use the lot." It is a vision which has resulted in his students being leaders in many fields of analytical science and in domains well away from chemistry.

Within the Royal Society of Chemistry West holds the Meldola Medal (1956), Perkin-Elmer Medal for Instrumentation and Analytical Chemistry (1976). Gold Medal for Analytical Chemistry (1977), and Redwood Lectureship (1974). Overseas awards include the Interan Medal (1977) of the Czechoslovak Chemical Society, Johannes Marcus Medal for Spectroscopy (1977) of the Spectroscopic Society of Bohemia, and Honorary Membership (1981) of the Japan Society of Analytical Chemistry. He became a Fellow (1979) of the Royal Society of Edinburgh and in 1989 a Fellow of the Royal Society of London. In the Queen's New Year's Honours List for 1988 he was made a Commander of the Order of the British Empire (CBE) for his contributions to chemistry and international science.

During his Birmingham days West had already become a member of the Council of the Society for Analytical Chemistry (1956–1972), serving on various of its Committees. This culminated in his election to the Presidency of the Society during 1969–1971. Whilst he was in London, West became increasingly involved in the wider scientific community. Within the Chemical Society (later Royal Society of Chemistry), he served as Honorary Secretary (1972–1975) and on some important committees. He played a prominent role in the negotiations which led to the amalgamation in the U.K. of the Chemical Society, Royal Institute of Chemistry, Faraday Society, and Society of Analytical Chemistry.

Also, West has worked within the committee structure of the Royal Society, serving on analytical international matters. More recently his role has broadened, and he served on the Department of Health and Social Security's Expert Group on Sudden Infant Death Syndrome (Cot Death), the Ministry of Defence's Gruinard Island (Anthrax) Group, and is chairing the recently formed Scientific Advisory Committee to the Guildford and Woolwich Enquiry.

In November 1987, having reached the statutory age of sixty, West retired from MI and was given the status of Professor Emeritus by the University of Aberdeen. His release from the duties of Director enabled him to devote more time to international science. He had already been an active Commission and Division member in the International Union of Pure and Applied Chemistry (IUPAC) since 1963, rising to President of the Analytical Chemistry Division (1977–1981). After a period as Assistant Secretary General (1981–3), he was elected Secretary General of the Union and served two four-year periods in that office (1983–1991). During this time he was responsible for introducing the scheme of Affiliate (individual) Membership, and helping to broaden the scope of the classically-oriented Divisional activities of IUPAC into interdisciplinary areas, such as chemistry and the environment. In addition, acting as the official representative to the General Committee of the International Council of Scientific Unions (ICSU), West strove to increase the involvement of the Union—and chemistry as the central science—in the activities of ICSU, which had been rather neglected for several years. Two initiatives of his are presently under consideration of implementation by ICSU, namely the consequences of use of chemical weapons and a study of the world's future energy supplies. In 1990–2 West became Chairman of the Standing Finance Committee of ICSU and a member of the Executive Board.

Several of West's former research students from Birmingham and IC now hold Chairs of Chemistry in Canada, Japan, the U.K., and U.S.A., and prominent positions in a wide range of industries. For instance, Lay Har Tan Ng comments "Through his inspiration a good number of his students and postdoctoral associates have carried his influence to Hong Kong, and made reputations for themselves in the civil service, in industry, and in the academic circles here. Prof. West's sound judgement and fairmindedness have made him much sought after as an external examiner." West has published over 400 research papers, books, and monographs (see pages 1411–1428 for details), and lectured worldwide on his research work.

Tom West is a devoted family man, having married Margaret Officer Lawson, a mathematics student who he met while a student himself at the University of Aberdeen. Their three children—Ann, Ruth and "young" Tom—were all born in Birmingham and, although they are now themselves all married and living as far away as in northern France, Tom and his wife are regular visitors each year to their various homes and their four grandchildren, Alexander and Marianne Cochennec and Catherine and Sarah West.

SOME MEMOIRS ABOUT PROFESSOR T. S. WEST

In the biography "Thomas Summers West", earlier in this issue, we have distilled the essence of his work and style of life. This has been done with the help of several former students and colleagues, who have contributed their reminiscences. Inevitably, some of the flavour has been lost in the process of condensing a full life into a brief account. The following letters, reproduced in their entirety, go some way towards redressing the balance. They capture the sense of his personal impact from different perspectives.

* * *

I consider this a great opportunity to write some of my best memories of Tom West in honour of his 65th birthday.

Tom West is a person who has made a lasting impression on me. I had the honour of being one of his research students at Imperial College London for about eighteen months in the early 1970s on my first overseas visit.

During that period of time, we had many brief discussions, and each time I would become a little wiser. He was very caring, meticulous and at the same time very precise in his methods of approach; at times he sparkled with brilliance. Although my research was of no great significance, what I learned, particularly from him, did turn out to be of much significance to me later.

I recall some of the everyday conversation. One day in his room, I happened to smoke a small-sized cigarette, rather unenthusiastically. He smiled and remarked "You are like me". This, I could understand, because he too smoked only sparingly. But what I could not understand was when he remarked the same thing when I was just returning after delivering a talk about our research work, the programme having been arranged under his guidance. To be told after the talk that I was like him left me wondering; in my view there is no comparison between him and me.

In 1972 at an SAC symposium in Glasgow, while delivering a paper, he howled from a top back-bench and many heads turned around. I did not know that he himself was running a short strip of film about my research work. While the film was running I looked silently at the screen without explaining the action. The loud shout jerked me to attention, and I realised my mistake.

During conversations, I was used to addressing him as "Professor West/Sir". One day, he stoutly told me "From now on call me Tom"; I do not remember that I took his advice.

I enjoyed and gained greatly from being associated with him.

Thank you Tom. I wish you many happy returns of the day.

Iswori Lal Shrestha
Deputy Director General
Department of Mines and Geology
Kathmandu, Nepal

* * *

For many of those who studied under Prof. West at Imperial College, the portals of the Advanced Analytical Laboratory marked the entrance to a career in one branch or another of science, in which analysis would play a part. I imagine Tom always thinks of those who followed so directly in his footsteps, even though perhaps not to the topmost heights he occupied, as his best and most worthy products. The exponential flowering of a multitude of research papers, each with a name or two known to have been students of the master, must have given and continue to give him inordinate satisfaction.

Sadly, I cannot claim to be numbered among this favoured band, since directly from Imperial College I was claimed by Mammon, destined ever after to earn my corn in the halls of commerce and finance. I am now able to reveal that one of the best kept secrets in this area of human

endeavour is that many of its problems are susceptible to Tom's type of analytical treatment. By this, I mean the application of tried and tested methods, clear labelling, the careful collection of data, rigorous and unbiased processing into final form, and due noting of negative results.

Many are the examples I can cite: the coal exploration prospect in Latin America, where my short demonstration of the "alternate quarter and shovel" sampling technique struck fear into all concerned; the fascinating discussion with the clerk in the Punjab cotton ginning plant on the distinction between accuracy and precision; the Andean economist gathering the tin mine assay information, whose only question was "What answer do you want?"; the African broker who needed persuading that 90% of his clients could not all be above average; and the Eastern European banker requiring confirmation that his new bank could profitably lend at 6% while borrowing at 8%.

Tom West's special way of letting the lowliest 3rd year dissertation student in on the mysteries of experimental discipline or of curbing some flight of fancy by a desperate would-be PhD student searching for that nugget of knowledge, stayed with me sufficiently for application (he might say distortion) to these other worldly uses.

His use of metaphor and allegory would likewise have come in handy in some of the tighter spots, my only recorded success being to explain spectroscopy to an unsmiling audience in Egypt by quoting from Omar Khayyam:

"In and out, above, about, below,
'Tis nothing but a Magic Shadow show,
Held in a box whose candle is the Sun,
Round which we phantom figures come and go."

To conclude, my message is a simple one: the great teachers, such as Tom West, so influence their pupils that not only is the effect seen in their area of immediate specialisation, but also other apparently distant spheres are guided by the unseen hand.

* * *

I met Tom West many years ago in one of the biennial general assemblies of IUPAC. He was heavily involved with the work of the analytical chemistry division. Tom represents the very best traditions of modern analytical chemistry, and his personality is ideally suited to the demanding requirements of the subject. He is meticulous and gives attention to every detail in all his work—the outcome is that he has always produced very good and useful results.

Tom is a warm-hearted, cheerful person and works well with other colleagues. He is also highly committed to his work and loyal to friends and to institutions. These qualities became further underlined when I came to know him closely in the late 1970's and early 1980's.

I recollect a rather awkward day during the IUPAC general assembly at Lyngby in 1983, when I was rather depressed. I was a candidate for the post of Vice-President of IUPAC. There was a suggestion that I withdraw from the election, to avoid certain misunderstandings. However, many gave me support and urged me to go through the democratic process. I remember Tom's wise counsel at that time. After I was elected as Vice-President, I worked closely with Tom on various aspects of the Union. He was then Secretary General. When I became President in 1985, Tom's advice and support became invaluable. There he was like a rock, always dependable and available. I enjoyed working with him and treasure his friendship. His urge to contribute constructively and with humility has endeared him to all his colleagues and associates.

My association with Tom continued later as Past-President of IUPAC and also as coordinator of the horizontal programme on chemistry and advanced materials. I believe that in Tom I have found a fine friend of great talent and indisputable human qualities.

4th March 1992

My first contact with Tom was after graduating in the early 1960's, when I decided to look for graduate work in analytical chemistry. In those opulent times, I was trying to decide between the abundance of offers I had received from graduate schools in the United States, when I happened to read an excellent review that Tom had written for the Royal Institute of Chemistry monograph series on advances in analytical chemistry. It was this article more than anything else that prompted me to apply to Birmingham, and eventually to join the Belcher-West group there. Whether Tom can be accused of stemming the brain drain or of promoting it is an open question

At Birmingham, even though I was not working for Tom, I have a keen recollection of his accessibility and of the fact that he was always willing to spend a few minutes discussing your work. These discussions were very important to me in shaping my research interests and future career direction, and consequently I was very honoured a few years later to be invited to join Tom's group at Imperial College.

During my early years at Imperial, I must also say that Tom gave me enormous support and encouragement in starting my research in electroanalytical chemistry, even though it was outside his own main interests and those of the rest of the research group there.

I have many happy memories of our time together at Imperial. Of the many social events, a dinner organized by the late Peter Keliher, at which Tom was to be the guest of honour, stands out. This was held at an infamous Chelsea Bistro, noted for its ambience and cheap wine. The dinner was indeed famous for the amount of wine consumed and for a rendition by Peter of "we are poor little lambs who have lost our way" not calculated to inspire hope in fresh graduate students. Unfortunately, in those pre-plastic days, when the bill finally arrived, the budget had been well and truly blown and, after much pocket searching, the guest of honour was prevailed upon to dig into his sporran and bail us out.

A more recent event was held here in Toronto during the 1988 North American Chemical Congress. This was the first TS West Group North American reunion at which TSW was the guest of honour. Unfortunately, at the last minute, due to an unexpected IUPAC commitment, Tom was unable to attend. Not to be thwarted, his devoted followers pressed ahead with the event, and a life-sized model of the boss was constructed to fill his place and is still available, for hire, for future events.

On a more serious note, like most of his students, I owe Tom a deep debt of gratitude for his support, advice and guidance over the years. May his semi-retirement years be long, happy and healthy.

* * *

Working with the International Union of Pure and Applied Chemistry gave me the opportunity to meet many wonderful and very interesting people. Among all these chemists, one of them immediately struck me by his kindness, by his very open mind, by his simple approach. That was Thomas West, that was in 1979.

For twelve years, we worked together for the Union. We both served as Bureau members. Then Tom West became Secretary General, and later I was elected Vice-President and became President. This four-year period of office for me (1987–1991) merits special mention.

During this time I received continuous support and friendly help from Tom West to fulfill the presidential duties, which are not always easy. But that was only part of his contribution: the visible part of the iceberg. I found a man of exception, the main qualities of whom were generosity and full devotion to his duty.

He never made a move or gave his opinion on a problem dealing with the Union, without giving deep thought to it and without considering the benefit it might bring to the Union. Actually, when I say to the Union, this is not the right way to describe things. Tom West always thought first about people, about Union members, about our fellow chemists.

May I take as an example the tremendous efforts he made to set up the IUPAC Affiliate Membership Scheme (later termed Programme). Undoubtedly, the development of AMP was his very own work. The way he presented the Programme and its progress to the Council at general assemblies in warm words was a perfect example of his behaviour. He strongly supported a way to associate more chemists with the work of the Union, especially those from developing countries. Indeed, they have chemists who are so isolated and who need so much help. This action was typical of the generosity of Tom West.

One of the duties of our Secretary General is to maintain the Secretariat of the Union in good shape and to support its activities. He took great care of our Oxford Secretariat and of its staff, again with his personal touch, paying great attention to personal problems. Doing this he greatly contributed to the development of its work.

This presentation could be continued with other examples. Meeting Tom West was very rewarding to me and I am sure he will allow me to say that, thanks to IUPAC, we became good friends. One day, he described to me his visit to South Africa, and particularly to the Krüger National Park. He told me: you will be surprised if you go there, to see how clear is the sky and how bright are the stars during the night. They are so brilliant that they look very close indeed. One could say that every time Tom West presented his views on a problem, he had such a way to explain the problem, that the solution appeared quite clearly, just like the stars in the sky of South Africa.

On behalf of the International Union of Pure and Applied Chemistry I am pleased to acknowledge his invaluable contribution.

82. A New Spectrophotometric Reaction of Beryllium. *Analyt. Chem.*, 1963, **35**, 311. (with A. M. Cabrera)
83. An Investigation of the Chelatometry of Copper(II) with Ethylenediamine-*N*,*N*,*N*′,*N*′-tetra-*n*-proprionic Acid. *Talanta*, 1963, **10**, 247. (with I. P. Sanderson)
84. 4(2-pyridylazo)resorcinol as a Selective and Sensitive Spectrophotometric Reagent for Niobium(V). *Talanta*, 1963, **10**, 1013. (with R. Belcher and T. V. Ramakrishna)
85. Cyclo-tris-7-(1-azo-8-hydroxynaphthalene-3,6-disulphonic acid) as Spectrophotometric Determination of Small Amounts of Calcium. *Analyt. Chem.*, 1963, **35**, 2131. (with M. L. Herrero)
86. Nueva Reaccion Espectrofotometrica, Selectiva Para Cobre(II). *Anales Soc. Real Espan. Fis y. Quim.*, 1963, **596**, 281. (with R. Belcher and A. M. Cabrera)
87. A New Colour Reaction of Nb(V) with Bromopyrogallol Red. *Chem. & Ind.*, 1963, 531. (with R. Belcher and T. V. Ramakrishna)
88. A Selective and Sensitive Colour Reaction for Silver. *Talanta*, 1964, **11**, 1533. (with R. M. Dagnall)
89. The Selective Solvent Extraction of Trace Amounts of Silver. *Talanta*, 1964, **11**, 1627. (with R. M. Dagnall)
90. The Determination of Trace Amounts of Silver by Atomic Absorption Spectroscopy. *Talanta*, 1964, **11**, 1257. (wtih R. Belcher and R. M. Dagnall)
91. Observations on the Atomic-Absorption Spectroscopy of Lead in Aqueous Solution in Organic Extracts and in Gasoline. *Talanta*, 1964, **11**, 1553. (with R. M. Dagnall)
92. New Methods in Analytical Chemistry. (with R. Belcher and C. L. Wilson) Chapman and Hall, London, pp. 366. Third Ed., 1964.
93. Submicro Methods of Organic Analysis. Part XX. The Determination of Phosphorus and Arsenic. *J. Chem. Soc.*, 1965, 2044. (with R. Belcher and A. M. G. MacDonald)
94. A Method for the Direct Determination of Oxygen in Organic Compounds. *Talanta*, 1965, **12**, 43. (with R. Belcher and D. H. Davies)
95. The Determination of Niobium by Bromopyrogallol Red. *Talanta*, 1965, **12**, 681. (with R. Belcher and T. V. Ramakrishna).
96. A Spectrophotometric Method for the Determination of Thorium. *Anal. Chim. Acta*, 1965, **32**, 301. (with P. Kusakul)
97. A Spectrofluorimetric Method for the Determination of Beryllium and Aluminium in Submicrogram Amounts. *Analyt. Chem.*, 1965, **37**, 137. (with G. F. Kirkbright and C. L. Woodward)
98. El Negro Sulfon Solido F Como Reactivo Espectrofotometrico de Cationes. Effecte del Ion Manganoso Sobre la Reaccion con Differentes Cations. *Anales Real Soc. Espan. Fis y Quim.*, 1965, **61B**, 701. (with F. Burriel and A. M. Cabrera)
99. El. Negro Sulfon Solido F Como Reactivo Espectrofotometrico de Cationes. III. Aplicacion a la Determinacion de Co(II). *Anales Real Soc. Espan. Fis y Quim.*, 1965, **61B**, 703. (with F. Burriel and A. M. Cabrera)
100. El Negro Sulfon Solido F. Como Reactivo Espectrofotometrico de Cationes. IV. Aplicacion a la Determinacion de Niquel. *Anales Real Soc. Espan. Fis y Quim.*, 1965, **61B**, 839. (with F. Burriel Marti and A. M. Cabrera)
101. Determination of Lead with 4-(2-pyridylazo)-resorcinol. I. Spectrophotometry and Solvent Extraction. *Talanta*, 1965, **12**, 583. (with R. M. Dagnall and P. Young)

102. Determination of Lead with 4-(2-pyridylazo)-resorcinol. II. Application to Steel, Brass and Bronze. *Talanta*, 1965, **12**, 589. (with R. M. Dagnall and P. Young)
103. The Spectrofluorimetric Determination of Microgram Amounts of Scandium with Salicylaldehyde Semicarbazone. *Proc. S.A.C. Conf., Nottingham*, Society for Analytical Chemistry, 1965, 474. (with G. F. Kirkbright and C. Woodward)
104. Spectrophotometric Determination of Copper(II) with Acid Alizarin Black S.N. *Anal. Chim. Acta*, 1965, **33**, 164. (with M. L. Hosain)
105. Spectrofluorescence of Aluminium and Gallium with Salicylidene-o-aminophenol. *Chem. & Ind.*, 1965, 1499. (with R. M. Dagnall and R. Smith)
106. Spectrofluorimetry of Microgram Amounts of Thallium I. *Talanta*, 1965, **12**, 517. (with G. F. Kirkbright and C. Woodward)
107. Spectrofluorimetry as a Trace Analytical Technique. I. General Considerations. *Lab. Practice*, 1965, 922.
108. Spectrofluorimetry as a Trace Analytical Technique. II. Apparatus and Techniques. *Lab. Practice*, 1965, 1030.
109. The Determination of Aluminium in Steel. *The Analyst*, 1965, **90**, 13. (with R. M. Dagnall and P. Young)
110. Analytical Applications of Ternary Complexes. II. Spectrophotometric Determination of Copper as Rose Bengal Bisphenanthrolinium Copper (II). *Talanta*, 1966, **13**, 753. (with B. W. Bailey and R. M. Dagnall)
111. Analytical Applications of Ternary Complexes. III. A Spectrofluorimetric Method for the Determination of Submicrogram Amounts of Copper. *Talanta*, 1966, **13**, 1661. (with B. W. Bailey and R. M. Dagnall)
112. Analytical Applications of Ternary Complexes. IV. Titration of Macro and Micro Amounts of Cyanide. *Talanta*, 1966, **13**, 1667. (with R. M. Dagnall and M. T. El Ghamry)
113. Carminic Acid as a Reagent for the Spectrofluorimetric Determination of Molybdenum and Tungsten. I. Development of Procedures. *Talanta*, 1966, **13**, 1637. (with G. F. Kirkbright and C. Woodward)
114. Carminic Acid as a Reagent for the Spectrofluorimetric Determination of Molybdenum and Tungsten. II. Determination of Molybdenum in Mild Steel. *Talanta*, 1966, **13**, 1645. (with G. F. Kirkbright and C. Woodward)
115. Spectrophotometric Determination of Antimony with Bromopyrogallol Red. *Talanta*, 1966, **13**, 507. (with D. H. Christopher)
116. Some Spectrofluorimetric Applications of the Cerium(IV)–Cerium(III) System. *Anal. Chim. Acta*, 1966, **36**, 298. (with G. F. Kirkbright and C. Woodward)
117. Spectrofluorimetric Determination of Microgram Amounts of Scandium and Separation by Solvent Extraction. *The Analyst*, 1966, **91**, 23. (with G. F. Kirkbright and C. Woodward)
118. A Sensitive and Selective Spectrophotometric Procedure for the Determination of Phosphorus. *The Analyst*, 1966, **91**, 89. (with V. Djurkin and G. F. Kirkbright)
119. Spectrofluorimetric Determination of Submicrogram Amounts of Aluminium Using Salicylidene-o-aminophenol. *Talanta*, 1966, **13**, 609. (with R. M. Dagnall and R. Smith)
120. Spectrofluorescence of the Magnesium Complexes of Some Quadridentate-azomethines. *J. Chem. Soc.*, 1966, 1595. (with R. M. Dagnall and R. Smith)
121. Some Sensitive and Selective Reactions in Inorganic Spectroscopic Analysis. *The Analyst*, 1966, **91**, 69.
122. Inorganic Trace Analysis. (Inaugural Lecture, Imperial College.) *Chem. & Ind.*, 1966, 1005.
123. The Determination of Trace Amounts of Copper in Niobium and Tantalum by Atomic-Absorption Spectroscopy. *The Analyst*, 1966, **91**, 411. (with G. F. Kirkbright and M. K. Peters)
124. Rapid Determination of Molybdenum in Alloy Steels by Atomic-Absorption Spectroscopy in a Nitrous Oxide-Acetylene Flame. *The Analyst*, 1966, **91**, 700. (with G. F. Kirkbright and A. M. Smith)
125. Determination of Trace Amounts of Lead in Steels, Brass and Bronze Alloys by Atomic-Absorption Spectroscopy. *Anal. Chem.*, 1966, **38**, 358. (with R. M. Dagnall and P. Young)

126. Determination of Cadmium by Atomic-Fluorescence and Atomic-Absorption Spectrophotometry. *Talanta*, 1966, **13**, 803. (with R. M. Dagnall and P. Young)
127. An Investigation of Some Experimental Parameters in Atomic Fluorescence Spectrophotometry. *Anal. Chim. Acta*, 1966, **36**, 269. (with R. M. Dagnall and K. C. Thompson)
128. Novye Visokizbivateznye i. Chuvstviteznye Spectrophotometricheskye Reagenty. *Zuhrnal Analiticheskoi Khimi (USSR)*, 1966, **21**, 913.
129. The Catechol Violet Colour Reaction for Tin(IV) Sensitized by Cetyltrimethylammonium Bromide. *The Analyst*, 1967, **92**, 27. (with R. M. Dagnall and P. Young)
130. The Spectrofluorimetric Determination of Magnesium with *N,N'*-bis-salicylidene-2,3-diaminobenzofuran. *The Analyst*, 1967, **92**, 20. (with R. M. Dagnall and R. Smith)
131. A Linear to Logarithmic Signal Converter for Use with Recording Spectrophotometers. *Anal. Chim. Acta*, 1967, **39**, 125. (with D. Alger, G. F. Kirkbright and M. D. Mayhew)
132. A Specific Spectrofluorimetric Determination of Terbium as its EDTA/Sulphosalicylic Acid Complex. *The Analyst*, 1967, **92**, 358. (with R. M. Dagnall and R. Smith)
133. Studies in Atomic-Fluorescence Spectroscopy. III. Microwave Electrodeless Discharge Tubes as Spectral Sources for Atomic-Fluorescence and Atomic-Absorption Spectroscopy. *Talanta*, 1967, **14**, 551. (with R. M. Dagnall and K. C. Thompson) (Part I see ref. 126, Part II see ref. 127)
134. Studies in Atomic-Fluorescence Spectroscopy. IV. The Atomic-Fluorescence Spectroscopic Determination of Selenium and Tellurium. *Talanta*, 1967, **14**, 557. (With R. M. Dagnall and K. C. Thompson)
135. Studies in Atomic-Fluorescence Spectroscopy. V. The Spectroscopic Behaviour and Analytical Determination of Antimony. *Talanta*, 1967, **14**, 1151. (with R. M. Dagnall and K. C. Thompson)
136. Studies in Atomic-Fluorescence Spectroscopy-VI. The Spectroscopic Behaviour and Analytical Determination of Bismuth. *Talanta*, 1967, **14**, 1467.
137. Molecular Emission Spectroscopy in Cool Flames. I. The Behaviour of Sulphur Species in a Nitrogen-Hydrogen Flame. *The Analyst*, 1967, **92**, 506. (with R. M. Dagnall and K. C. Thompson)
138. The Determination of Trace Amounts of Calcium, Magnesium, Iron and Nickel in Aluminium Salts by Atomic-Absorption Spectrophotometry with a Microwave Excited Source and Hollow-Cathode Lamps. *Talanta*, 1967, **14**, 823. (with G. B. Marshall)
139. The Emission Spectra of Nitrous Oxide-Supported Acetylene Flames at Atmospheric Pressure. *Talanta*, 1967, **14**, 789. (with G. F. Kirkbright and M. K. Peters)
140. An Indirect Sequential Determination of Phosphorus and Silicon by Atomic-Absorption Spectrophotometry. *The Analyst*, 1967, **92**, 411.
141. The Use of Separated Flames in Absorption, Emission and Fluorescence Studies in Flame Spectroscopy. *Talanta*, 1967, **14**, 1011. (with G. F. Kirkbright and A. Semb)
142. Determination of Small Amounts of Molybdenum in Niobium and Tantalum by Atomic-Absorption Spectroscopy in a Nitrous Oxide-Acetylene Flame. *The Analyst*, 1966, **91**, 705. (with M. K. Peters and G. F. Kirkbright)
143. Monograph "Chemical Spectrophotometry in Trace Characterisation" in "Trace Characterisation, Chemical and Physical" Editors: W. W. Meinke and B. F. Scribner. Monograph No. 100. National Bureau of Standards, Washington, D.C., U.S.A., 1967, pp. 215–301.
144. Atomic Analysis in Flames. *Endeavour*, 1967, **26**, 44.
145. The Use of Microwave Excited Electrodeless Discharge Tubes as Spectral Sources in Atomic Absorption Spectroscopy. *Atomic Absorption Newsletter*, 1967, **6**, 117. (with R. M. Dagnall and K. C. Thompson)
146. Preparation of Metal Halide-Mercury Microwave-Excited Electrodeless Discharge Tubes as Spectral-Line Sources. *The Analyst*, 1967, **92**, 597. (with M. J. Al. Ani and R. M. Dagnall)

189. Kinetochromic Spectrophotometry. II. Determination of Sulphate by Catalysis of the Zirconium-Methylthymol Blue Reaction. *Talanta*, 1969, **16**, 789. (with R. V. Hems and G. F. Kirkbright)
190. Recommendations for the Presentation of the Results of Chemical Analysis. *J. Pure & Applied Chem.* (IUPAC), 1969, **18**, 439. (with R. W. Fennell)
191. 3,5′Bis(dicarboxymethylaminomethyl)-4,4′-dihydroxy-*trans*-stilbene as a Selective Spectrofluorimetric Reagent for Cadmium. *Analyst*, 1969, **94**, 182. (with B. Budesinsky)
192. 1,5-Bis(Dicarboxymethylaminomethyl)-2,6-dihydroxynaphthalene as a Selective Spectrofluorimetric Reagent for Calcium. *Talanta*, 1969, **16**, 399. (with B. Budesinsky)
193. Spectrophotometric Determination of Selenium with Cyclohexanone. *Talanta*, 1969, **16**, 416. (with M. S. Cresser)
194. The Determination of Silicon by Flame Photometry and Atomic Fluorescence Spectroscopy with a Separated Nitrous Oxide-Acetylene Flame. *Anal. Chim. Acta*, 1969, **47**, 406. (with R. M. Dagnall, G. F. Kirkbright and R. Wood)
195. The Determination of Iron by Atomic Fluorescence Spectroscopy with a Modulated Microwave-Excited Electrodeless Discharge Tube. *Anal. Chim. Acta*, 1969, **47**, 563. (with L. Ebdon and G. F. Kirkbright)

196. The Determination of Tin by Atomic Fluorescence Spectroscopy with an Electronically Modulated Electrodeless Discharge Tube as Source. *Anal. Chim. Acta*, 1969, **46**, 207. (with R. F. Browner and R. M. Dagnall)
197. Preparation and Spectral Characteristics of Microwave-Excited Electrodeless Discharge Tubes for Palladium, Silver, Platinum and Gold. *Analyst*, 1969, **94**, 347. (with K. M. Aldous and R. M. Dagnall)
198. The Preparation of Electrodeless Discharge Tubes for Some Alkali and Alkaline Earth Elements. *Anal. Chim. Acta*, 1969, **44**, 457. (with K. M. Aldous and R. M. Dagnall)
199. An Investigation of the Performance of the Separated Air-Acetylene Flame in Thermal-Emission Spectroscopy. *Analyst*, 1969, **94**, 554. (with R. S. Hobbs and G. F. Kirkbright)
200. Spectroscopy in Separated Flames. V. The Argon- or Nitrogen-Sheathed Nitrous Oxide-Acetylene Flame in Flame Emission Spectroscopy. *Talanta*, 1969, **16**, 245. (with G. F. Kirkbright and M. Sargent)
201. Spectroscopy in Separated Flames. VI. The Argon or Nitrogen-Sheathed Nitrous Oxide-Acetylene Flame in Atomic Absorption Spectroscopy. *Talanta*, 1969, **16**, 1467. (with G. F. Kirkbright and M. Sargent)
202. The Atomic Fluorescence Spectroscopy of Cobalt with a High-Intensity Hollow-Cathode Lamp and a Microwave-Excited Electrodeless Discharge Tube as Sources. *Anal. Chim. Acta*, 1969, **45**, 205. (with B. Fleet and K. V. Liberty)
203. An Indirect Amplification Procedure for the Determination of Titanium by Atomic-Absorption Spectroscopy. *Analyst*, 1969, **94**, 754. (with G. F. Kirkbright, A. M. Smith and R. Wood)
204. Shielded Flame Emission Burner Assembly for Use with Atomic Absorption Spectrophotometers. *Laboratory Practice*, 1969, **18**, 1069. (with D. N. Hingle, G. F. Kirkbright and M. Sargent)
205. The Determination of Silicon in Low Alloy Steels by Atomic Fluorescence Spectroscopy in a Separated Nitrous Oxide-Acetylene Flame. *Analytical Letters*, 1969, **2**, 465. (with G. F. Kirkbright and A. P. Rao)
206. Comparison of Sensitivity of Atomic-Absorption and Atomic-Fluorescence Spectroscopy. *Spectroscopy Letters*, 1969, **2**, 179.
207. Electronically Modulated Microwave-Excited Electrodeless Discharge Tubes as Sources in Atomic Absorption Spectroscopy. *Anal. Chim. Acta*, 1969, **45**, 163. (with R. F. Browner and R. M. Dagnall)
208. Studies in Atomic Fluorescence Spectroscopy. VIII. Atomic Fluorescence and Atomic Absorption of Thallium and Mercury with Electrodeless Discharge Tubes as Sources. *Talanta*, 1969, **16**, 75. (with R. F. Browner and R. M. Dagnall)
209. Atomic Absorption and Fluorescence Spectroscopy with a Carbon Filament Atom Reservoir. Part I. Construction and Operation of Atom Reservoir. *Anal. Chim. Acta*, 1969, **45**, 27. (with X. K. Williams)
210. The Atomic-Emission Spectroscopy of the Rare Earth Elements in a Separated Nitrous Oxide-Acetylene Flame. *Analyst*, 1969, **94**, 864. (with D. N. Hingle and G. F. Kirkbright)
211. Indirect Amplification Determination of Thorium by Atomic Absorption Spectroscopy. *Spectroscopy Letters*, 1969, **2**, 69. (with G. F. Kirkbright and A. P. Rao)
212. Molecular-Emission Spectroscopy in Cool Flames. Part IV. The Determination of Chloride, Bromide and Iodide by Thermal-Emission Spectroscopy in the Presence of Indium Salts. *Analyst*, 1969, **94**, 643. (with R. M. Dagnall and K. C. Thompson)
213. The Microwave-Excited Emissive Detector in Gas-Phase Chromatography—I. *Talanta*, 1969, **16**, 797. (with R. M. Dagnall, S. J. Pratt and K. C. Thompson)
214. Emission Spectra Obtained from the Combustion of Organic Compounds in Hydrogen Flames. *Analyst*, 1969, **94**, 871. (with R. M. Dagnall, D. J. Smith and K. C. Thompson)
215. Microwave Excited Electrodeless Discharge Tubes Containing Organo-Sulphur and Phosphorus Compounds. *Analytical Chemistry*, 1969, **41**, 1851. (with R. M. Dagnall, K. M. Aldous and S. J. Pratt)
216. Recommended Nomenclature for Titrimetric Analysis. *J. Pure & Applied Chem.*, 1969, **18**, 429. (with E. B. Sandell)

217. Atomic Flame Spectroscopy in Trace Analysis. Part 1: Atomic-Absorption Spectroscopy. *Minerals Science & Engineering*, 1969, **1**, 44.
218. Determination of Chromium in Aluminium Salts by Atomic Absorption Spectroscopy. *Analyst*, 1970, **95**, 343. (with G. B. Marshall)
219. The Flame Spectroscopic Determination of Sulphur and Phosphorus in Organic and Aqueous Matrices by Using a Simple Filter Photometer. *Analyst*, 1970, **95**, 417. (with K. M. Aldous and R. M. Dagnall)
220. Recent Developments en Spectroscopie Atomique avec References Particulieres au Flammes et aux Sources Spectrales. *Methods Physiques D'Analyse* (GAMS) 1970, **6**, 3.
221. The Fluorescence and Phosphorescence Characteristics of Some Antioxidants and Ultraviolet Absorbers. *Anal. Chim. Acta*, 1970, **52**, 237. (with G. F. Kirkbright and R. Narayanaswamy)
222. Observations on the Preparation and Operation of Microwave Excited Electrodeless Discharge Tubes for Use in Atomic Spectroscopy. *Laboratory Practice*, 1970, **19**, 587. (with K. M. Aldous, D. Alger and R. M. Dagnall)
223. A Study of Some Matrix Effects in the Determination of Beryllium by Atomic Absorption Spectroscopy in Nitrous Oxide Acetylene Flames. *Talanta*, 1970, **17**, 203. (with B. Fleet and K. V. Liberty)
224. Determination of Very Small Amounts of Materials by the Techniques of Atomic Absorption and Atomic Fluorescence Spectroscopy. *Proc. Int. Symposium on Microtechniques, Graz*, 1970, **5**, 5–8.
225. Flame Emission and Atomic Absorption Spectrometry. *Chemistry & Industry*, 1970, 387.
226. Some Interference Studies in Atomic Fluorescence Spectroscopy with a Continuum Source. *Spectrochimica Acta*, 1970, **25B**, 61. (with M. S. Cresser)
227. Atomic Flame Spectroscopy in Trace Analysis. Part II. Atomic Fluorescence Spectroscopy. *Minerals Science & Engineering*, 1970, **2**, 31.
228. Kinetochromic Spectrophotometry. III. Determination of Fluoride by Catalysis of the Zirconium-Methylthymol Blue Reaction. *Talanta*, 1970, **17**, 433. (with R. V. Hems and G. F. Kirkbright)
229. A Solid Sample Reactor Injection Vessel for Gas Chromatography. *Anal. Lett*, 1970, **3**, 143. (with R. M. Dagnall and T. H. Risby)
230. Analytical Applications of Ternary Complexes. VIII. An Improved Reagent System for the Spectrophotometric Determination of Aluminium. *Talanta*, 1970, **17**, 13. (with J. E. Chester and R. M. Dagnall)
231. Some Observations on the Chemiluminescence of Atoms in Acetylene Flames Supported by Air and Argon-Oxygen Mixtures. *Anal. Chim. Acta*, 1970, **50**, 383. (with J. F. Alder and K. C. Thompson)
232. Some Preliminary Studies Concerning the Analytical Potentialities of an Augmented Diffusion Flame. *Anal. Chim. Acta*, 1970, **50**, 335. (with K. M. Aldous, R. M. Dagnall and L. C. Ebdon)
233. The Determination of Lead by Atomic Fluorescence Spectroscopy. *Anal. Chim. Acta*, 1970, **50**, 375. (with R. F. Browner and R. M. Dagnall)
234. An Investigation of the Determination of Germanium by Flame Photometry and Atomic Fluorescence Spectroscopy by Using a Separated Nitrous Oxide-Acetylene Flame. *Analyst*, 1970, **95**, 425. (with R. M. Dagnall, G. F. Kirkbright and R. Wood)
235. Spectrofluorimetric Determination of Submicrogram Amounts of Zirconium with Calcein Blue. *Anal. Chem.*, 1970, **42**, 784. (with R. V. Hems and G. F. Kirkbright)
236. Analysis by Flames. *British Science News*, 1970, **76**, 1.
237. Some Observations on the Determination of Zinc by Atomic Fluorescence Spectrometry Under Conditions Favourable for Analysis. *Anal. Chim. Acta*, 1970, **50**, 517. (with M. S. Cresser)
238. Absorptiometric Determination of Sulphide Ion. *Talanta*, 1970, **17**, 851. (with S. A. Rahim)
239. Atomic Absorption and Fluorescence Spectroscopy with a Carbon Filament Atom Reservoir. Part II. The Use of the Atom Reservoir in Atomic Fluorescence Spectroscopy. *Anal. Chim. Acta*, 1970, **51**, 355. (with R. G. Anderson and I. S. Maines)

240. Multi-Element Atomic Fluorescence Spectroscopy. Part I. Stimulation of Atomic Fluorescence of Mixtures of Bismuth, Mercury, Selenium and Tellurium, Cadmium and Zinc, Gallium and Indium by Means of Multi-Element Microwave Excited Electrodeless Discharge Tubes. *Anal. Chim. Acta*, 1970, **51**, 179. (with G. B. Marshall)
241. Multi-Element Atomic Fluorescence Spectroscopy. Part II. A Duel-Element Arsenic-Antimony Electrodeless Discharge Tube Spectral Line Source for Atomic Fluorescence and Atomic Absorption Spectroscopy. *Anal. Chim. Acta*, 1970, **51**, 272. (with A. Fulton and K. C. Thompson)
242. Atomic Absorption and Fluorescence Spectroscopy with a Carbon Filament Atom Reservoir. Part III. A Study of the Determination of Cadmium by Atomic Fluorescence Spectroscopy with an Unenclosed Atom Reservoir. *Anal. Chim. Acta*, 1970, **51**, 365. (with J. F. Alder)
243. The Selection of Line Pairs for the Iron 'Two-Line' Method of Flame Temperature Measurement. *Spectrochimica Acta*, 1970, **25B**, 465. (with G. F. Kirkbright and M. Sargent)
244. Multi-Element Atomic Fluorescence Spectroscopy. Part III. A New Type of Dual Element Microwave Excited Electrodeless Discharge Tube. *Anal. Chim. Acta*, 1970, **51**, 530. (with M. S. Cresser)
245. Atomic Fluorescence Spectrometry of Aluminium, Molybdenum, Titanium, Vanadium and Zirconium in Inert Gas Separated Nitrous Oxide-Acetylene Flames. *Anal. Chem.*, 1970, **42**, 1029. (with R. M. Dagnall, G. F. Kirkbright and R. Wood)
246. Spectrophosphorimetric Measurement of Niobium Oxinate at Liquid Nitrogen Temperature for Determination of Microgram Amounts of Niobium. *Anal. Chem.*, 1970, **42**, 782. (with G. F. Kirkbright and J. V. Thompson)
247. Application of Capillary Burners in Flame Spectrometry. *Anal. Chem.*, 1970, **42**, 939. (with K. M. Aldous, R. F. Browner and R. M. Dagnall)
248. A Microwave Excited Emissive Detector for Gas Chromatography. Further Studies with Sulphur Compounds. *Talanta*, 1970, **17**, 1009. (with R. M. Dagnall and S. J. Pratt)
249. Atomic Fluorescence Characteristics and Analytical Determination of Manganese in an Air-Acetylene Flame. *Talanta*, 1970, **17**, 965. (with L. Ebdon and G. F. Kirkbright)
250. The Applications of a Piezoelectric Scanning Fabry-Perot Interferometer to the Study of Atomic Line Sources. I. Assembly and General Application of the Instrumental System. *Spectrochimica Acta*, 1970, **25B**, 577. (with G. F. Kirkbright)
251. Vlam-Analyse. *Instrumentatie*, 1970, **4**, 11.
252. Developments in Atom Reservoirs and Line Sources for Atomic Absorption and Atomic Fluorescence Spectroscopy. *Pure & Appl. Chem.*, 1970, **23**, 99.
253. High Voltage Spark Excitation of Some Organic Molecules in Nitrogen and Argon Atmospheres. *Anal. Letts*, 1970, **3**, 475. (with R. M. Dagnall and D. J. Smith)
254. Some Analytical Aspects of Environmental Pollution: An Introduction. *Laboratory Practice*, 1971, **20**, 2.
255. Spectrofluorimetric Determination of Traces of Fluoride Ion by Ternary Complex Formation with Zirconium and Calcein Blue. *Anal. Chem.*, 1971, **43**, 136. (with Lay Har Tan)
256. A Spectrofluorimetric Method for the Determination of Small Amounts of Sulphate Ion. *Analyst*, 1971, **96**, 281. (with Lay Har Tan)
257. A Dewar Tube Sample Cell Assembly for Low Temperature Fluorimetry. *Anal. Chim. Acta*, 1971, **54**, 353. (with G. F. Kirkbright and P. J. Mayne)
258. A Microwave-Induced Argon Plasma System Suitable for Trace Analysis. *Anal. Chim. Acta*, 1971, **54**, 233. (with K. M. Aldous, R. M. Dagnall and B. L. Sharp)
259. Optimisation of Some Experimental Parameters in the Preparation and Operation of Microwave-Excited Electrodeless Discharge Lamps. *Anal. Chim. Acta*, 1971, **54**, 381. (with D. O. Cooke and R. M. Dagnall)
260. Emission Spectroscopy of Trace Impurities in Powdered Samples with a High-Frequency Argon Plasma Torch. *Anal. Chim. Acta*, 1971, **54**, 397. (with R. M. Dagnall and D. J. Smith)
261. The Application of Photon Counting as a Detection System in Atomic Fluorescence and Emission Spectrometry. *Spec. Letters*, 1971, **4**, 91. (with D. O. Cooke, R. M. Dagnall and B. L. Sharp)

EVALUATION OF SOME *AS*-TRIAZINES AND RE-EVALUATION OF PDT AND FERROZINE AS REAGENTS FOR SPECTROPHOTOMETRIC DETERMINATION OF RUTHENIUM

M. A. ISLAM
Department of Chemistry, University of Dhaka, Dhaka 1000, Bangladesh

W. I. STEPHEN†
School of Chemistry, University of Birmingham, Edgbaston, Birmingham, B15 2TT, U.K.

(*Received* 14 *April* 1992. *Accepted* 14 *May* 1992)

Summary—A sensitive method for the spectrophotometric determination of ruthenium with the ferroin-yielding *as*-triazines has been developed. This method has several advantages; complete reduction of ruthenium species to ruthenium(II) can be achieved by the recommended procedure, which shortens the colour development time, saves the unnecessary use of several-fold excess of the reagent and the molar absorptivity is increased significantly. A few of the new *as*-triazines together with the commercially available Ferene® have been evaluated as ruthenium(II) chromogens. 3-(2-Pyridyl)-5,6-diphenyl-*as*-triazine (PDT) and ferrozine, a sulphonated derivative of PDT, have been re-evaluated by the new method. It has been observed that the *as*-triazine acting as a bidentate ligand forms a tris-complex with ruthenium(II) similar to its reaction with iron(II).

A variety of chromogenic reagents has served as the basis for the spectrophotometric determination of ruthenium. Recent reference works[1,2] list more than forty reagents for ruthenium and the number of methods for the spectrophotometric determination of ruthenium is steadily increasing because of its commercial importance. The various methods differ considerably in sensitivity, tolerance to other ions, rate of reaction, useful concentration range and availability of the reagents, and there appears to be scope for the development of further procedures with readily available chromogenic reagents which give good sensitivity.

Recently, certain 3,5,6-trisubstituted-1,2,4-triazines have been prepared and evaluated as highly sensitive chromogenic reagents for the spectrophotometric determination of iron(II).[3] In the present study, consideration was given to the possible reaction of ruthenium with these chromogens in the light of its position in the periodic table and the analytical resemblance of certain compounds of ruthenium to those of iron. The behaviour of three new chromogens; 3-(2-py)-5,6-bis(*p*-methoxyphenyl)-*as*-triazine (PBMPT), 3-(2-py)-5,6-bis(4-biphenyl)-*as*-triazine (PBBT), 3-(2-py)-5,6-bis(4-biphenyl-4′-sulphonic acid)-*as*-triazine, diammonium salt (PBBT–DAS) with ruthenium has now been studied and their potential as analytical reagents has been assessed.

Sporadic attempts have been made to apply this class of spectrophotometric reagent for iron, based on its reaction with the ferroin-yielding functional group, to the spectrophotometric determination of ruthenium. However, all these methods suffer from certain difficulties.

The method of Banks and O'Laughlin[4] which utilises 1,10-phenanthroline is very sensitive to the amount of the reducing agent (hydroxylammonium chloride) and requires more than 20 hours heating for full colour development. The larger the amount of reducing agent present, the lower is the rate of formation of the complex and apparent shift in the wavelength of maximum absorbance towards higher wavelengths. The absorption maximum at longer wavelength was greater when the amount of hydroxylammonium chloride added was increased, or the amount of 1,10-phenanthroline was decreased. This was explained by postulating that a species might be formed involving the hydroxylammonium ion. The method with 4,7-diphenyl-1,10-phenanthroline[5] in the presence of the reducing agent, hydroxylammonium chloride, and using

†Author for correspondence. Present address: The Garden House, Binghill, Milltimber, Aberdeen AB1 0JL, U.K.

a buffer system containing sodium acetate and ammonium hydroxide, produces a broad absorption band of the ruthenium complex at 445–470 nm. Embry and Ayres[6] attempted to develop the colour of the 2,4,6-tris (2-py)-*s*-triazine–ruthenium complex with hydroxylammonium chloride as a reducing agent following the work of Banks and O'Laughlin;[4] however, lower values of absorbances were obtained. The colour was therefore developed in the presence of 20–50% by volume of ethanol without the addition of another reducing agent. They report that the complex contains the ruthenium(III) species. Karma and Ayres[7] have also reported that ruthenium(III) reacts with 3-(2-py)-5,6-diphenyl-*as*-triazine (PDT) in aqueous ethanol medium at pH 5 to give a magenta coloured $[Ru(PDT)_2]^{2+}$ complex. The molar absorptivity at 485 nm was 2.1×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$. They also noted that the PDT appears to reduce ruthenium(III) under their experimental conditions, because the same value of absorbance was obtained in the presence of any added reducing agent and with only the complexing agent present under the experimental conditions, and again when reducing agents such as hydroxylammonium chloride or hypophosphite were present. The composition of the complex in solution was determined by continuous variation and mole-ratio methods and it was reported that PDT acts as a tridentate ligand and forms a bis-complex with ruthenium(II). However, it is well known that reagents of this class acting as bidentate ligands tend to form tris-chelates with iron(II).[8,9] Kundra and his coworkers[10] have developed a method for the spectrophotometric determination of ruthenium(III) with the widely used iron reagent, ferrozine, a sulphonated derivative of PDT. They reported that ruthenium(III) forms a bis-complex with ferrozine having a molar absorptivity of 3.1×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ at 480 nm. Three hours of heating and a 120-fold excess of ferrozine were needed for full colour development.

In this study, we have taken the opportunity of re-evaluating PDT and ferrozine as ruthenium(II) chromogens because in earlier work incomplete reduction and variable composition with ferroin analogues may have occurred. A sensitive iron(II) chromogen: 3-(2-py)-5,6-bis[2-(5-furylsulphonic acid)]-*as*-triazine, disodium salt (Ferene)[11] has also been evaluated as a ruthenium(II) chromogen.

EXPERIMENTAL

Reagents

PBMPT, PBBT, PBBT–DAS and PDT were synthesised in this laboratory;[3] ferrozine® and Ferene® were obtained from Aldrich and Sigma Chemical Companies respectively and were used as received. A typical stock solution (0.005*M*) of the organic reagents was prepared by dissolving the requisite amounts in a small volume of ethanol, in some cases a drop or more of concentrated AR hydrochloric acid was added to dissolve the reagent. The solution was then diluted to volume with spectroscopic grade ethanol. Sulphonated derivatives of organic reagents were dissolved in distilled water. Dilution of the stock solution was made for the determination of the composition of the complexes.

A standard solution of ruthenium(III) chloride in 5% hydrochloric acid (containing 1000 μg/ml and prepared as a standard for atomic absorption use) was obtained from Aldrich Chemical Company. This solution was diluted to obtain the required concentration.

A range of conventional buffer solutions, nominally 1*M* in strength was prepared containing, where appropriate, one or more of the following analytical grade chemicals: hydrochloric acid, acetic acid, sodium acetate, ammonium acetate, ammonium chloride and aqueous ammonia solution. Solutions at different pH intervals in the range 2.5–11 were thus obtained.

All other reagents were of analytical grade.

Effect of variables

Systematic investigations were made of the effect of variables (such as the choice of reducing agent and pH of the buffer solution, length of heating time and excess of complexing agent) on the rate and completeness of complexation. This was done by preparing a series of solutions in which all but one variable were held constant.

Analytical procedures

Recommended procedures for the reduction of ruthenium(III) to ruthenium(II). Place 5 ml of standard ruthenium(III) chloride solution in 5% hydrochloric acid (1000 μg/ml) and a weighed amount, 0.15–0.20 g, of AR metallic zinc shot (8–30 mesh) in a 100-ml stoppered conical flask. Add 2 ml of concentrated acetic acid to this mixture. Gently swirl the flask for 8-10 min (the solution turns completely blue within this time). Carefully transfer the solution into a 250-ml

Table 1. Summary of the results of spectrophotometric reactions of some *as*-triazines with ruthenium(II)

Photometric reagent	Colour dev. time (hr)	λ_{max}/nm	Composition M: L	ϵ/l · mole^{-1} · cm^{-1}	Solution medium	Colour stability
PDT	1.0	475 (485)*	1:3 (1:2)*	3.5×10^4 (2.1×10^4)*	EtOH-H_2O	Excellent
Ferrozine	1.0	478 (480)†	1:3 (1:2)†	3.56×10^4 (3.15×10^4)†	Aqueous	Excellent
PBBT	1.5	484	1:3	4.63×10^4	EtOH-H_2O	Excellent
PBBT-DAS	2.0	485	1:3	5.50×10^4	EtOH-H_2O	Excellent
PBMPT	1.5	483	1:3	4.70×10^4	EtOH-H_2O	Excellent
Ferene	2.0	505	1:3	4.63×10^4	Aqueous	Good (around 48 hours)

*Ref. 7.
†Ref. 10.

standard flask. Wash the unused metallic zinc with 5 ml of concentrated acetic acid and then several times with distilled water and transfer the washings into the flask. Dry the unused zinc and weigh. Dissolve an exact amount of zinc used in the reduction process in acetic and hydrochloric acids and dilute to 250 ml keeping the same acid concentrations for this reagent blank solution.

Recommended procedure for colour development. Add 0.5–2.5 ml of ruthenium(II) solution (20 μg/ml), 5 ml of complexing agent solution and 5 ml of pH 3 buffer solution to a 25-ml standard flask in the above order and heat for different lengths of time (Table 1) for each complexing agent at a boiling water bath temperature and make up the volume with either ethanol (spectroscopic grade) or distilled water (Table 1). In the case of the PBBT-complex, the colour should be developed by refluxing, rather than heating, because of its low solubility in aqueous-ethanol medium. Similarly, prepare the reagent blank solution with metallic zinc solution taking the highest equivalent amount of ruthenium solution.

Spectra of all solutions in the visible region were recorded with a Shimadzu UV–Vis recording spectrophotometer, UV-240 against reagent blanks in the appropriate solvents. Absorbance measurements at fixed wavelength were made on a CE 505 (Cecil Instrument) spectrophotometer using 1-cm matched glass cells.

Sensitivity Determination

With each complexing agent, a series of metal complex solutions was prepared following the recommended procedure. Absorbances of the solutions were recorded at wavelength of maximum absorbance (Table 1) against the similarly prepared reagent blank solution. In all cases at least five different solutions of each complex were prepared and the molar absorptivity (ϵ) of the complex at the wavelength of maximum absorbance (λ_{max}) was calculated from the linear regression coefficient.

Determination of composition of the complex

The composition of all complexes in solution was determined by the mole-ratio method; once by varying the amount of complexing agent, keeping the amount of ruthenium constant; and again by varying the amount of ruthenium, keeping the complexing agent constant. The results of this study are summarised in Table 1.

Colour stability of the complexes

The colour stability of the solution of the complexes was observed by measuring the absorbances at different time intervals and the results are summarised in Table 1.

Table 2. Effect of reducing agent on the formation of PDT-ruthenium(II) complex

Ruthenium solution 1.6 μg/ml	Reducing agent added	Corresponding λ_{max}	Corresponding absorbance (1 cm cell)
Ru(III)	2 ml of 10% hydroxylammonium chloride	480 nm	0.42
Ru(III)	10–15 mg of ascorbic acid	475 nm	0.54
Ru(III)	10–15 mg of sodium hypophosphite	475 nm	0.50
Ru(III)	None	475 nm	0.56
Ru(II)	Metallic zinc and acetic acid	475 nm	0.61

Table 3. Effect of pH on the formation of PDT-ruthenium(II) complex

pH of the buffer soln.	Buffer system	Corresponding λ_{max}	Absorbance at λ_{max}
2.5	Sodium acetate acetic acid and hydrochloric acids	475 nm	0.560
3.0	Sodium acetate/ acetic acid and hydrochloric acids	475 nm	0.575
4.0	Sodium acetate and acetic acid	475 nm	0.530
5.0	Sodium acetate and acetic acid	475 nm	0.450
6.0	Sodium acetate and acetic acid	475 nm	0.350
6.48	1*M* ammonium acetate	490–535 nm	0.290
9.0	1*M* ammonium chloride and ammonia solution	470–530 nm	0.240
11.0	Ammonia solution	510–540 nm	0.140

RESULTS AND DISCUSSION

Typical examples of the effect of variables on the rate and completeness of complexation are given in Tables 2–5. During the preliminary study, following the work of Banks and O'Laughlin[4], it was revealed that hydroxylammonium chloride seems to be quite unsuitable for the reduction of ruthenium(III) to ruthenium(II) prior to complexation with this type of reagent. It always gave variable absorbances and different wavelengths of maximum absorbance (λ_{max}) depending on the amount of reducing agent and heating time. The shift of the absorption maxima towards longer wavelengths was greater when the amount of hydroxylammonium chloride added was increased, or the amount of complexing agent was decreased. The value of absorbance also decreases with an increase of hydroxylammonium chloride. When no reducing agent, other than the complexing agent is present, ruthenium(III) always gives higher absorbances than with hydroxylammonium chloride and the wavelength of maximum absorbance remains constant.

Table 4. Effect of heating time on the formation of PDT-ruthenium(II) complex

Heating time (hours)	Corresponding absorbance at λ_{max}
0.25	0.490
0.50	0.515
0.75	0.530
1.00	0.550
1.50	0.550
2.00	0.560
2.50	0.560
3.00	0.560
3.50	0.565

With the hope of finding a suitable reducing agent for the reaction conditions, ascorbic acid and sodium hypophosphite were tried. With both reductants, the same wavelength of maximum absorbance was obtained as when no reducing agent was added. However the absorbances were lower than with it. At this stage, it was considered that either a ruthenium(III) complex was forming or the complexing agent itself was acting as a reducing agent. To clarify the matter, the 1,10-phenanthroline complex of ruthenium(III) or ruthenium(II) was formed with and without a reducing agent; each complex gave the same wavelength of maximum absorbance. Then the ruthenium(II) complex of 1,10-phenanthroline was prepared following the method of Dwyer and his coworkers.[12] The absorption spectrum of this complex solution and the complex solution developed without any added reducing agent were exactly the same. These observations suggest that the complexing agent and ethanol are enough to reduce ruthenium(III) to ruthenium(II).

During further study, it was observed that the freshly diluted solution of ruthenium(III) gives higher absorbances. This may be due to oxidation of ruthenium(III) to (IV) and/or to hydrolysis of the ruthenium(III) ions. Either the

Table 5. Effect of the amount of PDT on the formation of PDT–ruthenium (II) complex

hydrolysed species or ruthenium(IV), or both, may not be reduced to ruthenium(II) by the complexing agent or ethanol for complexation. To overcome this problem of hydrolysis or of oxidation, metallic zinc in the presence of acetic acid was tried for the reduction of ruthenium (III) or (IV). It always gave reproducible results and even higher values of absorbance than without any added reducing agent with the freshly diluted solution. Further studies were then carried out in which reduction with metallic zinc was incorporated into the experimental procedure.

These observations suggest the following possibilities: (i) the triazine molecule and ethanol are able to reduce ruthenium(III) to ruthenium (II), the preferred form for complexation, (ii) since all reducing agents used in this study except hydroxylammonium chloride give the same absorbance maxima, the hydroxylammonium ion may participate with the complexing agent to form a different ruthenium(II) complex, (iii) the lowering of the absorbance and the bathochromic shift of the λ_{max} with an increase of the hydroxylammonium ion and a lowering of the amount of triazine suggest that the hydroxylammonium ion is competing with the triazine molecule for complexation with ruthenium(II) under the experimental conditions and (iv) complete reduction of ruthenium species to ruthenium(II) by metallic zinc in the presence of acetic acid allows unhindered complexation with the triazine molecule and provides the highest overall absorption.

When the pH was varied by adding different buffer solutions, it was observed (Table 2) that in the case of the buffer system containing sodium acetate and acetic acid or hydrochloric acid within the pH range 2.5–6.0, the same absorption maximum was always obtained. The maximum absorbance occurred between 2.5-3.0 pH units. At higher pH, the absorbance gradually decreased. Buffer systems containing nitrogen species lead to further decreases in the absorbances and shifts of the absorption maxima towards longer wavelengths. Apparently, the larger the amount of the nitrogen-containing species in the buffer system, the lower is the absorbance and more pronounced is the bathochromic shift of the λ_{max}. It is clear from this observation that nitrogen-containing species in the buffer system are also taking part in complex formation with the ruthenium(II), as was the case with hydroxylammonium ion, resulting in a bathochromic shift of the λ_{max} and a lowering of the absorbance. The effect of heating time on the development of the colour suggests that the larger the complexing agent, the longer the heating time required for full colour development (Table 1); also that there is no advantage in prolonged heating. Since the ruthenium species is being reduced to ruthenium(II) prior to complexation, only a small excess of the reagent is required for full colour development. Kundra and his coworkers[10] report the use of a several-fold excess of ferrozine® and a three hour heating time for full colour development. This may be explained on the basis of its dual functionality as reducing and complexing agent. The results of the spectrophotometric measurements are summarised in Table 1.

Ruthenium(II) chromogens

3-(2-Pyridyl)-5,6-diphenyl-as-*triazine (PDT).* This compound has been re-evaluated as a ruthenium chromogen by the recommended procedures. It is by far the poorest of the ruthenium(II) chromogens tested in this study. The visible absorption spectrum of its ruthenium(II) complex [Fig. 1(a)] shows a single absorption peak at 475 nm with a molar absorptivity of 3.5×10^4. The composition of the complex has been determined by the mole-ratio method and it was observed that the ferroin-yielding PDT forms a tris-complex with ruthenium(II) acting as a bidentate ligand similar to its reaction with iron(II).[13] Incomplete reduction of ruthenium species to ruthenium(II) by the complexing agent and ethanol and hence incomplete complexation resulted in Karma and Ayres[7] obtaining a lower molar absorptivity of

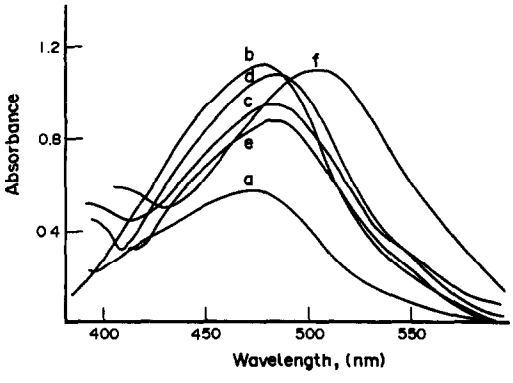

Fig. 1. Visible absorption spectra of ruthenium(II) complexes of (a) PDT, (c) PBBT, (d) PBBT–DAS and (e) PBMPT in aqueous-ethanol medium and (b) Ferrozine® and (f) Ferene® in aqueous medium recorded against reagent blanks in 1 cm glass cells at ruthenium concentrations of (a) 1.6 ppm, (b) 3.2 ppm, (c) 2.4 ppm, (d) 2.0 ppm, (e) 2.0 ppm and (f) 2.4 ppm.

2.1×10^4 at 485 nm. This also led them to the formulation of a bis-complex. The colour of the complex shows excellent stability.

Ferrozine®, the sulphonated derivative of PDT. The visible absorption spectrum of the ferrozine–ruthenium(II) complex shows a single absorption peak [Fig. 1(b)] at 478 nm with a molar absorptivity of 3.56×10^4 in aqueous medium. The sensitivity of this compound is comparable with that of PDT towards ruthenium(II) but its aqueous solubility is a significant advantage. It also forms a tris-complex with ruthenium(II) as with iron(II).[14] The reported λ_{max} (480 nm) by Kundra and his coworkers[10] is almost the same, but their molar absorptivity is lower. The higher value obtained and the lower heating time required in this study occur because the reagent itself is not sufficient to reduce the ruthenium species completely to ruthenium(II) for complexation. Incomplete reduction and hence complexation led them also to the formulation of a bis-complex. The commercial availability of the ferrozine® reagent, the high molar absorptivity and extreme stability of the complex in aqueous medium make the compound an effective chromogenic reagent for the determination of ruthenium.

3-(2-Pyridyl)-5,6-bis(4-biphenyl)-as-*triazine (PBBT).* This new compound, which contains a ferroin-functionality shows considerable promise as a ruthenium(II) chromogen. The molar absorptivity of 4.63×10^4 at 484 nm in aqueous-ethanol medium is much higher than PDT. The higher sensitivity and lower solubility in aqueous-ethanol medium compared to PDT system was predictable because of the presence of more phenyl groups. The biphenyl groups enhance the delocalisation of electrons in the molecule more than the phenyl groups and result in an increase in sensitivity and bathochromic shift of the λ_{max}. This reagent also forms a tris-complex of excellent colour stability.

PBBT–DAS, the sulphonated derivative of PBBT. This is the most sensitive reagent in this particular study. The spectrum of the ruthenium (II) chelate has a maximum at 485 nm [Fig. 1(d)] with a molar absorptivity of 5.5×10^4 in an aqueous-ethanol medium. The spectrum of the aqueous solution is very similar to that of an aqueous-ethanolic solution, but with a much lower sensitivity and solution stability. The molar absorptivity in aqueous medium is 4.3×10^4 at 485 nm. Precipitation of the complex was first noticed after about 12 hr of colour development. This may arise from the involvement of more aromatic rings. However, by developing the colour in aqueous medium and then diluting with ethanol, two advantages accrue: it gives excellent stability to the colour and increases the sensitivity from 4.3×10^4 to 5.5×10^4. This reagent also forms a tris-complex with ruthenium(II). The very high molar absorptivity and extreme stability of the complex in aqueous-ethanol medium make the compound the most effective spectrophotometric reagent so far reported for the determination of trace amounts of ruthenium. Ease of preparation of the parent compound and its sulphonation is an extra advantage.

*3-(2-Pyridyl)-5,6-bis(*p*-methoxyphenyl)*-as-*triazine (PBMPT).* The results for this compound (Table 1) show it to be an effective reagent for ruthenium(II). Its sensitivity, 4.7×10^4 at 483 nm, compares well with PBBT, which indicates that the methoxy group *para* to the phenyl group (*p*-methoxyphenyl) is as active or even better than the phenyl group (4-biphenyl) in enhancing the sensitivity of the reagent. This phenomenon has also been observed with iron(II).[3] Owing to the presence of the methoxy group, the compound and its metal chelate are highly soluble in aqueous-ethanol media. The colour of the complex solution is extremely stable; it will give the same absorbance, within experimental error, even after 45 days. The sensitivity, high solubility and ease of preparation of the compound[3] make this a particularly useful chromogenic reagent for ruthenium.

Ferene®. The spectrum of this ruthenium(II) chelate [Fig. 1(f)] has a maximum at 505 nm with a molar absorptivity of 4.63×10^4. Ferene forms a tris-complex with ruthenium(II) acting as a bidentate ligand similar to its reaction with iron(II).[11] Its sensitivity compares well with PBBT and PBMPT with an extra feature of aqueous solubility. Its sensitivity towards ruthenium(II) is much higher than ferrozine, but the colour of the complex is much less stable (around 48 hr). During this present investigation it has been observed that the ferene solution itself appears to be somewhat unstable under normal conditions and requires storage in the refrigerator. This lesser colour stability of the complex solution may be due to the decomposition of or change in the excess ferene molecules present in the system. However, commercially available Ferene® shows great promise as a possible chromogenic reagent for ruthenium.

CONCLUSION

Certain reagents with the ferroin-functional group can also serve as suitable and sensitive colour-forming reagents for the spectrophotometric determination of ruthenium(II). Complete reduction of ruthenium species to ruthenium(II) can be achieved before complexation by metallic zinc and acetic acid. The main conclusion to be drawn from the present study is that nitrogen-containing species either as a reducing agent or buffer component should not be used during the spectrophotometric determination of ruthenium with these type of reagents. The hydroxylammonium ion and perhaps the ammonium ion compete with the triazine molecule for complexation with the ruthenium(II) species under the experimental conditions. This casts doubt on the reliability of the existing procedures for the determination of ruthenium with this type of reagent. Some of the reagents employed are already commercially-available and others can be prepared easily from commercially-available reactants. The ease of preparation of PBBT, PBBT–DAS and PBMPT, the very high sensitivity and exceptional colour stability of their chelates make these and others very effective reagents for the spectrophotometric determination of trace amounts of ruthenium.

REVERSED-PHASE LIQUID CHROMATOGRAPHY OF ALKALOIDS: MASKING EFFECTS OF INORGANIC SALTS

WASSILY NOWICKY, LIANG-FENG HAN, WLADYSLAWA NOWICKY, VIKTOR GUTMANN* and WOLFGANG LINERT

Institute of Inorganic Chemistry, Technical University of Vienna, Getreidemarkt 9, A-1060 Vienna, Austria

(*Received* 19 *February* 1992. *Accepted* 5 *March* 1992)

Summary—The addition of salts (investigated cations Na^+, NH_4^+, K^+, KBu_4^+ combined with the anions acetate, Br^-, SCN^- and I^-) can be used to eliminate peak tailing and to decrease retention of cationic species in the course of the separation of alkaloids from Chelidonium majus L. by reversed-phase chromatography on a ODS Hypersil column, using water–acetonitrile–methanol mixture as eluent. These findings are interpreted in terms of a silanol masking effect. The extended donor–acceptor concept is used to interpret the effectiveness of different salts in masking the active sites of the stationary phase.

Reversed-phase high-performance liquid chromatography is usually not applicable to compounds with unprotected basic atoms.[1] This is believed to be due to interactions between the basic compounds and the acidic silanol groups at the stationary phase surface.[2–6] By addition of organic amines or ammonium salts to the mobile phase the separation behaviour can be improved, and in some cases the selectivity of the stationary phase is altered.[2,5–15] Recently, it has been shown that for the separation of alkaloids in chelidonium majus L. by means of reversed phase liquid chromatography, peak shape and resolution are improved in the presence of potassium iodide.[15] The effect of such addition can be explained on the basis of masking active silanol groups of the stationary phase. This led us to investigate the influence of salts–additives with cations and anions of different softness, namely Na^+, NH_4^+, K^+ and NBu_4^+ and acetate, Br^-, SCN^- and I^-, respectively.[16–18]

EXPERIMENTAL

Apparatus and materials

The chromatographic system consisted of a Hewlett-Packard (Palo Alto, CA., U.S.A.) Model 1090 Liquid Chromatograph, equipped with a HP Model DR5 Solvent Delivery System, and a HP 1090 option 44 Auto-injector. Detection was performed with a HP 1090 option 80 UV Diode-array Detector. An ODS Hypersil column (RP C^{18}, Hewlett-Packard) (100 × 4.6 mm I.D., 5-μm particle size) was used.

Acetonitrile (LiChrosolv, Merck, Darmstadt, F.R.G.), methanol (Reinst, Merck) and water (Chromasolv for gradient elution, Riedel-de Haen, Seelze, F.R.G.), sodium thiocyanate (Merck), potassium thiocyanate (Merck), sodium acetate (Merck), ammonium acetate (Merck) and potassium bromide (Merck) were of analytical reagent grade. Tetrabutylammonium iodide (NBu_4I) was prepared in our laboratory. The following standard alkaloids have been kindly supplied, namely: sanguinarine, allocryptopine by L. Jusiak (Lublin, Poland); methoxychelidonine, oxysanguinarine, dihydrosanguinarine, dihydrochelerythrine, (−)-stylopine by J. Slavik and L. Slavikova (Brno, CSFR.); berberine and protopine by W. Debska (Poznan, Poland); chelidonine by the late F. Kuffner (Vienna, Austria). The structures of these alkaloids are given in Fig. 1.

Plants of Chelidonium majus L. were collected from fields near Vienna, Austria. The extraction of the alkaloids from Chelidonium majus L. was carried out as described recently.[18] Standard alkaloids were dissolved in methanol at concentrations of 0.3 mg/ml and stored in airtight flasks in the dark. Water was adjusted to pH 3.6 with acetic acid (3.8m*M*) or to pH 8.5 with sodium hydroxide. Methanol contained appropriate concentrations of the respective inorganic salt. A mixture of 45% water, 25% acetonitrile and 30% methanol was used and a flow-rate of

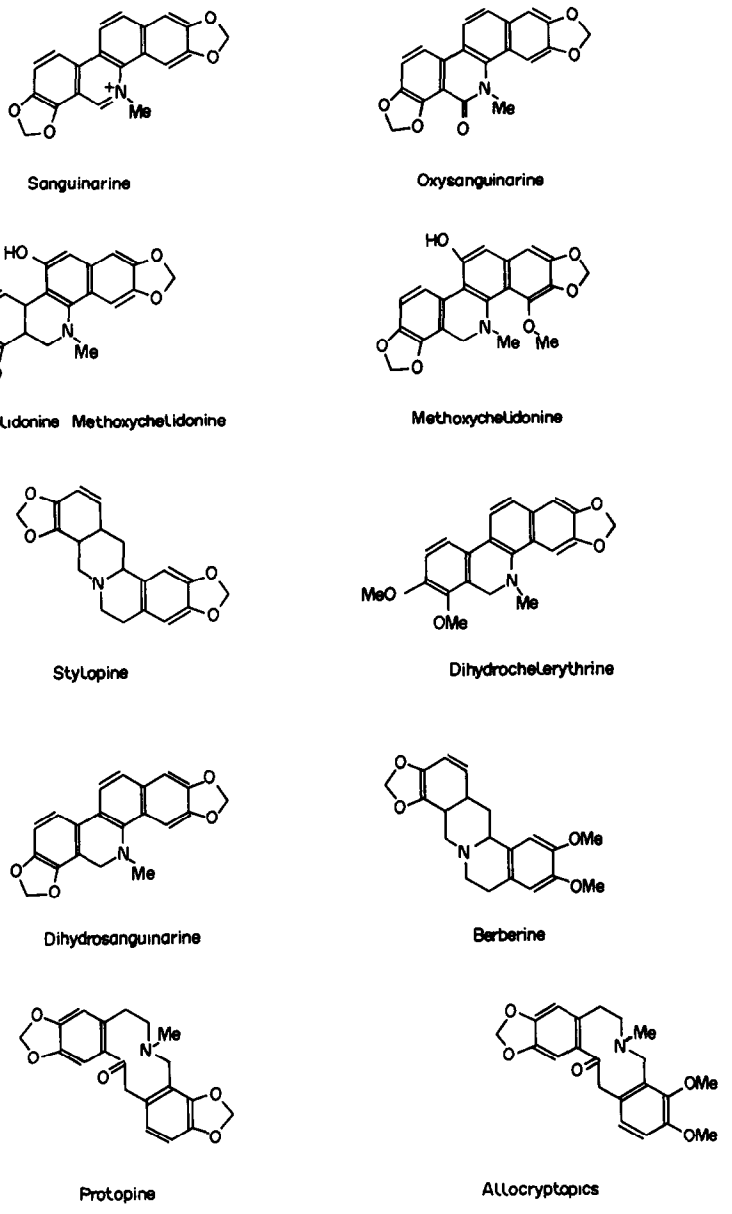

Fig. 1. Structures of the ten alkaloids from Chelidonium majus L.

1.2 ml/min employed, unless stated otherwise. Because of the low buffering capacity of the mobile phases, only 0.1–2 μl of the solute were injected. The chromatograms were taken at 30° and monitored at 285 nm with a band-width of 30 nm. The reference wavelength was 400 nm with a band-width of 100 nm. Retention time data were measured from the peak minima.

RESULTS AND DISCUSSION

Effect of type and concentration of the added salts

Without addition of salts strong peak tailing was found for most of the cationic alkaloids. Many of them could not be eluted with salt free water–acetonitrile–methanol mixtures. Uncharged alkaloids, produce almost symmetrical peaks without added salt and the peak performance is not affected by the addition of salts. Figure 2 shows the influence of increasing concentration of the investigated salts in the mobile phase on the retention of allocryptopine, at pH = 3.6 and at pH = 8.5. Allocryptopine was selected as a test compound because of its wide spread of retention properties at pH = 3.6–8.5. In all cases the capacity factor k' of the alkaloid was decreased and the peak tailing becomes smaller with increasing salt concentration. Salts with soft anions or soft cations

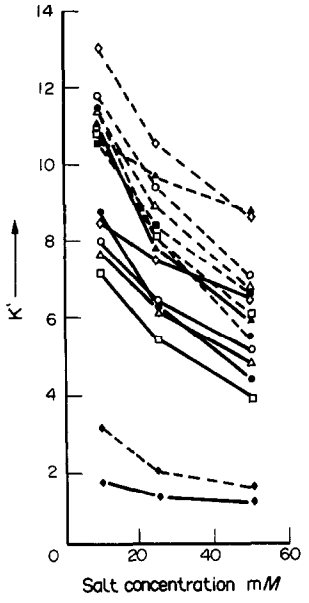

Fig. 2. Effect of the nature of the salt additives in the mobile phase on the capacity factor of allocryptopine. Eluent: 3.8m*M* acetic acid (pH 3.6)–acetonitrile–methanol (45:25:30 —full lines); water (pH 8.5)–acetonitrile–methanol (45:25:30 —dashed lines). Fig. 3. Influence of potassium thiocyanate concentration on the capacity factors, *k'*, for the ten alkaloids. Compounds: 1 = methoxychelidonine; 2 = chelidonine; 3 = allocryptopine; 4 = protopine; 5 = (-)-stylopine; 6 = berberine; 7 = oxysanguinarine; 8 = sanguinarine; 9 = dihydrochelerythrine; 10 = dihydrosanguinarine. Eluent: 3.8m*M* acetic acid–acetonitrile–methanol (45:25:30; pH 3.6). Dashed lines represent calculated curves.

(*e.g.*, tetrabutylammonium iodide) have greater influence than salts with hard anions or hard cations (*e.g.*, sodium acetate). The influence was greater as the softness of both cations and anions was increased.

Figure 3 shows the variation of capacity factors, *k'*, with the mobile phase concentration of potassium thiocyanate for ten alkaloids from Chelidonium majus L. Addition of potassium thiocyanate decreases the capacity factor for most of the alkaloids. The retention times of most alkaloids is also decreased with increasing concentration of potassium thiocyanate but dihydrochelerythrine, dihydrosanguinarine and oxysanguinarine were not affected. Because the latter alkaloids can be extracted easily into organic solvents even from acidic aqueous solution[19] they may be present as free bases under the above given chromatographic conditions. Potassium thiocyanate (Fig. 4) effects the retention of chelidonine, sanguinarine, allocryptopine and protopine. Methoxychelidonine and (−)-stylopine are not affected at this pH value, indicating again their presence as free bases. At a pH = 8.5 and $c_{KSCN} > 130$m*M* the alkaloids allocryptopine and protopine were eluted before methoxychelidonine. This indicates that the unprotected nitrogen atoms play an important role in the retention mechanism of the nitrogen-containing samples in a reversed-phase system.

At an unmodified silica surface the retention of the cationic alkaloids approaches zero as the concentration of sodium acetate is drastically increased.[20] This suggests two kinds of adsorption

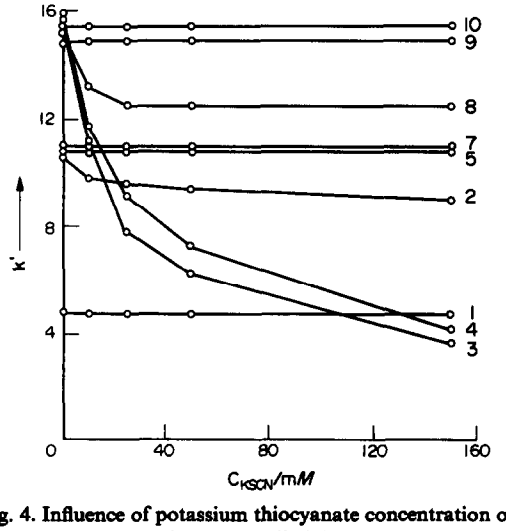

Fig. 4. Influence of potassium thiocyanate concentration on the capacity factors, *k'*, for the alkaloids. Compounds as in Fig. 3. Eluent: water–acetonitrile–methanol (45:25:30; pH 8.5).

sites in the reversed-phase system, one on which uncharged samples are predominantly retained with potassium thiocyanate, and a second one on which potassium thiocyanate competes with the cationic samples.

According to these findings the following equilibria may influence the retention procedure:

$$Q_m^+ + Z_m^- + A_s \rightleftarrows QZA_s \quad (1)$$

$$Q_m^+ + A_s^* \rightleftarrows QA_s^* \quad (2)$$

$$B_m^+ + Z_m^- + A_s^* \rightleftarrows BZA_s^* \quad (3)$$

In this Q_m^+ represents a cationic alkaloid present in the mobile phase. Z_m^- and B_m^+ are anions and cations respectively of an added salt. A_s are adsorption sites, which remain unaffected by added salt and A_s^* are salt-influenced adsorption sites. The subscripts m and s refer to mobile phase or stationary surface, respectively. The species in the mobile phase are distributed to the stationary phase where they occupy areas, A_s or A_s^*. The equilibrium constants for these processes are:

$$K_{QZ} = [QZA_s]/\{[Q_m^+][Z_m^-][A_s]\} \quad (3)$$

$$K_Q^* = [QA_s^*]/[Q_m^+][A_s^*] \quad (4)$$

$$K_{BZ}^* = [BZA_s^*]/\{[B_m^+][Z_m^-][A_s^*]\} \quad (5)$$

Quantities with and without asterisk refer to adsorption sites A_s and A_s^*, respectively. Concentrations in the mobile phase are in molar and concentrations in the stationary phase are expressed in moles/g of solid phase. $[A_s]$ and $[A_s^*]$ are the concentration of free adsorption sites of moles/g of solid phase at equilibrium. (Acetate is omitted in the case pH = 3.6 because it has only small effect on the peak tailing.)

It can be assumed that the capacity factor, k'_Q, of the eluate Q^+ bound to the stationary phase can be expressed as the sum of the capacity factors for the two processes:

$$k'_{Q'} = k'_{Q,A} + k^*_{Q,A} \quad (6)$$

The capacity factors of Q^+ ($k'_{Q,A}$) depend on the phase-ratio W_s/V_m and the distribution ratios:

$$k'_{Q,A} = \frac{W_s[QZA_s]}{V_m[Q_m^+]} \quad (7)$$

$$k'_{Q,A^*} = \frac{W_s[QA_s^*]}{V_m[Q_m^+]} \quad (8)$$

where the phase-ratio is the ratio of the solid phase to the mobile phase in the column given in g/l. The stationary phase has limited adsorption capacities which are characterized by K_0 and K_0^*, respectively:

$$K_0 = [A_s] + [QZA_s] \quad (9)$$

$$K_0^* = [A_s^*] + [QA_s^*] + [BZA_s^*] \quad (10)$$

A combination of equations (3)–(10) yields

$$k'_Q = \frac{W_s K_0 K_{QZ}[Z_s^-]}{V_m(1 + K_{QZ}[Q_m^+])} + \frac{W_s K_0^* K_Q^*}{V_m(1 + K_Q^*[Q_{mm}^+] + K_{BZ}^*[B_m^+][Z_m^-])} \quad (11)$$

It is assumed that $K_{QZ}[Q_m^+]$ in the first term can be omitted at sufficiently low sample concentration leading to:

$$k'_Q = \frac{W_s K_0 K_{QZ}[Z_m^-]}{V_m} + \frac{W_s K_0^* K_Q^*}{V_m\{1 + K_Q^*[Q_m^+] + K_{BZ}^*[B_m^+][Z_m^-]\}} \quad (12)$$

Equation (12) shows that the capacity factor increases with decreasing alkaloid concentration and leads to peak tailing. The competing effect by an added salt on the distribution of the sample at the adsorption sites A_s^* decreases the influence of the term containing the sample concentration in equation (12), because the significance in equilibrium (2) is decreased. At sufficiently high concentration of an added salt, the second term in equation (12) can be simplified so that peaks become symmetrical as observed:

$$k'_Q = \frac{W_s K_0 K_{QZ}[Z_m^-]}{V_m} + \frac{W_s K_0^* K_Q^*}{V_m\{1 + K_{BZ}^*[B_m^+][Z_m^-]\}} \quad (13)$$

Equation (13) is non-linear in $[B^+]$ and $[Z^-]$ and contains the concentrations of the added salt in its cationic and anionic form as independent variables. For a given solute, when the eluent composition and flow-rate are unchanged at constant temperature with a fixed column, the terms $W_s K_0 K_{QZ}/V_m$, $W_s K_0^* K_Q^*/V_m$ and K_{BZ}^* are invariant. Hence, for each cationic solute the values of $W_s K_0^* K_{QZ}^*/V_m$, $W_s K_0^* K_Q^*/V_m$ and K_{BZ}^* can be fitted by a non-linear least square regression. The fitted lines show good agreement with the experimental values (dashed lines in Fig. 3). The term K_{BZ}^*, which is the equilibrium constant for the adsorption of the added salt on the adsorption sites A_s^*, remains fairly constant, whereas the other two terms changes for different samples. The values of $W_s K_0 K_{QZ}/V_m$,

Table 1. $W_s K_0 K_{QZ}/V_m$, $W_s K_0^* K_Q^*/V_m$ and K_{BZ}^* values calculated to produce the best fit of experimental data. For chromatographic conditions see Fig. 4

Solute	$W_s K_0 K_{QZ}/V_m$	$W_s K_0^* K_Q^*/V_m$	K_{BZ}^*
Methoxychelidonine	32	2.9	8175
Chelidonine	57	5.7	564
Allocryptopine	69	6.1	9
Protopine	76	6.7	7655
(−)-Stylopine	129	7.1	6935
Berberine	175	10.5	7606
Sanguinarine	383	15.0	6922

$W_s K_0^* K_Q^*/V_m$ and K_{BZ}^* calculated for the cationic solutes of the alkaloids at pH of 3.6 are summarized in Table 1. On the other hand it should be pointed out that an ion-pair formation model[12] leads to equations which cannot be brought into accordance with the experimental results.

The less satisfactory curve fits for both tertiary and quarternary alkaloids at higher pH value may be due to heterogeneity of the stationary phase in the presence of residual silanol groups. At pH > 4.5 a dissociation of the acidic silanol groups may occur. This results in a retardation owing to the ion-exchange effect.[21] The general retention decreases for the cationic alkaloids at lower pH values (Figs. 2–4). This can be explained by decreasing dissociation of the acidic silanol groups at lower pH value so that the ion-exchange effect is mainly prevented in this case. In contrast to the cationic species the retention of the uncharged species was found to be independent from the pH values (Figs. 3 and 4).

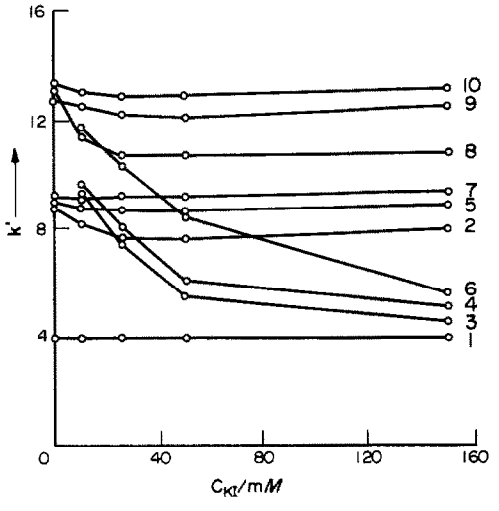

Fig. 5. Influence of potassium iodide concentration on the capacity factors, k', for the alkaloids. Compounds as in Fig. 3. Mobile phase: water (pH 8.5)–acetonitrile–methanol. Potassium iodide was added to methanol. Gradient: water–acetonitrile–methanol = 50:20:30 to 20:50:30 in 15 min. Flow-rate 0.8 ml/min to 1.5 ml/min in 15 min.

Selectivity of separation

It has been noted, that with an inorganic salt added to the mobile phase the alkaloids were eluted faster, together with better peak symmetry and increase in peak resolution. In our previous study[18] good separation was achieved by adding 150mM potassium iodide to the eluent and by using an appropriate gradient elution program. Figure 5 illustrates the capacity factors of ten alkaloids from Chelidonium majus L. obtained after addition of potassium iodide to the eluent and application of a gradient elution program. It can be seen that the alkaloids, except for allocryptopine, berberine and protopine, are eluted in the same order with all concentrations of potassium iodide. Elution times of the cationic samples decrease as the concentration of the added salt is increased while alkaloids presumably present as free bases show only small changes. Thus retention can be controlled by

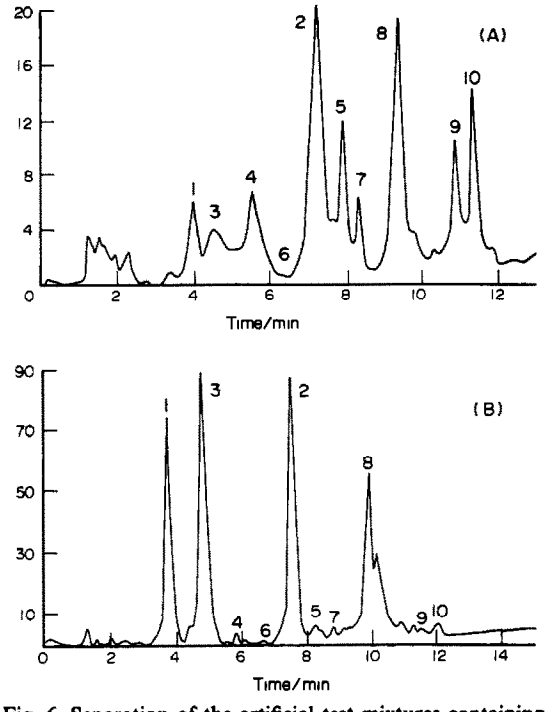

Fig. 6. Separation of the artificial test mixtures containing ten alkaloids and the crude drug extract of Chelidonium majus L. by reversed-phase HPLC. Chromatographic conditions as in Fig. 6. (A) Chromatogram of the artificial test mixture containing ten alkaloids. Potassium iodide 0.15M was added to methanol; (B) chromatogram of the crude drug extract of Chelidonium majus L. 0.15M potassium iodide was added to methanol.

selection of an appropriate salt concentrtion. Figure 6(a) shows a chromatogram of a test mixture of ten alkaloids from Chelidonium majus L. at a potassium iodide concentration of 150m*M*. Figure 6(b) shows a chromatogram of a crude extract from Chelidonium majus L. under the same chromatographic conditions as in Fig. 6(a).

Buytenhuys *et al.*[22] have shown that sodium chloride, sodium acetate, ammonium acetate, potassium acetate and tetramethylammonium acetate are increasingly adsorbed in the given order at pH of 5 on unmodified silica in aqueous solvents. The salts are adsorbed on the silica surface as neutral molecules because under the above-given conditions no ion-exchange process accrues [this is also confirmed by the good fit of the experimental data with equation (13)].[21] According to the similarity rules of the HSAB-concept, hard–hard interactions and soft–soft interactions lead to more stable compounds than hard–soft interactions. The "softer" the cation of the salt with a given anion, the stronger pronounced is its acceptor ability towards the oxygen atom of the silanol group. Consequently, the "softer" the cation, the stronger it will reduce the retention of the alkaloids.[22] The retention order of allocryptopine upon added salts is in agreement to the adsorption ability of the respective salts (Fig. 2).

(*Received* 15 *March* 1992. *Accepted* 31 *March* 1992)

Summary—Inhibition of the enzyme acetylcholinesterase (AChE) using a carbamate compound was measured in 30 Crl: CD®BR Sprague Dawley rats. Erythrocyte, plasma, and brain tissues were analyzed using modifications of the Ellman technique[1] on two different clinical chemistry analyzers. Both EDTA and heparin anticoagulated whole blood were used for the erythrocyte and plasma tests. Results demonstrated similar inhibition of the enzyme in all three tissues between the control and dosed groups using the two technique modifications and instruments. Final inhibition of plasma and erythrocyte AChE for the control *vs.* treated groups (males and females combined) was 89.5% *vs.* 82% and 39% *vs.* 38% for the Technicon AutoAnalyzer® *vs.* the Boehringer Mannheim Hitachi® 704, respectively. Inhibition of the left and right brain segments for the control *vs.* treated groups (males and females combined) was 35% *vs.* 39% and 33.2% *vs.* 29% for the Technicon and the Hitachi, respectively. All inhibitions were significant at the 5% level using two tailed Dunnett's *t*-Test. Hemolysates prepared from EDTA whole blood packed cells gave more consistent results on the Hitachi 704.

In the product safety and effectiveness testing arena, evaluation is traditionally assessed by determining the effects of the test material on changes in the physiologic parameters of the animal model. Compounds tested range from materials that will be added to foods for consumption, pharmaceuticals and agricultural chemicals. In the latter case, the evaluations of compounds that will be used in pesticides must assure both the safety of the user and the efficacy of the pesticide. A high-profile test in pesticide evaluation, particularly in carbamate- and organophosphate-based compounds, is the measurement of the inhibition of the enzyme, AChE.

A number of techniques, both manual and automated, are currently used to measure AChE activity in erythrocytes, plasma and the brain. Several kits are manufactured, and most commonly, the methodology is based on the Ellman technique or modification of that technique.[1] Some investigators using this basic technique maintain that measurement of whole blood hemolysates rather than packed cell hemolysates is more effective in measuring erythrocyte AChE inhibition. Considerable controversy exists in the industry concerning appropriate analytical methods that will standardize the assay of AChE. However, automated analysis provides a cost effective method for evaluating the enzyme inhibition on large numbers of samples collected at one time.

The accurate measurement of inhibition induced by carbamate-based compounds presents unique challenges because of the rapid reversal of this effect. Rapid processing and automated analytical methods are thus preferred. A further difficulty in the testing of the animal model is the occurrence of varied responses in tissues from different animal species. Techniques generally require adjustment of the original substrate concentrations, reaction temperature, and pH of the reaction system to maximize the AChE inhibition in given tissues and species.

*Author for correspondence.

This investigation was designed to compare inhibition of the AChE in plasma, erythrocyte, and brain tissue of rats using both an internally developed modification of the Ellman technique on a Technicon Single channel AutoAnalyzer System (considered the reference system in this case) and a modification of the Reagent Set Cholinesterase® Kit by Boehringer Mannheim Corporation, Inc.[2] on the Boehringer Mannheim Hitachi 704 Chemistry Analyzer.

EXPERIMENTAL

Equipment and materials

The following equipment and materials were used: Hitachi 704 Chemistry Analyzer, Boehringer Mannheim Corporation, Indianapolis, IN, U.S.A. Technicon AutoAnalyzer, Technicon Corporation, Tarrytown, NY, U.S.A. BMD Reagent Set Cholinesterase Kit No. 124117, Boehringer Mannheim Corporation, Indianapolis, IN, U.S.A. Potassium phosphate, monobasic, anhydrous, Sigma Chemical Co., St Louis, MO, U.S.A. Sodium phosphate, dibasic, anhydrous, Sigma Chemical Co., St. Louis, MO, U.S.A. Triton-X-100, Sigma Chemical Co., St Louis, MO, U.S.A. Precitrol Normal and Precitrol Abnormal Control Sera, Boehringer Mannheim Corporation, Indianapolis, IN, U.S.A. ICN Digiflex® Automatic Pipette Dilutor. Temperature controlled centrifuge. Analytical balances. Magnetic and vortex mixers. Adjustable semiautomated pipette and pipette tips. Volumetric and serolog ical pipettes. Electric tissue grinder. Trizma Base, (Tris[hydroxymethyl]amino-methane) Sigma Chemical Co., St Louis, MO, U.S.A. 5,5-Dithiobis-(2-nitrobenzoic acid), DTNB Sigma Chemical Co., St Louis, MO, U.S.A. Cholinesterase Acetyl (EC 3.1.1.7) Sigma Chemical Co., St Louis, MO, U.S.A. Reduced Glutathione, Sigma Chemical Co., St Louis, MO, U.S.A. Sodium Chloride, Sigma Grade, Anhydrous, Sigma Chemical Co., St Louis, MO, U.S.A. Demineralized water. Brij®-35, 30% Solution Aqueous, Fisher Scientific.

Procedure for the Hitachi 704 Chemistry Analyzer

Reagents. Stock phosphate buffers were prepared by dissolving 9.0727 grams of monobasic potassium phosphate in one litre of demineralized water and 14.2 grams of anhydrous dibasic sodium phosphate in one litre of demineralized water. The working phosphate buffer was prepared by mixing 55 ml of the potassium phosphate stock with 945 ml of the sodium phosphate solution, adjusting the final pH to 8.0 (+/−0.05) and adding 100 μl of Triton X-100 to each 100 ml.

Triton-saline solution, used in the processing of brain tissue, was prepared by adding 100 μl of Triton X-100 to 100 ml of isotonic saline and mixing until complete dissolution was achieved.

The Hitachi analyzer procedure required two reagents, R1 and R2. These are prepared from reagents supplied in the BMD Reagent Set Cholinesterase Kit.

R1 working solution was prepared by dissolving the contents of one bottle (buffer/chromogen) with 100 ml of demineralized water.

Stock R2, the substrate, was prepared by dissolving the substrate provided with the kit with 30 ml of demineralized water. For working R2 substrates, one ml of the working substrate solution was diluted with two ml of demineralized water.

Procedure for the Technicon AutoAnalyzer

Reagents. Tris buffer was prepared using 6.05 g of Tris[hydroxymethylamino]methane, 6.65 g of sodium chloride, 40 ml of 1*N* hydrochloric acid, and approximately 975 ml of demineralized water. The buffer was adjusted to a pH of 7.50 (+/−0.05) at room temperature and adjusted to a volume of one litre with demineralized water. Immediately prior to use, 0.5 ml of Brij-35 was added to the buffer.

DTNB was prepared by dissolving 100 mg of DTNB in one litre of the Tris buffer adding the Brij-35 just prior to use. This was prepared fresh for each run.

Acetylthiocholine iodide (5m*M*) was prepared for use as the substrate in the analysis of the brain tissue. Acetylthiocholine iodide (10m*M*) was prepared for use as the substrate in the analysis of the plasma and erythrocyte samples.

A stock 100μM/ml reduced glutathione standard was prepared with demineralized water. Working standards of 1, 3, 5, 7, 9 and 10μM were prepared from the stock standard just prior to a run and were used to prepare the standard curve. Standards were run approximately every 30 samples, along with controls and water blanks to minimize carry over from the 10μM standard.

Study design

Thirty animals, fifteen males and fifteen females, were selected for the study. Animals weighing less than 300 grams were not used. The study animals were assigned to two groups (Groups 1 and 2) using computer-generated random numbers: five males and five females to control group 1; 10 males and 10 females to treatment group 2. The treatment dose carbamate of an insecticide was selected to produce significant AChE inhibition with no morbidity, and blood and brain samplings were performed after at least 12 (males) or 5 (females) weeks of dosing. Blood was collected from the orbital sinus after animals were anesthetized with CO_2/O_2 and assayed for plasma and erythrocyte AChE activities. There were two blood sampling intervals six days apart. Brain tissues were harvested from all animals sacrificed (using sodium pentobarbital anesthesia and exsanguination) on the day of the second blood collection. Left and right brains were isolated, placed in 50-ml screw cap conical centrifuge tubes and snap frozen in a preparation of methanol and dry ice. They were transported on dry ice to the laboratory and stored in a −70°F freezer pending analysis.

Sample processing

Samples for the erythrocyte and plasma analyses were collected in both EDTA and heparin anticoagulants. The Technicon procedure uses heparinized whole blood. The Boehringer Mannheim Diagnostics procedure recommends EDTA anticoagulated whole blood. Consequently, parallel testing involved analyzing both types of anticoagulated whole blood for the isolation of plasma and erythrocytes to determine if either offered a significant advantage.

The orbital sinus plexus was used as the collection site for all plasma and erythrocyte AChE assays. Animals were not fasted (feed and water) prior to sample collection. Samples were collected and transported on a slurry of crushed ice and water to help retard reversal of the carbamate inhibition. Transport to the clinical laboratory occurred within 15 min of collection. Samples were centrifuged upon arrival at 5° at 4000 rpm for 10 min to separate the plasma. For the Technicon procedure, male rat plasma was diluted 1:2 prior to analysis and female plasma was diluted 1:4. No dilution of the plasma was required for the assay on the Hitachi 704. Plasma samples were analyzed immediately after appropriate processing.

The standard procedure for the Technicon required washing the erythrocytes in isotonic saline in graduated conical centrifuge tubes prior to analysis. The supernatant was removed after recording of the packed cell volume (PCV), and saline was added to the cells to achieve a 1:4 dilution. All cell preparations were maintained at 5° and mixed with a transfer pipette just prior to uptake by the analyzer. This dilution was then analyzed at 37° on the AutoAnalyzer.

A 1:21 dilution of the original packed cells was prepared for the Hitachi 704 analysis. Using the Digiflex® Automatic Dilutor, 100 μl of packed cells and 2000 μl of pH 8.0 phosphate buffer with 0.1% Triton X-100 were flushed into a 13 mm × 100 mm test tube. The resulting hemolysate was vortexed to ensure clarity. Samples were maintained at 5° throughout the diluting and processing steps. Each hemolysate was again vortexed briefly immediately prior to placing in the instrument sample cup in position for sample uptake by the instrument. The analysis then proceeded at 37° based on programmed sample and reagent volumes and incubation times, as shown in the outline of the System Parameters in Table 1.

The brain tissues homogenates were prepared in cold isotonic saline with 0.1% Triton X-100 using a Wheaton® tissue grinder. The resulting dilution in saline was 1:20 based on brain weight. The homogenates were maintained at 5° throughout the grinding and diluting process.

The homogenates were mixed and then filtered into the Technicon AutoAnalyzer cups immediately prior to analysis for subsequent determination at 37°. For analysis on the Hitachi 704, a portion of the homogenate was centrifuged at 4000 rpm at 5° for 10 min. The resulting supernatant was maintained between 2 and 8° until the preparation was placed in the Hitachi sample cup immediately prior to sample uptake. The analysis proceeded at 37° with the addition of reagents and reaction times controlled by the previously determined system parameters set for the instrument, as shown in Table 1.

RESULTS AND DISCUSSION

Results shown for the erythrocyte and plasma determinations were carried out on samples of heparinized whole blood for the Technicon AutoAnalyzer procedure and on EDTA whole blood for the Hitachi 704 procedure. Previous comparison of the two anticoagulants showed no significant difference in the plasma determinations on the Hitachi 704 using heparin and EDTA. Hemolysates prepared from EDTA whole blood packed cells gave more consistent results on the Hitachi 704. EDTA was therefore determined to be the anticoagulant of choice for the Hitachi 704 analyses based on this experience and the manufacturer's recommendations.

Inhibition of plasma AChE at the first sampling interval was 85% for male rats and 87% for female rats on the Technicon AutoAnalyzer (Table 2). At the second sampling interval, plasma AChE inhibition was 88 and 91% in males and females, respectively (Table 2). Plasma AChE inhibition on the Hitachi 704 showed the same pattern but was less than the Technicon AutoAnalyzer. Inhibition of the first interval was 79% for male rats and 84% for female rats. On the second interval, inhibition was 80 and 84% for males and females, respectively (Table 3).

Erythrocyte AChE inhibition measured on the AutoAnalyzer was 45 and 43% in male and female rats, respectively, on the first interval. On the second interval, the inhibition was 41 and 37%, for males and females, respectively (Table 2). A similar pattern was demonstrated in the results from the Hitachi 704. The inhibition in

erythrocytes of male and female rats on the first interval was 35 and 43%, and the second interval, 34 and 42%, respectively (Table 3).

The left and right brain segments were both used to compare inhibition in this study. Inhibition of brain AChE for the left brain was 31 *vs.* 43% for the AutoAnalyzer and the Hitachi 704, respectively, in male rats. Inhibition of AChE in the right brain segment for males was 30 *vs.* 27% for the two instruments, respectively (Table 4). In the female rats, inhibition of left brain AChE was 39 *vs.* 35% for the AutoAnalyzer and the Hitachi 704, respectively. Right brain inhibition was 36 *vs.* 31% (Table 4). More inhibition of left brain AChE than of right brain AChE was demonstrated by both instrumental techniques; however, the range between brain segments was broader for the Hitachi 704 than for the AutoAnalyzer. No apparent sex related pattern was evident.

Inhibition of plasma AChE, within and between instrument systems, was very consistent. Lower values were noted in males *vs.* females, which has been shown historically in this laboratory to be characteristic of the rat. Therefore, a lower dilution was required for male *vs.* female plasma in the AutoAnalyzer method. The ability of the Hitachi 704 to measure the activity in units/litre made this dilution step unnecessary for either sex in plasma measurements. The typical pattern, however, was maintained. Values for percent inhibition were similar for both systems. More variation was found in the AutoAnalyzer measurement between days 51 and 57 than on the Hitachi system. This may be attributed to the more cumbersome and lengthy processing steps necessary to prepare the samples for the AutoAnalyzer. Consequently, the decrease shown between days 51 and 57 is probably spurious and caution should be exercised in over-interpretation of the apparent decrease.

The AutoAnalyzer measured less erythrocyte AChE inhibition at the second interval than at the first. In contrast, the Hitachi measured the same inhibition of erythrocyte AChE at both intervals. Caution must again be applied in over-interpreting the variation shown by the AutoAnalyzer, probably due to inherent variation in the procedure. Erythrocyte measurements were more varied between the instruments than the plasma measurements. In general, measurement in erythrocytes is hampered by the color (hemoglobin) of the hemolysates and the difficulty in achieving a clear hemolysate that is free of erythrocyte ghosts. The incorporation of dialysis within the Technicon analysis allows for reduction in both membrane ghosts and for dilution of the hemoglobin color.

Measurement of AChE inhibition in the left and right brain segments demonstrated less inhibition in the right segment than in the left segment. There appeared to be a possible sex related pattern in the AutoAnalyzer method. This pattern was reversed in the left brain measurements on the Hitachi. A similar, though less marked pattern was shown in the right brain measurement for the Hitachi. Again, caution must be exercised in over-interpretation.

CONCLUSION

There are definite advantages to rapid measurement of AChE inhibition, especially in

the diagnosis and treatment of acute carbamate poisoning. Both analytical systems demonstrated AChE inhibition of similar magnitude between control and treated groups of the rats, regardless of sex, and in all three types of samples. However, optimization and standardization of the assay are still controversial since membrane-bound enzyme may still not be completely measured in supernatant of brain homogenates or in hemolysates that may contain considerable numbers of erythrocyte-membrane ghosts. The Hitachi method developed here for this study, compared well with this laboratory's reference method on the Technicon Auto-Analyzer. Therefore, the combined advantages in reduced analytical time, higher sample through-put, less sample manipulation, increased ability to control temperature and cost effective automation make the Hitachi 704 our system of choice.

Summary—Stricter environmental controls on the emission and discharge of chemical pollutants are creating an increased demand for the development of improved chemical sensor devices. Although electrochemical sensors show great promise for this task, their utility has been constrained by a number of practical problems, the most serious being the effect of surface adsorption of impurities leading to non-reproducible response. This review presents a survey of recent advances in electrochemical sensor technology which have attempted to improve the performance of these devices. Three main areas of development have been addressed; advances in sensor design and measurement techniques, novel approaches to conferring electrode selectivity and the use of microminiaturization and microelectronics fabrication techniques. Recent applications and future prospects for the measurement of toxic metals, organics and gases including volatile organic compounds are surveyed.

The invention of polarography by Heyrovsky[1] in 1923, by introducing a readily polarizable, microelectrode with a constantly renewed surface provided the creative spark from which the development of most electrochemical sensors have been derived. Although polarography has played an important role in chemical analysis, it was the limitations of the dropping mercury electrode, its limited sensitivity, poor mechanical stability and especially its limited anodic range, that provided the original impetus for the development of new designs of electrochemical sensors. During the last three decades the need for sensors of all types has increased dramatically with their critical involvement in most areas of our technological society including industrial automation, process control, medicine and public health, energy control and environmental quality monitoring.

In many of these applications, especially in process control and environmental quality, monitoring sensors are required to operate in a continuous monitoring mode, either in-line or on-line. Electrochemical sensors have played an important role in the measurement of both chemical and biological substances and it is worth noting here that Tom West's group at Imperial College were among the first to study the application of these devices in continuous analysis.[2–4]

The purpose of the present brief review is to focus on the major requirements for chemical or electrochemical sensors in environmental pollution monitoring in three main areas of toxics in water, organics and gases including volatile organics (VOCs). Rather than attempt a comprehensive review of electrochemical sensors in the environmental area, the aim has seen to focus on the most significant developments and on those areas and technologies which show the most promise for meeting future needs.

The last 15 years has seen enormous advances in sensor technology, especially in the development of sensor devices for measuring physical parameters such as pressure, flow, or temperature, motion or position. This has resulted mainly from the application of the mass production techniques of microelectronics to sensor manufacturing. The use of microfabrication, micromachining and photolithography has enabled the development of small relatively low

*Author address for correspondence.

cost solid state devices and has largely eliminated the specialist construction methods of the past.[5] Microelectronic sensors are now available for measurement of parameters such as pressure, temperature, humidity and flow where both the sensing element and the electronics are incorporated at the chip level. These trends also had the goal of developing so-called "intelligent sensors" where the measurement step and some level of decision making would be incorporated in the sensor-microchip unit[6] although with current advances in distributed process control this goal is no longer so critical.

Comparable advances in chemical sensor technology have been far less dramatic, reflecting the complexity of the chemical sensing process, especially the multiple levels of interactions at the sensor-sample interface.[7,8] A major trend in chemical sensor research has attempted to emulate the developments in physical sensors using solid state technology. This has generated somewhat mixed results; on the one hand, two decades of research into CHEMFET and ISFET devices[9] has failed to spawn any significant introduction of commercially viable sensors. In contrast, these efforts have generated an enormous level of interest in microelectronic approaches to sensor design including microfabrication and the use of microstructures. It is undoubtedly this line of research which is providing one of the most fruitful avenues of current developments in chemical sensors.[10]

As a result, the earlier classification of electrochemical sensors as either potentiometric, conductimetric or amperometric devices has now been expanded to include various hybrid devices including solid state, electrocatalytic and membrane phenomena.[11] This expanded research horizon is also required in order to solve the formidable barriers of conferring sensor selectivity, eliminating problems of surface contamination and also developing devices that are capable of operating in real world harsh environments. Despite these barriers, electrochemical sensors have generated a high level of interest both for the monitoring and the destruction of pollutants.[12,13]

Sensor requirements

Researchers frequently ignore market needs when developing new sensor devices. In this context it is worth noting that the target application for a sensor will significantly affect the performance requirements of sensitivity, selectivity, accuracy, precision, long term stability and ease of maintenance. In research applications, sensor specifications may not be too critical due to the nature of the measurements and the high skill level of research operators. In contrast, for on-line measurements, especially for process control applications, the sensor performance is much more critical. Even within various types of process control applications the sensor requirements may vary widely. The operating criteria for devices which are used in an alarm or warning situation may not be too critical since an alarm event would normally be monitored by an operator. With online analytical instrumentation, where analytical data may be required for environmental regulatory authorities, a higher level of performance may be required although frequent calibration is often possible. The most rigorous requirements are those in process control where the sensor signal is used to trigger an external action, for example, the use of a pH sensor to activate the discharge of a waste treatment tank. It is interesting to note that electrochemical sensors have been used in the first two of these examples, whereas to date, only the pH electrode has found use in the latter area.

One of the major problems in operating electrochemical sensors in continuous monitoring applications has been the difficulty of maintaining electrode stability and long-term performance. Surface contamination by solution impurities and electrolysis products has long been the bane of electroanalytical chemists. The problem has been most exhaustively studied in classical solid electrode voltammetry but the conclusions are fairly general. The most comprehensive study of this problem has been made by Tenygl,[14] who recommends the use of practical common sense, ensuring purity of solvents and supporting electrolytes and minimising concentration of analytes. In addition he describes a wide variety of approaches to maintaining electrode stability and reproducibility, including mechanical cleaning, potential cycling or the use of a semi-permeable membrane to protect the sensor surface. Even intermittent pyrolysis has been used as a cleaning method. However, while each of the above methods has found success in specific cases, they do not provide a universal solution to the problem. Perhaps the approach recommended by the present authors of using low-cost, single analysis, disposable sensors may be the most effective approach.[15]

TRENDS AND DEVELOPMENTS

Overlaying all recent develpments in electrochemical and chemical sensor design has been the rapid advances in microcomputer based instrumentation which has made high levels of data acquisition and processing readily accessible at very modest cost. In parallel, at least three major paths have been followed in sensor development which are in many cases overlapping. The first is the improvements in classical electrochemical sensor designs and construction, including flow-through devices and improvement in sensor selectivity by using selective membranes or interposed chemical reaction layers. These ideas are not new, however, and have been actively explored for more than 20 years. More fundamental are the approaches to conferring sensor selectivity by the use of chemical, biological processes or modified electrode surfaces. A third area is the developments in solid state technology and the use of microminiaturization with its spin-offs in the development of microelectrodes and micro sensor arrays.

Hydrodynamic voltammetry

Since amperometric devices dominate the applications of electrochemical sensors in pollution control, it is worthwhile to briefly review the basic principles governing the operation of these devices in a flowing stream. The general technique describing the application of amperometric processes in continuous analysis is hydrodynamic voltammetry (HDV). During the 1970s limiting current-mass transfer relationships were derived for various electrode geometries under varying mass-transfer conditions and cell geometries.[16] As the review by the present authors[16] points out, these studies do have relevance to sensor design since they theoretically indicate the most promising geometries by defining the effect of operating parameters such as electrode area and solution flow dynamics on the measured response.

Most of the sensors in this class operate as hydrodynamic chronoamperometric devices [measurement of current (i) *vs.* time (t) in a flowing stream]. In this approach only a small fraction of the electroactive component in the sample stream is actually reduced or oxidized. A question which is often raised is whether coulometric devices in which 100% of the analyte is consumed in the measurement step should be more sensitive. At first sight it might be predicted that coulometry should provide a more sensitive technique than amperometry, but in fact the reverse is true. There are several reasons for this; first, the signal from coulometric sensors is a step function rather than a peak and second, the signal/noise ratio for coulometric detectors is generally poor due to the effect of the large background charging current resulting from the expanded surface area of the coulometric electrode. In reality, as the electrode area increases, the current increase per increment in area actually decreases since it is only the first, smallest part of the electrode that senses the peak and does most of the work. Also, the background current (noise, charging current, H_2O reduction, *etc.*) increases almost linearly with area. The overall result is that the S/N is actually worse at higher electrode areas compared to lower.

Apart from sensitivity, the ease of manufacture and maintenance and long term response stability are also important factors in the selection of sensor design. Although originally it was the limitations in the dropping mercury electrode which stimulated the search for alternative electrode materials and structures, recent work at the Heyrovsky Institute has given a new impetus to classical polarography.[17] This work has resulted in significant improvements in capillary design and advances in programmable electrode drop geometry including microdrops, drops with stepwise growing area and variable meniscus area drops. These developments should reflect in the wider application of polarography in environmental analysis.

The practical consequences of hydrodynamic voltammetry is evidenced by the wide range of electrode structures and cell geometries that have been used in continuous analysis. The most significant of these is the use of electrochemical sensors as detectors in HPLC which has included numerous clinical and environmental applications.[18] However, it is worth noting that the most widely used electrode configuraton, the wall-jet cell, was first demonstrated as a practical flow sensor in Tom West's laboratory.[19]

Approaches to conferring electrode selectivity

The second major area of research in the chemical sensor field has been directed towards

a study of methods for conferring sensor selectivity. Various approaches have been adopted including the development of ion or molecular sensitive ligands, the modification of electrode surfaces to adapt selective chemistry and the use of multiple, less selective sensor arrays linked to a pattern recognition process.

The driving force for these concepts was undoubtedly the elegant work of Simon and colleagues[20] who designed and synthesized a range of cationic responsive macrocyclic polyether compounds exhibiting strong selectivity to a range of cations, including K^+, Ca^{2+}, Mg^{2+} and Na^+. This work has translated into the development of a number of practical, commercial ion-selective electrodes which have found important applications in laboratory and clinical analysis.

Comparable research efforts in the field of biosensors, which has aimed to develop receptors selective to a wide range of organic or biochemical analytes has been interesting, but in general far less commercially successful. This situation simply reflects the complexity of the interfacial reactions involved in this type of measurement.

Thompson and Krull have reviewed the problems of molecular recognition in chemical sensors and the impact on the development of biosensors.[21] They have discussed the principles of selective binding in the biosensor concept and outline the techniques for measuring the change in surface free energy associated with a selective chemical reaction. The interaction between the substrate and the biosensor causes a change in surface free energy which may be monitored by observing the electrochemical potential changes. However, the magnitude of this change is small, being governed by the Nernstian relationship so that it may be preferable to allow this chemical reaction to modulate a larger amount of signal energy. This can be achieved using either amperometry or by measuring the change in mechanical motion via the piezoelectric effect.

Most of the developments in biosensor research has focussed on biological molecular recognition systems such as enzyme/substrate or antibody/antigen reactions. In order to develop a sensor for a specific organic analyte it may be necessary to bind it to one of these processes. To date, applications in the area of environmental monitoring have been limited. Examples include the use of immobilized enzyme ion-selective electrodes to measure pesticides which are able to inhibit enzyme reactions.[22] In general, although the practical problems facing the development of biosensors are formidable, there is an enormous demand for this type of device. In the environmental area, for example, we can expect future advances to have important applications in public health screening, for example in the monitoring of the effects of toxic chemicals in the workplace.

The other major development in the approach to electrode selectivity has been based on the concept of chemically modified electrodes.[23] In this approach, ionic interaction, complexation, catalytic or size exclusion effects are used to confer increased selectivity and/or sensitivity for the analyte. Modified surfaces may be formed by chemisorption, covalent bonding or *in situ* polymerization of the selective agent or by mixing the electrode material with the ligand and pressing to form a composite. Applications cover a broad spectrum; for example, dithiocarbamate modified electrodes have been used to determine trace levels of mercury.[24] One interesting process which uses this approach is the application of metal doped electrocatalysts which have shown promise for the anodic oxidation of organics.[25] These materials operate by stabilizing the anodic $O_2/^{\cdot}OH$ hydroxyl free radical couple which is the critical step in the oxidation process.

Solid state technology

Following Bergveld's report on the first prototype chemically sensitive semiconductor device[26] the field of solid state technology became one of intense research activity, especially in the biosensor area. However, as Buck pointed out,[10] many of the electrical engineers and solid state physicists, and indeed many of the chemists who enthusiastically embraced this field, overlooked two critical factors. The first is that these devices often have to work in a harsh environment, much more aggressive than that for corresponding physical devices. The second factor was that the market for these devices is not only much smaller than for physical sensors but is also much more specialized and fragmented.

The early enthusiasm was for the use of the field effect transistor as the measuring step. While applications to the measurement of gases (hydrogen, hydrogen sulphide and ammonia)

have been successful,[27] serious problems have been encountered in measurements in liquids primarily due to difficulties in encapsulation. There would seem to be no obvious justification for using the FET route since microfabrication offers much better options using other measurement steps. Amperometric and potentiometric sensors have, for example, been made on SiO_2 or Si_3N_4 passivated silicon chips using photolithography and microfabrication.[28] According to Buck,[10] microminiaturization techniques should be much more effective when applied to faradaic rather than the non-faradaic, blocked electrode field effect processes.

This is evidenced by the fact that the application of microminiaturization techniques to traditional amperometric devices is already showing great promise. Ultramicroelectrodes which may typically have an electrode diameter of 10–30μM offer a number of important advantages over conventional sized electrodes including reproducible geometries, and ease of mass production. Carbon fibre microelectrodes, for example[29] show faster response times and higher sensitivities than macro electrodes and give typical S-shaped response curves. The rate of electrolysis at ultramicroelectrodes is also comparable to the rate of diffusion. Consequently, the diffusion zone is much more stable and does not move out into the solution as is the case with macro electrodes.

Another major advantage of the microminiaturization approach is the ability to construct multisensor arrays. These may be designed with individual sensors selective to different species or they may be relatively non-selective elements where multicomponent analysis is effected by the use of pattern recognition methods. Examples of this approach include the use of an array of electrocatalyst filaments and amperometric sensors to monitor organic gases at a hazardous waste site[30] and the analysis of electroplating wastes used an array of thin film mercury sensors to measure Ni^{2+}, Cd^{2+}, Pb^{2+} and Cu^{2+} and a hydrated iridium oxide substrate as pH sensor.[31] Recently, the construction of electrodes with a diameter of 0.2 μm (2000Å) has been reported.

APPLICATIONS

From the perspective of both problem area and type of instrumentation required, three major areas of applications can be identified. These cover methods for toxic metals and inorganics in water, the measurement of toxic organics in liquids, and the measurement of toxic gases and volatile organics (VOCs).

On-line monitoring of toxic metals and inorganics

Contamination of drinking water and the natural environment by toxic metals is a serious problem. In the US alone there are over 30,000 abandoned chemical dump sites, many of which are leaking various pollutants into local water courses. The Comprehensive Environmental Response and Cleanup Liability Act (CERCLA) is directed at the clean-up of all of these sites and is estimated to cost over $200 billion although, unfortunately, a large portion of the $12 billion spent so far has gone to lawyers. Apart from legal fees, the initial plan for orphan site clean-up calls for a site assessment and for monitoring all water runoffs for many of the priority pollutants. This is providing a strong incentive for the development of continuous metals analyzers. The other major incentive is for monitoring effluents from existing waste generators such as electroplating plants, electronics products manufacturers and some mining operations. In these applications two types of analytical measurement are generally required; monitoring of the performance of waste treatment equipment to detect either malfunction or for example, saturation of an ion exchange column. The second type of measurement is an end-of-pipe analysis to ensure that the plant discharge meets compliance. In the former case, fairly simple metal monitors which can provide an alarm response in the range 5–20 ppm are adequate whereas the requirements for discharge monitoring are much more rigorous. These may be required to accurately measure lead to local discharge standards which in California, for example, are 0.1 ppm for Pb and 0.5 ppm for Cu. A third application area is in the monitoring of drinking water where permissible metal levels are much lower, generally in the ppb levels (USEPA recommended standards are Pb 0.005 and Cu 0.02 ppm).

During the last decade, in the area of trace and ultratrace inorganic analysis, polarographic techniques, especially pulse, differential pulse

and anodic stripping voltammetry have provided strong competition for spectroscopic techniques. For automated trace metals analysis it would seem that online anodic stripping voltammetry is now the technique of choice. The practical viability of the approach was demonstrated by Fleet *et al.*[3] and Vydra *et al.*[32] in the mid-1970s. However, during the last few years there have been some major advances in cell design, instrumentation and control systems. An improved version of the wall-jet cell using microprocessor control has been used in continuous flow ASV[33] while a similar approach using a thin-layer cell and the flow injection principle has also been described.[34]

These developments have led to the introduction of several commercial instruments designed for field analysis of toxic metals. Two examples illustrate alternate design approaches. A portable, semi on-line voltammetric analyzer developed by Chemtronics[35] uses a glassy carbon working electrode, operates on 0.1–5-ml batch samples and provides automatic deaeration and system calibration. Targetted at industrial effluent and domestic water supply analysis, measureable metals include Sb, As, Bi, Cd, Cu, Au, Pb, Hg, Tl and Zn over the concentration range down to 10 ppb. A different approach has been developed by the Singapore group, Eutech Cybernetics which has developed a hand held metal monitor, also based on the ASV principle. A novel feature of this system is the use of disposable electrode strips on which the electrodes have been screen printed. Designed as a dedicated metal monitor for copper or lead, each unit has high and low operating ranges; 0.01 to 0.7 ppm and 0.5 to 3.0 ppm. The main applications of the Electrascan are also drinking water and industrial effluent monitoring. The use of disposable electrodes, as was discussed earlier has some significant advantages including elimination of the need for electrode pre-conditioning which is a tedious feature of most stripping voltammetric methods. It also avoids problems of cross contamination of samples which may occur in continuous flow systems. The simplified operating procedure aims to eliminate the need for skilled technicians which is a pre-requisite for most electrochemical techniques. A two-point calibration is first carried out on one of the two electrodes in the Electrascan sample chamber, using calibrating standards. Next, one drop of activating solution is added to a 1.0-ml sample then a 100-μl aliquot introduced into the cell chamber (a small depression above the electrode strip) and the analysis is completed and the result displayed in approximately 100 sec.

Two other important advances in this area, briefly referred to earlier, should also be noted. Improvements in the design and fabrication of the dropping mercury electrode by Novotny *et al.*[17] has provided a much more robust, versatile sensor with wide ranging applications in environmental monitoring. The second area is the work of Glass *et al.* at Lawrence Livermore Laboratories on the development of metal sensing sensor arrays.[31] This approach offers another approach to the development of a relatively low cost, multicomponent analyzer with cheap, disposable electrodes.

Organics

Monitoring of organic pollutants presents a formidable challenge, partly due to the large number of toxic substances and also to the complexity of the sample medium in many applications. The list of toxic organics defined as priority pollutants by the EPA includes over 120 compounds while the EC Priority List contains a similar number. Toxic organics result from a variety of sources; pesticides, insecticides and herbicides are found in runoffs from agricultural land where they may contaminate water supplies and enter the biological food chain. Residues of these materials are also found in soils, plant and animal tissues. Industrial sources include residues and waste by-products from chemical, pharmaceutical and a variety of manufacturing processes, aqueous effluents containing typically low levels of organics and volatile organic compounds (VOCs) in atmospheric emissions. Another major source of organic pollutants are the vast number of abandoned chemical dump sites where often a complex soup of toxic chemicals is present in the runoffs.

Electrochemical approaches have found wide application to monitoring organic pollutants since in the majority of cases the toxic or reactive grouping in a pollutant will also exhibit electrochemical activity. The basic techniques of classical polarography, solid electrode voltammetry, cathodic and anodic stripping voltammetry and a.c. polarography or tensammetry have all found wide application of organic pollution monitoring.[12] For example, polarography has

been used to measure a range of toxic substances which contain reducible functional groupings including carcinogens such as polycyclic aromatics, nitroso and azo dyes. Anodic voltammetry using solid electrodes has been used to analyze toxic and carcinogenic organics, phenols, amines, benzidines and chlorophenols. The two main problems faced in this type of analysis are first the need for pre-concentration, and second the elimination of interferences from other electroactive impurities. The most successful approach to solving both of these problems has been the use of high performance liquid chromatography with electrochemical detection.[18]

Other polarographic variants which have found use in organic pollutant analysis are the techniques of cathodic and anodic stripping voltammetry. Some of the early work on cathodic stripping voltammetry was carried out in Tom West's laboratory. Determination of the sulphur and chlorine containing pesticides, for example, was carried out by first pre-concentrating onto a mercury film electrode as an insoluble Hg-complex surface layer.[36] This adsorbed layer is then stripped off during the cathodic voltage scan. Another example is the determination of organotin fungicides which are used as antifouling agents. In the determination of this type of compound by anodic stripping voltammetry the pre-concentration step involves the formation of an organotin free radical which is adsorbed onto the mercury electrode and subsequently stripped off in the anodic voltage scan.[37]

A further class of electrochemical measurements uses a.c. or tensammetric methods to measure adsorption/desorption processes.[12] These have been used as a general indication of water quality, and also to measure specific surfactants, for example in sea water after the clean up of an oil spill.[38] In this method, an a.c. signal is superimposed on the normal d.c. waveform using phase selective detection. The presence of surfactants results in adsorption/desorption peaks with the peak potential giving some indication of the surfactant type. All of these polarographic or amperometric based approaches offer the possibility of developing specific detector systems for organic pollutants. The examples of portable, low cost, single or multiparameter instruments described earlier[13,28,35] clearly demonstrate the possibilities.

A number of other electrochemical approaches to monitoring of organics show promise. The measurement of complex organic vapour emissions from hazardous waste sites has been attempted using a sensor array system comprising two electrocatalyst filaments and two voltammetric detectors, one platinum and one rhodium. By carrying out a series of analyses using varying settings of filament current and electrode potential, a response pattern is generated from which the presence of chlorinated hydrocarbons, particularly chloroform and 1,1,1,-trichlorethylene can be confirmed.[30]

Another area showing promise is the various organic electrode processes developed from industrial electrosynthesis and more recently adapted to the destruction of toxic organics.[39] Reductive dechlorination of polychlorinated biphenyls can be carried out on a carbon filter cathode[40] and should provide an amenable route for the measurement of this important class of pollutants. The direct oxidation of organics using metal doped catalytic electrodes was mentioned earlier[25] and also shows considerable promise. A process which could have wide application to the coulometric analysis of toxic organics is anodic oxidation via the use of Ag(II) generated in a $AgNO_3/HNO_3$ analyte. The Ag(II) intermediate reacts with water to form hydroxyl free radicals which are highly oxidizing species. This process has already been used to detoxify organic waste streams at pilot scale level.[41] As a final example, amperometric or coulometric oxygen sensors are now routinely used to measure oxygen uptake in 5-day biological oxygen demand (BOD) measurements. An accelerated, 3-minute measurement has recently been proposed as a rapid screening method for organic pollutant levels in wastewaters.

Gases and VOCs

The rigorous requirements of the Clean Air Act and similar legislation in other industrialised nations has created a strong demand for reliable, low cost gas sensors. Environmental legislation based on the "command and control" approach having failed to bring about desired improvements in air quality, alternative, market based approaches including the trading of pollution permits are now being introduced. These approaches present even greater demands on sensor technology. For example, the Southern California Air Quality District is proposing to link NO_2

sensors from more than 100 electrical utility companies, directly to its computer tracking system. Although current technology relies on chemiluminescence methods, as emission standards are reduced there are prospects for the use of sensitive electrochemical devices. Plans to monitor VOC emissions in a similar fashion are facing obstacles due to the lack of available sensors and an indirect approach based on chemicals usage has been proposed.

Electrochemical sensors have already demonstrated considerable success for monitoring air pollutants[42] and show great promise for meeting future more rigorous legislation. The main gases of interest are O_2, CO, H_2S, NO, NO_2, HCN, NH_3, Cl_2 and HCl; other pollutant gases for which sensors are required and are currently being developed include HF, O_3, arsine and phosphine along with a range of volatile organic compounds. The whole spectrum of electrochemical techniques has found application in gas analysis, reflecting the less aggressive conditions in gaseous media compared to measurements in liquids. The application of potentiometry (with interposed chemical reaction layers), amperometry, chemical field effect transistors, semiconductor and electrocatalytic devices have all been described.

The potentiometric pH electrode modified with the inclusion of an interposed reaction layer has been widely used for the measurement of NH_3, SO_2 or NO_2 which diffuse into the reaction layer and effect a pH change.[12] Applications of potentiometric devices, however, are limited both in versatility and via the Nernstian response in terms of sensitivity. Amperometric devices, in contrast, have demonstrated a much wider range of applications and superior sensitivity, especially for the ppm/sub-ppm range required for most gaseous pollutants.[42,43] The use of a semi-permeable membrane to allow selective transport of the electroactive material and at the same time protect the electrode from contamination by the sample solution originates from the work of Clark in the 1950s.[44] Since then major advances in electrode construction have been made including novel electrode/electrocatalytic materials, the use of 3-electrode potentiostatic construction to reduce consumption of electroactive material and the use of solid polymer electrolytes to improve the robustness of the devices. The use of selective chemical filters for example, has been used to extend both the selectivity and sensitivity of amperometric gas sensors.[42]

The development of semiconductor gas sensors has also been an active area of research.[8,9] In these devices a catalytic coating is placed over the gate of the semiconductor device and the adsorption of the gas alters the drain current. The earliest of this principle are the CHEMFET devices which used the field effect transistor with gates constructed out of palladium or iridium and which showed a selective response to hydrogen and hydrogen containing molecules such as ammonia or hydrogen sulphide.[27,45] These devices show detection limits of around 1 ppm in air. Other types of integrated thin film semiconductor devices have since been developed using a range of electrocatalyst coatings. SnO_2 is the most common catalyst coating but ZnO_2, ZrO_2, WO_3, In_2O_3 and TiO_2 have also been used for specialized applications.[46] Semiconductor detectors are now finding widespread application in gas analysis either as selective detectors or for multicomponent analysis using pattern recognition. Simplified designs are also used as thermistor detectors in the "Figaro" type of smoke detector. Selective detection of ozone has been reported using In_2O_3 as catalyst coating,[47] while a Ru supported TiO_2 electrocatalyst has been used in the selective detection of trimethylamine which is used to monitor the freshness of fish.[48] An important example of multicomponent analysis is the report of a multicatalyst sensor array which acts as a "chemical nose".[46]

CONCLUSIONS

Increasingly stringent environmental legislation has created a large demand for chemical pollution sensors. In turn, electrochemical sensors are showing great promise for monitoring a wide range of pollutants including trace toxic metals in water, organics and gases. Although advances in the last two decades have not been as dramatic as those in other areas of sensor technology, future prospects are extremely bright. In particular, new techniques of electrode fabrication such as the use of ultramicro sensors or disposable electrodes offer real promise for overcoming the bane of electrochemical analysis, lack of stability due to sensor passivation.

Other advances, such as the development of sensor arrays provide an innovative approach

to the design of instrumentation for low cost multiparameter pollution monitoring. This approach could result in the development of moderately priced pollution monitoring equipment capable of working in a field environment and which could compete strongly with the much more costly, laboratory based techniques such as ion-chromatography or GC coupled mass-spectrometry.

INDIVIDUAL AND SIMULTANEOUS DETERMINATION OF URIC ACID AND ASCORBIC ACID BY FLOW INJECTION ANALYSIS

ALA'DDIN M. ALMUAIBED and ALAN TOWNSHEND*
School of Chemistry, University of Hull, Hull HU6 7RX, U.K.

(*Received* 18 *February* 1992. *Accepted* 5 *March* 1992)

Summary—Flow injection methods for the individual and simultaneous determination of ascorbic acid and uric acid are proposed. A spectrophotometer and a miniamperometric detector are connected in sequence. The calibration graphs for uric acid obtained by measuring its absorbance at 293 nm and its current at +0.6 V are linear up to at least 80 and 70 μg/ml, respectively, with an rsd ($n = 10$) of 1% for both methods at mid-range concentrations. The calibration graph for ascorbic acid with amperometric detection is linear up to 80 mg/l. with an rsd ($n = 10$) of 0.8% at 30 mg/l. The simultaneous determination of uric acid and ascorbic acid is based on measurement of the absorbance of uric acid at 393 nm and amperometric determination of both analytes at +0.6 V. The average relative errors of the analysis of binary mixtures of uric acid and ascorbic acid are 2.2 and 4.2%, respectively.

The determination of ascorbic acid has received great attention in analytical chemistry due to the wide use of ascorbic acid in soft drinks, human and animal food, and drugs. It is also important clinically to determine its concentration in blood, urine and in some tissues. Many flow injection methods have been proposed for determination of ascorbic acid. Each has its advantages and disadvantages. For instance two spectrophotometric procedures for determination of ascorbic acid using chloramine T have been described by Lazaro *et al.*[1] The first is carried out in the presence of potassium iodide and starch (linear range 15–150 mg/l.), the second in the presence of potassium bromide and bromide/methyl red using a flow injection titration. The same authors[2] also applied the above procedures for determination of ascorbic acid in urine. Another spectrophotometric assay has been described by Hernandez-Mendez *et al.*[3] in which iodine is generated in the flow system as triiodide or the triiodide/starch complex giving a steady absorbance at 350 or 580 nm, respectively. The decrease in the absorbance caused by ascorbic acid was measured. Amperometric detection has also been used for determination of ascorbic acid. For example, Fogg *et al.*[4] reported a procedure in which the measurement is made at +0.19 V *vs.* SCE in pH 5.5 acetate buffer. The calibration graph is rectilinear up to *ca.* 60 mg/l. A reticulated, vitreous carbon, flow-through electrode has been used by Strohl and Curran in an amperometric method for ascorbic acid.[5]

Owing to the demand for measurements of uric acid in biological fluids, many enzymatic[6–8] and nonenzymatic[9] flow injection methods have been reported for its determination. For example, a recent flow coulometric detector involving an immobilized uricase reactor and an electrolyte cell was fabricated and used for determination of uric acid.[8] The calibration graph is linear over the range 1×10^{-4}–$1 \times 10^{-3} M$ with a relative standard deviation (RSD) of <1%.

Ascorbic acid and uric acid are both present in biological fluids such as blood and urine. There is no flow injection method reported so far to measure both analytes simultaneously. Therefore, the present paper describes a combination of spectrophotometry and amperometry for simultaneous determination of ascorbic acid and uric acid. The procedure is based on measurement of the absorbance of uric acid at 293 nm[10] and amperometric detection of both analytes at +0.6 V.

EXPERIMENTAL

Reagents and chemicals

Distilled, demineralized water was used throughout. Ascorbic acid (AnalaR, BDH), ethanol and urea were obtained from BDH.

*Author for correspondence.

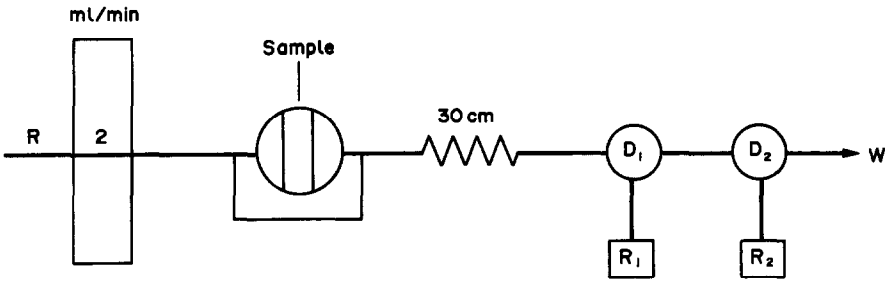

Fig. 1. Manifold used for individual and simultaneous determination of uric acid and ascorbic acid: R, carrier stream (0.05*M* succinate buffer, pH 3.0); D_1, spectrophotometer; D_2, miniamperometric detector; R_1 and R_2 are recorders; W, waste.

Xanthine, hypoxanthine and cysteine were obtained from Sigma Chemical Co. and uric acid from Hopkin and Williams. Succinate buffer (0.05*M*) (AnalaR, BDH) was used throughout.[11]

Apparatus

Spectrophotometric measurements were made with an LKB Ultrospec II spectrophotometer equipped with a flow cell (volume 18 μl, light path 10 mm). Amperometric measurements were made with a miniamperometric detector constructed by Masoom and Townshend[12] and used later by Almuaibed and Townshend for enzymatic determination of oxalate.[13] The components, including injection valve, pump, manifold and reaction coil tubing, were as reported earlier.[14]

Flow injection manifolds and procedures

The manifold used for determination of individual and simultaneous determination of uric acid and ascorbic acid is shown in Fig. 1. The spectrophotometer and a miniamperometric detector were connected in-line. Two recorders were used as shown in Fig. 1. When uric acid solutions were injected into the carrier stream (0.05*M* succinate buffer, pH 3.0), the absorbance and amperometric signals were measured at 293 nm and +0.6 V, respectively. When ascorbic acid solutions were injected into the same carrier stream, the amperometric signal was also measured at +0.6 V. For mixtures of uric acid and ascorbic acid, therefore, the uric acid was measured at 293 nm, and the sum of the two acids by the response at 0.6 V. A 30-μl injection was used for all measurements.

RESULTS AND DISCUSSION

Optimization studies for uric acid with spectrophotometric and amperometric detection

The effect of flow rate on the response for 50 μg/ml uric acid was investigated over the range 0.8–2 ml/min. The peak height absorbance decreases by *ca.* 25% as the flow rate increases from 1 to 2 ml/min, probably because of dispersion. The amperometric peak height for 50 mg/l. uric acid was nearly constant as the flow rate increased from 0.8 to 2 ml/min. Thus, 2 ml/min was used in subsequent experiments in order to increase the sample throughput rate.

The effect of pH was investigated by using 0.05*M* succinate buffer over the pH range 3–7 as the carrier stream. It was found that there was no significant effect on the amperometric peak height for 50 μg/ml uric acid over the above range. The peak height absorbance increased by 60% as the pH increased from 3 to 7. It was also found that ascorbic acid (40 mg/l.) absorbance increased significantly as the pH increased from 3 to 7; ascorbic acid does not absorb at pH 3, which was selected for further work.

The effect of the coil length was examined over the range 10–70 cm. It was found that the spectrophotometric peak height for 50 μg/ml uric acid decreased by 30% as the coil length increased from 30 to 70 cm. The amperometric signal also decreased, by 20%, as the coil length increased from 30 to 70 cm. Thus 30 cm was selected for subsequent work.

The effect of ascorbic acid on the peak height absorbance for 60 mg/l. uric acid was examined over the range 10–50 mg/ml. There was no effect.

Analytical performance

Under the conditions established, the calibration graph for uric acid using spectrophotometric detection was linear up to at least 80 μg/ml. The calibration graph and peaks are shown in Fig. 2. The least-squares linear equation over the range was: peak height absorbance $= 8.2 \times 10^{-3}$ [uric acid] (mg/ml) + 2.1×10^{-3} ($r = 0.999$, $n = 6$). The detection limit (2 × noise) and sample throughput rate

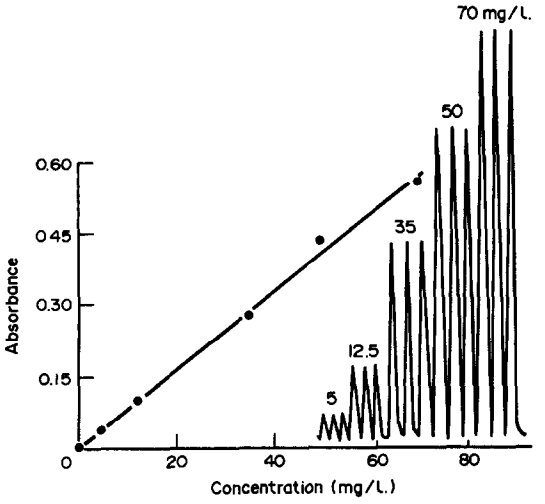

Fig. 2. Calibration graph and peaks for uric acid (spectrophotometric detection).

were 0.1 μg/ml and 100/hr, respectively. The RSD for 10 replicate injections of 30 μg/ml uric acid was 1%.

The calibration graph for uric acid using amperometric detection under the optimized conditions is linear over the range 0–70 μg/ml. The least-squares linear equation was: peak height (mm) = 1.27[uric acid](mg/ml) + 1.16 ($r = 0.998$, $n = 6$). The detection limit (2 × noise) and sample throughput rates were 0.12 μg/ml and 80/hr, respectively. The RSD for 10 replicate injections of 40 μg/ml uric acid was 1%.

Optimization studies for ascorbic acid with amperometric detection

The effect of the pH of the succinate buffer pH on the peak height for 50 μg/ml ascorbic acid was studied over the range 3–7. It was found that there was no significant effect on the peak height, so pH 3.0 was used for further work, as for uric acid.

The effect of flow rate over the range 0.8–2 ml/min on the responses for 50 mg/l. ascorbic acid was also investigated. The peak height was nearly constant over the above range, so 2.0 ml/min was selected for further work, as for uric acid.

Analytical performance

When the optimized conditions were used, the calibration graph for ascorbic acid was linear up to at least 80 μg/ml. The calibration graph and peaks are shown in Fig. 3. The least-squares linear equation was: peak height (mm) = 1.14[ascorbic acid](mg/ml) − 0.45 ($r = 0.999$, $n = 6$). The detection limit (2 × noise) and sample throughput rate were 0.15 μg/ml and 80/hr, respectively. The RSD for 10 replicate injections of 30 μg/ml ascorbic acid was 0.8%.

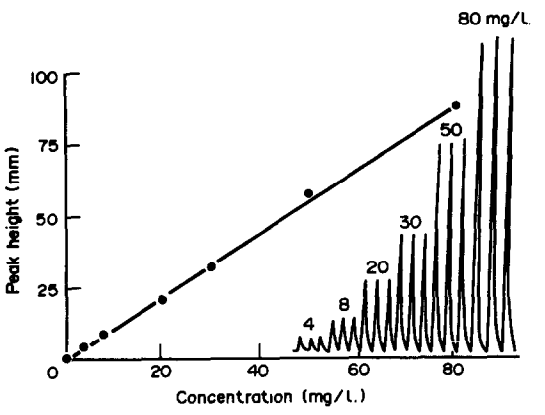

Fig. 3. Calibration graph and peaks for ascorbic acid.

Simultaneous determination of ascorbic acid and uric acid

The manifold shown in Fig. 1 was used for this determination. Succinate buffer (0.05M) (pH 3.0) was again used as carrier stream at a flow rate of 2 ml/min for this determination. The concentration of uric acid in the mixture was determined directly from the calibration graph shown in Fig. 2. Ascorbic acid was determined as follows. The amperometric signal equivalent to the uric acid concentration obtained from the spectrophotometric measurement was estimated from the amperometric calibration results for uric acid alone. This signal was subtracted from the total amperometric signal for the mixture and the remaining signal used to ascertain the ascorbic acid concentration from the ascorbic acid calibration graph (Fig. 3). Three synthetic mixtures of uric acid and ascorbic acid were analyzed. The results are shown in Table 1. Relative errors for uric acid were all $<3\%$, and those for ascorbic acid $\leqslant 5\%$.

Table 1. Simultaneous determination of uric acid and ascorbic acid

Conc. taken (*mg/l.*)		Conc. found (*mg/l.*)*			
Uric acid	Ascorbic acid	Uric acid	RE (%)	Ascorbic acid	RE (%)
5.00	5.00	5.13	2.6	4.75	5.0
5.00	10.00	5.11	2.2	10.31	3.1
10.00	5.00	10.17	1.7	4.78	4.4

*Mean of 3 readings.
RE, relative error.

Interference study

Uric acid and ascorbic acid are present in some biological fluids such as urine and blood. These types of fluids are very complex due to the presence of a variety of species at a variety of concentrations. Thus some compounds were selected, which are normally present in such biological fluids, to study the selectivity of the proposed system. Glucose (50 mg/l.), ethanol (60 mg/l.), urea (100 mg/l.), xanthine (20 mg/l.), hypoxanthine (20 mg/l.), cysteine (50 mg/l. with spectrophotometry, 1 mg/l. with amperometric) were injected into the system individually and with 20 mg/l. uric acid or ascorbic acid. They had no effect.

CONCLUSIONS

An on-line combination of spectrophotometry and amperometry has been successfully applied for determination of uric acid and ascorbic acid together in flow injection analysis. The method is simple, rapid, reproducible and sensitive.

DETERMINATION OF NITRIC ACID IN AMBIENT AIR USING DIFFUSION DENUDER TUBES

G. B. MARSHALL* and N. A. DIMMOCK
National Power PLC, Technology & Environmental Centre, Kelvin Avenue, Leatherhead, Surrey KT22 7SE, U.K.

(*Received* 22 *January* 1992. *Accepted* 5 *March* 1992)

Summary—A method has been developed for the determination of gaseous nitric acid in air based on its separation from particulate nitrate aerosol using diffusion denuder tubes. An integrated value of nitric acid concentration in air is obtained. The experimentally derived absorption efficiencies of the diffusion denuder tubes ranged from 87.6 to 96.9%. The standard deviation of the method was calculated as 0.10 $\mu g/m^3$ for nitric acid concentrations in the range 0.54–1.72 $\mu g/m^3$. A correction procedure, using two diffusion denuders in series, should be applied if measurements are made in the presence of high levels of nitrogen oxides.

The measurement of gaseous nitric acid in ambient air is important in atmospheric chemistry studies. Together with particulate nitrate aerosol, and peroxyacetyl nitrate (PAN), it is a sink for oxides of nitrogen which are emitted by both coal fired power stations and automobiles. It is a precursor in the formation of ammonium nitrate particles, which cause visibility reduction, and is also a contributor to direct acid and nitrogen deposition.

Methods for the determination of nitric acid in the atmosphere are complicated by the need to differentiate it from particulate nitrate aerosol which is present at similar concentrations. Early attempts to measure nitric acid (and particulate nitrate) used filter pack assemblies.[1] The first filter of Teflon or quartz removes nitrate aerosol, while nitric acid passes through unabsorbed and is collected on a second filter of either nylon, or sodium chloride impregnated on an inert material.

Doubts exist as to whether filter methods are effective in separating nitric acid from nitrate aerosol. Because of shifts in the nitric acid, ammonia, ammonium nitrate equilibrium (caused by temperature, relative humidity or acidity change) on the filter, compared with that in the atmosphere, erroneous results can occur.[2,3] Ammonium nitrate absorbed on the first filter can volatilize to release nitric acid, which is subsequently absorbed on the second filter to give positively biased nitric acid concentrations.

Ammonium nitrate can also react with acidic particles on the first filter to yield nitric acid, again leading to positively biased nitric acid values.

In addition nitric acid can be absorbed by basic particles on the first filter leading to negatively biased nitric acid concentrations.[4]

Because of the difficulties experienced with filter packs, workers are turning increasingly to the use of diffusion denuder tubes to determine nitric acid. These are based on the principle that, when air is drawn through a tube coated with a selective absorbent, separation of particles from gaseous species is achieved due to the much more rapid diffusion of gaseous species to the tube wall compared with that of the particles. Hence nitric acid gas diffuses rapidly to the wall of the diffusion denuder tube and is retained, whereas nitrate aerosol particles pass through unabsorbed. The theory and operation of diffusion denuder tubes has recently been reviewed.[5]

Previously, coatings of magnesium oxide,[6] sodium carbonate[7,8] and nylon[9] have been used to absorb nitric acid. In a previous paper from these laboratories[10] a coating of sodium fluoride, chosen because of its alkalinity and inertness, was found effective in absorbing hydrogen chloride in a diffusion denuder tube. This paper describes the development of a method, and its performance characteristics, for

*Author for correspondence. Present address: Chemistry Department, Birkbeck College, University of London, 29 Gordon Square, London WC1, U.K.

nation of nitric acid in ambient air with a similar diffusion denuder tube.

THEORY

The theory of diffusion–denuder tubes has been discussed fully by ourselves.[11] In brief, the air sample is drawn through a cylindrical tube coated with a selective absorbent, and the molecules of nitric acid diffuse to the wall according to the mathematical model first developed by Gormley and Kennedy.[12]

$$\frac{C}{C_0} = 0.819 \exp\left(-14.6272 \frac{\pi DL}{4F}\right) \quad (1)$$

where C = mean concentration of nitric acid in the air leaving the tube, C_0 = concentration of nitric acid in the incoming air, D = diffusion coefficient of nitric acid in air, L = length of the coated tube and F = flow rate of air.

Separation of gaseous nitric acid from particulate nitrate aerosol is achieved because of the much more rapid diffusion of gaseous nitric acid molecules to the wall of the tube than particulate nitrate—the latter passing through the tube unabsorbed. For particulate absorption to be avoided it is important that the flow of air through the coated part of the tube is laminar and this is so if the Reynolds Number is <2000. For the experimental conditions used in this work (air flow 2 litre/min and tube diameter 3 mm) the Reynolds Number is calculated to be 988. To ensure laminar flow through the coated region of the tube there should be an uncoated section of tubing of length 15 cm upstream of the coated tube. Deposition of particles by gravitation can be avoided by sampling with the tube in a vertical position (with either downward or upward flow) and Brownian diffusion of particles to the tube walls can be considered insignificant because of the relatively small diffusion coefficients of the particles of size 0.01 μg → 10 μm expected to be present in ambient air.

EXPERIMENTAL

Sampling apparatus

The diffusion–denuder tubes consisted of glass tubes of length 95 cm and i.d. 3 mm. An etch mark was made 15 cm from one end, and into this 15-cm length of tube was placed a PTFE tubular insert of diameter sufficient to make a gas-tight fit. The remaining 80-cm length was coated with the selective absorbent. Before initial use, the tubes were soaked overnight in a chromic acid cleaning solution, washed with demineralized distilled water and stored completely submerged under water in a specially prepared storage cylinder. The air sampling apparatus is shown in Fig. 1. Air was drawn through the diffusion-denuder tube by a diaphragm pump (Capex 2D, Charles Austen Ltd) and the volume measured by a gas meter (Model G4, UGI Meters Ltd). The flow of air was controlled by a needle valve (Fisher Controls Ltd).

Nitrate measurement

Nitrate measurements were made on the aqueous extracts from the diffusion denuder tube by ion chromatography (Dionex). A standard AS4 separator column was used with micromembrane suppressor (AMMS). Loop size was 0.5 ml and the eluent was a mixture of 2.25mM sodium carbonate and 2.80mM sodium bicarbonate.

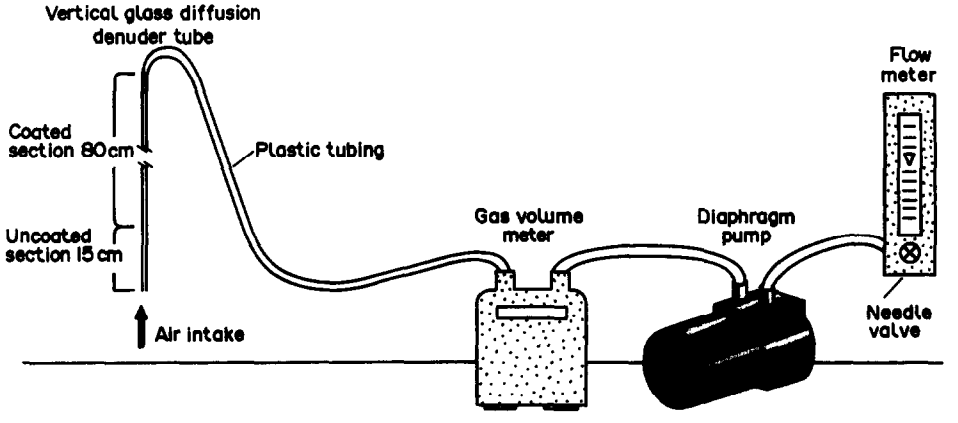

Fig. 1. Apparatus for sampling gaseous nitric acid in ambient air by diffusion denuder tube.

Reagents

Sodium fluoride stock solution, 40 g/l. A 40-g weight of sodium fluoride (BDH Analar grade) was dissolved in demineralized distilled water and made up to one litre with demineralized distilled water.

Ethanolic sodium fluoride coating solution. A 0.5-ml portion of the 40 g/l. fluoride stock solution was diluted to 10 ml with ethanol (BDH Spectrosol grade). This coating solution was prepared fresh every day for each batch of tubes to be coated.

Procedure

Before coating, the diffusion–denuder tube was washed successively with dimineralized distilled water, methanol (BDH Analar grade), and ethanol (BDH Spectrosol grade). The open end of the 80-cm section of the tube was then placed in the ethanolic sodium fluoride coating solution and, with the aid of a pipette filler, was filled to the etch mark and then allowed to drain back into the sodium fluoride container. This operation was repeated five times. The coated tube was then allowed to drain for 20 sec and was then dried by pumping dry air through it for 20 sec with a diaphragm pump. (If left to store both ends of the tube were then sealed immediately with Parafilm (Gallenkamp Ltd).) The unsealed diffusion–denuder tube was then placed in position in the sampling apparatus (see Fig. 1) and sampling commenced at about 2 litres/min. At the end of the sampling period the tube was removed, sealed at both ends with Parafilm, and the volume sampled was recorded.

Immediately before analysis the Parafilm was removed from both ends with a scalpel (care was taken to avoid contamination). The open end of the coated section of the exposed diffusion–denuder tube was then placed in 5 ml of demineralized distilled water contained in a small sample vial. With the aid of the pipette filler the water was drawn into the tube to the etch mark and then allowed to drain out. This operation was repeated five times.

The concentration of nitric acid in air (assuming 100% efficiency of absorption) is given by:

$$C_0 = \frac{aw}{v}$$

where

C_0 = concentration of nitric acid in air, $\mu g/m^3$.

a = concentration of nitric acid in the washing solution, $\mu g/l$.

v = volume of air sampled, litres.

w = volume of washing solution, ml, this is typically 5 ml.

RESULTS

Method development

The method was developed and tested by sampling laboratory air.

The appropriate tube length and flow rate were selected by reference to equation (1). For a 95% absorption efficiency, *i.e.*, $C/C_0 = 0.05$, the required length of coated tube can be calculated (given a flow rate of 2 litres/min (3.33×10^{-5} m^3/sec) and a diffusion coefficient of 1.15×10^{-5} m^2/sec for nitric acid in air[7] to be 70 cm. To maintain consistency with previous work with hydrogen chloride measurements in air[10] all diffusion denuder tubes were 95 cm in total length with a coated section of 80 cm. In addition, this increased length of coated section will allow for lower values of the diffusion coefficient as has subsequently been reported by Benner *et al.*[13] A flow rate of 2 l./min was used in all work.

Absorption efficiencies for a single tube were calculated as previously[11] by connecting two tubes in series and analysing separately after exposing to sample air. Absorption efficiency was then calculated as

$$\frac{\text{first tube concentration} \times 100}{\text{first tube} + \text{second tube concentration}}$$

Absorption of nitric acid on glass

Early work revealed that nitric acid can be absorbed by glass. For instance, when two diffusion denuder tubes, one coated with sodium fluoride and the other uncoated, were exposed to a source of nitric acid from a permeation tube calibrator, the coated tube gave a nitric acid concentration of 0.30 $\mu g/m^3$ while the uncoated one gave 0.25 $\mu g/m^3$.

In addition, further experiments showed that nitric acid (or perhaps particulate nitrate) was absorbed on the 15 cm pre-laminar flow region of the diffusion-denuder tube, as shown by positive nitrate concentrations measured in the washing solutions by ion chromatography. An attempt was made, by analysing separate sections of the tube, to determine if a constant proportion of the total nitric acid present had been absorbed on the pre-laminar flow region.

If this was so it would allow the true nitric acid concentration to be calculated by applying a correction factor to the results from the coated section. *i.e.*, that section where it can be assumed that no nitrate particles had been absorbed. No such constant ratio was found.

Ferm[7] found with sodium carbonate coated diffusion denuder tubes that there was similar deposition of nitric acid on the uncoated pre-laminar flow region. His solution was to analyse all the diffusion denuder tube rather than just the coated section and assume that no nitrate aerosol particles would be deposited, and hence analysed as nitric acid, in the pre-laminar flow region.

Rather than make this assumption the possibility of coating the pre-laminar flow region with a material with a negligible sorption efficiency for nitric acid was investigated. Spicer and Schumacher[14] and Appel *et al.*[15] have reported that, of the materials tested, PTFE has the lowest sorption efficiency for nitric acid.

Accordingly, PTFE sleeves of length 15 cm were prepared (Polypenco TW12), and inserted into the pre-laminar flow region of the diffusion denuder tube. It was assumed that the change in flow, caused by the reduced diameter of the pre-laminar flow tubing, did not induce turbulence. Before use they were thoroughly washed with demineralized distilled water and dried in an oven at 130°.

Table 1 shows results for diffusion denuder tubes prepared with PTFE inserts in the pre-laminar flow region of the tube and exposed to varying levels of nitric acid. The percentage of nitric acid (1.0 → 3.6%) absorbed in the pre-laminar flow region is very much lower than the levels, (up to 40% and variable) recorded for tubes with no inserts. Accordingly, in all subsequent work, measurements were made with PTFE inserts in the 15-cm pre-laminar flow region of the diffusion denuder tube.

Table 1. Absorption of nitric acid in the coated and uncoated (PTFE lined) sections of diffusion denuder tubes

	Coated section		Uncoated section	
	$\mu g/m^3$	Percentage of total	$\mu g/m^3$	Percentage of total
1	10.25	98.3	0.18	1.7
2	8.75	98.7	0.12	1.3
3	9.74	97.7	0.23	2.3
4	8.36	97.9	0.18	2.1
5	8.77	99.0	0.09	1.0
6	9.91	96.4	0.37	3.6

Nitric acid measurements in the presence of nitrate aerosol particles

In our previous work[10] it was shown that for particles of size range 0.01–4 μm there should be insignificant deposition and hence interference from these particles with the experimental conditions used. Larger particles can be precluded from entering the diffusion denuder tube and depositing by gravitation by orientating the tube in a vertical position.

Attempts were made to confirm these findings experimentally with an aerosol generator, as described previously.[10] Nitric acid measurements were made at the air intake point of the aerosol generator and compared with measurements made, in the presence of varying concentrations of ammonium nitrate aerosol, at the exit from the generator. In the presence of no added aerosol, nitric acid measurements at the exit of the generator tube were significantly less than those in the air intake to the tube. It can be concluded that nitric acid was being absorbed on the walls of the generator and so rendering comparisons of nitric acid measurements in ambient air with nitric acid measurements in the presence of added aerosol invalid. Quantitative comparisons of nitric acid in the presence and absence of aerosol cannot therefore be made in the same way as in our earlier work.[10] Nevertheless an indication of whether aerosols are deposited on the coated section of the diffusion denuder tube can be made by generating successively increasing concentrations of aerosol and comparing measured nitric acid concentrations as before. The levels of ammonium nitrate aerosol were increased from 4.2–22.6 $\mu g/m^3$ but no concomitant increase in measured nitric acid concentration was evident, from which it can be concluded that nitric acid measurements by diffusion denuder tube are free from interference from particulate aerosol.

Diffusion denuder tube storage

Experiments were performed to ascertain whether coated diffusion denuder tubes could be stored, both before use, and after exposure prior to analysis. It is important that the ends of the coated tubes are sealed with Parafilm immediately after preparation. When this was done, sealed tubes could be left unexposed for several days, with neither deterioration in absorption capacity nor contamination.

To ascertain whether exposed tubes could be left standing before analysis, room air (seeded

artificially with nitric acid, by opening a bottle of concentrated nitric acid for a few seconds) was sampled through two separate tubes in parallel. One tube was analysed immediately and the other tube was left for a period of time before analysis. All determinations were performed in duplicate. Results are given in Table 2.

From these results it can be concluded that exposed tubes can be left for at least eight days before analysis but for the most precise work it is recommended that tube preparation be done immediately before exposure and then analysis carried out immediately afterwards.

Interferences

Measurements of gaseous nitric acid in ambient air will be taken in the presence of varying levels of nitrogen oxides, peroxyacetyl nitrate (PAN), and nitrous acid. These gases present a potential interference because of their possible deposition on the diffusion denuder tube wall and subsequent conversion to nitrate giving positively. biased nitric acid concentrations.

Nitrogen oxides

All acid gases can be deposited, to a certain extent, on sodium fluoride coated diffusion denuder tubes. To test for the effect of nitrogen dioxide, relatively high levels (50 ppb) were passed from a permeation tube calibrator into diffusion denuder tubes for periods ranging from 12 to 24 hours. The tubes were then processed for nitrate determination in the normal manner. The experiment was carried out on three occasions and 0.42 and 1.44% of the incoming nitrogen dioxide was measured as apparent nitric acid.

It is likely that NO_2 will be converted to nitrite on the diffusion denuder tube wall and Perrino *et al.*[16] have postulated the following reaction

$$2NO_2 + H_2O \rightarrow HNO_2 + HNO_3$$

Table 2. Effect of storage on exposed denuder tubes

Nitric acid concentration $\mu g/m^3$ for storage period (days)						
Immediate analysis	One	Two	Three	Four	Six	Eight
1.01	1.00					
1.13		1.13				
1.13			1.18			
1.14				1.17		
0.29					0.27	
0.29						0.25

Nitrite can then be oxidised to nitrate on the diffusion denuder surface depending on the levels of photochemical oxidants present, in particular, ozone. Perrino *et al.*[16] estimated that in the presence of 45 ppb O_3, and with a two hour exposure, there was a 13% oxidation of nitrite to nitrate. This increased to 84% in the presence of 500 ppb O_3 with the same exposure. It can therefore be concluded that nitric acid measurements would be difficult in photochemical smog episodes unless appropriate corrections are made.

Eatough *et al.*[17] have suggested a procedure to correct for interference from nitrogen oxides. Given that the percentage deposition of NO_2 is relatively small the amount of NO_2 deposited in a second diffusion denuder placed in series with the first will be the same as that on the first denuder. Therefore if the nitrate formed in the second tube is taken from that in the first the net figure gives nitrate due to nitric acid deposition alone. (Nitric acid will be fully deposited in the first tube.)

Peroxyacetyl nitrate

PAN can undergo alkaline hydrolysis to yield acetate and nitrite ions[18] and it is feasible that this reaction could occur on the diffusion denuder tube wall.

$$CH_3C(O)OONO_2 + 2OH^- \rightarrow CH_3COO^- + NO_2^- + O_2 + H_2O$$

Because of the oxidation of nitrite to nitrate on the diffusion denuder tube wall (especially in the presence of high levels of ozone) PAN is a potential source of positive bias in nitric acid measurements. In an attempt to assess the amount of PAN deposition in the sodium fluoride coated diffusion denuder tube and the resultant amount of extractable nitrate, large concentrations (100 ppm and 250 ppm) of PAN were drawn into a diffusion denuder tube from a 200-ml container on separate occasions. PAN was generated by the photolysis of acetone in the presence of NO_2 and air.[19] The apparent concentration of nitric acid was equivalent to 1.7 and 1.0% of the 100 and 250 ppm original PAN. If required, this can be corrected for in an exactly similar way as for NO_2 but because the concentrations of PAN in ambient air are comparable to those of nitric acid its potential interference effect can, in most situations, be considered to be insignificant.

Nitrous acid

Ferm and Sjodin[20] obtained quantitative recovery of nitrous acid in sodium carbonate coated diffusion denuder tubes, and similar absorption within sodium fluoride coated tubes can be expected. Nitrous acid is converted to nitrite ion on the diffusion denuder wall which can then be oxidised to nitrate ion as previously discussed. High levels of nitrous acid are therefore a potential interference and will give positively biased nitric acid concentrations. Nitrous acid concentrations in air are, however, usually significantly less than nitric acid concentrations, particularly during the day and in summer, and so can probably be ignored. Concurrent measurements of nitrite ion by ion chromatography will indicate whether its effect needs to be considered.

Performance characteristics

The performance characteristics of the analytical method were assessed. In all cases the procedure as described previously was followed.

Calibration line

A fresh calibration line was prepared for each batch of samples. Calibration standards were prepared from Analar sodium nitrate at concentrations between 1 and 12 μmol/l. (62–744 μg/l.[3] NO_3^-). Within this range the calibration was linear.

Diffusion denuder tube absorption efficiency

The percentage of nitric acid absorbed on the coated diffusion denuder tube was measured by connecting two tubes in series and analysing each tube separately. Different volumes of room air were analysed on separate occasions and the results are given in Table 3. Absorption efficiencies ranged from 87.6 to 96.9%. This scatter is probably due to the difficulty of accurately measuring the low levels of nitric acid in the upper tube, *i.e.*, a relatively large error was introduced because the nitrate levels in the upper tube were at or near the blank level.

Table 3. Absorption efficiency of nitric acid denuder tubes

No	Volume sampled (litres)	Measured concentration of nitric acid: Upper tube, $\mu g/m^3$	Measured concentration of nitric acid: Lower tube, $\mu g/m^3$	Absorption efficiency, %
1	2478	0.032	0.725	95.8
2	2541	0.024	0.746	96.9
3	3267	0.014	0.237	94.4
4	2791	0.018	0.296	94.3
5	2798	0.014	0.248	94.7
6*	638	0.079	2.249	96.7
7*	638	0.167	2.167	92.8
8	2597	0.017	0.12	87.6
9	3314	0.009	0.128	93.4
10	3330	0.022	0.191	89.7

*Air sampled from a nitric acid permeation tube calibrator.

Precision

The precision of the analytical method was estimated by sampling room air through two tubes in parallel on separate occasions. The nitric acid concentration in the air samples ranged from 0.54 to 1.72 $\mu g/m^3$ and the standard deviation was estimated to be 0.10 $\mu g/m^3$.

Tube blank

It is important that blank diffusion–denuder tubes are included in any series of measurements, by coating, sealing and analysing in exactly the same way as sample tubes. The levels of nitric acid found in the 5 ml of demineralized distilled water used for dissolution of the coating should be $\ll 10$ $\mu g/l$.

AUTOMATED DETERMINATION OF SULPHITE AND SULPHUR DIOXIDE BY COOL FLAME MOLECULAR EMISSION SPECTROMETRY AFTER REDUCTION TO HYDROGEN SULPHIDE WITH SODIUM TETRAHYDROBORATE III

TOYIN A. AROWOLO and MALCOLM S. CRESSER*

Department of Plant and Soil Science, University of Aberdeen, Meston Building, Aberdeen, AB9 2UE, U.K.

(*Received* 14 *April* 1992. *Accepted* 14 *May* 1992)

Summary—An automated method for the determination of sulphite and sulphur dioxide by cool flame molecular emission spectrometry is described. The method is based on the reduction of both compounds to hydrogen sulphide with sodium tetrahydroborate III. The sample which is mixed with $NaBH_4$ is acidified with 6*M* hydrochloric acid and carried by a continuous-flow stream into a gas–liquid separator where the evolved hydrogen sulphide is swept by nitrogen into a cool, hydrogen–nitrogen-entrained air flame. The intensity of the blue diatomic S_2 emission generated is measured at 384 nm. The proposed method has a detection limit for sulphite of 0.029 μg/ml and relative standard deviations of 1.2 and 1.5% for 1 and 5 μg/ml respectively. The calibration graph is linear up to 24 μg/ml sulphite and samples can be analysed at a rate of about 40/hr. The method has been applied to the determination of SO_2 in air and sulphite in wines.

Sulphur dioxide is one of the most important gaseous pollutants causing widespread concern. It is emitted into the atmosphere during various industrial processes and by the burning of fossil fuels. Its adverse effects on living organisms are well known.[1] Sulphite, an anion of major importance, is widely used as an antioxidant in the pharmaceutical and food industries, as an oxygen scavenger in water for steam generation, and in the production of paper pulp. Sulphite is also often produced as an intermediate in the analysis of sulphur-containing materials and strict control over its concentration in industrial products is necessary. Consequently, the development of analytical methods for the determination of both sulphur dioxide and sulphite has attracted considerable attention.

Several methods[2–4] have been described for the analytical determination of both compounds, including ion-chromatography,[5] conductimetry,[6] amperometry,[7] flame photometry,[8] meca,[9] chemiluminescence,[10] UV/Vis spectrophotometry,[11,12] and flow injection analysis.[13] Several workers[9,14–16] have shown that temperature enhances the sensitivity obtained in analytical techniques employing gas-phase sample introduction for the determination of sulphite or SO_2. This is because of the increase in the rate of reaction, reduction in solubility of SO_2 with increasing temperature and reduction in the viscosity of the reaction mixture. All these factors lead to an increase in the evolution rate of SO_2 at high temperature (*e.g.*, 50°) and hence an improvement in the sensitivity. A major drawback in this approach is the condensation of water vapour at the top of the gas–liquid separator and sometimes in the connection tubing leading to the absorption cell or flame. This leads to poor precision because of the reabsorption of the sulphur dioxide by the water droplets and the obstruction of the smooth flow of the gas. In the automated gas phase molecular absorption spectrometric method (GPMAS) for sulphite which we reported earlier,[16] this problem was solved by wrapping the gas–liquid separator with a heating tape. Alder and Kargosha[14] attached a small Liebig condenser at the outlet of their apparatus to prevent the steam from reaching the flame. These alterations make the set-up cumbersome, and it is desirable to develop a sensitive gas-phase sample introduction method for SO_2 determination that can readily be carried out at room temperature.

Techniques using gas-phase sample introduction have commonly been applied to both sulphide and sulphite because acidification of

*Author for correspondence.

solutions of these ions readily produces hydrogen sulphide and sulphur dioxide respectively. However, the literature shows that, whenever the same technique is applied to both ions, sulphide determination always yields better sensitivity and a lower detection limit than that of sulphite.[16–19] For example in a recent paper from this laboratory describing a simple and sensitive automated method for the determination of sulphide in environmental samples by cool flame molecular emission spectrometry,[20] sulphite interfered. The technique was based on passing the hydrogen sulphide liberated on acidification of samples with 3*M* hydrochloric acid into a cool, nitrogen–hydrogen diffusion flame and the resulting S_2 molecular emission was measured at 384 nm. The technique was more than an order of magnitude less sensitive for sulphite than for sulphide and analysis at 50° did not substantially improve the sensitivity. As an alternative way of enhancing the sensitivity of sulphur dioxide determination at room temperature using a gas-phase sample introduction technique, converting sulphite to hydrogen sulphide appeared potentially attractive, because of the better sensitivity which can be obtained.

Tin(II) chloride[21] and Raney nickel[22] have been proposed as reducing agents for sulphite. However, sodium tetrahydroborate(III) has been used extensively in the generation of covalent hydrides in atomic absorption spectroscopy.[23] In this paper, an improved and automated method for the determination of sulphite and sulphur dioxide is described. The method involves the reduction of both species with $NaBH_4$ and acidification with 6*M* hydrochloric acid. The released hydrogen sulphide is swept into a cool, nitrogen–hydrogen flame and the resulting S_2 molecular emission is measured at 384 nm. The method has been successfully applied to the determination of sulphur dioxide in air and sulphite in wine.

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade.

Sulphite stock solution, 500 μg/ml. This solution was prepared by dissolving 0.197 g of anhydrous sodium sulphite, Na_2SO_3 [Merck (formerly BDH)], in 250 ml of antioxidant solution. Working standards were freshly prepared each day in antioxidant solution[16] by the least number of dilution steps possible.

*Stock sodium tetrachloromercurate(II) (TCM) solution, 0.04*M. Prepared by dissolving 10.86 g of mercury(II) chloride, 5.96 g of potassium chloride, and 0.066 g of disodium dihydrogen ethylenediaminetetraacetate (Na_2H_2EDTA) in water, and diluting to the mark in a one-litre standard flask.

Stock sulphamic acid solution, 0.6%. Prepared by dissolving 0.6 g of sulphamic acid in 100 ml of water.

Sodium tetrahydroborate(III) solution, 0.2%. Prepared by dissolving 2 g of $NaBH_4$ in one litre of 0.1*M* sodium hydroxide. After filtration, this solution was stored in a dark glass bottle. The solution remains usable for 2–3 days.

Interferent solutions, 1000 μg/ml. Solutions of a range of cations and anions were prepared from analytical-reagent grade salts.

Table 1. Optimum conditions used for the determination of sulphite and sulphur dioxide by Automated Cool Flame Emission Spectrometry

Conditions	Optimum value
Flow rates (l./min):	
H_2 flow rate	0.65
N_2 flow rate	2.31
N_2 (carrier gas) flow rate	0.075
Wavelength	384 nm
Slit width	1.0 mm
Bandpass	3.0 nm
Hydrochloric acid	6*M*
Sample time	45 sec
Wash time	45 sec

Apparatus

The atomic absorption spectrometer, burner and other apparatus used in this study have been described elsewhere.[20] A diagram of the flow manifold used is shown in Fig. 1 and the operating parameters for the various parts of the instrument and manifold are shown in Table 1.

Instrumental operation

To obtain optimum sensitivity, the different parameters affecting the generation, and hence the subsequent determination of H_2S, such as concentration of acid, carrier gas flow, concentrations and volume of the sodium tetrahydroborate(III) solution and volume of sample solution were studied.

There was no significant difference in the emission intensity obtained from 5 μg/ml of sulphite when $NaBH_4$ was mixed with the sample first before the addition of hydrochloric acid and vice-versa. However, the former approach was used in this study. It was important to mix the reagents thoroughly; hence the need for three mixing coils (28 turns each) as shown in Fig. 1. The flow rate of the carrier gas and the point at which it was introduced into the system led to a fast and efficient mixing of the reagents and also to the efficient stripping of the evolved hydrogen sulphide.

Procedure

Except where otherwise stated, the experimental procedure is the same as previously reported for sulphide.[20] A maximum sampling rate of 40 samples per hour was possible because the baseline was re-established quickly between consecutive peaks.

RESULTS AND DISCUSSIONS

Optimization of experimental conditions

Effect of HCl concentration. The effect of hydrochloric acid concentrations (between 1 and 8*M*) on the emission intensity of hydrogen sulphide obtained from the reduction of 5 μg/ml sulphite was investigated. The results, which are shown in Fig. 2, indicate that the volume of hydrogen sulphide evolved from a given sulphite solution depends on the molarity of hydrochloric acid introduced into the manifold. The relative emission intensity increases gradually at the beginning, then sharply until about 6*M* when it approaches a plateau. Hydrochloric acid at a concentration of 6*M* was selected as the best compromise for subsequent work. This corresponds to a molarity of 1.02*M* in the final solution.

Effect of $NaBH_4$ concentration. The effect of varying the concentration of sodium tetrahydroborate(III) on the emission intensity of hydrogen sulphide obtained when 5 μg/ml of sulphite was taken through the procedure is shown in Fig. 3. When higher concentrations of $NaBH_4$ were used, rapid evolution of hydrogen bubbles was observed in the waste manifold tube. These hydrogen bubbles later formed small gas pockets which segment the waste liquid stream and prevent the smooth flow of the waste liquid. Since accumulation of the waste liquid in any part of the system is not desirable (except in the waste bottle) and for economic reasons, a concentration of 0.2% $NaBH_4$ at a flow rate of 1.0 ml/min was used subsequently in this study.

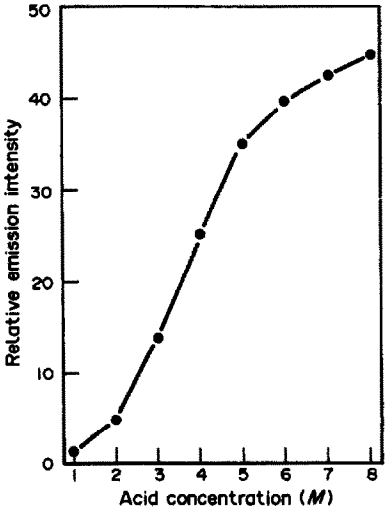

Fig. 2. Effect of HCl concentration on the emission intensity of 5 μg/ml sulphite.

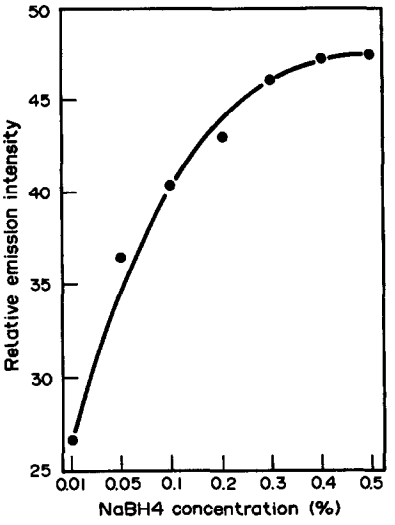

Fig. 3. Effect of $NaBH_4$ concentration on the emission intensity of 5 μg/ml sulphite.

Optimization of flame composition. The effect of flame composition on the emission intensity of hydrogen sulphide was studied. Hydrogen flow rates were held constant while the nitrogen flow rate was varied. The results, which are shown in Fig. 4, were obtained by monitoring the emission at 384 nm of hydrogen sulphide obtained from a 5-μg/ml sulphite standard solution. The optimal composition of the flame was 0.65 l. H_2/min and 2.31 l. N_2/min.

Analytical parameters. Using the optimized conditions shown in Table 1, the calibration graph ($\log I$ *vs.* $\log C$) of the proposed method was linear up to 24 μg/ml of sulphite ($\log I = -1.56 + 1.82 \log C$ with $r = 0.9994$). When aqueous sulphite solutions (as SO_2) stabilized by alkaline antioxidant reagent [(AAR) – 0.1*M* NaOH/0.001*M* EDTA] or 0.005*M* TCM or 0.01*M* TCM were analysed by the proposed procedure, straight line calibration graphs were obtained as shown in Fig. 5. This confirms that the method is applicable to aqueous solutions of sulphite which are stabilized by the two antioxidants. The limit of detection (signal to noise ratio = 3) was 0.029 μg/ml sulphite and the relative standard deviations for 1 and 5 μg/ml sulphite were 1.2 and 1.5%, respectively ($n = 10$). A comparison of this approach (involving the use of $NaBH_4$) with our earlier approach of simple acidification of sulphite samples and sweeping the SO_2 generated into flame was investigated by analysing standard sulphite solutions by both techniques. The results shown in Fig. 6 indicate that the use of $NaBH_4$ increases the sensitivity very substantially. When aqueous standard solutions of sulphite (0–7.5 μg/ml sulphur dioxide) were analysed by the proposed procedure, the equation of the graph obtained by the method of least squares was:

$$\log I = -0.59 + 1.99 \log C$$

with $r = 0.9999$ ($n = 6$)

The slope is very close to the theoretical slope of 2. Comparison of the detection limit, sensitivity and linear range from this work with the corresponding parameters quoted in the literature for sulphite determination by other

techniques[16,18,19] indicate the usefulness of the proposed approach.

Interferences

Interferences from anions were studied by analysing a 5 μg/ml standard solution of sulphite spiked with known amounts of the ions. The responses were compared with those obtained from an uncontaminated sulphite solution. No significant interference was observed from 100 μg/ml Cl^-, Br^-, I^-, CO_3^{2-}, NO_3^-, PO_4^{3-} and SO_4^{2-}. The effect of nitrogen dioxide, a common interferent in the determination of atmospheric SO_2 was also studied. A 100-μg/ml concentration of nitrite depresses the signal of 5 μg/ml sulphite by approximately 16%. Addition of 0.6% sulphamic acid to the solution containing sulphite and nitrite (100 μg/ml) prior to analysis did not restore the peak. However, up to 60 μg/ml nitrite could be tolerated in the determination of 5 μg/ml sulphite. This is an improvement on the very low allowable concentration of nitrite reported earlier for sulphite determination by GPMAS.[16] No emission was observed when pure solutions of the anions were introduced into the manifold.

As expected, sulphide interferes with the proposed method. Solutions containing sulphite and sulphide should be divided into two, one stabilised with sulphide antioxidant buffer[17] (SAOB) and the second with alkaline antioxidant reagent (AAR). The two solutions should then be analysed by the proposed method with and without $NaBH_4$. Sulphide is not affected significantly by SAOB or AAR or whether $NaBH_4$ is included in the manifold or not. However, sulphite does not give a peak when stabilized by SAOB (possibly because it contains ascorbic acid). Therefore, stabilizing a sample containing sulphide and sulphite with SAOB and analysing without adding $NaBH_4$ will ensure that the sulphite peak is suppressed and hence the amount of sulphide in the mixture can be determined. Results of the total amount of both ions present in the mixture can be obtained by stabilizing with AAR and analysing, using $NaBH_4$ as the reducing agent. The amount of sulphite in the mixture can then be obtained by difference.

The effects of cations on the determination of 5 μg/ml sulphite in the proposed method were also investigated. Since the extent to which some metal ions interfere in the determination of sulphite depends on the method, it is important to determine the threshold concentrations at which these metal ions start to interfere. Standard solutions of sulphite were therefore spiked with known amounts of the interfering metal ions and taken through the analytical procedure. No emission was observed when pure solutions of any of the metal ions were introduced into the manifold. A summary of the results obtained, which is shown in Table 2, indicates that disodium EDTA at concentrations in the range 0.001–0.01*M* is effective in removing the interferences of some metal ions. Of all the cations investigated, only Mn^{2+} and Fe^{2+} interfered significantly with the proposed method. The results in Table 2 show that only 2.5 μg/ml Fe^{2+} and 5 μg/ml Mn^{2+} can be

Table 2. Effect of various ions on the determination of 5 μg/ml sulphite by the proposed method

†No significant improvement when EDTA was used.

tolerated in the determination of 5 μg/ml sulphite by the proposed method. Since the maximum reported values[12] of these ions in the atmosphere are low, they should not interfere significantly with the determination. These cationic interferences are due to the formation of stable complexes or insoluble compounds with sulphite.

Application

Determination of sulphur dioxide in air. The proposed method looks attractive particularly for SO_2 determination in air because it does not suffer seriously from nitrogen dioxide interference. Some methods in the literature have this major set-back. It was therefore decided to investigate the application of the proposed method to SO_2 determination in air.

The most widely applicable method for the collection and determination of sulphur dioxide in air is that of West and Gaeke.[4,11,12] The gaseous sulphur dioxide is absorbed into a solution of potassium or sodium tetrachloromercurate, TCM. The retention of the sulphur dioxide is due to the formation of monochlorosulphonato–mercurate(II) complex. The latter is treated with formaldehyde and specially purified, acid bleached pararosaniline, to form a red–violet complex, pararosanilinemethylsulphonic acid, and the absorbance is measured at 548 or 575 nm.

The application of the proposed method to the determination of sulphur dioxide stabilized by various concentrations of TCM was investigated in an attempt to establish the optimum TCM concentration that would be suitable for absorbing sulphur dioxide from air. The results in Fig. 7 indicate that TCM concentrations in the range 2–10mM did not affect significantly the emission intensity from 5 μg/ml of sulphite while concentrations greater than 0.01M reduced the emission intensity drastically. Therefore, complete recovery of sulphite occurs from TCM concentrations $<0.01M$. When 30mM was used, the emission intensity from 5 μg/ml sulphite was quenched completely. It was therefore decided that the final concentration of TCM in the analyte solution should not exceed 0.01M TCM. If air is purged through higher concentrations of TCM, then appropriate dilution should be made to ensure that the final concentration of TCM does not exceed 0.01M.

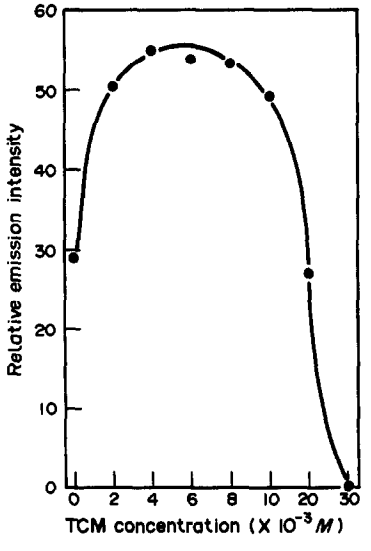

Fig. 7. Effect of TCM concentration on the emission intensity of 5 μg/ml of sulphite.

Analysis of atmospheric sulphur dioxide in the vicinity of the University Chemistry laboratory was carried out by both the conventional West–Gaeke method and the proposed method. One cubic meter of air was sampled from outside the laboratory window. The air was pulled through a fritted glass bubbler containing 20 ml of the absorbing solution for a period of about 1 hr at a flow rate of about 15 l./min. The

absorbing solution was then transferred to a 25-ml standard flask and made to the mark with TCM. Aliquots of the solution were subsequently analysed by the method of West–Gaeke[4] and by the proposed method. The results obtained by both methods are in good agreement as shown in Table 3. Also, samples collected from a permeation tube system were diluted with TCM and analysed by the proposed method and the West–Gaeke method. The results are shown in Table 4. Again the agreement is good.

Determination of sulphur dioxide in wines. The proposed method was also applied to the determination of total SO_2 in wines. A 50 ml aliquot of the wine sample was first reacted with 10 ml of 25% sodium hydroxide for 10 min[24] at room temperature to liberate aldehyde-bound sulphite. Aliquots of the treated wine were then diluted twenty times with 0.01*M* TCM and analysed by the proposed method. However, analysis of some samples of wines at this level of dilution gave poor and unreproducible results. This is because some of the evolved gaseous SO_2 were trapped by liquid droplets and consequently prevented from reaching the flame. This is possibly due to a matrix effect of the wine which limits the diffusion of sulphur dioxide. Fifty-fold dilution of such wine samples with 0.01*M* TCM solved the problem. The results are compared with those obtained by the standard method recommended by the EEC[25] which involves the direct titration with iodine after a prior alkaline hydrolysis. The results in Table 5 show reasonable agreement between the two methods. Recovery studies were carried out by analysing, using the proposed method, aliquots of the treated wine samples spiked with known amounts of the standard solution. The results which are shown in Table 6, indicate recovery in the range 95.4–105.4%, with a mean recovery of 100.7% and a relative standard deviation of 2.4%.

CONCLUSION

The conversion of sulphite and sulphur dioxide [fixed as disulphitomercurate(II)] to hydrogen sulphide by reduction with $NaBH_4$ has been used to provide a sensitive, cool flame emission spectrometric method for the determination of sulphur dioxide and sulphite. The proposed method, which is more sensitive than some of the earlier reported methods, is simple, versatile and capable of good precision. It offers speed and convenience of operation for the routine analysis of large numbers of samples. Interferences are known but their effects may be minimized if not totally eliminated. An attractive feature of the method is its relative freedom from nitrogen dioxide interference (added as nitrite) and its selectivity in the presence of sulphate which is not reduced. A maximum of forty samples can be analysed in one hour and the results obtained by the proposed method correlate well with those obtained using an official method. Considering the excellent sensitivity obtained in this work because of the use of $NaBH_4$ and the large number of techniques based on acidification of sulphite and SO_2 stabilized samples prior to their determination, the adoption of the proposed approach is to be recommended.

(*Received* 2 *December* 1991. *Revised* 28 *February* 1992. *Accepted* 28 *February* 1992)

Summary—An improved automated photo-oxidation procedure to determine dissolved organic phosphorus in soil solutions is described. Organically combined phosphorus is converted quantitatively to orthophosphate under UV radiation and an excess of dissolved oxygen. The orthophosphate is determined spectrophotometrically using the Murphy and Riley procedure, modified by increasing the concentration of ascorbic acid. Fluoride was added to the system to overcome potential interference when working with soil solution. The limit of detection was 0.64 μg/l. PO_4^{-3} – P and calibration was linear over the range studied (5–1000 μg/l. PO_4^{-3} – P).

An adequate supply of soil phosphorus in a plant-available form is essential to sustain current levels of agricultural production. Despite the low solubility of soil phosphorus (P) compared to several other nutrients, some is still lost naturally through weathering and leaching processes.[1] Organic phosphorus may account for 3–75% of the total P in soil.[2] Organically-bound P is generally only available to plants once it has been mineralized and the rapid mineralization of simple organic compounds such as phospholipids, phosphosugars, nucleotides and nucleic acids is therefore of considerable importance.[3]

Several workers have reported that organic P occurs in soil solution at concentrations up to 20 times those of inorganic P.[4] In such solutions and in surface waters, phosphorus occurs in both particulate and dissolved forms. Analytically it is useful to further subdivide the dissolved phosphorus fraction. The fractions commonly used to characterize dissolved phosphorus include:[5]

(i) Total dissolved phosphorus (TDP), conventionally defined as the phosphorus which may be filtered through a membrane filter (0.45 μm). Such filtrate may include colloidal material in addition to dissolved phosphorus. TDP may be determined by converting all forms of P present after filtration to orthophosphate (using hydrolysis and oxidation) and subsequent spectrophotometric determination of the orthophosphate. Alternatively TDP can be determined by an atomic spectrometry technique such as inductively coupled plasma–atomic emission spectroscopy.

(ii) Dissolved reactive phosphorus (DRP), defined as the fraction of dissolved phosphorus which will react directly with molybdate ions to form a phosphomolybdate complex. This fraction contains primarily orthophosphate and any readily acid-hydrolysable phosphate compounds.

(iii) Dissolved unreactive phosphorus (DUP), defined as what is left when DRP is substracted from TDP. This fraction includes condensed phosphates (poly-, meta- and ultraphosphates) and resistant dissolved organic phosphorus (several organic acids and a variety of phosphate esters).

To study the transfer of P fluxes in ecosystems it is necessary, especially for nutrient-poor, organic soils to be able to determine these three P fractions. Furthermore, there is a need for a technique for determination of dissolved organic P (DOP) in its own right.

The use of UV photochemical oxidation as a first step towards detecting low levels of organic

*Author for correspondence.

material in water is convenient.[6] Armstrong *et al.*[7] reported the complete oxidation of organic carbon to carbon dioxide and the release of organically bound phosphorus and nitrogen under the action of UV radiation at wavelengths below 250 nm. Further investigations of the oxidation of organic matter and the release or organic phosphorus, nitrogen and iron have demonstrated that photo-oxidation in the presence of oxygen, or oxygen-releasing compounds, is at least as efficient as chemical oxidation.[8–10] A segmented-flow AutoAnalyser system, using a silica coil irradiated with UV light, has been adapted by a number of workers for determination of the organic carbon component in water samples.[11–13] One potential advantage of photochemical oxidation for organic P determination is that condensed phosphates are not broken-down except in strong acid solutions.[14] The organically combined phosphorus is converted quantitatively to orthophosphate under UV radiation in the presence of dissolved oxygen. Therefore, if dissolved reactive phosphorus (DRP) is determined colorimetrically before irradiation, and DRP plus oxidized organic P after irradiation, the difference between the two values should give the amount of DOP in the sample.

Most automated methods for the determination of phosphate following UV radiation are concerned primarily with the determination of TDP, which can only provide a limited amount of information on P cycling. The determination involves the hydrolysis of condensed phosphates either by photo-oxidation in the presence of acid or by heating irradiated samples in the presence of diluted acid.

McKelvie *et al.*[15] developed a semi-automated system for the spectrophotometric determination of DOP in natural waters using flow injection (FI) and in-line photo-oxidation. They used tin(II) chloride reduction of phosphomolybdate for the spectrophotometric determination of the dissolved reactive phosphorus (DRP) produced by the photo-oxidation. However, the use of tin(II) chloride as a reductant in the determination of DRP has some shortcomings:[16] the absorbance is markedly temperature-dependent, the colour is relatively unstable, large amounts of soluble salts, arsenates and copper interfere, and the method is unsatisfactory at high concentrations.

The semi-automated flow injection procedure proposed by McKelvie *et al.*[15] appears to suffer from several limitations which make it inadequate for analysis of soil extracts. When their procedure was applied to "real samples", the relationship between TDP, DOP and DRP was given by:

$$[\mathrm{TDP}] = 1.200([\mathrm{DOP}] + [\mathrm{DRP}]) - 0.001$$

The high slope value was attributed to the probable occurrence of condensed phosphates in some samples, although no direct experimental evidence was presented to support this suggestion. The equation implies a linear relationship between condensed phosphate P and ([DOP] + [DRP]), a surprising observation if correct. Only when data for 16 of the 25 samples analysed was rejected was a slope close to unity (1.013) obtained.

An alternative explanation is that organic matter photochemical oxidation was incomplete for more organic-rich samples under the chemical conditions and with the photoreactor eventually used.

McKelvie *et al.*[15] went to considerable lengths to overcome problems of bubble production from the autodecomposition of irradiated, strongly alkaline persulphate in the FI manifold, but still found that precision was adversely effected by bubble production effects. Moreover, orthophosphate and gluscose-6′-phosphate gave significantly different calibration graphs as a consequence of interruption of flow by bubble production.

In McKelvie's work, it was assumed that inorganic concomitants did not interfere, but the present authors encountered problems from aluminium released from organic complexes following photo-oxidation. This aluminium could be retained in the oxidation coil, probably as hydrous oxide, which subsequently retained phosphate, causing low recoveries and calibration drift. Such an effect could also have contributed to the high slope of the [TDP] *vs.* ([DOP] + [DRP]) plot mentioned above.

The present authors therefore decided to evaluate a segmented-flow system, in which bubble removal should be greatly facilitated, and a method for overcoming aluminium interference. It was further decided to attempt to minimise unnecessary dilution, and to exploit the improved precision attainable by the Murphy and Riley[17] procedure, rather than the tin(II) chloride method, for colorimetric orthophosphate determination, in an attempt to push the detection limit below that of 10 μg/l. claimed by McKelvie *et al.*[15]

EXPERIMENTAL

Instrumentation

DOP manifold. The manifold developed is shown in Fig. 1. It was set up taking into consideration the required mixing volume ratios, colour development time and the need for thorough mixing of samples and reagents. Mixing coils used were 15-turn and 45-turn respectively (20-mm coil diameter, 2-mm i.d.); the delay coil was 22-turn (165 mm coil diameter, 2 mm i.d.). A Sterilin Instruments autosampler (10 samples/hr) and a Chemlab CPP 15 peristaltic pump were used for sampling and reagent delivery.

The UV irradiation system consisted of a 50-turn silica coil (32-mm coil diameter, 1-mm i.d.) irradiated by a Voltarc UV-Lux tube.

Orthophosphate determination (DRP) in irradiated samples was carried out using a procedure modified from Murphy and Riley.[17] The absorbance of the phosphomolybdenum blue was measured at 882 nm using a 40-mm flow cell in a CE 393 Digital Grating Spectrophotometer connected to a 2 pen Kompensograph X-T C1012 Recorder.

The difference in DRP values for irradiated and non-irradiated sample (UV lamp on and off) gives the amount of dissolved organic P present in the sample.

Reagents

All aqueous solutions were prepared with milli-Q ultra pure water. Unless otherwise indicated, all reagents were AnalaR grade or equivalent.

DOP Manifold

Fluoride. A 1.105-g weight of sodium fluoride was dissolved in 100 ml of water.

Saturated potassium persulphate. A 6.4-g weight of potassium persulphate was dissolved in 100 ml of water. Warm to dissolve, and allow to cool to room temperature; stand to allow some crystallization, otherwise it will crystallize in the manifold tube.

Mixed reagent. Potassium antimonyl tartrate solution (a): dissolve 0.2908 g of $K(SbO)C_4H_4O_6.\frac{1}{2}H_2O$ in 100 ml of water. Ammonium molybdate solution (b): dissolve 12 g of $(NH_4)_6Mo_7O_{24}.4H_2O$ in 250 ml of water. Sulphuric acid (2.5*M*) (c): dilute 148 ml of concentrated sulphuric acid to one litre with water. Mix the three solutions thoroughly and make up to two litres with water. This reagent must be kept in a dark cupboard.

Ascorbic acid. Dissolve 11 g of $C_6H_8O_6$ in 250 ml of water and add 150 μl of aerosol 22 as wetting agent. This solution is stable for about one week at 4° in the dark.

Phosphorus model compounds

A range of phosphorus compounds found in natural waters was analysed by the proposed method to quantify individual responses to

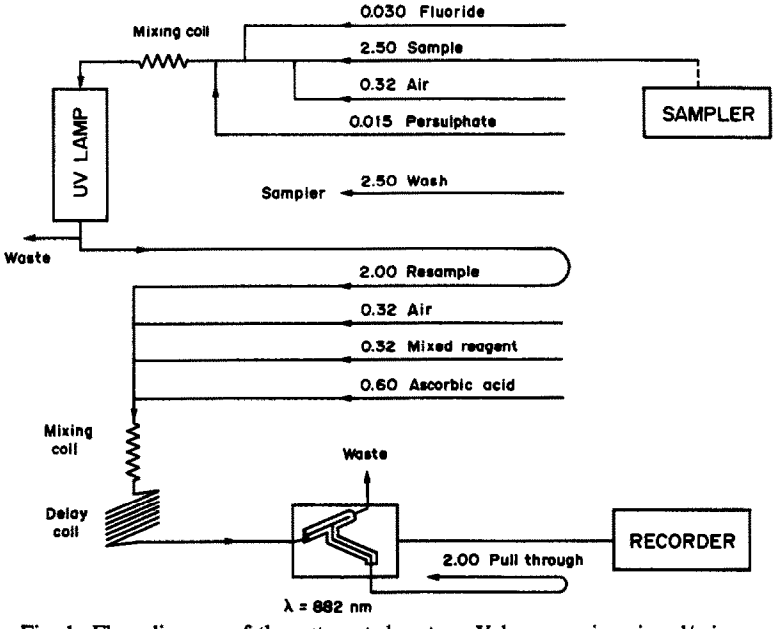

Fig. 1. Flow diagram of the automated system. Values are given in ml/min.

the method. The compounds studied were potassium dihydrogen phosphate, trimetaphosphate trisodium salt, tetrasodium pyrophosphate, α-D-glucose-1-phosphate, β-glycerophosphate, phytic acid, 2-aminoethylphosphonic acid, adenosine-2′(3′)-phosphoric acid monohydrate, nicotinamide adenine dinucleotide (reduced form), and adenosine-5′-triphosphoric acid disodium dihydrogen salt (general purpose reagent grade).

Working standard solutions of these compounds were prepared in the range 5–1,000 μg/l. P by dilution of the stock solutions. All the solutions were stored at 4° to minimize risk of microbial growth.

Optimization of the method

To optimize the signal:noise ratio, the Murphy and Riley procedure was modified by increasing the amount of ascorbic acid, and using persulphate as an oxidizing agent. Fluoride was added to the system to prevent interference from Al released upon organic matter breakdown. These aspects are discussed later.

Soil extracts and suction cup lysimeter samples: TDP, DOP and DRP analysis

Samples were collected at Glensaugh Research Station (National Grid Reference NO 660803). The soil is a peaty podzol (Typic placaquad, Strichen association, Gaerlie series) typical of the area. Porous ceramic suction cup samplers[18] were installed and samples collected every two weeks when water had been sucked into the cups. Soil cores, 100 mm in diameter and 120 mm deep, were collected at monthly intervals. All soil was sieved (< 6 mm) immediately on return to the laboratory, and stored field-moist at 4°.

Water extracts were obtained by shaking soil and water at a 1:10 ratio (m:v). Solutions were centrifuged at 2000 *g* for 15 min, and the supernatant solutions were further centrifuged (19000 *g*, 30 min), then filtered through a No. 42 filter paper to remove traces of suspended material. Solutions were stored at 4° prior to chemical analysis. Blanks were prepared similarly.

Total dissolved phosphorus values were obtained following a persulphate digestion method.[19] Dissolved organic phosphorus and dissolved reactive phosphorus values were obtained by the proposed method.

RESULTS AND DISCUSSION

Optimization of the method

Colour development. The automated method consists of two stages:

(1) Photo-oxidation of the sample; the sample is exposed to UV radiation in the presence of an oxidizing agent. Organically-bound phosphorus is released as inorganic phosphate.

(2) Determination of DRP; by the spectrophotometric determination as a reduced phosphomolybdate complex in acid solution after irradiation of the sample.

The amount of ascorbic acid used had to be increased to overcome residual effects of the oxidizing agent used in the first stage. To optimize the concentration of ascorbic acid, 4.2 ml of 500 μg/l. $PO_4^{-3} - P$, spiked with 20 μl of 30% m/v hydrogen peroxide solution (100 volume), was passed through the silica coil, with the UV lamp either on or off. The solution was collected and analysed colorimetrically (manually) using different concentrations of ascorbic acid. A 10-mm flow cell was used in this experiment [Fig. 2(a)].

In Fig. 2(a), the horizontal axis represents the final concentration of ascorbic acid in the sample, before any oxidation. The concentration of ascorbic acid required to give maximum absorbance in the presence of 20 μl of 30% m/v hydrogen peroxide should be $> 0.04M$ with the lamp on and $> 0.064M$ with the lamp off. When the UV lamp is on, hydrogen peroxide will be partially decomposed to O_2, and partially used in the decomposition of the organic matter. Therefore, less ascorbic acid is required compared to the amount needed when the UV lamp is off. In normal working conditions, the UV lamp will be on and, therefore, the minimum concentration of ascorbic acid required would be $0.04M$.

A similar experiment was carried out using a saturated persulphate solution as an alternative oxidizing agent; 4.2 ml of 250 μg/l. $PO_4^{-3} - P$ solution was spiked with 30 μl of saturated potassium persulphate; the sample was analysed colorimetrically (40-mm flow cell) using the same range of concentration of ascorbic acid as in the previous experiment, but the UV lamp was always off. In this case, the minimum concentration of ascorbic acid required to give maximum absorbance in the presence of persulphate was $> 0.016M$ [Fig. 2(b)]. An excess of

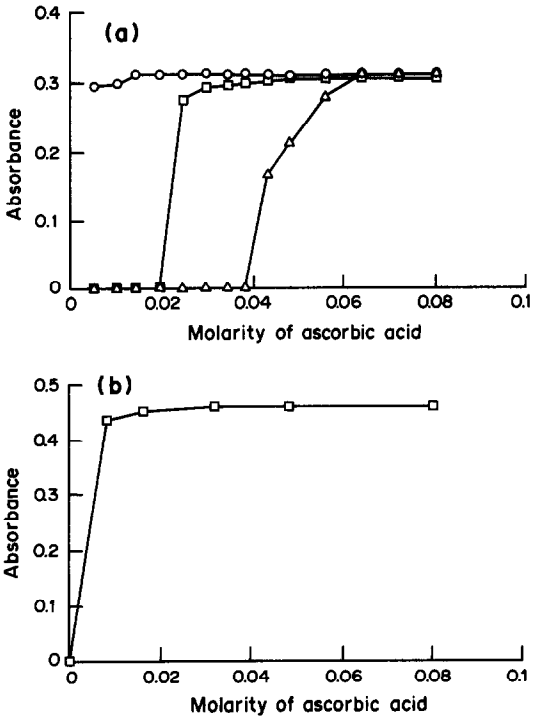

Fig. 2. Optimization of the final concentration of ascorbic acid in the assay (a) with hydrogen peroxide and UV lamp switched on (—□—), with hydrogen peroxide but the UV lamp switched off (—△—) and without hydrogen peroxide or UV illumination (—○—); (b) with potassium persulphate and UV lamp switched on (—□—).

ascorbic acid (0.046*M*) was chosen as final concentration in the sample stream.

Oxidizing agent

Initially, hydrogen peroxide was chosen as oxidizing agent to provide a source of hydroxyl radicals which, in addition to ultraviolet radiation, will decompose dissolved organic matter and convert organic phosphorus to inorganic phosphate. The amount of hydrogen peroxide added to the system was optimized in order to maximize the signal: noise ratio and to avoid the formation of unwanted products which could be produced in the presence of an excess of hydrogen peroxide. Phytic acid and several soil extract samples were run using different concentrations of hydrogen peroxide prepared by dilution of a 30% m/v hydrogen peroxide solution (100 volume). Peak heights were recorded (Fig. 3).

The optimum concentration of hydrogen peroxide was found to be between 3 and 4.5% m/v (Fig. 3). Peak heights decreased when using a 6% m/v concentration and peak shapes were not clearly defined when the amount of hydrogen peroxide was increased to 9% m/v (Fig. 4). From 3 to 4.5% m/v hydrogen peroxide, the

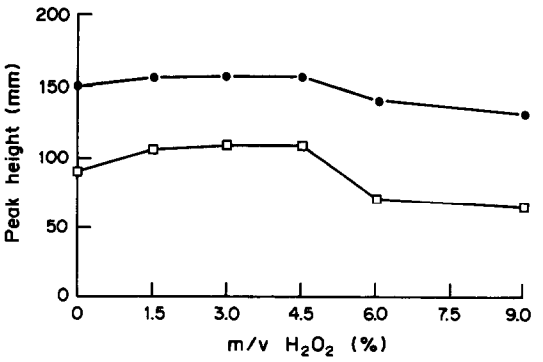

Fig. 3. Optimization of the amount of hydrogen peroxide (a) using phytic acid as a standard (—●—) and (b) using a soil extract sample (—□—).

peak heights were constant, but the baseline was less stable when using hydrogen peroxide solutions stronger than 3.75% m/v; therefore the optimum hydrogen peroxide concentration was found to be 3% m/v. However, when samples from suction cup lysimeters were run through the system, the analytical response for DOP + DRP was generally smaller than the one obtained for DRP alone. This phenomenon did not occur with a saturated potassium persulphate solution as oxidizing agent (Table 1). It is probable that oxygen gas release rates from hydrogen peroxide upon irradiation are different in the presence and absence of soil organic matter in the suction cup samples. This may be due to the presence of particulates acting as nucleation centres, thus causing different mixing patterns between samples and the organic-free standards. Persulphate was therefore used in subsequent work, rather than hydrogen peroxide.

Addition of fluoride

When soil solution samples were run through the system, following synthetic standards, a decrease in the peak heights for the next batch

of standards run after the samples was observed (Table 2). Thus running the samples resulted in a source of phosphorus removal, possibly via contamination of either manifold tubes and/or of the silica coil. Manifold tubes were replaced but the loss of phosphorus was still observed indicating that the silica coil was contaminated.

One possible explanation for this source of phosphorus loss could be aluminium interference. When organic matter of acid organic soil origin is decomposed under UV radiation in the presence of hydrogen peroxide or potassium persulphate, aluminium is liberated, and may be adsorbed on the surface of the silica coil in the form of hydrous aluminium oxide which then strongly adsorbs phosphorus: $Al(OH)_2^+ + H_2PO_4^- \rightarrow Al(OH)_2H_2PO_4$. The problem was solved using a new silica coil and spiking the standards with a concentrated solution of fluoride. Fluoride forms a strong complex with aluminium and therefore prevents the aluminium oxide accumulation and subsequent loss of phosphorus. Experiments were carried out to establish that aluminium was the source of contamination by adding 1,000 μg/l. Al^{3+} to standards and passing them through a clean silica coil, then looking at the difference in the absorbance between standards with and without aluminium. The results proved that aluminium was the problem.

The stability of the colour developed in the modified phosphomolybdenum blue reaction in the presence of a large amount of fluoride was studied. No differences in absorbance values occurred, but it was found that the rate of reaction decreased in the presence of fluoride. A delay coil was incorporated into the manifold to give around 12 min of colour development time which was sufficient to reach maximum absorbance.

300	296	241
400	416	351
500	489	413

Recovery, linearity and limit of detection

The recovery of phosphorus from different phosphorus compounds was measured using the proposed method. Firstly, 200 μg/l. P solutions of each compound were run using the autoanalyzer procedure with the UV lamp off to ensure that the analytical response for DOP was not due to DRP impurities. The same solutions were run with UV lamp on and without persulphate, and with UV lamp on with persulphate. The results (Table 3) show that complete recovery was achieved for several compounds but very low recovery was obtained for the inorganic condensed phosphorus (trimetaphosphate, pyrophosphate) and for the condensed organic compounds (adenosine triphosphate (ATP), nicotinamide adenine dinculeotide, reduced form (NADH)]. The apparent recoveries, in addition to DRP for the condensed organic compounds (Table 3), could be due to organic impurities. Furthermore, total recovery was achieved without using persulphate, which means that UV radiation, in addition to the dissolved oxygen present either from the air bubbles or in the water, was enough to release organic phosphorus bound in the ester form [phytic acid, α-*D*-glucose-1-phosphate, β-glycerophosphate, adenosine-2′(3′)-phosphoric acid], or via a C—P bond (2-aminoethylphosphonic acid). The recovery values for adenosine-2′(3′)-phosphoric acid (AMP) and adenosine-5′-triphosphoric acid show that the UV radiation, in addition to hydroxyl radicals, will release the organic phosphorus but as an orthophosphate group for AMP and probably as

Table 3. Recovery of model phosphorus compounds

Compounds	Recovery 1 (%)	$\sigma(n-1)$ (%)	Recovery 2 (%)	$\sigma(n-1)$ (%)
Phytic acid	100.50	0.10	101.50	0.02

a triphosphate group for ATP, and the latter cannot be determined by the colorimetric phosphomolybdenum blue method. The same explanation could be applied to NADH. In other words UV radiation in addition to the hydroxyl radicals does not break P–O–P bonds. If it did, the analytical response would be total dissolved phosphorus.

The complex chemical nature of phosphorus containing organic compounds likely to be encountered in soil solution requires the use of persulphate to ensure complete photo-oxidation (Table 4).

Sugimura and Suzuki[21] reported that neither UV photo-oxidation methods or low temperature chemical oxidation methods are 100% efficient for oxidizing organic carbon in seawater. However, a comparison of total organic carbon determined either by an automated photo-oxidation procedure (similar to the one described here) and a furnace combustion procedure (TOCsin II, Phase Sep.) showed a high degree of correlation for a range of natural water samples containing up to 52 μg/ml.[22]

*UV lamp on and without potassium persulphate.
†UV lamp on and with potassium persulphate.
Values are in μg/l. P

The linearity of the DOP automated procedure was checked (Fig. 5). The range studied was from 5 to 1,000 μg/l. $PO_3^{-3} - P$. The calibration shows good linearity over this range ($r^2 = 0.9999$, peak height (mm) $= -9.14 + 2.12[\mu g$ 1. P]). Limit of detection[20] (defined as the determinant concentration giving a signal equal to the blank signal, Y_B, plus three standard deviations of the blank, S_B) was 0.64 μg/l. P which could be improved by using a 50-mm flow cell.

Soil extract and suction cup lysimeter samples: TDP and (DOP + DRP) analysis

Analyses for TDP (acid persulphate digestion) and DOP + DRP (autoanalyser) were

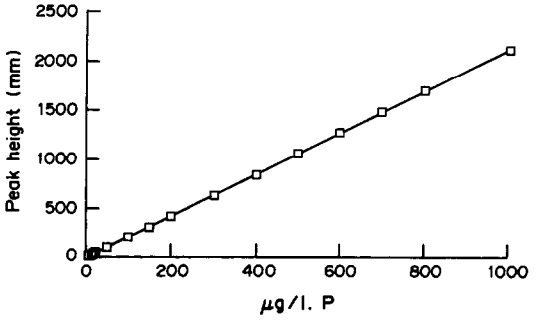

Fig. 5. Calibration graph using orthophosphate standards. Orthophosphate was run as standard.

carried out in twenty suction cup lysimeter samples and twenty soil extract samples.

Comparison of TDP values with DRP + DOP values in both types of sample are represented in Fig. 6(a) and 6(b). For suction cup lysimeters a good correlation was obtained ($r^2 = 0.998$, TDP = 1.8 + 1.048[DOP + DRP]); in this type of sample TDP and DOP + DRP values are almost equal which means that the DUP fraction is formed almost entirely of DOP. However, for soil extract samples the values obtained for TDP were higher than the ones obtained for DOP + DRP {Fig. 6(b), $r^2 = 0.982$, TDP = 56.2 + 1.005 [DOP + DRP]}; therefore in this type of sample the DUP fraction is formed primarily by DOP and a residual fraction formed by dissolved condensed P compounds (DCP). The relationship between each of the different phosphorus fractions (TDP, DRP, DOP and DCP) will be expected to vary with factors such as soil type, climate and fertilizer additions.

CONCLUSIONS

The detection limit obtained with the proposed procedure, 0.64 μg/l., was substantially better than the detection limit of 10 μg/l. obtained by McKelvie *et al.*[15] Such a low detection limit was necessary for analysis of some of the soil solution samples studied. A satisfactory and simple procedure has been found for overcoming interference from aluminium. The segmented flow system obviates the need for adding a high pH sodium tetraborate buffer to absorb evolved carbon dioxide. Results for lysimeter samples suggested that condensed phosphate concentrations were negligible in all the samples tested, and very small for the soil extracts. This is in marked contrast to the results of McKelvie *et al.*[15] for waters. They needed to suggest, for effluent-rich samples, a linear relationship between condensed phosphate and ([DOP] + [DRP]). The results reported in this work require no such assumption.

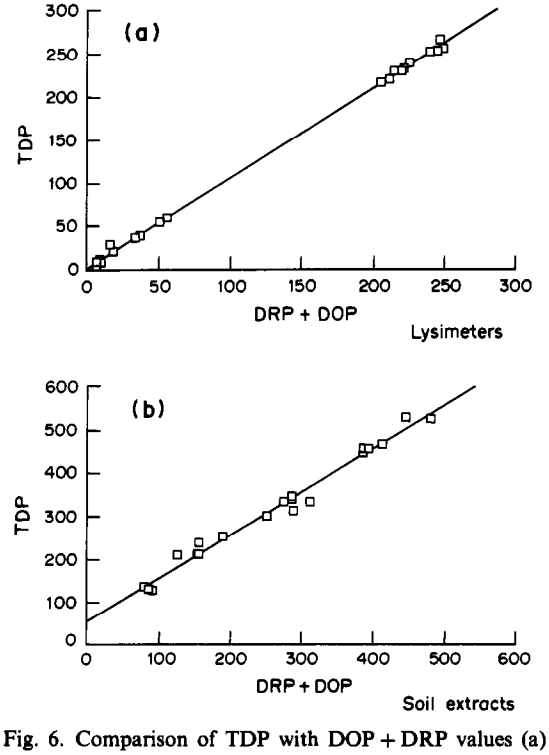

Fig. 6. Comparison of TDP with DOP + DRP values (a) when working with suction cup lysimeter samples and (b) when working with soil extract samples. Values are given in μg/l. P.

COLORIMETRIC DETERMINATION OF ETHANOL IN THE PRESENCE OF METHANOL AND OTHER SPECIES IN AQUEOUS SOLUTION

S. A. RAHIM* and S. G. GEESO
Department of Chemistry, College of Science, Mosul University, Mosul, Iraq

(*Received* 1 *March* 1992. *Accepted* 31 *March* 1992)

Summary—Ethanol is coupled with diazotized *p*-aminobenzoic acid, to give a coloured product with maximum absorption at 436 nm. The coloured product has a molar absorptivity of 1.02×10^4 l.mole^{-1}.cm^{-1} and Beer's law is obeyed over the range 0.5–4.0 μg/ml. The relative standard deviation is less than 4.76% and the relative errors are within −2.89–3.9%. The suggested method is rapid, simple, selective and sensitive.

The official AOAC method[1] for the quantitative determination of ethanol in distilled spirits is based on distillation and measurement of specific gravity. This method cannot be used if other alcohols such as methanol are present. Determination of alcohol by measuring its volume in pure form[2] is a lengthy procedure that requires considerable technique and is not suitable for routine analysis. Determination of alcohol in the distillate by measuring physical properties such as specific gravity and refractive index[3–5] is not well suited to very small quantities, or to mixtures containing other volatile ingredients. There are a number of methods based on oxidation with potassium permanganate,[6] iodine pentoxide,[7] or potassium dichromate.[8–19] Other methods include bromometric measurement of ethylene alcohol vapors,[20] conversion of alcohol to ethylnitrite and formed by pyrolytic dehydration of measurement of nitrite formed,[21] spectrophotometric determination of reduced trivalent chromium,[5] or determination by enzymic,[22] amperometric,[23] interferometric,[24] and spectrophotometric[18,19,25,26] methods. These methods are not specific because compounds such as methyl alcohol, ether, chloroform, or formaldehyde interfere. The spectrophotometric methods based on oxidation with potassium dichromate[18,19] and on conversion of ethanol to ester[26] are lengthy and need heating.

This paper presents a novel, simple, rapid, selective and sensitive procedure for the estimation of ethanol, by coupling with diazotized *p*-aminobenzoic acid in alkaline aqueous solution.

EXPERIMENTAL

Reagents

All reagents used were of analytical or microanalytical reagents grade.

Hydrochloric acid, 0.5M aqueous solution.

p-*Aminobenzoic acid, 1.25%*. Freshly prepared in 0.5*M* hydrochloric acid.

Sodium nitrite, 7.5%. Freshly prepared, aqueous solution.

Diazotized p-*aminobenzoic acid.* Freshly prepared by cooling both *p*-aminobenzoic acid and sodium nitrite solutions to about 5°, then mixing 100 ml of *p*-aminobenzoic acid and 10 ml of sodium nitrite solutions, and stirring the mixture for about 5 min. The reagent is stable for more than 20 hr, when stored in a dark and cold place (about 5°).

Sodium hydroxide, 30% aqueous solution.

Stock standard ethanol solution (1 mg/ml). Prepared in water by accurate dilution of an absolute ethanol (99.8%).

Working standard ethanol solution, (0.05 mg/ml). Prepared in water by dilution of stock standard ethanol solution.

Interferent solutions were aqueous.

*Author for correspondence.

Table 1. The optimization of the reagents used in the recommended procedure

Studied property	Optimum value
Concentration of *p*-aminobenzoic acid solution	1.25%
Concentration of sodium nitrate solution	7.5%
Concentration of hydrochloric acid solution	0.5*M*
Stability period of diazotized *p*-aminobenzoic acid Solution	>20 hr
Volume of diazotized *p*-aminobenzoic acid solution	3 ml
Concentration of sodium hydroxide solution	30%
Volume of sodium hydroxide solution	1 ml

Procedure for calibration graph

Pipette 0.1–0.8 ml of working standard ethanol solution into 10-ml standard flasks. Add 3 ml of diazotized *p*-aminobenzoic acid solution and 1 ml of sodium hydroxide solution to each, then dilute to volume with (5–10°) distilled water. Prepare a reagent blank by diluting 3 ml of diazotized *p*-aminobenzoic acid solution and 1 ml of sodium hydroxide solution to 10 ml with (5–10°) distilled water. Measure the absorbance of the standards against the reagent blank within 10 min after dilution in 1-cm cells at 436 nm.

Effect of interferences

In order to study the effect of interferences on the proposed method for the determination of ethanol, pipette suitable aliquot of interferent solutions, each into 10 ml standard flask containing 0.5 ml of working standard ethanol solution, and apply the general procedure on each one.

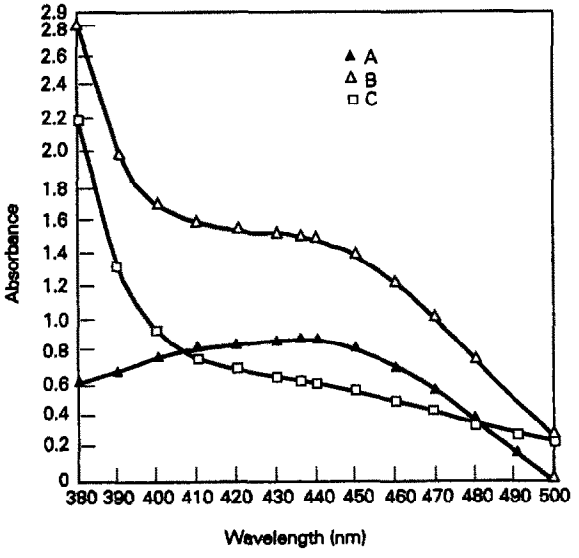

Fig. 1. Absorption spectra of ethanol (2.5 μg/ml)–diazotized *p*-aminobenzoic acid complex against reagent blank (A) and against water (B) and reagent blank against water (C).

RESULTS AND DISCUSSION

Ethanol can be coupled with diazotized *p*-aminobenzoic acid in strongly alkaline medium to produce an orange–yellowish compound. This reaction can be used for spectrophotometric determination of ethanol.

Under the optimum conditions (Table 1) the colour developed instantly and remained stable for about 10 min. The absorbance maximum was at 436 nm (Fig. 1) and Beer's law was obeyed over the range 0.5–4 μg/ml. The molar absorptivity of the product was 1.02×10^4 $l.mole^{-1}.cm^{-1}$.

Methanol, propanol, isopropanol, *t*-butylalcohol, ethyl acetate, acetic acid and acetone, were found not to interfere in the analysis (Table 2).

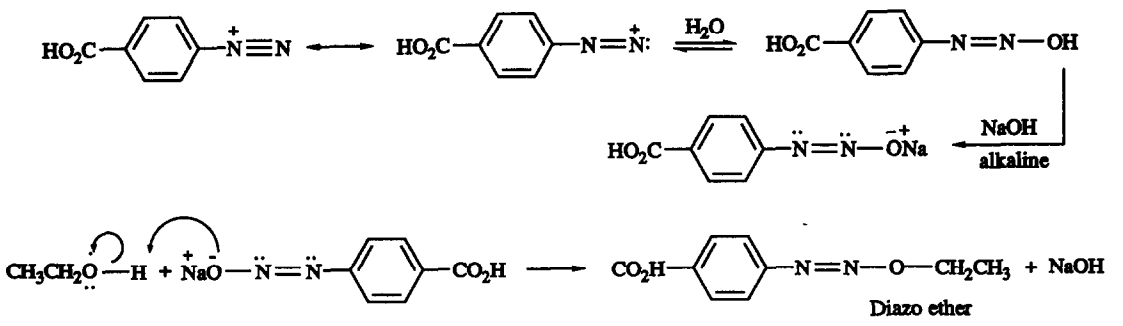
The values of relative standard deviation (3.2–4.76%) and relative errors (−2.89-3.9%) (for 4 results), show that the method has good precision and accuracy.

The proposed method has the advantages of being simple, rapid, selective and sensitive. The method has the additional advantage that the coloured product is soluble in water, so it does not precipitate and needs no extraction. The method also has advantage over the spectrophotometric methods[18,19,25,26] that no heating is required.

Table 2. Effect of methanol and other organic species on the determination of 0.025 mg of ethanol

Organic compound	Taken, mg	Ratio of interferent to ethanol	Ethanol recovery, %
Methanol	112.5	450	102.7
Propanol	62.5	250	100
Isopropanol	62.5	250	98.55
t-Butylalcohol	125	500	95.7
Ethyl acetate	187.5	750	95.5
Acetic acid	187.5	750	101.56
Acetone	0.025	1	97.4

*Average of 3 results.



Scheme I

Scheme I represents a possible reaction pathway for the formation of the diazo ether compound.

SEPARATION AND IDENTIFICATION OF SUGARS AND MALTODEXTRINES BY THIN LAYER CHROMATOGRAPHY: APPLICATION TO BIOLOGICAL FLUIDS AND HUMAN MILK

F. BOSCH-REIG, M. J. MARCOTE, M. D. MINANA
Departamento de Química Analítica, Facultad de Ciencias Químicas, Valencia, Spain

M. L. CABELLO*
Unidad de Metabolopatías Congénitas, Hospital Universitario "La Fe", Avda. Campanar, 46009 Valencia, Spain

(*Received* 27 *March* 1992. *Accepted* 1 *April* 1992)

Summary—A monodimensional thin layer chromatography method to separate several sugars of clinical interest is described. The separation and identification of 14 sugars (*L*-fucose, *D*-galactose, *D*-glucose, lactose, *N*-acetylglucosamine, *D*-maltose, *D*-manose, *L*-sorbase, fructose, *D*-xylose, glucuronic acid, *N*-acetyllactosamine, 3′ and 6′ sialyllactose) and maltodextrines (G_2–G_8) is possible by using two different eluents mixtures, as well as two different detection reagents. The method has been applied to separate sugars, maltodextrines and oligosaccharides in several biological fluids (blood, urine and faeces), in an infant milk and in human milk. It is a very simple technique (with a high sensitivity) that can be used in any lab.

The presence of anomalous amounts of carbohydrates can be detected in blood, urine and faeces of patients with inborn errors in the metabolism of carbohydrates, such as essential fructosuria and others.[1–7]

In the present method, urine does not need to be desalted as in most cases, either by column[4–8] or by precipitation.[5,9]

Over the last few years, the increasing popularity of breastfeeding has stimulated interest in the sugar content of human milk.

It is known that the carbohydrate concentration of human milk is about 7 g/100 ml; 80% lactose and the rest oligosaccharides (1–1.2 g/100 ml in nature milk, 2–2.5 g/100 ml in colostrum).[14]

It has not yet been possible to reproduce the structure of these oligosaccharides. They are substituted by maltodextrines in "adapted" milk formula, keeping the total sugar concentration at 7–8 g/100 m.[15]

The biological role of human milk oligosaccharides is not completely understood, but it seems clear that they have a very important anti-infective action for breast-fed infants.[16]

Kobata *et al.* isolated and characterized most of the oligosaccharides in human milk using very sophisticated technology.[9–18] At first they used pooled milk from several donors as starting material, but then observed that the type of oligosaccharides present in individual samples of milk can vary with the ABO or Lewis blood type of the donor. The enzymes involved in their synthesis are also responsible for the formation of the structural determinants of these blood types.

All oligosaccharides in human milk have some general structural principles in common, they all derive from lactose and contain, besides galactose and glucose, *N*-acetylglucosamine and/or more of *L*-fucose and *N*-acetyl-neuraminic acid molecules.

Another advantage of the method is that sugars may be identified without using internal standards.

Thin layer chromatography has been applied specifically to the study of the role placed by the oligosaccharides obtained from human blood, urine and milk[10,11,13] in metabolic pathways.

*Author for correspondence.

Several sugars obtained from animal urines have been studied by thin layer chromatography and high pressure liquid chromatography.[12] It can be seen in the references in the literature that certain sugars have been studied, however a complete study of separation, identification and application to biological fluids of carbohydrates has not been done.

EXPERIMENTAL

Samples and solvent systems

Aqueous solutions of the following sugars were prepared:

L-fucose, *D*-galactose, *D*-glucose, lactose, *N*-acetylglucasamine, *D*-maltose, *D*-manose, *L*-sorbose, *D*-xylose, fructose (0.7 g/100 ml), glucuronic acid (0.21 g/100 ml), *N*-acetyllactosamine (5.00 g/100 ml) 3′ and 6′ sialyllactose (1.70 g/100 ml) and maltodextrines (G_2–G_{10}) (8.33 g/100 ml).

All sugars were obtained from commercial sources (Merck, Sigma). Less concentrated solutions were obtained by diluting the original ones.

Blood samples, as well as fresh and twenty-four hour urine samples were taken from the ones available in the laboratory.

Faeces samples belonged to preterm infants. The milk samples used were from either one donor, 15 days and 45 days after the delivery, or several donors, 15 days after the delivery.

An infant milk formula containing lactose and maltodextrines (56.9 g/100 g milk), 15% in water.

Blood was delipidated using a chloroform: metanol 2:1 mixture in a ratio 1:10, mixed for 5 min and centrifuged for 25 min at 5000 rpm. Then it was ready to be applied to the plate.

Urine required no previous treatment and could be directly applied to the plate.

Faeces were analysed after being diluted in distilled water 1:2 and centrifuged 25 min at 5000 rpm. The supernatant was applied to the plate.

Milk samples were delipidated by centrifugation at 1500 rpm for 30 min and diluted 1:2 with distilled water. One-millilitre aliquots were kept at −20° until they were analysed.

Two elements mixtures were used: in-butanol/ethanol/water (3:2:1) and pyridin/ethyl acetate/acetic acid/water (5:5:3:1).

Chromatography

Cellulose plates (20 × 20 cm, 0.1-mm thick) were used (Merck Art. 5716). Cellulose plates (20 × 20 cm, 0.5-mm thick) were used for preparative chromatography (Merck Art.).

Aliquots (3 μl), were spotted on the 0.1-mm plates with a micro syringe, at 1.5-cm intervals and 2 cm from the lower edge of the plates. Then they were developed by the ascending technique. A three-fold development, with the same eluent mixture, is used in order to improve separation. A good separation was obtained when the eluent was allowed to run 14.5 cm from the edge of the plate. The time required for a single run is approximately two and a half hours.

In the preparative chromatography milk samples aliquots (850 μl) were applied as a streak on the 0.5-mm plate. A three-fold development was also used. Guide strips were developed with silver nitrate reagent to locate the bands. The required bands on the unsprayed area were scrapped off onto test tubes, 1 ml of distilled water was added to each and tubes were shaken thoroughly. Sugar was separated from cellulose powder by centrifugation at 4.500 rpm for 5 min.

Detection reagents

The following reagents were used: silver nitrate solution prepared by dissolving 3 g of silver nitrate in 12 ml of distilled water adding 500 ml of acetone.

Ethanolic sodium hydroxide solution prepared by diluting 50 ml of 10*N* sodium hydroxide in 450 ml of ethanol.

Sodium thiosulphate (5%) was also used.

The developed plates were allowed to dry at room temperature and dipped into AgNO solution for one minute. When dry they were sprayed with the ethanolic sodium hydroxide solution until dark brown spots appeared on a light brown background.

If the plates must be kept for a long time, they must be sprayed with a 5% $Na_2S_2O_3$ solution once they are dry.

Elson-Morgan reagent

1% Acetillacetone in butanol is treated with a 1/20 volume of 50% potassium hydroxide–ethanol (1:4 v/v).

p-Dimethylaminobenzaldehide solution: 1 g of *p*-dimethylbenaldehide is dissolved in 30 ml

of ethanol of concentrated HCl and 30 ml of *N*-butanol.

When the plate was dry, it was sprayed with the acetylacetone solution, heated at 100° for 5 min and then sprayed with *p*-dimenthylbenzaldehide solution. *N*-Acetylaminated sugars appear immediately as violet spots.

RESULTS AND DISCUSSION

Aqueous solutions of the following sugars were chromatographed on 0.1-mm cellulose plates: *N*-acetylglucosamine, fucose, xylose, manose, sorbose, glucose, galactose, *N*-acetyllactosamine, glucuronic acid, maltose, lactose, 3′-sialyllactose and 6′-sialyllactose, using *N*-butanol/ethanol/water (3:2:2) as eluent and with a 3-fold development. All sugars were detected with both silver nitrate and Elson-Morgan reagents. The R_f values and sensitivities are shown in Table 1.

Similarly, an aqueous solution of maltodextrines was also chromatographed using two different eluents: (1) n-butanol/ethanol/water (3:2:2) and (2) pyridine/ethyl acetate/acetic acid/water (5:5:1:3). Then maltodextrines were located with silver nitrate reagent. The method sensitivity for maltodextrines is 6.25 μg and the R_f values are shown in Table 2.

As can be seen in Table 1 fucose and *N*-acetylglucosamine have the same R_f but they could be identified by the detection reagents. Both of them can be visualized with silver nitrate reagent, but only *N*-acetylglucosamine can be detected with Elson-Morgan reagent.

Table 2 shows that only G_2 to G_7 components of maltodextrines can be separated with eluent (2). G_2 to G_8 can be separated with eluent (1).

Table 2. R_f values, using two different eluents mixtures, of maltodextrines in aqueous solutions

Sugar	R_f (eluent 1)	R_f (eluent 2)
G_2	0.73	0.48
G_3	0.65	0.35
G_4	0.56	0.26
G_5	0.46	0.19
G_6	0.38	0.14
G_7	0.31	0.10
G_8	0.24	—

However G_9 and G_{10} components cannot be separated either with eluent (1) or with eluent (2).

It can be said that the described aqueous solutions of sugars and maltodextrines have been identified either by their R_f or by selecting the suitable detection reagent.

When sugars were added to blood, fresh urine, twenty-four hour urine and faeces, these biological fluids were chromatographed and it was seen that there is very good agreement between the R_f of the standard solutions and those of the biological fluids, as shown in Table 3.

Samples of infant milk were also chromatographed. Its sugar content according to the manufacturer was lactose and maltodextrines. *N*-Butanol/ethanol/water (3:2:2) was used as eluent and the detection reagent was silver nitrate. On the chromatogram shown in Fig. 1 can be seen that lactose and maltodextrines were identified, as well as minor sugars like galactose and glucose. Therefore, this procedure allows the identification of sugars with a sensitivity that may be considered high.

Seven spots were detected when samples of milk from a donor who had delivered a full term infant 15 days before, were chromatographed.

Table 1. R_f values and sensitivity in μg of sugars in aqueous solutions

Sugar	R_f	μg ($AgNO_3$ R.)	μg (Elson-MorganR.)
6′-Sialillactose	0.35	3.19	—
3′-Sialillactose	0.42	3.19	—
Lactose	0.48	0.56	—
Maltose	0.48	0.21	—
Glucuronic Acid	0.55	0.09	—
N-Acetillactosamine	0.58	3.0	3.0
Galactose	0.65	0.14	—
Glucose	0.69	0.11	—
Sorbose	0.70	0.21	—
Manose	0.73	0.21	—
Xilose	0.78	0.11	—
Function	0.74	0.11	—
Fucose	0.81	0.11	—
N-Acetilglucosamine	0.81	0.42	2.1

Table 3. R_f values of sugars in several biological fluids (blood, faeces and urine)

Sugar	R_f values		
	Aqueous solution	Blood	Faeces
Xilose	0.78	0.78	0.78
Fructose	0.74	0.73	0.74
Glucose	0.69	0.69	0.69
Galactose	0.65	0.65	0.65
Glucuronic Acid	0.55	0.53	0.54
Lactose	0.48	0.47	0.48
Sugar	Fresh urine	Twenty-four hour urine	
Xilose	0.78	0.78	
Fructose	0.74	0.74	
Glucose	0.69	0.69	
Galactose	0.66	0.66	
Glucuronic Acid	0.55	0.55	
Lactose	0.48	0.48	

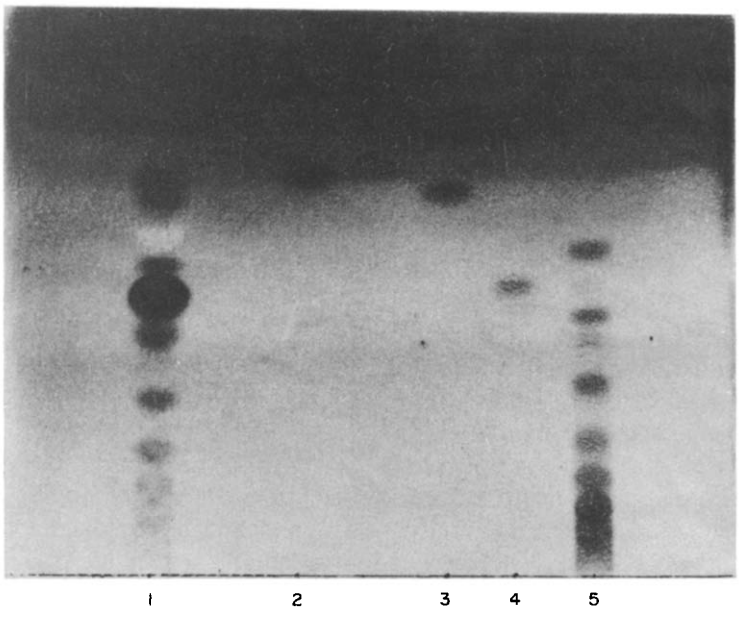

Fig. 1. Chromatogram of sugars of an infant milk; 1: infant milk:water (1:1); 2: glucose: 14 mg/100 ml; 3: galactose: 14 mg/100 ml; 4: lactose: 70 mg/100 ml; 5: maltodextrines: 830 mg/100 ml.

As shown in Fig. 2, spots 1, 2, 3 and 4 were confirmed to be glucose, lactose, 3′-sialyllactose and 6′-sialyllactose respectively. Spots 5, 6 and 7 were confirmed to be fractions of oligosaccharides. They were isolated by preparative chromatography and they all released glucose, galactose and fucose when mild hydrolysis was carried out. Spot 5 also contains *N*-acetyl glucosamine as it reacts with Elson-Morgan reagent.

Samples of milk of the same donor 45 days after she gave birth were also chromatographed (Fig. 3). The chromatogram was quite similar to the former. However, the fractions of oligo-

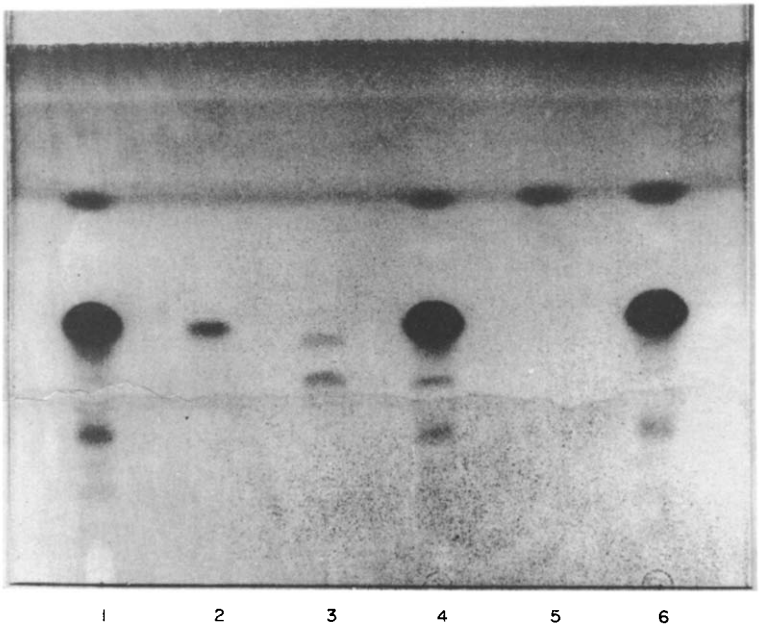

Fig. 2. Chromatogram of human milk; 1: human milk:water (1:1); 2: lactose: 70 mg/100 ml; 3: 3′ and 6′ sialyllactose: 210 mg/100 ml; 4: human milk: 3′ and 6′ sialyllactose (1:1); 5: glucose: 14 mg/100 ml; 6: human milk: glucose (1:1)

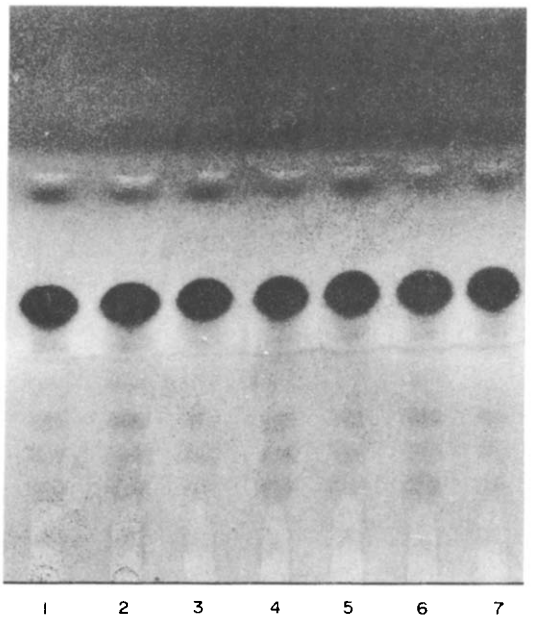

Fig. 3. Chromatogram of human milk from the same donor 1, 3, 5 and 7: sample of milk after 45 days of delivery. 2, 4 and 6: sample of milk after 15 days of delivery.

saccharides were in less concentration and subsequently the glucose concentration was increased.

When samples of milk from different donors, who had delivered babies 15 days before, were chromatographed, strong differences were observed in the chromatogram as a function of the donors (Fig. 4).

Therefore, it can be said that the chromatogram of sugars from milk depends fundamentally on the donor, the maturity of the milk and its origin (human and infant milk formula). All of that can be detected by thin layer chromatography which is a very simple technique that can be used in any laboratory.

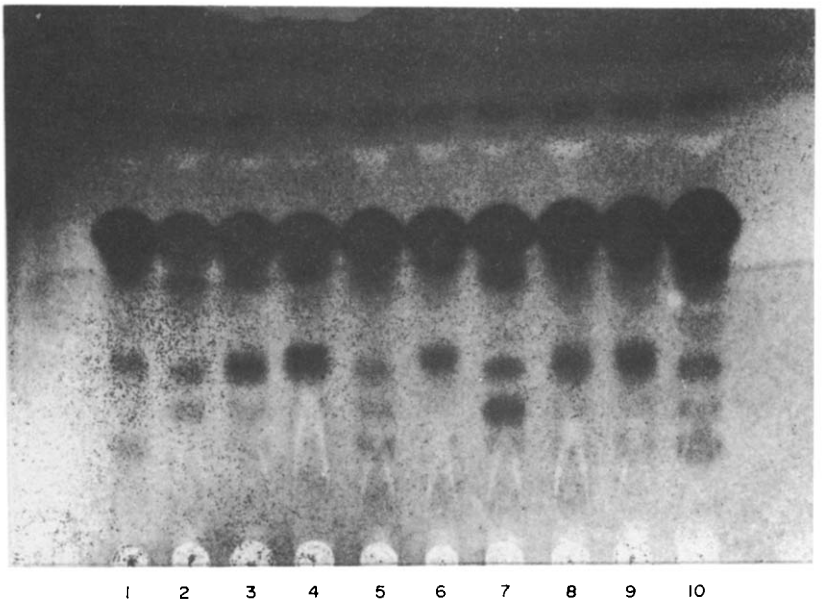

Fig. 4. Chromatogram of sugars of milks from several donors 1–10 spots belong to milks from different donors.

A FLOW-CELL OPTOSENSOR FOR LEAD BASED ON IMMOBILIZED DITHIZONE

WALACE A. DE OLIVEIRA* and RAMAIER NARAYANASWAMY†
Department of Instrumentation and Analytical Science, UMIST., P.O. Box 88, Manchester M60 1QD, U.K.

(*Received* 24 *March* 1992. *Accepted* 31 *March* 1992)

Summary—Dithizone immobilized on XAD-4 resin has been studied as a sensor element of an optical sensor for lead using a flow-cell. Using this arrangement, lead in solution has been determined in the concentration range 1×10^{-5}–$3 \times 10^{-7}M$ with a detection limit of $1 \times 10^{-8}M$ (*i.e.*, 2 μg/l.). The standard deviation of the method for the measurement of lead at a concentration of $1 \times 10^{-6}M$ was found to be 7%. The response of the sensor was reproducible and can be regenerated using 0.01*M* hydrochloric acid followed by citrate-hydroxylamine solution.

The toxicity of heavy metals is very high and their adverse effects upon human life are well recognized.[1] Among the heavy metals, lead is one which merits great environmental concern[2] because it is widespread and has contaminated the whole biosphere. It is believed that no other chemical pollutant has accumulated in humans so close to the threshold of potential clinical poisoning.[3] Therefore, there is a great need of monitoring the concentration of lead in the environment.

Determination of lead in environmental samples is usually performed by atomic absorption spectrometry or other methods.[2] In some instances, however, it is desirable to perform the analysis *in situ*, or to monitor the pollutant concentration continuously and remotely. Optical fibre chemical sensors have the potential to meet this demand[4,5] provided characteristics such as sensitivity and reliability can be achieved.

The mostly widely studied spectrophotometric reagent for lead is probably dithizone (diphenylthiocarbazone). The spectrophotometric procedure based on this reagent and solvent extraction technique was an official method for many years[6,7] and has proved to be reliable. Though other reagents such as immobilised Xylenol Orange[8] has been studied in the development of optical lead sensors, the possibility of using the dithizone reaction as the basis in the development of an optical sensor for lead was pursued.

EXPERIMENTAL

Instrumentation

The instrumentation employed in this work was similar to that previously reported.[9] It comprises a quartz-halogen lamp (12V, 30W) whose optical radiation was modulated by an optical chopper (Bentham 218) set at a frequency of 430 Hz and focused onto the end of a bifurcated optical fibre (Optronics). The optical fibre was inserted perpendicular to the axis of a cylindrical compartment of a flow cell (4 mm long and 3 mm in diameter) fabricated from a perspex block. A fine wire mesh was placed at one end of this compartment to block the reagent phase, which was loaded into the flow cell with the aid of a peristaltic pump (Watson-Marlow 202V).

Light reflected from the reagent phase was collected by the optical fibre and guided to a monochromator (ISA Instruments H-1061) and subsequently detected by a photomultiplier (Hamamatsu R446). The signal was enhanced by a current amplifier (Bentham 286) and a lock-in amplifier (Bentham 223) synchronized with the optical chopper frequency, and was recorded on a chart recorder (BBC SE120).

Reagents and solutions

All chemicals were of analytical reagent grade. The citrate (0.01*M*)/hydroxylamine

†Author for correspondence.

hydrochloride (0.05M) solution was made by dissolving appropriate amounts of these chemicals in demineralized, distilled water and adjusting the pH to 8.0 with ammonia solution.

The standard solutions of lead were freshly prepared by dissolving dried lead nitrate in the citrate/hydroxylamine hydrochloride solution.

Procedure

A calibration curve was obtained by the following procedure: to 10.0 mg of Amberlite XAD-4 (mesh < 70 μm), 10 ml of a saturated solution of dithizone in methanol was added and allowed to stand for about one hour. The whole suspension was then sucked into the flow cell with the help of the peristaltic pump. About 5 ml of the citrate/hydroxylamine solution was passed through the reagent phase before measurements were taken.

The measurements were carried out using two procedures as described below. In the method of 'kinetic analysis', the standard solutions of lead were allowed to flow at a constant flow-rate, and the analytical signal was recorded as a function of time. For measurements using the 'concentration procedure', only the initial and final values of reflectance were recorded. The light path was blocked during the addition of lead solutions and the regeneration of the reagent phase to avoid any photodegradation. The reagent phases were regenerated by passing about 5 ml of 0.01M hydrochloric acid followed by about 5 ml of citrate/hydroxylamine solution through the flow-cell.

The measurements were expressed as the relative reflectance, defined as the reflectance of the lead complex minus that of the immobilized dithizone alone.

RESULTS AND DISCUSSION

Immobilization

Immobilization of dithizone was carried out with both non-ionic (Amberlite XAD-2, XAD-4 and XAD-7) and ionic (Amberlite IRA-400) resins. Best results were obtained with the Amberlite XAD-4 which was chosen for further investigations. The effect of experimental parameters on immobilization was studied by varying the time (in the range 60–210 min), concentration of dithizone (from $1 \times 10^{-5}M$ to saturated solutions) and particle size of the resin (<70 to 200 μm). It was observed that reagent phases with lower concentrations of dithizone yielded good sensitivity but lower stability, whereas those with higher concentrations of the reagent produced more stability but sluggish response. Optimum conditions of response were determined using a time of 60 min, fresh saturated solutions of dithizone and XAD-4 beads with diameter less than 70 μm. No leaching of the reagent was observed upon passage of aqueous solutions (citrate–hydroxylamine solution or dilute hydrochloric acid) through the immobilized dithizone.

Figure 1 shows the diffuse reflectance spectrum of the immobilized dithizone and that of the lead complex. It can be noted that the formation of the complex causes a large increase in reflectance, which is due to a sharp change in colour of the reagent phase from green to red. The maximum divergence between the two spectra was observed at 650 nm and this wavelength was, therefore, used for the analytical measurements.

Photodecomposition studies

It was observed that the immobilized dithizone was susceptible to photodecomposition caused by the light from the quartz-halogen lamp. This resulted, with time, in an increase in reflectance which affected the accuracy of the measurements. The sensitivity to light of solutions of dithizone has been frequently studied.[7,10] Meriwether *et al.*,[11] for example, found that in benzene solutions decomposition was fast with a radiation of low wavelength, but with light of wavelengths above 400 nm there

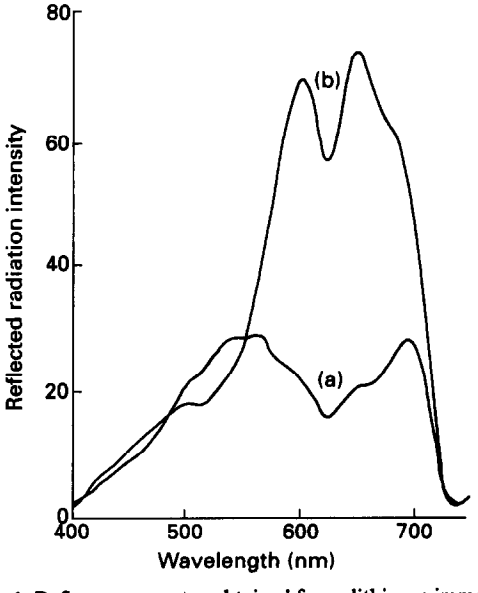

Fig. 1. Reflectance spectra obtained from dithizone immobilized on XAD-4, (a) before and (b) after reaction with lead ions.

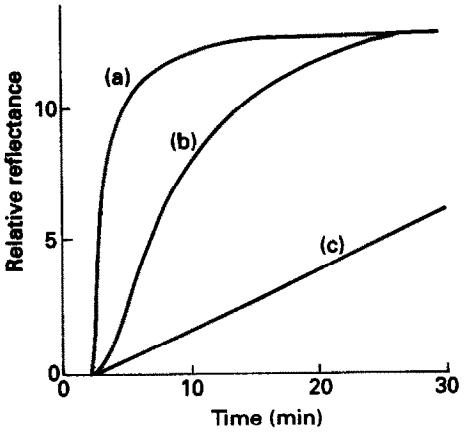

Fig. 2. The variation of relative reflectance with time obtained by using solutions of lead ions at concentrations of (a) $1.0 \times 10^{-4}M$; (b) $1.0 \times 10^{-5}M$ and (c) $1.0 \times 10^{-6}M$, in the flow-cell at a flow-rate of 0.65 ml/min.

was no decomposition. Accordingly, an attempt to avoid photodecomposition was made by inserting a coloured glass filter in front of the light source which eliminated light below 580 nm. This, however, diminished the photodecomposition rate but did not eliminate it. It appears that the adsorption of dithizone on the cross-linked copolymer (styrene–divinylbenzene) has created an environment that is more susceptible to photodecomposition than in solution. However, photodecomposition was almost eliminated by installing a band-pass filter (Ealing Electro Optics) which allows only a narrow passage of radiation with a peak at 650 nm. With this filter, the increase in relative reflectance due to photodecomposition, during a period of three hours, was about 1% of the magnitude of the average analytical signal. For much shorter exposure times used during the measurement in this work, therefore, this error can be neglected.

Dynamic range

Typical analytical curves of signal response as a function of lead concentration are shown in Fig. 2. It can be noted that the slopes of the curves are smaller at lower concentrations. All curves, however, were observed to reach the same constant value in reflectance at which further passage of lead solutions caused no more increase in the relative reflectance. This point represents the state where all of the immobilized dithizone had been consumed by reaction with lead ions. Under this circumstance it is preferable to use a kinetic analysis approach. This can be done by choosing a specific time that embraces the range of concentration of interest. Setting, for example, a time of 15 min enables determination of lead in the range 1.0×10^{-5} to $1.0 \times 10^{-6}M$. As can be seen in Fig. 3(a), a linear relationship between the relative reflectance and the logarithm of concentration, was obtained within this concentration interval with a correlation coefficient of 0.993.

In order to extend the dynamic range to lower concentrations without overexposing the dye to the light source, the concentration procedure was used. It consists of measuring the relative reflectance before and after the passage of a fixed volume of sample solution. This volume is chosen to encompass the desired range of sample concentration. In order to evaluate the possibility of lead determinations at lower concentrations, a volume of 100 ml was used. Figure 4 shows a typical experimental response. Between each measurement, the light path was blocked in order to reduce the photodegradation of reagent. The standard (or regenerating) solutions were allowed to flow through the reagent phase and the relative reflectances were

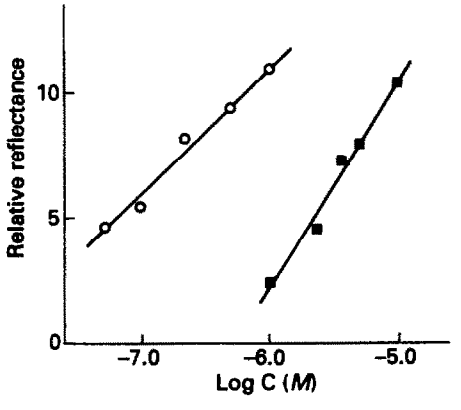

Fig. 3. Calibration plots obtained by the kinetic approach (■) and the concentration procedure (○).

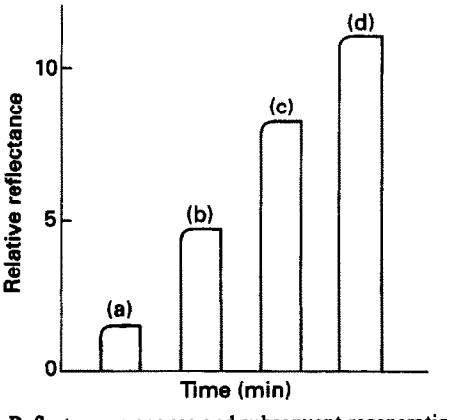

Fig. 4. Reflectance response and subsequent regeneration of the sensor obtained at lead concentrations of (a) $0.0M$; (b) $5.0 \times 10^{-8}M$; (c) $2.2 \times 10^{-7}M$ and (d) $1.0 \times 10^{-6}M$.

recorded. A linear relationship between the relative reflectance and concentration was observed [Fig. 3(b)] with a correlation coefficient of 0.990.

The limit of detection of lead, defined here as the concentration equivalent to a signal four times the standard deviation of the blank, was estimated as $1 \times 10^{-8}M$. The reproducibility of the response was evaluated by performing several measurements using the same standard solution and reagent phase. This resulted in the relative standard deviation for 7 samples containing $1.0 \times 10^{-6}M$ lead solution of 7%.

Regeneration of sensor

Regeneration of the reagent phase can be accomplished by passing about 5 ml of $0.01M$ hydrochloric acid followed by about 5 ml of citrate–hydroxylamine solution. The passage of dilute solution of hydrochloric acid washed out lead instantly and completely. This is not surprising because lead ions react with the basic form of dithizone (HDz) and the lead dithizonate, $Pb(HDz)_2$, is formed only in neutral and basic media. Using the concentration procedure, more than 10 cycles of complexation and decomplexation of lead were possible without any sign of decreasing response.

The immobilized dithizone is best stored in the dark in the refrigerator, and in a solution of citrate–hydroxylamine or dilute hydrochloric acid. Under these conditions the reagent phase was found to be stable for at least one month.

Load of the immobilised reagent

The amount of the dithizone immobilised on XAD-4 was determined by desorbing the dye with chloroform and determining its concentration spectrophotometrically. Thus, 10 μmole of dithizone was found per 1.0 g of XAD-4. This value can be compared with the amount of lead ion necessary to saturate the reagent phase. From Fig. 2 it can be noted that about 16 ml of $1.0 \times 10^{-5}M$ solution of lead were required to reach the constant value in relative reflectance. This indicates that approximately 0.16 μmole of Pb^{2+} ions were necessary to saturate the dithizone contained in 10 mg of resin. This is higher than the stoichiometric value (0.05 μmole) and seems to indicate that, at the operating conditions of the peristaltic pump, some of the lead ions pass through the flow cell without reacting with the reagent phase. However, at saturation, a complete change of colour of the reagent phase (from green to red) is noted and it can be assumed that all of the immobilized dithizone has formed the metal complex. Furthermore, one can visualize that the molecules of dithizone adsorbed on the polymeric matrix as having a structure that favours the metal complex formation.

Comparison with solvent extraction

The behaviour of the immobilized dithizone resembles that observed in the solvent extraction method. Although, in the basic medium dithizone becomes yellow in colour, the immobilized form remains green in the citrate solution at pH 8.0. Furthermore, the colour change due to complex formation on the surface of the solid matrix is similar to that found in the solvent extraction procedure. It appears that the immobilized reagent can be considered as a solid solution phase capable of extracting a number of metal ions from the aqueous phase. Vast amounts of literature available on such extraction procedures[7,12] may be used as a guidance in the development of sensors for these metal ions and also in the study of interferents in a particular sensor, which will be similar to that reported in the literature.

CONCLUSIONS

The experimental procedures developed in the present work have enabled the determination of lead ions in solution over a wide concentration range (about 3–4 orders of magnitude). The low detection limit for lead determination is suitable in the analysis of most environmental samples including drinking water (for which the recommended upper safe limit is 50 μg/l.).[13] Dithizone has been used as a preconcentrating reagent in conjunction with other techniques such as atomic absorption spectrophotometry.[14,15] The advantage of the method reported here is that it can be operated remotely and in a real-time basis. The method can find application in flow injection analysis[16] and in on-line as well as field applications of lead analysis.

WATER SORPTION ISOTHERMS ON AMINOPROPYLTRIETHOXYSILANE COATED SURFACE ACOUSTIC WAVE SENSORS

JULIE T. WOOD and JOHN F. ALDER*
Department of Instrumentation and Analytical Science, UMIST, P.O. Box 88, Manchester M60 1QD, UK

(*Received* 1992. *Accepted* 14 *May* 1992)

Summary—Water sorption isotherms were obtained on surface acoustic wave sensors (SAWS) coated with aminopropyltriethyoxysilane (APTES), and on uncoated SAWS of which the substrate material was polished ST-quartz. The isotherms were obtained at 25°, 30° and 40° over the range 1–80% relative humidity (RH). The isotherms exhibit BDDT type III characteristics typical of weak gas–solid interaction. The isotherms showed good fit to quadratic equations relating frequency change on exposure to humid air with relative humidity. There was no significant hysteresis in the isotherms when the SAWS was taken through a cycle of relative humidity at any of the three temperatures employed. These results are similar to those obtained in earlier work on FPOL and polyvinylpyrollidone coated SAWS. They demonstrate that a correction algorithm based on a quadratic equation should be possible to overcome water vapour response of coated SAWS.

Surface acoustic wave sensors (SAWS) have been employed widely over the last decade and are still the subject of active research. In this laboratory, and previously in the analytical chemistry laboratories at Imperial College under the direction of Professor T. S. West, we have carried out extensive studies on the interaction of gaseous species with coated quartz bulkwave piezoelectric crystals (PZX)[1,2] and latterly their more recent SAWS counterparts.[3]

All sensors that rely upon reversible sorption of gas onto their surface as a prerequisite to the sensing process, will exhibit a response which is closely related to the sorption isotherm of the gas over the surface. It may not be exactly the same, because of non-linear response in the relationship between partial pressure of the gas (p) over the surface, mass of material sorbed (m) and the response function of the sensor R(m.p). In the work ongoing in this laboratory a series of experiments is being carried out to determine the nature of the response isotherms of SAWS coated with materials which exhibit selectivity towards target species, but also, and almost inevitably, exhibit response to water vapour. Previous work has specifically addressed the sorption of water vapour onto polyvinylpyrrolidone and F-POL (a fluorinated polyether-polyol),[4] which are known to respond to organophosphonate compounds[5–7] and it was demonstrated that the isotherms for water resembled the BDDT type III, characteristic of weak gas–solid interactions, and could be modelled using a quadratic equation relating SAWS frequency change to the relative humidity of the challenge gas.

The present work studied the response of aminopropyltriethyoxysilane (APTES) coated SAWS, which is known to sorb nitrobenzene,[8] to water vapour. This was the preliminary step in a continuing programme to study the interaction between the surface of coated SAWS and a two-component vapour system, nitrobenzene and water, in air.

EXPERIMENTAL

The experimental rig used to generate the humidified atmospheres was in all respects identical to that described by Fox and Alder.[4] The SAWS employed were manufactured for the authors by Plessey (Towcester, U.K.) and comprised a pair of 70 MHz delay lines on a quartz substrate. The SAWS and its associated oscillator have been described elsewhere.[9] The output of each SAWS controlled oscillator was to a Philips PM6673 frequency counter (Philips, Cambridge, U.K.) with digital-analogue converter output to a strip chart recorder.

*Author for correspondence.

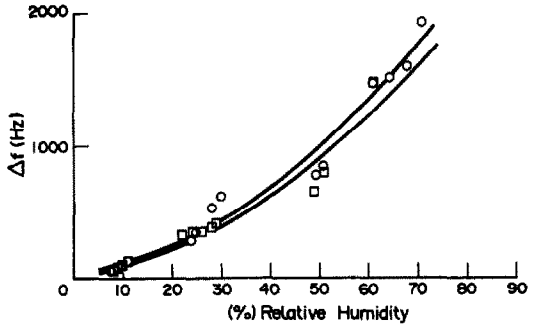

Fig. 1. Sorption isotherm at 25° onto APTES coated (side 1 —□—) and notionally uncoated (side 2 —○—) SAWS. It can be seen that there is no significant difference between the responses of the two sides, almost certainly an indication that the coating had crept from side 1 to side 2. Error bars are standard deviation.

The rig ran continuously throughout the period of the experiments. Relative humidity could be maintained to within ±0.5% and temperature within ±0.5° over a period of 9 months. Equilibrium of the SAWS to switched dry–wet air stream was of the order 15–100 min, depending on the actual change imposed.

Coating of the SAWS with APTES was achieved using a fine (00000 grade) paintbrush (available from model makers shops). A 20% solution of APTES in toluene was brushed on to the area in between the electrodes on one side of the SAWS only. The procedure employed was to first wash the SAWS free of grease using methylene chloride in a clean glass beaker and then allow it to dry in the oven at 60°, and cool in a desiccator. It was then placed in the oscillator circuit and maintained in the test cell at 25° and 1% relative humidity (RH) (±0.5% RH) as read on a Vaisala HMP123 humidity meter (Vaisala, Cambridge, U.K.). When the frequency of the SAWS had become stable, the side of SAWS exhibiting the lower frequency was coated. This caused the frequency difference between the coated and uncoated sides to separate further, thus minimising the problem of the oscillators associated with the two sides, locking

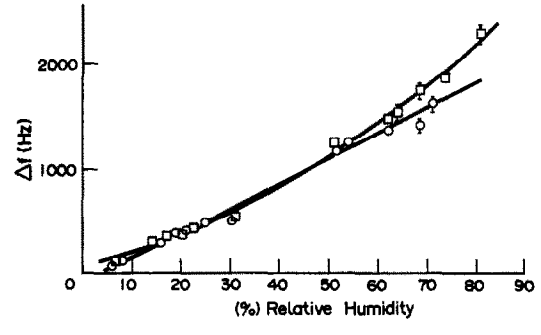

Fig. 2. Sorption isotherm at 30°; see legend to Fig. 1.

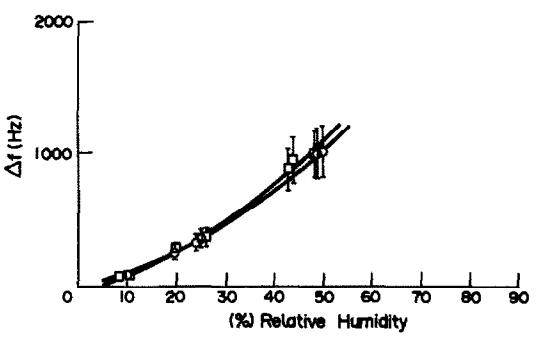

Fig. 3. Sorption isotherm at 40°; see legend to Fig. 1.

together. The coated SAWS was then placed in an oven at 45 ± 2° overnight to evaporate volatile materials and allow the coating to relax. The SAWS was then brought to equilibrium in the last cell at 25° 1% RH and the new frequencies noted. The resonant frequency of the uncoated side was virtually unchanged (±100 Hz) whereas the frequency of the coated side had reduced. On one occasion, for example, this was −5.39 kHz which corresponded to a coating of approximately 21 ± 3 molecular layers, calculated from the equation

$$\Delta f = (k_1 + k_2)\, f_o^2\ \text{m/A}$$

where k_1 and k_2 are the material constants for quartz,[10,11] f_o is the unperturbed frequency, m is the mass of coating and A is the surface area over which the coating was applied. Much of the work reported here was carried out with the 21 layer coated SAWS.

The coated SAWS was maintained in the test chamber[4] in a stream of air maintained at different relative humidities and one of the temperatures 25,30 or 40° (±0.5°). The flow rate chosen was 410 cm³/min which was shown to give reasonable response time between the humid and dry air flows (approximately 1 min on switchover to 95% change of frequency).

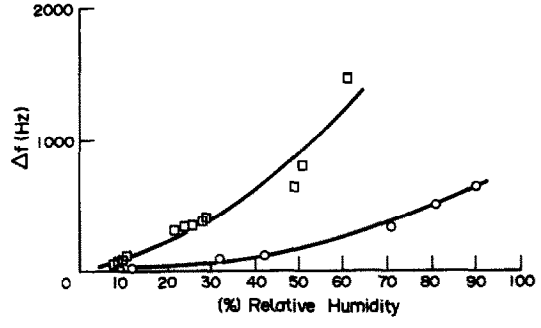

Fig. 4. Sorption isotherm at 25° onto APTES coated side 1 (—□—) of the same SAWS as in Fig. 1, (same data) compared with sorption isotherm onto a clean, uncoated SAWS at the same temperature, (—○—).

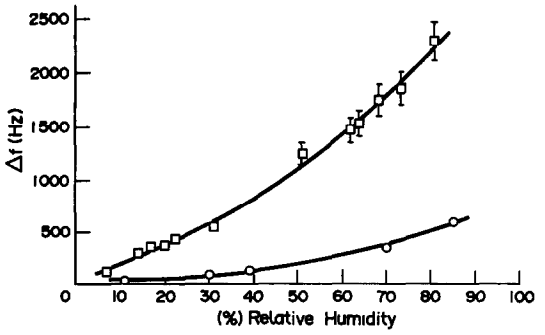

Fig. 5. Sorption isotherm at 30° onto APTES coated side 1 (—□—) of the same SAWS as Fig. 2, (same data) compared with sorption isotherm onto a clean, uncoated SAWS at the same temperature, (—○—).

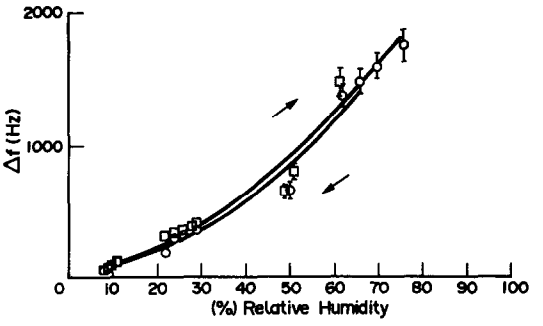

Fig. 7. APTES coated SAWS (side 1 as in previous figures) exposed to relative humidity cycle at 25°. Isotherms drawn (—○—) for ascending RH: (—□—) for descending RH.

The changes in relative humidity took longer to stabilize (15 min typically). RH could be maintained to within about 0.5% RH. The whole system was maintained in this regime for several months during the course of the experiments.

The sorption isotherms were obtained by first stabilizing the SAWS in a dry (1% RH) atmosphere at the chosen temperature and noting the frequency and the frequency stability. The flow was then switched to the humid air at the same temperature and allowed to stabilize again. These cycles were then repeated, each taking about 15 min. The RH was then changed and the cycles repeated to obtain the data points on the isotherms. Each isotherm took between one and three weeks to obtain.

RESULTS AND DISCUSSION

It was noted that the frequency stability degraded as the temperature of the SAWS increased from 25 to 40°, being typically ±2 Hz p-p at 25° degrading to ±10 Hz p-p at 40° for the uncoated, and ±15 Hz for the coated side, in dry air. In humid air the problem was worse, for example, the SAWS exposed to 80% RH at 40° for 2 hr exhibited noise of about ±15 Hz p-p, rendering it virtually unusable as a sensor. The authors are not sure what causes this effect, but it is at least in part influenced by the presence of the coating, as the noise is greater on the coated side of the sensor.

Isotherms were initially obtained using the dual SAWS described above, one side coated with APTES and the other side notionally uncoated. Figures 1–3 show the isotherms for 25°, 30° and 40° respectively. One notes however, that the two sides of the SAWS behaved in a very similar manner, with hardly any significant difference between them. This was not thought to be a true result. The isotherms were obtained for another SAWS device which had been thoroughly cleaned with methylene chloride, and indeed had never been coated with APTES. The isotherms at the three temperatures are given in Figs 4–6, for the uncoated, second SAWS, and the truly coated side of the first SAWS. The initial frequencies [$f_0 x$) of the two SAWS oscillators were very similar. One can clearly see a difference between the sorption isotherms onto the uncoated SAWS and the coated device in these figures. This indicates that some of the coating had crept from the coated, to the uncoated side of the dual SAWS. One would expect to detect an APTES monolayer

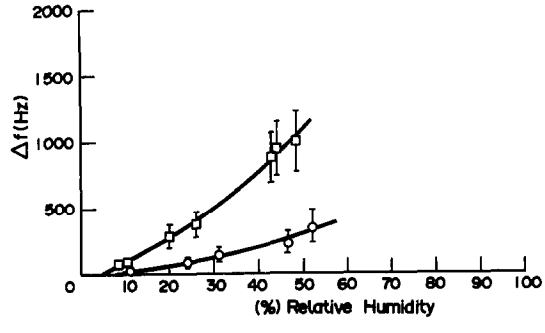

Fig. 6. Sorption isotherm at 40° onto APTES coated side 1 (—□—) of the same SAWS as Fig. 3, (same data) compared with sorption isotherm onto a clean, uncoated SAWS at the same temperature, (—○—).

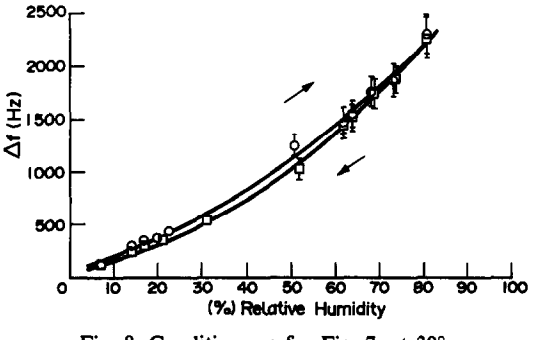

Fig. 8. Conditions as for Fig. 7, at 30°.

coverage on a 70 MHz SAWS as it represents about a 240 Hz frequency shift. Irreproducibility in manipulating and fitting the SAWS in its socket however, somewhat blurs these small changes in frequency, and a partial monolayer could readily be missed using this method of diagnosis. The water sorption isotherms onto the uncoated SAWS were similar in shape and magnitude to those obtained in previous studies in this laboratory, using 158 MHz devices.[4] The fact that creep was not evident using the FPOL and polyvinylpyrrolidone coatings in the previous work[4] was possibly due to the much higher molecular weight and viscosity/lower mobility of the polymers compared to the lower molecular weight APTES.

As was found in previous studies,[4] the sorption isotherms resemble the BDDT type III behaviour[12] which are characteristic of weak gas–solid interactions, particularly where the sorbed gas is polar and acts as sites for stronger polar-polar sorption of further water molecules. One would expect therefore a quadratic relationship between the frequency change on exposure of the SAWS to water vapour, and the relative humidity. Using a curve fitting routine "Techcad", quadratic functions of the form $y = ax^2 + bx + c$ were fitted to the data points obtained, and the best fit curves are shown as the solid lines in the Figs 1–6. It must be emphasized that these are purely empirical fits and although they show good regression analysis coefficients to the measured data, they have no detailed quantitative relationship to the underlying isotherm theory.[12] Table 1 shows the equation coefficients and the regression coefficient for the Figs 4–6. The effect of cycling the coated SAWS through a range of relative humidity was essayed at 25°, 30° and 40°. Quadratic functions were fitted to the data in ascending and descending order and the data shown in Figs 7–9. From the data it can be seen that there is no significant hysteresis in the cycle.

Table 1. Table of water sorption isotherm equation coefficients. Fitting the isotherm data to an equation of the form $y = ax^2 + bx + c$ where y represents frequency change (Δf/Hz) and x represents relative humidity (% RH)

Data from Figure	Coating	Temp (°C)	Equation coefficients (c)	(b)	(a)	Regression coefficient
4	APTES	25	9.6	5.74	0.24	0.978
4	Uncoated	25	68.3	−3.21	0.10	0.996
5	APTES	30	65.3	11.95	0.18	0.998
5	Uncoated	30	71.0	−2.31	0.10	0.995
6	APTES	40	−41.0	11.24	0.23	0.997
6	Uncoated	40	0.79	1.66	0.09	0.989

CONCLUSIONS

This work has shown that SAWS coated with APTES demonstrate sorption isotherms for water vapour which can be represented by quadratic equations which fit well over the range 1–70% RH at 25–30° and up to 50% RH at 40°. At higher temperatures and higher RH the frequency response becomes increasingly noisy for reasons which are at present not clear. Hysteresis in the adsorption and desorption curves is almost indiscernible at 25, 30 or 40° with the coating employed (21 ± 3 monolayers). These results indicate that it should be possible to partially correct the response of an APTES coated SAWS for water vapour adsorption up to 30° and 70% RH by data processing. There is bound to be a further effect due to competition between water vapour and competing target analytes for active sites, which will further complicate the response characteristics of coated SAWS. Current work in this laboratory is investigating the response of APTES coated SAWS to nitrobenzene, in atmospheres of varying relative humidity and temperature.

Acknowledgements—We are grateful to the Plessey Company for the gift of the 70 MHz SAWS.

POLARIMETER DESIGN FOR A NITROGEN LASER SOURCE

ROGER STEPHENS
Department of Chemistry, Dalhousie University, Halifax, Canada B3H 4J3

(*Received* 12 *March* 1992. *Accepted* 31 *March* 1992)

Summary—The system uses a Brewster angle reflector as a passive amplifier. This device reduces intensity without causing a serious reduction in either the signal of interest or the signal-to-noise ratio. It also reduces the need for a high quality analyser. However, polariser quality is critical and determines the background light level at the detector. The present work allowed shot-noise-limited operation to be attained. However full optimization was not achieved because of excessive background transmission at optimum alignment.

Laser sources have been used in polarimetry to achieve high sensitivity, for example in the detection of optically active compounds by liquid chromatography.[1,2] The sensitivity which is obtained is the result of the good signal-to-shot-noise ratio inherent in a high photon count. In practice however the task of designing a laser polarimeter to actually reach the shot noise limit is not trivial, because of the need to reject flicker noise: a requirement which becomes progressively more difficult to meet as the source intensity is increased. Various ways to approach this problem have been described.[3–5]

The difficulty of reaching the shot noise limit is compounded if a pulsed source such as a nitrogen laser is used. Flicker noise associated with pulse-to-pulse variability is high. Severe demands are placed on optical and electronic linearity. Selective modulation and synchronous detection cease to be easily employed. Finally, Davis *et al.* have warned of a risk of degraded polariser performance at the flux levels produced by a nitrogen laser,[6] which means that a high background can be expected at the detector even if polariser and analyser are exactly crossed.

Although obvious difficulties are involved in the use of a pulsed source for polarimetric measurements, such a system is potentially interesting for several reasons: examination of transient phenomena becomes easier; ultraviolet observation becomes more accessible; and optical rotation caused by non-linear interactions can be expected.[7–9] With these benefits in mind the present work was carried out to look at the feasibility of building an instrument around a nitrogen laser source and to examine its capacity to reach the shot noise limit. The method of design used the technique of passive amplification.[10,11]

THEORY

In the system employed here a linearly polarized laser beam undergoes optical rotation in the medium of interest and is then reflected from a glass plate aligned close to the Brewster angle. The effect of the plate is to amplify the angle of optical rotation at the cost of a reduction in beam intensity.[12] This is precisely the combination of characteristics needed to deal with an intense pulse, giving high sensitivity towards the signal of interest while avoiding an overload of the detector.

The schematic optical train shown in Fig. 1 will be described by means of the Jones calculus.[13] Preliminary experimental examination showed that the Jones matrices of polariser P_x and of the glass plate G could be written:

$$P_x = \begin{pmatrix} 1 & iA \\ iA & 0 \end{pmatrix} \quad (1)$$

and

$$G = \begin{pmatrix} K_x & 0 \\ 0 & K_y \end{pmatrix} \quad (2)$$

where $i = \sqrt{-1}$ and all other variables are real. Hence the Jones vector of light reflected from the plate G is given by:

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix} = \begin{pmatrix} K_x \cos\Theta & 0 \\ K_y(iA\cos\Theta - \sin\Theta) & 0 \end{pmatrix} \begin{pmatrix} E_x^\circ \\ 0 \end{pmatrix} \quad (3)$$

where E_x° is the amplitude of light emerging from P_x and second order terms, involving

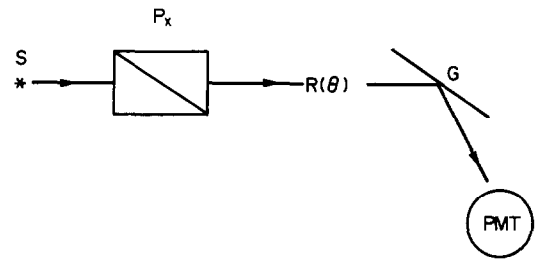

Fig. 1. Schematic optical train. S = source, P_x = polariser, G = glass reflector plate, PMT = photomultiplier.

AK_x for instance, have been neglected since K_x is small when G is aligned close to the Brewster angle. If

$$A \ll K_y \sin \Theta \tag{4}$$

then equation (3) describes light of an intensity reduced from its incident value by a factor of $K_x^2 \cos^2 \Theta + K_y^2 \sin^2 \Theta$ and an angle of optical rotation which has been amplified by K_y/K_x. Thus it is essential for A to be as small as possible in order to satisfy equation (4), and hence to maximise the amplifying effect of the glass reflector plate G and to minimise the background transmission of the system. The level to which A can be reduced is a measure of the purity of the linear polarization of the source.

Interestingly equation (3) remains valid even when an imperfect analyser is used to measure the Jones vector

$$\begin{pmatrix} E_x \\ E_y \end{pmatrix}.$$

For instance, a Wollaston prism will serve to spacially separate E_x and E_y. By analogy with equation (1) the Jones matrix, **W**, of the Wollaston prism becomes:

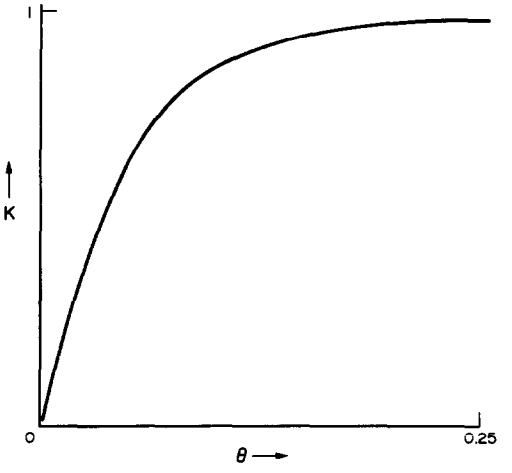

Fig. 2. K *vs.* Θ; K calculated as the ratio of equation (9)/equation (10) in units of $\sqrt{N^\circ}\,\Delta\Theta$.

$$\mathbf{W} = \begin{pmatrix} 1 & iB \\ iB & 1 \end{pmatrix} \tag{5}$$

and the Jones vector of light emerging from **W** remains the same as in equation (3) when second order terms are neglected.

The intensities corresponding to the Jones vector of equation (3) are:

$$I_x = K_x^2 \cos^2 \Theta I_x^\circ \tag{6}$$

$$I_y = K_y^2(\sin^2 \Theta + A^2 \cos^2 \Theta) I_x^\circ \tag{7}$$

where $I^\circ = E_x^{\circ 2}$.

The ratio, R, of the photon count on I_x, I_y over an integration time t is:

$$R = (I_y t \pm \sqrt{(I_y t)})/(I_x \pm \sqrt{(I_x t)})$$

$$= (N_y \pm \sqrt{N_y})/(N_x \pm \sqrt{N_x}) \tag{8}$$

Table 1. Summary of optical parameters

Reflector plate, G	$K_x = 3 \times 10^{-3}$, $K_y = 0.25$
Transmission efficiency of optical train, excluding G	15%
A^2 [equation (1)]	1×10^{-6}
X-channel photomultiplier characteristics:	
Photomultiplier quantum efficiency	15%
Gain (fixed)	4200
Output	1 volt across 0.001 μF
Half-width of output pulse	2 μsec
Estimated average cathode current	5 mA
Average anode current	0.5 mA
Laser output	5 μJ, 2 nsec duration
N^0 [equation (11)]	5×10^{12}
Calculated value of $\Delta\theta$ for unity signal-to-noise ratio from equation (11)	2×10^{-4}

Transmission and gain measurements were made using dc emission at 338 nm from a silver hollow cathode lamp. Photomultiplier characteristics were measured on the I_x channel at the same (fixed) gain used during data acquisition. The y-channel output at zero offset was 0.45 V across 0.001 μF, rising to 1 V at 0.06° offset at a gain of 4×10^5.

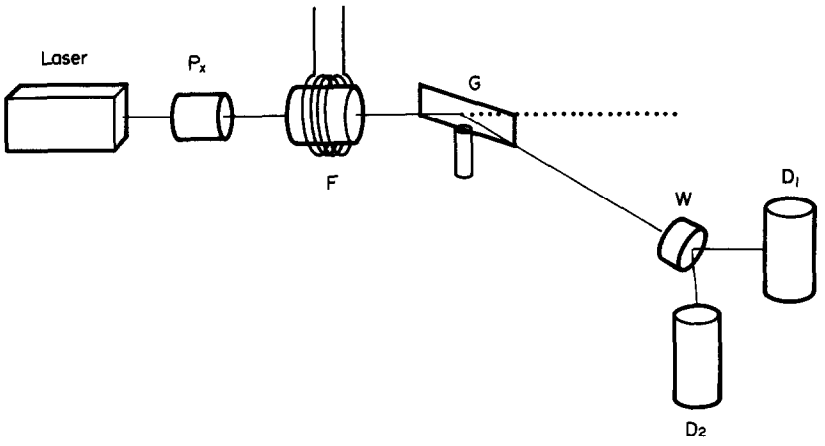

Fig. 3. Apparatus. P_x = polariser, F = Faraday cell, G = glass reflector plate, W = Wollaston prism, D1 and D2 = x- and y-polarisation detectors.

for a photon count $N = It$

$$\approx (N_y/N_x)(1 \pm 1/\sqrt{N_y})(1 \pm 1/\sqrt{N_x})$$

Hence

$$\frac{dR}{d\Theta} = 2K_y^2 \sin\Theta / K_x^2 \cos^3\Theta$$

i.e., the signal of interest, ΔR, is:

$$\Delta R \approx 2K_y^2 \sin\Theta \, \Delta\Theta / K_x^2 \cos^3\Theta \qquad (9)$$

with a shot noise level on R of

$$\sqrt{(N_y(N_x + N_y)/N_x^3)} \qquad (10)$$

The signal-to-noise ratio, r, is given by the ratio of equation (9) to equation (10) and can be written in the form

$$r = K\sqrt{N^\circ}\,\Delta\Theta \qquad (11)$$

where $N^\circ = I^\circ t$ is the source count. The limiting value of K for $A \to 0$, $\Theta \to 0$ is $2K_y$. Figure 2 shows values of K, calculated as the ratio of equation (9)/equation (10) and using experimental values of A^2, K_x^2, K_y^2 from Table 1, plotted against Θ. The maximum value of K in Fig. 2 is 0.99, corresponding to a minimum value of $\Theta \approx 1/\sqrt{N^\circ}$ for $r = 1$. The reduction in K from its upper limit of $2K_y$ results from the drop in signal-to-noise ratio, relative to an ideal system, which occurs when optical linearization is used to minimize the effect of background transmission.

In terms of the signal-to-noise ratio the procedure described above is equivalent to measuring the optical rotation signal of interest while simultaneously generating a reference pulse to correct for variations in source intensity. The present method of description is advantageous in that it identifies an optical geometry which will tolerate spatial inhomogeneity of the beam and which minimizes the intensities to which the detectors are subject. Both of these factors are important in allowing a full correction for laser power fluctuations to be obtained.

EXPERIMENTAL

The apparatus is shown in Fig. 3. The x- and y-polarised beams emerging from the Wollaston prism, W, corresponding to I_x and I_y in equations (6) and (7), were directed onto two 1P28 photomultipliers (detectors D1, D2 in Fig. 3). Dynode voltages were drawn from conventional divider chains using 100 K resistors for voltage division.

Following the procedure described earlier,[12] the plate G was aligned initially at the Brewster angle. The angle was then increased until the

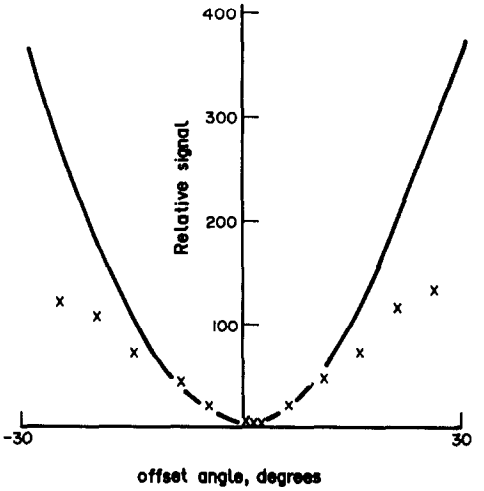

Fig. 4. Signal versus offset angle of polariser P_x. Solid curve: quadratic fit on lowest 6 point.

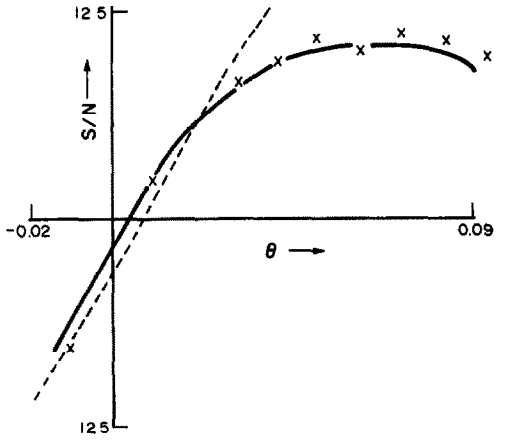

Fig. 5. Signal-to-noise ratio versus offset angle of polariser P_x. Solid curve: experimental. Dashed curve: signal-to-noise ratio calculated from equation (11) using the K values from Fig. 2 and the data in Table 1.

intensity of the x-polarised signal increased about 10-fold. Similarly, the y-polarised signal was raised above background by applying a small, known offset angle to polariser P_x, corresponding to the value of Θ in equation (9). The signal of interest, $\Delta\Theta$, was generated by the Faraday cell shown in Fig. 3. Construction of the cell has been described.[12]

All measurements were made on a laboratory-built dual channel boxcar integrator with delay and window times optimized to match the anode pulses of the photomultipliers. The two signals from the boxcar output channels went to a DEC MINC 11 computer, which calculated their ratio after each laser pulse; *i.e.*, the ratio corresponding to R in equation (8). Values of R and the R-to-noise ratio were

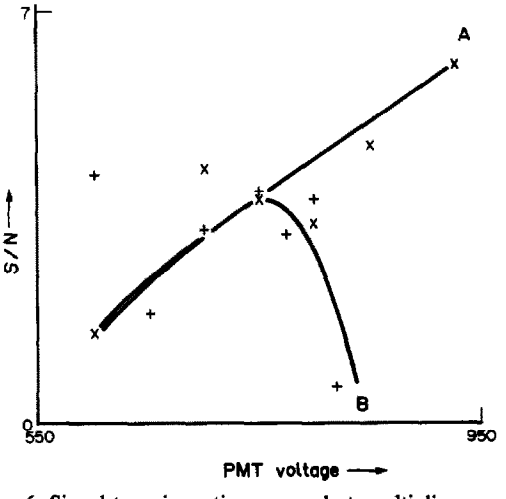

Fig. 6. Signal-to-noise ratio versus photomultiplier supply voltage. Curve A: offset angle on polariser $P_x = 0.02°$. Curve B: offset angle = 0.1°.

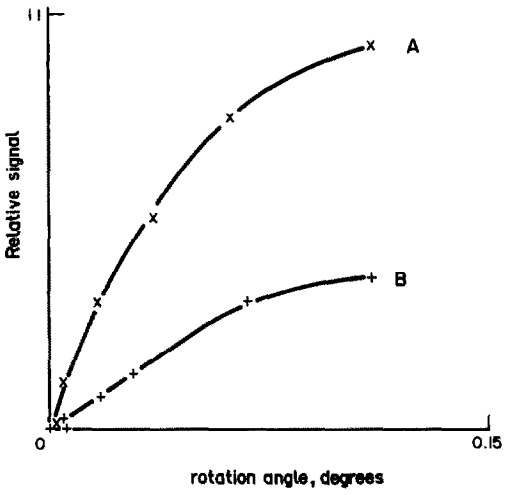

Fig. 7. Signal dependence on angle of rotation in Faraday cell. Curve A: photomultiplier supply voltage = 800 V. Curve B: 750 V.

displayed as the mean and standard deviation of up to 25 laser pulses. In order to minimize errors caused by detector non-linearity on the I_x channel the computer program rejected pulses with a value of N_x differing by more than 15% from the mean. Values of R were transferred to a chart recorder for a visual record as in Fig. 8 below.

RESULTS AND DISCUSSION

Light levels at the detectors

Some relevent characteristics of the apparatus are summarized in Table 1. The data in the Table lead to estimates for the photocathode and anode currents of 5 and 0.5 mA respectively for the I_x channel photomultiplier. The anode current is lower than the cathode current because of the increased pulse width at the anode. However, and even when the increased pulse width is considered, the current ratio is clearly inconsistent with the measured steady state gain. Therefore it was assumed that flux levels at the x-channel detector were high enough to cause the device to operate outside its usual linear response range, and to require the software correction mentioned above to limit the variation in I_x which would be accepted.

Detector non-linearity

Figures 4–7 show the observations which were made to determine the extent to which photomultiplier non-linearity was likely to affect the y-channel.

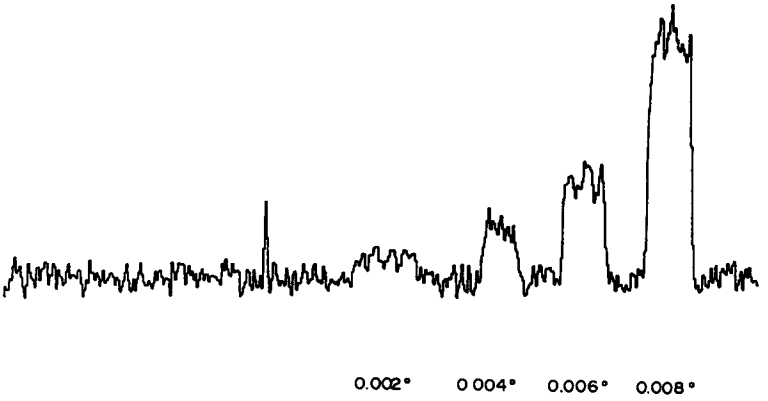

Fig. 8. Experimental signals from Faraday cell measured on single pulses from the laser.

Figure 4 shows the signal from the y-channel detector versus the angle of rotation of P_x. The solid line is the ideal $\sin^2 \Theta$ response curve fitted to the points close to the origin. Deviations at high light levels are obvious. That detector non-linearity is significant even at low offset angles is suggested by the results of Fig. 5, which shows that the signal-to-noise ratio falls off from the expected value, calculated on the basis of the curve in Fig. 2, at values of Θ above about 0.02°. Detector non-linearity means that pulse-to-pulse variations are no longer cancelled by the division of x- and y-channel signals: *i.e.*, flicker noise starts to degrade the signal-to-noise ratio.

Figure 6 shows the signal-to-noise ratio versus photomultiplier supply voltage at values of Θ of 0.02° and 0.1°. If the quantum efficiency of the photocathode is assumed to be independent of voltage then the maximum observed in curve B appears to represent an electron loss within the tube which occurs at higher voltages. Comparison of curves A and B shows the loss to be associated with the higher offset angle and, hence, the higher intensity. The data in Fig. 6 are one of several sets which were taken on successive days to determine that the pattern was consistent.

Similar behavior is evident in Fig. 7, which shows calibration curves at the two photomultiplier voltages used in Fig. 6. The upper curve shows the output stages to be able to handle a higher current than is demanded by the lower curve: nevertheless non-linearity on both curves is still apparent.

Capacitive de-coupling of the dynode load resistors and de-focussing of the incident beam, to cover a larger area of the photocathode, failed to change these observations. It is thought that they arise as a result of electron loss during transit through the tube when electron repulsion at high current densities overcomes the focussing effect of the dynode fields and allows spatial spreading of the electron beam to occur.

Signal optimization

The curve in Fig. 2 shows that the offset angle, Θ, should be sufficiently large for the effect of background transmission, [caused by incomplete source polarization; the 'A' term in equations (1) and (4)], to be insignificant. At the same time Θ should be small enough to avoid the detector non-linearity and degradation of signal-to-noise performance seen above. These requirements cannot be met simultaneously if the background transmission is too high. In the case of the present apparatus and with the laser output reduced to a level close to threshold the first condition requires Θ to be above about 0.1° (Fig. 2); the second requires Θ to be below about 0.02° (Fig. 5): *i.e.*, the degree of polarization of the source is a little below the limit of compromise.

Figure 8 shows experimental signals for Θ fixed at 0.05°. Unity signal-to-noise ratio is about 1×10^{-3}°. The noise dependence on intensity, under the same conditions, was determined by means of a variable aperture located between the laser and polariser P_x to vary the power delivered by the beam. Slopes of the resulting log plots of noise versus intensity varied between 0.4 and 0.7. Thus shot noise still appears to be dominant for the compromise value $\Theta = 0.05$°. However the response function K now falls below the optimum by a factor of about 3, using the curve in Fig. 2. Increasing the offset angle Θ improves K but degrades the signal-to-noise ratio, and vice versa: *i.e.*, the results shown in Fig. 8 are considered to be

essentially optimal for the particular combination of components used in the present apparatus.

CONCLUSIONS

It is considered that the instrumental design described here offers a viable way to use a photomultiplier to detect optical rotation on kilowatt-level light pulses. Operation close to the shot noise limit was found to be possible, although the present system failed to achieve an optimum signal-to-noise ratio. The reason for the shortfall lies in the need to avoid intensities where detector non-linearity and correspondingly increased flicker noise become evident. For the same reason higher laser power cannot be usefully employed with the existing arrangement.

Detector non-linearity is thought to be the result of electron scatter at high photocathode currents. Although appropriate modification and correction for this effect is possible, for example by an extension of the software correction used here, it is felt that the problem of detector non-linearity can probably be dealt with more satisfactorily by modification of the optical train. Equations (1)–(4) show that such modification can be approached through an improvement to the polarization quality of the source.

(*Received* 15 *March* 1992. *Accepted* 31 *March* 1992)

Summary—A method is described for the determination of arsenic, which combines a continuous flow hydride generation technique with an inductively coupled plasma atomic emission detection system. Some atomic absorption preliminary studies are described as well. Arsine is generated with $NaBH_4$ from a didodecyldimethylammonium bromide (DDBA) vesicular medium. The analytical performance of this vesicles-enhanced method is superior to the generation of the hydride from aqueous media: the detection limit (0.6 ppb) is improved by a factor of 2 and greater tolerance to interferences is observed for arsine generation from DDBA vesicles. Precision of As determinations is also improved. The proposed method has been validated for low As levels determinations in two Certified Reference Materials (CRM) sediments with satisfactory results. The potential of organized media to improve hydride generation is addressed.

The toxicity of arsenic to humans is widely recognised and consequently its determination in the environment and foodstuffs is of great importance. In sea and estuarine water, most arsenic is present as arsenate [As(V)], although low levels of arsenite [As(III)] and organoarsenicals (monomethylarsonic acid, dimethylarsinic acid, arsenobetaine, arseno-sugars, etc.) are also found.[1] These species are also found in marine organisms and terrestrial plants.

Although it is widely recognised that inductively coupled plasma atomic emission spectrometry offers adequate sensitivity for most environmental and clinical analyses, arsenic concentration levels in water samples are too low to be detected by ICP–AES.[2]

The necessarily low efficiency of nebulization, to prevent quenching of the plasma, is a serious drawback in the determination of toxic metals by ICP–AES due to the high sample consumption and its wastage before the measuring process. The introduction of samples in the vapour phase to the plasma provides a solution to these problems. Sensitivity is improved due to the increase of the transport efficiency and interferences may be overcome by the vapour generation.

Thompson *et al.*[3–5] first reported the combination of hydride generation techniques with ICP. Since then, a number of reports have appeared that discuss fundamental studies and applications[6–10] and theoretical aspects of hydride generation with ICP–AES. Particularly, the determination of arsenic by ICP based on arsine generation has been demonstrated to be subject to interferences, particularly from transition metal ions, which may affect the hydride generation process.[4,10–12] An approach to improve the selectivity could be a previous liquid–liquid separation of arsenic from interfering elements,[13] or a continuous on-line separation/hydride generation in the so-called "tandem on-line" technique used for As determination by ICP–AES and where the hydride is generated directly from the organic phase.[14]

The introduction of organic solvents into the ICP, however, continues to present particular difficulties[15] and therefore the use of micelles and other organised media, with a hybrid aqueous/organic character, could prove advantageous. In fact, we found that the presence of liquid solutions of "organized media", *e.g.*,

*Author for correspondence.

micelles and vesicles, may enhance the kinetics of the hydride generation.[16]

The singular characteristics of "organized media" such as solubilizing power, ability to build up a new "microenvironment", organizing reactants at molecular level, capacity to change the kinetics of a process, could provide a powerful tool for enhancing the sensitivity of arsenic and other hydride forming elements. In addition, their availability to react selectively with opposite charged reagents could also be used to improve the selectivity.

The purpose of the present work was to examine the ability of "organized media" to improve the analytical performance of hydride generation–ICP–AES technique by using arsenic as a model element.

As a result of our studies, a sensitive and selective analytical method for the determination of arsenic by ICP–AES has been developed. This method is based on continuous flow arsine generation from vesicles of didodecyldimethylammonium bromide (DDBA). The validity of the method for real sample analysis has also been tested through the successful determination of low levels of arsenic in some environmental samples.

EXPERIMENTAL

Apparatus

ICP–AES measurements. A Unicam ICP, model PU7000 spectrometer was used for emission measurements. It has a 40.68 MHz free-running radio-frequency generator, which includes an internal voltage regulator. A fixed quartz torch is used. The spectrometer uses a coarse-ruled echelle grating, and cross dispersion with a quartz prism for order sorting, resulting in a two dimensional spectrum, at the focal plane.[17] The nebuliser used consists of two platinum screens (dual platinum grid nebuliser): as the sample is nebulised from the first screen a primary aerosol is formed; the particle size is further reduced by impaction on a second screen. The nebuliser can act as an on-line gas–liquid separator when properly adjusted. As the liquid flows over the screens the hydride gases are entrained in an argon stream and are carried to the torch. The liquid is pumped through the drain to waste (Fig. 1). (This system is similar to that used by Watting and Collier[2]).

Flame AAS measurements. A Perkin-Elmer Model 2280 atomic absorption spectrophotometer equipped with an electrodeless discharge lamp operated at 7 mA from an external power supply and a deuterium background corrector was used for AAS measurements. In this case, a laboratory-made hydride generator/gas–liquid separator system previously described[13] was used throughout for sample introduction of arsine (Fig. 2). A Perkin–Elmer MS-10 hydride generator was used for non-continuous (batch) measurements.

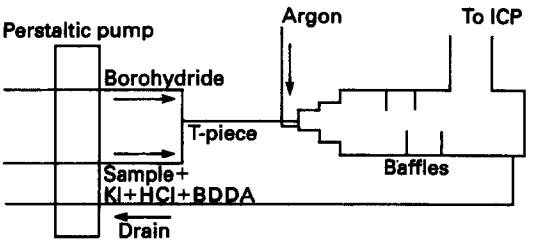

Fig. 1.

An ultrasonic device Sonics & Materials, Model VC500, 250 Watts was used to prepare the vesicle solutions.

Reagents

A stock solution of arsenic (1000 μg/ml) was prepared by dissolving 1.320 g of As_2O_3 in 25 ml of 0.1*M* sodium hydroxide, hydrochloric acid was then added until pH 7.0 and this solution was made up to 1.0 litre with redistilled water. The working solutions were prepared fresh by diluting appropriate aliquots from the stock solution.

Sodium tetrahydroborate (III) solution (1.5% w/v) was prepared by dissolving tetrahydroborate (III) powder (Carlo Erba) in demineralized Milli-Q water stabilized by 0.1% sodium hydroxide. Working solutions were prepared weekly and filtered before use.

Potassium iodide stock solution (10% w/v) was prepared by dissolving 25 g of potassium iodide in 250 ml of demineralized Milli-Q water.

Hexadecyl-trimethylammonium bromide (CTAB) solution ($10^{-2}M$) was prepared by dissolving the surfactant in water by gentle warming. The other surfactants assessed were prepared in a similar way.

Didodecyldimethylammonium bromide (DDAB) solution ($10^{-2}M$) was prepared by dissolving the surfactant powder in water and then sonicating for 12 min in an ultrasonic device, in order to obtain vesicles.

All reagents used were of analytical-reagent grade and redistilled or Milli-Q water was used throughout.

Procedures

Sample preparation. A 0.5-g weight of the sediment sample is weighed and placed into a nickel crucible, with 4 grams of potassium hydroxide. The crucible is then introduced into a furnace and heated at 500° for 30 min. The ashes are dissolved in 50 ml of 1*M* hydrochloric acid, and filtered before analysis. This solution is made up to 100 ml and analysed by ICP–AES.

Non-continuous (batch) measurements. The sample is transferred into a 10-ml flask and made up to volume with demineralized Milli-Q water. An aliquot is placed into the reaction vessel and hydrochloric acid and potassium iodide are added. It is then mixed with a 8% $NaBH_4$ solution in the MS-10/HG system. The generated arsine is swept into the heated quartz T-tube by a continuous stream of argon.

Continuous measurements. An aliquot of 5 ml is placed into a 50-ml flask and 4.2 ml of hydrochloric acid, 1 ml of 10% potassium iodide and 4.2 ml of $10^{-2}M$ DDAB are added and this solution is made up to volume with demineralized Milli-Q water. This solution was continuously pumped through one of the channels of the peristaltic pump, while a 1.3% solution of $NaBH_4$ was pumped through the second channel. Both flows were mixed at a T-piece where the hydride formation takes place. The gaseous and liquid mixture is passed through the grid nebuliser; the liquid is drained and the gaseous products are swept into the plasma, by the argon flow across the nebuliser.

RESULTS AND DISCUSSION

AAS studies

In our study of hydride generation methodology using organized media instead of aqueous media, the ability of different "organized media"[16] to enhance the sensitivity of As determinations was investigated. Arsine generation was carried out in a Perkin-Elmer MS10 commercial hydride generator. Optimum instrumental conditions selected for such determination are summarized in Table 1.

Table 1. Instrumental conditions in AAS measurements for As

Lamp current	7 mA
Spectral band width	0.7 nm
Wavelength selected	193.7 nm
Air/acetilene flow ratio	4

The following organised media were tested in concentrations below and above their critical micellar concentrations (cmc's):

—Cationic surfactant: CTAB (Hexadecyl-trimethylammonium bromide). (cmc = $9.2 \times 10^{-3}M$)
—Anionic surfactant: SDS (Sodium Dodecyl Sulphate). (cmc = $8.1 \times 10^{-3}M$)
—Non-ionic surfactant: TX-100 (TritonX-100). (cmc = $2\ 10^{-4}M$)
—Vesicles: DDAB (Didodecyldimethylammonium Bromide).

The net signals obtained generating the arsine from these four media, were compared with those obtained from aqueous media. Results showed that maximum Abs_s/Abs_b ratios (where Abs_s is the absorption due to the sample and Abs_b the absorption due to the blank), were obtained with DDAB vesicles.

To evaluate the relative merits of this methodology, we compared the sensitivity under optimized conditions of arsine generation AAS from water, DDBA and TX-100 (the three media which provided higher signals). These experiments were performed in both, continuous and non-continuous hydride generation systems, and the results observed were as follows:

Generation from a batch device (Perkin-Elmer MHS-10). An aliquot of the sample solution is placed in the sample reservoir, along with hydrochloric acid and potassium iodide. An 8% borohydride solution and an argon stream were used to generate and transport the arsine to a quartz tube placed on the flame of the AAS spectrometer.

Results obtained for the three media are given in Table 2. As shown in the Table, the precision was relatively poor when using a non-continuous generation system. Better results seemed to be obtained using vesicles of DDAB. To increase the precision of measurements a continuous generation system was investigated.

Table 2. Comparison of analytical performance of arsine generation–AAS in various media

	L.D.		Precision (%)	
Media	*A*	*B*	*A*	*B*
Water	36 ng	4 ppb	25	6.7
BDDA	17 ng	1 ppb	23	6.9
TX-100	136 ng	—	39	—

A: Batch.
B: Continuous.

Generation from a continuous hydride generation device. A schematic diagram of this hydride generator is shown in Fig. 2. The liquid streams of sample solution, or blank, in 0.2% potassium iodide solution [to ensure that all arsenic is in the As (III) form], 1*M* hydrochloric acid solution and the reducing reagent, 1% $NaBH_4$ were pumped continuously and merged at a T-piece where the hydride formation takes place. The mixture of liquid and gas then arrives to an interface vessel (filled with 3-mm o.d. Pyrex beads) which provides a smooth separation of liquid and gas. The gaseous products, arsine and hydrogen, are swept through the vessel into the quartz tube of the AAS system by a continuous stream of argon. This argon stream was optimized and fixed at 0.045 l./min. The waste liquid is drained via a U-tube system, as can be seen in Fig. 2.

Using this system, we compared the analytical characteristics of arsine generation, in terms of detection limit and precision, from the two better media, that is DDAB vesicles and water. As shown in Table 2, detection limits (3 σ_b where σ_b is the standard deviation of blanks) found were: 1 ng/ml of As using BDDA and 4 ng/ml generating AsH_3 from aqueous media, the precision being similar in both cases (around $\pm$ 7% for 12 ppb solutions of As).

Thus, organized media do enhance the analytical characteristics of hydride generation-AAS determination of As.

The use of micelles and other organized media are particularly useful in ICP–AES, because they provide a microenvironment similar to that of organic solvents for reactions.[16] However, they offer superior performance and are more compatible with plasma operation; in fact, extinguishing, de-stabilization and background levels of the ICP, are all minimized by using micellar solutions instead of organic solvents.[13,18]

Therefore the use of organized media was also tested for hydride generation–ICP–AES determination of As.

HG–ICP studies

The first step was to optimize the experimental generation of AsH_3 and its continuous introduction into the plasma using a Philips HG system (see Fig. 1). In a second step, the following organised media: Tritón X-100, CTAB, and DDAB were assayed and compared with aqueous AsH_3 generation. Preliminary studies showed that CTAB produces a slight precipitate with potassium iodide, while TX-100 did not produce any improvement in the ICP–AES signal (as observed by AAS). Therefore, an

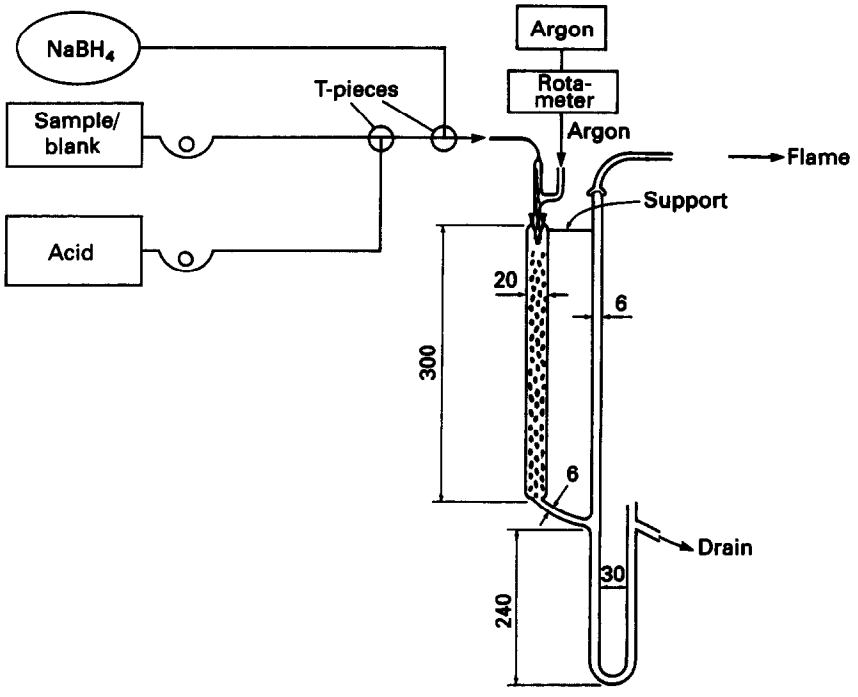

Fig. 2.

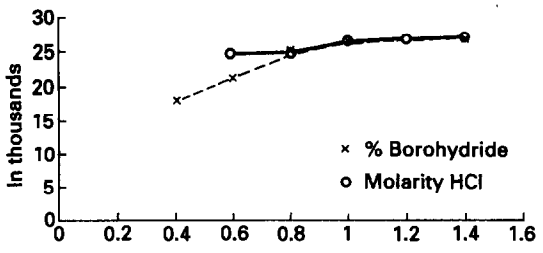

Fig. 3.

organized media of vesicles of DDAB was finally selected for further experiments.

Optimization of the instrumental parameters

The criterion for optimization was taken to be the best signal-to-background ratio, $SBR = (I_e - I_b)/I_b$ (where I_e is the intensity for the sample, and I_b for the blank).

Selection of the analytical line. The two most sensitive analytical emission lines for arsenic were tested: 193.695 nm and 197.198 nm. The observed values of SBR were 7.2 for the former and 6.5 for the latter analytical line, using a 50-ppb standard.

Optimization of chemical parameters for AsH_3 generation. Optimum hydrochloric acid and $NaBH_4$ concentrations were investigated using 50 ppb arsenic, a 0.5% potassium iodide solution as reducing agent and working at both emission lines sequentially. A univariant search was used in this instance to establish the optimum hydrochloric acid and $NaBH_4$ concentrations in the aqueous phase. The emission intensities obtained for each hydrochloric acid and $NaBH_4$ concentrations, are given in Fig. 3. It can therefore be seen why $1M$ hydrochloric acid and 1.3% $NaBH_4$ were selected for the subsequent work.

It was observed that the ICP signal became higher with higher DDAB concentration. However, above $8.4 \times 10^{-4}M$ of the surfactant a precipitate formed in the presence of potassium iodide. Therefore, reductants other than potassium iodide were assayed in order to reduce As (V) to As (III). The behaviour of potassium iodide, titanium (III) chloride and sodium sulphite compared in vesicles of DDAB. Figure 4 summarizes the observed results which showed that the signal obtained when using $TiCl_3$ or Na_2SO_3 was always lower than that obtained for potassium iodide. For this reason, a potassium iodide concentration of 0.5% was selected to ensure that all arsenic is in the As (III) form.

Table 3. Optimum operating conditions in ICP–OES measurements

Plasma	
Coolant gas flow	11 l./min
Pressure of Ar in nebuliser	35 psi
Forward power	1.5 kW
Hydride generation system	
$NaBH_4$ concentration	1.3% m/v in 0.1% NaOH
$NaBH_4$ uptake rate	2.1 ml/min
Sample acidity	$1M$ in HCl
Sample uptake rate	4.2 ml/min
DDAB conc.	$8.4 \times 10^{-4}M$

The overall optimum conditions found are summarized in Table 3, and they happened to be the same in both media tested (water and DDAB).

Analytical performance, characteristics of the DDAB–HG–ICP–AES determination of arsenic. Using the optimum conditions previously obtained (Table 3), sensitivity, selectivity, and precision of As determination by HG–ICP–AES using aqueous or DDAB media were evaluated.

Calibration graphs obtained in both media are shown in Fig. 5 and show that the sensitivity (slope of calibration curve) is twice when using vesicles; the linear analytical range obtained extended from 6 ng/ml to, at least 100 μg/ml using DDAB and from 13 ng/ml to 100 μg/ml for water media, while the detection limts ($3\sigma_b$) were 0.6 ng/ml for BDDA and 1.3 ng/ml for aqueous media.

The precision was evaluated by analysing ten replicates of a solution containing 50 ng/ml of arsenic with AsH_3 generation from aqueous and DDAB media. Relative standard deviation observed were $\pm 3.2\%$ using aqueous and $\pm 2.3\%$

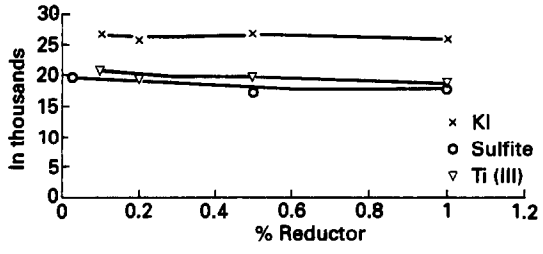

Fig. 4.

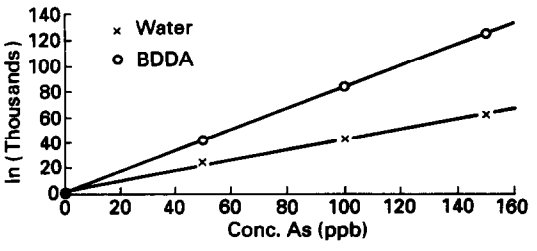

Fig. 5.

in DDAB media. Therefore, the precision of arsine generation (see Table 2 for similar AAS measurements) seems to be clearly improved by adding vesicles to aqueous solutions.

Interference studies

In order to investigate potential interferences from aqueous and DDAB media, solutions containing 25 ng/ml of arsenic (III) with various amounts of foreign ions were prepared. These solutions were analysed for As following the recommended procedure in the presence and absence of DDAB vesicles.

All the results obtained are summarized in Table 4 in a comparative manner. As it can be seen in this table, some interferences are reduced (as in the case of Bi, for instance) or eliminated (in the case of Ti) when hydride generation is performed from DDAB vesicles. There is, however, an important interference in DDAB: when Sb is present in concentrations above 20 μg/ml, it produces precipitates (with DDBA) which seriously inhibit the introduction of the sample due to blocking of tubing.

Table 4. Interferences of some elements in As determination by HG–ICPAES

Interferent	Relationship	Recovery (1) (Water)	Recovery (2) (DDBA medium)
Bi	1:1000	50	
	1:500	52	75
	1:300	54	98

Zn	1:1000	100	
	1:500		101

Table 5. Results of the analysis of some sediments (reference materials)

Sediment	Observed value (μg/g)	Certified value (μg/g)
CRM 277	47.6 ± 1.0	47.3 ± 1.6
CRM 320	74.1 ± 3.3	76.7 ± 3.4

Results show that in general terms the method proposed using DDAB seems to be more selective than the method using aqueous solution and thus it can be favourable for the determination of As in real samples.

Application to real samples

In order to test the analytical usefulness of the proposed method for the determination of low levels of As in environmental samples, we analysed two different certified sediments, namely, CRM 227 and CRM 320 (estuarine and river sediment respectively) from B.C.R. (E.C.).

Sample dissolution and preparation was carried out as described elsewhere[11] with hydride production and determination using the developed methodology.

The results obtained are given in Table 5 (each value given is the average of three determinations) and demonstrate that the DDAB–HG–ICP–AES procedure proposed here provides good accuracy and precision for this type of analytical problem.

CONCLUSIONS

Long-chain surfactants have been proposed to improve the sensitivity of many analytical methods of atomic spectrometry. Sample transport in nebulizers and atomization efficiency enhancements in the flame had been invoked to rationalize the observed sensitivity improvements. Other workers, however, found very little or no sensitivity enhancement by surfactants, while recent research on the topic[18,19] tends to indicate that transport efficiency does not increase on addition of most varied surfactants.[18] Micelles thus appear to have limited application for ICP–AES conventional nebulisation.[19]

Conversely, micelles, and other organized media such as vesicles, could be most helpful in atomic methods based on hydride generation. As we have shown in a preliminary communication[16] the hydride generation is a chemical

reaction which can be improved in the presence of such "organized" media, at least from two different points of view:

(a) Micelles, vesicles, *etc.*, are able to "organize" reagents at a molecular level, as has been repeatedly shown[20] for coloured and photoluminiscent reactions. This could affect sensitivity (effective concentration of reactants is higher in the microenvironment created by the organized medium than in water) and selectivity of hydride generation (*i.e.*, by selecting oppositely or identically charged micelles for the analyte and interferences respectively).

(b) Not only thermodynamic constants but kinetics of the reactions can also be altered by organized media.

Our results for As have shown that, at least modestly, all the expected improvements (detection limits, selectivity and precision) have been realized using vesicles of DDAB in the continuous (and batch) generation of arsine.

The "organized medium"-enhanced technique for hydride generation allows a fast and precise determination of As by ICP–AES and could be extended to other hydride forming elements. Moreover, analysis of environmental samples using the developed method gives results close to the certified values. Speciation of As is an important requirement for this application; this challenge could be approached using micellar chromatography[21] for separation of species and the proposed DDAB-arsine generation ICP–AES for detection.

Research in this direction of As speciation is currently in progress in our laboratory.

(*Received* 27 *March* 1992. *Accepted* 31 *March* 1992)

Summary—Two flow injection procedures have been investigated for the determination of some elements in silver electrolysis solutions, for which the problem of the formation of silver acetylide needs to be addressed. A single line manifold was found to give acceptable results for limited time periods, but for prolonged operation it was necessary to remove the silver. This was achieved with a recirculating reactor in which the silver was precipitated as the chloride and retained on a filter of nylon fibers. Good recoveries of copper, iron, nickel and zinc from solutions containing up to 100 g/l. silver were obtained with over 95% of the silver retained on the filter. The filter was regenerated rapidly by flushing with ammonia solution.

A major driving force in research in analytical atomic spectrometry is the need to remove matrix interferences. The use of flow injection (FI) techniques for the separation of analyte and matrix species is proving to be of considerable versatility and several methods of FI separation and preconcentration have recently been reviewed.[1] Although most of the FI procedures have already been described in an off-line batch mode, there are some practical problems associated with their use which have mitigated against their use in favor of some instrumental based methods of interference removal or compensation. As well as the dangers of contamination and loss, batch procedures are often labor intensive and time consuming. Flow injection methodology, as an approach to automation, is a versatile alternative to manual procedures. Due to the inherent high precision of flow-based procedures, most of the physical and chemical manipulations of the sample can be reduced to the actions of filling and injecting the contents of a sample loop. Flow injection techniques also have the additional benefit of providing a safe, contamination-free enclosed sample handling system.

*Author for correspondence.

Precipitation is the oldest method of chemical separation.[2] Precipitation methods are satisfactory for macro separations, although precipitates are usually contaminated with foreign ions present in solution, although these would not themselves have been precipitated under the given experimental conditions. Developments in trace analysis and the methods of separation and preconcentration have led to the study of the possibility of using precipitation techniques for matrix isolation. Precipitation is useful for removing the major constituent of a sample if this interferes with the subsequent determination of trace components. Conditions can be chosen such that a considerable amount, if not all, of the major constituent can be precipitated without causing losses, by co-precipitation, of the trace constituents to be determined. For example, Karabash *et al.*[3] studied coprecipitation of trace elements with the aid of radio-tracers and have shown that in the precipitation of lead sulfate from a 6*M* nitric acid solution, many trace elements remained (85–100%) in solution, which is sufficient for trace analysis purposes.

Several groups of workers have shown tha it is possible to use precipitation and redissolution in a flow injection manifold for the purposes of preconcentration of trace

components and the removal of potentially interfering matrix components. For the small quantities of precipitate involved it is possible to retain the solid phase on an in-line filter of either stainless steel,[4] cellulose acetate[5] or even to retain the analyte element co-precipitated on the interior of an open knotted tube reactor.[6]

The insertion of a filter directly in-line does not cause a problem when the amount of precipitate is small, but for large amounts of solid the use of a precipitation manifold with direct coupling to an atomic spectrometer presents some difficulties due to the changes in flow rate which occur as the precipitate collects on the filter medium. This is particularly true if a high concentration of a matrix species is to be removed by precipitation.

To overcome this problem, the use of a recirculating, closed-loop manifold for sample pretreatment is described. The use of closed loop recirculating systems in flow systems predates flow injection methodology[7] and continuous flow recirculation manifolds have been used as part of sample pretreatment procedures. Carbonell *et al.*[8] have described the digestion of sewage sludge samples in a continuous flow reactor. The aim of the study was the on-line digestion and the determination of trace metallic elements in solid samples using the slurry approach coupled with microwave oven digestion in an FIA system. In this procedure the partially digested sample was returned into a sample reservoir and a subsample was injected into a single line manifold for transport to the flame atomic absorption spectrometer. Lazaro *et al.*[9] described a procedure for the on-line leaching of iron from plant material with the aid of ultrasound and the entire recirculating loop formed the loop of the injection valve. On injection, the sample stream merged with a reagent stream containing 1,10-phenanthroline and the product of the reaction was detected spectrophotometrically at 512 nm. The use of recirculating loops for several different flow injection sample pretreatment procedures has recently been discussed by Tyson *et al.*[10] These procedures concerned dilutions for calibration purposes, on-line extraction and matrix isolation.

The determination of metals in solution with high concentrations of silver by flame atomic-absorption spectrometry with an air/acetylene flame can be problematical due to the formation of solid silver acetylide in the spray chamber. This leads to blockage of both the nebulizer and the burner and it is a serious hazard as it may detonate if allowed to dry.[11]

The aim of these studies was to investigate the possibilities for determining trace amounts of metals in silver electrolysis solutions by matrix removal of the silver by precipitation and retention on an on-line filter.

EXPERIMENTAL

Two atomic absorption spectrometers with continuum source background correction (Perkin-Elmer models 5000 and 1100B) were used. For the model 5000, the signal was recorded on a Houston Instrument Model 200 XY recorder connected to the analog signal output of the spectrometer. For the model 1100B, the signal was printed on an Epson model LQ-850 printer. Hollow cathode lamps were operated at the manufacturer's recommended currents. Wavelengths of 324.8 nm for copper, 232 nm for nickel, 248.3 nm for iron, 213.7 nm for zinc and 328.1 nm for silver were used and the appropriate single element hollow cathode lamp was used in each case. An air–acetylene flame was used in all determinations. The instruments were used for each element according to the manufacturers' specification.

The single line manifold is shown in Fig. 1. A Gilson Minipuls 3 variable speed peristaltic pump was used with a Rheodyne model 5020 6-way injection valve. Teflon tubing (0.08 mm i.d.) tubing and flangeless fittings (Supelco) were used to complete the manifold. The injection loop volume was 70.7 μl. The recirculating flow manifold (see Fig. 2) was constructed from PTFE tubing of 0.8 mm or 0.5 mm internal diameter. The filter column consisted of a borosilicate glass column 50 mm × 3 mm (Omnifit) filled with nylon fibers (PolyScience Inc., Pennsylvania). A multichannel variable speed peristaltic pump (Ismatec model MS-4 Reglo 8-100, Cole Parmer, Chicago, IL, U.S.A.) was used to pump liquid in the manifold. Valves were either 6-port rotary valves (Rheodyne model 50, Alltech, South College, Pennsylvania) for sample introduction into the manifold and

Fig. 1. Single line manifold. C is a distilled water carrier stream, S is the sample injection valve and AA is the model 5000 spectrometer. The connection between the valve and the detector was the minimum length of tubing possible.

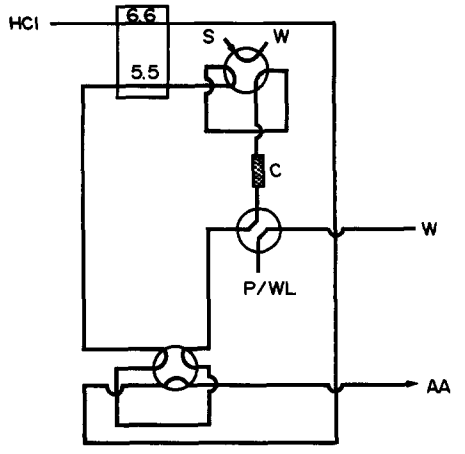

Fig. 2. Recirculation closed loop manifold for the matrix isolation of silver in the determination of trace metals. AA is the model 1100B Spectrometer, S is the sample injection valve, P/WL is the precipitant/wash liquid, HCl is 2*M* hydrochloric acid solution and W is waste.

the injection of subsamples into the spectrometer or 4-port distribution valve (Omnifit, model 1114) for introduction of the precipitant or the wash liquid into the manifold.

The manifold was operated by first filling the loop with the precipitant (hydrochloric acid) via the four way selection valve and then injecting the sample into the manifold at the point labelled S in Fig. 2 and turning the valve so that the precipitant flowed through the sample loop. The precipitate formed was retained on the filter column labelled C and the sample was allowed to circulate for a predetermined period of time after which a subsample of the contents in the recirculation loop was injected into the spectrometer via a single line manifold. After injection of the subsample, the loop was filled via the selection valve with ammonium hydroxide solution (1 + 1) to dissolve precipitate on the column and wash the loop. The loop was then rinsed with distilled demineralized water and was then filled with fresh precipitant and the procedure repeated.

Copper, iron, nickel and zinc standards were made from the dilution of 1000 mg/l. standards (Fisher Scientific). The silver solutions were prepared from silver nitrate crystals (Fisher Scientific). Hydrochloric acid (Baker Instra-analyzed, Fisher Scientific) was used for the precipitation reactions and ammonium hydroxide (ACS Certified, Fisher Scientific) was used for all washings. Distilled dimineralized water (Barnstead Inc.) was used for all dilutions and washing of the manifold. All solutions were stored in high density polyethylene bottles.

Procedures

Single line manifold. The effect of flow and the concentration of dissolved silver on copper absorbance were investigated. To investigate the effect of the formation and build-up of precipitate in the spray chamber a 2.0-ppm copper solution was introduced continuously at a fixed flow rate of 2.5 ml/min between each change in silver concentration. The calibration solutions covered the range 0–60 ppm copper. Two samples were analyzed by the single line flow injection procedure and by EDTA titration.

Recirculating loop manifold

Effect of the recirculation time. This was studied by filling the loop with demineralized water and injecting samples of 10 mg/l. Cu and allowing them to recirculate for different lengths of time between 1.5 and 10 min.

Effect of the concentration of the precipitant. The effect of the concentration of the HCl precipitant over the range 0.2 to 2.0*M* was studied for a solution containing 10 mg/l. Cu and 50 g/l. Ag.

Tolerable level of silver in the sample injected. The effect of varying the silver concentration between 1 and 100 g/l. was studied for a fixed concentration of copper.

Optimization of the flow parameters. The flow rate of the carrier to the spectrometer was optimized by injecting a subsample of the solution into the spectrometer at varying flow rates. The flow rate was varied between 3.2 and 8.6 ml/min. The flow rate within the loop was also varied between the same values.

Effect of the sample volume injected. The volume of sample solution injected into the manifold was varied between 70 and 185 μl.

Effect of subsample injected into the spectrometer. Volumes of the subsample injected into the carrier stream for transport to the spectrometer were varied between 111 and 462 μl.

Recovery studies. The recovery of copper, zinc, nickel and iron at concentrations of 10 mg/l. in the presence of varying amounts of silver between 1 and 100 g/l. were studied.

Breakthrough of silver. The amount of silver that was not retained on the filter column was investigated by monitoring the silver absorbance for the same samples used for the recovery studies.

Calibration. Under the optimum conditions, a 163-μl sample volume and a subsample of

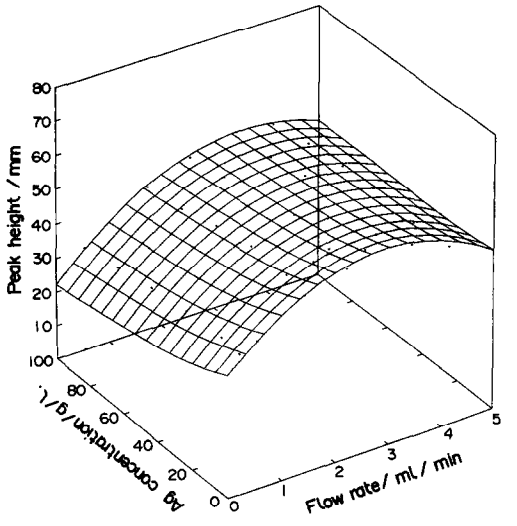

Fig. 3. Response surface for variation of flow rate and silver concentration for the single line manifold.

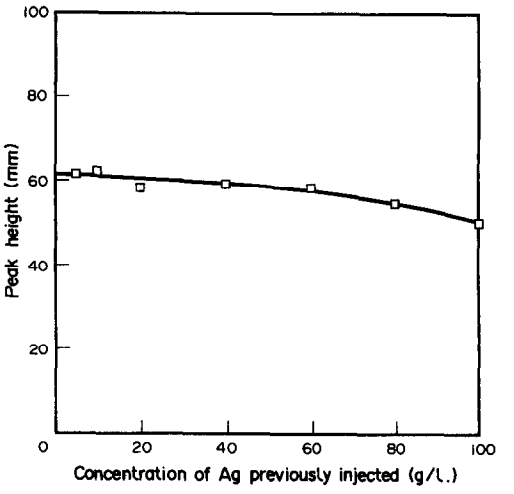

Fig. 4. Response of a constant concentration of copper as a function of the concentration of silver injected.

237 μl, calibration plots were generated for copper, nickel, iron and zinc in the range of 0 to 30 mg/l. and the amounts of these trace elements in synthetic samples with silver matrix determined. Three samples from the Royal Canadian Mint (RCM 1, RCM 2 and RCM 3) were also analyzed for copper by the standard addition method. Both the normal calibration plots and the standard additions plots were generated using standard solutions containing 1000 mg/l. silver.

RESULTS AND DISCUSSION

Single line manifold

The effects of the flow rate and silver concentration are shown in Fig. 3. The surface plot shows the variation of the peak height with changes in both flow rate and Ag concentrations. Peak height remained independent of the silver concentration except at very high concentrations. Changes in flow rate affected the measured absorbance. A decrease in the flow rate below 2.5 ml/min caused a significant decrease in the peak heights observed. The effect of the build up of precipitate is shown in Fig. 4. There was a small change in response over the silver concentration range indicating that the amount of this type of material deposited in the nebulizer does not seriously impede the solution from reaching the flame in the short term. However, over prolonged periods of operation it was found necessary to clean the system.

A typical analysis sequence is shown in Fig. 5. The values for the copper concentrations of two samples determined by this procedure were 0.44 and 5.13 g/l. whereas the values obtained by EDTA titration were 0.441 and 5.36 g/l., respectively.

Recirculating loop manifold

Peak height was used to characterize the absorbances. All the standard deviations and relative standard deviations quoted are based on four replicate measurements. The total volume of the recirculation loop was 660 μl, the optimum volume of sample injected in the manifold

Table 2. Calibration plots

	r^2
Nickel Absorbance = $1.3500 \times 10^{-3} + 3.4510 \times 10^{-3}$ [Ni]	0.998
Copper Absorbance = $4.9493 \times 10^{-3} + 4.0174 \times 10^{-3}$ [Cu]	0.995
Zinc Absorbance = $1.8911 \times 10^{-2} + 1.6589 \times 10^{-2}$ [Zn]	0.991
Iron Absorbance = $1.8893 \times 10^{-3} + 4.5314 \times 10^{-3}$ [Fe]	0.996

was 163 μl and the optimum subsample volume injected into the spectrometer was 237 μl. It was observed that circulating the sample in the manifold for 4.5 min was sufficient to let the contents of the sample mix so that a reasonable reproducibility could be obtained, see Fig. 6. For times of less than 4.5 min the reproducibility was poor. In effecting a good filtration for these studies the differences between the two principal types of colloidal precipitates, hydrophobic and hydrophilic, is important. Hydrophilic precipitates are difficult to separate by filtration and to wash and are likely to coprecipitate numerous substances. On the other hand, hydrophobic precipitates, such as silver chloride, have a low water affinity and are purer and more readily filterable.[2] It was observed that the precipitation was very efficient at a hydrochloric acid concentration of 2*M* and this was chosen for further experiments. This concentration was high enough such that only a small amount of precipitate was not retained on the first pass of the precipitate through the filter column. The recoveries obtained are shown in Table 1. These results indicate there is no problem with coprecipitation and also varying silver concentrations do not give significantly different recoveries. The recoveries for nickel were higher than for the other elements and to investigate a possible enhancement by silver or iron, solutions containing varying amounts silver or iron in a fixed concentration of nickel were nebulized directly into the spectrometer. However, no significant difference between the absorbance of the sample containing no silver and the samples containing the largest amount of silver (1000 mg/l.) or iron (500 mg/l.) was observed.

There was no significant difference between the peak heights obtained for the different flow rates in the recirculating loop. A flow rate of 5.5 ml/min was chosen for further experiments. It was observed that large volumes of samples did not significantly affect the peak height, although peak area increased proportionately. In a manner similar to that observed with the single line manifold, as the flow rate of the carrier was varied it was observed that the peak height increased in a direct proportion. The highest flow rate used, 8.6 ml/min, gave the highest mean absorbance but the precision was poor so a flow rate of 6.6 ml/min was used throughout the experiment.

The manifold can accommodate a silver concentration of up to 90 g/l. but above this concentration the flow in the manifold is impeded and the precision of the measurements get worse. For example the RSD for the recovery of copper in the presence of 100 g/l. silver was 15% compared with 4% in the presence of 90 g/l. silver. The precision (measured as the relative standard deviation of 4 replicate determinations) was below 5% for almost all the measurements made at or below this concentration of silver. It was observed that even for a sample containing 90 g/l. silver, more than 95% of the silver was retained on the column. It was noted that proportion of the precipitate retained increased as the silver content in the solution analyzed increased. This was

considered to be related to an increased rate of crystal growth at higher concentrations. The calibration plots for all the elements were linear (see Table 2) and the results obtained for the synthetic samples are shown in Table 3. Two samples previously analyzed by the Royal Canadian Mint and found to have 3.65 and 3.00 g/l. copper were analyzed and found to contain 3.72 ± 0.12 and 3.10 ± 0.12 g/l. copper, respectively. The ± terms are standard deviations calculated from the calibration plots.[12]

CONCLUSION

The coupling of a chemical pretreatment whose kinetic character would make interfacing a flow injection manifold directly with a flame atomic absorption spectrometer difficult has been achieved by the use of a flow injection valve as interface between the reactor and the carrier stream for delivery to the instrument. In this manner, the kinetics of the two operations are decoupled and each procedure can be optimized separately. It has been demonstrated that it is possible to remove substantial proportions of a potentially interfering matrix by precipitation in a flow injection system.

KINETICS OF ALUMINIUM FLUORIDE COMPLEXATION IN SINGLE- AND MIXED-LIGAND SYSTEMS

GEOFFREY S. TOWNSEND and BRYON W. BACHE*
Department of Geography, The University, Cambridge, CB2 3EN, U.K.

(*Received* 30 *March* 1992. *Accepted* 9 *April* 1992)

Summary—The complexation reaction between Al^{3+} and fluoride was studied over concentration ranges 2–50μM fluoride, 0.5–500μM aluminium, pH 2.5–5.0, at ionic strength 0.1 and temperatures of 298 and 283 K. The initial rate of formation of AlF^{2+} was strongly dependent on pH, reaching a minimum at pH 3, and was considerably slower at the lower temperature. Addition of salicylate increased the reaction rate, probably because of the corresponding increase in the initial concentration of $AlOH^{2+}$. These effects of pH, temperature and competing ligands will therefore be critical in determining the composition of acid natural water systems and in particular the speciation of soluble aluminium.

Aluminium is a key element in acid ecosystems because its ionic forms, which begin to dissolve as pH drops below 6, are toxic to many organisms. In acid waters where aluminium toxicity has been associated with poor biological productivity, a number of inorganic and organic ligands are present that affect the speciation of the aluminium ions in solution.[1] Furthermore, the mobilization and transport of aluminium from sparingly soluble forms in soils into percolating waters and thus into streams and lakes depends critically on both the chemical combinations of aluminium and the rates of flow of water.[2] One is frequently dealing with non-equilibrium conditions in these systems. As part of a wider study on rate processes in aluminium mobilization from soils to surface waters,[3] it became necessary to study the kinetics of the complexation of aluminium ions in solution with soluble ligands that affect its speciation. The most important of these are the fluoride ion and organic ligands. Organic matter soluble in acid solutions is frequently called "fulvic acid", but this is poorly defined chemically apart from containing COOH and phenolic OH functional groups. Salicylic acid is commonly used as a surrogate for fulvic acid because it contains these functional groups, and it is particularly useful in the present study because it can be easily determined by fluorimetry.

The relative rates at which aluminium complexes are formed may determine their biological activity, particularly as thermodynamic equilibrium is believed to be attained only rarely in natural waters.[4] Previous studies of the rates of complex formation of aluminium with fluoride[5] and salicylic acid[6] were conducted at higher concentrations, ionic strengths and temperatures than are relevant in natural water systems. These also considered only a single ligand at a time whereas natural systems contain a mixture of ligands. The difference between ligands in the temperature dependence of their reaction rates may also result in a competitive advantage being given to the formation of one particular complex, and this effect will be superimposed on other factors such as the concentrations of the ligands concerned and the solution pH.

Because fluoride complexes are more stable than any of the other expected soluble aluminium complexes, the approach adopted here was first to study their rate of formation, and then to study the competitive complexation reactions with the addition of salicylate.

EXPERIMENTAL

Reagents

Three stock solutions (1×10^{-4}, 1×10^{-3} and $5 \times 10^{-3} M$) of sodium fluoride were prepared from Analar grade salt after drying at 373 K for 24 hr, and transferred to polyethylene bottles. All subsequent fluoride solutions were prepared fresh daily from these stock solutions. Aluminium solutions were prepared fresh each day from Spectrosol aluminium nitrate solution, and their concentrations verified by the catechol violet colorimetric method. Salicylic acid

*Author for correspondence.

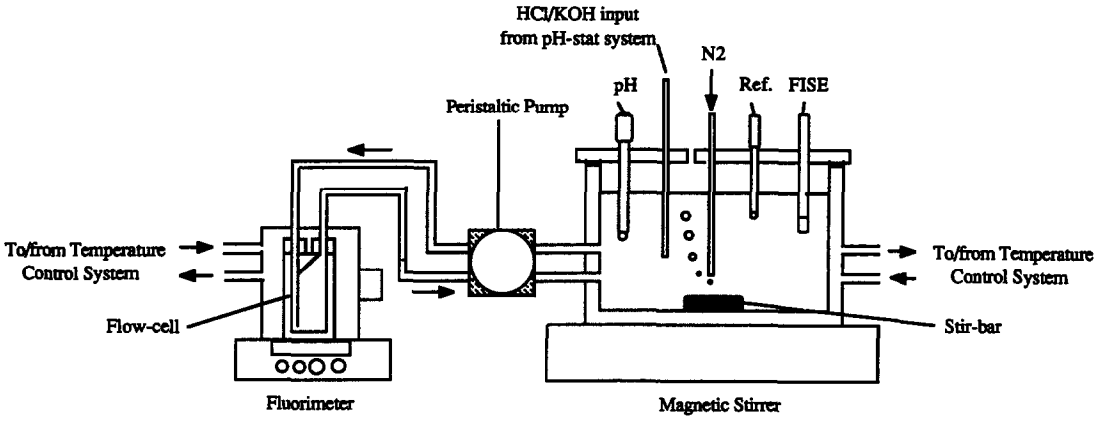

Fig. 1. Experimental reaction system for simultaneous determination of fluoride and salicylate. (FISE = fluoride ion selective electrode).

solutions were prepared fresh each day to prevent possible polymerization[7] and were standardized by potentiometric titration with potassium hydroxide.

Apparatus

All containers used were washed by soaking in 10% nitric acid and rinsed with distilled and demineralized water prior to use. Experiments were performed in the reaction vessel shown on the right of Fig. 1 when using inorganic components alone, with the addition on the left of Fig. 1 to measure salicylate concentrations by fluorimetry for the competitive complexation reactions. The combination of the two systems allowed the fluoride and the salicylate complexation reactions to be monitored simultaneously. Fluoride activities were determined with a Philips fluoride ion-selective electrode and a saturated calomel reference electrode with an E.D.T. ECM202 digital voltmeter. The pH was controlled with a Radiometer TTT 85 pH-stat system with a combined pH electrode, adding hydrochloric acid or potassium hydroxide to maintain a specific pH. Hydrogen ion concentrations were calculated from pH measurements using the Debye-Huckel approximations. The volumes of HCl/KOH required were predetermined so that the amounts of potassium chlorate required to maintain the required ionic strength could be calculated for each experiment. The reaction vessel was surrounded by a thermostatted water jacket connected to a Grant constant temperature water bath and purged with oxygen-free nitrogen. Salicylate concentrations were measured with a Zeiss model DMR21 spectrofluorimeter equipped with two grating monochromaters each with a fixed 10-nm band pass, which was used with a 10-mm flow-through quartz cuvette and Watson Marlow peristaltic pump. Outputs from the pH meter, the spectrofluorometer and the voltmeter were recorded by Linseis chart recorders.

Procedures

Before each run, the fluoride ISE was calibrated for the appropriate concentration range and pH with eight standard solutions. The response time of this electrode was less than one second and so was well able to monitor the slower Al-F complexation reactions. For each kinetic run, 500 ml of the fluoride reaction mixture was placed in the reaction vessel, and stirred to the desired constant temperature with a Teflon stir bar.

Two separate procedures were used in the experiments: (i) aluminium solutions were added to fluoride in the reaction vessel in discrete steps, and the reaction monitored until equilibrium was attained between successive additions. (ii) A single aluminium addition, of concentration 10× the fluoride concentration, was injected into the solution and the reaction monitored to equilibrium. Initial fluoride concentrations were 2×10^{-6} to $50 \times 10^{-6} M$, initial aluminium concentrations were 5×10^{-7} to $5 \times 10^{-4} M$, pH was controlled within the range 2.5–6.0, ionic strength was 0.10 and temperature 298 K. Some experiments were also performed at ionic strength 0.05, and some at 283 K. For the competitive complexation experiments, an initial fluoride concentration of $10^{-5} M$ was used, with salicylate concentrations from 10^{-6} to $10^{-4} M$, pH between 3.0 and 6.0 and ionic strength 0.10. Each experiment was performed in duplicate and the means are reported in the results.

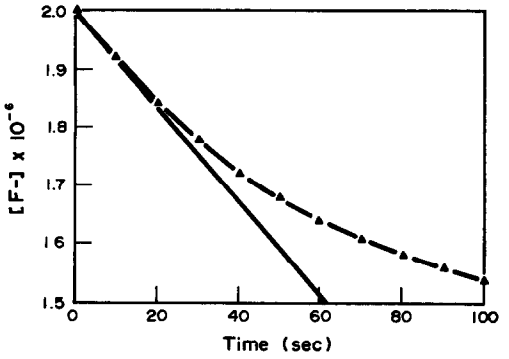

Fig. 2. Typical plot of fluoride concentration as a function of time, with tangent drawn at $t = 0$, from which initial rate was derived.

RESULTS AND DISCUSSION

Reaction rate for aluminium-fluoride complexation

Determining rate laws and constants from integrated equations is fraught with problems, particularly if secondary or reverse reactions may be involved. It is preferable to use initial reaction rates, for which the concentration of reactant or product is plotted against time for the short initial period of the reaction during which concentrations change so little that the instantaneous rate is hardly affected.[8]

During the titrations, the potential of the fluoride ISE becomes more positive with respect to the calomel electrode, indicating a decrease in the free F^- concentration resulting from the formation of the complex ion AlF^{2+}. The tangent to the rate curve at time = 0 then gives the initial reaction rate. We used this initial rate (IR) method, used previously for fluoride kinetics by Srinivasan and Rechnitz.[5] The majority of the kinetic runs gave plots whose tangents could be drawn with a reproducibility of about ±3%. The method is illustrated for a typical experimental run in Fig. 2. To calculate a rate constant, it is preferable to define the rate of formation of AlF^{2+} rather than the rate of free fluoride consumption. This was done and the results for all 26 experiments are summarized in Table 1.

Rate equation and mechanisms of complex formation

In all cases the initial rate of formation of AlF^{2+} was first order with respect to $[Al^{3+}]$ but not with respect to [F]. At constant initial fluoride concentration, rate/[F] increased with $[F^-]$, an effect that was more pronounced at higher pH, (Fig. 3) indicating the need for fluoride concentration terms in the rate equation. At constant pH the rate/$[Al^{3+}]$ values were approximately constant, so that a rate equation of the following form was indicated:

$$\text{Initial rate (IR)} = (d[AlF^{2+}]/dt)_{t=0}$$
$$= K_1[Al^{3+}][F^-] + K_2[Al^{3+}][F^-]^2$$

This equation was tested between pH 2.5–6.0 over the entire range of concentrations investigated using a non-linear least squares programme; the comparison between the observed rates and the calculated rates gave a standard deviation of 3.7%. The same rate equation resulted from a detailed theoretical consideration of possible reaction mechanisms[3,5,9,10] where K_1 and K_2 are defined in terms of the rates of a number of possible reactions in which HF, F^- and OH^- penetrates the $Al(H_2O)_6^{3+}$ aquo ion.

Effect of pH on reaction rate

Figure 3 indicated the importance of pH on the reaction rate, but this is further demonstrated in Fig. 4 by the dependence of both K_1 and K_2 on pH, both reducing rapidly as pH drops from 5.5 to about 3, but then whereas K_2 drops to zero K_1 increases at pH below 3. The combined effect is to give a minimum rate of Al-F complexation at pH about 3. The consequences of this for natural water systems are considerable, indicating that fluoride will be important for mobilizing aluminium into soluble complexes at pH values around 5, but it is likely to be much less effective in more acid systems.

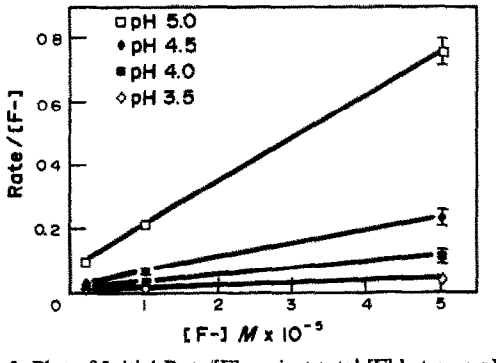

Fig. 3. Plot of Initial Rate/[F] against total [F] between pH 3.5 and 5.0. $[Al^{3+}] = 5 \times 10^{-4} M$. Error bars = ±S.E.

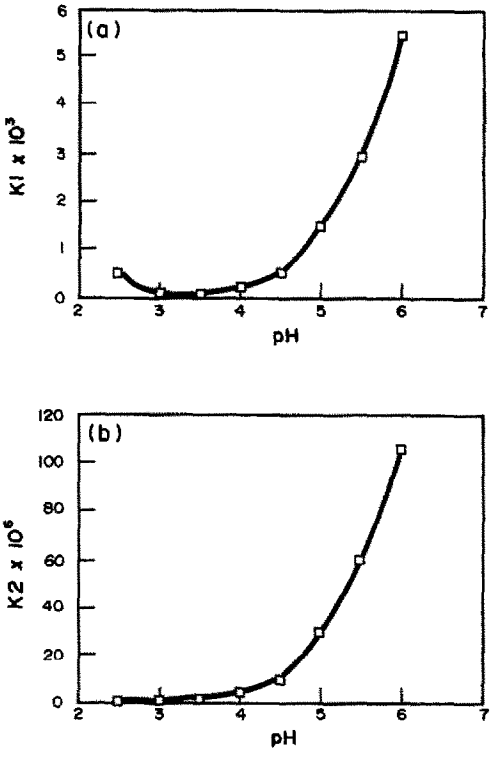

Fig. 4. Dependence of (a) K_1, and (b) K_2 on pH at 298 K.

Effect of salicylate on fluoride complexation rate

Plots were made of the initial reaction rate (IR) against the other variables in the system. The following plots were found to be linear, with slopes from 0.92 to 1.1

log(IR) vs. $[Al^{3+}]$,

at constant pH, [F] and $[SA_{tot}]$.

log(IR) vs. $[F^-]$,

at constant pH, [Al] and $[SA_{tot}]$.

This is good evidence of first order dependence on both $[Al^{3+}]$ and $[F^-]$. However, plots of log(IR) against log(SA) were not linear which suggests a fractional order with respect to [SA]. These results, together with a non zero intercept for a plot of IR/[Al][F] against $[SA_{tot}]$ at constant pH, suggest that a suitable experimental rate equation for the complexation of fluoride with aluminium in the presence of salicylic acid can be expressed as:

$$IR = (-d[F^-]/dt)_{t=0}$$
$$= k_i[Al^{3+}][F^-] + k_{ii}[Al^{3+}][F^-][SA_{tot}],$$

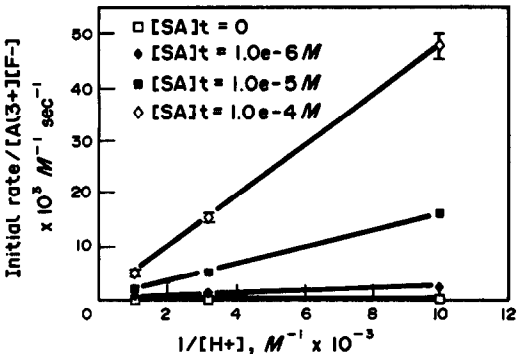

Fig. 5. Plot of Initial Rate/$[Al^{3+}][F^-]$ against $1/[H^+]$ for various total salicylate concentrations, $[SA]_t$. Error bars = ±S.E.

where k_i and k_{ii} are observed rate constants that are functions of the hydrogen ion concentration. Detailed mechanisms for these reactions according to the Eigen[9] treatment were proposed and these gave a rate equation similar in form to the above experimental rate equation.

The effect of salicylate on the fluoride complexation rate is demonstrated effectively in Fig. 5, where $IR/[Al^{3+}][F^-]$ is plotted against $1/[H^+]$. It can be seen that the presence of salicylate *increases* the rate of fluoride complexation at a constant pH, and that this increase is pH dependent. The theoretical derivation indicates that the reactions that either produce or utilize $AlOH^{2+}$ become increasingly important at the expense of reactions which produce or utilize Al^{3+}. It appears that the increase in the initial rate of fluoride complexation is caused by a significant increase in the initial concentration of $AlOH^{2+}$. Other evidence[10] also suggests that $AlOH^{2+}$ complexes with ligands faster than does Al^{3+}.

These results are at variance with opinions on the kinetics of concurrent reactions in natural water chemistry, which are thought to proceed independently in relative isolation.[11] Clearly, the presence of a third component that alters the speciation of one or both of the reactants can have a considerable effect on the system as a whole.

Temperature dependence

The data in Table 1 show that the initial rate of fluoride complexation is at least an order of magnitude slower at 10° than at 25°. Comparable data for salicylic acid are not available, but data for fulvic acid[3] show that its rate of complexation with aluminium is less temperature dependent. In mixed ligand systems lower temperatures may favour the more rapid organic complexations, depending on the temperature coefficient of the competing reactions, and so can be an important determinant of aluminium speciation.

RAPID SEQUENTIAL DETERMINATION OF INORGANIC MERCURY AND METHYLMERCURY IN NATURAL WATERS BY FLOW INJECTION—COLD VAPOUR-ATOMIC FLUORESCENCE SPECTROMETRY*

WEI JIAN and C. W. MCLEOD†

Chemical Analysis Research Centre, Division of Chemistry, Sheffield City Polytechnic, Sheffield, S1 1WB, U.K.

(*Received* 10 *July* 1992. *Accepted* 10 *July* 1992)

Summary—A novel method for the rapid sequential determination of inorganic mercury and methylmercury in natural waters at the ng/l. level has been developed. Trace enrichment and separation of mercury species are achieved using a microcolumn of sulphydryl cotton which has a relatively high affinity for methylmercury. The limit of detection for methylmercury based on processing of a 0.5-ml sample volume was 6 ng/l. Application to river waters is demonstrated.

The past two decades have seen a remarkable increase in our understanding of the impact of trace elements in environmental and biological systems. The toxicity of mercury and its compounds is well known but differences in relative toxicity demand, for regulatory purposes, that species sensitive methodology is available. Substantial literature on mercury speciation exists[1] with many schemes based on original work of Westöö,[2] *i.e.*, conversion of organic bound mercury to the halide derivative, isolation of the organic mercury halide via multiple extractions with benzene or toluene and quantitation by diverse techniques viz gas chromatography (GC) with electron capture detection,[3] plasma emission spectrometry,[4,5] GC–mass spectrometry[6] and flow injection–ICP mass spectrometry.[7]

Some of the most promising speciation procedures for mercury are based on cold vapour atomic spectrometry. In the scheme of Oda and Ingle,[8] tin chloride and sodium borohydride were used to selectively reduce inorganic and organomercury species, respectively, and achieve a rapid (3 min) sequential monitoring capability. Limits of detection, based on processing a 1-ml sample were 3–5 ng/l. Birnie[9] developed a flow injection–cold vapour–atomic absorption (FI–CV–AFS) procedure for automated continuous monitoring of inorganic and total mercury in wastewater. On-line oxidation of organic mercury was effected by potassium persulphate reagent using a heated reaction coil and differential measurements (i.e., inorganic and total; organomercury by difference) corresponded to analysis with and without oxidant stream flowing. Determination of inorganic and total mercury using flow injection-cold vapour-atomic fluorescence spectrometry has also been proposed,[10] a novel aspect of the work being the use of a flow-through UV irradiation cell for sample digestion/oxidation.

The present investigation utilises a FI–CV–AFS system and speciation measurement is based on time-resolved detection of inorganic and methylmercury species after separation/enrichment on a microcolumn of sulphydryl cotton. The microcolumn, essentially a scaled-down version of that utilized by Lee[11] for trace enrichment of methylmercury in lake waters (prior to GC analysis), proved extremely effective in the FI–AFS system. Method development studies aimed at system characterization/optimization are presented together with basic analytical performance data and speciation results for mercury in rivers.

EXPERIMENTAL

Apparatus

Flow injection–cold vapour–atomic fluorescence measurements were performed with a Merlin mercury detector (P S Analytical)

*Presented in part at Euroanalysis VII, Vienna 1990.

equipped with a peristaltic pump (Ismatec) and a rotary injection valve (Omnichem). A microcolumn (PTFE tubing, 6 cm × 1.5 mm ID) with sulphydryl cotton fibre (~0.015 g) was used for trace enrichment of methylmercury. A schematic diagram of the FI–CV–AFS system is shown in Fig. 1.

Reagents and materials

Tin chloride solution (3% w/v) in hydrochloric acid (15% v/v) was freshly prepared from tin chloride 2-hydrate salt (Spectrosol, BDH), concentrated hydrochloric acid (Aristar, BDH) and high purity water (Millipore). A bromide/bromate solution (0.5% KBr + 0.14% $KBrO_3$ w/v) was made by dissolving potassium bromide/potassium bromate salts (Analytical reagents, Fisons) in Millipore water. Hydrochloric acid solution (0.01*M*) was prepared from concentrated hydrochloric acid (Aristar, BDH) and Millipore water. Inorganic mercury working solutions were prepared by dilutions of commercial stock solution (Spectrosol, BDH, 1000 mg/l.). Methylmercury stock solution was prepared by dissolving methylmercury chloride salt (Organics, BDH) with a small amount of acetone (Analar, BDH) and then diluting with Millipore water. Methylmercury standard solutions for calibration were freshly prepared from serial dilution of the stock. Sulphydryl cotton, prepared according to the method of Lee,[11] was evenly packed into microcolumns. adjusted to 3 immediately prior to analysis (the time delay between sampling and analysis was less than 4 hr).

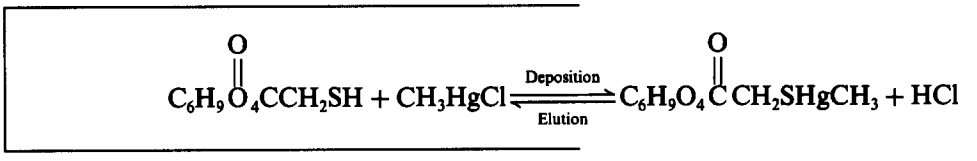
Analytical procedure

The carrier (0.01*M* HCl), oxidant (Br^-/BrO_3^-) and reductant ($SnCl_2$) streams were continuously pumped at flow rates of 1.5 ml/min each. On injection of sample (0.5 ml) into the carrier stream, inorganic mercury passed through the column and underwent reduction/phase separation before atomic fluorescence detection. Hydrochloric acid (3*M*) was then injected to elute methylmercury from the column, the species first being oxidized by bromide/bromate solution and then reduced as before. In this way, a rapid sequential monitoring of methylmercury and inorganic mercury was achieved.

RESULTS AND DISCUSSION

Deposition/elution of methylmercury

It is well known that the sulphydryl group (−SH) has a relatively high affinity for mercury. This prompted us to investigate the possibility of preparing and utilizing microcolumns packed with sulphydryl cotton to effect on line enrichment/separation of mercury species. It was suspected that the deposition/elution process for methylmercury would proceed in the FI system according to the scheme:



Sample collection and pretreatment

River water samples, collected in a precleaned polypropylene bucket, were filtered (0.45 μm) at site using on-line filter apparatus. The filtrate was collected in precleaned glass volumetric flasks (200 ml capacity) which contained 1 ml of concentrated nitric acid (Aristar, BDH). On return to the laboratory sample pH was ad-

To study relative affinity of the mercury species synthetic standard solutions of methylmercury and inorganic mercury were injected into the FI system while monitoring fluorescence as a function of time. The fluorescence-response curves given in Fig. 2 clearly indicate that inorganic mercury was not retained on the microcolumn since immediately after sample

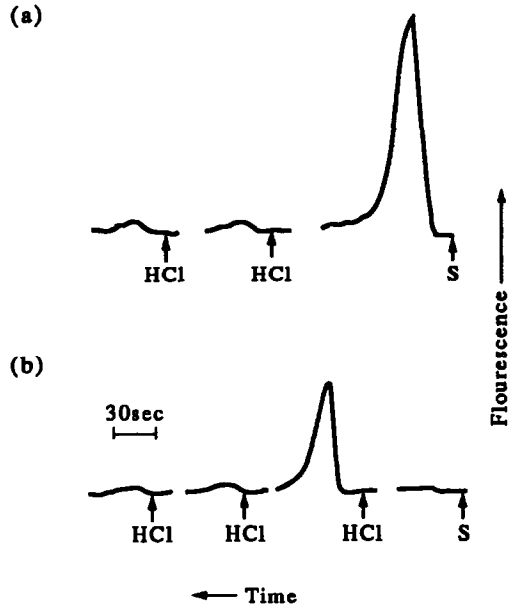


Fig. 2. Fluorescence *vs.* time response for (a) inorganic mercury (0.5 ml, 2.0 μg Hg/l.) and (b) injection/elution of methylmercury chloride (0.5 ml, 2.0 μg Hg/l.). Operating conditions, see Experimental.

injection a breakthrough signal is evident. In contrast methylmercury underwent deposition and a subsequent injection of eluant (3*M* HCl) was required to effect elution. Thus in the case of a solution containing a mixture of inorganic mercury and methylmercury it is possible to achieve a rapid sequential monitoring capability for the two species (Fig. 3).

The reduced signal strength in the case of the response for methylmercury suggests incomplete recovery/analyte losses associated with the deposition/elution process and/or subsequent redox reactions. Systematic studies were, therefore, performed in an attempt to characterize and optimize key system parameters.

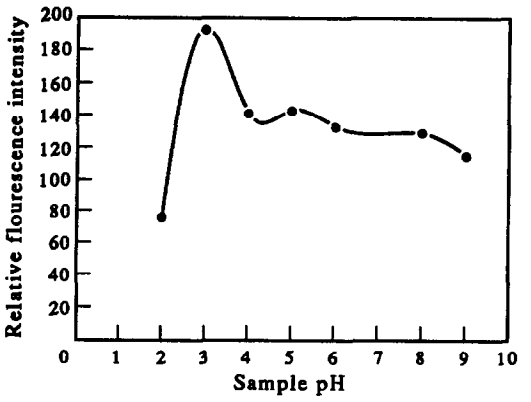

Fig. 4. Effect of sample pH on analytical response. Sample, 0.5 ml of methylmercury chloride (2.0 μg Hg/l.). Eluant, 0.5 ml HCl (3*M*). Operating conditions, see Experimental.

Effect of sample pH

The affinity of sulphydryl cotton for methylmercury was dependent on sample pH. Using the operating procedures as specified in the Experimental section it was found that methylmercury underwent deposition/elution over a wide pH range while inorganic mercury was not retained. Fluorescence response, as a function of pH, given in Fig. 4 reveals maximum signal strength for methylmercury at about pH 3 while the reduced response at pH 2 is an indication of analyte breakthrough during the deposition stage. Subsequent studies were performed with solutions adjusted to pH 3.

Effect of eluant volume

Hydrochloric acid (3*M*) was effective in eluting methylmercury from the microcolumn. However residual signals on subsequent (repeat) injections of eluant (see Fig. 2) were registered unless volumes of at least 0.5 ml were used. Typical results for processing of methylmercury

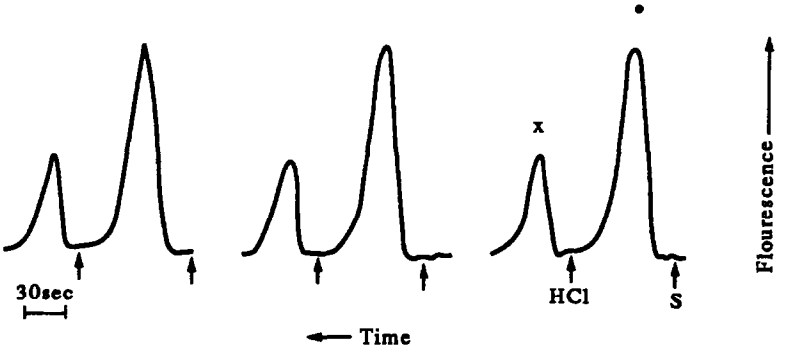

Fig. 3. Fluorescence *vs.* time response (in triplicate) for injection/elution of mixed standard solution–0.5 ml methylmercury chloride (2.0 μg Hg/l.)/inorganic mercury (2.0 μg Hg/l.): ● inorganic mercury x methylmercury. Operating conditions, see Experimental.

Table 1. Analysed values for methylmercury for various eluant volumes

Volume of Eluant (HCl, 3*M*)	Concentration of methylmercury (μg Hg/l.) 1st injection	2nd injection
0.25 ml	1.88, 1.85	0.117, 0.159
0.50 ml	2.10, 1.92	Not Detected, Not Detected
1.0 ml	1.99, 2.02	Not Detected, Not Detected

standard solution (2.0 μg Hg/l.) are presented in Table 1 and it is seen that an eluant volume of 0.25 ml achieves an elution efficiency of about 93% relative to 0.5- and 1.0-ml injections. In subsequent work an eluant volume of 0.5 ml was selected and 2 sequential injections were used to guard against the possibility of residual signals/memory effects.

Effect of mixing coil length

A critical aspect of method development was mixing coil length since this controls to a considerable extent the degree of mixing of eluate and oxidant streams and hence oxidation efficiency and signal strength. There was concern that the rate of oxidation in the FI system might not be sufficiently rapid given that official methods for total mercury determination in waters using batch techniques specify, after addition of oxidant to sample, a reaction time of at least one hour.[12] As shown in Fig. 5, a significant enhancement in signal strength was realised by employing a mixing coil at least 3 m in length. Thus, in the present FI system, on-line oxidation of methylmercury using bromide /bromate reagent proceeded rapidly and with high conversion efficiency (>80%). Subsequent work utilized a mixing coil 4 m in length.

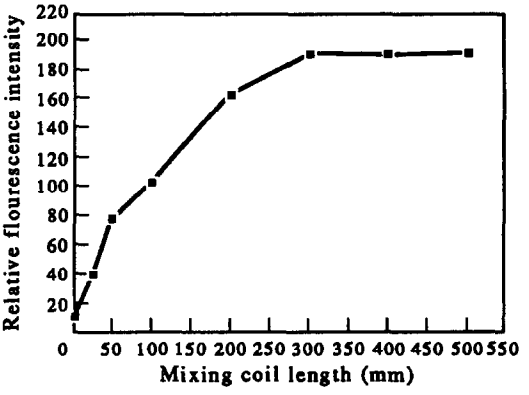

Fig. 5. Effect of mixing coil length on analytical response. Sample, 0.5 ml of methylmercury chloride (2.0 μg Hg/l.). Eluant, 0.5 ml HCl (3*M*). Operating conditions, see Experimental.

Analytical performance

Calibration and limit of detection. A calibration graph, based on processing standard solutions of methylmercury chloride, was linear over the concentration range examined (50 ng/l.–10 μg/l.; sample volume, 0.5 ml). The limit

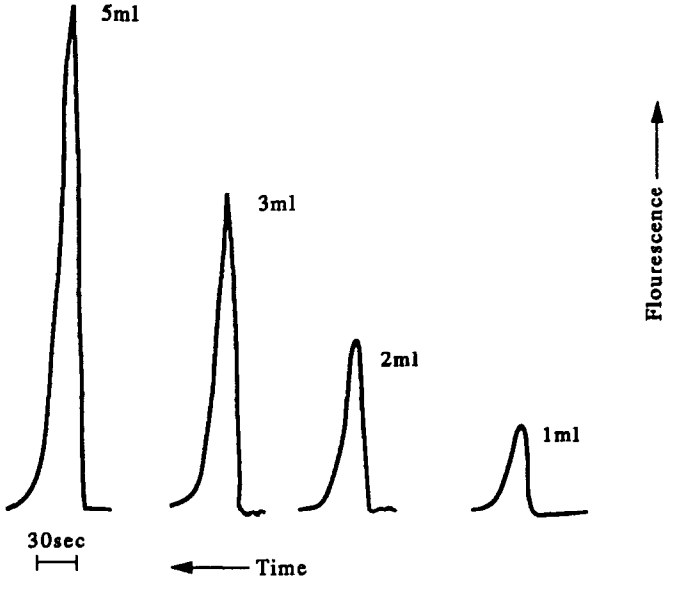

Fig. 6. Effect of sample injection volume on analytical response. Sample, methylmercury chloride (2.0 μg Hg/l.). Eluant, 0.5 ml HCl (3*M*). Operating conditions, see Experimental.

of detection based on 10 replicate injections of eluant and 3 × the standard deviation of the corresponding background signals was calculated as 6 ng/l. methylmercury.

An important feature of the FI system is the in-built trace enrichment capability. As shown in Fig. 6, processing of moderate sample volumes (1–5 ml) results in significant improvements in method sensitivity such that determinations at the ng/l. level and below are realistic. As a performance indicator processing of a 50-ml sample resulted in an enrichment factor of about 200.

Interferences

The possibility of a reduced deposition efficiency for methylmercury in the presence of diverse foreign ions was examined since metal ions are retained by the sulphydryl cotton microcolumn.[13] A methylmercury standard solution (2.0 μg Hg/l.), a tap water sample spiked with methylmercury (2.0 μg Hg/l.) and a methylmercury standard solution (2.0 μg Hg/l.) spiked with multielement solution (Al, Mg, Fe, Zn: 20 mg/l; As, Cd, Cr, Cu, Mn, Pb: 4 mg/l.) were processed as previously and fluorescence intensities for the three solutions are presented in Table 2. It is clear that no significant enhancements/suppressions occurred for the spiked samples. It can be concluded, therefore, that the presence of co-existing metal ions did not impair uptake of methylmercury and the proposed method may be suitable for natural waters analysis.

Analysis of waters

The FI method was applied to the analysis of a tap water and a series of river water samples. All samples were filtered (Millipore, 0.45 μ) before analysis and also spiked with methylmercury chloride (at the 10 or 20 ng/l. level) to check recovery. A sampling volume of 20 ml was used to achieve preconcentration in the case of the methylmercury species. The results obtained are presented in Table 3 and reveal relatively low concentrations of methylmercury with acceptable precision and recovery. Unfortunately due to lack of sensitivity it was not possible to quantify inorganic mercury directly (on-line preconcentration applicable only for methylmercury) and thus a total mercury determination was performed after acid digestion and conventional AFS measurement. The data are consistent with literature values for mercury in fresh water (150–700 ng/l. for industrial regions) and indicate a predominance of the inorganic fraction relative to methylmercury.

Table 2. Analysed values for methylmercury in standard solutions and spiked samples

CONCLUSIONS

An FI–AFS system incorporating a microcolumn of sulphydryl cotton has provided a novel route for rapid sequential measurement of inorganic mercury and methylmercury. On-line preconcentration affords high sensitivity in the case of methylmercury determination. Although application to river waters was demonstrated there is some concern regarding reliability of data given the notorious instability of methylmercury species.[8] It is proposed to investigate and evaluate the possibility of stabilizing methylmercury species at the sampling stage by passage of water samples through sulphydryl cotton microcolumns. The microcolumns are then returned to the laboratory and inserted into the FI–AFS system for elution/quantitation. Preliminary data for this new field sampling/flow injection measurement approach are promising.[14] The suitability of sulphydryl cotton microcolumns for multielement field sampling/flow injection/ICP analysis is also receiving attention.

INVESTIGATIONS OF V_2O_5–BASED LPG SENSORS*

A. R. RAJU, KANNAN SESHADRI and C. N. R. RAO†

CSIR Centre of Excellence in Chemistry and Materials Research Centre, Indian Institute of Science, Bangalore 560012, India and
Jawaharlal Nehru Centre for Advanced Scientific Research IISc campus, Bangalore 560012, India

(*Received* 20 *March* 1992. *Accepted* 1 *April* 1992)

Summary—Sensor characteristics of V_2O_5 dispersed on oxide supports such as Al_2O_3, TiO_2 and ZrO_2 with respect to various gases and vapours including liquefied petroleum gas (LPG) have been investigated. Of all the systems studied, 20 mol% V_2O_5 dispersed on ZrO_2 shows the highest sensitivity for LPG, the log sensitivity–log concentration (in ppm) plots being linear up to 1000 ppm or more. The sensitivity is not affected by humidity or recycling. Addition of P_2O_5 to V_2O_5 however destroys the sensitivity. Considering all aspects, 20 mol% V_2O_5/ZrO_2 is suggested for use as a practical LPG sensor. ESR spectroscopy indicates the formation of V^{4+} species on exposure of V_2O_5/ZrO_2 or TiO_2 to LPG. *In-situ* high-temperature x-ray diffraction measurements show the formation of an unusual monoclinic form of VO_2 on exposure to LPG at 625 K which gets oxidized back to V_2O_5 on exposure to air.

Hydrocarbon gases, widely used as industrial and domestic fuels, have often proved to be hazardous because of explosions caused by leaks. It is therefore of vital importance to develop good sensors for hydrocarbon gases. While there have been attempts to use different materials as hydrocarbon sensors, good sensitivity has been obtained only with platinum supported on ZnO or SnO_2.[1–4] Supported Pt is not as selective as one would desire since it also acts as a sensor for H_2, alcohol and possibly other gases and vapours as well. Palladium dispersed on Fe_2O_3 detects hydrocarbons, but with considerably lower sensitivity.[5] We have been interested in finding a suitable sensor for liquefied petroleum gas (LPG) which is essentially a mixture of n-propane and n-butane by employing catalytic oxides and avoiding the use of noble metals. We have found that V_2O_5 dispersed on ZrO_2 serves this purpose excellently. We have carried out detailed experiments to determine the sensor characteristics of pellets or wafers of V_2O_5 dispersed on Al_2O_3, TiO_2, ZrO_2 and other oxide supports for different gases and vapours. We have also examined the dependence of the sensitivity on the pellet thickness as well as humidity. In order to understand the nature of interaction of aliphatic hydrocarbons (LPG) with the active surface of V_2O_5, we have employed electron spin resonance (ESR) spectrocopy and *in-situ* x-ray diffraction. The study has shown that hydrocarbon-sensing by V_2O_5 dispersed on oxide supports involves facile reduction to a novel monoclinic form of VO_2.

EXPERIMENTAL

Fine powders of ZrO_2, TiO_2 (anatase), γ-Al_2O_3 and ZnO were prepared by hydrolysing zirconium nitrate, titanium tetrachloride, aluminium nitrate and zinc nitrate respectively with liquid ammonia followed by calcination in air at 670 K for 6 hr. Fumed silica was used as the starting material for SiO_2. $LaCoO_3$ powder was prepared by solid state reaction of La_2O_3 and CoO at 1300 K for 24 hr. Vanadium oxide was supported on these metal oxides by wet impregnation with oxalic acid solution of ammonium meta-vanadate.[6-9] Sb_6O_{13}[10] and P_2O_5[11] were supported by using antimony chloride and ammonium dihydrogen phosphate solutions respectively. Wet impregnation was carried out at 350 K for 12 hr followed by drying at 370 K. The final products were heated slowly to 670 K and kept for 6 hr and then cooled to room temperature in air.

The powders obtained after wet impregnation were made into pellets (10 mm diameter and 1, 2 and 5 mm thick) under 20 KPa/cm^2 pressure. The pellets were heated at 770 K for 12 hr. Thick films were made by using pastes prepared by mixing equal amounts of nitrocellulose and amyl acetate to the dispersed powders. The

*Dedicated to Professor T. S. West, a dear friend of the senior author (C.N.R.R.) who worked closely with Tom for several years in IUPAC.

†Author for correspondence.

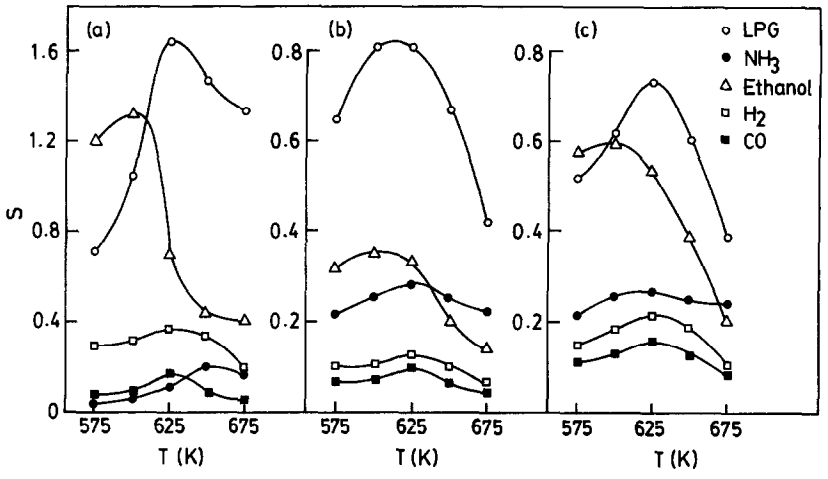

Fig. 1. Temperature-variation of the sensitivity of 20 mol% V_2O_5 dispersed on (a) ZrO_2, (b) TiO_2 and (c) Al_2O_3 for different gases and vapours (400 ppm).

paste was screen-printed on alumina (99%) substrates followed by heat treatment at 850 K for 6 hr. Conducting silver paint (Acheson Electrodag 915, England) was used for contact purposes. The thick films did not show good sensitivity (usually $<50\%$ of the pellets of the same composition) and were therefore abandoned in preference to the pellets.

Sensitivity of the gas sensors was measured by applying 9 V (DC) across the sensor and monitoring the current through the sensor element. The experimental set-up used for the measurements had been described elsewhere.[12] The sensitivity, S, of the sensor was calculated by using the expression

$$S = (\sigma g - \sigma a)/\sigma a$$

where, σg and σa are the conductivities of the sensor in the presence of test gas and dry air respectively. The effect of humidity on the sensitivity was studied by passing air with known humidity content through the cell.

Electron spin resonance (ESR) studies were carried out with a Varian E-109 x-band spectrometer. High-temperature x-ray diffraction measurements were made by employing a JEOL JDX-8P diffractometer fitted with an *in-situ* cell designed and fabricated in the laboratory.[13]

RESULTS AND DISCUSSION

In Fig. 1 we show plots of the sensitivity of 20 mol% V_2O_5 dispersed on ZrO_2, TiO_2 and Al_2O_3 supports to various gases and vapours including LPG, ethanol, CO and H_2. We generally find that the sensitivity is not high for NH_3, CO and H_2 independent of the oxide support, but is good for ethanol, specially at 600 K. The

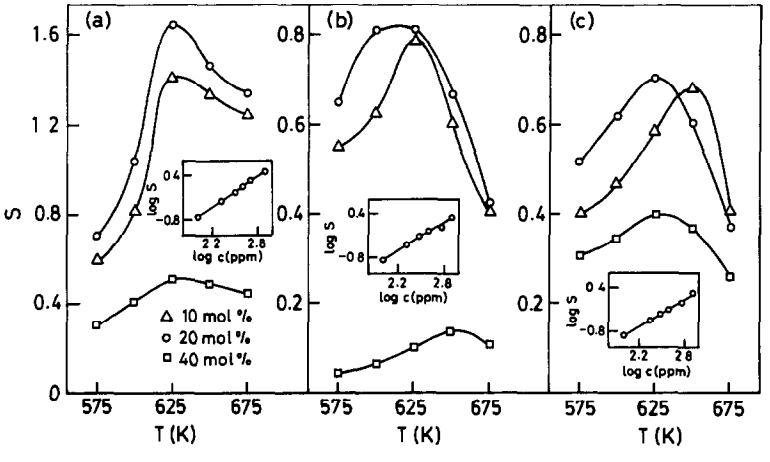

Fig. 2. Temperature-variation of the sensitivity to LPG (400 ppm) for different loadings of V_2O_5 on (a) ZrO_2, (b) TiO_2 and (c) Al_2O_3. Insets show the log sensitivity–log concentration (ppm) plots for 20 mol% V_2O_5 dispersed on oxide supports.

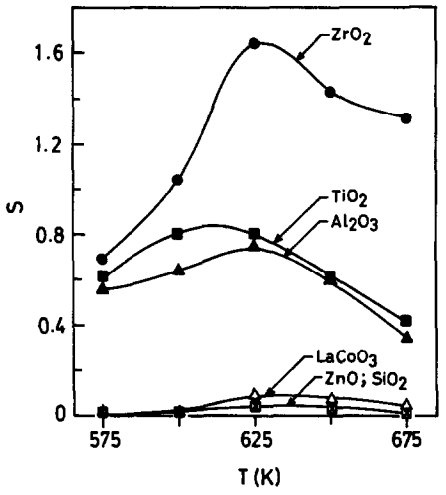

Fig. 3. Temperature-variation of the sensitivity of 20 mol% V_2O_5 dispersed on ZrO_2, TiO_2, Al_2O_3, $LaCoO_3$, ZnO and SiO_2 supports to LPG (400 ppm).

sensitivity is highest for LPG around 625 K with all the supports studied. Sensitivity for LPG is highest with 20 mol% V_2O_5/ZrO_2, although 20 mol% V_2O_5/TiO_2 is also satisfactory; it appears that either of the two supports will be adequate. We have examined the dependence of the sensor characteristics (Fig. 2) on V_2O_5 loading and found 20 mol% V_2O_5 to possess maximum sensitivity for LPG, specially when dispersed on ZrO_2. In Fig. 3 we compare the sensitivity of 20 mol% V_2O_5 dispersed on various oxide supports. The sensitivity is negligible in the case of ZnO, SiO_2 and $LaCoO_3$ supports. In the insets of Fig. 2 we have shown the variation of the sensitivity with the concentration for 20 mol% V_2O_5 dispersed on ZrO_2, TiO_2 and Al_2O_3. The log S–log C (in ppm) plots are linear up to 1000 ppm or more, the minimum detection limit for LPG in air being 10 ppm. Since the lower flammability limit for LPG in air is 1000 ppm, the sensitivity of 20 mol% V_2O_5/ZrO_2 is more than adequate for sensing purposes. At 1000 ppm of LPG, the sensitivity of 20 mol% V_2O_5/ZrO_2 is 2.7 compared to 0.9 for Pd/γ-Fe_2O_3, 0.7 for γ-Fe_2O_3 and 3.0 for Pt/ZnO.

In Fig. 4(a) we show the variation of the sensitivity of 20 mol% V_2O_5/ZrO_2 to LPG after repeated cycling. We see negligible fatigue after 30 days, after repeated cycling. The effect of humidity on the sensitivity of 20 mol% V_2O_5/ZrO_2 to LPG is shown in Fig. 4(b). The sensitivity is not affected significantly even up to 80% relative humidity. We have studied the effect of other oxide additives on the sensitivity of the V_2O_5 dispersed on ZrO_2 and TiO_2. In Fig. 5 we compare the sensitivity plots for 10 mol% Sb_6O_{13} and V_2O_5:P_2O_5 solid solutions (total loading of the oxides, 20 mol%) with those of 20 mol% V_2O_5. Addition of P_2O_5 destroys the sensitivity of V_2O_5; sensitivity of Sb_6O_{13} is much lower than that of V_2O_5. The high selectivity of 20 mol% V_2O_5/ZrO_2 pellets to LPG as well as the negligible fatigue found by us, when subjected to repeated cycling and high humidity makes it viable as a practical LPG sensor.

All the measurements obtained hitherto pertained to pellets 2 mm thick. We have examined the dependence of the sensitivity on the pellet thickness. In Fig. 6 we show the sensitivity of pellets of 20 mol% V_2O_5/ZrO_2 of different thicknesses. The sensitivity essentially remains the same for pellets in the thickness range of 1–5

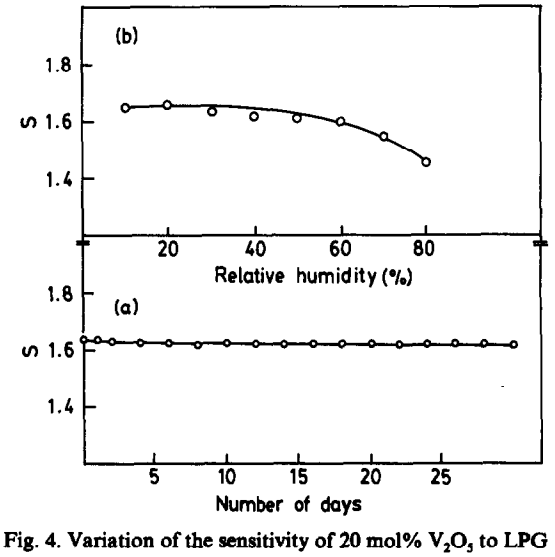

Fig. 4. Variation of the sensitivity of 20 mol% V_2O_5 to LPG (400 ppm) with (a) the number of days repeated cycling and (b) relative humidity.

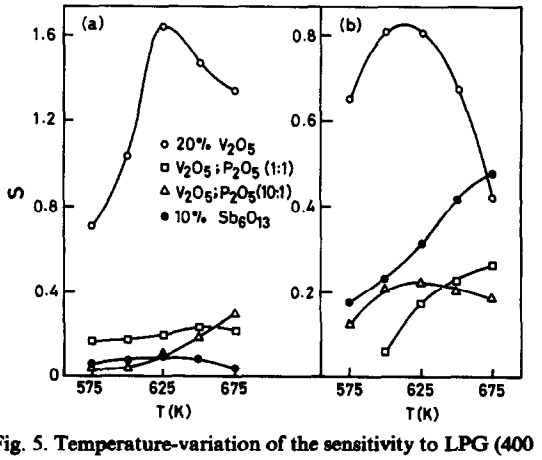

Fig. 5. Temperature-variation of the sensitivity to LPG (400 ppm) for different oxide loadings on (a) ZrO_2 and (b) TiO_2 supports.

mm. The 1-mm thick pellets would be best for practical applications, since they would require least electric power.

We were interested in understanding the mechanism of gas sensing of V_2O_5 dispersed on oxide supports. For this purpose, we have employed ESR spectroscopy to monitor the interaction between V_2O_5 and LPG. In Fig. 7 we compare the ESR spectra of 20 mol% V_2O_5 dispersed on ZrO_2 and TiO_2 before and after exposure to LPG vapours. Both V_2O_5/ZrO_2 and V_2O_5/TiO_2 show signals due to V^{4+} present on the surface; after exposure to LPG at 625 K, the

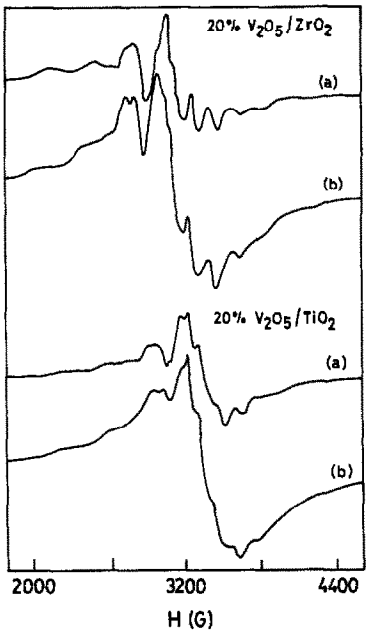

Fig. 7. ESR spectra of 20 mol% V_2O_5 dispersed on ZrO_2 and TiO_2 at 625 K. Spectra (a) and (b) are before and after exposure to LPG vapours.

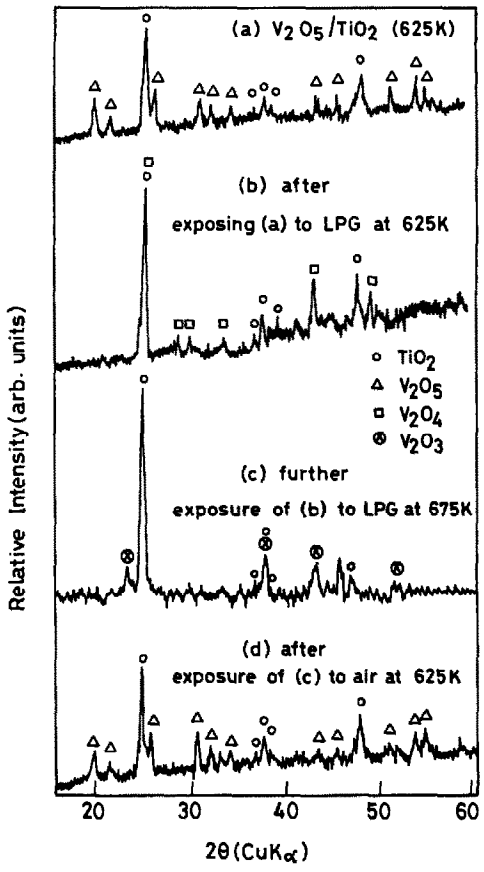

Fig. 8. X-ray diffraction patterns of 20 mol% V_2O_5/TiO_2: (a) at 625 K in air; (b) after exposure to LPG at 625 K; (c) further exposure of (b) to LPG at 675 K; (d) after exposure of (c) to air at 625 K.

intensity of the V^{4+} signal increases markedly showing that the aliphatic hydrocarbons reduce V_2O_5 to VO_2. When such a surface is again exposed to air at the same temperature, VO_2 is oxidized back to V_2O_5.

In order to investigate the nature of the reduction–oxidation of the vanadium oxides, we have carried out an *in-situ* x-ray diffraction study of 20 mol% V_2O_5/TiO_2 in the 625–675 K range. In Fig. 8 we show the x-ray diffraction patterns of V_2O_5/TiO_2 before and after exposure to LPG at 625 K. We clearly see features of VO_2 emerging after exposure to LPG at 625 K. The VO_2 so formed has a unique B′ monoclinic structure[14] ($a = 12.03$, $b = 3.693$, $c = 6.42$ Å, $\beta = 107°$, space group C2/m) which is different from the stable room temperature monoclinic structure ($a = 5.752$, $b = 4.538$, $c = 5.383$ Å, $\beta = 122.6°$, space group $P2_1C$) or the well-known 340 K rutile structure ($a = 4.551$, $c = 2.851$ Å, space group P4/mmm). The B′ monoclinic phase is related to V_6O_{13} and transforms to the stable monoclinic structure on

cooling. When V_2O_5/TiO_2 is exposed to LPG at a slightly higher temperature (675 K) or at 625 K for long periods, V_2O_3 is formed (Fig. 8). However, on exposure to air at 625 K, the surface is regenerated within two minutes and we get back V_2O_5. From these studies we conclude that sensing of LPG by V_2O_5 dispersed on oxide supports involves reduction–oxidation of V_2O_5.

Acknowledgements—The authors thank Mr. K. R. Kannan for the *in-situ* high-temperature x-ray diffraction cell and Ram Seshadri for his assistance in carrying out measurements.

Summary—Four lipophilic sulphur and/or nitrogen containing calixarene derivatives have been tested as ionophores in Ag(I)-selective poly (vinyl chloride) membrane electrodes. All gave acceptable linear responses with one giving a response of 50 mV/dec in the Ag(I) ion activity range 10^{-4}–$10^{-1}M$ and high selectivity towards other transition metals and sodium and potassium ions. This ionophore was also tested as a membrane coated glassy-carbon electrode where the sensitivity and selectivity of the conventional membrane electrode was found to be repeated. The latter electrode was then used in potentiometric titrations of halide ions with silver nitrate.

Calixzarenes[1] are cyclic oligmers of phenol–formaldehyde condensates which when derivatized at the phenolic oxygen group show receptor inophoric activity. Derivatives containing a wide range of functional groups have been synthesized and have been shown to have the ability to complex alkali and alkali-earth metal cations selectively into the cavity present in the cone conformation.[2] A number of calixarene derivatives have been incorporated as neutral carriers into ion-selective electrodes sensitive to sodium ions,[3–6] potassium ions[7] and ceasium ions.[8,9] The sodium selective electrodes have been used successfully in the determination of sodium in human blood[4,10] and recently a sodium selective CHEMFET has been reported.[11] A polymeric tetrameric calixarene has been used in a modified carbon paste electrode for the stripping voltammetry of copper, lead and mercury.[12] Due to the success of these calixarene derivatives a number have been patented. However, calixarene based ion-selective electrodes sensitive to transition metal ions have not yet been reported as they would suffer interference from alkali metal ions. Crown compounds containing nitrogen and sulphur atoms in the ring have been incorporated into poly (vinyl chloride) membranes to give electrodes sensitive to Ag(I) ions with some Hg(II) interference.[13,14] By using calixarene derivatives with functional groups containing nitrogen and sulphur atoms the interference from alkali metal ions is expected to be significantly reduced.[15]

In this paper the performance of four calixarene derivatives, tested as ionophores for silver selective electrodes, is described. The most promising is also tested as a membrane-coated glassy carbon electrode. There are many descriptions on the usage of glassy carbon electrodes in voltammetry, amperometry, potentiometry and coulometry[16] but there are a limited number of reports on the usage as a substrate of the sensor phase in ion-selective electrodes. It has been recently used successfully in dip coated enzyme sensors[17] and tested as a substrate for a variety of sensor phases by Jovanoić *et al*[18]. Also carbon rods have been dip coated for use in lead(II) selective electrodes.[19] An application of these types of electrodes in potentiometric titrations of halide ions with silver nitrate is also described.

*Author for correspondence.

EXPERIMENTAL

Materials

The ionophores employed in this work were synthesized by S. J. Harris and M. A. McKervey and are shown in Fig. 1.

The membrane components, PVC (ISE grade), potassium tetrakis (4-chlorophenyl) borate (KTpClPB), 2-nitrophenyl octyl ether (2-NPOE) and AnalaR grade tetrahydrofuran (THF) were obtained from Fluka. The nitrates of sodium, potassium, nickel, copper(II), lead(II), cadmium(II), cobalt(II) and mercury(II) were of AnalaR grade as were the potassium chloride, bromide and iodide. The silver nitrate was obtained from Johnson Matthey Chemicals Ltd. All solutions and standards were made up with doubly distilled water.

Electrode preparation

The membrane components, [0.66% m/m ionophore, 0.17% m/m KTpClPB, 65.84% m/m 2-NPOE and 33.33% m/m PVC] were mixed and dissolved by stirring in THF overnight.

For the preparation of a conventional membrane electrode the resulting PVC–THF syrup was poured into a glass mould,[20] and the solvent was allowed to evaporate off at room temperature, over a period of 24 hr. A semi-transparent flexible membrane was obtained from which discs of 7 mm diameter were cut using a cork borer. These discs could be pasted, using THF, to an interchangeable PVC tip clipped to the end of the electrode body which consisted of an Ag–AgCl wire immersed in an internal solution of 5×10^{-4}M silver nitrate and 10^{-2}M nitric acid.

A membrane-coated glassy-carbon electrode was prepared as follows. Initially, the end of a glassy-carbon electrode (3 mm in diameter) was polished on Al_2O_3 slurry and air dried. It was then dip coated to a depth of 10 mm in a PVC–THF syrup and dried at room temperature. This was repeated three times. The PVC-THF syrup was of the same composition as that for the conventional membrane electrodes.

Fig. 1. Structure of ionophores.

Measurement of electrode potentials

All measurements were carried out at 25° in a thermostatted potentiometric cell. The electrochemical systems for the study were as follows:

Ag,AgCl|int. soln.(5×10^{-4}M $AgNO_3 + 10^{-2}$M HNO_3)|PVC membrane|sample|salt bridge ($1M$ KNO_3)|$1M$ KNO_3)$1M$ KNO_3|Hg_2Cl_2,Hg.

Carbon|PVC membrane|sample|salt bridge ($1M$ KNO_3)|Hg_2Cl_2,Hg.

The potential readings were measured using a Metrohm 654 millivot/pH meter and registered on a Linseis LM 24 chart recorder. The reference electrode was a Metrohm saturated calomel. The performance of the electrodes were assessed by measuring parameters such as slope, limit of detection, selectivity, response times and temperature dependence of the electrode. Selectivity coefficients (log $K_{Ag,M}$) were determined using the separate solution method[21] at a concentration of $0.1M$. Dynamic responses were measured by injection of 90.9 μl; of $1M$ silver nitrate solution into 10 ml of $10^{-3}M$ silver nitrate on a fast chart speed (10 cm/min) thus producing a $1 \times 10^{-3}M$ to $1 \times 10^{-2}M$ change in concentration. The temperature dependence was investigated by noting the potential change in solutions of $10^{-3}M$, $10^{-2}M$ and $10^{-1}M$ silver nitrate respectively over a temperature range of 5–45° (278–318 K). Lifetime of the electrodes was investigated by recalibrating them periodically and calculating the response over the linear range Reproducibility studies were carried out by determining the coefficient of variation for five consecutive potential readings in solutions of $10^{-3}M$ and $10^{-2}M$ silver nitrate respectively. The instruments used for the potentiometric titrations were a Metrohm E 536 Potentiograph and E 535 Dosimat.

RESULTS AND DISCUSSION

Four nitrogen and/or sulphur containing calixarene derivatives, shown in Fig. 1 were incorporated into poly (vinyl chloride) membrane electrodes and were shown to give acceptable linear responses to Ag(I) ion activity with limits of detection of between $10^{-3.8}$ and 10^{-4}M. The calibration graphs of Fig. 2(a) indicate that the degree of linearity of the response occurs in the order of:

ionophore (iv) > (iii) > (ii) > (i)

with ionophore (i) giving the lowest response of 38.26 mV/dec in the limited range of $10^{-3.8}$ to $10^{-1.8}$ M. This trend may be simply attributed to the number and type of "soft" donor atoms present within each ionophore. It should be noted that ionophore (iv) contains S atoms and no N atoms where as in ionophore (i) the opposite is true. When comparing the selectivity coefficients (log $K^{pot}_{Ag/M}$) for the electrodes based on ionophores (i) to (iv) in Fig. 2(b) it can be seen that Hg^{2+} and Na^+ ions are the major

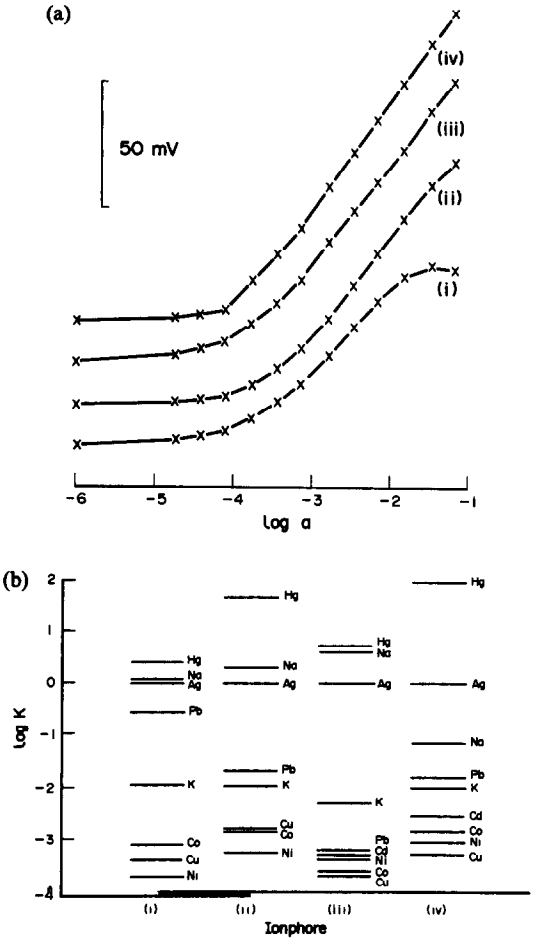

Fig. 2. (a) Potential responses of conventional membrane electrodes incorporating ionophores (i)–(iv) to silver (I) ion activity. (i) 38.26 mV/dec, (ii) 45.67 mV/dec, (ii) 47.64 mV/dec and (iv) 50.01 mV/dec. interferents followed closely by Pb^{2+} ions. Phase transfer and stability studies on a wide range of tetrameric calixarene derivatives have shown them to be excellent complexing agents for alkali and alkali-earth metal ions with, in the majority of cases, a clear preference for sodium ions[2]. However, very little work has been reported on tetrameric calixarene derivatives with functional groups containing "soft" donor atoms such as N and S atoms which according to Pearson[15] are more likely to complex heavy metal ions such as Ag^+, Hg^{2+} and Pb^{2+}. With ionophores (i) to (iv) the soft donor atoms are imparting some selectivity to heavy metals but there is still a significant response to Na^+ ions. Ionophore (iii) is a calixarene with mixed ligating functional groups, one being the ethyl ester. In general the trends in extraction and stability constants observed in a homo calixarene containing a certain functional group are still discernible in the mixed calixarene.[2] Since the homo calixarene containing the ethyl ester has been incorporated into a poly (vinyl chloride) membrane and has been shown to be a successful sodium ion-selective electrode,[6,8,22] it is not surprising that ionophore (iii) has the most severe Na^+ interference. The Hg^{2+} interference is caused most strongly by the S donor atom as Hg^{2+} is a strongly thiophilic metal ion.[23] When the membranes came in contact with Hg^{2+} and Pb^{2+} ions the silver response was tested immediately afterwards and also after 3 and 24 hr respectively, the electrodes being stored in $0.1M$ silver nitrate when not in use. The effect of the ions on the membranes was in the following orders;

Pb^{2+} effect. ionophore (ii)$\gg$(iv) > (i) > (iii)

Hg^{2+} effect. ionophore (ii)$\gg$(i) > (iv) > (iii)

Ionophore (ii) did not have its full silver response back after 24 hr after contact with Pb^{2+} ions but in the case of contact with Hg^{2+} ions it had almost its full response back. Ionophores (ii) to (iv) were all regenerated in less than 3 hr but the Hg^{2+} ions in general had a stronger poisoning effect than the Pb^{2+} ions. It must be borne in mind that these membranes were in contact with interfering ions up to concentration of $0.1M$. Smaller concentrations would have a less detrimental effect. Na^+ ions had no poisoning effect on the membrane with it's response being totally reversible.

Further work was carried out on ionophore (iv) as it gave the best Ag(I) ion calibration slope and the best selectivity towards all the ions tested with the exception of Hg^{2+} ions. A membrane-coated glassy carbon electrode (B) was tested under the same conditions as the conventional membrane electrode (A). The properties of the two types are summarized in Table 1. The sensitivities and selectivities of the two electrodes are very alike with B being slightly more sensitive, with a higher Ag(I) ion response slope. In comparing the full responses (in the concentration range of 10^{-6} to $10^{-1}M$) against all the interfering ions, in Fig. 3, it can be seen that the responses are almost identical. Most of the ions gave practically no response but the Na^+ response had a slope of 25 mV/dec and Pb^{2+} a slope of 17 mV/dec. The Hg^{2+} response behaved relatively linearly up to a concentration $10^{-1.8}M$ where it became anionic in nature. This is known as the "anion effect"[24] and is usually reduced by the addition of incorporated ion exchangers within the membrane. In the case of our membrane which has KTpClPB as an incorporated ion exchanger the transition of the response into an anionic function is obtained only when complete consumption of free

carriers has occurred.[25] In the linear range of the Hg^{2+} response a slope of 80–90 mV/dec is obtained compared to the expected Nernstian slope of 29.6 mV/dec for a divalent metal cation. This response characteristic may be due to the formation of charged associates within the membrane[26] and has been noticed previously in Hg(II) and Ag(I) selective poly (vinyl chloride) membrane electrodes based on dithia crown ethers[13] where this unusual response was attributed to the formation of $Hg(TPB)^+$ ions in the membrane so perhaps the response in this case is due to $Hg(TPClB)^+$ ions. On preparation of a membrane containing no ion exchanger there is a large increase in anion interference, the Ag(I) ion response has a slope of < 10 mV/dec and the membrane has a very dark brown/yellow colour (characteristic of a very old stored membrane) after a few days. However, the Hg^{2+} response is nearer to divalent in nature. Electrode type B has a marginally shorter response time than type A which is probably due to the much thinner film (0.2 mm) formed on the carbon surface. Temperature studies indicate that both electrodes are affected very little by temperature, with type B being slightly more stable. Examining the lifetime calibration slopes in Table 1 it can be seen that at day 22 electrode type B gives a slope of 42.42 mV/dec but the potential readings for this slope have shifted up by 230 mV from the original potential readings. On day 111 electrode A had a calibration slope which differed by only 20 mV from the original potential readings. Reproducibility studies on new and old membranes of both types show that type A membranes have steady readings even after 111 days whereas after only 6 days type B membranes have erratic readings. The initial readings of both are very similar.

Membrane electrodes of type B were used in potentiometric titrations of halide ions against silver nitrate as these electrodes were easier and quicker to prepare and did not require long conditioning times. Figure 4 shows that the membrane was successful in resolving a mixture of Cl, Br and I ions. The reversal of potential occurring in the presence of iodide and to a lesser extent of bromide ions is reproducible and does not affect the accuracy of the titrations. Though we did not investigate this matter further, it can probably be attributed to the adsorption of precipitate particles on the electrode surface, causing increased cell resistance. By physically removing the precipitate from the electrode surface, potential readings can be restored more or less to their expected values.

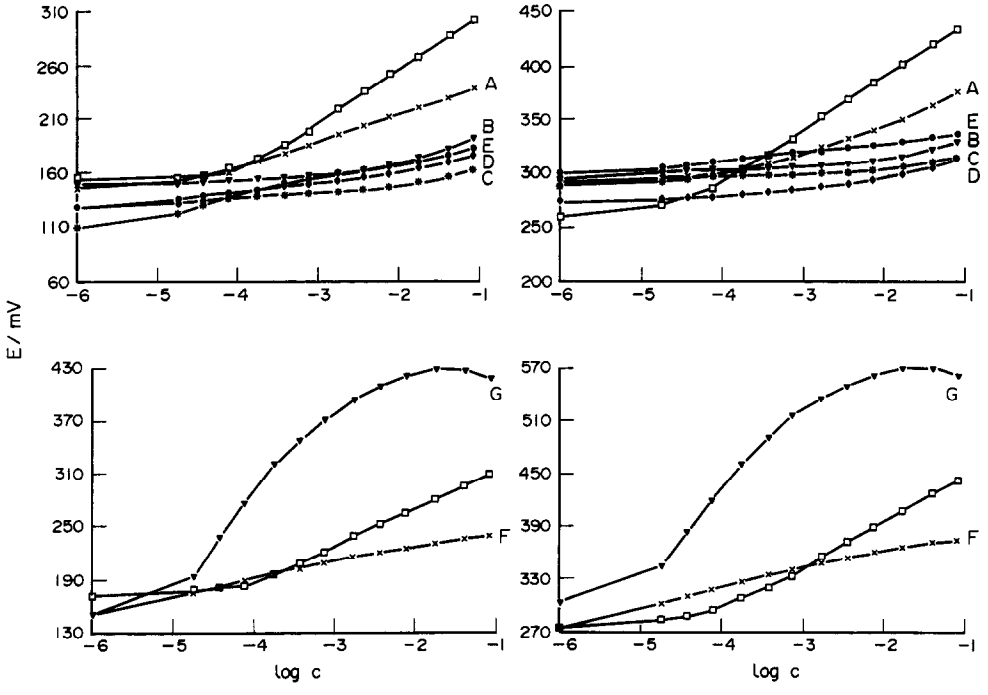

Fig. 3. Response of silver-selective electrodes to metal cations. (A) Na, (B) K, (C) Ni, (D) Co, (E) Cu, (F) Pb and (G) Hg. (unlabelled response) Ag. (a) conventional membrane electrode. (b) membrane-coated glassy carbon electrode.

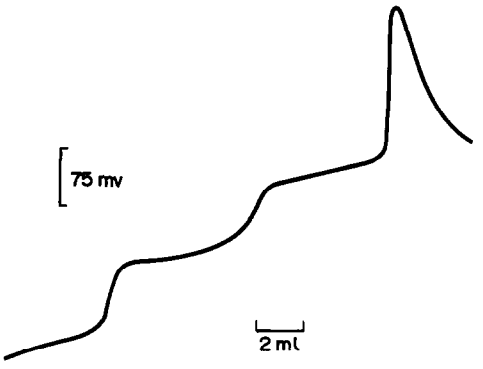

Fig. 4. Potentiometric titration of a mixture of 4.5 ml KI, 5.5 ml KBr and 6.5 ml KCl (all 0.1*M* concentration) with 0.1*M* $AgNO_3$ using a membrane-coated glassy carbon electrode incorporating ionophore (iv).

CONCLUSIONS

Conventional membrane electrodes and membrane-coated glassy-carbon electrodes based on ionophore (iv) were found to be successful Ag(I) selective electrodes. Both types exhibited good linear responses and good sensitivity and selectivity. They responded quickly and reversibly and gave good temperature stability. However conventional membrane electrodes were more beneficial for long-term use as they were found to be more stable and reproducible with time.

COULOMETRIC TITRATION IN THE STUDY OF METAL ION-LIGAND EQUILIBRIA

STANISŁAW GŁĄB and ADAM HULANICKI*
Department of Chemistry, Warsaw University, Pasteura 1, 02-093 Warsaw, Poland

URSZULA NOWICKA
Department of Chemistry, University of Teachers College, 08-110 Siedlce, Poland

(*Received* 16 *March* 1992. *Accepted* 31 *March* 1992)

Summary—The coulometric titration technique is applied to evaluation of stability constants of metal complexes with ligands which have protolytic properties. The validity of the procedure was checked by studying several well-known systems. The proposed method can be used with success when metal ions are not reduced at the working cathode. Constants for calcium and magnesium complexes with components of some biologically important buffers, so-called Good buffers, were evaluated under experimental conditions (ionic strength of 0.16*M*, 37°) used in clinical analysis.

The most commonly used method for determination of stability constants of metal complexes with ligands which have protolytic properties is based on alkalimetric titration of solution containing the protonated form of ligand alone and in the presence of metal ion.[1] The changes in hydrogen ion-activity or concentration are followed with a glass electrode calibrated with appropriate standards. In the latter case for calibration of glass electrode the so-called "E^0-titration"[2] is used, in which a strong acid is titrated with a strong base. At constant ionic strength the EMF of a cell linearly depends on the logarithm of the hydrogen ion concentration.

In the alkalimetric titration of the protonated form of the ligand necessary for the determination of the ligand protonation constant a strong base used as a titrant may be successfully generated coulometrically. The advantages of the application of coulometric titrant generation for determination of protonation constants were pointed out previously.[3–5]

There are only a few papers in the literature in which the ligand in the presence of metal ion is alkalimetrically titrated by an electrolytically generated titrant. Such a procedure was used by Paris and Gregoire[6,7] who have determined the hydrolysis constants of beryllium(II)[6] and titanium(III).[7]

The aim of this paper is to check the possibility of the coulometric titration in studies of complexation equilibria. It requires more systematic studies of the titrant (strong base) electrogeneration efficiency in solutions containing metal ions with various redox properties. In order to check the applicability of coulometric titration for determination of stability constants of complexes some well-known metal–ligand systems were studied for comparison. The proposed method was used for the study of calcium and magnesium complexes with components of some biologically important buffers, so-called "Good" buffers,[8] for which stability constants, until now, have not been determined under experimental conditions (ionic strength—0.16*M*, 37°) used in examination of biological samples and in clinical analysis. Some buffers from this group are used as components of calibration standards for blood electrolyte measurements with calcium and magnesium ion-selective electrodes. Such buffer components should either not complex these metal ions or form complexes of known stability constants.

Among advantages in this procedure the simplicity as well as extreme precision and accuracy should be mentioned and make such procedure especially useful even for low-stability complexes.

EXPERIMENTAL

Reagents

Analytical grade acids. Citric, nitrilotriacetic (NTA), perchloric, succinic and tartaric acids were used.

Ethylenediaminetetraacetic acid, disodium salt dihydrate (EDTA). Analytical grade.

Cadmium nitrate tetrahydrate, copper(II) nitrate hydrate, calcium nitrate tetrahydrate, iron(III) nitrate nonahydrate, magnesium nitrate hexahydrate, sodium perchlorate monohydrate were all analytical grade reagents.

Components of buffer for the physiological pH range were *N*-(2-acetamido)- 2-aminoethanesulphonic acid (ACES), 4-morpholineethanesulphonic acid (MES), 3-{[Tris-(hydroxymethyl)methyl]-amino}-1-propanesulphonic acid (TAPS), (2-{[Tris(hydroxymethyl)-methyl]amino}-1-ethanesulphonic acid (TES) (Aldrich).

Apparatus

Coulometric analyser OH-404 Radelkis, pH-meter OP-208/1, Radelkis with the glass indicator electrode and the silver–silver chloride reference electrode (Ingold P 1883).

Measurements were carried out at 25 and 37° in a two-compartment coulometric cell equipped with a magnetic stirrer. The solutions were deaerated and kept under argon gas.

Procedures

The anode and cathode (2 ml) compartments of the coulometric cell were separated by two G-4 sintered glass discs and the space between them was filled with 3% aqueous sodium perchlorate in 3% agar-agar. Both electrodes of the generating system were platinum, the surface area of the working electrode was $A = 0.25$ cm^2. The reference electrode of the indicator system was connected through an electrolytic bridge containing 0.1 or 0.16*M* sodium chloride depending whether the ionic strength of titrated solution adjusted with sodium perchlorate was equal to 0.1 or 0.16. The current $i = 3$ mA provides 100% generation efficiency of the base in sodium perchlorate solutions.[3]

The solutions titrated coulometrically contained approximately 5 μmoles of perchloric acid for calibration of indicator electrode system, or 5 μmoles of protonated ligand in the case of determination of the protonation constant.

For determination of stability constants the solutions contained a mixture of protonated ligand (approx. 5 μmoles) and the examined metal ions, approx. 5 or 50 μmoles depending whether the studied complexes are strong or very weak.

Solutions of metal ions were standardized by volumetric complexometric methods.[9]

The current potential curves were obtained by measuring the current *vs.* potential of the working cathode measured against a silver-silver chloride electrode.

RESULTS AND DISCUSSION

Experimental data obtained in the course of coulometric titration of the protonated ligand with electrogenerated strong base were used for protonation constant calculations.[3] The protonation constant of a ligand (K_H) is evaluated from the Henderson-Hasselbach equation:

$$\log k_H = -\log[H^+] + \log \frac{[HL]}{[L]}$$

which was transformed into a form directly applicable to coulometric titration:

$$\log K_H = -\log[H^+] + \log \frac{Q_{ep} - Q - FV([H^+] - [OH^-])}{Q + FV([H^+] - [OH^-])}$$

where V is the volume of solution, F is the Faraday constant, and Q_{ep} is the charge consumed until the titration end-point. The pairs of values Q and $[H^+]$ (or $[OH^-]$) were evaluated from the coulometric titration curve, $E = f(Q)$, of an acid examined.

In the case of diprotic acids, when $\log K_{1H} - \log K_{2H} < 2.3$ the constants were calculated from the titration curve using the least square-procedure.[10]

The evaluation of hydrogen ion concentration $[H^+]$ requires the calibration of the indicator electrode, because:

$$\log[H^+] = (E_a^0 - E)F/2.3RT$$

where E_a° is a calibration constant. This constant is evaluated from coulometric titration of perchloric acid carried out at a given temperature and ionic strength.[3] Stability constants of metal–ligand complexes were calculated from the experimental data obtained in the course of alkalimetric titration of solution containing a mixture of protonated ligand and metal ion. The stability constants were calculated from an equation given by Yoshino *et al.*[11] For the

system of ligand $H_M L$ and metal ion where a series of complexes MH_iL ($i = 0, 1, \ldots N$) is formed, the stability constant of the complex MH_nL is given by the equation:

$$K^{M}_{MH_nL} = \frac{[MH_nL]}{[M][H_nL]} = \frac{(B_nC_n - A_nD_n)(C_nC_L - A_nC_H)}{(B_nC_H - D_nC_L)(A_nB_nC_H + D_nC_nC_M - A_nD_nC_M - B_nC_nC_L)}$$

where

$$A_n = \sum_{i=0}^{N} \frac{[H^+]^i K_i}{[H^+]^n K_n}$$

$$B_n = \sum_{i=0}^{N} \frac{[H^+]^i K^1_i}{[H^+]^n K^1_n}$$

$$C_n = \sum_{i=0}^{N} \frac{i[H^+]^i K_i}{[H^+]^n K_n}$$

$$D_n = \sum_{i=0}^{N} \frac{i[H^+]^i K^1_i}{[H^+]^n K^1_n}$$

$$C_H = (N - a)C_L - [H^+] + [OH^-],$$

where C_L is the total concentration of ligand, C_M is the total metal ion concentration, and a is the titration fraction;

$$a = NQ/Q_{ep}$$

$$K^1_i = K^H_{MHL}\, K^H_{MH_2L} \cdot \ldots \cdot K^H_{MH_2L} \quad (K^1_0 = 1)$$

$$K_i = K_{1H}\, K_{2H} \ldots . K_{iH} \quad (K_0 = 1)$$

The calculation of $K^M_{MH_nL}$ requires the knowledge of protonation constants of complexes:

$$K^H_{MH_iL} = \frac{[MH_iL]}{[MH_{i-1}L][H]}$$

These constants can be evaluated from the dependence of the average number of hydrogen ions bound to complexes on hydrogen ion concentration (formation curve).

Before applying the procedure of coulometric determination of protonation constants and stability constants to the Good buffers and their complexes with calcium and magnesium some ligand–metal ion systems were used to check the applicability of methods and to compare the calculated values with literature data. The undesirable electrode reactions which can obviously influence the current efficiency of the electrogeneration of a base may appear when studying complexes of metal ions being easily reduced at the cathode. Therefore cations with various redox properties (Ca^{2+}, Mg^{2+}, Cd^{2+}, Cu^{2+}, Fe^{3+}) were chosen to check the applicability of the use of coulometry for determination of stability constants of their complexes. A current–potential curve recorded for the supporting electrolyte (0.1*M* sodium perchlorate) alone and in the presence of investigated metal ions allows one to check whether 100% current efficiency of titration processes is obtainable. Experiments made at pH 2.5 and 6.0 (these values are within the pH range of metal ion–ligand mixtures titrated coulometrically) indicated clearly for which system that proposed method can be used (Figs. 1 and 2). No disturbance in 100% base electrogeneration occurs for solutions of Ca^{2+}, Mg^{2+} and Cd^{2+}. Only reduction of water or reduction of hydrogen ions (in the case of more acidic solutions) and water occur at the platinum cathode. Therefore, coulometry cannot be used for the study of complexation of easily reduced metal ions, *e.g.*, Cu^{2+} and Fe^{3+}. Reduction of metal ions at the working cathode results not only in current efficiency of titration processes below 100% but also decreases the

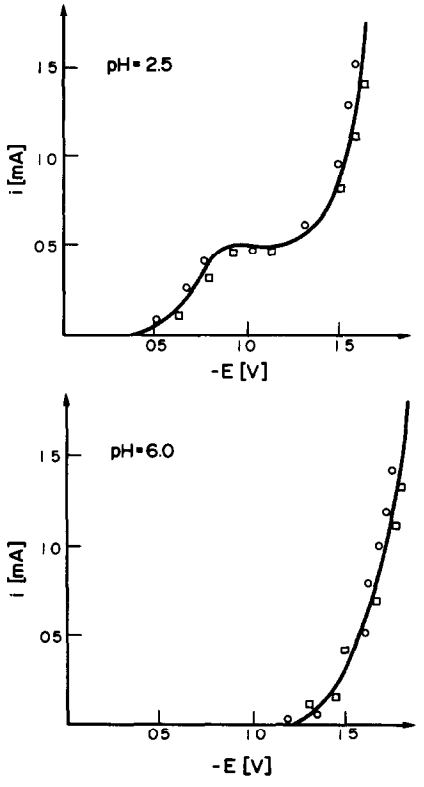

Fig. 1. Current–potential curves for 0.1*M* $NaClO_4$ (solid lines), 0.1*M* $NaClO_4 + 2 \times 10^{-3}M$ Ca^{2+} (○), and 0.1*M* $NaClO_4 + 2 \times 10^{-3}M$ Mg^{2+} (□).

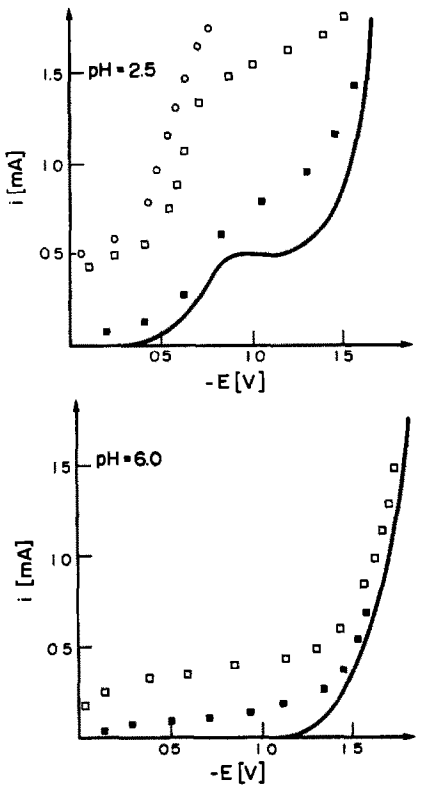

Fig. 2. Current–potential curves for 0.1 M $NaClO_4$ (solid lines), 0.1 M $NaClO_4 + 2 \times 10^{-3}$ M Cu^{2+} (□), 0.1 M $NaClO_4 + 2 \times 10^{-3}$ M $Cu^{2+} + 2 \times 10^{-3}$ M NTA (■), and 0.1 M $NaClO_4 + 2 \times 10^{-3}$ M Fe^{3+} (○).

total metal ion concentration in the course of measurement. The obtained results compared to literature data (Table 1) confirm the statement and indicate that coulometry can be used with success not only for determination of protonation constants but also stability of metal complexes when metal ions are not reduced.

The coulometric method is especially valuable when the complexes are very weak and the error of the conventional titration procedure becomes significant. This is the case of some buffers which are used for biological experiments and form weak complexes with calcium and magnesium. In those systems the stability constants of calcium and magnesium complexes are below 10. In such a case the difference between the titration curves in the presence and absence of metal ion is small. This is clearly shown in Fig. 3 where curves for one of the Good buffers (MES) as well as for EDTA in the absence and in the presence of calcium ions are presented. The estimated smallest value of the constant which can be evaluated equals approximately 1 when we assume that a minimal reasonable shift of the titration curve of the ligand in the presence and absence of excess of metal ion is equal to 1 mV. The protonation constants of Good buffer components as well as stability constants of their complexes with calcium and magnesium, determined under conditions used in biological and clinical measurements, are collected in Table 2. When the literature data for comparable conditions were available the agreement was found quite satisfactory.

Table 1. Protonation constants of ligands and stability constants of their complexes determined by coulometric titration at $I = 0.1$ and 25°. In brackets literature data[12] are given

Ligand	log K_H	log K_{CaL}	log $_{CaL}$
EDTA	10.15 (10.08)	10.75 (10.62)	15.9 (16.3)
	6.00 (6.03)		
NTA	9.40 (9.49)	6.3 (6.4)	10.99 (11.25)
	2.65 (2.67)

	2.70 (2.73)		

CONCLUSIONS

The coulometric generation of a strong base was adapted for determination of stability constants of metal complexes with ligands having protolytic properties. The proposed method of determination of stability constants offers several advantages, some worth mentioning are:

No need for preparation of standard solutions.

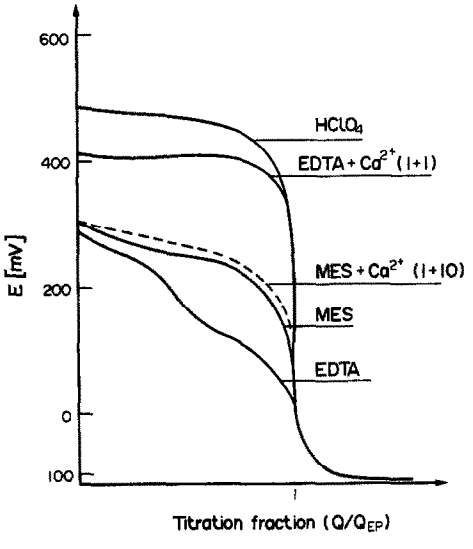

Fig. 3. Coulometric titration curves of $HClO_4$, EDTA, EDTA + Ca^{2+}, MES, and MES + Ca^{2+}.

Table 2. Protonation constants of some buffer components and stability constants of their calcium and magnesium complexes determined by coulometric titration at $I = 0.16$ and 25 or 37°. Data in brackets[8] at $I = 0.1$ and 20 or 37° [a] are given for comparison

	$\log K_H$		$\log K_{CaL}$		$\log K_{MgL}$	
Compound	25°	37°	25°	37°	25°	37°
ACES	6.62 (6.9)	6.35 (6.56)[a]	0.4 (0.4)	0.2	0.4 (0.4)	0.3
MES	6.02 (6.1)	5.96 (5.98)[a]	0.5 (0.7)	0.3	0.6 (0.8)	0.5
TAPS	8.21	7.98	No complexation*		No complexation	
TES	7.30 (7.5)	7.08 (7.14)[a]	No complexation		No complexation	

*Titration curve in presence of metal ion to the titration curve of the ligand alone was not shifted or the shift was lower than 1 mV.

Better precision than that obtained in a standard procedure.

Applicability to weak complexes.

Applicability to microsamples.

The most important disadvantage is the limitation of the method to such complexation systems in which the metal ions are not reduced in the potential range used for reduction of water at the working electrode of the generation system.

APPLICATION OF FREE-RADICAL CHROMOGENS TO DETERMINATION OF NITRITE AND NITRATE IONS BY EPR SPECTROMETRY

ERIC P. K. TSANG, D. THORBURN BURNS and BRIAN D. FLOCKHART*
School of Chemistry, Queen's University of Belfast, Belfast, BT9 5AG, U.K.

(*Received* 27 *February* 1992. *Accepted* 21 *April* 1992)

Summary—Various azines and substituted phenylene diamines are oxidized by the nitrite ion to give stable radicals in an autocatalytic reaction. This finding has now been developed into highly sensitive methods for nitrite determination by EPR spectrometry. Thus, when the reagent is phenothiazine, the detection limit for nitrite is 0.012 ppm, the relative standard deviation at 0.05 ppm is 1.9%, and the analytical range is 0–1.5 ppm. With *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine as the reagent, the corresponding values are 0.025 ppm, 2.6%, and 0–1.3 ppm. Nitrate can be determined after prior reduction to nitrite. A mixture of nitrite and nitrate ions can also be quantitatively analysed. The EPR methods were applied to the determination of the nitrite and nitrate contents of prepacked cooked ham and of soft-spreading cheese. The results agreed well with those obtained by ISO and AOAC standard methods for these samples.

Electron paramagnetic resonance (EPR) as a quantitative analytical tool has not been greatly exploited. Its present applications lie mainly in the determination of selected metals, either by their natural paramagnetic states[1] or through the use of spin labels.[2] Several factors may explain this limited use. An EPR spectrometer is seldom situated in the laboratory dedicated to analytical chemistry; only paramagnetic substances, and substances that can be converted to a paramagnetic form with sufficient stability for a spectrum to be recorded, are suitable for analysis by EPR spectrometry; the analytical basis of the technique has been less well researched than those of most other spectroscopic methods.

Alkali nitrites and nitrates are used as additives in a variety of foods to prevent bacterial spoilage and food poisoning. However, concern exists over the presence of nitrate in the diet, not because of any intrinsic behaviour of the ion itself, but rather in its ability to form nitrite by microbiological or other biochemical reduction processes. Consequently, whenever nitrate is ingested in food, there is always the possibility that some of it will be reduced to nitrite. Under the acidic conditions in the stomach the nitrite ion can react with dietary components to form products that are often associated with carcinogenesis.[3] It is therefore highly desirable that the amounts of nitrite and nitrate in foodstuffs should be closely monitored. Various methods are available for this purpose.[4–6] The present paper describes the application of EPR spectrometry to the determination of these ions, individually and in admixture. A preliminary account of the work has been published.[7]

The early research of Michaelis *et al.*[8] on one-electron oxidation–reduction processes revealed many classes of organic compound that exhibit this behaviour. Compounds investigated included phenothiazine and its derivatives. Subsequently, other workers studied the stable radical obtained from the oxidation of phenothiazine.[9–11] Stable radicals are also formed when the *p*-phenylenediamines are oxidized.[12,13] Sawicki *et al.*[14] showed that nitrite can oxidize such compounds to give coloured products suitable in some cases for spectrophotometric determinations and they concluded that free radicals are present. The present EPR methods for the determination of nitrite and nitrate ions are based on this principle, *viz.*,

Nitrite + reagent → stable free radical.

(capable of one-electron oxidation)

The formation of the free radical is autocatalytic[14] and hence nitrite can be determined at trace levels by EPR spectrometry.

*Author for correspondence.

EXPERIMENTAL

Apparatus

The EPR measurements were made with a Varian E-109 spectrometer operated at *ca.* 9.5 GHz with a magnetic field modulation of 100 kHz. The resonator was a Varian E-231 rectangular cavity operating in the TE102 mode. The spectrometer was interfaced to a Varian E-900 data processing system. The sample cells were quartz tubes with an internal diameter of 2.0 mm and a wall thickness of 3 mm. Spectra were recorded at room temperature (20°).

Reagents

The stock nitrite solution was obtained by dissolving analytical reagent grade sodium nitrite (dried to constant weight at 110°) in demineralized water. Other nitrite solutions were obtained by dilution. The stock nitrate solution was prepared by dissolving analytical reagent grade potassium nitrate in demineralized water. Phenothiazine was recrystallized twice from heptane–ethylcyclohexane and *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine once from methanol, before use. Glacial acetic acid, of analytical reagent grade, was distilled twice; it was degassed before use by bubbling nitrogen through it and then subjecting it to a freeze-evacuate-thaw cycle.

Preparation of spongy cadmium

Zinc rods were immersed in aqueous cadmium sulphate (AnalaR, 80 g, dissolved in one litre of water). After two hours the deposit of cadmium was scraped off the rods and was washed by decantation using two one litre volumes of water. Care was taken that the cadmium sponge was always covered with water. It was transferred to a food blender using 0.1*M* hydrochloric acid and the bulk of the sponge was reduced to *ca.* 40 mesh. It was again washed with water, allowed to stand overnight under water, and then transferred to a column of height 2 dm and internal diameter 8 mm. The cadmium was activated by passing successively through the column 25 ml of 0.1*M* hydrochloric acid, 50 ml of water, and 25 ml of buffer of pH 9.6. This buffer was prepared by diluting 20 ml of concentrated hydrochloric acid to 500 ml with water, adding 50 ml of aqueous ammonia and then bringing the total volume to one litre.

Finalised procedures

Determination of nitrite. Phenothiazine. A 0.1-ml volume of test solution, delivered from an Agla micrometer syringe, was diluted to 10 ml with a solution of 0.05% (w/v) phenothiazine in glacial acetic acid. The EPR measurements were made 50 min after mixing.

A 0.01% solution of the reagent was used for test solutions that contained <0.1 ppm nitrite. All solutions of the reagents were stored in the dark. Nitrite solutions to which the reagent had been added were kept in the dark until the due time to record the spectrum.

N,N,N′,N′-Tetramethyl-*p*-phenylenediamine. A 0.1-ml volume of test solution, delivered from an Agla micrometer syringe, was diluted to 10 ml with a 0.05% (w/v) solution of the reagent in glacial acetic acid. One millilitre of sulphamic acid (0.1% solution of the acid in ethanol) was added after 40 min to stabilize the signal. EPR measurements were taken 10 min later. A 0.01% solution of the reagent was used for solutions that contained <0.1 ppm nitrite.

Determination of nitrate. An aliquot quantity of the test solution was added to the column of spongy cadmium, the flow rate through the column was adjusted to 4–6 ml/min, and the eluate was collected in a 100-ml standard flask. As the column emptied, the reservoir and column wall were washed with three 15-ml volumes of water. The flask was removed and the volume made up to 100 ml. The nitrite content was determined by one of the methods described.

Determination of an admixture of nitrite and nitrate

A 50-μl volume of 12*M* hydrochloric acid was added to 2 ml of test solution and the nitrite was removed by volatilization as nitrosyl chloride, nitrogen being blown over the solution for 5 min.[15] The nitrate was then determined after prior reduction to nitrite by spongy cadmium. The nitrite plus nitrate content of another 2-ml sample of the test solution was obtained by reduction followed by determination of the total nitrite present.

RESULTS AND DISCUSSION

Instrumental variables

A linear relationship between the signal amplitude (peak-to-peak height of the first derivative absorption curve) and the amplitude of the magnetic field modulation held up to 10 G (1 mT). This latter modulation amplitude was subsequently used in the quantitative measurements and it removed the resolution of the

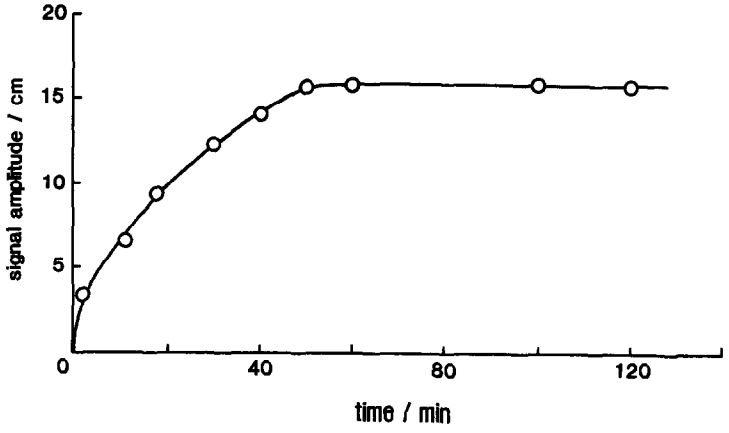

Fig. 1. Signal amplitude of the phenothiazine–nitrite–acetic acid system as a function of time.

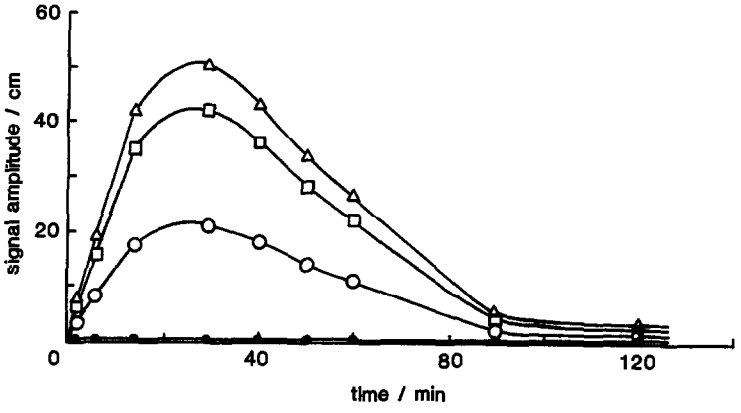

Fig. 2. Signal amplitude of phenothiazine in acetic acid as a function of time: solution kept in the dark (●); solution exposed to daylight (○); solution irradiated with light from a xenon lamp for 2 min (□) and for 4 min (△).

spectra.* The relative standard deviation of the measurements was lower for over-modulated spectra whether signal amplitudes or signal intensities (obtained by double integration of the first derivative curves) were used, and this is especially advantageous when the concentration of the analyte is low.

A microwave power level of 160 mW, which produced no observable saturation, and a scan time of 2 min, were employed.

Determination of nitrite

Phenothiazine. The variation of signal amplitude with time when phenothiazine was added to a nitrite solution is shown in Fig. 1. Little change in amplitude occurred after ~50 min. The radical remained stable for at least 4 hr. Glacial acetic acid is a better solvent than either ethanol or an ethanol–glacial acetic acid mixture with respect to the amplitude of the signal and the stability of the radical associated with the phenothiazine–nitrite system. Degassing of the solvent was necessary to reduce the signal attributable to the reagent itself to a barely detectable resonance.

In the determination of nitrite with phenothiazine as the reagent, exclusion of light is of critical importance. When a degassed reagent solution was exposed to daylight, an EPR signal developed and reached a maximum after ~30 min of exposure (Fig. 2). Another portion of the solution that had been kept in the dark gave a signal scarcely larger than the inherent low noise level of the spectrometer setting (Fig. 2). A flat quartz cell (faces *ca.* 0.3 mm apart) was filled with reagent solution, mounted in the cavity, and irradiated with light from a xenon lamp (Osram XBO, 150 W), the light being focused onto the cell by means of a quartz lens. One

*The phenothiazine-nitrite system and the phenylenediamine-nitrite system gave well-resolved EPR spectra. These and other related spectra will be the subject of a later publication.

Fig. 3. EPR spectrum (first derivative) of phenothiazine in acetic acid after irradiation with light from a xenon lamp.

sample of solution was irradiated for 2 min, another sample for 4 min; the results are presented in Fig. 2. Irradiation with light from a xenon arc lamp produced the same pattern of results as observed with samples exposed to daylight, but the effects were more pronounced. Figure 3 shows the spectrum given by irradiated solutions; a similar spectrum was obtained from solutions exposed to daylight. Clearly, when working with solutions of this reagent, light must be excluded until the analysis has been completed.

The concentration of phenothiazine was not critical in the range 0.05–0.4% for solutions containing more than 0.1 ppm of nitrite. With a reagent concentration of 0.05% the plot of signal amplitude versus nitrite concentration was linear in the range 0.1–1.5 ppm, but curvature was present in the range 0–0.1 ppm. By reducing the reagent concentration to 0.01%, a linear calibration plot was also obtained in the latter range. For both the higher and lower ranges of nitrite concentration, the correlation coefficient was 0.999.

The relative standard deviation at 0.3 ppm was 1.2% (ten signal amplitude measurements); the corresponding value for a solution containing 0.05 ppm nitrite was 1.9%. The detection limit at three times the standard deviation of the field blank was 0.012 ppm. The relative standard deviation of the measurements based on signal intensities was 2.8% at 0.3 ppm nitrite.

Inorganic oxidizing agents such as chlorate and perchlorate interfered with the determination of nitrite; low results were obtained. Nitrate had a similar effect. Sulphite could be tolerated up to a sulphite-to-nitrite mole ratio of 2000 to 1.

The volume of nitrite solution (aqueous) employed for an analysis was set at 0.1 ml. The signal amplitude decreased as the volume of this solution was increased in the range 0.1–1 ml. Water with its high dielectric constant results in electric loss and a marked lowering of the cavity Q.

N,N,N′,N′-*Tetramethyl*-p-*phenylenediamine*. The variation of signal amplitude with time when the reagent was *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine is shown in Fig. 4. Even after 2 hr the signal was still increasing. The addition of sulphamic acid (1 ml of 1% solution in ethanol) effectively stabilized the signal. This effect is illustrated in Fig. 4 which incorporates the results of several separate experiments. The compromise chosen for the analytical measurements was to add the sulphamic acid 40 min after mixing the nitrite and reagent solutions, and to record the spectrum 10 min later. Daylight had no noticeable effect on the reagent solution.

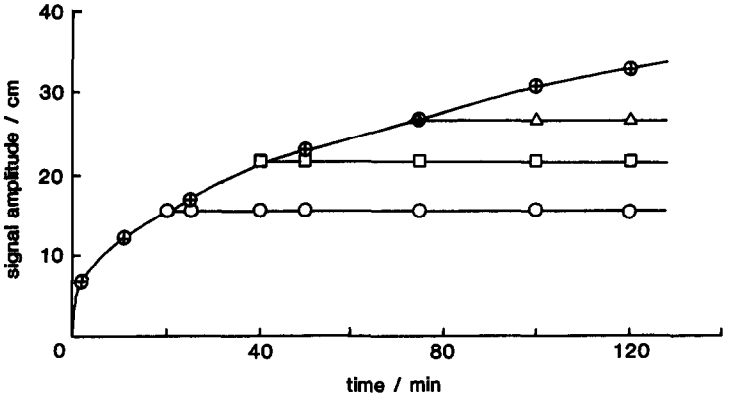

Fig. 4. Signal amplitude of the *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine–nitrite–acetic acid system as a function of time (⊕). Signal amplitude of the *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine–nitrite–acetic acid–sulphamic acid system as a function of time. Sulphamic acid added after: 20 min (○); 40 min (□); 75 min (△).

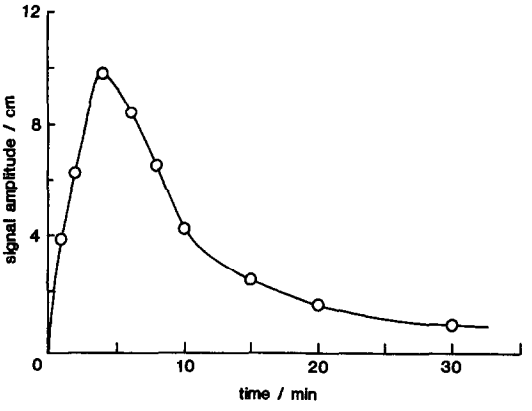

Fig. 5. Signal amplitude of the *N,N,N′,N′*-tetramethylbenzidine–nitrite–acetic acid system as a function of time.

When a reagent concentration of 0.05% was used, a linear calibration graph was obtained in the range 0.1–1.3 ppm, whereas curvature was present in the range 0–0.1 ppm. By reducing the reagent concentration to 0.01%, linearity was also produced in the latter range. For both the higher and lower ranges of nitrite concentration, the correlation coefficient was 0.998.

The relative standard deviation at 0.3 ppm was 1.5% (ten signal amplitude measurements). The detection limit at three times the standard deviation of the field blank was 0.025 ppm. The relative standard deviation of the measurements based on signal intensities was 3.1% at 0.3 ppm nitrite.

The presence of strong oxidizing agents produced high results for nitrite; low results were obtained when nitrate was present; sulphite did not interfere with the determination up to a mole ratio of at least 1000 to 1.

Other reagents. When the reagent was *N,N,N′,N′*-tetramethylbenzidine the signal amplitude reached a maximum *ca.* 3 min after the reagent was added to a nitrite solution and it then decreased rapidly (Fig. 5). Attempts to stabilize the signal by adding sulphamic acid were unsuccessful. Measurements had therefore to be made 3 min after mixing. When a reagent concentration of 0.05% was used, a linear calibration graph was obtained in the range 0.1–0.5 ppm. Curvature was present in the range 0–0.08 ppm, but this was removed when the reagent concentration was reduced to 0.01%. The relative standard deviation at 0.3 ppm was 5.4%, and the detection limit at three times the standard deviation of the field blank was 0.035 ppm. The poor reproducibility is consistent with the signal amplitude-time curve. Low results were obtained in the presence of nitrate, chlorate and perchlorate. At a mole ratio of 60 to 1, sulphite did not interfere with the determination.

Two compounds related to phenothiazine, namely, phenoxazine and chloropromazine, were investigated as possible reagents for nitrite determination. Phenoxazine was less sensitive than phenothiazine and more prone to interferences, although the EPR signal reached its maximum amplitude in a shorter time (~25 min). The EPR signal from a chloropromazine-nitrite system decayed rapidly, rendering this compound unsuitable for nitrite determination. The *N,N,N′*-trimethyl-*p*-phenylenediamine-nitrite system gave a weak signal even at 4 ppm nitrite and was not investigated further.

Determination of nitrate

Nitrate solutions of known concentration were passed through the reduction column and the nitrite content was determined by both the phenothiazine method and the *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine method (subsequently referred to as the phenylenediamine method). The results are summarized in Table 1.

Determination of admixtures of nitrite and nitrate

Solutions containing known amounts of nitrite and nitrate were analysed according to the procedure described in the experimental section. Both the phenothiazine method and the phenylenediamine method were used for nitrite determination. The results are summarized in Table 2.

Table 1. Determination of nitrate

Method	Nitrate added (ppm)	Nitrate found* (ppm)	Recovery (%)

Applications

The EPR methods were applied to the determination of the nitrite and nitrate contents of pre-packed cooked ham and of soft-spreading cheese. In Tables 3 and 4 the results obtained by the EPR methods are compared with those given by International Standards Organization (ISO)[16] and Association of Official Analytical Chemists (AOAC)[17] standard methods for these samples. The samples were prepared for analysis by the respective ISO and AOAC procedures.[16,17] Statistical analysis (students' *t* test) between the EPR and ISO results and between the EPR and AOAC results revealed no significant difference between the methods (at the 95% confidence level).

CONCLUSION

A large number of spectrophotometric methods are available for the determination of nitrite ion.[14] The EPR methods now described provide alternative viable analytical methods of high sensitivity and with an accuracy that compares favourably with the other procedures. Moreover, the new methods are simple and extraction is not required. Further, these methods can tolerate large amounts of reducing agents which should permit their application to pollution studies, such as the determination of nitrogen dioxide in the presence of sulphur dioxide. An additional advantage is that they are applicable to coloured solutions. A drawback of the EPR methods herein is the long procedural time (50 min).

A preliminary investigation has shown that the EPR methods are also suitable for other oxidizing agents such as perchlorate, although they are less sensitive when applied to ions other than the nitrite ion.

STABILITY-INDICATING METHOD FOR THE DETERMINATION OF CLORAZEPATE DIPOTASSIUM—I. VIA ITS FINAL DEGRADATION PRODUCTS

M. G. EL-BARDICY, L. I. BEBAWY* and M. M. AMER
Analytical Chemistry Department, Faculty of Pharmacy, Cairo University, Cairo, Egypt

(*Received* 22 *April* 1991. *Revised* 7 *August* 1991. *Accepted* 9 *August* 1991)

Summary—A sensitive spectrophotometric procedure is described for the determination of 1,4-benzodiazepine (clorazepate dipotassium) in the presence of its degradation products. The procedure is based on acid hydrolysis of clorazepate dipotassium to yield its final degradation products *viz.*, 2-amino-5-chlorobenzophenone and glycine. The amino-chlorobenzophrenone is extracted from the neutralized hydrolysate with diethyl ether, the extract is evaporated, the residue is dissolved in methanol and its absorbance measured at about 240 nm or 380 nm. Glycine, left in the aqueous layer after etherial extraction of aminochlorobenzophenone, is treated with ninhydrin reagent in the presence of pyridine and the bluish violet colour formed is measured at about 560 nm. The suggested procedures determine 20–100 mg of clorazepate dipotassium via its degradation products aminochlorobenzophenone and glycine with mean accuracies of 100.0 ± 0.5% at 560 nm, 100.2 ± 0.6% at 380 nm and 99.8 ± 0.5%. The suggested procedures are suitable for stability-testing of clorazepate dipotassium in bulk powder and in pharmaceutical preparations.

Clorazepate dipotassium,7-chloro-1,3-dihydro-2-oxo-5-phenyl-1H-1,4-benzodiazepine-3-carboxylic acid, dipotassium salt, is the active ingredient in tranxene® which is marketed as an anti-anxiety agent.[1] Several methods have been reported for the quantitative analysis of clorazepate dipotassium, including GLC,[2–4] HPLC,[5–7] TLC,[8] colorimetry,[9] fluorimetry,[10] spectral methods and polarography.[11] In the present communication, two procedures, spectrophotometric and colorimetric are described for the determination of clorazepate dipotassium after hydrolysis to amino chlorobenzophrenone and glycine.

EXPERIMENTAL

Apparatus

U.V./Vis spectrophotometer (Shimadzu UV-120) was used.

Reagents

All chemicals were of analytical grades.

Clorazepate dipotassium. Working standard, kindly supplied by Nile Pharmaceutical Co., Cairo, Egypt.

Hydrochloric acid, ~6N Aqueous solution.

Sodium hydroxide, ~6N Aqueous solution.

Diethyl ether. Chemically pure (Prolabo.).

Methanol. Spectroscopic grade (Merck).

Citric acid–citrate buffer, pH 5.[12]

Ninhydrin–citrate reagent. A 5% solution in citric acid–citrate buffer, pH 5.

Pyridine. Chemically pure (Merck) containing no ammonia and gives no colour with ninhydrin–citrate reagent when heated in a boiling water bath for 15–20 min.

Benzene–methylene chloride; 9:1. (Prolabo.)

N-desmethyldiazepam working standard. Kindly supplied by Arab Drug Co., Cairo, Egypt.

2-Amino-5-chlorobenzophenone (Aldrich).

Glycine. (B.D.H.)

Procedure

Bulk powder. To prepare the sample solution accurately, weigh about 20–100 mg of clorazepate dipotassium, dissolve in 10 ml of water and extract with 3 × 20 ml of a mixture of benzene–methylene chloride (9:1). Transfer the aqueous layer into a 100-ml loosely stoppered (or covered) conical flask, add 25 ml of 6*N* hydrochloric acid, stopper the flask and heat at 100° for 1 hr. Cool to room temperature and add 25 ml of 6*N* sodium hydroxide; assure that the solution

*From National Organization of Drug Control and Research.

is just alkaline to litmus. Cool again and quantitatively transfer the contents into a 150-ml separating funnel. Extract with 3 × 20 ml of diethyl ether and combine the etherial extracts together for the determination of aminochlorobenzophrenone. Retain the aqueous layer for the determination of glycine.

Determination of aminochlorobenzophenone. Evaporate the combined etherial extracts just to dryness and dissolve the residue in 20 ml of methanol. Transfer the methanolic solution into a 50-ml standard flask, dilute to volume with methanol and mix well.

1. Pipette an aliquot of the methanolic solution corresponding to 0.4–2 mg of clorazepate dipotassium into a 25-ml standard flask and dilute to volume with methanol. Measure the absorbance of the solution at 380 nm against methanol as a blank.

2. Transfer an aliquot volume (equivalent to 2 mg) from the above solution into a 25-ml standard flask and dilute to the mark with methanol. Pipette an aliquot volume corresponding to 0.08–0.56 mg of clorazepate dipotassium into a 25-ml standard flask and dilute to volume with methanol. Measure the absorbance of this solution at 240 nm against methanol as a blank.

Calculate the concentration of clorazepate dipotassium from a calibration curve prepared simultaneously, or from the A (1%, 1 cm) = absorbance of 1% solution in a 1 cm cell, which amounts to (1) 106.9 at 380 nm or 469.26 at 240 nm for clorazepate dipotassium or (2) 188.5 at 380 nm or 827.62 at 240 nm for 2-amino-5-chlorobenzophenone; the result of amino-chlorobenzophenone can be expressed as clorazepate dipotassium if multiplied by 0.567, or from the following regression equations: at 240 nm: $y = 1.85x + 0.006$, $R = 1$ for clorazepate dipotassium and $y = 3.17x + 0.027$, $R = 0.984$ for 2-amino-5-chlorobenzophenone and at 380 nm: $y = 0.42x - 0.005$, $r = 1.001$ for clorazepate dipotassium, and $y = 0.37x + 0.003$, $r = 0.994$ for 2-amino-5-chlorobenzophenone, where y is absorbance, x is concentration and r is correlation coefficient.

Determination of glycine. Transfer the aqueous layer, quantitatively, into a 100-ml standard flask and complete to volume with citric acid–citrate buffer solution (pH 5). Introduce an aliquot volume of the solution, corresponding to 0.3–1.5 mg of clorazepate dipotassium, into a 25-ml standard flask, add 3.5–4 ml of the citric acid–citrate buffer, 1 ml of the ninhydrin–citrate reagent, 1 ml of pyridine and heat in a boiling water bath for 15–10 min. Cool to room temperature, complete to volume with water and measure the absorbance of the violet colour at 560 nm against a blank prepared by treating 20–100 mg as described for preparing the sample solution above, but omitting heating at 100° for 1 hr, adding 25 ml of 6*N* hydrochloric acid and 25 ml of 6*N* sodium hydroxide to the aqueous layer, and instead using the aqueous layer as described under determination of glycine above.

Calculate the concentration of glycine from a calibration curve prepared simultaneously or from the A (1%, 1 cm) = absorbance of 1% solution in a 1 cm cell, which amounts to: (1) 175.7 for clorazepate dipotassium, or (2) 959.9 for glycine; the result of glycine can be expressed as clorazepate dipotassium if multiplied by 0.183, or from the following regressing equations: $y = 0.699 + 0$ and $r = 1$ for clorazepate dipotassium or $y = 3.5x + 0.05$ and $r = 0.959$ for glycine.

*For capsules**

Evacuate the contents of 20 capsules, mix thoroughly, weigh and calculate the average weight in each capsule. Transfer an accurate weight of the mixed sample, equivalent to about 20–100 mg of clorazepate dipotassium, dissolve in 10 ml of water and extract with 3 × 20 ml of a mixture of benzene–methylene chloride (9:1). Filter the aqueous layer through a filter paper into a 100-ml conical flask and proceed as mentioned for preparation of the sample solution for bulk powder, starting at the point "... add 25 ml of 6*N* hydrochloric acid, stopper the flask and heat at 100° for 1 hr ...".

RESULTS AND DISCUSSIONS

Although clorazepate dipotassium is stable in alkaline medium, it is readily hydrolysed in acid medium. Upon standing at room temperature for half an hour in 2*N* hydrochloric acid it is completely degraded to *N*-desmethyldiazepam.[11] Under more drastic conditions, *i.e.* heating with 6*N* hydrochloric acid at 100° for 1 hr, it is completely degraded yielding 2-amino-5-chlorobenzophenone and glycine.[2]

The proposed procedure depends upon the determination of clorazepate dipotassium via

*The drug is available in the Egyptian market as capsules only.

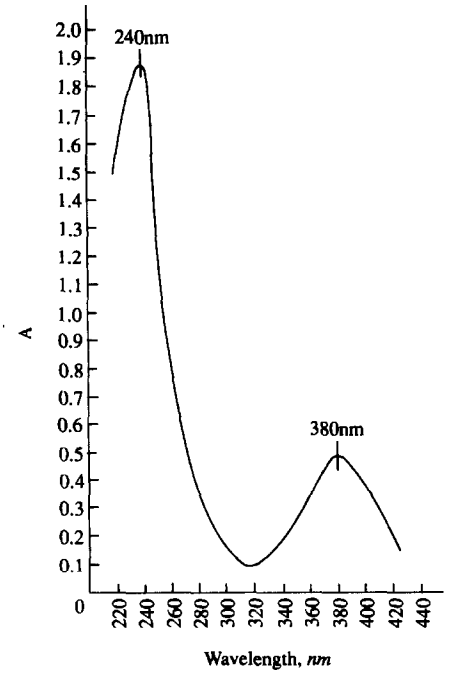

Fig. 1. Spectrum of 2-amino-5-chloropenzophenone in methanol after the hydrolysis of clorazepate dipotassium (1.2 mg/25 ml).

its degradation products, namely, 2-amino-5-chlorobenzophenone and glycine, after hydrolysis with 6*N* hydrochloric acid at 100° for 1 hr.

Before hydrolysis, the solution is extracted with a mixture of benzene–methylene chloride to extract 2-amino-5-chlorobenzophenone and *N*-desmethyldiazepam which might be present due to partial degradation, and which will be hydrolysed to give 2-amino-5-chlorobenzophenone and glycine.

The first procedure is spectrophotometric, and depends upon the determination of 2-amino-5-chlorobenzophenone which is produced quantitatively by drastic aicd hydrolysis of clorazepate dipotassium. The absorption spectrum

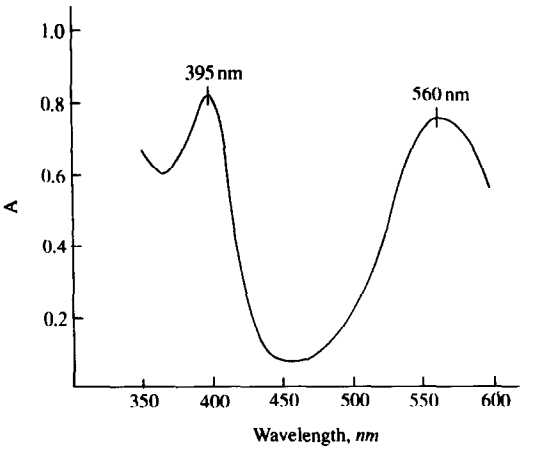

Fig. 2. Spectrum of glycine–ninhydrin pyridine complex.

is shown to possess two maxima at 240 nm and at 380 nm, Fig. 1.

A linear relationship prevails between the concentration of the hydrolysed clorazepate dipotassium or 2-amino-5-chlorobenzophenone and the absorbance at 240 and 380 nm.

The optimum conditions for quantitative degradative hydrolysis of clorazepate dipotassium to yield 2-amino-5-chlorobenzaphenone and glycine were studied and confirmed by TLC.

On analysing different concentrations 0.08–0.56 mg at λ_{max} 240 nm and 0.4–2.0 mg at λ_{max} 380 nm of an authentic sample of clorazepate dipotassium, the results in Table 1 were obtained.

The second procedure is colorimetric, and depends upon the determination of glycine in the aqueous layer left after the extraction of amino-chlorobenzophenone by reaction with ninhydrin in the presence of pyridine. The spectrum of the violet colour produced has two maxima at 560 nm and 395 nm (Fig. 2).

The experimental conditions for maximum colour development were optimized. The use of

	C.V.				0.2%	0.7%	1.2%	

1 ml of 5% ninhydrin and 1 ml of pyridine gave the highest colour intensity upon heating for 15–20 min on a boiling water bath. The citric acid–citrate buffer solution of pH 5 ± 0.2 proved to be a suitable medium for maximum colour formation, which is then stable for up to 1 hr.

A linear relationship was found between the concentration and the absorbance at 560 nm. On applying the proposed procedure to different concentrations (0.3–1.5 mg) of an authentic sample of clorazepate dipotassium, the results in Table 1 were obtained.

The blank used in the spectrophotometric procedure is methanol, because extraction with benzene–methylene chloride mixture before hydrolysis removes any degradation products, if present, except glycine. In the colorimetric procedure however, the blank used is prepared as for sample solution but without previous hydrolysis, because glycine is not extracted in the solvent mixture and remains in the aqueous layer.

To assess the stability-indicating efficiency of the proposed procedure, the degradation products, *N*-desmethyldiazepam, 2-amino-5-chlorobenzophenone and glycine, were mixed with the authentic sample of clorazepate dipotassium in different ratios and analysed by the proposed procedures. The results obtained are shown in Table 2. It is clear that the accuracy of the proposed procedure is not affected by the presence of 20–80% of these degradation products and the results are nearly the same as in Table 1.

Applying the proposed procedures to the analysis of tranxene capsules, the results obtained are shown in Table 3.

The validity of both procedures was assessed by applying the standard addition technique. The results are presented in Table 4.

It is obvious from the results shown in Table 1 that the suggested procedures can determine 0.08–0.56 mg and 0.4–2.0 mg of clorazepate

dipotassium with accuracies of $100.0 \pm 5\%$ and $100.2 \pm 0.6\%$ at λ_{max} 240 nm and 380 nm respectively by spectrophotometry and 0.3–1.5 mg with an accuracy of $99.8 \pm 0.5\%$ by the colorimetric method.

Comparing the results by the proposed procedure with those from the non-aqueous titration procedure for bulk powder,[13] it is evident that this latter procedure is not selective for the intact molecule, since it also determines the degradation products.

The most important advantage of the suggested method over other methods is that, with the exception of the HPLC method, it determines only the intact clorazepate dipotassium in the presence of its degradation products. Moreover, the method is inexpensive, rapid, sensitive and applicable over a convenient range of clorazepate dipotassium concentrations.

SUBSTITUTIONAL COMPLEXOMETRIC DETERMINATION OF MAGNESIUM IN HOMOGENEOUS WATER–DIOXAN MEDIUM, BASED ON DECOMPOSITION OF MgEDTA WITH 8-QUINOLINOL AND TITRATION OF RELEASED EDTA WITH CALCIUM

ASSEN KAROLEV
Institue of Ferrous Metallurgy, Sofia 1870, Bulgaria

(*Received* 31 *July* 1989. *Revised* 5 *December* 1991. *Accepted* 15 *December* 1991)

Summary—A method based on a substitution reaction between MgEDTA and 8-quinolinol, and titration of the liberated EDTA with calcium is proposed. The reaction is performed in homogeneous 50–60% dioxan medium at pH 10, in which magnesium forms a soluble and stable 8-quinolinol complex.

Sinha and Roy[1] have proposed a complexometric determination of magnesium by selective conversion of the MgEDTA complex into the insoluble magnesium 8-quinolinolate, liberating an equivalent quantity of EDTA. The mixture is first titrated with EDTA to determine the sum of the two metal ions, then heated to 50–60° after addition of excess of 8-quinolinol and a known amount of calcium chloride. The calcium and magnesium 8-quinolinolate complexes are formed. The calcium precipitate is dissolved with excess of EDTA, the surplus of which is then titrated with a standard calcium solution.

In a second paper[2] these authors reported that the method was improved by extraction of the magnesium 8-quinolinolate into chloroform. Calcium remained in the aqueous solution as CaEDTA and the EDTA liberated from MgEDTA was titrated in the aqueous solution with calcium.

From a practical point of view, it would be better to perform the second titration in homogeneous medium, such as a 50–60% dioxan solution in water, in which the magnesium 8-quinolinolate complex is stable and soluble. Calcium can also form an 8-quinolinolate complex but this is less stable than the EDTA complex and is not produced under the conditions used. A preliminary evaluation of the equilibrium constant for the susbstitution reaction

$$MgY^{2-} + 2Ox^{-} + Ca^{2+} = CaY^{2-} + Mg(Ox)_2 \quad (1)$$

is necessary (Ox^{-} represents the 8-quinolinolate anion). Under the back-titration conditions (pH = 10 and considerable excess of 8-quinolinol), the conditional equilibrium constant is:

$$K'_{eq} = \frac{[CaY][Mg[Ox]_2]}{[MgY][Ca']^2[Ox']^2} = \frac{\beta_{CaY}\beta_{Mg(Ox)_2}}{\beta_{MgY}\alpha_{Ca(Ox)}\alpha^2_{Ox(H)}} = \frac{10^{10.7} \times 10^{11}}{10^{8.7} \times 255 \times 32.6^2} = 3.7 \times 10^7 \quad (2)$$

where primes indicate conditional quantities[3] and charges are omitted for simplicity.

The CaEDTA and MgEDTA stability constants (for aqueous solution, ionic strength 0.1) are taken from Ringbom.[3] It is assumed that they both change to the same extent in the water–dioxan medium. The stability constants for the magnesium 8-quinolinolate and the protonation constants for EDTA and 8-quinolinol in 60% dioxan medium are taken from Perrin.[4] The value of $\alpha_{Ca(Ox)}$ is calculated for a typical $0.05M$ initial concentration of 8-quinolinol (C_{Ox}) and $0.001M$ initial concentration of magnesium (C_{Mg}) in the solution obtained after the EDTA titration of Mg + Ca and addition of dioxan and 8-quinolinol:

$$\alpha_{Ox(H)} = 1 + \beta^H_1[H] + \beta^H_2[H]^2 = 1 + 10^{11.5} \times 10^{-10} + 10^{15.5} \times 10^{-20} = 32.6 \quad (3)$$

$$\alpha_{Ca(Ox)} = 1 + \beta_{Ca(Ox)}[Ox] + \beta_{Ca(Ox)_2}[Ox]^2 \quad (4)$$

and since at the equivalence point of the back-titration

$$[Ox] = \frac{[Ox']}{\alpha_{Ox(H)}} \approx \frac{C_{Ox} - 2C_{Mg}}{\alpha_{Ox(H)}} \quad (5)$$

$\alpha_{Ca(Ox)}$ is given by

$$\alpha_{Ca(Ox)} = 1 + \frac{10^{4.4} \times 4.8 \times 10^{-2}}{32.6} + \frac{10^{8.0} \times (4.8 \times 10^{-2})^2}{32.6^2} = 255 \quad (6)$$

Although the value of the conditional equilibrium constant (K'_{eq}) is large, it is smaller than that corresponding to 99.9% completion of the substitution reaction ($K'_{99.9}$) at the equivalence point for a titration involving 0.001*M* concentrations of calcium and magnesium:

$$K'_{99.9} \sim \frac{(C_{Ca} + C_{Mg}) \times C_{Mg}}{0.001C_{Mg} \times 0.001(C_{ca} + C_{Mg}) \times (C_{Ox} - 2C_{Mg})^2}$$

$$= \frac{2 \times 0.001 \times 0.001}{0.001 \times 0.001 \times 0.001(0.001 + 0.001) \times (0.050 - 0.002)^2}$$

$$= 4.3 \times 10^8 \quad (5)$$

The theoretical value of [Ca'] (which would be nearly equal to [MgY]) at the equivalence point of the back-titration is calculated by use of the equation:

$$K'_{eq} = \frac{[CaY][Mg(Ox)]}{[MgY][Ca'][Ox']^2} = \frac{(C_{Ca} + C_{Mg} - [Ca'])(C_{Mg} - [Ca'])}{[Ca']^2(C_{Ox} - 2C_{Mg})^2}$$

$$= 3.7 \times 10^7 \quad (6)$$

Hence

$$3.7 \times 10^7(C_{Ox} - 2C_{Mg})^2[Ca']^2 = C_{Ca}C_{Mg} + C_{Mg}^2 - 2C_{Mg}[Ca'] - C_{Ca}[Ca'] + [Ca']^2 \quad (7)$$

Since $[Ca']^2 \ll 3.7 \times 10^7(C_{Ox} - 2C_{Mg})[Ca']^2$ it can be neglected. Then

$$3.7 \times 10^7(0.050 - 0.002)^2[Ca']^2 + 0.003[Ca'] - 2 \times 10^{-6} = 0 \quad (8)$$

and the calculated

$$[Ca'] \approx [MgY] = 0.5 \times 10^{-5}M.$$

Consequently the concentration of unchanged MgEDTA is only $100 \times 0.6 \times 10^{-5}/10^{-3} = 0.5\%$ of the initial MgEDTA concentration, and substitution reaction (1) is 99.5% complete.

If the initial molar concentration of the calcium is ten times that of the magnesium the substitution reaction will be less complete (99.0%), but for determination of relatively low concentrations of magnesium this is acceptable. A similar calculation for $10^{-3}M$ calcium and magnesium but only 0.025*M* 8-quinolinol shows that the reaction would be 99.5% complete, indicating that the 8-quinolinol concentration is not critical provided it does not exceed about 0.05*M*.

EXPERIMENTAL

Reagents

Titrants. Standardized 0.025*M* Na_2EDTA and calcium chloride solutions.

Buffer solution, pH 10. Dissolve 70 g of ammonium chloride in about 300 ml of water, mix the solution with 570 ml of concentrated ammonia solution (s.g. 0.880) and dilute to 1 litre with water.

8-Quinolinol. A 0.25*M* solution in 1,4-dioxan.

Methylthymol Blue indicator. A 1% solid mixture with potassium nitrate.

Procedure

To a nearly neutral solution containing calcium and up to 6–7 mg of magnesium, add 10 ml of buffer and about 100 mg of indicator mixture, and titrate with EDTA until the colour changes from blue to pale grey. This titration gives the sum of the calcium and magnesium. Add a slightly greater volume of dioxan than that of the titrated solution, and 5–20 ml of the 8-quinolinol solution, depending on the magnesium content expected. Add another portion of indicator and titrate with standard calcium solution until the colour changes to greenish yellow. The amount of calcium consumed is equivalent to the magnesium content.

Table 1. Complexometric determination of magnesium and calcium in synthetic solutions

Mg added, *mg*	Ca added, *mg*	Mg found,* *mg*	Ca found,* *mg*
1.00	1.00	1.03 ± 0.02	1.02 ± 0.04

Table 2. Magnesium and calcium determination in standard samples*

Sample	Certified values % MgO	Certified values % CaO	MgO found,* %	CaO found,† %
SOD 116-83 VR8 limestone	0.56	54.98	0.58	55.1
S 2 USSR slag	2.71	44.2	2.62	44.0
SM 3 DDR slag	7.73	45.43	7.61	45.3
AN DDR calcium sulphate	0.32	40.73	0.31	40.8

*Ca and Mg in the slags were determined after preliminary separation of Fe, Al and Mn by hydroxide precipitation. The Fe, Al and Mn content in the limestone and calcium sulphate being very low, the calcium and magnesium titrations were performed in the presence of the hydroxide precipitates.

†Mean of 3 replicates.

RESULTS AND DISCUSSION

Typical results for analysis of mixtures of standard magnesium and calcium solutions are shown in Table 1, and those for analysis of some standard samples are shown in Table 2.

The amount of 8-quinolinol to be added is not critical, but the concentration in the final solution should not exceed 0.05*M*, and the quantity added must provide an adequate excess relative to the amount of magnesium present.

The procedure given will provide a back-titration of about 10 ml of 0.025*M* calcium solution for 6 mg of magnesium, and for smaller amounts of magnesium better precision can be obtained by use of 0.01*M* calcium solution, but lower concentrations than this should not be used, as the end-point is then difficult to detect.

Methylthymol Blue is preferred as the indicator, since it gives a sharper end-point than other indicators do. At pH 10, pCa_{trans} ($=\log \beta'_{CaInd}$) is 5.5 for Methylthymol Blue, 4.0 for murexide and 4.5 for Metalphthalein.[5] It is convenient to make a glass scoop to hold 100–120 mg of the solid indicator.

The method has good reproducibility and accuracy and is especially suitable for samples containing much more calcium than magnesium. If desired, photometric detection of the end point can be used (at $\lambda = 610$ nm).

SPECTROPHOTOMETRIC DETERMINATION OF CHROMIUM(III, VI) BY USE OF CHROMIUM(III, VI)–CHROME AZUROLS–CETYLPYRIDINIUM BROMIDE–HYDROXYLAMINE HYDROCHLORIDE–ZINC(II) SYSTEM

FANG GUOZHEN and LUO JIKUEN

Department of Chemistry, Sichuan University, Chengdu, Sichuan, 610064, People's Republic of China

(*Received* 9 *November* 1989. *Revised* 9 *November* 1991. *Accepted* 27 *December* 1991)

Summary—This paper shows that the sensitivity of the Cr(III, VI)–Chrome Azurol S (CAS)–cetylpyridinium bromide (CPB)–hydroxylamine hydrochloride system can be increased and the wavelength of maximum absorption slightly shifted by addition of zinc(II) and that the analytical data are practically identical for both Cr(III) and Cr(VI), indicating that under the conditions used both initial oxidation states of chromium yield the same final oxidation state, Cr(III). On the basis of the Cr(III, VI)–CAS–CPB–$NH_2OH \cdot HCl$–Zn systems a new, highly sensitive and selective method for spectrophotometric determination of microamounts of Cr(III, VI) has been developed, with molar absorptivity of 1.27×10^5 l. mole^{-1}. cm^{-1} for the complex at 620 nm and linear calibration up to 0.4 μg/ml chromium. Various foreign ions do not interfere. The method can be applied to direct determination of chromium in steels.

Existing spectrophotometric methods for determining chromium(III) are not very sensitive ($\epsilon < 10^5$ l. mole^{-1}. cm^{-1}.[1] The sensitivity of the Cr(III)–Chrome Azurol S (CAS) system may be increased by addition of cetyltrimethylammonium bromide (CTMAB)[2] or cetylpyridinium bromide (CPB).[3] The purpose of this paper is to explore another path for increasing the sensitivity of determination of chromium. One such possibility is by formation of mixed-metal complexes, as shown for the chromium–Eriochrome Cyanine R–manganese system,[4] the lanthanide–Bromopyrogallol Red–yttrium system[5–8] and the scandium–Arsenazo III–molybdenum system.[9]

Horiuchi and Nishida[10] have developed a spectrophotometric method for zinc with CAS and zephiramine. We have found that (*a*) the sensitivity of the spectrophotometric determination of Cr(VI) by means of the Cr(VI)–CAS–CPB system can be increased by adding $NH_2OH \cdot HCl$; (*b*) the sensitivity of the Zn–CAS–CPB–$NH_2OH \cdot HCl$ system at pH 5.7 is very low ($\epsilon = 37.1$ l. mole^{-1}. cm^{-1} at 500 nm, and 5.5 at 620 nm), but the Zn–Cr(III, VI)–CAS–CPB–$NH_2OH \cdot HCl$ system ($\epsilon = 1.27 \times 10^5$ at 620 mm) is much more sensitive than the Cr(III, VI)–CAS–CPB–$NH_2OH \cdot HCl$ system ($\epsilon = 5.6 \times 10^4$ at 620 nm); (*c*) with the Zn/Cr mixed-metal system the absorption spectra, calibration graphs and complex compositions obtained with Cr(III) and Cr(VI) are nearly identical, so the same procedure may be used for determination of either Cr(III) or Cr(VI) alone or of total chromium(III, VI) without prior oxidation or reduction treatment.

The proposed method is a new, highly sensitive and selective procedure for determination of chromium.

EXPERIMENTAL

Apparatus

Absorbance measurements were made with a type 72 photoelectric spectrophotometer (made in China) suitable for measuring absorbance at wavelengths from 420 to 700 nm. Absorption spectra were obtained with a Shimadzu UV-240 recording spectrophotometer.

Reagents

All reagents were of analytical grade unless specified otherwise, and demineralized water was used throughout.

Chromium(III) standard solution, 2 μg/ml. Dissolve 0.5000 g of chromium metal (purity 99.99%) in 20 ml of concentrated hydrochloric acid and a small quantity of water (with warming) and cool. Transfer the solution to a

500-ml standard flask, make up to the mark with water, and mix well.

Chromium(VI) standard solution, 2 μg/ml. Dissolve 0.2830 g of $K_2Cr_2O_7$ (previously dried at 140°) in water, and dilute the solution with water to volume in a 1-litre standard flask and mix well. Dilute 5.00 ml of this solution to 500 ml.

Chrome Azurol S (CAS) solution, $3.2 \times 10^{-3}M$.

Cetylpyridinium bromide (CPB) solution, $5.0 \times 10^{-3}M$. Dissolve 0.96 g of CPB in 500 ml of hot water and cool.

Hydroxylamine hydrochloride solution, 50 mg/ml.

Disodium ethylenediaminetetra-acetate (Na_2 EDTA) solution, 20 mg/ml.

Zinc(II) solution, 10 mg/ml. Dissolve 11.04 g of $ZnSO_4 \cdot 7H_2O$ in 250 ml of water containing 1 ml of $0.25M$ sulphuric acid.

Iron(III) solution, 1 mg/ml Fe(III). Dissolve 4.32 g of $NH_4Fe(SO_4)_2 \cdot 12\ H_2O$ in 500 ml of water slightly acidified with sulphuric acid.

Acetic acid–sodium acetate buffer, pH 5.7. Dissolve 109 g of $CH_3COONa \cdot 3H_2O$ in 500 ml of water containing 5.65 ml of glacial acetic acid and mix.

Saturated aqueous 2,4-dinitrophenol solution.

Calibration

(*i*) Pure solution: transfer known volumes of standard solution containing up to 10 μg of chromium(III or VI) to 25-ml standard flasks [if chromium(III) is used add 1 drop of 2,4-dinitrophenol solution and adjust the colour of the solution to slightly yellow with $0.5M$ sodium hydroxide to make the solution nearly neutral]. To each flask add 1.5 ml of pH 5.7 buffer, 1.4 ml of CAS solution, 2.0 ml of CPB solution, 1.5 ml of Zn(II) solution and 1.5 ml of $NH_2OH \cdot HCl$ solution and mix well. Heat the flasks in a gently boiling water-bath for 20 min, then cool them rapidly to room temperature. Dilute each solution to the mark with water. Measure the absorbance in a 1-cm cell at 620 nm against a reagent blank containing 15 mg of Zn(II).

(*ii*) Steel analysis: proceed as described above, but in addition to each portion of chromium(III or VI) standard solution add 1 ml of 1 mg/ml Fe(III) solution.

Analysis of steel samples

Dissolve an appropriate amount of sample in warm $3M$ hydrochloric acid, decompose any carbides by addition of the minimum of concentrated nitric acid needed, boil off nitrous fumes, cool, filter if necessary and dilute to volume in a suitable size of standard flask. Transfer a known volume of this solution, containing up to 10 μg of chromium, to a 25-ml standard flask. Add 1 drop of 2,4-dinitrophenol solution, then $0.5M$ sodium hydroxide until the solution is slightly yellow. Add 1.5 ml of hydroxylamine hydrochloride solution, swirl for 1 min, add 1.5 ml of pH-5.7 buffer, 1.4 ml of CAS solution, 2.0 ml of CPB solution and 1.5 ml of Zn(II) solution. Heat the flask in a boiling water-bath for 20 min, then add 5.5 ml of EDTA solution. Shake the solution for 1 min, allow to stand for 4 min, then cool it rapidly. Dilute the solution to the mark with water and mix. Measure the absorbance at 620 nm in a 1-cm cell against a reagent blank containing 1 mg of Fe(III) and 15 mg of Zn(II).

RESULTS AND DISCUSSION

Preliminary experiments

Qualitative tests showed that a large amount of Mn(II), As(V) or Zn(II) gives a weak colour reaction with CAS, CPB and $NH_2OH \cdot HCl$ in the absence of chromium(III or VI), but the colour intensity of the Cr(III or VI)–CAS–CPB–$NH_2OH \cdot HCl$ system is increased by addition of Zn(II).

The wavelengths of maximum absorption of the Zn(II)–CAS–CPB–$NH_2OH \cdot HCl$, Cr(III or VI)–CAS–CPB–$NH_2OH \cdot HCl$ and Cr(III or VI)–Zn(II)–CAS–CPB–$NH_2OH \cdot HCl$ systems are 500, 610 and 620 nm, respectively (Fig. 1). The sensitivity of the Cr(III or VI)–CAS–CPB–$NH_2OH \cdot HCl$ colour reaction is increased by a factor of *ca.* 2 by the presence of Zn(II). For this combined system, however, the total absorbance is not equal to the sum of the individual Cr–CAS–CPB and Zn–CAS–CPB absorbances, when the reference solution is a reagent blank that does not contain zinc (Fig. 1, curves 2–6), but when the reference solution is a reagent blank containing the same amount of zinc as is present in the test solutions, the total absorbance is increased by an amount equal to the difference between the absorbance of the reagent blank (Fig. 1, curve 1) and the Zn–CAS–CPB absorbance (Fig. 1, curve 2). In addition to this, the absorption spectrum obtained is practically the same, irrespective of the initial oxidation state of the chromium.

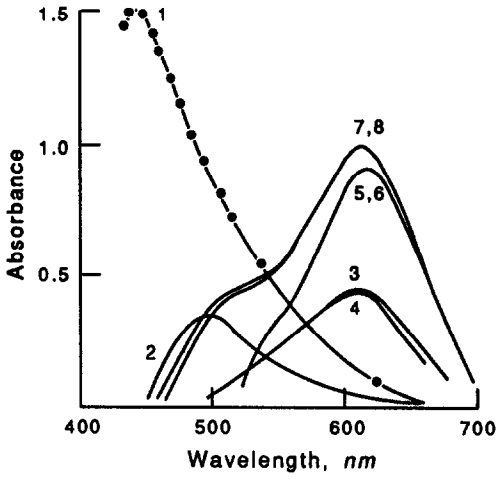

Fig. 1. Absorption spectra: (1) reagent blank (buffer, CAS, CPB, $NH_2OH \cdot HCl$) *vs.* water; (2) Zn(II) + reagent blank *vs.* reagent blank; (3) Cr(III) + reagent blank *vs.* reagent blank; (4) Cr(VI) + reagent blank *vs.* reagent blank; (5) Cr(III) + Zn(II) + reagent blank *vs.* reagent blank; (6) Cr(VI) + Zn(II) + reagent blank *vs.* reagent blank; (7) Cr(III) + Zn(II) + reagent blank *vs.* Zn(II) + reagent blank; (8) Cr(VI) + Zn(II) + reagent blank *vs.* Zn(II) + reagent blank. Conditions: Zn(II) 15 mg; Cr(III) 10.6 μg; Cr(VI) 10.0 μg; pH 5.7 buffer 1.5 ml; 3.2×10^{-3} *M* CAS 1.4 ml; 5×10^{-3} *M* CPB 1.5 ml; $NH_2OH \cdot HCl$ 75 mg; total volume 25 ml; 1-cm cells.

These facts indicate that a mixed-metal Cr(III)–CAS–CPB–Zn(II) complex is formed, and that the excess of CAS is all bound in a Zn(II)–CAS–CPB complex. The zinc added therefore performs two functions, increasing the sensitivity by (a) forming a chromium complex having a higher molar absorptivity than the simpler Cr–CAS–CPB complex, and (b) reducing the absorbance of the reagent blank by complexing with the excess of CAS. The role of the hydroxylamine appears to be solely the reduction of Cr(VI) to Cr(III).

Choice of conditions

Zinc concentration. Figure 2 shows that a large amount of zinc is needed, indicating that

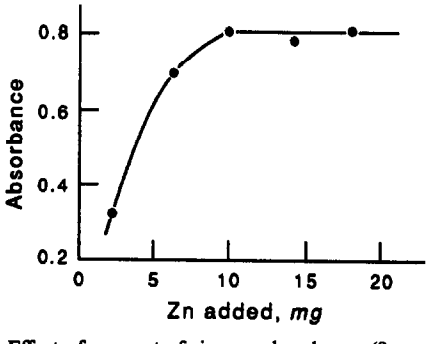

Fig. 2. Effect of amount of zinc on absorbance (8 μg of Cr).

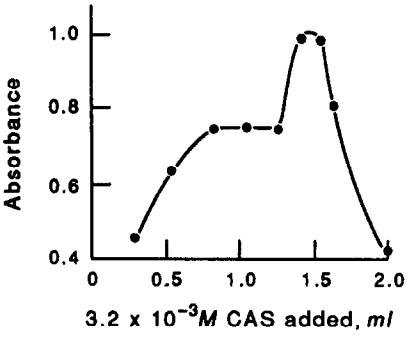

Fig. 3. Effect of CAS concentration on absorbance (10.6 μg of Cr).

the mixed-metal complex is not very much more stable than the parent chromium complex.

CAS and CPB concentrations. Figures 3 and 4 show the effect of the concentration of these two reagents. The optimum range is 1.4–1.5 ml of $3.2 \times 10^{-3}M$ CAS and 1.5–4.0 ml of $5 \times 10^{-3}M$ CPB per 25 ml of final solution. The apparent irregularity with lower amounts of CPB is presumably associated with the critical micelle concentration of this surfactant.

$NH_2OH \cdot HCl$ concentration. This was found not to be critical in the range 1.5–2.5 ml of 50-mg/ml solution per 25 ml of final solution.

Buffer solution. Maximal absorbance is obtained with 1.0–1.5 ml of buffer solution per 25 ml; larger amounts of buffer give lower absorbance, presumably because of competitive side-reactions with chromium(III).

Heating time. Maximal absorbance is obtained with heating times of 20–30 min at 100°.

Characteristics of the complex

The composition of the mixed-metal complex cannot be determined by the usual spectrophotometric methods, because of the nature of the system and the large excess of zinc necessary.

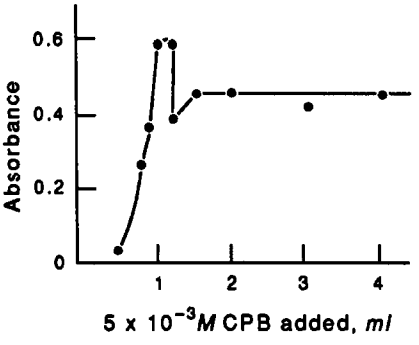

Fig. 4. Effect of CPB concentration on absorbance (5 μg of Cr).

Table 1. Determination of total chromium in some synthetic solutions

Cr(III)/Cr(VI) mole ratio	Total Cr taken, μg/25ml	Total Cr found,* μg/25ml
1:4	10.0	9.9 ± 0.1
1:1	10.0	10.0 ± 0.2
4:1	10.0	9.8 ± 0.2

*Mean ± standard deviation of 5 replicates

Table 2. Determination of chromium in some standard alloy steels

Samples	Certified value, %	Cr found,*
Chromium–silicon steel	1.38	1.43 ± 0.05
Low alloy steel	1.00	0.96 ± 0.04
Chromium–vanadium steel	0.77	0.76 ± 0.22

*Mean ± standard deviation of 6 replicates.

Once formed, the complex has constant absorbances for at least 2-hr.

Effect of foreign ions

The limiting concentration of foreign ions was taken as that concentration which caused an error of not more than 5%. In 25 ml of final solution the presence of at least 1 mg of Mn(II) and V(V), 0.8 mg of As(V), 0.5 mg of Ni(II), 0.4 mg of W(VI), 0.33 mg of Mo(VI) and 0.1 mg of Sn(IV) caused no interference. Addition of an appropriate amount of EDTA as masking agent after development of the colour allows up to 1 mg of Fe(III), 0.3 mg of Al(III) and Co(II) and 0.1 mg of Pb(II) to be tolerated.

Precision and accuracy

The method has been satisfactorily used to analyse synthetic solutions containing various ratios of chromium(III) and chromium(VI), and several alloy steels, with the results shown in Tables 1 and 2.

PHASE COMPOSITION ANALYSIS OF HYDROUS ALUMINIUM OXIDES BY THERMAL ANALYSIS AND INFRARED SPECTROMETRY

Zs. WITTMANN, E. KÁNTOR, K. BÉLAFI, L. PÉTERFY and L. P. FARKAS
Hungarian Oil and Gas Research Institute, József A. u. 34, H-8200 Veszprém, Hungary

(*Received* 22 *December* 1989. *Revised* 18 *February* 1992. *Accepted* 26 *February* 1992)

Summary—A general method for determination of the phase composition of hydrous aluminium oxides by thermal analysis and infrared spectrometry, and determination of the transformation temperature of mixtures of $Al(OH)_3$ and AlOOH into α-Al_2O_3 are described.

Six methods are available for production of high-purity alumina (purer than 99.9%): thermal cracking of ammonium alum; hydrolysis of organometallic compounds; the ethylene chlorohydrin process; thermal cracking of ammonium aluminium carbonate; the spark discharge process and the so-called modified Bayer process.[1] The properties of high-purity alumina depend on the different oxide phases obtained during calcination, and the crystal structure of these oxides depends on the mode of dehydration of the original hydrous aluminium oxide.

The transformation of different $Al(OH)_3$ and AlOOH samples into Al_2O_3 is shown in Fig. 1.[2–4] Bayerite, nordstrandite and pseudoamorphous aluminium hydroxide transform into α-Al_2O_3 through η- and θ-Al_2O_3. α-Al_2O_3 can be formed through χ- and κ-Al_2O_3 from gibbsite. The H_2O/Al_2O_3 mole ratios are 3 in gibbsite, bayerite, the rare nordstrandite and pseudoamorphous aluminium hydroxide. The hydrous aluminium oxides begin to lose water at about 200° and the loss is complete by about 500°. The different modifications of Al_2O_3 are produced at temperatures up to 1000–1200°, but at above 1200° there is only α-Al_2O_3.

The forms of AlOOH are boehmite and the rarely occurring diaspore. Boehmite transforms into α-Al_2O_3 through γ-, δ- θ-Al_2O_3, and diaspore is converted directly into α-Al_2O_3. The H_2O/Al_2O_3 mole ratios are 1 in both boehmite and diaspore. The loss of water from both is completed over the temperature range 380–550°.

The phase composition of a hydrous aluminium oxide can be determined by means of thermal analysis. In this paper a phase-composition analysis and the determination of the transformation temperature of the hydrolysis product of an organoaluminium into α-Al_2O_3 are described.

EXPERIMENTAL

A Derivatograph (5°/min heating rate, maximum temperature 1500°) was used. The DTA/DTG sensitivity ratio was 1:3. (500 mg) were placed in covered platinum cups and an air atmosphere was used throughout.

DTA and DTG curves for $Al(OH)_3$ (bayerite, gibbsite) and AlOOH (boehmite) were recorded and used for qualitative and quantitative analysis of the phase composition (Fig. 2).

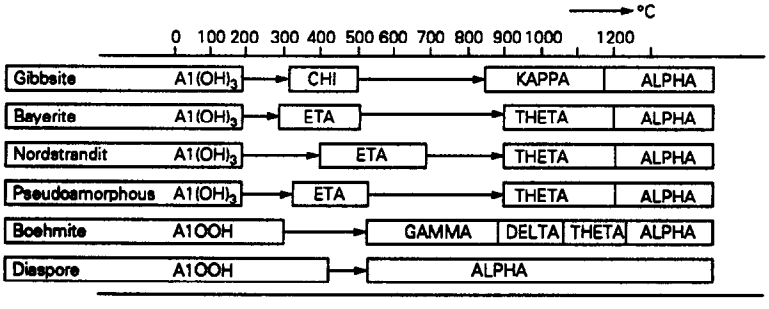

Fig. 1. Dehydration sequence of alumina hydrates (from Refs. 2–5).

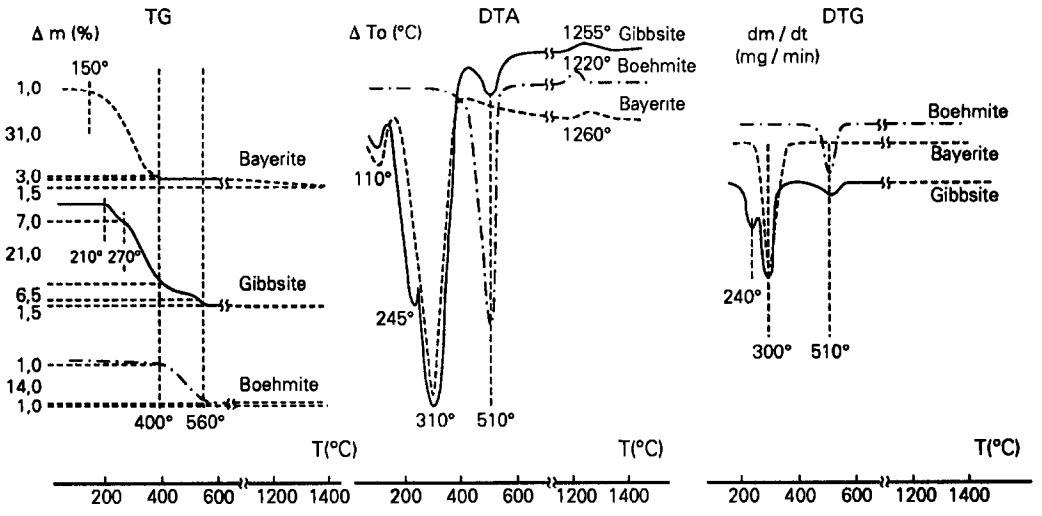

Fig. 2. Thermoanalytical curves of bayerite, gibbsite and boehmite.

The decomposition of bayerite is almost complete at 390°, with a peak temperature of 300°. There is 31% weight loss over the temperature range 150–390°, a further 3% at 390–560° and a final 1.5% at >560°. The dehydration of gibbsite proceeds in two major steps with 28% weight loss at 150–390° and 6.5% at 390–560°, and a final 1.5% at >560°. Boehmite loses 1% in weight up to 390° and a further 14% in the range 390–560°. These results (the averages of three replicate measurements) are in good agreement with the literature values.[5–8]

Water is evolved from $Al(OH)_3$ and AlOOH over two different temperature intervals, 150–390° and 390–560°.

The qualitative composition of a mixture of $Al(OH)_3$ and AlOOH can be determined on the basis of the weight losses over particular temperature intervals. A mixture of boehmite with either gibbsite or bayerite can be quantitatively analysed from the weight losses (Δm), as follows:

$$\begin{cases} \text{Bayerite} \quad (\%, \text{w/w}) = 100\ \Delta m \text{ (at 150–390°)}/31 \\ \text{Boehmite} \quad (\%, \text{w/w}) = 100\ [\Delta m \text{ (at 390–560°)} - 0.03 \times \%\ \text{bayerite}]/15 \end{cases}$$

$$\begin{cases} \text{Gibbsite} \quad (\%, \text{w/w}) = 100\ \Delta m \text{ (at 150–390°)}/28 \\ \text{Boehmite} \quad (\%, \text{w/w}) = 100\ [\Delta m \text{ (at 390–560°)} - 0.065 \times \%\ \text{gibbsite}]/15 \end{cases}$$

The thermoanalytical curves (Fig. 2) show the transformation temperatures into α-Al_2O_3 to be 1255° for gibbsite, 1220° for boehmite and 1260° for bayerite.

Table 1 gives the results obtained for various mixtures of bayerite, gibbsite and boehmite. The detection limits were examined with a mixture of known amounts of boehmite, bayerite and gibbsite and found to be 2%.

Table 1. Thermoanalytical analysis of bayerite, gibbsite and boehmite mixtures

Taken, % w/w			Found, % w/w		
Bayerite	Gibbsite	Boehmite	Bayerite	Gibbsite	Boehmite
90.0	—	10.0	90.3	—	9.3
10.0	—	90.0	9.5	—	91.4
50.0	—	50.0	50.3	—	50.0
—	30.0	70.0	—	31.3	68.5
20.0	40.0	40.0	20.5	40.9	38.7

The reproducibility obtained with two instruments was ±5% relative, and the repeatability for the same instrument and operator was ±3% relative.

The samples were also analysed by infrared spectrometry. The spectra of $Al(OH)_3$ (bayerite, gibbsite) and AlOOH (boehmite) are shown in Figs. 3 and 4 and the characteristic vibration bands are given in Table 2.

CONCLUSIONS

The thermoanalytical data for some samples are shown in Table 3 and the thermoanalytical curves of two different samples in Fig. 5. Moisture and any organic residues in the samples

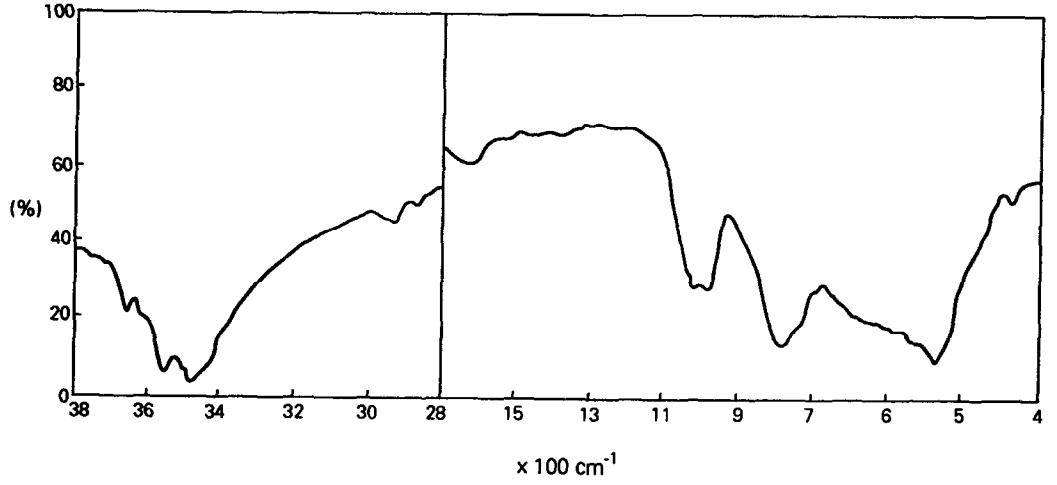

Fig. 4. Infrared spectrum of $Al(OH)_3$.

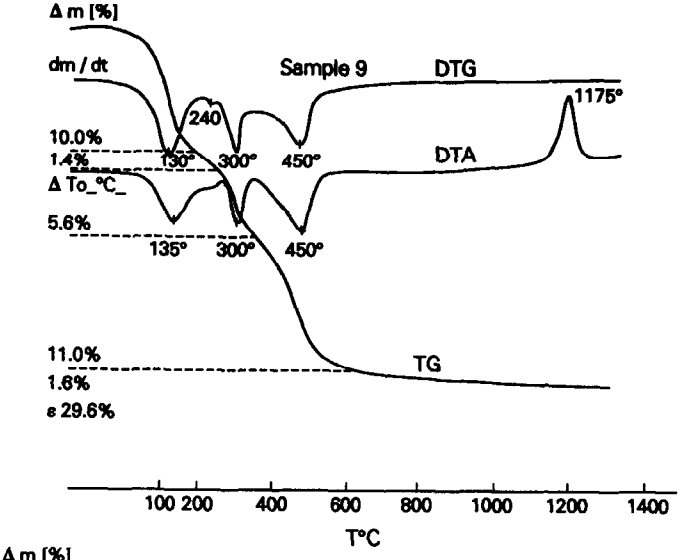

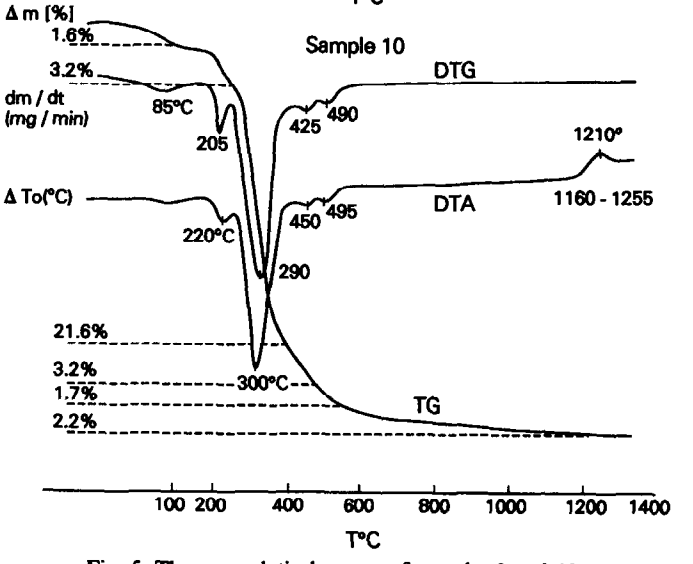

Fig. 5. Thermoanalytical curves of samples 9 and 10.

Table 2. Characteristic vibration bands (cm^{-1}) of AlOOH and $Al(OH)_3$

Vibrations	AlOOH	$Al(OH)_3$
Vibrational bands of AlO_6 octahedra	500, 630, 740	520, 770
OH deformation vibration	1160	980, 1020
OH stretching vibration	3100, 3300	3440, 3560, 3670

Table 3. Thermoanalytical and infrared results for aluminium hydrate samples

Sample	Moisture and organics	Thermoanalysis, % w/w		Infrared	
		$Al(OH)_3$	AlOOH	$Al(OH)_3$	AlOOH
1	4.0	71	25	+++	+
2	3.5	55	40	++	++
3	3.0	64	32	+++	++
4	3.0	76	21	+++	–
5	3.5	75	21	+++	–
6	8.0	43	48	++	++
7	3.0	50	48	++	++
8	10.0	23	67	+	+++
9	10.0	21	69	+	+++
10	1.6	89	9	+++	–

were lost at 120–130°. In the temperature interval 150–390° there are two dehydration steps, at 210–270° and 270–380°, characteristic of gibbsite. The amount of $Al(OH)_3$ can be calculated from the weight losses in both temperature intervals. In the temperature interval 390–560° boehmite is dehydrated.

The temperatures of transformation into α-Al_2O_3 depend on the proportions of $Al(OH)_3$ and AlOOH in the samples, and are shown in Fig. 6 as a function of the composition. The transformation temperature into α-Al_2O_3 seems to be $1170 \pm 5°$ over a very wide range of composition: 20–80% w/w $Al(OH)_3$ or AlOOH containing hydrated alumina. In the presence of about 10% w/w $Al(OH)_3$ or AlOOH the

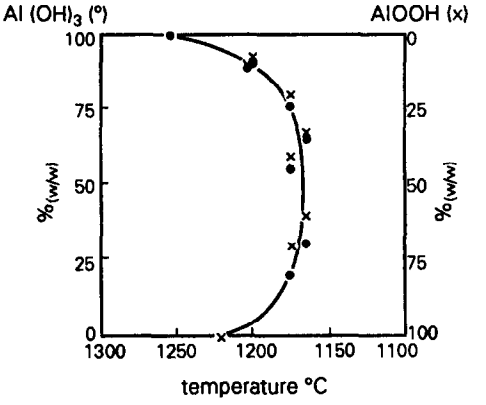

Fig. 6. Transformation temperature into α-Al_2O_3 from different $Al(OH)_3$ and AlOOH mixtures.

transformation temperature of the mixture is about 40° lower than that of the main component.

Only a semiquantitative estimation can be achieved on the basis of the infrared spectra. In Table 3 +++ indicates >60% w/w of a component, ++ about 40–50% w/w and + <25% w/w. The estimates found are in agreement with the results of the thermoanalytical measurements.

Summary—The application of hydrogen and deuterium ions obtained by anodic oxidation of hydrogen and deuterium dissolved in palladium, for the coulometric determination of bases (both individual and in mixtures) in propylene carbonate, is described. The current-potential curves at a palladium anode for supporting electrolyte indicator, titrated bases, hydrogen dissolved in palladium and deuterium dissolved in palladium showed that hydrogen and deuterium are oxidized at much less positive potentials than the oxidation potentials of other substances present in the solution. The generated H^+ and D^+ ions were used for the titration of bases (pyridine, quinoline, triethylamine, n-butylaniline, 2,2′-dipiridyl and aminopyrine) with visual and potentiometric detection. The oxidation of hydrogen and deuterium proceeded with 100% current efficiency. Two-component mixtures of bases (aliphatic + aromatic amine) were titrated successfully by using two indicators, Eosin and Crystal Violet. The relative error of the determination with respect to each individual base determination, was less than 2.5% for quantities of bases ranging from 1 to 3 mg.

Propylene carbonate (PC) is an aprotic dipolar solvent with a high permittivity ($\epsilon = 64$) and relatively large acidity scale; it dissolves many organic compounds and is not toxic.[1] However, solutions of strong mineral acids in PC are not stable which makes the classical volumetric determinations of bases in this solvent difficult. For potentiometric titration of bases in PC, Baranov *et al.*[2] used a standard solution of perchloric acid in PC–methanol/5 + 1, v/v mixture.

In our previous paper[3] it was shown that the difficulties encountered in the classical titrations of bases in PC can be avoided by using hydrogen ions obtained by anodic oxidation of various organic compounds (esters of gallic acid, phenols and ascorbic acid).

In comparison with the classical depolarizers, hydrogen and deuterium dissolved in palladium have advantages, since, by their applications, no foreign substances which can make worse the conditions for the titration of bases, are introduced into the solution. Hydrogen–palladium and deuterium–palladium electrodes have so far been successfully used in coulometric titrations of bases in water[4] and some non-aqueous solvents.[5–7]

Taking into account all good properties of propylene carbonate as a medium for the titration of bases, as well as the advantages of hydrogen and deuterium dissolved in palladium with respect to other depolarizers, in this paper we have investigated the behaviour of hydrogen–palladium and deuterium–palladium generator electrodes in coulometric titrations of bases in propylene carbonate as solvent.

EXPERIMENTAL

Reagents

All chemicals were of analytical reagent grade from Merck and Fluka. Liquid bases were first dried over fused potassium hydroxide and then distilled under reduced pressure. The concentration of organic bases was previously determined coulometrically with H^+ ions obtained

by the oxidation of hydroquinone at a platinum anode, in acetonitrile as solvent. The supporting electrolyte was 0.2*M* sodium perchlorate in propylene carbonate.

A saturated solution of Eosin in propylene carbonate or a 0.1% solution of Crystal Violet in the same solvent were used as indicators.

Propylene carbonate was used without purification. Deuterium oxide (heavy water), 99.8%, was purchased from the Radioisotope Division of IGN Chemicals.

Electrodes

The $(H_2/Pd)_{gener}$ and $(D_2/Pd)_{gener}$ electrodes were palladium plates (1 × 2 × 0.5 cm) saturated with hydrogen or deuterium obtained by electrolysis. The apparatus used is described in our previous paper.[6] The indicator electrode was a glass electrode and the reference electrode was SCE.

Procedure

Visual end-point detection. The supporting electrolyte is placed into the anode (2–3 cm^3) and cathode (3–5 cm^3) compartments of the electrolytic vessel up to the same level. A platinum spiral is dipped into the catholyte, a drop of Crystal Violet solution is added to the anolyte, and a $(H_2/Pd)_{gener}$ electrode is immersed into the anolyte. The current is turned on and the supporting electrolyte is titrated. A weighed amount of the base being determined is then added to the anolyte, and by simultaneously switching on the current and the chronometer H^+ ions are generated until the indicator color is changed. A further aliquot of the base is then added to the anolyte and the solution is again titrated. Several samples can be analyzed in the same supporting electrolyte.

Potentiometric end-point detection. The supporting electrolyte was poured into the cathode and anode compartments of the electrolyte vessel up to the same level.[6] The platinum cathode was dipped into the catholyte and $(H_2/Pd)_{gener}$ electrode, or $(D_2/Pd)_{gener}$ electrode, a glass electrode and an SCE were immersed in the anolyte. A weighed amount of the base being determined was added to the anolyte, the current was switched on; H^+/or D^+ ions were generated and the potentials were read. The titration end point was determined from the second derivative.

Determination of two component mixture of amines. In the determination of dicomponent mixtures of amines (an aliphatic and an aromatic amine) the supporting electrolyte is also placed into the cathode and anode compartments up to the same level. A drop of Eosin solution is added to the anolyte and the supporting electrolyte is titrated until the indicator colour changes. Then, a weighed amount of a mixture of bases is added to the anolyte and H^+ ions are generated until the color of Eosin is changed, whereby the aliphatic amine is titrated. An aliquot of the same mixture of bases is then titrated in the same way but by using Crystal Violet as indicator. The amount of the aromatic amine is determined from the difference.

RESULTS AND DISCUSSION

In order to check the possibility of applying H^+ ions obtained by anodic oxidation of hydrogen dissolved in palladium for the titration of organic bases in propylene carbonate, the current–potential curves for the supporting electrolyte indicator, titrated bases and hydrogen dissolved in palladium were first recorded. The current-potential curves (Fig. 1) for propylene carbonate, Crystal Violet, pyridine and hydrogen dissolved in palladium showed that hydrogen dissolved in palladium is oxidized at a more negative potential than the oxidation potentials of other components present in the solution. H^+ ions generated at the palladium anode were used for the titration of triethylamine, *n*-butylaniline, quinoline, pyridine, 2,2′-dipyridyl and aminopyrine in the presence of Crystal Violet indicator. The results obtained (Table 1) indicate

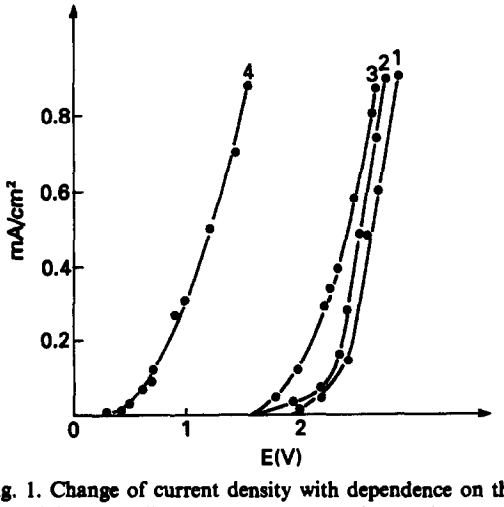

Fig. 1. Change of current density with dependence on the potential at the palladium anode: 1) propylene carbonate; 2) Crystal Violet; 3) pyridine and 4) $H_2(D_2)$ dissolved in palladium.

*The volume of the electrolytic vessel for potentiometric end-point detection is 4–5 times that for visual end point detection. Therefore, the concentration of the titrated bases are in each case approximately the same

†Visual end-point detection.

‡Potentiometric end-point detection (glass electrode—modified SCE).

that the current efficiency was 100%, when 2–7 mg of the investigated bases were titrated. With D_2/Pd generator electrode the current efficiency was also 100%.

In coulometric titrations of triethylamine, quinoline, *n*-butylaniline and 2,2′-dipyridil, respectively, the titration end-point was detected also by the potentiometric method, using the electrode couple: glass electrode-SCE. The titration curves obtained are shown in Fig. 2. The highest potential changes were detected in the titration of triethylamine (about 300 mV for 30 sec), whereas the lowest one in the titration of *n*-butylaniline (about 100 mV for 30 sec).

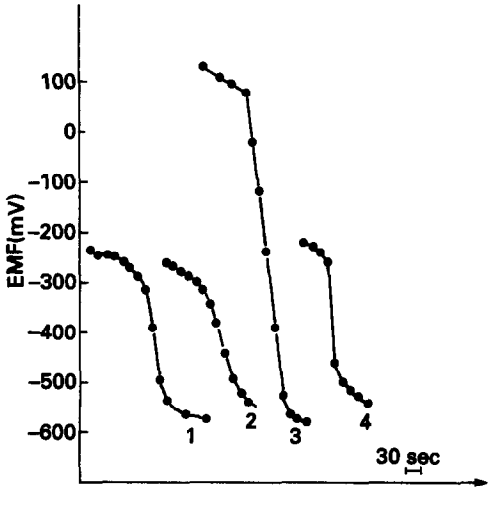

Fig. 2. Coulometric titrations curves for bases in propylene carbonate with a glass electrode and SCE: 1) quinoline; 2) n-butylaniline; 3) triethylamine; 4) 2,2′-dipiridyl.

The determination of dicomponent mixtures of bases

Since propylene carbonate has a differentiating effect on the strength of bases, in this solvent it is possible to titrate a mixture of bases differentially with perchloric acid, provided their pK values in water differ at least for 1.4 pK units.[2] In our previous paper,[8] two component mixtures of aliphatic and aromatic amines were coulometrically determined in acetonitrile as solvent, using two indicators (Eosin and Crystal Violet).

By using the differentiating effect or propylene carbonate on the strength of bases and the possibility of direct generation of H^+ ions by the oxidation of hydrogen dissolved in palladium, we have determined coulometrically mixtures of an aliphatic and aromatic amine in propylene carbonate visual end-point detection using Eosin and Crystal Violet (Table 2) as indicators.

Table 2. Coulometric determination of mixtures of aliphatic and promatic amines with H^+ ions generated by the oxidation of hydrogen dissolved in palladium with visual end-point detection using Eosin and Crystal Violet as indicator. $I = 0.010$ A.

Titrated bases	Taken, *mg*	Number of determination	Found, %
Triethylamine+	1.31	6	98.9 ± 1.6
2,2′-dipiridil	2.02	6	98.0 ± 1.0
Triethylamine+	1.15	6	100.6 ± 1.3
Quinoline	2.24	6	100.2 ± 2.5
Butylamine+	2.38	6	99.4 ± 0.2
Quinoline	1.44	6	100.9 ± 2.7
Butylamine+	3.00	6	101.1 ± 1.2
2,2′-dipirydil	2.99	6	99.0 ± 1.9

The results presented in Table 2 show that the relative error of the determination with respect to each individual base determination was less than 2.5% for base quantities ranging from 1 to 4 mg.

On the basis of these results it may be concluded that the oxidation of hydrogen and deuterium dissolved in palladium, in propylene carbonate as solvent, proceeds with 100% current efficiency and that the generated H^+ ions can be applied to the determination of two-component mixtures of bases. By using hydrogen and deuterium as anodic depolarizers it is possible to eliminate the use of standard solutions of acids which are unstable in propylene carbonate. Furthermore, their application brings no foreign organic compounds into the solution being investigation. At a current of 10 mA, a palladium plate with a volume of 1 cm^3 saturated with hydrogen can generate H^+ ions for more than 100 hr.

APPLICATION OF *p*-XYLENESULPHONIC ACID AS ASHING REAGENT IN THE DETERMINATION OF TRACE METALS IN CRUDE OIL

A. P. UDOH,* S. A. THOMAS and E. J. EKANEM†
Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 15 *July* 1991. *Revised* 9 *March* 1992. *Accepted* 23 *March* 1992)

Summary—The *p*-xylenesulphonic acid ashing procedure was applied to the determination of Ca, Cu, Fe, Mg, Na, Ni and Zn in crude petroleum. The optimum acid ratio was 1.0 g per gram of oil for determining Na and Ni and 0.5 g per gram of oil for the other metals determined. The simultaneous ignition of the oil-acid mixture while boiling prevented volatilization losses for Fe, Na and Ni, eliminated the coke residue and reduced the ashing time. The minimum sample size for efficient metal release was 15.0 g. Satisfactory recoveries of added Na and Ni and highly reproducible results were obtained. Results obtained by this method were similar to those obtained by standard methods for the same samples.

The determination of trace metals in petroleum oils has relied on ashing methods that aim at preventing metal losses by volatilization during the ignition of samples.[1–13] Benzenesulphonic acid destroys the porphyrin metallocomplexes present in an oil and renders the metals non-volatile.[14] A procedure for determining nickel and vanadium in petroleum distillates using this compound as ashing reagent has been reported[6,14] and was adopted by the Institute of Petroleum.[15] An extension of this procedure using *p*-xylenesulphonic acid as the ashing reagent for the determination of copper, iron, nickel and vanadium in refinery fluid catalytic cracking feedstock has been reported.[8] The application of this reagent to crude petroleum has not been reported: an examination of this reagent in the ashing of petroleum crude is presented in this article.

EXPERIMENTAL

Reagents and apparatus

All reagents used were of analytical reagent grade. Doubly distilled water was used to prepare all solutions. Stock solutions (1000 ppm) of Ca, Cu, Fe, K, Mg, Na, Ni and Zn were prepared from their carbonate (Ca), chlorides (K, Mg, Na), nitrates (Cu, Ni), oxide (Zn) or ammonium sulphate (Fe) and stored in polythene bottles; each was appropriately diluted to obtain working solutions. Lanthanum [5% (m/v)] as the nitrate was introduced in the working solutions used for determining Ca and Mg as buffer to minimize the interferences of ions like phosphate, aluminate and silicate.

The muffle furnace was a Carbolite (Sheffield, U.K.) capable of maintaining a constant temperature in the range 20–1200°.

K and Na were determined with a Corning-EEL flame photometer.

Other metals were determined with a Pye-Unicam SP 1900 atomic-absorption spectrometer equipped with a premix chamber and a 10-cm single slot burner head operated on the air-acetylene flame applying single element hollow cathode lamps as sources. Instrument parameters were appropriately optimized for each element determined.

Crude oil samples

The samples analysed were obtained from various Nigerian oil-drilling and refining companies. They were blends from particular production fields and were for either export or local refining. All samples were stored in polythene bottles and were assigned numbers to differentiate them in this work.

p-*Xylenesulphonic acid*

This ashing reagent was prepared as recommended by Vogel[16] and stored in a desiccator for use as required.

*Present address: University of Cross River State, Uyo, Nigeria.
†Author for correspondence.

Table 1. Optimization of *p*-Xylenesulphonic acid ratio

Acid ratio (g/g oil)	Concentration (ppm) of metal measured							
	Ca	Cu	Fe	K	Mg	Na	Ni	Zn

4.0	2.0	0.3	10.6	0.8	0.8	16.0	13.7	0.5
5.0	1.9	0.3	10.6	0.8	0.8	16.2	13.7	0.5

Sampling for analysis

The sampling procedure was to ensure even distribution of particles, sludge and water in the crude when a sample was taken for analysis. The crude was heated on a steam bath for at least thirty minutes; the container was then shaken vigorously to mix the oil before any sample was taken with a dropper.

Optimization of the ratio of p-*xylenesulphonic acid*

A 20.0-g oil sample, in each case, was mixed with varying masses of *p*-xylenesulphonic acid; the mixture was coked, charred and muffled at 500°; the resulting ash was digested and dissolved using 50% hydrochloric acid by the method reported later under 'proposed procedure' and the solution analysed for metals as presented in Table 1 for sample 1.

Heating procedure and muffling temperature

The acid–oil mixture was brought gently to boil on a heating mantle. It was then ignited with a flame as recommended by Row and Yates[8] until a charred mass was obtained. This charred mass was muffled at 500°.

The effect of igniting during coking

The acid–oil mixture was prepared in replicate in different beakers; each mixture was ignited at a different time interval after it was brought to the boil. The effect of this ignition is indicated in Table 2 for one of the four samples investigated.

Table 2. Effect of ignition during coking on metal recovery

Stage of ignition	Concentration (ppm) of metal measured							
	Ca	Cu	Fe	K	Mg	Na	Ni	Zn
Immediately on boiling	4.4	0.1	6.5	1.2	2.5	6.5	7.4	0.4
One hour after onset of boiling	4.3	0.1	6.4	1.2	2.4	6.1	7.4	0.3
No ignition applied at all	4.3	0.1	4.9	1.4	2.5	5.4	6.0	0.3

Optimization of the sample size

Varying masses of sample 5 were mixed with 1.0 g of *p*-xylenesulphonic acid per gram of oil, coked, charred and ashed before the metals were determined. The results are presented in Table 3.

Proposed procedure

A 20.0-g sample of crude oil is mixed with 1.0 g of *p*-xylenesulphonic acid per gram of oil in a 500-ml pyrex beaker. The mixture is brought to the boil, ignited and charred, and the carbon burnt off in a muffle furnace at 500°. The resultant ash is digested in 20.0 ml of hydrochloric acid (1 + 1) on a steam bath until the volume decreases to about 5.0 ml. This solution is transferred quantitatively and made up to 25 ml introducing 5.0 ml of 5% lanthanum solution. Flame photometry and flame atomic-absorption spectrometry were then applied to determine Ca, Cu, Fe, K, Mg, Na, Ni and Zn against a blank solution derived from only *p*-xylenesulphonic acid in the absence of oil.

Evaluation of the procedure

The reproducibility of the procedure was determined by applying the proposed procedure nine times in turn on sample 5. The reproducibility in the determination of the various determinant elements is indicated in brackets as percent relative standard deviations (RSD) in Table 3.

Table 3. Effect of sample size on metal release

Sample size, g	Concentration (ppm) of metal measured							
	Ca	Cu	Fe	K	Mg	Na	Ni	Zn
10.0	5.0	0.0	4.3	0.5	2.4	6.0	6.3	0.3
15.0	6.2	0.1	6.5	0.9	2.5	6.5	6.7	0.3
20.0	8.6	0.1	6.4	1.2	2.5	6.4	7.4	0.3
(RSD) (%)	(0.7)	(10.0)	(1.5)	(14.5)	(3.6)	(2.5)	(0.7)	(23.3)
25.0	8.8	0.1	6.6	1.0	2.3	6.7	7.5	0.4

Table 4. Recovery of added metal from a spiked crude oil sample

Metal added	Metal level (ppm) Added	Recovered	Recovery (%)
Na	2.0	1.8	91.0
	10.0	9.0	90.0
	100.0	95.0	95.0
Ni	2.0	1.9	95.0
	10.0	9.5	95.0
	100.0	97.0	97.0

To study the recovery of added determinant, 20.0-g replicates of sample 5 were spiked with various levels of sodium and nickel added as the cyclohexanebutyrates in amyl alcohol. Each mixture was then treated by the proposed procedure and Na and Ni determined; the results, after discounting the known sample level, are presented in Table 4.

In a comparison of methods, various crude oil samples were analysed for the same trace metals using the *p*-xylenesulphonic acid procedure described in this article, the sulphuric acid ashing procedure,[12,13] and the Institute of Petroleum (IP) procedure.[15] Samples were prepared and analysed in duplicate by each procedure and the mean results are compared in Table 5.

Table 5. Comparison of sample results obtained by three ashing procedures

Sample No.	Analyte	Measured levels (ppm) Proposed procedure	Sulphuric acid procedure	IP procedure

RESULTS AND DISCUSSION

The concentration of each element indicated in the ash increased with the ratio of *p*-xylenesulphonic acid per gram of oil until a peak concentration was obtained. The peak concentration was attained for sodium and nickel with 1.0 g of *p*-xylenesulphonic acid per gram of oil but for the other metals measured, the peak was attained with 0.5 g of *p*-xylenesulphonic acid per gram of oil. Once attained, the peak concentration remained unchanged when higher acid ratios were applied. Plotted against increasing *p*-xylenesulphonic acid ratios, the concentration of each element observed increased linearly to the peak value and, thereafter, maintained a plateau up to an acid ratio of 5.0 g per gram of oil. The same trend was observed for samples other than sample 1 to which the results of Table 1 relate. The two peak reagent: oil ratios were characteristic for the determinants investigated in this work. The differences in the acid ratio required to achieve maximum release of each metal have been explained[17] in terms of corresponding differences in the thermodynamic stabilities of the complexes of the metals in the oils. The trends observed in this work suggest that the complexes of sodium and nickel are thermodynamically more stable than those of the other elements.

The burning of the sample while boiling offered the advantage that the large volume of

coke produced in methods like the sulphuric acid ashing procedure[12,13] was eliminated; the ashing time was also much shorter, decreasing to about five hours. The muffling temperature of 500° was selected from a range of effective values to permit the use of ordinary pyrex beakers; they get disfigured at much higher muffling temperatures. A qualitative examination of the ash solution in (1 + 1) hydrochloric acid gave a negative test for SO_4^{2-} ion indicating that the metal sulphonates were converted already at 500° to the oxides of the metals.

Table 2 shows that similar results were obtained for Ca, Cu, K, Mg and Zn when ignition was started immediately on boiling and long (1 hour) after boiling had commenced as when ignition was not applied at all; slightly lower values were obtained for Fe, Na and Ni when there was no ignition at all than when ignition was applied. This trend was observed consistently for four samples included in this investigation. In all cases, delaying the ignition offered no advantage at all. These results provide some idea of the elements in crude oils that are more prone to volatilization losses; the simultaneous burning of the oil–acid mixture is important for these elements. The burning generally shortened the time required for charring the sample.

The results of element analysis of the ash presented in Table 3 indicate that at least 15.0 g of the oil is required for maximum release of most of the elements. For this work, 20.0 g of oil was applied to allow some safe margin. The Q-test showed that the value obtained for iron using 10.0 g of oil was divergent.

The RSD values inserted in Table 3 show that this technique yields highly reproducible analysis on crude oil samples, at least for most of the elements measured. The higher relative standard deviation (RSD) values observed for elements like copper, potassium and zinc arise from their rather low levels in the sample analysed.

The high recoveries reported in Table 4 indicate the merit of this method. Besides, Table 5 shows that the results from the procedure compare well with those from the sulphuric acid and the standard Institute of Petroleum ashing procedures. At the 98% confidence level, the Student t-test showed that there was no significant difference between the results obtained by the three procedures.

With particular reference to benzenesulphonic acid, the procedure and reagent presented in this article offer the following advantages. Whereas the benzenesulphonic acid method has been applied only to distillate fractions,[6,15] the p-xylenesulphonic acid reagent and method, hitherto reported only for ashing petroleum distillate fractions, are suitable also for whole crudes; to provide an alternative reagent, even with a capacity to cope with a more complex matrix, is an advantage of the p-xylenesulphonic acid method. Besides, benzenesulphonic acid is very hygroscopic and requires special handling such as storing in an oven at 90° and using special materials for transferring it; p-xylenesulphonic acid offers an advantage in that it can be prepared simply and maintained solid over a long period in a desiccator at room temperature. With the simultaneous ignition of the crude, the p-xylenesulphonic acid procedure yields a drastic reduction in ashing time to about 5 hr in the benzenesulphonic acid procedure,[6,15] a filtration stage which is delayed overnight for an element like zinc is included; the p-xylenesylphonic acid procedure described in this article removes the need for filtration as the ash is rendered carbon-free in about three hours of muffling. In addition to the advantage in speed of analysis, the exclusion of the filtration eliminates the associated chance of error arising from either contamination during the filtration or loss by removal of determinant with the particles filtered out. One sample preparation is adequate for the determination of all the elements included in this work, whereas, in the benzenesulphonic acid procedure, modifications are required for specific elements.

CONCLUSION

The p-xylenesulphonic acid ashing procedure has hitherto been applied mainly for the determination of trace and additive metals in petroleum distillate fractions. Its merits for the determination of Ca, Cu, Fe, K, Mg, Na, Ni and Zn and perhaps other metals in whole crudes have been demonstrated in this article. The procedure is fast, reproducible and accurate; it precludes the profuse formation of coke which is a nuisance in other similar methods. The much reduced ashing time renders the method particularly suitable for progressive monitoring of on-going blending processes in addition to quick determination of constituents in crudes.

AN IMPROVED COMPUTER MODEL OF STRUVITE SOLUTION CHEMISTRY

T. J. WRIGLEY, W. D. SCOTT and K. M. WEBB

Environmental Science, School of Biological and Environmental Sciences, Murdoch University, Murdoch 6150, Western Australia

(*Received* 5 *December* 1991. *Revised* 9 *April* 1992. *Accepted* 11 *April* 1992)

Summary—The computer model of the solution chemistry of struvite has been improved. Firstly, with ammonia as the prime calculation point in the liquid phase, the algorithm is smaller and faster. Secondly, the incorporation of distilled magnesium hydrogen phosphate in the model significantly increased the concentrations in solution. Thirdly, estimates of the activity coefficients are included. These improvements have but a marginal (5–10%) improvement in the fit. However, proceeding with this flexible modelling procedure using the symbolic manipulator, Maple, easily allows the inclusion of all possible species. The addition of associated ammonium phosphates improves the fit. The relative standard deviation of the fit of both Taylor's data and the data of Webb is improved from 0.5 to 0.2. Estimates of the association constants are included.

Magnesium ammonium phosphate hexahydrate ($MgNH_4PO_4 \cdot 6H_2O$, struvite) is found in wastewaters, soils and is responsible for up to 16 per cent of urinary calculi. Conditions required for struvite precipitation in wastewaters and growth in human urine have not been well described. The literature on the basic chemistry is sparse.[1] The solubility of struvite was computed by Verplaetse *et al.*[2] and improvements have been completed by Scott *et al.*[3] This latter model includes the electro-neutrality equation and allows full expression of the inherent two degrees of freedom in this system. This means that the output should characterise precipitation in the general sense, *i.e.*, when the component ratios are not just 1:1:1.

In this paper, further improvements of the model are described. Firstly, the programme has been reconstructed using ammonia (NH_3) as the first calculation point to decrease the size and improve the running of the original programme. Secondly, the effects of associated magnesium hydrogen phosphate and ammonium phosphate ions and other possible species were investigated. Thirdly, a routine to calculate activity coefficient corrections was included.

The final aim of this study is to develop a predictive model incorporating all present knowledge of the system and to determine the amount of solid (*i.e.*, all possible solid compounds) formed from solution following the additions of arbitrary amounts of N, Mg and P. This paper is intended for design and calculation at 30° for waste-water treatment in the tropics; the baseline data of Webb[4] is the primary comparison.

EXPERIMENTAL

Materials and methods

Dissolved magnesium hydrogen phosphate (dMHP). The original algorithm[3] fitted the data of Taylor *et al.*,[5] but a large error remained. This deficiency was partly removed when a soluble component of magnesium hydrogen phosphate (MHP) was considered in the algorithm. Taylor *et al.*[5] suggested that this species is present in such systems and they provide an estimate of the appropriate equilibrium constant. The incorporation of dMHP into the model required a restructuring of the Maple algorithm, adding an additional equilibrium constant for this dissolved/solid equilibrium. The data for 30° are listed in Table 1. The constants listed in the second column of the table are the best values using a least squares fit of the data from Webb[4] (see Scott *et al.*[3]). The mass balance equations for magnesium and phosphorus were also amended to include the dissolved species. It was not necessary to change the solid mass balances or the electro-neutrality equation, however the direct calculation of Plqd from a quadratic was not possible, in contrast to the model reported previously.[3]

Table 1. Solubility constants with derived values for ionic equilibrium during model calibration

Equilibrium	Literature K[8]	Predicted K values
$Mg^{2+} + NH_4^+ + PO_4^{3-} = MgNH_4PO_4$	1.41×10^{13}	6×10^{13}
$H^+ + H_2PO_4^- = H_3PO_4$	77.4	77
$H^+ + HPO_4^{2-} = H_2PO_4^-$	1.86×10^6	9×10^7
$H^+ + PO_4^{3-} = HPO_4^{2-}$	7.08×10^{10}	1.8×10^{12}
$3Mg^{2+} + 2PO_4^{3-} + 8H_2O = Mg_3(PO_4)_2 8H_2O$	1.58×10^{25}	1.0×10^{24}
$Mg^{2+} + OH^- = Mg(OH)^+$	380	1.4×10^6
$Mg^{2+} + 2OH^- = Mg(OH)_2$	7.94×10^{10}	7.94×10^{10}
$Mg^{2+} + HPO_4^{2-} = MgHPO_4$	6.6×10^5	1.7×10^6
$MgHPO_4(s) = MgHPO_4(aq)$	98×10^{-3}	98×10^{-3}

An improved algorithm. The reconstruction made it necessary to check the effect of structure on the calculation. Hence calculations were made in which the logic and the algorithm were deliberately changed. Generally this resulted in a faster algorithm that showed no significant change in computed values. All calculations were done in double precision with an accuracy of at least 15 digits and a range of 10^{-307} to 10^{+307} using Absoft Fortran on an Amiga 2000. Two different algorithms evolved; one based on the original calculation of the total phosphorus concentration in the liquid, Plqd, the other based on calculating the concentration of dissolved NH_3 in the liquid.

When Plqd is calculated, the [H] and total magnesium in the liquid, Mlqd, are the independent inputs. The calculation uses the mass and charge balance equations to produce a quadratic equation in Plqd. From this point $[PO_4^{3-}]$ is calculated from a version of the liquid P balance equation, $[Mg^{2+}]$ from the Mg liquid balance equation and $[NH_4^+]$ from a version of the electro-neutrality equation. The remaining concentrations are calculated as simple ratios from the equilibrium constants. Later it was discovered that greater deficiency was achieved by using the dissolved magnesium ion concentration $[Mg^{2+}]$ rather than Mlqd as one of the input independent arguments. Mlqd is the total of all dissolved magnesium containing ions in the liquid, in gram-atoms/litre. The results of this calculation were the same as the original but approximately one-half the number of terms was used and less time was required for the calculations.

The greatest efficiency was achieved when $[NH_3]$ was calculated first. In this case, [H] and $[Mg^{2+}]$ were input arguments as well as all species that can be directly calculated from these values including [OH], $[MgOH]^+$ and the solid mole fraction of $Mg(OH)_2$. A flow sheet of the improved programme is listed in Table 2. The concentration of dissolved ammonia $[NH_3]$ is calculated from the solid mass balance equation using Maple with $[PO_4^{3-}]$, in turn, calculated from the electroneutrality equation.

Activity coefficients. There are many theoretical methods of calculating activity coefficients.[6,7] All have deficiencies but they generally acknowledge a dependence of the activity coefficient of a single ionic compound on the ionic strength; I where,

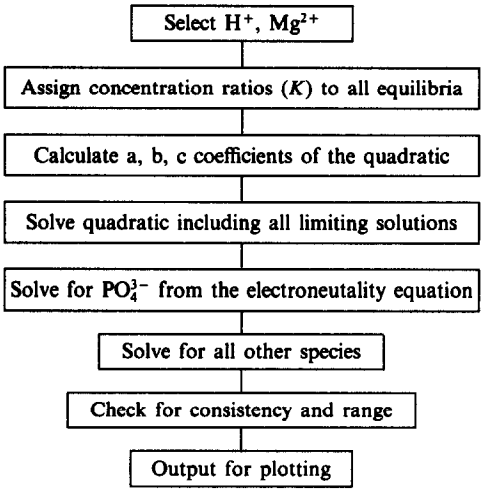
$$I = 0.5 \sum m_i z_i^2$$

m_i is the molarity

and z_i is the charge of species i.

The classic approximation is the Debye-Huckel equation (for $I < 0.01$). This equation relates the mean molar activity coefficient $\gamma \pm$ for both positive and negative ionic components to the charge on the ion, the charge on the ionic

Table 2. Flow sheet of the improved programme



Note: intermediate concentrates of species are calculated as necessary. The final algorithm includes an algorithm for calculating activity coefficients by iteration. It covers 18 equilibria and requires the solution of a quadratic for NH_3 using a Newton–Raphson technique.

environment and the ionic strength. In our case, $\gamma \pm$ values are used for individual ions in a multivalent solution. For this, we chose an *ad hoc* approach that allows for a complete mixture of ions in solution; a formula which reverts to the original Debye-Huckel form when only a simple equivalent salt is present. The equation used is

$$\gamma_i = 0.5\, z_i z_e \log I^{1/2} \qquad (1)$$

where $z_e = \Pi\, z_J^{y_J}$ is the equivalent charge of the environmental field of ion i, $y_J = m_J/\Sigma m_J$ is the fraction of charge contributed by ions of charge J to the 'pool' of ions of charge opposite in sign to ion i. Π is the overall product from ions that have the opposite charge to i. Σm_J is the sum over all ions of charge J.

The final, complete programme follows the general flow of Table 2 but includes an iteration to estimate activity coefficients. The algorithm begins to calculate concentrations with all activity coefficients equal to 1. Concentrations are estimated, then the activity coefficient ratios are estimated from equation (1) and new estimations of the concentration based on "corrected" equilibrium constants are found. Initially, the calculation was repeated twice with estimated activity coefficient values. Later with the inclusion of further ionic species the calculation was repeated until the activity coefficients came to final limiting values. The procedure includes various tests to assure that realistic concentrations and activity coefficients are calculated.

Changes to the contour plots

A series of plots incorporating combinations of (a) dissolved NH_3 as the prime variable (b) the inclusion of dMHP and (c) the influence of activity coefficients are presented in Figs. 1–3. Note that these data are all for 30°. Little change in the concentration of both Plqd and Nlqd was apparent when compared with the original algorithm at >30°. The curves show an increase in concentration of about an order of magnitude over the 25° values (see Fig. 1 in Ref. 3). Also, they have a different shape because the equilibrium constant values were rederived and the contouring package (Surface II) has difficulty fitting the limits of the curve.

The inclusion of dMHP increased the solubility of phosphorus and nitrogen. At a pH of 9, the inclusion of dMHP in the new algorithm increased the phosphorus from $10^{-1.8}$ to $10^{-1.3}$ when the total magnesium in the liquid is 10^{-6}.

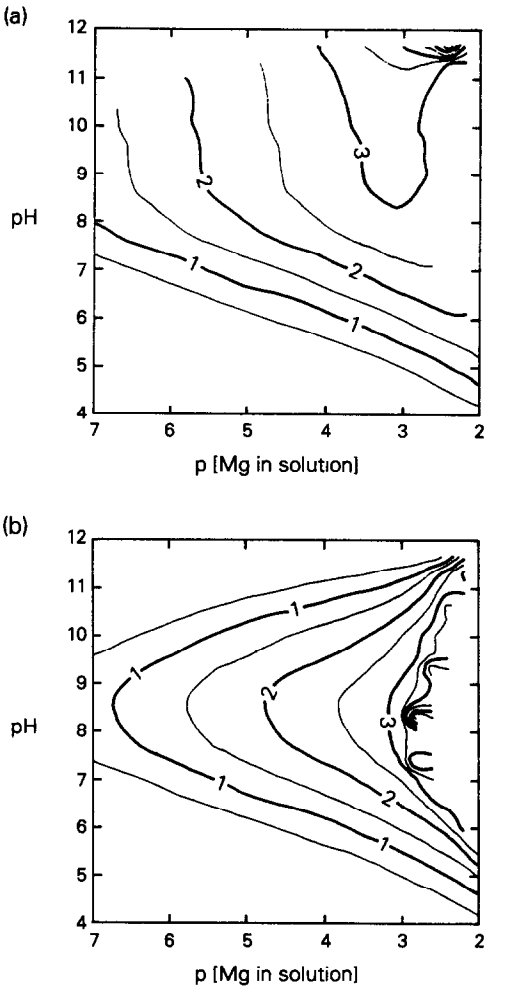


Fig. 1 (a). Concentration curve for the solubility of phosphorus and magnesium in solution when ammonia (NH_3) is the key variable. 30° lines are constant p [phosphorus in solution]. (b). concentration curve for the solubility of nitrogen and magnesium in solution when ammonia (NH_3) is the key variable. 30° lines are constant p [nitrogen in solution].

Nitrogen in solution Nlqd similarly increased from $10^{-1.3}$ to $10^{-0.8}$ [compare Figs. 1(a) and 1(b), and 2(a) and 2(b)].

The inclusion of activity coefficients in the new algorithm [Fig. 3(a) and (b)] had a more marked influence. In broad terms both Plqd and Nlqd increased in concentration by an order of magnitude. This shows more free ions with less dissolved solid; the inclusion of dMHP was somewhat overwhelmed by the inclusion of activity coefficients.

RESULTS AND DISCUSSION

Final algorithm

These changes did improve the fit, particularly at low concentrations, including the fitting

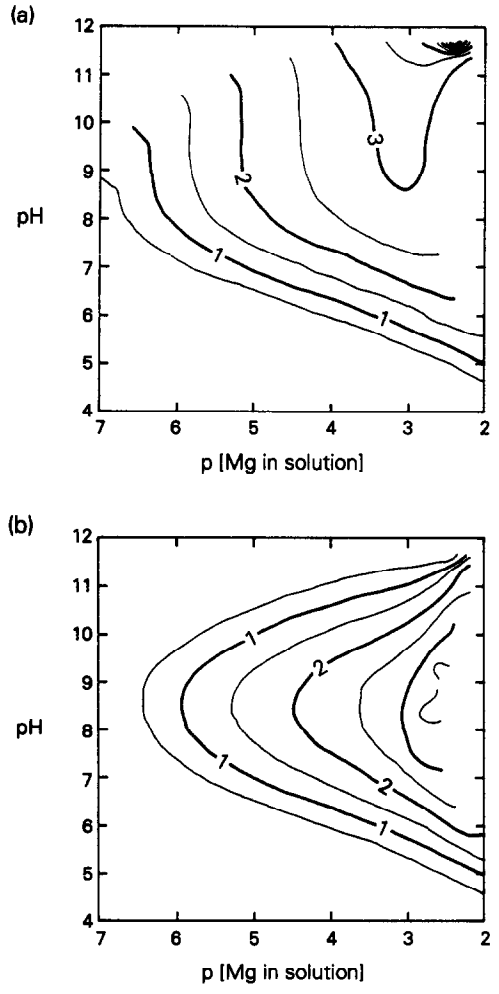

Fig. 2. (a) Concentration curve for the solubility of phosphorus and magnesium in solution with the inclusion of dMHP in the new algorithm. 30° lines are constant p [phosphorus in solution]. (b) Concentration curve for the solubility of nitrogen and magnesium in solution with the inclusion of dMHP in the new algorithm. 30° lines are constant p [nitrogen in solution].

of the data of Taylor *et al.*[5] at 25°. Still remaining, however was a general disparity between the absolute values of the calculated and measured values of phosphorus. This is apparent in Fig. 4 of Scott *et al.*[3]. Although there is a good correlation between the values ($r^2 = 0.85$), there is a difference between the absolute values which produce a relative standard error of about 0.5. This is unacceptable considering the exact nature of the calculation and the simple inorganic constituents involved. The above improvements only decrease the relative standard error by 5–10%. To find a reason for this disparity, every conceivable species was introduced into the algorithm. At this point the structure easily accommodated the changes; up to 18 different equilibria were considered.

This effort was rewarded by a lowering of the relative standard error by a factor of two. This was mostly a result of the inclusion of an associated ammonium phosphate ion. In the fitting of equilibrium constants, approximately 8 new values were predicted. Table 3 presents a summary of the results together with equilibrium constants and statistics. NH_3 is still a primary calculating variable but now the calculation requires the solution of a quartic equation. The 5 coefficients a, b, c, d and e required are complex functions of the equilibrium constants and the known concentrations of H^+, Mg^{2+}, OH^-, $MgOH^+$ and $Mg(OH)_2$

Fig. 3. found from a Maple programme. Copies of these functions and the entire programme used are available on request. The solution of the quartic follows a Newton–Raphson technique. Checks are built into the programme to disallow negative values of roots and also disallow concentrations to rise larger than molarities of one or mole fractions of one.

Table 3. Formation constants derived and used

	Taylor's data (25°)		Webb's data (30°)		
	Earlier value	Present value	Earlier value	Present value

Standard Relative Error	45%	26%	49%	22%	

Note: Earlier value refers to the algorithm with 12 constants and activity coefficient iteration, not the constants given by Scott *et al.* (1991). Present value refers to the algorithm with all features. The symbol* refers to a value derived from the literature; #, to a value that affects the fit but either has little effect on reducing the error or the number of data points that can be used in the fit are reduced. In the values given for the two solid magnesium phosphates, their ratio was retained at the known literature values; they had little effect on the fitting process. All the remaining constants were fit to the data by a trial and error procedure to minimise the relative value of the sum of the squares of the differences.

The main problem with this full algorithm, which also includes a multiple iteration for activity coefficient adjustment, is that the chance of success is small unless the initial trial is a good estimate. That means that a broad sweep of the input variable, H^+ and Mg^{2+} only gives a small number of successful results. A calculation to fit known data however is relatively easy. Figure 4 presents the calculated nitrogen in solution as contours at a given pH and pMlqd. The data for 30°, the experimental values of Webb,[4] are shown on the graph. Note that these data were used to drive the contours and the experimental Nlqd is about $0.1M$ for all points. The data also includes excess chloride ions at approximately $0.13M$.

In the final analysis, the improvement included dissolved ammonium magnesium phosphate and associated ammonium phosphate ions. Table 3 presents a summary of the values of equilibrium constants fitted to both the data of Taylor *et al.*[5] and Webb.[4] The coefficient of determination becomes 0.96 with Webb's data with a 22% standard relative error in the computed phosphorus values. The fit of the more dilute 25° data of Taylor *et al.*[5] is not as good with a coefficient of determination of 0.76 and a standard relative error of 26%. Considering that the algorithm of Scott *et al.*[3] shows a relative standard error of about 50% for both data sets; this is a marked improvement.

This is not totally clear as the computer algorithm is more difficult to fit to the data and fewer data points are actually used. Also more constants are calculated from the data; rather than 6, now we calculate about 8. Several of the constants have only a minor effect on the fit. Removal of outliers from the data set was explored and roughly half of the error is removed by the removal of 5 data points. The lowering of the degrees of freedom by about 2 due to the additional estimates is unlikely to be responsible for the better fit.

Points to be noted in reference to Table 3 include:

1. The data of Taylor *et al.*[5] are rather dilute, compared to Webb.[4] As would be expected, the associated ammonium phosphate ions are essentially absent. The expected formation constant for struvite from both studies is comparable to values quoted in the literature. We would suggest that the present algorithm should give best values of the solubility product at 25 and 30°.
2. Taylor *et al.*[5] delude to various constants for the solubility of ammonia hydrogen phosphate. The present values are of the same order of magnitude. Again, in this complex set of equilibria, it is most likely that the present algorithm compensates properly and can produce a satisfactory solubility constant for this species.
3. Many of the formation constants are only known to an order of magnitude. The effect is apparent when one adjusts the hydrogen phosphate constants for a best fit. The dihydrogen phosphate constant, in particular, varies by a factor of two or three with difference choices of the other constants.
4. The dissolved struvite is insignificant around 10^{-4} to 10^{-5}, in the presence of pure solid. The associated ammonium phosphate and associated ammonium phosphate ions are appreciable. At 1 millimolar NH_4^+ the associates $NH_4PO_4^{2-}$ and $(NH_4)_2PO_4^-$ are approximately in equal proportions and most of the PO_4^{3-} is associated. Note that the associates have no influence on the 25° data.[5] This is significant and needs to be checked using appropriately designed experiments.

A final graph is presented in Fig. 4. These are the standard curves showing dissolved nitrogen contours as used earlier to show the trends of the data, except they only show the two orders of magnitude exhibited by the data of Webb.[4] The figure shows minimal extrapolation and the limits of the information presented so far. The dissolved nitrogen contours exhibit an extraordinary "L" shape, that is extremely sensitive to the dissolved nitrogen. As the nitrogen varies by about a factor of 30% in the experiment, the H and Mlqd concentrations vary by about 2 orders of magnitude. Also the trend bifurcates so that no sensible relationship exists. Again further experiments are needed that pay great attention to holding the nitrogen levels constant. The experimental error of Webb[4] easily accounts for the 11% relative standard error observed and suggests that even greater control is necessary.

Speciation has not been reported in detail in the present work because of the numbers of individual species and an operational engineering requirement to see an overview. The curves suggest that gross changes occur in speciation in two decades of pH. Added excess passive anions and cations could easily limit the region in which the solid is in equilibrium with

the liquid. This is of great interest in kidney stone studies and the wastewater industry.

The final algorithm, including associated species, does improve the standard relative error and gives an acceptable fit. The standard relative error of the 25° data lowers to 26%; that of the 30° data lowered to 22%. There are many reasons for this including the increased degrees of freedom of the fit, the fact that not all of the set were considered and importantly the inclusion of the associated species. The actual number of the fitted constants is increased to about 8 since most of the species included had no effect (see Table 3, column 2). The dramatic change in the fit is most likely the effect of an associated ammonium phosphate in the solution, possibly ammonium phosphate ion.

CONCLUSIONS

The improvements incorporated into the model include a more efficient algorithm; all the known species as well as estimates of the activity coefficients. The inclusion of all possible species has pinpointed the need for associated ammonium phosphate ions. The fit is good in both a relative and an absolute sense with data sets at 25°[5] and 30°.[4] The presence of these species needs collaboration.

Clearly it is necessary to know all the species present in significant amounts to predict the amount of solid that will be formed and the present theoretical effort, with its variations and sensitivity, tests should at least give guidance to further laboratory and field experimentation. Preliminary design calculations are now possible; these will be the subject of a follow-up paper.

EXTRACTION AND SENSITIVE SPECTROPHOTOMETRIC DETERMINATION OF YTTERBIUM WITH 2-(3,5-DICHLORO-2-PYRIDYLAZO)-5-DIMETHYLAMINOPHENOL

LILIANA FERNANDEZ and ROBERTO OLSINA

Department of Analytical Chemistry (Dr Carlos B. Marone) Faculty of Chemistry, Biochemistry and Pharmacy, University of San Luis, Argentina

(*Received* 2 *April* 1992. *Revised* 13 *April* 1992. *Accepted* 13 *April* 1992)

Summary—The operating conditions for the absorptiometric determination of Yb(III) with the reagent 2-(3,5-dichloro-2-pyridylazo)-5-dimethylaminophenol (3,5-diClDMPAP) by a liquid–liquid extraction technique are presented. The complex yields a molar absorptivity of 1.54×10^5 l.mole^{-1}.cm^{-1} (λ_{max} = 588 nm) and an optimum concentration range of 0.025–1.360 mg/l., at pH = 10. The method developed has been applied to the determination of Yb(III) in synthetic and concrete mixtures.

At present only a small number of organic reagents allow the absorptiometric determination of ions belonging to the group of the rare earths, in high sensitivity conditions, by means of extractive techniques.[1–6] Most of these techniques are based on the formation of ionic pairs[7–9] or ternary complexes[10,11] with molar absorptivity in the order of 10^4 l.mole^{-1}.cm^{-1}.

One of the features of partition processes between two immiscible phases is that they cause the sensitivity and the selectivity of the chromatic reaction to be increased.

It is considered of interest to develop techniques involving liquid–liquid extractions with new organic reagents, which allow the determination of the above-mentioned ions by means of simple and high sensitivity methods.

In previous work,[12] we have pointed out the very good sensitivity showed by the chromatic reactions between the reagent 2-(3,5-dichloro)-2-pyridylazo-5-dimethylaminophenol (3,5-diClDMPAP) and several rare earth ions. This reagent has been used in the determination of La(III) in synthetic samples with highly satisfactory results.[13]

According to the very good results obtained, in the present work the study of Yb-3,5-diClDMPAP for an extractive-spectrophotometric methodology is proposed. The purpose is to obtain a better selectivity and then to study its potentiality as base of kinetic aspects.

Considering the importance of ytterbium in the production of X-ray sources, magnet alloys and in geochemical prospecting for the determination of rock genesis, the methodology developed will be applied to the determination of it in synthetic and concrete samples.

EXPERIMENTAL

Apparatus

A Varian UV–visible spectrophotometer with 10-mm optical-path glass cells was used for absorptiometric measurements. The pH measurements were carried out with an Orion 701-A pHmeter, equipped with a combined glass electrode and Ag-AgCl reference. The liquid–liquid extraction experiences were carried out in a mechanical shaker with up to 300 shakings/minute.

Reagents

Standard solution of 3,5-diClDMPAP. The reagent 3,5-diClDMPAP was synthesized in our laboratory according to usual synthesis and purification techniques.[12]

A $3 \times 10^{-3}M$ solution of the purified reagent dissolved in absolute ethanol was prepared.

Standard solution of Yb(III). A 1-mg/ml solution of Yb(III) was prepared from Yb_2O_3 of certified purity, dissolved in nitric acid and made up to volume with bidistilled water. The normalization was carried out according to the procedure described by Ryabchikov and Ryabukhin.[14]

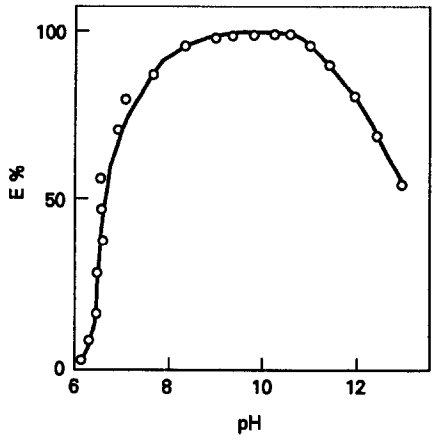

Fig. 1. Extraction curve of Yb(III)–3,5-diClDMPAP complex. $C_{Yb} = 4.5 \times 10^{-6}M$; $C_{organic\ reagent} = 9.0 \times 10^{-5}M$; equilibration time = 5 min; organic phase = benzene; working wavelength = 588 nm.

Buffer solution. A $1M$ solution of NH_4Cl was prepared, reaching the desired pH by the addition of the required volume of NH_4OH(c).

Other rare earths. All the reagents used were of analytical grade.

Extractive–absorptiometric procedure

An adequate aliquot of sample containing between 0.025 and 1.360 mg/l. Yb(III) is put into an extractive tube, then, the reagent dissolved in a minimum quantity of ethanol (reagent excess 10:1 with respect to metal ion concentration) and NH_4^+/NH_3 pH = 10 buffer solution (final concentration approximately $0.1M$) are added. The system is left to react for 10 min; the volume is made up to 0 cm^3 with bidistilled water and the solution mixed.

Next, 10 cm^3 of benzene are added and the system is manually shaken for 30 sec. The phases are separated and the absorbance of organic phase is measured at 588 nm against reagent blank.

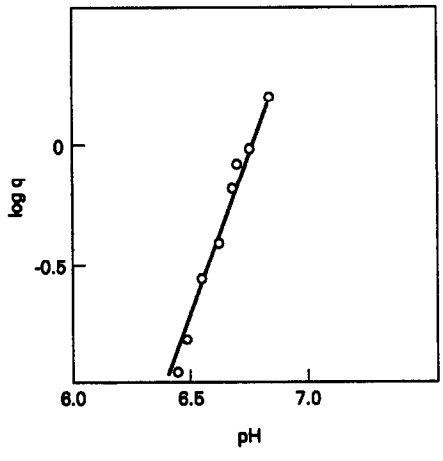

Fig. 2. Determination of n (number of displaced protons).

Procedure for the ytterbrium determination in samples

A column with strongly basic anion exchange resin Dowex 1 × 8 in the Cl^- form, 200 mesh was used. The resin was conditioned by means of successive washing with $1M$ hydrochloric acid, $1M$ sodium hydroxide, $1M$ hydrochloric acid and $0.2M$ EDTA disodic salt (Na_2H_2Y), until no Cl^- ions could be detected in the effluent. The resin was placed in a column of 6 mm diameter and 7 cm high.

An adequate aliquot of rare earth mixture, from the sample dissolution and later elimination of the matrix elements,[15] was evaporated to dryness and quantitatively turned into the respective anionic complexes with EDTA. It was dissolved at a volume of 200 μl of $5 \times 10^{-3}M$ Na_2H_2Y, pH = 4.7, and the sowing was carried out to the top of the column. Elution was performed with $5 \times 10^{-3}M$ Na_2H_2Y at a flow rate of 1 cm^3/min.

Fractions of 1.5 cm^3 were collected and analysed after removing organic matter with a HCl–HNO_3 mixture by an extractive–absorptiometric proposed procedure.

In the present working conditions Yb(III) is found in the first 37 cm^3 of elution.

RESULTS AND DISCUSSION

Extraction of the Yb(III)–3,5-diClDMPAP complex

The reagent 3,5-diClDMPAP reacts with the Yb(III) ion giving a dark red complex in excess of reagent ($\lambda_{max} = 588$ nm), which is hardly soluble in aqueous solution. If the system comes into contact with a non-aqueous solvent, the quantitative extraction of the complex is achieved after a few minutes of mechanical shaking. Benzene proved to be the most suitable solvent for this purpose, since it allows one to obtain higher absorptiometric sensitivity and stability.

Influence of pH. Extraction curve

In the absence of complexing agents in the aqueous phase, the Yb(III)–3,5-diClDMPAP complex begins to be extracted at pH = 6.2 and starts to decrease above pH = 11, which is expected due to the incipient hydrolysis of the metal ion (Fig. 1).

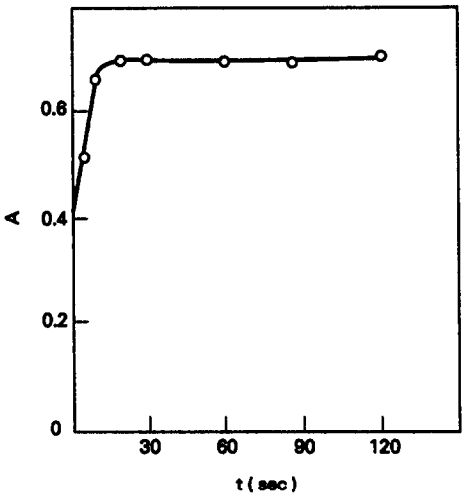

Fig. 3. Determination of equilibration time. $C_{Yb} = 4.5 \times 10^{-6}M$; $C_{organic\ reagent} = 9.0 \times 10^{-5}M$; reaction time = 10 min; organic phase = benzene; working wavelength = 588 nm.

The $pH_{1/2}$ value[16] for the reagent concentration of $1M$ is 2.68. The complexation–extraction equilibrium between the two immiscible phases can be expressed by:

$$Yb(III)_{aq} + [(n+r)HL]_{org} \rightleftharpoons [YbL_n(HL)_r]_{org} + n(H^+)_{aq}$$

and the logarithmic expression of the extraction constant is:

$$pK_{ext} = (n+r)\log(HL)_{org} + \log(HL)_{org} + n\ pH - \log q$$

where HL and q represent the organic reagent and the concentration ratio of the solute, respectively.

The results obtained after applying the equilibrium shift method[16] proved that $(n+r) = 3$; $n = 3$; $pK_{ext} = -8.05$ (Fig. 2), from which the following conclusions can be drawn:

(a) The stoichiometry of the extracted chelate is 3:1 (reagent:metal ion).
(b) No formation of adducts is observed.

Reaction and equilibrium time

It has been found previously that a minimum reaction time of 20 min is required for the quantitative formation of the La(III)–3,5-diClDMPAP complex.[13] This variable is investigated in detail.

In this experiment, the pH value was kept at 10, the Yb(III) concentration was set at $4.5 \times 10^{-6}M$. The reagent excess was 20:1 with respect to the metal ion, and it was added to the system dissolved in a minimum quantity of ethanol. This methodology was adopted in order to obtain an adequate extraction rate. Otherwise, following the conventional techniques of adding the reagent dissolved in the organic solvent, a quantitative extraction is only obtained after 3 hr of shaking.

The system was left to react for 1–30 min. Then, the solvent was added and the extraction was performed. Shaking was applied for 15 min. After separating the phases, the absorbance of organic phase was measured at 588 nm against reagent blank.

The results obtained showed that 5 min of reaction are needed prior to the extraction to allow for the quantitative formation of Yb(III)–3,5-diClDMPAP complex.

In an experiment analogous to the one described above, the reaction time was set at 10 min and the equilibration time was changed. It was determined that the system requires a minimum of 25 sec of manual shaking to obtain a quantitative extraction (Fig. 3).

Excess of reagent. Ionic strength

In order to verify the influence of the excess of reagent, an experiment was carried out in which the Yb(III) concentration was kept constant at $4.5 \times 10^{-6}M$, the reaction time was 10 min, the equilibrium time was 30 sec, the working pH was 10 ($0.1M$ NH_4^+/NH_3 buffer), and the reagent concentration was varied from 4×10^{-6} to $9 \times 10^{-5}M$.

Above a reagent to metal ion excess of 10:1 no variation took place in the complex absorbance. With respect to ionic strength it could be verified that it has no considerable effect upon the magnitude of the extraction within the interval 0.1 to $1M$.

Beer's law

Table 1 summarizes the experimental conditions which are most important for the spectrophotometric determination of Yb(III) with 3,5-diClDMPAP.

Table 1. Determination of Yb(III) with 3,5-diClDMPAP

Experimental conditions	
Working pH	10.0
Buffer solution	$0.1M$ NH_4^+/NH_3
Organic solvent	benzene
Maximum of reagent absorption	450 nm
Maximum of complex absorption	588 nm
Bathochromic shift	138 nm
fulfillment of Beer's law	0.025–1.363 mg/l
Molar absorptivity	$1.54 \times 10^5 \pm 2350$ $l.mole^{-1}.cm^{-1}$
Detection limit[17]	0.005 mg l.

Table 2. Determination of Yb(III) 3,5-diClDMPAP. Ternary mixtures

Samples		% Composition (w/w) molar relation	Yb(III) found	% Relative error
	Yb(III)	33.3	32.6 ($n = 6$)	
1	La(III)	33.3	$s = 0.141$	+2.0
	Ce(III)	33.3	$CL_{\alpha=0.05} = 32.6 \pm 0.05$	
	Yb(III)	50.0	49.2 ($n = 6$)	
2	La(III)	49.0	$s = 0.023$	−1.5
	Ce(III)	1.0	$CL_{\alpha=0.05} = 49.2 \pm 0.02$	
	Yb(III)	5.0	4.7 ($n = 6$)	
3	La(III)	45.0	$s = 0.23$	−5.2
	Ce(III)	50.0	$CL_{\alpha=0.05} = 4.7 \pm 0.19$	

It is important to note that by means of flame atomic absorption techniques, the detection limit for Yb(III) is 0.01 mg/l. against 5×10^{-3} mg/l. by the proposed technique.

Although the methodology developed here is inferior to techniques that make use of ovens (Electrothermal Atomization Technique: detection limit 2×10^{-4} mg/l.), it is, however, much simpler.

Resolution of rare earth mixtures

The reagent 3,5-diClDMPAP presents an adequate sensitivity for the absorptiometric determination of rare earth ions, but it is not highly selective.

Synthetic binary mixtures of Yb(III) and La(III) containing different proportions of both substances were solved with excellent results. This is due to the fact that the Yb(III) ion is selectively extracted with respect to La(III).

It is also possible to solve ternary mixtures of Yb(III), La(III) and Ce(III) with the results shown in Table 2.

The lanthanide determinations in geological and other samples require a preceding separation step, even though determination techniques such as ICP[18] are used. These separative procedures are time-consuming processes. Methods such as that of Crock *et al.*[15] based on ion exchange chromatography by sequential acid elution can be used for the initial separation of the lanthanides from the matrix elements (this yields to a relative error of 2% in the individual Yb determination).

In order to solve multielement lanthanide samples, chromatography of ionic exchange was used. Minczewsky and Dybczynski,[19] taking as a basis the formation of anionic complexes of rare earth elements with several organic ligands, have investigated

*Synthetic samples.

the possibility of separating them, using anionic resins. This is a rapid and effective method.

According to the results obtained by Minczewsky, the elution order is: Lu < Yb < Tm < Y < Ho < La < Ce < Tb < Pr < Gd < Pm < Eu.

The experiment showed that the separation of Yb(III) from La(III) is possible by the methodology described here (% relative error < 1%). Yb(III) was separated from Y(III) with an error of 3%. The elution order obtained by Minczewksy was confirmed, which guarantees the quantitative separation of Yb(III) from the rest of the lanthanides. Table 3 shows the results obtained in the processing of synthetic samples and other materials.

CONCLUSIONS

The reagent 2-(3,5-dichloro-2-pyridylazo)-5-dimethyl aminophenol has been used in the spectrophotometric-extractive determination of the Yb(III) ion. The results obtained have been highly satisfactory taking into account the high sensitivity reached and the simplicity of the operation. The proposed methodology is applicable to the analysis of concrete samples of interest.

SENSITIVE SIMULTANEOUS DETERMINATION OF BENZO(A)PYRENE, PERYLENE AND CHRYSENE BY SYNCHRONOUS SPECTROFLUOROMETRY IN NONIONIC MICELLAR MEDIA

J. J. SANTANA RODRIGUEZ and Z. SOSA FERRERA
Department of Chemistry, Facultry of Marine Sciences, University of Las Palmas de Gran Canaria, 35017 Las Palmas, Spain

(*Received* 5 *December* 1991. *Revised* 13 *April* 1992. *Accepted* 13 *April* 1992)

Summary—A synchronous spectrofluorometric method was developed for the simultaneous determination of benzo(a)pyrene, perylene and chrysene in a POLE micellar medium, with detection limits of 0.05 ng/ml, 0.28 ng/ml and 0.64 ng/ml, respectively. Good recoveries were obtained for sea water samples spiked with each hydrocarbon.

Polycyclic aromatic hydrocarbons (PAHs) are present in complex environmental matrices, such as crude oils and sediment extracts, often in association with other organic compounds.[1] Increased attention has recently been paid to these compounds in environmental chemistry due to the mutagenic character of some of these molecules.[2] Therefore, a highly selective analytical method is required for assessment of pollution in the environment.

Synchronous scan luminiscence spectrometry has been developed by Lloyd to simplify a fluorescence spectrum;[3] the excitation and fluorescence wavelengths are synchronously scanned under the optimized separation of these wavelengths. This technique has been used to characterize crude oils[4-6] and to identify and quantify polycyclic aromatic compounds.[7-12]

Although aqueous micellar systems continue to be the focus of intensive study in many disciplines[13,14] they have had few practical applications in the analyses of organic species.[15] Three major potential advantages can be accrued by the use of micelles in fluorometry. These include improved sensitivity, diminution of interferences, and greater experimental convenience.[16] However, the solutions of some surfactants exhibit fluorescence which may cause important disturbances in analytical signals.

In a former paper[12] it was established that fluorescence emitted by PAHs benzo(a)pyrene and perylene increases considerably in the presence of Triton X-100 micelles. However, the fluorescence due to this surfactant, may considerably affect analytical determinations of some PAHs.

This paper shows that the substitution of Triton X-100 (the most important non-ionic surfactant used for analytical purposes), for another non-ionic surfactant may result advantageous. By using Polyoxyethylene 10 lauryl ether (POLE) micelles, a sensitive method for simultaneous determination of a mixture of three PAHs, benzo(a)pyrene, perylene and chrysene by synchronous fluorescence spectrometry is proposed.

EXPERIMENTAL

Reagents

Stock solutions (0.23 mg/ml) of chrysene (Aldrich) and (0.25 mg/ml) of benzo(a)pyrene, B[a]P, (Aldrich) and of perylene (Sigma) were prepared in ethanol. Working solutions were prepared by appropriate dilution with ethanol.

The surfactants Brij-96 and Polyoxyethylene 10 lauryl ether (POLE) were obtained from Aldrich.

*Author for correspondence should be addressed.

Apparatus

Synchronous fluorescence measurements and spectra were made with a Perkin-Elmer MPF-44A recording spectrofluorometer equipped with a 150-W Osram XBO xenon arc, a Sabtronics 2010A digital read-out, a Selecta Frigitherm S382 thermostat and 1-cm quartz cells. The emission measuring system was calibrated daily via use of the Perkin-Elmer set of fluorescent polymer blocks.

General procedure for the determination of mixtures of benzo(a)pyrene, perylene and chrysene

To an aliquot containing 12.5 ng–2.5 μg of chrysene, 2.5 ng–2.5μg of benzo(a)pyrene and perylene, in the allowed ratios, in a 25-ml calibrated flask, add 5 ml of $1.0 \times 10^{-2}M$ POLE solution and the necessary volume of ethanol so that the final solution contains 2% (v/v) of organic solvent, and dilute to volume with demineralized water. The fluorescence intensity measures are made to synchronous maxima of each PAH: for chrysene $\lambda^0_{s,em} = 320$ nm ($\Delta\lambda = 42$ nm), for benzo(a)pyrene $\lambda^0_{s,em} = 386$ nm ($\Delta\lambda = 17.5$ nm) and for perylene $\lambda^0_{s,em} = 432$ nm ($\Delta\lambda = 17.5$ nm). The quantities of all hydrocarbons are determined from calibration curves obtained under the same experimental conditions.

Recovery of benzo(a)pyrene, perylene and chrysene in sea water

Sea water samples were passed successively through filters of different porosity (50, 30 and 5 μm) and by UV radiation. After verifying that they do not present fluorescence, they were spiked by suitable amounts of each PAH and analysed according to the above method.

RESULTS AND DISCUSSION

Conventional spectra

Polycylic aromatic hydrocarbons are slightly soluble in water. In order to study the spectrofluorometric behaviour of benzo(a)pyrene, perylene and chrysene, ethanol–water solutions were used.

We refer to aqueous solutions as containing 2% (v/v) ethanol–water. Solutions containing the same volume of ethanol, to which sufficient surfactant is added in order to ensure a surfactant concentration greater than its critical micellar concentration, are referred to as micellar solutions.

I_F–$C_{surf.}$ curves allow one to select such a surfactant concentration and additionally, confirm that the changes observed in the fluorescence of PAHs are directly related to the formation of a micellar system. This can be seen for POLE in Fig. 1.

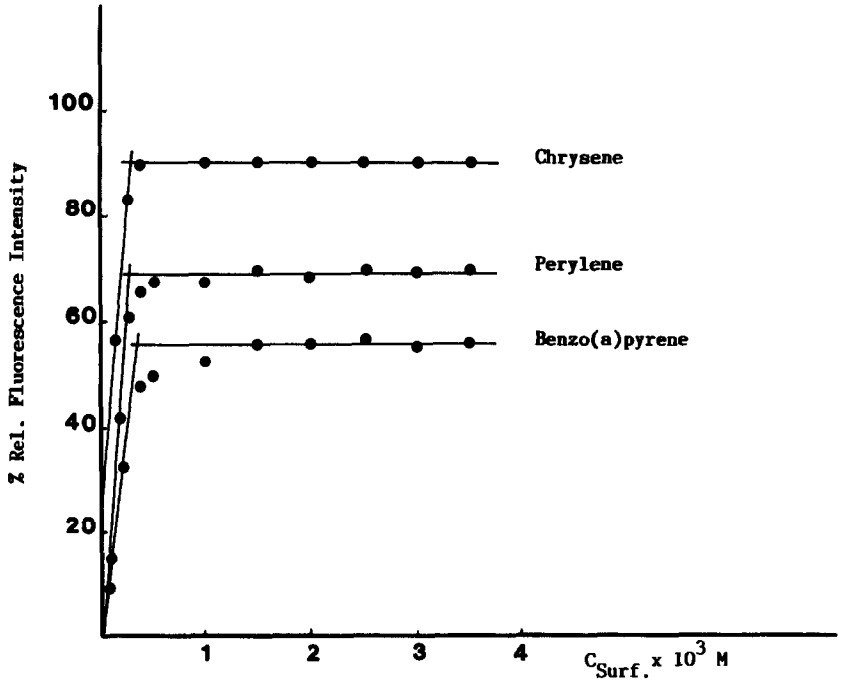

Fig. 1. Effect of POLE concentration on the fluorescence intensity of benzo(a)pyrene, perylene and chrysene. $C_{PAH} = 2.0 \times 10^{-6}M$.

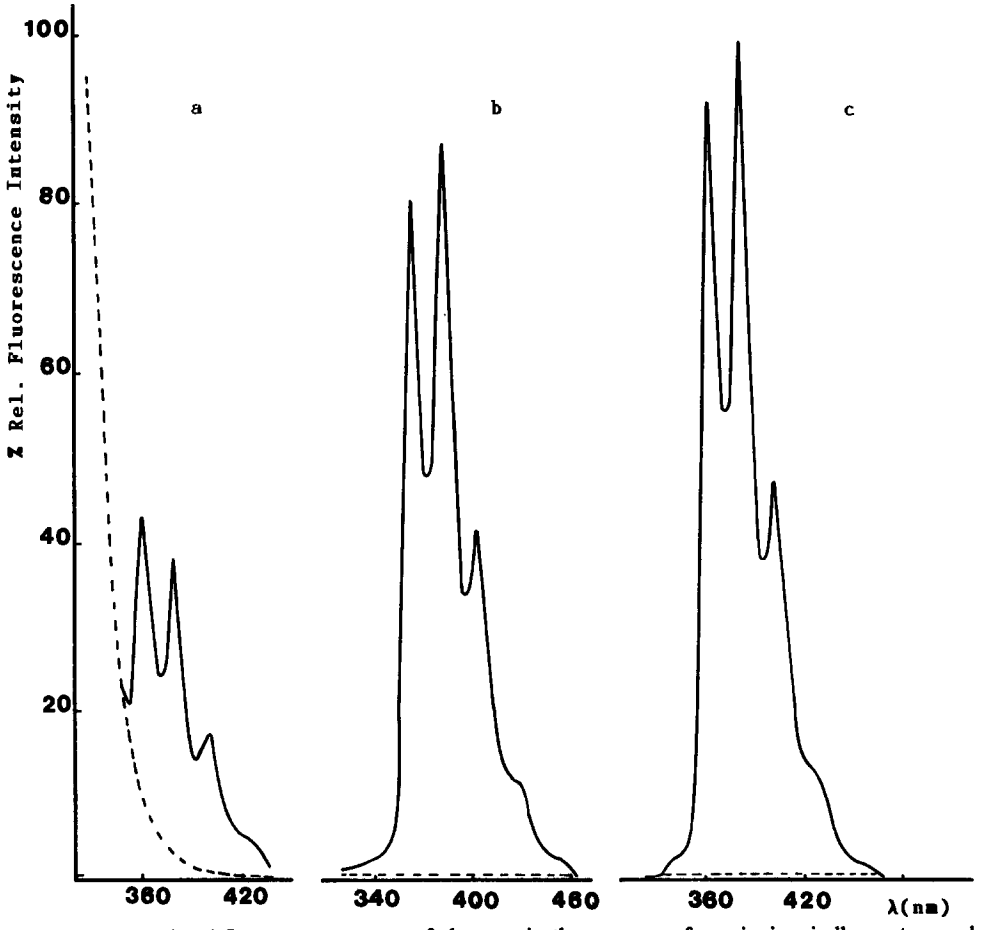

Fig. 2. Conventional fluorescence spectra of chrysene in the presence of non-ionic micellar system and of each surfactant. Triton X-100 (a), Brij-96 (b) and POLE (c). $C_{PAH} = 2.0 \times 10^{-6} M$, $C_{Surf.} = 1.0 \times 10^{-3} M$. $\lambda_{exc} = 273$ nm.

Figure 2 shows the emission spectra of chrysene in the presence of a non-ionic micellar system, as well as of each surfactant. In high concentrations, Triton X-100 originates a fluorescence emission that interferes remarkably with the chrysene emission. It does not occur

*Ratio of fluorescence intensity in micellar and aqueous media.
†Wavelengths of excitation.
‡Wavelengths of emission.
Values in parentheses refer to the peak half-widths; dash (—) indicates that the peaks were extensively overlapped.

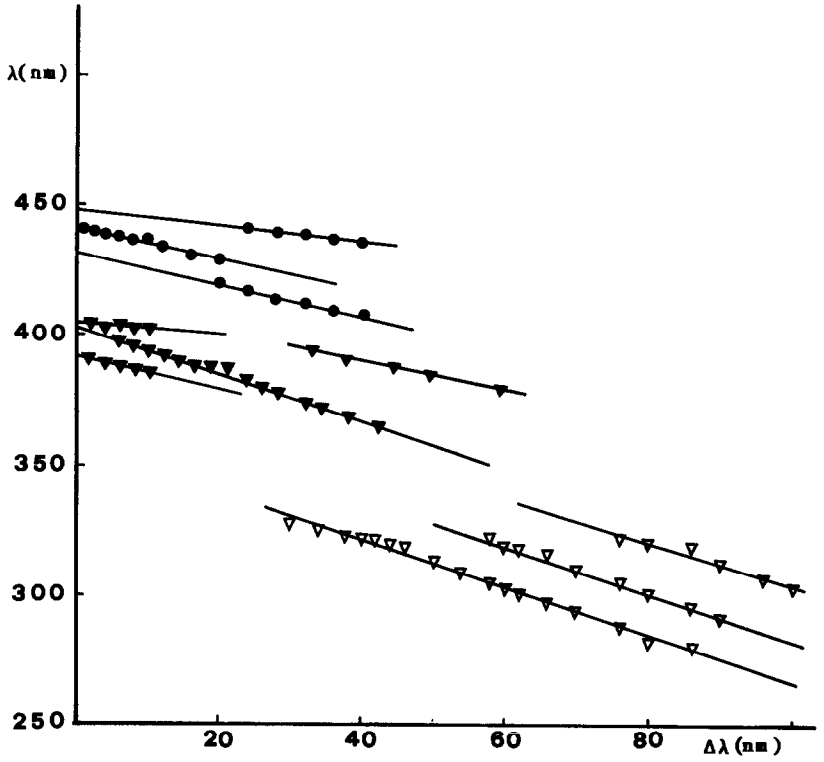

Fig. 3. Effect of $\Delta\lambda$ on the values $\lambda_{s,em}$. $C_{PAH} = 2.0 \times 10^{-6}M$. $C_{PAH} = 2.0 \times 10^{-6}M$, $C_{POLE} = 1.0 \times 10^{-3}M$. Benzo(a)pyrene (▼), perylene (●) and chrysene (▽).

with perylene and benzo(a)pyrene because the wavelengths of its excitation and emission maxima are above 350 nm and 400 nm respectively.

Some important characteristics of the excitation and emission spectra are summarized in Table 1. The excitation and emission spectra of PAHs in neutral micellar media of POLE and Brij-96 are similar with regard to the number of peaks and wavelengths of maximum intensity.

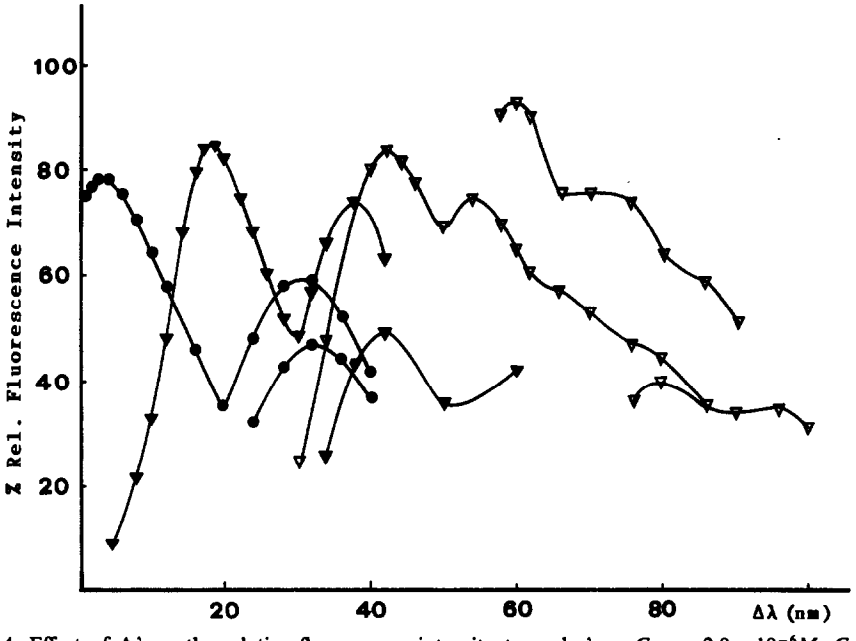

Fig. 4. Effect of $\Delta\lambda$ on the relative fluorescence intensity to each $\lambda_{s,em}$. $C_{PAH} = 2.0 \times 10^{-6}M$, $C_{POLE} = 1.0 \times 10^{-3}M$. Benzo(a)pyrene (▼), perylene (●) and chrysene (▽).

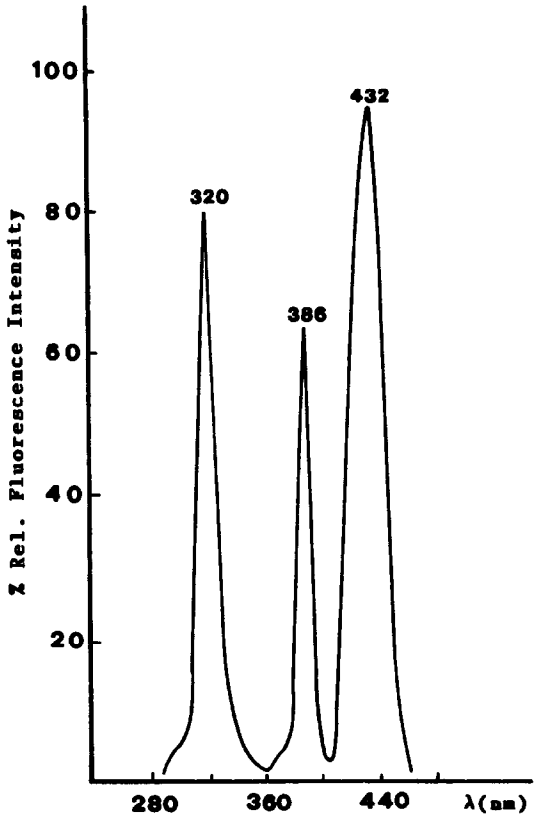

Fig. 5. Synchronous fluorescence spectra of a mixture of benzo(a)pyrene, perylene and chrysene in micellar medium. $C_{POLE} = 2.0 \times 10^{-3} M$. Chrysene: $\Delta\lambda = 42$ nm, $C_{PAH} = 2.0 \times 10^{-6} M$. Benzo(a)pyrene and perylene: $\Delta\lambda = 17.5$ nm, $C_{PAH} = 2.0 \times 10^{-8} M$.

Comparing both media, aqueous and micellar, the most important differences are observed in the excitation spectra. It slightly enhances the definition of chrysene and benzo(a)pyrene in micellar medium. Quite the reverse of perylene, in which an important shift towards longer wavelengths is produced. This shift has a great analytical interest because it introduces a differential factor between perylene and the other two PAHs. The half-widths obtained in micellar medium are similar or narrower than those obtained in aqueous medium.

With the same experimental conditions, the use of micellar media produces an important increase in fluorescence intensities emitted by the three PAHs and in particular by perylene. This sensitivty is higher when POLE is used as a surfactant.

Synchronous spectra

In aqueous medium, the synchronous spectra of the three PAHs show several bands of different intensity only slightly defined. The introduction of a micellar medium, not only produces an important sensitivity but also allows synchronous spectra, in which the correct selection of $\Delta\lambda$ would let the analysis of each PAH in the presence of the others.

Between the maximum of emission at the shortest wavelength and the maximum of excitation at the longest wavelength ($\lambda^0_{em} - \lambda^0_{exc}$) of conventional spectra, differences of 38–41 nm, 15–18 nm and 3 nm are produced for chrysene, benzo(a)pyrene and perylene, respectively, in micellar media of Triton X-100, Brij 96 and POLE. These values of $\Delta\lambda$ could be adequate for the determination of the three PAHs by synchronous spectrofluorometry. However, as for Triton X-100, $\lambda^0_{em} - \lambda^0_{exc} = 48$ nm, the synchronous spectra of Triton X-100 and chrysene overlap. The highest intensity of the signals obtained in the presence of POLE recommend the use of this surfactant with analytical purposes. In order to modify the spectral bandwidth of the synchronous signal, $\Delta\lambda$ and Stokes shift parameters can be varied experimentally. The most important parameter in the simultaneous analysis of mixtures is the selection of the optimum wavelength difference between both monochromators.

*Mean of three determinations.

For chrysene, perylene and benzo(a)pyrene, synchronous fluorescence spectra were obtained over a range of $\Delta\lambda$ from 1 to 100 nm. The results found are shown in Figs. 3 and 4 from which the following considerations can be made: the spectral distribution is a function of $\Delta\lambda$ and the fluorescence intensity depends strongly on $\Delta\lambda$.

The experimental results show that it is necessary to use $\Delta\lambda = 30$–45 nm for chrysene, $\Delta\lambda = 12$–32 for benzo(a)pyrene and $\Delta\lambda < 19$ nm for perylene, to obtain synchronous spectra of only one peak and an adequate fluorescence intensity. In these intervals of wavelengths, maxima intensities were obtained for $\Delta\lambda = 42$ nm, $\Delta\lambda = 17$–19 nm and $\Delta\lambda = 3$–4 nm, for chrysene, benzo(a)pyrene and perylene, respectively. These values of $\Delta\lambda$ correspond to $\lambda^0_{s,em} = 322$ nm, $\lambda^0_{s,em} = 386$ nm and $\lambda^0_{s,em} = 439$ nm.

A great concordance exists between $\Delta\lambda$ deduced from the conventional fluorescence spectra and the experimental $\Delta\lambda$. In addition, it must be stressed that the values of $\lambda^0_{s,em}$ are practically the same as the peak wavelength of the maximum of excitation at the longest wavelength on the conventional spectrum (λ^0_{exc}).

Figure 5 shows the synchronous spectrum of a synthetic mixture of the three PAHs using the same $\Delta\lambda$ for benzo(a)pyrene and perylene.

Analytical considerations

In order to develop a procedure for the analysis of binary and ternary mixtures of PAHs, the analytical characteristics were evaluated.

For chrysene and benzo(a)pyrene its optimum $\Delta\lambda$ was selected whereas for perylene the same $\Delta\lambda$ was chosen as for benzo(a)pyrene in order to simplify the experimental process.

In the presence of POLE, linear calibration graphs for each PAH were obtained by plotting the fluorescence intensity measures on the synchronous spectra against hydrocarbon concentration. The linear concentration ranges are 0.1–100 ng/ml for benzo(a)pyrene and perylene and 0.5–100 ng/ml for chrysene. The detection limits[17] are 0.05 ng/ml, 0.28 ng/ml and 0.64 ng/ml for benzo(a)pyrene, perylene and chrysene, respectively.

When the method was applied to two series of eleven samples containing 5 and 50 ng/ml for each PAH, the relative standard deviations obtained were $\pm 3.1\%$ and $\pm 0.95\%$ for benzo(a)pyrene, $\pm 3.8\%$ and $\pm 0.28\%$ for perylene, and 0.8% and 0.65% for chrysene.

The analysis of samples containing various ratios of two of these hydrocarbons shows that the determination of their mixtures is feasible up to the following ratios. B[a]P:Perylene = 1:25; Perylene:Chrysene = 1:5; B[a]P:Chrysene = 1:100 and Chrysene:B[a]P = 1:1. The criterion for interference was a variation of more than $\pm 4\%$ in the hydrocarbon concentrations found.

Table 4. Simultaneous analysis of synthetic binary mixtures of benzo(a)pyrene, perylene and chrysene in sea water

Determination of mixtures of benzo(a)pyrene, perylene and chrysene

The procedure is not only very sensitive for the determination of benzo(a)pyrene, perylene and chrysene but also allows the analysis of binary and ternary mixtures. Tables 2 and 3 show the results obtained for some synthetic samples.

The method was applied to the simultaneous determination of benzo(a)pyrene, perylene and chrysene in sea-water spiked with suitable amounts of each hydrocarbon. The results shown in Tables 4 and 5 indicate good recovery data.

HPLC ANALYSIS OF THIMEROSAL AND ITS DEGRADATION PRODUCTS IN OPHTHALMIC SOLUTIONS WITH ELECTROCHEMICAL DETECTION

JESUS R. PROCOPIO, Mª PILAR DA SILVA, Mª DEL CARMEN ASENSIO, Mª TERESA SEVILLA and LUCAS HERNANDEZ

Department of Analytical Chemistry and Instrumental Analysis, Autonoma University of Madrid, 28049 Madrid, Spain

(*Received* 3 *February* 1992. *Revised* 13 *April* 1992. *Accepted* 13 *April* 1992)

Summary—A reverse-phase high-performance liquid chromatographic assay using amperometric detection on a glassy-carbon electrode has been developed for analysis of thimerosal and its main degradation products, thiosalicylic acid and dithiodibenzoic acid, in ophthalmic formulations. A potential value of 0.9 V *vs.* Ag/AgCl was chosen for simultaneous detection of thimerosal and thiosalicylic acid, obtaining limits of detection of 1.0 and 0.2 ng injected, respectively. A potential value of 1.2 V was applied for simultaneous determination of all three compounds studied, obtaining in this case limits of detection of 3, 4 and 4 ng injected for thimerosal, thiosalicylic acid and dithiodibenzoic acid, respectively. The results obtained reveal the utility of the HPLC method in quality control of commercial products containing thimerosal with good detectability.

Thimerosal (sodium ethylmercurythiosalicylate) [TMS] is an organomercurial compound widely used as both topical antiseptic and antimicrobial preservative. It is the preservative used for soft contact lens care solutions. Stability studies have revealed that this compound is unstable in aqueous solution,[1,2] mainly in glass bottles, though thimerosal can be lost from ophthalmic solutions stored in plastic containers.[3,4] It has also been reported that the presence of halides can have an adverse influence on its stability.[5]

The decomposition of thimerosal in aqueous solution has been reported previously,[2,4] and it was shown that the major degradation products were thiosalicylic acid [TSA] and ethylmercury salts (Fig. 1). Thiosalicylic acid can also undergo irreversible oxidation to 2,2′-dithiodibenzoic acid [DTDBA].

Analytical methods previously developed for thimerosal determination in ophthalmic solutions have included polarography,[6] atomic-absorption spectrometry using a carbon rod atomiser,[7] and colorimetry.[8] These techniques, based on total mercury or total organic mercury, do not indicate accurately the amount of intact thimerosal present in solution. High-pressure liquid chromatography has been suggested as a simple, specific method for analysis of intact thimerosal and its degradation compounds.[9–13] In previous works, several HPLC methods have been developed for simultaneous determination of TMS and its degradation products. Meyers and Colm[10] reported a method, using an ODS reverse-phase column, for separation of TMS and TSA, but the method was poor in sensitivity (>5 μg/ml) and it did not provide adequate resolution of both compounds. Reader and Lines[4] obtained an adequate resolution of TMS and its major decomposition products and good sensitivity on a ODS reverse-phase HPLC using ionic suppression. In all these methods UV detection was used. Coulometric detection has been applied to HPLC analysis of TMS alone in an ophthalmic solution, obtained a detection limit of 0.4 ng (at signal/noise ratio = 2) for an injection volume of 50 μl.[13]

Because thimerosal and its degradation compounds are often present in microquantities (usually less than 10 μg/ml or 40 μg/ml for TMS, depending on sample type, and less than 1 μg/ml for TSA and DTDBA), and the poor utility of methods found in the bibliography for analysis of three compounds in real samples, it was necessary to develop a suitable method with a low detection limit. The objectives of this study were to develop an HPLC assay for thimerosal and its degradation compounds, in ophthalmic solutions, using amperometric detection. The choice of this detection mode

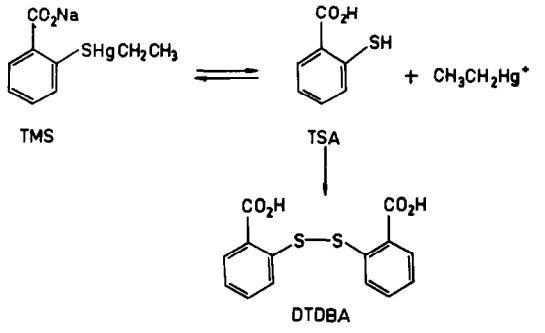

Fig. 1. Scheme for the decomposition of thimerosal in aqueous solutions.

presents several advantages: wide linear dynamic range, good reproducibility and detection limits in the low nanogram to picogram range. Additionally, response selectivity can be controlled by appropriate choice of the working potential.

EXPERIMENTAL

Reagents

Thimerosal TMS (Alcon Iberhis, Spain), thiosalicyclic acid TSA and 2,2′-dithiodibenzoic acid DTDBA (Sigma, U.S.A.) were used without further purification. Methanol, phosphoric and acetic acids were analytical reagent grade (Carlo ERBA, Italy). A stock solution of thimerosal was made up in water whereas stock solutions of other compounds were made up in methanol, in the concentration range 1000–2000 μg/ml. The solutions were stored at 4°, preserved from light.

Apparatus

The HPLC system consisted of a Gilson model 302 pumping system, equipped with a membrane damper, and a Rheodyne model 7125 injector equipped with a 20-μl loop. The detector was a Methrom model 461 amperometric detector, equipped with a Methrom model 656 flow cell of less than 1-μl volume. A glassy carbon electrode (Methrom 6.0805.010) with an area of 7 mm^2 was used as working electrode. The column temperature was thermostated at $25.0 \pm 0.2°$ with a glass jacket using a Selecta model Digiterm S-613 thermostat. A Spectra physics SP-4290 integrator was used to record and integrate all chromatograms.

Chromatographic condition

The column was a 150 × 4 mm stainless steel prepacked reverse-phase column containing 5-μm Spherisorb C18 particles (Tracer). The mobile phase was methanol–water (60:40, v/v) containing 0.02*M* acetic acid or phosphoric acid. This solution was filtered through a Millipore (Waters) Durapore filter (0.45-μm pore size) and deareated by stirring under vacuum for 10 min. The pressure at a flow rate of 1 ml/min was 140 bar. The detector was operated both 0.9 and 1.2 V *vs.* Ag/AgCl, with a sensitivity of 10 nA full scale. Quantification was carried out by comparison of the peak areas and heights obtained from test solutions with the peak areas and heights obtained from standard solutions registered in the same conditions.

As TSA suffers a quick decomposition by light in the chromatographic conditions, injection of the samples at neutral pH was necessary in order to obtain a good response for this compound.

Determination of TMS in ophthalmic solutions by HPLC method

The samples were made homogeneous by stirring for 5 min. Samples containing 0.001% TMS (10 μg/ml) were filtered and directly injected into the chromatographic system. For the samples containing 0.004% TMS (40 μg/ml) a dilution (1 ml of sample to 10 ml in water) was made previous to injection.

RESULTS AND DISCUSSION

Electrochemical studies

The electrochemical behaviour of TMS and its main decomposition products, TSA and DTDBA, was characterized by both cyclic and hydrodynamic voltammetry on glassy carbon electrode, in order to choose the operating parameters. Figure 2 shows the cyclic voltamperograms of the studied compounds at the 60 μg/ml concentration level in 0.02*M* phosphoric acid and in the presence of 60% (v/v) methanol. For TMS and DTDBA the voltamperograms reveal a single anodic wave with peak potentials at 1.08 and 1.20 V (*vs.* SCE) respectively. The TSA presents two peaks in the voltamperograms at 0.64 and 1.18 V. Absence of cathodic waves during the reverse scan of the CV cycle indicates an irreversible oxidation for all compounds.

By comparison of the peak heights of each compound, the electrochemical oxidation mechanism of TMS probably involves one electron transfer from a sulphur atom to the electrode surface yielding a transient radical cation.

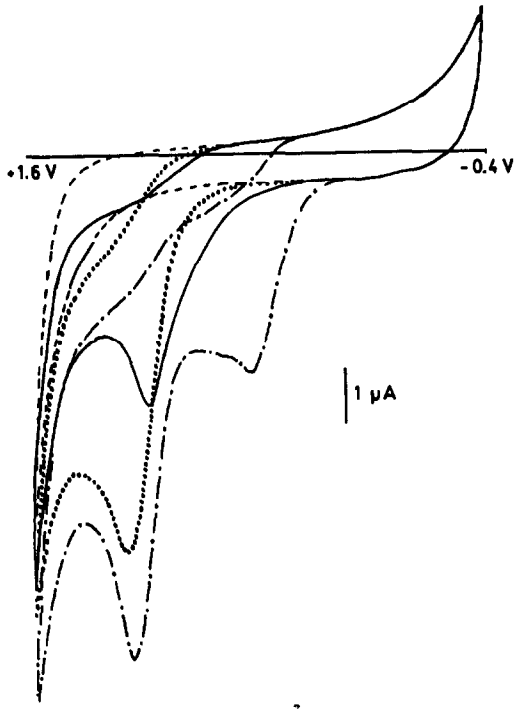

Fig. 2. Cyclic voltamperograms of studied compounds at the 60 μg/ml concentration level in chromatographic conditions. TMS (—) TSA (-·-·-); DTDBA (···); background (---).

The first wave observed for TSA is probably due to a one electron transfer with subsequent dimerization to form thiuram disulphide, DTDBA, which is subsequently oxidized at higher potentials in a two-electron transfer, giving the second anodic peak. According to this assumption, the wave observed at 1.2 V for DTDBA corresponds to oxidation of disulphide linkage. The electrochemical behaviour of all compounds studied is presently under investigation.

As shown in the cyclic and hydrodynamic voltamperograms, TMS reaches a better signal at potentials higher than 1.0 V, while for DTDBA a maximum signal is obtained at 1.2 V. TSA can be efficiently oxidized at potentials higher than 0.8 V, obtaining an optimal signal at potentials higher than 1.1 V. According to these results an average potential of 0.9 V for simultaneous detection of TMS and TSA, and a potential of 1.2 V for TMS, TSA and DTDBA can be chosen. Detection limits and linearities, for concentrations ranging between 0.10 and 10.0 μg/ml, were evaluated at these values of potentials. The results of sensitivity, limits of detection and linearities found are shown in Table 1. Better detection limits and higher linearities for TMS and TSA were obtained at 0.9 V, because of lower backgrounds and noises found at this potential value, obtaining better signal-to-noise ratios. The limit of detection found for TMS at 0.9 V is in the same order of magnitude than in the bibliography,[13] using a coulometric detector.

Replicate samples of three compounds were injected at the 1-μg/ml concentration level, in order to obtain a measure of method reproducibility. The method exhibits good reproducibility with relative standard deviation of 1.4 and 2.9% for TMS and TSA at 0.9 V, respectively. At a potential of 1.2 V, the relative standard deviation was higher than at 0.9 V, obtaining values of 2.9, 4.1 and 3.5% for TMS, TSA and DTDBA, respectively. Typical chromatograms are shown in Fig. 3.

Determination of TMS in ophthalmic solutions

Several soft lens products containing TMS in concentrations of 0.001 (10 μg/ml) and 0.004% (40 μg/ml) (Alcon Iberhis, Spain) were analysed using the proposed method, some of these at the time of their manufacture and others up to three years old. Concomitants present in samples do not interfere, only a slow decrease of retention times of TMS because of presence of polymers in samples that can coat the column packing was observed, as it was previously reported.[10] No change was observed for TSA and DTDBA. In addition, an increase of the analytical signal of TMS was observed without an increase of background or noise, when successive sample solutions were injected. Figure 4 shows chromatograms obtained for real samples in these conditions.

Table 1. Statistical treatment of calibration graphs and limits of detection (signal-to-noise 1:3)

Compounds	Detection potential, V	Sensitivity, nA ml/μg	L.D.* ng	Correlation coefficient
TMS		33.5	3	0.9985
TSA	+1.2	48.9	4	0.9907
DTDBA		34.5	4	0.9988
TMS	+0.9	9.3	1	0.9994
TSA		65.9	0.2	0.9996

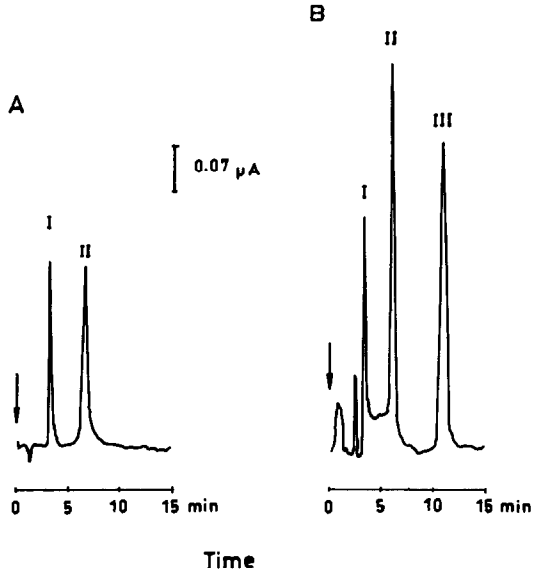

Fig. 3. Chromatograms of thiosalicyclic acid (I), thimerosal (II) and dithiodibenzoic acid (III). Potential of the detector: (A) 0.9 V and (B) 1.2 V *vs.* Ag/AgCl.

The results obtained for TMS concentrations by the HPLC method are compared in Table 2 with those obtained by the cold-vapour atomic absorption spectrophotometric (CVAAS) standard method. The products assayed at the time of manufacture gave similar results by the HPLC and CVAAS methods, however older products contained, according to the HPLC method, significatively less TMS than the initial amount, specially the product type B.

These results indicate that the CVAAS method is not adequate for checking the ageing of the ophthalmic solutions by degradation of TMS. In most cases, as can be deduced from Table 2, only a light diminution of TMS amount is observed in comparison with the diminution observed by the HPLC method. The CVAAS technique detects only the total amount of mercury in the sample but, as a consequence of the degradation process, the total concentration of mercury does not vary, because the decomposition compound, ethyl mercury ions contains mercury as the intact TMS. Lower concentrations of mercury encountered for TMS by the CVAAS method in relation to the initial content in most of the samples may be due to adsorption processes of TMS or ethylmercury on the container walls.[4]

Table 2 shows TMS concentrations obtained for different formulations stored in similar conditions. From the results, an important effect of concomitant nature in each formulation on the degradation rate of TMS could be inferred. Also it was observed that samples stored in the darkness keep their TMS level larger than samples stored in subdued sunlight.

With the proposed method it is also possible to distinguish between TMS and its decomposition products, TSA and DTDBA. So, samples that seem unaltered by the CVAAS technique, by the HPLC method show an important diminution of TMS concentration and appreciable amounts of degradation products. In Table 3 the results obtained in the determination of TSA and DTDBA content in some significant samples are shown. It is observed that in the darkness TSA is the main degradation compound, but in presence of light DTDBA is the principal degradation compound from both TMS and TSA.

All these results reveal the utility of the HPLC method with electrochemical detection in the quality control of commercial products containing TMS. This is an easy, quick and feasible method not only for determination of TMS

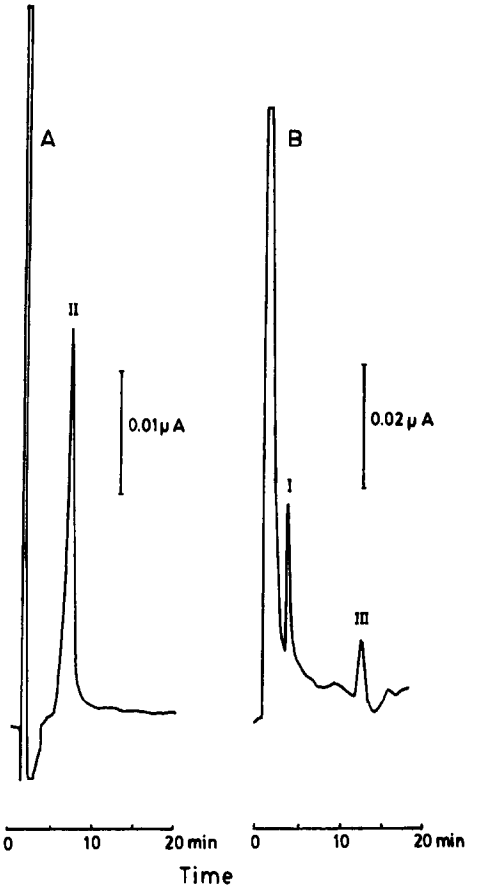

Fig. 4. Chromatograms of real samples. (A) sample B1, electrode potential 0.9 V. (B) sample A6, assay data 10/91, electrode potential 1.2 V. Compounds: TSA (I), TMS (II) and DTDBA (III).

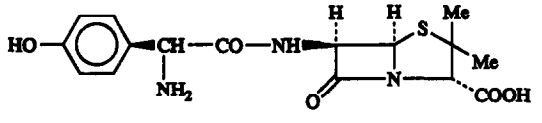
POTENTIOMETRIC STUDIES OF BINARY AND TERNARY COMPLEXES OF AMOXYCILLIN

MOHAMED M. SHOUKRY
Department of Chemistry, Faculty of Science, Cairo University, Giza, Egypt

(*Received* 1 *May* 1991. *Revised* 3 *March* 1992. *Accepted* 13 *April* 1992)

Summary—The formation equilibria for the binary complexes of copper(II), nickel(II), cobalt(II) and zinc(II) with amoxycillin (Amx) and for the ternary complexes M(Arm)(Amx), where Arm refers to aromatic amines, namely 2,2′-dipyridyl or 1,10-phenanthroline, were investigated by a potentiometric technique. The protonation constants of amoxycillin and conditional stability constants of the formed complexes were determined at 25° (=0.1*M* $NaNO_3$). Probable mode of chelation with amoxycillin is discussed.

Lactam antibiotics, such as amoxycillin, represent the most important class of drugs against infection diseases caused by bacteria.[1,2] It is known that the antibiotic action is related to the ability of these compounds to form complexes with metal ions. This stimulated a great deal of investigation on the complexing properties of the antibiotics as ligands.[3,4] Investigation of the binary and ternary complexes of amoxycillin may therefore help toward understanding the driving forces which lead to the formation of such complexes in biological systems. In connection with our previous studies of the binary and ternary complexes of biological significance,[5,7] the present investigation reports potentiometric studies of the binary and ternary complexes of some transitional metal ions with amoxycillin and aromatic amines, 2,2′-dipyridyl (Dpy) and 1,10-phenanthroline (Phen), as secondary ligands.



Scheme 1. Amoxycillin

EXPERIMENTAL

Apparatus

Potentiometric titrations were performed with a Metrohm 686 Titroprocessor equipped with a 665 Dosimat (Metrohm, Herisau-S.). The titroprocessor and electrode were calibrated with standard buffer solutions prepared according to NBS specifications.[8] All titrations were carried out at 25 ± 0.1°, in a purified nitrogen atmosphere using a titration vessel described previously.[9]

Materials and reagents

Amoxycillin trihydrate is (6R)-6-(α-*D*-*p*-hydroxyphenylglycylamino)penicillanic acid trihydrate. It was obtained from Gulphar Pharmaceutical Co. (Ras El-khima, U.A.E.). 2,2′-Dipyridyl and 1,10-phenanthroline monohydrate (Merk Chem. Co., Darmstadt-D) were utilized as supplied. Solutions of metal ions were prepared from their nitrate salts (BDH, U.K.). Amoxycillin solution was prepared, immediately before use, by exact weighing of the substance, which was then dissolved in aqueous equimolar nitric acid solution. The aromatic amines were in diprotonated form by dissolution in nitric acid. Concentrations of stock solutions of the metal ions were determined by conventional analytical methods.[10] All solutions were prepared in demineralized water.

Procedure and measuring techniques

Prepare the following mixtures (A–D) and titrate potentiometrically with standardized sodium hydroxide solution (0.25*M*).

(A) 40 ml of solution containing $5.0 \times 10^{-3}M$ Amx and 0.1*M* $NaNO_3$.
(B) 40 ml of solution containing $2.5 \times 10^{-3}M$ metal ion, $5.0 \times 10^{-3}M$ Amx and 0.1*M* $NaNO_3$.
(C) 40 ml of solution containing $5.0 \times 10^{-3}M$ metal ion, $5.0 \times 10^{-3}M$ Arm and 0.1*M* $NaNO_3$.

(D) 40 ml of solution containing $5.0 \times 10^{-3}M$ metal ion, $5.0 \times 10^{-3}M$ Arm, $5.0 \times 10^{-3}M$ Amx and $0.1M$ $NaNO_3$.

The protonation constants of amoxycillin were determined by titrating mixture (A). The formation constants of the binary complexes formed in solution were determined by titrating mixture (B). With the concentrations in mixture (B), the 1:1 and higher complexes are allowed to form. The stability constants, $K^{M(Arm)}_{M(Arm)(Amx)}$, for the ternary complexes were determined by titration of mixture (D), utilizing the data obtained within the pH range corresponding to the complete formation of the $[M(Arm)]^{2+}$ complex.

The calculations were performed using the computer program MINIQUAD-75[11] loaded on an IBM-4331 computer. The model selected was that which gave the best statistical fit to, and proved chemically consistent with the titration data, without showing any systematic bias in residuals, as elsewhere described.[11] Tables 1 and 2 summarize the obtained results.

RESULTS AND DISCUSSION

Protonation of amoxycillin

Amoxycillin protonation constants were determined by direct potentiometric, pH measurements because all protonation reactions were observed to take place within the potentiometrically measurable pH range (2–11). Amoxycillin behaves as triprotonic acid $[H_3L^+]$, where the differential log protonation constants were found to be 2.41, 7.19 and 9.38. In considering the nature of the donor groups involved in successive protonation reactions, it is helpful to invoke the protonation constants of cephalexin (7.18 and 2.62)[12] analogue, where the protonation centres are the amino and carboxylic groups. In acid medium amoxycillin is protonated to give a cationic species H_3L^+. Addition of base produces, in a first stage, the deprotonation of carboxylic group ($pK_{a1} = 2.41$) yielding the zwitter ion species $H_2L^{\pm}$, existent in the pH range 4–6. When the pH is increased the deprotonation of the amino group $-NH_3^+$ ($pK_{a2} = 7.19$), followed by that of the phenolate group ($pK_{a3} = 9.38$).

*The symbol 1 is the stoichiometric coefficient corresponding to [M–Arm] species.

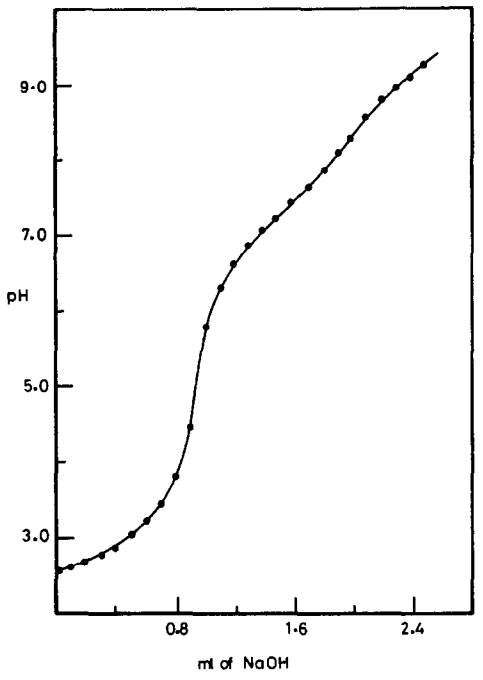

Fig. 1. Potentiometric titration curve of nickel(II)–amoxycillin complex. The solid curve through the experimental points is the theoretical curve. Approximately one-fifth of the experimental points are shown.

same is proven in Fig. 1, where an excellent fit can be observed between the experimental data points from the titration of nickel–amoxycillin complex, taken as a representative, and the theoretical curve calculated from the values of protonation constants of amoxycillin and formation constants of the corresponding complexes. The potentiometric results of the copper–amoxycillin system reveals the formation of $[CuHL]^+$ complex species. The [CuL] species was not detected as the solution turned turbid at pH 4.7.

The acid dissociation constant of the protonated complex species is given by relation (1);

$$pK^{H}_{(M)(L)(H)} = \log K^{(M)}_{(M)(L)(H)} - \log K^{(M)}_{(M)(L)} \quad (1)$$

The value of pK^H of the protonated complexes is in the range 7.55–8.03. This value may compare with the protonation constant (pK_{a3}) of the phenolate group if the increase of its acidity as a result of metal complex formation with the amino group would be considered.

Ternary complexes of amoxycillin

The potentiometric titration curves of M^{II}–Arm system in the presence (mixture D) and absence (mixture C) of amoxycillin reveals their coincidence in the region $0 \leqslant a \leqslant 2$, ($a$ = number of moles of base added per mole of ligand), where the 1:1 M^{II}–Arm complex is formed. The formation of a ternary complex is ascertained by comparison of the mixed-ligand titration curve with the composite curve obtained by graphical addition of the amoxycillin titration data to that of the M^{II}–Arm titration curve. The mixed-ligand system was found to deviate considerably from the resultant composite curve indicating the formation of a ternary complex.[13] Therefore, it is assumed that in the presence of both ligands, the aromatic amine is ligated to the metal ion, then followed by ligation of amoxycillin, *i.e.*, the ternary complex formation could be considered in stepwise equilibria [equations (2) and (3)]

$$M + Arm \rightleftharpoons [M\text{–}Arm] \quad (2)$$

$$[M\text{–}Arm] + Amx \rightleftharpoons [M\text{–}Arm\text{–}Amx] \quad (3)$$

The relative stability of the ternary complexes, as compared to that of the corresponding binary complexes, can be quantitatively expressed in different ways. A review on those methods[14] has shown that, for a variety of reasons, the most suitable comparison is in terms of $\Delta \log K$. Table 2 demonstrates the difference in stabilities of the binary and ternary complexes in terms of $\Delta \log K$ as defined by equation (4):

$$\Delta \log K = \log K^{(M)(Arm)}_{(M)(Arm)(Amx)} - \log K^{(M)}_{(M)(Amx)}. \quad (4)$$

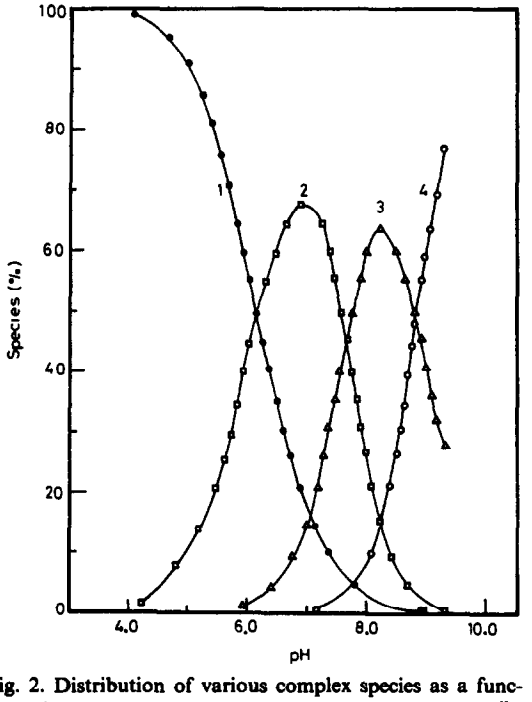

Fig. 2. Distribution of various complex species as a function of pH for the nickel(II)–amoxycillin system: (1) $[Ni^{II}]$, (2) [Ni(HL)], (3) [Ni(L)] and (4) [Ni(L)(OH)].

Table 3. Maximum proportions of the amoxycillin complexes

Species	% Proportion of species	pH
Amoxycillin

[Ni(L)]	63	8.3
[Co(L)]	43	8.3
[Zn(L)]	10	7.5
$[Ni(L)(OH)]^-$	75	9.2
$[Co(L)(OH)]^-$	76	9.0
$[Zn(L)(OH)]^-$	64	7.9
Ternary complexes		
$[Cu(Phen)(HL)]^+$	67	5.6
$[Cu(Dpy)(HL)]^+$	53	4.9
$[Ni(Phen)(HL)]^+$	49	7.5
$[Ni(Dpy)(HL)]^+$	50	7.2
$[Co(Phen)(HL)]^+$	30	7.6
$[Co(Dpy)(HL)]^+$	33	7.5
$[Zn(Phen)(HL)]^+$	21	7.4
$[Zn(Dpy)(HL)]^+$	23	7.3
[Cu(Phen)(L)]	45	6.5
[Ni(Phen)(L)]	48	8.4
[Ni(Dpy)(L)]	38	8.0
[Co(Phen)(L)]	38	8.6
[Co(Dpy)(L)]	36	8.4
[Zn(Phen)(L)]	35	8.0
[Zn(Dpy)(L)]	29	8.0

In general, one expects to observe negative values for $\Delta \log K$, because more coordination positions are available for bonding of amoxycillin in the binary than in the ternary complexes. The $\Delta \log K$ values are found to be invariably negative. This means that the amoxycillin forms a more stable complex with the free metal ion than with the M^{II}–Arm one.

The concentration distribution diagrams in terms of formation percent as a function of pH were obtained for complexes formed in solution in the metal ion–amoxycillin and metal ion–aromatic amine–amoxycillin systems. Figure 2 shows the distribution diagram of nickel–amoxycillin complex, as a representative example. The maximum percent of formation of the protonated (H_3L^+) and deprotonated (L^{2-}) forms of amoxycillin, given in Table 3, are obtained under the prevailing experimental conditions. The same is true for the hydrxo-complex species [M(L)(OH)]. The maximum proportions of the complexes formed in solution are given in Table 3.

Based on the potentiometric results, the formation of the metal chelates with amoxycillin can take place through the vicinal amino and carbonyl groups as proposed. Such a suggestion is supported by the literature data[15,16] reported for cephalexin, which is structurally related to amoxycillin. Attempts made to isolate the complexes in a pure state were unsuccessful. Supportive structural elucidation on the mode of coordination of the metal ions in binary and ternary complexes needs further studies, *e.g.*, nuclear magnetic resonance studies of the solution chemistry of diamagnetic metal complexes. However, such studies are not available now and will be considered in the future.

APPLICATION OF RIDGE TRACE ANALYSIS IN DIRECT SPECTROPHOTOMETRIC CALIBRATION

WEI WANZHI, ZHU WENHONG and YAO SHOUZHUO

Department of Chemistry and Chemical Engineering, Hunan University, Changsha 410012, People's Republic of China

(*Received* 6 *December* 1991. *Revised* 23 *April* 1992. *Accepted* 24 *April* 1992)

Summary—The use of ridge trace analysis for multivariate calibration problems is described. Application is made to the simultaneous quantitative determination of components for several pharmaceutical systems with unknown sample UV spectra by the direct calibration technique. The results indicate that with the help of ridge trace analysis and ridge regression, the parameter k can be selected to obtain estimation of the colinearity of a system based on the stability of relative concentration as a function of k. Much information about the system to be analyzed can be obtained, such as whether there is colinearity among the variables, which measurement wavelength range is suitable for performing quantitative analysis, which components cannot be measured and which components can only be measured as a sum, and whether the quantitative model is correct.

For quantitative analysis of complex samples containing more than one component, multiple calibration techniques must be used and the widespread availability of computers makes their application possible. By far the most commonly used statistical methods for multicomponent determinations are multiple linear calibration procedures.[1] They are utilized to establish quantitative models between analyte concentration and instrumental response through regression analysis on the data of a calibration set, and then to estimate the component concentrations in unknown samples with the model and the response of the samples, when the number of analytes is known and they possess different distinct characteristics in the measurement. Unfortunately, many components to be analyzed in multicomponent samples have almost the same measurement characteristics, due to the limitation of analysis methods. For these cases, some special regression techniques must be adopted to gain more stable parameter estimation,[2] and ridge regression is one of the most generally used techniques.[3–5] Recently, ridge regression was introduced for chemical analyses[6,7] but there is no literature concerning the wider application of ridge trace analysis in analytical chemistry.

To detect and quantify analytes in multicomponent samples by spectrophotometry, the direct calibration process can be applied, *i.e.*, the pure spectra of analytes to be determined are utilized for obtaining coefficients to build a linear model of the relationship between concentration of the analytes and response. Then the spectrum of an unknown sample is placed into the model and the concentrations can be estimated through the following linear model with regression at the same time:

$$[\mathbf{R}] = [\mathbf{K}][\mathbf{C}] + [\mathbf{E}] \quad (1)$$

where $[\mathbf{K}]$ is an $m \times p$ coefficient matrix of p analytes pure spectra in m measurement wavelengths; $[\mathbf{R}]$ is an $m \times 1$ vector of unknown sample spectrum in m measurement wavelengths; $[\mathbf{C}]$ is a $p \times 1$ vector of the concentrations for p analytes in the sample and $[\mathbf{E}]$ is an $m \times 1$ residual vector. When MLR (multiple linear regression) is used to estimate the component concentrations of an unknown sample, equation (1) is rearranged to solve for $[\mathbf{C}]$

$$[\mathbf{C}] = ([\mathbf{K}]^{\mathrm{T}}[\mathbf{K}])^{-1}[\mathbf{K}]^{\mathrm{T}}[\mathbf{R}] \quad (2)$$

The main difficulty with the use of MLR for model (1) is the inversion of $[\mathbf{K}]^{\mathrm{T}}[\mathbf{K}]$ when there is a high degree of colinearity.[4] Colinearity is the lack of independence between the columns of $[\mathbf{K}]$. The less independent these columns, the more error or instability is produced when determining the inverse.

Ridge regression, on the other hand, is a procedure with which a more stable estimation

of [C] can be achieved. Ridge regression can be defined from

$$[\mathbf{C}](k) = ([\mathbf{K}]^{\mathrm{T}}[\mathbf{K}] + k[\mathbf{I}])^{-1}[\mathbf{K}]^{\mathrm{T}}[\mathbf{R}] \quad (3)$$

where k is a constant ($0 < k < \infty$) and [I] is a $p \times p$ unit square matrix. Since the eigenvalues of $[\mathbf{K}]^{\mathrm{T}}[\mathbf{K}]$ and $[\mathbf{K}]^{\mathrm{T}}[\mathbf{K}] + k[\mathbf{I}]$ are $\lambda_1, \ldots, \lambda_p$ and $\lambda_1 + k, \ldots, \lambda_p + k$, respectively, when some λ_i approaches zero, *i.e.*, there is colinearity in the system, $\lambda_i + k$ will be larger than λ_i and it can be expected that $[\mathbf{C}](k)$ is more stable than [C]. Particularly, some $k > 0$ is found to make

$$E(\| [\mathbf{C}](k) - [\tilde{\mathbf{C}}] \|^2) < E(\| [\mathbf{C}] - [\tilde{\mathbf{C}}] \|^2) \quad (4)$$

where $[\tilde{\mathbf{C}}]$ is a $p \times 1$ vector of the true concentrations of the analytes, and the left of equation (4) is as small as possible. In practice, the optimum value of k relies on the unknown model parameters [C] and σ^2, and the relation between k, [C], and σ^2 is unknown. Therefore, it cannot be known before regression and must be determined from the experimental data, which makes the estimation of $[\mathbf{C}](k)$ complex. There are many techniques to select a suitable k,[8] and ridge trace analysis is an important and basic technique to determine k. So called ridge traces are a group of curves which indicate that for each i ($i = 1, \ldots, p$) when k increases from zero to ∞, $C_i(k)$, as a function of k, varies with k. Because ridge traces reflect some properties of a multiple linear system to be analyzed, much valuable information can be obtained with the ridge trace analysis.

The purpose of this study was to provide evidence that ridge trace analysis, as a helpful tool for linear multivariate analysis, can be used to obtain some useful quantitative and qualitative information for linear systems of analytical chemistry, such as spectrophotometric systems. This study also investigated how to obtain ridge traces and how to perform ridge trace analysis through several known analysis systems. Since the characteristics about the system are important for acquiring correct analytical results, ridge trace analysis is of considerable interest for analysts.

EXPERIMENTAL

Instrument and reagents

A Hitachi 557 double wavelength/double beam spectrophotometer was used to obtain the pure spectra of components and the spectra of all samples, and an IBM PC/XT computer was used to treat the experimental data. Analytical reagent grade chemicals and distilled water were used. Salicylic acid, thymol, phenol, benzoic acid, resorcinol, theobromine, theophylline, caffeine, amidopyrine, phenacetin, phenobarbital and ephedrine were of Pharmacopoeia (1985, P. R. China) quality.

Procedure

Salicylic acid, thymol, phenol, benzoic acid and resorcinol, accurately weighed, were dissolved in minimum volumes of 95% alcohol and then the five solutions were diluted with suitable volumes of water, respectively. The pure spectra of the five components were obtained by scanning the five solutions from 250 to 330 nm in the spectrophotometer. Two samples of salicylic acid, thymol, phenol and benzoic acid, two samples of salicylic acid, thymol and phenol, and ten samples containing different quantities of the above five components were prepared and fourteen sample spectra were obtained in the same wavelength range. The seven other pharmaceutical samples, accurately weighed, were dissolved in water to form seven single-component solutions, and then seven pure spectra from 230 to 300 nm were obtained. Eight samples, the composition proportions according to the prescription of some tablets, were compounded and eight spectra were obtained in the same wavelength range. At the same time, the spectral stability for both single component and mixture samples was tested.

Computation

Ridge traces can be obtained with equation (3), but an inversion must be determined for each k. Here, a simple computation method is introduced for ridge traces. [U] is defined as

$$[\mathbf{U}] = \begin{bmatrix} [\mathbf{R}]^{\mathrm{T}}[\mathbf{R}] + k & [\mathbf{R}]^{\mathrm{T}}[\mathbf{K}] \\ [\mathbf{K}]^{\mathrm{T}}[\mathbf{R}] & [\mathbf{K}]^{\mathrm{T}}[\mathbf{K}] + k[\mathbf{I}] \end{bmatrix} \quad (5)$$

If [A] is a $(p+1) \times (p+1)$ orthogonal square matrix and

$$[\mathbf{A}][\mathbf{U}][\mathbf{A}]^{\mathrm{T}} = [\Lambda] = \mathrm{diag}(\lambda_1 + k, \ldots, \lambda_{p+1} + k) \quad (6)$$

then the following equations give the $[\mathbf{C}](k)$ as a function of k

$$C_{j-1}(k) = -\left(\sum_{i=1}^{p+1} \frac{a_{i1}a_{ij}}{\lambda_i + k}\right) \Big/ \left(\sum_{i=1}^{p+1} \frac{a_{i1}^2}{\lambda_i + k}\right) \quad (7)$$

for $j = 2, \ldots, p+1$, where a_{ij} is the element of [A]. The computation in this work was carried out on an IBM PC/XT computer and all

programs were written in BASIC. All spectra were disintegrated at intervals of 2 nm to form spectral vectors and the data vectors and matrices were mean-centered and scaled to unit variance in each column. All estimated concentrations in the plots of ridge traces were the relative concentrations for the pure spectra, so that all components possess almost the same sensitivity. Copies of the data and programs are available from the authors.

RESULTS AND DISCUSSION

Colinearity for a four component system by ridge trace analysis

Ridge trace analysis is a useful means to analyze the system behaviour, and the interaction and relation among the variables. A basic application is that it can be used to judge whether there is colinearity for a given system. In spectrophotometry, direct calibration, when the composition of a system is known, can be used to determine a suitable measurement wavelength range to improve the stability of concentration estimation. For a pharmaceutical sample containing 20.05 mg/l. salicylic acid, 12.42 mg/l. thymol, 10.36 mg/l. phenol and 29.55 mg/l. benzoic acid (the pure spectra of the four components are in Fig. 1), 250–270 nm was selected to determine them quantitatively. From the ridge trace plot, Fig. 2, it can be seen that the four curves change morbidly with a slight increase of k, so the wavelength range was poor for the simultaneous determination. When the range of 250–290 nm was used, the curves (Fig. 3) were

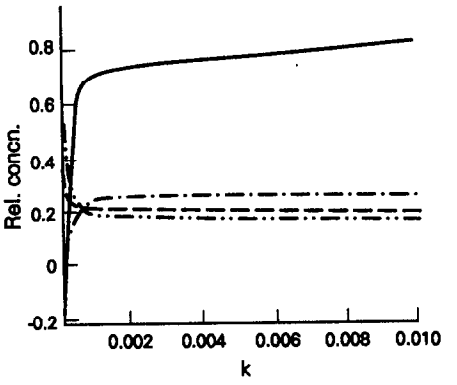

Fig. 2. Ridge traces of the four-component sample with wavelength range from 250 to 270 nm. (——) salicylic acid (rel.con. 0.06542); (—··—) thymol (rel.con. 0.2271); (—·—) phenol (rel.con. 0.2582); (– – –) benzoic acid (rel.con. 0.2319).

all smooth and steady, which shows that the colinearity had been removed from the system, and hence this wavelength range was suitable for quantitative analysis of the components, with the techniques based on the principle of least squares.

From practice, for good linear (*e.g.*, spectrophotometric) systems, when there is obvious colinearity among the variables, the change of ridge traces is obvious with the increase of k from 0 to 0.005, with the largest relative errors far larger than 0.1. The estimated concentrations were −6.49, 30.43, 0.89 and 46.04 mg/l. with the first wavelength range, and 19.92, 11.89, 9.96 and 29.30 mg/l. with the second wavelength range, respectively, when MLR was used. The results of the latter were far better than those of the former. Of course, if a better wavelength range cannot be found, MLR cannot be used, and biased estimators must be adopted. In multicomponent determination with an array of sensors, colinearity is an important factor which affects the quantitative precision,[9] hence ridge

trace analysis can be used to select a suitable array for a given system.

Ridge regression of a five-component system

Ridge regression, as an important biased estimator, can be utilized to obtain a more stable concentration estimation for colinearity systems and ridge trace analysis is a basic technique to acquire the ridge regression parameter k. Ten samples, Table 1, of five ingredients were analyzed with ridge regression. The pure spectra of the components are in Fig. 1. The ridge traces of sample one, Fig. 4, indicated there was colinearity in the system since the ridge traces of thymol, phenol and resorcinol change obviously with a slight increase in k from zero. When k increases from 0 to 0.005, the percentages of estimation change were 87 for thymol, 8 for phenol and −21 for resorcinol, only 1 for salicylic acid and 3 for benzoic acid respectively. The reason the former three curves changed markedly can be assessed qualitatively from Fig. 1, where the pure spectra of thymol and resorcinol are very similar and the spectrum of phenol is slightly similar to them. From Fig. 4, it can be seen that when k was larger than 0.005, the five curves were all stable, so $k = 0.005$ can be selected to gain a biased concentration estimation for the components with ridge regression. The results of ridge regression with $k = 0.005$ for ten samples are listed in Table 1. The average recoveries and standard deviations of the five components were 99.01% (1.27%), 106.27% (3.59%), 100.12% (4.21%), 99.71% (2.19%) and 93.15% (2.78%) with ridge regression and 99.69% (1.34%), 56.17% (21.91%), 84.86% (11.18%), 101.48% (2.50%) and 131.86% (20.67%) with MLR, respectively, which show that though the estimation with ridge regression was biased, it was more precise and accurate than that with MLR.

Ridge trace analysis of seven-component system

For more complex colinearity systems, for which the qualitative composition is known, ridge trace analysis can be used to quantitatively determine the ingredients which ordinarily cannot be measured due to their low contribution to a sample spectrum. Using ridge trace analysis, we can know which ingredients can only be measured as a sum and which ingredients can be measured individually with biased estimators.

A common pharmaceutical tablet preparation contains theobromine, theophylline, caffeine, amidopyrine, phenacetin, phenobarbital and ephedrine. The pure spectra of these components is plotted in Fig. 5. Eight samples, Table 2, were prepared, the compositions of which were according to the prescription proportion of tablets.

The ridge trace of sample one (Fig. 6) can give the following information. First, the concentration estimation of ephedrine approaches zero stability for any k, so it cannot be determined accurately with the measured data, and the variable can be removed from the regression model. Whether a variable can be considered close to zero depends on many factors, *e.g.*, the analysis requirement and the instrumental noise level. For spectrophotometry, if the absolute concentration estimation is always smaller than 0.02, the variable can be safely treated as zero. Second, the other six curves changed markedly with an increase in k from 0 to 0.005, which

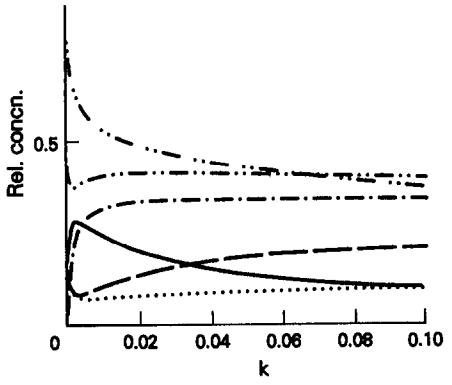

Fig. 6. Ridge traces of sample one for the seven-component system (— —) theobromine (rel.concn. 0.155); (——) theophylline (rel.concn. 0.163); (· · ·) caffeine (rel.concn. 0.0758); (— · · —) amidopyrine (rel.concn. 0.443); (— · · · —) phenacetin (rel.concn. 0.727); (— · —) phenobarbital (rel.concn. 0.0425); (– – – –) ephedrine (rel.concn. 0.00099).

shows that there was colinearity in the system, so biased estimators must be used to achieve a good concentration estimation. On the other hand, the traces of caffeine, amidopyrine, phenacetin and phenobarbital were more stable when k was larger than 0.015, and hence 0.015 can be selected as the ridge regression parameter. Third, although the curves of theophylline and theobromine were unstable, the sum of the two traces was basically equal at any k, so only the sum of them can be estimated.

Additionally, it can be seen from Fig. 6 that when $k = 0.015$, the concentration estimation proportion for caffeine, amidopyrine and the sum of theophylline and theobromine approached the composition of the tablet. That of phenacetin and phenobarbital was not reasonable, *i.e.*, the former was too low and the latter was too high, which did not conform to the prior information about the system. However, the two ridge traces showed that the concentration estimation sum of them is more stable with the change of k, so the total quantity of them can be estimated with ridge regression. Of course, for this situation, there is no common law that can be obeyed, but the analyst's experience and the signal of estimation are both helpful for obtaining the correct conclusion. From our practice, the situation is rare, and the situation where the concentration estimation is closer to the true concentration with the k slightly larger than zero for colinearity systems is common.

For more complex systems, the pure spectra of components cannot give the above information. For example, the spectral behaviours of theobromine and caffeine were closer than those of theobromine and theophylline, but ridge analysis shows that caffeine can be individually quantified and theobromine and theophylline can only be measured as a sum.

From the analysis, it can be seen that for the theophylline compound tablet system with UV spectrophotometry, there are four ingredients that can be simultaneously quantified, *i.e.*, caffeine, amidopyrine, the sum of theobromine and theophylline, and the sum of phenacetin and phenobarbital. Based on this, the model of six variables was used to estimate their concentrations for eight unknown samples with ridge regression and $k = 0.015$. The results are listed in Table 2, where the concentrations of theobromine and phenacetin were, respectively, the concentration sums of theobromine and 1.15 times theophylline, and phenacetin and 0.850 times phenobarbital. Values of 1.15 and 0.850 were the maximum absorption coefficient ratios of the latter to the former, respectively. The average recoveries and standard deviations were 103.99 (1.63%), 109.5 (45.60%), 92.83 (0.86%) and 105.3 (2.26%) with ridge regression and 96.44 (4.74%), 164.60 (31.15%), 90.30 (6.62%) and 103.86 (3.43%) with MLR for theobromine, caffeine, amidopyrine and phenacetin respectively. The estimation improvement with ridge regression for caffeine and amidopyrine was obvious and the estimation for the two sums with ridge regression was more stable than that with MLR.

With the help of ridge trace analysis, some qualitative information about a system to be analyzed can be obtained, when the composition of analytes is partially known.

Ridge trace analysis of three-component system with four-component model

When there is obvious absorption interference in a sample spectrum, more pure spectra can be used to build a calibration model to determine the composition of the sample and after the determination of a suitable model, a better concentration estimation can be reached. When the estimations of some components are stable about zero or close to zero with a slight increase of k, the variables can be removed from the model to achieve higher estimation precision for the components which can be quantified.

The pure spectra of salicylic acid, thymol, phenol and benzoic acid were used to set up a model of four variables to regress the spectrum of a sample containing 26.15 mg/l. salicylic acid,

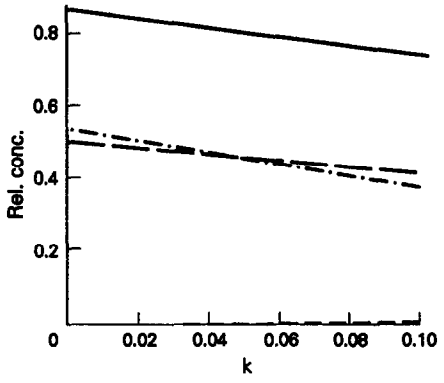

Fig. 7. Ridge traces of the three-component system with the four-component model. (——) salicylic acid (rel.concn. 0.8532); (— —) thymol (rel.concn. 0.4649); (— · —) phenyl (rel.concn. 0.5621); (– – – –) benzoic acid (rel.concn. 0.0000).

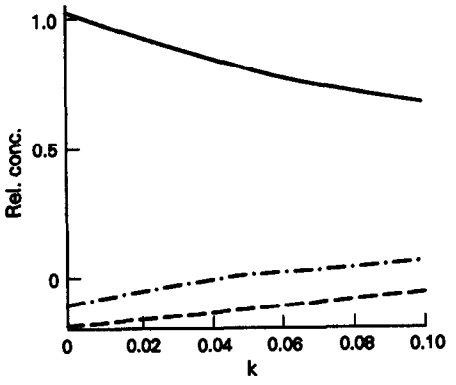

Fig. 9. Ridge traces of the incorrect three-component model for the three-component sample. (——) thymol; (— · —) phenol; (– – – –) benzoic acid.

25.43 mg/l. thymol and 22.55 mg/l. phenol. Figure 7 shows that the four curves were all stable, so the system was linear and there was no colinearity among the variables, and a good estimation can be obtained with MLR. The benzoic acid curve was negative when $k = 0$, then rapidly became positive with increased k, stabilizing at about zero. This indicates that there was no benzoic acid in the sample. The results of the four-variable model and three-variable model with MLR were 26.25 and 26.20 mg/l. for salicylic acid; 26.82 and 26.58 mg/l. for thymol; and 21.37 and 21.40 mg/l. for phenol respectively. The latter was slightly better than the former. This fact indicates that the correct determination of variables and models with ridge trace analysis is valuable for acquiring both qualitative information and a better quantitative estimation.

Ridge trace analysis of unknown systems

Another use of ridge trace analysis is the determination of whether a system obeys a given model built with some pure spectra when the composition of the system is unknown. To illustrate how to perform the analysis, two samples were prepared, *i.e.*, sample 1 containing 20.05 mg/l. salicylic acid, 12.43 mg/l. thymol, 20.72 mg/l. phenol and 59.1 mg/l. benzoic acid, and sample 2 containing 20.01 mg/l. salicylic acid, 28.04 mg/l. thymol and 24.08 mg/l. phenol. The two sample spectra were both the linear combinations of the component pure spectra. For the first sample, the model of three variables (thymol, phenol and benzoic acid) was used in the regression. The ridge traces (Fig. 8) possess the following characteristics: when k increased from 0 to 0.005, the three curves were all stable, *i.e.*, there was no colinearity for the model. The estimation of phenol was far smaller than zero with $k = 0$ and still smaller than zero with $k < 0.03$ and, except for benzoic acid, the other two curves changed gradually with an increase in k. Since the negative concentration was not caused by colinearity and the ridge traces of phenol and thymol were not very stable, it can be concluded that the model was not correct. For sample 2, the model of three pure spectra (thymol, phenol and benzoic acid) was utilized, and a similar ridge trace plot (Fig. 9) was obtained, so the same result can be achieved.

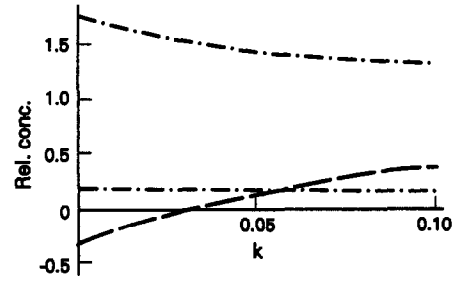

Fig. 8. Ridge traces of the three-component model for the four-component sample. (——) thymol; (— —) phenol; (— · —) benzoic acid.

CONCLUSION

The main advantage of ridge trace analysis is its presentation and its relative simplicity. A group of curves reflects many system behaviour characteristics, such as the relation and interaction among the variables, and gives much valuable system information not convenient with other single multivariate analysis techniques.

Furthermore, the ridge trace algorithm is easy to program and the ridge trace plot is easy to obtain with microcomputers. Since multivariate analysis, especially multivariate linear analysis, is an important tool for obtaining qualitative and quantitative information from experimental data, ridge trace analysis has general importance for analytical chemistry, though it was only used for UV spectrophotometry in this paper. Of course, because of the complexity of systems and analysis demands, it is sometimes difficult to acquire totally correct results with only ridge trace analysis.

On the other hand, it should be noted that ridge trace analysis is only one of many possible multivariate analysis techniques that can be used for obtaining the same information as in this paper. There are several methods for selecting a suitable wavelength range[10] and the calibration matrix condition number is the most general measure of selectivity.[11] A number of research works indicate that many procedures, such as principal component regression, partial least-squares, and stepwise regression, can all perform well for colinearity and for building correct models,[1,12] while many techniques can be used to select a set of suitable variables for models and to obtain optimal models with the PRESS and *F*-tests.[2,13] The ability to combine these techniques with multivariate data provides a high-power analysis tool that may give far more correct and far more qualitative and quantitative information than individual techniques.

(*Received* 30 *April* 1992. *Accepted* 1 *May* 1992)

Summary—The bioaccumulation of gold at antheral cells from the flower *Datura innoxia* is investigated by incorporating these plant cells into a carbon paste matrix. The resulting plant-modified electrode offers a preferential uptake of gold from dilute solutions. The voltammetric behavior of the surface-bound gold is examined under different preconcentration conditions. Scanning electron microscopy offers useful insights into the gold collection process. Convenient measurements of micromolar gold concentrations are possible, with effective self cleaning allowing the use of a single electrode in multiple determinations (R.S.D. of 4.8% for 50 repetitions). The sensitivity and selectivity enhancements associated with the preferential bioaccumulation process, and the convenient surface regeneration, offer the prospect of using the flower-biomass containing electrodes as sensors for gold.

Biological organisms have the potential to preferentially accumulate specific elements.[1,2] The incorporation of such organisms onto electrode surfaces can shed useful insights into their interaction with these metals, and offers a great promise for electroanalytical work. In particular, chemically modified electrodes (CMEs) have been used for studies of metal uptake by nonliving algal biomass, and demonstrated applicability for electroanalysis[3,4] and electrocatalysis.[5] Recent work illustrated the utility of higher plant cells from lichens[6] and peat mosses,[7] as surface modifiers for preconcentration/voltammetric measurements.

The present article describes the bioaccumulation and voltammetric behaviour of gold at flower-cells modified electrodes. In particular, carbon paste electrodes containing antheral cells from *Datura innoxia* are used to effectively bind gold from dilute solutions. Early spectroscopic studies have illustrated the biosorption of cadmium and europium onto the cell walls of the *Datura innoxia* biomass.[8,9] Such bioaccumulation has been attributed to several types of binding sites on the *Datura innoxia* wall. The collection and voltammetry of gold at *Datura innoxia* modified electrodes, as reported in the following sections, hold great promise for electrochemical sensing applications, as well as for elucidating the metal/plant interactions.

*Author for correspondence.

EXPERIMENTAL

Apparatus

Two 10-ml cells were used for the preconcentration and measurement steps; these contained the gold/0.01*M* hydrochloric acid solution and 0.1*M* perchloric acid, respectively. The modified working electrode, the Ag/AgCl reference electrode (Model RE-1, BAS) and a platinum wire auxiliary electrode joined the measurement cell through holes in its Teflon cover. A voltammetric system (EG&G PAR 264A) was used to conduct the experiment. Data were recorded on a EG&G PAR Model 0073 X-Y recorder. Scanning electron microscopy was done with a Phillips 501B SEM.

Electrode preparation

Antheral cells from *Datura innoxia* were obtained and prepared as previously reported.[8,9]

The flower-cells modified carbon paste electrode (11% plant by weight) was prepared by throughly mixing 80 mg of mineral oil (Aldrich) with 26 mg of the plant powder, and then adding 125 mg of graphite powder (Acheson 38, Fisher) and mixing again until a uniform paste was achieved. A portion of the plant-containing paste was packed into the end of a glass tube (3-mm i.d.); a copper wire was inserted through the opposite end to establish electrical contact. The paste surface was smoothed on a weighing paper.

Procedure

The first smooth electrode surface was preconditioned by immersing the electrode in a stirred 25 mg/l. gold solution (in 0.01*M* hydrochloric acid) for 4 min, recording the differential pulse voltamperogram (from +0.85 to +0.20 V) in a 0.1*M* perchloric acid solution, and repeating these steps (*ca.* 5–7 times) until a stable gold peak was obtained.

The preconcentration/medium-exchange/voltammetric scheme[3] was used in all experiments. For the preconcentration step, the modified electrode was immersed in a stirred 10-ml gold test solution (in 0.01*M* hydrochloric acid) for a given period of time; the preconcentration proceeded at open circuit. The electrode was then removed from the preconcentation solution, rinsed with water, and placed in the measurement cell (containing 0.1*M* perchloric acid). After 15 sec the initial potential (+0.85 V) was applied for 10 sec before the voltamperogram was recorded. The scan was terminated at −0.4 V. The scan was repeated to verify the absence of the gold peak. The electrode was then rinsed and placed in the preconcentration cell for the next cycle.

RESULTS AND DISCUSSION

Surface-bound *Datura innoxia* cells incorporate gold(III) onto the electrode. Figure 1 compares cyclic voltamperograms obtained with the plain (A) and plant biomass (B) carbon paste

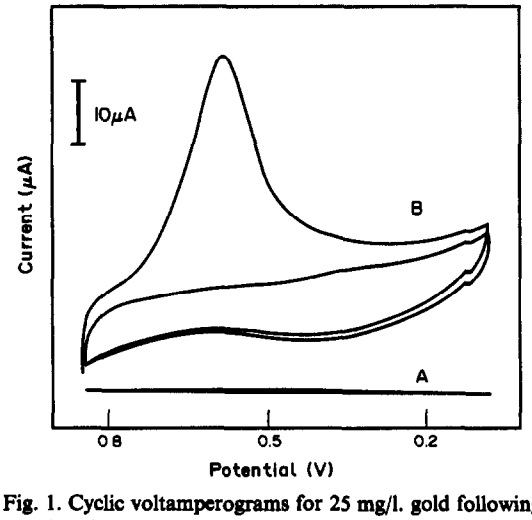

Fig. 1. Cyclic voltamperograms for 25 mg/l. gold following 10-min stirring at the unmodified (A) and plant biomass modified (B) carbon paste electrodes. Scan rate, 10 mV/sec. Accumulation solution, 0.01*M* HCl; measurement solution, 0.1*M* $HClO_4$.

electrodes following 10 min stirring (open-circuit conditions) in a 25 mg/l. gold solution and transfer of the electrode to a perchloric acid blank solution.

Voltammetric peaks are not observed when the unmodified electrode is used, as expected in the absence of gold collection. In contrast, the first scan (designated as 1) at the modified electrode exhibits a distinct current response (E_p = +0.58 V), corresponding to the reduction of the surface-bound gold(III). Reoxidation is not observed upon scanning in the positive direction. No peaks are observed upon subsequent scans. A similar redox behavior was reported for bioaccumulation/voltammetric experiments at algae-containing carbon pastes,[4] but using significantly higher gold concentrations.

Scanning electron microscopy can offer valuable insights into the collection of gold at *Datura innoxia* modified electrodes. Figure 2 shows scanning electron micrographs of the biomass modified electrode following immersion in the blank (a) and 20 mg/l. gold (b, c) solutions for 10 (b) and 60 (a, c) min, and scanning the potential from +0.85 to +0.20 V (to reduce the accumulated species). The open-circuit "collection" from the diluted gold solution resulted in the appearance of surface-bound gold particles. The size of these metallic particles is greatly influenced by the accumulation period, from *ca.* 0.5 μm following 10 min preconcentration to about 5–10 μm after 60 min accumulation. In contrast, the analogous micrograph following immersion in the blank solution revealed no gold particles.

The collection of gold(III) on a flower biomass electrode can be used as an effective preconcentration step prior to the voltammetric measurement. Figure 3(A) shows differential pulse voltamperograms for 25 mg/l. gold after different preconcentration times. Short accumulation periods yield well-defined peaks for mg/l. (ppm) concentrations. The longer the preconcentration time, the more gold is collected, and the larger the peak current. For a 5-min preconcentration period, a 9-fold enhancement of the peak height is observed over that attained following 20-sec stirring [compare curves (a) and (h)]. Although such sensitivity enhancement is important, the procedure also offers improved selectivity based on the discriminative properties of the preconcentration and the medium-exchange steps (see interference study below). Also shown in Fig. 3(B) are plots of peak

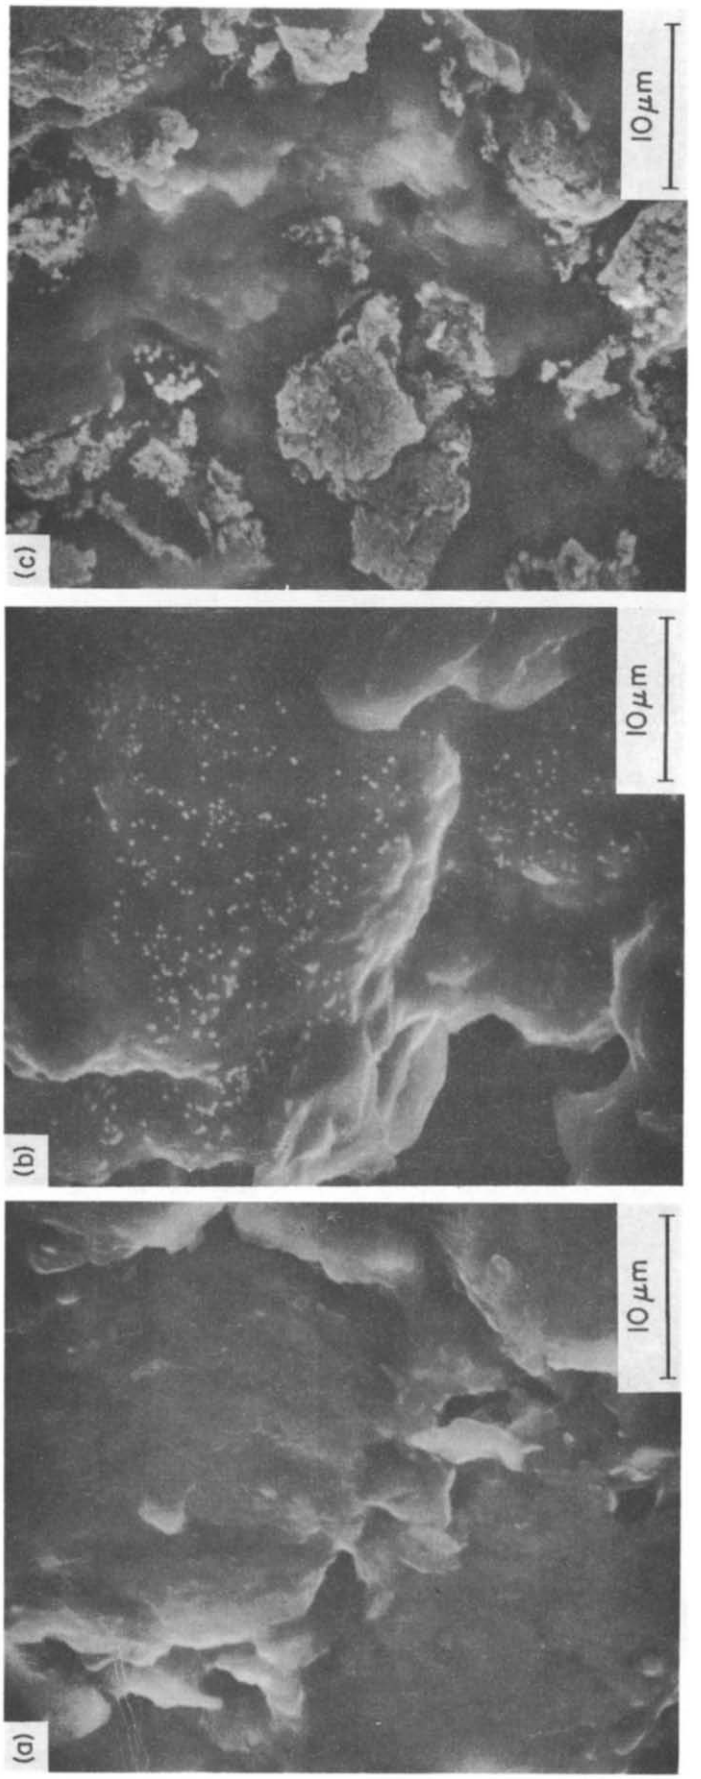

Fig. 2. Scanning electron micrographs of the plant biomass electrode following immersion (stirring) in the blank (a) and 20 mg/l. gold (b, c) solutions for 60 (a, c) and 10 (b) min. Magnification, 2500×.

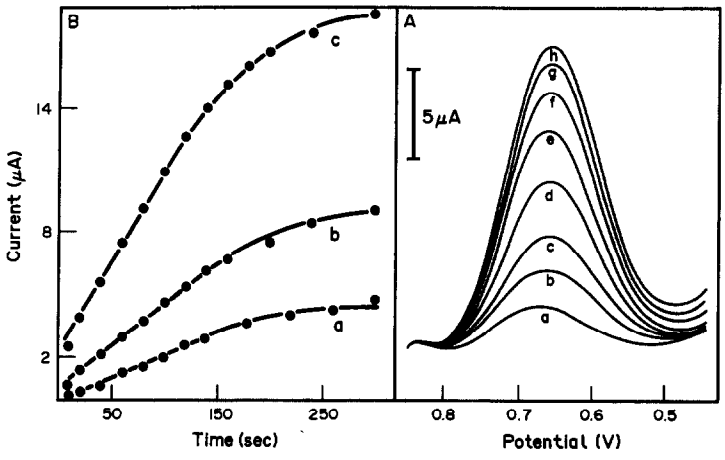

Fig. 3. (A) Differential pulse voltamperograms for 25 mg/l. gold after different preconcentration times. 10 (a), 40 (b), 60 (c), 100 (d), 140 (e), 180 (f) and 240 (g) sec. (B) Resulting peak current *vs.* preconcentration time plots for 5 (a), 10 (b), and 25 (c) mg/l. gold. Differential pulse waveform with 10 mV/sec scan rate and 50 mV amplitude. Details of the preconcentration/medium-exchange voltammetric scheme are given in the Experimental section.

current *vs.* preconcentration time for different gold concentrations [5 (a), 10 (b), and 25 (c) mg/l.]. The rate of gold biosorption is independent on the concentration. The peak currents rise rapidly at first and then more slowly. Apparently, the binding reached equilibrium in accumulation for 4 min.

The solution pH has a profound effect upon the uptake (and hence the voltammetric response) of gold. As illustrated in Fig. 4 a large response is obtained following accumulation from highly acidic solutions. A rapid decrease in the peak is observed upon increasing the pH between 2 and 6; no response is obtained at higher pH values. Such a profile is characteristic of an anion-exchange binding process, as expected for the tetrachloroaurate anion. A similar pH profile was reported for the collection of this gold anion at algae-modified electrodes.[4] The exact identity of the positively charged sites on the *Datura innoxia* cells remains to be elucidated. Various negatively charged groups have been identified earlier on the *Datura innoxia* cells in connection with electrostatic uptake of cations.[8,9] A medium-exchange step, *i.e.*, transfer of the electrode (following the accumulation) to a more favorable electrolyte can be used to improve the selectivity of preconcentrating CMEs.[10] The most favorable response was obtained using a 0.1*M* perchloric acid solution in the voltammetric cell.

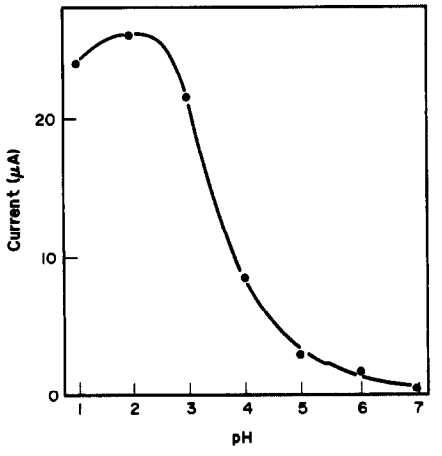

Fig. 4. Dependence of the gold peak (25 mg/l.) on the pH of the preconcentration solution. Four min accumulation. Other conditions, as in Fig. 3.

Most preconcentrating modified electrodes require a "cleaning" step (before the next preconcentration/voltammetric cycle) to eliminate memory effects.[10] Such a step is not needed with the flower biomass electrode, since the metallic gold product of the voltammetric scan does not contribute to the subsequent voltammetric response. (No peak is observed by repeating the scan in the measurement solution.) In addition, despite the presence of metallic gold, the bioaccumulation continues in a reproducible fashion, due to the very large gold(III) binding capacity. The reproducible accumulation and effective self-cleaning are illustrated in Fig. 5, from a prolonged series of 50 preconcentration/voltammetric repetitions with 10 mg/l. gold, during a continuous 5-hr period. Such a long operation yielded a highly stable response, with a mean peak current of 11.0 μA,

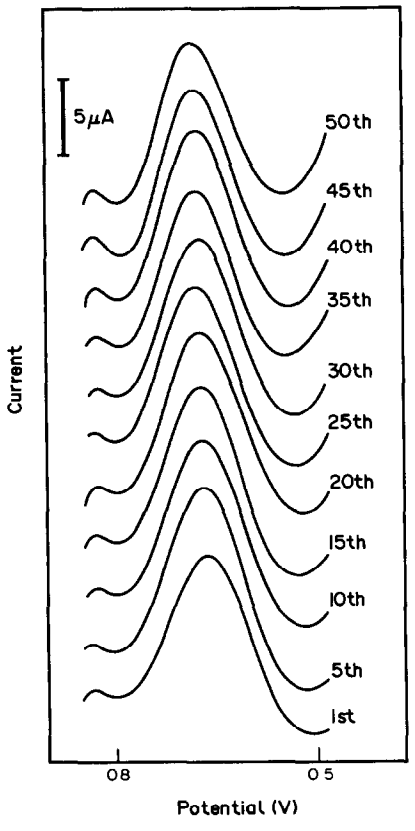

Fig. 5. Sensor performance under continuous use. Repetitive measurement of 10 mg/l. gold over a five hour period. Four min accumulation. Other conditions, as in Fig. 3.

a range of 10.4–11.9 μA, and a relative standard deviation of 4.8%. Analogous measurements of gold at algae-modified electrodes required surface regeneration via immersion in a sodium cyanide solution.[4] The high stability and simple operation of the flower-biomass electrodes hold great promise for their use in voltammetric sensing of gold.

High selectivity is also essential for such sensing applications. Co-existing metal ions (whether electroactive or not) can interfere with the determination of gold if they compete for binding sites. The following metal ions (20 mg/l.) were tested and found not to affect the 10 mg/l. gold response: Cu(II), Pb(II), Zn(II), Ni(II), Ti(IV), In(III), Fe(III), Hg(II), and Mn(II). In contrast, additions of 20 mg/l. Cd(II), Tl(I) and V(V) resulted in 18, 25 and 34% diminutions, respectively, of the 10 mg/l. gold response. The interference study suggests a relatively high selectivity associated with the coupling of preferential binding (to the flower biomass) and the medium-exchange step.

Figure 6 displays pulse voltamperograms for gold solutions of increasing concentration [2.5–25 mg/l. (a)–(h)], following 4 min accumulation (A), along with the resulting calibration plot (B). The well-defined peaks increase linearly with the gold concentration up to 15 mg/l., and then start to level off. The slope of the linear portion corresponds to 1.12 μA . l./mg (correlation coefficient, 0.999). A detection limit of 0.5 mg/l. gold can be estimated from the signal-to-noise characteristics (S/N = 3) of these data. In contrast, a higher detection limit of 4.8 mg/l. gold was reported for analogous measurements at the algae modified electrode.[4]

In conclusion, this work has illustrated the utility of flower cells as surface modifiers in connection with preconcentration/voltammetric measurement schemes. The unique bioaccumulation process at this flower biomass permits effective preconcentration of gold from dilute solutions. Lower detection limits are obtained in comparison to electrodes modified by algal biomass. The electrodes are simple and inexpen-

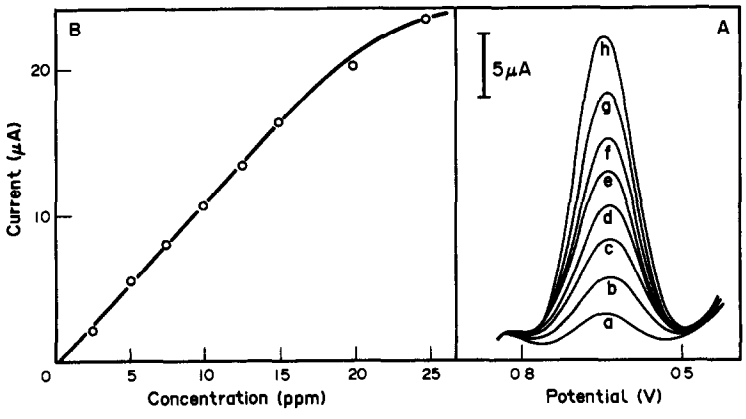

Fig. 6. Dependence of the peak current on the gold concentration. Voltamperograms for increasing gold concentration [2.5 (a), 5.0 (b), 7.5 (c), 10 (d), 12.5 (e), 15 (f), 20 (g) and 25 (h) mg/l. (A), along with the resulting calibration plot (B).

sive to prepare. Besides its sensing implications, the voltammetric study offers a better understanding of the gold collection process (although the exact binding mechanism is still not clear). This work serves as a basis for future work on using higher plant cells in electroanalytical (preconcentration/voltammetric) applications.

Summary—Determination of cadmium in river water by sequential metal vapor elution analysis (column temperature; >1500 K) with argon and hydrogen carrier gas and with atomic absorption spectrometric detection is described. The column is made of a molybdenum capillary tube (i.d. 1.22 mm) and the temperature is 1760 K. The cadmium vapor was separated from those of calcium, iron and sodium. The calibration graph was linear up to 15 μg/ml. Relative standard deviations of 0.8–4.3% were obtained in the range 1 to 15 μg/ml. Cadmium in spiked samples (river water) was determined. The results were in good agreement with the amount spiked.

Sequential metal vapor elution analysis (SMVEA) or super high temperature gas chromatography with atomic absorption spectrometric detection (SHTGC–AAS) has been recently developed. The potential of this technique for the separation of gaseous species at high temperatures (>1500 K) has been recognized by us.[1–3] Yanagisawa *et al.*[4–7] have reported the separation of some volatile elements in argon carrier gas by use of a separative column atomizer and detection by an atomic absorption or emission spectrometer. However, few SMVEA studies for various elements have been reported.

In this study, the separation of cadmium from calcium, iron and sodium by SMVEA–AAS with argon and hydrogen carrier gas is evaluated. The determination of cadmium in river water by SMVEA–AAS is described.

EXPERIMENTAL

Apparatus

The high temperature column unit of SMVEA were reported in detail in a previous paper.[1] An open tubular column is made of a molybdenum tube (i.d. 1.22 mm, wall thickness 0.406 mm, length 250 mm) (99.95% purity, Goodfellow). The column consisted of three portions; atomization, separation, and detection portions. A 0.5-mm diameter hole is drilled at the midpoint of the atomization portion to inject the sample solution. The detection portion has a 0.8-mm hole, perpendicular to the hole in the atomization portion, for atomic absorption measurement. A monochromator (Nippon Jarrell-Ash 0.5 m Ebert-type), a lock-in amplified (NF LI-575), a memoriscope (Kikusui 5516ST), and a microcomputer (NEC, PC-9801RX) are used for AA signal detection in this study. The absorption signal from the amplifier was fed into the microcomputer. The column temperature was measured with an optical pyrometer (Chino Works). Two pinhole apertures were placed in front of and in the rear of the detection hole portion to provide a narrow beam of light about 0.8 mm in diameter and to remove background emission from the column surface.

Hollow-cathode lamps (Hamamatsu Photonics Co.) were used as light sources. The atomic resonance lines for measuring the absorption signal were 228.8, 422.7, 248.3 and 589.0 nm

*Author for correspondence.

for cadmium, calcium, iron and sodium, respectively.

Reagents

Stock solution (1 mg/ml) of cadmium, calcium, iron, and sodium were prepared as chlorides in 0.1*M* hydrochloric acid. The test solutions for the measurement were mixed and diluted from the stock solutions with distilled-demineralized water just before use. All chemicals used were of analytical grade purity.

Procedure

The column temperature was in the range 1760–1870 K. The atomization temperatures were in the range 1760–1940 K. The carrier gas was argon (1.0 ml/min) and hydrogen (0.5 ml/min). The purge gas flow rates in the column chamber were 3.0 l/min for argon and 200 ml/min for hydrogen. The slight hydrogen flow rate was needed to protect the metal column from oxidization by residual oxygen in the column chamber and in the argon.

After stopping the carrier gas, a 1-μl aliquot of sample solution was pipetted into the atomization portion. The sample was dried at 400 K for 10 sec and pyrolysed 760 K for 10 sec. After allowing the carrier gas to flow, the column was heated at 1760 K and the residue in the atomization portion was atomized at 1760 K for >1 min.

RESULTS AND DISCUSSION

The separation of cadmium from calcium, iron and sodium by SMVEA–AAS with argon and hydrogen carrier gas was evaluated. Calcium, iron and sodium are relatively rich in river water; these species interfere with determinations of cadmium by conventional AAS with metal atomizers,[8-9] and so they were selected for the present study. In the separation study, the amounts of Cd, Ca, Fe and Na introduced into the column were 15 ng, 200 ng, 10 ng and 1 ng, respectively.

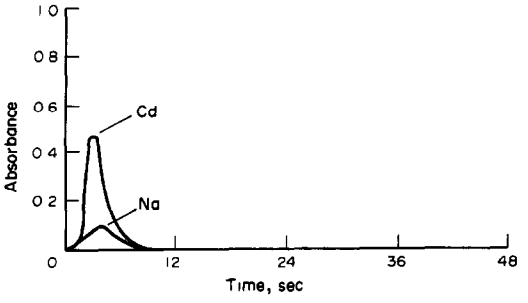

Fig. 1. Profile at the column temperature of 1870 K by sequential metal vapor elution analysis. Atomization temperature; 1940 K, carrier gas; Ar 1.0 and H_2 0.5 ml/min, purge gas; Ar 3000 and H_2 200 ml/min.

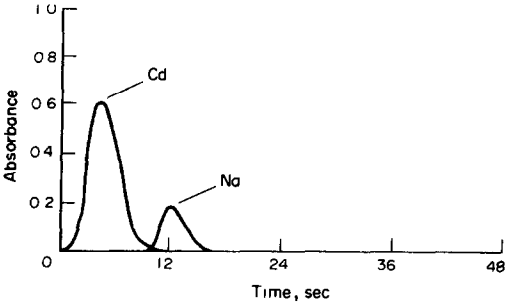

Fig. 2. Profile at the column temperature of 1760 K by sequential metal vapor elution analysis. Atomization temperature; 1760 K, carrier gas; Ar 1.0 and H_2 0.5 ml/min, purge gas; Ar 3000 and H_2 200 ml/min.

In general, the column temperature influences retention time and separation power. Therefore, the performance characterization of the metal column in the SMVEA-AAS was evaluated at column temperatures between 1760–1870 K and atomization temperatures between 1760–1940 K. Figure 1 shows a typical unseparated graph was obtained with a column temperature of 1870 K and with an atomization temperature of 1940 K. The cadmium vapor in the argon and hydrogen carrier gas was separated from Ca, Fe and Na at 1760 K of column and atomization temperatures, as shown in Fig. 2. The retention times (t_r) and the relative standard deviations under the optimal conditions are listed in Table 1. From Figs 1 and 2, the separation of cadmium at relatively low column temperature is preferable to high temperature. Even though the relative standard deviation of the t_r values for cadmium was poor, cadmium could still be separated and determined. Profiles for Ca and Fe were not detected in the capillary tube column. At atomization and column temperatures higher than 1940 K, Ca and Fe were separated, but cadmium was then not separated from sodium. At 1760 K, it seems that the residue of Ca and Fe remained in the column. By continual heating of the column, however,

*The number of analysis; 3.

no memory effect for these elements was observed in the system.

From these results, the separation mechanism of Cd and Na at the column temperature of 1760 K may be due to the differential vapor pressure between cadmium (b.p. 1040 K) and sodium (b.p. 1156 K).[10] However, by considering the void volume (150 mm column; 0.175 ml), the actual flow rate of the carrier gas (9.01 ml/min = 0.150 ml/sec at 1760 K) and the atomization rate (<1 sec at 1760 K), the signals of Cd and Na appear in a much longer time than the throughput time (<1.17 sec) of the carrier in the column. Therefore, the separation mechanism may be the differential vapor pressure of analyte and the interaction of the elements and the inside surface of the column.

The relative standard deviation for peak area calculated for 6 repeated measurements of 15 ng cadmium was 0.8%.

Under optimal experimental conditions, cadmium in river water was determined. The calibration curve was prepared from cadmium standard solutions and the peak areas of the absorbance. The calibration graph was linear up to 15 ng. Relative standard deviations of 0.8–4.3% were obtained in the range 1–15 ng of Cd. Cadmium in spiked samples (river water) was determined. The recoveries were found to be excellent (Table 2).

As described above, the major benefits of the SMVEA with a high temperature column were; (1) direct separation of metal vapor, (2) elimination of chemical interference occurring in conventional AAS, (3) simplicity and low-cost, (4) possibility of using tandem mass spectrometry as a detector.

Consequently, the remarkable performance of SMVEA with the metal column may allow accurate determination of various elements in complex samples.

ANALYTICAL DATA

SPECTROPHOTOMETRIC DETERMINATION OF THE STABILITY CONSTANT OF THE Eu(III)–MUREXIDE COMPLEX

SHASHI JAIN and PINAKI GUPTA-BHAYA*
Department of Chemistry, Indian Institute of Technology, Kanpur, Kanpur 208 016 (UP), India

(*Received* 24 *September* 1988. *Revised* 16 *December* 1991. *Accepted* 24 *December* 1991)

Summary—The values of the stability constants of the Ca(II) and lanthanide(III) complexes of murexide reported in the literature were determined without proper correction for binding of buffer ions to the metal ion. The constants are best determined without a buffer present. Accurate values of conditional stability constants for the Eu(III)–murexide complex (relative standard deviation better than 3%), of the differential molar absorptivity of the Eu(III)–murexide complex with respect to murexide at 480 nm (relative standard deviation better than 0.5%) and of the molar absorptivity of murexide at 520 and at 506 nm (precision better than 0.4%) at pH 5.0 and 6.5 at 15, 25 and 35° are reported. The accuracy and precision of the concentration of metal ion in solution determined by using these conditional stability constants are discussed.

The stability constants of metal–dyestuff complexes are important for the detection and determination of low concentrations of metal ions. Besides their analytical use, metallochromic indicators are used to determine concentrations of free metal ion in a mixture of metal ion and ligand for determination of stability constants and rate constants of metal–ligand systems. Murexide has been used in this way for various metal ions, in particular calcium(II) and lanthanide(III), but accurate values of metal–murexide (MMu) stability constants are not always available.

In earlier determinations of metal–murexide stability constants,[1–3] buffers were used to keep the pH constant when the absorbances of mixtures of metal ions at different concentrations with murexide at fixed concentration were measured against murexide at the same total concentration, but side-reactions of the metal ion with the buffer or other background anions (from electrolytes added to keep the ionic strength constant) were ignored. The stability constants thus obtained[1–3] were therefore conditional constants. The free metal ion concentrations in solution calculated by using these conditional constants are incorrect. Balaji *et al.*[1] pointed out that the true stability constants (K) can be obtained from the conditional values K' (calculated by ignoring metal-binding by the buffer) by means of the relation

$$K = K'(1 + \sum_i K_{MB_i}[M][B]_t^i) = K'\alpha,$$

where the K_{MB_i} values are the metal–buffer stability constants and $[B]_t$ is the total concentration of buffer. It is assumed that the free buffer concentration $[B]_f$ is approximated by $[B]_t$ since $[B]_t \gg [M]_t$. If α is incorrectly determined, K may have high precision, but will have low accuracy. The authors used literature values (corrected for changes in experimental conditions) of K_{MB} to calculate α. These K_{MB} values had been obtained from pH titrations, and had good precision, but also a large systematic error arising from lanthanide hydrolysis.[4] Also, they were based on use of high concentrations of buffers (acetate and phosphate) that bind certain metal ions fairly strongly, making $\alpha \gg 1$. Even a small error in the values of K_{MB_i} makes α inaccurate to a significant extent. This could be ignored for

$$\sum_i K_{MB_i}[M]_f[B]_t^i \ll 1.$$

$[M]_f$ is calculated from

$$[M]_f = [M]_t - [MMu] - \sum_i [MB_i].$$

*Author for correspondence.

In the experiments of Balaji *et al.*[1] the minimum error in the values of K_{MB} used is 10%.[5] Since $[B]_t$ is large, the error in

$$\sum_i [MB_i]$$

is of the order of $[M]_f$. This leads to a very large relative error in $[M]_f$ and therefore in K_{MMu}. The effect of metal ion–chloride association was not considered.

The ideal buffer would have a small but accurately and precisely known stability constant for its metal-complex, and a pK value close to the desired pH, so that its concentration can be kept low. The pH values used here were 5.0 and 6.5. Some good buffers for these values weakly bind metal ions.[6] Many nitrogenous heterocycle buffers, *e.g.*, Pipes [piperazine-di(ethanesulfonic acid)] react with murexide, and Tes [*N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid], pK 7.5, seems the only choice for use at pH 6.5, but is poor because a high Tes concentration is necessitated by its low buffer capacity at this pH. The binding constant of Tes and Eu(III) is not known, but its effect cannot be ignored even if it is small, because of the high Tes concentration needed. If [Tes] is ~ 100 mM and K_{MB} is ~ 10, then if $[B]_f = [B]_t$, [MB] is $\sim 7\%$ of [MMu] (assuming use of typical concentrations). At pH 5.0, Bistris [bis(2-hydroxyethyl)imino-tris(hydroxymethyl)methane] or acetate buffer can be used, but Bistris binds several metal ions strongly.[7] A preliminary experiment (with murexide to indicate the free metal concentration) showed that the stability constant of the Eu(III)–Bistris complex is $\sim 10^5$. The stability constant of the Eu(III)–acetate complex is large,[5] with an error of 10% as estimated by the authors. The effect of lanthanide hydrolysis introduces an additional unestimated error.[4] An accurate value of the Eu(III)–acetate equilibrium constant is thus not available.

In view of all this, the Eu(III)–murexide equilibrium is best examined in the absence of a buffer. The accuracy depends on having the same pH and total murexide concentration in both cuvettes, one containing Eu(III) and the other not, since otherwise $\Delta A = \Delta\epsilon[MMu]$ will not hold for the difference in absorbance (ΔA); $\Delta\epsilon$ is the difference between the molar absorptivities of murexide and the complex. Addition of a metal solution to unbuffered murexide solution will change the pH, and restoration of this to the original value while keeping the total murexide concentrations equal must be done directly in the cuvette. The error in so doing is insignificant and less than that due to the uncertainty in K_{MB}. The values of K_{MMu} however, should be determined at a definite ionic strength maintained by a sufficiently high inert electrolyte concentration (0.100M KCl is recommended by IUPAC and IUPAB[8]). The values of K_{MMu} reported in this paper can only be used in calculating the free metal ion concentration in metal–ligand titration experiments aimed at determination of metal–ligand stability constants if these are conducted at a sufficiently high ionic strength. This is because in such titrations the concentrations of metal and ligand are varied over as wide a range as possible, and in the absence of an ionic-strength adjuster the ionic strength of the metal–ligand mixture will change considerably, since the metal ion and quite often the ligand will be charged. Such an adjustment, however, introduces the risk of side-reactions of the cation and anion of the "inert" electrolyte with the ligand and the test metal ion, respectively.

EXPERIMENTAL

Reagents

Eu_2O_3 (purity 99.9%, Sigma); murexide (analytical grade, Koch-Light) with purity checked by C,H,N analysis (Ca^{2+} was found to be absent). Other chemicals were analytical grade. All the reagent solutions were prepared in the appropriate buffer (acetate for pH 5, Tes for pH 6.5) and adjusted to ionic strength 0.100M with potassium chloride.

Europium solution. Eu_2O_3 was dissolved in hydrochloric acid and the solution evaporated to dryness. This step was repeated 3 or 4 times and the $EuCl_3$ obtained was dissolved in the buffer. The solution was standardized by weight titration of 100 μl with EDTA at pH 5.0, with Xylenol Orange as indicator.[9] The [EDTA]/[Eu] ratio was about 0.25, and the standardization error was about 0.5%.

In this and all the other experimental work, high precision was achieved by weighing to find the volumes of reagents dispensed, with careful adjustment to the desired values by dispensing from μl-pipettes. The maximum error was ~ 1 μl.

Murexide solution. A freshly prepared solution of murexide (in demineralized water) was filtered, then lyophilized. Thermogravimetry showed that the product contained no water of

hydration. A buffered solution in 0.1*M* potassium chloride at 25° deteriorated in ~1.5 hr at pH 5 and ~3.5 hr at pH 6.5. Calculation of the concentration requires the molar absorptivity (ϵ) to be known. Schwarzenbach and Gysling[2] reported its value at 520 nm, pH 8.53 and an unspecified temperature. It is expected to be dependent on pH and may depend on temperature owing to a change in solvation. We have redetermined ϵ under the experimental conditions of interest, by dissolving a weighed quantity of lyophilized murexide in 1000 ml of buffer solution (15m*M* acetate buffer at pH 5.0 and 100m*M* Tes buffer at pH 6.5) of ionic strength 0.100 (adjusted with potassium chloride) and measuring the absorbance at 520 and 506 nm against the corresponding buffer blank. The molecular weight of non-hydrated murexide was used to calculate the concentration. Two independent measurements agreed within ~0.1%.

Determination of $\Delta\epsilon$

Identical volumes of murexide solution in the acetate or Tes buffers just mentioned, of ionic strength adjusted to 0.100*M* (KCl), were added to the reference and sample cuvettes. A preliminary experiment was used to find what concentration of europium chloride solution would be needed for 100 μl of it to convert all the murexide into its europium complex, and 100 μl of the appropriate solution (in the correct buffer) was added to the murexide solution in the sample cell. An identical volume of buffer/KCl solution was added to the murexide solution in the reference cell. The absorbance of the sample solution was measured (ΔA) and divided by the total murexide concentration (which was equal to the concentration of the europium complex) to give $\Delta\epsilon$. The value was checked by making further 100-μl additions of europium solution to the sample cell and buffer/KCl solution to the reference cell and redetermining ΔA.

The following considerations show that $\Delta\epsilon$ values reported here can be used at a given pH even when the buffer and KCl are absent. (*a*) We have found that the molar absorptivity of murexide at 480 nm is 2% higher in 100m*M* potassium chloride than in Tes buffer alone. The same is true for the europium complex. Thus $\Delta\epsilon$ (EuMu – Mu) at 480 nm is not affected significantly by the presence of potassium chloride. (*b*) The Eu(III)–Tes complex, free Eu(III) and Eu(III)–Cl^- complex absorb negligibly at 480 nm. The buffer contributes very little sodium ion compared to the amount of potassium present. Thus the presence of buffer also does not affect $\Delta\epsilon$ at 480 nm. (*c*) $[K^+]_f$ nearly equals $[K^+]_t$ in both cuvettes. The value of $[Mu]_f$, however, is nearly zero in one cuvette and is non-zero in the other. Thus [KMu] is different in the two cells, but this is of negligible consequence since 480 nm is at the tail end of the difference spectrum of murexide in the presence and absence of 100m*M* potassium chloride (the difference is only ~2%). The maximum of the difference spectrum is at 518 nm, where the difference is ~8%). Values of $\Delta\epsilon$ determined in the absence of buffer agreed with those reported in Table 2, within experimental error.

Metal–murexide stability constant

Identical volumes of murexide solution were added to the two cuvettes, the concentration of murexide being such that the absorbance at 520 nm was between 0.65 and 1.05. Metal solution was then added to the sample cell and an identical volume of water to the reference cuvette, followed by enough potassium chloride solution to make the ionic strength 0.100*M* in both cuvettes. The concentration of metal was chosen so that [MMu] and $[Mu]_f$ were similar.

The pH of the test solution was adjusted by addition of dilute sodium hydroxide solution (pH ~8), the approximate volume of base needed having already been estimated in a separate experiment. The solution was mixed and the final pH checked with a microelectrode inserted into the cuvette. The pH was almost always within 0.05 of the pH of the murexide solution in the reference cuvette. If it was slightly outside this range, a measured small volume (1–2 μl) of base or acid was added by μl-pipette to bring the pH closer to the desired value, and an identical volume of potassium chloride solution ($\mu = 0.100M$, pH equal to that of the solution in the reference cuvette) was added to the reference cuvette. The liquid lost when the microelectrode is removed after the pH measurement does not affect the accuracy, because it does not alter the concentration. In spite of a small difference in pH (~0.05) between the two cuvettes the reproducibility is 1–3%. The analysis of errors given later shows that inaccurate adjustment of pH does not significantly contribute to the error.

The Hellma cells have small openings and were kept tightly stoppered during spectral

measurements and weighings. The loss by evaporation was negligible.

The absorbance of the test solution (ΔA) was measured against the murexide reference solution at the desired temperature (thermostatically controlled cell compartment) at 480 nm (the wavelength of the maximum in the difference spectrum) in a Cary 17D spectrophotometer. The mean absorbance and its standard deviation were noted from the digital read-out. The reagent concentrations were chosen to make ΔA high (>0.5) so that its standard deviation of 0.002 was insignificant.

Table 2. Differential molar absorptivity ($\Delta\epsilon$)

pH	Temperature, °C	$\Delta\epsilon \pm s$,* 10^4 l.mole^{-1}.cm^{-1}
6.5	15	1.312 ± 0.003
	25	1.289 ± 0.005
	35	1.264 ± 0.005
5.0	15	1.385 ± 0.006
	25	1.351 ± 0.006
	35	1.325 ± 0.004

*Average of six independent measurements. Concentration of murexide being saturated is in the range 3.39–$6.7 \times 10^{-5}M$. The $\Delta\epsilon$ values are independent of the absolute value of the concentration of murexide and the presence of KCl and buffer salts.

RESULTS AND DISCUSSION

Trends and comparison with literature values

The values of ϵ, $\Delta\epsilon$ and K_{MMu} are given in Tables 1, 2 and 3 respectively. The values of ϵ at pH 5.0 and 6.5 are equal within experimental error, as expected in view of the pK value of murexide. There is a small but significant decrease in ϵ with increasing temperature at both 520 and 506 nm. The ratio of the two values of ϵ can be used as an indicator of the quality of the murexide sample. Schwarzenbach and Gysling[2] reported a value of 1.35×10^4 l.mole^{-1}.cm^{-1} for ϵ at 520 nm in veronal buffer (pH 8.53) at an unspecified temperature. This value lies between the values determined by us at 15° and 25°. Schwarzenbach[10] has published the spectra of murexide at pH 7 and 13, without giving numerical values of the absorbance. An approximate estimate made from the plot shows that the difference in ϵ is $\sim 5\%$ at λ_{max}. At pH 13 two protons (p$K_{a1} = 9.2$, p$K_{a2} = 10.5$) are completely dissociated; at pH 8.53 the first dissociation is only about 17% complete, so a difference of only $\sim 1\%$ is expected between the spectrum at pH 8.53 and that at pH ≤ 7.0. The difference between the ϵ values determined by us and those reported by Schwarzenbach and Gysling[2] is of that order. The values of $\Delta\epsilon$ decrease with increase in temperature or pH, whereas the values of K_{MMu} decrease with decrease in pH or increase in temperature. The values differ significantly from those determined by Balaji *et al.*,[1] who took into account the effect of metal–buffer interaction incorrectly. For 25°, pH 5.0 and $\mu = 0.100M$, they reported $\log K = 5.42$. The value reported here is $\log K = 4.20$. The value reported by Geier[3] for 12°, pH 4.0, $\mu = 0.100M$, without consideration of metal–buffer interaction (the chemical nature of the buffer was not specified) was $\log K = 4.18$. At 15°, pH 5.0, $\mu = 0.100M$, we found $\log K = 4.28$. As $\log K$ decreases with decrease in pH our result seems in good accord with Geier's.

Table 1. Molar absorptivity of murexide

Temperature, °C	ϵ*, 10^4 l.mole^{-1}.cm^{-1}	
	At 506 nm	At 520 nm
15	1.260 ± 0.0005	1.365 ± 0.002
25	1.247 ± 0.001	1.341 ± 0.002
35	1.233 ± 0.001	1.323 ± 0.002

*Range of two independent measurements, one for $7.672 \times 10^{-5}M$ murexide and the other for $7.995 \times 10^{-5}M$.

Nature of the constants and their range of validity

In the calculation of K, we consider Mu and MMu as single species without regard to protonation. These constants are thus conditional constants dependent on pH. As is shown below, binding of K^+ to Mu and metal ion to Cl^- causes further complications. The values of K are calculated assuming that a 1:1 complex is

Table 3. Log$K$ of Eu(III)–murexide association equilibria

pH	Temperature, °C	$\log K \pm s$*
5.0	15	$5.278_4 \pm 0.006_4$
	25	$5.205_0 \pm 0.007_7$
	35	$5.143_6 \pm 0.004_6$
6.5	15	5.525 ± 0.013
	25	5.435 ± 0.011
	35	5.365 ± 0.012

*Average of 6 or 7 measurements; titration points for [MMu] = 60% of [Mu]$_t$ or [M]$_t$ are omitted. Inclusion of these points increases the value of s. These values do not include the effect of binding of K^+ to murexide and that of Eu(III) to Cl^-, but these conditional stability constants yield correct values of free Eu(III) in solution (see Results and Discussion).

formed, which appears to be valid over the range of concentrations explored ($3–4 \times 10^{-5}M$ [MMu], $2.5–5 \times 10^{-5}M$ $[M]_f$, $3–5 \times 10^{-5}M$ $[Mu]_f$) because the K_{MMu} values obtained are the same within 1–3% at a given temperature and pH.

Estimate of precision

The maximum error of the volume measurements made by weighing was 5×10^{-5} ml (maximum weighing error 0.05 mg) and is negligible. The error in absorbance measurement was estimated from the fluctuation in the digital read-out, and an absorbance of 0.6 or above had a maximum error of ~0.3%, equivalent to a relative standard deviation (s) of ~0.1% (99% confidence). The europium concentration has a relative standard deviation of ~0.5%, which is wholly due to the end-point error and the burette reading error. The EDTA concentration has a maximum error of ~0.5%, arising from the purity of the EDTA used, the weighing error and the error in making up the solution to standard volume. This error does not affect the precision but alters the accuracy since only one EDTA solution is made. The error in the volume of europium solution taken for titration is negligible because the volume is measured by weighing. The error in measuring the molar absorptivity depends on the absorbance (maximum error ~0.3%) and the murexide concentration error (weighing error ~0.2%, volume error in dilution to 1000 ml ~0.04%), and thus is ~0.3% maximum, equivalent to a relative standard deviation of ~0.1% (the value observed, Table 1).

From these values it can be calculated that the relative standard deviation of K_{MMu} is about 1.2%, in agreement with the precision found experimentally. We conclude that adjustment of the pH directly in the cuvette does not lead to any additional error. The maximum error in the pH was ±0.05, the reading error of the pH-meter.

The values of $\log K_{MMu}$ in Table 3 are quoted to four (pH 5.0) and three (pH 6.5) decimal places even though the third (pH 5.0) and the second (pH 6.5) places respectively are in error. This is done to avoid truncation errors. The quantity of eventual interest to us is $[M]_f$, which is calculated from $[M]_f = [MMu]/[Mu]_f K_{MMu}$ and has a calculated error of ~1.6%. Any truncation should be done at this stage.

Effect of binding of potassium by murexide

Potassium chloride at $0.1M$ concentration was used to maintain the ionic strength constant. Though the affinity of murexide for potassium is less than that for Eu(III), it cannot be ignored. The difference $[Mu]_t - [MMu]$ gives only the apparent concentration of free murexide, $[Mu]'_f$. The true value is $[Mu]_f = [Mu]'_f - [KMu]$. [KMu] is given by $K_{KMu}[K^+]_f[Mu]_f$; since $[K^+] \sim 10^4[Mu]$, $[K^+]_f \simeq [K^+]_t$ and $[Mu]_f = [Mu]'_f/(1 + K_{KMu}[K^+]_t) = [Mu]'_f/\alpha_{Mu(K^+)}$. As the value of K_{KMu} in aqueous medium is not known, $[Mu']_f$ of necessity remains a conditional concentration. However, a crude value for the constant might be estimated from the reported values for non-aqueous media[11] and the difference in dielectric constant, and appears likely to be in the range 1–25. If so, $\alpha_{Mu(K^+)}$ would be in the range 0.1–2.5 and would change $[Mu]_f$ by a factor of between ~0.3 and 0.9.

Inability to calculate α prevents us from calculating the true value of $K_{EuMu'}$ but does not affect the value of free Eu(III) ion concentration determined in a solution by use of murexide as indicator. It can be readily shown, using $[Mu]'_f = \alpha_{Mu(K^+)}[Mu]$ that the measured values of $\Delta\epsilon$ (Table 2) equal $\{\epsilon_{EuMu} - [\epsilon_{Mu}(1/\alpha) - \epsilon_{KMu}(1 - 1/\alpha)]\}$, where $\alpha = \alpha_{Mu(K^+)}$, and that $\Delta A = \Delta\epsilon[EuMu]$ holds, even if $\epsilon_{Mu} \neq \epsilon_{KMu}$. At 480 nm, however, ϵ_{Mu} differs negligibly from ϵ_{KMu}. Therefore [EuMu] calculated as $(\Delta A/\Delta\epsilon)$ is correct and is unaffected by $\alpha_{Mu(K^+)}$. The conditional K_{EuMu} reported in Table 3 uses $[Mu]'_f$ for calculation. If $[Mu]_f$ were used instead, we would obtain $K_{EuMu}(\text{corrected}) = \alpha_{Mu(K^+)}K_{EuMu}$ (conditional). Then $[Mu]'_f K_{EuMu}(\text{conditional}) = [Mu]_f K_{EuMu}(\text{corrected})$. We conclude that $[Eu]_f$ calculated as $[EuMu]/\{[Mu]'_f K_{EuMu}(\text{conditional})\}$ is unaffected by the factor $\alpha_{Mu(K^+)}$.

Effect of side-reactions of Eu(III)

The value of the free europium concentration used in calculating K_{MMu} obtained by subtracting [MMu] from $[M]_t$ is not its true value, but is a conditional quantity $[M']_f$, because of side-reactions with chloride. $[M']_f = \alpha_{M(Cl)}[M]_f$ where $\alpha_{M(Cl)} = \{1 + \beta_1[Cl^-]_t + \beta_2[Cl^-]_t^2\}$ (β_1 and β_2 are the stability constants for $EuCl^{2+}$ and $EuCl_2^{2+}$). The reported values[12–18] of β_1 and β_2 were determined at high ionic strengths, and after being corrected to $\mu = 0.1M$ yield a temperature-independent mean value of $\alpha = 1.088 \pm 0.01$ for $\mu = 0.1M$ (KCl).

In contrast to the effect of $\alpha_{Mu(K+)}$, that of $\alpha_{M(Cl)}$ can be corrected for, but since inability to calculate $\alpha_{Mu(K+)}$ already prevents us from calculating the true K_{EuMu}, we do not apply the correction due to $\alpha_{M(Cl)}$. It turns out once again, that the value of $[Eu]_f$ in a solution, determined by use of murexide as indicator, is not seriously affected by $\alpha_{M(Cl)}$. If we use the conditional K_{EuMu} value reported in Table 3 in calculating the ratio $[EuMu]/\{[Mu]'_f K_{EuMu}\}$ we obtain $[Eu]'_f$. The desired quantity $[Eu]_f$ can then be calculated from $[Eu]'_f$ by using the value of $\alpha_{M(Cl)}$. The precision of $[Eu]'_f$ is only slightly worse than that of K_{EuMu} (the worst is ~3%, Table 3). The precision of $\alpha_{M(Cl)}$ as calculated from the mean values of $\beta_{1,2}$ for the Eu(III)–Cl^- association given in 16 reports is ~1%. Twelve of these values differ from the mean value by ~1%, 3 by ~3%, and only one[18] differs from it significantly (~7%), but that work perhaps detected only one of several Eu(III)–Cl^- complexes. The precision of $\beta_{1,2}$ in the individual reports varies, the best being ±4%.[14] The accuracy and precision of $[Eu]_f$ is thus slightly inferior to that of $[Eu]'_f$.

Potential use of K_{MMu}

In metal–ligand mixtures of various concentrations of metal and ligand, values of $[M]'_f$ and $[M]_f$ can be calculated from K_{MMu}. The titration data can then be analysed by a computer program to obtain the best values of the stability constants of the metal–ligand complexes. In our laboratory, we have successfully used this technique to determine the β-values for Eu(III)–amino-acid complexes.[19] Determination of $[M]_f$ by use of murexide as a metallochromic indicator is also useful in stopped-flow or temperature-jump relaxation experiments aimed at the determination of the rate constants of metal–ligand interaction.

A LEAD(II) ION SELECTIVE ELECTRODE VIA A METAL COMPLEX OF POLY(HYDROXAMIC ACID)

K. ANUAR* and S. HAMDAN

Department of Chemistry, Faculty of Science and Environmental Studies, Universiti Pertanian Malaysia, 43400 UPM Serdang, Selangor, Malaysia

(*Received* 6 *September* 1991. *Revised* 6 *November* 1991. *Accepted* 6 *November* 1991)

Summary—A new lead(II) electrode has been constructed with poly(hydroxamic acid) (PHXA) as the active material and silicone rubber as the supporting material. The electrode gave near Nernstian response over the concentration range 4×10^{-5}–$1 \times 10^{-2}M$ lead(II). The detection limit of the electrode is approximately $4 \times 10^{-6}M$ and the electrode works well in the pH range 4.5–6.0. The response time was 50–120 sec over the whole concentration range and the electrode has a working life of at least 4 weeks. Iron(III) severely poisoned the electrode membrane. Nickel(II) and mercury(II) gave very strong interference compared to copper(II), silver(I), cobalt(II), sodium(I), potassium(I), zinc(II) and cadmium(II) which gave some or little interference. Values determined with atomic absorption (AAS) and a commercial lead(II) electrode were in good agreement with those measured with the lead(II) electrode reported here.

Ion selective electrodes (ISE) have been the subject of great interest over the past few years and their development has opened up the field of potentiometry. The field has developed rapidly because the analysts need rapid, accurate and low-cost analysis. Many compounds, either organic or inorganic, have been used for molecular recognition in ion selective electrodes[1–6] and some of these have been successfully developed commercially.[7–9] The aim of this study was to explore the use of a metal complex of the compound poly(hydroxamic acid) as a cationic sensor in ion selective electrodes. It is known that poly(hydroxamic acid) forms stable complexes with many metal ions.[10,11] Its use in analytical applications has been extensively demonstrated in extraction, purification and separation of metal ions.[12–14]

EXPERIMENTAL

Reagents

All reagents including lead nitrate were analytical grade. Solutions were prepared with doubly distilled water. Poly(hydroxamic acid) (PHXA) was prepared as described in the literature.[15] Silicon rubber (Selleys) is commercially available and was directly used.

Instruments

The emf values were measured with an Orion Research Model 601A/digital/Ionalyzer and a TOH pH meter HM7B was used for pH measurements. In the comparison study, an atomic-absorption spectrometer model IL 651 was used. A saturated calomel electrode (SCE) was used as reference electrode for all emf readings.

Preparation of membranes and electrode

Poly(hydroxamic acid) is not soluble in most organic solvents, so it is impossible to prepare a thin membrane by solvent casting such solvents. Preparations of homogenous membranes made with PHXA were not stable. Hence, heterogenous membranes were made by using silicon rubber as a supporting matrix and were found to be satisfactory.

PHXA was ground in a mortar and then mixed with silicone rubber. The mixture was spread on a filter paper, covered with another filter paper and pressed gently between two glass plates before leaving to dry. When the membrane had dried and hardened, a disc of 1.0-cm diameter was cut out and the filter papers were detached. A large number of membranes of different compositions (thickness 0.5–0.8 mm) were prepared. The membranes were fixed at

*Author for correspondence.

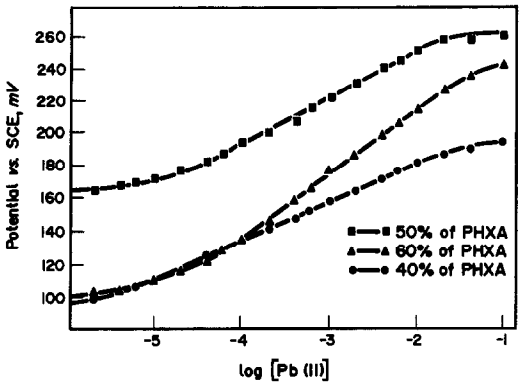

Fig. 1. Response curves of lead selective electrode for different composition of PHXA in the membrane.

one end of a glass tube with silicon rubber and left to dry.

The dried membrane was then equilibrated with 0.1M lead nitrate solution for a week and clean platinum was used as the internal electrode. The 0.1M lead nitrate solution was used as reference solution for the lead selective electrode and a saturated calomel electrode (SCE) was used as reference for all emf measurements at $27 \pm 0.1°$.

RESULTS AND DISCUSSION

Dependence of electrode potential on log [lead(II)]

Typical calibration curves of lead selective electrodes in the concentration range 1×10^{-6}–$1 \times 10^{-1}M$ lead(II), using different compositions of PHXA in the membranes are shown in Fig. 1. The slope, Nernstian limit and detection limit for each composition of the electrode are presented in Table 1.

Results from Table 1 showed that membranes with 50% PHXA content gave slopes which are closest to the theoretical Nernstian slope. This was then selected for further studies. Although membranes with 40 and 60% give a non-Nernstian slope, the responses are linear over the concentration range 4×10^{-5}–$1 \times 10^{-2}M$. However a membrane with 40% PHXA content shows a better Nernstian response. The table also shows that after a few weeks the slope changed for specific compositions. This is probably due to the effect of ageing on the asymmetry potential of the membranes, as observed by Wilson *et al.*[16]

Response time, reproducibility and stability

The response time for emf measurements during calibration of lead selective electrode was not studied in detail. At concentrations of 1×10^{-4} and $1 \times 10^{-5}M$, stable readings were obtained in about 50 sec or less. With more dilute solutions a 1–2 min period was required to obtain stable readings. The potential remains stable for at least 10 min. It was found that measurements were more stable with slow rather than fast stirring.

The standard potentials (E') of the electrode were reproducible to ± 1 mV over 5 hr. The standard potentials drifted about ± 7 mV over the first three weeks of its usage. After 3 weeks of its usage, the performance of these electrodes

Table 1. Slope, Nernstian limit and detection limit[17] of lead selective electrodes using various membrane compositions

Composition of PHXA		1st week	2nd week	3rd week
40%	Slope (mV/decade)	22.2	21.7	22.2
	Nernstian limit ($\times 10^{-5}M$)	0.9	1.0	0.5
	Detection limit ($\times 10^{-6}M$)	1.1	1.5	1.0
50%	Slope (mV/decade)	29.6	28.1	26.5
	Nernstian limit ($\times 10^{-5}M$)	4.0	1.8	2.0
	Detection limit ($\times 10^{-6}M$)	8.0	4.8	2.4
60%	Slope (mV/decade)	39.3	36.1	35.0
	Nernstian limit ($\times 10^{-5}M$)	4.4	4.2	9.5
	Detection limit ($\times 10^{-6}M$)	10.0	6.5	22.0

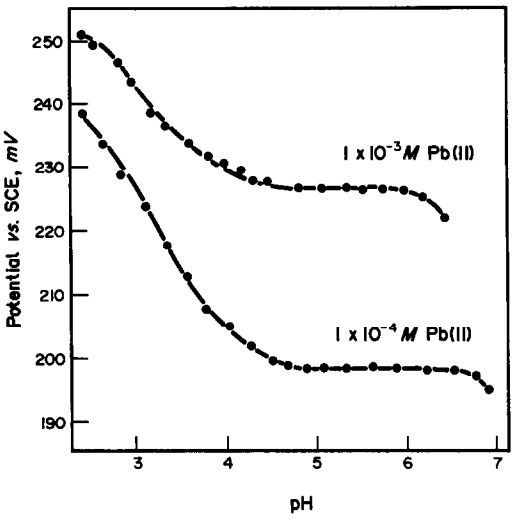

Fig. 2. Response curves of pH dependence of lead selective electrode on membrane potential.

deteriorated and reconditioning of the membrane was necessary. The life-time of these electrodes is approximately 3 to 4 weeks.

Effect of pH on membrane potential

The pH-dependence of the electrode response has been investigated at two lead(II) concentrations, 1×10^{-4} and $1 \times 10^{-3}M$, and the results are shown in Fig. 2. This figure shows that the pH working range of the electrodes is between pH 4.5 and 6. The positive shift of potential at pH below 4.5 is most probably caused by the proton interference and the negative potential shift in basic solution is observed at a pH greater than 6, where the lead hydroxide starts to precipitate.

Table 2. Selectivity coefficient, K^{pot}_{PbB}, for lead selective electrode in $1 \times 10^{-3}M$ solutions of interfering ions B

Interfering ions B	K^{pot}_{PbB}
Ni(II)	0.640
Cd(II)	0.023
Zn(II)	0.032
Cu(II)	0.20
Ag(I)	0.061
Hg(II)	0.830
Co(II)	0.070
Na(I)	0.120
K(I)	0.240

Selectivity of electrodes

The selectivity of the electrode with respect to copper(II), cadmium(II), nickel(II), zinc(II), iron(III), silver(I), mercury(II), cobalt(II), sodium(I) and potassium(I), were checked by the mixed solution method in lead(II) in the presence of a fixed concentration ($1 \times 10^{-3}M$) of the interfering ions.[17] The selectivity coefficient, K^{pot}_{PbB} of the electrode for each interfering ion is presented in Table 2. It was observed that in the presence of iron(III) at a concentration of $1 \times 10^{-3}M$, there was no emf response for various concentrations of lead(II) used. This suggests that iron(III) severely poisoned the electrode membrane and may be due to the strong complexation of iron(III) with PHXA compared to lead(II). Nickel(II) and mercury(II) gave very strong interference compared to copper(II), cobalt(II), silver(I), sodium(I), potassium(I), zinc(II) and cadmium(II) which gave some or little interference. This indicates that the electrode can give a good

Table 3. Comparison study for determination of lead(II) prepared sample solution by using atomic absorption spectroscopy (AAS), Orion commercial lead(II) selective electrode (OPb-SE) and prepared lead(II) selective electrode (Pb-SE)

		Concentration of lead(II), M

selectivity of iron(II) in the presence of these ions.

Comparison study with atomic-absorption spectrometry (AAS) and Orion lead selective electrode (commercial electrode)

A comparison of the results obtained for lead(II) determination of prepared sample solutions with other procedures is given in Table 3. From Table 3, it is shown that the lead selective electrode prepared (Pb–SE) performed well as compared with Orion commercial electrode (OPb–SE) and with atomic absorption spectrometry. Our electrode provides an excellent alternative to the more expensive commercial electrodes, especially when the risk of damage to the membrane is high.

CONCLUSION

From the study, it was found that the PHXA metal complex of lead(II) has the ability to perform as a sensor in lead selective electrodes. It is cheap and can be easily constructed in a normal analytical laboratory. Its performance is satisfactory and it provides an excellent alternative to the more expensive commercial electrodes.

(*Received* 25 *November* 1991. *Revised* 9 *January* 1992. *Accepted* 7 *February* 1992)

Summary—An optical waveguide sensor for the detection of acid vapors is described. The chemically sensitive reagent coating consists of bromothymol blue indicator suspended in a Nafion polymer film. The sensor uses a 562 nm LED source and a phototransistor detector. Response to hydrochloric acid and hydrogen sulphide vapors is both rapid and reversible, with an estimated detection limit for hydrogen sulphide of less than 15 ppm. The sensor exhibits generalized response to protonic acid vapors, but does not produce an indicator response to carbon dioxide, even at large concentrations (1100 mg/l.) in the presence of water vapor. The sensor exhibits a systematic interference from water vapor which may be corrected by a differential approach, either using a reference sensor (Nafion/no indicator) or by monitoring sensor response at two wavelengths.

Chemical sensor technologies have been used increasingly for the detection or monitoring of toxic/hazardous vapors in the workplace environment. Applications include portable sensors or dosimeters to monitor individual personnel exposure, or fixed-site sensors to monitor ambient concentrations of chemical species. Sensors under development include elecrochemical piezoelectric and optical sensors.[1-5] The great attraction toward these technologies is their capability for rapid, sensitive response at low cost.

The need for a reliable sensor for the detection of toxic acid vapors in ambient atmospheres has led to the research efforts reported herein. The specific application of interest was the development of an end-of-service sensor/alarm for protective equipment, such as gas masks, *etc.* Some of the technologies mentioned above have demonstrated ability to detect acid vapors.[6-13] Optical techniques have the advantage of being potentially less expensive, more selective and less susceptible to electromagnetic interference.[3,14] An absorbance-based optical sensor for the detection of acid vapors has been developed and evaluated using optical waveguide (OWG) technology. Relevant information concerning the OWG operating principles and the chemical reagents employed are presented, as well as discussions of possible sensor configurations to correct for interferences and/or humidity effects.

THEORY AND DESIGN CONSIDERATIONS

Theory

The sensitivity of the sensor is dependent on the optical properties of the reagent and/or analyte, and on the concentration of the optically active component in the light path.[14] Fiber optic or optical waveguide (OWG) sensors can be classified as absorbance/reflectance, or fluorescence-based sensors. The sensitivity of the former techniques can be improved by (1) increasing the concentration of absorbing species, or (2) maximizing the interaction of the incident light with the reagent, *i.e.*, by taking advantage of multiple internal reflection (MIR) light propagation. A typical MIR waveguide sensor consists of a thin, optically transparent substrate coated with a chemically sensitive reagent film. A light source focused on one end of the waveguide introduces radiant energy of an appropriate wavelength (and bandwidth) to the waveguide. This radiant energy then propagates by multiple internal reflection along the length of the waveguide. At the opposing end of the waveguide, the exiting light is focused onto an optical detector. The light wave can interact with the reagent film either directly as it passes through the film, or via an evanescent wave perpendicular to the direction of propagation if the light wave is reflected at the film/substrate

*Authors for correspondence.

interface.[15] Any change in the optical properties of the reagent film that result in a change in the intensity of light reaching the detector constitutes a sensor response. These changes can include absorbance, scattering, and fluorescence/luminescence. If these changes occur in response to chemical stimuli, then the OWG acts as a chemical sensor. The use of such devices as chemical sensors has been described previously.[16–18]

The ideal sensor characteristics include the following: rapid, sensitive response; reproducibility; selectivity; small size/portability; low cost and low power consumption. For optical sensing systems, the critical components include the colorimetric reagent(s), the radiative source, the waveguide and its geometry, and the detector. Each of these system components will be considered with respect to the impact on the desirable sensor characteristics listed above.

Source/detectors

The ideal source must exhibit stable output of sufficient intensity in the spectral region of interest. Light emitting diodes (LEDs) are readily available at low cost from commercial sources, having maximum emission output in the spectral region between 550–680 nm. The LEDs have a squarewave output, which provides higher optical output than sine wave outputs. Typical bandwidths for these sources are in the order of 10–50 nm. While these sources are not as intense as others (*e.g.*, lasers or tungsten lamps), they are of sufficient intensity to achieve the required response sensitivity/detectability for the absorbance-type sensor considered here.[16–18] As detectors, inexpensive phototransistors are available which provide adequate sensitivity to light in the visible region.

Colorimetric reagents

The most familiar acid sensitive colorimetric reagents are pH indicators. These materials exhibit changes in their absorbance properties in the visible region upon exposure to acid vapors.[3] Thus, these materials were studied initially to determine whether any suitable reagents could be identified for use with the OWG sensor. The following criteria were used in the selection process:

(1) The reagent must be stable in air.

(2) The reagent must form thin films with good adhesive properties when suspended in polymer films.

(3) The spectral properties of the reagent indicator must be compatible with the sensor source/detector components under consideration; *i.e.*, the resulting film must exhibit a color change in the visible region upon exposure to acid vapor.

EXPERIMENTAL

Materials

A variety of polymers and pH indicators were tested as potential sensor films and are listed in Table 1(a). Among the selected polymers were polyisobutylene (PIB), polyvinyl alcohol (PVA), polyvinylpyrrolidone (PVP), polyethylene glycol (PEG), polyethyleneimine (PEI), and a perfluorinated sulphonic acid polymer,

Table 1. Indicator and polymer properties

A. Coating materials—polymers and indicators

Polymers	*MW range*	*Indicators*	*pH transition range*
PIB	380,000	Thymol Blue	1.2–2.8; 8.0–9.6
PVA	31–50,000	Bromothymol Blue	6.0–7.6
PVP	40,000	Bromcresol Green	3.8–5.4
PEG	600/1500	Litmus	5.0–8.0
PEI	50–60,000	Methyl Red	4.8–6.0
Nafion	(unknown)	Bromcresol Purple	5.2–6.8
		Phenolphthalein	8.0–9.6

B. Indicator/polymer film behavior

Coating	*Dry color*	*Acid exposure**	*Base exposure*
BTB/NAF†	violet	yellow → violet(R)	yellow → blue (R)
BCG/PVP	blue/green	blue → yellow (N)	yellow → blue (R)
MR/PEG	red orange	orange → purple (R)	orange → yellow (R)
BCG/PEG	yellow	yellow → colorless (R)	yellow → blue (R)

*The acid and base responses were reversible (R) or non-reversible (N), as indicated.

†The BTB–NAF film dries in the R form, but can be converted to the Y^- form by exposure to water vapor.

Nafion (NAF; 5% solution in alcohol). The Nafion was obtained from Solution Technologies; the remaining polymer materials were obtained from Aldrich. All materials were used as received. With the exception of PIB, these polymers contain proton donor and/or proton acceptor functionalities. One of these polymers (Nafion) is an ionomer containing sulphonic acid groups attached to a perfluorinated polyethylene backbone.[19] Nafion is of particular interest because it can be processed into thin membranes that would be well suited to an optical sensor. These materials were evaluated on the quality of the resulting films when cast on a glass surface.

Indicators were selected based on the observed color transitions and on the pH transition ranges. Available indicators included thymol blue, bromothymol blue, litmus, phenolphthalein, Methyl Red, bromcresol purple, and bromcresol green (see Table 1). The majority of these indicators undergo a visible color change when exposed to slightly acidic conditions. The notable exceptions are phenolphthalein (transition in the basic range) and thymol blue (transition in the low pH/strong acid range).

Optical electronic components (LEDs, phototransistors) for the construction of the OWG were obtained from Newark Electronics.

Equipment

UV–Vis absorbance spectra (300–750 nm) were obtained in the NIU Chemistry department with a Minichrom Scanning Monochromator (Optometrics), using a tungsten lamp source and a PM tube detector. A sample flow cell was constructed using 1.0 cm × 1.0 cm quartz tubing, with inlet and outlet tubes fixed onto the cell to permit introduction of acid vapors during the spectral scan.

Waveguide studies were performed using an OWG electronics module built by the NIU Chemistry Electronics shop (schematic available upon request). The circuitry is similar in design to that described previously.[16] It consists of a pulsed LED source to minimize thermal drift, and a series of amplification/rectification stages to filter and amplify the PT detector output signal. Amplification of the signal can be controlled using a 10-turn 100 K variable resistor (GAIN), and the zero can be adjusted with a NULL OFFSET potentiometer. The 0% and 100% transmittance signals are adjusted to be compatible with the data acquisition computer. Data collection for the spectral and waveguide studies was performed with a Hyundai 286 microcomputer via an IBM data acquisition and control adapter (DACA) card using software developed at the NIU Chemistry department.

Coating selection/screening

Solutions were prepared by dissolving the polymers and indicators in suitable solvents, usually methanol or methanol/water. Final solutions contained approximately 1 mg/ml each of polymer and indicator. Test films were prepared by casting a small volume of the solution(s) on the surface of clean glass slides and allowing the solvent to evaporate. The resulting films were then evaluated based on film quality and response characteristics, as described below. These films were then exposed to HCl vapor to determine relative response behavior. The results of these preliminary screening tests are summarized in Table 1(b). Several of the indicators failed to exhibit an acceptable color change upon exposure to the acid (phenolphthalein, litmus). The remaining indicators gave good visible color-change response to acid vapor in some polymers but not in others; PIB-indicator films gave no response, which supports the observation that the supports the observation that the support polymer must exhibit some proton donor–acceptor behavior in order to activate the proton-transfer indicator color change. Some acid response was exhibited by the PEG-indicator films, but the PEG produced viscous, oily films that were difficult to work with in our sensor application. Previous work using thymol blue in PVA-clad optical fibers cited good sensitivity to acid vapors;[10] preliminary results using PVA films in our lab, however, showed poor reversibility. The most promising results were obtained using the bromcresol green/polyvinylpyrrolidone (BCG–PVP) and bromothymolblue/Nafion (BTB–NAF) films. Both of these indicator films had good adhesion properties and dried to produce robust thin films exhibiting uniform surface coverage. The BCG–PVP film exhibited a blue color upon drying, typical of the basic form of the indicator. Exposure to acid resulted in an irreversible conversion to the acid form (yellow) which persisted after removal from the acid vapor. Subsequent exposure to NH_3 vapors produced a blue color, which reverted to yellow upon exposure to dry air. This indicator film would be suitable as a dosimeter for acid gases or for

on/off alarm applications, but was not considered further for these studies. In its acid-treated form, the BCG–PVP film might be used as a reversible NH_3 sensor.

The various structures for the bromothymol blue indicator dye are given in Fig. 1, along with the absorbance maxima, λ_{max}, the approximate pK_a for transitions between forms (in aqueous solution), and the associated visual colors. It is worth noting that the transition from the blue form (B^{2-}) to the yellow form (Y^-) takes place under very slightly basic conditions in aqueous solution, but the transition from the Y^- form to the red (R) form requires very acidic (4–5*M*) conditions. The BTB–NAF film dried in the fully protonated form (R) which is red–violet in color, but exposure to water resulted in conversion to the yellow form (Y^-). This film exhibited reversible response to hydrochloric acid vapor. Subsequent exposure to acid vapor resulted in conversion to the R form, which recovered slowly to the Y^- form after removal from the acid vapor. Because of the reversible nature of this indicator film to acids, it was selected for futher evaluation as an acid vapor sensor.

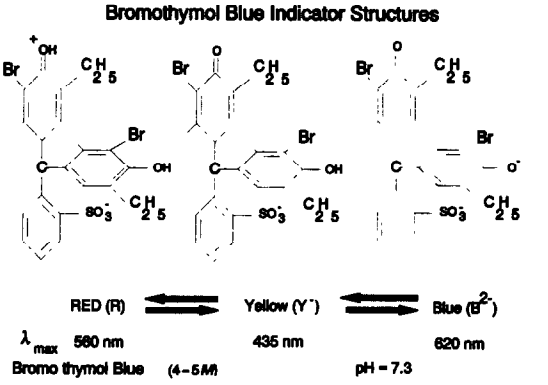

Fig. 1. Structural formulas for the three forms of bromothymol blue dye indicator, with corresponding absorbance maxima λ_{max} and transition ranges in aqueous solution.

Spectral studies

The BTB–NAF coating was studied by UV–Vis spectrophotometry to determine appropriate wavelengths to be used for the selection of components in the construction of an OWG sensor. A thin film was coated on a quartz slide, which was placed inside the flow cell. Spectral scans were performed while acid vapors of varying concentrations were passed through the cell. Acid vapors were generated by bubbling dry air carrier through a flask containing hydrochloric acid solutions of varying concentrations.

The spectra for the film are shown in Fig. 2 under exposure to hydrochloric acid vapors from solutions of different concentration. The BTB–NAF film exhibits two absorbance maxima, each of which exhibits acid vapor concentration dependence. The first maxima occurs at 435 nm and corresponds to the Y^- form of the indicator. As the film is exposed to increasing concentrations of acid vapor, the 435-nm peak decreases and undergoes an apparent slight blue shift, while there is a corresponding increase in absorbance at 562 nm corresponding to the

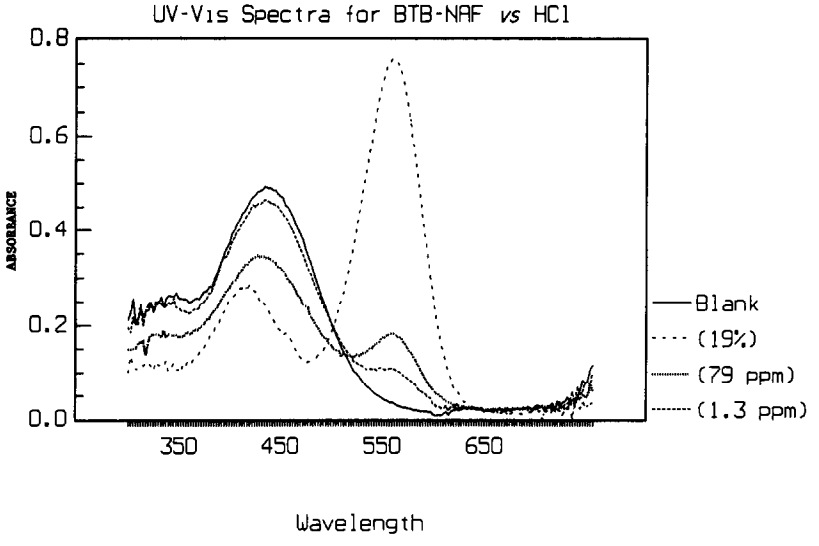

Fig. 2. UV–Vis spectra of bromothymol blue indicator in Nafion film exposed to (1) dry air (2) 12*M* HCl (19% vapor) (3) 5*M* HCl (79 ppm vapor) and (4) 2*M* HCl (1.3 ppm vapor).

R form of the indicator. The absorbance wavelengths for the indicator suspended in the Nafion film are essentially identical to the corresponding λ_{max} for the aqueous forms of the indicator.

OWG sensor construction

Using the results of the spectral studies, a yellow LED having maximum emission intensity at 562.5 nm was selected as the source. This wavelength corresponds to the absorbance maximum for the indicator film in the R form. The detector consists of a phototransistor (PT). The OWG substrate consists of a thin-walled glass capillary tube (75 mm long, 1.2 mm o.d., 0.2 mm wall thickness) coated with the film. A small diameter plug was inserted inside the capillary to block light travelling down the center of the tube. Thus, only light that has traversed the waveguide via reflection inside the capillary walls will reach the photodetector. The LED–OWG–PT components are held in rigid contact using plastic rods that have been drilled out to accommodate the optical components and the waveguide. The entire sensor configuration is enclosed by a glass tube having inlet/outlet ports to introduce/vent the carrier/acid vapor gas streams.

OWG test procedures

Acid vapor studies at NIU were performed by bubbling carrier gas (dry N_2) through a vessel containing hydrochloric acid solutions of varying concentration. The voltage output from the OWG electronics was monitored using the computer data acquisition system while the sensor was alternately exposed to dry air and acid vapor. Increases in acid (H^+) concentration in the film will shift the indicator from the Y^- to the R form, with a corresponding increase in absorbance at the 562-nm wavelength. This translates into a decrease in light reaching the PT detector (decreased voltage output). Typical data curves are presented and discussed in the Results and Discussion section.

Additional tests were performed at Transducer Research, Inc. facilities (Naperville, IL).

RESULTS AND DISCUSSION

Sensor response is determined by an increase in absorbance at 562 nm for the R form of the indicator, which will produce a decrease in light intensity reaching the PT detector. The long-term and short-term waveguide response to acid vapors is not straightforward, and appears to be dependent on three separate phenomena. These phenomena include water sorption by the Nafion, irreversible interactions between the acid vapor and the Nafion, and the interaction between the indicator and the acid vapor. These factors are discussed in more detail below.

Nafion–water response

Acid vapors were generated by bubbling dry carrier gas through an aqueous solution of hydrochloric acid. The concentration of hydrochloric acid in the vapor phase was varied by serial dilution of the hydrochloric acid solution in the bubbler. This procedure obviously produces water vapor as well as acid vapor. Thus, it was necessary to determine the sensor response to water vapor, if any, to determine possible interference effects. The water tests are summarized graphically in Fig. 3. In Fig. 3(a) (insert) the response of a Nafion film to water vapor is presented. The introduction of only water vapor to the Nafion coated waveguide results in an increase in PT signal of nearly 40%, or 2 V. This increase in signal is reproducible upon repeated exposure to water vapor. To determine if this effect is due to condensation of water from a nearly saturated vapor stream, tests were performed, using water bubblers at two different temperatures. The results are shown for a BTB–NAF coated sensor in Fig. 3(b). The first 4 exposures represent responses to nearly saturated water vapor, produced from a bubbler at room temperature, and produced significant increases in OWG sensor signal. Five subsequent exposures were made using a bubbler that was maintained in an ice bath, and produced only a slight increase in signal. This increase in response to water vapor constitutes a potential interference, and also prevents us from determining the inherent sensitivity of the sensor to acid vapor. Initial attempts to dry the vapor stream with a desiccating agent were successful in reducing the response to water vapor. However, these drying agents also appeared to remove acid vapor, and response of the sensor to acid streams was dramatically reduced when drying tubes were utilized in-line. All subsequent acid vapors were generated from solutions maintained in an ice bath to reduce the response from water vapor.

Acid vapor generation

Vapor streams of hydrochloric acid (g) were produced by bubbling carrier gas (N_2) through

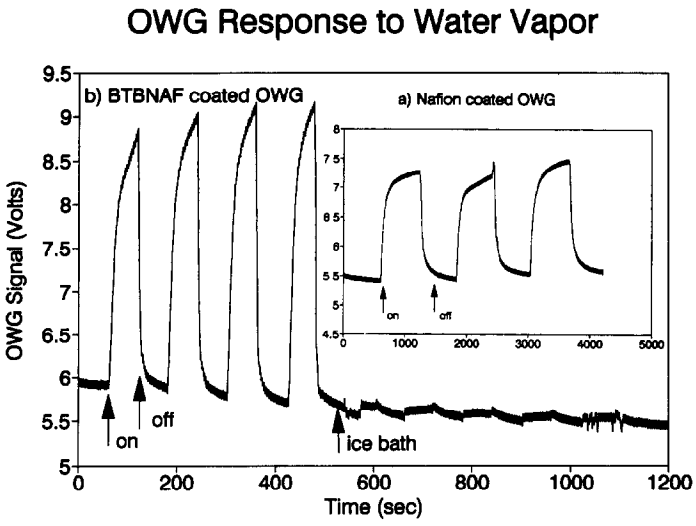

Fig. 3. Response of the OWG to water vapor. In the insert (a), the response of a Nafion coated waveguide to water vapor from a bubbler at room temperature; (b) the response of a BTB–NAF coated waveguide to water from a bubbler at room temperature, and the reduced response when the bubbler temperature is reduced to 0° in an ice bath.

hydrochloric acid solutions of varied concentration. The concentration of hydrochloric vapors produced in this manner have been estimated using thermodynamic data (free energy, activity coefficients) and equations from Ref. 20 and 21 and are summarized in Table 2. The efficiency of vapor generation was estimated by bubbling nitrogen at a constant flowrate (155 ± 5 ml/min) through a known volume of 6.0*M* hydrochloric acid solution over a 24-hr period, at an ambient temperature of $\approx 19.5°$. The amount of hydrochloric acid stripped from the solution was determined by titrating aliquots of the hydrochloric acid solution before and after bubbling. After correcting for volume changes in the bubbler solution, the hydrochloric acid vapor generated from a 6.0*M* hydrochloric acid solution was calculated to be 0.34 mg/l. (228 ppm). This can be compared to the value of 0.52 mg/l. calculated at 25° from thermodynamic data,[20] and corrected for the variation in activity coefficients as a function of temperature.[21] Taking into consideration the difference in temperature, the vaporization efficiency at 20° for the 6.0*M* hydrochloric acid solution is in the order of 80%. Thus, the estimated concentrations in Table 2 represent upper limits only; hydrochloric acid vapor concentrations reported in this work have been corrected to account for vaporization efficiency.

Based on the estimations discussed above, a 2.0*M* bubbler solution (16% v/v solution; 2.08 molal) at room temperature (20°) will produce an acid vapor concentration of approximately 0.0019 mg/l. (1.3 ppm). Thus, the estimated hydrochloric acid vapor concentrations used to construct Fig. 2 are as follows: blank (0.0 mg/l.; 0.0 ppm), 2.0*M* (0.0019 mg/l.; 1.3 ppm), 5.0*M* (0.12 mg/l.; 79 ppm), 12.0*M* (290 mg/l.; 19%). For the single pass absorbance measurements presented in Fig. 2, a detection limit for hydrochloric acid vapor of < 1 ppm is estimated,

which corresponds to vapor produced from a bubbler containing $\simeq 1.5M$ hydrochloric acid. It should be noted that the detection limit gives above represents an upper limit for a single pass optical detection system. Application of this reagent system to a multiple internal reflection OWG device would be expected to provide an improvement in sensitivity and detection limits of several orders of magnitude due to an increase in the effective cell path length.

Indicator–acid response

For the OWG sensor, any change in the optical properties of the film that translates into a change in light intensity reaching the photodetector will affect the analytical signal. A typical response of the BTB–NAF optical waveguide sensor to hydrochloric acid is given in Fig. 4 ($1.2M$ hydrochloric acid solution at 0°; 0.4 ppm). Upon exposure to the acid vapor, the signal from the phototransistor decreases rapidly, consistent with the increase in absorbance at 562 nm by the R form of the indicator. Removal of the acid vapor results in a slow return to the Y^- form. A more rapid recovery could be accomplished by exposing the sensor to base and/or water vapor; in any event, the signal fails to return completely to the original baseline response. Repeated exposure to high acid concentrations results in a gradual decrease in the baseline signal intensity. It is worth noting that repeated exposure of these sensors to acid vapor produced a very reproducible minimum signal, even though the sensor signal did not return to the original baseline after removal of the acid vapor.

To verify that the observed response was, in fact, the result of absorbance by the indicator, the following experiment was performed. The sensor was exposed to acid vapor from $0.06M$ hydrochloric acid in an ice bath (0.01 ppm vapor) while the sensor output was monitored upon illumination of the OWG with a yellow-green LED (562 nm). This experiment was repeated with a red LED source, having a maximum emission intensity at 680 nm. This wavelength is well removed from the absorbance λ_{max} for the R form (562 nm) and Y^- form (435 nm) of the indicator. The results are presented in Fig. 5. At the 680-nm wavelength there is minimal change in signal upon exposure to acid (bottom trace) whereas the sensor exhibits significant decrease in signal at 560 nm, confirming that the observed signal is due to absorbance by the R form of the indicator.

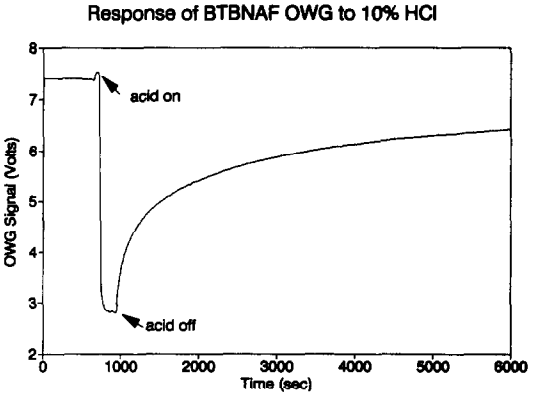

Fig. 4. Response of BTB–NAF OWG to HCl vapor produced from a 10% (v/v) solution ($1.2M$; 0.4 ppm).

Nafion–acid response

Repeated exposure of films resulted in a gradual decrease in sensor response in the form of a long term reduction in the sensor baseline signal. It was postulated that the Nafion was undergoing fatigue upon acid exposure, resulting in an irreversible decrease in transmittance properties.

Waveguides coated with Nafion films (no indicator) were exposed to acid vapors, and the transmittance at 562 nm was monitored. These results are presented in Fig. 6. The test was performed using an 8% hydrochloric solution maintained in an ice bath (0.24 ppm hydrochloric acid vapor) to reduce the effects of water on the sensor response, as discussed previously. As the Nafion film was exposed to repeated one minute cycles of dry air/acid vapor the sensor baseline steadily decreased. Upon exposure to acid vapor, the sensor response undergoes a reproducible decrease of approx. 170 mV.

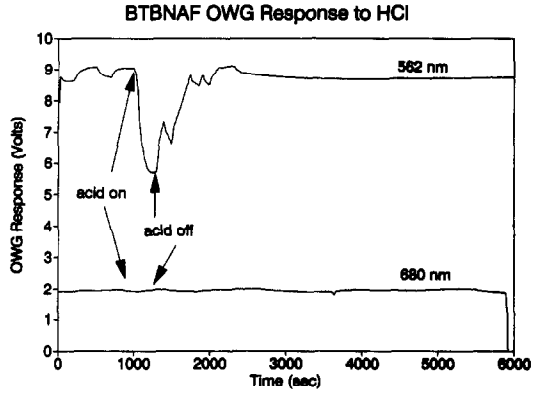

Fig. 5. BTB–NAF OWG response to vapor from 0.5% HCl solution ($0.06M$; 0.8 ppb) using 560-nm yellow LED (top trace) and 680-nm LED (bottom trace).

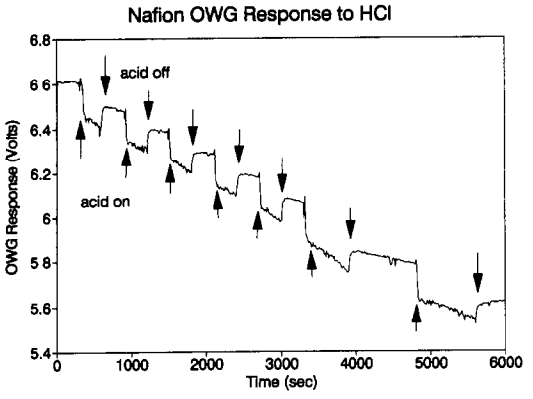

Fig. 6. Change in transmittance of Nafion coated OWG upon repeated exposures to vapor from 8% HCl solution (1*M*; 200 ppb).

Returning to dry air results in partial recovery of sensor signal, but there is still a net irreversible signal change of approx. 110 mV. The extent of irreversible signal decrease seems to increase as the acid concentration increases, and constitutes a dosimetric response. The 170-mV response of the Nafion OWG to 0.24 ppm hydrochloric acid (Fig. 6) can be compared with the nearly 4.5 V response of the BTB–NAF film to 0.4 ppm hydrochloric acid (Fig. 4). Obviously, the indicator response is nearly 20 times more sensitive to acid vapor than the Nafion alone, and will be the predominant response mechanism of the OWG sensor.

Changes in the optical properties in the Nafion film upon exposure to acid vapor may be the result of several phenomena. First, the decrease in light intensity reaching the PT detector may be due to changes in the refractive index of the polymer film; second, the introduction of acid vapor may result in increased scattering losses in the film. If there is an irreversible absorption of a small amount of acid vapor, these mechanisms could result in the long term decrease in the transmittance baseline of the sensor.

OWG response to CO_2

One of the proposed uses of this sensor is as a monitor in protective equipment, such as a gas mask. In such an environment, the sensor could also be exposed to exhaled gases, including CO_2 and water vapor. This combination of gases could potentially form an acidic mixture. The sensor response to combinations of these gases was investigated, and is displayed in Fig. 7.

Sample streams of dry nitrogen, water vapor and CO_2 were generated in the following manner. Dry nitrogen was supplied from a gas cylinder. This dry gas stream could be sent directly to the sensor or diverted through a water bubbler. A vessel containing dry ice was incorporated into the vapor flow system via a T-junction. The flow of CO_2 vapor into the flow stream could be controlled by opening or closing a restrictor. With the restrictor completely open, the flow of CO_2 from the vessel was $\approx$750 ml/min. Opening the restrictor 2 turns would permit a CO_2 flow-rate of $\approx$200 ml/min. The flow of dry nitrogen in the system was 160 ± 5 ml/min. Thus, when CO_2(g) was bled into the vapor stream the approx. [CO_2(g)] was 55% (by volume) or 1100 mg/l. (62%). [For comparison, the CO_2 concentration in the atmosphere is a fairly constant 300 ppm, and the content of exhaled air is $\approx$70 mg/l. (4%).]

Vapor streams of dry nitrogen, dry nitrogen + CO_2, and water vapor + CO_2 were sent to the OWG. Upon exposure to dry air + CO_2 there is a slight increase in the sensor signal, and a return to the original baseline when the CO_2 is removed. When water vapor is included in the CO_2 stream there is an additional small increase in signal. This is consistent with the OWG response to water vapor as noted above. The total response to CO_2(g) under the test conditions was an increased signal of $\approx$100–150 mV. To counteract this increase in signal would require an indicator response (signal decrease) equivalent to 3×10^{-4} ppm hydrochloric acid. From these results, it is concluded that CO_2 alone does not constitute a significant interference. The CO_2 with water could produce a protonic acid which would be expected to produce an indicator response, since the indicator undergoes a transition as a result of a proton transfer reaction. The fact that no response is

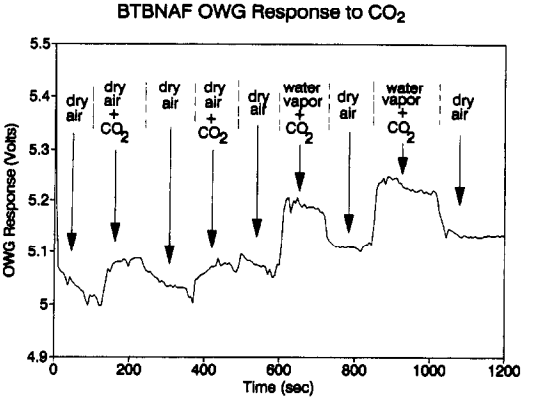

Fig. 7. Response of BTB–NAF OWG to CO_2 (1100 mg/l.) in dry nitrogen, and in water vapor.

observed, even in the presence of water, may be due to the fact that carbonic acid (H_2CO_3) is a very weak acid ($K_a = 4.3 \times 10^{-7}$). Alternatively, it is possible that H_2CO_3 is not formed to any great extent upon the addition of CO_2 and H_2O to the Nafion film. Without formation of the protonic acid, no indicator response would be expected.

Minimum detectability

In order to determine the minimum detectability of the sensor, the sensor response to a calibrated acid vapor source was necessary. The vapor generating apparatus used at NIU could not be calibrated at low acid concentrations for reasons discussed above. Further testing was performed at the TRI facilities to determine the minimum detectability of the sensor using a calibrated hydrogen sulphide dry gas mixture (228 ppm in N_2). The choice of hydrogen sulphide as the test gas was based on the fact that it is a highly toxic, acidic vapor. As such it would be among the class of vapors that the OWG sensor was designed to detect. The sensor output (in mV) was monitored with a strip chart recorder as the sensor was exposed to alternating streams of dry air and H_2S/N_2 mixtures of varying concentrations at flow-rates of approx. 200 ml/min. The H_2S/N_2 gas mixture was diluted with laboratory air that was scrubbed with a charcoal/molecular sieve trap. Thus, the final mixture contained some O_2 but water vapor (RH) was minimized. The results are summarized in Fig. 8. As was the case upon exposure to hydrochloric acid, the OWG sensor signal decreased upon exposure to hydrogen sulphide (note that the y-axis in Fig. 8 gives the OWG signal in negative mV), indicating an increase in absorbance at 562 nm. The sensor exhibits good linearity of response over the concentration range studied (0–228 ppm). Assuming a S/N equal to three as the detection limit, and using a value of 5 mV for rms noise for the OWG sensor, a minimum detectability of 15 ppm hydrogen sulphide is calculated.

The actual detection limit is probably lower than this figure for several reasons. The gas canister used for the calibration was nearly 2 years old, and the concentration of H_2S normally decreases 1–5% per year.[22] Further, the response of the sensor to hydrogen sulphide directly from the canister was significantly higher (nearly a factor of 2) than the response to undiluted hydrogen sulphide that had been diverted through the dilution apparatus. The hydrogen sulphide vapor stability in contact with many surfaces is poor. Thus, the concentration of hydrogen sulphide actually delivered to the sensor is probably less than calculated based on the concentration of hydrogen sulphide calibration gas and the performed dilutions.

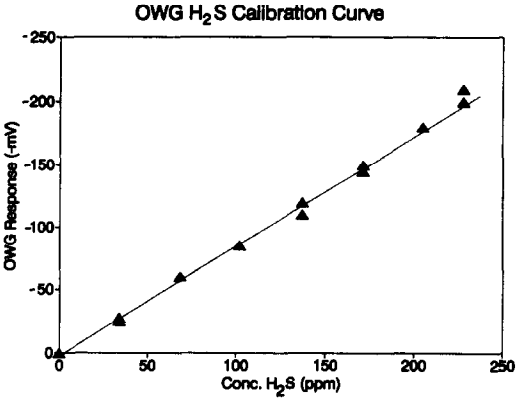

Fig. 8. Calibration curve for BTB–NAF OWG sensor, demonstrating linear response (−mV) to H_2S vapor between 0 and 228 ppm.

Interpretation of indicator response

The observed OWG signal is likely to be the net result of interactions between the indicator, the Nafion polymer (assumed to be in the acid form), and the acid vapor. From the hydrochloric acid spectral studies it is obvious that small concentrations of hydrochloric acid in the BTB–NAF film are sufficient to shift the indicator from the Y^- to the R form via proton donation from the acid to the indicator. Although these indicator dyes were originally designed for use in aqueous systems, it is worth noting that this response is observed even in the absence of water vapor. Apparently the Nafion matrix is sufficiently polar to permit proton transfer processes without significant water concentration in the membrane. Although no spectral studies were performed to verify this transition for the weak acid hydrogen sulphide exposure, the decrease in OWG sensor signal is consistent with an increase in absorbance at the 562-nm wavelength of the LED source. If hydrogen sulphide also donates a proton to the indicator, formation of the R form would result. Loss of a proton from hydrogen sulphide produces HS^-, which is a proton acceptor. If the proton from hydrogen sulphide is donated instead to the sulphonic acid group on the Nafion polymer then it is possible that the HS^- might

accept a proton from the Y^- form to produce the B^{2-} form. It should be noted that the λ_{max} for the B^{2-} form of the indicator at 620 nm is very broad and overlaps the 562-nm band considerably. Thus, a transition to the B^{2-} form would also produce absorbance at 562 nm with a corresponding decrease in the observed OWG signal. Further studies are planned to determine the exact nature of the response mechanism for weak acids.

Sensor configurations

The sensitivity of the OWG can be compromised by the presence of water vapor. The polymer used as the supporting matrix for the indicator reagent interacts with water vapor to produce an increase in OWG signal which constitutes a systematic interference. The normal indicator-acid response produces a decrease in the sensor signal. Two possible dual-sensor configurations are presented here that may correct for the systematic water vapor interference.

In one configuration, two waveguides can be coated with identical BTB–NAF films, with each waveguide having its own photodetector and LED. One waveguide will use an LED at 562 nm, while the other waveguide will use an LED at 680 nm. The 562-nm sensor response will be the net result of both water and acid, whereas the 680 LED response will be due only to water effects. Taking the difference between the two waveguide responses will correct for the effects of water on the acid sensor response. A potential problem with this approach is that it uses two different LEDs; long term drift or differences in LED intensities will produce discrepancies in the difference signal over time. The second configuration would circumvent this problem by using only one LED of 562 nm. The two waveguides will be coated with BTB–NAF and Nafion films respectively, and each will have its own photodetector. The Nafion film would respond to water, while the BTB–NAF film would respond to water and acid. Again, the difference between the two signals would correspond to the acid response.

Water vapor may also constitute a chemical interference if the presence of water vapor interrupts the acid–indicator interactions. Preliminary results indicate that the nature of the acid/indicator interaction is significantly affected by the polymer matrix.[23] Additional studies are planned to further investigate the nature of this interference.

CONCLUSIONS

Results indicate that the BTB–NAF indicator film provides a sensitive response in an optical waveguide configuration, particularly when the multiple internal reflection system is employed. The Nafion acts as a supporting film for the bromothymol blue reagent, providing good contact with the substrate surface. In addition, the ionic nature of the Nafion polymer facilitates transport of the polar acidic vapors to the indicator. It exhibits general sensitive and reversible response to the protonic acid vapors, hydrochloric acid and hydrogen sulphide, but does not exhibit a measurable indicator response to carbon dioxide. The detection limit for hydrogen sulphide is estimated as <15 ppm. The lowest hydrochloric acid vapor reported during this work, from $0.06M$ hydrochloric acid (0.01 ppm) produces a signal of nearly 3 volts. The OWG sensor is clearly several orders of magnitude more sensitive towards hydrochloric acid. This variable sensitivity for acid vapors may be due to the relative strength of the acid (hydrogen sulphide has a K_a of 1.0×10^{-7}).

The potential interferences from water and the acid effects on Nafion must be considered. While long term acid exposure will produce a decrease in baseline signal this effect is not considered to be a serious problem for several reasons. First, the magnitude of signal decrease is smaller than the indicator acid response by a factor of 20 or more. Second, the time frame over which this effect would become a problem is long compared to the time frame in which the indicator response to acid would signal the end of service of an acid-scrubbing filter. Finally, both the acid effect on Nafion and the acid indicator response produce a decrease in signal, so the cumulative effect would be a long term decrease in signal in the presence of acid. This effect will be more dramatic at higher acid concentrations. If this sensor is used as an alarm device to signal the end of service for protective equipment (gas masks) then it would produce an alarm response before high acid concentrations are present. Thus, the useful lifetime of the sensor would not be affected by this phenomenon.

The effect of water as a systematic interference is more serious, but can be dealt with instrumentally as discussed above. Future work should focus on the stability and sensitivity of these sensors. Specifically, the effects of polymer–indicator interactions on the response

mechanism of the sensor should be determined more quantitatively. In addition, further characterization of the response mechanism is planned. A more thorough understanding of polymer–indicator–acid vapor interactions/reactions will lead to significant analytical improvements in sensitivity and long-term stability.

Acknowledgements—The authors would like to acknowledge the efforts of Larry Gregerson of the NIU/Chemistry Department machine shop, Charles Caldwell of the NIU/Chemistry electronics shop, and Ed Hyland of the NIU/Chemistry glass blowing shop for all their assistance in the design and construction of the OWG sensor cells and electronics. In addition, the authors wish to thank W. R. Seitz for helpful discussions/suggestions regarding indicator chemistry. This project has been supported in part by NIOSH grant No. 2 R44 OHO2312-02.

RELEASE OF COPPER FROM COMMERCIAL SOLID-STATE COPPER ION-SELECTIVE ELECTRODES

BOY HOYER
Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Åarhus C, Denmark

(*Received* 9 *December* 1991. *Revised* 30 *March* 1992. *Accepted* 30 *March* 1992)

Summary—The release of copper from two commercial solid-state cupric ion-selective electrodes [Orion 94-29 Cupric Electrode (I) and Radiometer F1112 Selectrode (II)] was measured by immersion in the following media: 0.1*M* potassium nitrate (pH = 4.7), 0.5*M* sodium chloride (pH = 4.7) and 0.1*M* nitric acid. In the 0.1*M* potassium nitrate medium, the amount of copper released from both electrodes causes interference when they are used for the determination of cupric ion at the $10^{-7}M$ level. In comparison with the 0.1*M* potassium nitrate medium, the copper release in the 0.5*M* sodium chloride and 0.1*M* nitric acid media was increased for electrode II but not for electrode I. The release of copper was not affected by removal of oxygen from the media but can be substantially lowered by coating the electrodes with a thin cation-exchange membrane (Nafion). The mechanism of copper dissolution is investigated.

It has been known for many years that the use of a solid-state cupric ion selective electrode (Cu–ISE) can cause sample contamination owing to dissolution of copper from the membrane material.[1] For prototype electrodes prepared from CuS it has been shown that copper dissolution is accelerated by oxidants,[2] chloride[3] and copper-binding ligands,[4] while reductants have the opposite effect.[2]

In spite of the relevance to practical analysis, no systematic and quantitative study on the dissolution of copper from commercially available Cu–ISE's under realistic measuring conditions has been undertaken. It is the aim of the present study to provide such data. The electrodes selected for study were an Orion and a Radiometer Cu–ISE which employ different ion-sensing materials. The copper dissolution was also measured after coating the electrodes with a cation-exchange membrane (Nafion) which has previously proven beneficial for suppression of the chloride interference effect without impairing the functioning of the electrode.[5]

The procedures used complied with the recommendations of the manufacturers of the Cu–ISE's and no special measures such as chemical pretreatment were taken to either reduce or enhance the copper dissolution. The corrosion of the Cu–ISE's was measured in a non-interfering medium, a medium resembling seawater with a high chloride content, and an acidic medium.

EXPERIMENTAL

Apparatus

The Cu–ISE's were a new Orion 94-29 Cupric Electrode and a Radiometer F1112 Selectrode which had been in regular use for four years. The Radiometer electrode was kept dry with the sensing element covered with a rubber cap, when not in use. The copper-selective membranes in the Radiometer and the Orion electrodes are respectively a $Cu_{1.8}Se$ monocrystal and a CuS–Ag_2S pressed pellet with diameters of 5.5 mm and 7.5 mm respectively. Both electrodes employ a solid state internal contact. During corrosion experiments, the Cu–ISE was immersed in a cell thermostatted to 28 ± 2° with a water jacket.

Determination of cupric ion was done by potentiometric stripping analysis (PSA) using a programmable electrochemical analyzer.[6] The working electrode was a mercury-plated glassy carbon electrode, while the reference electrode and the counter electrode were a Radiometer K401 saturated calomel electrode (SCE) and a platinum rod, respectively.

Reagents

All electrolyte media were prepared from Merck Suprapur chemicals and triply distilled water. Other reagents were of analytical grade. Cupric ion standards were prepared from Merck Titrisol stock solution. A 5% solution of the Nafion perfluorosulphonate ionomer (1100

equiv. wt.) was obtained from Solution Technology (Mendenhall, Pennsylvania, U.S.A.). The 0.1*M* potassium nitrate and 0.5*M* sodium chloride media were buffered to pH 4.7 by addition of $10^{-2}M$ acetate buffer prepared from acetic acid and sodium hydroxide.

Procedure

The Radiometer Cu–ISE was maintained by regular polishing with Radiometer D709 abrasive agent and 0.25-μm diamond paste, while the Orion electrode was polished with Orion 948201 polishing strips. After abrasion, the electrodes were rinsed copiously with ethanol and distilled water. Overnight, the Cu–ISE's were stored in distilled water.

Corrosion experiments were carried out by immersing the Cu–ISE in a polyethylene beaker containing 10 ml of solution. Stirring was done by means of a Teflon-coated magnetic bar. For deaeration, the measuring cell was closed with plastic film, and argon was bubbled through the solution for 10 min prior to and also during the immersion of the Cu–ISE. The Cu–ISE was preconditioned for at least 15 min in the same medium used in the subsequent corrosion experiment. This medium was also used for storage between repetitive measurements and for rinsing of the electrode.

Coating of the Cu–ISE's with Nafion was carried out as previously described.[5]

The instrumental settings for PSA were as follows: plating potential, −700 mV *vs.* SCE, plating time, 60 sec; rest potential, 0 mV *vs.* SCE; rest time, 15 sec; background electrolysis time; 1 sec. In the 0.5*M* sodium chloride medium, the rest potential was decreased to −100 mV *vs.* SCE. Prior to PSA, all samples were spiked with 250μM of Hg(II) while $1.3 \times 10^{-2}M$ sodium chloride was added to the 0.1*M* potassium nitrate and 0.1*M* nitric acid media. Quantitation of copper was done by standard addition.

All experimental work was carried out in a clean bench. The blank value of the overall analytical procedure was routinely determined and was found to be insignificant in comparison with the copper concentrations determined.

RESULTS AND DISCUSSION

In Table 1, the copper ion concentrations resulting from dissolution of the Cu–ISE's are summarized. The oxidation state of the copper ions released is not known, and the signal obtained in PSA may therefore be made up of contributions from Cu(I) as well as Cu(II). Generally, the sensitivity in PSA is dependent on the chemical form of the metal determined. However, with the preelectrolysis potential used the sensitivity towards copper is governed by mass transport, and the PSA signal is proportional to $D^{2/3}$, where D is the diffusion coefficient of the metal species being preconcentrated onto the working electrode.[7] Equilibrium calculations showed that the addition of Hg(II) prior to PSA ensures quantitative oxidation of Cu(I) to Cu(II) in the 0.1*M* nitric acid and 0.1*M* potassium nitrate media, but not in the 0.5*M* sodium chloride medium owing to the stabilization of Cu(I) and Hg(II) by chloride. However, Cu(I) as well as Cu(II) are predominantly

Table 1. Release of copper from commercial Cu–ISE's in various media

Electrode and medium	Release of cupric ion/n*M**			
	bare, no deaeration	bare, deaeration	Nafion-coated, no deaeration	Nafion-coated, deaeration
Radiometer 0.1*M* KNO_3 (pH = 4.7)	65	66	60	51
Radiometer 0.5*M* NaCl (pH = 4.7)	210	210	64	53
Radiometer 0.1*M* HNO_3	290	240	150	110
Orion 0.1*M* KNO_3 (pH = 4.7)	71	46	< 30	< 30
Orion 0.5*M* NaCl (pH = 4.7)	67	81	< 30	< 30
Orion 0.1*M* HNO_3	82	89	44	42

*Electrodes were immersed for 5 min in 10 ml of the medium. The values quoted are averages of four or more separate corrosion experiments. The relative standard deviation of the copper concentration obtained in such repeated experiments was typically 15%.

present as chloride complexes in the latter medium and the difference in their diffusion coefficients will be small.

Even in a non-corrosive medium (0.1*M* potassium nitrate), the release of copper ion from both electrodes is sufficient to seriously affect measurements of cupric ion at the $10^{-7}M$ level. No systematic change in the copper release was observed during repetitive corrosion experiments which implies that a steady-state situation is established. The response time of the Orion Cu–ISE is at least 5 min at a cupric ion concentration of $10^{-7}M$ (Ref. 8) which equals the immersion time in the measurements on which Table 1 is based. As the response time increases dramatically with decreasing concentration below the $10^{-7}M$ level,[8] the results in Table 1 should be considered as a lower limit to sample contamination when using the Cu–ISE's for measurement of Cu(II) in the submicromolar range.

In contrast to the Orion Cu–ISE, the release of copper from the Radiometer Cu–ISE in the 0.5*M* sodium chloride and 0.1*M* nitric acid media was much higher than in the 0.1*M* potassium nitrate medium. This difference between the electrodes is even more pronounced when the areas of the ion-sensing elements are taken into consideration. Sample deaeration prior to and during immersion of the electrodes has surprisingly little effect on the results which implies that oxidation of the membrane during immersion is not the dominating mechanism of copper dissolution. The soluble copper species must therefore be present in the bulk or on the surface of the electrode material prior to immersion. The cases where the release of copper is increased by deaeration can be explained by increased convection in the solution due to argon bubbling. However, sample dearation is still important with the Radiometer Cu–ISE in measurements of micromolar or submicromolar concentrations of Cu(II) owing to the high redox sensitivity of the membrane.[9]

Table 2. Rate of copper release from commercial Cu–ISE's

Electrode and medium	Dissolution rate* of copper ion/n*M*/min	Correlation coefficient
Radiometer ÷ Nafion in 0.5*M* NaCl (pH = 4.7)	16	0.96
Radiometer + Nafion in 0.5*M* NaCl (pH = 4.7)	3.0	0.99
Radiometer ÷ Nafion in 0.1*M* HNO_3	50	0.99
Radiometer + Nafion in 0.1*M* HNO_3	14	0.96
Orion ÷ Nafion in 0.5*M* NaCl (pH = 4.7)	5.5	0.98
Orion ÷ Nafion in 0.1*M* HNO_3	15	0.99
Orion + Nafion in 0.1*M* HNO_3	3.1	0.98

*The dissolution rate was calculated by linear regression on a ($[Cu]_T$, $T_{immersion}$) data set with $T_{immersion}$ = 5, 10, 15 and 20 min. The media were not deaerated.

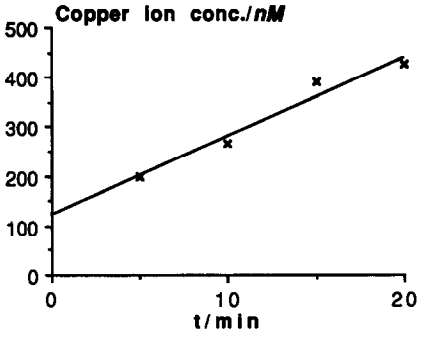

Fig. 1. Effect of immersion time on the release of copper from a Radiometer Cu–ISE. Experimental conditions: bare electrode immersed in 10 ml of non-deaerated 0.5*M* NaCl (pH = 4.7).

Nafion-coating of the Cu–ISE's suppressed the release of copper in all combinations of Cu–ISE and medium. A polymer membrane poses a diffusional barrier to mass transport, and it is therefore to be expected that transport-related processes such as the dissolution of the Cu–ISE will be slower, but this advantage is partially offset by the increased response time of the electrode.[8] Furthermore, the Nafion polymer is a cation-exchange resin which selectively hinders the permeation of anions by Donnan exclusion. The latter mechanism explains the particularly large decrease in copper release from the Radiometer Cu–ISE in the 0.5*M* sodium chloride medium obtained by Nafion-coating. This polymer has previously been employed to suppress the chloride interference on a Cu–ISE.[5] Also, the Donnan exclusion effect of the Nafion coating causes an accumulation of anionic dissolution products from the Cu–ISE which counteracts the dissolution process.

In order to measure the dissolution rate of copper the increase in copper ion concentration was measured for immersion times between 5 and 20 min in the 0.1*M* nitric acid and 0.5*M* sodium chloride media. The results are given in Table 2, and a typical data set is plotted in Fig. 1. In all cases, a highly significant linear relationship (*cf.* Table 2) and a positive intercept

on the concentration axis was obtained. Clearly, a considerable fraction of the copper contamination from the Cu–ISE is constant and not related to the immersion time. This observation is in agreement with previous work of Blaedel and Dinwiddie,[8] who showed that the exposure of a moist Orion Cu–ISE to air (associated with transfer between solutions) corroded the electrode and caused copper contamination of the solution in which the electrode was subsequently immersed.

It has been shown[10] that the sensing element of the Orion Cu–ISE is composed of the minerals jalpaite ($Ag_{1.55}Cu_{0.45}S$) and acanthite (Ag_2S), while the sensing element of the Radiometer Cu–ISE is composed of berzelianite ($Cu_{1.8}Se$) and a surface layer of umagite (Cu_3Se_2) generated by prolonged use. Unfortunately, no solubility data on the mentioned copper-containing minerals could be found. For comparison, the solubilities of CuS, Cu_2S, CuSe and Cu_2Se were calculated in the media employed with the relevant side reactions of S^{2-}, Se^{2-}, Cu^{2+} and Cu^+ taken into account. Thermodynamic data were taken from Smith and Martell.[11] In all cases, the copper concentrations resulting from dissolution of the Cu–ISE by far exceeded the calculated equilibrium values. This discrepancy can be explained by two mechanisms. Firstly, the membrane material itself may contain traces of soluble copper compounds which are either introduced in the fabrication process or formed during storage of the electrode. Secondly, such compounds may be generated by surface oxidation of the membrane material during use of the electrode. As discussed above, surface oxidation of the membrane was evident in the present study, but the leaching mechanism must also be involved because the amount of copper released increased linearly with immersion time in a non-oxidizing medium such as 0.5*M* sodium chloride (*cf.* Fig. 1). Although this medium contained dissolved oxygen, surface oxidation of the Cu–ISE can still be ruled out because deaeration of the immersion medium did not suppress the release of copper from the Cu–ISE's (*cf.* Table 1). These findings are in agreement with previous work on laboratory-made Cu–ISE's. Heine and Van der Linden[12] showed that copper sulphate is slowly formed by oxidation of jalpaite in dry air and even more so in ambient air. Problems with oxidation of sulphides in connection with preparation of pressed-pellet CuS electrodes have also been reported.[2,13] No analogous investigations have been performed for the copper selenide minerals, but the relative susceptibilities of the sulphide- and selenide-based electrodes towards oxidation can be estimated from the following standard potentials:

$$S(o) + 2e^- \leftrightarrow S^{2-};\ E^0 = -0.51\ V$$

$$Se(o) + 2e^- \leftrightarrow Se^{2-};\ E^0 = -0.78\ V$$

$$SO_4^{2-} + 4H_2O + 8e^- \leftrightarrow S^{2-} + 8OH^-;\ E^0 = -0.69\ V$$

$$SeO_4^{2-} + 4H_2O + 8e^- \leftrightarrow Se^{2-} + 8OH^-;\ E^0 = -0.36\ V$$

Thus, selenium is more easily oxidized from state −II to 0 than sulfur, while the opposite holds for the oxidation from state −II to +VI. In the present study, the Radiometer Cu–ISE did release more copper than the Orion Cu–ISE in the 0.5*M* sodium chloride and 0.1*M* nitric acid media, but the difference may also be attributed to the different history of the electrodes as the Radiometer Cu–ISE was older, had been in prolonged use and was kept in an ambient laboratory atmosphere. Therefore, it is possible that the layer in which oxidation of the membrane had occurred was so thick that the polishing procedure did not fully remove it.

Harsányi *et al.*[14] measured the release of copper in acetate buffer from a laboratory-made, pressed-pellet CuS electrode which had been pretreated in a reducing medium. After normalization with respect to immersion time, immersion volume and electrode area, this electrode released at least 20 times as much copper as the Radiometer and Orion electrodes did in the 0.1*M* potassium nitrate medium. However, the copper release could to a large extent be remedied by treatment of the precipitate with sulphide prior to pressing.[14]

In conclusion, the detection limit of commercial Cu–ISE's is limited not only by their Nernstian range, but also by sample contamination from dissolution of the membrane material. Measurements of Cu(II) in the micromolar and submicromolar range with these electrodes must therefore be critically evaluated. Apart from future improvements in the fabrication procedures of the Cu–ISE's, sample contamination by copper can be minimized by use of large sample volumes and by Nafion-coating of the Cu–ISE. The contamination problem can also be remedied by mounting of

the Cu–ISE in a flow configuration, and Nernstian calibration to very low cupric ion levels[15] can be achieved. However, large sample volumes must be available.

OPTICAL HUMIDITY AND AMMONIA GAS SENSORS USING REICHARDT'S DYE-POLYMER COMPOSITES

YOSHIHIKO SADAOKA,* YOSHIRO SAKAI and YU-UKI MURATA
Department of Applied Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790, Japan

(*Received* 17 *March* 1992. *Revised* 10 *April* 1992. *Accepted* 10 *April* 1992)

Summary—Optical intensity reflected at 750 nm by Reichardt's betain dye-polymer (PMMA or PEO) composite increased with an increase in humidity and was not affected by ammonia vapor. For the composites treated with hydrochloric acid, the intensity at around 590 nm decreased with an increase in ammonia concentration, and the sensitivity was enhanced by the presence of water vapor. The treatment with hydrochloric acid induced the formation of phenolic group, O^-–H^+ and N^+–Cl^- in the dye. The sorption of NH_3 decreases the ionic interactions.

A number of optical fibre sensors have been devised for the measurement of physical parameters like temperature and displacement. There has been an increasing interest in optical sensors to detect gas species in the atmosphere such as H_2O, NH_3, NO_2, organic vapor.[1–7] Chemical sensors based on optical fibres offer several advantages, *i.e.*, the sensors are electrically safe, their signals are not influenced by electrical disturbances, and the separation of the sensor element and actuators is easy. Most optochemical sensors are composed of polymer thin films with dyes whose absorption or fluorescence characteristics are a function of the concentration of chemical species. It is well known that Reichardt's dye exhibits one of the largest solvatochromic effects of any known molecule.[8] It is extremely sensitive to solvent polarity. The absorption peak of Reichardt's dye dissolved in non-polar solvent such as hexane, toluene, benzene is observed at around 850 nm and the coexistence of polar molecules such as water, alcohol and acetone induces the blue shift. The degree of the blue shift is expected to increase with increasing hydrogen bond donor strength and polarity of solvent.[9] The electronic transition leading to the solvatochromic band involves charge delocalization from the phenoxide oxygen into the pyridium ring and the phenyl groups attached thereto.[10] Recently, Paley *et al.*[11] have reported that the absorption wavelength of Reichardt's dye dispersed in a polymer matrix is very sensitive not only to the solid polymer matrix but also to humidity in ambient air since the sorbed water acts as acidic site which binds to the basic $-O^-$ site on Reichardt's dye. It seems that dye-polymer composites are useful materials to fabricate chemical sensor's that are selective for ambient gases since the position of absorption bands is a function of hydrogen bond acidity or polarity of sorbed molecules. Furthermore, it is expected that the selectivity can be controlled by the polarizability and/or acidity of the polymer matrix.

We propose a new type of optochemical sensor fabricated with Reichardt's dye for determining humidity and ammonia concentration in ambient air. This sensor can be operated in the longer wavelength range and at room temperature.

EXPERIMENTAL

Reichardt's betain [2,6-diphenyl-4-(2,4,6-triphenylpyridino)phenolate], poly(methyl methacrylate) (PMMA, MW = 12,000) and poly (ethylene oxide) (PEO, MW = 5,000,000) were obtained from Aldrich. For thin film preparation, Reichardt's dye was dissolved in acetone–water mixture with PEO (dye:PEO = 20:5 in weight) and in acetone with PMMA (dye:PEO = 20:5 in weight). Thin films were formed on alumina plates and quartz oscillating element (4 MHz) by solvent casting. The humidity and/or ammonia concentrations of test gases were controlled by mixing 1% ammonia diluted with standard air (21% O_2 + 79% N_2), humid air prepared by bubbling standard air through water, and standard air. The impurity con-

*Author for correspondence.

centration in standard air was as follows: CO < 1 ppm, CO_2 < 2 ppm, HCl < 1 ppm and H_2O < 10 ppm. The desired concentration of ammonia and humidity was achieved within 20 sec by using a special chamber (volume less than 20 cm^3) to measure optical response and weight gain of the film. The Y-type bundled flexible quartz fibre (2 mm in diameter) was fixed just in front of the film. Light from a D_2/I_2 lamp was guided into the fibre and directed to the film; the reflected light was collected by the same optical fibre. The collected light was analyzed by using a photospectrum analyzer (MCPD-1000, Otsuka electronics) in the region of 400–1100 nm. The water and/or ammonia contents were measured using a quartz oscillator as a microbalance. The weight and weight gain for the film exposed to the test gases were estimated from the oscillating frequency of the quartz oscillating element coated with film. All of the measurements were performed at 30°.

RESULTS AND DISCUSSIONS

Humidity sensing characteristics

In Fig. 1, the reflection spectra in dry air and in 50% RH (relative humidity) air for the composite films formed on alumina substrate are shown. In these cases, the spectrum observed for the uncoated alumina substrate (plate) was used as a reference. The position of the absorption band of Reichardt's dye dispersed in polymer was influenced by the polymer matrix, *i.e.*, the wavelength of the peak was 700 nm in dry air and 600 nm in 50% RH air for PMMA composite and 660 nm in dry air

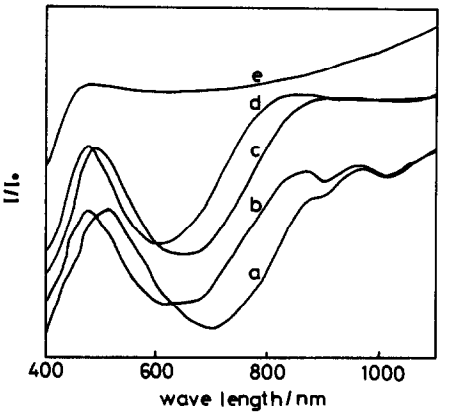

Fig. 1. Spectra of dye-polymer composites. (a) PMMA, in dry air, (b) PMMA, in 50% RH air (c) PEO, in dry air, (d) PEO, in 50% RH air (e) PEO treated with HCl, in 50% RH air.

and 600 nm in 50% RH air for PEO composite, respectively. The absorption peak was dependent on the polymer matrix even in a humid atmosphere and the humidification induced the blue shift. It is well known that the absorption peak of Reichardt's dye dissolved in solvent appears at 453 nm for water, 515 nm for methanol, 550 nm for ethanol, 677 nm for acetone, and 828 nm for benzene. For the polymer composites, the absorption peak in a humid atmosphere appeared at a longer wavelength than that of the dye dissolved in water. The hydrogen bond acidity or polarizability of the sorbed water is less than the liquid water. Since the water sorption ability can be controlled by the hydrophilicity of the polymer, the wavelength of reflection peak for humidity detection is easily controlled by the selection of polymer species. In Fig. 2, the spectral changes are shown as a function of the humidity for PMMA composite. In this case, the spectrum observed for the composite film in dry air was used as a reference. The optical intensity of the reflection peak observed around 770 nm increased with humidity and the wavelength of the peak became shorter while that of the reflection peak appeared at around 550 nm was decreased. The reflection peak observed at around 770 nm is more sensitive to the humidity than that at 550 nm. Humidity dependence of the wavelength of the peak appeared at around 770 nm and it's optical intensity is shown in Fig. 3. Similar dependencies were observed for the PEO composite (Fig. 4). The sensitivity for humidity in the optical intensity and in the wavelength of the peak of PMMA composite is higher than that of PEO composite. The difference in the sensitivity to humidity may be caused by the difference of hydrophobicity of polymer species.

Ammonia sensing characteristics

While for PEO composite, an absorption band appeared at 700 nm in atmosphere, the treatment with hydrochloric acid vapor induced a disappearance of the absorption band as shown in Fig. 1. A similar phenomenon was confirmed for the composite treated with nitric acid vapor. The treatment with hydrochloric acid caused the formation of phenolic OH, which was confirmed by infra-red spectroscopy. For the PEO composite treated with hydrochloric acid vapor, the spectra in the range between 400 and 1100 nm was only slightly influenced by the humidification but strongly affected by the ammonia vapor. The position of the absorption peak was only slightly affected by the concentration of ammonia. The results observed in dry air and in air with 50% RH are

shown in Figs. 5 and 6. As a reference, the spectrum observed for the composite film in ammonia-free air was used. The introduction of ammonia induced a decrease in the optical intensity at around 600 nm. The peak wavelength was not affected by concentration and was the same as observed for untreated-dye–PEO composite. It seems that the bond strength of O^-–H^+ and of N^+–Cl^- was weakened by the sorption of ammonia. Ammonia concentration dependence of the optical intensity at 590 nm is shown in Fig. 7 for the PEO composite treated with hydrochloric acid. The sensitivity and it's response time for ammonia was accelerated by the coexistence of water vapor. The 90% response time in the optical intensity for ammonia was about 120 sec in dry air and 30 sec or less in 50% RH air. For the PMMA composite treated with hydrochloric acid vapor, the optical intensity at around 600 nm also became sensitive to ammonia and the sensitivity was accelerated by the water vapor while the sensitivity was considerably less than these for the PEO composite. The humidifi-

cation induced the blue shift (about 10 nm). Furthermore, the exposures to dry air with 5000 ppm ammonia and to 50% RH air with the same concentration of ammonia did not induce the changes of the reflection spectra for the composites untreated with hydrochloric acid. It seems that the active site for ammonia molecules is the phenolic OH group.

Gas sorption characteristics

A water sorption isotherm for PMMA and PEO composites was examined to clarify the sensing mechanism (Fig. 8). For both composites, water content monotonically increased with the humidity. As well known, PEO is soluble in water and is more hydrophilic than PMMA. The water sorption ability of PMMA was about 2-fold less than that of PEO. For Reichardt's dye, a considerable amount of water could be sorbed and the sorption ability for water was higher than that of PMMA and was comparable to PEO alone. When the PMMA composite untreated with hydrochloric acid was exposed to dry air with 5000 ppm ammonia, an increase in the weight was observed to be 0.3 mg/g or less as shown in Fig. 9. The humidification of the test gases enhanced the sorption of ammonia. A weight increase of 0.8 mg/g was observed when ammonia gas (5000 ppm) was introduced in 50% RH air. A weight increase by the exposure to 50% RH air was about 15 mg/g. The amount of sorbed ammonia when 5000 ppm ammonia was introduced, was about 20-fold less than that of the water. The treatment of PMMA composite with hydrochloric acid vapor enhanced the sorption of ammonia and

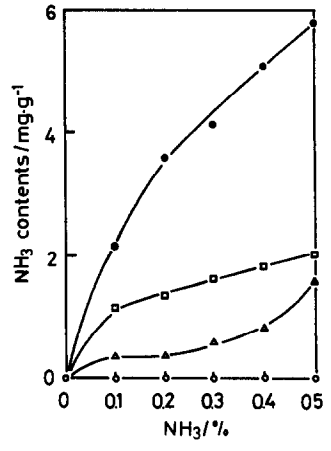

Fig. 10. NH_3 sorption isotherms of PEO composites. (○) untreated with HCl, in dry air, (△) untreated with HCl, in air with 50% RH, (□) treated with HCl, in dry air, (●) treated with HCl, in air with 50% RH.

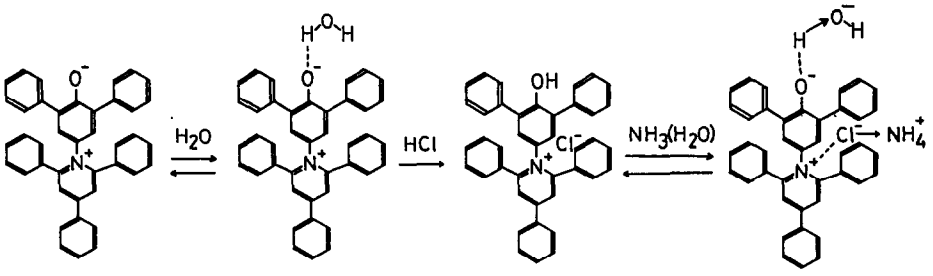

Fig. 11. A proposed sensing mechanism for H_2O and NH_3 detection.

an increase in weight by the exposure to 50% RH air with 5000 ppm ammonia was only about 2 mg/g which was 10-fold less than the water content (20 mg/g) at 50% RH. For the PEO composite untreated with hydrochloric acid, the sorbed water was estimated to be about 35 mg/g in 50% RH air (Fig. 8). The introduction of 5000 ppm ammonia to 50% RH air induced 1.5 mg/g enhancements while no distinguishable enhancements in weight by the sorption of ammonia could be observed for the same in dry air (Fig. 10). The relatively large water uptake suggests that the spectral shifts observed in response to humidity for the composites without hydrochloric acid treatment are due to changes of polarity in the dye environment. The relatively small weight gain for ammonia compared to the weight gain for films exposed to water suggests that this is a chemical effect. A preliminary model based on our experimental results can be expressed as shown in Fig. 11.

CONCLUSIONS

The optical intensity in the reflection mode and the wavelength of maxima observed at 750 nm for Reichardt's betain dye–PMMA composite were very sensitive to the humidity and insensitive to ammonia vapour. The optical intensity monotonically increased with the humidity. Similar behaviour was also observed for the PEO composite while the sensitivity was considerably less than that for PMMA composite. The hydrogen bonding of sorbed water to phenoxide oxygen should stabilize the ground state and results in the negative chromism (hypso-chromic). By using the composite treated with hydrochloric acid, the reflection spectra with a peak at 600 nm became sensitive to ammonia vapor especially for PEO composite. Sensitivity for ammonia was accelerated by the coexistence of water. The treatment with hydrochloric acid induced the formation of phenolic group, -OH and N^+–Cl^- in the dye. The sorption of ammonia forming ammonium cation and hydroxyl anion, decreases the bond strength of O^-–H^+ and N^+–Cl^-.

Aims and Scope

Talanta, published monthly, provides a forum for the publication of *original research papers*, *preliminary communications*, *annotations* and *reviews* in all branches of pure and applied analytical chemistry. Other features are *analytical data* (stability constants,, etc.) and *letters to the editors*. Papers on fundamental studies and novel instrumentation development are especially encouraged. The latter include physical, inorganic and organic chemistry measurement instrumentations that are unique. New electronic developments are welcome. Novel applications in areas such as clinical chemistry, environmental analysis, geochemistry, materials science and engineering, pharmaceutical and drug analysis, etc. are welcome. Since classical spectrophotometric measurements and applications, titrimetry, *etc.*, are well established, studies in such areas should demonstrate a unique and substantial advantage over presently known systems (with respect to reagents or a particular application). Contributions will be expected to be of the high standard set and maintained by *Talanta* and to make a definite and useful contribution to analytical chemistry: they must be new publications. Papers must be written in English. *Reviews* of rapidly expanding fields or of hitherto widely scattered material are welcome but should be critical. *Original papers* and *reviews* are refereed in the usual way. *Preliminary communications* (intended for the rapid publication of novel ideas and lines of research) are refereed urgently and published direct from typescript to give utmost speed of publication. *Correspondence* of interest to analytical chemists is published at the discretion of the Editors-in-Chief.

TALANTA: CHEMICAL SENSORS

Talanta: Chemical Sensors is a new section of *Talanta*, for presenting significant experimental and theoretical research results relevant to chemical sensing.

This section has been created in recognition of the growing need to perform chemical analysis *in situ* with sensing devices. Original research articles either as *full papers* or as *preliminary communications* will be published. In addition, occasional short reviews of topics of interest to sensor scientists will be considered.

Topics relevant to *Talanta: Chemical Sensors* include: experimental characterization of new sensing devices, theory to describe the response properties of sensing devices, significant and timely applications of sensors to important analytical problems, molecular recognition chemistry of potential value for chemical sensing, interfacing biological catalysts and receptors to physical readouts, and instrumentation development, particularly miniaturization, of potential value for chemical sensing.

Manuscript Submission. Instructions for authors are given at the end of this issue. Please **submit three copies** of the manuscript to the appropriate Editor-in-Chief. Manuscripts from North and South America, Japan, China, Australia, India and other countries in that half of the world should be sent to Gary Christian. Manuscripts from Europe, the Middle East and Africa should be sent to Elo Hansen.

NOTICE

FOURTH INTERNATIONAL SYMPOSIUM ON PHARMACEUTICAL AND BIOMEDICAL ANALYSIS

Baltimore, Maryland, U.S.A.
April 18–22, 1993

The Fourth International Symposium on Pharmaceutical and Biomedical Analysis (PBA '93) will be held in April 1993 in the historic port city of Baltimore. This meeting will follow the highly successful Symposia held in Barcelona, Spain (PBA '87), York, U.K. (PBA '90) and Boston, U.S.A. (PBA '91). All those involved in the analysis of drugs, related materials and endogenous compounds, in all areas of the pharmaceutical and biomedical sciences, are cordially invited to attend.

The principal scientific themes include:

- Advances in Separation Techniques—LC, CE, SFC, GC
- Analysis of Bulk Substances and Formulations
- Analysis of Enantiomers
- Analytical Biotechnology
- Analytical Considerations in Performulation and Drug Delivery Studies
- Assay Validation
- Bioanalysis in Clinical and Preclinical Drug Development
- Pharmaceutical Quality Control
- Sample Preparation and Derivatization Techniques
- Spectroscopy and Spectroscopic Methods, NMR, MS, UV, FL

The scientific program will feature invited keynote speakers, submitted lectures and posters. As in previous Symposia in this series, poster discussion sessions will be organized around specific topics to allow exchange of ideas and research results in a more relaxed and less formal atmosphere. The Scientific Sessions will be preceded on the Sunday morning and afternoon by a series of workshops on a number of topical themes, presented by internationally recognized scientists in their respective fields.

All papers submitted will be published after reviewing in a special issue of the *Journal of Pharmaceutical and Biomedical Analysis*. Registered participants will receive a complimentary copy of the Proceedings, the Book of Abstracts, and entry to the Exhibition.

NOTICE

1992 CPAC SUMMER INSTITUTE ON PROCESS ANALYSIS AND CONTROL

The Center for Process Analytical Chemistry (CPAC) at the University of Washington will sponsor the 1992 CPAC Summer Institute, to be held July 6–16, 1992, in Seattle. A series of one and two-day modules on selected topics in process analysis and control will be presented by CPAC investigators.

The Center is a National Science Foundation Industry/University Cooperative Research Center sponsored by about fifty sponsors from the chemical industries. The Institute is designed for industrial and academic scientists and engineers who would like an intensive course on research and applications in this rapidly evolving field. Participants will come away with the fundamentals of process monitoring and control technologies as well as applications to industrial and environmental problems. The courses will provide attendees with a better understanding of how to implement sensing, data processing, and control methods in their own organisation. The power of multivariate methods of data analysis to enhance process monitoring, modeling and control is a common theme to be explored in the Institute. Topics to be covered include the following:

July 6	Flow Injection Analysis *Gary Christian and Jarda Ruzicka (Chemistry)*
July 7–8	Sensors and Sensor Systems: Optical, Mass, Electrochemical, and Thermal *Lloyd Burgess (Chemistry), Sinclair Yee and Pat Carey (Electrical Engineering)*
July 9–10	Signal Processor Integrated Circuitry for Sensor Applications *Mani Soma (Electrical Engineering)*
July 13	Chemometrics *Bruce Kowalski (Chemistry)*
July 14	NIR Spectroscopy *James Callis (Chemistry)*
July 15–16	Model–Predictive Control *Larry Ricker (Chemical Engineering)*

Participants may register for one or more modules, in any combination. For further information and registration details, please contact: Dr. Deborah L. Illman, Associate Director, CPAC, BG-10, University of Washington, Seattle, WA 98195, U.S.A. [Tel: (1 206) 685 2326].

NOTICES

NATO ASI ON MULTIFUNCTIONAL MESOPOROUS INORGANIC SOLIDS

Hotel Tivoli Sintra, Sintra, Portugal
5–17 April 1992

Call for Papers

Mesoporous materials have pore diameters in the range 20–150Å. There is an urgent need to understand the fundamental aspects regarding the synthesis, characterization and application of such materials which may be used for separation processes with or without membranes, catalysis, non-linear optics, corrosion-resistant coatings, sensors and battery electrodes and electrolytes. Three types of inorganic materials will be discussed:

(1) Mesoporous materials from layered compounds such as phosphates, phosphonates, layered double hydroxides and clays.
(2) Sol gel derived mesoporous oxides such as zirconia and titania.
(3) Hydrothermally derived mesoporous zeolites.

It is believed that there is a common theme between these three classes in that the requirements of pore size, methods of characterization and applications are similar. Consequently, the ASI will allow experts from the various fields to explore the fundamental aspects.

Potential participants are invited to apply as early as possible to:

Prof. César A C Sequeira
Instituto Superior Técnico
Av. Rovisco Pais

Portugal

ANNUAL CHEMICAL CONGRESS

MANCHESTER (UMIST)
13–16 April 1992

FIRST CIRCULAR

The 1992 Annual Chemical Congress of the Royal Society of Chemistry will take place at Manchester during 13–16 April 1992.

In addition to the symposia, the Congress will include the following principal lectures:

The Royal Society of Chemistry Presidential Address	Sir Rex Richards President, The Royal Society of Chemistry
Robert Robinson Lecture	Professor G Stork Columbia University, New York, U.S.A.
Theophilus Redwood Lecture	Professor A Hulanicki University of Warsaw, Poland

SCIENTIFIC PROGRAMME

Analytical

New directions in chromatography

Dalton

Developments in the chemistry of the main group elements

Invited lecturers: A Cheetham, J Dwyer, E. Flanigan, Z Gabelica, J C Vedrine, A Julbe, J F Nixon, F Mathey. O Stelzer, O J Scherer, J D Woollins, P P Power, N Burford, A Sullivan, F J Feher, R Househalter

It is planned to arrange a poster session in association with this symposium.

Education

From secondary school to honours degree: the formation of tomorrow's professional chemists.

Faraday *jointly with* **Analytical**

Characterization of solids and surfaces

Industrial

Surface analysis techniques and applications

Invited lecturers: C D Battich, J A Busby, J E Castle, J Comyn, J A Creighton, M Davies, K Delargy, R McIntyre, C G Pantano, J B Pethica, A Swift, R Wild and J Yarwood

Perkin

Asymmetric processes

Invited lecturers: D H G Crout, S G Davies, C Gennari, H Kagan, W Oppolzer, I Paterson, M T Reetz, W R Rousch, S M Roberts, N S Simpkins, H Yamamoto & others to be announced

Professional Affairs Board *jointly with* **Younger Chemists Committee**

Chemists, careers and changes

Historical

Manchester chemists

Invited lecturers: R Bud, D Cardwell, W Cocker, J H S Green, K Magee, J W Nicholson, P N Reed, C A Russell, K Schofield, A S Travis, T I Williams

Interdivisional, *organized by the Sonochemistry Group*

Sonochemistry

It is planned to arrange a poster session in association with this symposium.

Interdivisional, *organized by the Chemical Information Group in association with the Institution of Chemical Engineers*

Data for chemists and chemical engineers

Invited lecturers: Dr Ruttledge, D. L Baulch, S Goodwin, A Johns, D Ilton, W A Wakeham B Edmond

External Relations/Women Chemists

Food additives (provisional)

Water Chemistry Forum, *jointly with* **Analytical**

Title to be announced

FOURTH INTERNATIONAL SYMPOSIUM ON SUPERCRITICAL FLUID CHROMATOGRAPHY AND EXTRACTION

20–22 May 1992
Sheraton-Springdale Hotel, Cincinnati, Ohio, U.S.A.

First Circular
Call for Papers

The symposium will include oral, poster and discussion sessions. Plenary lectures by leading authorities in SFC and SFE will also be included.
The scientific program will include:

Multidimensional SFC and SFE
Off-line and on-line SFE
Physicochemical applications of SFC
Preparative SFC and SFE
Stationary phase and column packing
Optimization studies in SFE and SFC
Applications in regulatory analysis
Microextraction and analysis
Fluid purification
Quantitation in SFE
Matrix effects in SFE
Coupled techniques with SFC and SFE

Scientific and Organizing Committee

Keith Bartle (University of Leeds)
Thomas Chester (Procter & Gamble)
Jerry King (NCAUR-ARS/USDA)
Larry Taylor (VPI & SU)

Submission of Presentation Titles

Authors intending to submit papers for the symposium are encouraged to submit a tentative title as soon as possible. Abstract deadline will be 1 March, 1992. Abstracts (1000 words) will be printed in the symposium proceedings.

Application for a limited number of student scholarships can be made by submitting a poster abstract along with a supporting letter from the mentor to the organizing committee.

For further information please contact:

2nd FECHEM CONFERENCE ON EDUCATION IN ANALYTICAL CHEMISTRY ANALYTICAL CHEMISTRY—A KEY FOR A SAFER FUTURE FOR MANKIND

will be organized by
the Czechoslovak Chemical Society
on behalf of the Working Party on Analytical Chemistry of the
Federation of European Chemical Societies
at Charles University, Prague
on August 31–September 1, 1992

The Conference will deal with all aspects of education in analytical chemistry and will consist of invited plenary lectures, contributed oral and poster presentations, a panel discussion and a section devoted to audiovisual aids and the use of computers for education in analytical chemistry.

Contact address:

Dr. J. Barek, Department of Analytical Chemistry, Charles University, Albertov 2030,
12840 Prague 2, Czechoslovakia

ANABIOTEC '92

4th International Symposium on Analytical Methods, Systems and Strategies
in Biotechnology Noordwijkerhout, The Netherlands 21–23 September 1992

Call for Papers

Analytical methods, systems and strategies are an integral part of academic and industrial research in biotechnology. Scientists working in this broad field, ranging from biodetection to advanced instrumental analysis, share a common interest in the interdisciplinary approach required to be successful in analysis in biotechnology; and they have a common interest in sharing this knowledge at ANABIOTEC.
Topics planned include:

- Chromatography; HPLC, GC, preparative and displacement chromatography, sample preparation
- Spectroscopy; NMR, IR, MS.
- Separation techniques, such as capillary zone electrophoresis (CZE), field flow fractionation (FFF).
- Flow Injection Analysis (FIA).
- Biodetection (such as DNA/RNA probes, immuno-analysis).
- Hyphenated techniques.
- Kinetic methods.
- New developments.

More detailed information can be obtained from:

Symposium Secretariat: ANABIOTEC
c/o CAOS, W.G. Plein 475, 1054 SH Amsterdam, The Netherlands

Announcement and Call for Papers

NINETEENTH ANNUAL MEETING OF THE FEDERATION OF ANALYTICAL CHEMISTRY AND SPECTROSCOPY SOCIETIES

20–25 September, 1992
Adams Mark Hotel, Philadelphia, Pennsylvania, U.S.A.

The nineteenth annual meeting of the Federation of Analytical Chemistry and Spectroscopy Societies (FACSS) will be held at the Adams Mark Hotel. FACSS is considered by many to be the premier annual technical analytical meeting. This year's conference will provide an expanded technical program with an emphasis on emerging technologies in analytical, spectroscopic and chromatographic sciences.

The deadline for submission of your title and a preliminary 100 word brief is **4 March, 1992.** A title submission form appears on the next page.

For information concerning the scientific program, please contact **Barry Lavine, Program Chairman**, Dept. of Chemistry, Clarkson University, Potsdam, NY 13676.

Nominations are requested for the **Tomas Hirschfeld Student Awards,** which will be presented at the conference for the most outstanding papers submitted by graduate students. The student nominees will give their papers at the FACSS conference. To be considered for these awards, students must submit the title of their paper, two letters of nomination including one from their graduate advisor, any preprints/reprints, and a 250-word abstract to the FACSS National Office by 4 March, 1992.

Contributed papers are solicited in all areas of analytical chemistry including atomic and molecular spectroscopy, chromatography, laser spectroscopy, mass spectrometry, nuclear magnetic resonance, process analysis, computers and software, environmental analysis, and biotechnology. The scientific program will also include various award symposia.

For general information please contact: **Matthew Klee, General Chairman,** Hewlett Packard Corp., P.O. Box 800, Avondale, PA 19311.

For other information please contact the FACSS National Office: FACSS, P.O. Box 278, Manhattan, KS 66502 or phone (301)-846-4797.

12th INTERNATIONAL SYMPOSIUM ON MICROCHEMICAL TECHNIQUES

CORDOBA, SPAIN
7–12 September 1992

The Symposium will be held from September 7 to 12, 1992 at Córdoba (Spain) in the Palacio de Congresos, 10 m from the Mosque in the old quarter.

Topics

ISM-92 will cover both pure and applied aspects of analytical chemistry related to micro- and trace-analysis. Special attention will be paid to the application of modern instrumental techniques in the field of trace-analysis.

Scientific Programme

Plenary and keynote lectures will be presented by invited speakers. For the general sessions, contributions are requested for presentation in either oral or poster sessions.

Papers

All delegates will be offered to submit a full paper for publication in a 1992 special conference issue of Analytica Chimica Acta. All invited and submitted papers will be reviewed by ACA in the normal way. All registered participants will receive a copy of the ACA conference issue.

Abstracts

An abstract of 200–350 words (1 page) should be submitted as soon as possible but no later than 1 December 1991 for consideration by the Scientific Committee. The deadline for abstracts is 15 January 1992. All registered participants will receive the book of abstracts.

Abstracts are to be submitted on good quality white paper (A4). The abstract itself must be typed, single spaced in English within an area equivalent to 13 cm wide by 19 cm high.

Main Topics

- Electrochemical Detection in FIA/CFA/HPLC
- Developments in Stripping Analysis
- Pharmaceutical and Biomedical Applications of ElectroAnalysis
- (Bio)sensors and Chemically Modified Electrodes
- New ElectroAnalytical Techniques and instrumentation
- Environment Applications of ElectroAnalysis

Invited Speakers

K. Stulik, Czechoslovakia
C. M. G. van den Berg, United Kingdom
J.-M. Kauffmann, Belgium
L. Gorton, Sweden
H. P. van Leeuwen, The Netherlands

Exhibition

An exhibition will be arranged in conjunction with the Conference.

FOURTH INTERNATIONAL SYMPOSIUM ON PHARMACEUTICAL AND BIOMEDICAL ANALYSIS

Baltimore, Maryland, U.S.A.
April 18–22, 1993

The Fourth International Symposium on Pharmaceutical and Biomedical Analysis (PBA '93) will be held in April 1993 in the historic port city of Baltimore. This meeting will follow the highly successful Symposia held in Barcelona, Spain (PBA '87), York, U.K. (PBA '90) and Boston, U.S.A. (PBA '91). All those involved in the analysis of drugs, related materials and endogenous compounds, in all areas of the pharmaceutical and biomedical sciences, are cordially invited to attend.

The principal scientific themes include:

- Advances in Separation Techniques—LC, CE, SFC, GC
- Analysis of Bulk Substances and Formulations
- Analysis of Enantiomers
- Analytical Biotechnology
- Analytical Considerations in Performulation and Drug Delivery Studies
- Assay Validation
- Bioanalysis in Clinical and Preclinical Drug Development
- Pharmaceutical Quality Control
- Sample Preparation and Derivatization Techniques
- Spectroscopy and Spectroscopic Methods, NMR, MS, UV, FL

The scientific program will feature invited keynote speakers, submitted lectures and posters. As in previous Symposia in this series, poster discussion sessions will be organized around specific topics to allow exchange of ideas and research results in a more relaxed and less formal atmosphere. The Scientific Sessions will be preceded on the Sunday morning and afternoon by a series of workshops on a number of topical themes, presented by internationally recognized scientists in their respective fields.

All papers submitted will be published after reviewing in a special issue of the *Journal of Pharmaceutical and Biomedical Analysis*. Registered participants will receive a complimentary copy of the Proceedings, the Book of Abstracts, and entry to the Exhibition.

ERRATUM

Arrhenius Plots for Activation Energy of Atomization in Graphite-Furnace Atomic-Absorption Spectrometry

C. L. Chakrabarti and S. J. Cathum

(*Talanta*, 1991, **38**, pp. 157–166)

Printing corrections for Table 3 were omitted by the printer, and the correct table is as follows:

Table 3. Activation energy values for atomization of copper obtained using equation (25)

E_a, *kJ/mole* Test number 1	2	3	Average E_a, *kJ/mole*	Location of the data points on the absorbance signal profile used for calculation of E_a
355	325	344	341	At or immediately after the appearance
349	343	325	339	temperature, i.e., at "low" temperatures.
328	355	338	340	
337	343	343	341	
338	311	343	336	
304	284	321	303	From the "transition region" temperature, *i.e.*, between the "low" and the "high" temperature.
271	254	296	274	At longer times after the appearance temperature,
242	230	268	247	*i.e.*, when temperature is "high". The temperature
217	210	220	216	increases as one descends the columns of Table 3.

The following corrections were also omitted:

p. 157 (right-hand column), $-Ea/R$ should be $-E_a/R$

p. 161, after equation (32): $X = \ln(k_{1\infty}/k_{2\infty})$

p. 161, *Standard solutions*. The phrase "containing 5.00 ng/ml copper" should have been deleted in the sentence "Test solutions containing 5.00 ng/ml copper were prepared by serial dilution of the stock solution just before use".

p. 163 (left-hand column), (third horizontal row) should be (second horizontal row from the top).

Talanta, Vol. 39, No. 11, pp. V–VI, 1992
Printed in Great Britain.

FOREWORD

Professor Tom S. West

This special issue of *Talanta* is in honour of the sixty-fifth birthday of Professor Tom West.

Professor West is an analytical chemist of high international standing, who has also contributed significantly to other aspects of national and international science.

The papers for the honour issue are contributed by his former colleagues and research students at University of Birmingham, Imperial College London, and the Macaulay Institute Aberdeen, as well as by some colleagues from the time when he was Secretary General of IUPAC. The coordinating editors are Jack Betteridge and Mo Williams, who were amongst his first research students in Birmingham, and both of whom were involved in the editorial team of *Talanta* in the early 1960s. Professor West was himself a member of the Editorial Advisory Board of the journal for several years, and much of his research work has been published therein.

We all wish him good health in the coming years and success in his continuing scientific efforts.

* * *

TRIBUTE TO TOM WEST

During the 1960s and 1970s, Tom West and I competed as scientists in the field of atomic spectroscopy. This was a healthy and wonderful time for both of our groups. I had great respect for the energy, innovation, and wonderful publications which came forth from the Tom West group

at Imperial College. After Tom went to Aberdeen, he continued his fine research although at a lesser rate. Tom West has been a major player in the past 30 years or more in analytical chemistry. His contributions are enormous in number and excellent in substance. This special issue of TALANTA honours Tom West as a teacher, scholar, administrator, researcher, innovator, friend, and colleague. Thanks Tom for leading the way for so many of us.

J. D. WINEFORDNER

Talanta, Vol. 39, No. 10, pp. V–VI, 1992
Pergamon Press Ltd. Printed in Great Britain

TALANTA ADVISORY BOARD

The Editorial Board and the Publisher of *Talanta* take pleasure in welcoming the following as members of the Advisory Board of the Journal.

A. BERTHOD R. J. HURTUBISE
J. F. VAN STADEN Z. FANG
B. KARLBERG

Alain Berthod, born in 1950, graduated in Chemistry in 1974. He received his Ph.D. degree in 1979 from the Chemistry Department of the University of Lyon, France. Since then, he has been appointed as Researcher by the French National Research Institution (C.N.R.S., Centre National de la Recherche Scientifique). He obtained the French State Doctorate in 1983. He is currently Professeur Agrégé in the Laboratoire des Sciences Analytiques at Lyon University, team CNRS # 435, directed by J. M. Mermet. His research interests include the use of liquid ordered media (micellar solutions, emulsions and microemulsions) in analytical science: electroanalysis in ordered media, micellar liquid chromatography and emulsion formulation. In 1986 and 1987, he spent 18 months as a sabbatical visiting scientist in Professor J. D. Winefordner's Group in Gainesville, Florida, U.S.A. where he developed hyphenated laser-chromatography techniques. He is currently working on new methods of separation: micellar chromatography, countercurrent chromatography and enantiomer separations. He authored or co-authored more than 80 papers on these topics. He serves as a paper reviewer for most international analytical chemistry journals and is a member of the editorial board of the Journal of Liquid Chromatography.

Zhaolun Fang graduated from Beijing (Peking) University, People's Republic of China in 1957. He became a Research Associate in 1965, an Associate Professor in 1977, and a full Professor in 1986 at the Institute of Applied Ecology (formerly Institute of Forestry and Soil Science) of the Chinese Academy of Sciences (Academia Sinica), Shenyang, People's Republic of China. He is currently Director of Flow-Injection Analysis Research Centre of the Institute, with concurrent posts as Director of Instrumental Analysis Centre of the Chinese Academy of Sciences (Shenyang Branch), Member of the Board of Directors of the Chinese Chemical Society, Chairman of the Committee on Flow-Injection Analysis of the Chinese Instrument Society, and Professor at the Shenyang College of Pharmacy. He received awards from the Chinese Academy of Sciences in 1981, 1982 and 1990. His research interests include flow-injection analysis atomic spectrometry with applications in environmental and biological fields, and has published over 120 research papers and co-authored three books in these areas.

Robert J. Hurtubise is Professor of Chemistry at the University of Wyoming in Laramie, Wyoming, U.S.A. He received his B.S. and M.S. degrees in chemistry from Xavier University, Cincinnati, Ohio, U.S.A. and his Ph.D. degree in analytical chemistry from Ohio University, Athens, Ohio, U.S.A. In addition to holding academic positions, Dr. Hurtubise has also worked in the pharmaceutical industry. Professor Hurtubise's research interests include the theoretical and practical aspects of solid-matrix luminescence analysis, the solid-matrix and solution luminescence of DNA adducts and related biological samples, and the theoretical and applied aspects of high-performance liquid chromatography and capillary electrophoresis. He has lectured widely and has published over a hundred research papers, numerous review articles, five chapters, and two books. His most recent book is entitled *Phosphorimetry: Theory, Instrumentation and Applications.* In addition to his association with *Talanta*, he serves on the Editorial Advisory Board for *Analytical Instrumentation.*

Bo Karlberg received his B.S. degree in chemistry and mathematics from the University of Lund in 1967 and his Ph.D. degree in analytical chemistry from the University of Umeå in 1973. Since then he has been working as a research chemist at Astra Pharmaceuticals, Södertälje, in 1973–1979 and later at Bifok/Tecator, Sollentuna, where he still holds a part-time position. In 1991 he was appointed Associate Professor at Stockholm University. He was among the early researchers on response mechanisms of glass electrodes and other ion-selective electrodes but later directed his research towards automation of wet chemistry procedures based on the continuous flow approach (FIA in particular). His current research interests lie in environmental analysis and monitoring. He has organized several international meetings including the Flow Analysis II meeting in Lund in 1982.

Jacobus (Koos) F van Staden joined SASOL in the early sixties after his matriculation examinations, whereafter he went on study leave in 1966 to the University of the Orange Free State where he received his B.Sc. (1968), B.Sc. Honours (1969) and M.Sc. (1970) degrees. He returned to SASOL with main responsibility for gas chromatography, mass spectrometry,

corrosion and wet chemistry. Hereafter he moved to the University of Zululand (1973), Pretoria Technikon, South Africa (1975) before joining the University of Pretoria, South Africa (1976) where he is now full Professor and Head of Analytical Chemistry. He obtained a D.Sc. degree from the University of Pretoria in 1978. He received the Robertson award (1967–1970) and the D F du Toit Malherbe award (1980) for his research on flow-injection analysis. Koos is a fellow of the Royal Society of Chemistry, member of the South African Chemical Institute (currently Chairman of the Publicity committee and member of Council), member of the South African Council for Natural Scientists and currently Chairman of the Chemistry Section of the South African Academy for Science and Art. He was the Chairman of the first national symposium on Analytical Science in South Africa and is currently National Representative for South Africa of the Commission on General Aspects of Analytical Chemistry of IUPAC. His main interests are in automatic methods and process control (continuous flow systems and flow injection analysis), separation techniques and chromatography, electrochemical sensors, spectrometric detectors and water- and environmental-pollution analysis. Koos is also active in Chemical Education and is currently Subject Editor (Chemistry) of *Spectrum*, the journal for Teachers of Mathematics, Physical Science and Technology. He is the (co)-author of over 130 scientific publications (full length articles in specialist journals and popular scientific articles), 12 books (of which one has a chapter in flow injection atomic spectroscopy), over 25 internal research reports and over 90 representations at conferences, symposiums, seminars and work-shops in North-America, Europe, Britain, Japan and Africa. He serves on the Advisory Editorial Boards of some international journals.

EDITORIAL

The Editorial Board and the Publisher of *Talanta* take pleasure in welcoming Dr. Lars Kryger as the new Review Editor for the journal, and also in welcoming Professor Totaro Imasaka and Dr. Milan Meloun as new members of the Advisory Board.

Lars Kryger received his M.Sc. degree in 1971 after specializing in inorganic and structural chemistry in the group of S. E. Rasmussen, Aarhus University, Denmark. In 1975, after studying under D. Jagner (now Göteborg, Sweden), he received his Ph.D. in analytical chemistry. Following one year as a post doctoral fellow with S. P. Perone, Purdue University, Indiana, he returned to Aarhus University where he is now employed as a lecturer. His current research interests include the development of computerized electroanalytical instruments and electrochemical trace analysis. Furthermore, he collaborates with R. P. Baldwin's group (Louisville, Kentucky) on the construction and characterization of modified electrodes. In 1981 he received the Louis Gordon Memorial award for a *Talanta* review on Pattern Recognition methods. In addition to his association with *Talanta*, he serves as a member of the Advisory Board for *Mikrochimica Acta*. For two years during his early career Lars Kryger worked as a science teacher in Tanzania. He is married, has a son and a daughter, and enjoys sailing, cooking and social winter bathing.

Totaro Imasaka received his B.S., M.S., and Ph.D (Dr. of Engineering) degrees from the Department of Applied Chemistry, Faculty of Engineering, Kyushu University, graduating in 1978. After one-year of postdoctoral studies at Stanford University, he returned as a research associate to Kyushu University. From 1979 to 1980 he worked as a lecturer at Kyushu University. He was appointed associate professor in 1981 and Professor in 1991. He was a recipient of the 1984 Young Chemist Award presented by The Chemical Society of Japan. Professor Imasaka's current research interest is trace analysis using laser spectroscopy, and for ten years he has studied time-resolved fluorescence spectrometry and thermal lens spectrophotometry. Recently, he has focused his attention on supersonic jet spectrometry combined with fluorescence spectrometry and multiphoton ionization mass spectrometry. He also invented semiconductor laser spectrometry for practical trace analysis. More recently he has concentrated his attention on developing a multi-color laser based on four-wave mixing for analytical applications. He has published over 100 original papers and 50 review articles, he has also served as the organizer of several international meetings in Japan.

Milan Meloun was born in 1943 in Czechoslovakia, graduated in physical chemistry in 1965 from Purkyne University Brno, received a Ph.D. degree in analytical chemistry in 1973 from the University of Chemical Technology Pardubice, a RNDr degree in chemometrics from Charles University, Prague in 1975 and most recently a D.Sc. degree in chemometrics and analytical chemistry from the Technical University of Prague in 1990. For more than 20 years he has read Instrumental Methods of Analytical Chemistry at the University of Chemical Technology in Pardubice. He is also Secretary of the Chemometrics section of the Czechoslovakia Chemical Society. From 1979 to 1981 he introduced courses of Statistical Data Treatment, Chemometrics and Data Processing in instrumental Analytical Chemistry during his visiting Professorship at the University of Baghdad. In 1988–1990 he gave courses of Chemometrics at the Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm. Dr. Meloun's research interests lie in the computer-assisted interpretation of solution composition and complex-forming equilibria, and regression analysis of potentiometric, spectrophotometric and extraction data. He has published over 70 papers, and has given 75 lectures at scientific conferences. He has also co-authored 10 books and 7 textbooks. A critical survey of up-to-date algorithms demonstrated by a detailed solution of 50 analytical equilibria problems is featured in his book *Computation of Solution Equilibria* (Horwood, 1988) and a methodology and programs in two chapters in

Computational Methods for the Determination of Formation Constants (Plenum Press, 1986). During the last 10 years he has been concerned with developing statistical software for chemometrics and results are demonstrated on 400 solved problems in his two-volume textbook *Chemometrics in Instrumental Analysis* (Horwood, 1991).

OBITUARY

Professor Nobuhiko Ishibashi, 1928–1991

It was with great shock that we learned during the "Flow Analysis V" conference in Kumamoto, Japan that its principal organizer and General Secretary, Professor Nobuhiko Ishibashi, suddenly and unexpectedly had passed away on August 23, 1991. At the reception of the event, held in the evening prior to the opening of the conference, Professor Ishibashi was his ever enjoyable self, obviously taking pleasure in the secured success of the imminent conference, which had assembled more than 160 participants from 28 different countries from all continents. Although noting that he had a slight flu, Professor Ishibashi was determined to engage in the full programme of the conference, and was looking forward to his own presentation on the last day of the meeting. He died in the evening before that. It thus befell a deeply moved Professor Keihei Ueno instead to give a eulogy on his old friend and colleague at the very same time all participants had been expecting to listen to another of Professor Ishibashi's always interesting and informative presentations.

Professor Ishibashi received a bachelor's degree in engineering from Kyushu University in 1951. Following a short period in industry, he returned to his *Alma Mater* the same year as a research associate at the Department of Applied Chemistry. In 1956 he became Assistant Professor, then Associate Professor in 1957, and finally, after having earned his D.Eng. degree in applied chemistry in 1961, he was in 1966 appointed to Professor of the newly established chair in applied analytical chemistry at the university. Professor Ishibashi stayed at Kyushu University until March of this year when he, in accordance with the laws of his country, retired, yet only to transfer his vitality and enthusiasm to the private University of Kiniki.

Professor Ishibashi's early research interest was focused on electrochemistry, a subject which despite his later diversification into other research areas, continued to have his special attention throughout his academic career. Thus, in addition to publishing numerous papers on electrochemistry, he was the inventor of several ion-selective electrodes now commercially available. In this context, it should be emphasized that his theory on the intrinsic selectivity coefficient (Jyo–Ishibashi theory) has been most useful for the understanding of the selectivity and sensitivity of ion-selective electrodes. He has made valuable contributions in absorptiometry and fluorometry, where his work on lasers as light sources in high-sensitivity spectrometry in 1977 earned him the distinction of attaining the lowest detection limit for fluorescein recorded thus far (0.02 ppt). He was a pioneer in using diode lasers in analytical spectrometry methods such as thermal lensing, photoacustics and fluorometry. In the last field he promoted the combination of the supersonic jet and synchronous scan techniques to extend the selectivity of laser fluorometry of aromatic compounds. Yet to many analytical chemists in Japan, but particularly in the international scientific community, he will most likely be remembered as the *avant-garde* of Flow Injection Analysis in his native country. He not only took the initiative to introduce this novel concept of continuous flow analysis into Japan, but was a most active practitioner of FIA himself, producing a long array of papers dealing with a variety of applications. As its principal inspirator and orator, his was the founding father of the Japanese Association of Flow Injection Analysis in 1983 and the vital nucleus behind its promotion of the very first periodical devoted entirely to FIA, that is, the Journal of Flow Injection Analysis. Professor Ishibashi was instrumental in the later transformation of the journal, which originated as a national journal where all articles were published in Japanese, into a truly international outlet, attracting authors from all over the world.

As a result of his advanced and visional research activities Professor Ishibashi was bestowed with several national awards over the years: The Sano Award from the Electrochemical Society of Japan (1962), the Analytical Award from the Japanese Society for Analytical Chemistry (1974), the Shimadzu Award from the Shimadzu Foundation (1988) and the Chemical Society Award from the Chemical Society of Japan (1990). During his research career he was the author of more than 250 scientific papers, served on the editorial advisory board of several international periodicals (notably Analytica Chimica Acta, Analytical Chemistry and Mikrochimica Acta), and was Vice-President of the Japanese Society for Analytical Chemistry (1980–81) and of the Electrochemical Society of Japan (1987–88).

But what Professor Ishibashi very likely will be remembered for, at least for a non-Japanese who never had the privilege to be his student, coworker or colleague, was his always contagious enthusiasm, open mind, unbound energy and passion for science. It was always a pleasure to meet and talk with him at international meetings, and he will be dearly missed by his many friends in the international scientific community.

We mourn the departure of a genuine and good colleague, and express our sympathy to his wife who often accompanied him at international events. Although taken away much too early, we take comfort in the fact that Professor Ishibashi died in the midst of what he truly appreciated and amongst those who truly appreciated him.

RONALD BELCHER MEMORIAL AWARD 1992

Dr. Mian Jiang

The third Ronald Belcher Memorial Award has been awarded to Dr. Mian Jiang of Wuhan University, Peoples' Republic of China. Dr. Mian is particularly interested in Electroanalytical Chemistry and Chemically Modified Electrodes and intends using the award in a visit to European research workers in the field.

The Belcher award is made in Commemoration of the late Professor Belcher's outstanding contributions to analytical chemistry, international relations and understanding, and his interest in student welfare. The award is made in alternate years in the form of a grant to enable a young analytical scientist to travel abroad.

OBITUARY

Professor Jiri Stary

Throughout the Summer and early Fall of 1991, Professor Jiri Stary fought a losing battle with an illness which gradually weakened him until he died on October 3rd. It is hard to believe that he is gone, leaving his many friends, colleagues, students and family mourning. His qualities as a researcher and a teacher made him loved by all. Though a man of soft words and a friendly smile, he was an uncompromising believer in personal freedom, human rights and decent behavior. Thus on every occasion throughout his entire life, he scrupulously avoided advancing himself by political means, an attitude many people in his position did not, or did not dare, to adopt. Even in the most difficult times he remained firm, and with his unpretentious style, sought refuge in his research. He was a true scholar who pursued his work, driven by curiosity and a joy of discovery.

Jiri Stary was born in the Czech village of Zbizuby on the 26th of July, 1933. He obtained his M.S. degree at the Charles University in Prague, and his Ph.D. degree at the Moscow State University in 1958. Following his studies at the Joint Institute of Nuclear Science in Dubna and Moscow State University, he obtained the prestigious title of Doctor of Sciences in 1965, perhaps as the youngest Czechoslovakian scientist ever to obtain this degree. He spent his professional career at the Department of Nuclear Chemistry of the Technical University in Prague, where he became a full Professor in 1980. Since 1969 he was a member of the Analytical Division of the IUPAC and ultimately became the National Representative. Professor Stary was Associate Editor of the *Journal of Radioanalytical and Nuclear Chemistry* and he was a member of the editorial boards of several journals. His own publications comprise over 120 papers, 20 reviews and 4 monographs.

His work in the area of radiochemical separations, his discovery of substoichiometric separations and his studies on solvent extraction equilibria, published in many international journals, including *Talanta*, comprise knowledge of a lasting value. His monograph, "*Solvent Extraction of Metal Chelates*" (Pergamon Press, Oxford), is as useful today as it was when it was first published in 1965. Though never honored by prestigious international awards (which he never sought), Jiri Stary was indeed in the league of the giants of the Czech School of Chemistry, as Jaroslav Heyrovsky or Rudolf Pribyl were.

I was blessed to join him as a junior colleague soon after he was hired in 1958 at the Department of Nuclear Chemistry in Prague by a famous polar explorer, Professor Behounek. We worked together for a number of years in the early sixties, and I was swept by his enthusiasm and impressed by his deep knowledge of complex chemistry. It was not unusual for him at that time to spend days and nights in a row in a dingy antiquated basement laboratory at the Chemical Institute of the Charles University in Albertov in order to learn as much as possible about how to separate short-lived radioisotopes. It is conceivable that his extensive work in radiochemistry, especially during his early years in the Soviet Union, planted the seed for the illness which ultimately killed him.

To those who have known him, it is hard to accept that he has gone so early. It would perhaps be easier to believe that he continues his calculations and experiments somewhere in the Universe in a Laboratory where administrative paperwork cannot reach him. If that is so, we all may hope to join him one day, and to enjoy research and life as he indeed did.
