(*Received* 27 *May* 1991. *Revised* 18 *July* 1991. *Accepted* 26 *July* 1991)

Summary—This paper demonstrates how the absorbance increment (ΔA) between two wavelengths selected according to the fundamental criteria for application of the H-Point standard additions method (HPSAM) are only related to the analyte concentration. A procedure for calculation of the unknown analyte concentration with no bias error by applying HPSAM to ΔA values in much the same way as the method of standard additions (MOSA), is reported. The method was also applied to a calibration with a single standard. The results obtained on 6 samples with maximal separations between 65 and 0 nm are reported. Finally, the proposed method was applied to the resolution of different phenol-*o*-cresol mixtures.

The selectivity of virtually all analytical methods reported lately is normally studied either on the basis of experimental measurements or by using mathematical algorithms taking due account of the potential mutual interferences of the different species involved; all these studies have resulted in significant gains in the knowledge and performance of analytical separation methods.

A number of methods aimed at increasing analytical selectivity by using algebraic expansions have been reported lately thanks to the rapidity with which results can be obtained and to the vast amount of information they provide. Many of these developments have emerged from the spectroscopic field; such is the case with:

(*a*) The application of derivative spectroscopy to real problems subject to constant systematic errors and to the resolution of multi-component mixtures with fairly overlapped absorption spectra.[1,2]

(*b*) The use of multi-variate calibration, whether direct (when the spectra of all the components are known) or indirect (which calls for no individual interference data but requires the use of standards including all the components to be determined and the content in each interferent to be varied over a sufficiently wide range for the algorithm used to succeed in evaluating its effect).[3–7]

(*c*) The implementation of deconvolution methods, which isolate the spectrum of the analyte from the overall sample spectrum, thereby allowing it to be quantified.[5–7]

Despite the remarkable achievements in this field, the obtainment of reliable results is rendered difficult by samples including components with strongly overlapped or unknown spectra and/or unknown concentrations.

The H-Point Standard Additions method[8–10] was developed as an alternative to existing methods for solving the above-mentioned problems. It allows the analyte concentration to be calculated free from all constant systematic and proportional errors even in the presence of a direct interferent in the sample to be assayed. It relies on the use of the analytical signals obtained at two wavelengths where the absorbance is the same for the interferent and different for the analyte; the application of the Method of Standard Additions (MOSA) under these conditions thus leads to two straight lines at each wavelength which intercept at the so-called H-point, defined by the coordinates $(-C_H, A_H)$, where C_H is the analyte concentration and A_H is the analytical signal yielded by the interferent, which can thus be quantified as well.

The foundation of the HPSAM was described in two earlier papers.[8,9] A third, more recent paper, reported its application to the resolution of mixtures of two components with extensively or completely overlapped spectra.[10]

*Author for correspondence

This paper shows how the application of the HPSAM can be simplified by using a single calibration graph when only the analyte concentration must be calculated or only the overall sample spectrum is available; it is also of use in applying the single-standard calibration method.[11]

As shown below by solving several major analytical problems, the analytical signal used (ΔA) is only dependent on the analyte concentration and should therefore be preferred to the absorbance.

The proposed modified HPSAM allows the determination of the analyte concentration with no systematic errors in the presence of a direct interferent and any constant systematic error, thereby making any preliminary separation step dispensable and enhancing selectivity.

THEORETICAL BACKGROUND

The consideration about the HPSAM made in earlier papers[8,9] are applicable here in using ΔA as the analytical signal as described below.

Consider a sample containing two compounds X (analyte) and Y (interferent). The equations resulting from application of the MOSA to the two HPSAM wavelengths, λ_1 and λ_2, will be:

$$A_1 = b_0 + b + M_1 C_i + \text{TYB} \quad (1)$$

$$A_2 = A_0 + A' + M_2 C_i + \text{TYB} \quad (2)$$

where A_1 and A_2 are the absorbances measured at the two selected wavelengths for the different solutions assayed, b_0 and A_0 bear the same meaning for the analyte of the solution containing sample alone and b and A' for the interferent, M_1 and M_2 denote the slope of the MOSA plots and TYB stands for the Total Youdan Blank, which will normally be the same at the two wavelengths, especially taking into account their closeness (for other information, refer to reference 9). C_i denotes the different added concentrations of pure analyte ($i = 0, 1, \ldots, n$).

Application of the HPSAM under the condition that the absorbance values of the interferent at the two wavelengths are the same ($b = A'$), yields:

$$A_1 - A_2 = \Delta A_{1,2} = b_0 - A_0 + (M_1 - M_2)C_i \quad (3)$$

According to this equation, the absorbance increment depends exclusively on the analyte concentration, so the plot of $\Delta A_{1,2}$ *vs.* C_i will be a straight line of ordinate $b_0 - A_0$ and slope $M_1 - M_2$ (Fig. 1). The analyte concentration can thus be calculated from ΔA values by applying the HPSAM to the intercept of the straight line, at the H-point of which

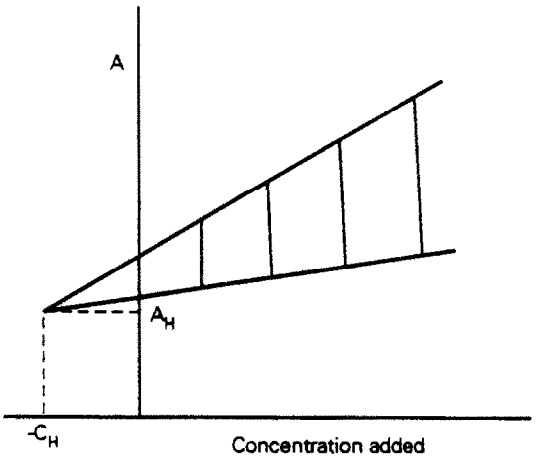

Fig. 1. The plot of the HPSAM.

$$-C_i = -C_H = (b_0 - A_0)/(M_1 - M_2) \quad (4)$$

The ΔA value obtained after each addition will be exclusively related to the analyte concentration as the interferent absorbance will be the same at the two wavelengths, so its contribution to ΔA will be zero even if the intensity of its analytical signal changes on successive analyte additions because of interaction with the analyte. Therefore, the analytical signals will be free from constant systematic errors (and also from proportional errors thanks to the features of the MOSA).

Consequently, when only the analyte concentration must be calculated or only the sample matrix spectrum is known, a single calibration plot of ΔA against the added analyte concentration allows one to calculate the unknown concentrations free from any bias error from the intercept of the line in the same way as with

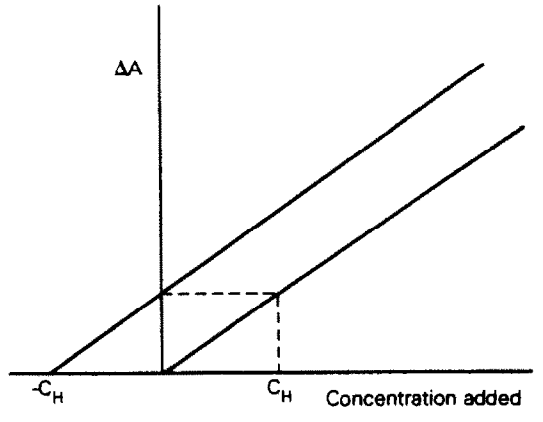

Fig. 2. The plot of the HPSAM with ΔA values.

the MOSA, but with no systematic errors. Figure 2 illustrates the two possibilities of using the HPSAM plots to calculate the analyte concentration.

On the other hand, routine work usually involves determining the analyte in a given sample by using the single-calibration method, which requires the sample signal (A_s), the analytical signal (A_r) and the concentration of standard used (C_r) to be known. Thus, the analyte concentration can be calculated from spectroscopic data by using the equation:

$$C_s = (A_s/A_r)C_r \quad (5)$$

The variables required to obtain unbiased results by applying the MOSA are A_s and the analytical signal (A_t) yielded by a solution containing the sample plus a certain known added concentration of pure analyte (C_a). The equation to be applied in this case is:

$$C_s = (A_s/A_a)C_a = [A_s/(A_t - A_s)]C_a \quad (6)$$

Applying the HPSAM to ΔA values requires them to be known for the original sample and the solution including the added pure analyte at the two selected wavelengths, as well as the analyte concentration added. The equation to be used will thus be:

$$C_s = [\Delta A_s/(\Delta A_t - \Delta A_s)]C_a \quad (7)$$

We applied the HPSAM to various mixtures of dyes, and phenol plus *o*-cresol featuring spectral maximum differences between 65 and 0 nm by using ΔA values to check the performance of the proposed method in terms of accuracy and precision in determining the analyte concentration only. The results showed the HPSAM based on the use for ΔA values to be a viable alternative to the obtainment of unbiased results wherever the working conditions allow for its application.

EXPERIMENTAL

We prepared aqueous solutions of Carmine Indigo, Thymol Blue, Methyl Red, Congo Red and Arsenazo III by weighing appropriate amounts of the indicator-grade reagents, as well as phenol/*o*-cresol mixtures form ACS phenol (Merck) and *o*-cresol (Merck). The required pH was adjusted with hydrochloric acid or sodium hydroxide.

Sample spectra were recorded on a Shimadzu UV-240 spectrophotometer and absorbances were measured at each wavelength by means of the OPI-2 unit used.

RESULTS AND DISCUSSION

Table 1 lists the results obtained by applying the HPSAM to six dye mixtures (the corresponding analyte is underlined in each case). It also gives the equations of the HPSAM plots for each replicate and the results obtained from them, as well as the average and precision. The results were satisfactory in all instances and consistent with those obtained by applying the unmodified HPSAM.

The homogeneity of the variance of the straight lines obtained at each wavelength for all the mixtures assayed was checked by applying Bartlett's test.[12] We also checked the coincidence of such lines by the ANOVA method.[12] As χ^2_{tab} was greater than χ^2_{cal} for all the sets of straight lines obtained (Table 2), the corresponding variances were thus homogeneous. The ANOVA method revealed F_{tab} to be greater than F_{cal}, so the different lines were coincident for all the mixtures assayed.

Figure 3 shows the HPSAM plots obtained with ΔA values for all the mixtures assayed. Their slopes vary with the absorbance at the two wavelengths; however, their intercepts yield the correct analyte concentration in each case. For $\Delta A = 0$, the abscissa represents the analyte concentration estimated by applying the HPSAM with ΔA values.

The mean relative errors in the analyte concentrations are listed in Table 3, which also gives the average slope for each mixture assayed, the interferent absorbance at the two selected wavelengths and the separation between maxima. As can be seen, the relative error does not depend on the interferent absorbance, but rather on the slope of the calibration graph. The results are all quite satisfactory.

These data were processed by applying equation (7) to a single-standard calibration plot. The results obtained by carrying out several additions and using ΔA values are listed in Table 4, which also gives the analyte concentration found in each replicate, the average concentration, the standard deviation and the relative error made in the determination.

The results obtained were accurate and precise for all the mixtures assayed, so the HPSAM based on ΔA can be safely applied to routine work.

As shown above, when only the analyte concentration is to be calculated, the HPSAM

based on ΔA values is equally applicable provided the spectrum yielded by one or several compounds in the presence or absence of matrix effects is known because the HPSAM compensates for constant bias errors and proportional errors, and converts uncorrectable errors introduced by a direct interferent into constant, correctable bias errors. Then, the analyte concentration is calculated from the intercept of the straight line obtained in the plot of ΔA *vs.* added analyte concentration, or from equation (7) if a single-standard calibration is made.

Finally, we applied the HPSAM based on ΔA values to various synthetic mixtures of

0	0.097	7912	−3.6

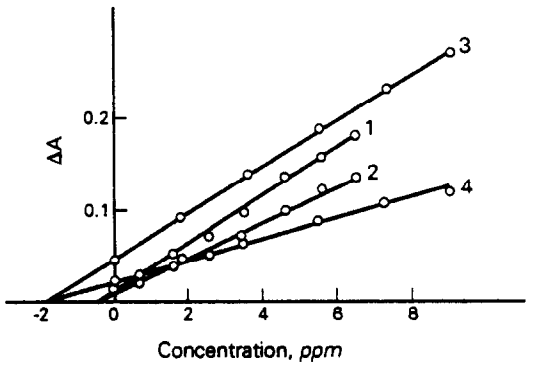

Fig. 4. The plots of the HPSAM with ΔA values for the 82 commercial grade of phenol (1, 2) and for the 50 commercial grade of *o*-cresol (3, 4). Chosen wavelengths (nm): 1 226,241; 2. 238,230; 3. 229,243 and 4 234, 239.

commercially available phenol and *o*-cresol, 82% commercial grade phenol (84.0:16.0 w/w phenol/*o*-cresol), and 50% commercial grade *o*-cresol (49:49.2 phenol/*o*-cresol/*m*- and *p*-cresol + 2,6-xylenol). Neither *m*-, nor *p*-cresol or 2,6-xylenol were used as their contribution to the interferent spectrum in the spectral region of interest was small and constant as a result of their extreme dilution.

The spectrophotometric resolution of the phenol/*o*-cresol mixtures was rendered difficult by the closeness of the absorption maxima of the two components in 0.1*M* sodium hydroxide (234 and 287 nm for phenol, and 237 and 289 for *o*-cresol) and the similarity between their absorptivities.

To determine the commercial grade phenol, the MOSA was applied to a sample containing 3.1 mg/l. phenol and concentrations of *o*-cresol (the analyte) between 0.6 and 6.5 mg/l. The commerical grade *o*-cresol was determined similarly in a sample containing 2.0 mg/l., to which phenol concentrations in the range 2.0–9.1 mg/l. were added. All the solutions were 0.1*M* in sodium hydroxide. The absorbance of the solutions was monitored over the wavelength range 244–224 nm. The slit width used was 1 nm and three replicates were run in each case.

Figure 4 shows the HPSAM plots obtained by using ΔA values. Two wavelength pairs were selected for each commercial grade; the experiments were conducted by considering phenol and *o*-cresol as respective interferents in the determinations of the 82 and 50% commercial grade compounds. The results were quite good in all instances (see Table 5). As can

Table 5. Results obtained by the method for the mixtures of aromatic compounds

Commercial grade	Analyte	wt%	Measurement wavelengths	$C_{found} + S$
82	*o*-cresol	16.0	238, 230	16 ± 1
			226, 241	14.5 ± 0.6
50	phenol	49.0	234, 239	49.5 ± 0.5
			229, 243	49.0 ± 0.5

be seen from Fig. 4, the wavelengths 226 and241 nm, and 229 and 243 nm used for the former and latter grade, respectively, provided steeper slopes—and hence better results—than the other two pairs used (238 and 230 nm for the 82% grade, and 234 and 239 nm for the 50% grade).

The average percent relative error in the analyte concentration was always less than 10% in analysing the two commercial grades with single-standard calibration.

Therefore, the HPSAM based on the use of ΔA values provides good results, however close the absorption maxima and similar the absorptivities of the two components of the mixture, and however high the interferent/analyte concentration ratio may be.

CONCLUSIONS

As shown above, the HPSAM can be applied by using absorbance increments as analytical signals whenever only the analyte concentration must be determined. ΔA values are directly (and exclusively) related to the analyte concentration and thus allow this to be calculated free from bias errors from the intercept of the straight line obtained by plotting ΔA against the analyte concentration.

The proposed method is also applicable to routine analyses by using single-standard calibration.

Summary—Organic compounds and natural materials such as dimethylglyoxime, *p*-nitrophenol, α-nitroso-β-naphthol, 4-(2-pyridylazo)-resorcinol, phenylhydrazine hydrochloride, monopyrazolone, residual fuel oil and coal can be rapidly decomposed in the melting state with various ratios of sulphuric acid–lithium sulphate (v/w) mixture containing catalysts, oxidizing agents or reducing agents such as elemental selenium powder, cupric sulphate, ceric sulphate and stannous sulphate. The quantitative recovery of nitrogen in the melting medium can be obtained with the Kjeldahl method.

It is well known that the apparatus and operation of the Kjeldahl method are very simple, which readily allows the determination of nitrogen in a large number of samples. Thus, in analogy with the Dumas method,[1] the Kjeldahl method has been widely used for the determination of nitrogen in various organic materials, but the classical Kjeldahl method suffers the disadvantage that the decomposition time is long[2–4] and complete recovery of nitrogen cannot be obtained from certain organic materials.[5]

It is actually impossible to determine nitrogen in organic compounds that contain azo, diazo, nitro, nitroso, oxime, hydrazine and pyrazolone groups with the classical Kjeldahl method. Compounds with the first six groups can of course be converted into amino compounds with catalysts[5] such as Zn–Fe powder in hydrochloric acid media, and then Kjeldahl determination of nitrogen is possible. This is not possible with heterocyclic N–N groups.[5] The gas volumetric method for determining N–N groups by oxidative fusion with chromic acid has been successfully employed to determine the heterocyclic nitrogen in indazolinone derivatives.[6]

Previous studies[7–8] have shown that a liquid medium of sulphuric acid–lithium sulphate (20 ml, 10 g) mixture can easily decompose refractory oxides such as hafnium oxide, titanium dioxide, zirconium oxide, and if a strong oxidizing reagent such as ceric sulphate, manganese dioxide, potassium permanganate or potassium periodate is added, the more refractory chromium(III) oxide can be decomposed in a few minutes. However, decomposition of organic compounds takes a long time in a liquid medium.

However, if more lithium sulphate is added to the sulphuric acid–lithium sulphate mixture, for example, changing to molten acidic lithium sulphate (ALS) flux at a $H_2SO_4 : Li_2SO_4 . H_2O$ ratio of 15 ml : 30 g instead of liquid medium (20 ml, 10 g) many organic compounds can be completely decomposed with ease. This paper demonstrates the rapid decomposition of organic compounds such as dimethylglyoxime, *p*-nitrophenol, α-nitroso-β-naphthol, 4-(2-pyridylazo)-resorcinol, phenylhydrazine hydrochloride and monopyrazolone, and natural samples such as residual fuel oil and coal in this melting medium and the quantitative recovery of nitrogen with the Kjeldahl method.

EXPERIMENTAL

Reagents

Boric acid, lithium sulphate monohydrate, potassium hydroxide, hydrochloric acid, sulphuric acid, selenium metal powder and stannous sulphate were analytical grade from Wako Pure Chemical Co. Ceric(IV) sulphate tetrahydrate (min. 98%) was from Merck. All other reagents were analytical grade. Demineralized distilled water was used throughout. The mixed

indicator was prepared by dissolving bromocresol green (0.075%) and methyl red (0.050%) in ethanol.

Organic samples

Dimethylglyoxime (DMG), p-nitrophenol and phenylhydrazine hydrochloride were from Kanto Chemical Co., Inc., analytical grade. Monopyrazolone (1-phenyl-3-methyl-5-pyrazolone) and α-nitroso-β-naphthol were analytical grade from Wako Pure Chemical Co. 4-(2-Pyridylazo)-resorcinol (PAR) was Dojindo Laboratories dotite reagent. The Standard Reference Material 1632b of Coal (bituminous) was from the National Institute of Standards and Technology of the U.S.A. The standard sample of nitrogen in residual fuel oil was from Japan Petroleum Institute.

Apparatus

The Kjeldahl distillation apparatus used was of the Parnas-Wagner type of Sibata Scientific Technology Ltd.

Decomposition procedures

Decomposition of organic materials with molten ALS flux. Weigh out roughly 30 g of $Li_2SO_4.H_2O$ into a dry 100-ml Kjeldahl flask. Add 11 or 15-ml of concentrated sulphuric acid to the flask in such as way that any solid caught in the neck is washed down. Place a small short-stemmed funnel in the neck of the flask and heat the flask with a Bunsen burner in a well ventilated fume-hood, with the flask at 45° from the vertical. Start with a strong flame, rapidly increasing the temperature until the acid begins to fume after hydrate water is boiled off. Continue heating for about 10 min until a clear melting medium (molten ALS flux) is obtained, then cool the flask, rotating gently until the melt solidifies (solid ALS flux) into thin sheets or cakes on the bottom or sides. When the ALS flux from the $H_2SO_4/Li_2SO_4.H_2O$ (15 ml, 30 g) mixed system is cooled, accurately weigh approximately 10–100 mg of organic sample such as DMG, monopyrazolone, α-nitroso-β-naphthol and PAR, and transfer into the flask without a catalyst. For a 0.1-g coal powder sample or residual fuel oil sample, the decomposition requires a catalyst such as 1.0 g of elemental selenium powder and concentrated sulphuric acid (15 ml). For the ALS flux from the $H_2SO_4/Li_2SO_4.H_2O$ (11 ml, 30 g) mixed system, accurately weigh approximately 50 mg of *p*-nitrophenol with a catalyst of about 0.1 g of selenium metal powder, transfer into the flask and add 4 ml of concentrated sulphuric acid to the flask in such a way that any solid caught in the neck is washed down. Natural samples such as coal powder or residual fuel oil were decomposed by addition of about 1.0 g of elemental selenium powder and 19 ml of concentrated sulphuric acid to the ALS flux of the H_2SO_4–$Li_2SO_4.H_2O$ (11 ml, 30 g) mixture.

Fix the flask on a stand, and start with a gentle flame for 5 min. When the contents have melted, after 5 min increase to a strong flame and continue the heating for about 10 min. Immediately before the molten ALS flux has cooled off add 30 ml of concentrated sulphuric acid to the flask and swirl gently. Let the flask stand for a few minutes, then cautiously add about 50 ml of water little by little. After cooling to room temperature with tap water, transfer the contents into a 200-ml standard flask and dilute to the mark with water. An aliquot of this sample solution is analysed by the Kjeldahl method for nitrogen.

Decomposition of organic compounds with the molten state of powdery ALS flux. Weigh out roughly 100 g of $Li_2SO_4.H_2O$ and transfer to a 500-ml beaker. Add 50 ml of concentrated sulphuric acid, cover the beaker with a watch glass, and heat with a Bunsen burner on a wire-gauze with asbestos. Begin with a strong flame, rapidly increasing the temperature until the acid begins to fume, after hydrate water is boiled off continue the heating for about 20 min. Pour the clear melted medium (ALS flux) onto a glass plate and allow to cool to room temperature.

Grind the cooled solid with a mortar and pestle, and store the powdered material of ALS flux in a desiccator. For decomposition of the organic compound, weigh out roughly 50 g of the powdered and cooled ALS flux and 0.1 g of selenium metal powder, and then add them to a dry 100-ml Kjeldahl flask. Rotate and shake the flask in order to blend the powders. Accurately weigh approximately 50 mg of finely powdered organic compound, and transfer into the flask. Mix the powders in a shaker and swirl gently. Fix the flask on a stand and place a small short-stemmed funnel in the neck of the flask. Start with a strong flame, rapidly increasing the temperature until the contents begin to melt, and continue heating for about 15–20 min. Before the ALS flux cools, add 30 ml of concentrated sulphuric acid to the flask and shake until the solution is completely mixed. Transfer to a

200-ml standard flask and dilute to volume with water.

Decomposition of coal with molten ALS flux containing $CuSO_4$. Weigh out 30 g of $Li_2SO_4.H_2O$ and transfer into a dry 100-ml Kjeldahl flask. Add 2.5 g of $CuSO_4.5H_2O$ to the flask and then 20 ml of concentrated sulphuric acid in such a way that any solid caught in the neck is washed down. Place a small short-stemmed funnel in the neck of the flask and heat with a Bunsen burner. Continue the heating with a strong flame for about 10 min until a clear green melting ALS flux is obtained, and then cool the flask.

When the contents are cool, accurately weigh approximately 0.1 g of coal powder and 5.0 ml of concentrated sulphuric acid, by pipette, and transfer into the flask. Fix the flask on a stand and heat with a gentle flame for 5 min. When the contents become a clear green melted ALS flux after 5 min, increase to a strong flame and continue the heating for about 15 min. Immediately before the ALS flux is cool, add 30 ml of concentrated sulphuric acid to the flask, mix the contents completely and dilute to 200 ml with water by the method stated above.

Decomposition of phenylhydrazine with molten ALS flux containing $SnSO_4$. Accurately weigh approximately 15 mg of phenylhydrazine hydrochloride and transfer into a dry 100-ml Kjeldahl flask. Weigh out roughly 30 g of $Li_2SO_4.H_2O$ and 0.2 g of tin(II) sulphate and add to the flask. Shake the flask to blend the powders. Add 20 ml of 13.5*M* sulphuric acid to the flask in such a way that any solid caught in the neck is washed down. Place a small short-stemmed funnel in the flask and fix the flask on a stand at 45° from the vertical. Start with a gentle flame and continue heating for about 30 min. Then heat with a strong flame until the acid begins to fume after all water is boiled off, and continue the heating for about 20 min. Before the clear molten ALS flux is cool, add 30 ml of concentrated sulphuric acid to the flask, mix the contents completely, and dilute to 200 ml with water by the method stated above.

Kjeldahl determination of nitrogen

Take 20–50 ml portions (accurately measured) of the sample solutions and transfer to the Kjeldahl distillation apparatus. Generate ammonia with sodium hydroxide solution and absorb the ammonia in 30 ml of saturated boric acid solution. Continue the steam distillation until about 100 ml of liquid have passed over so that all the ammonia may be recovered. Add a few drops of indicator to the ammonia absorption media and titrate the H_3BO_3–NH_3 solution with standard 0.1*M* hydrochloric acid, using a 1-ml microburette.

RESULTS AND DISCUSSION

Organic compounds having groups of azo, diazo, nitro, nitroso, hydrazine, oxime and pyrazolone are among the most difficult to rapidly decompose and quantitatively recover nitrogen with the classical Kjeldahl method.[5] However, if a melting ALS flux such as H_2SO_4–Li_2SO_4, H_2SO_4–Li_2SO_4–Se, H_2SO_4–Li_2SO_4–$CuSO_4$ or H_2SO_4–Li_2SO_4–$SnSO_4$ is used, these organic compounds can be rapidly decomposed and the nitrogen content quantitatively recovered. Fusion[6,9] and catalysts[4,10–16] are effectively utilized in the Kjeldahl method. The molten state of the ALS flux is analogous to that of a fusion flux.

Decomposition of DMG, monopyrazolone, α-nitroso-β-naphthol, PAR and p*-nitrophenol*

Organic compounds such as DMG, monopyrazolone, α-nitroso-β-naphthol, and PAR can be rapidly and easily decomposed by heating for 10–30 min with the molten state of ALS flux from H_2SO_4–$Li_2SO_4.H_2O$, without a catalyst. However, elemental selenium powder seems to be one of the most effective catalysts in the decomposition system and reduces the decomposition time of α-nitroso-β-naphthol (from 20 to 15 min) and PAR (from 10 to 7 min). The complete decomposition of these organic compounds with the concentrated sulphuric acid and lithium sulphate monohydrate (15 ml, 30 g) mixture requires heating for long periods such as 30–60 min because the coordinated water of lithium sulphate gives rise to bubbles in the flask. Therefore, before decomposing the organic compounds, the hydrate water in the mixture of H_2SO_4–$Li_2SO_4.H_2O$ should be completely removed by heating. After the organic compounds are decomposed, concentrated sulphuric acid (30 ml) must be added to the hot melting ALS flux to prevent the solidification of the liquid state. The solidifying medium, ALS flux in other words, cannot be rapidly dissolved with water or dilute sulphuric acid at room temperature. DMG, α-nitroso-β-naphthol and PAR can be completely decomposed with molten ALS flux from the H_2SO_4–$Li_2SO_4.H_2O$ (15 ml, 30 g) mixture without a catalyst in the

Kjeldahl flask for 10–20 min and the nitrogen content in the samples can be quantitatively recovered (Tables 1, 2 and 3). The decomposition time for monopyrazolone is about 30 min, but the nitrogen can only be recovered quantitatively heating for 10 min longer with a strong flame. The decomposition method for determining N–N groups in monopyrazolone with molten ALS flux and no catalyst, oxidizing agent or reducing agent was successfully employed to determine the heterocyclic nitrogen (Table 4). For the complete decomposition of *p*-nitrophenol, the catalyst and a few milliliters of concentrated sulphuric acid need to be added to the ALS flux from the H_2SO_4–$Li_2SO_4.H_2O$ (11 ml, 30 g) system before the melt. Furthermore, the ratio of H_2SO_4/Li_2SO_4(ml/g) in the melting ALS flux is very important for complete decomposition of these organic compounds. After the *p*-nitrophenol (~50 mg), elemental selenium powder (~0.1 g) and concentrated sulphuric acid (4 ml) are added the ALS flux H_2SO_4–$Li_2SO_4.H_2O$ (11 ml, 30 g) in the Kjeldahl flask, the mixture should be gently heated for about 10 min and after melting of the ALS flux, it can be heated rapidly up to a high temperature. The organic compound can be decomposed in about 20 min and the quantitative recovery of nitrogen in *p*-nitrophenol can be obtained with the procedure, with a standard deviation of 0.20% nitrogen at the 10% level (Table 5).

Decomposition of phenylhydrazine hydrochloride

The quantitative recovery of the nitrogen content in phenylhydrazine hydrochloride cannot be obtained with the decomposition systems of ALS flux and powdery ALS flux containing

selenium. The solid ALS flux and the powdery ALS flux cannot be used for decomposing phenylhydrazine hydrochloride because the nitrogen in this compound appears to be volatilized before the ALS flux is completely melted. Therefore, a suitable reductant, such as tin(II) sulphate and water are required for decomposition of phenylhydrazine. A recovery of only 60–70% of the nitrogen content in phenylhydrazine hydrochloride is obtained with the decomposition system of a H_2SO_4–$Li_2SO_4.H_2O$–$SnSO_4$ (15 ml, 30 g, 0.2 g) mixture in the Kjeldahl flask at 60 or 90 min. However, a quantitative recovery is obtained by adding a little water. The phenylhydrazine hydrochloride (~15 mg) can be decomposed by heating with a gentle flame for about 30 min with the H_2SO_4–H_2O–$Li_2SO_4.H_2O$–$SnSO_4$ (15 ml, 5 ml, 30 g, 0.2 g) mixture, followed by heating with a stronger flame for about 10 min to boil off the

water, and then continuing for about 20 min. Consequently, the H_2SO_4–H_2O–$Li_2SO_4.H_2O$–$SnSO_4$ mixture for the decomposition of phenylhydrazine hydrochloride is considered best for recovery of nitrogen (Table 6).

Decomposition of residual fuel oil and coal

Table 7 gives the results obtained for analysis of a standard sample of nitrogen in residual fuel oil of the Japan Petroleum Institute. The residual fuel oil (~ 0.1 g) can be rapidly decomposed by addition of about 1.0 g of elemental selenium powder and 19 ml of concentrated sulphuric acid to the ALS flux from the H_2SO_4–$Li_2SO_4.H_2O$ (11 ml, 30 g) system. The certified value of nitrogen in the standard sample of residual fuel oil is $0.589 \pm 0.08\%$ and the determination value of nitrogen under the recommended conditions is 0.59% (S.D. 0.01). Therefore, the decomposition of samples and the recovery of nitrogen in the residual fuel oil under the recommended procedure is complete. Table 8 gives the results obtained for analysis of NIST standard reference material of coal under the various decomposed conditions. Decomposition with the molten state of the ALS flux from the H_2SO_4–$Li_2SO_4.H_2O$ (15 ml, 30 g) mixture without catalyst gave low recovery of nitrogen in coal. Similarly, the decomposition with the H_2SO_4–Li_2SO_4–$Ce(SO_4)_2$ system gives lower than the certified value of nitrogen in coal. Hence, a suitable catalyst, such as elemental selenium powder or cupric sulphate, is required for complete recovery of nitrogen in coal by the ALS flux decomposition system. Heating with the ALS flux from H_2SO_4–$Li_2SO_4.H_2O$ (15 ml, 30 g), elemental selenium (1 g) and concentrated sulphuric acid (15 ml) decomposes 0.1 g of coal powder in about 8 min and the recovery of nitrogen in coal is complete. However, more addition of concentrated sulphuric acid (such as 20 ml) to the ALS flux gave low results. Heating with the ALS flux from H_2SO_4–$Li_2SO_4.H_2O$–$CuSO_4.5H_2O$ (20 ml, 30 g, 2.5 g) and concentrated sulphuric acid (5 ml) decomposes 0.1 g of coal powder in about 20 min and the determined value of nitrogen in coal is exactly equal to the certified value, but more addition of concentrated sulphuric acid, such as 10 ml, to the ALS flux gave a lower value than the certified value. It is suggested that the ratio of H_2SO_4/Li_2SO_4 (ml/g) in the melting state of the ALS flux is very important for complete decomposition of coal samples and quantitative recovery of nitrogen.

This decomposition system comprises many variations from mixing the ALS flux with various ratios of $H_2SO_4/Li_2SO_4.H_2O$ and catalysts, oxidizing agents[8] or reducing agents. Therefore, this is a potentially widely useful and rapid decomposition method for various organic, biological and environmental materials.

APPLICATION OF ELECTRON PROBE MICRO-ANALYSIS TO THE ESTIMATION OF CHLORINE IN ALUMINA-BASED HETEROGENEOUS CATALYSTS

V. J. KOSHY,* K. V. RAO, G. KALPANA and V. N. GARG

Research Centre, Indian Petrochemicals Corporation Limited, PO: Petrochemicals, 391 346, Vadodara, Gujarat, India

(*Received* 24 *July* 1990. *Revised* 2 *July* 1991. *Accepted* 3 *July* 1991)

Summary—Chlorine in alumina-based catalysts has been determined with a scanning electron microscope attached to an energy dispersive x-ray analyser (SEM–EDX). The method is less time consuming compared to conventional methods involving sample dissolution followed by titrimetry, absorption spectrophotometry or ion chromatography. The spectrometer is calibrated with laboratory prepared standards. This technique is found suitable for the estimation of chlorine in the range 0.1–1.0% (w/w) with a relative standard deviation < 10% for chlorine levels above 0.2%.

Noble metal catalysts, mainly platinum supported catalysts, are employed in several petrochemical processes like dehydrogenation, reforming and isomerization. It is well known that the chlorine ion which gets incorporated during impregnation of platinum into the alumina support has profound influence on the physicochemical properties of the catalyst.[1] Chlorine balance in the catalyst is critically important for optimum activity, selectivity and stability of the catalyst during reforming operations.[2–4] It is therefore important to monitor the level of chlorine in the catalysts during their preparation as well as usage in commercial plants.

Argentometric titration,[1] x-ray fluorescence spectrometry,[5] absorption spectrometry[6] and ion-chromatography[7] are the techniques reported for the estimation of chlorine in catalysts. In the present study, the possibility of using the Scanning Electron Microscope in conjunction with an Energy Dispersive X-ray Analyser (SEM–EDX) is investigated. This technique has been widely used for qualitative identification of elements, but rarely for their quantitative estimation in catalysts. The accurate quantification of elements by x-ray emission methods is based on availability of reference materials whose matrix and composition match fairly well with those of the samples to be analysed.[8] Since these standards were not available, they were prepared in our laboratory and their chlorine content was ascertained by spectrophotometry.

EXPERIMENTAL

A Scanning Electron Microscope (JEOL, JSM-35C) in conjunction with an energy dispersive x-ray analyser (Kevex, model 7000-77) was employed for this study. EDX spectra were recorded on a Hewlett–Packard 7015 B X-Y recorder. Absorbance measurements were recorded on a Varian Superscan-3 spectrophotometer with matched 1-cm silica cells.

All reagents used were of GR grade. γ-Alumina pellets (3.2 mm) from Alfa Products were used as the support material for preparation of standards. Doubly distilled water was used in all the experiments.

Preparation of standard samples

Sodium chloride was dried at 100° for 4 hr. About 1.65 g was weighed accurately into a 100-ml standard flask and made up with water to prepare a stock solution containing 10 mg/ml chloride. A 5.0-g portion of finely powdered and dried (<210 mesh, 200° for 12 hr) γ-alumina was taken in six separate 100-ml round bottom flasks. To each of them was added 0, 1, 2, 3, 4 and 5 ml, respectively, of sodium chloride solution. The total volume of solution in each flask was adjusted to 15 ml with water and the contents were kept at 40° for 4 hr with constant stirring. Subsequently, the samples were dried

IPLC Communication No.: 173.
*Author for correspondence.

with a Buchi Rotavapor and the final drying was carried out in an air oven at 100° for 4 hr. These samples were cooled and transferred into airtight containers and preserved in a desiccator. The chlorine contents of laboratory-prepared standards were estimated by the spectrophotometric method,[6] using Fe(III)–$Hg(SCN)_2$ reagent.

Preparation of samples for SEM–EDX measurements

All standards and catalyst samples were ground to pass through a 210-mesh sieve. Pellets of 13-mm diameter and 2-mm thickness were prepared with a hydraulic press at a pressure of 10 tons/cm^2 and a retention time of 2 min. The flat surfaces of the spacers that came into contact with the pellet were mirror-polished so that the specimen (pellet) had a very smooth surface. The pellet was cut into four quadrants and one quadrant was mounted on a carbon stub with silver conducting paste with the smooth surface facing upwards. Since all the specimens were non-conducting, a carbon layer of 400 Å thickness was coated by using a JEOL JEE-4X vacuum evaporator in order to avoid charge build-up and specimen heating during the analysis.

Spectra acquisition

The sample, after mounting and carbon coating, was kept in the specimen chamber of the scanning electron microscope. The electron flux was kept constant by maintaining the x-ray count rate of 4000 cps on a clean aluminium stub. The count rate did not change throughout the spectral acquisition, indicating that there was no loss of surface chlorine due to electron beam impingement. The other conditions used in operating the x-ray analyser are given in Table 1.

RESULTS AND DISCUSSION

The spectra obtained from the various samples have been analysed by different computer programs like ASAP, ZAF and LSQ supplied by Quantex software. The LSQ program was found to be the most suitable in the present case. It uses a background filtering routine and determines the area of peak in terms of counts per second in the range of interest, *i.e.*, 2.62 keV for chlorine K_α emission. Figure 1 shows the x-ray emission spectrum of alumina samples in the presence and absence of chlorine.

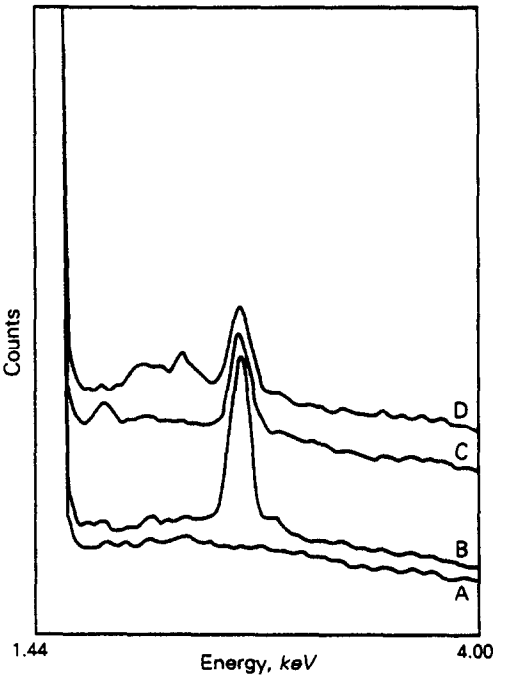

Fig. 1. EDX spectra of (A) support (γ-Al_2O_3), (B) standard (0.95% Cl/γ-Al_2O_3) (C) catalyst (Cl/Pt/γ-Al_2O_3—3 in Table 2) and (D) catalyst (Cl/Pt–Re/γ-Al_2O_3—5 in Table 2).

Evaluation of standards

The uniformity as well as stability of the laboratory-prepared standards have been tested by recording their EDX spectra and analysing them by the LSQ method. Four standard samples having chlorine contents of 0.14, 0.36, 0.61 and 0.95% (w/w) were chosen and six spectra were acquired from different portions of each sample. This exercise was carried out on the basis of the assumption that non-uniformity of chlorine distribution in the sample would result in a difference in the analyte signals obtained from different portions of the same sample specimen. The variation in the results was less than 3%, suggesting that the samples were uniform. The chlorine peak intensity measurement of each standard sample was performed over a period of three months and the variation observed from time to time was 5–8%

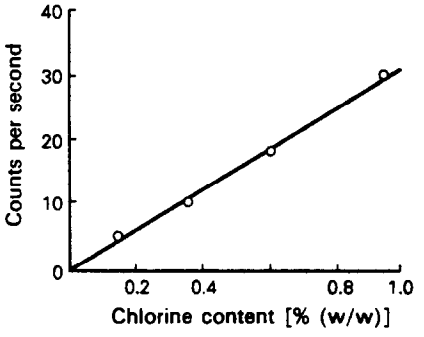

Fig. 2. Relationship between counts per second and chlorine content with LSQ program.

Table 2. Chlorine content of various laboratory-prepared Alumina supported Pt–Re catalysts with different composition

Sample No.	Chlorine content (% w/w) by SEM–EDX	Spectrophotometry
1	0.13 ± 0.04	0.11 ± 0.01
2	0.15 ± 0.03	0.13 ± 0.01
3	0.60 ± 0.02	0.65 ± 0.02
4	0.78 ± 0.02	0.77 ± 0.02
5	0.69 ± 0.03	0.66 ± 0.01
6	0.77 ± 0.03	0.74 ± 0.01

when each of the standards was analysed with the stored calibration graph. Hence it is considered essential to acquire fresh standard spectra and construct a calibration graph each day, before sample analysis. The calibration graph obtained on a particular day is presented in Fig. 2.

Analysis of alumina-based catalyst samples

The EDX spectrum A in Fig. 1 shows the absence of any x-ray emission in the region of 2.62 keV energy. The chlorine peak is clearly shown in spectrum B corresponding to the calibration standard. Spectra C and D show the well-defined chlorine peak sufficiently separated from all concomitant emission lines, enabling accurate computation. Catalyst samples, designated 1 through 6, were analysed by the LSQ routine and the results are presented in Table 2. The standard deviations in the order of 0.04% in chlorine content show good reproducibility of the method. The mean values of chlorine obtained by SEM–EDX agree well with the spectrophotometric results.

The method has been applied successfully in the case of platinum on alumina as well as platinum–rhenium on alumina catalysts. However, under the experimental conditions employed, *i.e.*, channel width of 10 eV, Ru ($L_\alpha = 2.56$ keV) and Rh ($L_\alpha = 2.70$ keV) can cause interferences.

CONCLUSION

A simple, rapid and direct method has been developed for the estimation of chlorine in catalysts with Quantex software LSQ method. Laboratory prepared standards are suitable for calibration purposes. It is essential that spectra of calibration standards be acquired prior to the analysis of catalyst samples. Noble metals like Ru and Rh can cause interference by virtue of their L_α emission. The spatial resolutions of this technique make it useful for profiling studies, an objective in our laboratory.

SIMULTANEOUS DETERMINATION OF ALUMINIUM AND BERYLLIUM BY FIRST-DERIVATIVE SYNCHRONOUS SOLID-PHASE SPECTROFLUORIMETRY

FERMÍN CAPITÁN, ELOISA MANZANO, ALBERTO NAVALÓN, JOSÉ LUIS VILCHEZ and LUIS FERMÍN CAPITÁN-VALLVEY*

Department of Analytical Chemistry, University of Granada, E-18071 Granada, Spain

(*Received* 15 *November* 1990. *Revised* 3 *June* 1991. *Accepted* 11 *June* 1991)

Summary—A method for the simultaneous determination of aluminium and beryllium in mixtures by first-derivative synchronous solid-phase spectrofluorimetry has been developed. Aluminium and beryllium reacted with morin to give fluorescent complexes, which were fixed on a dextran-type resin. The fluorescence of the resin, packed in a 1-mm silica cell, was measured directly with a solid-surface attachment. The constant wavelength difference chosen to optimize the determination was $\Delta\lambda = \lambda_{em} - \lambda_{ex} = 75$ nm. Aluminium was measured at $\lambda_{ex}/\lambda_{em} = 445/520$ nm and beryllium at $\lambda_{ex}/\lambda_{em} = 430/505$ nm. The range of application is between 0.5 and 5.0 ng/ml for both aluminium and beryllium. The accuracy and precision of the method are reported. The method has been successfully applied to the determination of aluminium and beryllium in synthetic mixtures and natural waters.

Several organic ligands have been proposed for the separate determination of aluminium(III) and beryllium(II) that take advantage of the fact that these two ions, and other cations with empty *d* and *f* orbitals, give sensitive fluorogenic reactions with a wide range of organic reagents,[1,2] particularly in coordination processes. One of these reagents, morin, is especially suitable for the determination of beryllium given its high sensitivity.

Spectrofluorimetry is often used, even in routine laboratory work, to determine both aluminium and beryllium alone. However, differentiating them in mixtures is more difficult because of their broad and featureless emission spectra, and because their spectra strongly overlap. This fact is usually found in fluorescent complexes of inorganic ions with organic reagents that generally show spectral characteristics of the reagent alone, slightly modified by the inorganic ion.

Synchronous spectrofluorimetry in combination with derivative techniques has been shown to be useful (even in routine analysis by giving advantages of speed and simplicity) in the analysis of mixtures of fluorescent compounds in solution when their spectra show strong overlapping.

In relation to the analysis of mixtures of inorganic compounds by derivative synchronous spectrofluorimetry, the following have been described: binary and/or ternary mixtures of titanium, zirconium and hafnium, through the formation of fluorescent complexes with diacetyl monoxime nicotinylhydrazone,[3] gallium in the presence of aluminium with di-2-pyridinylmethylen-2-furoylhydrazone,[4] gallium and zinc mixtures with salicylaldehyde thiocarbohydrazone,[4,5] aluminium and zinc with 8-hydroxyquinoline-5-sulphonic acid, in the presence of hexadecyltrimethylammonium bromide,[6] beryllium and aluminium with morin[7] and molybdenum and tungsten with carminic acid.[8]

The solid-phase spectrofluorimetry technique combines the measurement of solid-surface fluorescence with the use of a solid support, (*e.g.*, a dextran-type resin), to preconcentrate the analyte, rendered fluorescent by the use of an appropriate reagent. This approach is useful for the analysis of very dilute solutions, such as in water analysis.[9–13]

In this paper we combine the solid-phase spectrofluorimetry methodology with first-derivative synchronous spectrofluorimetry. Hence, the aluminium and beryllium mixtures are resolved by complexation of both ions with morin and later adsorption on a dextran-type resin, using the above technique.

*Author for correspondence.

EXPERIMENTAL

Apparatus

All the spectrofluorimetric measurements were conducted with a Perkin–Elmer LS 5 luminescence spectrometer, equipped with a Xenon discharge lamp (9.9 W) pulsed at line frequency, Monk-Gillieson F/3 monochromators, a Quantic Rhodamine 101 counter to correct the excitation spectra, a Hamamatsu R928 photomultiplier, and a variable-angle solid–surface accessory designed and constructed by the authors.[14–16] In order to compare all spectrofluorimetric measurements and to ensure reproducible experimental conditions, the LS 5 spectrometer was checked daily. A fluorescent polymer standard of *p*-terphenyl ($10^{-7}M$) gave a relative fluorescence intensity of 90% at $\lambda_{em} = 340$ nm, $\lambda_{ex} = 295$ nm, slit widths of 2.5 and 2.5 nm and a sensitivity factor of 0.594. For synchronous excitation measurements, both excitation and emission monochromators were locked together and scanned simultaneously.

The LS 5 spectrometer was interfaced to an IBM PC XT-286 microcomputer, using RS 232C connections for spectral acquisition and subsequent calculation of the excitation–emission matrices and of the derivative spectra.[16,17] Smoothed and derivative spectra were calculated by the Savitzky and Golay method[18,19] and contour plots in the excitation–emission plane were produced, linking points of equal fluorescence intensity. An Olivetti DM 100 printer was used for graphical representation.

Further, we used a Braun Melgunsen Thermomix 1441 thermostatic water-bath circulator for temperature control, a Crison 501 digital pH-meter with a combined glass-calomel saturated electrode and an Agitaser 2000 rotating agitator.

Reagents

All reagents were of analytical-reagent grade unless stated otherwise.

Sephadex G-15 resin (Pharmacia Fine Chemicals). Used without pre-treatment to prevent contamination.

Morin (2′,3,4′,5,7-pentahydroxyflavone) (Merk) solution, 0.02% w/v in absolute ethanol. More dilute solutions were prepared by appropriate dilution with absolute ethanol. Morin was purified following the procedure described by Laitinen and Kivalo.[20] The dilute morin solutions were prepared fresh every other day and the concentrated solutions were prepared weekly.

Aluminium(III) stock solution, 0.1 mg/ml. Prepared from aluminium nitrate [$Al(NO_3)_3 \cdot 9H_2O$] (Merck) and gravimetrically standardized with oxine.[21] Solutions of lower concentration were obtained by dilution with doubly-distilled water.

Beryllium(II) stock solution, 0.1 mg/ml. Prepared from beryllium sulphate ($BeSO_4 \cdot 4H_2O$) (Merck) and standardized by the phosphate method.[22] Working solutions were prepared by appropriate dilutions with doubly distilled water.

Buffer solutions. Solutions of the required pH were prepared from $0.1M$ acetic acid and $0.1M$ sodium acetate.

Fluorescence measurements

The measured relative fluorescence intensity (RFI) of the resin beads, containing the fluorescent products and packed in a 1-mm silica cell, was the diffuse transmitted fluorescence (DTF) emitted from the resin at the unirradiated face of the cell. The optimal angle between the cell plane and the excitation beam was 45° in all instances.

Procedures

Basic procedure. A 500-ml water sample containing between 0.25 and 2.5 μg of aluminium and between 0.25 and 2.5 μg of beryllium, was transferred into a 1-litre polyethylene bottle and 7 ml of 6.2×10^{-3}% morin solution, 10 ml of pH 5.75 acetic acid/acetate buffer solution and 100 mg of Sephadex G-15 resin were added. The mixture was shaken mechanically for 15 min. Afterwards, the resin beads were collected by filtration under suction and with the aid of a pipette, packed in a 1-mm cell together with a small volume of the filtrate. A blank solution containing all the reagents except both aluminium and beryllium was prepared and treated in the same way as described for the sample. We recorded the synchronous spectra (at $20.0 \pm 0.5°$) with the following fixed instrumental parameters: $\Delta\lambda = \lambda_{em} - \lambda_{ex} = 75$ nm; with a scan speed of 120 nm/min, and a spectrometer response time of 1 sec. The spectra were then stored on a disk file, corrected for the blank signal, and the first-derivative spectra with an interval of 15 nm were calculated.

First-derivative analytical signals were measured as the vertical distance from the first-derivative synchronous spectrum at

$\lambda_{ex}/\lambda_{em} = 445/520$ nm to the base line for aluminium and from $\lambda_{ex}/\lambda_{em} = 430/505$ nm to the base line for beryllium, respectively.

Calibration graphs were constructed in the same way with aluminium(III) and beryllium(II) solutions of known concentrations.

Procedure for natural waters. The above-mentioned reagents were added to a volume of natural water sample containing an adequate amount of Al(III) and Be(II) levelled off at 500 ml with doubly-distilled water and placed in a one-litre polyethylene bottle, as described above. The standard addition method was used for calibration.

Reference method. Determination of both aluminium and beryllium by AAS with a dinitrogen oxide–acetylene flame after extraction with oxine–MIBK was used as a reference method.[23]

Treatment of the sample. Natural waters (preserved by addition of 0.25 ml of concentrated nitric acid per litre) were filtered through a 0.45-μm membrane filter paper (Millipore) into a polyethylene container carefully cleaned with nitric acid.[23]

RESULTS AND DISCUSSION

Effect of experimental variables

Morin forms fluorescent complexes with aluminium(III) and beryllium(II) that are retained on ion-exchanger resins. The 1:1 aluminium complex is fixed in cationic Sephadex (SP C-25) with optimum pH being 5.3,[10] whereas the 1:1 beryllium complex is retained on anionic Sephadex (QAE A-25) at pH 11.5.[9] Given the different charges of these complexes, the simultaneous fixation of both complexes on ion-exchangers is not possible. We have selected a dextran-type resin without fixed ionic groups (Sephadex G-15) in order to adsorb both complexes.

Sorbed on Sephadex G-15 resin, morin has an excitation maximum at 443 nm and an emission maximum at 497 nm. The aluminium complex shows an excitation maximum at 430 nm and exhibits maximum fluorescence at 506 nm. The beryllium complex has its excitation maximum at 441 nm and exhibits maximum fluorescence at 519 nm. At these wavelengths the reagent fluorescence is low.

The fixation mechanism of both complexes on Sephadex G-15 resin is different due to its non ionic-exchanger nature. It might take place through the ligand molecules because of possible hydrogen-bond formation, as demonstrated by the fixation of morin alone on this resin.

The fluorescence emission of the aluminium complex fixed on Sephadex G-15 resin is maximum at around pH 5, and that of the beryllium complex at about pH 12. The shape of pH influence on RFI differs from what is observed in solution: optimum pH for the Al complex is 3.5, and 12.0 for the Be complex. In the latter complex a slight maximum at pH 5.5 is observed. In order to simultaneously obtain a fluorescence signal for both complexes, a pH of 5.75 was selected (pH value of equal fluorescence intensity for both complexes). Acetic acid/acetate was used as buffer solution, see Fig. 1.

The fluorescence of both complexes decreases with an increase in buffer concentration. A $0.002M$ concentration of pH 5.75 buffer was selected to obtain an adequate buffering capacity without excessive loss of sensitivity.

A $2.4 \times 10^{-6}M$ (8.1×10^{-5}%) reagent concentration was chosen as optimum in order to have an appropriate reagent excess ([morin]/[metal] molar ratio of around 22 for Al and 7 for Be). Lower molar ratios reduce the fluorescence intensity of both complexes while higher molar ratios increase the blank signal.

The RFI decreases when the temperature of measurement increases [-0.4%/°C between 5 and 70° for the Al(III) complex and -0.6%/°C

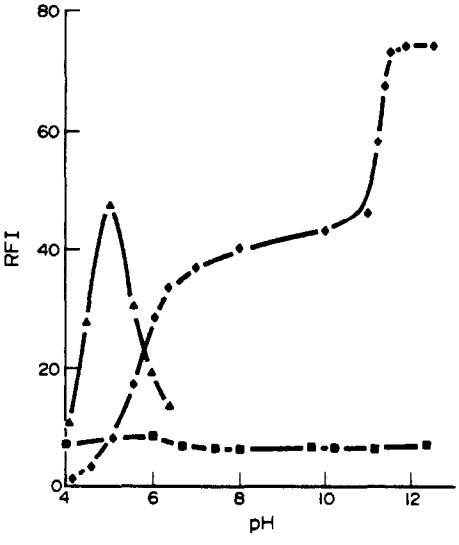

Fig. 1. Influence of pH on RFI in resin phase. (▲) Aluminium–morin complex. (◆) Beryllium–morin complex. (■) Morin alone. [morin] = $7.3 \times 10^{-7}M$, [Al(III)] = 3 μg/l., [Be(II)] = 2.5 μg/l., 500 ml of sample, 100 mg of Sephadex G-15.

for the Be(II) complex], but this effect is completely reversible for both complexes. All RFI measurements reported here were taken at $20.0 \pm 0.5°$.

The stirring time necessary for maximum RFI development was 15 min for both complexes. For stirring times longer than 25 min, RFI decreases slightly (19% at 35 min) for the Be complex. The Al complex remains unaltered with an increase in stirring time. Fluorescence for both complexes is developed immediately, remaining constant for at least 2 hr before equilibration. Variation in the order of addition of reactants was shown to have no effect on the emission intensity.

Selection of the optimum $\Delta\lambda$ for synchronous scanning

The extent of the overlap of these complexes has been examined by obtaining total fluorimetric information available in the excitation–emission matrix. Suitable plots of excitation *vs.* emission wavelengths have been drawn from the three-dimensional spectra. This allows us to select the most suitable trajectory in the excitation–emission matrix to obtain synchronous fluorescence spectra for the complete resolution of overlapping component peaks. The optimum scan path for determining aluminium and beryllium in mixtures seems to be a $\Delta\lambda$ of 75 nm, because it passes near the maximum of both complexes, allowing the determination without a considerable loss of sensitivity.

Figure 2 shows synchronous spectra of aluminium and beryllium complexes with morin fixed on Sephadex G-15 and of a mixture of both complexes, corrected for the blank signal, and maintaining a constant interval between the emission and excitation wavelengths of 75 nm.

Because of the large overlap of the spectra, the determination of aluminium and beryllium by synchronous spectro-fluorimetry is subject to considerable difficulties. This overlap has been resolved by taking the first-derivative of the spectrum. Figure 3 shows the first-derivative synchronous fluorescent spectra of aluminium and beryllium complexes with morin fixed in Sephadex G-15 and of a mixture of both complexes.

Assuming that the derivative of a spectral band is equivalent to the sum of the derivatives of its individual bands, we have chosen suitable wavelengths to take measurements proportional

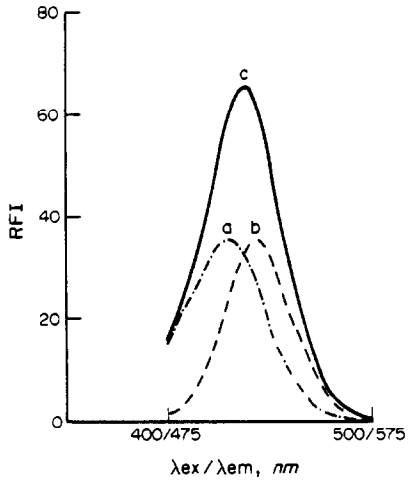

Fig. 2. Synchronous fluorescence spectrum of (*a*) aluminium–morin complex, (*b*) beryllium–morin complex and (*c*) a mixture of both complexes. ($\Delta\lambda = 75$ nm).

to the concentration of aluminium and beryllium for the preparation of the calibration graphs.

When the first-derivative spectrum of one of the two components is zero, the total derivatives spectrum is only a function of the concentration of the other component and *vice versa*. In fact, the height $h_2(\lambda_{ex}/\lambda_{em} = 445/520$ nm) is proportional to the aluminium concentration, whereas h_1 ($\lambda_{ex}/\lambda_{em} = 430/505$ nm) is proportional to the beryllium concentration (Fig. 3).

Instrumental parameters

For recording the first-derivative spectra, a scan speed of 120 nm/min and a response time of the spectrometer of 1 sec were chosen. It was

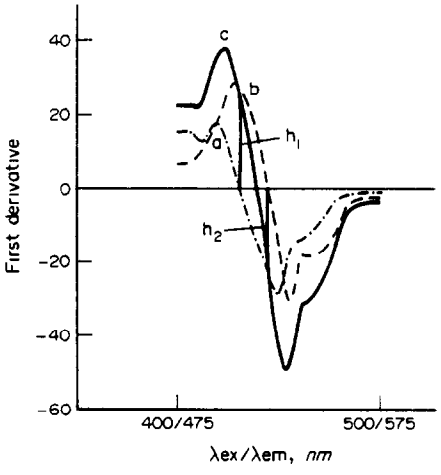

Fig. 3. First-derivative synchronous spectrum of (*a*) aluminium–morin complex, (*b*) beryllium–morin complex and (*c*) a mixture of both complexes. ($\Delta\lambda = 75$ nm).

Table 1. Statistical analysis of the determination of aluminium (0.5–5.0 μg/l.) and beryllium (0.5–5.0 μg/l.) in mixtures by first-derivative synchronous solid-phase spectrofluorimetry

Element determined	Other element present	μg/l.	Slope	Intercept	Correlation coefficient
Al(III)	Be(II)	—	6.33	1.57	0.997
		2.0	6.13	1.67	0.996
		4.0	6.09	1.74	0.997
Be(II)	Al(III)	—	7.88	1.65	0.997
		2.0	7.69	1.82	0.998
		4.0	7.58	2.04	0.996

found that these values did not appreciably affect the derivative signal obtained, because the differentiation was accomplished numerically and not electronically. An interval of 15 nm was selected for the calculation by the Savitzky and Golay[18,19] method, as this gives the best signal-to-noise ratio.

Analytical parameters

In order to test the mutual independence of the analytical signals for aluminium and beryllium, *i.e.*, to show that h_1 and h_2 are independent of aluminium and beryllium concentrations, respectively, three calibration graphs were obtained from height (h) measurements for standards containing between 0.5 and 5.0 μg/l. aluminium, in the absence of beryllium and in the presence of 2.0 and 4.0 μg/l. beryllium, respectively.

Following the same procedure, three calibration graphs were prepared for standards containing between 0.5 and 5.0 μg/l. beryllium, in the absence of aluminium and in the presence of 2.0 and 4.0 μg/l. aluminium, respectively.

The analytical parameters for all the calibration graphs are summarized in Table 1.

The IUPAC detection limits ($K = 3$)[24] are 0.1 μg/l. for Al(III) and 0.06 μg/l. for Be(II). The quantification limits ($K = 10$)[25] are 0.4 μg/l. for Al(III) and 0.2 μg/l. for Be(II). The relative standard deviations (RSD %) ($P = 0.05$, $n = 10$) are 4.6% for 2.0 μg/l. Al(III) and 3.6% for 2.0 μg/l. Be(II).

Effect of foreign ions

A systematic study was made of the effect of the ions commonly found in natural waters on the determination of 3.0 μg/l. Al(III) and 3.0 μg/l. Be(II). An 8000-μg/l. level of each potentially interfering ion was tested first. If interference occurred, the ratio was reduced progressively until interference ceased. The tolerance level was defined as the amount of foreign ion producing an error not exceeding ±5% in the determination of the analyte. The results are summarized in Table 2.

It is important to note that the interference level can be reduced by sample dilution. Taking into account the concentration range for the method proposed here and the average level for aluminium to be higher than that for beryllium in water, a minimum of five-fold dilution is required.

Applications

Determination of aluminium and beryllium mixtures in synthetic samples. The proposed method has been applied to the analysis of several synthetic mixtures of aluminium and beryllium in different ratios. Table 3 summarizes the results calculated from the calibration graphs.

Table 2. Effect of foreign ions on the simultaneous determination of 3.0 μg/l. aluminium and 3.0 μg/l. beryllium

*Data are the average value of three determinations.

†From Ortigosa del Monte. The content of aluminium found was 14.5 μg/l. (by AAS 15.0 μg/l.) The content of beryllium was lower than the quantification limit in this instance.

‡From Genil River. The content of aluminium found was 22.0 μg/l. (by AAS 22.5 μg/l.). The content of beryllium was lower than the quantification limit in this instance.

Determination of aluminium and beryllium in natural waters. The method was applied to the determination of both aluminium and beryllium in water samples by the standard additions method. Raw water from Granada City supply (Genil River) and mineral water from the Ortigosa del Monte (Segovia) spring were selected as representative samples. The volume of water used for the determination was 50 ml for raw water and 100 ml for mineral water.

The loss of sensitivity by a matrix effect can be evaluated by the slope's ratio between the standard calibration graph and the standard-additions calibration graph. The ratios found were 1.01 for aluminium and 0.98 for beryllium in Ortigosa del Monte water and 0.85 for aluminium and 1.34 for beryllium in raw water.

The average aluminium and beryllium contents in the samples studied, based on three determinations, are shown in Table 4.

Recovery studies were carried out to check the accuracy of the proposed method: various amounts of aluminium(III) and beryllium(II) were added and recovery percentages were determined. Table 4 shows the results obtained.

In conclusion, the present paper provides a practical application of derivative synchronous spectrofluorimetry in combination with the solid-phase spectrofluorimetry methodology to multicomponent analysis. The combination of both techniques allows the simultaneous determination of aluminium and beryllium in low level mixtures, without previous pre-concentration nor separation.

(*Received* 4 *March* 1991. *Revised* 3 *June* 1991. *Accepted* 24 *June* 1991)

Summary—The retention mechanism was studied for the cations of the alkaline earth metals and Zn^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+} and Bi^{3+} on a C_{18} column permanently coated with sodium dodecylsulphate, with aqueous mobile phases containing cupric chloride or sulphate, or cerous nitrate. The dependencies of the logarithm of the capacity ratio on the logarithm of the eluent concentration were linear, demonstrating that ion-exchange was the predominating separation mode; the slopes of these dependencies were in good agreement with the values predicted from the ion-exchange theory. Indirect UV photometric detection yielded limits of detection (LOD) of 21, 44, 120 and 275 ng in the volume injected, 20 μl, for Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, respectively, with the $10^{-2}M$ copper(II) chloride mobile phase; the respective LOD values decreased to 0.8, 1.6, 3.0 and 6.7 ng with the $5 \times 10^{-4}M$ cerium(III) nitrate eluent. The method was found to be primarily suitable for determination of the alkaline earths and was applied to analyses of surface and mineral waters.

Ionic substances are often separated by ion-exchange chromatography, especially by the method known under the name, ion chromatography.[1] The mechanism of ion exchange is primarily characterized by linear dependences between the logarithm of the analyte capacity ratio and the logarithm of the concentration of the eluting ion.[2–8] The linearity of this dependence has often been confirmed in separation of cations,[3–7,9–11] but there may be considerable differences between their experimental and predicted slopes.[5,7,12,13] The slope is determined by the ratio of the electric charges carried by the analyte and the eluent ion and it has been pointed out[5] that the effective charges may vary owing to steric effects preventing interaction of the cations with a stoichiometric number of the exchange sites on a low-capacity cation exchanger. Some considerations of the effective charge on metal ions in ion-exchange chromatography have been summarized by Lederer.[14]

In addition to fixed-site cation exchangers, reversed-phase stationary phases can also be employed for separations of cations when suitable hydrophobic ion-pairing agents are present in the system (*e.g.*, alkyl sulphates or sulphonates). An ion-pairing agent can be added to the mobile phase, but it has been shown[15] that some of these agents that contain a sufficiently long alkyl chain are strongly adsorbed on the stationary phase and thus can be pre-adsorbed, so that they need not be present in the mobile phase during separations. It is assumed that ion exchange occurs at these modified stationary phases.

The mechanism of ion-pair separation of various organic substances with octyl, decyl and dodecyl sulphonates was studied by Knox and Hartwick.[16] Hori *et al.*[17] recently discussed the relationships between the hydrophobicity of analytes and their retention in separation systems with C_{18} stationary phases, in the presence of sodium dodecyl sulphate which was either present in the mobile phase or used to pre-coat the stationary phase.

Columns containing C_{18} stationary phases permanently coated with dodecylsulphate were used for separations of alkali metals and alkaline earths,[18] the rare earths[19] and also organic anions employing an ion-exclusion mechanism.[20] The mechanism of the retention of cations has not been studied, except for the finding that the dependence of the logarithm of the capacity ratio of Na^+ on the logarithm of

*Author for correspondence

the concentration of the NH_4^+ eluent is linear, suggesting that ion-exchange takes place.[20] Therefore, we studied the mechanism of retention of the alkaline earths, Zn^{2+}, Ni^{2+}, Co^{2+}, Cd^{2+} and Bi^{3+} on a C_{18} column permanently coated with sodium dodecylsulphate (SDS). The mobile phases contained Cu^{2+} or Ce^{3+} eluent ions that permitted indirect UV photometric detection.[9,10,21–23]

EXPERIMENTAL

Apparatus

The liquid chromatograph consisted of a HPP 5001 pump, an LCI 30 injection valve with a 20-μl sampling loop, a TZ 4261 chart recorder (all from Laboratorní Přístroje, Prague, Czechoslovakia) and the model 732 870 variable-wavelength UV/Vis photometric detector (Knauer, Berlin, Germany). Glass columns 150 × 3 or 30 × 3 mm, Separon SGX C 18, 5 μm, were obtained from Tessek, Prague, Czechoslovakia and were precoated with a sodium dodecylsulphate (SDS) solution. A short guard column, 30 × 3 mm, packed with Separon SGX, 7 μm (Tessek) was placed between the pump and the injection valve. Separon SGX C_{18}, is based[24] on totally porous, spherical silica gel with an average specific surface area of 500 m^2/g and a pore volume of 1 ml/g. The average mass of the material in a 150 × 3 mm column is 0.4 g. The carbon content corresponding to the octadecyl modifier is 18%, which corresponds to a surface concentration of bound octadecyl groups of 2.03 μmoles/m^2. The dead volume equals about 0.3 ml for the 150 × 3 mm column.

The mobile phases were deaerated in an ultrasonic bath. The mobile phase flow-rate was 0.3 ml/min and the measurements were carried out at laboratory temperature (20 ± 2°).

Chemicals

All the chemicals used were of reagent-grade purity (Lachema, Brno, Czechoslovakia). The SDS substance was research grade, obtained from Serva, Heidelberg, Germany. The solutions were prepared in demineralized water. The eluents involved $CuCl_2$, $CuSO_4$ and $Ce(NO_3)_3$; the working solutions were prepared by diluting 1M stock solutions (0.1M cerium nitrate stock solution). Stock solutions of the test metal cations were prepared from the corresponding chlorides or nitrates, at a concentration of 0.1M. For quantitative analyses, these solutions were standardized by complexometric titrations. The metal ion stock solutions were appropriately diluted with water immediately before the measurements.

Column preparation

The method was analogous to one described previously.[19] The columns were washed first with methanol for 2 hr at a flow-rate of 0.1 ml/min, briefly with water and then with a $5 \times 10^{-3}M$ SDS at the same flow-rate followed again by a brief washing with water. The capacity of the column was measured dynamically, with a cerium nitrate mobile phase, using the retention of the La^{3+} and Pr^{3+} ions. As these ions exhibit the same retention characteristics, it can be assumed that the selectivity coefficient for the La^{3+}–Ce^{3+} and Pr^{3+}–Ce^{3+} ion exchange is close to unity. The ion-exchange capacity can then be calculated as the product of the column dead volume, the mobile phase concentration and the capacity ratio for the La^{3+} ion.[20]

The column capacity, at given SDS concentration and flow-rate, depends on the time of washing with the SDS solution and the shape of the dependence corresponds to the Langmuir isotherm. For the 30 × 3 mm column, the dependence of the capacity Q (μeq) on the time of washing with SDS (hours) can be expressed by the linearized equation,

$$Q^{-1} = 9.76 \times 10^{-3} + 30.54 \times 10^{-3}/t, \quad (1)$$

with a correlation coefficient of $r = 0.9996$, for a flow-rate of 0.1 ml/min, a SDS concentration of $5 \times 10^{-3}M$ and within a time interval of $t = 0.5$–3 hr. The amount of SDS bound to the stationary phase in the 150 × 3 mm column is *ca.* 70 μmoles. This corresponds to an SDS surface concentration of 0.35 μmoles/m^2 and a C_{18}-to-SDS ratio of *ca.* 6:1. The optimal time of washing the 150 × 3 mm column with the SDS solution is 2 hr; the column capacity is then *ca.* 65 μeq. The exchange capacity of SDS apparently approaches 100%.

The prepared column is stable for several weeks. Prior to use, it must be washed with the mobile phase until the baseline stabilizes (*ca.* 1–2 hr). The column is highly stable when aqueous mobile phases are used: With 10^{-3}–$10^{-2}M$ copper(II) chloride or copper(II) sulphate and 10^{-4}–$10^{-3}M$ cerium(III) nitrate, no change in the retention characteristics was observed during continuous use for at least two weeks.

RESULTS AND DISCUSSION

Separation

It is assumed that the retention on a reversed-phase column coated with SDS is governed by the ion-exchange equilibrium,

$$yM_m^{x+} + xE_s^{y+} \rightleftarrows yM_s^{x+} + xE_m^{y+}, \qquad (2)$$

where M^{x+} is the analyte, E^{y+} is the eluent cation and the subscripts m and s refer to the mobile and stationary phase, respectively.

The capacity ratio, k_M, is given by

$$\log k_M = \frac{1}{y}\log K_{M,E} + \frac{x}{y}\log\frac{Q}{y} + \log\frac{w}{V_M} - \frac{x}{y}\log[E^{y+}]_m \qquad (3)$$

in the simplest case without side equilibria,[7] where $K_{M,E}$ is the selectivity coefficient, Q is the ion exchange capacity of the column, w is the weight of the stationary phase and V_M is the volume of the mobile phase in the column.

Equation (3) predicts a linear relationship between $\log k_M$ and the logarithm of the concentration of the eluting ion in the mobile phase; the slope of this dependence is given by the ratio of the charges of the analyte and the eluting ion. This equation yields the slopes in the absence of complexation reactions of the analyte and eluting cations with the mobile phase anions; Haddad and Foley[7] reported more complex relationships considering these side equilibria.

The slopes of the experimental dependences of $\log k_M$ *vs.* $\log c_E$, obtained over ranges of 2×10^{-3}–$2 \times 10^{-4}M$ for copper chloride and copper sulphate and 1×10^{-4}–$5 \times 10^{-3}M$ for cerium nitrate, are given in Table 1. The slopes are in very good agreement with the values calculated from equation (3), except for Cd^{2+} and the copper chloride eluent, where the experimental value is greater than the predicted slope due to complexation between Cd^{2+} and chloride.[25] The ion-exchange interaction then involves both the Cd^{2+} and $CdCl^+$ ions.

Table 1. The slopes of the $\log k_M$ *vs.* $\log c_E$ plots

Cation	Eluent $CuCl_2$	$CuSO_4$	$Ce(NO_3)_3$
Mg^{2+}	−0.951	−0.908	−0.675
Ca^{2+}	−0.978	−0.906	−0.676
Sr^{2+}	−0.964	−0.914	−0.660
Ba^{2+}	−1.022	−0.920	−0.669
Zn^{2+}, Ni^{2+}, Co^{2+}	−0.958	−0.907	−0.671
Cd^{2+}	−1.212	−0.950	−0.674
Bi^{3+}	—	—	−0.946

The theoretical slopes are −1.000 for the divalent analytes and the Cu^{2+} eluent ion and −0.667 for the same analytes and the Ce^{3+} eluent ion.

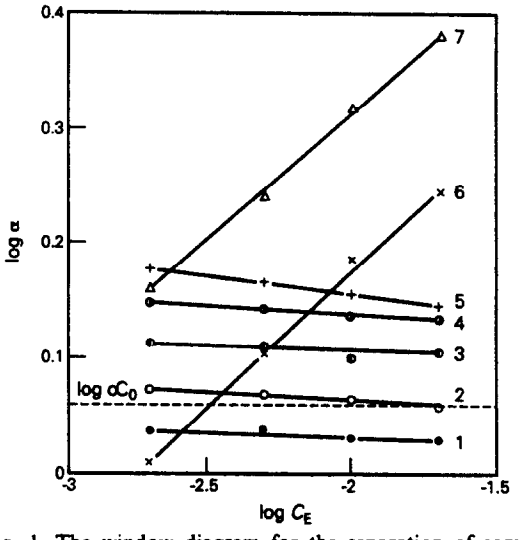

Fig. 1. The window diagram for the separation of some divalent cations with the $CuCl_2$ eluent. For conditions see Fig. 2. The analyte couples: 1—Mg^{2+}, Zn^{2+}; 2—Sr^{2+}, Ca^{2+}; 3—Ca^{2+}, Zn^{2+}; 4—Ca^{2+}, Mg^{2+}; 5—Ba^{2+}, Sr^{2+}; 6—Mg^{2+}, Cd^{2+}; 7—Ca^{2+}, Cd^{2}.

In separations of the alkaline earth cations on low-capacity, fixed-site cation exchangers, the slopes of the $\log k_M$ *vs.* $\log c_E$ plots were significantly dependent on the radii of the hydrated cations.[5,12] We did not observe this dependence in our measurements. The apparent reason for this is the fact that the adsorbed SDS molecules are not rigidly bound to the C_{18} stationary phase and their functional groups can be oriented in such a way that steric hin-

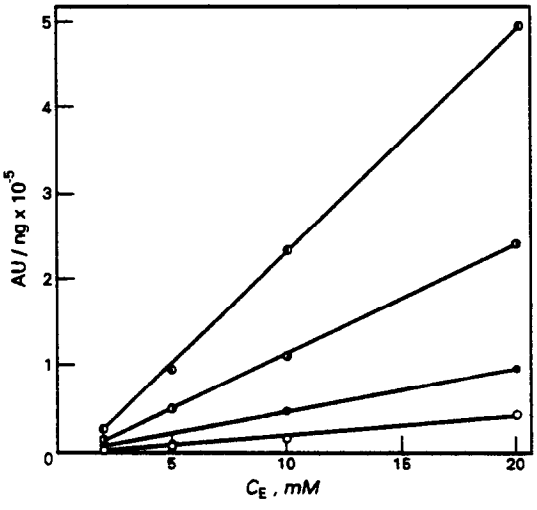

Fig. 2. Dependence of the sensitivity of measurement on the concentration of the $CuCl_2$ eluent. The 150 × 3 mm column, coated with $5.10^{-3}M$ SDS for 2 hr at a flow rate of 0.1 ml/min. 1—Ba^{2+}, 2—Sr^{2+}, 3—Ca^{2+}, 4—Mg^{2+}.

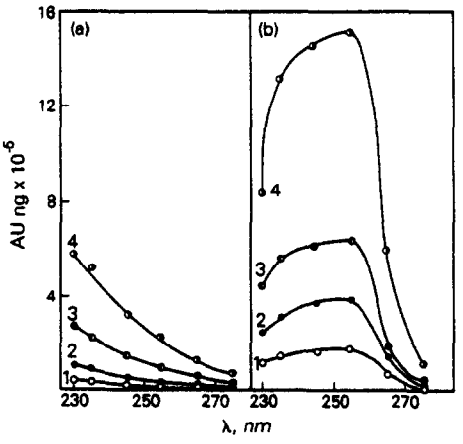

Fig. 3. Dependence of the sensitivity of measurement on the wavelength. For the conditions see Fig. 2; (*a*) $10^{-2}M$ $CuCl_2$, (*b*) $5 \times 10^{-4}M$ $Ce(NO_3)_3$. 1—Ba^{2+}, 2—Sr^{2+}, 3—Ca^{2+}, 4—Mg^{2+}.

drance causing a decrease in the effective charge of the analyte in ion exchange on fixed-rate stationary phases, does not occur.

The alkaline earths are resolved well with all the mobile phases used. On the other hand, Zn^{2+}, Ni^{2+} and Co^{2+} exhibit virtually identical retention characteristics The Cd^{2+} ion has a different retention with the copper chloride eluent.

The separation was optimized with window diagrams,[26] with relative retention, α_{21},

$$\alpha_{21} = k_{M2}/k_{M1} \quad (4)$$

as the criterion. The window diagram for the separation of some divalent cations with the copper chloride eluent is given in Fig. 1. Only the Ca^{2+}–Cd^{2+} and Mg^{2+}–Cd^{2+} couples exhibit a pronounced dependence of the relative retention on the eluent concentration, due to the complexation between Cd^{2+} and chloride, mentioned above. In view of the given efficiency of the separation system, the value of $\alpha_{21} = 1.15$ was selected as the critical relative retention (it is given by the dashed line in Fig. 1). Under the given conditions, magnesium cannot be adequately resolved from Zn^{2+}, Ni^{2+} and Co^{2+}. Cadmium is not resolved from calcium when the eluent concentration is less than *ca.* $3.2 \times 10^{-3}M$. The resolution of calcium and strontium deteriorates at high concentrations of the copper chloride eluent. When using $10^{-2}M$ copper chloride eluent, a mixture of Cd^{2+}, Zn^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+}, for example, can be readily separated.

Detection

The sensitivity of indirect photometric detection is independent of the mobile phase concentration,[4,27] but detectability of the analytes can be affected by the changes in the retention characteristics and consequent variations in the elution curve shape caused by changing the eluent concentration. Figure 2 depicts the sensitivity (AU/ng) dependence on the concentration of the copper chloride eluent for the Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+} ions. Similar dependences were also obtained for the cerium nitrate eluent.

The sensitivity dependences on the wavelength are given in Fig. 3 for the copper chloride and cerium nitrate eluents. With copper chloride, the sensitivity increases with decreasing wavelength in accordance with the shape of the Cu^{2+} absorption spectrum;[22] however, at wavelengths of less than *ca.* 230 nm, the baseline

Table 2. The limits of detection and the calibration plot parameters for determination of the alkaline earth metals

Cation	Limit detection *ng*	Calibration plot parameters: Slope, AU/*ng*	Intercept, AU	Correlation coefficient, $n = 9$
		$10^{-2}M$ $CuCl_2$ eluent

Ca	63.3 ± 4.5	58.6	58.4 ± 7.2	54.0	10.1 ± 0.3	7.5
Sr	<DL	0.21	<DL	0.07	3.22 ± 0.06	3.5
Ba	0.61 ± 0.06	0.42	0.55 ± 0.05	0.69	1.55 ± 0.06	1.85

Mg and Ca were determined with the $10^{-2}M$ $CuCl_2$ eluent, Sr and Ba with the $5 \times 10^{-4}M$ $Ce(NO_3)_3$ eluent.

noise greatly increases with a consequent increase in the limits of detection. When using the cerium nitrate eluent, the highest sensitivity is attained around 255 nm, again in agreement with the absorption spectrum of Ce^{3+} (a value of 253.6 nm was recommended for a spectrophotometric determination).[28]

The detection characteristics for Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+} at 254 nm are summarized in Table 2. The sensitivities of detection (the slopes of the calibration plots) are by about one order of magnitude higher with the cerium nitrate eluent, owing to the higher absorption coefficient of the Ce^{3+} ion.[25] The limits of detection obtained with the cerium nitrate eluent are comparable with those reported earlier,[23] while the values obtained by us with the copper chloride eluent are somewhat lower.

Ion-exchange chromatography with indirect photometric detection is commonly associated with the appearance of system peaks.[29,30] However, these peaks need not necessarily appear or be detected. We only observed system peaks in some cases and their retention times were always shorter then those of the analytes, so that there were no problems in repeated determinations.

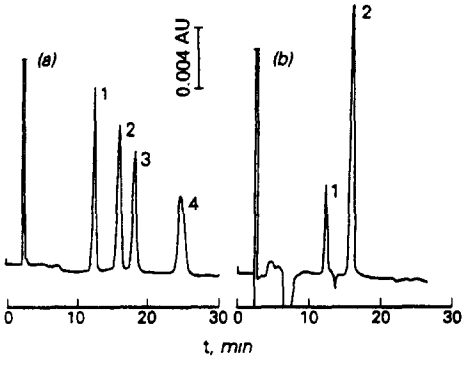

Fig. 4. Determination of the alkaline earths with the $10^{-2}M$ $CuCl_2$ eluent. For the conditions see Fig. 2. (*a*) Standard mixture: 1—Mg^{2+} (0.5 μg), 2—Ca^{2+} (0.8 μg), 3—Sr^{2+} (1.7 μg), 4—Ba^{2+} (2.7 μg). (*b*) Mineral water sample S-1.

Application

The method was applied to determination of the alkaline earth metals in mineral and surface waters; the $10^{-2}M$ copper chloride eluent is suitable for analyses involving analyte concentrations of the order of tens of mg/l., while $5 \times 10^{-4}M$ cerium(III) nitrate should be used when the analyte concentrations are from tenths to units of mg/l. Examples of the chromatograms are given in Figs. 4 and 5, the results are listed in Table 3 and compared with the values obtained by atomic-absorption spectrometry; the agreement is satisfactory. As can be seen from Fig. 6, rapid and sufficiently efficient separations of the alkaline earths can also be attained with the short 30 × 3 mm column.

REDUCTION OF INJECTION VARIANCE IN FLOW-INJECTION ANALYSIS

BEVERLY F. JOHNSON,* ROBERT E. MALICK and JOHN G. DORSEY†
Department of Chemistry, University of Cincinnati, Cincinnati, Ohio 45221-0172, U.S.A.

(*Received* 31 *December* 1990. *Revised* 26 *June* 1991. *Accepted* 26 *June* 1991)

Summary—In order to achieve maximum sensitivity in flow-injection analysis, sample dispersion must be kept to a minimum. This dispersion process, however, is not well understood. Studies of the dispersion process have concentrated on dispersion within the flow manifold while dispersion due to the injection process has been largely ignored. Here sample injection loops packed with inert glass beads and a Serpentine II (distorted) empty loop were constructed and compared to traditional empty sample loops. Digitization of the response curves and subsequent calculation of the statistical moments were used to compare the contribution of each sample loop type to the total system dispersion. Both packed and Serpentine II sample loops were shown to decrease dispersion and increase throughput in flow-injection systems. Plots of peak variance *vs.* injection volume show variance increasing 1.67 times faster with traditional open sample loops compared to packed loops. When combined with other peak width minimization techniques, this method should further lower concentration limits of detection.

Flow-injection analysis has become an extremely popular alternative to manual solution handling, and offers more rapid analysis, with greater precision, higher sample throughput, and lower reagent consumption.[1,2] The only aspect of flow injection that suffers in comparison to manual alternatives is the limit of detection. Flow injection is (as is chromatography) a dilution technique. From the moment of sample injection, the sample is continuously diluted until it passes through the flow detector. The minimization of this dilution process would then improve the limit of detection, and by decreasing the peak width, would also improve throughput. We have been interested in both chemical and physical ways of decreasing peak dispersion.[3,4]

The dispersion coefficient, D, introduced by Růžička and Hansen[5] is a simple descriptor for the dispersion process in flow-injection analysis. It does not, however, contain information in the time domain nor does it provide any information about the peak shape and is therefore of limited use for guiding the design of flow manifolds. The dispersion coefficient is defined as C^0/C^{max} where C^0 is the original solute concentration and C^{max} is the solute concentration at the peak maximum recorded after dilution. Since it is a purely physical descriptor, D was not intended to be used in the presence of a chemical reaction.

The use of peak shape and peak width as descriptors to gain more information about dispersion has been applied less often. Poppe first reported the similarity between chromatographic and flow-injection systems in terms of the system contributions to band broadening.[6] As with chromatographic systems, the total variance of the system is affected by the individual variance contributions from the injection device, manifold tubing and connectors and the detector volume and electronic time constants. The total band broadening in a non-reacting system is due to the sum of these individual variance contributions:[7]

$$\sigma^2 \text{ peak} = \sigma^2 \text{ injection} + \sigma^2 \text{ transport} + \sigma^2 \text{ detection} \quad (1)$$

If the detector is well designed, the variance contribution from the detector will be at least five times less than the variance caused by the injection device and transport phenomena. If modern LC detectors with fast electronics and small volume flow cells are used, this condition is usually met and the band broadening due to the detector can be neglected.

The effect of a chemical reaction upon peak broadening is also of importance but has been studied less. Painton and Mottola were the first to study the influence of a chemical reaction on peak broadening in a flow-injection system.[8–10]

†Author for correspondence.

Since that time additional reports have appeared.[11-14] It is generally concluded that at reasonable flow velocities the contribution to overall peak broadening from the reaction kinetics is negligible compared to the transport contribution.

Ramsing *et al.* first suggested the use of variance (second statistical moment) as a measure of peak width and for study of the relationship between peak width and dispersion.[15] Reijn *et al.* suggested the use of statistical moments in order to gain fundamental information about the dispersion process.[11] Since the determination of statistical moments requires extensive manual calculations or the use of digital data acquisition, their application to peak analysis has been limited. Foley and Dorsey, using an exponentially modified gaussian (EMG) peak shape model, developed simple empirical equations allowing manual calculation of statistical moments based simply on peak width measurements.[16] Jeansonne and Foley recently reviewed the use of the EMG peak shape model in chromatography and flow-injection analysis.[17] Brooks and Dorsey recently verified the applicability of the EMG model for real flow-injection peaks over a wide range of flow rates for coiled, knitted and Serpentine II manifolds, single-bead string reactors and a coiled reactor with a single confluence point.[3]

In the vast majority of cases, the dispersion due to the injection process is ignored. In the theoretical models developed for dispersion, delta functions are assumed for the injection profiles and variance due to transport (and chemical reaction in some cases) is taken as the only dispersion process. Ramsing *et al.* have concluded, however, that the starting point of dispersion in an empty sample loop is located at the middle of the sample zone prior to its injection.[15] Reijn *et al.*[7] and Coq *et al.*[18] have discussed injection variance and demonstrated that the mode of injection can have a large influence on dispersion profiles in chromatography and flow-injection analysis and that this effect becomes worse as the injection volume is increased. Injection variance is a potentially worse problem in flow injection, however, as in chromatographic analysis sample focusing typically occurs, or concentration occurs at the top of the column.

Typically the sample loop on the injection device is a piece of empty tubing in which laminar flow profiles dominate during the injection process. The laminar flow profiles make it impossible to obtain the plug injections desired. Using a coiled configuration for the sample loop helps to overcome some of the band broadening but coiling is not possible for small sample loops and thus laminar flow profiles prevail causing the associated band broadening.

Timed injections have been used in order to achieve plug injection profiles at the cost of needing computer control to obtain reproducible injection volumes.[18] In this method a loop twice as large as the desired injection volume is used. Only the front half of the loop is injected into the system thereby avoiding the region of the sample loop where the carrier stream has replaced some of the sample because of the developing laminar flow profiles.

The use of packed sample loops decreases the injection variance by blunting the edges of the laminar flow profiles, and has been recommended for chromatographic systems.[18] The increased radial mixing caused by the packing causes a decrease in the axial dispersion and should provide a more plug-like injection profile. This paper discusses the use of packed sample loops to minimize band broadening and produce near plug injection profiles for flow-injection analyses. In addition, a single Serpentine II empty sample loop was constructed and its performance compared to a single packed loop of the same volume. Two solutes were tested, one non-reacting solute (methyl ethyl ketone) and one that underwent an on-line reaction to give a detectable product (oxidation of pyridoxal in the presence of cyanide). Statistical moments were used to evaluate and compare the response curves for empty and packed sample loops.

EXPERIMENTAL

Apparatus

The flow-injection apparatus consisted of a TosoHaas (Philadelphia, PA) Model TSK-6010 dual piston reciprocating HPLC pump, an ABI Analytical Kratos Divison (Ramsey, NJ) Spectroflow 757 variable wavelength absorbance detector and a Recordall (Fisher Scientific, Fairlawn, NJ) Series 5000 recorder. The flow manifold was made of 0.5 mm i.d. Teflon tubing in either a linear configuration (approximately 30 cm) or a coiled configuration (150 cm coil wound around a 1.3 cm core, total length approximately 230 cm). Temperature control was maintained with a water bath equipped

with an Allied Model 73 (Fisher Scientific) Circulator.

The samples were introduced with a modified Rheodyne (Cotati, CA) Model 5020 sample injection valve with 0.8-mm i.d. Teflon sample loops. The injection volumes were determined by "injecting" a loop of standardized 6*M* hydrochloric acid into a flask and titrating with standardized sodium hydroxide. For the smallest injection volumes (12.74 μl packed and 23.16 μl empty) the valve was modified (Fig. 1) in order to give the smallest volumes possible from the 0.8 mm i.d. Teflon tubing. The Serpentine II loop was produced from 0.5 mm i.d. Teflon tubing, constructed on an epoxy/fiberglass electronic breadboard according to the procedure given by Curtis and Shahwan.[19]

Nonporous glass beads (150–212 μm; Sigma Chemical Co., St. Louis, MO) were used to fill the packed loops. The packing was performed with a HPLC pump with a reservoir containing the glass beads placed at the pump outlet. For the smallest packed loop [constructed as in Fig. 1(a)] a piece of FISHERbrand Quantitative Grade, 5–10 μm filter paper (Fisher Scientific) was placed between the cap and stator with small holes cut out at the flanged ends of the loop "Fill" line and the nearest end of the sample loop. The injector was assembled in the FILL position so that one of the grooves on the rotor was between the two holes in the filter paper. The sample loop "Fill" line was attached to the outlet of the glass containing reservoir and the pump was started. The glass beads moved through the "Fill" line and sample loop until they were stopped by the filter paper. For the larger loops, the sample loop tubing was cut in half and each end was flanged. Each half of the loop was filled with glass beads (filter paper again used to keep the glass in the loop) and the flanged ends were joined with a 1/4 28 union and flanged fittings (Upchurch Scientific, Ann Arbor, MI).

After a loop was completely packed, the injector cap was removed and a new piece of filter paper installed. Flow in the FILL position is from the "Fill" port, across the the groove in the rotor to the loop inlet, through the loop to loop outlet, across rotor, and to "Waste" [Fig. 1(b)]. In order to reduce the amount of back pressure experienced when the sample loop was filled with sample, two holes were cut into the filter paper at the positions of loop "Fill" and "Waste". The glass beads were held in the loop

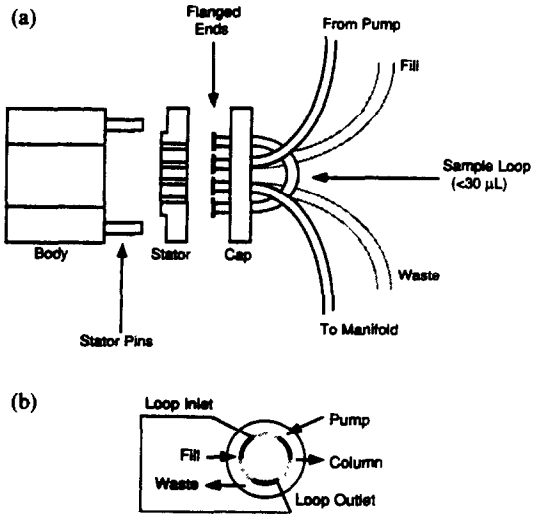

Fig. 1. (a) Modified Rheodyne 5020 Teflon rotary injection valve. (b) Flow diagram for modified Rheodyne 5020 Teflon rotary injection valve. Solid line represents the rotor in FILL position and shaded line represents the rotor in INJECT position.

by the filter paper at loop inlet and outlet. The valve was then reassembled for injections.

Solutions

Class 1B methyl ethyl ketone (Fisher Certified) and potassium cyanide (Certified A.C.S.) were obtained from Fisher Scientific. Pyridoxal was purchased from Sigma Chemical Co. All chemicals were used as received. All solutions were made with water purified by a Barnstead (Milford, MA) Nanopure system equipped with a 0.2-μm filter.

The carrier stream and sample solvent for the methyl ethyl ketone studies were both water. The carrier stream for the pyridoxal studies was 0.015*M* potassium cyanide in 0.06*M* (pH 6.74) phosphate buffer. The pyridoxal sample solvent was 0.06*M* (pH 6.74) phosphate buffer. The standards were prepared fresh daily.

The methyl ethyl ketone studies were carried out at ambient temperature in an unregulated laboratory and the methyl ethyl ketone was detected at 254 nm. The pyroxidal studies were conducted either at room temperature (unregulated) or at 49° by immersing the reaction coil in a water bath. The reaction product, 4-pyridoxolactone, was detected at 355 nm.

Procedure

The flow-rate was set at 1.0 ml/min for all studies. Each sample was injected at least three times and the results averaged. For the statistical moment determinations, the chart speed was

set at 20 cm/min to facilitate digitization and measurement. The digitization was performed with a Houston Instruments (Houston, TX) HIPAD Plus 11" × 17" digitizing tablet and the data were collected with an IBM PC XT Compatible. The statistical moments were calculated on an IBM PC AT 286 Compatible.

RESULTS AND DISCUSSION

Statistical moments

The statistical moments in units of time are defined by the following equations:[20]

zero-th moment

$$M_0 = \int_0^\infty h(t)\,dt \tag{2}$$

first central moment

$$M_1 = \frac{\int_0^\infty (t)\,h(t)\,dt}{M_0} \tag{3}$$

higher central moments

$$M_n = \frac{\int_0^\infty (t - M_1)^n\,h(t)\,dt}{M_0} \tag{4}$$

where $h(t)$ is the peak height at time t and the notation "central" indicates that the moment is taken around the first moment. If the peak is not normalized, the zero-th moment of the peak is the peak area. The first moment is the peak centroid or center of gravity which corresponds to the time of appearance of peak maximum for a Gaussian peak profile. The second moment is the variance and when taken around the first moment is a measure of the peak width. The third moment is the skew and is a measure of the magnitude and direction of the peak's asymmetry. The fourth moment is the kurtosis or excess and is a measure of the peak flattening relative to a Gaussian profile. All higher odd moments provide information on the peak symmetry while the higher even moments give information similar to that provided by the fourth moment.

The standard method for statistical moment determinations is the summation method. The peak is divided into small vertical slices and summation of the terms within the integrals of equations (2)–(4) is performed:

$$M_n = \frac{\sum_{\text{all } i} t_i^n y_i}{\sum_{\text{all } i} y_i} \tag{5}$$

where y_i is the peak height "count" in the ith interval.[20] This method makes no assumptions about peak shape and can be used for peaks which cannot be fit by Gaussian or modified Gaussian functions for which simple manual methods are available for moment calculations.

Digital data are necessary for the moment calculations. Digital data acquisition is often used but presents some problems. One of the major drawbacks is the need to rely on the computer system to appropriately assign the peak start and peak stop times. This is difficult for the system to achieve if there is a noisy or drifting baseline. Some work has been conducted on measuring the error in the statistical moments due to peak sensing capabilities, random noise, baseline position and baseline drift.[20–22] Chesler and Cram have detailed criteria for selecting the limits for peak area integration and the number of data points required for precision and accuracy in the calculated moments.[21]

Here the analog response curves recorded by the strip chart recorder were subjected to manual peak tracing and computer digitization. The digitization for each peak was started on the baseline about an inch before the rising portion of the response curve and was ended about an inch after the peak tail had leveled off after the decreasing portion of the response curve. In this way, it can be assumed that the entire peak area was covered in the digitization and errors associated with the start–stop algorithms should be minimized.

The digitized data were then processed by the computer with the summation method and the zero-th, first and second statistical moments were calculated. It should be noted that while interesting information may be contained in the higher moments, the error associated with moments higher than M_2 causes significant inaccuracies in the results. Since the value of the first moment is used in the calculations of all the higher moments, any error in the first moment is amplified as the moments increase. Additionally, as the higher moments are calculated, the leading and tailing portions of the response curves figure into the calculations to a greater extent. Thus any drift or noise in the baseline will have a serious effect on the accuracy of the calculated moments. However, it is possible to use these higher moments to identify trends in the data.

Non-reacting solute

One commonly used application for flow-injection is simply automated sample handling where the controlled dispersion aspect of the technique is used to reproducibly introduce a solute to a flow detector. For these non-reacting solutes, physical dispersion should be the only band broadening process present. The decrease in dispersion due to the packing in the sample loop should be evident at the detector if the manifold remains the same for the packed and empty sample loop situations. A short, linear manifold was chosen for the non-reacting solute since the manifold was used only to facilitate reproducible transport of the solute from the injector to the detector.

The response curves for similar injection volumes with packed and empty sample loops are shown in Figs 2 and 3 for relatively small and large injection volumes respectively. The injection volumes for the packed and empty loops are not exactly the same since the lengths of tubing used to make the packed loops were approximated based on the volume of the empty loops and assuming that the packing material would occupy approximately 60% of the tubing volume. The volumes used for Fig. 2 represent typical FIA injection volumes, and it is clear that even though curve *a* represents 5 μl more volume than *b*, the peak is actually narrower! Figure 3 shows the curves representing much

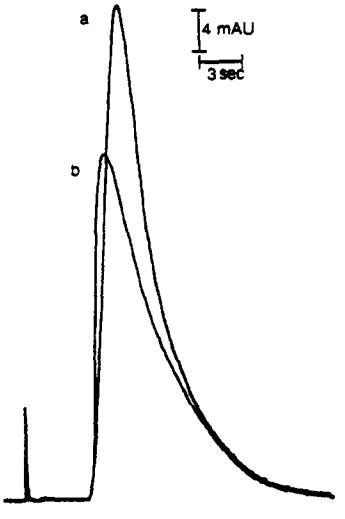

Fig. 2. Response curves for 1.0 mg/ml methyl ethyl ketone with small packed and empty sample loops. Peak (*a*) corresponds to the 28.20-μl packed sample loop and peak (*b*) corresponds to the 23.16-μl empty sample loop. (Manifold 30 cm linear; detection wavelength 254 nm; carrier stream water; flow-rate 1.0 ml/min; room temperature. Other conditions as in experimental section.)

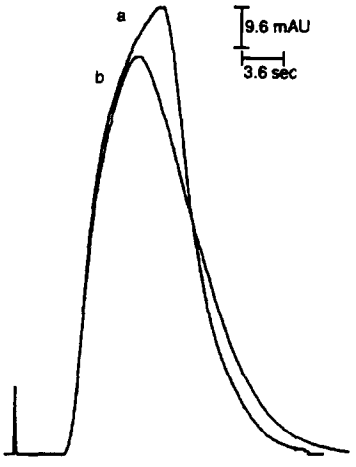

Fig. 3. Response curves for 1.0 mg/ml methyl ethyl ketone with large packed and empty sample loops. Peak (a) corresponds to the 123.3-μl packed sample loop. Peak (*b*) corresponds to the 115.6-μl empty sample loop. (Manifold 30 cm linear; detection wavelength 254 nm; carrier stream water; flow-rate 1.0 ml/min; room temperature. Other conditions as in experimental section.)

larger volumes, as would be used to try to obtain the lowest possible concentration limits of detection. It is evident that the response curves cannot be fit by Gaussian or modified Gaussian functions. Thus it is inappropriate to rely on the derived equations, which assume these functions, for accurate statistical moment calculations.

The average values of the peak height and the calculated moments for both the packed and empty sample loops are given in Table 1. When the peak area is plotted against the injection volume the relationship is linear for both the packed and empty sample loops over the considered injection volume range. It was expected that for a non-reacting system, the slopes and y-intercepts of the peak area versus injection volume plots would be the same regardless of the injection profile and this was found to be true.

The relationship between the peak centroid and the injection volume is linear for both empty and packed sample loops. As the injection volume is increased, the centroid of the peak occurs at larger volumes. As the injection volume is increased in a non-reacting system, the rising edges of the response curves coincide but the tailing becomes more extreme. This peak broadening with increasing injection volume causes the center of gravity to occur at larger volumes. Figure 4 shows the relationship between the peak variance (second moment) and the injection volume for both types of sample

Table 1. Peak characteristics for 1.0 mg/ml methyl ethyl ketone comparing packed and empty sample loops. (Manifold, 30 cm linear; detection wavelength, 254 nm; carrier stream, water; flow-rate, 1.0 ml/min; room temperature. Other conditions as in experimental section.)

	Volume injected, μl				
Packed loops	12.74	28.20	74.35	123.3	169.4
Peak height (mAU)	21.98	52.86	99.28	114.0	127.5
Peak area (mAU ml)	1.706	4.297	11.86	16.99	23.62
Peak centroid (μl)	126	144	179	198	228
Peak variance (μl^2)	2700	2700	3400	4600	5200
Empty loops	23.16	51.13	115.6	171.6	
Peak height (mAU)	36.48	62.75	97.15	113.2	
Peak area (mAU ml)	3.379	7.361	16.35	23.22	
Peak centroid (μl)	155	185	225	249	
Peak variance (μl^2)	3200	3800	5700	7400	

loops. The results show that packed sample loops are clearly superior to empty loops in terms of the injection device's contribution to total dispersion, with the ratio of the slopes being 1.67. This has important implications for the ability to improve the concentration limit of detection by increasing the injection volume. Furthermore, this also improves the throughput of the system, as

$$S_{max} = 60\,Q/k\sigma_v \qquad (6)$$

where S_{max} is the maximum throughput (samples/hr), Q is the flow-rate (ml/min) k is a factor depending on acceptable carryover and is generally taken to be 4 and σ_v is the volume standard deviation of the peak (the square root of the second moment).[1]

Prompted by a reviewer's suggestion, we also compared a Serpentine II empty loop to the packed loop. As this was performed at a later time, the flow system and detector were different, and these values should not be directly compared to those in the Tables. The Serpentine II empty loop ($V = 149.7$ μl) displayed a peak height of 138.0 mAU, a peak area of 24.98 mAU ml, a peak centroid of 256 μl, and a peak variance of 6691 μl^2. The packed loop ($V = 149.4$ μl) employed in the same system displayed a peak height of 141.3 mAU, a peak area of 25.09 mAU ml, a peak centroid of 265 μl, and a peak variance of 6325 μl^2. For packed and Serpentine II loops of the same volume, there is no real difference in any of these calculated moments.

Reacting solute

As with the non-reacting solute, the response curves for the reacting system cannot be fit to a Gaussian or modified Gaussian function and thus digitization of the analog signal was necessary for moment determinations. The peak characteristics for all injection volumes are given in Table 2. The relationship between peak area and injection volume for both types of sample loops is shown in Fig. 5. The peak areas are relatively independent of sample loop type and, within experimental error, follow the same curve. Unlike the non-reacting solute,

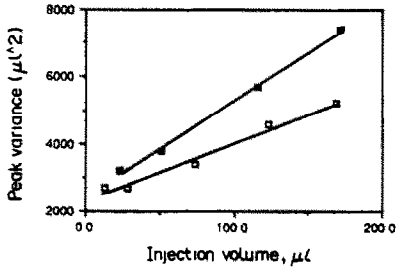

Fig. 4. Peak variance *vs.* injection volume for 1.0 mg/ml methyl ethyl ketone comparing packed and empty sample loops. The open squares represent packed sample loops (correlation coefficient = 0.9800) and the solid squares represent empty sample loops (correlation coefficient = 0.9977). (Manifold, 30 cm linear; detection wavelength, 254 nm; carrier stream, water; flow-rate, 1.0 ml/min; room temperature. Other conditions as in experimental section.)

†This empty loop was in the Serpentine II configuration.

the relationship between peak area and injection volume was not linear for pyridoxal. The pyridoxal reaction follows pseudo-first order kinetics in the presence of excess cyanide[23] and thus the reaction rate decreases as the amount of cyanide is decreased. At large injection volumes, the amount of cyanide present in the center of the sample zone is small and the reaction is slowed. Since the time between injection and detection remains constant, a slower reaction produces a smaller amount of product which yields a smaller peak area.

The relationship between the peak centroid and the injection volume is also complicated by the presence of the reaction. Since the amount of product formed as the injection volume is increased does not follow a linear relationship, it is not surprising that the change in the center of gravity of the detected product peak is nonlinear as well.

Figure 6 shows the trends of the variance as the injection volume is increased. The crossover in the curves for the packed and empty loops was unexpected but may be explained as follows. Due to the decreased injection variance with the packed sample loops, the reaction comes closer to completion compared to the empty loop situation. The reagent is able to reach the center of the sample zone sooner when packed loops are used and thus a longer reaction time is available. For the same reason, the reaction comes closer to completion for small injection volumes than for large injection volumes. Brooks *et al.*[14] have found that a chemical reaction actually causes a decrease in peak broadening relative to a non-reacting system. Thus the extent of reaction attained before the detector is reached determines whether the chemical reaction or the physical flow processes control the final peak width. If the reaction is near completion the sample may behave more like a non-reacting solute and the decrease in dispersion due to the reaction will be lost.

For the small packed sample loops, the reaction approaches completion throughout the sample plug before that in the empty sample loop and the solute begins to act like a non-reacting solute. This translates into a larger dispersion for the packed loop compared to the empty loop. For the large sample volumes, however, the reaction does not come as close to completion and the decrease in dispersion due to the packed sample loop is augmented by the decrease in dispersion due to the reaction. This translates into larger dispersion with empty loops compared to the packed loops.

The moment analysis on the peaks produced from the Serpentine II empty loop is also shown in Table 2. The Serpentine II loop produced

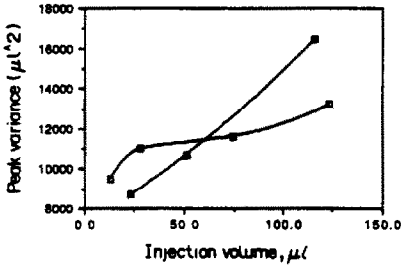

Fig. 6. Peak variance *vs.* injection volume for 0.1 mg/ml pyridoxal comparing packed and empty sample loops. The open squares represent packed sample loops and the solid squares represent empty sample loops. (Manifold 230 cm coiled; detection wavelength 355 nm; carrier stream 0.05*M* KCN in 0.06*M* (pH 6.74) phosphate buffer; flow-rate 1.0 ml/min; temperature 49°. Other conditions as in experimental section.)

split peaks, and no determination of these values could be made. In an effort to resolve the situation, the volume of the loop was reduced. A sample of response curves under varying conditions is shown in Fig. 7. Response curve (*a*) was obtained by replacing the reaction coil with the 30-cm linear manifold used for the methyl ethyl ketone. Response curve (*b*) was obtained after removing the reaction coil from the water bath and equilibrating to room temperature. Response curve (*c*) was obtained with the same conditions as for the pyridoxal reaction given above. Curve (*c*) exhibits a flat-topped peak with a maximum at 0.89 AU. Reducing the temperature (and thereby the extent of reaction) leads to a smaller peak, 0.30 AU, without a flat top. Reducing the length of tubing also leads to a smaller peak, curve (*a*), which is slightly larger (0.39 AU) than curve (*b*), again without a flap top. The sample zone produced by the Serpentine II loop allows for complete reaction to take place, yielding a steady-state response.

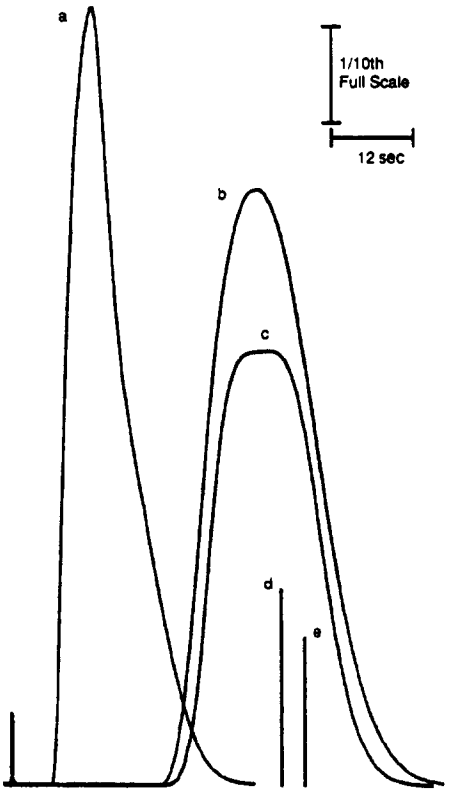

Fig. 7. Response curves for 1.0 mg/ml pyridoxal with 108.4 μl Serpentine II sample loop. Peak (*a*) corresponds to the 30-cm linear manifold at 22°, peak (*b*) corresponds to the 200-cm coiled manifold at 22°, and peak (*c*) corresponds to the coiled manifold at 49°. [Peaks (*a*) and (*b*) were 0.5 AUFS while peak (*c*) was 2.0 AUFS. Bars (*d*) and (*e*) correspond to the heights of peaks (*a*) and (*b*), respectively, scaled to the same full scale as peak (*c*). Other conditions as in experimental section.]

Figures of merit

In order to determine the effect of packed sample loops on the figures of merit, calibration plots were prepared for both the non-reacting and reacting systems with packed and empty sample loops. The results are given in Tables 3 and 4 for the non-reacting and reacting systems respectively. It can be seen that by decreasing the injection variance there is improvement in the limit of detection, especially as the injection volume is increased.

§This empty loop was in the Serpentine II configuration, see text for values and discussion.

A single Serpentine II loop was also compared to a packed loop. As these data were taken on a different flow system with a different detector, these data should not be directly compared to the Tables. The figures of merit calculated for the Serpentine II empty loop were sensitivity = 0.866 mAU/mg ($r^2 = 0.9999$), limits of detection = 13.8 ng and 0.0922 μg/ml, and LDR limits of 0.749–1490 μg. The figures of merit calculated for the same volume packed loop were sensitivity = 0.895 mAU/mg ($r^2 = 0.9998$), limits of detection = 20.0 ng and 0.134 μg/ml, and LDR limits of 1.49–1490 μg. The Serpentine II loop for a non-reacting solute exhibited similar sensitivity to the same volume packed loop. The LOD both as an amount and as a concentration was somewhat improved in the Serpentine II loop. This is due to the absence of the increased pressure drop across the packed loop. This pressure drop leads to a pressure pulse and refractive index gradient, both of which act to increase the standard deviation of the blank signal. This also allowed an improved lower LDR limit.

CONCLUSIONS

It has been shown that the use of injection devices equipped with packed or Serpentine II (distorted) sample loops significantly decreases the dispersion and resulting peak width in both reacting and non-reacting systems. For a non-reacting system, sample throughput and limits of detection are correspondingly improved. The effect of increased injection volume has been studied and it is shown that the improvements obtained with packed sample loops are especially great at large injection volumes. This advance, especially when combined with other peak width minimization techniques such as highly distorted flow manifolds[3] and solute focusing[4] should allow for extremely low limits of detection for most flow injection applications.

AMPEROMETRIC FLOW-INJECTION ANALYSIS OF HYDRAZINE BY ELECTROCATALYTIC OXIDATION AT COBALT TETRAPHENYLPORPHYRIN MODIFIED ELECTRODE WITH HEAT TREATMENT

WEIYING HOU, HUAMIN JI and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, People's Republic of China

(*Received* 4 *April* 1991. *Revised* 25 *May* 1991. *Accepted* 3 *June* 1991)

Summary—Chemically modified electrodes prepared by treating the cobalt tetraphenylporphyrin modified glassy-carbon electrode at 750° (HCME) are shown to catalyze the electrooxidation of hydrazine. The oxidation occurred at +0.63 V *vs.* Ag/AgCl (saturated potassium chloride) in pH 2.5 media. The catalytic response is evaluated with respect to solution pH, potential scan-rate, concentration dependence and flow-rate. The catalytic stability of the HCME is compared with that of the cobalt tetraphenylporphyrin adsorbed glassy-carbon electrode. The stability of the HCME was excellent in acidic solution and even in solutions containing organic solvent (50% CH_3OH). When used as the sensing electrode in amperometric detection in flow-injection analysis, the HCME permitted sensitive detection of hydrazine at 0.5 V. The limit of detection was 0.1 ng. The linear range was from 50 ng to 2.4 μg. The method is very sensitive and selective.

Hydrazines represent an important family of organic compounds with wide use in a number of industrial and pharmacological applications. Their detection and quantitation have attracted considerable analytical interest. As a consequence, recent activity has been directed toward the development of sensitive and selective analytical methods for the determination of hydrazines in a variety of sample matrices.

In recent years, electrochemical techniques have been shown to provide a sensitive and selective approach for the detection of numerous compounds following high-performance liquid chromatography.[1,2] The major requirement for the useful application of such electrochemical methods to liquid chromatography (LCEC) is that the analyte of interest should be oxidizable or reducible at a comparatively low potential. Unfortunately, many compounds of considerable analytical interest undergo electrolysis only at electrode potentials substantially different than their thermodynamic redox potentials. For these compounds, detection by LCEC usually cannot provide optimum levels of sensitivity and selectivity and extreme cases can provide no useful quantitation at all. One promising approach for minimizing overpotential effects is the use of electrocatalytic chemically modified electrodes (CMEs).

Baldwin's group and others have reported application of CMEs in high-performance liquid chromatography (HPLC)[3–16] or flow-injection analysis (FIA). Hydrazine has a large overpotential toward electrooxidation at ordinary carbon surfaces, and a high potential (>1.0 V) was essential for the detection of hydrazine in acidic solution. Therefore, it is not suited for quantitation via conventional electrochemical approaches. Baldwin's group used electrochemically treated glassy-carbon electrodes for the oxidative detection of hydrazine compounds in LC.[17] They also used carbon paste modified electrodes containing cobalt phthalocyanine (CoPC) for the oxidative detection of hydrazine in FIA.[3] Wang *et al.* used cobalt phthalocyanine/cellulose acetate (CoPC/CA) CMEs for oxidative detection of hydrazine and other compounds in FIA.[12] They also used glassy-carbon electrodes coated with mixed-valent ruthenium(II,III) cyanide films for oxidative detection of hydrazine compounds.[16] Dong *et al.* found that the metal (Fe, Co) tetraphenylporphyrin (FeTPP, CoTPP) modified glassy-carbon electrodes with heat treatment (HCME) exhibited excellent electrocatalytic stability towards the reduction of oxygen in

*To whom correspondence should be addressed.

acidic solution.[18,19] In this paper, we found firstly that the HCME exhibited strong electrocatalytic activity and excellent stability for the oxidation of hydrazine in acidic solution, and used the HCME for electrocatalytic and flow-injection–amperometric detection of hydrazine. We also examined the catalytic behaviour of hydrazine at the CoTPP adsorbed glassy-carbon electrode (CoTPP/GC).

EXPERIMENTAL

Reagents

The synthesis and purification of cobalt tetraphenylporphyrin were the same as in the literature.[19] Hydrazine sulphate was from the Beijing Institute of Chemical Reagents. Other reagents were analytical grade. Solutions were prepared with doubly-distilled water unless otherwise stated. Hydrazine sulphate solutions for use in flow-injection were prepared with the mobile phase.

Apparatus

A laboratory-built cyclic voltammetric analyser was used for cyclic voltammetry. A three-electrode cell system with a glassy carbon (GCE) or HCME working electrode, a silver-silver chloride (saturated potassium chloride) reference electrode, and a platinum auxiliary electrode was employed in the conventional electrochemical experiment.

The flow-injection system consisted of a JASCO LCP-350 pump, an injection valve (made in China) with a 10-μl sample loop, and a laboratory-built thin-layer flow-through electrochemical detector. A laboratory-built bipotentiostat[20] was used to control the detector. The injector and detector were connected by a 44-cm length of 0.5-mm inner diameter Teflon tube. The mobile phase was 0.1M potassium dihydrogen phosphate (containing 1mM EDTA). The flow-rate was 0.5 ml/min.

Electrode preparation

HCME. Glassy-carbon electrodes (GCE) (10 mm × 10 mm) were polished with 300-mesh magnesium oxide powder to a bright finish. The electrodes were then cleaned with distilled water and acetone respectively in an ultrasonic bath. These electrodes are referred to as the fresh bare electrodes. After drying, a small amount of CoTPP (about 0.5 mg CoTPP for six GCEs) was placed on the GC surface and the GC electrode was ground on another GC electrode, then placed into a 15-ml quartz tube filled with nitrogen gas. The latter was placed in a horizontal quartz furnace with autocontrol temperature equipment under a continuous flow of N_2. The temperature was increased slowly to 750°, held for one hour, and cooled to room temperature. The electrodes were then removed for electrochemical measurement. The resulting electrodes are referred to as the HCMEs.

CoTPP/GC electrode. A glassy-carbon electrode was polished with 0.3 μm of α-Al_2O_3 powder, added to $10^{-3}M$ CoTPP for several minutes and then cleaned with distilled water. The electrode is referred to as the CoTPP/GC electrode.

Fabrication of thin-layer flow-through electrochemical cell

The laboratory-built thin-layer electrochemical detector was similar to a conventional thin-layer electrochemical detector.[2] The effective cell volume is 1 μl. A saturated calomel reference electrode was employed.

RESULTS AND DISCUSSION

Cyclic voltammetric behaviour of hydrazine at the HCME

Figure 1 shows the cyclic voltamperograms in a conventional cell obtained for a GCE and a HCME (12.6 mm^2) immersed both in blank solution and containing 10mM hydrazine sulphate solution with different pH values. The cyclic voltamperograms of 10mM hydrazine in 0.2M potassium nitrate + 0.05M potassium dihydrogen phosphate (pH 2.5) shows that no obvious oxidation peak was obtained at a GCE in the potential range 0.2–1.2 V, while a well-defined oxidation peak with peak potential (E_p) of 0.63 V was observed at the HCME. Even after the reverse of the potential sweep, the catalytic oxidation peak still appears at the same E_p value, and no reduction wave was observed. The oxidation of hydrazine at the HCME is irreversible. In the reports of using a CME for electrocatalytic oxidation of hydrazine,[21–26] the catalytic oxidation peak still often appears after the reverse potential sweep.[23–26] From Fig. 1, the overpotential of hydrazine oxidation is greatly reduced and the oxidation current of hydrazine is enhanced by the use of the HCME. Also as shown in Fig. 1, when the pH of the supporting electrolyte increased, the E_p was shifted negatively and the peak current (i_p) increased. This suggests that hydrogen ions were produced in this reaction.[22,24] No obvious peak was observed when the pH was larger than 7.0.

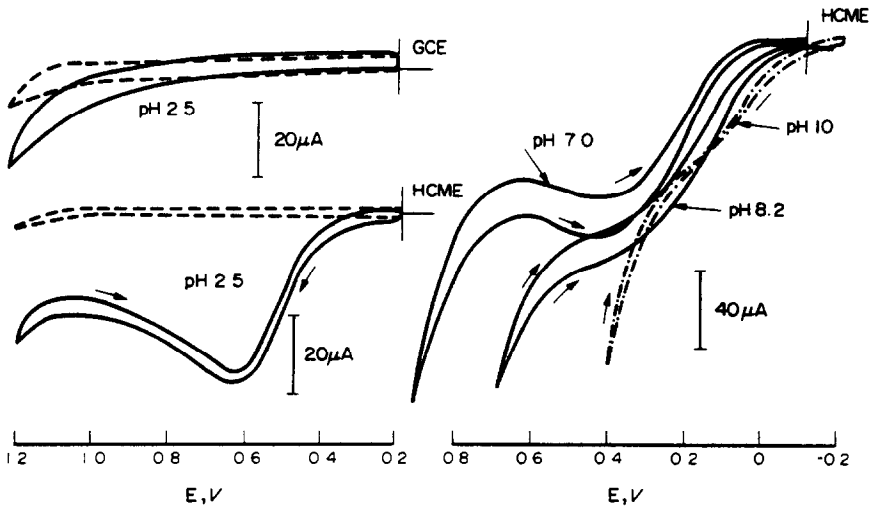

Fig. 1. Cyclic voltamperograms of hydrazine sulphate at a GCE and a HCME in 0.2*M* KNO_3 + 0.05*M* KH_2PO_4 solution with different pH values. (– – –): blank solution, (— · — · —): containing 10 m*M* hydrazine sulphate solution, scan-rate, 100 mV/sec.

The effect of the scan-rate, v, on i_p and E_p of cyclic voltammetry of hydrazine was examined over the 10–400 mV/sec range. The resulting i_p and E_p were not changed. So the oxidation process of hydrazine at a HCME was controlled by the kinetics of the catalytic reaction.

The catalytic stability of the HCME for the oxidation of hydrazine was examined in acidic and neutral electrolyte solution. After the HCME was scanned potentially for seven thousand cycles at 2 V/sec over the 0.2–1.2 V range in 0.2*M* potassium nitrate + 0.05*M* potassium dihydrogen phosphate solution (pH 2.5) containing 10m*M* hydrazine, the E_p, i_p and peak shape of the cyclic voltamperogram which was recorded at a scan-rate of 100 mV/sec were not changed. If the HCME was scanned over the 0–1.0 V range (2 V/sec) in pH 7.0 solution with the same conditions for five thousand cycles, the i_p was reduced to 70% of the initial value, and E_p moved slightly to a more positive potential. Moreover, the hydrazine oxidation on the HCME at both pH values produces gas, as can be observed from the numerous small bubbles on the surface of the HCME when the solution containing hydrazine was scanned potentially for many continuous cycles. We suggest that the gas is probably nitrogen gas, produced by 4-electron oxidation of hydrazine.

The above results show that the HCME exhibited strong electrocatalytic activity and excellent stability to the oxidation of hydrazine in acidic media.

We also examined the electrochemical behaviour of some other compounds [ascorbic acid, cysteine, oxalic acid, glucose, $NaNO_2$, KSCN and $K_4Fe(CN)_6$] at the HCME. The results of experiments indicated that the HCME did not exhibit electrocatalytic characteristics for these compounds. Otherwise, CoPC/CA modified glassy-carbon electrodes exhibited electrocatalytic activity to N_2H_4 at about 0.6 V, oxalic acid, ascorbic acid and cysteine,[12] while carbon paste modified electrodes containing CoPC exhibited electrocatalytic activity to N_2H_4 at −0.1 V,[3] cysteine,[4] oxalic acid,[5] carbohydrates,[6] and glassy-carbon electrodes coated with mixed-valent ruthenium(II,III) cyanide films exhibited electrocatalytic activity to N_2H_4[16] at 0.88 V, SCN^-[27] and cysteine.[28] The electrochemically pretreated glassy-carbon electrodes exhibited electrocatalytic activity to N_2H_4[17] at about 0.2 V, ascorbic acid[29] and oxalic acid.[29] It can be seen that the HCME exhibited higher selectivity toward the oxidation of hydrazine than the reported papers.[3,12,16,17] The specific modification scheme of the HCME which results in the different catalytic mechanisms from the CoPC modified carbon paste electrode is probably the reason for the highly selective reaction for hydrazine. Moreover, the stability of the HCME was better than in the reported papers[3,12,16,17] from the results of cyclic voltammetric experiments.

Cyclic voltammetric behaviour of hydrazine at a CoTPP/GC electrode

To make a comparison with the HCME, we examined the electrocatalytic behaviour of the

CoTPP/GC electrode toward the oxidation of hydrazine. Figure 2 shows cyclic voltamperograms obtained for a CoTPP/GC electrode immersed both in a blank solution and one containing 10mM hydrazine sulphate. A well-defined oxidation peak with an E_p of 0.69 V was observed at the CoTPP/GC electrode. After the reverse of the potential sweep, the catalytic oxidation peak also appears at the same E_p value, but the peak current was small. The twentieth cyclic voltamperogram was recorded in the potential range of 0.2 to 1.2 V at 100 mV/sec. The 650th cyclic voltamperogram was recorded at 100 mV/sec after 650 cycles at 2 V/sec. It can be seen that i_p decreased quickly before the tenth cycle and then decreased slowly. When the CoTPP/GC electrode was scanned for 10, 20 and 650 cycles, the i_p was respectively reduced to 47, 35 and 26% of the initial value. However, after the CoTPP/GC electrode was scanned for 10 cycles in the range 0–1.2 V at 100 mV/sec, it lost its electrocatalytic activity. This indicated that the CoTPP/GC electrode easily lost its electrocatalytic activity at high potentials (> 1.0 V).

The effect of the scan rate, v, on the i_p was evaluated over the 10 mV/sec–400 mV/sec range. The resulting dependence of i_p versus $v^{1/2}$ is linear, indicating diffusion control.

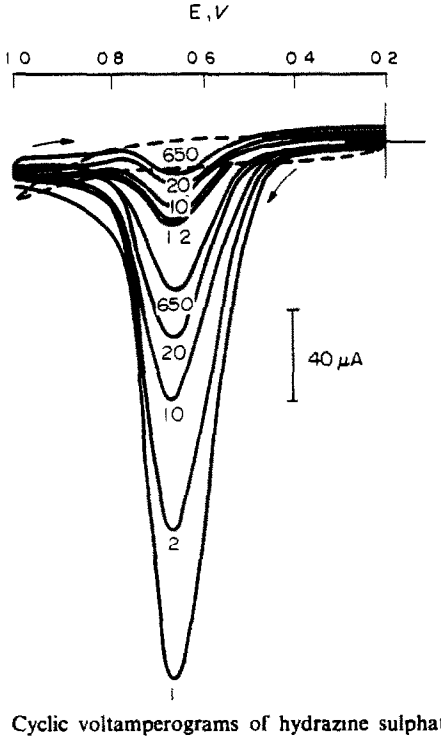

Fig. 2. Cyclic voltamperograms of hydrazine sulphate at CoTPP/GC electrode in 0.2M KNO_3 + 0.05M KH_2PO_4 (pH 2.5) solution. Scan rate, 100 mV/sec; (– – –): blank solution, (——): containing 10mM hydrazine sulphate solution; Figures refer to number of cyclic scans.

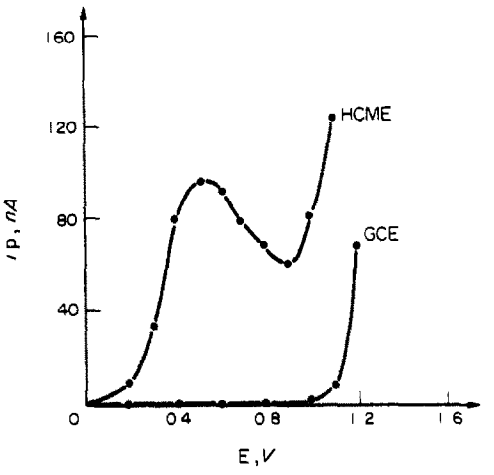

Fig. 3. Hydrodynamic voltamperograms of 20 ng/μl hydrazine sulphate at the GC electrode and 5 ng/μl hydrazine sulphate at HCME electrode. Mobile phase, 0.1M KH_2PO_4 (containing 1 mM EDTA), pH 4.5; flow-rate, 0.5 ml/min.

It can be seen that the electrocatalytic oxidation process of hydrazine was controlled by the kinetics of catalytic reaction at the HCME and was controlled by a diffusion reaction at a CoTPP/GC electrode. The HCME was very stable and reproducible to the electrocatalytic oxidation of hydrazine.

Flow injection amperometric detection of hydrazine

Despite some uncertainty concerning the catalysis mechanism, it was apparent that hydrazine oxidation at relatively low potentials produced by the use of the HCME should make its use attractive in a number of analytical applications. One area where their use could be of particular advantage is as sensing electrodes for the detection and determination of hydrazines in flowing systems. To this end, the response of the HCME placed in a laboratory-built thin-layer flow-through cell was examined.

Hydrodynamic voltamperograms (HDVs) obtained for hydrazine sulphate via flow-injection are shown in Fig. 3. The bare electrode (GCE) requires extremely high operating potentials to detect the hydrazines, and hence it exhibited large background currents and potential interferences. The HCME-based detector exhibits peak-shape HDVs with marked decreases in overpotentials. Such a peak-shaped response was observed previously at CoPC modified carbon paste electrodes.[4,5] An anodic

wave reached a maximum at approximately +0.5 V *vs.* SCE and rapidly decreased at higher potentials. Also provided for comparison is the HDV obtained at the bare glassy-carbon electrode which, as in CV, showed no response at potentials lower than +1.0 V. On the basis of the HDVs, it was apparent that the optimum potential for FIA detection of hydrazine sulphate at the HCME should be chosen at +0.5 V *vs.* SCE. The peaks in FIA are shown in Fig. 4 with a detection potential at +0.5 V. As expected, a well-formed oxidation peak was obtained at +0.5 V only when the HCME was employed and not for glassy-carbon electrodes.

The effect of the flow-rate on the i_p was evaluated over the 0.2–1.3 ml/min range. When the flow-rate was increased from 0.2–0.4 ml/min, the i_p decreased. When the flow-rate was increased from 0.4 ml/min to 1.3 ml/min, the i_p increased.

Stability problems often characterize the electrocatalytic response at the HCME-based detector. With a series of 40 replicate injections of a standard solution containing 20 ng/μl hydrazine sulphate within 1 hr, and 10 replicate injections within 6 hr, the coefficients of variation of peak current were found to be 2.2 and 4.5% respectively; the peak height after 6 hr was 83% of its initial value.

The concentration dependence of the HCME-based detector was evaluated for successive injections of hydrazine solutions of increasing concentration, 50 ng–2.4 μg (operating potential, +0.5 V). The electrocatalytic peak current increased linearly with increasing concentrations of hydrazine; the slope of the resulting calibration plot corresponded to a sensitivity of 2.2 nA/ng (correlation coefficient, 0.999). Similar injections of 1 ng/μl hydrazine solution were used to estimate the detection limit. The signal-to-noise characteristics (S/N = 3) indicated a detection limit of 0.01 ng/μl, *i.e.*, 0.1 ng in the 10 μl sample.

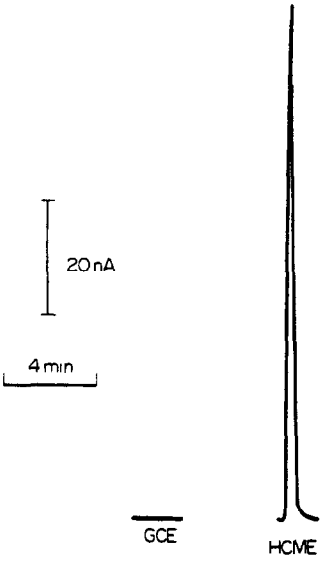

Fig. 4. Flow-injection responses of 5 ng/μl hydrazine sulphate at the GCE and the HCME at 0.5 V. Other conditions were the same as in Fig. 3.

Because practical chromatographic applications often required the use of a binary mobile phase containing substantial amounts of organic modifiers, it was important to establish whether the HCMEs were stable and retained their electrocatalytic properties in the presence of common organic solvents. Consequently, the effect of moderate fractions of methanol on the performance of the electrode in LCEC was also examined. This was accomplished by performing flow-injection experiments. During continuous flow-injection runs using 50% (v/v) CH_3OH/0.1*M* potassium dihydrogen phosphate (containing 1m*M* EDTA), 40 replicate injections within 1 hr and 14 replicate injections of 5 ng/μl hydrazine sulphate within 7 hr yielded coefficients of variation of 1.0 and 4.8% respectively; the peak height after 7 hr was 80% of its initial value, indicating that the HCME was stable even in the solution containing organic solvent.

From the above results, it can be expected that the HCME is especially suitable for electrochemical detection with liquid chromatographic separation because the HCME was stable in acidic solution and the solution containing organic solvent. Without question, the detection and quantitation of hydrazine in the flow-injection or LCEC context are greatly facilitated by the use of the cobalt tetraphenylporphyrin modified glassy-carbon electrode with heat treatment. In the wider sense, this work clearly illustrated some of the advantages which can be expected by use of judiciously selected electrocatalytic CMEs in flowing systems for the quantitation of high overpotential analytes. It would seem that, by use of electrocatalytic CMEs, the current range of applicability of FIA and LCEC technique might be considerably increased.

(*Received* 3 *January* 1991. *Revised* 21 *May* 1991. *Accepted* 4 *June* 1991)

Summary—Preconcentration on a trioctylphosphine oxide (TOPO) chemically modified tungsten wire matrix followed by graphite furnace atomic-absorption spectrophotometry measurement is described for the determination of trace gold in waste water. The TOPO modified tungsten wire matrix, after accumulating the gold, is placed in a graphite cup for direct atomization and measurement. Under the selected conditions, the absorbance is proportional to the concentration of gold over the range 0.4–18 ng/ml and the detection limit is 0.2 ng/ml. This method is sensitive and convenient. It has been applied to some waste waters with satisfactory results.

The determination of trace Au(III) is significant in the exploration of gold mines and the recovery of gold. There are several methods for the determination of gold. For example, atomic-absorption spectrometry,[1–7] liquid chromatography,[8] anodic-stripping voltammetry,[9,10] polarography,[11,12] ion-selective electrodes[13,14] and spectrophotometry[15–18] have been employed for the determination of traces of gold. However, some of these methods require strictly controlled experimental conditions while the sensitivity of others is not high enough for determining trace amounts of gold. In this work, TOPO is adsorbed onto a tungsten wire matrix. Traces of gold are preconcentrated on the TOPO modified tungsten wire matrix which is then transferred into a graphite cup for direct atomization and measurement by atomic-absorption spectrometry. The entire procedure is very simple, including the preparation of the TOPO–tungsten wire matrix.

EXPERIMENTAL

Apparatus

A Hitachi 180-80 polarized Zeeman atomic-absorption spectrophotometer was used. In the preconcentration step, the solution was stirred with a Teflon-covered stirring bar, rotated by a magnetic stirrer (78-HW).

Reagents

All solutions were prepared from doubly-distilled water. A stock standard solution containing 1 mg/ml of gold in 1*M* hydrochloric acid was used to prepare secondary standard solutions. Trioctylphosphine oxide (TOPO) $5 \times 10^{-3}M$ was prepared in ethanolic solution.

Procedure

Preparation of TOPO modified tungsten wire matrix. Wind the tungsten wire (diameter 0.5 mm) into a coil (diameter 3 mm, Fig. 1) and add 6 μl of $5 \times 10^{-3}M$ ethanolic TOPO onto the tungsten wire coil with a micro-syringe. Dry under an IR lamp for 2 min. TOPO melts in the process and attaches itself firmly onto the tungsten wire coil.[19]

General procedure. Transfer measured amounts of standard Au(III) solution or 2 ml of waste water sample into a 50-ml standard flask, add 10 ml of 5*M* hydrochloric acid, and dilute to the mark with water. Transfer it into a

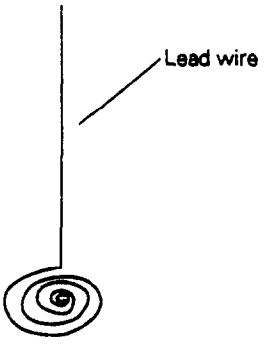

Fig. 1. Tungsten wire coil.

beaker. Submerge the TOPO modified tungsten wire coil in the solution, start the magnetic stirrer, and preconcentrate for 2 min. Then remove the TOPO modified tungsten wire coil from the beaker and blot with filter paper. The TOPO modified tungsten wire coil is then transferred to the graphite cup (Fig. 2). The lead wire (Fig. 1) is near the side of the cup wall to avoid the light path. After this, start the atomization procedure and measure the absorbance under the conditions given in Table 1.

Table 1. Atomization conditions

Gold lamp current	10 mA
Wavelength	243 nm
Bandpass	1.3 nm
Sheathing gas (Ar) flow-rate	200 ml/min
Drying temperature and time	80–120°, 10 sec
Ashing	400°, 20 sec
Atomization temperature and time	2700°, 7 sec
Cleaning temperature and time	2800°, 3 sec

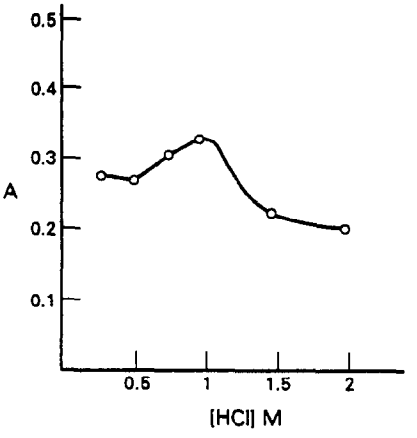

Fig. 3. Relationship between the absorbance and concentration of hydrochloric acid. Au(III), 10 ng/ml.

RESULTS AND DISCUSSION

Effect of the concentration of hydrochloric acid

Comparative tests of various media, such as acetic acid, sulphuric acid and potassium chloride were studied. Among these media, hydrochloric acid was found to be best. Variation of the concentration of hydrochloric acid from 0.3 to 2*M* was investigated. The result indicated that the optimum condition for the determination of gold is to have a medium of 1*M* hydrochloric acid. (Fig. 3).

Effect of amount of TOPO

Figure 4 shows the dependence of absorbance on the amount of TOPO solution used. Because of the strongly polar nature of the P-O groups in TOPO, the extraction of gold from acidic solutions by TOPO is very effective. Au(III) can form a complex with TOPO in 1*M* hydrochloric acid. The reaction can be expressed as follows:[20]

$$HAuCl_4 + TOPO = [TOPO \cdot H]\,[AuCl_4]$$

Figure 4 shows that, between 0 and 6 μl, the more TOPO on the surface of the tungsten wire coil, the larger the absorbance. Without TOPO modification, a pure tungsten wire coil does not preconcentrate gold. When TOPO is above 6 μl, the absorbance varies only slightly. Therefore 6 μl of TOPO solution is recommended.

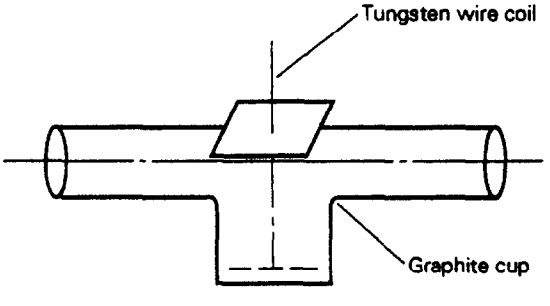

Fig. 2. Position of tungsten wire coil in graphite cup.

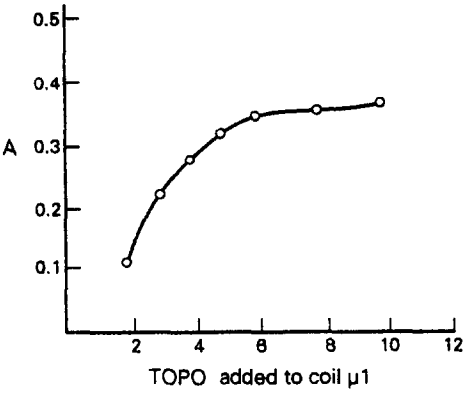

Fig. 4. Dependence of absorbance on the modification amount of TOPO. Au(III), 10 ng/ml.

Table 2. Results for the recovery of gold from waste water

Sample	Au(III) added, *ng*	Au(III) found, *ng*	Recovery, *%*
1	—	2.7	
	2.0	4.9	110
2	—	2.6	
	2.0	4.5	95
3	—	1.5	
	2.0	3.7	110

Effect of preconcentration time

The longer the preconcentration time, the more gold is adsorbed, and the longer the absorbance. With times above 8 min, the preconcentration quantity would tend to saturate, so the absorbance varies slightly with preconcentration time. It takes only 2 min to preconcentrate because preconcentration for 2 min can meet the requirement when the sample is determined. Higher sensitivity with less critical timing can be reached by using longer preconcentration time.

Relationship between concentration of Au(III) and absorbance

Under the selected conditions, a linear relation was obtained between absorbance and concentration of Au(III) in the range of 0.4–18 ng/ml, the detection limit is 0.2 ng/ml for 2 min preconcentration time.

Reproducibility

A tungsten wire coil was treated with TOPO 8 times, under previously selected conditions and the absorbance for each modification was measured to give a coefficient of variation of 1.8%. This shows that the results obtained with the TOPO tungsten wire are in good agreement with each other.

Effect of foreign ions

The experimental results show that amounts of 1000-fold Ca(II), Mg(II), 100-fold Zn(II), Al(III), Cu(II), Pb(II), Fe(III), Ti(IV), Cr(III), Co(II), Cd(II), Ba(II), K^+, NO_3^-, SO_4^{2-}, 50-fold As(III), Hg(II), Na^+, Ag^+, PO_4^{3-}, 20-fold Bi(III), Ni(II) do not interfere in the determination of gold.

Sample analysis

The recovery of gold added to three different waste water samples (2 ml) is shown in Table 2. Recoveries at the 1 ng/ml level were 95–110%.

STUDY OF HETEROGENEOUS EQUILIBRIA IN SATURATED SOLUTIONS OF SOME SPARINGLY SOLUBLE 8-HYDROXYQUINOLINES

TOMISLAV J. JANJIĆ* and LIDIJA B. PFENDT
Faculty of Chemistry, University of Belgrade, P.O., Box 550, 11001 Belgrade, Yugoslavia

MIRJANA B. ALEKSIĆ
Faculty of Pharmacy, University of Belgrade, 11001 Belgrade, Yugoslavia

(*Received* 15 *April* 1991. *Revised* 25 *June* 1991. *Accepted* 25 *June* 1991)

Summary—Heterogeneous equilibria in saturated aqueous solutions of 8-hydroxyquinoline (A), 2-methyl-8-hydroxyquinoline (B) and 5-chloro-8-hydroxyquinoline (C) were investigated at constant ionic strength (1*M* sodium chloride), at 25.0 ± 0.1°, by the application of the following methods: the formation function method, the method of bound protons, the method of free proton sites and the solubility method. The following equilibrium constants were determined: $K_{s1} = [H_2A^+]/[H_3O^+]$, $K_{s2} = [HA]$ and $K_{s3} = [H_3O^+][A^-]$. Their mean *pK* values are: −2.88, 2.42 and 12.09 for A, −3.27, 2.71 and 12.73 for B, and −0.34, 3.88 and 12.75 for C. In addition, the acidity constants of investigated 8-hydroxyquinolines were determined by pH-metric titrations. The values obtained for these constants were consistent with those calculated on the basis of corresponding equilibrium constants determined in heterogeneous systems.

Heterogeneous equilibria in saturated solutions of sparingly soluble protolytes have been poorly investigated to date. Besides other applications, such investigations offer the possibility of calculating the distribution of the equilibrium species as a function of pH in corresponding heterogeneous systems and consideration of the buffer properties of these systems which represent two-phase buffers.[1–6] All this is of particular interest for such analytical reagents and pharmacologically active substances which are sparingly soluble protolytes.

In our previous papers we have investigated systems in which the solid phase was a sparingly soluble acid[1–4] or base.[5,6] Continuing these investigations, in this work we have studied equilibria in systems containing sparingly soluble ampholytes, namely: 8-hydroxyquinoline, 2-methyl-8-hydroxyquinoline and 5-chloro-8-hydroxyquinoline. All these compounds are important analytical reagents.[7]

The methods used in this study are described in our previous papers but when necessary they were adapted for investigation of ampholytes. Among the aforementioned ampholytes only heterogeneous equilibria of 8-hydroxyquinoline[8–10] have hitherto been investigated, but by other methods and under different experimental conditions.

EXPERIMENTAL

The following apparatus was used: a PHM-62 pH meter (Radiometer) with a glass-calomel electrode assembly; a TTT-60 titrator with an ABU-12 autoburette (Radiometer) and a Beckman DU-2 spectrophotometer.

All reagents used were of analytical reagent grade from Merck. Stock solutions of sodium hydroxide and hydrochloric acid were standardized pH-metrically and the solutions of investigated ampholytes were prepared by weighing dry substances and dissolving them in hydrochloric acid. The investigations were carried out at constant ionic strength (1*M* sodium chloride) and at 25 ± 0.1°. The calibration of the pH-meter and the measurement of hydronium ion activity are described in our previous paper.[5] The pc_H and pc_{OH} values were calculated from measured pH values (pH_{GE}) by using the following equations: $pc_H = pH_{GE} + 0.10$, $pK_w^c = pc_H + pc_{OH} = 13.74 \pm 0.01$. Stock solutions for the determination of equilibrium constants in heterogeneous systems were $1 \times 10^{-1}M$ relative to 8-hydroxyquinoline and 2-methyl-8-hydroxyquinoline in $1 \times 10^{-1}M$ hydrochloric

*Author for correspondence.

acid, and $1 \times 10^{-2}M$ relative to 5-chloro-8-hydroxyquinoline in $1.5 \times 10^{-2}M$ hydrochloric acid.

Aliquots of 20 ml of these solutions were made alkaline with sodium hydroxide solution on account of solid phase separation, and were kept at constant temperature with vigourous stirring. The equilibration time was followed pH-metrically and amounted to 3–5 min. From pH_{GE} values measured at equilibrium state, the formation function, *i.e.*, the mean number of protons bound per mole of the ampholyte, was calculated. Solutions were then separated from the insoluble part by centrifugation. Aliquots of these solutions were titrated pH-metrically with sodium hydroxide or hydrochloric acid and from data obtained the concentration of protons which are or can be bound to species originating from the investigated ampholytes in the solution, was calculated. From other parts of these solutions the stoichiometric solubility of investigated ampholytes was determined. Solutions were acidified with hydrochloric acid until pH = 1.0 and the actual concentration of the corresponding 8-hydroxyquinolines was determined spectrophotometrically. Measurements were made at 355, 350 and 375 nm, *i.e.*, at the absorption maxima of 8-hydroxyquinoline, 2-methyl-8-hydroxyquinoline and 5-chloro-8-hydroxyquinoline, respectively; the validity of Beer's law was verified previously. The acidity constants were determined by the classical pH-metric titration of the corresponding hydrochlorides with standard sodium hydroxide. The concentrations of titrated solutions were: 8-hydroxyquinoline, $2.5 \times 10^{-3}M$; 2-methyl-8-hydroxyquinoline, $1 \times 10^{-3}M$; and 5-chloro-8-hydroxyquinoline, $2 \times 10^{-4}M$.

In the processing of experimental data, corrections were made for volume changes; the data were processed by means of suitable programs with a Texas Instrument TI-66 programmable calculator.

RESULTS AND DISCUSSION

In saturated aqueous solutions of investigated ampholytes, the following equilibria may take place between the solid phase and (HA)s and the solution:

$$(HA)_s + H_3O^+ \rightleftharpoons H_2A^+ + H_2O$$

$$K_{s1} = \frac{[H_2A^+]}{[H_3O^+]} \qquad (1)$$

$$(HA)_s \rightleftharpoons HA$$

$$K_{s2} = [HA] \qquad (2)$$

$$(HA)_s + H_2O \rightleftharpoons H_3O^+ + A^-$$

$$K_{s3} = [H_3O^+]\,[A^-] \qquad (3)$$

The corresponding equilibrium constants were determined by the application of the formation function method, the method of bound protons and the method of free proton sites, as well as by the stoichiometric solubility method. These methods were described in our previous papers,[1-6] but in this work they were adapted for the study of heterogeneous equilibria of sparingly soluble ampholytes. In view of the fact that acid–base processes in ampholyte solutions are separated since $pK_{a2} > (pK_{a1} + 4)$, in the solution in which $pH < (pK_{a2} - 2)$ it may be assumed that $[A^-] \rightarrow 0$, whereas in the solution of $pH > (pK_{a1} + 2)$, it may be taken that $[H_2A^+] \rightarrow 0$.

In addition, the acidity constants of investigated ampholytes K_{a1} and K_{a2} ($K_{a1} = [H_3O^+][HA]/[H_2A^+]$; $K_{a2} = [H_3O^+][A^-]/[HA]$) were determined according to the Rossotti–Rossotti method.[11]

Formation function method

This method is based on the determination of the mean number of protons bound per mole of the ampholyte:

$$\bar{n}_{tot} = \frac{2[H_2A^+] + [HA] + [HA]_s}{C_{tot}^{app}} \qquad (4)$$

In equation (4) $(HA)_s$ corresponds to the number of moles of the ampholyte which are precipitated from one litre of the solution, and C_{tot}^{app} denotes the apparent stoichiometric concentration of the ampholyte, *i.e.*, the concentration which would be present in the solution, provided the total amount of the precipitate is dissolved.

From mass-balance it follows that:

$$C_{tot}^{app} = [H_2A^+] + [HA] + [A^-] + [HA]_s \qquad (5)$$

The combination of equations (1) and (3) with equations (4) and (5) gives the following relation:

$$C_{tot}^{app}(\bar{n}_{tot} - 1) = K_{s1}[H_3O^+] - \frac{K_{s3}}{[H_3O^+]} \qquad (6)$$

In case $[A^-] \rightarrow 0$ we find:

$$C_{tot}^{app}(\bar{n}_{tot} - 1) = K_{s1}[H_3O^+] \qquad (7)$$

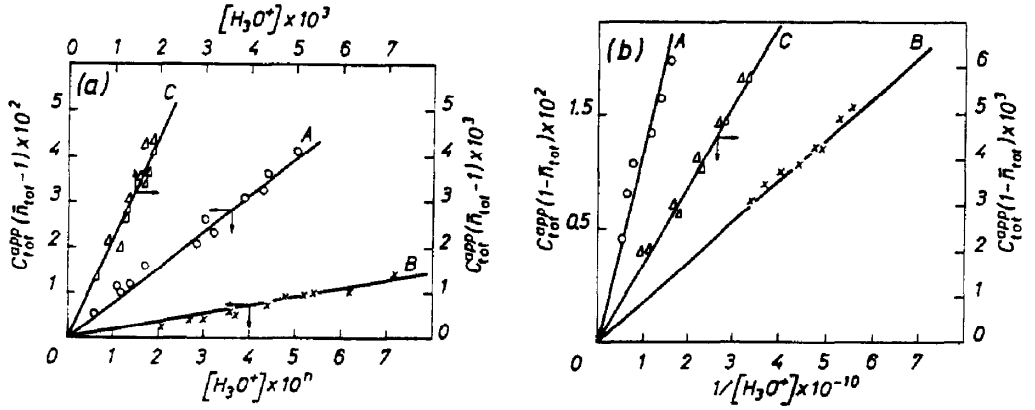

Fig. 1. Plots of (a) $C_{tot}^{app}(\bar{n}_{tot}-1)$ *vs.* $[H_3O^+]$ and (b) $C_{tot}^{app}(1-\bar{n}_{tot})$ *vs.* $1/[H_3O^+]$, used for the determination of equilibrium constants by the formation function method. A denotes 8-hydroxyquinoline ($C_{tot}^{app}=1\times10^{-1}M$), B 2-methyl-8-hydroxyquinoline ($C_{tot}^{app}=1\times10^{-1}M$), C 5-chloro-8-hydroxyquinoline ($C_{tot}^{app}=1\times10^{-2}M$); $I=1M$ (NaCl), $t=25°$; $n=5$ for A and 6 for B.

whereas in case $[H_2A^+]\to0$ we obtain the relation:

$$C_{tot}^{app}(1-\bar{n}_{tot})=\frac{K_{s3}}{[H_3O^+]} \tag{8}$$

From the dependences given by equations (7) and (8) the corresponding equilibrium constants K_{s1} and K_{s2} for all three investigated ampholytes were calculated by linear regression analysis (Fig. 1). For the calculation of $\bar{n}_{tot}$ from experimental data the following relation was used:

$$\bar{n}_{tot}=\frac{C_{tot}^{app}+[Cl^-]+[OH^-]-[H_3O^+]-[Na^+]}{C_{tot}^{app}} \tag{9}$$

where $[Cl^-]$ and $[Na^+]$ denote the concentrations of Cl^- and Na^+ ions originating from added hydrochloric acid and sodium hydroxide, respectively. The concentration of H_3O^+ ions was calculated from measured pH_{GE} values, and the concentration of OH^- from the corresponding ion product of water.

Method of bound protons and method of free proton sites

The concentration of bound protons, $[H_b^+]$, in saturated solutions of ampholytes is given by the following equation:

$$[H_b^+]=2[H_2A^+]+[HA] \tag{10}$$

By combining equations (1), (2) and (10) we obtain:

$$[H_b^+]=2K_{s1}[H_3O^+]+K_{s2} \tag{11}$$

Equation (11) offers the possibility of calculating K_{s1} and K_{s2} in acidic solutions. $[H_b^+]$ is experimentally determined from data obtained by pH-metric titration of saturated acidic solutions of ampholytes with sodium hydroxide by means of the following dependence:

$$[H_b^+]=[Na^+]-[H_3O^+] \tag{12}$$

The concentration of free proton sites, $[H_f^+]$, in saturated solutions is given by the following relation:

$$[H_f^+]=[HA]+2[A^-] \tag{13}$$

The combination of equations (2), (3) and (13) gives:

$$[H_f^+]=K_{s2}+2\frac{K_{s3}}{[H_3O^+]} \tag{14}$$

Equation (14) makes the calculation of equilibrium constants K_{s2} and K_{s3} in alkaline solutions possible. Experimentally $[H_f^+]$ is determined by the pH-metric titration of saturated alkaline solutions of ampholytes with hydrochloric acid according to the following relation:

$$[H_f^+]=[Cl^-]-[OH^-] \tag{15}$$

By applying the linear regression analysis to the corresponding dependences expressed by equations (11) and (14) all three equilibrium constants in heterogeneous systems of investigated ampholytes were calculated (Fig. 2).

Solubility method

This method is based on the spectrophotometric determination of the stoichiometric solubility, S, of investigated ampholytes at different pH values:

$$S=[H_2A^+]+[HA]+[A^-] \tag{16}$$

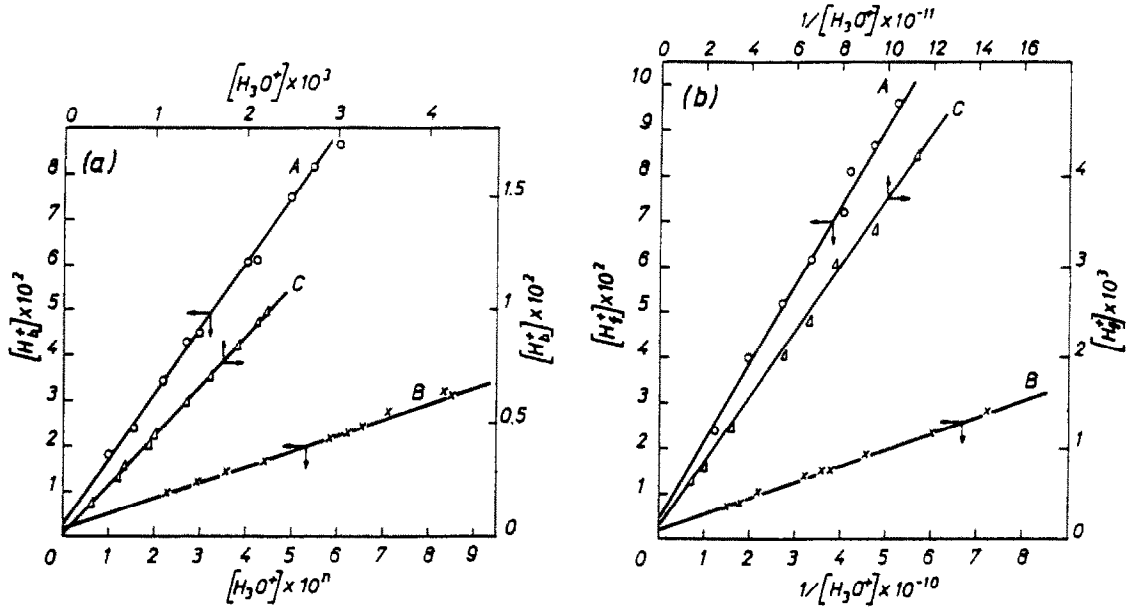

Fig. 2. Plots of (a) $[H_b^+]$ *vs.* $[H_3O^+]$ and (b) $[H_f^+]$ *vs.* $1/[H_3O^+]$, used for the determination of equilibrium constants by the methods of bound protons and of free proton sites, respectively. $I = 1M$ (NaCl), $t = 25°$; $n = 5$ for A and 6 for B; A, B and C as in Fig. 1.

From equations (1)–(3) and equation (16) the following dependence is obtained:

$$S = K_{s1}[H_3O^+] + K_{s2} + \frac{K_{s3}}{[H_3O^+]} \qquad (17)$$

When $[A^-] \to 0$

$$S = K_{s1}[H_3O^+] + K_{s2} \qquad (18)$$

and when $[H_2A^+] \to 0$ the following relation is obtained:

$$S = K_{s2} + \frac{K_{s3}}{[H_3O^+]} \qquad (19)$$

On the basis of dependences expressed by equations (18) and (19) all three equilibria constants were calculated by linear regression analysis (Fig. 3).

Determination of acidity constants

The acidity constants were experimentally determined by the pH-metric titration of solutions according to the Rossotti–Rossotti method.[11] Since the protolytic processes of investigated ampholytes are separated, the acidity constants can be determined independently

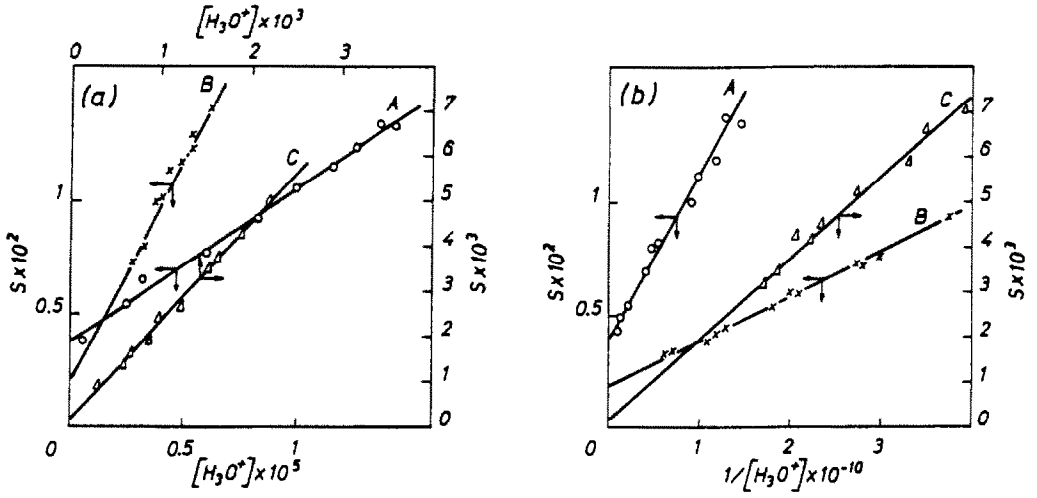

Fig. 3. Plots of (a) S *vs.* $[H_3O^+]$ and (b) S *vs.* $1/[H_3O^+]$ used for the determination of equilibrium constants by the solubility method. $I = 1M$ (NaCl), $t = 25°$; A, B and C as in Fig. 1.

Table 1. Concentration equilibrium constants ($\bar{x} \pm \sigma/\sqrt{n}$) in the heterogeneous and homogeneous systems studied. $I = 1M$ (NaCl); $t = 25°$

*Calculated according to equation (23) and (24), respectively.

†By pH-metric titration in a homogeneous system.

from one another. For their calculation the following equations were used:

$$K_{a1} = [H_3O^+]\frac{2-\bar{n}_H}{\bar{n}_H - 1}, \quad (\bar{n}_H > 1) \qquad (20)$$

$$K_{a2} = [H_3O^+]\frac{1-\bar{n}_H}{\bar{n}_H}, \quad (\bar{n}_H < 1) \qquad (21)$$

The value $\bar{n}_H$ was calculated from experimental data according to the following expression:

$$\bar{n}_H = \frac{C_{tot} + [Cl^-] + [OH^-] - [H_3O^+] - [Na^+]}{C_{tot}} \qquad (22)$$

where C_{tot} denotes the stoichiometric concentration of ampholytes.

In addition, the acidity constants of investigated ampholytes were calculated from the corresponding equilibrium constants in heterogeneous systems, with the following dependences:

$$pK_{a1} = pK_{s2} - pK_{s1} \qquad (23)$$

$$pK_{a2} = pK_{s3} - pK_{s2} \qquad (24)$$

The equilibrium constants determined in this paper are summarized in Table 1, which shows that there is a good agreement among the constants determined by different methods. Small differences among them, as well as the differences in the range of standard deviations of individual mean values, can be understood if we take into account the fact that the equilibria in a heterogeneous system are affected by the quality of the separated precipitate which, as it is known, depends on a number of factors being not easily controlled.[12] However, a good accordance between the acidity constants determined in the solution by the pH-metric titration method and those calculated from equilibrium constants determined in the corresponding heterogeneous systems, point not only to the correctness of the equilibria assumed, but also to the reliability of the constants determined. This is of a particular interest for indirect determination of acidity constants in cases where, on account of a small protolyte solubility and similarities in absorption spectra of various protolyte species, the application of the classical pH-metric and spectrophotometric methods are not possible.

As already mentioned heterogeneous equilibria have so far been investigated only for 8-hydroxyquinoline. In all cases the method used was the bromometric determination of its solubility at 25°. Stone and Friedman[8] found $pK_{s2} = 2.21$ (0.1M borax–sodium carbonate buffers), whereas Irving *et al.*[9] reported 2.32 (various buffers, $I = 0.1M$). Klygin and Kolyada[10] found $pK_{s1} = -2.71$, pK_{s2} 2.35 and pK_{s3} 12.10 (ionic strength is not specified). The

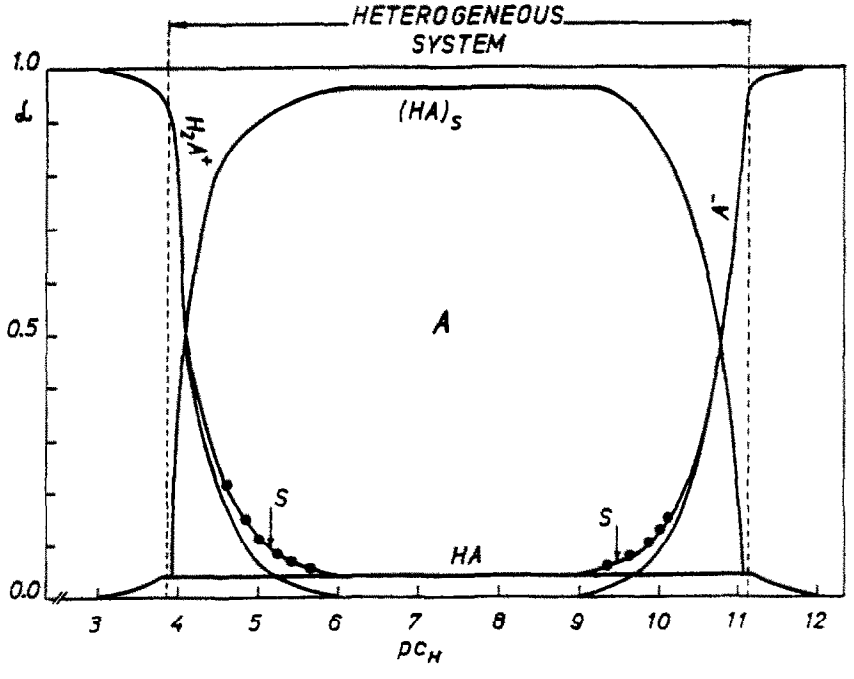

Fig. 4(A).

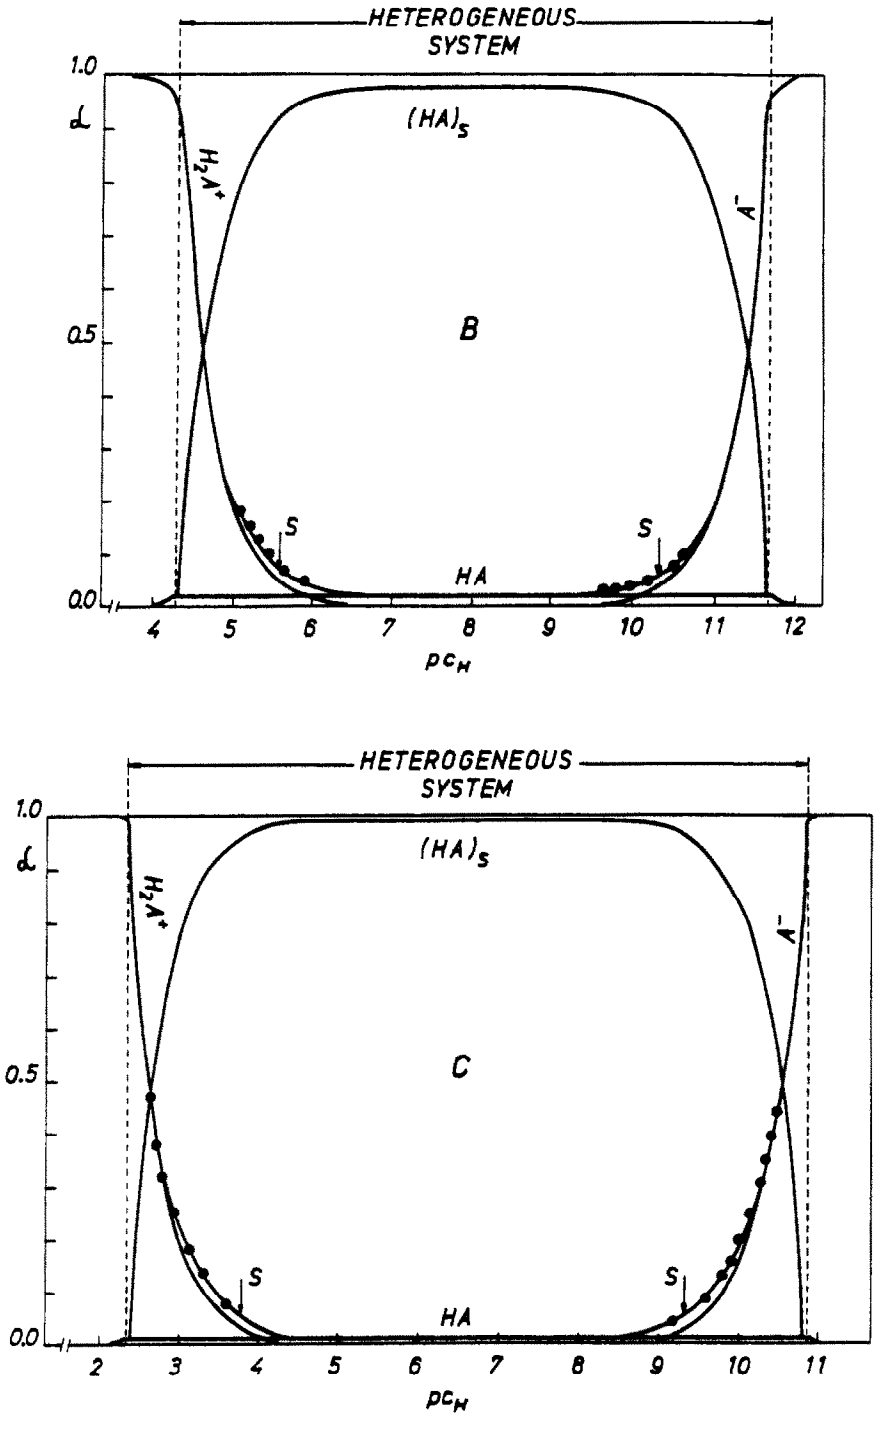

Fig. 4. Distribution diagrams and solubility curves (S) in the function of pc_H; (●●●●) experimental data; A, B and C as in Fig. 1.

results reported by these authors, although obtained from the solutions of different electrolytes and ionic strengths, are in relatively good accordance with our results.

On the basis of pK-values determined, the distribution of all equilibrium species in the function of pc_H was calculated by the usual procedure[13] (Fig. 4.) In addition, by differentiating equation (17) and by setting $dS/dpc_H = 0$ we obtained the equation for the calculation of the pc_H value at which the solubility of the investigated ampholytes is the lowest:

$$(pc_H)_{min_S} = \frac{pK_{s3} - pK_{s1}}{2} \quad (25)$$

By using equation (25) the $(pc_H)_{min_S}$ values were calculated for 8-hydroxyquinoline, 2-methyl-8-hydroxyquinoline and 5-chloro-8-hydroxyquinoline to be 7.48, 8.00 and 6.54, respectively.

The equilibrium constants determined in this work, in addition to other applications, are indispensable for the calculation of buffer characteristics of two-phase buffer systems consisting of a sparingly soluble ampholyte as the solid phase and its saturated solution (buffered phase), which will be a subject for our further investigation.

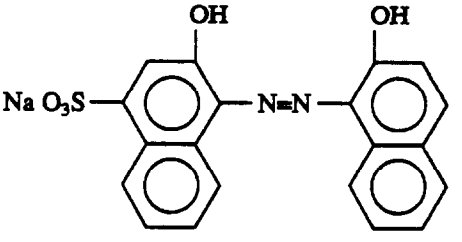
CALCON-MODIFIED SILICA GEL SORBENT. APPLICATION TO PRECONCENTRATION OR ELIMINATION OF TRACE METALS

R. KOCJAN and S. PRZESZLAKOWSKI
Department of Inorganic and Analytical Chemistry, Medical Academy, 20-081 Lublin, Poland

(*Received* 17 *November* 1990. *Revised* 10 *June* 1991. *Accepted* 10 *June* 1991)

Summary—Silica gel impregnated with a mixture of Aliquat 336 and Calcon was used as chelating sorbent for preconcentration of metals from dilute aqueous solutions and their separation as well as for additional purification of analytical grade sodium and potassium salts from other metals. The relative capacities of sorbent towards 33 metal ions were determined in the pH range 1–9 as well as the concentrations of hydrochloric and perchloric acid eluting the retained metals. It was found that Calcon was not eluted from sorbent with 5*M* perchloric and 10*M* hydrochloric acids. The rate of sorption for Mg, Ca, Cu, Zn, Al, Cr(III) and Fe(III) was also studied and it was found that relatively high flow-rates (up to 5 ml/min) can be used for solutions passed through the column. The sorbent was used for preconcentration of traces of some metals from aqueous solutions before their determination by AAS, for separation of metal ion mixtures by column extraction chromatography and for additional purification of potassium chloride solutions used as supporting electrolyte in determination of some heavy metals by anodic stripping voltammetry.

The determination of trace elements often requires their preconcentration and separation from a matrix of macroamounts of other metals.[1] On the other hand, the use of very sensitive analytical methods for metals requires the reagents of a very high purity which are used in preliminary chemical operations. One of the most commonly used methods for preliminary concentration of metals from aqueous solution is based on the utilization of chelating sorbents and many such materials containing different chelating groups have been proposed.[2] However, the synthesis of such sorbents is difficult and except the chelating resin containing aminoacetic groups (known as Chelex), others are not commercially available. The chelating sorbents can be obtained in a very simple manner by the impregnation of silica gel with a mixture of Aliquat 336 (methyltricaprylammonium chloride) and chelating reagent containing sulphonic groups,[3] since it was found that many such reagents are very strongly extracted into solutions of liquid anion exchangers in organic solvents.[4–9] Several silica gels modified in this way with nitroso-R-salt,[10,11] thorin,[12] Eriochrome Black T,[13,14] Chromotrope 2B[15] and calconecarboxylic acid[16] have been described but the disadvantage of them (except the last one) was the partial elution of the chelating reagent with perchloric or hydrochloric acid solutions of the concentration required for elution of metals forming very stable chelating complexes which makes impossible the use of the same column in several sorption–elution processes.



A molecule of Calcon (a reagent used as indicator in complexometric titrations[17] and in colorimetric determination of calcium and magnesium[18]) is more hydrophobic than the molecules of chelating reagents used earlier and therefore the properties of silica gel modified with Calcon and some applications of this sorbent are described in this paper.

EXPERIMENTAL

All experiments were done at room temperature (21 ± 2°).

Reagents

Aliquat 336 (Fluka, Switzerland) was purified to remove iron. Calcon (Merck, FRG) was used as supplied without further purification. Silica

gel 100, 0.063–0.2 mm (Merck, FRG) previously fractionated (the fraction of particle size 0.1–0.2 mm being collected) and purified from iron in the manner described previously[10] was used as a support for the stationary phase.

Aqueous metal ion solutions

Aqueous metal ion solutions were prepared by dilution of Titrisol standard metal salt solutions (Merck, FRG) or were prepared from appropriate analytical grade reagents (nitrate of Ag, Hg(I), U(VI), Ga, In, Bi, La, Th or $K_2Cr_2O_7$ and K_2TeO_3). Working solutions were freshly prepared from standard metal salt solutions by dilution with doubly-distilled water and adjusted to an appropriate pH with a mixture of hydrochloric acid and potassium chloride (pH 1 and 2), tartrate buffer (pH 3–6) or borax buffer (pH 9). Solutions of perchloric and hydrochloric acids (Suprapur, Merck, FRG) were used as eluents.

Apparatus

A single beam AAS 1N (Zeiss, GDR) atomic-absorption spectrophotometer was used for determination of Ca, Mg, Sr, Cu, Fe, Co, Ni, Zn, Cd, Mn, Ag, Pb and Hg; barium, sodium and potassium were determined by flame emission spectrometry. Other metals were determined spectrophotometrically with a UV–Vis VSU 2P spectrophotometer (Zeiss, GDR). All pH measurements were made with a Mera-Elwro N 517 (Poland) direct reading pH meter with a glass-calomel electrode assembly. A voltammetric analyser UPE-2a (Radius, Poland) was used in determination of traces of lead, cadmium, copper and zinc in potassium chloride or sodium chloride solutions by anodic stripping voltammetry. A graphite electrode, impregnated with epoxy resin and coated with a mercury film *in situ* was used as a working electrode with a working area of 12.5 mm^2. The details of the preparation of this electrode were described by Sykut *et al.*[19]

Procedure

The impregnating solution was prepared by shaking an appropriate volume of 0.01*M* Aliquat 336 in freshly distilled chloroform with 5 volumes of 0.001*M* aqueous Calcon. After separating the phases, the organic phase was filtered through a cellulose filter to remove the remaining aqueous solution. Silica gel was impregnated with a chloroform solution of Aliquat 336 plus Calcon in the following manner. A 200-ml volume of the organic solution (containing 1 mmole of Calcon and 2 mmoles of Aliquat 336) was mixed with 8.63 g of silica gel. The diluent was then evaporated with a vacuum evaporator on a water bath. The chelating sorbent obtained contained 0.1 mmoles of Calcon and 0.2 mmoles of Aliquat 336.

Small glass columns (110 × 5 mm) dry packed with 0.4 g of sorbent were used for the determination of the relative capacities of the sorbent toward metal ions. A 10-ml volume of the solution containing 1 mg of the metal ion to be tested (previously adjusted to an appropriate pH) was passed through the column over a period of 10 min, and unretained metal was determined in the eluate by AAS or spectrophotometrically.

The influence of the contact time on the relative capacity of the sorbent towards some chosen metal ions was investigated by the static method. The sorbent (0.4 g) was then shaken with 5 ml of the metal salt solution (previously adjusted to pH 6 except iron where the pH was adjusted to 1) containing 0.3 mg of the metal ion investigated. The mixture was subsequently centrifuged and the metal ion in the solution was determined.

The influence of the flow-rate on the capacity of the sorbent was investigated by using small columns packed with 0.4 g of the sorbent. A 5-ml volume of the solution containing 0.3 mg of the metal ion being tested was then passed through the column and unretained metal was determined in the eluate. The flow-rate was regulated with a syringe pump.

In a similar manner column experiments were performed under conditions where the relative capacity of the sorbent was somewhat higher (about 25%) than the amount of metal ion in the solution being passed through the column. Columns packed with 0.5 g of the sorbent were then used and 5-ml volumes of the solution were passed through the column.

Glass columns (249 × 8 mm) dry packed with 5 g of sorbent were used for the separation of metal ion mixtures. After the column had been washed with 10 ml of pH 5 buffer solution, a 10-ml volume of the synthetic solution of pH 5 containing 100 μg of each metal ion separated was passed through the column. The metals were eluted with perchloric acid solutions, 5-ml fractions being collected. Elution under hydrostatic pressure (head pressure 380 mm H_2O) was used. Metals were determined in single fractions by AAS or spectrophotometrically.

Voltammetric determination of metals was performed in the following manner. Volumes of 10 ml of 0.5*M* potassium chloride (analytical grade) to which mercuric nitrate was subsequently added [the concentration of $Hg(NO_3)_2$ in the resulting solution was $10^{-4}M$] were passed through the column packed with 5 g of the sorbent. The column packed with 1 g of sorbent was used only when doubly distilled water or sodium chloride Suprapur solution was analysed. Into one previously purified potassium chloride solution 2 μl volumes of standard Cu^{2+}, Cd^{2+}, Pb^{2+} and Zn^{2+} ions of 100 ppm concentration were introduced (concentration of each metal ion added in the solution was then 20 ppb). Oxygen was removed from analysed solutions with a stream of argon of a special purity. The solutions were (except one sample) electrolysed for 3 min at -1.2 V. Anodic oxidation of metals was subsequently performed at the following conditions: amplitude 1.2 V; potential change of 10 mV/sec.

RESULTS AND DISCUSSION

The relative affinities of inorganic and simple organic anions to strongly basic solid or liquid anion exchangers have been described in many papers and apparent equilibrium constants were collected in several monographic books,[20,21] the highest affinity always being found for perchlorate ions. Since extraction of chelating reagents containing sulphonic groups by Aliquat 336 can be described with simple anion exchange reactions, the relative affinities of anions of sulphonated chelating reagents to Aliquat 336 can be at least qualitatively compared on the basis of displacement of these anions from the ion-pair by anions of strong mineral acids: stripping the reagents from their organic solutions or elution of these coloured anions from impregnated silica gels. Several such quantitative data for Alizarin Red S, stripped or eluted with different acids have been estimated recently[22,23] and it has been found that, in both cases, the ability of anions displacing this reagent increased in the following order: $CH_3COO^- < SO_4^{2-} < Cl^- < NO_3^- < ClO_4^-$. In preliminary experiments performed presently it was found that Calcon is very strongly extracted from aqueous solutions into Aliquat 336 in chloroform and a partial elution of this chelating reagent from silica gel impregnated with a mixture of Aliquat 336 and Calcon required high concentrations of 5*M* perchloric or 10*M* hydrochloric acids which suggested a very high stability of this ion pair.

The concentrations of both acids at which partial elution of various sulphonated chelating reagents from modified silica gels (6, 11–15, 24) begins are collected in Table 1. The data are comparable since each sorbent contained 0.1 mmoles of the reagent per g and 0.2 mmoles (reagents containing one sulphonic group) or 0.4 mmoles (other reagents) of Aliquat 336. These results suggest that the stabilities of ion-pairs composed with an alkylammonium cation and an anion of the reagent increase in the following order: ferron < nitroso-R-salt < Chromotrope 2B ~ Alizarin Red S < Calmagit < Titan yellow < calconecarboxylic acid < Calcon; the hydrophobicity of these reagents increase in the same order.

The relative capacities of silica gel modified with Calcon toward some chosen metal ions (estimated by the static method) depended on shaking time: maximal values of the capacity for magnesium, calcium and zinc were reached relatively quickly whereas for aluminium and chromium longer shaking times (60 and 75 min) were required. Maximal capacity values toward aluminium and chromium distinctly decreased with increasing flow-rate of the solution passed through the column packed with sorbent (maximal values at very low flow-rates—up to 0.2 ml/min—were reached), contrary to magnesium, calcium and zinc, when the sorbent capacities remained constant even at a high flow-rate of 5 ml/min. These results suggest that the main factor determining the sorption kinetics is the speed of complex formation which is especially low

Table 1. Concentrations (*M*) of hydrochloric and perchloric acids to give elution of the chelating reagent from silica gel impregnated with a mixture of Aliquat 336 and sulphonated chelating reagent (sorbents contained 0.1*M* of the reagent per g)

	Ferron	Nitroso-R-salt	Chromotrop 2 B	Alizarin Red S	Calmagit	Titan Yellow	Calone-carboxylic acid	Calcon
HCl	0.1	0.5	2	2	5	5	10	10
$HClO_4$	0.005	0.005	0.005	0.005	0.07	0.5	2.5	5

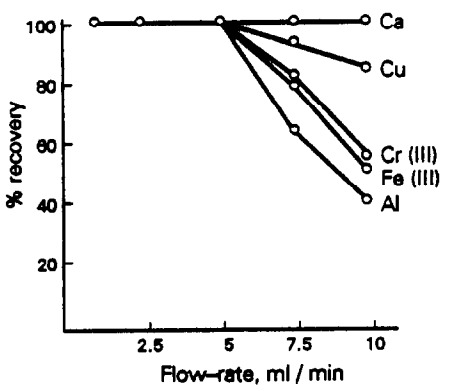


Fig. 1. Percent recovery of some metals as a function of flow-rate of the solution passed through the column packed with silica gel modified with Calcon.

for inert aquocomplexes of aluminium and chromium.

However, when the concentrations of metals in aqueous solution were lower than the maximal capacities of the sorbent, the quantitative retention even for chromium and aluminium was reached at high flow-rates of the solution passed through the column, up to 5 ml/min^{-1}, see Fig. 1.

The relative capacities of silica gel modified with Calcon toward metal ions are differentiated and for all metals increase with the pH of the aqueous metal salt solution. It should be added that relative capacities toward such metals as aluminium and chromium should be somewhat higher than the values given in Table 2 since the capacities were estimated at relatively high elution rates (1 ml/min).

All retained metals can be eluted from the sorbent with dilute solutions of mineral acids (0.1*M* perchloric acid or 1*M* hydrochloric acid, see Table 2) which do not elute Calcon from the sorbent, making it possible to repeat the sorption–elution process many times in the same column. The column can be regenerated in a simple manner; by washing with doubly distilled

Table 2. The relative capacities of silica gel modified with Calcon toward metal ions (micromoles/g) and minimal concentrations of acid (*M*) required for elution (1 g of the chelating sorbent contained 0.1 mmoles of calcon and 0.2 mmoles of Aliquat 336)

water to remove the mineral acid solution used as eluent.

Although in the experimental conditions used some metals could be retained by a sorbent containing an excess of quaternary alkyl-ammonium chloride relative to the amounts of Calcon also in the form of simple anions (SeO_3^{2-}, TeO_3^{2-}, MoO_4^{2-} and $Cr_2O_7^{2-}$ or CrO_4^{2-}) or chloride complexes [some metals retained from solutions of pH 1 and 2 buffered with a mixture of HCl and KCl are Fe(III), Bi, Sb, In], the increase of the relative capacity of the sorbent with pH for other metal ions indicate their retention in the form of metal complexes with Calcon.

Different concentrations of mineral acids eluting various retained metals from the sorbent can be utilized for the separation of metal ion mixtures and some examples extractive–chromatographic separations performed are illustrated by Fig. 2. It should be added that the chromatographic bands were relatively sharp even for metals [Bi, Fe(III) and Sb] which should hydrolyse in the pH 5 solutions introduced into the column—recoveries for these metals were higher than 96%.

One experiment was performed for separation of traces of some metals from macroamounts of alkali or alkaline earth metals. A 100-ml volume of the synthetic aqueous solution was adjusted to pH 3.5 with tartrate buffer. The solution contained 1% Na, 0.14% Mg, 0.04% Ca and K, and 5×10^{-5}% Zn, Cu and Fe(III). This solution was passed through the column packed with 5 g of the sorbent. After the column had been washed with 15 ml of doubly distilled water, the unretained metals (Ca, Mg, Na and K) were found in the collected eluate. The retained metals (Cu, Zn and Fe) were then eluted with 5 ml of 0.5*M* perchloric acid and determined in the eluate by AAS. Recoveries higher than 95% were found for each retained metal ion. Thus the proposed sorbent can be utilized for preconcentration of traces of heavy metals from aqueous solutions and for elimination of the matrix effect of alkali and alkaline earth metals in the determination of heavy metals by conventional analytical methods.

Since all metals except alkali metals are retained from aqueous solutions of pH $\geqslant 4$ on silica gel modified with Calcon, it was expected that this sorbent can find application in additional purification of alkali metal salts. Voltamperograms for potassium chloride solutions illustrated by Fig. 3 confirmed this supposition: it was found that analytical grade

4—KCl solution after passing through the column packed with silica gel modified with Calcon
5—as in curve 4 but after 10 min electrolysis.

potassium chloride solution which is usually used as a supporting electrolyte in polarography and anodic stripping voltammetry, contained considerable amounts of Cu, Cd, Pb and Zn. It was also found that even doubly distilled water (to which a purified solution of potassium chloride was added) and aqueous solutions of sodium chloride Suprapur contained traces of these metals, especially copper and lead. After passing potassium chloride solutions through the column packed with modified silica gel, these metals were removed and only traces of copper were found after elongated electrolysis (10 minutes instead normally used 3 minutes). Thus, in author's opinion, columns packed with silica gel modified with Calcon can be useful for simple purification of supporting electrolyte solutions used in determination of several metals (especially of Pb and Cd) by ASV in various materials which makes it possible to utilize the very high sensitivity of this method which is normally limited by impurities present in supporting electrolyte and in doubly distilled water.

OXIDANTS FOR THE COLORIMETRIC DETERMINATION OF PINDOLOL

M. S. MAHROUS, A. S. ISSA and N. S. AHMED

Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt

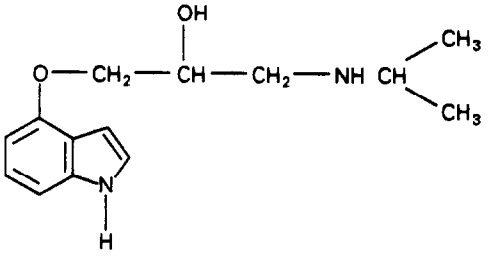
(*Received* 22 *May* 1991. *Revised* 24 *April* 1991. *Accepted* 23 *May* 1991)

Summary—A simple, sensitive and accurate colorimetric method is described for the quantitative determination of pindolol either in the pure form or in its tablets. The method is based on the oxidation of the indole moiety in pindolol with potassium persulphate or hydrogen peroxide—in acid medium—to give a highly coloured product that exhibits maximum absorption at 535 nm and 570 nm, respectively. Beer's law is obeyed over concentrations ranging from 0.07–0.35 mg/10 ml for potassium persulphate and 0.1–0.5 mg/10 ml for hydrogen peroxide with mean recoveries of 99.6 ± 0.6 and 99.8 ± 0.9%, respectively. The method is applied for the assay of pindolol tablets without any interference due to tablet fillers.

Pindolol is a B-adrenergic receptor blocking agent. It is used in the treatment of hypertension and to reduce the incidence of attacks in angina pectoris.

Pindolol has been determined by a non-aqueous titration method.[1] It was also determined spectrophotometrically,[2–4] colorimetrically[5,6] and fluorimetrically where excitation is at 263 nm and emission at 305 nm.[7] Thin-layer chromatography was also used for pindolol determination.[8]

The present work is concerned with the ability of pindolol, which is an indole derivative, to be oxidized with potassium persulphate or hydrogen peroxide. The oxidation leads to the development of a highly coloured oxidation product that can be used for the quantitative colorimetric determination of pindolol.



Scheme 1

EXPERIMENTAL

Instrumentation

Perkin–Elmer Model 550S spectrophotometer with matched 1-cm quartz cells was used.

Reagents

Potassium persulphate solution, 0.1% w/v.
Hydrogen peroxide solution, 5% w/v.
3-Sulphuric acid (AR), 96% w/v.

Materials

Pharmaceutical grade pindolol (Sandoz Co.).
Visken tablets, 5 mg pindolol/tablet (Sandoz Co.).

Preparation of calibration curves

A series of 1–5 ml portions of an alcoholic solution containing 0.07 mg/ml pindolol for potassium persulphate or 0.1 mg/ml for hydrogen peroxide was transferred to 10-ml measuring flasks. Each solution was diluted to about 5 ml with ethanol, treated with 1 ml of potassium persulphate or hydrogen peroxide reagent, cooled in ice for 5 min, then 2 ml of sulphuric acid were added dropwise while mixing and cooling. The flasks were left at room temperature for 40 min then diluted to volume with water. The developed colours were measured at 535 nm for potassium persulphate and at 570 nm for hydrogen peroxide against a reagent blank treated similarly (Fig. 1).

Analysis of pindolol tablets

Twenty tablets of the drug were weighed and powdered. A quantity of the powdered tablets equivalent to 8 mg of pindolol was transferred to a 100-ml measuring flask, followed by the addition of about 50 ml of alcohol. The mixture was shaken for 15 min, then the flask was made

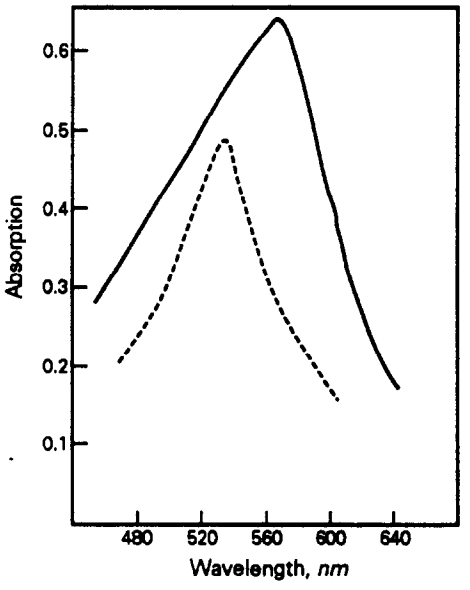


Fig. 1. Absorption curves for pindolol oxidation products.

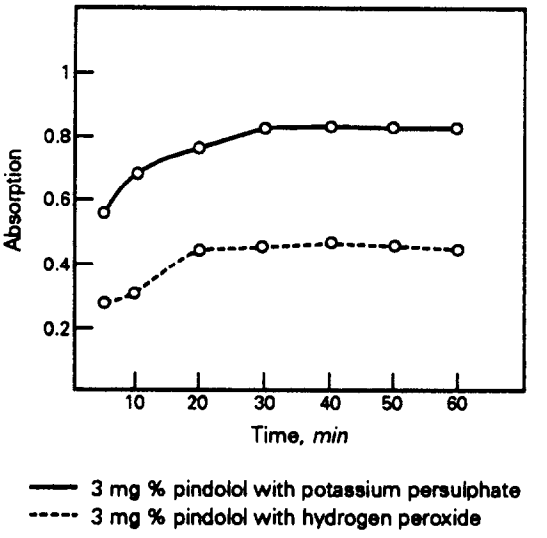

Fig. 2. Colour development and stability of pindolol oxidation products.

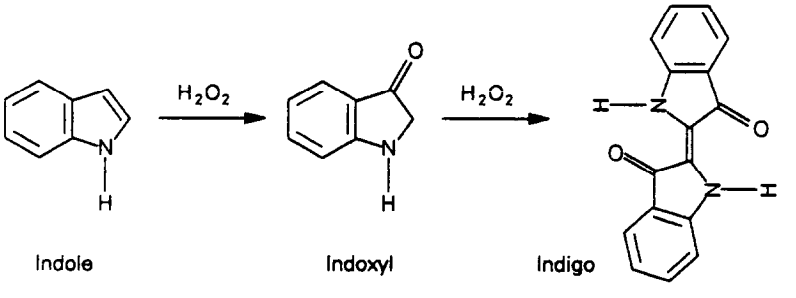
up to volume with alcohol and the solution mixed and filtered (1 ml = 0.08 mg/ml pindolol). The filtrate was used for the determination of pindolol, applying the procedure described under the preparation of calibration curves.

RESULTS AND DISCUSSION

Houlihan *et al.*[9] reported that indole is readily oxidized by a variety of oxidants and the extent of oxidation depends on the oxidant and the experimental conditions. Indoxyl is frequently observed as an intermediate in the oxidation process. Thus oxidant converts indole to indoxyl, which is then reoxidized, mainly to indigo. This can be illustrated as follows:



Scheme 2

In this work, this reaction was utilized for the colorimetric determination of pindolol as an indole derivative, using potassium persulphate and hydrogen peroxide. The colour formed was measured at 535 nm for potassium persulphate with a quantity ranging from 0.07–0.35 mg/10 ml and at 570 nm for hydrogen peroxide with a quantity ranging from 0.1–0.5 mg/10 ml pindolol. The molar absorptivities were 0.7×10^3 $l.mole^{-1}.cm^{-1}$ and 3.7×10^3 $l.mole^{-1}.cm^{-1}$, respectively.

The influence of various factors on the colour development was studied to determine the optimal conditions. Potassium persulphate was maximally effective when using 1 ml of 0.1% w/v solution and hydrogen peroxide was most effective when using 1 ml of 5% w/v solution. The intensity of the colour was found to increase with time and the colour reached its maximum intensity after 40 min and then remained stable for more than 1 hr (Fig. 2). Also, the most effective volume of sulphuric acid was found to be 2 ml.

Table 1. Determination of pindolol powder by the proposed and non-aqueous titration methods

Mean % and S.D.	101.0 ± 0.6		101.3 ± 0.7		101.5 ± 0.8

*Visken tablet, 5 mg/tablet (Sandoz Co.).

These proposed reagents gave good recoveries and reproducibility. The results obtained were compared with the non-aqueous titration method[1] and were found to show the same reproducibility. The mean percentage recoveries show no difference when compared with the non-aqueous titration[1] demonstrating the accuracy of the method (Table 1).

The regression equations and regression coefficients were derived with the least squares method:[10]

$$A = 0.003 + 0.283C,\ r = 0.999,$$

and

$$A = 0.003 + 0.1583C,\ r = 0.996$$

for potassium persulphate and hydrogen peroxide, respectively, where C is in mg%. These equations were utilized for computation of different unknown drug concentrations.

Pindolol was also analysed in its tablets and the results obtained were compared with the non-aqueous titration method[1] and found to show the same reproducibility (Table 2). The results in Table 2 show that tablet fillers formulated with pindolol do not interfere with these methods.

The proposed methods are sensitive and specific compared with the non-aqueous technique.[1]

THE CHEMISTRY OF IRON IN BIOSYSTEMS—V†

STUDY OF COMPLEX FORMATION BETWEEN IRON(III) AND TARTARIC ACID IN ALKALINE AQUEOUS SOLUTIONS

V. SALVADO and X. RIBAS

M. VALIENTE‡
Química Analítica, Universitat Autònoma de Barcelona, 08193 Bellaterra, Barcelona, Spain

(*Received* 30 *May* 1990. *Accepted* 24 *May* 1991)

Summary—Complex formation between Fe(III) and tartaric acid (H_2L) has been studied in 0.5*M* $NaNO_3$ medium at 25° by potentiometry at pH 4.5–11. The following complex species and corresponding values of the stability constants (charges omitted) are proposed:

$$2Fe + 2L + 5H_2O \rightleftharpoons Fe_2(OH)_5L_2 + 5H^+; \quad \log^* \beta_{-522} = 4.95$$

$$Fe + L + 3H_2O \rightleftharpoons Fe(OH)_3L + 3H^+; \quad \log^* \beta_{-311} = -1.55$$

$$Fe + L + 5H_2O \rightleftharpoons Fe(OH)_5L + 5H^+; \quad \log^* \beta_{-511} = -21.2$$

These results are in good agreement with those reported for this system in acid. The results may be presented as the degeneration of the "core + link" mechanism observed in the acidic zone. Structures are suggested for the complex species formed.

Systematic investigations of complex formation in aqueous solutions between Fe(III) and various carboxylate ligands have been carried out in our laboratory.[1–4] Tartrate (L) is a ligand that can prevent precipitation of hydrated ferric oxide in aqueous solutions. The complex formation between Fe(III) and tartaric acid in the acid pH range 1.5–4.5 was studied earlier.[1] The results obtained in the present work indicate that the species FeL, $Fe_2(OH)_3L_2$ and $Fe_3(OH)_6L_3$ are formed by stepwise polynuclear complex formation of the "core + links" type, a mechanism proposed by Sillén.[5] In the Fe(III)–tartrate system, the species FeL is the "core" and the polynuclear species result from stepwise addition of the "link" group $Fe(OH)_3L_2$. The "link" group was not detected as an individual species in the acidic range studied.

No literature data for Fe(III)–tartrate system have yet been reported for alkaline aqueous solutions. The present work attempted to investigate the behaviour of this system in alkali in order to extend the previous information from acidic conditions.

†Part IV—V. Salvadó, X. Ribas and M. Valiente, *Polyhedron*, 1990, **9**, 2675.
‡Author for correspondence.

EXPERIMENTAL

Free hydrogen-ion concentrations at equilibrium, *h*, were measured for solutions prepared from stock solutions of ferric nitrate, tartaric acid, nitric acid and sodium nitrate. The potentiometric technique used was that described previously.[1] Values of *h* are obtained from the Nernst equation:

$$E_i = E_i^0 + 59.16 \log h + E_j \qquad (1)$$

where E_i^0 is a constant and E_j is the liquid-junction potential. Both these parameters were determined by a Gran titration[6] when no ferric and tartrate ions were present in the test solution. This was done in both the acidic and basic pH regions, and is the calibration of the system.

A computer system[7] was employed to monitor the titration experiments. The emf measurements utilized a glass electrode (Metrohm 1028) and a double-junction reference electrode (Orion 9002) containing 0.5*M* sodium nitrate as outer filling solution, which also served as a salt bridge.

For the different experiments the analytical concentrations of Fe(III), B, and tartrate, C, were in the range 2.0–6.0mM and 5.0–20.0mM respectively and kept constant within each experiment. The pH values ranged from 4.0 to 11.0. Particular care was needed because of the low buffer capacity of the solution, and the well known difficulty of obtaining accurate emf measurement in the alkaline range. The measured potentials were considered to be stable when their variation was less than 0.1 mV in 10 min. All solutions were kept under an atmosphere of nitrogen.

The data indicated that equilibrium conditions had been achieved, because reproducible results were obtained in back-titration experiments, see Fig. 1.

The experiments were done at $25 \pm 0.1°$.

RESULTS

Figure 1 shows the experimental data obtained in the pH range 4.5–11.0, plotted as Z *vs.* $-\log h$ for the various concentrations B and C. Z represents the number of hydrogen ions bound per ligand entity, defined by:

$$Z = (A - h + K_w/h)/C \qquad (2)$$

where A represents the analytical concentration of hydrogen ions. Full symbols in Fig. 1 represent back-titration data. The good agreement between direct titration and back-titration results indicates that no irreversible processes interfere with the complexation reactions.

As reported before,[1] the formation of complexes between Fe(III) and tartaric acid can be expressed by the general equation:

$$p\mathrm{H} + q\mathrm{Fe} + r\mathrm{L} \rightleftharpoons \mathrm{Fe}_q\mathrm{H}_p\mathrm{L}_r; \quad {}^*\beta_{pqr} \qquad (3)$$

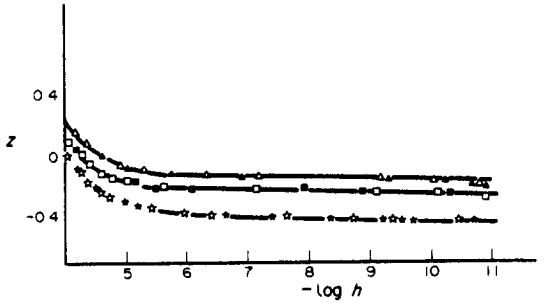

Fig. 1. Z plotted *vs.* $-\log h$ for the various experiments. Filled points represent back-titrations. Solid lines were calculated for model III of Table 1. ☆ [Fe] 4.8mM, [L] 31mM; □ [Fe] 1.8mM; [L] 30mM; △ [Fe] 1.5mM, [L] 48mM.

where ${}^*\beta_{pqr}$ represents the formation constant of the species formed. Charges are omitted throughout, for simplicity.

The stoichiometry of the complexes and the constants ${}^*\beta_{pqr}$ were determined by numerical analysis of the experimental data with the computer program LETAGROP–NYTIT.[8] The treatment is based on the minimization of the error square sum, U, defined by:

$$U = \sum_{N_p} (E_{calc} - E_{exp})^2 \qquad (4)$$

where E_{exp} represents the experimental emf values, E_{calc} is the corresponding value calculated by the program for the model with corresponding stability constants, and N_p is the number of experimental points. In our case, the program is also fed with the information corresponding to the binary systems, *i.e.*, hydrolysis of Fe(III),[3] the protolytic equilibria of tartaric acid and the information for this ternary system in the acidic zone.[1] In the present case, the calculation starts by testing the fit of the previous results in the acidic range to the new experimental information. The results of these calculations are given in Table 1. In model I, ${}^*\beta_{pqr}$ for the complexes FeL and $Fe_2(OH)_3L_2$, which are present in low concentration only at pH > 4.5, were fixed while the stability constant for the predominant $Fe_3(OH)_6L_3$ was varied. A large deviation of this model from the experimental data, reflected by the U and σ values, is observed. Therefore, models II and III were proposed by adding new species, including polynuclear and mononuclear complexes,

Table 1. Resumé of the results obtained from numerical treatment of the experimental data for the system Fe(III)–tartrate in the alkaline region†

Model	(p, q, r)	U	σ, mV	log ${}^*\beta_{pqr}$
(I)	(0, 1, 1)	0.36×10^5	82.0	Fixed
	(−3, 2, 2)			Fixed
	(−6, 3, 3)			13.95 Max. 14.47
(II)	(−6, 3, 3)	0.15×10^3	1.46	14.00 ± 0.08
	(−5, 2, 2)			4.95 ± 0.17
	(−3, 1, 1)			-1.54 ± 0.10
	(−4, 1, 1)			Rejected
	(−5, 1, 1)			-21.21 ± 0.10
(III)‡	(−6, 3, 3)	0.10×10^3	1.16	14.00 ± 0.05
	(−5, 2, 2)			4.95 ± 0.04
	(−3, 1, 1)			-1.55 ± 0.034
	(−5, 1, 1)			-21.21 ± 0.10

†The standard deviation σ (mV) is defined as $(U/(N_p - N_k\beta))^{1/2}$. N_k is the number of constants adjusted. The error in the constants is given as $\pm 3\sigma(\log {}^*\beta)$. When $\sigma(k) > 0.2\beta$, the "best" value of log ${}^*\beta$ and the maximum value, Max. = log $[{}^*\beta + 3\sigma({}^*\beta)]$ are given.

‡After correction for possible analytical errors.

e.g., $Fe_2(OH)_5L_2$, $Fe(OH)_3L$ and $Fe(OH)_5L$, in addition to complexes formed in the acidic range. Model III provides the best fit to the experimental data and can be expressed by the following reaction equations:

$$2Fe + 2L + 5H_2O \rightleftharpoons Fe_2(OH)_5L_2 + 5H; \quad \log {}^*\beta_{-522} = 4.95 \quad (5)$$

$$Fe + L + 3H_2O \rightleftharpoons Fe(OH)_3L + 3H; \quad \log {}^*\beta_{-311} = -1.55 \quad (6)$$

$$Fe + L + 5H_2O \rightleftharpoons Fe(OH)_5L + 5H; \quad \log {}^*\beta_{-511} = -21.2 \quad (7)$$

Figure 2 shows the individual values of the differences $E_{calc} - E_{exp}$ (in mV) over the pH range studied. It can be seen that the proposed model shows no systematic deviations from the experimental data.

Figure 3 represents the distribution diagram of the species, calculated by the program HALTAFALL.[10]

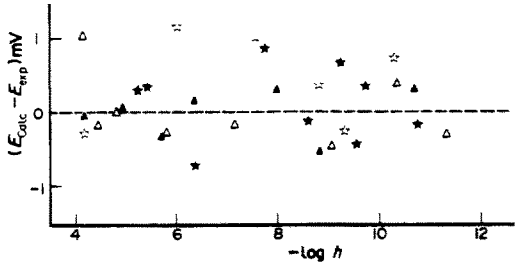

Fig. 2. $E_{calc} - E_{exp}$ (mV) *vs.* $-\log h$. E_{calc} corresponds to the emf values calculated by the program on the basis of the proposed model III. ☆ [Fe] 4.8m*M*, [L] 31m*M*; △ [Fe] 1.8m*M*, [L] 30m*M*; filled points represent back-titrations.

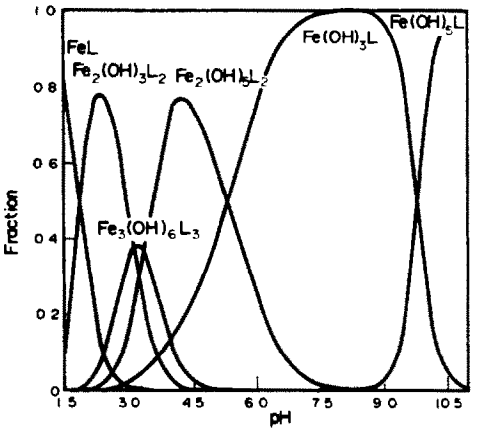

Fig. 3. Distribution diagram for the Fe(III)–tartrate complex species as a function of $-\log h$, including the species previously obtained in the acid range.[1] $[Fe^{3+}] = 2.0mM$ and $[L] = 20mM$.

DISCUSSION AND CONCLUSIONS

Equations 5–7 correspond to complex formation between Fe(III) and tartrate ions in aqueous 0.5*M* sodium nitrate as ionic medium in the pH range 4.5–11.0.

In Fig. 1, the full lines represent theoretical values of Z *vs.* $-\log h$ calculated on the basis of the proposed model. The observed agreement with the experimental data gives a high confidence level to this model.

The model is also in agreement with the behaviour of this system in acid solutions.[1] Complex formation between Fe(III) and tartaric acid can be explained as occurring by a "core + link" mechanism where the species FeL represents the "core" and the species $Fe(OH)_3L$ is the "link". That is, the mechanism of formation of polynuclear species can be represented by the following equations:

$$FeL + Fe(OH)_3L \rightleftharpoons Fe_2(OH)_3L_2 \quad (8)$$

$$Fe_2(OH)_3L_2 + Fe(OH)_3L \rightleftharpoons Fe_3(OH)_6L_3 \quad (9)$$

The result of this study in the alkaline region includes the species $Fe(OH)_3L$ which was formulated as a "hypothetical link" in the acidic region. As observed in Fig. 3, this species predominates only at pH > 5, which may explain why it was not detected in the previous study. On the other hand, the species $Fe_2(OH)_5L_2$ may correspond to a first step in the hydrolytic degradation of the polynuclear species $Fe_3(OH)_6L_3$ which predominates at pH 4.0.

Such a hydrolytic process could be expressed by the reaction:

$$2Fe_3(OH)_6L_3 + 3H_2O \rightleftharpoons 3Fe_2(OH)_5L_2 + 3H \quad (10)$$

In accordance with Fig. 3, the hydrolytic process can be assumed to proceed by further steps to produce the mononuclear species $Fe(OH)_3L$ and $Fe(OH)_5L$ as suggested by the equations:

$$Fe_2(OH)_5L_2 + H_2O \rightleftharpoons 2Fe(OH)_3L + H \quad (11)$$

$$Fe(OH)_3L + 2H_2O \rightleftharpoons Fe(OH)_5L + 2H \quad (12)$$

$Fe(OH)_3L$ is the most stable of those species in the pH range studied, as shown by Fig. 3. Possible structures for the species present in the acid range have been suggested.[1] Figure 4 shows structures proposed for the species present at pH > 5.

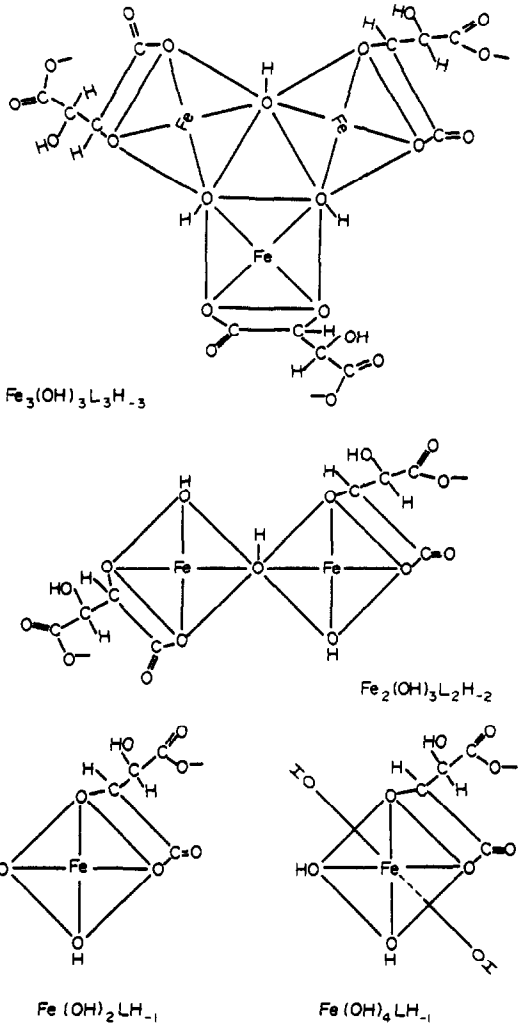

Fig. 4. Structures suggested for the complex species found in the alkaline region of the Fe(III)–tartaric acid system. (L_nH_{-n} means co-ordination of n tartrate anions L, each of which has lost a proton from a hydroxy group.)

The species $Fe_3(OH)_6L_3$, considered as the end product of the nucleation process in the acidic range, is now the origin for the degenerate species, $Fe_2(OH)_5L_2$, $Fe(OH)_3L$ and $Fe(OH)_5L$. The denucleation process should therefore be written as:

$$2Fe_3(OH)_3L_3H_{-3} + 3H_2O \rightleftharpoons 3Fe_2(OH)_3L_2H_{-2} + 3H$$

$$Fe_2(OH)_3L_2H_{-2} + H_2O \rightleftharpoons 2Fe(OH)_2LH_{-1} + H$$

$$Fe(OH)_2LH_{-1} + 2H_2O \rightleftharpoons Fe(OH)_4LH_{-1} + 2H$$

This model suggests that the species $Fe(OH)_3LH_{-1}$ should be rejected, since it would have an asymmetric structure, which should favour the formation of $Fe(OH)_4LH_{-1}$.

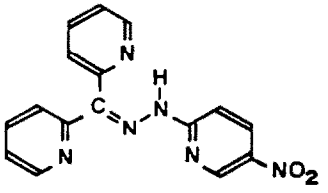
EXTRACTIVE–SPECTROPHOTOMETRIC DETERMINATION OF TRACE IRON(II) WITH DI-2-PYRIDYLMETHANONE 2-(5-NITRO)PYRIDYLHYDRAZONE

TOSHIHIRO TAKAOKA, TOSHIKI TAYA and MAKOTO OTOMO
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso, Showa, Nagoya 466, Japan

(*Received* 14 *May* 1991. *Accepted* 16 *July* 1991)

Summary—The optimum conditions for the extractive–spectrophotometric determination of trace iron(II) with di-2-pyridylmethanone 2-(5-nitro)pyridylhydrazone have been established. Iron(II) reacts with this reagent at pH 2.0–7.5 to form an uncharged 1:2 (metal-to-ligand) complex, which can be extracted with toluene. Beer's law is obeyed over the range up to 0.84 μg/ml of iron(II) at 505 nm. The molar absorptivity of the extracted species is 5.83×10^4 l·mole^{-1}·cm^{-1}. The proposed method is extremely sensitive and reproducible, and has been satisfactorily applied to the determination of total iron in freshwater samples by adding ascorbic acid to reduce iron(III).

Di-2-pyridylmethanone 2-pyridylhydrazone (DPPH), a *NNN*-tridentate heterocyclic hydrazone ligand, has been used for the spectrophotometric determination of several metal ions, including cobalt(II)[1] and iron(II).[2] Iron(II) reacts with this reagent in acidic media to form a dipositively charged bis complex, $Fe(HL)_2^{2+}$ (HL is a neutral form of the ligand), which undergoes successive deprotonation to monocationic [$Fe(HL)L^+$] and uncharged bis (FeL_2) complexes with a decrease in the acidity of the solution. Although all of the complex species can be used for the spectrophotometric determination of iron(II), the $Fe(HL)_2^{2+}$ species [1.40×10^4 l.mole^{-1}.cm^{-1} at 540 nm in 28% (v/v) aqueous dioxane] has the highest molar absorptivity.[3]



(I)

In a previous paper[4] we have introduced an improved ligand, di-2-pyridylmethanone 2-(5-nitro)pyridylhydrazone (DPNPH, I)—a nitration derivative of DPPH—as a useful and extremely sensitive chromogenic reagent for certain transition metal ions, including palladium(II). The greatly enhanced sensitivity of the new ligand obtained by introducing a strongly electron-withdrawing nitro group to the 5-position of the pyridine ring in the hydrazine moiety, was explained by a prolonged conjugated system (quinoid structure) of the metal complex resulting from the redistribution of the electron-pair previously shared by the imino nitrogen. This paper describes a highly sensitive and precise method for the extractive spectrophotometric determination of iron(II) with DPNPH. The proposed method, which permits the determination of sub-ppm levels of iron(II), can be applied to the determination of total iron in freshwater samples in the presence of ascorbic acid without a tedious preconcentration step.

EXPERIMENTAL

Apparatus

Spectrophotometric measurements were made with a Hitachi Model 150-20 spectrophotometer with matched 1.00-cm quartz cells. A Toa Dempa HM-30S pH meter was used for pH adjustments. All measurements were performed at 25°.

Reagents

All solutions were prepared with analytical-grade chemicals and doubly distilled water unless otherwise stated. Toluene was distilled before use.

Iron(II) solution. Iron(II) standards were obtained by dilution of 0.01*M* ammonium iron(II) sulphate acidified with sulphuric acid

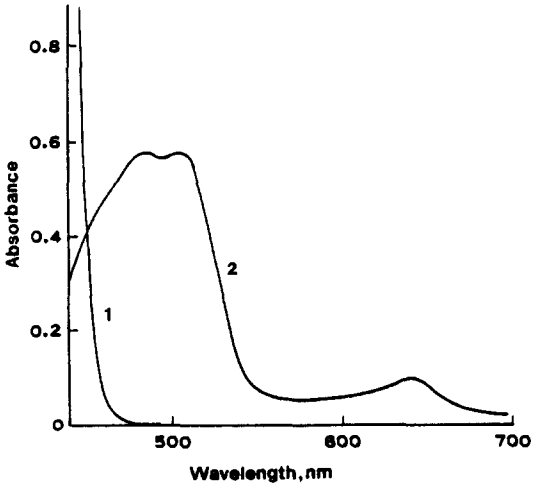


Fig. 1. Absorption spectra of DPNPH and its iron(II) complex extracted into toluene. Fe(II) $1.0 \times 10^{-5}M$, pH 4.60, DPNPH $2.0 \times 10^{-3}M$. (1) DPNPH *vs.* toluene, (2) Fe(II)–DPNPH complex *vs.* reagent blank.

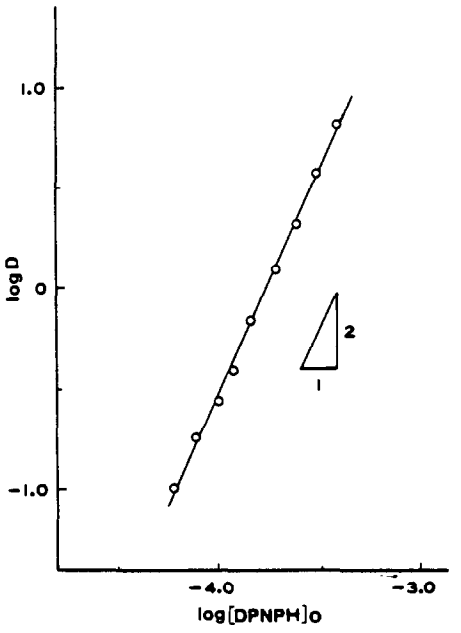

Fig. 2. Logarithmic plot for iron(II) distribution. Fe(II) taken $1.0 \times 10^{-5}M$, pH 4.60, measurement at 505 nm.

standardized against a standard potassium permanganate solution.

DPNPH. The ligand was synthesized as previously described[4] by diret interaction of equimolar portions of di-2-pyridyl ketone and 2-hydrazino-5-nitropyridine. The acid–base characteristics of the ligand were also described previously.[4] A $2.0 \times 10^{-3}M$ DPNPH in toluene was freshly prepared daily.

General procedure

Into a 50-ml separating funnel, transfer a suitable aliquot of sample solution containing up to 8.4 μg of iron(II, III) with 1 ml of 1% ascorbic acid and 2 ml of $1M$ acetate buffer adjusted to pH 4.6. Dilute to 10 ml with water and equilibrate with exactly 10 ml of $2.0 \times 10^{-3}M$ DPNPH in toluene by mechanical shaking for 30 min. Measure the absorbance of the organic phase at 505 nm against a reagent blank.

RESULTS AND DISCUSSION

Characteristics of the complex

The iron(II) complex formed with the reagent is sparingly soluble in water, but readily soluble in various organic solvents such as aromatic hydrocarbons, partially halogenated aliphatic

hydrocarbons, acetic esters and ketones. Toluene was chosen as the extracting solvent, because it gave negligibly low blank absorbance at the selected wavelength. Under the optimum conditions of the reagent concentration, pH and shaking period, iron(II) can be quantitatively extracted from aqueous solution with a single 10-ml portion of DPNPH in toluene over the concentration range studied. The intensity of the colour thus obtained remains unchanged for at least 18 hr. Figure 1 illustrates the visible absorption spectrum of the iron(II) complex extracted into toluene, along with that of the reagent blank. The absorption spectrum is characteristic for iron(II), three absorption maxima being located at 485, 505 and 640 nm. Iron(III) did not react with DPNPH and should be reduced by ascorbic acid.

Effects of experimental conditions

A pH study for the formation and extraction of the iron(II) complex was performed between pH 1.5 and 9.0, using 4.2 μg of iron(II). The absorbance of the organic phase as a function of the pH of the aqueous phase was maximal and constant over the pH range 2.0–7.5. Below pH 2, unextractable complex species [possibly $Fe(HL)_2^{2+}$ and/or $Fe(HL)L^+$ species] remained in the aqueous phase.

A maximal and reasonably constant absorbance was obtained by using more than $7.5 \times 10^{-4}M$ DPNPH in the organic phase.

Addition of 1.0 ml of 0.1% ascorbic acid was sufficient for preventing oxidation of iron(II) to the trivalent state. It was also found that a shaking period of 15 min is sufficient for complete equilibrium, provided the volume ratio of aqueous to organic phase is between 0.5:1 and 4:1.

Conformance to Beer's law and comparison of sensitivity

The analytical species of interest obeys Beer's law over the concentration range up to 0.84 μg/ml iron(II) in the organic phase. The molar absorptivity (ϵ) of the complex was 5.83×10^4 $l.mole^{-1}.cm^{-1}$ at 505 nm (it was 6.23×10^4 $l.mole^{-1}.cm^{-1}$ at 510 nm in *o*-dichlorobenzene), which is higher than or comparable with those of the respective complexes with DPPH in aqueous solution ($\epsilon = 1.53 \times 10^4$ $l.mole^{-1}.cm^{-1}$ at 538 nm),[2] di-2-pyridylmethanone 2-quinolylhydrazone in benzene ($\epsilon = 3.14 \times 10^4$ $l.mole^{-1}.cm^{-1}$ at 504 nm),[5] 2-pyridyl-3′-sulphophenylmethanone 2-pyridylhydrazone in aqueous solution ($\epsilon = 4.79 \times 10^4$ $l.mole^{-1}.cm^{-1}$ at 379 nm),[6] 2-pyridylmethanone 2-pyridylhydrazone in chloroform ($\epsilon = 5.00 \times 10^4$ $l.mole^{-1}.cm^{-1}$ at 405 nm)[7] and 2-pyridylmethanone 2-(5-nitro)pyridylhydrazone in benzene ($\epsilon = 6.54 \times 10^4$ at 496 nm[8]; benzene is highly toxic and appropriate precautions should be taken). The reproducibility of the proposed method, expressed as the standard deviation of the absorbance, was 0.13% for 5.6 μg of iron(II) (10 replicates).

Composition of the complex

The extraction method,[9] where metal distribution is followed in the presence of a reasonable excess of ligand, was used to find the composition of the extracted species. The plot of log D against log $[DPNPH]_{org}$ at pH 4.60, where D denotes the distribution ratio of iron(II) between the two phases and $[DPNPH]_{org}$ is the equilibrium concentration of DPNPH in the organic phase, is shown in Fig. 2. A straight line with a slope equal to about 2 demonstrates a 1:2 metal-to-ligand ratio complex being extracted.

Effect of diverse ions

The effect of diverse ions on the determination of 5.6 μg of iron(II) is summarized in Table 1. The tolerance limit of foreign ions was taken as that value which caused an error of not more than $\pm 2\%$ in the absorbance. For some interfering ions, suitable masking agents were used together as indicated in the table.

Determination of iron in freshwater

The proposed method was applied to the determination of the total iron in tap-water and lake water samples. The sample solution was acidified (pH 1.5) with hydrochloric acid immediately after sampling. Five or ten millilitre portions of the sample were analysed for iron without a preconcentration process. The results shown in Table 2 are in good agreement with

Table 2. Determination of total iron in freshwater samples

§Sample taken = 10.0 ml.

each other and with those obtained by inductively coupled atomic emission spectrometry (ICP–AES) performed for comparison.

In conclusion, the tridentate hydrazone ligand, DPNPH, is worthy of use as a chromogenic reagent for the spectrophotometric determination of iron(II) at sub-ppm levels.

(*Received* 11 *October* 1990. *Revised* 7 *June* 1991. *Accepted* 10 *June* 1991)

Summary—A new spectrophotometric method for determining the extraction constants of quaternary complexes is described. The method has been applied to a study of the distribution between water and toluene in the V(V)–salycylhydroxamic acid–nitrate–trioctyl methyl ammonium system, determining its conditional extraction constant in toluene for several pH values.

In previous works[1–4] a graphical method has been proposed, based on the effect of dilution on the degree of dissociation of the complexes, for determining extraction constants as well as differentiating mono- and poly-nuclear complexes.[2,3]

In the present paper this method has been extended to determination of the solvent extraction constant of a mixed ligand complex forming a quaternary system in the organic phase. The method has been applied to the determination of the apparent extraction constant of an ion-pair association complex formed between a mixed ligand complex and an ammonium quaternary salt as extractant agent.

THEORY

Let us consider the formation of a mixed ligand complex and its extraction forming a quaternary complex by means of the equilibria:

$$M(w) + nX(w) \overset{k_{1n}}{\rightleftharpoons} MX_n(w)$$

$$MX_n(w) + mY(m) \overset{k_{nm}}{\rightleftharpoons} MX_nY_m(w)$$

$$MX_nY_m(w) + qB(o) \overset{K_e}{\rightleftharpoons} MX_nY_mB_q(o)$$

where 'w' is the aqueous phase, 'o' the organic phase and $m, n, q \geq 1$. Where X, Y and B are three different ligands on the coordination sphere, and M the metallic ion.

The conditional extraction constant, K_c, when only one metallic complex is extracted, for a particular pH value is:

$$K_c = \frac{[MX_nY_mB_q](o)}{[MX_nY_m](w)[B]^q(o)} \quad (1)$$

and

$$k_{1n} = \frac{[MX_n](w)}{[M](w)[X]^n(w)} \quad k_{nm} = \frac{[MX_nY_m](w)}{[MX_n](w)[Y]^m(w)}$$

where K_{1n} and K_{nm} are respectively the formation constants of the binary and ternary complexes in the aqueous phase.

$$P_c = \frac{[MX_nY_mBq](o)}{[MX_nY_mBq](w)} \quad E_B = \frac{[B](o)}{[B](w)}$$

where P_c and E_B are respectively the partition coefficient of the quaternary complex and the extraction coefficient of the ligand.

C_M, C_X C_Y and C_B are the initial concentrations of ligand X, Y and B respectively and C_M is the initial concentration of the cation.

Let us consider a 1:1 phase volume ratio and the initial conditions; C_x, $C_Y \gg C_M$ and $C_B/C_M = q$ and only one extractable species —$MX_nY_mB_q$ (o)—in the operational conditions.

Under these conditions we can define the molar ratio of MX_nY_m in the aqueous phase as:

$$\Phi = \frac{[MX_nY_m](w)}{C_M - [MX_nY_mB_q](o)} \quad (2)$$

And by material balance

$$\Phi = \frac{K_{1n}K_{nm}[X]^n(w)[Y]^m(w)}{1 + K_{1n}[X]^n(w) + K_{1n}K_{nm}[X]^n(w)[Y]^m(w)}$$

it is noted that $\Phi = f$ (X) (w), (Y) (w) and so is a constant in the conditions mentioned above. By substitution of [B](o) (from material balance) and MX_nY_m(w) [from equation (2)] in (1)

$$K_e^* = \frac{K_e \Phi E_B^q}{(E_B + 1)^q} = \frac{[MX_nY_mB_q](o)}{q^q(C_M - [MX_nY_mB_q](o))^{q+1}} \quad (3)$$

in the operational conditions the degree of extraction of the metal α_e is

$$\alpha_e = \frac{[MX_nY_mB_q](o)}{C_M} = \frac{A}{A_o}$$

where A is the absorbance of the complex and A_o the absorbance when the complexation and extraction of the cation is complete ($\alpha_e = 1$)

Substituting the values of $[MX_nY_mB_q](o)$ in equation (3)

$$A/A_o C_M^q = q^q K_e^* (1 - A/A_o)^{q+1} \quad (4)$$

Provided that the Beer-Lambert law is obeyed, when an initial concentration of metallic ion "b_o" is diluted by a factor β the corresponding value of $A_o(b_o)$ is decreased by the same factor, *i.e.*, $b = b_o/\beta$ and $A_o(b) = A_o(b_o)/\beta$.

Substitution of b and $A_o(b)$ into equation (4) gives

$$Y = \frac{(\beta A)^{1/q+1}}{(b_o/b)^{q/q+1}} \quad [q^q K_e^* A_o(b_o)]^{1/q+1} \times [1 - A/A_o(b_o)] \quad (5)$$

A plot of Y against βA gives a straight line. When

$$b_o/\beta \to \infty, \quad Y \to 0 \quad \text{and} \quad \beta A \to A_o(b_o).$$

Thus the intersection of the straight line with the abcissa provides the value of $Ao(bo)$. The slope of the straight line is

$$\frac{(q^q K_e^*)^{1/q+1}}{A_o(b_o)^q}$$

which allows the calculation of the extraction constant. In order to plot Y, the left hand side of equation (4), against βA, it is necessary to know the complex stoichiometry and to make an approximation, since the unknown term $A_o(b_o)$ appears in the ordinate. This can be effected if $A_o(b_o)$ is considered as the greatest experimental value obtained for βA.

The precision of the method will depend on the value of α_e

$$K_e^* = \frac{\alpha_e}{q^q(C_M^q(1 - \alpha_e)^{q+1})}$$

this equation can be differentiated to give

$$\frac{dK_e^*}{K_e^* d\alpha_e} = \frac{(1 - \alpha_e)^q(1 + q\alpha_e)}{\alpha_e(1 - \alpha_e)^2}$$

and by approximation to finite increments

$$\frac{\Delta K_e^*}{K_e^*} = \frac{(1 - \alpha_e)^q(1 + q\alpha_e)}{\alpha_e(1 - \alpha_e)^2} \Delta\alpha_e$$

If a reasonable value of $\Delta\alpha_e$ such as ± 0.01 is accepted, the relative error can be calculated as a function of α_e and q. So, the highest precision of $\log K_e^*$ (± 0.03) is obtained, when $q = 1$, for α_e values between 30–70%.

EXPERIMENTAL

Reagents and apparatus

Salycylhydroxamic acid (SHA) solution ($10^{-2}M$) was prepared by dissolving 1.5314 g of the acid (Jenssen) and diluting to one litre with demineralized water. A $1.89 \times 10^{-3}M$ vanadium(V) solution was prepared by diluting ammonium monovanadate (Merck) solution standardized gravimetrically with silver nitrate. A $1M$ potassium nitrate solution was prepared by dissolving 202.22 g of potassium nitrate (Merck) in one litre of demineralized water. Samples are buffered with acetic acid/sodium acetate solution. A trioctylmethylammonium

chloride (TOMA) solution $9.45 \times 10^{-4}M$ was prepared by dissolving 0.3819 g of $C_{25}H_{54}N^+Cl^-$ (Serva) and diluting to one litre with toluene. All reagents were of analytical reagent grade.

A Baush Lomb Spectronic 2000 spectrophotometer and an Orion 801 pH-meter were used.

Procedure

Into a 100-ml separating funnel, 0.5 ml of $10^{-2}M$ SHA solution, 3 ml of $1M$ potassium nitrate, 1 ml of HAc/AC^- buffer solution (pH 4.2–5.3 and $C = 0.2M$), suitable aliquots of V(V) of 3.78×10^{-4}–$1.32 \times 10^{-4}M$ were transferred, diluted to 10 ml with demineralized water and mixed well. Then 10-ml of trioctylmethylammonium chloride toluene solution of identical concentration to the one of V(V) were added and shaken vigorously for 3 min before the phases were allowed to separate. The organic phase was transferred to a flask containing anhydrous sodium sulphate. The absorbance of each extract was measured at 620 nm against a reagent blank prepared with the same reagent concentration, but no vanadium(V). It is convenient to increase the cell path length by a factor equal or proportional to the dilution factor. In this fashion, the value of βA is obtained directly.

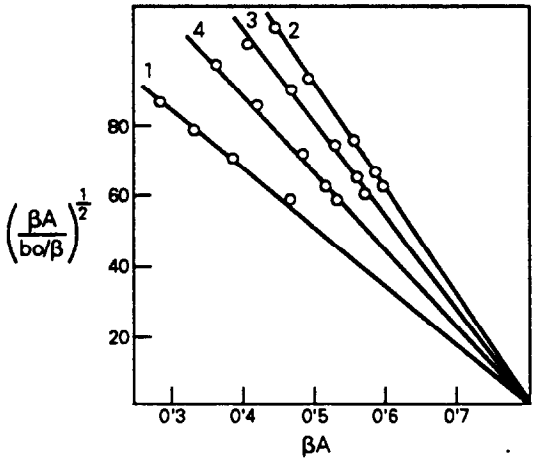

Fig. 2. Determination of K_c^* at several pH values for the V(V)–SHA–NO_3–TOMA system. pH = (1) 4.2; (2) 4.5; (3) 5.0; (4) 5.3.

RESULTS AND DISCUSSION

Vanadium–SHA–nitrate–TOMA system

The study of the A *vs.* pH curves (Fig. 1) and the application of the Job, Joe-Yones and Asmus methods to determine the stoichiometry, showed that for pH values in the aqueous phase between 3.0–5.5 a single complex is extracted into the organic phase. The stoichiometry of this complex is 1:1:2:1 for V(V):NO_3:SHA:TOMA. This implies that the extraction occurs through the ion-pair formation between the anionic complex $[V(V)NO_3(SHA)_2]^-$ and the TOMA cation. Both the ion-pair formation and the extractions were almost instantaneous with only 30 sec of shaking required for complete extraction of the complex. The absorbance of the extract remains stable for at least 15 min and the spectra show a maximum at 620 nm. The degree of extraction (αe) of the metal is ≈ 1 in the same pH interval when the ratio TOMA/V(V) ≥ 10.

Determination of conditional extraction constants at different pH values

The conditional extraction constants were determined for an initial metallic ion concentration of $1.51 \times 10^{-4}M$ at different pH values (4.2, 4.5, 5.0 and 5.3). Table 1 shows the results obtained. In all cases the corresponding plots (Y *vs.* βA) shown in Fig. 2 are straight lines (Table 2) when the stoichiometry TOMA/mixed ligand complex is 1:1, which confirms this

Table 2. Regression parameters for straight lines shown in Fig. 2

pH	4.2	4.5	5.0	5.3
r	0.996	0.999	0.991	0.996

value. These straight lines intersect the abcissa to give a value of 0.815 which leads to a molar absorptivity, ϵ^*, of $5{:}40 \times 10^3$ l.mole^{-1}.cm^{-1}. The same value is obtained when calculated by the Beer-Lambert law. The data obtained by application of equation (5) are given in Table 3, and Fig. 3 shows the relationship between log K_e^* and pH, resulting in a maximum value of about pH = 4.5 (log $k_e^* = 8.66$ at 20°).

CONCLUSION

The present method allows the spectrophotometric calculation of extraction constants as well as the verification of stoichiometries of different ligand complexes containing four components. It is based on the effect of dilution on the degree of dissociation of the complexes. The calculation is performed on spectrophotometric measurements of the quaternary complex formed in the organic phase, using the stoichiometric ratio of extractant ligand and metallic ion ($C_B/C_M = q$). The method used does not require a complex mathematical model, which simplifies the expressions used as well as the data processing. Because of the complexity of these quaternary systems, previous experimental work is required to ensure adequate extraction conditions where only one metallic complex is present in the organic phase, and to ensure the absence of spectral overlapping with other components which could be present in the solution.

Summary—A simple scheme for potential indirect electrochemical detection in flow analyses (liquid chromatography and ion chromatography) with experimental examples is presented. The proposed scheme exploits the influence of the analyte on the reduction current of an intrinsic mobile phase additive—oxygen—at the detector electrode, and utilizes the resulting changes in background current as an analytical signal. Several analytes: chloropromazine, ascorbic acid, nitrate and sulfate, cause a shift in the oxygen reduction peak, particularly at the AuCl electrode, that results in a cathodic or anodic shift in the current at a fixed potential.

Liquid chromatography (LC) with electrochemical (EC) detection, LCEC, is a highly sensitive and selective tool used in a myriad of analyses relating to agricultural, environmental and clinical samples. However, reductive LCEC is plagued by the well-known interference from oxygen reduction. Although this interference can easily be "tuned-out" by saturating both the sample solution to be injected and the mobile phase (which also acts as the supporting electrolyte in LCEC) with a suitable inert gas, the resulting increase in analysis time is usually undesirable. The objective of initiating the work reported here was to extract analytical advantages out of this misfortune of reductive electroanalyses. The idea was to explore the possibility of interference of the analyte species in the process of oxygen reduction and to use the resulting changes in reductive current as an analytical signal.

In recent times several procedures for the indirect detection of analytes after their separation on a chromatographic column have been reported.[1–13] These methods exploit the displacement of a signal generating species (deliberately added to the mobile phase) at the detector with the concomitant changes in the background signal (baseline) acting as an analytical signal. Depending on the nature of the mobile phase additive, one of the conventional methods (such as UV–VIS, fluorescence, electrochemical, *etc.*) is used for the detection of the background signal. Of particular interest to us are those methods which rely upon the signal generated by an electroactive mobile phase additive.[10–12] In these methods the analyte interferes with the electroactivity of the additive at the detector electrode and gives rise to an easily detectable change in the background current. The trouble and time spent in adding an additive to the mobile phase can be saved by realizing the fact that a universal additive is always present in almost all the solutions. This intrinsic additive is oxygen which is highly electroactive and provides a large and stable reductive background signal. Clearly, a novel detector for LC and IC (ion chromatography) can be developed if a change in this background current via interference caused by the analyte can be realized in practice.

In this paper we present our preliminary data demonstrating that the indirect electrochemical detection via interference of analyte with the phenomenon of oxygen reduction is a reality. This has the following advantages over other indirect detection methods: (i) no additive is required because an intrinsic species, oxygen, serves this function and (ii) the need for oxygen removal is eliminated which offers the advantage of reduced analysis time.

*Present address: Department of Chemistry, California State Polytechnic University, Pomona, CA 91768-4032, U.S.A.

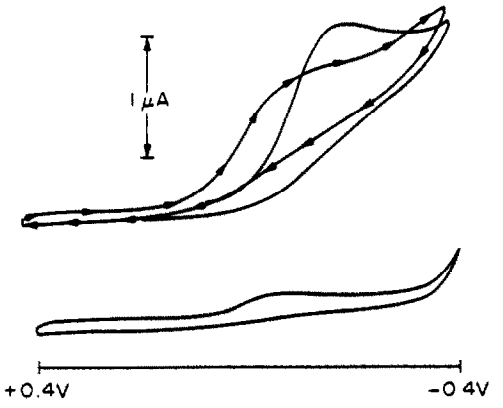

Fig. 1. Cyclic voltamperograms at the Au electrode in air equilibrated MP-1 in the absence (upper CV with arrows) and presence (upper CV without arrows) of 1m*M* chloropromazine. The lower CV was obtained in deaerated MP-1. The scan rate for all CVs was 20 mV/sec.

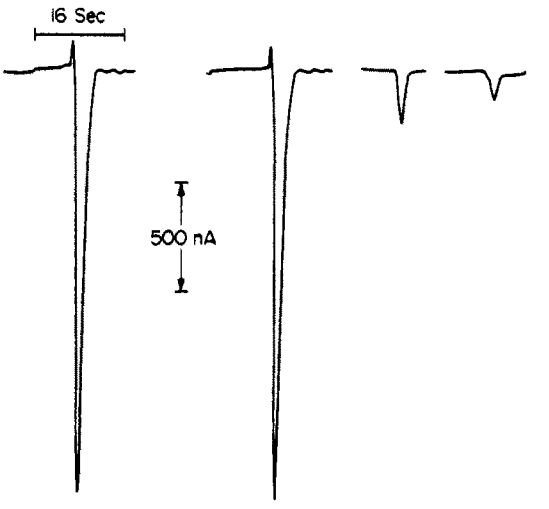

Fig. 3. Two successive FI traces of 1 nmole of chloropromazine under an applied potential of −0.3 V at Au (two smaller traces on the right hand side) and at AuCl (two larger traces on the left hand side) electrode. The MP-1 flow rate was 0.3 ml/min.

EXPERIMENTAL

Apparatus

Cyclic voltammetry measurements were made with a PAR model 173 potentiostat–galvanostat in conjunction with a PAR model 175 universal programmer. A BAS voltammetry gold electrode (0.02-cm^2 area), a BAS model RE-1 Ag/AlCl electrode and a platinum wire electrode were used as working, reference and counter electrodes, respectively.

The flow injection, FI, system consisted of a Beckman model 110 pump; an Altex model 210 injector with 20-microliter loop and a BAS model LC4B/17AT electrochemical detector. The EC transducer employed a BAS gold working electrode, a BAS model RE-4 Ag/AgCl/gel reference electrode, a stainless steel counter electrode and a BAS model TG-2M Teflon gasket. The mobile phase and supporting electrolyte (MP-1) for ascorbic acid and chloropromazine consisted of 0.05*M* chloroacetic acid containing 15 mg/l. sodium octyl sulfate and 150 mg/l. disodium EDTA. For anions we used a 2.5 m*M* aqueous solution of potassium hydrogen phthalate (KHP) as the mobile phase (MP-2). The detector temperature was held at 25°.

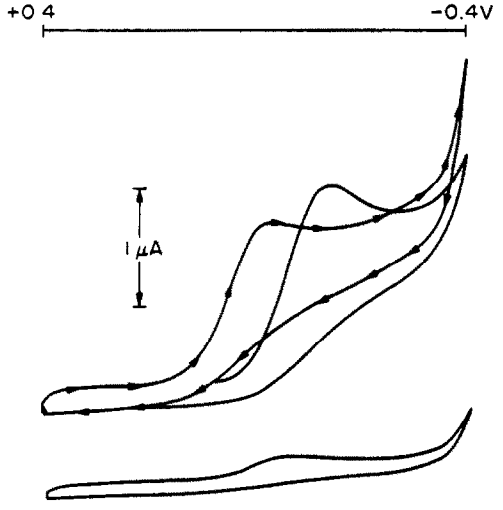

Fig. 2. Cyclic voltamperograms at AuCl electrode in air equilibrated MP-1 in the absence (upper CV with arrows) and presence (upper CV without arrows) of 1m*M* chloropromazine. The lower CV was obtained in deaerated MP-1. Scan rate for all CVs was 20 mV/sec.

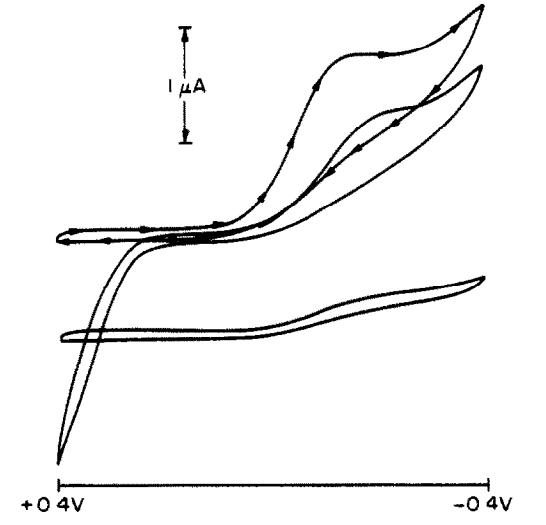

Fig. 4. Cyclic voltamperograms of Au in air equilibrated MP-1 in the absence (upper CV with arrows) and presence (upper CV without arrows) of 1m*M* ascorbic acid. Lower CV was obtained in deaerated MP-1. Scan rate for all the CVs was 20 mV/sec.

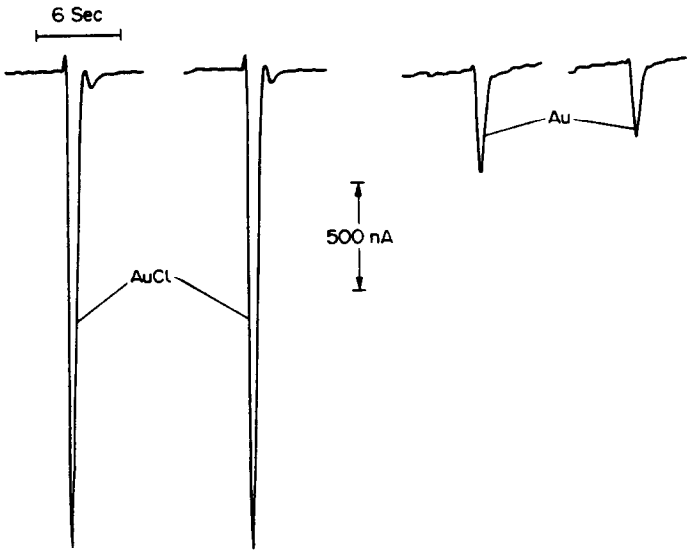

Fig. 5. Two successive FI traces of 10 nmole ascorbic acid under an applied potential of −0.1 V at Au (right) and at AuCl (left) electrodes. The MP-1 flow rate was 1 ml/min.

Reagents

Sodium octyl sulfate (Sigma), *L*-(+)-ascorbic acid (MC/B), chloropromazine (Sigma) and disodium EDTA (Fisher) were used as received. All solutions prepared by dissolving the reagents in the appropriate mobile phase were freshly prepared before use.

Preparation of gold-chloride electrode

Prior to their use the gold electrodes were hand polished on a pad of microcloth (Buehler) to a mirror finish by sequentially using 1-micron and 0.3-micron alumina suspensions (Buehler micropolish II). These electrodes were then ultrasonically cleaned for 10 min with frequent water replacement. Polished electrodes were either used unmodified or were subjected to the following electrochemical modification procedure in 0.37*M* hydrochloric acid for 300 sec.[14,15] The potential program used for this purpose consisted of oxidation–reduction cycles, from 0.0 to 1.15 ± 0.05 V (anodic limit cannot be extended beyond 1.2 V because the onset of chlorine evolution prohibits the formation of a smooth and reproducible chloride film) at a scan rate of 100 mV/sec in the anodic direction, and at a scan rate of 1100 mV/sec in the cathodic direction. The first cycle initiated, and the last cycle terminated, at +0.4 V. Since the chloride deposition mainly takes place at higher positive potentials, *i.e.*, towards the end of the anodic scan, a slow forward (anodic) scan

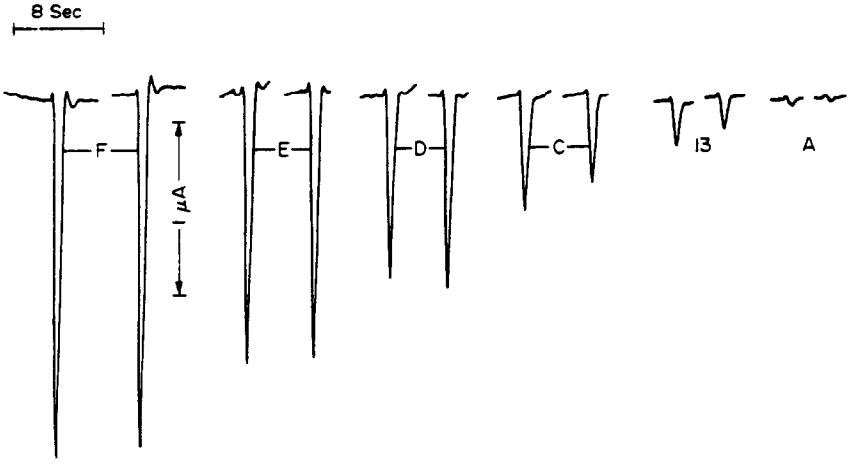

Fig. 6. Two successive FI traces of 10 nmole ascorbic acid at the Au electrode at each of the following applied potentials: 0.00 V(A), −0.10 V(B), −0.15 V(C), −0.20 V(D), −0.25 V(E), −0.30 V(F). The MP-1 flow rate was 1 ml/min.

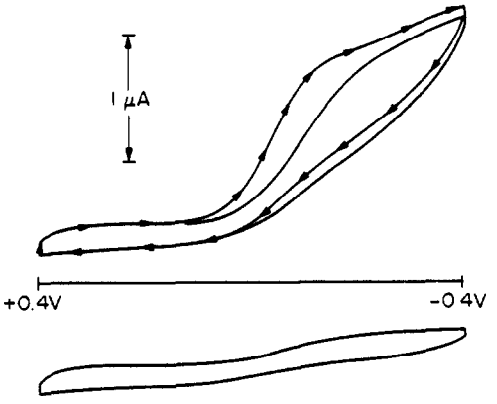

Fig. 7. Cyclic voltamperograms of AuCl electrode in air equilibrated MP-2 in the absence (upper CV with arrows) and presence (upper CV without arrows) of 10m*M* nitrate ions (sodium salt). The lower CV was obtained in deaerated MP-2. Scan rate for all the CVs was 20 mV/sec.

ensures a fixed deposition time and a fast cathodic reversal reduces the desorption time. The net result of this procedure is the formation of a smooth and reproducible chloride film on the Au electrode. This film is visible to the eye as a glassy, copper color layer.

RESULTS AND DISCUSSION

If the redox potential of an analyte is equal to or more cathodic than the redox potential of oxygen, then the faradaic activity of such an analyte would make its indirect detection quite difficult. Thus, our first consideration in demonstrating the indirect electrochemical detection via interference of an analyte with the oxygen reduction process was the selection of a few species that are electroinactive at potentials corresponding to oxygen reduction. With this restriction in view, we otherwise arbitrarily selected two organic species (L-ascorbic acid and chloropromazine) and three inorganic ions (nitrate, sulfate, and ferrous) for preliminary tests. For organic species, we used MP-1 as supporting electrolyte in cyclic voltammetric and FI studies. For similar experimentation involving anions, we used MP-2 as the supporting electrolyte. The compositions of these mobile phases are given in the experimental section. These mobile phases were selected merely on the basis of their successful use in other studies for LC (MP-1) and IC (MP-2).

Cyclic voltamperograms, CVs at the Au electrode in the absence and presence of 1m*M* chloropromazine are shown in Fig. 1. The lower CV in this figure was obtained in the nitrogen saturated MP-1 containing no additives. This CV, when contrasted with the upper CVs, clearly establishes that the reductive waves in the latter CVs arise from the electroreduction of oxygen. Further, a comparison of the upper CVs reveals that chloropromazine strongly interferes with the oxygen electroactivity as evidenced by a large cathodic shift in the oxygen reduction wave. The corresponding interference at gold chloride electrode is shown in Fig. 2. Description of various CVs in this figure is the same as that outlined above for the Au electrode. A comparison of appropriate CVs in Fig. 1 and Fig. 2 establish a stronger interference of chloropromazine with oxygen reduction at the gold chloride electrode. These observations indicate that: (i) an indirect signal for LC detection can be obtained by injecting the analyte species in a flow stream moving past the detector electrode held at a potential corresponding to the oxygen reduction process and (ii) the signal obtained at the gold chloride electrode will be much stronger as compared to that which can be generated at the gold electrode. Flow injection traces of 1 nanomole of chloropromazine (obtained at an applied potential of -0.3 V) shown in Fig. 3 give evidence of the soundness of these conclusions. Notice that the signal at the gold chloride electrode is more stable and larger (about ten times) than that at the gold electrode.

Cyclic voltamperograms at the Au electrode in the absence and presence of 1m*M* ascorbic acid, AA, are shown in Fig. 4. The lower CV in this figure pertains to nitrogen saturated MP-1 in the absence of AA. Like chloropromazine, AA interferes with the redox activity of oxygen (compare upper CVs). The anodic wave shown by one of the upper CVs is due to the oxidation of AA and it lies in a potential region outside the oxygen reduction regime. Hence, the electrochemical oxidation of AA does not interfere with oxygen reduction and the observed signal is attributable to the influence of AA on the oxygen current. The FI traces shown in Fig. 5 indicate that this interaction is strong enough to give a large signal. Further, as expected, the performance of the gold chloride electrode is superior to that of the gold electrode.

For a given concentration of an analyte and a given mobile phase flow rate, we expect a profound influence of changing electrode potential upon the magnitude of the observed indirect signal. This expectation is based on the oxygen reduction trend shown in Fig. 4. Observe that the background signal increases with cathodic

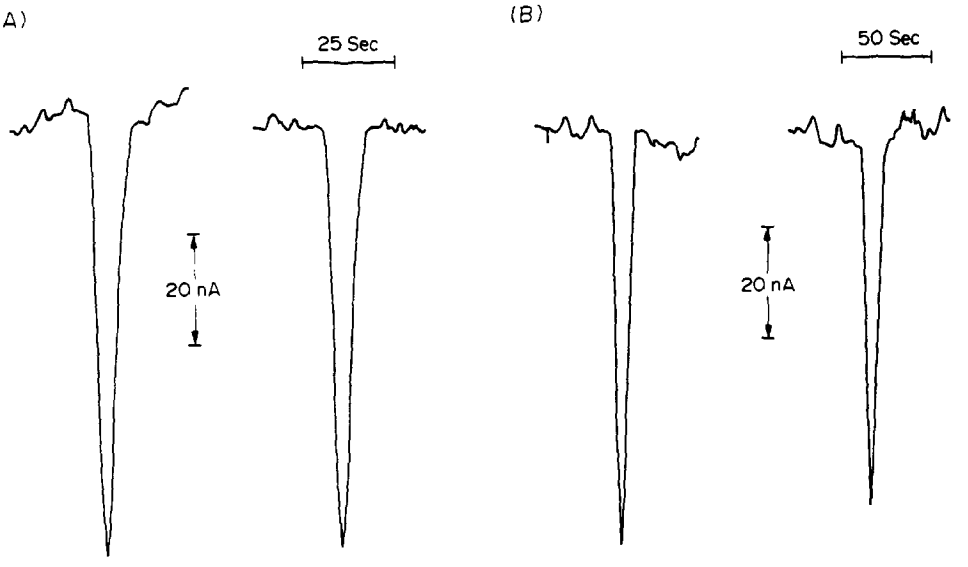

Fig. 8. Two successive FI traces of (A) 10 nmole sulfate ions and (B) 20 nmole nitrate ions under an applied potential of −0.1 V at AuCl electrode. The MP-2 flow rate was 0.1 ml/min.

potential, indicating that in the flow-injection work an increasingly larger anodic change in the background current in the presence of ascorbic acid will result at higher (more cathodic) applied potentials. This trend is clearly seen in Fig. 6 which displays two successive FI traces for 10 nmolar AA at various applied potentials.

Additional experimental observations extending the application of the proposed indirect electrochemical detection scheme are presented in Figs. 7 and 8. Shown in Fig. 7 are the CVs of the gold chloride electrode in the absence and presence of 10m*M* nitrate (sodium salt). The lower CV in this figure obtained in the absence of nitrate in deaerated MP-2 establishes that the reductive waves in upper CVs belong to the process of oxygen reduction. Similar CVs were obtained for other ions (sulfate and ferrous) investigated. For all species tested, we found a strong interference (of these species) with the oxygen reduction wave and they were all indirectly detected in our FI experiments. Two successive FI traces for 10 nmolar sulfate ions [Fig. 8(A)] and 20 nmolar nitrate ions [Fig. 8(B)] are shown in Fig. 8 (both ionic species were injected as their sodium salts). These traces were obtained at the gold chloride electrode and the corresponding traces obtained at the gold electrode were much weaker.

In conclusion, with ample examples we have clearly demonstrated that the influence at the detector electrode of the analyte molecules or ions on the oxygen reduction signal provides an indirect signal for their detection, providing this interaction disturbs the process of oxygen reduction. The proposed scheme has the potential for designing a novel EC detector for flow analyses such as ion chromatography and liquid chromatography. The only limitation of this scheme is the requirement that the analyte must affect the oxygen reduction process and be electroinactive in the potential regime corresponding to the electroactivity of oxygen. Interaction of analyte species with the signal generating mobile phase additive (oxygen) seems to be a universal property. In many cases, the effect can be enhanced through the selection of an appropriate electrocatalyst (the detector electrode) for oxygen reduction. Our recent CV experiments in 0.5*M* sulphuric acid have clearly indicated substantial anodic and cathodic shifts in the oxygen reduction onset potential, respectively, at the AuCl and AuBr electrodes, as compared with the Au electrode. Further, using a dual electrode configuration, the electroactivity of the analyte species at the detector electrode can be eliminated by its electrolysis at the upstream electrode. The catalytic behaviour of the AuCl electrode towards oxygen and other species is probably due to the well known inner-sphere electron transfer via the metal ligand bridge. These bridges are known to provide a lower activation energy barrier to electron transfer as compared to the corresponding solvent assisted path. Similar work with a large number of other species is continuing and will be published in the near future.

LETTER TO THE EDITORS

CORRECTION FACTORS FOR THE GLASS ELECTRODE REVISITED

SIR,

When a pH meter is calibrated with aqueous buffers and the pH measurement is made in mixed solvent solutions, the absolute error in pH is given by[1]

$$pH^* - B = \log U_H^0 \quad (1)$$

where pH^* is $-\log a_H$ in the mixed solvent and B is the reading of the pH meter. The term $\log U_H^0$ is usually called the *correction factor* which is applied to the glass electrode.[2-4] If the stoichiometric concentration C of a strong acid in a mixed solvent is known, the pH^* value may be readily calculated as

$$pH^* = -\log C - \log f_H^* \quad (2)$$

where f_H^* is the activity coefficient for the hydrogen ion in the studied medium. From equations (1) and (2), we obtain

$$\log U_H^0 = -\log C - \log f_H^* - B \quad (3)$$

which allows the direct calculation of the correction factors.

Since the landmark work of van Uitert,[2] the experimental way for determining $\log U_H^0$ has essentially remained the same. This consists of preparing mixed solvent solutions containing final concentrations, C_{HR} of a strong acid and C_{NaR} of its sodium salt (that fulfill $C_{HR} + C_{NaR} = 0.02$), in a temperature-controlled system, and then measuring the steady pH meter reading B. Values for $\log f_H^*$ at this ionic strength are computed by using Debye–Hückell relationships.[5] However, this procedure leads to a correction factor for only the given B value in the mixed solvent considered. Accordingly, the constant nature of the correction factor in a given solvent mixture along the pH scale should be considered with caution. Moreover, Douhert[6] showed that the correction factors for several organic aqueous mixtures depend on the measured pH of the solvent mixture. Accordingly, the reported data on correction factors for solvent mixtures should be re-examined for the whole empirical pH scale in order to avoid biased results when these are applied to the evaluation of pK_a values.[7-12]

We have recently proposed a straightforward method for evaluating correction factors covering the whole pH meter readout range.[13] In the case of dioxane–water mixtures, the correction factors are pH dependent which will cause a bias in the evaluation of, say, acidity constants in non-aqueous media. Our investigation of several other solvent mixtures is now in progress and we expect to find similar behaviour with regard to the non-constant nature of pH of the correction factors to be made to the glass electrode.

BOOK REVIEWS

Unified Separation Science: J. C. GIDDINGS, Wiley Interscience, New York, 1991. Pages xxiv + 320. £43.65.

This book is a distillation of the work of the author and others, on the multifaceted subject of molecular separation which impinges on nearly all the scientific disciplines from the biological to the physical sciences. Although it is clearly written it is by no means for the beginner, but for the graduate with a mathematical background knowledge of physical phenomena. Its stated objective is that it is 'for the purpose of education and not necessarily to train'.

After a general introduction the book is divided essentially into two sections. Chapters one to six review comprehensively the theoretical basis of separation, covering transport, flow and equilibrium phenomena. Many of the concepts and terms pertaining to separation, diffusion, capillary and packed bed flow, viscosity, zone formation, random walk processes, *etc.*, are developed mathematically, although this treatment is balanced with a readable narrative.

A bridging chapter rationalizes and classifies the various separation methods, concentrating initially on codification and then on the categorization of flow-assisted separation. Having classified the various techniques, the last five chapters deal with specific classes, utilizing the theoretical concepts developed earlier. Techniques described include electrophoresis, sedimentation, field flow fractionation and an in-depth consideration of chromatography, which covers molecular migration, plate-height and optimization.

At the end of each chapter are graded exercises to facilitate the reinforcement of the concepts. Fortunately answers are also provided. Each chapter is well referenced and there is also a comprehensive bibliography containing the author's publications.

In this advanced text the author has succeeded, as the title states, in presenting a unified approach to this complex subject in that the inter-relationships of the mechanisms involved in molecular separations have been examined effectively in detail.

G. G. SKELLERN

HPLC in Clinical Chemistry: I. N. PAPADOYANNIS, Dekker, New York, 1990. Pages x + 488. $115.00 (US and Canada), $138 (elsewhere).

This reference text offers a prominent contribution to the literature on clinical analysis by HPLC and covers a wide range of drugs and biological components. The chapters, which include the subject groups alkaloids, antiobiotics, steroids and proteins, contain considerable experimental detail of literature methodologies reported in relatively recent publications. These aspects cover the topics of clinical sample preparation, multicomponent separation and moreover in some instances, the inclusion of a typical pharmaceutical preparation assay. Additionally there are useful introductory sections, prior to the HPLC text, which discuss other spectroscopic and chromatographic methods and point to advantages and disadvantages of these techniques.

Preceding the major text the author has included a preliminary section of introductory information on "Instrumentation in HPLC". Although this section is generally useful, segments such as septum injection, pneumatic and motor-driven pumps are rather outmoded in modern HPLC. It is considered that micro and narrow bore HPLC columns, multichannel detection, method optimization and automation of clinical assay would have provided useful enhancements. Additionally further discussion in mass spectrometry to include "soft" ionization techniques and reference to quadruple analysers and MS-MS would have been beneficial. However, this is a minor criticism of the book and does not detract from its overall usefulness as a practical reference text.

B. J. CLARK

Multivariate Calibration: H. MARTENS and T. NAES, Wiley, Chichester, 1989. Pages xvii + 418. £75.00 (Hardback), £29.50. (Softback).

The adoption of chemometric methods (statistical procedures which allow otherwise unavailable or non-obvious conclusions to be drawn from the multivariate data typical of modern analytical instruments) is a striking feature of modern analytical science. These methods, like all computer-based procedures, have many pitfalls for the naive or unwary, but the overall effect of their introduction has undoubtedly been positive, and nowhere more so than in the field of calibration. This book covers the methods of multi-variate calibration developed up to 1987–8, including virtually all those now in general use.

The book begins with an excellent, often humorously written, chapter on the need for calibration methods; this is worth reading, even by those who do not wish to face the rigours of linear algebra as outlined in the second chapter. The basic principles of matrix and vector manipulation are covered in only a dozen or so pages; this is a little too compressed for the many chemists who will start with little or no knowledge of this area, and I have seen better summaries in other chemometrics texts. The same chapter outlines the basics of statistics as applied to calibration methods. The third chapter, no less than 160 pages long, contains the meat

B. J. CLARK

Multivariate Calibration: H. MARTENS and T. NAES, Wiley, Chichester, 1989. Pages xvii + 418. £75.00 (Hardback), £29.50. (Softback).

The adoption of chemometric methods (statistical procedures which allow otherwise unavailable or non-obvious conclusions to be drawn from the multivariate data typical of modern analytical instruments) is a striking feature of modern analytical science. These methods, like all computer-based procedures, have many pitfalls for the naive or unwary, but the overall effect of their introduction has undoubtedly been positive, and nowhere more so than in the field of calibration. This book covers the methods of multi-variate calibration developed up to 1987–8, including virtually all those now in general use.

The book begins with an excellent, often humorously written, chapter on the need for calibration methods; this is worth reading, even by those who do not wish to face the rigours of linear algebra as outlined in the second chapter. The basic principles of matrix and vector manipulation are covered in only a dozen or so pages; this is a little too compressed for the many chemists who will start with little or no knowledge of this area, and I have seen better summaries in other chemometrics texts. The same chapter outlines the basics of statistics as applied to calibration methods. The third chapter, no less than 160 pages long, contains the meat

of the book, including lengthy discussions of principal components regression and partial least squares. Some illustrative chemical examples are given, and if the reader is by this stage fully conversant with matrix notation, *etc.*, this central section of the book will be extremely rewarding.

The remainder of the text is also excellent. Chapter 4 deals with the crucial but frequently neglected question of method validation. Chapter 5 covers outlier detection, and it is notable that the authors are not enthusiasts for robust regression methods. Chapter 6 covers the design of calibration experiments, a topic which might seem to have merited earlier treatment, but which in practice sits nicely at this juncture. Chapter 7 is an equally successful account of data pre-treatments such as linearization. The book concludes with an illustrative example studied in some detail, and there is also a bibliography, a glossary of symbols and terms, and—for once—an excellent index. Computer programs are not provided, or even recommended, despite the authors' association with the well-known UNSCRAMBLER package.

This book is not, nor is it expected to be, an easy read. However, it covers a complex and crucial area of data handling supremely well, and must take its place on the bookshelves of all serious analytical scientists.

J. N. MILLER

Statistical Methods in Applied Chemistry: J. CZERMINSKI, A. IWASIEWICZ, Z. PASZEK and A. SIKORSKI, Elsevier, Amsterdam, 1989. Pages xviii + 493. US$ 179.50, Dfl. 350.00

This is a thorough mathematical treatment of the science of statistics as applied to chemistry. It covers all the major topics of parametric and non-parametric statistics, *e.g.*, random variables, the various distribution functions, parameter estimation, hypothesis testing, analysis of variance, correlation and regression (multiple linear and non-linear regression are included). Chemical data are used in all the examples.

A chapter on "Methodological Guidelines" gives details of the statistical procedures used in particular chemical problems, covering areas such as limit of detection and sensitivity, precision and accuracy, propagation of errors, the effects of rounding errors, and sampling. The final chapter gives two extended examples of data analysis, one for a technological problem and the other for an analytical one.

Fourteen useful tables of statistical data are included, and also a collection of computer programs written in Turbo Pascal, together with some tables of test data.

This will be a useful book for the serious research worker, but the mathematics is probably too advanced to make it suitable as a student text-book, even at postgraduate level. The translation is adequate, but could have been greatly improved by a translation editor.

M. MASSON

of the book, including lengthy discussions of principal components regression and partial least squares. Some illustrative chemical examples are given, and if the reader is by this stage fully conversant with matrix notation, *etc.*, this central section of the book will be extremely rewarding.

The remainder of the text is also excellent. Chapter 4 deals with the crucial but frequently neglected question of method validation. Chapter 5 covers outlier detection, and it is notable that the authors are not enthusiasts for robust regression methods. Chapter 6 covers the design of calibration experiments, a topic which might seem to have merited earlier treatment, but which in practice sits nicely at this juncture. Chapter 7 is an equally successful account of data pre-treatments such as linearization. The book concludes with an illustrative example studied in some detail, and there is also a bibliography, a glossary of symbols and terms, and—for once—an excellent index. Computer programs are not provided, or even recommended, despite the authors' association with the well-known UNSCRAMBLER package.

This book is not, nor is it expected to be, an easy read. However, it covers a complex and crucial area of data handling supremely well, and must take its place on the bookshelves of all serious analytical scientists.

J. N. MILLER

Statistical Methods in Applied Chemistry: J. CZERMINSKI, A. IWASIEWICZ, Z. PASZEK and A. SIKORSKI, Elsevier, Amsterdam, 1989. Pages xviii + 493. US$ 179.50, Dfl. 350.00

This is a thorough mathematical treatment of the science of statistics as applied to chemistry. It covers all the major topics of parametric and non-parametric statistics, *e.g.*, random variables, the various distribution functions, parameter estimation, hypothesis testing, analysis of variance, correlation and regression (multiple linear and non-linear regression are included). Chemical data are used in all the examples.

A chapter on "Methodological Guidelines" gives details of the statistical procedures used in particular chemical problems, covering areas such as limit of detection and sensitivity, precision and accuracy, propagation of errors, the effects of rounding errors, and sampling. The final chapter gives two extended examples of data analysis, one for a technological problem and the other for an analytical one.

Fourteen useful tables of statistical data are included, and also a collection of computer programs written in Turbo Pascal, together with some tables of test data.

This will be a useful book for the serious research worker, but the mathematics is probably too advanced to make it suitable as a student text-book, even at postgraduate level. The translation is adequate, but could have been greatly improved by a translation editor.

(*Received* 1 *May* 1991. *Revised* 3 *July* 1991. *Accepted* 29 *July* 1991)

Summary—A simple dual channel dropping dispenser has been used for the simultaneous introduction of aqueous solutions of sample and reagent directly into a continuous flow of an organic solvent. Each aqueous segment forms an enclosed reaction system, completely surrounded by a film of the organic phase, which prevents any carry over between segments. An analytical signal is measured directly on the moving segments of precisely defined volumes of the homogenized reaction mixture. The applicability of this "microbatch" technique for the determination of light-absorbing species, for sample dilution and one-standard calibration, and for providing acid–base titrations on a microlitre scale is demonstrated with simple examples.

The automation of liquid sample and reagent processing was greatly facilitated by the introduction of flow analysis (FA) with a great variety of working principles. All but the simplest of manifolds for FA includes one or more confluence points. Many designs have been presented and claimed to give improved mixing.[1–6] Regardless of the angles between the channels, the flow is strictly laminar under the conditions used in one phase FA (flow rates and channel i.d.) thus, no turbulence will aid the mixing.[3,4] The two streams leaving the confluence point mix through diffusion during transport in the following tubing. This is a relatively slow process requiring a long residence time for acceptable mixing. Coiling, knitting or otherwise introducing a number of points where the direction of flow is changed creates a radial flow and mixing is improved.[6]

In an air-segmented continuous flow analyser[1] (SCFA) with the sample, gas for segmentation, and reagents sequentially introduced into the flow system by peristaltic pumping at fixed flow rates, each segment is intensely mixed due to the intensive intrasegmental flow. If a second stream is merged with the segmented flow the contents of this flow is rapidly mixed into segments of the same phase. This is the standard procedure in air segmented systems and has also been used in liquid–liquid segmented flow.[7] However, if the added flow is too large, the original segmentation pattern might be disturbed by the new flow forming segments of its own.

In an "encapsulated chemistry" technology[5,6] system marketed by Technicon, CHEM I, precisely defined volumes of the sample and reagent(s), sequentially introduced into the system together with a capsulating fluorocarbon liquid, intercalate with air bubbles of two different sizes. The smaller bubbles separate individual reaction components prior to their mixing and forming segments of reaction mixture in a "vanishing zone" (a widening of the tube diameter over a short length[5]). A drawback with this system is the very complicated mechanism needed for creating a suitable segment pattern and the presence of a compressible phase obviating the attainment of a stable flow.

The air-carrier continuous analysis system[8] (ACCAS) allows the mixing of a fixed volume of the sample with fixed volumes of one or more reagents, introduced either simultaneously or sequentially with an electronically controlled system of valves. The complex valve system seems to limit the practical value of the method.

During our studies of the segmentation process in liquid–liquid extraction flow-injection analysis (FIE), it was found that the multichannel coaxial segmentor[9,10] allows the operations performed by a dispenser, a confluence

*Author for correspondence.

point, a mixing coil and a segmentor to be combined in one unit. The theory behind the formation of droplets, and other processes in these systems have been outlined in previous papers.[9-11] When applying this theory to the present system it must be kept in mind that here droplets of the aqueous phase are formed at the junction of the inlet capillaries drilled in a lipophilic material. Such a system could be useful not only for FIE but also for fundamental chemistry studies involving kinetic measurements since the starting point is better defined than in systems based on the slow mixing in unsegmented flow and there is practically no dispersion. The idea of concurrently starting a reaction and creating a reaction "vessel" in a segment flow was the basis for this work in which its applicability is demonstrated with simple examples.

EXPERIMENTAL

Chemicals and apparatus

Air, chloroform (E. Merck, FRG, analytical grade) and Freon 113 (1,1,2-trichloro-1,2,2-trifluoroethane, technical quality) saturated with water were tested as carrier fluids. Aqueous $1\mu M$–$1.5mM$ solutions of Bromocresol green (BCG) or Neutral Red (NR) were used. All other chemicals were of analytical grade and used without purification. Distilled water and all other solvents and solutions were degassed in a Branson 2200 ultrasonic bath (Branson, USA) before use.

The multichannel dropping dispenser (Fig. 1) comprises two parts, a polyvinylidenedifluoride (PVDF)/glass main part and a PVDF screw with the inlet capillaries. The main part is constructed from a 14-mm long thick-walled glass tube (6 mm i.d., 9 mm o.d.) clamped between two PVDF pieces with 4 screws. The glass tube allows visual checking of the droplet formation process and the homogenization of the reaction mixture. The lower of the two PVDF parts is threaded to accommodate the screw containing the inlet capillaries and has an inlet (0.7 mm) for the organic carrier fluid. The upper part has an extension which fits tightly into the glass tube. The end of this extension has a conical chamber with an outlet (0.7 mm) for the segmented flow in its apex. Connections to the rest of the flow system is made with flanged 1/16″ o.d. Teflon tubing. The screw with inlets for the aqueous solutions has two capillary channels (0.3 mm dia., 5 mm long, $\approx 20°$ angle) meeting right at the surface of the screw. In order to simplify the machining of this part a much wider bore (1.6 mm) was used for the rest of the connection and the Teflon tubing was drawn into this bore and tightened with an O-ring seal. The on-tube detector and the data handling procedure have been described previously.[9,10] For this work a transparent FEP tubing of 1.5 mm i.d. was used in the detector because it gives higher measurement precision and sensitivity.

In this work three different measuring modes have been used: signal height, the absorbance recorded for an aqueous segment as compared to the absorbance of an organic segment; signal area, the integrated signal over the length of the segment; relative signal area, signal area divided by the length of the segment (in seconds). The last mode should be favourable as it uses as many measurements of the signal as possible and compensates for the slight variation in segment length. However, there are some problems connected with the determination of the end-points of segments with low signals.

RESULTS AND DISCUSSION

Repeatability of the droplet formation

The repeatability of droplet formation was slightly better for Freon-113/water than for the chloroform/water system, thus Freon-113 was subsequently used as the carrier fluid. The lower toxicity of this solvent was also taken

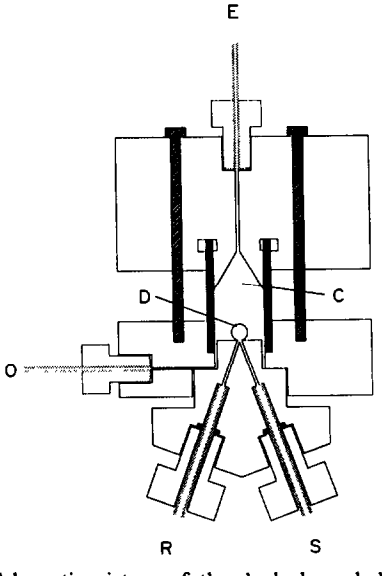

Fig. 1. Schematic picture of the dual channel dropping dispenser. R–reagent, S–sample, O–organic phase, E–segmented outflow, C–conical chamber, D–droplet.

into account. The segmentation repeatability was not satisfactory ($s_r \approx 10\%$) with air as the carrier, although the droplet formation was seemingly very regular. Serious pulsation of the resulting segmented flow occurred because of the compressibility of the air segments. Also, the baseline noise was worse by one order of magnitude than when the carrier fluid was Freon-113. The small droplets of aqueous phase clinging to the walls of the measuring tube were not completely removed by the air segments. Their appearance in the light path, and their movement, was accompanied by a serious increase both in the baseline signal and in the baseline noise.

To establish regular film formation the segment length of the organic phase cannot be reduced indefinitely, thus the lowest organic phase flow rate (Q_o) used was 0.2 ml/min.

Direct determination of light absorbing species

The determinations of the blue alkaline (L^{2-}, 627 nm) and yellow acidic (LH^-, 420 nm) forms of Bromocresol green (BCG) and of copper(II) ions in acidic solution were chosen as examples. The aqueous solution was pumped through both inlet capillary channels to eliminate effects of eccentricity of the junction, and the analytical signal was measured on the aqueous phase segment at 600 and 420 nm, respectively. The organic phase flow was stopped after some preselected time (usually after 10 segments have passed through the detector) and the analytical signal was then also measured for a continuously pumped solution of the analyte at "steady state" to compare the signal levels.

The analytical signal increases linearly with the analyte concentration from negative to positive values passing through an area with signals of the same order as the baseline noise ($S_0 < 10s_0$). The calibration graphs are linear in the range 6.2–154μM BCG and 0.01–0.8M copper(II) ions. The correlation coefficients were good for signal height and signal area *vs.* concentration but considerably worse for the calibration based on relative signal area. This is due to a large spread in the values for samples with signals close to zero. For these samples the measurement of segment length is difficult and this shows up as errors in the relative signal area (Fig. 2).

The values agree well with those obtained by continuous pumping of the analyte solutions without segmentation through the measuring tube as demonstrated by the slopes and intercepts of the Youden graphs: ($y = 1.02x - 0.06$, $0.992x + 0.08$ and $1.01x + 0.02$ with correlation coefficients of 0.993, 0.989 and 0.997, respectively).

Dilution and one solution calibration

Pumping an aqueous solution containing either 30.8μM BCG or 0.1M Cu simultaneously with water into the inlet capillary channels at constant flow-rate ratio $Q_1/Q_2 = 1$ or 2 keeping the total flow-rate constant at $Q_t = 0.5$ ml/min, makes it possible to dilute the sample solution, the degree of the dilution depending on the Q_1/Q_2 ratio. The resulting signal values differ by less than 3 and 2% from those obtained by continuously pumping a corresponding non-segmented aqueous phase.

Data obtained by changing the phase flow-rate ratio Q_1/Q_2 in steps from 0.5 : 0 to 0 : 0.5 of the sample solution (154μM BCG) and water at a constant total flow-rate $Q_t = 0.5$ ml/min was used in order to construct a calibration graph from dilution experiments. A linear dependence was obtained between the analytical signal and analyte concentration which fits well with graphs obtained by pumping aqueous phase only and also with graphs obtained earlier, using a series of solutions of different concentration.

Indirect determination of analyte concentration

As an example of a fast reaction, BCG in its alkaline form was pumped together with 0.1M hydrochloric acid at a constant total flow-rate $Q_t = 1.6$ ml/min and $Q_1/Q_2 = 1$ and 0.5 into the inlet capillary system. This example is suitable for studying the mixing efficiency and the influence of the reaction rate. The analytical signal

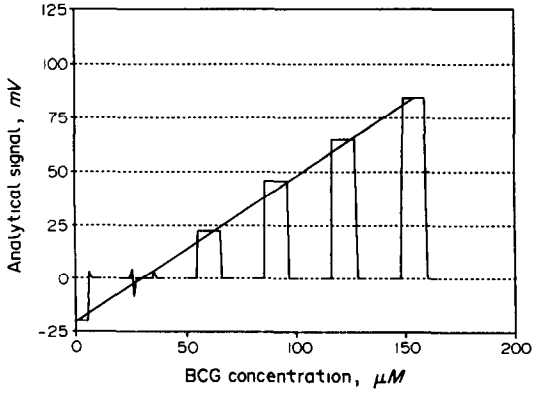

Fig. 2. Calibration graph for the direct determination of the blue alkaline form of BCG (at 600 nm) with the signal shape indicated at the different levels.

was measured at the absorption maximum of the acid form LH^- of BCG at 420 nm.

The solutions are very rapidly mixed and the yellow acidic form of BCG is generally formed quantitatively already during the droplet formation, especially at the higher total flow-rate and when the flow-rate ratio is close to 1. No significant difference in the analytical signal was found when the signal was measured 10 or 60 cm downstream from the dropping device ($y = 1.00x + 0.03$ for the Youden graph). Consequently, the reaction seems to be quantitative already at the beginning of the measuring tube. The calibration graph is linear in the range 3.1–154μM BCG.

Acid–base titration

A sodium hydroxide solution ($c = 0.1M$) containing 92.4μM BCG or 80μM Neutral Red (NR) as an indicator was titrated with 0.1M hydrochloric acid by changing the flow-rate ratio between the two solutions stepwise at a constant total flow-rate $Q_t = 1.6$ ml/min. The analytical signal was measured at the absorption maximum of the blue and red forms of the indicator (600 and 560 nm, respectively) and a titration curve with a very sharp change of the analytical signal at the equivalence point at $Q_1/Q_2 = 0.93 \pm 0.08$ and 0.96 ± 0.08 ($n = 5$) was obtained (Fig. 3). The repeatability of the procedure is relatively poor ($s_r = 8.5$ and 7.3%) as a result of experimental factors influencing the measurement precision (flow-rate, flow-rate ratio, pulsation *etc.*).

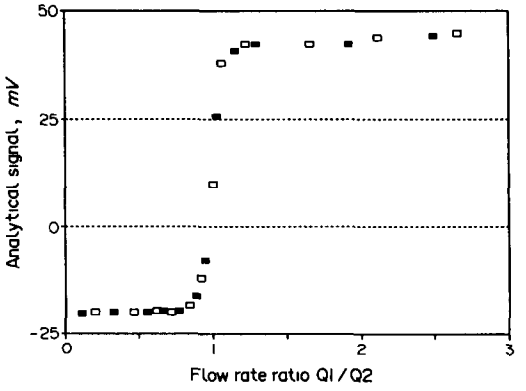

Fig. 3. Titration of 0.1M NaOH with 0.1M HCl in the presence of 92.4μM BCG (600 nm) by varying the flow-rate ratio Q_1/Q_2. Filled squares represents data obtained when the flow-rate ratio was changed from 0.1 to 2.5. Open squares represents results obtained when the flow-rate ratio was changed back to 0.1.

CONCLUSIONS

The system presented is based on the simultaneous formation and mixing of small aqueous droplets of the reaction mixture in a flowing organic fluid, immiscible with the aqueous phase. The concentration of a particular component in each droplet of the reaction mixture is governed by the flow-rate ratio of the component streams of aqueous phase and by the actual concentration of the component in each solution. The droplets form closed reaction systems completely isolated from each other by segments of organic phase, and by a film of organic phase on the tubing wall, which prevent any analyte and reagent carry-over during the transport through the capillary system of the analyser. The reaction yield is determined by the experimental conditions in each individual closed reaction system and by the kinetics of the reaction.

The rapid mixing taking place during drop formation and the fact that the system provides negligible dispersion in a flow of incompressible media makes the system suitable for kinetic studies. It can also be useful for the application of slow reactions because no dispersion occurs during transport through even very long capillaries.

With the low flow-rate of the organic phase ($Q_o = 0.2$–0.5 ml/min) used to form segments, the total consumption of the organic solvent does not exceed the volume of 25 ml/hr. This fact together with the completely closed measuring system and recycling of the organic solvent minimizes the environmental hazards connected with the use of Freon-113 or chloroform.

The use of a fast reading "on-tube" detection system makes it possible to measure the analyte concentration in each aqueous segment in a liquid/liquid segmented flow. Both direct and indirect analytical methods can be used. The sensitivity of the technique may be improved by integrating the analytical signal over the whole period when the segment passes through the transparent tubing. The precision of measurement is good due to the use of a larger number of segments for mean value calculations.

Sample introduction could most easily be obtained with the aid of a conventional loop injector and a carrier stream. However, since very little sample is actually needed to obtain a measurement (2–5 μl) a direct introduction of the sample into the forming droplet seems possible. Titrations could be performed by

connecting a perfusor pump to one of the capillaries of the dispenser and introducing the sample for short periods at different flow-rate ratios relative to the titrator flowing through the other capillary. With such a system, under computer control, a titration curve could rapidly be obtained with as little as 1–2 ml of sample.

FLOW INJECTION AND SOLVENT EXTRACTION WITH INTELLIGENT SEGMENT SEPARATION. DETERMINATION OF QUATERNARY AMMONIUM IONS BY ION-PAIRING

CHERRYLEEN C. LINDGREN and PURNENDU K. DASGUPTA*
Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 27 *June* 1991. *Revised* 17 *July* 1991. *Accepted* 17 *July* 1991)

Summary—Organic solvent segments are introduced into a premixed stream of the sample and an ion-pairing dye by a 3-way valve at regular intervals. The major mechanism of "extraction" in such a system appears to be the adsorption of the ion-pair on conduit walls and subsequent elution by the organic solvent. Following passage through the conduit, the immiscible organic segment is isolated in the loop of a 6-port valve; loop filling is sensed by a pair of conductivity sensors located respectively at the fill and drain ports of the loop and appropriate logic circuitry. The isolated segment is then injected into a purely organic carrier and detected by a suitable optical detector. Results are reported for a number of parametric studies that characterize this system. With immobilized adsorbents on conduit walls for preconcentration, a limit of detection of $<10^{-7}M$ tetrabutylammonium ion can be obtained with bromothymol blue as the ion-pairing agent.

In-line solvent extraction procedures play an important role in the current practice of flow-injection analysis.[1,2] There are many approaches to the introduction of extractant segments and their separation; this has been summarized and attendant advantages/disadvantages pointed out.[3] In many cases it is possible to perform an optical measurement of the extractant segment without physical separation of the phases; Kuban *et al.*[4] demonstrate a recent example of this. However, if post-extraction chemistry must be carried out, a physical separation of the phases is mandatory.

From the point of view of robustness and reliability for long-term unattended operation, an approach was developed in this laboratory to introduce the extractant segment by a loop injector. Further, for aqueous extractants introduced into nonaqueous sample streams, the extractant segment was automatically isolated downstream by a second loop injector.[3,5] To perform intelligent switching of this valve, the conductivity across its loop is measured. When the valve is completely filled with the aqueous extractant, the conductivity between the probes placed between the fill and drain ports of the loop rises abruptly and the loop contents are injected into a purely aqueous carrier stream. Unfortunately, the reverse task of isolating a nonconductive organic segment intercalated in an aqueous sample cannot be directly accomplished in this manner. Even a partial filling of the loop with the nonconductive segment indicates lack of conductivity between the probes placed across the loop. In this paper, we demonstrate a reliable means for accomplishing this task in conjunction with a wall-preconcentration technique. The determination of cationic surface active agents is chosen as an example; the rationale for this choice and a review of the relevant ion-pair extraction literature is given below.

The annual production of cationic surfactants is projected to be 863.1 million lbs by the year 2000.[6] Cationic surfactants are commonly used in fabric softeners and conditioners, hair rinses, oil-based petroleum drilling muds and as foam controllers in laundry detergent. Quaternary ammonium compounds, the most important group of cationic surfactants, have biocidal properties and are used as disinfectants/sanitizers (*e.g.*, in alcohol-free mouthwash) and algaecides. Their presence in discharged water is a major problem because they are lethal to a variety of microorganisms at micromolar levels.[7,8]

Auerbach[9] was the first to introduce a method of measuring cationic surfactants involving the

*Author for correspondence.

addition of an optically absorbing lipophilic dye anion, such as bromophenol or bromothymol blue (BTB) and extraction of the resulting ion-pair into an organic solvent followed by photometric measurement of the latter. Dyes of this family, including bromocresol green, continue to be particularly popular for this application;[10-12] ternary ion-aggregates involving the analyte cation, the dye and a protonated quinine cation have also been used for some applications.[13,14] Other absorbing anionic pairing agents have included Orange II,[15,16] $[Co(SCN)_4]^{2-}$,[17,18] picrate,[19,20] Erdmann's salt,[21] the anionic oxidation product of diphenylcarbazide by chromate,[22] Methyl Orange,[23] thiocyanate,[24] Brilliant Red S,[25] 2,6-dibromophenolindopenol,[20] eosin,[26] the anionic complex of Chrome Azurol S with Fe,[27] and Bengal Red.[28] Fluorescent pairing agents used include anthracenesulfonate,[29,30] Rosin, Erythrosin and Bengal Pink B,[31] and 2,4,5,7-tetrabromo-3,6-dichlorofluorescein.[32]

Bromothymol Blue was regarded as a convenient and adequately sensitive ion-pairing agent for the purpose of this study. At pH below 7, it exists predominantly as the yellow sulfonate monoanion (BTB^-). In alkaline solutions, a phenolic proton also ionizes, resulting in the blue dianion (BTB^{2-}, pK 7.1).[33] The following parameters were available from preliminary studies[34] for $(n\text{-}C_4H_9)_4N^+$ as the surface active ion Q^+ for the ion-pair extraction with BTB^-. The extracted ion-pair displays a broad band absorption maximum at 415–430 nm; ϵ_{430} for $Q^+.BTB^-$ in $CHCl_3$ is 1.8×10^4. The extraction can be made reasonably selective for quaternary ammonium ions (over, for example, trialkyl- and dialkylammonium ions) by extracting from mildly alkaline solutions; extraction efficiency (in the $Q^+.BTB^-$ form) decreases in strongly alkaline solutions. If the extraction constant K_{ex} is defined to be $[Q^+.BTB^-]_{org}/[Q^+]_{aq}[BTB^-]_{aq}$, $K_{ex} \simeq 10^7$ at pH 8.6 with $CHCl_3$ as the extractant. Extraction efficiencies observed with other aliphatic halogenated solvents, *e.g.*, CH_2Cl_2 or 1,2-dichloroethane are not markedly different. The magnitude of the extraction constant indicates that in the presence of a large excess of the ion-pairing agent, extraction efficiencies in typical manual extraction systems should be nearly quantitative. Very recently, Yamamoto and Motomizu[35] have examined the extraction behavior of a large number of sulfonephthalein dyes with a variety of quaternary ammonium ions. They find that K_{ex} values are the highest with BTB and their quantitative findings are in good agreement with the above data.

EXPERIMENTAL

Reagents

Bromothymol Blue (Kodak) and tetrabutylammonium sulfate (Aldrich) were used without further purification. Aqueous solutions of BTB were maintained at a pH of 8.5–8.8. Technical grade chloroform was used as the extractant. Before use, solutions were generally ultrasonicated for 10 min to avoid bubble formation in the manifolds.

Apparatus

Six-port injector valves were electropneumatically driven rotary devices (type 5020 P, Rheodyne Inc., Cotati, CA) and 3-way valves used were fast-acting (<25 msec), low internal volume (7.4 μl per passage) elastrometric-tubing solenoid valves (type LFYA 1203032H 12 V, 2 W, ~25 msec actuation time, The Lee Company, Westbrook, CT). Wetted parts for both valves are fluoropolymers. Pumping was provided by pneumatic pressure or by a multichannel peristaltic pump (Minipuls 2, Gilson International), as indicated. Except as noted, connecting or conduit tubing was polytetrafluoroethylene (PTFE, type SW, Zeus Industrial Products, Raritan, NJ). The photometric detector used was a Spectromonitor III with a 6.5-mm path length cell (Laboratory Data Control, Riviera Beach, FL) set at 430 nm.

Design of conductivity probes

The present instrumental design consisted of one pair each of conductivity probes placed at the fill and drain ports of the segment isolation valve (*vide infra*). The design of the probes is critical. In each pair of probes, the electrodes must be as close to each other as practical without significant problems from wall films bridging them. Probes based on inserted tubular metal segments or metallic fittings placed on each side of a nonmetallic union represent significant hold up volumes; these devices lead to frequent segment breakage as well. The best arrangement devised involved two fine nichrome wires (32 ga., 0.23 mm dia) placed 2 mm apart through small bore holes drilled through the walls of the tubing connected to the valve, one pair each immediately adjacent to the drain and fill ports. The exterior of the

PTFE-tube was etched with a sodium/naphthalene etchant (Chemgrip, Norton Performance Plastics, Akron, OH) so that the inserted wires can be sealed in place with a graphite epoxy adhesive (Dylon Industries, Berea, OH).

Extractant segment isolation valve controller

The necessary circuitry is shown in Fig. 1. Conductivity sensors S1 and S2 are components of a bridge circuit with each sensor status being monitored by respective halves of a dual operational amplifier (A, B) used here as voltage comparators. The 5 mΩ potentiometers provide a "sensitivity adjust" control for each sensor. When the resistance in the sensor becomes high, the comparator output becomes high causing the transistor (Q1, Q2) to conduct and sensor tripped status is indicated by the corresponding light emitting diode (LED), L1 and L2. The high output status is also transmitted to the inputs (1, 2) of the NAND gate N. Only when *both* sensors are tripped does the NAND gate output become low, triggering timer T on the falling edge. Valve inject status LED (L3) is illuminated and the air solenoids (S) governing the pneumatically driven valve are turned on by relay K via optocoupler C. The latter is used to couple the timer output for driving the solenoids because

the major current spikes produced by the solenoids otherwise interfere with reliable operation of the logic circuitry. Timer T remains in the inject position for a period selected by switch SW, a 12-position switch that connects a resistor (4.7–56.4 kΩ in increments of 4.7 kΩ) at this junction, resulting in timer periods of 5–60 sec in increments of 5 sec, and then returns to the load position again.

Manifolds

Three variations of the basic manifold design shown in Fig. 2 were used. In system 1, the sample and the BTB reagent are pumped peristaltically with polyvinylcholoride (PVC) pump tubing, merged at a PTFE tee, mixed in conduit M (knotted, 0.86 × 700 mm) and flow through segmentation valve V1, extraction conduit EP and load/drain ports of segment isolation valve V2. Valve V1 and pump P are alternately powered by a double pole double throw relay, programmed by a microprocessor controlled timer (LS 100, Minarik Electric, Los Angeles, CA) such that pump P is on only when V1 and chloroform flow are off. Chloroform is introduced when V1 is turned on; the segment volume is controlled by the pneumatic pressure on the chloroform reservoir or more conveniently by V1 on-time. Restrictors (R1, R2, 0.46 × 1000 mm) are placed at the waste outlet of V2 and the detector exit to inhibit bubble formation. Chloroform flows from the second reservoir by pneumatic pressure as a carrier through valve V2 and the detector. The detector output was recorded on a strip-chart recorder (Omniscribe, Houston Instruments, Houston, TX) and the data processed manually. Experiments conducted with this manifold included parametric studies on the effects of conduit diameter, segment length, conduit length, flow-rate, extent of conduit wall adsorption and the geometrical configuration of the conduit. All of the above experiments were conducted with $10^{-5}M$ $(n\text{-}C_4H_9)_4N^+$ and $2 \times 10^{-5}M$ BTB.

System 2 was adopted to work at trace sample concentrations at which it was necessary to avoid perceived sample loss on PVC tubing. In this configuration, only the dye was pumped (at a flow-rate, f_1) by pump P. The PTFE sample conduit was merged with the dye as before but the sample channel was not pumped by positive pressure. Rather, a second pump P2 aspirated the waste stream from the drain port of V2 at a flow-rate, f_2 (Vilton® pump tubing). The sample flow-rate is given by $f_2 - f_1$. Segmenting chloroform flow also occurs by aspiration of pump P2 when V1 is on. Mixing conduit M (0.86 × 1000 mm) was used in the serpentine-II configuration[36] for enhanced mixing. The extraction/preconcentration conduit consisted of flexible wall tubing with adsorbent imbedded on the wall. Macroreticular poly(styrenedivinylbenzene) (Amberlite XAD-2, TosoHaas) was ground into a fine dust with a grinding mill. Polyethylene (1.67 mm i.d., Clay-Adams, Inc., New York, NY) or Tygon® tubing (1.5 mm i.d., Norton Performance Plastics) was inserted in a glass tube to prevent major deformation,

packed with the powdered absorbent and placed in an oven (170–200°) for a very short period (20–60 sec). The tube walls soften to such a degree that some of the adsorbent becomes heat-embedded in the walls of the tube. A similar technique for embedding porous glass in conduit walls has been previously reported by Gosnell *et al.*[37] Excess loosely held absorbent is removed by blowing compressed air through it and followed by thorough washing with water. Experiments conducted with this system included parametric studies on the preconcentration conduit configurations and injection frequency.

In system 3, we sought to combine the simpler aspects of system 1 with the preservation of sample integrity provided by system 2. This was achieved by keeping the configuration of system 1 but replacing the usual PVC pump tubes with modified PTFE-lined pump tubing. Very thin wall heat-shrink PTFE tubes (Zeus Industrial Products) which just fit inside a PVC pump tubing are taken. The inside of the PVC pump tubes are sprayed with a silicone spray lubricant (Slipicone, Dow-Corning) to facilitate insertion of the above PTFE tubes. Approximately 1 cm of the PTFE tubes are allowed to protrude out of the PVC tube termini, and then standard wall thickness PTFE tubes are forcibly inserted inside the thin wall PTFE tubes and crimped in-place with nichrome wire crimps. Any liquid (from organic solvents to concentrated sulphuric acid) can be pumped with these tubes; however, flow-rate remains constant over a shorter period than standard PVC tubes pumping dilute aqueous solutions. Experiments conducted with this system included the evaluation of performance at low analyte concentrations with the Tygon preconcentration conduit and the determination of the limits of detection (LOD).

RESULTS AND DISCUSSION

Segmentation and segment isolation

Highly reproducible and reliable segmentation was provided very conveniently by the 3-way valve. Kuban and Ingman[38] reported similar experience with such devices. Although they found that the performance deteriorates at flow-rates >2.5 ml/min, such flow-rates are not commonly used.

Probe placement and strategy of isolation of a conductive segment in a nonconductive solvent by conductivity sensing and the associated electronic circuitry have previously been described.[5] The reasons for the failure of this strategy to work in the present experiment have been outlined earlier. In a typical arrangement for intelligent valve control, once the sensor(s) indicate that the loop is filled with the desired segment, the valve is switched. The isolated segment is thus injected into a miscible carrier which transports it to a detector; further chemistry can be performed en route if desired. The valve remains in the inject position for some preset period of time adequate to complete the injection and then returns to the load position. For the present system, it may seem at first that placing a single pair of probes at the drain port of the loop should be adequate. As long as the extractant segment is sufficiently greater in volume than the isolation loop, loop-filling will be indicated by the excess nonconductive extractant triggering the sensor. The problem with this concept appears at the next stage of operation: when the valve switches back to the load position, the aqueous stream flushes small portions of the organic carrier liquid remaining in the rotor grooves of the valve, which triggers the sensor again, this time falsely. It is possible to formulate a scheme with a flip-flop[39] such that the valve will switch every alternate time the sensor is tripped. Experience showed that the pitfall of this approach is that if it once triggers on the wrong event, it remains locked on the erroneous sequence. An alternative approach studied was to provide a second delay time after the valve returns to the load position; during this period the sensor output is ignored such that small amounts of organic solvent that quickly exit after each switching of the valve are ignored as well. The system took long periods to be initialized and even then did not prove reliable. The use of two pairs of electrodes, constituting two independent conductivity sensors located at the fill and the drain ports of the loop, proved to be a robust approach. This design and the associated logic circuitry as described in the experimental section provided reliable performance in isolation of the segment and its injection into a miscible carrier.

Parametric studies

In conventional flow-injection extraction systems, the typical situation involves very short extractant segments ($\leqslant$1 cm in length) and extraction occurs largely at the interface film of the phase that wets the conduit wall. The wall film thickness varies as a function of fluid velocity and the bridging of the individual

extractant segments by the wall film is the principal cause for dispersion;[40-42] air-segmented systems behave similarly.[43,44] In the present study, the extractant segment length is typically $\geqslant 10$ cm and more often than not there is only one extractant segment resident in the conduit at any given time. Clearly, the concept of wall films bridging individual extractant segments is inappropriate in this case. As will be apparent in the following, adsorption of the ion-pair on the walls of the conduit (or solvent film left thereon) and its subsequent removal by the extractant segment constitutes a major "extraction" mechanism beyond extraction through the phase boundaries. The relative importance of the two factors is dependent on the frequency of injection of the extractant segment, *i.e.*, the period over which the material is allowed to accumulate or preconcentrate on the wall. Because of these basic differences, fundamental studies of the experimental variables are needed for this system; lessons from the more conventional extraction systems, thorough as some of these studies are,[40-42] are not directly applicable. For brevity, the following symbols are used in the description below for the respective parameters: conduit diameter (d), length (l), extractant segment length (l_e), extractant segment volume (V_e), residence time (t_R), flow-rate (f) and injection cycle period (p). Unless otherwise specified to be coiled, knotted or serpentine, the conduit is linear (bend radius $\geqslant 50$ cm).

Variation of extractant conduit diameter (constant $V_e t_R$, f, p)

Different tube lengths were taken to provide the same residence volume. Two separate sets of experiments were conducted: (a) $d = 1.35$, 0.86, 0.56 mm; $f = 1.5$ ml/min, $t_R = 36$ sec; and (b) $d = 1.5$, 0.86, 0.46 mm; $f = 1.0$ ml/min, $t_R = 46$ sec. In this and the following experiments, the injection cycle period is relatively small ($p = 2$ min) and $V_e = 90$ μl, except as stated. The extractant segment can be approximated by a right circular cylinder; for the long segments used in this work, the surface area of the segment is essentially its lateral surface area, the area of the menisci can be neglected. Thus, the surface area is approximately equal to $4V_e/d$. Figure 3 shows that the relationship between the observed signal and $1/d$ is approximately linear and the best fit lines through each data set are roughly parallel. The residence volume in the conduits of set (a) are only about 17% larger than those in (b); relative to this, the signal is much higher in (a). This could not solely be attributed to higher flow velocities; because the flow velocities in the two smallest tubes in cases (a) and (b) are essentially the same. Circulation within the segment, which renews the interfacial boundary layer depends both on the flow velocity and the conduit diameter in a complex manner.[45,46]

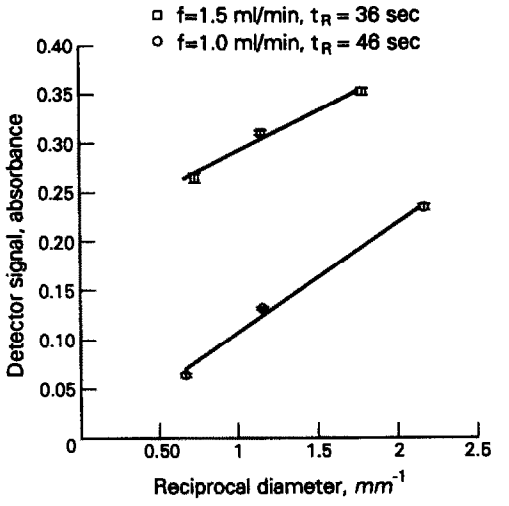

Fig. 3. Effect of the conduit diameter on analytical sensitivity. In this and all subsequent figures, ± 1 standard deviation is indicated by the error bar.

Variation of extractant segment length (constant d, l, t_R, f, p)

For $d = 0.86$ mm, and $f = 1$ ml/min, l_e was varied from 10.0 to 29.0 cm. V_e is linearly related to l_e and if essentially the same amount is extracted by each segment regardless of its length, the detector signal is expected to increase linearly with $1/l_e$. The results are shown in Fig. 4. A linear relationship between $1/l_e$ and the detector signal is observed for all but the shortest segment; saturation at the interface may have commenced for this situation—the precision in this case is also the poorest. It is interesting to note that the abscissa intercept for the extrapolated line corresponds to a finite value (corresponding to a length of ~ 55 cm). Indeed, this intercept should occur at a finite positive value because the extraction conduit length is finite and increasing amounts of extractant displaces corresponding amounts of sample. Thus, increasing l_e systematically decreases the amount of sample in contact with the conduit.

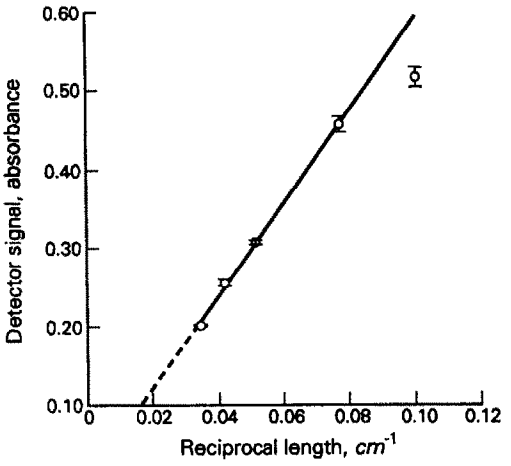

Fig. 4. Effect of the extractant segment length on analytical sensitivity. The straight line is the best fit line drawn through the lower four points and the dotted portion is extrapolated.

Variation of extractant conduit length (*constant* d, v_e, f, p)

The detector outputs obtained for $l = 3.21$, 3.71, 4.21, 4.71, 5.21 and 6.21 m ($d = 0.86$ mm, $l_c = 16$ cm, $f = 1.5$ ml/min) are shown in Fig. 5. For $p = 2$ min and the stated values of d and f, two segments will be present in the conduit at $l \geqslant 5.2$ m (at which point, the intersegment distance is 4.9 m). Interestingly, the signal increases essentially linearly up to $l = 4.7$ m and thereafter becomes constant. The latter should not be construed as saturation of the extractant segment, greater signals can be obtained if p is increased (*vide infra*). Increasing the length of the conduit increases both the residence time and the available surface area for adsorption. An unambiguous determination of the effect of the individual factors on the signal is difficult. Similarly, the available sample volume for extraction increases linearly with conduit length, at least up to $l = 5.2$ m (at this point, the second segment is introduced before the first leaves the system). Can the increase in signal be attributed simply to greater sample volume available for extraction? Intuitively, it does not seem plausible that the presence of additional sample at distances of $\geqslant 3$ m from the segment can make much difference to the overall extraction yield via direct interphase mass transfer; it is not likely that axial mass transport within the aqueous phase is that efficient. On the other hand, if we extrapolate to zero conduit length, a finite signal is suggested—this ordinate intercept is an indirect measure of the extraction yield via direct interphase mass transfer. Note that with increasing conduit length, the attainment of a plateau response is rather abrupt and also coincides approximately with the entrance of a second segment into the system. We believe that these observations are consistent with the hypothesis that the signal increases with increasing conduit adsorption area. The effective upper limit of the available conduit length ahead of any segment is set in the above experiments by the chosen values of p, d and f to be ~ 5 m regardless of the actual conduit length. Note that t_R continues to increase with l throughout, even though the signal does not increase beyond $l \geqslant 5$ m. This supports the adsorption hypothesis; t_R in this case is not a critical parameter.

Variation in flow-rate (*constant* l, v_e, p)

The results of flow-rate variations for three different tube diameters are shown in Figs. 6 and 7. Qualitatively, the signal increases with increasing fluid velocity within each class of tube diameter but the slopes are different from one diameter to another. At very high fluid velocities, standard deviation abruptly increases and shortly thereafter frequent segment breakage has been observed to occur. The extraction yield may actually decrease past a certain point as observed in the results for $d = 0.86$ mm. As previously noted for the experiments with variations in d at constant t_R (Fig. 3), a higher velocity promotes greater circulation within the segment and may thus improve mass transfer at the interfacial boundary. Certainly the data in Fig. 6 indicate that the effect of a greater flow-rate overshadows the effect of the corresponding decrease in residence time. The considerable difference in response between the

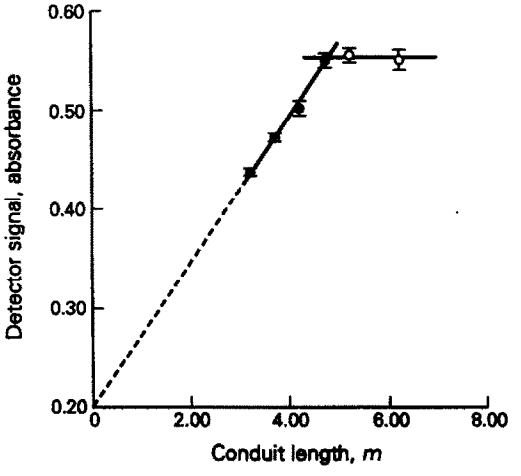

Fig. 5. Effect of conduit length on analytical sensitivity. The injection cycle period used limits the effective upper length to ~5 m.

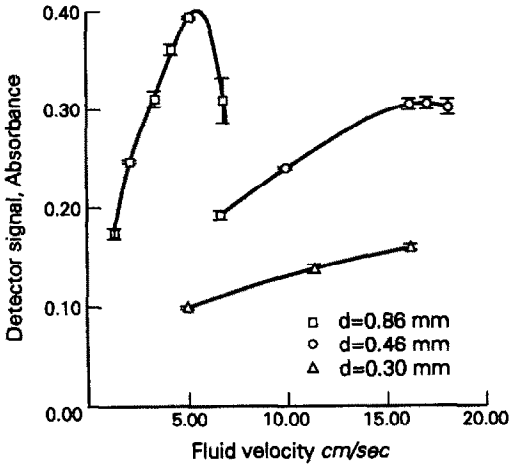

Fig. 6. Effect of flow-rate shown in terms of fluid velocity on analyical sensitivity.

different tube diameters at comparable velocities, however, imply that the velocity is not the only factor. Since essentially the same conduit length ($l = 2.21$ m for $d = 0.86$, 0.46 mm, $l = 2.0$ m for $d = 0.30$ mm) was used for the experiments, the total sample volume theoretically available in the conduit for direct extraction through interfacial transfer is dependent on the square of the diameter. The differences in the actual signal observed at any given velocity for the three different tube diameters are significantly lower than that suggested by a d^2 dependence. More importantly, considerations based solely on the velocity dependence and sample volume availability cannot explain why the curves for the three different tube diameters as a function of flow-rate are virtually parallel (Fig. 7). An alternative explanation is as follows. For a given value of p, the amount of sample passed through the conduit before the introduction of an extractant segment is linearly related to f. Given that a fixed fraction of the influent ion-pair may adsorb on the wall (until saturation occurs), the observed dependence on flow-rate can be due to adsorption of the ion-pair on the conduit wall and its subsequent elution by the organic solvent.

Variations of injection cycle period (all other parameters constant)

The walls of an extruded PTFE conduit are smooth and offer a relatively small adsorption area. Typically it is considered to be inert and adsorption effects are seldom regarded to be of importance. Nonetheless, much of the foregoing results strongly suggest that adsorption on conduit walls may play a major role in the present system. The definitive experiment in this regard is to vary the injection cycle period while keeping all other parameters constant. The results are shown in Fig. 8 ($l = 4.50$ m, $d = 0.86$ mm, $f = 1.0$ ml/min). Observed signals increase well beyond an injection period equal to t_R. This can only be explained by adsorption on the conduit wall. At low cycle periods, the signal increases linearly with the period, characteristic of preconcentration systems; saturation eventually occurs at $p \geqslant 7$ min. It is interesting to note that if the linear pattern is extrapolated, the ordinate intercept is essentially zero, suggesting that the great majority of the "extraction" may be occurring via the adsorption/elution pathway. However, we have also observed that the magnitude of this intercept

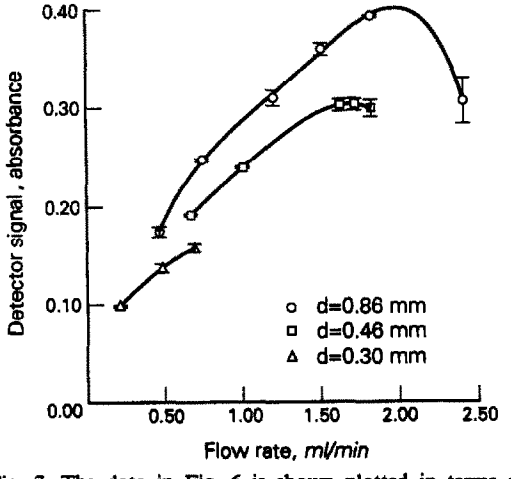

Fig. 7. The data in Fig. 6 is shown plotted in terms of flow-rate.

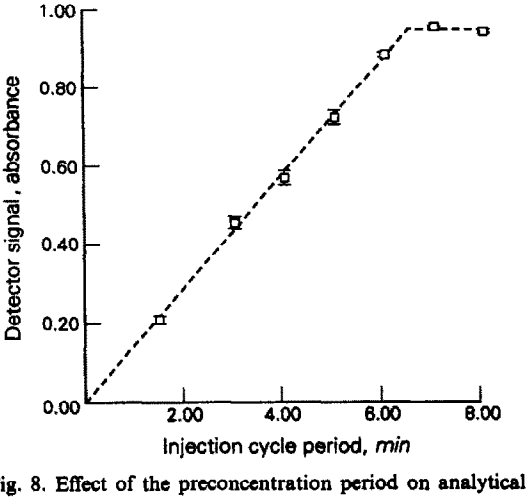

Fig. 8. Effect of the preconcentration period on analytical sensitivity.

increases at higher flow rates: either preconcentration is less efficient because the efficiency of mass transfer to the wall under laminar flow conditions decreases with increasing flow-rate (see, for example, the Gormley–Kennedy equation[47]) or higher fluid velocities increase the magnitude of direct interfacial extraction. In either case, the relative importance of the latter process is enhanced. Nevertheless, the results shown in Fig. 9 indicate that the system behaves most like a conventional adsorbent-based preconcentration system in that although total available surface area (conduit length) has an influence on the onset of saturation and the plateau absorbance at saturation, the behavior is largely governed by the total volume "preconcentrated".

It is not possible to determine from the available data as to the details of the adsorption process. From the magnitude of the "extraction" yield, we estimate that more than monolayer coverages are involved. This suggests that solvent films play a role; but this could not be unequivocally established. Amankwa and Cantwell[48] have recently examined the adsorption of tetrahexyl-ammonium-BTB ion-pairs at a chloroform water interface. Their data indicate that BTB^- competes with $Q^+.BTB^-$ for adsorption at the interface and the adsorption of the ion-pair is decreased by an excess of BTB^-.

Variation in geometrical configuration of the conduit

Relative to a linear configuration, geometrically deformed configurations promote greater mass transport to the wall and may thus improve preconcentration efficiency. For 3–4-m conduits ($d = 0.86$ mm, $f = 1.5$ ml/min), the gain was marginal ($\leqslant 15\%$), however, upon coiling the conduit to a coil of diameter ~ 1 cm. No further increase in efficiency was observed in knitting the conduit on a perforated board in crisscross and serpentine II configurations,[36] even though these configurations promote better radial mass transport than coiled conduits. On the other hand, these highly deformed configurations led frequently to segment breakage and were not further pursued.

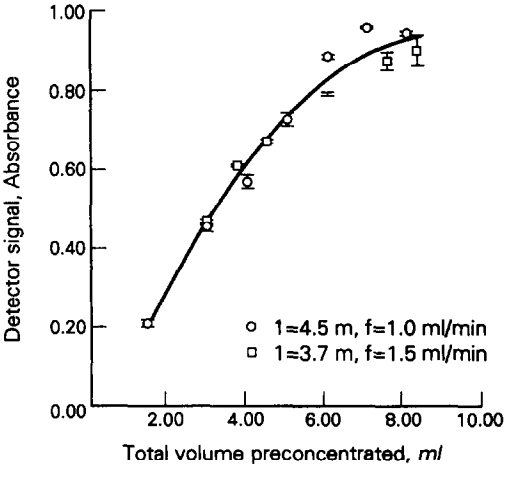

Fig. 9. Analytical sensitivity as a function of total volume passed through the conduit prior to extractant introduction. The data represent two different combinations of conduit length and flow-rate.

Wall-imbedded adsorbent preconcentration conduits

Because it was apparent after the foregoing studies that the present system essentially operates in a preconcentration mode via wall adsorption, it was deemed advantageous to use conduits with greater available surface area for adsorption. This was accomplished with imbedding adsorbent on the walls of the conduit. It is also necessary at this point to consider the merits of such a system as opposed to using a packed column filled with adsorbent[49] and eluting the adsorbed analyte with a miscible solvent (immiscible solvent segments cannot be used with a packed column without disintegrating the segment). While the latter system is obviously simpler, trace analysis by optical detection methods is inhibited by major refractive index disturbances. It may be possible in the future to completely correct for refractive index changes,[50] the present system meanwhile offers a practical alternative with low flow resistance and can deal with real samples without scrupulous filtration. The latter is an important advantage with many real samples in that the potential analyte loss is minimized.

The addition of a single 16-cm polyethylene conduit containing wall-imbedded adsorbent to an existing 3.3-m PTFE extraction conduit increased the signal by over 40%, clearly indicating that it is advantageous to have a greater surface area available for adsorption. Using a 24-cm absorbent imbedded polyethylene tubing, a coiled (*ca.* 1.5-cm coil diameter) configuration proved to be $\sim 18\%$ more efficient than the linear configuration, essentially the same increase observed with PTFE conduits upon coiling. Using $2\mu M$ $(n\text{-}C_4H_9)_4N^+$ as the analyte, the detector output is shown as a function of injection cycle period for a 2-m Tygon conduit in Fig. 10. The conduit is resistant to saturation up

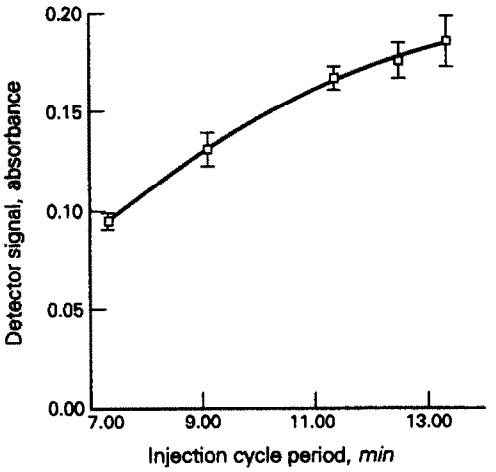

Fig. 10. Analytical sensitivity for the determination of $2\mu M$ $(n\text{-}C_4H_9)_4N^+$ for a 2-m long coated wall Tygon conduit as a function of preconcentration period (flow-rate 1.2 ml/min).

to very substantial preconcentration periods. Using a practical preconcentration period of 4.3 min ($f = 1.2$ ml/min), the response of the system in the $0\text{–}2\mu M$ analyte concentration range was studied. The response equation can be summarized as:

$$\text{Signal (abs)} = 3.64(\pm 0.14) \times 10^{-2}\, C(\mu\text{M}) + 0.0019 \pm 0.0013, r^2 = 0.9977$$

The computed blank absorbance agrees well with the observed value of 0.0024 ± 0.0001 (note that uncertainty in this measurement is equal to the intrinsic noise level of the detector used). Based on the uncertainty of the blank, an LOD of $\sim 8 \times 10^{-8} M$ was computed. In comparison, a sample containing $2 \times 10^{-8} M$ $(n\text{-}C_4H_9)_4N^+$ was experimentally indistinguishable from the blank while a sample containing $7 \times 10^{-8} M$ analyte produced a mean absorbance signal of 0.0029.

The ultimately attainable LOD depends, of course, on the detectability of the ion-pairing dye itself, as long as a reasonably low and reproducible blank can be maintained. With an experimental arrangement identical to that used above, we have observed that the use of 3-hydroxy-2-napthoic acid (3H2NA) as the pairing agent ($4\mu M$, pH 10) provides ultralow detection limits; for example, with detection at 250 nm, $(n\text{-}C_4H_9)_4N^+$ concentrations of 0 and $7nM$ respectively produced absorbance signals of 0.144 ± 0.001 and 0.176 ± 0.001. This compound is also intensely fluorescent and further work may provide an attractive means to measure ultratrace amounts of cationic surfactants with this reagent, albeit the response may be nonlinear over a large range.

The present system operates in the sample preconcentration mode; the sample is aspirated or pumped for fixed periods of time rather than a fixed volume being introduced by a loop injector. The large sample volumes used and wall adsorption leads to significant carryover; however, it is completely eliminated when samples are alternated with wash solutions as in segmented flow analyzers.

CONCLUSIONS

If hydrophobic organic solvent extractable adducts/ion-pairs/chelates can be formed from aqueous analytes upon addition of appropriate reagents, they can be preconcentrated on conduit walls. Such adsorption is promoted by coating the conduit walls with suitable nonpolar adsorbents. The preconcentrated analyte is then detected after elution with an immiscible organic solvent. For trace analysis of real samples where sample availability is not a problem and the necessity of filtration can be a nuisance, this approach can be particularly attractive, whether the technique of segment isolation presented in this paper is used, or direct measurement is made with an on-tube detector.[4,42,51]

(*Received* 29 *January* 1991. *Revised* 9 *July* 1991. *Accepted* 10 *July* 1991)

Summary—Eight octocoral species from two reefs off the Venezuelan coast were analyzed to determine their Cd, Cu, Ni, Pb and Zn content. A microwave sample work-up procedure, including drying and acid digestion, was developed and found to be faster and more convenient than conventional methods. Accurate and precise results were obtained for the determination of the metals of interest, using graphite furnace atomic-absorption spectrometry (GFAAS) with L'vov platforms. The accuracy of the results was checked against synthetic standards prepared to simulate the matrix of the analyzed octocoral species. Standard deviation values for synthetically prepared standards were less than 1% in all cases. On the other hand, standard deviations for sample results were considerably higher due to heterogeneity of the samples and environmental conditions at the sampling sites.

The quality of the marine environment has been severely affected by the discharge of a great variety of pollutants. Therefore, marine organisms such as mussels, fish and others, which are known to accumulate contaminants, have found great use as biological indicator organisms of marine pollution.[1,2]

One of the various marine environments which have been found to be particularly threatened by pollution are the coral reefs,[3–5] which are considered amongst the most productive but also most vulnerable marine ecosystems. It is therefore of great importance to monitor pollutants such as heavy metals in coral reefs, and to investigate their potential effects upon them. The accurate analysis of heavy metals in different coral species could also help to determine the possible uses of corals as biological indicator organisms of marine pollution. As such, corals have recently been used as chronological indicators of heavy metal pollution in the ocean.[6–8] These studies required the use of skeletarian corals, which are generally low in organic carbon (0.1–6%), and therefore show a low tendency to accumulate heavy metals. Octocorals on the contrary, have a much higher organic carbon content (40–80%), and have been found more useful as bioindicators of pollution.[9,10]

Relatively few reports have appeared in the literature concerning the analysis of heavy metals in octocorals.[9,10] However, their use as bioindicators of marine pollution seems very promising and needs to be investigated further. With this in mind, the present study was aimed at developing a relatively simple, accurate and precise method for the sample preparation and analysis of heavy metals in octocorals.

In this report, we describe such a procedure for the determination of Cd, Cu, Ni, Pb and Zn in octocoral samples by means of microwave drying and digestion followed by graphite furnace atomic-absorption spectrometry. Microwave heating has been used for drying[11,12] and acid digestion[13–19] of various types of samples in order to increase the efficiency of the sample treatment. Conventional drying and digestion procedures were also used for sample preparation in this work. Due to contamination problems, samples obtained in this way were not used for final analysis. However, the tests with the conventional approach were useful for comparison of both sample treatment procedures in respect of speed of drying and dissolution of the octocoral samples.

EXPERIMENTAL

Sampling

Eight octocoral species (see Table 1) were sampled from two coral reefs. One of these was

Table 1. Heavy metal concentrations in octocoral species

located between the bays of Falucho and Caño Martin on the Isla de La Blanquillas' southern shore, located about 200 km north of the Venezuelan coast at Barcelona. The second sampling station was a coral reef located on the central bay of Isla Larga, located about 0.8 km north of the Venezuelan coast at Puerto Cabello. The eight octocoral species were selected based on their abundance in Venezuelan coastal waters. Each species was sampled in triplicate. Both sampling sites are basically unpolluted particularly the Isla de La Blanquilla, which has no permanent inhabitants, and no tourism.

Samples were collected by divers, at a maximum depth of 6 m. Pieces between 10 and 20 cm in length were cut off with stainless steel scissors and immediately collected in acid cleaned[20,21] zip-lock plastic bags. The samples were not in direct contact with the divers hands at any time. The bags were opened under water and inverted over the diver's hand, leaving the pre-cleaned surface to the outside. This "inverted glove" was used to hold on to the coral while it was cut off with stainless steel scissors. The bag was then re-inverted over the sample, the seawater was decanted, and the sample immediately placed on dry ice and kept frozen at $-10°$ until analysis. All glassware and plastic materials were purified before use according to reported procedures.[20,21]

Microwave drying and sample dissolution

Subsamples of approximately one gram (dry weight) were cut off the original samples with stainless steel scissors, placed in precleaned glass beakers and immediately covered with a watch glass. The samples were then microwave predried at "medium low" (40% total power) during time intervals of between 20 and 50 min, depending on the water content of the octocoral species. After this pre-drying step, the samples were taken to constant weight by leaving them in a precleaned, nitrogen pressure flushed (to remove small dust particles) oven, at 120° overnight. During this period the oven was kept closed at all times.

Since octocorals contain a flexible but very dense interior support, consisting almost exclusively of organic matter, dried samples could not be crushed and homogenized with a mortar. Therefore, the whole dried sub-sample was weighed and transferred to a 200-ml thick-walled, acid cleaned[20,21] Pyrex glass reusable test tube containing 10 ml of concentrated nitric acid and immediately sealed with a specially

designed screw cap. Details of the modified tubes used for sample digestion are described elsewhere.[22] The sample was then irradiated at 40% total power for 4–6 periods of one minute each. Each heating cycle was followed by cooling of the tubes in a water bath to room temperature. Once cool, the dissolved sample developed a supernatant layer of greasy appearance. The sample was then set aside for a period of about 5 hr to allow the greasy layer to separate. This suspension was removed by filtration through acid-cleaned glass wool. Once filtered, the sample filtrates were made up to 25 ml and stored in sealed polyethylene containers at room temperature for GFAAS analysis.

In order to establish whether the greasy layer contained significant amounts of metals, it was analyzed as follows. Since this material was insoluble in concentrated acids and hydrogen peroxide, the organic phase which was retained in the glass wool was first rinsed with distilled demineralized water and then dissolved in a minimum amount of analytical grade ethanol. The ethanol phase was collected in a clean glass container. After allowing the ethanol to evaporate at room temperature, 10 ml of analytical reagent grade nitric acid were added to the glass container and the solution was analyzed by GFAAS. No appreciable difference in heavy metal content could be observed between these samples and those of the pure acid. Therefore, it was concluded that the greasy layer contained insignificant amounts of metals compared to the octocoral samples and could be discarded.

Conventional drying and sample dissolution

Samples, contained in beakers covered with a watch glass, were pre-dried in a water bath for periods of at least 8 hr. Once dried, these samples were taken to constant weight in an oven at 120° overnight as described previously. For acid digestion, 10 ml of nitric acid were added to the beakers which were then heated on a water bath for at least three days. As the volume of acid decreased, more acid was added to maintain a constant level. Further steps were similar to those described in the previous paragraph, including filtering of the greasy layer that formed upon cooling the digest.

Sample analysis

Samples were analyzed for their cadmium, copper, lead and nickel content by GFAAS, using electrothermal atomization and L'vov platforms. Zinc was analyzed by flame atomic-absorption spectrometry (FAAS) with a fuel-lean air-acetylene flame. Prior to the analyses by GFAAS, the wavelength, the carrier gas flow, and the temperatures and time of drying, ashing and atomization steps were optimized. Starting with the standard conditions recommended by the instrument manufacturer, each parameter was then varied, keeping the others fixed, until the highest absorption signal for each analyte was obtained. The best set of instrumental conditions obtained is shown in Table 2. Matrix interference was checked by comparison of the slopes of calibration graphs with those using standard addition methods. Since matrix effects were apparent for the GFAAS measurements, quantitation was performed with the standard addition method.

Instrumentation

A commercial domestic National Panasonic Model NE 6660 microwave oven, provided with a variable timing cycle, a variable heating cycle with power settings from "warm" to "high" (60–600 W) and a rotary tray, was used for the microwave sample treatment. The use of the rotating tray allowed a more homogeneous and uniform exposure of the samples to the incoming radiation, thus leading to a more efficient drying and digestion process. Details of the sample containers for microwave irradiation have been given elsewhere.[22]

For AA analyses, graphite furnace atomic-absorption measurements were made on a Perkin–Elmer Model 503 spectrometer equipped with a HGA-2100 graphite furnace atomiser, using pyrolytic graphite coated graphite tubes and pyrolytic graphite L'vov platforms. Samples were manually injected onto the

platform by means of micropipettes with disposable plastic tips.

Flame atomic-absorption measurements were made on a Perkin-Elmer Model 2380 spectrometer, with an air-acetylene flame. Both spectrometers were provided with deuterium-arc background correction systems.

Recovery study and blanks

Since octocorals possess a highly complex matrix and since no certified standard material was available to match this matrix, a synthetic standard was prepared for this study. To simulate the matrix of the octocorals, an exactly known amount of microwave dried NIES mussel standard material was combined with the appropriate amount of a calcium carbonate solution required to obtain a final mixture of 61% organic matter, represented by the NIES mussel standard, and 39% calcium carbonate. This organic/carbonate ratio is representative of the ratios of the species studied. Triplicates of this mixture (0.5 g) were placed inside the modified glass tubes and microwave digested in the presence of 10 ml of nitric acid.

The synthetic solutions containing certified amounts of the analytes of interest were used to carry out recovery studies. Precision and accuracy were determined based on comparisons of the reported metal contents of the standard reference material used with experimentally determined values.

The calcium carbonate solution used for the preparation of the synthetic reference material was previously purified by extraction with HPLC grade chloroform after the addition of a 1% APDC solution and an acetic acid–ammonium acetate buffer solution to keep the pH at 4.5. The APDC and buffer solutions were also purified prior to use.[23–25]

Triplicates of blanks, prepared in a similar way as the samples, but having no NIES mussel material, were also analyzed for the trace elements of interest.

Reagents

Standard solutions for calibration and optimization of the analytical conditions were prepared by conventional dilution of stock solutions containing 1000 μg/ml of the analytes as nitrates. Nitric acid was of analytical-reagent grade. Distilled, demineralized water (specific resistivity of 18 Mohm/cm) from a Millipore water purification system was used for the preparation of samples, blanks and standards.

RESULTS AND DISCUSSION

It has been reported in the literature that microwave drying significantly decreases the time required for the process,[11,12] and should certainly minimise the possibilities of sample contamination. In the case of the octocorals, conventioanl pre-drying and final drying to constant weight conditions required at least 8 and 12 hr, respectively, while the microwave pre-drying required 20–50 min, depending on the moisture content of the samples, followed by a 12-hr final drying period to constant weight. In addition, microwave pre-dried and digested blanks consistently presented substantially lower metal concentration levels than those prepared by conventional pre-drying in the open on the water bath followed by microwave digestion. This was particularly the case for lead, where for conventional drying followed by microwave digestion, the concentrations in the blanks were 90–95% of those in the samples. Copper, cadmium and nickel levels in the blanks were 50–70% of those in the samples. In contrast, heavy metal concentrations in blanks, pre-dried and digested with the microwave oven, were at parts per billion levels, with the highest concentration corresponding to Zn, 120 ppb, and the lowest corresponding to Cd, 0.1 ppb. This range of blank values can be considered negligible in comparison to the concentrations found for the metals of interest in the octocoral samples analyzed (see Table 1).

These results show that microwave heating greatly reduces the time of sample drying, and minimises significantly the possibility of sample contamination during preparation for AA analysis.

Our results also show, as in previous work, that microwave heating should apply to the acid digestion process. In fact, samples were completely digested in only 4–6 min of microwave heating, while conventional digestions could take up to 4 days.[9] Therefore, as expected, the use of microwave heating for acid digestions significantly reduces the time for sample preparation. In addition, the method not only minimises the amounts of chemicals required for the digestion, and therefore contamination *via* impurities in reagents, but also reduces the risks of sample contamination and sample loss when the samples are treated in sealed tubes.

Table 1 shows the data obtained for the determinations of Cd, Cu, Ni, Pb and Zn in the eight octocoral species. Each column represents the

average concentration obtained in three samples analyzed in triplicate for each sampling site. For all species, the lowest concentration levels were observed for cadmium, while the highest were those for zinc. Standard deviations were, in most cases, relatively high. This could be attributed to the heterogeneous character of this type of sample. In addition, variations in metal concentrations within one species, between sites, and between species are likely to be due to environmental and biological factors which will be discussed and published elsewhere.

Cadmium and copper levels in Venezuelan octocorals were similar to those reported for the Great Barrier Reef.[9] Cadmium concentrations were somewhat higher, while copper concentrations were lower, than those reported for the northern Florida reef tract.[10] Concentrations of Ni, Pb and Zn in the Venezuelan octocorals were, in all cases, one to two orders of magnitude higher than those reported for the Australian octorals, and in the case of lead, for the Florida octocorals. These differences are likely to be due to differences in the environmental conditions of the sampling sites.

Accuracy studies were carried out to check the reliability of the measurements. The analysis of synthetically prepared certified standards, whose matrix closely simulates that of the octocoral samples, produced recovery efficiencies of 98.9, 99.6, 95.4, 99.7 and 99.4% for Cd, Cu, Ni, Pb and Zn, respectively. These results indicate that microwave drying of the NIES standard reference material and the microwave digestion procedure used to bring the synthetically prepared standard into solution, allow for accurate determinations of Cd, Cu, Ni, Pb and Zn in the studied samples.

In conclusion, a fast, efficient, precise and accurate procedure was developed for the analysis of octocorals, making use of microwave heating for the drying as well as acid digestion of the samples, and graphite furnace atomic-absorption spectrometry with L'vov platforms for the measurement of their metal content. The use of microwave heating significantly reduces the time of drying and acid digestion process when compared to conventional methods, and minimises the contamination of samples during handling in the laboratory.

A NEW CATALYTIC POLAROGRAPHIC SYSTEM FOR DETERMINATION OF TRACE AMOUNTS OF TUNGSTEN

DEZHONG DAN
Department of Applied Chemistry, Chengdu College of Geology, Chengdu, Sichuan, People's Republic of China

JUN RE
103 Factory, Chengdu Branch, Bureau of Chinese Civil Airplane Administration, Chengdu, Sichuan, People's Republic of China

(*Received* 24 *May* 1988. *Revised* 20 *July* 1991. *Accepted* 1 *August* 1991)

Summary—A new catalytic polarographic system for the determination of trace amounts of tungsten is described. It is found that the tungsten–2-mercaptobenzothiazole (MBT) complex yields a sensitive catalytic hydrogen wave at −1.10 V (*vs.* SCE) in strongly acidic medium. The peak height is a linear function of tungsten concentration over the range 0.004–1.4 μg/ml in 0.9*M* H_2SO_4–20 mg/ml NaCl–0.01 μg/ml MBT medium. The method can be applied for determination of trace amounts of tungsten in geochemical materials.

Several catalytic polarographic systems for tungsten, mainly involving the sulphuric acid–benzilic acid–potassium chlorate–cetyltrimethylammonium bromide and sulphuric acid–hydrocyanic acid–potassium chlorate systems have been used for the determination of trace amounts of tungsten.[1–4] Recently these systems have been improved, but the organic reagent used is still benzilic acid.[5,6]

We have found 2-mercaptobenzothiazole (MBT) to be an excellent reagent for the determination of tungsten by linear sweep polarography (LSP). MBT can cause a catalytic hydrogen wave in polarography.[7] This paper reports the polarographic behaviour of MBT in strongly acid medium. There is a sensitive and well-defined catalytic hydrogen wave in a solution of 0.9*M* sulphuric acid–20 mg/ml sodium chloride. The peak height is enhanced by the presence of tungsten, and is a linear function of tungsten concentration over the range 0.004–1.4 μg/ml in 0.9*M* sulphuric acid–20 mg/ml sodium chloride–0.01 μg/ml MBT medium. Interferences can be eliminated by heating to fuming with sulphuric acid, cooling, diluting, and neutralizing with sodium hydroxide. The procedure has been successfully used for the determination of tungsten in geochemical standard materials.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade. The MBT (Third Reagent Factory of Shanghai), was used without further purification.

Tungsten stock solution, 2 mg/ml. This was made by dissolving 3.590 g of sodium tungstate dihydrate in demineralized water, adding about 50 mg of sodium hydroxide and diluting accurately to 1000 ml with demineralized water. Working solutions were prepared by further dilution.

Apparatus

A Model JP-1A oscillopolarograph (Chengdu Instrumental Factory, China) was used. For derivative linear sweep polarography (derivative LSP), the operating conditions were drop-time 7 sec, scan-rate 250 mV/sec, scan from −0.8 to −1.3 V, mercury head 55 cm, and mercury flow-rate 0.5 mg/sec. The three-electrode system comprised a dropping mercury electrode (DME), platinum counter-electrode, and saturated calomel electrode (SCE) as reference. All potentials were referred to the SCE. The electrolytic cell was a 10 ml-beaker.

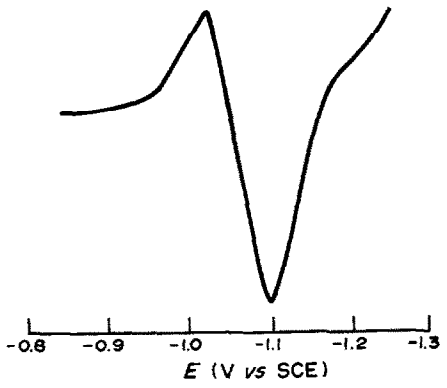

Fig. 1. Derivative polarogram: 0.9*M* H_2SO_4–20 mg/ml NaCl–0.01 μg/ml MBT–0.5 μg W.

Procedures

To the tungsten standard solution in a 25-ml standard flask, add 2.5 ml of sulphuric acid (1 + 1), 2.5 ml of 20% sodium chloride solution and 0.25 ml of 1 μg/ml MBT solution, dilute to volume with demineralized water, and let stand for about half an hour. Record the derivative linear sweep polarogram from −0.8 to −1.3 V (*vs.* SCE).

Analysis of samples. Weight 0.1–0.25 g of geochemical sample into a 50-ml PTFE crucible, add 10 ml of concentrated hydrochloric acid, and heat gently for a few minutes on a hot-plate. Add 3 ml of concentrated nitric acid, 5 ml of 47% hydrofluoric acid and 2 ml of 60% perchloric acid, and heat. Evaporate the solution until no more fumes are evolved. Cool, add 1 ml of hydrochloric acid (1 + 1) to dissolve the residue, then transfer the solution to a 25-ml beaker, rinsing the crucible with demineralized water. Add 2 ml of sulphuric acid (1 + 1), heat the solution until the yellow colour disappears,

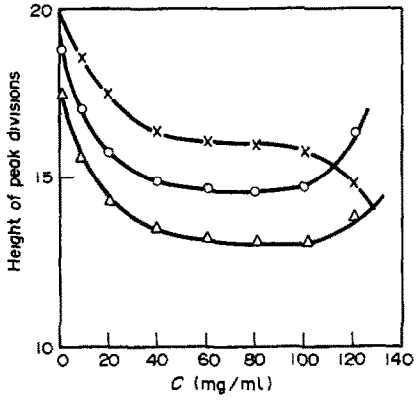

Fig. 2. Effect of supporting electrolytes on the peak height: 0.9*M* H_2SO_4–0.01 μg/ml MBT–0.5 μg W. ○, NaCl; △, KCl, ×, NH_4Cl.

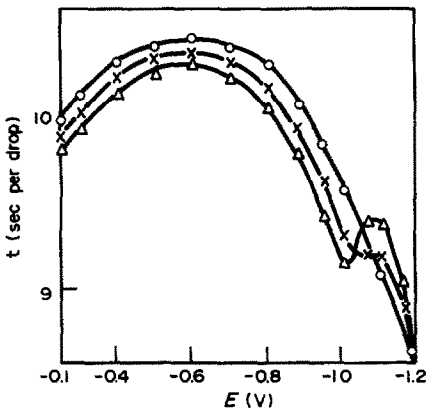

Fig. 3. Electrocapillary curves: ○, 0.9*M* H_2SO_4–20 mg/ml NaCl; ×, 0.9*M* H_2SO_4–20 mg/ml NaCl–0.01 μg/ml MBT; △, 0.9*M* H_2SO_4–20 mg/ml NaCl–0.01 μg/ml MBT–0.5 μg W.

transfer the solution to a 25-ml standard flask, dilute to volume with 5% sodium hydroxide solution and mix. Allow the precipitate to settle. Pipette 10 ml of the clear solution into a 25-ml standard flask, add the reagents as described above, and dilute to volume. Let stand for half an hour, then polarograph as described.

Calibration graph. Add 2 ml of sulphuric acid (1 + 1) to portions of standard tungsten solution (to cover the range 0.004–1.4 μg/ml). Evaporate the solutions till fuming and heat for 2 min longer. Cool, dilute to volume in 25-ml standard flasks with 5% sodium hydroxide solution and mix. Pipette 10 ml of a solution into a 25-ml standard flask, add 3.2 ml of sulphuric acid (1 + 1), and polarograph as described above. Run a blank and apply a correction for it.

RESULTS AND DISCUSSION

Optimum condition for catalytic system

Tungsten can give a sensitive catalytic wave at about −1.10 V (*vs.* SCE) in presence of MBT

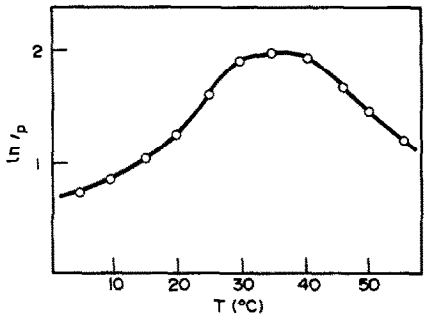

Fig. 4. Effect of temperature on peak height. Conditions as for Fig. 1.

Table 1. The effect of foreign ions

Ions, X	Maximum concentration ratio tolerated, [X]/[W]
Alkali and alkaline-earth metals	no interference
Fe(II), Fe(III), Cu(II), Cd(II) Bi(III), Sb(III), Ga(III)	500–800
Ag(I), Co(II), Ni(II), Zn(II) Pt(IV), Ti(IV), Se(IV), Ta(V) Mo(VI)	40–80
Hg(II), Mn(II), In(III), Ge(IV) Te(IV), V(V), Os(IV)	1–5
Pd(II), As(III), Ru(III), Rh(III) Au(III), Cr(VI), NO_3^-	interfere seriously

in acidic medium, in LSP (Fig. 1). The peak potentials depend on the species of acid used. A well-defined peak is obtained with sulphuric acid medium, and the peak height is constant over the range 0.9–2*M* sulphuric acid. At low acidity the peak height decreases and at pH > 5, the wave disappears.

If the supporting electrolyte concentration is not high enough, it is difficult to obtain a stable catalytic wave. Potassium, sodium and ammonium chlorides were tested and the sodium salt was found the most suitable, as the sensitivity was reasonably high and the peak height did not change much with salt concentration in the range 20–100 mg/ml (Fig. 2).

MBT is a key factor for the catalytic wave, as the background current increases with MBT concentration, but the peak height is considerably enhanced by the presence of tungsten (VI). It was found that 0.01 μg/ml MBT was sufficient to give reasonable sensitivity, low background, and wide linear range. To sum up, the optimum composition of the catalytic system was found to be 0.9*M* sulphuric acid, 20 mg/ml sodium chloride, 0.01 μg/ml MBT.

Once the test solution had been prepared, the peak height obtained with it decreased slightly during the first 30 min, then remained unchanged for a day. The peak current was a linear function of tungsten concentration over the range 0.004–1.4 μg/ml, and different sensitivities could be used for different ranges.

Table 2. Determination of tungsten in six Chinese standard reference materials

Sample	Recommended value, $\mu g/g$	This method, $\mu g/g$
GBW07302	24.4 ± 2.7	23.7; 24.0; 22.7
GBW07303	2.9 ± 0.7	3.3; 3.3; 3.4
GBW07304	2.5 ± 0.8	3.0; 1.9; 1.8
GBW07305	3.2 ± 0.6	3.3; 3.2; 3.8
GBW07306	25 ± 3	26; 26; 26
GBW07308	1.95 ± 0.44	1.79; 1.77; 1.79

Characteristics of the catalytic wave

The electrocapillary curves are shown in Fig. 3. When MBT and MBT plus tungsten were present the surface tension of the mercury drop was decreased and a sharp change in drop time appeared at between −1.0 and −1.2 V.

The peak height changed with temperature over the range 5–55° (Fig. 4), the temperature coefficient being +7% per degree at <30°, and −6% per degree at >40°. The peak height was almost constant over the temperature range 30–40°. The behaviour of the background current is similar to that of the tungsten-enhanced wave.

The effect of surfactants on the peak current was examined. The peak height is considerably decreased by the addition of 1 or 2 drops of solutions (at the concentrations given in parentheses) of surfactants such as sodium lauryl sulphate (1 mg/ml), gelatin (1 mg/ml), tetrabutylammonium iodide (0.1 mg/ml), Triton X-100 (0.1 mg/ml) to the medium used. The peak height is greatly increased by the presence of 0.1 mg/ml poly(vinyl alcohol), but the reason for this enhancement effect is not known.

The peak height is proportional to the height of the mercury head.

These results indicate that the catalytic wave has adsorption characteristics. Hydrogen bubbles can be observed at the surface of the dropping mercury electrode, if large amounts of MBT or tungsten are present in the system. It is clear that the current is due to catalytic discharge of hydrogen ions. On the basis of these observations, it may be deduced that MBT can yield a catalytic hydrogen wave, the catalysis being enhanced by presence of tungsten.

Effect of foreign ions

More than forty ions were examined for possible interference in the determination of tungsten. The results of Table 1 show that the system has good selectivity. Most common metal ions have little effect. Of the ions tested, only As(III), Ru(III), Rh(III), Au(III), Pd(II) and Cr(VI) interfered seriously, the last five causing a decrease in the peak current, and As(III) causing the wave to split. Of the anions tested, only nitrate was found to interfere. Prior

separation is unnecessary since the sample solution is prepared by fuming with sulphuric acid, followed by the addition of sodium hydroxide to precipitate interfering species.

Application

Six Chinese standard stream-sediment reference materials were analysed by the method. These samples are used throughout China as primary-control standards for the trace-element analysis of geological-exploration samples. They are well homogenized and have a particle size of 200 mesh. The results (Table 2) compare well with the recommended values.[8]

Summary—A new polarographic method is described for the determination of nitrite/nitrogen oxides. The nitrite is first diazotized with *p*-aminobenzoic acid, followed by coupling to 8-hydroxyquinoline to produce an azo dye. This azo dye is adsorbable on a mercury drop electrode and its reduction is reversible. The linear response range is 6×10^{-9}–3×10^{-7} g/ml. The detection limit is 4×10^{-9} g/ml. This method has been applied to the determination of nitrogen oxides in the air.

The oxides of nitrogen found in air consist mainly of nitrogen monoxide and nitrogen dioxide, most of which results from the combustion of fossil fuels, the exhaust gas from internal-combustion engines, and waste gas released by steelworks, metal smelters, and factories that produce and use nitric acid. Experiments with animals show that oxides of nitrogen can affect the respiratory organs,[1] and cause the extension of bronchial asthma and other diseases. Therefore, it is important to monitor and determine the oxides of nitrogen in the air.

Many methods have been introduced for determination of nitrite/nitrogen oxides.[2–10] Spectrophotometric methods are often used, but some suffer from poor sensitivity. However, the polarographic and adsorptive cathodic stripping voltammetry methods can give greater sensitivity.[11,12] The method proposed in this paper uses a tube filled with chromium trioxide to oxidize nitrogen monoxide to nitrogen dioxide, which is then absorbed in alkaline sodium arsenite solution to produce nitrite, followed by diazotization of *p*-aminobenzoic acid and coupling to 8-hydroxyquinoline (oxine) to form an azo dye. The azo dye can be reduced at the dropping mercury electrode in pH-7.5 medium. The content of nitrogen oxides in the air can thus be determined.

EXPERIMENTAL

Apparatus

A JP-1A oscillopolarograph, a voltammetric analyser and a model 883 D.C. polarograph were used, in a three-electrode configuration, with an *x*–*y* recorder. A dropping mercury working electrode was used, except for the cyclic voltammetry, for which a hanging drop mercury electrode was used. The counter-electrode was a platinum wire. All potentials were measured against a saturated calomel electrode (SCE). The electrolytic cell was a 10-ml beaker.

For sampling, a commercially available gas sampling device was used, fitted with an oxidizing tube containing chromium trioxide and a trap for interferents (Fig. 1). The trap contained cotton wool impregnated with lead acetate. The oxidizing tube contained about 8 g of the oxidizing agent, between two plugs of cotton wool. The oxidizing agent[13,14] was prepared by making a paste of 5 g of chromium trioxide (CrO_3) with a little water, mixing this with 95 g of 14–16 mesh silica, and drying the mixture at 105°.

Reagents

A 1-mg/ml nitrite stock solution was prepared from sodium nitrite which had been dried at 105–110° for 2 hr, and a working standard solution was obtained by diluting the stock solution with triply distilled water.

p-Aminobenzoic acid solution (1 mg/ml) was prepared by dissolving 0.10 g of *p*-aminobenzoic acid in 10 ml of ethanol and diluting to 100 ml with water.

8-Hydroxyquinoline (oxine) solution, 10 mg/ml, was prepared by dissolving 1.00 g of oxine in 2 ml of 6*M* hydrochloric acid and diluting to 100 ml with water.

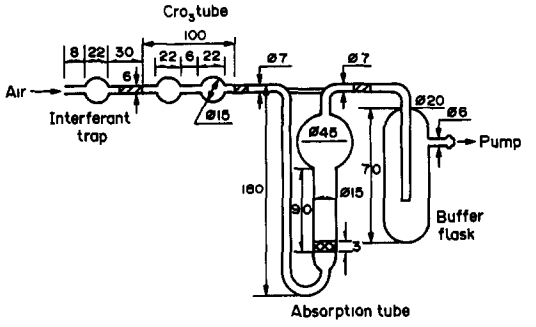

Fig. 1. Sampling device for nitrogen oxides (dimensions in mm).

Alkaline sodium arsenite solution[6] was prepared by dissolving 1.0 g of arsenious oxide and 5.2 g of sodium hydroxide in water and diluting to 2 litres.

Sodium hydroxide solution (0.1*M*) was also prepared. Triply distilled water was used throughout.

Procedure

Pipette an aliquot of the standard solution of nitrite into a 10-ml beaker, add 0.5 ml of the *p*-aminobenzoic acid solution (giving a pH of ~1.5) and after about 1 min add 0.3 ml of the oxine solution followed by 1.0 ml of 0.1*M* sodium hydroxide. The solution turns orange. Dilute to 10 ml with water and mix thoroughly. Let stand for 2 min and record the derivative polarogram from −0.40 to −0.90 V (*vs.* SCE), starting the potential scan at −0.40 V (Fig. 2). Figure 3 shows the D.C. polarogram.

For air analysis, place 6 ml of the alkaline sodium arsenite solution in the absorption tube, and draw air through the sampling apparatus at 400 ml/min for 50 min. Transfer into a 10-ml beaker 1 ml of the sample solution thus obtained, add 0.5 ml of *p*-aminobenzoic acid solution, adjust the pH to *ca.* 1.5, then proceed as above by adding the oxine *etc.*

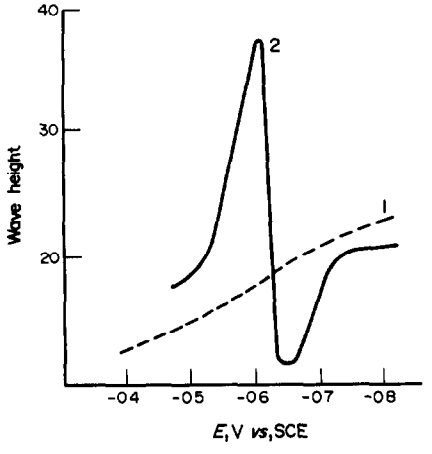

Fig. 2. Derivative single sweep polarogram of azo dye. 1, Oxine, 0.3 mg/ml; *p*-aminobenzoic acid, 0.05 mg/ml; pH 7.5. 2, 1 + 0.3 μg/ml NO_2^-.

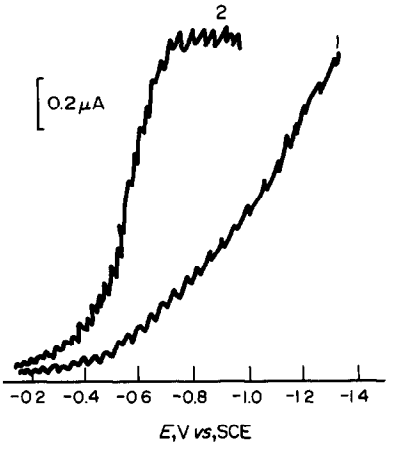

Fig. 3. D.C. polarogram of azo dye, conditions as for Fig. 2, except for NO_2^-, 0.5 μg/ml.

RESULTS AND DISCUSSION

Optimum conditions

The effects of the *p*-aminobenzoic acid and oxine concentrations and pH on the peak height are shown in Fig. 4. The optimum final concentrations are 0.05 and 0.3 mg/ml respectively and the optimum pH is about 7.5.

Linear range and reproducibility

Under the optimum conditions chosen, the peak height is proportional to the nitrite concentration in the range 6×10^{-9}–3×10^{-7} g/ml and the detection limit is 4×10^{-9} g/ml. A relative standard deviation of 4.1% was obtained for seven determinations of 1×10^{-8} g/ml nitrate.

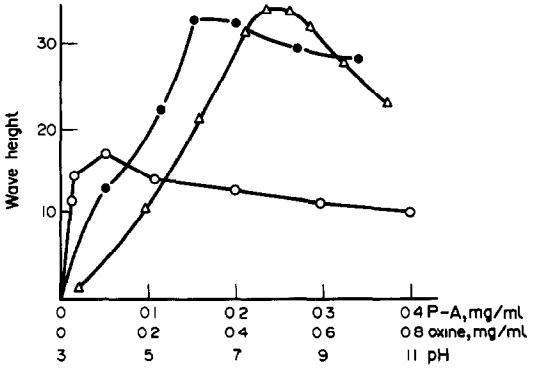

Fig. 4. Effect of reagent concentrations and pH on peak height for azo dye. NO_2^-, 0.05 μg/ml; ○, *p*-aminobenzoic acid (P-A); ●, oxine; △, pH.

Effect of other ions

It was found that a 1000-fold NO_3^- or SCN^-, 500-fold SO_4^{2-}, $S_2O_3^{2-}$, F^- or Hg(II), 200-fold PO_4^{3-} or Mo(IV), 60-fold Bi(III), 50-fold Pb(II), Zn(II), Co(II) or Ti(IV) and 30-fold Al(III) or Cd(II) concentration ratio to NO_2^- has no effect on the determination of nitrite. In addition, arsenite does not interfere.

Effect of height of the mercury column

The peak height is directly proportional to the mercury column height, indicating adsorption of the azo dye on the dropping mercury electrode, and that an adsorption wave is obtained.

Electrocapillary curves

The drop times (t, sec/drop) at various potentials were investigated (Fig. 5). From curve 3, it can be seen that the electrocapillary curve was considerably lowered by the presence of the azo dye, which was adsorbed very strongly at the electrode, resulting in the surface tension of the mercury drop being reduced.

Cyclic voltammetry

Figure 6 shows single sweep voltamperograms measured at the hanging mercury drop electrode. A reduction peak is formed when the potential is scanned between −0.4 and −0.9 V (*vs.* SCE), and arises from reduction of the —N=N—group in the azo dye. The reduction is apparently reversible, as there is only a small difference between the reduction and the oxidation potentials when the scan direction is reversed. The number of electrons (n) transferred in a reversible surface reaction can be calculated from the peak width at half height, $W_{1/2}$, by the equation[15] $n = 3.52\ RT/FW_{1/2}$. We found that $W_{1/2}$ (Fig. 6) was 50 mV (at 23°). From this value, $n = 2$, confirming that the reduction peak is due to reduction of the azo group (—N=N—) to a hydrazo group (—NH—NH—).

Sampling

Christie *et al.*[16] have reported that nitrogen dioxide is trapped in alkaline sodium arsenite with an efficiency of ~95%, so alkaline sodium arsenite solution was chosen as the absorption solution. The oxidation efficiency[13,14] can reach 99% when nitrogen monoxide in air is oxidized by chromium trioxide at a relative humidity of 30–80%, ambient temperature and a flow-rate of 500 ml/min. No interference results from the presence of a 5-fold amount of O_3 (relative to NO_x) but the presence of a 3-fold amount of H_2S or 20-fold amount of SO_2 will cause interference. The interference can be overcome by fixing a trapping tube filled with cotton-wool impregnated with lead acetate upstream of the oxidizing tube (Fig. 1).

Typical results, together with those obtained by a standard method,[5] are given in Table 1. The agreement is satisfactory.

DETERMINATION OF GALLIUM BY ANODIC STRIPPING SQUARE-WAVE VOLTAMMETRY

DETECTION OF A Ga–Zn INTERMETALLIC COMPOUND AND ITS DESTRUCTION BY Sb IN AN NaSCN–$NaClO_4$ SUPPORTING ELECTROLYTE

PABLO COFRÉ* and KARIN BRINCK
Facultad de Química, Pontificia Universidad Católica de Chile, Vicuña Mackenna 4860, Santiago, Chile

(*Received* 3 *October* 1990. *Revised* 28 *December* 1990. *Accepted* 13 *January* 1991)

Summary—Reproducibility for successive determinations with a hanging mercury drop electrode is assessed in relation to solution stirring, drop size and back-diffusion to the mercury thread. The effect of experimental parameters such as drop size, deposition time and gallium concentration on the observed stripping current is investigated. The interference of zinc present in a $0.5M$ NaSCN + $4.2M$ $NaClO_4$ supporting electrolyte on the gallium detection limit and calibration plots is described. Formation of an intermetallic compound with a Zn:Ga ratio of 2:3 and its destruction by co-deposition of zinc with Sb are reported. A detection limit of $10^{-8}M$ gallium was obtained in the presence of $10^{-5}M$ Sb(III).

The determination of trace amounts or trace concentration levels of gallium is of interest in different fields. The discovery of the special affinity of gallium for specific tissues and the anti-tumor activity in either radioactive or non-radioactive isotope form has stimulated studies of its cytotoxicity and retention by tissues and revealed a need for precise and rapid methods for trace determinations of this metal.[1,2] In the semiconductor industry gallium is used as one of the doping elements. Determination of trace amounts of gallium present as GaAs in ZnS·CdS powders and films requires the measurement of 10^{-8}–10^{-6} g of the metal in microscopic weighed samples.[3] More recently, exposure to gallium arsenide particulates in the air has been identified as a potential health hazard in the semiconductor industry and therefore methods for the determination of nanogram and sub-nanogram levels of gallium in blood, tissues and other biological materials are required for investigation of the distribution characteristics of this element.[4] Anodic stripping voltammetry appears to be a good choice for this application.

The electroanalytical determination of gallium by voltammetric (including stripping) techniques is faced with the problem of the irreversibility of the electrode process in acidic media.[5] Different supporting electrolyte compositions have been tried in polarographic studies[6] in order to obtain a reversible process and studies in thiocyanate or salicylic acid based electrolytes[7a] are of special interest. An NaSCN-based supporting electrolyte, together with the high ionic strength (normally obtained with $NaClO_4$) essential for electrochemically reversible behaviour,[8,9] has been used in thorough studies on phase-selective anodic stripping analysis (PSAS) for trace concentrations of gallium.[10,11] A $0.5M$ NaSCN + $4.5M$ $NaClO_4$ supporting electrolyte allowed the detection of gallium down to $8.55 \times 10^{-8}M$, but linear dependence of the PSAS current on concentration was obtained only above $10^{-6}M$.[10] Linear dependence of PSAS current on electrode area has been reported,[10] but its theoretical substantiation was based on equations derived for chronopotentiometric stripping[12] rather than PSAS. The dependence of PSAS current on deposition time has been studied for $8.55 \times 10^{-6}M$ gallium in $0.5M$ NaSCN + $4.5M$ $NaClO_4$ supporting electrolyte[10] and for $9.72 \times 10^{-6}M$ gallium in $1M$ NH_4SCN.[11] Both studies showed a negative deviation from linearity for long deposition times, but neither reported experiments at lower gallium concentrations.

Reproducibility studies based on ten determinations in a $1M$ NH_4SCN electrolyte at 60°

*Author for correspondence.

produced a 4.4% relative standard deviation for a $9.72 \times 10^{-7}M$ gallium solution.[11] However, the results showed a gradual increase in the PSAS current with run sequence, on which the authors made only minor comments.

Several metal ions can interfere in potentiometric stripping analysis for gallium. Zinc can hinder the gallium stripping signal in a pH 4.0 acetate buffer[13] and has been recognized as a potential interferent in thiocyanate-based electrolytes.[10] Attempts to obtain a Zn-free $NaSCN–NaClO_4$ supporting electrolyte have led to the use of glass-immobilized 8-hydroxyquinoline for sequestering trace metals[14] which appears to be an effective but slow procedure.

This work is focused on the use of square-wave voltammetry for the stripping step. A thorough study of different experimental parameters has been performed in order to understand all the observed deviations from ideal behaviour. The problem of back-diffusion into the mercury thread, the effect of the Zn(II) present in the supporting electrolyte on the calibration plots and detection limit and the presence of a Zn–Ga intermetallic compound and its elimination by Sb are discussed.

EXPERIMENTAL

Apparatus

All the experiments were carried out with an EG & G Princeton Applied Research model 384B polarographic analyser provided with a model 303A static mercury drop electrode, glass cells and a silver/silver chloride (saturated KCl solution) reference electrode (SSCE). Modified cells with a side-tube at the bottom for the collection of mercury drops[15] were used, except for experiment *A* in Table 1. All the stripping currents were plotted on a Houston Instruments model DMP-40 plotter.

The 303A electrode was modified by inserting a toggle switch to allow manual on/off control of the solenoid valve which dispenses the mercury drops. The switch, together with the dislodge-adjustment potentiometer at the rear, allowed the execution of several strippings from a single drop or strippings from consecutive drops. In the normal mode, the 303A electrode will dispense and dislodge two mercury drops between runs. Solutions were degassed with high-purity argon presaturated with an aqueous solution of the supporting electrolyte and stirred with an EG & G 305 magnetic stirrer, at its "slow" rate (nominally 400 rpm).

The different gallium concentrations were obtained by spiking with a stock solution dispensed from Gilson Pipetman micropipettes, models P20 and P200.

Reagents

Sodium thiocyanate was Fluka *purum* p.a. Sodium perchlorate was made by neutralization of Merck *pro analysi* sodium carbonate with Baker Analyzed perchloric acid. Gallium stock solutions were made by dissolution of Strem Chemicals 99.999% pure gallium(III) oxide in the smallest amount of Merck *pro analysi* concentrated hydrochloric acid. Zinc(II) sulphate and antimony(III) chloride were Merck *pro analysi*. Pierce Chemical Co. glass-immobilized 8-hydroxyquinoline was used in our attempts to purify a $0.5M$ NaSCN + $4.2M$ $NaClO_4$ supporting electrolyte, as was constant-potential electrolysis at a stirred mercury pool electrode. However, all the experiments reported in this paper were conducted with chemicals used without further purification. Distilled water was obtained from a high-performance automatic self-flushing still,[16] which ensured purity for trace analysis.

Procedure

All the glassware was soaked in $6M$ nitric acid for 24 hr prior to use. The $0.5M$ NaSCN + $4.2M$ (or $0.85M$) $NaClO_4$ supporting electrolyte was adjusted to pH 2.0 and 10 ml were placed in a dry cell and degassed for 300 sec before measurement. This solution was then spiked with the corresponding stock solution to give the desired concentration and degassed for another 30 sec. The presence of Zn in the supporting electrolyte was confirmed and quantified by spiking with a $0.1M$ $ZnSO_4$ solution and use of a built-in standard addition program.

Gallium was preconcentrated on the mercury drop at different constant deposition potentials (E_d) and for different deposition times (t_d) with constant solution stirring. This was followed by a 5-sec rest period prior to stripping, which was carried out by using square-wave voltammetry with a 100 Hz 2 mV step. Peak stripping currents (i_p) were automatically measured by a tangent fit program and the peak potentials (E_p), referred to the SSCE, were also recorded.

The dispensing and dislodging of single mercury drops was obtained under manual control with the additional toggle switch and the dislodge-adjustment knob at the rear of the 303A electrode.

RESULTS AND DISCUSSION

Reproducibility

After several deposition–stripping cycles had been run with the same gallium solution, each on a different mercury drop, an apparent stabilization of the stripping current was obtained. Ten successive cycles performed from that point on provided the results for reproducibility.

Experiment *A* in Table 1 allowed the accumulation of mercury drops on the cell bottom, which was apparently accompanied by a gradual decrease in average stripping current, possibly because of a progressive change in stirring efficiency. Experiment B, however, was performed with evacuation of the mercury drops into the side-arm between each run. This meant that the cell position on the magnetic stirrer was not exactly the same for each run. The results show a higher average stripping current, presumably because of more efficient stirring. The poorer reproducibility is probably due to the use of a star-shaped stirrer bar which does not spin around a single axis but tends to precess in a fashion which is irreproducible and very dependent on the stirrer position. The smaller relative standard deviation (rsd) in experiment *A* was due to more reproducible stirring, since the cell position was not altered between runs. The difference between the currents for the first drop in experiments A and B could be due to the larger rsd of the latter.

Several trial experiments starting with a fresh charge of mercury in the 303A electrode always showed an initial steady increase in stripping current for successive runs on the same solution, in spite of the use of a new drop for each cycle. This was further investigated by using a more negative deposition potential which also allowed the deposition of any zinc present in the supporting electrolyte. Figure 1 shows that the gallium (a) and zinc (b) stripping currents gradually increase with run sequence, but tend to level off. A plot of the ratio of the gallium and zinc stripping currents (c) shows a fairly constant value, with a 3% relative standard

deviation. This suggests that the phenomenon responsible for the curvature in (a) and (b) is not specific for gallium.

Our first concern was whether successive mercury drops differed in area. An experiment was run in which each mercury drop was collected and weighed after stripping. The results in Table 2 show that the stripping current increases at a rate much greater than the electrode area, which eliminates changes in electrode size as an explanation for the results in Fig. 1.

A more likely cause could be the presence of residual metals (zinc or gallium) remaining in the mercury drop electrode, owing to incomplete stripping. After one deposition step on a small drop, several consecutive strippings were run on the same drop. The results in Fig. 2 show the change in zinc (a) and gallium (b) stripping currents with stripping sequence. A gradual decrease was observed for zinc whereas an abrupt current drop was obtained for gallium. This is consistent with the zinc diffusion coefficient in mercury being higher than that for gallium.[7b] The non-zero and constant stripping current is due to deposition occurring during the time elapsed in going from the initial potential to the stripping potential during the stripping step, even in the absence of any programmed deposition step. These results suggest that some residual metals may be present in the mercury. However, the 303A electrode will dispense and dislodge two mercury drops between runs and any metals remaining in the first drop after a stripping cycle should be flushed away. The question, therefore, is whether the metals could have diffused into the mercury thread in the capillary, as reported by Neeb *et al.*[17]

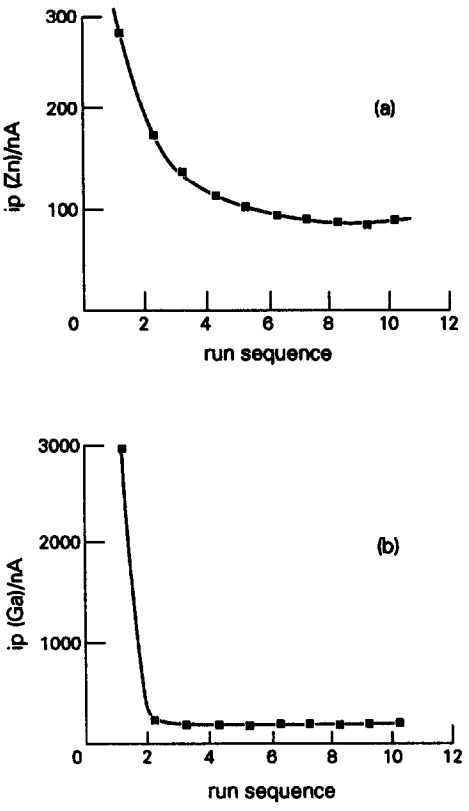

Fig. 2. Zinc (a) and gallium (b) stripping currents after a single deposition step on a single mercury drop (small size) as a function of consecutive stripping steps on the same drop. [Ga] = $2 \times 10^{-6}M$; [Zn] = $1.3 \times 10^{-7}M$; $t_d = 360$ sec; $E_d = -1.100$ V; slow stirring rate.

*Electrode area (S) was obtained from $S = 0.8505\ W^{2/3}$, where W is the drop weight in mg.

An experiment consisting of a single deposition step followed by successive strippings from the end of the capillary after consecutive drops had been dislodged was run in order to detect any concentration profile in the mercury capillary. Figure 3 shows the results obtained for zinc (a) and gallium (b) stripping peaks. The maximum observed after drop number five was dislodged proves that back-diffusion occurs.

Now we can explain the results in Fig. 1. When starting with a fresh mercury electrode, there is always a certain amount of metal (zinc or gallium) lost during the deposition step due to diffusion into the mercury capillary thread. This is maximal when the mercury thread is free from metals (zinc or gallium in this case), *i.e.*, when the concentration gradients that develop are maximal. After the first deposition–stripping cycle is completed, a fraction of the deposited metal remains in the mercury thread, although two mercury drops have been dispensed and

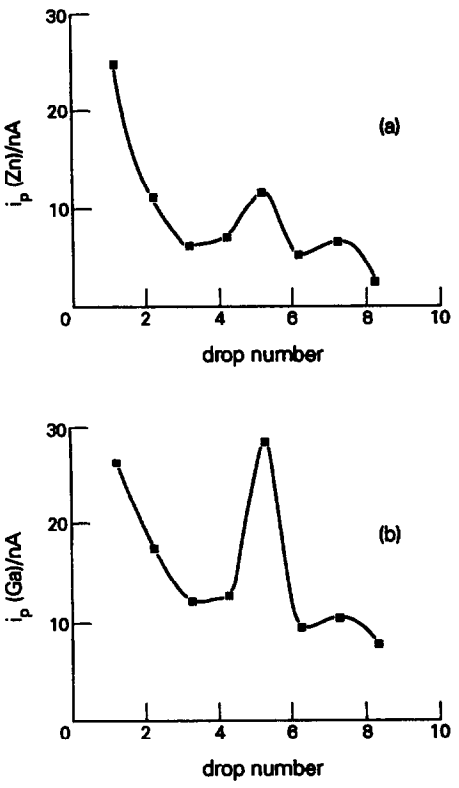

Fig. 3. Zinc (a) and gallium (b) stripping currents after a single deposition step as a function of drop sequence after drop dislodgement. [Ga] = $2 \times 10^{-6} M$; [Zn] = $1.3 \times 10^{-7} M$; t_d = 360 sec; E_d = −1.100 V; slow stirring rate.

dislodged. Therefore, the loss of metal due to back-diffusion is lower during the next cycle because the concentration gradient along the capillary is lower, and a higher stripping current is observed. An equilibrium between the amount of metal being deposited and the amount of metal lost can eventually be obtained after several consecutive runs, leading to a constant stripping current.

The appearance of the maximum shown in Fig. 3 can be explained as follows. The dimensions of the capillary of the 303A instrument, as reported by the manufacturer, are length 12.7 cm, internal diameter 0.15 mm, giving a volume of 2.24 mm^3 for the mercury thread. As the volume of a medium size drop (2 mm^2 surface area) is 0.26 mm^3, the capillary can hold the equivalent of almost nine drops of this size. The consequence of back-diffusion of deposited metal into the mercury thread from the mercury drop will be an exponential-type profile for the metal concentration in the thread. During the stripping step a corresponding profile will develop in the opposite direction in the thread, resulting in a maximum in the concentration distribution along the capillary. When a new mercury drop is extruded, this maximum will move along the capillary in the direction of the drop. Its relative position in the thread (and hence the drop number at which it reaches the end of the capillary) will depend on a number of time-dependent factors.

Drop size

The effect of drop size on the magnitude of the stripping current when back-diffusion occurs cannot be easily predicted. The results in Table 3 were obtained with a fresh mercury electrode and with this condition the currents are not maximal. However, the observed trend is that higher currents are obtained with smaller drops. A common mistake, which can even be found in the manufacturer's 303A operating manual, is to think that sensitivity varies directly with drop area. On the contrary, a simple theoretical analysis based on the following equations

$$V = (4/3)\pi R^3;\ S = 4\pi R^2;\ C = \frac{I_l t_d}{nFV};\ I_l = kS$$

leads to the conclusion that the metal concentration C obtained in a spherical mercury drop of radius R, surface area S and volume V, during a deposition time t_d under conditions of constant limiting current I_l will be proportional to $1/R$. However, the impact of loss by back-

diffusion on the metal concentration in the mercury drop is higher for a smaller drop because the ratio of capillary cross-sectional area to drop volume is higher.

The results in Table 3 show that higher stripping currents were observed with smaller drops, *i.e.*, the effect of a higher area/volume ratio predominated over the increased loss by back-diffusion.

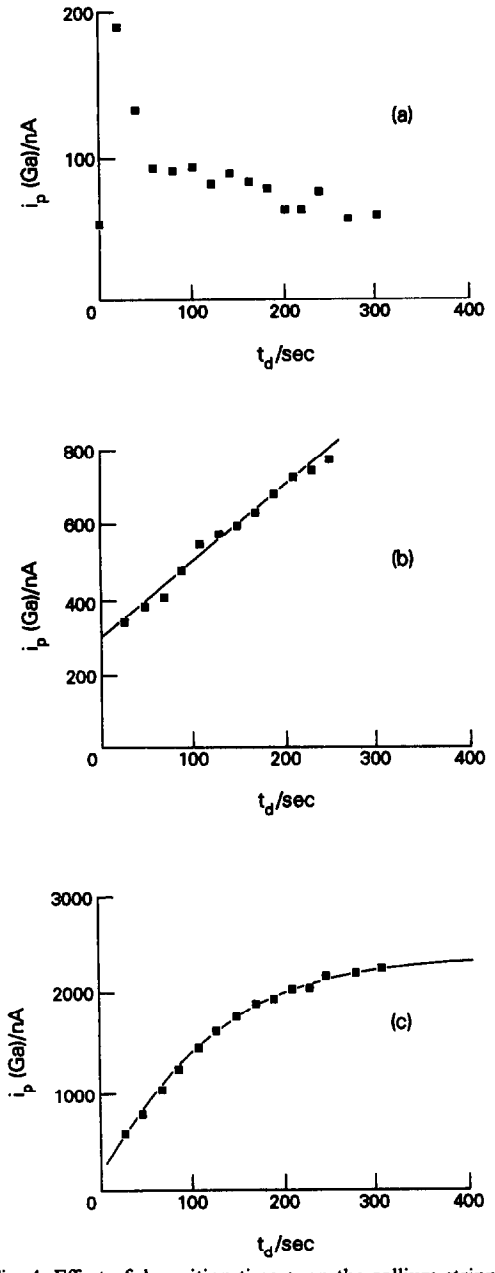

Fig. 4. Effect of deposition time t_d on the gallium stripping current for (a) $10^{-7}M$ (b) $2 \times 10^{-7}M$ and (c) $5 \times 10^{-7}M$ gallium. [Zn] = $1.3 \times 10^{-7}M$; $E_d = -0.900$ V; medium size drop; slow stirring rate.

Deposition time

Experiments were performed in order to determine the effect of deposition time (t_d) on the gallium stripping currents at different concentration levels. Figure 4 shows three different types of behaviour. For the lowest gallium concentration (a), an initial current rise is followed by a gradual decay for longer times. This is due to use of a deposition potential ($E_d = -0.900$ V) only slightly more negative than and too close to the rest potential for that particular concentration. After the first amount of gallium is deposited, a gallium amalgam is formed, resulting in a negative shift of the rest potential so that no further deposition occurs. The gradual decay in stripping current is a consequence of increasing loss by back-diffusion with time.

For the medium gallium concentration (b), the rest potential is more positive, so that deposition is not interrupted and an almost ideal linear dependence is observed. Deposition times longer than those plotted result in a negative deviation. The positive intercept is due to the amount of gallium deposited, even for a programmed deposition time $t_d = 0$, during the time elapsed from the start of the stripping cycle (E_i) to the point of actual stripping.

For the highest gallium concentration (c), the plot increases non-linearly and then tends to level off. This is due to increasing loss by back-diffusion as the metal concentration builds up in the mercury drop. For sufficiently long deposition times, the stripping current becomes independent of deposition time as a steady state between the rate of deposition and rate of back-diffusion is reached.

From these experiments we concluded that a more negative deposition potential ($E_d = -1.100$ V instead of -0.900 V) and a deposition time at the plateau ($t_d = 360$ sec) should be used.

Calibration graphs

The effect of gallium concentration on the stripping current was explored from 10^{-8} to $10^{-5}M$ and is shown in Fig. 5(a) and (b). No change in peak shape with concentration was detected in this range. Figure 5(a) shows a linear calibration plot for the range $3–10 \times 10^{-7}M$ but curving at lower concentrations. No stripping current was observed for concentrations lower than $2 \times 10^{-7}M$. We found later that this was due to the presence of zinc in the electrolyte.

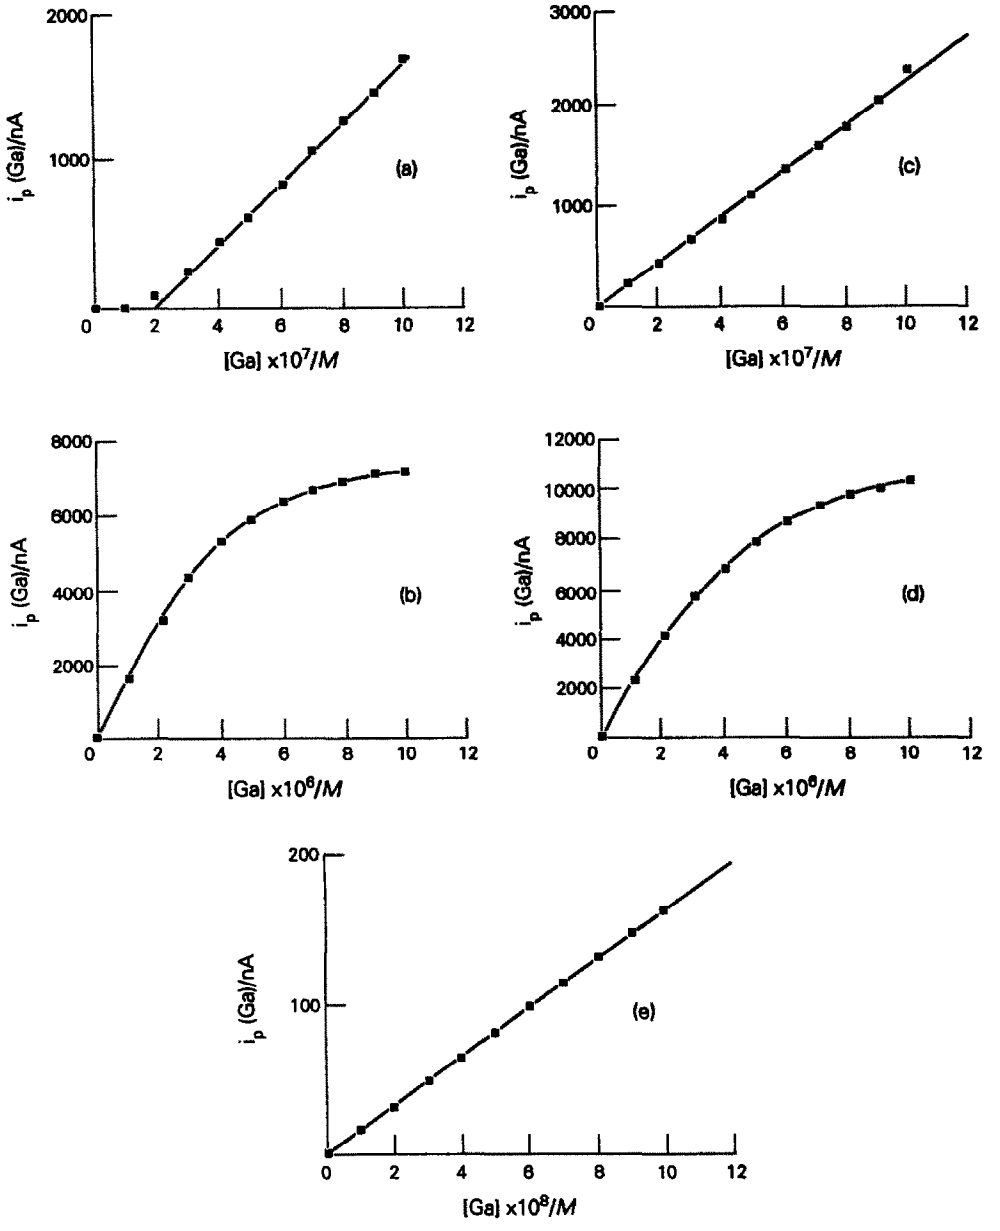

Fig. 5. Effect of gallium concentration on the gallium stripping currents in the absence (a, b) and presence (c, d, e) of $10^{-5}M$ Sb(III). $t_d = 360$ sec; $E_d = -1.100$ V; small drop size; slow stirring rate.

Similar curvature had previously been described but no explanation was given.[10] A higher concentration range of $1–10 \times 10^{-6}M$ is shown in Fig. 5(b), where the calibration plot is linear up to $2 \times 10^{-6}M$, with a negative deviation at higher concentrations. This resembles the curvature in Fig. 4(c) for long deposition times. Again this is due to loss by back-diffusion. The higher the gallium bulk concentration, the higher the concentration gradient that develops within the mercury, with a consequently greater loss of gallium. For sufficiently high bulk concentrations, the stripping current will eventually become independent of gallium concentration as a balance between the rates of deposition and back-diffusion is reached.

A study of different metal interferences[18] showed that some degree of "current enhancement" was obtained in the range $10^{-8}–10^{-7}M$ for gallium stripping currents in the presence of a tenfold molar ratio of Sb(III) to Ga(III). Calibration curves were obtained in the presence of $10^{-5}M$ Sb(III), as in Fig. 5(c)–(e). Stripping currents were detected down to $10^{-8}M$ and, as shown in Fig. 5(c), a straight line which goes through the origin was obtained for the range

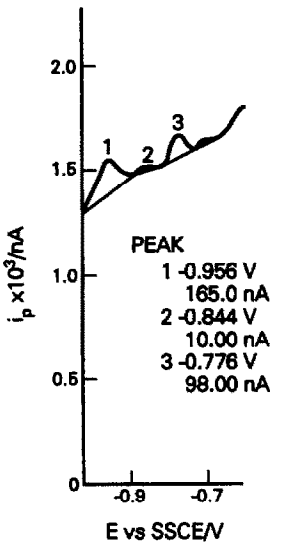

Fig. 6. Stripping peaks for gallium ($E_p = -0.776$ V), zinc ($E_p = -0.956$ V) and Zn–Ga intermetallic compound ($E_p = -0.844$ V) in a $0.5M$ NaSCN + $4.2M$ $NaClO_4$ supporting electrolyte (pH 2.0) containing $3.2 \times 10^{-7}M$ gallium and $1.3 \times 10^{-7}M$ zinc; $t_d = 150$ sec; $E_d = -1.030$ V; small drop size; slow stirring rate.

$1–10 \times 10^{-7}M$, in contrast to Fig. 5(a). Figure 5(d) shows a plot for the range $1–10 \times 10^{-6}M$ very similar to that in Fig. 5(b), although the stripping currents are somewhat higher. A straight line was also obtained for the range $1–10 \times 10^{-8}M$, as shown in Fig. 5(e), provided that the gallium stripping currents were previously normalized with the zinc stripping peak as an internal standard (thus correcting for minor differences in stirring rate) and a blank subtraction was applied.

Zn–Ga versus Zn–Sb intermetallic compounds

The absence of stripping currents for gallium concentrations below $2 \times 10^{-7}M$, the curvature in Fig. 5(a) and the effect of Sb(III) led us to the conclusion that zinc present in the supporting electrolyte was responsible for this behaviour. Even if a deposition potential was chosen so that no zinc was deposited, its interfering action persisted. If the Zn:Ga concentration ratio in solution and the deposition potential E_d were carefully adjusted (Fig. 6), an intermediate peak between the gallium (−0.776 V) and zinc (−0.956 V) stripping peaks was observed. This intermediate peak was not observed if an excess of either zinc or gallium was present.

Experiments were performed with a $0.5M$ NaSCN + $0.85M$ $NaClO_4$ electrolyte. The lower $NaClO_4$ concentration results in a lower zinc concentration and residual current. Figure 7 shows the observed stripping peaks for different deposition potentials, E_d. For $E_d = -1.000$ V, no zinc (−0.990 V) was deposited and only the gallium stripping peak (−0.798 V) was observed (a). For $E_d = -1.030$ V, an intermediate stripping peak was observed at −0.896 V and the gallium peak was somewhat lower (b), but no zinc deposit was observed. When E_d was

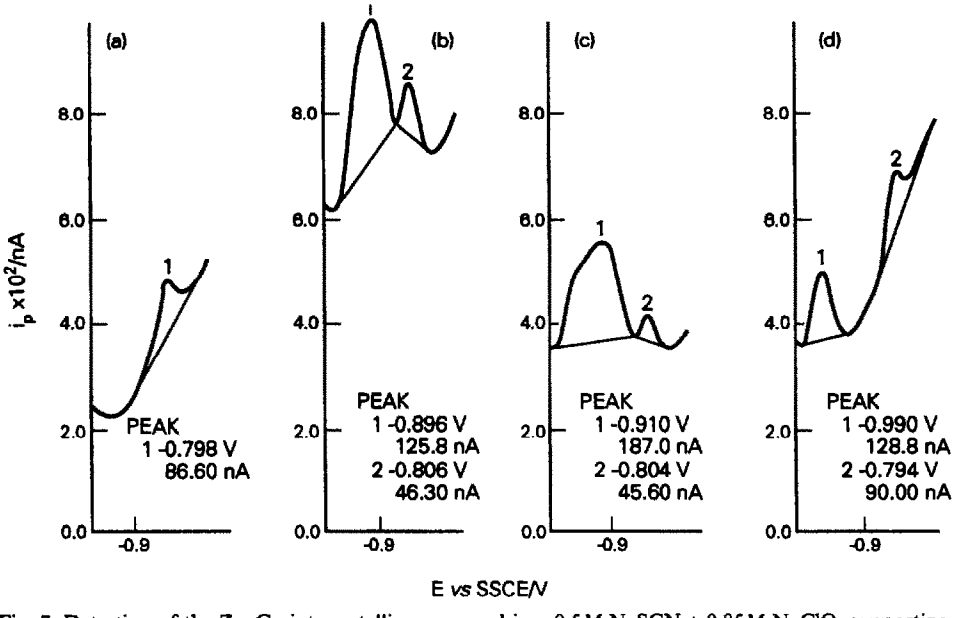

Fig. 7. Detection of the Zn–Ga intermetallic compound in a $0.5M$ NaSCN + $0.85M$ $NaClO_4$ supporting electrolyte (pH 2.0) containing $10^{-7}M$ gallium and $2.5 \times 10^{-8}M$ zinc by adjusting the deposition potential (E_d) to (a) −1.000, (b) −1.030, (c) −1.050 and (d) −1.060 V. $t_d = 360$ sec. Medium drop size; slow stirring rate.

-1.050 V, the intermediate peak was still observed at a slightly more negative potential (-0.910 V), while a shoulder corresponding to the zinc stripping appeared at a more negative potential (c). With $E_d = -1.060$ V, the intermediate peak was no longer observed and the zinc and gallium stripping peaks were completely resolved (d). The observed intermediate peak is attributed to a Zn–Ga intermetallic compound. As the deposition potential was made more negative, the Zn:Ga concentration ratio in the amalgam increased, until the stoichiometric ratio for the intermetallic compound was obtained and a distinct peak was observed, as in Fig. 7(b). For more negative potentials, zinc in excess of the stoichiometric ratio was deposited and the intermetallic compound was no longer detected, as in Fig. 7(d). Attempts to avoid the formation of the Zn–Ga intermetallic compound by using $E_d = -1.000$ V, at which no zinc deposit was detected, rather than $E_d = -1.1$ V [as used for Fig. 5(a)] did not produce a zero intercept. This is an indication that the intermetallic compound was being deposited at a lower potential close to that of gallium.

An estimate of the Zn–Ga intermetallic compound stoichiometry can be inferred from Fig. 5(a), which is equivalent to a titration curve with an equivalence point at $2 \times 10^{-7}M$ Ga(III) for a $1.25 \times 10^{-7}M$ Zn(II) concentration. If the Zn^{2+} concentration in the electrolyte was increased by spiking with a $10^{-4}M$ stock solution, the equivalence point was observed at a higher Ga(III) concentration. If the metal concentrations in the amalgam are assumed to be proportional to their bulk solution concentrations, Zn:Ga = 2:3 is obtained for the intermetallic compound. This kind of titration has been applied for determining the stoichiometry of a Ga–Ni intermetallic compound.[13]

The Zn–Ga intermetallic compound will hinder gallium detection at low concentrations in electrolytes containing Zn(II). However, the addition of Sb(III) to a Zn(II)-containing electrolyte will destroy the Zn–Ga intermetallic compound by formation of the well-known Zn–Sb intermetallic compound, which has a higher formation constant.[7c]

$$Zn_2Ga_3 + 2Sb \rightarrow 2ZnSb + 3Ga$$

This explains why gallium concentrations down to $10^{-8}M$ could be detected, as shown in Fig. 5(e), and linear calibration plots were obtained [Fig. 5(c) and (e)] for 10^{-8}–$10^{-6}M$ Ga in the presence of added Sb(III).

The destruction of the Zn–Ga intermetallic compound by Sb was confirmed by performing a plating–stripping cycle with and without added Sb(III) in a $10^{-7}M$ gallium solution in a Zn(II)-containing electrolyte. Figure 8(a) shows the intermetallic compound stripping peak at -0.884 V, together with the gallium stripping peak at -0.804 V in the absence of Sb(III). The addition of $10^{-5}M$ Sb(III) completely suppressed the Zn–Ca intermetallic compound peak while the gallium peak was enhanced as shown in Fig. 8(b).

Attempts to obtain a completely Zn(II)-free supporting electrolyte by constant-potential electrolysis on a mercury cathode or by using glass-immobilized 8-hydroxyquinoline[14] either failed or proved to be too time-consuming. The effect of adding Sb(III) to Zn(II)-containing supporting electrolytes appears to be a very simple and attractive alternative for overcoming interference by zinc. Zn–Ga intermetallic compound formation and its interfering action are thus suppressed.

CONCLUSIONS

Better reproducibility can be obtained with an aged rather than a fresh 303A mercury drop

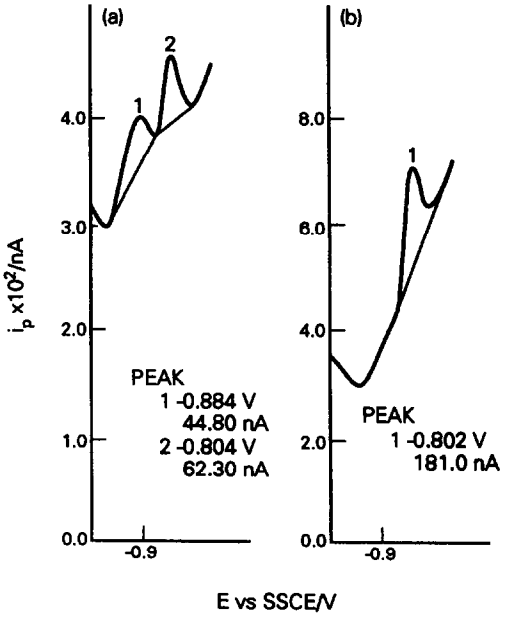

Fig. 8. Detection of the Zn–Ga intermetallic compound in a $0.5M$ NaSCN + $0.85M$ $NaClO_4$ (pH 2.0) supporting electrolyte containing $10^{-7}M$ gallium and $2.5 \times 10^{-8}M$ zinc (a) without Sb(III) and (b) with $10^{-5}M$ Sb(III). $t_d = 360$ sec; $E_d = -1.020$ V; medium drop size; slow stirring rate.

electrode, because of the problem of back-diffusion. The use of a standard addition method is recommended over the use of calibration plots. If a deposition potential, E_d, of -1.100 V is used, the simultaneous deposition of Zn and Ga will allow the use of the zinc stripping peak as an internal standard. This is especially useful in the lower concentration range $1–10 \times 10^{-8}M$, which will give linear calibration plots if an excess (*e.g.*, $10^{-5}M$) of Sb(III) is added. The formation of a Ga:Zn = 3:2 intermetallic compound has been recognized as the cause of the Zn interference, but it can easily be eliminated by addition of Sb(III) to the Zn(II)-containing electrolyte. The choice of a deposition potential of -1.000 V, although it would prevent the deposition of Zn metal, does not prevent deposition of the Ga–Zn intermetallic compound.

A deposition time, t_d, of 360 sec has been found appropriate for the range 1×10^{-8}–$2 \times 10^{-6}M$ and the use of a small mercury drop rather than a medium or large size drop, gives the highest sensitivity and lowest residual currents.

A FIELD-INDUCED POISING TECHNIQUE FOR PROMOTING CONVERGENCE OF STANDARD ELECTRODE POTENTIAL VALUES OF THERMALLY OXIDIZED IRIDIUM pH SENSORS

MICHAEL L. HITCHMAN* and SUBRAMANIAM RAMANATHAN†

Department of Pure and Applied Chemistry, University of Strathclyde, 295 Cathedral Street, Glasgow, G1 1XL, U.K.

(*Received* 18 *June* 1991. *Revised* 17 *July* 1991. *Accepted* 17 *July* 1991)

Summary—An electrochemical technique based on reversible charge ejection/injection is shown to be an effective procedure for bringing about the convergence of standard electrode potential values in a batch of thermally prepared iridium oxide pH sensors. Such a convergence simplifies electrode calibration procedures. The rationale for the technique and the results obtained are discussed in terms of adjustment of the proportions of iridium(III) and iridium(IV) oxides at the electrode surface.

In an investigation of thermally oxidized iridium electrodes for pH monitoring we noticed that a batch of electrodes, prepared at the same time and under the same conditions, showed a wide variation in equilibrium potential values (*e.g.*, as much as 120 mV) in aqueous buffer solutions even though their potential–pH responses were all essentially Nernstian (*i.e.*, 59 mV/pH). When the electrodes were subjected to highly corrosive acid electrolytes[1] or high temperature buffer solutions[2] the effect could be even more pronounced. Furthermore, we found that the time for any given electrode to reach a stable equilibrium potential value in an aqueous buffer also showed a large variation, *e.g.*, from a matter of hours to many days. This state of affairs is clearly quite unsatisfactory if solid state sensors such as iridium oxide electrodes are to be used routinely for pH monitoring because of the need for each individual electrode to be calibrated frequently. Of course, a batch of glass electrodes is also known to have a spread of equilibrium potential values, particularly if the batch comprises sensors from different manufacturers. However, for a batch from the same supplier, modern manufacturing techniques ensure close agreement between electrodes (*e.g.*, usually within a few millivolts) and certainly settling down times are rapid (*e.g.*, typically within a few minutes after immersing in a buffer solution).[3] Therefore, if thermally prepared iridium oxide electrodes are to be considered as robust sensors for pH monitoring it is obviously desirable that interelectrode agreement and stabilization times be improved so that calibration procedures are simplified.

In our studies of iridium oxide electrodes prepared by potential cycling[4,5] we have reported that the apparent standard electrode potential of such electrodes is very dependent on whether the electrode surface is left in an "oxidized" or "reduced" state immediately prior to measurements in aqueous buffer solutions; here "oxidized" means the electrode potential was scanned to the anodic voltammetric peak observed in 0.5*M* sulphuric acid while "reduced" indicates that the scan was terminated at a cathodic potential corresponding to the onset of hydrogen evolution. It thus occurred to us that closer agreement between equilibrium potentials for different thermally oxidized electrodes in the same buffer solutions could be achieved by adjusting the state of oxidation of the electrode surfaces and hence the apparent standard electrode potentials. From our experience with the potential cycled electrodes we would also expect this to lead to better control of stabilization times.

In this paper we consider the mechanism of pH response that could be operating for thermally oxidized iridum electrodes and we report on a field-induced poising technique for the enhancement of the behaviour of thermally oxidized electrodes for use as pH sensors.

EXPERIMENTAL

Iridium oxide electrodes were made from iridium wires of length 1 cm, diameter 0.5 mm and purity 99.9% (Goodfellow Metals). An electroactive coating was formed by soaking the wire in $2M$ sodium hydroxide and then heating the wetted wire at 800° in a furnace for 30 min.[6] This process was repeated three times in order to obtain a uniform blue-black coating. The electrode was then cooled in air and immersed in doubly distilled water for two days. This step ensured that the iridate coating formed by the thermal treatment was converted to iridium oxide. A small area of the oxide coating was then scraped off at one end of the wire in order to expose the base metal and on to this a length of platinum wire (Johnson Matthey Chemicals Ltd.) was spot welded to form an ohmic contact. This junction as well as the platinum wire was encapsulated with heat-shrink PTFE tubing (Farnell Electronics) such that only the iridium oxide surface was exposed to the solution. When not in use the electrode was stored in distilled water.

All reagents used were of AnalaR grade and solutions were made up in water which had been twice distilled in glass. Buffers were prepared according to standard recipes.[7] The pH values of the buffers were checked with a glass electrode calibrated in Corning precision buffers with pH values of 4.000 and 7.000.

A Corning 150 pH/ion meter was used for potentiometric measurements. It had an impedance of $10^{12}\ \Omega$ and the current drawn was typically 1 pA. A voltage output from the pH meter was fed to a Keithley Model 175 DVM which was used for logging the potentiometric data. A PAR model 363 potentiostat/galvanostat, controlled by a PAR model 175 universal programmer, was used for electrochemical charge injection and ejection treatment of the electrodes with an appropriate waveform. Cyclic voltamperograms were recorded on a Houston Omnigraphic 2000 X-Y plotter.

An Ingold combination glass electrode containing $3M$ potassium chloride and saturated with silver chloride was used to check the pH of the buffer solutions. An Ingold double junction saturated calomel electrode (SCE) containing saturated potassium chloride as inner electrolyte and potassium nitrate as outer electrolyte was used to provide a stable reference potential during open circuit potential measurements of the iridium oxide electrodes in buffer solutions. During cyclic voltammetric experiments and charge injection and ejection treatments the outer electrolyte was the same as that in the cell.

Two principal procedures were used for investigating the behaviour of the thermal iridium oxide electrodes. The first procedure was that associated with the study of the mechanism of pH response of the electrodes. For this a three electrode configuration was used with a thermal oxide as the working electrode, an iridium counter electrode and the SCE reference described above. Initially the open circuit potential in $0.5M$ sulphuric acid was allowed to stabilize and then a voltage ramp with a sweep rate of 1 mV/sec was used to perturb the oxide/electrolyte interface with either an anodic or cathodic sweep. At the end of the potential sweep the oxide electrode was disconnected from the potentiostatic circuit and its open circuit potential was monitored in the same electrolyte for one hour. For this part of the investigation four electrodes which had previously been used in various electroanalyses,[1,2] and which showed a wide span of equilibrium potentials for identical measuring conditions, were selected.

The second procedure, used for promoting the convergence of apparent E^0 values, was similar to the first procedure in that oxide electrodes in a three electrode configuration were treated with a voltage sweep of 1 mV/sec from the rest potential in $0.5M$ sulphuric acid. Here, though, the end potential was always 600 mV *vs.* SCE; the reason for choosing this potential is discussed below. The same four electrodes as used in the first procedure were again used. For some experiments the effect of a period of potential holding at the end of the sweep was explored. In all cases after the potential treatment the open circuit potential of the electrode was monitored in pH 4 buffer.

All measurements were made at $25 \pm 0.1°$.

RESULTS AND DISCUSSION

Figure 1 shows the variation with time of the apparent standard electrode potentials ($E^{0'}$), as determined from Nernst plots, for four freshly prepared iridium oxide electrodes. The wide range of initial $E^{0'}$ values from $\sim$760 to $\sim$930 mV is apparent as is the very slow drift towards a common value of *ca.* 730 mV. Plot A in Fig. 2 shows the wide spread of equilibrium potential values, from 289 mV to 425 mV, for measurements made in pH 4 buffer with the four

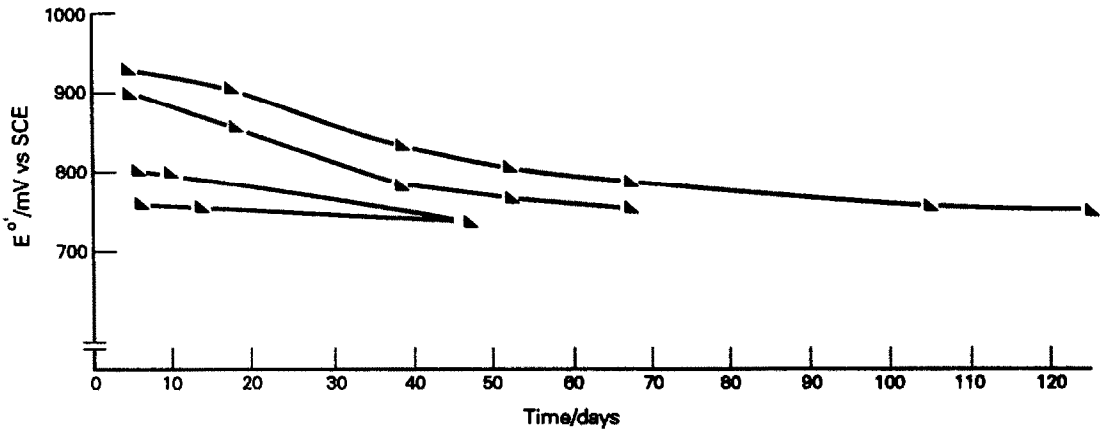

Fig. 1. Variation in apparent standard electrode potentials ($E^{0'}$) with time for thermally oxidized iridium electrodes. Measurements made in buffer solutions pH 2–12.

electrodes which had previously been routinely used in various electroanalyses.[1,2] The corresponding range of $E^{0'}$ values from ~525 to ~661 mV was calculated on the assumption of a 59 mV/pH dependence; such a dependence was always found in this work (*cf.* Table 2) and has been observed by others under a variety of conditions.[8–10] Table 1 gives $E^{0'}$ values which have been calculated from literature data for thermally oxidized iridium electrodes. A wide variation in $E^{0'}$ values is also seen. From these results it is evident that not only is it necessary to individually calibrate electrodes when they are used initially, but also over a long period of time due to the slow drift in $E^{0'}$ values. It is significant in this context to note that the $E^{0'}$ values for the four freshly prepared electrodes all tend to the same value with time, and this leads one to consider what is occurring during this period of drift.

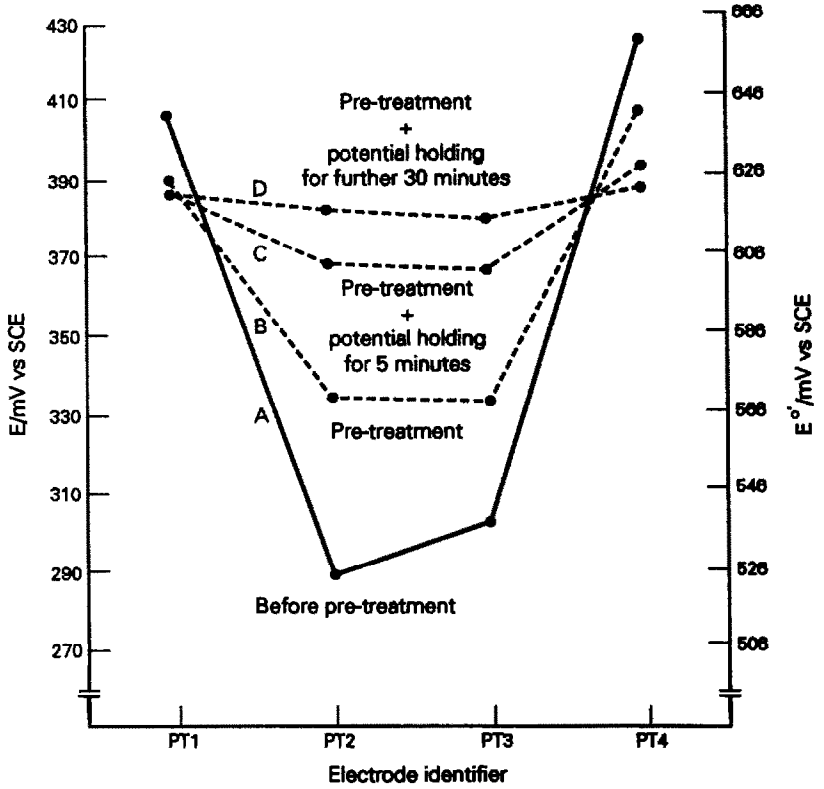

Fig. 2. Equilibrium and apparent standard electrode potential values of electrodes before and after electrochemical pretreatments (cf. Fig. 4).

Table 1. $E^{0'}$ values for thermally oxidized iridium electrodes at 25°

$E^{0'}/mV$ vs. SCE	Remarks	Reference
727.2	Calculated from tabulation of E vs. pH results	6
672.3	Calculated from data at 4°. A temperature coefficient of −1.27 mV per °C was assumed	8
618.7	Calculated from open circuit potential response at pH 6.84 and pH 7.38 at 37°. A temperature coefficient of −1.27 mV per °C was assumed	9
516.7	Interpolated from E vs. pH graph	10

Pourbaix[11] gives three equilibria involving iridium oxide and protons:

$$Ir_2O_3 + 6H^+ + 6e^- \leftrightharpoons 2Ir + 3H_2O \quad (1)$$

$$IrO_2 + 4H^+ + 4e^- \leftrightharpoons Ir + 2H_2O \quad (2)$$

$$2IrO_2 + 2H^+ + 2e^- \leftrightharpoons Ir_2O_3 + H_2O \quad (3)$$

For each of the three reactions it is apparent that there would be a Nernstian response of 59 mV/pH but what is a little surprising is that the theoretical standard electrode potential given by Pourbaix for each equilibrium is also identical with a value of 681 mV *vs.* SCE. Which of the three equilibria is responsible for the pH response of thermally oxidized iridium electrodes is therefore not immediately obvious. Macur[6] has proposed that reactions (1) and (2) are both involved while Papeschi *et al.*[8] have proposed reaction (2) as the potential determining equilibrium. Other workers though, notably Burke *et al.*,[12] Ardizzone *et al.*[13] and Kinoshita and Madou,[14] all using iridium oxide deposited on a titanium substrate, have suggested that reaction (3) is the dominant equilibrium. On purely theoretical grounds the equilibrium with the highest exchange current density would be expected to be the dominant one, but for equilibria with comparable degrees of reversibility mixed control of the rest potential could be expected. However, on more empirical grounds the fact that the thick oxide formed on iridium by thermal oxidation is known to be a highly impervious overlayer[6] would suggest that the involvement of the underlying metal in an equilibrium with protons in solution would be more unlikely. Therefore reactions (1) and (2) are not likely to be significant contributors to the rest potential and we concentrate solely on reaction (3).

Table 2. Nernstian slopes for thermally oxidised electrodes before and after electrochemical pretreatment

Electrode number	Nernstian slope, *mv/pH*	
	Before pretreatment	After pretreatment
PT1	59.0	58.8
PT2	58.0	58.2
PT3	58.4	58.7
PT4	59.2	59.1

The dependence of the equilibrium potential on the activities of the various species in reaction (3) can be represented by

$$E = E^0 + \frac{2.303RT}{2F} \log_{10} \frac{[IrO_2]^2 [H^+]^2}{[Ir_2O_3]} \quad (4)$$

or, in terms of pH, by

$$E = E^0 + \frac{2.303RT}{2F} \log_{10} \frac{[IrO_2]^2}{[Ir_2O_3]} - 0.591 \text{ pH}$$

$$= E^{0'} - 0.0591 \text{ pH} \quad (5)$$

The Nernstian dependence of potential observed under a variety of conditions[2,8–10] is clearly in accord with equation (5). However, what can also be seen is that the apparent standard electrode potential $E^{0'}$ obtained by extrapolation of the Nernst plot to pH = 0 will depend on the relative mole fractions of Ir(IV) and Ir(III) oxides. This is analogous to the mixed oxidation states one gets with anodically oxidized iridium electrodes[5] and with hydrogen tungsten bronzes.[15] It now becomes apparent why a wide range of $E^{0'}$ values is found for thermally oxidized iridium electrodes where there has been no careful control over the degree of oxidation. It is interesting to note in this context that in Fig. 1 all of the initial values of $E^{0'}$ are higher than the final values. Although there was no careful control of the extent of oxidation of the iridium, nevertheless the strong oxidizing conditions would suggest a greater tendency to form the Ir(IV) oxide than the Ir(III) oxide. Therefore any subsequent adjustment in solution of the ratio of the two oxides present in the surface of the oxide film to achieve equilibrium values would be expected, according to equation (5), to lead to a diminution of $E^{0'}$. If this hypothesis is true then any deliberate redistribution of the relative activities of the two oxide species in an oxidized layer would be expected to shift the value of $E^{0'}$ and hence the measured value of an equilibrium potential. Using the first electrochemical procedure described above an electrode with a rest potential of 549.6 mV in 0.5*M* sulphuric acid

was anodically oxidized to 700 mV. The rest potential of 658 mV of the electrode in 0.5*M* sulphuric acid after this treatment was more positive, as would be expected if the proportion of IrO_2 in the oxide layer had been increased. Conversely, an electrode with an initial rest potential of 621.5 mV in 0.5*M* sulphuric acid had a rest potential of 511.8 mV after a cathodic sweep to 470 mV, *i.e.*, a more negative value as would be expected if the amount of Ir_2O_3 had been increased. Thus the ejection of charge from or injection of charge into a thermally oxidized iridium electrode with corresponding anodic or cathodic conversion of the oxide layer, together with the previously noted imperviousness of such a layer, would seem to support the mixed oxidation state hypothesis for a mechanism of pH response, similar to that found previously for hydrous oxide electrodes.[5] Other explanations for the behaviour of oxide electrodes have been suggested by Fog and Buck,[16] but they concluded that the "pronounced potential drifts in the presence of redox reagents seem to show that a variable composition (non-stoichiometry) of the solid phases influences the potential..." and this is consistent with our observations and hypothesis. A more direct technique, such as XPS as used by Hall and Sherwood[17] for the study of anodically formed oxides, could possibly help to clarify the mechanism of the field-induced poising technique.

We can now turn to considering the possibility of improving interelectrode agreement and stabilization times for thermally oxidized iridium electrodes. Before doing that, though, one should note a further point about the charge ejection/injection procedure. The mild potential perturbation condition of 1 mV/sec was deliberately chosen to ensure near equilibrium conditions were maintained at the electrode/electrolyte interface and that hydrous oxide formation did not occur.[18] This precautionary measure seemed to have been successful as any significant amount of hydrous oxide formed with involvement of the water in the potential determining equilibrium would have resulted in a super-Nernstian dependence of equilibrium potential on pH.[5] This was not observed after the anodic or cathodic treatment of the two electrodes. The Nernst plots still showed a slope close to 59 mV/pH (*cf.* Table 2).

If we wish to electrochemically pretreat a thermally oxidized iridium electrode in order to improve its comparability to other electrodes and its temporal stability then it would seem appropriate to aim for conditions which would bring about the achievement of the thermodynamic equilibrium ratio of iridium(IV) oxide to iridium(III) oxide. A potential close to the theoretical value of E^0 of 681 mV *vs.* SCE might be expected to be appropriate. The results in Fig. 3 indicate this is not an unreasonable assumption since electrode Y treated with a sweep end potential of 700 mV shows much less potential drift than electrodes X and Z which were treated with end potentials of 800 mV and 100 mV respectively. Further investigations

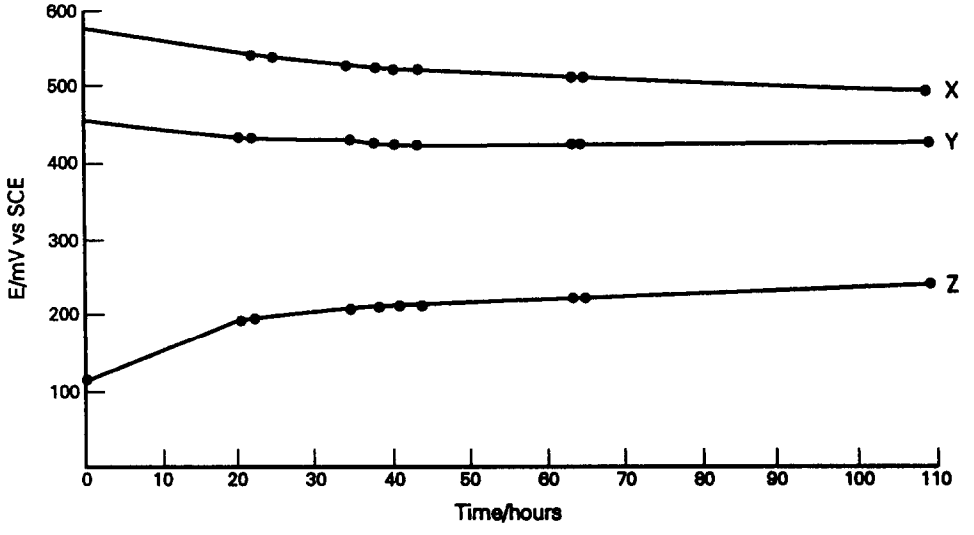

Fig. 3. Open circuit potential decay of electrodes in pH 4 buffer after exploratory pretreatment to different end potentials in 0.5*M* H_2SO_4. X—pretreatment to 800 mV; Y—pretreatment to 700 mV; Z—pretreatment to 100 mV.

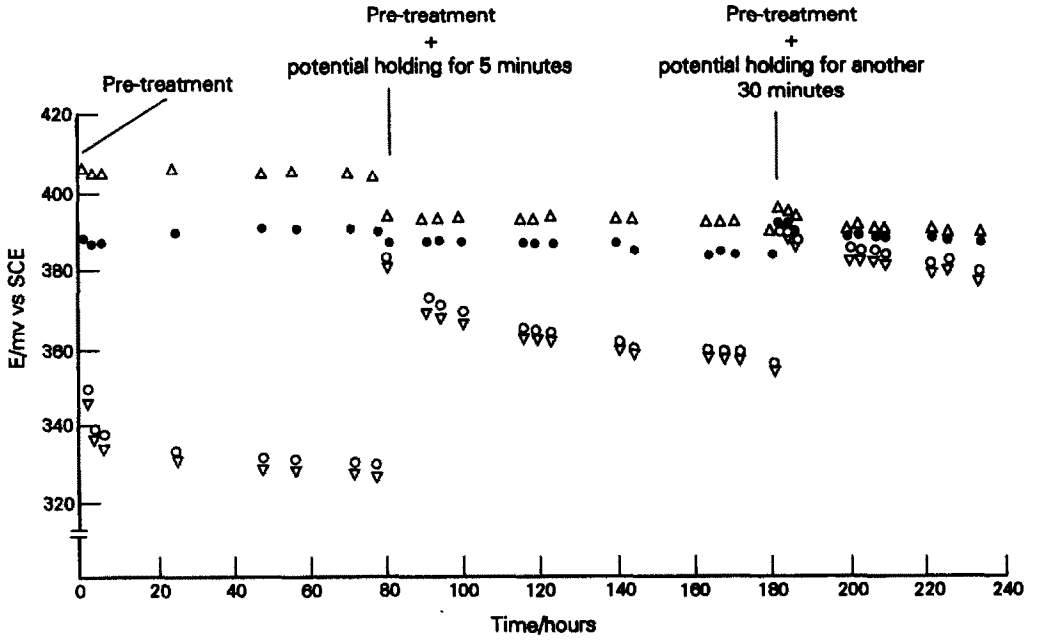

Fig. 4. Open circuit potential decay of electrodes in pH 4 buffer after pretreatment to 600 mV in 0.5*M* H_2SO_4 and different holding times.
● PT1 ○ PT2 ▽ PT3 △ PT4

showed that a sweep end potential of about 600 mV *vs.* SCE for treatment in 0.5*M* sulphuric acid was very effective. Plot B in Fig. 2 shows that electrochemical treatment according to the second procedure described above of four electrodes with initially very disparate values of $E^{0'}$, and hence equilibrium potentials, leads to a greater comparability. A significant reduction in potential drift is also observed (Fig. 4). However, there are still quite significant potential differences between the four electrodes after the slow potential sweep treatment. This probably arises from some degree of kinetic irreversibility associated with the interconversion of the two forms of iridium oxide. Certainly there is some evidence of this when cyclic voltamperograms are run with increasing anodic reversal excursions (Fig. 5). The current does not immediately decay to zero as it would for a truly reversible Faradaic process but instead an anodic current

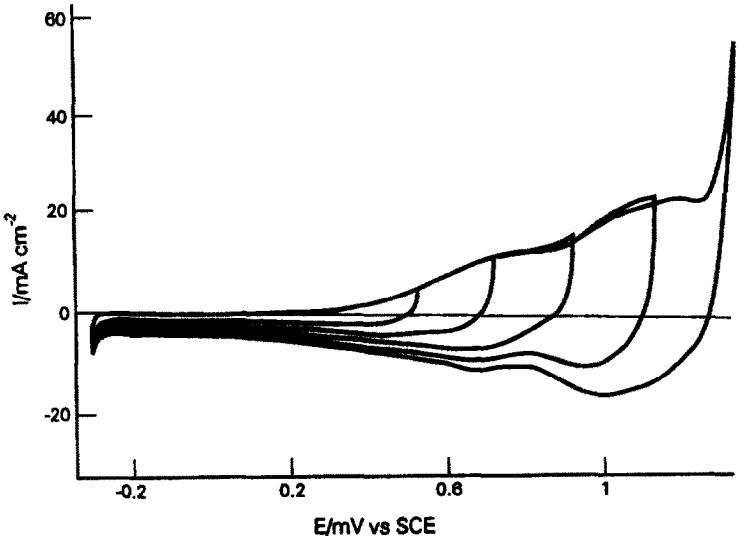

Fig. 5. Cyclic voltammetry of a thermally oxidized iridium electrode in 0.5*M* H_2SO_4. Scan rate 50 mV/sec.

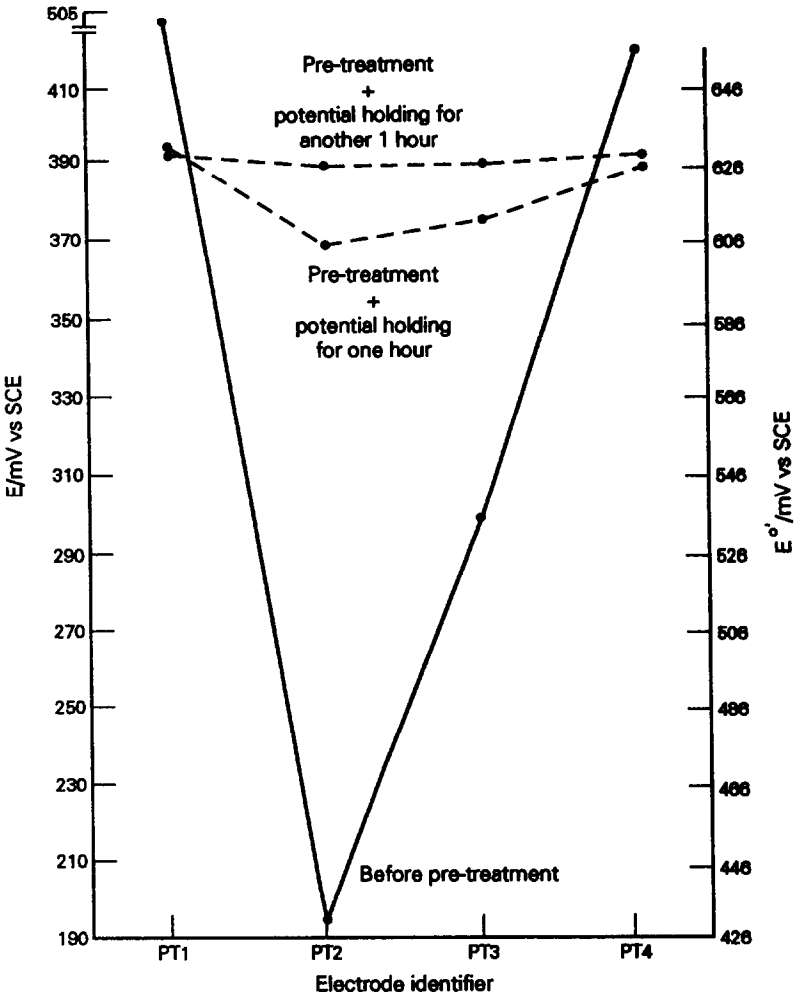

Fig. 6. Equilibrium potential values of electrodes in pH 4 buffer before and after "correcting" pretreatment in 0.5*M* H_2SO_4. Before the "correcting" pretreatment, the electrodes were electrochemically modified with different end potentials: PT1—800 mV; PT2—100 mV; PT3—450 mV; PT4—700 mV. The "correcting" pretreatment was applied with an end potential of 600 mV.

prevails at the initial stages of the cathodic sweep. Therefore it seemed reasonable to assume that a more effective poising of the electrode would be achieved by a potential scan followed by a holding of the end potential. During such potential holdings the current flowing was observed to decay to residual levels and afterwards much closer agreement between both equilibrium potentials and $E^{0'}$ values was found (Plots C and D in Fig. 2). Furthermore, as shown in Fig. 4, the potential drift was reduced to no more than 2–3 mV per day. Figure 6 further illustrates the efficacy of the field induced poising technique for here the four electrodes were first electrochemically treated so that their rest potentials and $E^{0'}$ values were even more divergent than previously. The "correcting" procedure of sweeping to 600 mV and holding was then applied. The very good inter-electrode agreement is apparent. Table 2 shows also that the poising technique, while improving electrode comparability and reducing potential drift, does not disturb the Nernstian $(\partial E/\partial \mathrm{pH})_T$ response of the electrodes.

CONCLUSIONS

We have suggested that the pH response of thermally oxidized iridium electrodes involves an equilibrium between a higher and lower valent oxide. On this basis a simple electrochemical treatment technique has been devised to vary the relative activities of the two oxides and to allow poising of the apparent standard electrode potential at a value close to that of

true equilibrium. Thus the chemical potentials of electrons in the oxide overlayer tend to converge to very similar values in a batch of sensors and comparable pH responses can be achieved. Also because the electrode interface is in a near equilibrium state there is little potential drift over many hours. It may be that an investigation of other treatment potentials and treatment procedures would narrow the spread of equilibrium potential values even further and confer even greater potential stability on the electrodes. It may also be that the poising could be brought about by the choice of a suitable redox couple in solution. Whichever of the three equilibria, reactions (1), (2) or (3), applies, it has to be remembered that they are only half reactions and implicit in any adjustment of equilibrium position is the presence of a redox couple to constitute the other half reaction. The slow potential drifts observed for newly prepared oxide electrodes suggest a rather irreversible redox system with a very low exchange current for electron transfer with the oxide electrodes; a likely candidate would be the water/oxygen couple. A redox system with a higher exchange current might therefore also be suitable to use for poising the electrode potential. However, a redox couple method of poising would probably not be as convenient or as flexible as the field induced poising method which we have described and which does certainly provide the basis for initial quality control of a batch of sensors and also for reducing the need for frequent calibration. It is a technique which could also probably be used for other electrodes with equilibria involving two oxidation states of a solid component.

Acknowledgements—The support of an ORS award for SR is gratefully acknowledged. We are pleased to acknowledge financial support for this work from Ingold Messtechnik AG, and many useful discussions with Drs. R. Bucher and H. Buehler of that company. We also thank the referee of this paper for constructive and helpful comments about the effect of redox couples on oxide electrodes.

DETERMINATION OF DISSOLVED OXYGEN BY CATALYTIC REDUCTION ON NAFION–METHYL VIOLOGEN CHEMICALLY MODIFIED ELECTRODE

JIN LITONG, JIN PING, YE JIANNONG and FANG YUZHI
Department of Chemistry, East China Normal University, 3663 Zhong Shan Road (N), Shanghai, 200062, People's Republic of China

(*Received* 12 *February* 1991. *Revised* 3 *July* 1991. *Accepted* 3 *July* 1991)

Summary—A small size Nafion–methyl viologen chemically modified electrode (Nafion–MV CME) together with a small size electrolytic cell were constructed for the purpose of dissolved oxygen (DO) determination. The catalytic reduction of DO on Nafion–MV CME results in fast and sensitive DO determination. The mechanism of such detection is also considered.

Determination of DO can be accomplished by several methods such as chemical,[1] electrochemical[2] and EPR[3] approaches. However, some of these methods are time-consuming or suffer from high limits of detection. To our knowledge, determination of DO by using CMEs is relatively rare.[4,5] Not long ago, Xu and Dong[6] reported an approach for DO determination by cyclic voltammetry with iron tetraphenyl porphyrin and cobalt tetraphenyl porphyrin CMEs. Unfortunately, the construction of such CMEs is rather complicated and time-consuming. In the present work, DO is determined by using a Nafion–MV CME, which can be constructed conveniently and reproducibly. Because of the catalytic effect of a Nafion–MV CME toward DO, this method is also very sensitive. The results of DO quantitation in water samples by this method are in good agreement with those of Winkler's method. This method, therefore, provides a good alternative for the determination of DO.

EXPERIMENTAL

Reagents

Nafion 117 methanol solution (5%) was from Aldrich and was diluted to 0.1% with ethanol. Methyl viologen dichloride (Aldrich) was used as received. All other chemicals used were analytical grade or better.

Apparatus

All voltammetry experiments were performed with a model XJP-821 polarographic analyser (Jiangsu Electroanalytical Instrument Factory). All experiments employed a homemade plexiglass electrolytic cell with a Teflon electrode supporter (Fig. 1). The three-electrode system consists of a Nafion–MV CME working electrode, a saturated Ag/AgCl reference electrode and a platinum wire auxiliary electrode.

Nafion-MV CME construction

The glassy-carbon electrode (1 mm diameter) was polished with alumina paste and rinsed with water, then further cleaned ultrasonically in 1:1 nitric acid, acetone and doubly distilled water, successively. Next, the clean glassy-carbon electrode was dried under an IR lamp. Nafion was coated on the electrode by pipetting 5 μl of ethanol diluted Nafion (0.1%) onto the electrode surface, which was then dried under an IR lamp. Finally, the electrode was immersed in 0.1*M* methyl viologen aqueous solution for 20 min and then rinsed with doubly distilled water.

General procedure

Adjust 0.1*M* sodium chloride solution to pH 3 with hydrochloric acid, scan the applied potential from 0 to −0.8 V (*vs.* Ag/AgCl) at a rate of 80 mV/sec, and record the resulting voltamperogram. The electrocatalytic reduction peak of oxygen is found at −0.5 V (*vs.* Ag/AgCl), and the oxygen quantitation is achieved by measuring the current of this reduction peak.

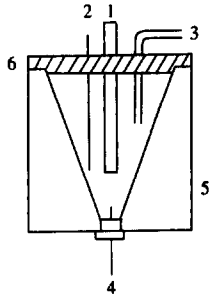

Fig. 1. Schematic drawing of the electrolytic cell: 1, Nafion–MV CME; 2, reference electrode; 3, degassing tube; 4, auxiliary electrode; 5, plexiglass; 6, Teflon. Cell size: 2.8 cm × 3.5 cm.

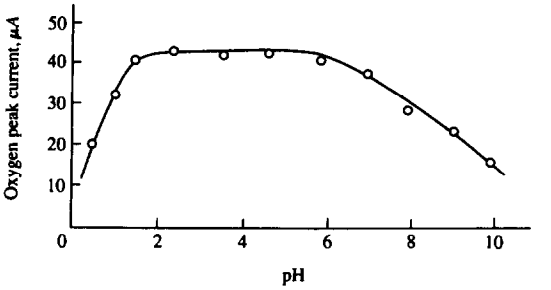

Fig. 3. Peak currents of oxygen reduction obtained at Nafion–MV CME in solutions with different acidity. Scan rate: 80 mV/sec.

RESULTS AND DISCUSSION

Catalytic reduction of oxygen at Nafion–MV CME

Figure 2 shows the voltamperogram of oxygen reduction at both the Nafion–MV CME (curve *a*) and a bare glassy-carbon electrode (curve *b*) in the same solution. The oxygen reduction peak is higher in curve *a* than that in curve *b*. Also, the peak potential of oxygen reduction is shifted anodically about 150 mV if the Nafion–MV CME is employed. These phenomena could be explained by the catalytic effect of the Nafion–MV CME towards oxygen reduction as described below:

$$[(SO_3^-)_2MV^{2+}] + e = [(SO_3^-)_2MV^+] \text{ (electrode reaction)}$$

$$[(SO_3^-)_2MV^+] + H^+ + 1/2O_2 = [(SO_3^-)_2MV^{2+}] + 1/2H_2O_2 \text{ (chemical reaction)}$$

Effect of scan rate

When keeping other conditions the same as described in the general procedure, the peak current of oxygen reduction increases with an increase in the scan rate. However, the background noise also increases accordingly. It was found that the optimum scan rate is 80 mV/sec in terms of maximum signal-to-noise ratio.

Effect of solution acidity

Supporting electrolytes with pH values ranging from 0.5 to 10.0 were prepared by adding different amounts of sodium hydroxide solution to 0.5*M* hydrochloric acid/sodium chloride solution. As can be seen from Fig. 3, the oxygen peak current reaches its maximum value at pH 1.5, then levels off until pH 6.0, and finally decreases when the pH value is higher than 6.0. Because of this feature, we used pH 3.0 supporting electrolyte in our subsequent experiments for DO determination.

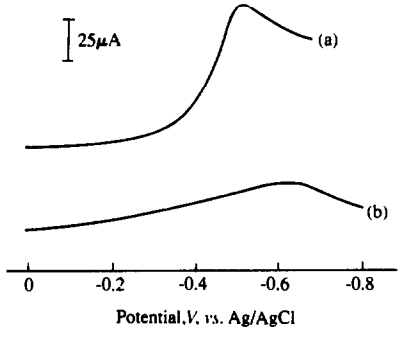

Fig. 2. Voltamperogram of oxygen reduction at both Nafion–MV CME (curve *a*) and bare glassy-carbon electrodes (curve *b*) in pH 3 0.1*M* NaCl/HCl solution (DO concentration: 7.5 ppm). Scan rate: 80 mV/sec.

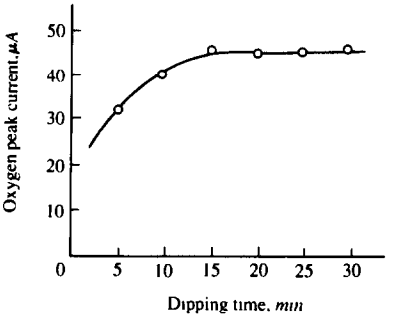

Fig. 4. Peak currents of oxygen reduction obtained in pH 3 0.1*M* NaCl/HCl solution at Nafion–MV CMEs constructed by dipping in 0.1*M* methyl viologen aqueous solution for different time period. Scan rate: 80 mV/sec.

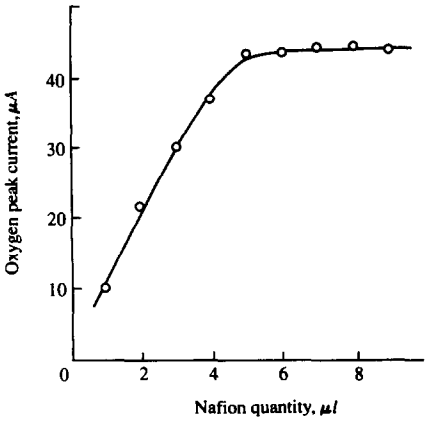

Fig. 5. Peak currents of oxygen reduction obtained in pH 3 0.1*M* NaCl/HCl solution at Nafion–MV CMEs constructed by applying different amounts of 0.1% Nafion ethanol solution. Scan rate: 80 mV/sec.

Effect of dipping time in MV solution

Sulphonic groups in the Nafion film possess strong electrostatic attraction towards MV^{2+}. It was found that the amount of MV^{2+} binding to sulphonic groups is a function of dipping time of Nafion coated electrode in MV solution. As shown in Fig. 4, the oxygen peak current reaches a plateau region when the dipping time is longer than 15 min. It is assumed that the binding sites of the Nafion film become saturated by MV^{2+} within 15 min. We use 20 min as the dipping time for Nafion–MV CME construction.

Effect of Nafion quantity

Nine different Nafion–MV CMEs were prepared by applying different amounts (1–9 μl) of 0.1% Nafion solution onto the glassy-carbon surfaces, followed by dipping into 0.1*M* MV solution for 20 min, and the resultant electrodes were then used for DO determination. As shown in Fig. 5, the oxygen response curve levels off when more than 5 μl of Nafion solution was employed. For this reason, we select 5 μl of Nafion solution in Nafion–MV CME construction.

Reproducibility and calibration curve

After choosing the optimum experimental conditions, the reproducibility of DO determination by catalytic reduction was examined. For ten parallel DO measurements, the relative standard deviation is 1.7%. The linear range of DO calibration is from 1.0 to 8.4 ppm (typical DO content in an oxygen saturated water at room temperature) with a correlation coefficient of 0.995.

Table 1. DO measurement in water samples

Sample	Nafion–MV CME method, *ppm*	Winkler's method, *ppm*	Relative error,* %
Doubly demineralized water	7.65	7.51	1.9
Demineralized water	7.15	7.11	0.6
Tap water	2.35	2.49	−5.6
Campus river water	2.20	2.38	−7.6

*Take the DO values by Winkler's method as standards.

Sample analysis

Four water samples were analysed for DO content by the Nafion–MV CME method[7,8] and also by Winkler's method.[9] The results listed in Table 1 demonstrate that the DO contents obtained by both methods are quite comparable.

CONCLUSION

The success of DO determination by the Nafion–MV CME is a good example of the analytical use of chemically modified electrodes. It appears that this method is a good alternative for DO quantitation because of its sensitivity, reproducibility, simplicity and reliability.

POLYCHLOROBIPHENYLS DIFFERENTIATION AND IDENTIFICATION BY GAS CHROMATOGRAPHY/FOURIER TRANSFORM INFRARED SPECTROSCOPY

P. DOUMENQ, M. GUILIANO and G. MILLE

Faculté des Sciences et Techniques de St Jérôme, Centre de Spectroscopie Moléculaire, URA 1409 CNRS, Avenue Escadrille Normandie-Niemen, 13397 Marseille Cedex 13, France

(*Received* 25 *October* 1990. *Revised* 13 *March* 1991. *Accepted* 21 *March* 1991)

Summary—Reference infrared vapour phase spectra of 20 polychlorobiphenyls (PCBs) have been obtained by gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR). These spectra are consistent with those of PCB obtained by diffuse reflectance IR spectroscopy (DRIFT) and with those of more simple molecular structures (iodochlorobenzenes, 1-bromodichlorobenzenes). The IR frequencies of the GC/FTIR spectra of PCB are assigned in terms of substitution patterns. This work shows that GC/FTIR can be a good approach for differentiation and identification of PCB in complex mixtures.

Since the work of Jensen[1] which showed the effects of polychlorobiphenyls (PCBs) in biological chain contamination, the PCB isomers have become a high-priority concern in industry, because of their potential toxicity and their persistence (non-volatility).[2–4]

The exceptional dielectric and physico-chemical properties of this class of compounds (thermal stability, resistance to acids, bases and corrosive agents, high boiling point, *etc.*) have led PCBs to be used in many industrial applications as heat-conductors, transformers, capacitors, *etc.*[2] Since being made commercial, about two million tons of PCB materials have been produced.

Polychlorobiphenyls are synthesized in industry by reaction of chlorine with biphenyl. The substitutions are non-selective and consequently a very complex mixture is obtained. Theoretically there are 210 isomers, but only 103 are sterically probable. The analytical techniques most widely used to study such complex mixtures are gas chromatography (GC) and gas chromatography coupled with mass spectroscopy (GC/MS).[5]

In the environment PCBs can be partially or totally degraded by microorganisms.[6] This degradation is dependent (even when it occurs in the laboratory under optimal temperature and aerobic conditions) on the number and the position of chlorine atoms on the aromatic rings. Enzymatic degradation methods (specific dioxygenases) occur in a preferential fashion. The initial attacks occur principally at non-chlorinated adjacent or adjoining carbons: -2,3 (-5,6) or -3,4 (-4,5). Before being able to understand the complexity of PCB mixtures, the specificity of the attacks and the degradation products variety, a PCB biodegradation study requires a good structural knowledge of the different isomers.

We had shown that mass spectroscopy, could not always differentiate some PCB isomers.[7] The mass spectra of certain isomers are so similar that they cannot be distinguished even when the reference spectra are in the data base.

This fact leads us to enter upon a study of PCB mixtures by GC coupled with Fourier transform infrared spectroscopy (GC/FTIR). This analytical technique combines the separation capabilities of GC with the possibilities of IR spectroscopy to differentiate aromatic isomers.[8–22] The advantage of IR is that it can readily differentiate isomeric compounds because of finite differences in their vibrational spectra, particularly in the "*fingerprint*" range. The ability of the IR data to distinguish isomers varying in the position of subtituents leads to unambiguous identification.

Even in the case of badly resolved peaks of the IR reconstructed chromatogram[23] it has been shown that data manipulation by special computer software allows the IR spectrum of each compound to be obtained.[22]

EXPERIMENTAL

GC/FTIR spectra were recorded with a 20 SXB Nicolet spectrometer interfaced with a

6180 Vega Carlo-Erba chromatograph (on-column injector, FID detector). Chromatographic separations were achieved with a fused-silica capillary column (0.4μM, SE 52 film, 30 m × 0.32 mm) at a helium flow-rate of 1 ml/min. A helium make-up of 2 ml/min was used. The oven was ramped at 5°/min from 70 to 270°. The end of the capillary column was passed through a transfer line maintained at 275°.

Vapour-phase infrared spectra were performed at 8 cm^{-1} resolution with a MCT detector (4000–650 cm^{-1}) by co-adding 16 interferograms. The chromatograms were reconstructed with the Gram-Schmidt algorithm.[23]

Gas chromatography/Fourier transform infrared spectra were obtained by injecting pure compounds (Interchim, Supelco, Altech) (between 100 and 500 ng per compound) and a standard mixture (DCMA PCB mixture, Supelco).

RESULTS AND DISCUSSION

Library

Before starting to analyse PCB mixtures by GC/FITR, it was necessary to create a specific library. This library (Table 1), although very incomplete (20 PCB), contains representative derivatives with one to seven chlorine atoms.

The limitation for the extension of this library is purely financial. Gas chromatography/Fourier transform infrared spectra of PCBs are given in Figs. 1 and 2. The signal to noise ratios of these spectra are good enough to allow their utilization for identification problems. The IR Gram-Schmidt (IR reconstructed chromatogram) of the DCMA PCB mixture is given in Fig. 3.

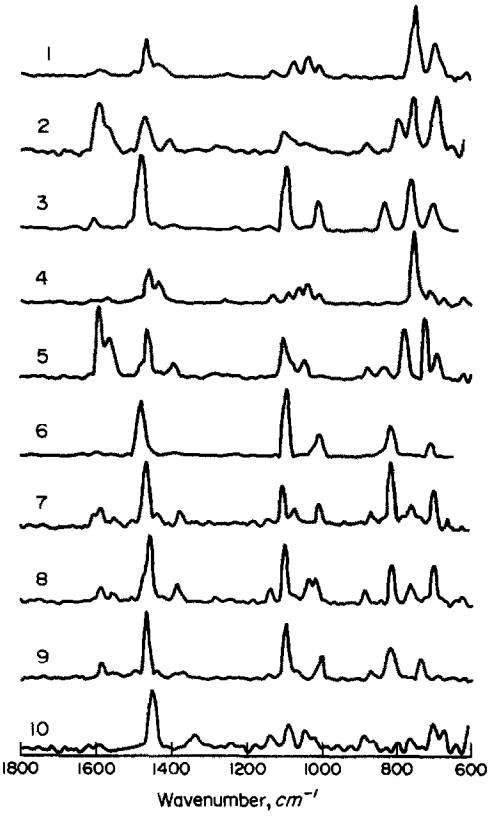

Fig. 1. GC/FTIR spectra between 1800 and 600 cm^{-1} of mono, di and trichloro PCB (spectra 1–10 correspond to PCB with the same number in Table 1).

Previous works

There are many IR studies of chlorobenzenes but only a few concerning polychlorobiphenyls.[24–26]

Nyquist *et al.*[24] studied many pentachlorobiphenyl isomers by FTIR with a diffuse reflectance accessory (DRIFT). Spectra were performed on solid samples obtained after evaporation of the solvent on potassium bromide powder.[24]

Barret and Steele[25] and Eaton and Steele[26] have analysed IR spectra of biphenyl and 4,4′-dichlorobiphenyl under different physical states (solid, liquid and vapour). They concluded that the molecules were not planar and they determined that the dihedral angle between the two aromatic rings was about 30–45°.[25,26]

Only two studies of PCBs by GC/FTIR have been done.[27,28] In these works, spectra were achieved with a matrix isolation technique.

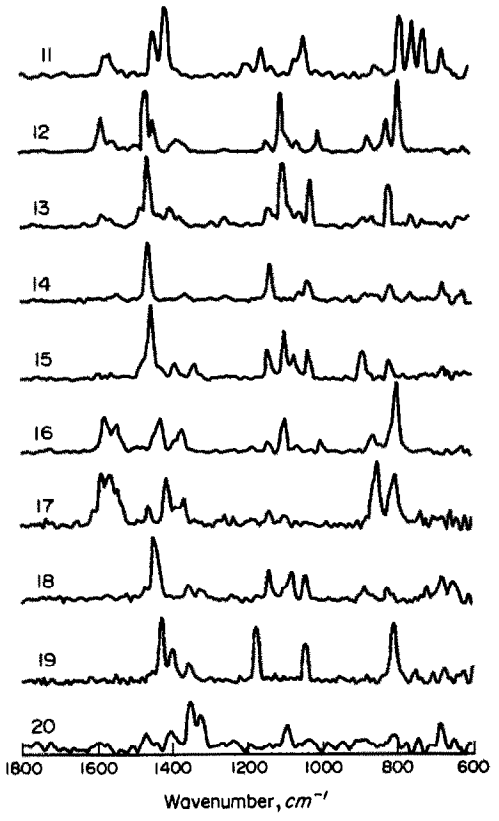

Fig. 2. GC/FTIR spectra between 1800 and 600 cm^{-1} of tetra, penta, hexa and heptachloro PCB (spectra 11–20 correspond to PCB with the same number in Table 1).

Results

The interpretation of PCB IR spectra is very difficult because group frequencies and intensities are influenced by several factors as follows:

(i) high number of IR bands (60 vibrations are theoretically expected in a PCB spectrum).

(ii) mass and substitution effects of the chlorine atoms.

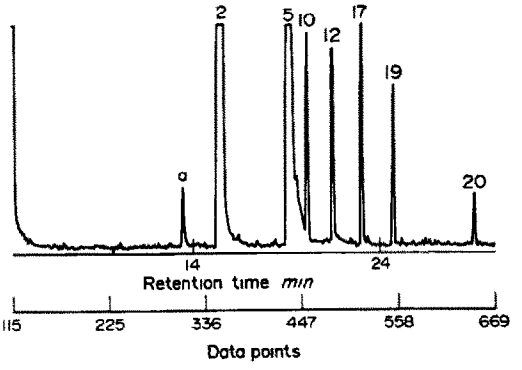

Fig. 3. Gram-Schmidt of the DCMA PCB mixture (Supelco). Peaks 2, 5, 10, 12, 17, 19, 20: see Table 1 for the compound names. a: biphenyl.

(iii) molecular symmetry effects on the vibration activities.

(iv) vibrational coupling effects (the υCCl stretching mode may be coupled with one aromatic ring vibration to generate 2 vibrations, one of which appears between 900 and 700 cm^{-1} (out-of-plane CH aromatic bending vibrations range).

We have attempted two different approaches in interpreting PCB IR spectra: comparison of a GC/FTIR PCB isomer spectrum with (i) the IR spectrum of the same compound obtained by the classical technique and (ii) the IR spectra of simple homologous chlorobenzenes.

Table 2 compares the IR frequencies of the 2,3′,4,5′,6-pentachlorobiphenyl spectrum obtained by Nyquist *et al.*,[24] who used the DRIFT technique, with the corresponding one achieved by GC/FTIR. This GC/FTIR spectrum has been obtained by injecting a standard mixture of 10 PCBs and corresponds to an injected quantity of 600 ng of 2,3′,4,5′,6-pentachlorobiphenyl. Table 2 shows that the two results are very similar, in spite of the GC/FTIR analytical conditions (8 cm^{-1} resolution, low injected quantity, number of scans limited to 16 which lead to a signal to noise ratio decrease). Moreover, the change in physical state of the sample in DRIFT and GC/FTIR techniques

(solid state *vs.* vapor state) leads only to very small shifts in IR wavenumbers.

Consequently, previous data concerning PCB IR spectra, and more particularly the work of Nyquist *et al.*,[24] may be directly used to identify a PCB isomer via its GC/FTIR spectrum.

In Table 3, symmetrical dichlorobiphenyl GC/FTIR spectra are compared with IR spectra of *ortho*, *meta* and *para* homologous iodochlorobenzenes.[29–35] The comparison between GC/FTIR spectra of 2,2',3,3'-; 2,2',4,4'-; 2,2',5,5'- and 3,3',4,4'- biphenyls and IR spectra of homologous 1-bromodichlorobenzenes are given in Table 4.[36] In these two tables the absorptions assigned to C—I or C—Br bonds and the weak intensity absorptions of chlorobenzenes are omitted. Tables 3 and 4 show that the spectrum of a PCB isomer can be directly deduced from that of a homologous chlorobenzene derivative.

The case of assymetrical PCBs requires the comparison of two different chlorobenzene derivatives as shown by Nyquist *et al.* for pentachlorobiphenyl isomers.[24]

Assignment of the principal bands

The bands due to stretching vibrations of the CH aromatic bonds appear in the 3100–3000 cm^{-1} spectral range. These absorptions, often weak, are not very useful for structural identification and will not be examined in this work.

In the 1650–1400 cm^{-1} range, the C=C aromatic stretching vibrations which are sensitive to the substitution appear. Four bands are expected in this range.[29–36] A doublet is located between about 1620–1585 cm^{-1} and 1590–1540 cm^{-1}. These bands are generally weak in PCB spectra; the second component is not always observed. On the other hand, two strong bands are observed at 1590 and 1560 cm^{-1} and at 1589 and 1562 cm^{-1} respectively for 3-chlorobiphenyl and 3,3'-dichlorobiphenyl. These two strong bands are then characteristic of a 3-chloro structure. We also find two strong absorptions between 1585 and 1540 cm^{-1} in GC/FTIR spectra of 2,3', 4,5', 6- and 2,2', 4,4', 6-pentachlorobiphenyls as in DRIFT spectra of 2,2',4,6,6',- and 2,3',4,4',6-pentachlorobiphenyls.[24] These two bands can be used to characterize the 2,4,6-trichloro structure.

The second doublet appears between 1485 and 1409 cm^{-1}. We also observe one or two absorptions between 1400 and 1325 cm^{-1} in all the PCB spectra.

The 1200–1000 cm^{-1} range exhibits five principal bands at 1152 ± 21 cm^{-1}, 1060 ± 15 cm^{-1}, 1030 ± 10 cm^{-1}, 1006 ± 4 cm^{-1} and 1088 ± 15 cm^{-1}. This last band can be assigned to a CCl stretching vibration.[29–36]

Between 900 and 650 cm^{-1}, out-of-plane bending vibrations of CH aromatic bonds (γCH) are expected, which are highly characteristic of the ring substitution. For all PCBs we find one isolated hydrogen CH band at 879 ± 9 cm^{-1}. This band is shifted slightly in the case of a 2,4,6-trichloro structure from 879 to 855 ± 5 cm^{-1}. Two adjacent hydrogen atoms give a CH band at 810 ± 6 cm^{-1}. This band is observed at a slightly higher frequency (830 cm^{-1}) for 4-chlorobiphenyl. A structure with three adjacent hydrogen atoms is charac-

terized by a CH vibration between 782 and 777 cm^{-1} and by a ring vibration near 700 cm^{-1}. In the case of four or five adjacent hydrogen atoms, we observe the CH vibration at 750 ± 13 cm^{-1} and a ring vibration, for a mono-substituted ring only, at 697 ± 3 cm^{-1}.

The second coupled CCl vibration gives IR bands which are variable in frequency (between 800 and 700 cm^{-1}) and in intensity.

Significant absorption bands of GC/FTIR PCB spectra and their assignments are given in Table 5.

CONCLUSION

The GC/FTIR technique is a good approach for studying PCB complex mixtures because of on-line separation and generation of a unique spectrum for each of the individual PCB isomers.

Specific IR group frequencies correlated with subsitution patterns allow the differentiation between PCB isomers which is of great importance for environmental studies. The interest of such analysis had been previously demonstrated by Grainger and Gelbaum for tetrachlorodibenzo-*p*-dioxines.[37]

To continue this study, the library of GC/FTIR spectra of PCB must be extended. However, this work shows that previous IR work concerning PCB or chlorobenzenes may be used for interpreting GC/FTIR spectra which are not included in the library.

In order to separate and identify specific PCB isomers in environmental complex samples, the GC/FTIR technique appears to be very complementary to GC and GC/MS ones.

DETERMINATION OF SULPHA-DRUGS WITH A PIEZOELECTRIC SENSOR

L.-H. NIE, T.-Q. WANG and S. Z. YAO*

New Material Research Institute, Department of Chemical Engineering, Hunan University, Changsha 410082, People's Republic of China

(*Received* 30 *June* 1989. *Revised* 29 *March* 1991. *Accepted* 23 *April* 1991)

Summary—A piezoelectric sensor is used for the determination of sulpha-drugs, as pure substances and in their dosage forms, by an indirect micro method based on reaction of the sulpha-drug with bromine and reduction of the resultant *N*-bromoderivative with iodide to form iodine, which after extraction is monitored with a piezoelectric quartz sensor. The response of the sensor is linear from 2×10^{-5} to $4 \times 10^{-4} M$ sulpha-drug.

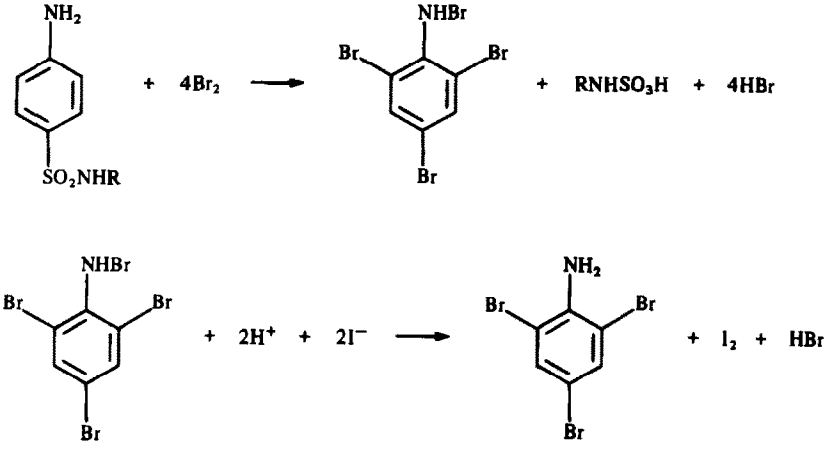
Sulpha-drugs are widely used in the treatment of infections, especially for patients intolerant to antibiotics. The nitrite titration method[1–3] has been recommended for the determination of most pharmacopoeial sulpha-drugs and their dosage forms, but diazo salts and nitrous acid are unstable and the diazotization reaction may be affected by a number of factors, and measures have to be taken to avoid erroneous results. Recently a new method has been proposed for the determination of sulpha-drugs by conversion into an *N*-bromoderivative which is then determined iodometrically.[4] A piezoelectric sensor has been proposed for the determination of iodide in aqueous solution,[5] and in the present work, these two techniques are combined for the determination of medically important sulpha-drugs, as the pure substances and in their dosage forms. As proposed by Amin and Shaba,[4] the *N*-bromoderivative is formed by reaction with bromine water and is reduced with iodide to produce an equivalent amount of iodine. The iodine is then extracted and measured with a silver-plated piezoelectric quartz crystal.

*Author for correspondence.

EXPERIMENTAL

Apparatus and reagents

The apparatus used for the determination was as reported previously.[5] The piezoelectric crystal was a 9-MHz cut quartz crystal 12.5 mm in diameter, with a silver-plated electrode (6 mm in diameter) on each side. The electrode holder was directly connected to an oscillator built with an *IC* circuit powered by a d.c. voltage regulator.



Frequency changes produced by adsorption were measured with a digital counter (model 72, Shijiazhong Electronic Factory No. 4). All chemicals used were of analytical-reagent grade. Doubly distilled water was used throughout.

Standard solutions of sulpha-drugs (0.01*M*) were prepared by dissolving 86.1 mg of sulphanilamide, 107.1 mg of sulphacetamide, 125.1 mg of sulphadiazine or 126.6 mg of sulphamethoxazole in about 15 ml of ethanol (for sulphadiazine and sulphamethoxazole 1*M* hydrochloric acid was added dropwise until complete dissolution was achieved) and then diluting to volume with water in a 50-ml standard flask. Less concentrated solutions were prepared by serial dilution.

Potassium iodide was dissolved in deaerated water to give a 0.01*M* solution, which was kept in an amber-glass bottle.

A saturated solution of bromine water, 90% formic acid solution and 0.5*M* sodium acetate were also prepared.

Procedure

Mix a known volume of the sample solution (not exceeding 3 ml) and 2 ml of saturated bromine water in a separatory funnel (flushed with nitrogen), let stand for 20 min, then add 2 ml of 90% formic acid solution to destroy the excess of bromine. Five min after the solution has become colourless, add 1 ml of 0.01*M* potassium iodide, shake the mixture for 5 min, then add 10 ml of carbon tetrachloride and shake for 1.5 min. Allow the phases to separate, transfer the organic layer into a measuring cell marked at 10 ml, and add carbon tetrachloride to the mark. Start the magnetic stirrer and immerse the piezoelectric quartz crystal (initial oscillation frequency F_1 in air). After exactly 5 min, remove the crystal, dry it with an electric blower and record the frequency (F_2). Run a reagent blank under the same conditions. After each measurement, wash the crystal with ammonia solution (1 + 5), rinse with water and dry it with the electric blower. Correct the frequency change ($\Delta F = F_1 - F_2$) for the blank. Prepare a calibration plot by use of the standard solutions.

Determination of sulphamethoxazole in co-trimoxazole tablets

Weigh 20 tablets and grind them to a fine powder. Accurately weigh a portion of the powder and triturate it with a minimum amount of 1*M* sodium hydroxide at 60° to dissolve the sulphamethoxazole. After cooling, transfer the mixture into a 50-ml standard flask and dilute to volume with water. Leave for 2 hr to let the undissolved trimethoprim settle. After filtration, analyse the filtrate for sulphamethoxazole as described above.

Determination of sulphacetamide in ophthalmic solution

Dilute the ophthalmic solution with distilled water to give a *ca.* $10^{-4}M$ solution. Pipette 2 ml and proceed as described above.

RESULTS AND DISCUSSION

The effect of the reaction medium has been examined for the determination of sulpha-drugs. Water was found to be the most appropriate medium, resulting in a higher frequency change at the same concentration of the sulphonamide compound, e.g., for 0.4m*M* sulphanilamide the frequency change with water as the reaction medium was 819 Hz, whereas in 0.5*M* sodium acetate it was only 104 Hz (a 10-ml sample solution was used). The effect of dilution was also investigated by adding different amounts of water to 1 ml of sample solution. No significant effect is caused by the dilution when the total volume of the diluted sample does not exceed 8 ml, but above this the frequency change tends to decrease. In the present work, the sample solution was diluted to 2–3 ml.

Effect of bromination conditions on the frequency change

A 1-ml sample of 0.2*M* sulphanilamide was used to test the effect of bromination time on the determination of sulpha-drugs. The result is shown in Fig. 1. The frequency change becomes maximal and constant after about 15 min. Up to 68 μg of sulphanilamide (or 100 μg of sulphadiazine) reacts completely with 1.2 ml of saturated bromine water. Use of up to 2 ml of saturated bromine water has no significant effect on the result, but less than 1.2 ml gives smaller frequency changes (Fig. 2). To remove the excess of bromine, 2 ml of 90% formic acid solution is sufficient.

Factors affecting the liberation of iodine

Iodine is liberated on addition of potassium iodide to the reaction system containing the *N*-bromoderivative. There was no significant change in the amount of iodine liberated when 0.75–1.25 ml of 0.01*M* potassium iodide was

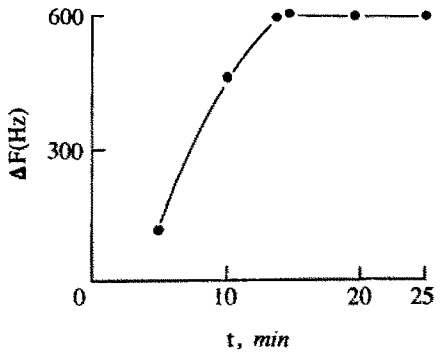


Fig. 1. Effect of bromination time on the determination of $2 \times 10^{4}M$ sulphanilamide.

added. Less than this gave low results in the determination of the sulpha-drug. The frequency change remained virtually unvaried for an iodine-liberation time of 3-9 min. A shorter time resulted in a smaller frequency change.

Factors affecting the iodine extraction

A number of organic solvents were examined as extractants for the iodine produced. A 10-ml volume of carbon tetrachloride was sufficient for quantitative extraction, whereas smaller volumes gave poorer results. Complete extraction was achieved within 30 sec. Chloroform, methylene chloride, benzene and n-heptane can also be used, but are either more volatile or highly flammable, and the first three are regarded as carcinogenic.[6] Diethyl ether and di-isopropyl ether gave much smaller frequency changes and so are unsuitable.

Factors affecting the frequency change

The frequency change increases with the length of time the piezoelectric crystal is immersed in the extract. Sufficient sensitivity can be achieved in 5 min for the determination of microgram levels of the sulpha-drugs. For sub-microgram levels, a longer immersion time is proposed. Varying the temperature from 8 to 35° had no significant influence on the frequency change.

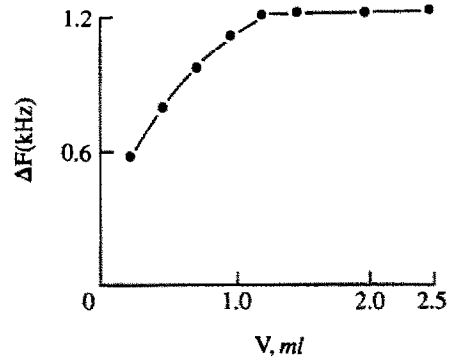

Fig. 2. Effect of the amount of saturated bromine water added to $4 \times 10^{4}M$ sulphanilamide.

Restoration and life-span of the piezoelectric crystal

In the present work, ammonia solution (1 + 5) is proposed for removal of the iodine adsorbed on the crystal surface. Other reagents can also be used, e.g., 10 mg/ml sodium hydrogen sulphate solution or $1M$ sodium carbonate, but a longer immersion time is required. Sodium hydroxide solutions are unsuitable because they cause etching of the quartz crystal, which increases its oscillation frequency and hence affects the sulpha-drug determination.

The life-span of the piezoelectric quartz crystal varies from *ca.* 80 to 300 measuring cycles, depending on the quality of the silver-plated electrode and the amount of iodine adsorbed.

Calibration and reproducibility

The frequency change of the crystal is in direct proportion to sulpha-drug concentration over the range 2×10^{-5}–$4 \times 10^{-4}M$. The standard deviation was 20.4 Hz for 6 determinations of $2 \times 10^{-4}M$ sulpha-drug, corresponding to a relative standard deviation of 3.7%.

The iodine liberated in the reaction is stoichiometrically equivalent to the amount of sulpha-drug. Most commercially available piezoelectric quartz crystals are coated with silver, hence, crystals with silver-plated electrodes were used in the present work, but gold-plated quartz crystals can also be used.

The sensitivity and precision of the sulpha-drug determination in this paper are poorer than those in the analytical system for iodide, based on use of the Leipert multiplication reaction.[5] In addition, the relative magnitude of the blank is large, which also impoverishes the sensitivity.

Table 1. Measurement of sulpha-drugs

	Concentration, $10^{-4}M$	
Sulpha-drug	Taken	Found
Sulphanilamide	4.00	4.06
	0.200	0.194
Sulphadiazine	4.00	4.16
	0.200	0.205
Sulphacetamide	4.00	3.92
	0.400	0.387
Sulphamethoxazole	2.00	2.06
	0.200	0.204

Table 2. Analysis of pharmaceutical preparations

Pharmaceutical preparation	Nominal content	Found	
		Piezoelectric	Pharamacopeial[3]
Sulphacetamide sodium ophthalmic solution	10% (sulphacetamide sodium)	9.82; 9,35; 9.62; 9.77; 10.06; 10.07% (9.78 ± 0.27)%*	(9.88 ± 0.21)%*
Co-trimethoprim tablets†	0.4 g/tablet (sulphamethoxazole)	432; 421; 439; 424; 420; 437 mg per tablet (428 ± 9) mg per tablet*	(419 ± 8) mg per tablet*

*Mean and SD.
†Each tablet contains 0.08 g of trimethoprim and 0.4 g of sulphamethoxazole.

Interferences

Various ions were added to a $2 \times 10^{-4}M$ sulphanilamide solution to examine interference in the technique. Alterations in the frequency change by more than 5% were considered to result from interferences. No significant interferences were caused by 50-fold molar ratio (to sulpha-drug concentration) of potassium, ammonium, sodium, nitrate, bromide, chloride, sulphate, phosphate, carbonate, oxalate, formate and sulphamate, 5-fold ratio of benzoate, tartrate, citrate, salicylate, phthalate, glucose, atropine, benzhexol, glycine, scopolamine and alanine, 3-fold ratio of aspartate and glutamate, equimolar amounts of chlorpheniramine and cocaine, and 0.1% of starch. Trimethoprim, toluidine, xylidine, aniline, phenetidine, procaine and benzocaine interfere. Other oxidants will oxidize iodide to iodine and cause interference if they are not destroyed by formic acid, but such oxidants would seldom be present along with sulpha-drugs.[3]

Analytical applications

The method was applied to the determination of sulpha-drugs (Table 1). It can be applied to the determination of sulpha-drugs in pharmaceutical preparations. The results (Table 2) are in agreement with those obtained by the pharmacopoeial method.[3]

ANALYSIS OF ANIONS BY SOLID-STATE SPOT-TESTS

ALI MOHAMMAD,* NAIM FATIMA and SHARAD TIWARI
Analytical Laboratory, Department of Applied Chemistry, Z.H. College of Engineering and Technology, Aligarh Muslim University, Aligarh 202002, India

(*Received* 24 *March* 1989. *Revised* 23 *May* 1991. *Accepted* 22 *July* 1991)

Summary—Trituration and capillary solid-state spot-tests for 25 anions with a number of organic and inorganic reagents have been examined. A comparative study of the corresponding reactions in solution has also been made. Incorporation of a glass-wool plug in the capillary improves the selectivity. Schemes are presented for possible use of the technique.

The capillary solid-state spot-test technique reported by this laboratory[1] offers a simple and inexpensive tool for identification of many organic and inorganic solids, and in some cases for their determination.[2–4] The screening procedure can easily be adapted for use by mobile laboratories in the field. The choice of indicative parameters in this technique, such as the colour, length and direction of movement of the coloured boundary leads to selective or even specific detection, even of chemically closely related compounds. The tests can also be applied by trituration of the test compound and the reagent on a spot-plate.

Another novel feature of capillary solid-state spot-tests is that the boundary between the product and reactants can be clearly distinguished even when their colours are similar. Coloured anions such as CrO_4^{2-}, $Cr_2O_7^{2-}$, $Fe(CN)_6^{3-}$ *etc.* can be clearly detected in a glass capillary even if the product is yellow or orange. Likewise, coloured reagents can be easily utilized for detection purposes in a glass capillary. The enhanced selectivity due to the surface contact of the reactants is an added advantage. Reactivity in the solid state depends not only on the chemical nature of the crystal, but also on the positions occupied by ions, atoms or molecules in it.[5]

Earlier studies[2] showed that the colour produced by a reaction in solution is not always the same as that for the same reaction in the solid state, since the latter occurs with a minimum of atomic and molecular movement. Considerable work has been done on the detection and determination of anions in solution,[6,7] but none on systematic detection of anions in the solid state.

The present work summarizes our efforts to utilize the capillary solid-state spot-test technique for selective detection and systematic analysis of anions. It has already proved useful for common cations.[2] The technique has been modified by use of a glass-wool plug to make the test more selective or even specific.

EXPERIMENTAL

Reagents

All reagents used were of BDH analytical or laboratory reagent grade, and ground to 50–100 mesh size. The reagents used were *p*-dimethylaminobenzaldehyde (p-DAB), *p*-dimethylaminocinnamaldehyde (p-DAC), diphenylamine (DPA), *p*-toluidine (p-TD), benzidine (BD), benzidine hydrochloride (BDHC), diethylamine hydrochloride (DEAHC), barbituric acid (BTA), chromotropic acid (CA), sodium nitroprusside (SNP), phenolphthalein (PPL), potassium hydrogen sulphate (PHS), ferric chloride ($FeCl_3$), silver nitrate ($AgNO_3$), and 50% w/w intimate mixtures of p-DAB, DPA, p-DAC, p-TD, BTA, CA, KI, Na_2MoO_4, $FeCl_3$, $FeSO_4(NH_4)_2SO_4$ and $AgNO_3$ with PHS, and of SNP and PPL with NH_4Cl.

For detection in solution, ethanol or demineralized water, or a mixture of the two when required, was used as the solvent, and PHS and ammonium chloride were replaced by dilute hydrochloric acid and ammonia solution respectively.

*Author for correspondence.

Procedures

Solid-state detection. About 5–10 mg of the powdered test material was triturated with several mg of reagent in a depression on a white spot-plate with a glass rod. The colours developed at 30 or 40° and on heating to a higher temperature (60–100°) were recorded.

Detection in solution. One or two drops of an aqueous solution of the test material were mixed with a few drops of a concentrated solution of the reagent in a depression on the spot-plate. The colours developed at 40° and at higher temperatures were recorded.

Solid-state detection in capillaries. A 10-cm length of graduated capillary (3 mm internal diameter) was partly filled with powdered reagent from one end with the help of two iron rods, and the powdered sample was similarly packed from the other end. Care was taken to make the packing reproducible and that the two materials were in close contact in the middle of the capillary. The colour of the product formed at the junction, and the length and direction of movement of the coloured boundary at the desired temperature after specified time intervals were recorded.

Solid-state detection in capillaries modified with a glass-wool plug. An air gap between the reagent and the test material was created by placing a glass-wool plug (4–8 mm) in the middle of the capillary before filling it with the reactants. The test material and the reagent were then added from opposite ends of the capillary as usual. The capillary was kept at the desired temperature in an electrically heated oven. The colour formed either at the glass-wool/reagent junction or the glass-wool/test material junction was observed after a fixed time interval and the thickness of the coloured boundary was also recorded.

RESULTS AND DISCUSSION

The results obtained for the trituration reactions are summarized in Table 1. They were compared with those obtained in solution, and in many instances these colours were entirely different. For example, VO_3^- reacts with p-DAB + PHS to give a brown product in the solid state but a red precipitate in solution. Similarly, $Fe(CN)_6^{3-}$ gives an orange-yellow product with p-DAB + PHS at 60° in the solid state, and a brown product in solution. With the same reagent in the solid state $Fe(CN)_6^{4-}$ yields a green product which changes to blue-green, while in solution a yellow colour is observed. At 40°, $Cr_2O_7^{2-}$ reacts with p-DAB + PHS to give a red product in the solid state, which is immediately converted into a dark brown product, but at 60° only a dark brown product appears. A red colour does not occur in solution at any temperature. It appears that the red product is unstable and its formation is only possible in the solid state at lower temperature.

DPA can be used for the specific detection of CrO_4^{2-} in the solid state because this is the only one of the anions studied that gives any colour (green-yellow at 40°). In solution DPA forms a bright yellow product with CrO_4^{2-}, orange with $Cr_2O_7^{2-}$ and green-yellow with $Fe(CN)_6^{3-}$. The colours produced by DPA + PHS with NO_2^-, BrO_3^-, IO_3^-, SO_4^{2-} and $Cr_2O_7^{2-}$ are different in the solid state from those in solution. When BrO_3^- reacts with DPA + PHS the initial blue colour changes to green within a few minutes. In solution only a yellow-brown precipitate is obtained. IO_3^- behaves similarly in the solid state but in solution gives a green product. IO_4^- gives a green colour which changes into yellow in the solid state, and in solution a stable green product is formed. DPA + PHS reacts with MoO_4^{2-} only in solution, to give a green product. With $Cr_2O_7^{2-}$ and $Fe(CN)_6^{4-}$ it gives a yellow colour in the solid and green in solution.

p-DAC produces a green-yellow product with most anions in solution. The brown species formed with SCN^- in the solid state differs from that formed in solution (green-yellow). SO_3^{2-} gives an orange colour in the solid state but does not react in solution. SO_4^{2-} and NO_3^- produce a light orange colour in the solid at 40° but in solution both anions give a greenish yellow colour. For the detection of most anions on a spot-plate p-DAC + PHS was not suitable because of its own colour. However, the colours formed with S^{2-}, MoO_4^{2-}, $Fe(CN)_6^{4-}$, VO_3^- and $Fe(CN)_6^{3-}$ in the solid state differ from those formed in solution. p-TD + PHS gives coloured species with NO_2^- (light yellow), NO_3^- (red-brown). I^- (red-black), IO_3^- (blue-black), IO_4^- (red-violet), MoO_4^{2-} (blue-violet), VO_3^- (violet) and $Fe(CN)_6^{4-}$ (pink) in solution but does not react with these anions in the solid state. In the solid state, CrO_4^{2-} and $Cr_2O_7^{2-}$ give pale yellow and orange-yellow colours respectively with p-TD + PHS whereas in solution they produce violet and brown colours respectively. $Fe(CN)_6^{3-}$ gives a brown-yellow product in the solid state, but a red-violet product in solution.

With BD only two anions, $Cr_2O_7^{2-}$ and $Fe(CN)_6^{3-}$, react in the solid state at 40°, giving brown-yellow and green-yellow colours respectively, allowing their selective detection. In solution $Cr_2O_7^{2-}$ and $Fe(CN)_6^{3-}$ give violet and green-yellow products respectively, and $Fe(CN)_6^{4-}$ produces a brown precipitate. CrO_4^{2-} forms a green-yellow precipitate in solution, which interferes in the detection of $Cr_2O_7^{2-}$, whereas in the solid state it does not interfere, because of its complete inertness. At 80° BD reacts with $S_2O_8^{2-}$ (yellow solution), IO_3^- (yellow precipitate) and IO_4^- (brown precipitate) only in solution. NO_2^- produces a beautiful red precipitate with BDHC at 80°, which can be utilized for its selective detection. IO_3^- and IO_4^- give yellow and green-yellow precipitates respectively at 40°, whereas at 80° they produce brown and blue precipitates respectively, indicating formation of different species at the two temperatures. CrO_4^{2-} gives a blue-violet precipitate at 40° but at 80° it produces a dark brown precipitate along with a green solution. However, in the solid state only a green product is obtained at both temperatures. $Cr_2O_7^{2-}$ gives a brown product in the solid state but in solution gives brown-violet (40°) and brown (80°) precipitates. $Fe(CN)_6^{4-}$ does not react in the solid but gives light blue and yellow precipitates at 40 and 80° respectively. BDHC reacts to give coloured species with only three anions, CrO_4^{2-} (green), $Cr_2O_7^{2-}$ (brown) and $Fe(CN)_6^{3-}$ (orange-yellow) in the solid state at 40° and can be used for their selective detection.

DEAHC was found to be much less reactive towards anions both in the solid state and in solution. However, it can be used for the selective detection of CH_3COO^- and $S_2O_3^{2-}$ which produce yellow products in the solid state at 40°. At 80°, NO_2^- gives a yellow product, and I^- and SCN^- give light pink products.

BTA can be used for the selective detection of SCN^- and VO_3^- at 40°. SCN^- does not give any colour in solution but gives a pink colour in the solid state. VO_3^- gives a brown colour in the solid state and a yellow colour in solution. None of the other anions studied gives any colour in the solid state with BTA at this temperature. However, in solution the selectivity of BTA is reduced and seven anions produce coloured products at 40°; NO_2^-, producing a violet solution, can be distinguished from the rest of the anions. At 80°, $Fe(CN)_6^{4-}$ gives a green-yellow solution but does not react in the solid state.

Solid-state colour reactions of BTA + PHS can be used for the selective detection of Br^- (orange-yellow), I^- (yellow), SCN^- (violet), $Cr_2O_7^{2-}$ (brown), $Fe(CN)_6^{3-}$ (red) and $Fe(CN)_6^{4-}$ (blue). $Fe(CN)_6^{3-}$ can be distinguished from $Fe(CN)_6^{4-}$, and $Cr_2O_7^{2-}$ from CrO_4^{2-} in the solid state. Cl^- gives no colour with BTA + PHS and hence does not interfere in the detection of I^- and Br^- in the solid state. SCN^- gives a red-violet colour with aqueous BTA + PHS, but no coloured species was observed in solution when PHS was replaced by dilute hydrochloric acid. $Cr_2O_7^{2-}$ produces a blue-green colour with aqueous BTA + PHS, which changes to blue. Similarly, the yellow colour initially formed with $Fe(CN)_6^{3-}$ changes to green, but $Fe(CN)_6^{4-}$ gives only a green-blue colour. With an aqueous solution of BTA containing hydrochloric acid, NO_2^- produces a violet colour which is quickly converted into yellow. A red-brown precipitate is obtained with I^-. $Cr_2O_7^{2-}$ and $Fe(CN)_6^{4-}$ give very stable blue species whereas the green-yellow colour formed with $Fe(CN)_6^{3-}$ changes to green-blue. BrO_3^-, VO_3^-, SO_3^{2-} and $S_2O_3^{2-}$ also give coloured species with BTA in the presence of hydrochloric acid, but these anions do not react with aqueous BTA + PHS. CA is a selective reagent for the detection of $Fe(CN)_6^{3-}$. The colours obtained in the solid state with NO_2^- (brown), CO_3^{2-} (brown), and $Fe(CN)_6^{3-}$ (red-yellow) are different from those obtained in solution. At 80°, $S_2O_8^{2-}$ and $Fe(CN)_6^{4-}$ give light blue and yellow colours respectively, but only in solution. $Cr_2O_7^{2-}$ does not react in the solid state but in solution it gives a dark brown colour at 80°. CA + PHS gives colour reactions with many anions, and hence it can be used as a general reagent for detection of anions. It gives a brown colour with VO_3^-, yellow with $Fe(CN)_6^{3-}$ and light yellow with $Fe(CN)_6^{4-}$ in the solid state, but in solution gives a yellow colour with VO_3^-, green-yellow with $Fe(CN)_6^{3-}$ and blue with $Fe(CN)_6^{4-}$. Thus $Fe(CN)_6^{3-}$ can be distinguished from $Fe(CN)_6^{4-}$ in solution.

SNP can be used as a selective reagent for the detection of CrO_4^{2-}, $Cr_2O_7^{2-}$, I^- and $Fe(CN)_6^{3-}$ in the solid state, and in solution SO_3^{2-} can be detected selectively by means of the red colour formed. NH_4Cl + SNP can be used for the selective detection of I^-, $S_2O_8^{2-}$, CrO_4^{2-} and $Cr_2O_7^{2-}$ in the solid state at 40°. $Fe(CN)_6^{3-}$, $Fe(CN)_6^{4-}$ and $S_2O_3^{2-}$ can also be selectively detected at 80°. In solution this reagent produces coloured products with most of the anions and can be used as a general reagent.

It is also clear from Table 1 that PPL, which produces a pink colour with most anions in solution, can be used for the selective detection of CO_3^{2-} (pink), CrO_4^{2-} (green-yellow), $Cr_2O_7^{2-}$ (orange) and $Fe(CN)_6^{3-}$ (yellow) in the solid state. Amongst all the anions tested, only CO_3^{2-} and HCO_3^- give coloured products, violet and pink respectively, in the solid state at 100°, leading to their specific detection.

In solid-state spot-tests PHS has been used as a source of hydrogen ions.[8] We have observed that it is a good reagent for the selective detection of a few anions, in particular SCN^-, VO_3^-, CrO_4^{2-}, $Cr_2O_7^{2-}$, $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$. It produces an unstable violet product with SCN^- at 30°. With VO_3^- an orange colour in the solid state and a dark brown precipitate in solution are observed. CrO_4^{2-} shows an interesting pattern of colour changes with PHS at 30°. It gives an orange product which changes through yellow to brown in the solid state, whereas in solution a stable orange-yellow colour is obtained. However, at 80°, a green-yellow colour appears in solution. $Fe(CN)_6^{3-}$ forms a yellow product in the solid state and a green one in solution. $Fe(CN)_6^{4-}$ gives a blue product in both the solid state and in solution.

KI + PHS does not react with NO_3^- in the solid state but gives a red colour with it in solution. Cl^- and I^- react only in solution, to give a yellow colour and a dark brown precipitate respectively. BrO_3^- gives a blue precipitate in solution at 30°, and in the solid state reacts to give an orange-red product. Other anions which react only in solution are SO_4^{2-} (red-yellow), CO_3^{2-} (yellow), $C_2O_4^{2-}$ (yellow), PO_4^{3-} (yellow) and $Fe(CN)_6^{3-}$ (red-yellow). The colours formed with IO_3^-, VO_3^-, S^{2-}, SO_3^{2-}, $S_2O_8^{2-}$, $Cr_2O_7^{2-}$ and $Fe(CN)_6^{4-}$ are different in the solid state from those in solution. At 30°, $S_2O_8^{2-}$ gives a brown precipitate along with a violet gas but at 80° a red solution. Similarly, MoO_4^{2-} gives a blue precipitate along with a brown gas at 30°, and a green solution at 80°.

Na_2MoO_4 + PHS produces yellow-brown and violet products with I^- and SCN^- respectively in the solid state, whereas in solution it gives a green-blue colour with I^- and yellow with SCN^-. In the solid state HCO_3^- produces a colourless gas and no colour, whereas CO_3^{2-} gives a light yellow product along with evolution of a colourless gas. Br^- does not give any colour in solution, but in the solid state gives a yellow-brown (30°) or blue-yellow (80°) product. VO_3^- produces a blue-red product at 30° and a red-brown one at 80°, but only a yellow colour in solution. $Cr_2O_7^{2-}$ gives yellow and blue products at 30° and 80° respectively in the solid state, and an orange-yellow colour in solution. At elevated temperature Na_2MoO_4 + PHS cannot be used satisfactorily as a solid-state reagent, because of possible interference by its own colour.

$FeCl_3$ and $FeCl_3$ + PHS can be used as general reagents because they produce coloured species with most of the anions, but they require special care to ensure non-hygroscopic conditions. Furthermore, their utility in analytical solid-state spot-tests is restricted because of their own colour. The colour reactions of $FeCl_3$ with Br^-, I^-, SCN^-, VO_3^-, SO_3^{2-}, $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ in the solid state differ from those obtained in solution. $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ react with $FeCl_3$ + PHS to give brown and green products respectively in the solid state, and in solution both give a blue precipitate. I^- and SCN^- give a red precipitate in solution, whereas in the solid state I^- produces dark brown (30°) and green-yellow (80°) products. SCN^- gives a violet product in the solid state. $S_2O_8^{2-}$ gives a blue colour in solution at 30° and a yellow product in the solid state at 80°.

$FeSO_4(NH_4)_2SO_4$ + PHS can be used for the selective detection of VO_3^- (buff), $Fe(CN)_6^{3-}$ (blue) and $Fe(CN)_6^{4-}$ (blue) in the solid state at 30°. At this temperature, I^-, IO_3^-, IO_4^-, $C_2O_4^{2-}$, CrO_4^{2-}, $Cr_2O_7^{2-}$ and MoO_4^{2-} do not react in the solid state but produce colours in solution.

$AgNO_3$ reacts with I^- to give a light yellow colour in the solid state, which changes to black, but in solution a grey precipitate is obtained. $S_2O_8^{2-}$ shows similar behaviour in the solid state but produces an orange brown precipitate in solution. With $S_2O_3^{2-}$ the red product initially formed becomes dark-brown and then black. $AgNO_3$ + PHS gives violet and yellow-brown products with SCN^- at 30° and 80° respectively, but only a white precipitate is formed in solution. I^- gives light yellow (30°) and grey (80°) products in the solid state whereas in solution only a grey precipitate (30°) is produced. $Fe(CN)_6^{4-}$ gives light yellow (30°) and green (80°) products in the solid state and a grey precipitate in solution.

Capillary solid-state tests

In the solid-state spot-tests, the test material is triturated with the reagent to form an intimate mixture but in the capillary solid-state spot-tests the reactants are only in contact at the interface.

Thus, many colour reactions which occur on trituration are usually not noticed in the glass capillary tests. Therefore, the anions that give colour reactions by the trituration method were selected for further study in glass capillaries. Tables 2 and 3 summarize some of the results obtained for the glass capillary reactions. It is observed that many anions giving a colour reaction on the spot-plate do not react in the glass capillary, showing the greater selectivity of the latter technique. For example, CrO_4^{2-}, $Cr_2O_7^{2-}$, $Fe(CN)_6^{3-}$ and $Fe(CN)_6^{4-}$ do not react with p-DAB in the glass capillary but form coloured products on the spot-plate. Thus, p-DAB can be used for the specific detection of SCN^- by the capillary test (Table 3). It gives a yellow product at the junction, which moves towards the reagent, giving a 6-mm length of colour (after 1 hr at 60°).

p-DAC can be used for the specific detection of S^{2-} (yellow product) at 80° and for the selective detection of NO_3^- (pink-brown product) or SO_3^{2-} (yellow product) at 120° by the capillary method. Furthermore, NO_3^- can be clearly distinguished from SO_3^{2-} on the basis of the length of the coloured boundary: NO_3^- gives a 4.0-mm boundary length and SO_3^{2-} only 1.0 mm after 1 hr at 140°. In both cases the coloured boundaries move towards the test material, showing that p-DAC is the only species diffusing. SCN^-, SO_3^{2-}, SO_4^{2-} and $Cr_2O_7^{2-}$ do not react in the glass capillary.

p-TD can be used for the selective detection of CrO_4^{2-} and $Fe(CN)_6^{4-}$ by means of the products, green and buff respectively, obtained at the junction in capillaries. The boundary zone moves towards the test material in both cases, but is twice as long for CrO_4^{2-} as for $Fe(CN)_6^{4-}$. Interestingly, $Cr_2O_7^{2-}$ and $Fe(CN)_6^{3-}$ do not react in capillaries and hence CrO_4^{2-} can be detected in the presence of $Cr_2O_7^{2-}$. Similarly, $Fe(CN)_6^{4-}$ can be detected in the presence of $Fe(CN)_6^{3-}$.

BTA is found to be the most suitable reagent for the specific detection of NO_2^- by the capillary method. None of the anions which give coloured products in the trituration spot-test produces any colour at the junction in the capillary, except NO_2^-. It forms a pink boundary which moves towards the test material, to give a length of 4.0 mm after 3 hr at 120°.

$Fe(CN)_6^{3-}$ can be specifically detected by observing the orange product formed at the junction by reaction with BDHC. NO_2^- and SCN^- can be selectively detected at 80° with DEAHC as reagent. I^-, $Fe(CN)_6^{3-}$, CrO_4^{2-} and $Cr_2O_7^{2-}$ do not react in the capillary at this temperature but at 120°. CrO_4^{2-} gives a 1.0-mm red-brown boundary and $Fe(CN)_6^{3-}$ a 2.0-mm dark green boundary after 1 hr. In all cases the reagent is the diffusing species, since the coloured boundary always extends towards the test material.

Of all the anions which produce coloured products with CA on the spot-plate, only NO_2^- gives a red-orange ring at the junction in the capillary within 10 min at 30°, leading to its specific detection. This colour reaction is also specific at 80°. At this temperature NO_2^- gives a violet boundary which develops away from the reagent. However, at 120° VO_3^-, MoO_4^{2-} and $Fe(CN)_6^{3-}$ also react with CA to give thin black, red-brown and brown-black rings, respectively, at the junction, within 3 hr. Under these conditions NO_2^- gives a 6.0-mm red-violet boundary which is specific.

NO_2^- and NO_3^- react with p-DAB + PHS to give yellow-orange products at the junction. In the case of NO_3^- the product changes to green-brown on keeping for half an hour at 60°, giving a boundary length of 2.0 mm on the reagent side, and NO_2^- can be distinguished from NO_3^- on the basis of either boundary length or colour. Similarly, Br^- and I^- can be distinguished from each other by the colour of the junction; I^- and Br^- give orange and yellow products respectively (Cl^- does not produce a colour). IO_4^- gives an unstable yellow product which at 60° changes to brown within half an hour, whereas IO_3^- forms a quite stable orange product, which distinguishes it from IO_4^-. The red-brown boundary (4.0 mm) formed by BrO_3^- at 60° within half an hour with p-DAB + PHS can be utilized to distinguish BrO_3^- from VO_3^- (thin ring), IO_4^- or IO_3^- (0.5 mm). Similarly, CrO_4^{2-} (thin orange ring) can be distinguished from $Cr_2O_7^{2-}$ which gives a red boundary 4 mm in length. $Fe(CN)_6^{3-}$ reacts with p-DAB + PHS to give a transient orange colour which quickly changes to greenish-blue, whereas $Fe(CN)_6^{4-}$ gives only a blue product. The boundary length after half an hour at 60° is 3.0 mm for the former and 4.0 mm for the latter. In all cases the coloured boundaries move towards the reagent, showing that the test materials are the only diffusing species.

p-DAC + PHS gives coloured products at the junction only with SCN^- (violet), CrO_4^{2-} (dark brown) and $Fe(CN)_6^{3-}$ (dark brown) within 10 min at 30°. Amongst these only SCN^- shows a boundary length of 10.0 mm. Therefore, SCN^-

can be selectively detected. Cl^- reacts at 80° to give a dark brown product (2.0 mm) towards the reagent and a pink product (6.0 mm) towards the test material after 1 hr; I^- and Br^- do not form coloured species, however. Thus, Cl^- can be detected in the presence of I^- or Br^-. NO_2^- and NO_3^- both react with p-DAC + PHS, NO_2^- to give a brown boundary (2.0 mm) towards the reagent and NO_3^- a violet boundary (2.0 mm) towards the test material. Thus, NO_2^- can be distinguished from NO_3^- by means of the position of the boundary.

DPA + PHS gives a violet boundary with SCN^-, yellow with $S_2O_3^{2-}$ and blue with $Fe(CN)_6^{4-}$. NO_3^-, BrO_3^-, IO_3^-, CrO_4^{2-} and $Cr_2O_7^{2-}$ all produce green products. However, the green boundary moves only in the case of NO_2^- (1.0 mm) towards the reagent. Thus, NO_2^- can be selectively detected on the basis of boundary length. The coloured boundary formed with SCN^- gives the greatest length, leading to the selective detection of SCN^-.

Capillary solid-state spot-tests can be utilized for the specific detection of SCN^- and $Fe(CN)_6^{4-}$ with BTA + PHS and SNP + NH_4Cl respectively as reagents. Similarly, PPL + NH_4Cl can be used for the specific detection of CO_3^{2-} or HCO_3^-, which form pink products at 120°.

PHS can be utilized for the specific detection of VO_3^- at 40° and the selective detection of $Fe(CN)_6^{3-}$ or $Fe(CN)_6^{4-}$ at 80°. The coloured boundaries formed with VO_3^- (brown) and $Fe(CN)_6^{3-}$ or $Fe(CN)_6^{4-}$ (blue) do not show any movement during 1 hr at 80°. It is interesting to note that of 11 anions which produce coloured products with $AgNO_3$ on trituration, only $S_2O_3^{2-}$ and $S_2O_6^{2-}$ form black-brown products at the junction within 10 min at 40°. The coloured boundary formed with $S_2O_6^{2-}$ shows no movement, whereas $S_2O_3^{2-}$ gives a 2.0-mm boundary length, which distinguishes between them. At 80°, $AgNO_3$ gives coloured products with $Fe(CN)_6^{3-}$ (red), PO_4^{3-} (black-brown), I^- (black-brown), CrO_4^{2-} (black) and $Cr_2O_7^{2-}$ (black) at the junction. The coloured boundary moves only in the case of PO_4^{3-} (2.0 mm, 1 hr).

Ferrous ammonium sulphate can be utilized for the selective detection of NO_2^- and MoO_4^{2-}. NO_2^- gives a red ring (80°, 1 hr) and a red-brown boundary 1.0 mm in length (1 hr at 100°). Amongst all the anions which produce coloured products (Table 2) at 80°, only MoO_4^{2-} gives a boundary length of 2.0 mm, which can be used for its selective detection.

I^- can be selectively detected with Na_2MoO_4 + PHS on the basis of the length or direction (which is towards the test material) of the yellow-brown boundary formed at the junction. In all cases the coloured boundaries move towards the test material. $S_2O_6^{2-}$ forms a brown-black boundary (4.0 mm) at 100° which moves towards the reagent. Thus, $S_2O_6^{2-}$ can be distinguished from I^- on this basis, but not from the colour. VO_3^- gives a red ring at 40° but a brown ring at 80 or 100°. Of all the anions tested only SO_3^{2-} forms a blue ring at 40 or 80°. Therefore, it can be selectively detected. However at 100°, PO_4^{3-} also forms a blue ring at the junction.

At 40°, SCN^- reacts with KI + PHS to give a violet boundary (8.0 mm) towards the test material within 10 min. The other anions which give coloured products at the junction such as NO_2^- (red), BrO_3^- (yellow), IO_3^- or IO_4^- (orange), $S_2O_3^{2-}$ (red), $Fe(CN)_6^{4-}$ (blue) and CrO_4^{2-} (brown) show no boundary movement. Thus, SCN^- can be selectively detected on the basis of the boundary length. At 80° the formation of a 10.0-mm thick blue boundary by $Fe(CN)_6^{4-}$ allows its selective detection.

It is apparent from Table 2 that the colour reactions of some anions are temperature-dependent. For example $S_2O_3^{2-}$ gives only a red product with KI + PHS at 40°, whereas at 80°, it gives two coloured species. The red product formed at 40° shows no movement. However, at 80°, in addition to the red ring, a yellow product (2.0 mm) is also formed which moves towards the test material, and gives selective detection of $S_2O_3^{2-}$.

$FeCl_3$ can be used for the specific detection of SCN^- which gives a red-violet ring at 40°. Cl^-, Br^- and I^- can be distinguished from each other at 80° on the basis of the boundary length measured after half an hour (Table 2). NO_3^- can be detected in the presence of NO_2^- because at 80° a red ring appears only with NO_3^-. At 80°, CrO_4^{2-} gives a light brown boundary (3.0 mm) after 1 hr, but $Cr_2O_7^{2-}$ does not react. Thus, CrO_4^{2-} can be detected in the presence of $Cr_2O_7^{2-}$ and SO_3^{2-}. S^{2-} gives a red ring and SO_3^{2-} forms a yellow ring with $FeCl_3$.

It is clear from the discussion above that the capillary solid-state spot-tests are more selective than the conventional solid-state spot-tests and many anions can be selectively or specifically detected by performing the tests in a capillary. Table 3 summarizes the results obtained for the selective/specific detection of some anions by the capillary method. The selectivity of the

capillary technique can be further enhanced by introducing a glass-wool plug into the middle of the capillary, between the reactants. In this way the reactants do not come into direct contact and the reaction, if any, proceeds by vapour phase diffusion of the reagent or test material through the glass-wool plug. Such reactions may be termed solid–vapour phase reactions rather than solid–solid reactions. The glass-wool technique was applied to the anions which gave coloured products in glass capillaries, and the colour reactions observed are shown in

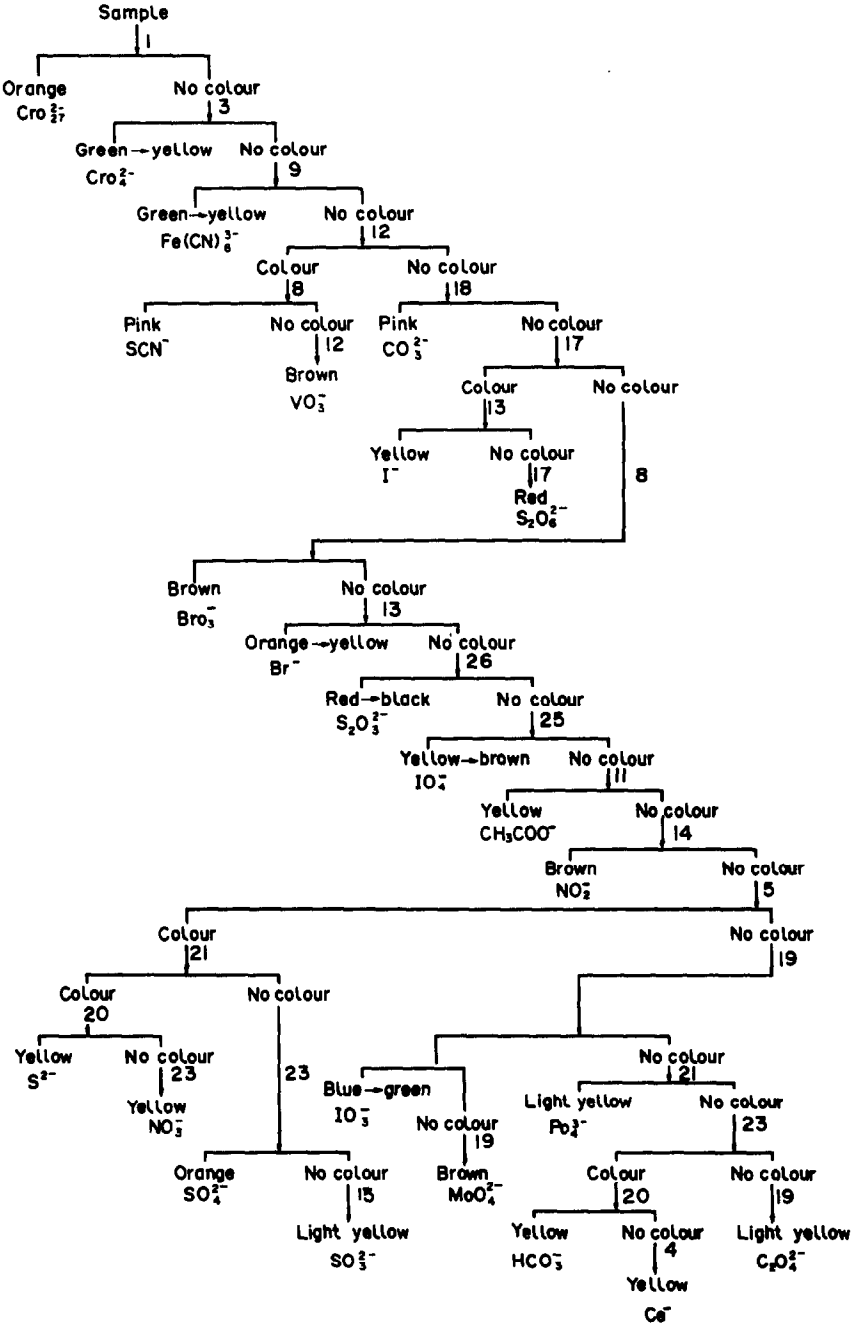
GW/R = glass wool/reagent junction.
GW/M = glass wool/test material junction.
* = Whole tube containing test material (CO_3^{2-} or HCO_3^-) becomes pink.
→ indicates a change in colour.
Other abbreviations as in Table 2. For reagent 28 see Table 3.

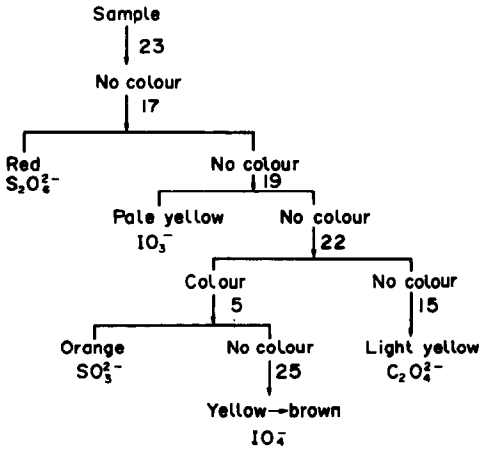
Table 4 and show that the glass-wool technique is superior to the ordinary capillary technique in terms of selectivity and specificity.

Applications

For obvious reasons (the main one being the complexity of the work that would be involved) the investigation was restricted to the sodium and potassium salts of the anions involved. It is a fairly simple matter to devise a systematic scheme for identification of one of these salts in the absence of the others, as shown in Scheme 1. It is also possible to devise a systematic scheme for analysis of a mixture containing almost all the anions examined in this work. The major problem in devising such schemes is that in contrast to schemes based on physical separation by precipitation or extraction, each test is applied to a portion of the original sample, so all the components are present in every test



Scheme 1.



Scheme 2.

performed. Hence the classification is based on elimination of groups of anions from consideration, by their failure to give a colour with a particular group reagent. For instance, if no colour is obtained with DPA + PHS in the trituration test, acetate, molybdate and phosphate are the only anions (of the 25 in the scheme) that may be present. However, if a colour *is* obtained, these three anions may also be present in subsequent tests, so their reactions with all subsequent reagents have to be taken into account in working out the scheme.

On the other hand, it is comparatively easy to use Table 1 to find small groups of anions that do not give a colour with a given reagent, and then to devise identification schemes such as that in Scheme 2.

The capillary tests can similarly (and more easily) be organized into a detection scheme, since additional information is provided by boundary movement of the products. Devising such schemes is an excellent exercise in logical thinking, as a part of student training.

As far as we are aware, this is the first attempt at systematic solid-state analysis for anions. Further publications will be concerned with the chemistry of the new reactions described.

CAPILLARY ZONE ELECTROPHORESIS SEPARATION AND LASER-INDUCED FLUORESCENCE DETECTION OF ZEPTOMOLE QUANTITIES OF FLUORESCEIN THIOHYDANTOIN DERIVATIVES OF AMINO ACIDS

SHAOLE WU* and NORMAN J. DOVICHI†
Department of Chemistry, University of Alberta, Edmonton, Alberta T6G 2G2, Canada

(*Received* 3 *June* 1991. *Revised* 15 *July* 1991. *Accepted* 15 *July* 1991)

Summary—Capillary zone electrophoresis, when combined with laser-induced fluorescence, is a very powerful technique for the separation and determination of minute amounts of labeled amino acids. This paper presents the determination of the fluorescein thiohydantoin derivative of 17 amino acids which takes 13.5 min. The detector, based on laser-induced fluorescence, is optimized with respect to laser power to produce detection limits, three standard deviations above background, ranging from 1 to 2 zeptomoles (1 zeptomole = 1 zmole = 10^{-21} = 600 analyte molecules) injected onto the capillary.

The Edman degradation reaction, based on phenylisothiocyanate (PITC), is the main technique used to elucidate the amino acid sequence of proteins and peptides.[1,2] Although the classic methodology allows the amino acid sequence determination from picomole amounts of proteins, many proteins of biological interest can only be isolated in much smaller amounts.[3] In order to obtain amino acid sequence information from the small amounts of proteins, a modified Edman-type reagent, fluorescein isothiocyanate (FITC), was introduced by Kawauchi and co-workers.[4,5] Under basic conditions, the molecule couples with the *N*-terminus amino acid to form the thiocarbamyl derivative (FTC) and under acidic conditions the terminal amino acid is cleaved as the thiohydantoin derivative (FTH). That is, to sequence proteins with FITC, it is necessary to determine FTH amino acids. These fluorescein amino acid derivatives are detectable in femtomole quantities by use of conventional technologies. The few reports of protein sequencing using this reagent have employed liquid chromatography separation and fluorescence detection.[3,6] The highly fluorescent reagent produces improvements in the minimum concentration of amino acid and protein that can be analyzed.

Additional improvements in the mass of protein required for analysis will follow from reduction in the size of sequencing instrumentation. A capillary-scale separation scheme is important in miniaturizing the sequencing instrumentation. This research group has developed a very sensitive detector for the capillary zone electrophoresis separation of nanoliter solutions of FTC and FTH derivatives of amino acids. Preliminary results for the capillary electrophoresis separation of the FTH amino acids were summarized elsewhere.[7] Detailed discussion of the separation of FTC amino acids has also been presented,[8,9] including separation conditions and photobleaching effects. FTC amino acids have been studied at the zeptomole level by Sweedler *et al.*[10] and Monning and Jorgenson.[11] In the former paper, a charged-coupled device was used to record the emission spectrum of minute samples eluted from the capillary whereas the latter paper reported a novel sample injector based on photobleaching of FTC amino acids.

In this manuscript, we present, for the first time, a simplified preparation of FTH amino acids; a comparison of different acids for conversion of FTC to FTH amino acids; the effect of pH on separation of FTH amino acids; a compilation of interferences in FTH amino acid separation by capillary zone electrophoresis (CZE); the absorbance and emission spectra of fluorescein with both FTH and FTC amino acid derivatives; the fluorescent quantum yield of

*Present address: Chemistry Division, Alberta Environment Centre, Vegreville, Alberta T0B 4L0, Canada.
†Author for correspondence.

FTC and FTH amino acids; the photobleaching characteristics of FTH amino acids; the detection limits for FTH amino acids; and the noise characteristics in high sensitivity fluorescence detection. It is not the purpose of this paper to present protein sequencing at the sub-attomole level. Rather, we are interested, at this point, in developing instrumentation that can be used to characterize the FTH derivatives with the highest possible sensitivity. Further work will address applications of this separation and detection technology to sequencing samples.

EXPERIMENTAL

Fluorescein thiohydantoin derivatives of amino acids were prepared in micro-scale with a method similar to that reported by Maeda *et al.*[4] Stock amino acid (Fluka) solutions, $5 \times 10^{-3}M$, were prepared in pH 9.1 carbonate buffer ($0.2M$) and stored at 4°. Stock $1.3 \times 10^{-3}M$ fluorescein isothiocyanate (Sigma) was prepared in pure (99.9%, HPLC grade) acetone and also stored at 4°. One milliliter of each amino acid solution was mixed with 0.1 ml of the FITC solution in a 1.5-ml disposable centrifuge vial and allowed to react for four hours at room temperature in the dark to produce the thiocarbamyl derivative. Next, 0.5 ml of each thiocarbamyl solution was mixed with 0.5 ml of trifluoroacetic acid and allowed to react for 15 hr in the dark to form FTH amino acids. These FTH amino acid solutions were stored at 4° until use. The FTH amino acids were diluted at least 4000-fold in $0.01M$ pH 7 phosphate buffer before injection.

Capillary electrophoresis separation of the FTH amino acids was performed in a 1.0-m long, 50-μm inner diameter fused silica capillary, Polymicro. A $10mM$ pH 7.0 phosphate buffer was used for the separation. The sample was injected electrokinetically at 0.5 kV for 10 sec, manually timed and the separation proceeded at 30 kV. The fluorescence detector was identical to that described before.[7-9,12] The detection end of the capillary was placed within the flow chamber of a sheath flow cuvette. A ~25-mW beam from an argon ion laser, $\lambda = 488$ nm, was focused into the cuvette. Fluorescence was collected at right angles to the radiation source, using a microscope objective of numerical aperture 0.65. The collected light was passed through a spectral band-pass filter to reject scattered laser light. The fluorescence was imaged onto a pinhole matched in size to the illuminated sample stream and detected with a high quantum yield photomultiplier tube. A 0.3-sec time constant electronic filter was used to smooth the photomultiplier output before display on a strip chart recorder.

Absorption spectra of FTH and FTC amino acids were measured with a Hewlett–Packard diode array spectrophotometer model 8451A. The uncorrected emission spectra were measured with a Turner Spectrofluorometer model 430.

RESULTS AND DISCUSSION

Separation

Several points can be made concerning the preparation and separation of these derivatives. We found that the precipitation of FTC amino acids before the cyclization reaction reported by Kawauchi *et al.*[5] can be eliminated, greatly simplifying the procedure. Although unreacted amino acids remain in the sample, they interfere with neither the separation by electrophoresis nor the detection by laser-induced fluorescence. Concentrated trifluoroacetic acid (TFA), 50% trifluoroacetic acid, $6N$ hydrochloric acid and $6N$ hydrochloric acid:acetic acid (1:1) were used for the cyclization reaction of FTC-arg in a 1:1 volume ratio for 15 hr at room temperature in the dark. The relative peak heights observed for the FTH-arg samples are listed in Table 1, normalized to the peak height produced for the mixed hydrochloric acid:acetic acid reaction. Concentrated TFA gave the highest sensitivity and was used for the cyclization reaction. The following abbreviations are used for the amino acids: alanine (ala), arginine (arg), asparagine (asn), aspartic acid/aspartate (asp), cysteine (cys), glutamine (gln), glutamic acid/glutamate (glu), glycine (gly), histidine (his), hydroxyproline (hpro), isoleucine (ile), leucine (leu), lysine (lys), methionine (met), phenylalanine (phe), proline (pro), serine (ser), threonine (thr), tryptophan (trp), tyrosine (tyr) and valine (val).

Table 1. Relative sensitivity *vs.* reaction acids used to form FTH–arginine

Reaction acids	Relative peak height
Concentrated trifluoroacetic acid	4
50% trifluoroacetic acid	2
$6N$ HCl	2.3
$6N$ HCl:acetic acid (1:1)	1

FTH amino acids are dianions under basic conditions. These derivatives possess low interaction with fused silica at pH greater than 7 and may be separated with high efficiency in capillary zone electrophoresis. A pH range of 6.5–10 of the eluting buffer (5–10m*M*) was tested. At pH lower than 7.0, the FTH amino acid peaks were broad and strongly tailed, presumably due to the interaction of the less negatively charged species with the wall of the capillary. At pH 8 and higher, multiple peaks corresponding to both the FTH and FTC derivatives, along with some unidentified peaks, were found for arg, ala and phe, presumably due to the decyclization reaction at high pH. The peak height of the FTH amino acids was usually lower than that of the corresponding FTC amino acids. Thus the pH range of the eluting buffer applicable to the separation of FTH amino acids in the capillary zone electrophoresis is rather narrow: 7.0–7.5. In this range most of the FTH amino acids show a single, well-resolved peak on the electropherogram.

Rather surprisingly, the retention time of some of the neutral amino acids depends upon the pH of the eluting buffer. For example, the eluting order is histidine followed by leucine at pH 7.0 but the order was reversed at pH 7.5. Presumably, the electron withdrawing properties of the particular side-chain of the amino acid can influence the ionization constant of the carboxylic acid group of fluorescein. Thus, reproducible pH is required to obtain consistent separations. Relatively low ionic strength buffers are used in the capillary zone electrophoresis separations to minimize the effect of Joule heating on the separation. It was necessary to take care in the preparation of the FTH solutions so that the sample was at the same pH and similar ionic strength as the separation buffer. Most simply, the trifluoroacetic acid can be driven off by passing nitrogen gas through the solution and the pH adjusted with the separation buffer.

Individual FTH amino acids were analyzed by capillary electrophoresis. Under the experimental conditions most of the FTH amino acids show one major peak except serine, threonine, glutamine and asparagine. FTH-ser and FTH-thr both contain a hydroxyl group and both show two peaks, as observed by Kawauchi *et al.*[5] in thin-layer chromatography, which may be caused by decomposition into the FTH-dihydro-derivatives.[4] The two serine peaks had similar heights. The first threonine peak is nearly twice as high as its second peak. FTH-gln has one major peak and two minor peaks with a peak height ratio of approximately 3:1:1. FTH-asn also has one major peak and two minor peaks with height ratio 3.5:1:1.

Several of the other FTH-amino acids show minor peaks in addition to one major peak, presumably due to degradation of the molecule under the derivatization conditions. FTH-arginine, which bears two amino groups, has one major peak and two minor peaks appearing right after the major peak and forming its tailing part, with peak height ratio 14:2:1. Alanine has one major peak and two minor peaks also with a peak height ratio of 14:2:1. Tyrosine has one major peak and one minor peak with peak height ratio 6:1. After reaction for 15 hr, FTH-cys, similar to FTC-cys, showed two peaks, presumably because the sulfhydryl group of cysteine was involved in the reaction with FITC. However, the first peak vanished and left only one peak after reaction for about 30 hr.

Under the conditions employed, the following sets of FTH amino acids cannot be separated: FTH-arg and FTH-lys; FTH-phe, FTH-met, and FTH-thr; FTH-cys and FTH-ser; and FTH-ile and FTH-trp. The separation of a mixture of 21 FTH-amino acids in an aqueous, low ionic strength buffer is shown in Fig. 1. The separation produces $\sim 1 \times 10^6$ plates for these analytes at this pH. A total of 17 peaks, including one reagent peak, are obtained and 12 amino acids may be identified unambiguously.

We have considered elsewhere the separation of the fluorescein thiocarbamyl derivatives of amino acids.[8,9] The FTC derivatives have an additional negative charge, as compared with the FTH derivatives, and consequently have higher electrophoretic mobility. However, the FTC derivatives migrate at lower net velocity than do the FTH derivatives (*e.g.*, 390 sec for FTH-arg *vs.* 518 sec for FTC-arg eluted in 94.5-cm capillary at 29 kV with 5m*M* pH 7.0 phosphate buffer). In both cases, electro-osmosis produces bulk flow in the capillary that is greater in magnitude but opposite in direction from electrophoresis. This electro-osmosis is due to the excess in positive charge in the free solution near the electric double layer at the surface of the fused silica capillary. Because the electro-osmosis opposes the electrophoretically induced motion of the analyte, the FTC molecules, with high electrophoretic mobility,

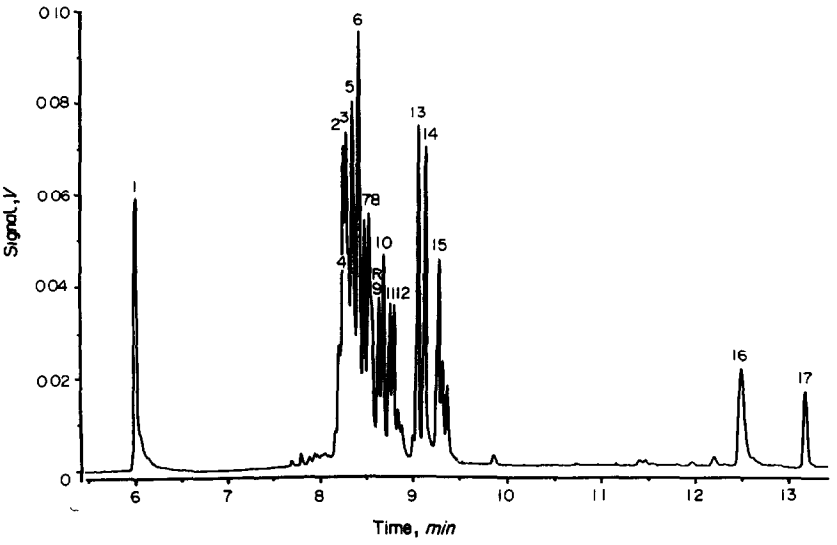

Fig. 1. Determination of FTH amino acids. Peak 1, arg; 2, his; 3, leu; 4, try; 5, ile and tyr; 6, met, phe and thr; 7, val, 8, hpro; 9, asp; 10, pro; 11, thr and ser; 12, ala; 13, gly; 14, cys and ser; 15, gln; 16, glu; 17, asp. Injected concentration was $2.2 \times 10^{-9}M$ for his, leu and gly, and $1.5 \times 10^{-9}M$ for glu and asp, and $1.1 \times 10^{-9}M$ for the others.

will move at lower net velocity than the FTH derivatives.

While FTC-leu and FTC-ile are not easily separated in CZE, the corresponding FTH derivatives can be separated. Similarly, while FTC-arg and FTC-lys are well separated, their FTH species cannot be separated. Thus, complete analysis of amino acids might be achieved by performing two separations, one with the FTC amino acids and one with the FTH amino acids. Alternatively, micellar chromatography may be applied to the separation of thiohydantoin derivatives of amino acids.[13]

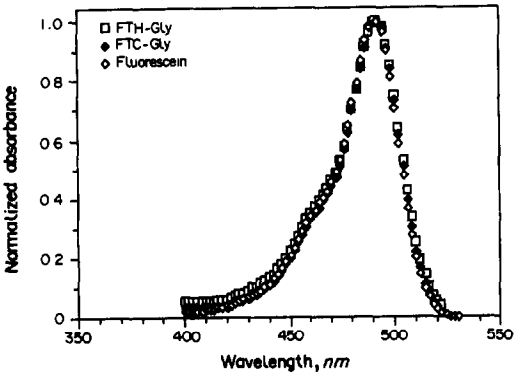

Fig. 2. The normalized absorption spectra of Fluorescein (◇), FTH-gly (□) and FTC-gly (◆). The measurements were performed on a Hewlett-Packard spectrophotometer model 8451A. The fluorescein solution contains $1.12 \times 10^{-6}M$ fluorescein in $0.1N$ NaOH. The FTC-gly solution was prepared by diluting the original reaction product (which contained $1.18 \times 10^{-4}M$ FTC-gly and 5×10^{-3} glycine in $0.2M$ of pH 9 carbonate buffer) with $5mM$ carbonate buffer (pH 10) to $1.18 \times 10^{-6}M$. The FTH-gly solution was prepared by diluting the original reaction product which contained $5.9 \times 10^{-5}M$, FTH-gly and $2.5 \times 10^{-3}M$ glycine in strong acidic solution (trifluoroacetic acid) with $0.1N$ NaOH first (to pH = 5) and then $0.2M$, pH 9 carbonate buffer and finally $10mM$ phosphate buffer (pH 7) to the concentration of $\sim 2 \times 10^{-6}M$.

Detection

The shapes of the absorption spectra of FTH-gly, FTC-gly, and fluorescein in the visible spectral range (400–600 nm) are very similar, with a slight enhancement in the blue absorbance of the thiohydantoin derivative (Fig. 2). The molar absorptivities of FTH-gly (pH 7), FTC-glycine (pH 10 and 7) and fluorescein (pH 13) at 488 nm and 322 nm (the latter wavelength was used as the excitation wavelength in the measurement of the emission spectrum) are listed in Table 2. Despite the

Table 2. Molar absorptivity*

Analyte	Molar absorptivity, $l.\mu mole^{-1}.cm^{-1}$ $\lambda = 322$ nm	$\lambda = 488$ nm
Fluorescein (pH 13)	120,000 ± 10,000	85,000 ± 2500
FTH-Gly (pH 7)	150,000 ± 20,000	82,000 ± 4000
FTC-Gly (pH 7)		77,000 ± 1000
FTC-Gly (pH 9)	150,000 ± 20,000	85,500 ± 2500
FTH-Tyr (pH 7)		59,000
FTC-Tyr (pH 9)		61,000
FTH-Ala (pH 7)		68,000
FTC-Ala (pH 9)		78,000

*Assuming FITC used was 100% pure and each reaction went to completion.

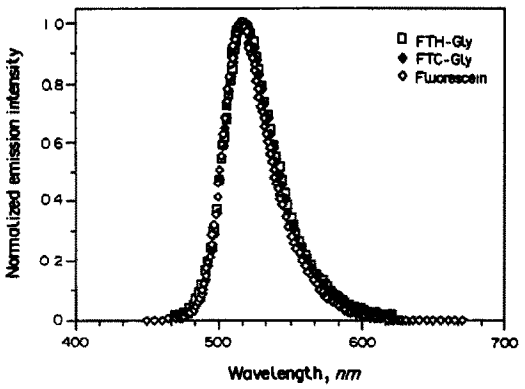

Fig. 3. The normalized emission spectrum of Fluorescein (◇), FTH-gly (□) and FTC-gly (◆). The measurements were performed on a Turner spectrofluorometer model 430, with an excitation wavelength of 322 nm, slit of 15 mm, range of × 100 and high sensitivity. The fluorescein solution contains $1.12 \times 10^{-7}M$ fluorescein in $0.1N$ NaOH. The FTC-gly solution was prepared by diluting the solution stated in Fig. 2 with 5mM carbonate buffer (pH 10) to $1.18 \times 10^{-7}M$. The FTH-gly solution was prepared by diluting the solution stated in Fig. 1 with 10mM (pH 7) phosphate buffer to $\sim 2 \times 10^{-7}M$.

differences in pH and ionic strength of the solvent, the molar absorptivities of fluorescein FTH-gly and FTC-gly at $\lambda = 488$ nm are similar. The differences of the molar absorptivities at $\lambda = 322$ nm are probably due to the presence of reaction byproducts for FTH-gly and FTC-gly but not in the sample of fluorescein. The molar absorptivities of FTH and FTC-tyr and -ala are somewhat lower than that of fluorescein. Similarly, the peak-heights for FTC-gly and FTH-gly are higher than the other derivatized amino acids.

The normalized emission spectra of fluorescein, FTH-gly, and FTC-gly are also very similar, Fig. 3, and the relative quantum yields of FTH-gly and FTC-gly, Table 3, can be estimated by comparison of their emission intensities with the emission intensity of fluorescein ($\Phi_{fluor} = 0.95$ for fluorescein in $0.1N$ sodium hydroxide).[14,15] The fluorescence quantum yield and emission spectra are similar for the other FTC and FTH amino acids that were studied. As a result, it is possible to tune the fluorescence detector of the capillary electrophoresis instrument to very high sensitivity for these derivatives.

Table 3. Fluorescence quantum yields of FTH-gly and FTC-gly*

Analyte	Quantum yield
FTH-Gly (pH 7)	0.4 ± 0.1
FTC-Gly (pH 7)	0.4 ± 0.1
FTC-Gly (pH 10)	0.5 ± 0.1

*Taking the quantum yield of fluorescein ($10^{-6}M$) in $0.1N$ NaOH solution as 0.95.[14,15]

See Fig. 3 for the preparation and concentration of the samples.

We have noted elsewhere that the fluorescence signal of FTC–amino acid derivatives does not increase linearly with laser power due to photodegradation.[9] Figure 4 shows the peak height and the detection limit of FTH amino acids as a function of the laser power. With increasing laser power, the fluorescent signal first increases and then, when the laser power is higher than 30 mW, becomes nearly constant. However, the background noise increased with laser power. As a result, the best detection limit was obtained at the laser power of about 25 mW.

Table 4 lists the detection limits of some FTH amino acids under capillary zone electrophoresis separation; detection limits range from 1 to 2 zeptomole (1 zeptomole = 1 zmole = 10^{-21} mole[16]). Generally speaking the detection limits for FTH–amino acids (except arginine) are about 1.5–2 fold superior to those obtained

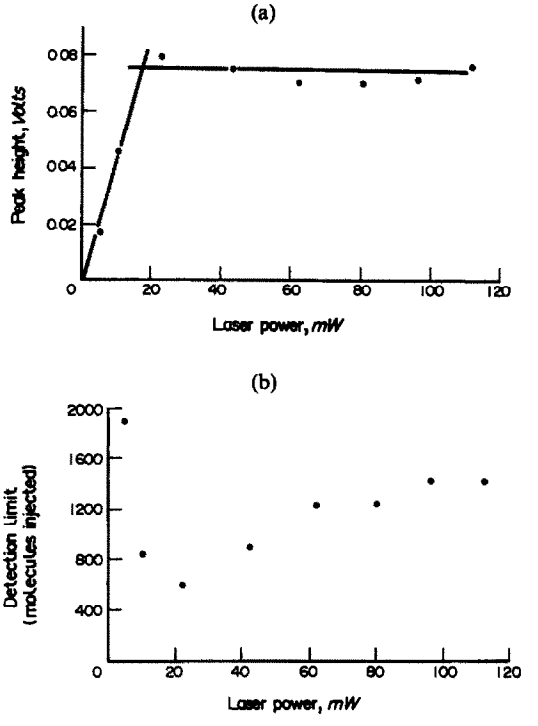

Fig. 4. The fluorescence signal of FTH amino acid by capillary zone electrophoresis and detected by laser induced detector as a function of the laser power applied. (a) Fluorescence signal (the straight lines give a guide); (b) detection limits (3σ) in units of number of analyte molecules injected.

Table 4. Detection limits of FTH amino acids

FTH amino acid	Injection volume, *nl*	Detection limit*		
		Concentration, $10^{-12}M$	Amount, *zmole*[16]	Molecules injected
Ala	0.59	2.5	1.4	800
Arg	0.76	2.6	2.0	1200
Asn	0.60	1.6	1.0	600
Asp	0.48	2.9	1.4	800
Glu	0.49	2.8	1.4	800
Gly	0.58	1.7	1.0	600
Hpro	0.60	1.8	1.1	650
Ile	0.62	2.1	1.2	700
Leu	0.62	1.9	1.2	700
Val	0.61	1.8	1.0	600

*Detection limits refer to the amount of analyte injected into the capillary that produces a signal three times larger than the standard deviation of the background signal.

for FTC–amino acids, both run with 10m*M* phosphate buffer at pH 7 elution buffer in electrophoresis, although their spectroscopic properties are similar as discussed above. This difference in detection limit arises because the retention time of the FTH amino acid is typically three-quarters of the retention time of the corresponding FTC amino acid. The peak height produced in the sheath-flow detector in capillary electrophoresis is inversely proportional to the retention time.[12]

It is interesting that the detection limit is not due to shot noise in the number of detected photons. Shot noise, governed by Poisson statistics, predicts that the noise in the measurements will scale as the square root of signal. Instead, a measurement of noise in the background signal as a function of laser power demonstrated a linear dependence of noise on signal; that is, the relative noise in the signal was constant, 0.5%. We presume that variations in the laser power, specified at 0.5%, are the major source of noise in this experiment. It is reasonable to assume that use of a more stable laser will produce a corresponding improvement in detection limit. The state of the art in ion laser stability is 0.1%. The use of this highly stable laser should result in a five-fold reduction in detection limits, from 600 analyte molecules to 120.

DECOMPOSITION OF $Cu(PCD)_2$ EXTRACTED INTO IBMK AND DIBK PHASES FROM HYDROCHLORIC ACID MEDIA

MASAHIKO MURAKAMI,* HIROSHI TADANO† and TAKEO TAKADA

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-Ku, Tokyo 171, Japan

(*Received* 5 *October* 1990. *Revised* 30 *April* 1991. *Accepted* 8 *May* 1991)

Summary—The decomposition of the bis(1-pyrrolidinedithiocarbamato) copper(II) complex [$Cu(PCD)_2$] extracted into isobutyl methyl ketone (IBMK) and di-isobutyl ketone (DIBK) from hydrochloric acid solution (0.01–8*M*) has been studied with UV-visible and ESR spectrometry. The mixed-ligand complex CuCl(PCD) is formed as an intermediate and $CuCl_2$ or $CuCl_3^-$, are formed as final products, in the decomposition of $Cu(PCD)_2$. The concentration of free hydrochloric acid dissolved in the extract has also been determined, and the effect of the free acid on the decomposition has been studied. The decomposition reaction of $Cu(PCD)_2$ extracted from hydrochloric acid solution can be thought of as a ligand substitution by Cl^-, and occurs with both IBMK and DIBK extraction.

Ammonium 1-pyrrolidinecarbodithioate (APCD) is one of the most widely used reagents for solvent extraction of metal chelates, since it forms stable and extractable chelates with a large number of elements in a relatively low pH region. Although dithiocarbamates, including APCD, are decomposed in acidic solution, APCD shows the highest stability amongst them.[1,2] We have studied the extraction of Cu(II) from highly acidic solution (0.01–8*M* hydrochloric acid) into isobutyl methyl ketone (IBMK)[3,4] or di-isobutyl ketone (DIBK)[5] with APCD. It was defined that the copper chelate is quantitatively extracted from such a media provided a large excess of reagent was used; DIBK is preferred for such a purpose.

In these studies, we observed the characteristic decomposition behaviour of the chelate extracted into both solvents; the copper chelate is stable for a certain period of time but then, it suddenly begins to decompose. As stated earlier, preventing the decomposition of the chelate is important for its extraction in strongly acidic media. It was also reported that the decomposition of the metal–PCD chelate extracted into IBMK causes problems in analysis; however, although several reports commented on the kinetic stability and decomposition of the metal–PCD chelate extracted into IBMK, they have merely discussed the practical point of view, and have not reported its behaviour in detail.[6–8]

Therefore, we have systematically studied the decomposition of the Cu(II)–PCD chelate extracted into IBMK and DIBK via UV-visible and ESR spectrometry, and have discussed its mechanism.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade. Water was redistilled from an all-glass apparatus. The standard stock solution (1000 μg/ml) of copper was prepared from 99.99% pure metal. The solution was appropriately diluted with water to give a desired working solution concentration. All solvents were used without further purification.

Procedure

Extraction. A 20-ml portion of hydrochloric or nitric acid of desired concentration and 2.5 ml of copper working solution were transferred to a 100-ml separating funnel, and 10 ml of IBMK or DIBK as well as 2.5 ml of APCD solution were added. Combinations of $1.6 \times 10^{-4}M$ copper and $8.0 \times 10^{-4}M$ APCD solutions, and $8.0 \times 10^{-4}M$ copper and $4.0 \times 10^{-3}M$ APCD solutions were chosen to give extracts containing $4.0 \times 10^{-5}M$ and $2.0 \times 10^{-4}M$ copper chelate, respectively.

*Author for correspondence.
†Deceased.

Through the present study, relatively dilute solutions of APCD (in both cases corresponding to about a 5-fold ratio to copper) were used, in order to hasten the point of time at which the chelate decomposes. After the mixture was mechanically shaken virogously, the aqueous phase had been withdrawn and the extract was filtered through a phase separation filter paper (Whatman 1PS "phase separators").

UV-visible measurements. All UV-visible spectra were measured with a Shimadzu model UV-240 spectrophotometer equipped with a water-surrounded cell holder and micro stirrer. A 10-mm and a 5-mm quartz cell were used for measurement of the samples containing $4.0 \times 10^{-5}M$ and $2.0 \times 10^{-4}M$ copper chelate, respectively. The spectrum was measured in the range 350–500 nm, at 45-sec intervals against IBMK or DIBK as reference. The sample was kept in the cell compartment of the spectrophotometer throughout the period, and the temperature was kept constant at 25°, with a Yamato CTE-22W "Coolnics" and a water-bath. Timing was started when the reagent was added to the mixture.

ESR measurements. ESR measurements were made with a JEOL model JES-ME-3X spectrometer and a 1-mm i.d. quartz capillary cell. A magnetic field was applied at 3300 ± 500G with 100 KHz modulation; and the modulation amplitude of 6.3G was used for the majority of the measurements. The magnetic field was calibrated with a JEOL model JES-FC-2 NMR marker and a Takeda Riken model TR-5766 frequency counter.

Formation of CuCl(PCD). The mixed ligand complex, CuCl(PCD), was formed from the reaction of $Cu(PCD)_2$ and $CuCl_2$ as follows. Into a centrifuge tube was transferred 5-ml of $Cu(PCD)_2$, $1 \times 10^{-4}M$ IBMK solution and 5 ml of $1 \times 10^{-4}M$ $CuCl_2$ IBMK solution, and the mixture was shaken vigorously for 2 min. To remove the remaining $CuCl_2$, 10 ml of water was added to the tube and it was mechanically shaken for 2 min. After the mixture had separated into layers, the upper phase was filtered through a phase separation filter paper.

Determination of free hydrochloric acid in the extract. The free hydrochloric acid dissolved in the DIBK and IBMK phase was determined as follows. A 25-ml volume of hydrochloric acid of the desired concentration and 10 ml of IBMK or DIBK were transferred to a 100-ml separating funnel and the mixture was mechanically shaken vigorously for 300 sec. It was then allowed to stand until the layers separated clearly. After they had separated, a suitable portion (1–5 ml) of the upper phase and 10 ml of water were transferred to a 100-ml separating funnel, and again the mixture was mechanically shaken vigorously for 120 sec. After the layers had separated, the pH of the lower phase was measured with a pH meter. Blanks for acidic impurities in the solvents and absorbed atmospheric carbon dioxide were obtained by pH measurements of water which had been shaken with fresh solvents.

RESULTS AND DISCUSSION

Analysis of the decomposition reaction of $Cu(PCD)_2$

UV-visible spectrum. The decomposition behaviour of $Cu(PCD)_2$ extracted from hydrochloric acid solution and its dependence on the acid concentration of the aqueous phase have been studied with UV-visible spectrophotometry. The change in absorbance of $Cu(PCD)_2$ extracted into IBMK at 433.5 nm is shown in Fig. 1, and the change in the absorption spectrum, at 45-sec intervals, of $Cu(PCD)_2$ extracted into IBMK is shown in Fig. 2; in both cases, the initial concentration of the chelate was $4.0 \times 10^{-5}M$. The absorbance of $Cu(PCD)_2$ extracted from both $2M$ [Fig. 1(a)] and $4M$ [Fig. 1(b)] hydrochloric acid were constant for a certain time and then suddenly decreased. The shape of the absorbance–time curves change with the acid concentration.

When $4.0 \times 10^{-5}M$ chelate extracted from $\leqslant 2M$ hydrochloric acid, it was shown that an inflection point is observed in the absorbance–time curve, and after that the rate of decrease in the absorbance declines with time. In

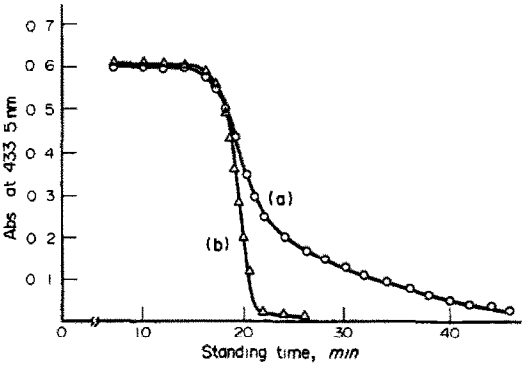

Fig. 1. Change in absorbance of Cu(II)–PCD chelate in IBMK phase: (a) extracted from $2M$ HCl, (b) extracted from $4M$ HCl; [APCD] $8 \times 10^{-5}M$.

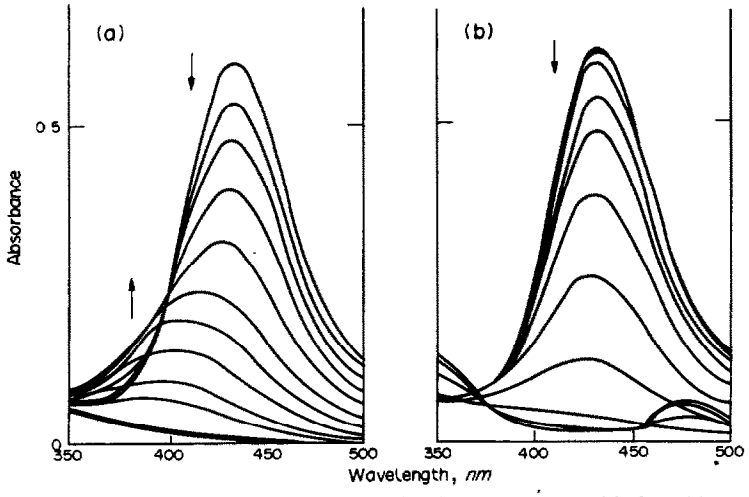

Fig. 2. Change in UV-visible spectra of Cu(II)–PCD chelate in IBMK phase with time: (a) extracted from $2M$ HCl, (b) extracted from $4M$ HCl; time intervals 45 sec; [APCD] $8 \times 10^{-5}M$.

the case of $2M$ [Fig. 1(a)], the inflection point is shown in the curve at the point when the absorbance is reduced to about 50% of its initial value (20–22 min of the standing time), and after that the slope of the curve becomes less steep. Such a profile of decreasing the absorbance was observed when the chelate was extracted from $\leqslant 2M$ hydrochloric acid. As the acid concentration of the aqueous phase was decreased to $\sim 0.01M$, the same profiles as that shown in Fig. 1(a) were observed, although the inflection point became obvious at an earlier stage of the decrease in the absorbance and although the rate of decrease in the absorbance was very slow.

The typical profile of the change in the absorbance spectrum for the above case is shown in Fig. 2(a); it shows the change in the absorbance spectrum of $4.0 \times 10^{-5}M$ $Cu(PCD)_2$ extracted into IBMK from $2M$ hydrochloric acid, at 45-sec intervals. The peak of the spectrum which initially existed at about 433.5 nm is gradually shifted to shorter wavelengths as the absorbance decreases. In this case, an isosbestic point was observed at about 400 nm in the early stages of the spectrum change. However, it shifted to a shorter wavelength with a decrease in absorbance, and then was no longer observed. Such a spectral change suggests the presence of an intermediate product and that the greater part of its spectrum is overlapped with that of $Cu(PCD)_2$. After the initial peak had disappeared, no absorption peak remained in the visible region, although a weak band was observed below about 400 nm [Fig. 2(a)]. This type of spectrum was observed when the copper chelate had been extracted from $\leqslant 2M$ hydrochloric acid.

When $4.0 \times 10^{-5}M$ $Cu(PCD)_2$ was extracted from $\geqslant 3M$ hydrochloric acid, the absorbance drops more steeply than when extracted from $2M$, as shown in Fig. 1(b). As shown in our previous studies,[4,5] such a drop in the absorbance was observed when $Cu(PCD)_2$ was extracted from 4–$8M$ hydrochloric acid solution into IBMK or DIBK phase, regardless of the amount of APCD. The change in the absorption spectrum for such a case is shown in Fig. 2(b) which shows the results for $4M$ acid. Although it is less marked than for $2M$ acid, the shift of the peak to shorter wavelength with a decrease in its absorbance was also observed, regardless of the acid concentration. The isosbestic point was slightly observed only in the very early stages of the decomposition, and little increase in absorbance was observed below about 400 nm.

However, the spectra of the final products are altered with the acid concentration. In contrast to the case of $2M$, an absorption peak was in the end observed with $4M$ acid at about 480 nm, ϵ being in the order of $1.5–2.0 \times 10^3$ $l.mole^{-1}.cm^{-1}$; a stronger absorption band than that shown in Fig. 2(a) appears in the region below 350 nm [Fig. 2(b)]. Such a spectrum was observed when the copper chelate was extracted from 3–$8M$ hydrochloric acid solution. However, in the case of $3M$ acid, the final spectrum was almost the same as Fig. 2(b), but its absorbance at 480 nm was lower than that shown in Fig. 2(b). It suggests that the final species shown in the case of $4M$ acid forms only partly at $3M$ concentration. The above results

for the change in the UV-visible spectrum suggest that the behaviour of the decomposition is gradually changed when the concentration of hydrochloric acid in the aqueous phase is increased from 2 to $4M$, when the initial concentration of $Cu(PCD)_2$ in the IBMK extract is $4.0 \times 10^{-5}M$.

On the other hand, when the initial concentration of $Cu(PCD)_2$ is increased to $2.0 \times 10^{-4}M$, similar profiles of a decrease in the absorbance and similar spectral changes as above were also observed. However, the acidity ranges, in which each profile was observed, shifted to higher values than those in the case of $4.0 \times 10^{-5}M$. When the chelate was extracted from $3M$ or below, the same profile as that in Fig. 1(a) and the same final spectrum as that shown in Fig. 2(a) were observed. It was observed, however, that a small peak due to the intermediate product remains at about 400 nm. The intensity of the remaining peak increased as the acid concentration was decreased which suggests that in these conditions the extent of progress in the decomposition reaction depends on the acid concentration. When the chelate was extracted from $\geqslant 4M$ hydrochloric acid, the absorbance dropped steeply with the same profile as shown in Fig. 1(b), and in the case of $5M$ or above, the same final spectra was observed as those shown in Fig. 2(b), whereas in the case of $4M$ these spectra were only partly observed. Thus, when the initial concentration of $Cu(PCD)_2$ is $2.0 \times 10^{-4}M$, the behaviour of the decomposition is gradually changed when the concentration of hydrochloric acid in the aqueous phase is increased from 3 to $5M$.

ESR spectrum. Figure 3(a) shows the initial ESR spectrum of $2.0 \times 10^{-4}M$ $Cu(PCD)_2$ extracted into IBMK from $4M$ hydrochloric acid, measured 12 min after the extraction. There were four split absorption bands, with ESR parameters of $g = 2.048 \pm 0.002$ and $a = 79 \pm 1G$. This spectrum agrees with those of the series of bis(N,N'-disubstituted-dithiocarbamato)copper(II) complexes in various organic solvents.[9,10] With the decomposition of $Cu(PCD)_2$ chelate, a decrease in intensity of this band and the appearance of a new absorption band were observed. Figure 3(b) shows the spectrum measured at 33 min after the extraction. ESR parameters of this band are determined as $g = 2.077 \pm 0.002$ and $a = 75 \pm 2G$. The line width, defined as the peak-to-peak separation in a splitting line, of the new absorption band is relatively broad

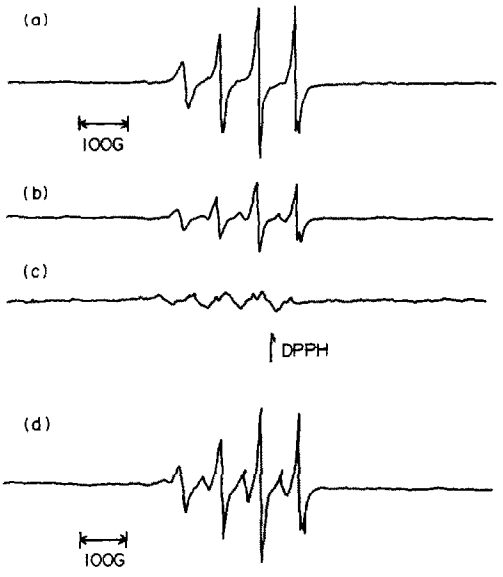

Fig. 3. Change in ESR spectra of Cu(II)–PCD chelate extracted in IBMK phase from $4M$ HCl [(a) 12 min, (b) 33 min and (c) 45 min after extraction, respectively] and (d) ESR spectrum observed in the reaction between $Cu(PCD)_2$ and $CuCl_2$ in IBMK.

(about $25G$). The intensity of the initial absorption band considerably decreased, and the new four splitting bands were overlapped with the initial band. Although the intensity of the new band once increased with decreasing that of the initial band [Fig. 3(c)], and soon it also decreases with time.

The appearance of this new band in the ESR spectrum corresponds to the existence of an intermediate species which is expected from the observations of the change in the UV-visible spectrum. Furthermore, when the chelate was extracted from $1M$ hydrochloric acid, it was found that the decomposition is stopped halfway and both bands remain, and it agrees with the behaviour observed in the UV-visible study on $2.0 \times 10^{-2}M$ $Cu(PCD)_2$. As mentioned above, it was observed that when the chelate was extracted from the aqueous phase of such an acidity the absorption spectrum due to the intermediate product remains. Therefore, it is taken that this new absorption band is due to the intermediate species.

Identification of the intermediate and the final product

Intermediate product. ESR spectra and parameters are similar to those of mixed-ligand copper(II) dithiocarbamate complexes with chloride, CuCl(dtc). Yordanov and Shopov[11] reported the ESR study on the formation of

these mixed ligand complexes by the reaction of some bis(N,N'-disubstituted-dithiocarbamato) copper(II) complexes with $CuCl_2$ in various organic solvent media, as follows:

$$Cu(dtc)_2 + CuCl_2 \rightleftharpoons 2CuCl(dtc) \qquad (1)$$

and the following parameters are reported for CuCl(dtc): $g = 2.073 \pm 0.002$ and $a = 72 \pm 2G$ in acetone, and $g = 2.076 \pm 0.002$ and $a = 69 \pm 2G$ in benzene. Although these parameters can be altered with a certain kind of solvent, they remain virtually unaltered with a substituent on the nitrogen atom in dithiocarbamic acid.

Hence, to identify the species of the intermediate, CuCl(PCD) complex was formed by the reaction of $Cu(PCD)_2$ with $CuCl_2$ in IBMK and its UV-visible and ESR spectra were measured, and compared with those which appear in the course of the decomposition of $Cu(PCD)_2$. Figure 3(d) shows the ESR spectrum which was observed with the reaction mixture of $Cu(PCD)_2$ and $CuCl_2$ in IBMK solution. Similar, to the spectrum which had been observed in the course of the decomposition of $Cu(PCD)_2$ [Fig. 3(b)], the four splitting absorption bands were overlapped with the absorption band of $Cu(PCD)_2$. The ESR parameters were determined to be $g = 2.075 \pm 0.002$ and $a = 74 \pm 1G$, values which closely agree with those of the intermediate. Furthermore, in the UV-visible spectrum of this reaction mixture, the absorption maximum appeared at about 420 nm, and it is similar to that observed in the course of the decomposition of $Cu(PCD)_2$ (Fig. 2). From these facts, it can be concluded that the intermediate product of the decomposition reaction of $Cu(PCD)_2$ extracted from hydrochloric acid media was CuCl(PCD).

Final products. UV-visible spectra of final products and their spectral change with hydrochloric acid concentration in the extract are similar to those of copper(II) chloride, $CuCl_2$, and the trichloro copper(II) complex, $LiCuCl_3$, in non-aqueous solution. Sawada *et al.* studied the equilibrium of copper(II) chloride with lithium chloride in acetic acid;[12] and in their paper, it was reported that when lithium chloride was added to a solution of copper(II) chloride, the $LiCuCl_3$ complex was formed, and this caused the following spectral change: the characteristic spectrum of $CuCl_2$, which shows an absorption maximum at 300 nm (ϵ is about 4×10^3 $l.mole^{-1}.cm^{-1}$), was changed to that of $LiCuCl_3$, which shows a maximum at about 310 nm (ϵ being of the order of several thousands) and at about 450 nm (ϵ being about 1×10^3 $l.mole^{-1}.cm^{-1}$).

On the basis of this report, it was attempted to measure the absorption spectrum of $CuCl_2$ dissolved in IBMK or DIBK. Although the value of ϵ could not be determined since $CuCl_2$ was sparingly soluble in both solvents ($10^{-4}M$ at most), a spectrum similar to that in acetic acid solution was observed. Furthermore, a spectrum similar to $LiCuCl_3$ and to the final product in the case of the copper chelate extracted from $3M$ or above hydrochloric acid solution, was observed when $CuCl_2$ was dissolved in the IBMK containing free hydrochloric acid. Hence, it was concluded that the final products of the decomposition of $Cu(PCD)_2$ extracted from hydrochloric acid media are copper(II) chloride complexes, and it was expected that the composition of the complex depends on the concentration ratio of the free hydrochloric acid to the initial copper(II) in the organic phase.

Effect of initial copper and free acid concentrations

From the results of above studies, it is noted that the decomposition profile and the final copper species depends on both the initial copper concentration and the hydrochloric acid concentration of the aqueous phase. It should be concluded that it is due to a change in the concentration ratio of the free hydrochloric acid to total copper in the extract. Hence, the free hydrochloric acid in the extract was determined, and the effect of the free acid on the decomposition behaviour was studied.

In the preceding paper,[5] we determined the free hydrochloric acid dissolved in the IBMK and DIBK phase with potentiometric titration. However, the titration could not be used in the present study since it was shown that the titration method could not be applied to the case in which the acidity of the aqueous phase is lower than 2 and $4M$ for IBMK and DIBK, respectively. In the previous study, it was also observed that when the extract is shaken with an aqueous phase the free acid can be almost completely transferred to the aqueous phase. Hence, we have tried to determine the free acid in the extract from the pH of the aqueous phase which had been used for washing the extract. To estimate the effectiveness of the method, the free acid concentrations in the DIBK phase which

Table 1. Comparison of titration and back extraction

Conc. of HCl in aq. phase (M)	Conc. of free acid in DIBK(M)	
	Titration	Back extraction
10	2.3×10^{-1}	3.4×10^{-1}
8	3.2×10^{-2}	3.1×10^{-2}
6	3.8×10^{-3}	3.7×10^{-3}
4	4.3×10^{-4}	2.9×10^{-4}

Aqueous phase 25 ml, organic phase 10 ml, shaking time 5 min.

had been determined by this method were compared with those of the titration. Table 1 shows that the values obtained with the present method closely agreed with that obtained by the potentiometric titration method. It indicates that the present method can be applied for determining a wide range of the free acid, and that it is a simpler and more rapid method compared to the titration.

The results of the determination of free acid dissolved in IBMK had been shaken with 0.1–5M hydrochloric acid shown in Table 2. It was observed that the free acid concentration of the extract is about 10^{-5}–$10^{-3}M$ in these conditions, and it corresponds to about 0.3–30-fold and 0.06–5.5-fold ratio to the total copper concentration of $4.0 \times 10^{-5}M$ and $2.0 \times 10^{-4}M$, respectively. Based on the free acid concentration obtained as above, the decomposition behaviours can be roughly classified by the ratio of the concentration of free acid to initial copper in the extract, as follows: (1) When the concentration of free acid is considerably higher than that of copper, the absorbance drops steeply as shown in Fig. 1(b), and the trichloro complex should be formed as the final product. (2) When the concentration of free acid is little more than that of copper, *i.e.*, about 2–3-fold, the absorbance again drops steeply [Fig. 1(b)]. However, the trichloro complex is only partly observed in the final products, the dichloro complex being the main species. (3) When the concentration of free acid is lower than that of copper, the decomposition is very slow and almost stops halfway.

Table 2. Free acid concentration in IBMK phase

Conc. of HCl in aq. phase (M)	Conc. of free acid in IBMK phase (M)
5	1.1×10^{-3}
4	3.4×10^{-4}
3	1.3×10^{-4}
2	4.5×10^{-5}
1	2.0×10^{-5}
0.1	1.3×10^{-5}

Aqueous phase 25 ml, organic phase 10 ml, shaking time 5 min, with filtration.

For example, in the case of an initial copper concentration of $4.0 \times 10^{-5}M$, the above decomposition behaviour [(1), (2) and (3)] was observed when the chelate was extracted from 4M or above; about 3M; and 2M or below hydrochloric acid solution, and they corresponded to 8.5-fold or above; about 3.3-fold; and 1.1-fold or below ratio to copper, respectively. Such a relationship as above between the decomposition and the concentration ratio of the free hydrochloric acid to the initial copper(II) is also observed when the initial copper(II) concentration is altered to $2.0 \times 10^{-4}M$. In this case, behaviour (1), (2) and (3) was observed when the chelate was extracted from 5M or above, 4M and 3M or below hydrochloric acid, and they corresponded to a 5.5-fold or above, 1.7-fold, and 0.65-fold or below ratio to copper, respectively. Thus, it was concluded that the decomposition behaviour and species of the final product are mainly determined by the relation between the copper concentration and the free acid concentration.

Difference between IBMK and DIBK

The decomposition behaviours of the chelate extracted into DIBK were compared with those of IBMK. On the whole, no difference in the behaviour of both solvents was found in both the UV-visible and ESR studies. In the case of DIBK, however, the same behaviour was observed as in the case of IBMK at higher acid concentration. For example, the same shape of the UV-visible spectra of the final products as that observed in up to $\sim 3M$ in IBMK extract [Fig. 2(b)] was observed in DIBK extract up to 6M. These facts indicate the difference in the amount of free hydrochloric acid remaining in each extract. As previously reported, the free acid in DIBK extract is much smaller than that in IBMK extract.[5]

CONCLUSIONS

Each species found in the respective steps in this reaction indicate that the decomposition reaction of $Cu(PCD)_2$ in the organic phase can be concluded to be the ligand exchange reaction of the copper complex with chloride. Based on the species in each step and considering the

effect of both concentrations of the free acid and the total copper on the decomposition behaviour, the following reaction scheme was assumed:

$$\begin{aligned} Cu(PCD)_2 + HCl &\rightarrow CuCl(PCD) \\ &\quad + C_4H_9N + CS_2 \\ &\quad \times CuCl(PCD) + (x-1)HCl \\ &\quad \rightarrow CuCl_x^{(2-x)} \ (x = 2 \text{ or } 3) \\ &\quad \rightarrow C_4H_9N + CS_2 \end{aligned} \qquad (2)$$

It is assumed that the free PCD^- ligand dissociated from the copper chelate reacts with a proton and is decomposed; Aspila and co-workers[13,14] made systematic studies on the decomposition mechanism of some dithiocarbamates, and concluded that only the acid form of the DTC molecule was decomposed into a corresponding amine [in this case, pyrrolidine (C_4H_9N)] and a carbon disulphide.

Such a decomposition of the dissociated PCD^- ligand is assumed as the "motive force" of decomposition of the copper chelate. In the present case, it seems that the PCD^- ligand is only slightly substituted with Cl^- if the ligand is not decomposed immediately after its dissociation from the copper chelate, since the formation constants of series of Cu(II) dithiocarbamato complexes are considerably larger than those of Cu(II) chloro complexes. Of course, it is expected that there are various other factors which affect the decomposition of $Cu(PCD)_2$ *i.e.*, decomposition of the ligand by its oxidation by air, presence of water dissolved in the extract, and so on. However, provided that the concentration of the free acid is sufficiently higher than that of the copper chelate, They are negligible and the above mechanism can be assumed.

In the present study, the same behaviour was observed in both solvents on the whole. Therefore, it was concluded that the above mechanism can be assumed in IBMK or DIBK system. To discuss the above mechanism in detail, the kinetics would need to be investigated. Some kinetic studies on the decomposition of $Cu(PCD)_2$ extracted from hydrochloric acid solution into IBMK or DIBK phases is in progress.

SPECTROPHOTOMETRIC STUDY OF THE REACTION OF ZINC WITH *O*-HYDROXYBENZENEDIAZOAMINOAZOBENZENE AND ITS APPLICATION

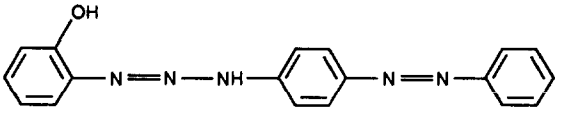
WEI-FENG YANG, WAN-RU CHEN,* CHUNG-GIN HSU and WEI WANG

Department of Chemistry, East China Normal University, 3663 Zhong-Shan Road (N), Shanghai 200062, People's Republic of China

(*Received* 25 *July* 1989. *Revised* 23 *July* 1991. *Accepted* 24 *July* 1991)

Summary—A highly sensitive and selective procedure for spectrophotometric determination of zinc has been developed. At pH 10.6, in the presence of emulsifier *p*-octylpolyethyleneglycol phenylether (OP), zinc forms an orange–red complex with *o*-hydroxybenzenediazoaminoazobenzene (HDAA) which has an absorption maximum at 525 nm. The molar absorptivity is 1.50×10^5 l.mole^{-1}.cm^{-1}. Beer's law is obeyed for zinc in the range 0–13 μg/25 ml. The method has been applied to the spectrophotometric determination of trace amounts of zinc in aluminium alloy and in human hair. The proposed method is simple, rapid and accurate. No heating or separation is required.

Numerous methods for the spectrophotometric determination of zinc have been reported,[1] but few of them give high sensitivity and simple operation. *o*-Hydroxybenzenediazoaminoazobenzene (HDAA), a derivative of benzenediazoaminoazobenzene,[2,3] synthesized in our laboratory, with the following structure



gives sensitive reaction with cadmium.[4,5] It was found that HDAA also gave a sensitive colour reaction with zinc in borax buffer of pH 10.6. The sensitivity for determination of zinc is superior to that of other triazenediyl reagents. In this work, the conditions for the zinc–HDAA complex formation were studied in detail. In the presence of the nonionic surfactant emulsifier OP, HDAA reacts instantaneously with zinc to form an orange–red 1:3 complex. The zinc–HDAA complex exhibits an absorption maximum at 525 nm with a molar absorptivity of 1.50×10^5 l.mole^{-1}.cm^{-1}. Beer's law is valid over the concentration range of 0–13 μg of zinc per 25 ml of solution. Using the masking agents, the colour reaction is free from interference by more than thirty ions investigated. The proposed method has been applied to the spectrophotometric determination of trace amounts of zinc in aluminium alloy and in human hair and offers the advantages of high sensitivity, simplicity, rapidity and high stability of the coloured solution, without heating or separation.

EXPERIMENTAL

Apparatus

Absorption spectra and absorbance were recorded with a Beckman DU-7HS spectrophotometer and a model 721 spectrophotometer (Shanghai Third Analytical Instruments Factory) with 1.0-cm cells. A Model pH S-2 pH meter (Shanghai Second Analytical Instruments Factory) was used to measure the pH values of the solutions.

Reagents

All reagents were of analytical reagent grade unless otherwise stated.

Standard zinc solution. Dissolve zinc oxide (99.99%) in sufficient concentrated hydrochloric acid, dilute to volume in a 100-ml calibrated flask and mix well. Dilute further to obtain a 5 μg/ml working standard solution.

HDAA solution. Dissolve 100 mg of HDAA in 500 ml of ethanol.

Borax buffer solution (pH 10.6). Add sodium hydroxide dropwise to a 0.05*M* borax solution to the required pH.

Emulsifier OP solution. A 5% w/v aqueous solution of OP (Shanghai First Reagent Factory) was used.

Recommended procedures

Procedure for study of the colour reaction of zinc. Take a test solution containing not more than 13 μg of zinc in a 25-ml calibrated flask, add 5 ml of pH 10.6 borax buffer, 2.5 ml of 5% emulsifier OP and 2.5 ml of 0.02% HDAA solution, successively dilute to the mark with water and mix well. Measure the absorbance at 525 nm in a 1.0-cm cell against a reagent blank.

Procedure for the determination of zinc in aluminium alloy. Take 0.2 g of a sample of alloy into a 100-ml beaker, add 10 ml of 20% sodium hydroxide and 3 drops of 30% hydrogen peroxide. Heat until the sample has been completely dissolved, then add 30 ml of distilled water. Heat the solution again to boiling and cool. Transfer the solution into a 100-ml calibrated flask, dilute to volume with distilled water and mix well. Filter the solution into a 200-ml beaker. Pipette 2.0 ml of the filtrate into a 25-ml calibrated flask and add hydrochloric acid (1 + 3) dropwise with swirling until a precipitate just appears and dissolves again. Finally, add 2.0 ml of 2% sodium fluoride, 1.0 ml of 0.5% thiourea solution, 2.0 ml of 1% sodium potassium tartrate and a few drops of 2% sodium hydroxide. Then follow the recommended procedure described above.

Procedure for the determination of zinc in human hair[6,7]

Place the hair sample, *ca.* 1.0 cm in length, in a 100-ml beaker, introduce sufficient 1% detergent solution to cover it and soak for 30 min at 60°. Pour out the detergent solution and wash the hair with distilled water until the foam completely disappears. Then add acetone and soak for 2 hr. Pour out the acetone and wash the hair three times with distilled water, dry for 90 min at 120° and store in a desiccator.

Place 0.2 g of treated human hair in a 100-ml beaker, add 5.0 ml of concentrated nitric acid, heat at a low temperature to decompose the sample and evaporate to almost 1.5 ml (the colour of the solution is bright orange–yellow). After cooling, add two portions of 1 ml of 30% hydrogen peroxide and each time heat continuously until the solution becomes colourless. Transfer the solution into a 50-ml calibrated flask, dilute to volume with distilled water and mix well. Pipette 1.0 ml of the solution into a 25-ml calibrated flask and add 1–2 drops of 2*M* sodium hydroxide, 2.0 ml of 1% sodium potassium tartrate and then follow the above recommended procedure for the determination of zinc.

*Tween-20; polyoxyethylene sorbitan monolaurate (Shanghai Chemical Reagent Supply Centre).

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of HDAA and the zinc–HDAA complex are shown in Fig. 1. The absorption maximum of the reagent is at 436 nm and of the complex at 525 nm.

Conditions for complex formation

Since a surfactant should be used as a solubilizing agent, various surfactants were tried for this purpose. Of the eight surfactants tried, namely cetylpyridinium chloride, polyvinyl alcohol, sodium dodecylbenzenesulphonic acid, polyvinyl pyrrolidone, polyethylene glycol 10,000, Tween-20,* Triton X-100 and emulsifier OP, it was found that Triton X-100 and emulsifier OP gave a remarkable increase in sensitivity of the zinc–HDAA complex, hence emulsifier OP was chosen for all subsequent work. The optimum amounts of 5% emulsifier OP solution added were 1.0–4.0 ml in 25 ml of solution. An addition of 2.5 ml was recommended.

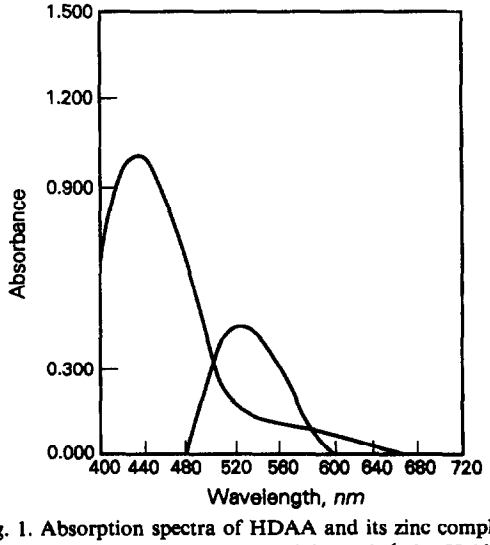

Fig. 1. Absorption spectra of HDAA and its zinc complex (1) HDAA against water HDAA, $3.02 \times 10^{-6}M$; pH 10.6; emulsifier OP, 0.6%. (2) Zn (10 μg)–HDAA complex against reagent blank HDAA, $3.02 \times 10^{-6}M$; pH 10.6; emulsifier OP, 0.6%.

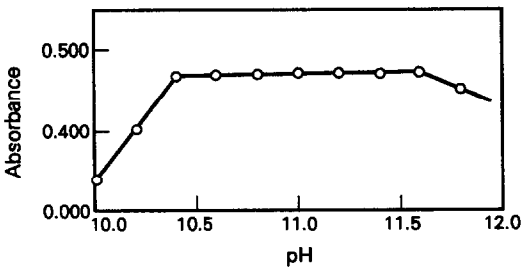

Fig. 2. Effect of pH. Absorbance of complex measured against corresponding reagent blank.

The absorbance of the complex depends on the pH of the solution, as shown in Fig. 2. The maximal and constant absorbance was attained in the pH range 10.4–11.6. Therefore a pH of 10.6 was chosen for the determination.

Addition of 2.0–7.0 ml of borax buffer gave maximal and constant absorbance of the complex for 5.0 μg of zinc. Hence an addition of 5.0 ml was appropriate.

Under the conditions employed, the volumes of 0.02% HDAA solution required to obtain maximal and constant absorbance for 5.0 μg of zinc were 2.0–5.0 ml, therefore 2.5 ml of HDAA solution were introduced.

Characteristics of the complex

In pH 10.6 borax buffer, the absorbance reached its maximum instantaneously and remained stable for at least 24 hr. Normal variations in laboratory temperature will have no effect on the complex, but the solution becomes turbid above 50°.

Adherence to Beer's law and sensitivity

The absorbance is a linear function of zinc concentration in the range 0–13 μg in 25 ml of solution. The apparent molar absorptivity of the complex is 1.50×10^5 l.mole^{-1}.cm^{-1}.

Composition of the complex

The composition of the complex was determined by the continuous variation method and the mole-ratio method. A ratio of zinc to HDAA was found to be 1:3 in the complex by both methods.

Effect of foreign ions

The effects of various ions on the determination of zinc was studied and their tolerance limits are listed in Table 1. If an error of 5% in the absorbance reading is considered tolerable, as shown in Table 1, most of the interfering ions can be masked and the selectivity of the method will be improved. Therefore, the method can be applied to the determination of trace amounts of zinc without separation.

Table 1. Tolerance limits of foreign ions in the determination of 5.0 μg of zinc

Foreign ion	Tolerance limit, μg	Ion/Zn(II)

Application to aluminium alloy and human hair

The method has been applied to the determination of zinc in real samples. The results obtained for standard samples of aluminium alloys, given in Table 2, agreed well with the certified values. The recovery of zinc was in the range 95.8–101.7%.

The results obtained for several human hair samples, presented in Table 3, agreed well with those obtained by atomic-absorption spectrometry. The recovery of zinc is in the range 99.92–101.2%.

ANALYTICAL NOTE

ERBIUM DETERMINATION IN PREFORMS OF OPTICAL FIBRES BY INDUCTIVELY COUPLED PLASMA–ATOMIC EMISSION SPECTROMETRY

A. LOPEZ-MOLINERO,* A. VILLAREAL and J. ANZANO
Department of Analytical Chemistry, Science Faculty, University of Zaragoza, 50009 Zaragoza, Spain

(*Received* 6 *November* 1990. *Revised* 25 *July* 1991. *Accepted* 2 *August* 1991)

Summary—Erbium which is used in the composition of heavy metal fluoride optical fibres was determined in preforms of these materials by inductively coupled plasma–atomic emission spectroscopy (ICP–AES). The new analytical procedure developed comprises: solid sample dissolution, via an alkaline fusion with sodium carbonate, and acid leaching with dilute hydrochloric acid, and measurements of emission intensities of 337.276 nm. This method has a detection limit of 31 ng/ml and a reproducibility of 0.90% r.s.d.

Optical fibre cables are now used extensively for telecommunications applications. In this field, the development of heavy metal fluoride (HMF) glasses for use in a new generation of low loss optical fibres is receiving considerable attention. The basic composition of HMF fibres includes fluorides of: metallic transition elements, alkaline, alkaline earth and rare earth elements. This last group includes erbium.

Control of the fibre composition is of great importance because the performance such as attenuation loss is expected to depend on the presence of impurities and the element concentration.

One of the characteristics of optical fibres is the extreme difficulty in decomposing and dissolving these inorganic solids. For the direct analysis of the solid, AAS with electrothermal atomization and hot hollow-cathode emission spectrometry[1] or by NAA[2] has been proposed. Nevertheless, several dissolution procedures have been published. They are based principally on acid attack ($HF–H_2SO4$),[3] but all are very time-consuming and require considerable experimental experience.

In this report we present the determination of erbium in preforms from which the HMF optical fibers are obtained. As dissolution procedure we propose a decomposition based on alkaline fusion and as determination method we measure the erbium ionic emission (at 337.276 nm) in solution by inductively coupled plasma–atomic emission spectroscopy (ICP–AES).

*Author for correspondence.

EXPERIMENTAL

Apparatus

A Perkin–Elmer P 40 plasma spectrometer, consisting of a 40-MHz free running generator operating at 1.0 kW and containing a dismountable torch was used. The observation height was 15 mm above the coil. Gas feed pressure to the plasma was 5 bar. The flow of gases were: nebulizer gas (0.7 l./min), intermediate gas (0.6 l./min) and outer gas (12 l./min). Solutions were introduced into the plasma by a cross-flow nebulizer at 1 ml/min solution uptake rate, utilizing a peristaltic pump.

Reagents

Standard erbium solution (1000 μg/ml) was prepared by dissolving 0.1143 g of erbium trioxide (Er_2O_3) in the least quantity of concentrated hydrochloric acid and subsequently dilution with demineralized water in a 100-ml standard flask. Another standard Er solution was prepared from 0.1322 g of erbium fluoride (ErF_3) and fusion with 0.92 g of sodium carbonate in a platinum crucible. The melt was dissolved in 25 ml of 1*N* hydrochloric acid and subsequently diluting with demineralized water in a 100-ml standard flask.

Solutions of other elements present in the fibre composition (Al, Ba, Cd, La, Li, Mg, Na and Zn) were prepared at a concentration of 1000 μg/ml from the corresponding nitrate (analytical grade quality). Solutions of other reagents were prepared by dissolution and/or dilution with demineralized water.

Standardization of erbium compounds

The erbium compounds (oxide and fluoride) were standardized by complexometric titration with EDTA, using Xylenol Orange as indicator.[4]

Preparation of the real samples

The sample was ground in an agate mortar to produce a powder with a particle size under 150 μm. This powder (0.1726 g) is mixed intimately with sodium carbonate. The proportion of sample to 'flux' is 1 : 7. The mixture is placed in a platinum crucible and heated appropriately. Then the solidified melt is dissolved in diluted hydrochloric acid (1*M*) and diluted with demineralized water in a 100-ml standard flask to give an acidity of 0.1*M* hydrochloric acid.

Analysis procedure

The standards for the calibration graph are prepared in a 100-ml standard flask from the standard erbium solution (Er_2O_3) diluting to volume with 0.1*M* hydrochloric acid. The erbium content of these solutions ranges from 0.10 to 100.00 μg/ml. The emission of the real samples at 337.276 nm is interpolated on the linear graph obtained.

RESULTS AND DISCUSSION

Choice of analysis line

The bibliography gives a list of the atomic and ionic emission lines of erbium which are potentially of use,[5,6] but only ionic lines are analytically useful. Their sensitivity and the possible interferences due to the main elements (as matrix effect or concomitant elements, and spectral interferences) that make up the sample and the fusion reagent were evaluated. As a result of this study, the ionic line at 337.276 nm with a 31-ng/ml detection limit is proposed as the analytical line.

Analysis conditions

Important matrix effects in the ICP are found to be due to variations in the acid content.[7,8] For that reason and because hydrochloric acid is necessary in the dissolution procedure, we studied the influence of the concentration of hydrochloric acid. We found that 1*M* hydrochloric acid depresses the intensity of erbium, by about 11%, as compared to aqueous solution, while 0.1*M* only results in a 6% decrease of the signal. Therefore, as a compromise, 0.1*M* hydrochloric acid was used to prepare the standards.

Table 1. Analysis of the artificial preform of optical fibre sample solution

Er added	Er found	% recovery	% r.s.d.
0.40	0.388	97.0	4.95

number of determinations = 10

composition of the artificial sample solution (μg/ml):

element	concentration	element	concentration
Na	3900	Cd	430
Ba	370	Zn	270
La	70	Al	20
Li	10		

Analysis of real samples

Reference materials with certified contents of erbium were not available. The accuracy of the method was therefore tested by analysis of an artifical solution prepared with the same content as that of real optical fibre samples. The results are shown in Table 1. The procedure was verified by standard addition to a solution obtained after real sample decomposition. The results obtained in this last solution by both calibration graph and standard addition methods are given in Table 2. The results are satisfactory and a *t*-test applied to compare the means of two determinations[9] revealed no significant difference at $P = 0.05$.

CONCLUSION

An alternative, rapid and simple procedure to analyse the preforms of optical fibres is proposed. It includes an alkaline fusion with dissolution of the melt in 1*M* hydrochloric acid. The obtained solution can be analysed by ICP–AES. Concomitant elements effects have not been detected but acid matrix matching is necessary.

MICELLAR ENHANCED SPECTROFLUOROMETRIC DETERMINATION OF CHLOROPHYLL *a* AND CHLOROPHYLL *b* IN FRESH WATERS*

JOSE J. SANTANA,† MARYANN GUNSHEFSKI and JAMES D. WINEFORDNER‡
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(*Received* 23 *May* 1991. *Revised* 31 *July* 1991. *Accepted* 31 *July* 1991)

Summary—The enhancement of the fluorescence of chlorophyll *a* and chlorophyll *b* in a non-ionic micellar media is used for the establishment of a new analytical method for the determination of these pigments. After optimization of the variables, including concentration of surfactant, pH, temperature and percentage of organic solvent, the analytical figures of merit are determined. High recovery percentages are found when the method is applied to the simultaneous determination of chlorophyll *a* and *b* in synthetic mixtures. Finally, the method is used for the determination of both chlorophylls in local fresh waters, finding excellent agreement with the results obtained by an HPLC/fluorescence method.

Determination of chlorophylls, as an indicator of phytoplankton biomass, is one of the most important measurements in oceanography and liminology. Measurement of chlorophyll concentration, above all, chlorophyll *a* and *b*, helps us to understand natural systems and is important in studies aimed at assessing the impact of pollution or other disturbances.

The standard analytical methods for chlorophyll determination are based on spectrophotometry[1–3] or spectrofluorometry.[4–6] In the last several years, high-performance liquid chromatographic (HPLC) methods have largely been used for the analysis of plant pigments.[7–10]

In the case of the determination of chlorophyll *a* and chlorophyll *b* in natural waters (sea water and fresh water), after filtration these pigments are extracted from phytoplankton with an organic solvent (normally 90% acetone) and are detected in this extract by any of the previously mentioned methods. However, it is possible that very small concentrations of chlorophyll *a* and chlorophyll *b* remain in the aqueous filtrate, despite the low solubility of these compounds in water. Because of the very low absorbance and fluorescence signals of the chlorophylls in aqueous medium, it is very difficult to determine "residual" amounts of chlorophyll *a* and chlorophyll *b* with standard methods.

However, in aqueous medium, the fluorescence of these pigments is enhanced in a micellar solution. The reasons for the reduction of non-radiative processes in the presence of a surfactant include the reduced motion of the fluorophore molecules (less dynamic quenching) and the reduction of quenching effects of oxygen or other species.[11] Micellar media and fluorescence techniques have been used previously to study the photochemical properties of chlorophylls.[12,13]

In this work, we present a study of the fluorescent characteristics of chlorophyll *a* and chlorophyll *b* in different media, including an anionic surfactant, sodium dodecyl sulphate (SDS), a cationic surfactant, dodecyltrimethylammonium chloride (DTMACl), and several non-ionic surfactants, isooctylphenoxypolyethoxyethanol (Triton X-100) and polyoxyethylene-23-lauryl-ether (Brij-35). Triton X-100 is chosen as the best surfactant for the enhancement of the fluorescence of chlorophyll *a* and chlorophyll *b*. The method is applied to the determination of these species in fresh waters, and the results are compared with those obtained by HPLC with fluorescence detection.

EXPERIMENTAL

Apparatus

A Perkin-Elmer LS-5 luminescence spectrophotometer (Perkin-Elmer, Norwalk, CT),

*Research supported by NIH 5R01-GM11373-28.
†On leave from the Dept. of Chemistry, University of Las Palmas de G.C., Las Palmas de G.C., Spain.
‡Author for correspondence.

fitted with a xenon discharge lamp and interfaced with a model CLS-3600 data station was used in the fluorescence mode for the collection of all room-temperature fluorescence spectra and intensity measurements. The excitation slit was set at a 10-nm band pass and the emission slit was set at a 5-nm band pass. A 505-nm long-pass filter was placed in front of the emission monochromator in order to minimize second-order scatter. Quartz cuvettes with a 1-cm path length were used.

The HPLC system consisted of an Altex (Berkely, CA) model 110A pump used with an Altex model 210 valve and a 20-μm sample loop. The Alltech column (Alltech Associates, Inc., Deerfield, IL) was 50 mm × 4.6 mm i.d., and filled with Spherisorb ODS (5-μm particle diameter). Fluorescence measurements were obtained with the LS-5 spectrophotometer with a cell volume of either 8 or 25 μl.

The Perkin-Elmer PECLS Application program, in the LC mode, was used to obtain the respective chromatograms and the calculation of peak area (or height).

Reagents

Spectrograde acetone (Eastman Kodak Co., Rochester, NY) was used for extraction and preparation of the stock solutions of chlorophyll *a* and *b*. HPLC-grade methanol (Fisher Scientific, Fair Lawn, NJ) was degassed with helium before use, and "nanopure" demineralized water (Barnsted System, Sybron Corp., Boston, MA) was used throughout.

Stock solutions (0.1*M*) of Triton X-100 (Fisher Scientific, Fair Lawn, NJ), sodium dodecyl sulfate (SDS) (Sigma Chemical Co., St. Louis, MO), dodecyltrimethylammonium chloride (DTMACl) (Eastman Kodak Co., Rochester, NY) and Brij-35 (Aldrich Chemical Co., Inc., Milwaukee, WI) were all prepared in "nanopure" water.

Standards of chlorophyll *a* and *b* were obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI) (Product Codes: 25,825-3 and 25,826-1 respectively). Stock solutions in 90% acetone were stored at about 5° in the dark.

Procedures

Determination of chlorophyll a *and* b *with Triton X-100 and fluorescence detection.* A known volume of sample or stock solution (containing 2–1000 ng of either chlorophyll *a* or *b*), 3.0 ml of 0.01*M* Triton X-100, and an adequate volume of acetone to produce a final solution of 1% acetone, was placed in a 10-ml standard flask. The fluorescence measurements were made with an excitation wavelength (λ_{ex}) of 431 nm and an emission wavelength (λ_{em}) of 673 nm for chlorophyll *a*, and a λ_{ex} of 462 nm and a λ_{em} of 654 nm for chlorophyll *b*. The analytical calibration curves were obtained from standard solutions prepared in the same manner.

Determination of chlorophyll a *and* b *using HPLC with fluorescence detection.* A known volume of sample or stock solution (containing 2–1000 ng of either chlorophyll *a* or *b*) and an adequate volume of acetone to produce a final solution of 90% acetone was placed in a 10-ml standard flask. A volume of 20 μl of each sample was then injected onto the HPLC column and eluted with a 97:3 methanol:water mixture for 5 min at a flow-rate of 1 ml/min. The respective chromatograms were obtained with an LC program with a λ_{ex} of 429 nm and a λ_{em} of 669 nm for chlorophyll *a*, and a λ_{ex} of 458 nm and a λ_{em} of 652 nm for chlorophyll *b*. The analytical calibration curves were obtained following the same procedure.

Determination of chlorophyll a *and* b *in fresh waters with fluorescence detection.* A volume of 500 ml of local lake water was prefiltered through Whatman filters (# 4) to remove any large particulate matter. This filtrate was then vacuum-filtered through a 47-mm Whatman glass microfiber filter (GF/C). Chlorophyll *a* and *b* were then extracted from the filter by pulverization and ultrasonication of the filter in 10 ml of cold (0–5°) solvent (90% acetone) in subdued light. The extracts (previously separated from the particulate residue by centrifugation), and the aqueous residual samples (2nd filtrate) were analyzed with both the above-mentioned techniques.

RESULTS AND DISCUSSION

Fluorescence characteristics of chlorophyll a *and* b *in different media*

In Table 1 the fluorescence characteristics of these pigments in different media and in the presence of different types of surfactants are given. Several conclusions can be made from these results:

(1) With a low percentage of organic solvent (1% acetone) present, the wavelengths of both chlorophylls (Fig. 1) are different than when a high percentage of organic solvent (90% acetone) is present.

Table 1. Fluorescence characteristics of chlorophyll *a* and *b* in the presence of different media*

Medium		Chlorophyll *a* λ_{exc}†	Chlorophyll *a* λ_{em}†	Chlorophyll *a* Rel.int.	Chlorophyll *b* λ_{exc}†	Chlorophyll *b* λ_{em}†	Chlorophyll *b* Rel.int

acetone:water +DTMACl	1:99	433	673	—‡	465	656	—‡

*Results using 100 ng/ml of chlorophyll and 0.01*M* surfactant.
†Wavelengths are all ±2 nm.
‡No enhancement of the fluorescence signal was observed.

(2) The relative intensities of fluorescence of chlorophyll *a* and *b* are much lower in "aqueous" medium (1% acetone) than in "organic" medium (90% acetone).
(3) The fluorescence behavior of chlorophyll *a* and *b* in aqueous medium (1% acetone) varies as a function of different types of surfactants. While an anionic surfactant (SDS) and a cationic surfactant (DTMACl) do not enhance the fluorescence of these pigments, non-ionic surfactants (like Triton X-100 and Brij-35) greatly increase the fluorescence signal. There is a different degree of enhancement from different non-ionic surfactants. The enhancement of the fluorescence is greater when using Triton X-100 than when using Brij-35. In addition, the excitation and emission wavelengths of chlorophyll *a* and *b* in non-ionic surfactants are practically the same as in organic medium (90% acetone), except in the case of Brij-35 where the excitation wavelength for chlorophyll *a* shifts to a shorter wavelength (15 nm). According to these results, Triton X-100 was chosen as the surfactant best suited for the determination of low concentrations of chlorophyll *a* and *b*.

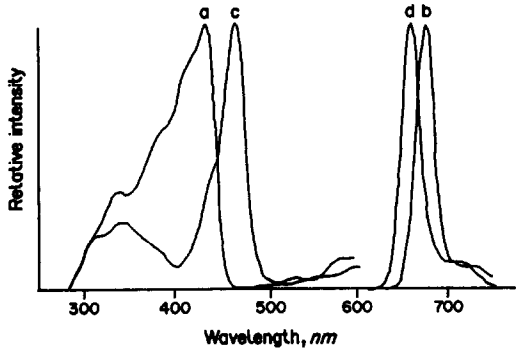

Fig. 1. Fluorescence spectra of chlorophyll *a* and *b* with Triton X-100 in 1% acetone. (*a*) Chlorophyll *a* excitation, (*b*) chlorophyll *a* emission, (*c*) chlorophyll *b* excitation, (*d*) chlorophyll *b* emission.

Optimization of variables

Figure 2 shows that the fluorescence intensities of both chlorophyll *a* and *b* change sharply with the concentration of Triton X-100 when it is close to the critical micellar concentration (cmc) (0.6m*M* for chlorophyll *a* and 0.4m*M* for chlorophyll *b*). For concentrations of surfactant higher than 1.0m*M* (believed to be the cmc of Triton X-100 in 1% acetone), the fluorescence intensity remains practically constant. According to these results, a post cmc concentration of 3.0m*M* of Triton X-100 was used for all other studies.

The study of the influence of pH shows that the relative fluorescence intensity remains constant from pH 2.5 to 12 for chlorophyll *a*, and from pH 3 to 12 for chlorophyll *b*. In more acidic media, the fluorescence signal rapidly decreases with decreasing pH. This last behavior

*Conditions: 3m*M* Triton X-100; 0.1 ppm chlorophyll; Perkin-Elmer LS-5 fluorimeter; λ_{ex} 431, λ_{em} 673 for chlorophyll *a*; λ_{ex} 462, λ_{em} 654 for chlorophyll *b*.

†Conditions: 50 ppb chlorophyll; Perkin-Elmer MPF-44A fluorimeter; λ_{ex} 429, λ_{em} 669 for chlorophyll *a*; λ_{ex} 458, λ_{em} 652 for chlorophyll *b*.

is a result of formation of decomposition products (pheophytins, pheophorbides) of chlorophyll *a* and *b* in the presence of a strong acid.

The influence of the % acetone on the fluorescence intensity of chlorophyll *a* is shown in Fig. 3. Since the solubility of chlorophyll *a* and *b* in water is very low, standard solutions in water could not be made, therefore in this work a concentration of 1% acetone is used as the initial point for the study. For both chlorophylls, the fluorescence signal does not vary with the % acetone in the range 1–30%. From 30–40% acetone, the relative fluorescence intensity drops suddenly and then slowly increases at higher percentages of acetone. This increase is similar to the behavior of chlorophyll *a* and *b* without surfactant, which suggests that this enhancement of the fluorescence signal is due to the acetone and not the surfactant. It is believed that at about 31% acetone the micelles begin to dissappear due to the higher polarity of the organic solvent.

The influence of temperature on fluorescence intensity of chlorophyll *a* and *b* has been carried out between 5 and 65° (Table 2). The results show that for chlorophyll *a* (1% acetone), the fluorescence increases slightly until 20°, remaining constant until 65°. However, for chlorophyll *b* (1% acetone), increasing the temperature decreases the fluorescence very slowly over the entire range of the study. Also, a study of the stability of chlorophyll *a* and *b* in the presence of Triton X-100, at each temperature, was performed; the fluorescence intensity did not vary with time for times less than one hour.

Table 3. Analytical figures of merit for the determination of chlorophyll *a* and *b* using Triton X-100 with fluorescence detection

Pigment	LDR*, *ng/ml*	Slope† log–log	Correlation coefficient	LOD‡, *ng/ml*	Precision§, %
chl *a*	0–100	0.97	0.999	0.04	5.0
chl *b*	0–100	1.00	0.999	0.09	2.9

LDR: linear dynamic range obtained from using 7 different analyte concentrations (ng/ml).

†Slope was calculated from the curve log fluorescence *vs.* log concentration.

‡LOD: limit of detection calculated by $3s_{blank}/m_{linear}$; s_{blank} = standard deviation of blank (16 values); m_{linear} = slope of linear coordinates calibration curve.

§Precision for the method was obtained by the following formula:

$$P_{method} = \frac{\sqrt{(s_{A+B}^2 + s_B^2)}}{I_{A-B}} 100$$

Sixteen determinations of 50 ng/ml analyte and their respective blanks were utilized to determine s_{A+B}, standard deviation of analyte and blank intensity; s_B, standard deviation of blank intensity; and I_{A+B}, average net analyte intensity.

Analytical figures of merit

Table 3 shows the analytical characteristics of this new method for the determination of chlorophyll *a* and *b* with Triton X-100 as the fluorescence enhancer. For a range between 0–100 ng/ml, there a linear relationship exists between the fluorescence signal and the concentration of both chlorophylls with high correlation coefficients. The limits of detection for chlorophyll *a* and chlorophyll *b* were 0.04 ng/ml and 0.09 ng/ml, respectively. These detection limits compare favorably with the previous most sensitive HPLC/fluorescence detection method for the determination of these pigments. Sixteen samples, each containing 50 ng/ml of either chlorophyll *a* or *b*, were determined; and 5.0 and 2.9% RSD values were obtained, respectively.

The selectivity of this new method was determined by using solutions containing different ratios of chlorophyll *a* and chlorophyll *b*. The results show that chlorophyll *a* can be determined in the presence of chlorophyll *b* up to a ratio of 3:1 (*b* : *a*), and chlorophyll *b* in the presence of chlorophyll *a* up to a ratio of 50:1 (*a* : *b*) without interference. In environmental samples (algae, natural waters), the chlorophyll *a* pigment is normally in excess with respect to chlorophyll *b*, therefore, our method can be applied to these types of samples.

Application to the determination of chlorophyll a *and* b *in synthetic mixtures and fresh waters*

The surfactant method was applied to the simultaneous determination of both chlorophyll *a* and *b* in synthetic mixtures. The results (Table 4) show an excellent recovery (96–108%) for different ratios and concentrations of chlorophyll *a* and *b*.

Table 5 shows the results obtained from the analysis of local fresh water samples (Newnans Lake, Gainesville, FL). The concentrations of chlorophyll *a* and *b* from the phytoplankton were determined with the surfactant method and the HPLC/fluorescence method mentioned previously. Figure 4 illustrates the chromatogram obtained for sample # 1. Excellent agreement was found between both methods.

Also, the soluble chlorophyll *a* and *b* in the residual water samples (2nd filtrate) was determined with the surfactant method in combination with the internal standard method. This procedure was used due to the limited sensitivity of the HPLC/fluorescence method. The results show that, even though chlorophylls are highly insoluble in water, a low concentration of

chlorophyll *a* and *b* can be determined by the micellar enhanced fluorescence method (see Table 4).

CONCLUSIONS

It is known that chlorophyll *a* and *b* are highly fluorescent in organic solvents (acetone, methanol, *etc.*). The study carried out in this work show that these pigments produce practically no fluorescence when the percentage of organic solvent present is low (<40%). However, under the same solvent conditions, the addition of a non-ionic surfactant greatly enhances the fluorescence of both chlorophyll *a* and *b*. This allowed us to present a new, very sensitive and selective method for the determination of chlorophyll *a* and *b* in environmental samples with Triton X-100 as the fluorescence enhancer. With this new method, determination of the concentrations of chlorophyll *a* and *b* in the phytoplankton was performed without prior chromatographic separation of the extract, and determination of the concentration of chlorophyll *a* and *b* in the residual water was also possible.

RELATIVE RESPONSE RATIOS FOR DUAL-ISOTOPE MEASUREMENTS VIA COELUTION AND GC/MS

LAWRENCE C. THOMAS and WALTER WEICHMANN
Department of Chemistry, Seattle University, Seattle, Washington 98122, U.S.A.

(*Received* 15 *May* 1991. *Revised* 14 *August* 1991. *Accepted* 14 *August* 1991)

Summary—Dual-isotope internal standard measurements by GC/MS which mimic isotope dilution may suffer from non-linear response relations, irreproducibilities or unduly large uncertainties because of variations in ionization efficiences for the respective isotopic forms in the MS source. Such variations may sometimes be avoided via extensive pretreatments, high resolution GC separations and careful control of instrumental parameters. However, an alternative approach is feasible which instead exploits advantages of decreasing GC resolution. By forcing both forms of each analyte to coelute, their relative ionization efficiencies in the MS source should be nearly constant, thereby effectively allowing for constant relative sensitivities over several orders of magnitude in concentration. Thus, constant relative response ratios, required for internal standard calculations, may be attained as a consequence of dramatically lowered GC resolution. Coelution results described herein show linear relative sensitivity relations over much broader ranges than observed for corresponding conventional calibrations with separated components. Coelution methods for dual-isotope GC/MS determinations are compatible with internal standard calculations and thereby offer a powerful alternative to the conventional approach of requiring expensive and labor-intensive additional pretreatments and separations to assure resolution of measured eluates.

Recently dual-isotope internal standard methods which mimic isotope dilution have become increasingly popular. Some GC/MS approaches have been adopted for use in important environmental measurements, *e.g.*, Methods 1624 and 1625 from the U.S. Environmental Protection Agency (EPA).[1] The general approach is to add known amounts of isotopically labelled compounds, otherwise identical to each target analyte, to samples prior to pretreatment. For each target analyte, both of its forms undergo identical treatment because they coexist in the same mixtures throughout the procedures. The isotopically labelled internal standard added prior to pretreatment, chromatographic separation and detection allows for compensation of pretreatment variables as well as injection variations if the two forms of the target analyte are chemically identical but isotopically different. The prepared sample is analyzed by GC/MS according to recommended protocols, with each target analyte and its isotopically labelled form typically eluting separately and being measured via their respective ion currents at their characteristic m/z values, often by selected-ion detection (SID).[1] The direct proportionality between relative sensitivities for the two forms and their relative concentrations is an important condition for valid use of the dual-isotope internal standard methods for quantitative analyses by chromatography.

Dual-isotope techniques using mass spectrometry of equilibrated mixtures of target analytes with appropriate isotopically labelled compounds have been used for many years to help ensure reliable analyses.[2] However, even dual-isotope methods are not always accurate, and it has been recommended that other quantitative methods be used if the two forms do not show baseline separation between themselves and from all potential interferants.[1] The excellent selectivity of MS measurements enhances discrimination from interferences, but MS is not always sufficient for reliable determinations. Moreover, the special sensitivity dependencies of MS upon a variety of variables, *e.g.*, pressure and coeluting species, may complicate GC/MS measurements considerably.[3] Unfortunately, requiring improved separations to be achieved via special pretreatments and modified instrumental variables can be unacceptably expensive and labor-intensive,[4,5] making valid optional approaches desirable.

Alternatively, procedures which exploit the special advantages of dual-isotope internal standard techniques but are not appreciably affected by potential interferences are attractive. Herein we describe an alternative approach which

requires coelution of respective labelled pairs and offers potential improvements in quantitative data quality. As shown herein, the coelution alternative for dual-isotope analyses may yield linear relative calibration relations, *i.e.*, constant relative sensitivities over several orders of magnitude of eluted analyte masses. Consequently, for appropriate situations, ensuring coelution may obviate many restrictive sample pretreatment and GC separation requirements, thereby potentially decreasing analysis costs for internal standard GC/MS methods which mimic isotope dilution.

THEORY

If an isotopically-labelled, *e.g.*, deuterated or ^{13}C-labelled, form d of a target analyte i is added to sample n prior to pretreatment, then the peak area for its elution and measurement by GC/MS and SID may be modelled as:

$$A_{\text{ind}} = \frac{V_{sn} C_{ind} E_{ind} V_{\text{col},n} S_{ind} V_{\text{inj},n}}{V_{cn}(V_{\text{col}} + V_{\text{split}})_n V_{cn}} \int_{\text{RT}-bw}^{\text{RT}+bw} k_{ind}(I_{ind})_t \, \text{d}t \quad (1)$$

with $(I_{ind})_t = (E_{\text{ion},ind})_t (E_{\text{ext},ind} E_{\text{sel},ind} P_{\text{mult},id} f_p)_t$

where A_{ind} is the peak area for analyte i from sample n and isotopic label d, V_s and V_c correspond to original sample volume and the volume after pretreatment, C is the concentration of the specified analyte in the sample, E is the efficacy of the pretreatment as the fraction of the specified substance recovered, V_{col} and V_{split} respectively correspond to carrier volumes which flow to the column and out of the split vent during the time the analyte resides in the injector, S is the fraction of the analyte which is in the carrier during the time the analyte resides in the injector, V_{inj} is the volume of pretreated sample injected, RT is the retention time of the analyte, bw is some selected multiple of the analyte's peak width, k relates electrometer current to the monitored response, E_{ion} is the ionization efficiency in the source for the target analyte at the specified time t, E_{ext} and E_{sel} are efficiencies of extraction from the source and delivery to the first stage of the electron multiplier through the m/z selector, and $P_{\text{mult}} f_{\text{p}}$ defines the response of the electron multiplier to incident selected ions.

Relative response factors (RRF) for naturally occurring analyte, i, indicated here as h, relative to its chemically identical isotopically labelled internal standard form, d, can be defined for the overall pretreatment and measurement, using known amounts of both forms in a reference sample, r:

$$\text{RRF}_{irhd} = (\text{A}_{\text{irh}}/\text{C}_{\text{irh}})(\text{A}_{\text{ird}}/\text{C}_{\text{ird}})^{-1} \quad (2)$$

In subsequent determinations, a known amount of the isotopically labeled form is added to each sample before analysis and the relative response factor is typically assumed to be invariant; thus, for sample m, using a relative response factor determined from reference sample r, *i.e.*, assuming $\text{RRF}_{imhd} = \text{RRF}_{irhd}$

$$C_{imh} = (C_{imd} A_{imh})(\text{RRF}_{imhd} A_{imd})^{-1}$$
$$= (C_{imd} C_{irh} A_{imh} A_{ird})(C_{ird} A_{imh} A_{irh})^{-1} \quad (3)$$

Unfortunately, measured areas are not always proportional to subsample concentrations, *i.e.*, the GC/MS sensitivity for a selected analyte typically is not constant over wide ranges in injected masses of analyte. Correspondingly, linear concentration *vs.* measured-area relations for GC/MS typically span only 1–2 orders of magnitude.[4,5] Consequently, relative response ratios also may fluctuate. Worse, if the injected mass of added reference substance varies, relative response ratios may become even more unreliable because of mathematical interactions between the two variable sensitivity relations. Therefore, unless typical dual-isotope internal standard methods which mimic isotope dilution are extremely well-controlled, calculations based upon relative response factors may be excessively imprecise or incorrect.[1]

Much of the nonlinearity in concentration *vs.* response relations for a given eluate may be caused by fluctuations in the MS ionization efficiencies which typically change dramatically in GC/MS as the eluates' effective concentrations and the source pressures change along with variations in the mass of eluate entering the source per unit time. Thus, $E_{\text{ion},inx}$ may change throughout elution of a component, typically diminishing as the rate of eluates entering the source increases. Baseline separation of the components, as is recommended,[1] therefore may exacerbate the undesirable effects of response *vs.* concentration non-linearities.

If instead, the components are coeluted rather than separated, then the relative ionization efficiencies of both the labelled and non-labelled forms will be essentially constant, because they coexist in the same environment at the same time. Consequently, if the relative extraction efficiencies of the ions from the source and their

relative efficiencies through the selector are reproducible, then the components' relative response factor should be invariant. For example, if only one reference solution r is used for assessing RRF, then

$$C_{\text{imh}} = \text{constant}(C_{\text{imd}})\frac{\int(I_{imh})_t\,\text{dt}}{\int(I_{imd})_t\,\text{dt}} \qquad (4)$$

Fortunately, if there are no SID interferences, coelution may thereby cause the quantitative calculation of analyte concentrations to follow a simple proportionality to relative areas, despite variations in sensitivities for specific components, *i.e.*, the relative sensitivities for the components are the same from run-to-run. With identical ionization efficiencies and other MS parameters stabilized, the relative currents detected for the two forms should vary directly with the relative concentrations of the two forms in the source, thereby allowing for valid internal standard calculations.

This alternative to assuring baseline separation is attractive, *i.e.*, ensuring coelution so that both forms of the target analyte are concurrently present in the same ionizing environment. With coelution of differently labelled forms of each analyte, relative GC/MS ionization efficiencies of the two forms should be constant, neglecting tiny differences at electron energies near their ionization potentials due to differences in ground-state vibrational and rotational energies because of their different reduced masses. For moderate-to-high resolution gas chromatography, the different forms typically separate. Effects of increased interferences due to lowered GC resolution must be considered and weighed against possible benefits of forced coelution. Consequently, despite tradition, for appropriate situations one might purposely decrease GC resolution in order to cause coelution of labeled and nonlabeled forms of the target analytes to achieve extended ranges of constant relative sensitivities, thus allowing for reliable quantitative analyses in dual-isotope internal standard GC/MS procedures.

EXPERIMENTAL

Reagents

Anthracene and decadeuteroanthracene were purchased from Aldrich Chemical Co., both at 99% purity. All solvents were Mallinkrodt ChromAR grade, and helium carrier gas was 99.9995% pure.

Apparatus

A Hewlett–Packard Model 5971A Mass Selective Detector interfaced to a Hewlett–Packard Model 5890 Series II GC was used, controlled and monitored by a Hewlett–Packard Model QS-20 Vectra Computer. Helium carrier gas was used with a 15-kPA pressure in the split/splitless inlet, yielding 1.0 ml/min carrier gas flow at 25°. A split ratio of 60:1 at 25° was used with a 1.0-min splitless period following injection. Injections of 1.0 μl were used unless otherwise stated.

Procedures

Mixed solutions of anthracene and decadeuteroanthracene were made in methanol, varying the molar concentrations from 10^{-5} to $2 \times 10^{-3}M$, with relative concentrations, [anthracene]/[d_{10}-anthracene], spanning 2000:1 to 0.01:1. Replicate ($n = 4$) 1-μl injections of each solution were made over several days, retuning the MS intermittently. They eluted isothermally at 160° over a 12-m by 0.2-mm i.d. fused silica capillary column with 0.33-μm thick cross-linked methyl silicone stationary phase. Selected ions, $m/z = 178$ and $m/z = 188$, were monitored over the elution duration of the two forms of anthracene. Peak areas were calculated by provided algorithms, and statistical calculations were made by conventional techniques.

RESULTS AND DISCUSSION

Decadeuteroanthracene and normal anthracene essentially coeluted via the isothermal elution (see Figs. 1 and 2). Sensitivities for each form, measured via parent ions, varied with concentration, as expected when several orders of magnitude are spanned (see Figs. 3 and 4). Uncertainties in sensitivities varied widely, *e.g.*, ±25% (rsd) for both anthracene and d_{10}-anthracene.

Relative sensitivities, however, varied proportionally, *i.e.*, linear log–log plot with slope = 1.0, for relative concentrations over more than three orders of magnitude (see Fig. 5), despite making measurements over several days and retuning the MS intermittently, *i.e.*,

$$\frac{C_{imh}}{C_{imd}} = \text{constant}\,\frac{\text{Area}_{imh}}{\text{Area}_{imd}} = \text{constant}'\,\frac{\int(I_{imh})_t\,\text{dt}}{\int(I_{imd})_t\,\text{dt}} \qquad (5)$$

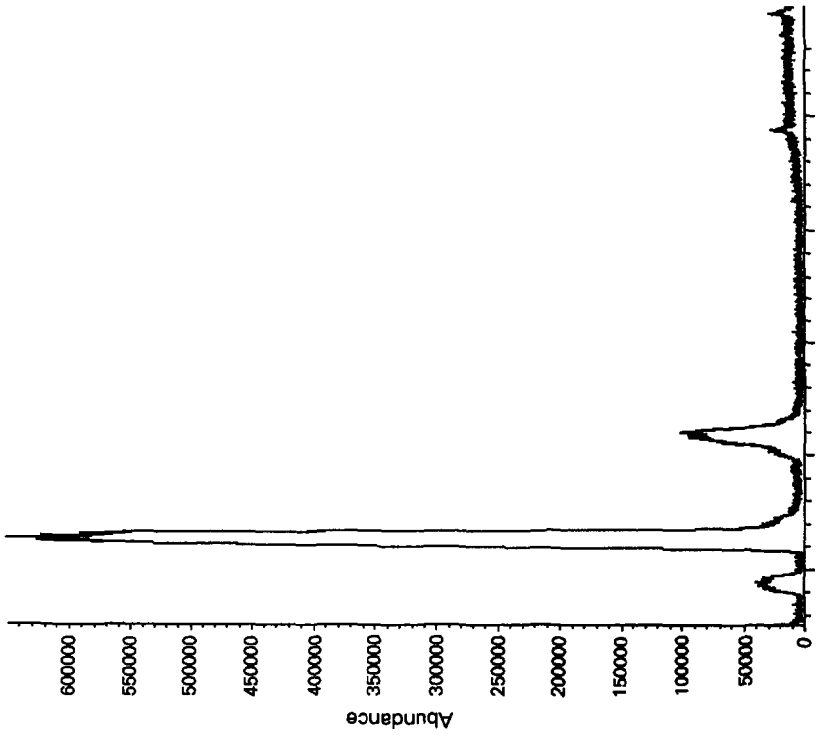

Fig. 1. GC/MS total ion chromatogram for isothermal (160°) coelution of decadeuteroanthracene and normal anthracene with a retention time of about 6.2 min; for a 1-μl injection containing 1.1×10^{-7} g of anthracene and 2.6×10^{-7} g of d_{10}-anthracene, along with dihydroanthracene at 4.4 min and anthraquinone at 10.8 min.

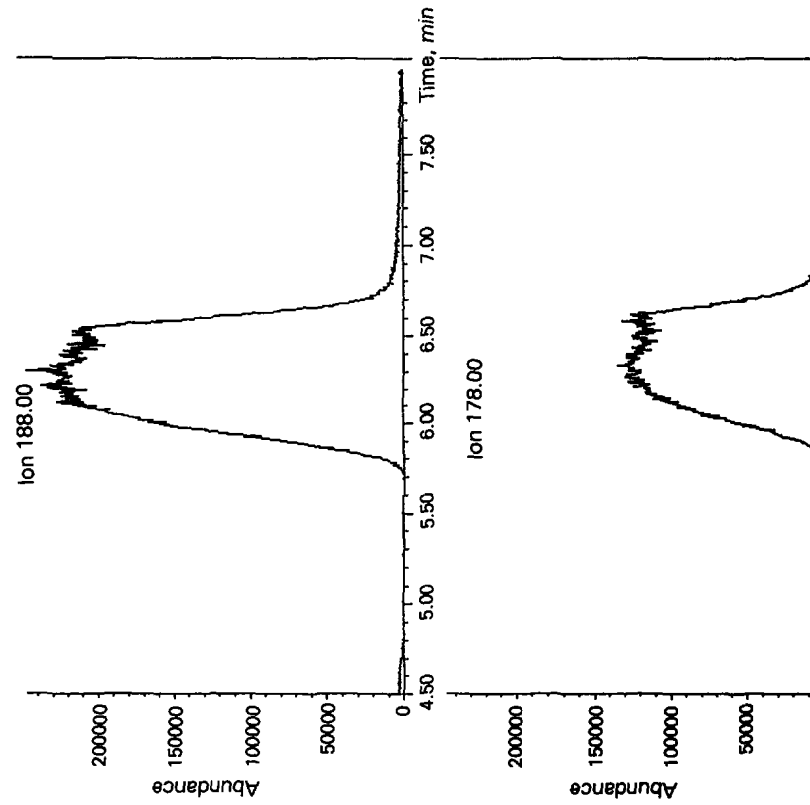

Fig. 2. GC/MS selected ion chromatograms for isothermal (160°) coelution of decadeuteroanthracene ($m/z = 188$) and normal anthracene ($m/z = 178$); relative concentrations for this result of a 1-μl injection was 2:1, respectively, in a total of 10^{-9} moles of combined anthracene and d_{10}-anthracene.

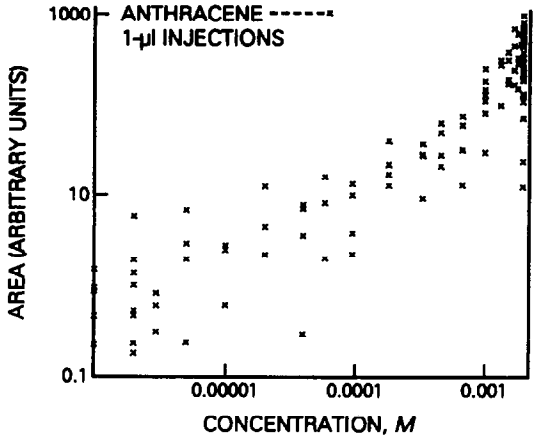

Fig. 3. Integrated response *vs.* concentration relationships for 124 1-μl injections of normal anthracene ($m/z = 178$), measured by selected-ion GC/MS, spanning concentrations from 10^{-6} to $2 \times 10^{-3} M$.

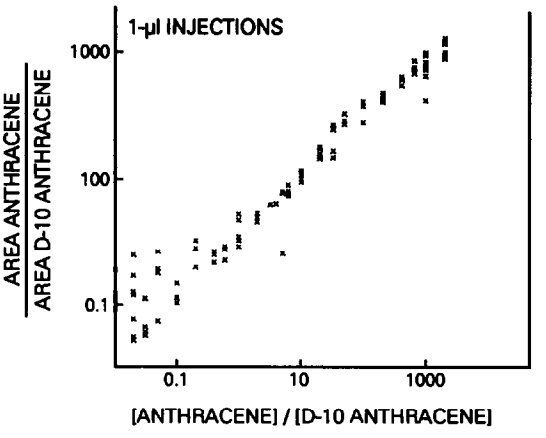

Fig. 5. Relative integrated response *vs.* relative concentration relationship for 124 1-μl injections of decadeuteroanthracene and anthracene. Each datum corresponds to the ratios ($A_{m/z=178}/A_{m/z=188}$) and ($C_{\text{anthracene}}/C_{\text{decadeuteroanthracene}}$), for a single 1-$\mu$l injection.

Moreover, uncertainties in relative sensitivities varied only about $\pm 10\%$ (rsd) for relative concentrations between 1 and 10^3, being somewhat larger when the concentration of one or the other form of analyte approached limits of detection. Consequently, adding a known amount of d_{10}-anthracene to samples containing normal anthracene target analyte is compatible with internal standard quantitative calculations for GC measurements. Moreover, coelution of the two forms helps ensure the required bases for valid use of internal standard techniques. Coelution of d_{10}-anthracene concurrently with normal anthracene caused their relative sensitivities to be constant, thereby compensating for fluctuations in measurement sensitivities resulting from variables such as GC/MS source pressures, and noninterfering coeluates.

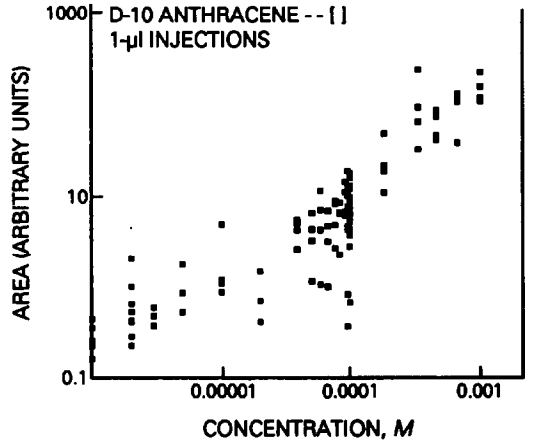

Fig. 4. Integrated selected ion response *vs.* concentration relationships for 124 1-μl injections of d_{10}-anthracene ($m/z = 188$), measured by GC/MS, spanning concentrations from 10^{-6} to $10^{-3} M$.

These results indicate that GC/MS measurements of isotopically labelled internal standards coeluting with corresponding normal target analytes are compatible with dual-isotope procedures which mimic isotope dilution. Of course, effects of increased interferences, reduced sensitivities and worse selectivities due to lowered GC resolution must be considered along with possible resulting benefits of forced coelution. However, by adding a small-but-reliably-measured amount of an isotopically labelled form of each target analyte to the samples, one may expect the labelled form to work as a reliable internal and recovery standard over a wide dynamic range, making accurate and precise determinations feasible. Also, coelution of the two forms should compensate for potential variations in relative sensitivities caused by variations in ionization efficiencies due to changes in source pressures, effective analyte concentrations in the source or the presence of many potential interferents.

The direct proportionality between relative sensitivities and relative concentrations is an important condition for use of internal standard methods for quantitative analyses by chromatography: dual-isotope internal standard procedures can be especially reliable for such determinations, and coelution can help ensure validity in their use. Consequently, in some circumstances, lowering GC resolution may improve quantitative GC/MS measurements when higher resolution separations become unreliable.

CATALYTIC POLAROGRAPHIC DETERMINATION OF TOTAL SELENIUM IN TEA LEAVES

LIU XUNJIAN,* TU YEFENG, ZHAO YANG, ZHU LING, LIU HSIAOYAN,† YU HONG, DING YUANCHEN and REN YUBEI

Department of Chemistry, Suzhou University, Suzhou 215006, People's Republic of China

(*Received* 29 *November* 1989. *Revised* 24 *August* 1991. *Accepted* 2 *September* 1991)

Summary—The catalytic polarographic determination of selenium(IV) by use of the $SeSO_3^{2-}$–KIO_3 system is sensitive, accurate, rapid and requires only small quantities of sample. The detection limit for selenium(IV) is 0.04 ng/ml in the final solution. The working range of the calibration is 0.04–2.5 ng/ml. Se(VI) present can be reduced with hot hydrochloric acid to Se(IV), allowing determination of the total selenium.

Selenium is one of the trace elements necessary in the human body, and there are numerous methods for its determination; examples include fluorimetry,[1] neutron-activation,[2] gas and liquid chromatography,[3] cathodic stripping voltammetry,[4] and a catalytic polarographic method.[5] Speciation of selenium in biomaterials and water samples has also been reported.[6–9] This paper reports the determination of total selenium in tea by the catalytic polarographic method. Only small quantities of sample are required and the tea leaves need not be ground before decomposition. It is not necessary to deaerate the solution before the polarography.

EXPERIMENTAL

Apparatus

A JP-2 type oscillographic polarograph with a three-electrode system was used. Dropping mercury and saturated calomel electrodes were used as the working and reference electrodes respectively. The auxiliary electrode was made of platinum. An automatic electric digestor and a micro-injector were also used.

Reagents

Standard solution of Se(IV). Dissolve 0.500 g of selenium powder with 10 ml of concentrated nitric acid in a beaker, on a boiling water-bath, dilute the solution to volume in a 100-ml standard flask and dilute it further as required.[8]

*Sodium sulphite solution, 1.3*M. Dissolve 8.2 g of anhydrous sodium sulphite in 50 ml of water. Discard the solution when it is three days old.

Buffer solution (pH 10). Add 40.2 g of ammonium chloride to 150 ml of concentrated aqueous ammonia solution and dilute to 200 ml with water.

Potassium iodate solution. Dissolve 4.2 g of potassium iodate in 100 ml of water.

Preparation of selenium-free sulphuric acid. Add 15 ml of concentrated hydrobromic acid to 100 ml of analytical-reagent grade sulphuric acid. Heat on an electric heater until fumes appear and then for half an hour longer. Store in a glass bottle after cooling.

Mixed-acid digestion solution. Mix selenium-free concentrated sulphuric acid and 70% perchloric acid in 3:4 v/v ratio.

Ammonium molybdate solution. Dissolve 5 g of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ in 100 ml of water.

Use analytical grade reagents or better, and water that has been doubly distilled in fused-silica apparatus.

Calibration

Prepare a series of calibration solutions in 20-ml standard flasks, by mixing appropriate volumes of standard Se(IV) solution with 0.40 ml of 70% perchloric acid and 2.0 ml of 1.3*M* sodium sulphite, letting stand for 20 min at room temperature, then adding 4.0 ml of the pH-10 buffer solution and 2.0 ml of potassium iodate solution and diluting to volume with

1	0.727	0.768	0.768	0.727	0.74_8	3.2
2	0.727	0.743	0.727	0.768	0.74_1	2.6
3	0.849	0.849	0.849	0.809	0.83_9	2.4

water. Place the flasks in a thermostatic bath at 25° for 10 min. For each solution record the first derivative polarogram over the voltage range from −0.6 to −1.1 V (*vs.* SCE). Measure the peak height of the catalytic wave at −0.87 V (*vs.* SCE) and plot the calibration graph.

Analysis of tea samples

Weigh 0.2 g of dried tea into a Kjeldahl flask, add 5.0 ml of mixed acid and 0.40 ml of the ammonium molybdate solution, and heat in an automatic digestor (set at 213°), until the solution becomes yellow. Remove the flask from the digestor, allow it to cool, and make the solution up to volume in a 25-ml standard flask.

Place an aliquot of the solution in a beaker, add 0.1 ml of 6*M* hydrochloric acid and 0.2 ml of 12*M* perchloric acid, and heat on a boiling water-bath for 20–30 min, until the volume is about 0.2 ml. Rinse the wall of the beaker with a small quantity of water, add 2.0 ml of 1.3*M* sodium sulphite and let stand at room temperature for 20 min. Continue as for preparing the calibration graph, to obtain the total selenium content.

RESULTS AND DISCUSSION

Se(IV) is reduced to Se by sulphurous acid in acid solution. In a pH-10 ammonia buffer Se forms $SeSO_3^{2-}$ with sulphite, and this produces a sensitive catalytic polarographic wave in the presence of potassium iodate. When standard additions of Se(IV) were made to aliquots of digest, the wave form and peak potential of the catalytic polarographic waves obtained were the same as for a standard solution, showing that the signal was due to the initial presence of Se(IV). If standard additions of Se(VI) were made, no increase in peak height was observed.

Table 2. Determination of recovery

Se present, μg/g	Se added, μg/g	Total Se found, μg/g	Recovery, %
0.75	0.50	1.21	92
	0.50	1.29	108
	0.50	1.21	92
0.74	0.50	1.29	110
	0.50	1.29	110
	0.52	1.21	94
0.84	0.50	1.45	90
	0.50	1.54	106
	0.50	1.54	90

The results in Tables 1–3 show that the coefficient of variation is less than ~5% and the average recovery between 95 and 105%.

In principle it is possible to determine both Se(IV) and Se(VI) in the same sample provided that no change in the proportions of the two oxidation states occurs during dissolution of the sample. The Se(IV) is determined in an aliquot of sample solution as described for calibration, and the total selenium is then determined in a second aliquot as described for the analysis of tea, the Se(VI) content being obtained by difference.

In the digestion procedure used for the tea samples, however, it is not certain that the proportions of Se(IV) and Se(VI) will remain constant, so only total selenium can be determined in this case. Various digesting agents were tested, including nitric acid/hydrogen peroxide mixtures, nitric acid/perchloric acid

Table 4. Comparison of results for total selenium

Sample	Se found	
	Present method	Flourimetry
Tea leaves	0.996 μg/g	0.952 μg/g
Well water	0.150 μg/ml	0.170 μg/ml
Standard sample*	0.313 μg/ml	

*Reference value = 0.300 μg/ml.

mixture with or without ammonium molybdate, and the 5 ml of 3:4 v/v mixture of sulphuric acid and perchloric acid plus 0.4 ml of 5% ammonium paramolybdate solution, and only the last of these gave satisfactory decomposition of the tea samples. Various heating times and temperatures were tried and heating at 213° until the solution becomes yellow (about 35 min) is recommended. Use of higher temperature resulted in loss of some selenium.

It was found that though the total selenium found in the tea leaves by this method was reproducible, the ratio of Se(IV) to Se(VI) in the digest varied considerably, depending on the time and temperature of the digestion. Hence for samples that require use of the digestion mixture for decomposition, only the total selenium should be determined. For samples that are already in solution, or can be brought into solution readily in the cold, the Se(IV) and Se(VI) present may both be determined.

It was established experimentally that Se(VI) is not reduced by heating with sulphurous acid at 60° for 20 min, so the Se(IV) determination is free from interference by Se(VI). The amount of paramolybdate added is not critical—addition of 0.1 ml of the 5% solution gives practically the same result as addition of 0.4 ml.

The calibration graph was found to be linear over the selenium range 2–10 ng in the 20 ml of solution used for the polarography.

The precision of determination of total selenium at a level corresponding to 1.0–1.2 μg/g in a sample of tea was found to be about 3% (relative standard deviation) and the recovery of an amount of standard corresponding to an addition of 0.5 μg/g ranged from 90 to 110% in individual determinations.

Analysis of various samples by the method for total selenium and by a fluorimetric comparison reference method gave the results shown in Table 4.

ENHANCED SEPARATION OF TRIVALENT LANTHANOIDS BY SOLVENT EXTRACTION WITH 18-CROWN-6 AND EDTA COMPLEXONATE

ROBERT FRAZIER and C. M. WAI*
Department of Chemistry, University of Idaho, Moscow, Idaho 83843, U.S.A.

(*Received* 12 *August* 1991. *Accepted* 29 *August* 1991)

Summary—The selectivities during solvent extraction of lanthanoids with macrocycles can be modified with complexonates in the aqueous phase. In the case of solvent extraction of lanthanoids with 18-crown-6 and trichloroacetic acid (TCA), addition of EDTA to the aqueous phase enhances the selectivities of lanthanoids by 3–7 times compared to those without the complexonate. This is due to the fact that the stability of lanthanoid–EDTA complexes increases in the opposite direction to the crown–TCA complexes across the lanthanoid series. The selectivities observed in this system are among the largest reported for the light lanthanoids. The effect of the complexonate on lanthanoid extraction can be explained by a simple model presented in this paper.

Macrocyclic polyethers (crown ethers) are known to form stable complexes of different stoichiometry with trivalent lanthanoids.[1] The stability of crown complexes in solvent extraction depends generally on the following four factors: crown cavity to cation diameter ratio, the counter anion, ligand flexibility, and the type of donor atoms (N, O or S) in the macrocyclic host.[2] Using 18-crown-6 to extract lanthanoid ions in aqueous solution with trichloroacetate (TCA) as counter anions, selectivities as good as the best commercial extractant, di-2-ethylhexyl-phosphoric acid (HDEHP) were obtained by Samy *et al.*[3] The relative stability constants of the lanthanoid complexes in this case decrease by three orders of magnitude from La^{3+} to Eu^{3+}. The large selectivity observed in this macrocyclic system has been attributed to the steric hindrance of the lanthanoid complex with TCA. The decrease in stability across the lanthanoid series with 18-crown-6-TCA complexes is significant, because it is opposite to many known lanthanoid complexonates in aqueous solution. Therefore, by choosing a proper complexonate, the two opposite trends may compliment each other resulting in enhanced selectivity for the extraction of lanthanoids by 18-crown-6. It is known that lanthanoid–EDTA complexes show increased stabilities from La^{3+} to Lu^{3+} and the complexation depends on pH.[4] This paper reports the enhanced lanthanoid selectivity in solvent extraction, using 18-crown-6 as an extractant, TCA as the anion and EDTA as a complexonate with 1,2-dichloroethane solvent. Hydrogen ion is used as a displacer to release lanthanoids complexed with EDTA in the aqueous phase.

*Author for correspondence.

EXPERIMENTAL

The 18-crown-6 extractant was purchased from Aldrich. The EDTA was Aldrich gold label and dried four days at 80° according to Schwartzenbach.[5] The La, Eu and Lu solutions were purchased as standard solutions from Aldrich and Thiokol. Lanthanoid solutions of Ce, Nd and Ho were prepared from their nitrates obtained from Aldrich. Praseodymium was prepared from its oxide obtained from Baker and Adamson. The solvent, 1,2-dichloroethane, was purchased from EM Science. Demineralised water was used in all experiments.

Radioisotope tracer techniques were used in the extraction experiments. Usually, lanthanoid solutions were irradiated in a TRIGA nuclear reactor with a steady flux of 6×10^{12} $n \cdot cm^{-2} \cdot sec^{-1}$ for one hour. An aliquot of this radioisotope solution was placed in a pyrex tube (50 ml), containing TCA, 18-crown-6, EDTA, and lanthanoids of known concentration in a total aqueous volume of 10 ml with a phase ratio (organic/aqueous) of 1.0. The pH of the solution was adjusted with lithium hydroxide or

nitric acid and measured with an Orion model 701A digital analyzer and Orion 8103 semi-micro combination electrode. The mixture was shaken for 45 min, which was determined to be equilibrium by a series of time dependent experiments, at 25.0 ± 0.5°, using a Burrell model 75 wrist-action shaker. After phase separation, samples of the organic and aqueous phases were taken with disposable pipettes and counted in polyvials on a large volume EG&G Ortec Ge(Li) detector with a resolution of 2.3 keV at 1332 keV. The following radioisotopes and characteristic gamma energies were used for the identification and quantification of the lanthanoids: ^{140}La (40.2 hr, 328, 487, 815, 1596 keV), ^{141}Ce (32.5 d, 145 keV), ^{143}Ce (33.7 hr, 293 keV), ^{142}Pr (19.2 hr, 1575 keV), ^{147}Nd (11.1 d, 91, 531 keV), ^{152m}Eu (9.3 hr, 121, 344, 841 keV), ^{166}Ho (26.8 d, 82 keV), and ^{177}Lu (6.7 d, 208 keV). The multichannel analyzer was an EG&G ADCAM model 950A. EG&G software was used to set visually-adjusted peak and background regions. A program was written to reduce data, correcting exactly for decay during counting. The details of neutron irradiation and gamma spectroscopy are described elsewhere.[6]

RESULTS AND DISCUSSION

Preliminary experiments showed the lanthanoid–EDTA complexes were insoluble in 1,2-dichloroethane. Calculations of the effective stability constants of La and Lu with EDTA also indicated that the lanthanoid ions would be released in the pH region 2–3. The distribution coefficients (D) of La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, Eu^{3+}, Ho^{3+} and Lu^{3+} in the pH range 1.9–2.8 and the experimental conditions are given in Table 1. The percent error is one-sigma counting statistic.

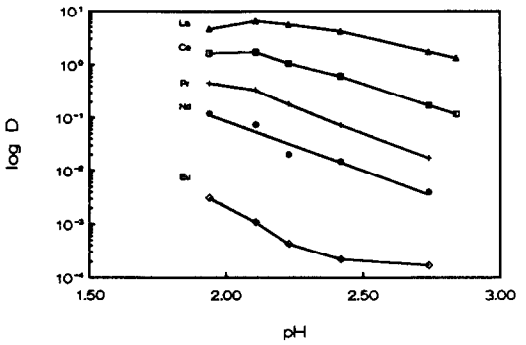

Fig. 1. Graph of log D versus pH. Experimental conditions: [TCA] = 1.1M [18-C-6] = 0.017M, Ln^{3+} = 1 × $10^{-4}M$ [EDTA] = 0.002M, 25 ± 0.5°, solvent = 1,2-dichloroethane, phase ratio = 1.0.

The D values for Ho are very small ($< 10^{-3}$) with relatively large errors and those for Lu are virtually unmeasurable. A significant observation of this system is the large selectivities for the light lanthanoids, *e.g.* the selectivities of La/Ce, La/Pr and La/Eu are 10.2, 101 and 1.04 × 10^4, respectively, at pH 2.74. These values are 3 to 7 times greater than the best selectivities reported by Samy *et al.*[3]

A graph of log D *vs.* pH for La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+} and Eu^{3+} is shown in Fig. 1. The graph is linear in the pH region 2.1–2.8, which can be accounted for by the following model. The complexation of a cation (M^{n+}) with a macrocycle (L) and a counter anion (A^-) can be generally expressed by the following equation:

$$M^{n+} + mL + nA^- = ML_mA_n \quad (1)$$

The extraction constant K is given by equation 2.

$$K = [ML_mA_n]_{org}/[M^{n+}][L]^m[A^-]^n \quad (2)$$

or

$$K = D'/[L]^m[A^-]^n \quad (3)$$

	35%					

Experimental conditions: [TCA] = 1.1M, [18-C-6] = 0.017M, Ln^{3+} = 1 × $10^{-4}M$ each, [EDTA] = 0.002M, solvent = 1,2-dichloroethane, temp = 25.0 ± 0.5°.

where D' is the distribution coefficient without EDTA. If two cations M_1 and M_2 have the same stoichiometry in the extraction process, the selectivity α is related to the relative extraction constants K_1 and K_2 by the following equation.

$$\alpha = K_2/K_1 = D_2/D_1 \quad (4)$$

If a complexonate such as EDTA (YH_4) is present in the aqueous phase, lanthanoid ions can displace one or more protons in the complexonate to form different water-soluble complexes. In the pH range 2–3, H_4Y and H_3Y^- are the two EDTA species present in water with the latter being the predominant one and having almost constant concentration in this region. The reaction of lanthanoid ions with the complexonate can be represented by the following reactions:

$$Ln^{3+} + H_3Y^- = LnH_2Y^+ + H^+ \quad (5)$$

$$Ln^{3+} + H_3Y^- = LnHY + 2H^+ \quad (6)$$

$$Ln^{3+} + H_3Y^- = LnY^- + 3H^+ \quad (7)$$

These reactions are of the following general form.

$$Ln^{3+} + H_3Y^- = LnH_{(3-n')}Y^{(2-n')} + n'H^+ \quad (8)$$

The distribution coefficient in the presence of complexonate is given by the following equation.

$$D = [LnL_mA_n]_{org}/([Ln^{3+}] + [LnH_{3-n'}Y^{(2-n')}]) \quad (9)$$

$$= [Ln_mA_n]_{org}/[Ln^{3+}](1 + K'[H_3Y^-]/[H^+]^{n'}) \quad (10)$$

$$= D'/(1 + K'[H_3Y^-]/[H^+]^{n'}) \quad (11)$$

where D' is the distribution coefficient without complexonate and K' is the equilibrium constant for reaction (8). Since excess EDTA is used, $[LnH_{3-n'}Y^{(2-n')}]/[Ln^{3+}]$ or $K'[H_3Y^-]/[H^+]^{n'} \gg 1$, and equation (11) can be simplified as the following.

$$D = D'/(K'[H_3Y^-]/[H^+]^{n'}) \quad (12)$$

Therefore,

$$\log D = \log D' - \log K'[H_3Y^-] - n'\text{pH} \quad (13)$$

In the pH range 2–3,$[A^-]$ is practically a constant because the pK_a value of TCA is very small, about 0.65. Since [L] ($1.7 \times 10^{-2}M$) is much larger than $[Ln^{3+}]$ ($1 \times 10^{-4}M$) in our experiments, it can also be considered as a constant. Consequently, D' should be a constant in this pH range, as observed experimentally by Samy *et al.*[3] It was pointed out previously that $[H_3Y^-]$ is also near a constant in this pH range. Therefore, log D should be linearly related to pH as shown in equation (14).

$$\log D = \text{constant} - n'\text{pH} \quad (14)$$

According to Fig. 1, the slopes for La^{3+}, Ce^{3+}, Pr^{3+} and Eu^{3+} are -1.2, -1.6, -2.1 and -2.8, respectively, indicating less protonated complexes are favored with the heavier lanthanoids. Consequently, the differences in relative D values increase with pH as shown in Fig. 1. At pH 2.7, the α value for La^{3+}/Ce^{3+} is 10.2 and for La^{3+}/Pr^{3+} is 101. With each unit increase in the Z number of the lanthanoids, the D value appears to decrease by approximately one order of magnitude from La^{3+} to Nd^{3+} at pH 2.8. We did not extend our experiments at pH higher than 3 because the D values for most of the lanthanoids studied became so small and could not be measured accurately.

According to equation (12) the selectivity with complexonate (α) is enhanced by the factor $(K_1'/K_2')([H^+]^{n_2'-n_1'})$ with respect to (α'), the selectivity without complexonate, for two metals as shown in equation (15).

$$\alpha = \alpha'(K_1'/K_2')([H^+]^{n_2'-n_1'}) \quad (15)$$

Since lanthanoid ions form protonated complexes with EDTA and their stability constants are not available in the literature, it is not possible to calculate the selectivity with equation (15). However, it is known that at pH > 3, lanthanoids form unprotonated complexes (LnY^-) with EDTA. Using the stability constants of LnY^- from Martell and Smith[7] and the D values obtained without EDTA as given in Table 2, the calculated selectivity of La/Ce ($\alpha_{La/Ce}$), and Ce/Pr ($\alpha_{Ce/Pr}$) are 11 ± 1 and 12 ± 1, respectively. Our measured values at pH 3.1 were 15 ± 1 for ($\alpha_{La/Ce}$) and 15 ± 3 for ($\alpha_{Ce/Pr}$), in reasonable agreement with the calculated values.

A comparison of the D values obtained without complexonate is given in Table 2. Data reported by Samy *et al.*, as taken from a figure,[3] are also given in the table. Their D values are for slightly different TCA and 18-crown-6 concentrations and should be about 20% greater than ours. After normalization, our data without EDTA agree well with those reported by Samy *et al.*[3] within experimental uncertainties. Furthermore, our experimental

Table 2. Distribution coefficients of lanthanoids without EDTA complexonate at 25.0 ± 0.5°

	D values	
	Literature*	This work†
La^{3+}	7.6	5.8
Ce^{3+}	2.0	1.6
Pr^{3+}	0.56	0.36
Nd^{3+}	0.10	0.096
Eu^{3+}	0.004	0.0039

*[TCA] = 1.0M, [18-crown-6] = 0.01M, $Ln^{3+} = 1 \times 10^{-5}M$ each, pH 3.0. (Ref. 3)

†[TCA] = 0.9M, [18-crown-6] = 0.011M, $Ln^{3+} = 1 \times 10^{-4}M$ each, pH 3.1.

results indicate that in the absence of EDTA, the D value for La^{3+} decreased by nearly a factor of 40 from pH 2 to 0.7. Other lanthanoids such as Pr^{3+}, Nd^{3+}, Eu^{3+} and Ho^{3+} showed a similar decrease in D at low pH. This decrease at low pH suggests that the lanthanoid-18-crown-6-TCA complex in 1,2-dichloroethane can be back-extracted with an acid solution. Experimentally, we have verified that lanthanoids extracted into 1,2-dichloroethane in this system can be stripped from the organic phase with 0.3M nitric acid. This reversibility is important for the recovery of lanthanoids in practical applications.

The model given has also been experimentally verified as follows: Substituting $K[A^-]^n[L]^m$ [equation (3)] for D' in equation (12) and taking the log gives the following linearization.

$$\log (D/[H^+]^{n'}) = \log K + n \log [A^-] + m \log [L] - \log K'[H_3Y^-] \quad (16)$$

Figure 2 shows the variation of $\log(D/[H^+]^{n'})$ with respect to log[L] in the pH region 2.1–2.9 using the n' values determined from Fig. 1. As

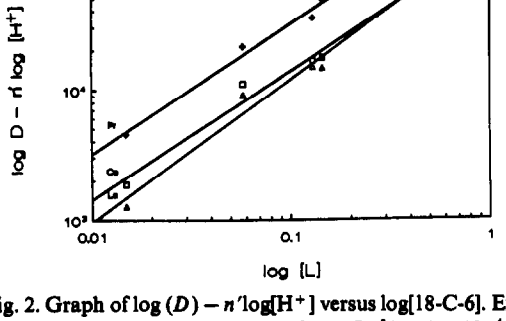

Fig. 2. Graph of $\log (D) - n'\log[H^+]$ versus log[18-C-6]. Experimental conditions: [TCA] = 0.93M, $Ln^{3+} = 1 \times 10^{-4}M$ each, [EDTA] = 0.002M, 25 ± 0.5°, solvent = 1,2-dichloroethane, phase ratio = 1.0.

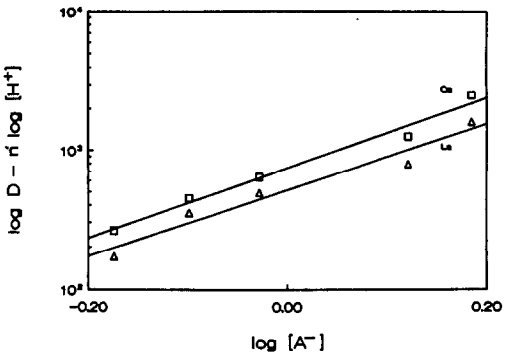

Fig. 3. Graph of $\log (D) - n'\log[H^+]$ versus $\log[A^-]$. Experimental conditions: [18-C-6] = 0.017M, $Ln^{3+} = 1 \times 10^{-4}M$ each, [EDTA] = 0.002M, 25 ± 0.5°, solvent = 1,2-dichloroethane, phase ratio = 1.0.

shown in Fig. 2, La^{3+}, Ce^{3+} and Pr^{3+} gave linear plots. The slope for La^{3+} was 1.1 and the slopes for Ce^{3+} and Pr^{3+} were 1.0, suggesting a 1:1 complex for the lanthanoids with 18-crown-6.

Figure 3 offers further support, showing a linear $\log(D/[H^+]^{n'})$ *vs.* $\log[A^-]$ plot. Slopes of 2.5 for La^{3+} and Ce^{3+} were obtained, which imply three TCA anions in the complex. Samy *et al.*[3] obtained slopes of 2.15 and 2.41 for La^{3+} and Ce^{3+}, respectively, without EDTA.[3] They explained these values as being a result of the decreasing activity coefficient with ionic strength.

In conclusion, EDTA showed enhanced selectivities for lanthanoids in solvent extraction with 18-crown-6 and TCA. The effect of the complexonate on lanthanoid extraction can be explained by a simple model presented in this paper. The selectivities observed in this system are among the largest reported in the literature for the light lanthanoids.

SIMPLE APPROACH FOR ELIMINATION OF BLANK PEAK EFFECTS IN FLOW-INJECTION ANALYSIS OF SAMPLES CONTAINING TRACE ANALYTE AND AN EXCESS OF ANOTHER SOLUTE

TAKESHI YAMANE* and MASAE SAITO
Department of Chemistry, Faculty of Education, Yamanashi University, Takeda-4, Kofu 400, Japan

(*Received* 17 *June* 1991. *Revised* 1 *August* 1991. *Accepted* 1 *August* 1991)

Summary—A blank peak effect in FIA systems often found for samples containing an excess of solute other than the analyte has been studied. Emphasis has been given to trace level determinations and a simple approach for elimination of this effect is presented. The present approach is based on the use of a large sample injection volume, which results in a portion of the sample plug being undiluted with carrier and hence prevents the formation of refractive index gradients in the undiluted portion. The quantitative performance of this approach was demonstrated with the determination of iron in the presence of 0.20*M* sodium chloride and cobalt in the presence of 0.10*M* glucose. No significant difference in the accuracy, precision, and limit of detection was observed between samples for iron both in the presence and absence of sodium chloride and for cobalt in the presence and absence of glucose. Despite using a large sample volume (0.89 ml for a 400-cm sample loop), the sample throughput was about 25/hr.

Flow-injection analysis (FIA) has proved to be a suitable tool for rapid, simple and reproducible determinations with rather inexpensive apparatus. Absorption spectrophotometry is the most widely used mode of detection in FIA because it can be applied to a wide variety of analytical problems. A blank peak appears where there is a difference in refractive index between the carrier solution and the injected sample solution. Such a situation can be illustrated by injecting a salt solution into the stream of distilled water as carrier. Despite the excellent stability of recent commercially available photometric detectors, this perturbation in the refractive index affects the real signal response and consequently causes deterioration of accuracy, precision, and limit of detection, especially in the case of determinations at trace levels.

Few reports[1–4] have mentioned this blank peak effect and its study is of analytical interest. Betteridge *et al.*[1] have discussed the origin of the blank peak and suggested two possible ways to compensate the refractive index problem: the first is to make the refractive index of the carrier equal to that of the sample by adding an inert solute, and the second one is to measure the absorbance on the over-all peak at the point where the "refractometric" peak passes the zero baseline. The first solution, however, requires extra manipulations and is troublesome. Success is not always achieved in finding the suitable salt and its concentration which can give the same refractive index as the sample solutions which may have large variations, because different solutes even at the same concentration may yield different refractive indexes. The second case requires a precisely timed pin-point measurement of absorbance when the signal is sharply decreasing or increasing. This is not easy and the analytical value is subject to operator error unless special equipment is used.

In this paper, the blank peak effect on trace level determinations with FIA has been studied extensively and a simple approach is presented to eliminate the refractive index problem by employing a large volume of sample. The usefulness of this approach is demonstrated with experiments for the determination of iron and cobalt with spectrophotometric detection with 1,10-phenanthroline (PHEN) and 2-(5-bromo-2-pyridylazo)-5-(N-propyl-N-sulphopropylamino)-phenol (PAPS), respectively.

THEORETICAL BACKGROUND

The origin of refractive index perturbation arises from the dispersion (dilution) of the sample plug in the carrier stream, resulting in

*Author for correspondence.

the formation of refractive index gradients. Therefore, a simple way to solve this refractive index problem should be provided by the measurement of the absorbance corresponding to a non-dispersed portion of the sample plug. The present approach for eliminating the refractive index problem is based on the provision of a non-dispersed zone in the sample plug and using this zone for measurement, in contrast to the use of larger dispersion with smaller volume samples as found in ordinary FIA systems.

The dispersion (D) occurring in an FIA system can be considered as the sum of the dispersions originating in the three main parts (D_i, D_t, and D_d) of the system:[5] D_i is concerned with the sample volume and the geometric aspects of the system, D_t is related to the reactor geometry, and D_d is related to the flow-cell geometry contribution to the dilution. According to Růžička and Hansen,[6] changing the injected sample volume is an effective way of changing the dispersion. The present study has mainly focused on the sample volume in order to provide a non-dispersed zone designated as "steady state" by Růžička and Hansen.[6]

EXPERIMENTAL

Reagents

Unless otherwise noted, all reagents were of analytical grade and were used as received. The standard solutions of iron and cobalt were prepared from a 100 μg/ml stock solution (Wako Pure Chemical Industries, Osaka, Japan) by suitable dilution, in which $1.0 \times 10^{-3}M$ ascorbic acid was added to the working standard solution of iron. The PHEN solution ($2.5 \times 10^{-3}M$) was prepared by dissolving the reagent (Dojindo Laboratories, Kumamoto, Japan) in 2.5 ml of $0.50M$ sulphuric acid with small amounts of water and then diluting to 250 ml with water. The working solution of PHEN ($2.5 \times 10^{-4}M$, pH 5.9) was prepared by mixing 25 ml of $2.5 \times 10^{-3}M$ PHEN solution, 0.0176 g of ascorbic acid, 25 ml of $1.0M$ sodium acetate solution and 1.6 ml of $1.0M$ acetic acid solution, followed by dilution to 250 ml with water. The PAPS solution ($5.0 \times 10^{-4}M$) was prepared by dissolving the reagent (Dojindo Laboratories) in water and then diluting to 250 ml. The working solution of PAPS ($1.0 \times 10^{-4}M$, pH 4.7) was prepared by mixing 50 ml of $5.0 \times 10^{-4}M$ PAPS, 20 ml of $1.0M$ sodium acetate solution, and 20 ml of $1.0M$ acetic acid solution, and finally diluting to 250 ml with water.

Manifold and apparatus

The flow system used consists of two channels, carrier C (distilled water) and chromogenic reagent R ($2.5 \times 10^{-4}M$ PHEN for iron or $1.0 \times 10^{-4}M$ PAPS for cobalt). The flow-rate of both streams was 0.75 ml/min. The sample solution is introduced into the carrier stream with a Daiflon six-way rotary valve with sample loop. The injected sample meets downstream with the reagent R and the metal complex formed during the merged zone is transported through the reaction coil (100-cm long) to the flow-cell (35-μl volume). The absorbance is monitored at 526 nm for iron or at 562 nm for cobalt. A Jasco Uvidec-320 spectrophotometer equipped with a flow-cell, a Sanuki DM2M-1024 pump, and a Toa-Dempa EPR-221A chart recorder were used. All pieces of tubing and sample loops were of 0.5 mm i.d. and made of Teflon.

RESULTS AND DISCUSSION

The effect of the presence of excessive salt on the signal response due to trace analyte was studied by injecting the 0.20-ppm iron solution with a 40-cm sample loop considered of normal size in ordinary FIA procedures. Sodium chloride was used as solute in order to produce a high refractive index in the sample solution. Distilled water was used as carrier. As shown in Fig. 1(a), when the solution containing only $0.20M$ sodium chloride was injected, a blank peak appeared as a set of sharp negative and sharp positive peaks. Peak heights increased

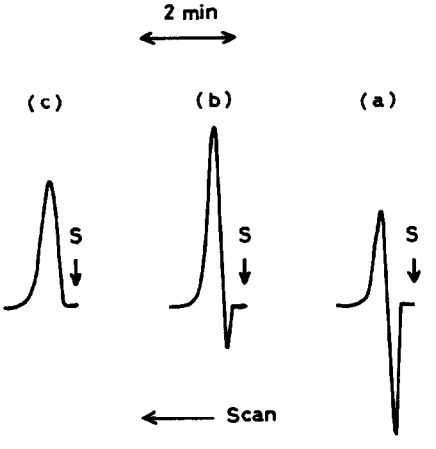

Fig. 1. Typical signal response with a 40-cm sample loop for injecting solutions containing (a) $0.20M$ sodium chloride, (b) 0.20 ppm iron and $0.20M$ sodium chloride in a mixture, and (c) 0.20 ppm iron. S denotes injection of sample.

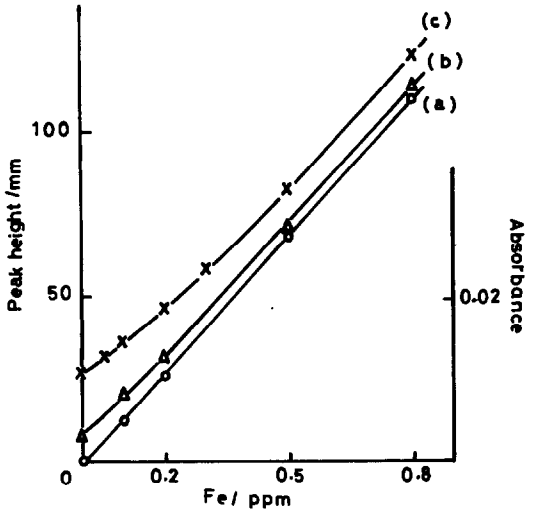

Fig. 2. Calibration graphs with a 40-cm sample loop for injection of (a) iron only, (b) iron in the presence of 0.10*M* sodium chloride, and (c) iron in the presence of 0.30*M* sodium chloride.

with an increase in salt concentration. Judging from the peak of the iron solution without sodium chloride, the peak for iron was evidently affected by the presence of sodium chloride. The peak for a mixture of iron and excess sodium chloride can well be understood as a result of contributions of refractometric and absorptiometric nature. This indicates that the refractometric response perturbs the shape of the analyte signal peak and thus obscures the absorptiometric response, especially for low concentrations of analyte. Figure 2 shows calibration graphs for sample injection with a 40-cm loop obtained by plotting the peak height, measured as the difference between the positive peak maximum and baseline absorbance, as a function of iron concentration. For the iron solution without sodium chloride a linear relationship was observed, but the graphs in the presence of sodium chloride did not pass through the origin due to the presence of the blank peak and showed a slight deviation from linear dependence at the lower concentration range. It can also be seen that the larger the concentration of sodium chloride, the larger the deviation of the slope from that of the linear calibration graph for iron only. This suggests that the additivity is not always guaranteed in the total contribution of refractometric and absorptiometric response, which is combined with a large blank value to control the limit of detection generating larger values than without a high concentration salt. Figure 3 shows the dependence of the shape of signal response on sample loop length with a reaction coil of 100-cm and a constant flow rate. In the blank signal, a plateau, close to the zero baseline, was observed with a sample loop larger than 300-cm, suggesting the presence of a steady state and the occurrence of no refractive index gradient in a limited portion of the sample plug. This was accompanied by a leading and a tailing peak still showing the presence of refractive index gradients at both ends of the sample plug. Also in the signal response for a solution containing 0.20 ppm iron together with 0.20*M* sodium chloride, there is good resolution for the response in the "steady state" zone of the sample plug if the sample loop is longer than 300-cm. This can be recognized as a plateau

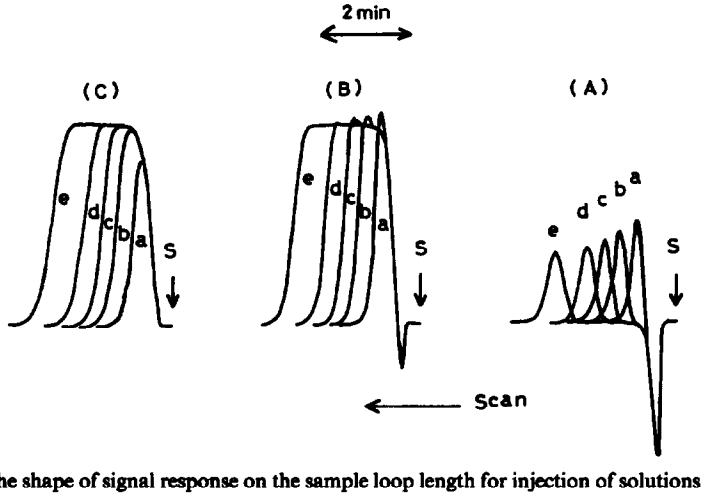

Fig. 3. Dependence of the shape of signal response on the sample loop length for injection of solutions containing (A) 0.20*M* sodium chloride, (B) 0.20 ppm iron and 0.20*M* sodium chloride in a mixture, and (C) 0.20 ppm iron. Sample loop length: (a) 100-cm, (b) 200-cm, (c) 300-cm, (d) 400-cm, (e) 600-cm.

(or as a shoulder) on the upper side of the ascending signal. The height of this plateau from the baseline was found to be independent of the sample loop length. There was no considerable difference in the height of this plateau for solutions of 0.20 ppm iron containing 0.10, 0.20 and 0.30*M* sodium chloride, even though the blank peak due to the refractive index of the sodium chloride solution proportionally increased with its concentration. This evidently shows that there is a portion of the sample plug which is unaffected by the carrier stream. In addition, no change in the height of this plateau was found even when the flow-rate was varied from 0.45 to 0.75 or even 1.0 ml/min.

The effect of the reaction coil length on the signal response for solutions containing 0.20 ppm iron and 0.30*M* sodium chloride in a mixture was studied with a 400-cm sample loop. No significant change in signal response (both in shape and in the height of the plateau) was observed by changing the reaction coil from 100 to 500-cm, although the plateau region tended to become smaller as a result of increased dispersion with increasing reaction coil (this became apparent with a 700-cm reaction coil). Similar results were observed for solutions containing only 0.20 ppm iron. Linear calibration graphs for iron solutions both in the presence and in the absence of 0.20*M* sodium chloride were obtained by plotting the height of this plateau against iron concentration ranging from 0 to 0.80 ppm. The equations for both linear graphs obtained by least squares are as follows: $Y = 0.892X$ and $Y = 0.894X$ (Y: peak height absorbance, X: iron concentration in ppm) for solutions in the presence and absence of 0.20*M* sodium chloride, respectively. The slopes for both linear graphs passing through the origin were in good agreement with each other. In the case of 0.10*M* sodium chloride and iron in a mixture, similar results were also obtained. These results show that real signal response due to the analyte, even in the presence of an excessively high concentration of salt, can easily be recognized and measured by employing a large sample volume, large enough to prevent the formation of refractive index gradients within a limited portion of the sample plug. It should be noticed that the use of a larger sample volume offers an additional advantage by improving sensitivity. In the present case, for instance, the peak height for 0.20 ppm iron increases by *ca.* 70% when increasing the sample loop from 40 to 400 cm.

Longer sample loops at a fixed flow-rate would appear more desirable for achieving better resolution of the non-dispersed zone and an easy and reliable measurement of real signal response due to analyte. This, however, would lengthen the determination time and consume more sample and reagents.

Dispersion and refractive index are also subject to variation by temperature changes, and the present approach would also serve to suppress signal fluctuations originating from temperature changes, although this is not at all effective for preventing the error that would arise from a change in reaction rate.

The recorded signal noise in the plateau for 0.20*M* sodium chloride solution was found to be almost the same as that in the baseline. The limits of detection, estimated as the signal equal to three times the standard deviation of the average blank signal, were 0.008 and 0.009 ppm for iron solutions in the presence and absence of 0.20*M* sodium chloride, respectively. In addition, good reproducibility could be obtained for iron solutions (0.20 ppm), both in the presence and in the absence of 0.20*M* sodium chloride, with relative standard deviations of 0.5 and 0.7%, respectively. Despite using a

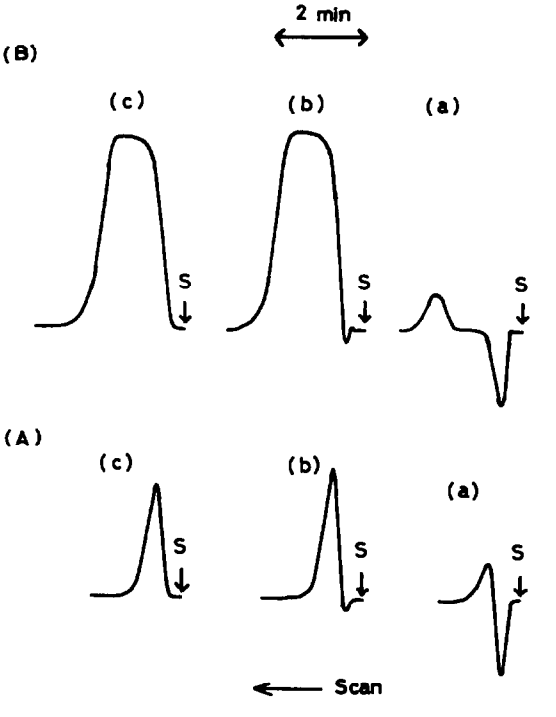

Fig. 4. Typical signal responses with (A) 40-cm sample loop and (B) 400-cm sample loop for solutions containing (a) 0.10*M* glucose, (b) 0.050 ppm cobalt and 0.10*M* glucose in a mixture, and (c) 0.050 ppm cobalt.

400-cm sample loop, the sample throughput was *ca.* 25/hr at a flow-rate of 0.75 ml/min.

In order to assess the feasibility of the present approach, the determination of traces of cobalt with PAPS as a chromogenic agent was performed with solutions containing glucose in place of sodium chloride. It is interesting to compare the characteristics of the two solutes: glucose is an undissociated species in aqueous solution, whereas sodium chloride is a strong electrolyte. Figure 4 shows typical signal traces for solutions containing 0.050 ppm cobalt, 0.050 ppm cobalt plus 0.10*M* glucose, and 0.10*M* glucose, with sample loops of 400 and 40-cm, respectively. A similar blank peak for solutions in the presence of 0.10*M* glucose as in the case of sodium chloride solution was clearly observed. By using the 400-cm sample loop, a plateau, showing that there was a portion of the plug which has undergone no dilution with carrier, was also obtained for glucose solutions both in the presence and in the absence of cobalt. The height of the plateau for 0.050 ppm cobalt in the presence of 0.10*M* glucose (measured as the difference from the baseline obtained for 0.10*M* glucose solution without cobalt) was in good agreement with the plateau observed for 0.050 ppm cobalt solution without glucose. Two linear calibration graphs passing through the origin and having the same slope were obtained for cobalt solutions, both in the presence and absence of 0.10*M* glucose. Table 1 illustrates the results for determination of trace iron added to the 0.20*M* sodium chloride solution and trace cobalt added to the 0.10*M* glucose solution, by using different sample loops of 40 and 400 cm with the FIA system as described above. Each metal concentration was calculated with reference to the calibration graph prepared by standard iron solutions without sodium chloride or standard cobalt solutions without glucose and by the respective use of 40–400-cm sample loops. It can be seen that considerable errors were observed for solutions containing a high concentration of solutes when using ordinary sample injection with a 40-cm loop. In contrast, no considerable blank peak effect on the analytical result was observed by use of a large sample volume with the 400-cm loop.

Table 1. Determination of iron and cobalt in the presence of sodium chloride and glucose, respectively, with use of 40- and 400-cm sample loops

Sample loop, *cm*	NaCl or glucose, *M*	Fe(Co) added, *ppm*	Fe(Co) found,* *ppm*
40	0.10 NaCl	0.10 Fe	0.15 Fe
	0.10	0.20	0.23
	0.10	0.50	0.52
	0.30	0.05	0.23
	0.30	0.10	0.27
	0.30	0.20	0.34
	0.30	0.50	0.61
400	0.20	0.10	0.10
	0.20	0.20	0.20
	0.20	0.50	0.51
40	0.10 Glucose	0.010 Co	0.022 Co
	0.10	0.030	0.041
	0.10	0.050	0.059
	0.10	0.080	0.086
400	0.10	0.010	0.009,
	0.10	0.030	0.031
	0.10	0.050	0.050
	0.10	0.080	0.081

*Results of 3 to 5 determinations.

In conclusion, the use of a large sample volume has proved to be a simple and attractive approach in order to eliminate the blank peak effect, especially at trace level determinations. The present approach was also found to provide advantages in improving the sensitivity by *ca.* 70% and stabilizing the signal response both for analyte and for the blank which may result in improved sensitivity and accurate and reproducible determinations, even when the analyte is present with a large excess of another solute.

DETERMINATION OF THALLIUM IN SOILS BY FLOW-INJECTION–DIFFERENTIAL PULSE ANODIC STRIPPING VOLTAMMETRY

ZENON LUKASZEWSKI and WLODZIMIERZ ZEMBRZUSKI
Institute of Chemistry, Technical University of Poznan, PL-60-965 Poznan, Poland

(*Received* 17 *November* 1990. *Revised* 8 *July* 1991. *Accepted* 26 *July* 1991)

Summary—A relatively simple and quick method for the determination of thallium in soils is described. The method does not require any separation prior to determination. Total decomposition of the sample was performed in a teflon bomb. The interferences of iron, aluminum and manganese were removed by media exchange performed in a flow-injection measuring system, and the other interferences were removed by the use of the base electrolyte consisting of 0.15*M* EDTA and 0.1*M* ascorbic acid. The contents of thallium in the examined samples of soil were between 100 and 350 ppb.

Thallium is a highly toxic element, however, it has not commanded a lot of attention from investigators because of its low content in the environment, owing to its low crystal abundance (0.7 μg/g).[1,2] On the other hand, the antropogenic sources of pollution with this metal exist and occasional ecological catastrophies caused by thallium arise (*e.g.*, Chernovcy, 1988). It is reported that thallium which is preconcentrated in the soil can dampen the vitality of soil microorganisms.[1] That is why the content of thallium in the environment, its speciation, circulation *etc.*, has a certain importance and should be systematically controlled.

A more extensive investigation of thallium in the environment cannot be performed because of the lack of quick and cheap methods for its determination which are resistant to interferences. This situation occurs because of the very low abundance of the element and the numerous interferences which are very difficult to overcome. That is why the majority of methods combines the final measurement with a preconcentration procedure, *e.g.*, extraction with spectrophotometry[3,4] or volatilization of thallium in the form of hydride with AAS.[5,6] Detection limits for different methods for determination of thallium are compared in a report by IUPAC.[7] Liem *et al.*[5] critically compared the detection limits of methods for determination of thallium also. The potential for stripping voltammetric methods is promising although both reports[5,7] differ very much in evaluation of detection limits of different methods. The lowest detection limit was achieved for the differential pulse mode. Also, the use of a mercury film electrode (MFE) gives a lower detection limit than HMDE. Extremely low concentration of thallium (10 ng/l.) was achieved when the mercury film was used together with a rotating disc.[8] Such a low detection limit is sufficient for the determination of thallium in environmental samples but interferences are the main problem.

The main interferences with thallium in voltammetry are caused by lead, tin and cadmium.[9] Also indium interferes with thallium under the conditions of a MFE,[10] but this interference can be removed by the use of a proper voltage scan-rate. The signals of thallium, lead and cadmium can be separated by the use of certain base electrolytes having alkaline pH.[11] However, in the matrices having practical importance the separate determination of thallium seems to be a more practical solution because of the great difference in the level of thallium on the one hand and the interferents (*e.g.*, lead) on the other hand. Dieker and van der Linden[12] proposed a method for the determination of thallium in the presence of a 10^5-excess of lead with an MFE produced *in situ*. The use of complexons as the base electrolytes is a very effective measure against the interferences. EDTA solution together with acetates, tartrates or citrates is used.[8,13,14] If surfactants are used together with the complexons the excess of lead against the thallium can be substantially increased (to 10^5–10^7).[15,16] The interference of copper can also be removed in this way.[17]

The interferences caused by the presence of iron and titanium turned out to be very difficult to overcome, although these metals do not accumulate in the mercury. These elements are present in many matrices at very high concentrations and their presence causes such problems that the determination is frequently impossible.[18,19] The interferences discussed can be limited by the use of properly selected surfactants. However, the simultaneous presence of several interferents is difficult to overcome, *e.g.*, the use of EDTA which limits the interference of lead involves the appearance of the peak of titanium which does not appear in the non-complexing electrolytes.[19]

Removing the interferents which do not undergo deposition in the form of an amalgam (iron, titanium, *etc.*) seems to be possible by means of media exchange performed after the preconcentration has been completed. Simple removal of analyte containing interferents, after deposition of thallium is completed and its replacement by the pure electrolyte, is possible only in a flow-injection measuring system in which such an operation is possible without breaking the electric contact in the circuit. If these interferents were not present during the stripping stage their interfering influence would be eliminated. A similar solution has recently been used for removing the surfactant from the measuring system after the deposition of cadmium, lead and copper is complete but before the stripping step[20] or for improving determination of copper.[21] The measuring system in these works was very similar to the flow-injection system.[22]

The aim of this paper is to develop a highly selective method for the determination of trace thallium, using media exchange in a flow-injection measuring system and proper selection of base electrolyte for removing interferences. Such a method should be sufficient for the determination of thallium in complicated environmental matrices. Soil seems to be a very good example of such a complicated environmental matrix which has large amounts of possible interferences. Limited deposition time, connected with the volume of analyte is a certain drawback in using a flow-injection system, but can be simply overcome by using circulation of the analyte during the time necessary for effective preconcentration of thallium.

Information on thallium content in soil is comparatively scanty. Chattopadhyay and Jervis have determined 0.17–0.22 ppm in garden soil[23] (the detection limit of this method is only 0.15 ppm) and Ure and Bacon 0.27 ppm.[24] Smith and Carson have reported 0.02–2.8 ppm in surface soils of the USA.[25] The largest antropogenic source of thallium is related to coal combustion.[1]

The normal level of lead in soil should not exceed 70 ppm,[1] although in polluted soils can be much higher. Iron, aluminum, titanium and manganese have the most common range from 0.5 to 5%, from 0.45 to 10%, from 0.1 to 0.9% and from 200 to 800 ppm, respectively.[1] The influence of antimony, bismuth and copper should also be taken into account. The content of antimony and bismuth does not exceed 1–2 ppm but copper can be several hundred ppm.[1] Such a ratio of these interferents should be expected in the solution obtained after the decomposition of the soil sample. The presence of iron(III) in the determined solution obtained after the decomposition of soil is extremely troublesome. Iron(III) causes the dissolution of the mercury film making the determination impossible. The use of supporting electrolyte consisting of EDTA and ascorbic acid can overcome this problem. The results of the determination of thallium in the soil with the use of such electrolyte and media exchange were preliminarily reported.[26,27]

EXPERIMENTAL

Apparatus

A Telpod (Poland) pulse polarograph model PP-04 was used. Voltamperograms were displayed on an Endim (GDR) 620.02 XY-recorder. The differential pulse amplitude was 50 mV and the scan-rate was 11.1 mV/sec. The flow-injection voltammetric system shown in Fig. 1 was used. A wall-jet type three-electrode flow-through cell was used. This cell consisted of: a mercury film electrode based on the epoxy resin impregnated graphite (manufactured in Maria Sklodowska-Curie-University), saturated calomel electrode (SCE) and platinum wire auxiliary electrode. The geometrical surface of MFE was 3.14 mm^2. The mercury film was deposited over 10 min from the solution consisting of 50μM mercury(II) nitrate and 0.1M potassium nitrate, and was washed with potassium nitrate solution. Only one mercury film was required for a whole day of measurements. The peristaltic pump 372.C (Elpan, Poland) was used with a flow-rate of 15 ml/min. During the

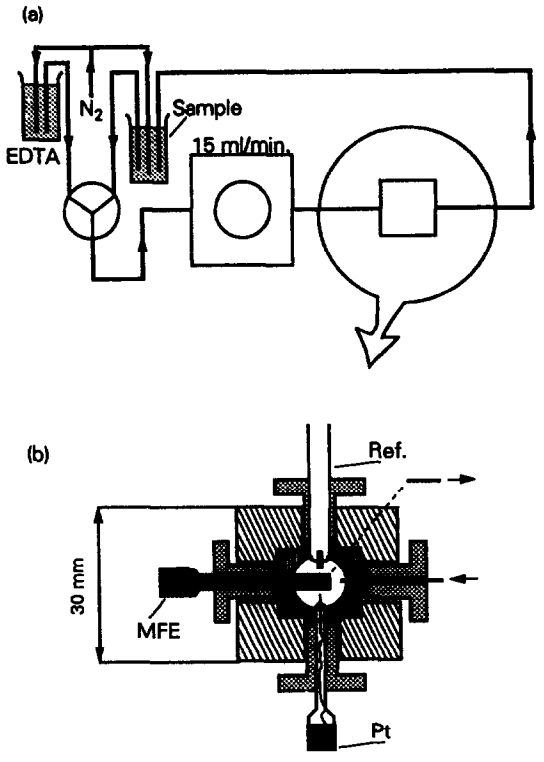

Fig. 1. The voltammetric flow-injection measuring system (a) with flow-through cell of wall-jet type (b). MFE—mercury film electrode based on epoxy resin impregnated pyrolitic graphite, Ref.—reference electrode (SCE), Pt—auxiliary electrode (Pt wire).

measurement, circulation of measured solution was used by junction of the outlet from the measuring system with an analysed sample in the beaker.

Another flow-injection voltammetric system was used for part of the experiments. This system was the first version of the final system and was characterized by the lower hydrodynamic effectiveness of the cell and, as a result, weaker analytical signal.

Reagents

The supporting electrolyte was 0.15*M* EDTA containing 0.1*M* ascorbic acid (pH 4.5), which was prepared from the analytical grade reagents (POCh). The pH of this solution was adjusted with sodium hydroxide solution (Merck). The carrier solution was 0.05*M* EDTA solution which was continuously deaerated with the purified nitrogen. The standard solution of Tl(I) was prepared from thallium(I) nitrate.

All solutions were prepared in triply distilled water in a fused-silica apparatus. Suprapure nitric and hydrochloric acids (Merck) and the analytical grade hydrofluoric acid and hydrogen peroxide (POCh) were used. The samples of soil were received from the Institute of Soil Science and Cultivation of Plants, Pulawy, Poland together with the determined contents of lead, iron and manganese.

Decomposition of soil

The soil sample (approx. 0.5 g) was transferred to the beaker of a teflon bomb and moistened with water. Hydrofluoric acid (2.5 ml) and 3.5 ml of a mixture of hydrochloric and nitric acids (3:1) were added. The teflon bomb was closed and put in the drying-oven for 3 hr (135°). The obtained solution was transferred into a teflon beaker and heated on a graphite heater until evaporated. In the final stage of the evaporation, 2 ml of hydrogen peroxide was added in a few portions, for decomposition of residual organic substances originating from soil. The residue was dissolved in 1 ml of hot hydrochloric acid. The solution of ascorbic acid in the amount corresponding to the final concentration of 0.1*M* was added and after a few minutes the corresponding amount of EDTA solution was added. The pH was adjusted to 4.5 and the volume was supplemented to 25 ml with water in the measuring flask.

Extraction of soil (slightly modified procedure of Wolf et al.*[28])*

The sample of soil (*ca.* 5 g) was placed in the conical flask equipped with a reflux condenser and treated with 20 ml of a mixture of hydrochloric and nitric acids (3:1) and put aside for 48 hr. Then the sample was heated for 2 hr and filtered. The filter was washed with 2*M* nitric acid and the filtrates were mixed. The obtained solution was evaporated. In the final stage of evaporation 2.5 ml of hydrogen peroxide were added in a few portions to completely destroy any organic matter. The residue was dissolved in 1 ml of hydrochloric acid and the procedure was continued as for decomposition of soil.

Measuring procedure

A portion of the solution (8 ml) was transferred to the beaker and was introduced into the flow-injection system. The solution was directed to the measuring cell and then back to the beaker with the sample. In this way the solution was in circulation. Now the preconcentration was started by application of a preconcentration potential. In all experiments preconcentration was carried out at a potential of −0.850 V with the exception of the experiments in which the

influence of preconcentration potential on the peak height was examined. The preconcentration time was 1–3 min depending on the thallium concentration. After the deposition stage was complete the valve was switched off and the analysed solution was replaced by the deaerated carrier solution (0.05*M* EDTA). Then the flow was stopped and the voltamperogram recorded after 15 sec of quiescent time. The evaluation of the concentration of thallium was performed by the method of two additions of standard. The pH remained constant throughout the measuring cycle and so did not require correction.

RESULTS AND DISCUSSION

The presence of ascorbic acid in the base electrolyte transforms iron(III) into iron(II), which highly improves possibilities for the measurement. However, it is still insufficient for the sensitive determination of thallium because of too high a base-line current. This is visible in Fig. 2(a), which shows the voltamperogram of a solution containing EDTA, ascorbic acid, aluminum, iron(II) [introduced in the form of iron(III)] and 10n*M* thallium. Aluminum and iron are present here in the ratio typical of their contents in the soil. Only a small bulge resulting from thallium is visible on this voltamperogram. Media exchange for pure 0.05*M* EDTA removes iron(II) as well as other interferents which do not form amalgams, and in this way radically improves the conditions for the determination of thallium [see Fig. 2(b)].

The correct selection of a deposition potential is very important. On the one hand, a sufficiently negative deposition potential guarantees a stable peak height of thallium (if it is located on the plateau of dependence of the peak height on the deposition potential). On the other hand, with the shifting of potential towards negative direction, the lead signal increases. Thus the selection of deposition potential is the compromise between these two tendencies. This is shown in Figs 3(a) and 3(b). Figure 3(a) shows the dependence of height of the peak of thallium on the deposition potential both in the pure EDTA solution (circles) and in the solution containing additionally iron(II) and aluminum(III) in the ratio typical of the solution obtained after decomposition of soil[25] (crosslets). Iron was introduced in the form of iron(III) for the control of effectiveness of its reduction. These two dependences are identical and their plateau is located starting from a potential of −0.850 V *vs.* SCE. The discussed

The base electrolyte for the case (*a*) whole cycle and for the deposition stage in the case (*b*) 0.15*M* EDTA + 0.1*M* ascorbic acid + 70m*M* of aluminum(III) + 20m*M* of iron(II) (pH 4.5). The base electrolyte for stripping stage in the case (*b*) 0.05*M* EDTA (pH 4.5). Concentration of thallium: 10n*M*. Preconcentration potential: −0.900 V *vs.* SCE; preconcentration time: 180 sec.

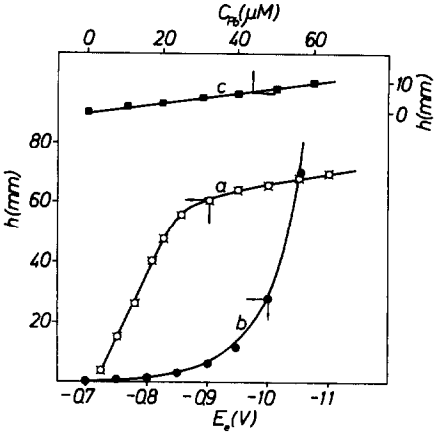

Fig. 3. The dependence of the peak height of thallium (a) and lead (b) on the deposition potential and the peak height of lead on its concentration (c) under conditions of the medium exchange. The base electrolyte for the deposition stage: 0.15*M* EDTA (pH 4.5) [Fig. 3(a)—circles] or 0.15*M* EDTA + 0.1*M* ascorbic acid + 70m*M* of aluminum(III) + 20m*M* of iron(II) (pH 4.5) (other cases). The base electrolyte for stripping stage (all cases): 0.05*M* EDTA (pH 4.5). Concentration of thallium: (a) 10n*M*, (b, c) 0; concentration of lead: (a) 0, (b) 10μ*M*, (c) variable. Preconcentration potential: (a, b) variable, (c) −0.850 V *vs.* SCE. Preconcentration time: (a, b and c) 300 sec.

dependence is shifted toward more negative values in the comparison with similar dependence measured with the use of HMDE.[16] The potential peak of thallium is also located at about −150 mV more negative than when using HMDE (−0.600 V *vs.* SCE). The dependence of the peak height of lead on the deposition potential under these conditions is shown in Fig. 3(b). It is obvious from this picture that the lead peak appears at a potential of −0.850 V *vs.* SCE which is necessary for the determination of thallium. The dependence of the peak height of lead on the concentration of this metal is shown in Fig. 3(c).

This dependence makes possible the evaluation of the positive error of determination of thallium caused by the presence of a certain concentration of lead. This error is negligible for $< 10\mu M$ lead which corresponds to 100 ppm lead in a 0.5-g soil sample.

The masking of the lead signal is caused by the presence of EDTA and the question arises as to whether the excess of free EDTA, *i.e.*, nonbounded with iron, aluminum, *etc.* is necessary for the effective masking of lead. The dependence of the peak height of lead on the preconcentration potential was examined under the following conditions: pure EDTA solution, a solution with an EDTA to iron ratio of 1:1 and a solution with an excess of iron *vs.* EDTA. The results are shown in Fig. 4 and the representative voltamperograms are shown in Fig. 5. The results shown in Fig. 4 were performed with the first version of a measuring system which

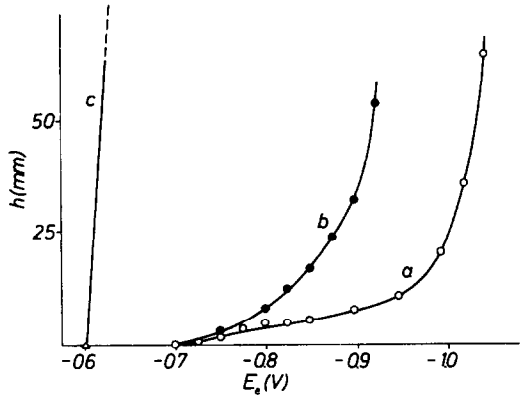

Fig. 4. The dependence of the peak height of lead on the preconcentration potential under conditions of absence (a) or in the presence of iron in the sample (b, c). The ratio of iron *vs.* EDTA: (a) 0, (b) 1, (c) 1.1. The base electrolyte for the deposition stage: $0.1M$ EDTA + $0.1M$ ascorbic acid + 0.1mM of lead(II) (pH 4.5). The base electrolyte of stripping stage: $0.05M$ EDTA. Preconcentration time: 180 sec.

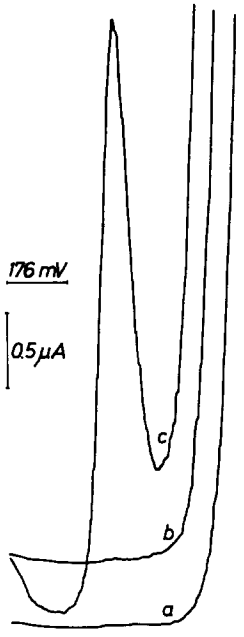

Fig. 5. The effect of excess or deficit of nonbounded EDTA on the tolerance of the system on the presence of lead. The ratio of EDTA *vs.* iron: (*a*) 7.5:1, (*b*) 1:1, (*c*) 1:2. The base electrolyte of deposition stage: $0.15M$ EDTA + $0.30M$ ascorbic acid (pH 4.5). Concentration of lead (deposition stage): 0.01mM. Concentration of iron (deposition stage): (a) 20mM, (b) 150mM and (c) 300mM. The base electrolyte of stripping stage: $0.05M$ EDTA (pH 4.5). Preconcentration potential: −0.850 V; preconcentration time: 900 sec.

was less sensitive and the results were further checked with the system finally used (Fig. 5). The higher concentration of ascorbic acid was used in the last case for more effective reduction of introduced amounts of iron(III) to iron(II). It is clearly visible in Fig. 4 and supported in Fig. 5, that if the concentration of iron and aluminum exceeds EDTA concentration lead is no more effectively masked and a huge peak arising from this metal appears. Thus the ratio of the weight of soil sample to the EDTA concentration must be synchronized and an excess of EDTA in the measured solution is necessary.

The possible interferences of antimony, bismuth and copper with the determination of thallium were predicted.[5] For this reason the tolerated excess of these metals was checked. Antimony or bismuth ($0.1\mu M$) or $1\mu M$ of copper was added to the 10nM thallium solution. Such a ratio is required because of the reported highest level of these elements in the soil.[1] The results of these experiments are shown in Fig. 6. The peaks of considered metals are located at (−0.240), (−0.240) and (−0.200) V *vs.* SCE respectively, under the

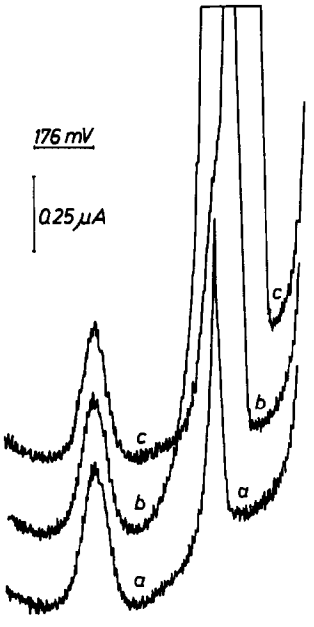

Fig. 6. The voltamperograms of solution containing thallium in the presence of an excess of antimony (a), copper (b) and bismuth (c). Concentration of thallium: 10n*M*. Concentration of antimony or bismuth: 100n*M*, concentration of copper: 1μ*M*. The base electrolyte of deposition stage: 0.15*M* EDTA + 0.1*M* ascorbic acid (pH 4.5). The base electrolyte of stripping stage: 0.05*M* EDTA. Preconcentration potential: −0.850 V *vs.* SCE; preconcentration time: 600 sec.

experimental conditions (deposition from 0.15*M* EDTA + 0.1*M* ascorbic acid solution at −0.850 V and stripping from 0.05*M* EDTA solution). No serious interferences of the investigated metals at such a ratio are observed.

Removal of interferences makes the determination of thallium in the real soil samples possible. The recovery and precision of such a determination has been checked. The representative soil sample (No. 126D8437—see Table 1) contained 1.07% iron, 270 ppm manganese and 8.5 ppm lead. It was analysed according to the described procedure, both alone as well as spiked with 250 ppb thallium. A 213-ppb concentration of thallium was found in the analysed soil (7 independent measurements, $S = 30.5$ ppb, $S_r = 14.3\%$). The spiked thallium was recovered in 94% (6 independent measurements, $S = 31.5$ ppb, $S_r = 7.2\%$). Such results seem to be satisfactory for such a complicated matrix and difficult decomposition procedure. Precision of measurement is satisfactory because it is typical of measurement on such a concentration level.

A concentration of 1n*M* thallium can be comparatively easily determined with 10–15 min preconcentration. Hence, the detection limit of 10 ppb (with 0.5 g of soil) can be achieved, and, if necessary, improved by prolonging deposition time. Lead is tolerated up to 100 ppm but higher contents cause a small positive error.

The developed method was used for the determination of thallium in several samples of soil. Parallel samples were totally decomposed or extracted with a mixture of nitric and hydrochloric acids according to the procedure described above. The results are given in Table 1, together with the content of iron, manganese and lead in the soil samples. It is visible that the content of thallium in the totally decomposed samples is roughly located between 100 and 350 ppb. The extraction of thallium leads to much lower results, which indicates only partial extraction (21–74%). Thus the extraction is the unproper way for the evaluation of total thallium content in the soil in contrast to the determination of zinc, lead, cadmium and copper in the soil,[25] where extraction is complete. The contents of thallium seem to be correlated with the content of iron and manganese. Of course, such a conclusion should be supported with much extensive examination.

Table 1. The results of the determination of thallium in different soil samples performed after the total decomposition of the samples and after the extraction of samples with the mixture of nitric and hydrochloric acids

Sample number	Content of iron, manganese and lead			Thallium content (average)		
	Fe, %	Mn, *ppm*	Pb, *ppm*	Total decomposition, *ppb*	Extraction, *ppb*	Extraction, %
99D8448A	0.23	120	9.0	97	27	28
127D8446	0.44	210	32	175	37	21
26D8321B	0.58	750	240	203	150	74
126D8437	1.07	270	8.5	213	74	35
29D8325B	1.36	400	31	353	148	42
36D8309F	2.91	710	29	355	176	50

The promising results for the determination of thallium in the soil, *i.e.*, sample having silicium, aluminum, iron, titanium, manganese and lead indicate that this element can also be determined in geological samples of similar composition, by means of a very similar procedure.

Acknowledgements—This work was supported by Research Program CPBP 01.17. We thank Professor A. Kabata-Pendias of the Institute of Soil Science and Cultivation of Plants, Pulawy, Poland for providing the soil samples with determined contents of iron, manganese and lead and for valuable discussion. We are grateful to Miss Anna Piela for her technical assistance in the measurements.

THE INFLUENCE OF COMPLEXING AGENTS ON THE EFFECTIVENESS OF ELECTROCHEMICAL MASKING WITH ANIONIC SURFACTANTS IN ANODIC STRIPPING VOLTAMMETRY

J. OPYDO
Institute of Chemistry, Technical University of Poznań, 60-965 Poznań, Poland

(*Received* 2 *May* 1991. *Revised* 25 *July* 1991. *Accepted* 2 *August* 1991)

Summary—The influence of sodium dodecyl sulphate, sodium dodecyl sulphonate and sodium stearinate on the anodic stripping peaks of Tl(I), Pb(II), Cd(II), Cu(II) and In(III) was investigated. The supporting electrolytes were 0.5*M* sodium sulphate solution, 0.2*M* citrate solution (pH 3.7, 4.6 and 7.3), 0.5*M* tartrate solution (pH 4.4) and 0.1*M* solution of EDTA (pH 4.4). The composition of complex compounds forming in a solution under experimental conditions was defined. The conditions of ion reduction of metals on hanging mercury electrode during the electrolytical deposition were investigated. The investigation included an analysis of voltammetric curves of the metal ions. The obtained results suggest that "electrochemical masking" is much stronger in electrolytes containing a complexing agent than in the sodium sulphate solution. The influence of the complexing agent may not be explained in terms of the interaction between the form of the complex and the charge of the adsorbed surfactant particles; rather the complexing process is connected with indirect inhibition, *i.e.*, by decreasing the rate of charge transfer reaction.

The influence of surfactants on the processes of metal ion electroreduction in electrochemical methods depends to a significant extent on the supporting electrolyte. There is an opinion that in the case of a simultaneous presence of surfactants and complexing agents the effect of "electrochemical masking" is stronger.[1,2] The literature describes many good examples of "electrochemical masking" performed in the presence of both these components.[3–11] It is also suggested that this phenomenon results from the character of actions between the form of a metal ion in a given solution and a charge of adsorbed particles of surfactants. This problem has been signaled by Jacobsen and co-workers[12,13] in relation to polarography waves. According to the mentioned authors the electrode processes of negatively charged metal ion complexes are strongly modified by an adsorbed layer of anionic surfactants, whereas cationic surfactants exert a large influence on the electrode processes of cationic metal complexes.

The present paper deals with the influence of complexing process while "electrochemical masking" of the peaks of Tl(I), Pb(II), Cd(II), Cu(II) and In(III) by anionic surfactants in dc anodic stripping voltammetry (ASV); the influence of nonionic polyethylene glycols and cationic surfactants on metal ion peaks in different supporting electrolytes was investigated in earlier papers.[14,15] The supporting electrolytes were 0.5*M* sodium sulphate solution, 0.2*M* citrate solution (pH 3.7, 4.6 and 7.3), 0.5*M* tartrate solution (pH 4.4) and 0.1*M* EDTA solution (pH 4.4). The anionic surfactants: sodium dodecyl sulphate (SDS), sodium dodecyl sulphonate (DS) and sodium stearinate (S), were applied at different concentrations. With the aim to determine the composition of complex compounds occurring in the solution we calculated a percentage portion of metal ions in individual complex forms arising in the solution under experimental conditions, *i.e.*, at a definite pH and concentration of the supporting electrolyte. The conditions of ion reduction of metals on the hanging mercury electrode during the electrolytic deposition were investigated. The investigation included an analysis of voltammetric curves of the metal ions.

EXPERIMENTAL

Apparatus

Voltammetric measurements were carried out with the Radelkis OH-105 polarograph with a voltage scan-rate of 400 mV/min. A hanging

mercury drop electrode was used as working electrode and SCE as a reference electrode. The surface area of the hanging mercury drop was 2.1 mm^2.

Reagents

Sodium dodecyl sulphate and sodium dodecyl sulphonate (Merck), sodium stearinate (POCh), were used without additional purifications. The supporting solutions were prepared from the analytical grade reagents: sodium sulphate, sodium tartrate, sodium hydrogen tartrate, sodium citrate, citric acid and EDTA. Standard solutions of Tl(I), Pb(II), Cu(II) and In(III) were prepared by dissolving the metals in nitric acid. Solutions with concentrations below 1m*M* were prepared just before use. Water was doubly distilled in a quartz still.

Procedure

The solutions examined were deaerated by a passage of purified nitrogen and were brought to $20 \pm 0.2°$ before measurement. In all the experiments preconcentration was done at a potential of -0.9 V *vs.* SCE for 180 sec, with the solution stirred. After switching off the stirrer, a stripping voltamperogram was recorded after a rest period of 1 min. Each measurement was made with a new drop.

Registration of cathodic voltammetric curves

The studied solution was deaerated and brought to $20 \pm 0.2°$ as above. Then, the $i - E$ curves of the cathodic metal ion reduction in the chosen supporting electrolytes were registered [in the case of Cu(II) the potentials ranged from $+0.2$ to -1.0 V, while the remaining ions ranged from 0.0 to -1.0 V *vs.* SCE]. The solution was uniformly stirred during these studies. The scan-rate of the electrode polarization amounted to 900 mV/min.

RESULTS AND DISCUSSION

The influence of anionic surfactants on the height of the anodic stripping peak of Tl(I) is not significant. The degree of thallium peak damping in all electrolytes, within the range of concentration of surfactants under investigation, does not exceed 20%.

The influence of anionic surfactants on the heights of the anodic stripping peaks of Pb(II), Cd(II), Cu(II) and In(III) in different supporting electrolytes is presented in Figs. 1–4, respectively. All the studies were carried out under identical conditions, *i.e.*, while performing deposition electrolysis for 180 sec at a potential of -0.9 V *vs.* SCE; this is a potential localized in the vicinity of that of a maximum adsorption of applied surfactants,[16,17] and on the "plateau" of most there is a dependence of the peak height on the deposition potential.[16] Concentration of the studied ions was 1μM (only that of Pb in EDTA was 1m*M*), and that of surfactants was changed in the range of 0.1–10 ppm in the case of S and in the range of 0.1–100 ppm in the case of other surfactants. The obtained results were presented as dependences of the relative peak heights (i_s/i_o) on surfactant concentrations (c), where: i_s is the peak height of a metal ion in the presence of a surfactant and i_o is the peak height of a metal ion in the absence of a surfactant. The studies did not cover only ions of Cd(II) and In(III) in EDTA solution, since the obtainment of Cd and In peaks in that electrolyte is connected to the performance of deposition electrolysis beyond the maximum adsorption range of the applied surfactants.

A percentage portion of metal ions in particular complex forms was calculated from the equations of complex formation equilibrium discussed previously.[18] Results of these calculations are summarized in Table 1; column 5 contains the corresponding pK values.[19] Thallium (I) was omitted in these calculations because it is a weakly or not at all complexing ion with the used supporting electrolytes.

Results presented in Figs. 1–4 evidently show that the peak damping of metal ion by the applied surfactants as a rule is significantly stronger in complexing electrolytes than in sodium sulphate solution. Doubts arise when analysing data of Table 1, whether the effectiveness of "electrochemical masking" may be related to a charge sign of the dominant complex in a solution or even to a complex stability. Anionic EDTA complexes, characterized by the largest stability, are in fact damped most strongly, but there are too many exceptions to this rule. In citrate basic electrolyte at pH 7.3, Pb has an anionic form ($Pb\,citr^-$) characterized by p$K = 6.3$, while in citrate electrolyte at pH 4.6 there dominates a neutral form (Pb citr) at p$K = 5.7$, in basic tartrate solution a neutral form (Pb tart) at p$K = 3.4$ was also dominant. Damping is smaller in citrate solution at pH 7.3 than at pH 4.6, and it is also smaller in tartrate solution. Similarly in sodium sulphate solution Cd(II) occurs mostly in the form of $[Cd(SO_4)_2^{2-}]$

Table 1. Characteristics of complex compounds formed under experimental conditions

Metal ion	Supporting electrolyte	Complex form	Ion content	pK
Pb(II)	0.2M citr. at pH 3.7	Pb citr$^-$	3.07	6.30

characterized by pK = 3.4. Peaks in that solution are damped by SDS, DS and S like in citrate solution at pH 3.7, in which there dominates a neutral form (CdHcitr) with a lower stability. In sulphate solution In(III) also has mostly the form of anionic complexes, *i.e.*, $[In(SO_4)_3^{3-}]$ (pK = 3.0) and $[In(SO_4)_2^-]$ (pK = 2.6). In all considered citrate solutions In(III) occurs in the form of a neutral complex (In citr) (pK = 6.2), and in tartrate solution it has a cationic form (In tart$^+$) (pK = 4.48). The peak of In(III) in the solutions characterized by dominance of neutral (citrates) and cationic (tartrates) forms is damped considerably more strongly than in sulphate supporting electrolyte, where it has an anionic form.

In the considered solution, Cu(II) occurs mainly in anionic forms of complexes, which suggests a small comparative value of these systems.

An inhibiting effect of surfactants is related to a decrease in the electrode process constant rate.[20-22] This decrease, however, immediately causes a fall in the current of reduction or oxidation only in the case when the electrode process is controlled by the rate of charge

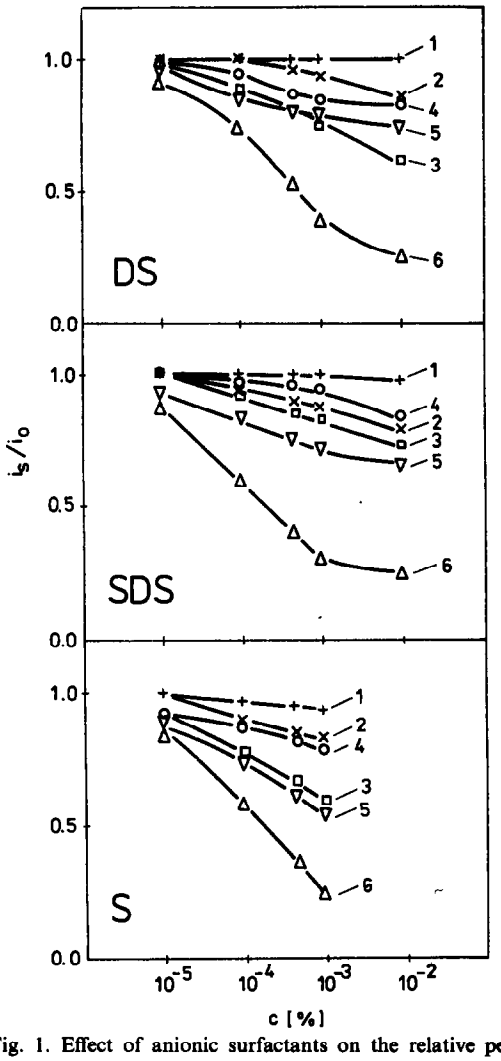

Fig. 1. Effect of anionic surfactants on the relative peak height of Pb(II) in 0.5*M* Na_2SO_4 (1), 0.2*M* citrate at pH 3.7 (2), 0.2*M* citrate at pH 4.6 (3), 0.2*M* citrate at pH 7.3 (4), 0.5*M* tartrate at pH 4.4 (5) and 0.1*M* EDTA at pH 4.4 (6). Concentration of Pb was 1m*M* in EDTA and 1μM in the remaining solutions. Deposition potential −0.9 V *vs.* SCE. Deposition time 180 sec.

transfer. When the electrode process is controlled by a slow depolarizer transport rate, a decrease of the electrode process constant rate may remain unnoticed. For that reason electrode processes with deviations from reversibility should be significantly more susceptible to the action of surfactants than reversible processes. The procedure used for investigation of metal ion electroreduction reversibility was the accepted rotating disc method[23] (under conditions of rotating fluid movement the electrolytical deposition stage in ASV assimilates with the rotating disc method). The obtained $i - E$ curves have the shape of polarography waves with well-developed limiting current. A logarithmic analysis of these waves permitted to present results in the form of the dependence $\log[(i_g - i)i^{-1}] = f(E)$, where i_g is a limiting current, i is the current at any point on the wave, and E is potential. Then directional coefficients γ as a criterion of electrode process reversibility were determined in the function $\log[(i_g - i)i^{-1}] = f(E)$. Results are presented in Table 2. It follows from this table that many considered systems containing a complexing agent show significant deviations from the curves of the reversible electrode process (*i.e.*, the process controlled by a slow rate of charge transfer). It may, therefore, be inferred that the complexing process is related to peak inhibition indirectly, *i.e.*, through a decrease in the rate of charge transfer reaction. Decreasing the

rate of the charge transfer reaction, a complex formation has the same effect as a surfactant, *i.e.*, contributes to peak damping.

In studies on the influence of surfactants upon anodic stripping peaks a significant role is also played by such parameters as concentration and the kind of applied surfactant as well as the kind of determinable ion.

As may be observed in Figs. 1–4, substances present in 0.1 ppm concentration either have no influence on the peak heights at all or cause only insignificant reduction. A concentration increase in the range 0.1–10 ppm causes a great increase in the influence of anionic surfactants. A concentration increase to 100 ppm has mostly no influence on an already more significant intensification of peak damping.

The influence of the kind of applied surfactants is not submissive to distinct rules. Comparatively small differences may be observed in the action of DS and SDS. This seems to indicate that a hydrophobic group has a greater inhibiting effect than a hydrophilic group.

More pronounced and regular differences were observed in the peak damping of individual ions in the order Tl < Pb < Cd < Cu < In which agrees with that of ionic potentials of particular metals. The values of the ionic potential after acceptance of ionic radius[24] are: Tl(I)–0.74, Pb(II)–1.59, Cd(II)–2.02, Cu(II)–2.50 and In(III)–3.26, respectively. A similar agreement has also been obtained for the influence of cationic surfactants and polyethylene glycols.[15,25]

AMPEROMETRIC DETECTION OF CATECHOLAMINES WITH LIQUID CHROMATOGRAPHY AT A NOVELLY CONSTRUCTED PRUSSIAN BLUE CHEMICALLY MODIFIED ELECTRODE

JIANXUN ZHOU and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, People's Republic of China

(*Received* 20 *February* 1991. *Revised* 8 *July* 1991. *Accepted* 10 *July* 1991)

Summary—A novel Prussian blue chemically modified electrode (CME) was constructed and characterized for liquid chromatography electrochemical detection (LCEC) of catecholamines. Both anodic and cathodic peaks could be obtained by monitoring at constant applied potential at anodic and slightly cathodic potential ranges (0.3–0.7 and −0.2–0.1 V *vs.* SCE), respectively. When arranged in a series configuration, using the modified electrodes as generating and collecting detectors, extremely high effective collection efficiencies of 0.91 (for norepinephrine) and 0.58 (for dihydroxyphenylacetic acid) were achieved in dual-electrode LCEC for catecholamines; and a linear response range over 3 orders of magnitude and a detection limit of 10 pg were obtained with a downstream CME as the indicating detector.

Liquid chromatography with electrochemical detection (LCEC) continues to grow in popularity for the sensitive determination of trace compounds in complex samples,[1] and is most highly publicised for its applications in neurochemistry. Up to 1986, over 800 papers had been published dealing with LCEC to solve neurochemical problems which would otherwise have been more time-consuming or even impossible to attack.[2] Among electrochemical flow detectors, amperometric detection at constant potentials has proved to be the most popular tool for solving a wide variety of practical analytical problems in neurochemical research by virtue of the facility in operation, sensitivity and excellent selectivity;[3] and catecholamines have been the primary target compounds among the major neurotransmitter groups penetrated by LC amperometric detection procedures. Single-electrode detectors at a constant applied potential have been widely employed for the determination of catecholamines in biological fluids,[4–10] including catecholamines in plasma[4–7] and brain tissue homogenate.[7–10] Amperometric dual-electrode detectors have recently become popular in LCEC monitoring of catecholamine-related species, which have three configurations termed parallel–adjacent, series, and parallel–opposed dual-electrode detectors,[11] according to the orientation of the electrodes with respect to the flow axis. Parallel–opposed dual-electrode detection has been explored to improve detectability of catecholamines in blood plasma[12] and serum.[13] Parallel–adjacent detectors have been employed to aid in identification of catecholamines in brain tissue.[14,15] Series dual-electrode configurations have been applied mainly to substantially enhance the selectivity for the determination of catecholamines,[16–20] because the system which is routinely operated in oxidative–reductive mode discriminates against chemically irreversible reactions upstream.

For series dual-electrode detectors, the fraction of upstream products that are converted at the downstream detector, termed collection efficiency (N), is the governing parameter for analytical applications of the downstream signal. The N value is highly dependent on the electrodes' size, shape and the configuration with respect to one another,[2,12] as well as the cell designs. Although as high as 60% collection efficiency would be obtained theoretically with horseshoe cell configuration,[2] series dual-electrode detection with N values less than 40% is the typical occasion encountered in LCEC procedures of catecholamines and other redox species.[12,20] High performance collection of catecholamines (N of 0.5–0.6) with LC amperometric detection has recently been achieved with an interdigitated microarray electrode (IDAE).[21]

*Author for correspondence.

This paper reports the attempts on LC amperometric monitoring of catecholamines with a chemically modified electrode (CME). A number of unique features were obtained compared with conventional LCEC procedures of catecholamines. These include extremely high collection efficiencies that could be readily obtained with series dual-electrode configuration which are highly recommended for the CMEs analytical applications in LCEC of catecholamines and perhaps other neurotransmitters.

EXPERIMENTAL

Reagents

Analytical reagent potassium ferricyanide was from Beijing Chem. Co. Epinephrine (E) was from Serva. Norepinephrine (NE), dopamine (DA) and 3,4-dihydroxyphenylacetic acid (DOPAC) were purchased from Fluka A.G. All these chemicals were used as received. Other chemicals were of analytical grade. Doubly distilled water was used for the preparation of all solutions. Catecholamines stock solutions (1 mg/ml) were prepared with 0.1*M* perchloric acid, stored at 4° in the dark. The mobile phase was always 0.1*M* phosphate buffer (pH 5.0) containing 1m*M* EDTA delivered at 1 ml/min, unless stated otherwise.

Apparatus

The instrumentation used was the same as in the previous report.[22] The electrochemical detector was a TL-5A thin-layer cell (BAS, U.S.A.) incorporating two glassy carbon electrodes of the same size. The auxiliary electrode was positioned across the thin-layer channel from the working electrodes to minimize ohmic losses for adequate potential control,[11] when the series dual-electrode arrangement was utilized. All potentials were measured and reported against a saturated calomel electrode (SCE), unless stated otherwise.

Working electrodes

Prussian blue chemically modified electrode (PB–CME). A glassy carbon (GC) electrode was modified with the procedure similar to that described earlier.[23] Prior to modification, the GC electrode was polished with a 0.5-μm alumina suspension on a smooth cloth, thoroughly ultrasonicated in a water bath and rinsed with water. The GC electrode was then subjected to potential cycling between −0.4 and 1.5 V *vs.* SCE at 1 V/sec for 30 min in 1m*M* ferricyanide solution in 0.5*M* potassium chloride.

Electrochemically pretreated GC electrode (EPGC). The polished and washed GC electrode was subjected to potential cycling as in the above procedure in 0.5*M* potassium chloride containing no ferricyanide.

RESULTS AND DISCUSSION

CME electrochemistry

On removal of the electrode from the ferricyanide solution after the modification was completed, no obvious changes of the electrode surface was observed. However, cyclic voltamperograms (CVs) similar to the ferro/ferricyanide redox couple were obtained (Fig. 1) when the electrode was washed and examined in 0.5*M* potassium chloride devoid of the redox species. Sharp and narrow peaks for oxidation and reduction exhibited characteristics of a surface reaction, with the peak currents, both anodic (i_{pa}) and cathodic (i_{pc}), increasing linearly with scan-rates (5–100 mV/sec). This indicated that such a modified electrode did incorporate a stably bound redox group characteristic of the adsorption type.

The nature and mode of the modification of the ferro/ferricyanide redox couple is not immediately clear yet. On extending the anodic sweep limit to +1.3 V *vs.* Ag/AgCl during the potential cycling with the CME in 0.5*M* potassium chloride, a second redox couple with E_p of *ca.* +1.0 V was repeatedly observed (not

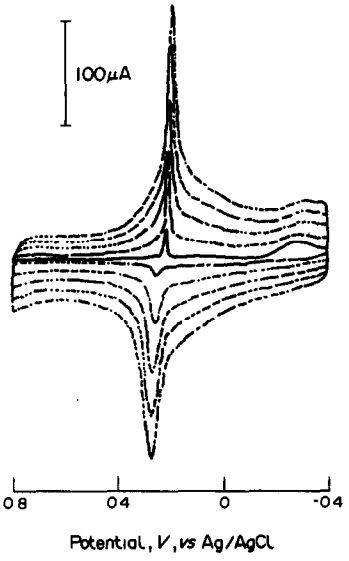

Fig. 1. Cyclic voltamperograms (CVs) with the CME in 0.5*M* KCl at a scan-rate of 5, 25, 50, 75 and 100 mV/sec.

shown), which is suggested to correspond to the Prussian blue/Berlin green redox couple on the electrode surface.[23] Based on evidence of the occurrence of this second redox couple, it was established that the incorporated species corresponded to Prussian blue (PB).[23]

Figure 2B shows the effect on the cyclic voltamperograms (CVs) obtained at the CME in 0.5*M* potassium chloride upon addition of dopamine to the blank supporting electrolyte. In the presence of dopamine, no changes of the background peaks at the CME was observed, but another pair of redox waves (with E_{pa} and E_{pc} of 0.40 and 0.34 V *vs.* Ag/AgCl at 100 mV/sec, respectively) appeared, corresponding to the dopamine redox group itself. Compared with CVs of dopamine at the bare GC electrode (Fig. 2A), the peak potential separation ΔE_p was significantly reduced (from 600 mV at the bare GC to 60 mV at the CME at 100 mV/sec), and the peak currents increased, indicating a greatly improved reversibility of the dopamine electrode process. In view of the fact that the CME modification procedure has in effect involved an electrochemical treatment process by alternative anodic and cathodic polarization at high speed, the effect of such electrochemical pretreatment on CVs of dopamine at the bare GC was determined with an EPGC electrode and is shown in Fig. 2C. Interestingly it was found that the CV behaviour of dopamine at the EPGC electrode was nearly the same as that at the CME, which might suggest that the redox couple (Prussian blue) sustained on the CME had little effect on the electrode process of dopamine. The small and smooth redox couple with E_p of *ca.* 0.20 V *vs.* Ag/AgCl observed on CVs at the EPGC corresponded to quinone groups bound at the GC surface.[24–26]

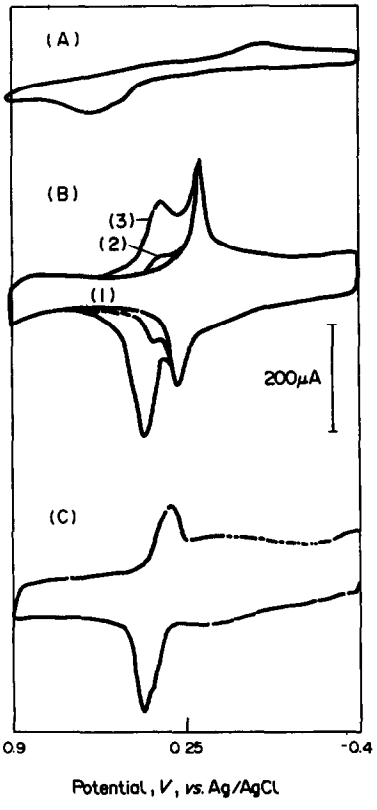

Fig. 2. Cyclic voltamperograms of dopamine at the bare GC (A), CME (B) and EPGC (C) electrodes. Scan-rate, 100 mV/sec. Dopamine concentration is 60 ppm for (A) and for (C); 0 ppm for curve 1 in (B), 10 ppm for curve 2 in (B) and 60 ppm for curve 3 in (B).

Flow-through amperometric detection

Single electrode detection. Figure 3(A) shows the hydrodynamic voltamperograms (HDVs) for catecholamines at the single PB modified CME, with 0.1*M* phosphate buffer (pH 5.0) containing 1m*M* EDTA as mobile phase. In the anodic potential region, a plateau response level was achieved at +0.45 V *vs.* SCE and beyond. Cathodic currents, however, arose in the cathodic potential range (more negative than 0.20 V), reaching maximal levels at around +0.05 V. The absence of 1m*M* EDTA in the mobile phase had little effect on the HDV behaviour of the analytes in the anodic response region; however, the cathodic currents decreased to a certain degree (20% at the maximum response level) in this EDTA free solution.

The flow-rate dependence on the anodic peak current of LC amperometric detection of catecholamines was studied and is shown in Fig. 4. It is clear that the current response always decreased with increasing flow rate, contrasting sharply with theoretical predictions,[27,28] with practical considerations for conventional LCEC of catecholamines with unmodified electrodes.[29] This unique flow-rate dependence is of advantage for the compatibility with microbore HPLC, high sensitivity being attained at rather low flow-rate of the mobile phase.

All these observations indicated that the detector response is not controlled by the process of direct electron transfer between the analytes and the GC surface. The specification of actual mechanism for the appearance of both anodic and cathodic peaks with LCEC of catecholamines, using the single CME working electrode remains difficult. There would be a possibility that the detector response was governed by the complexation of the solutes with iron ions

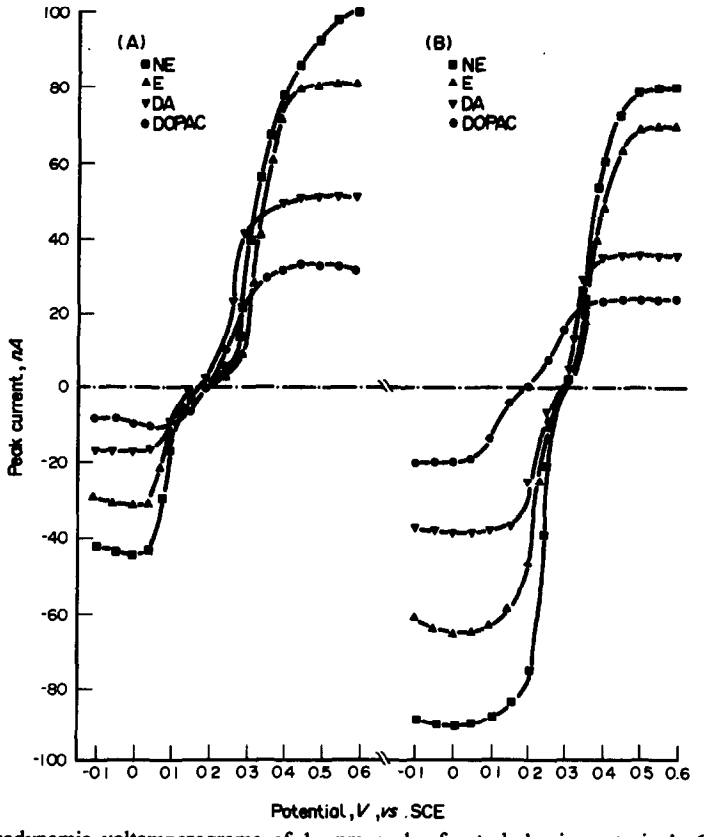

Fig. 3. Hydrodynamic voltamperograms of 1 ppm each of catecholamines at single CME (A) and downstream CME in series configuration (B) with the upstream CME monitored at 0.60 V *vs.* SCE. Column, Nucleosil C_{18} (7 μm) 200 × 4 mm i.d. Mobile phase, 0.10*M* phosphate buffer (pH 5.0) containing 1m*M* EDTA at a flow-rate of 1 ml/min. Injection volume, 10 μl.

[Fe(II) or Fe(III), determined by operating potential] present in the PB molecule.[30] The current response at the CME might result from the differences in solubility and electroactivity of complexes between the components in the mobile phase (EDTA, *etc.*) and the ligands (analytes) injected with Fe(II) or Fe(III) sustained on the CME surface. Eluted catecholamines may form more or less favoured soluble and electroactive iron complexes than the mobile phase components with Fe(III) or Fe(II), respectively, while monitoring the detector at either anodic or cathodic potential regions, and thereby resulting in an increased or a decreased current for iron ion redox reactions, and hence in amperometrically positive or negative peaks. Considering the EDTA effect on the HDV behavior of the analytes, these complexation kinetics would more likely occur in the cathodic response region.

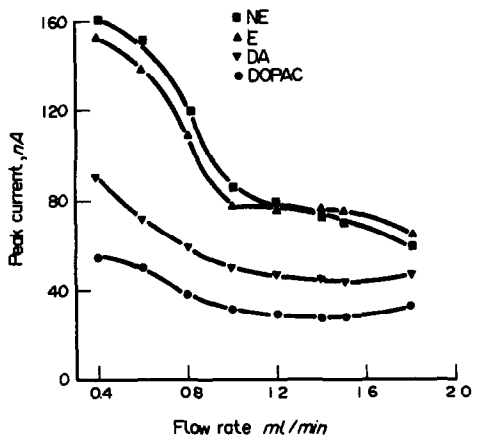

Fig. 4. Effect of mobile phase flow-rate on current response in LCEC of catecholamines at the CME. Potential, 0.45 V *vs.* SCE. Chromatographic conditions as in Fig. 3.

Figure 5 shows the dual-electrode chromatograms of catecholamines with parallel–adjacent configuration, using a bare GC electrode and a CME as indicator detectors, respectively. Distinct cathodic peaks of adequate sensitivity were observed with the CME at the applied potential of 0.0 V *vs.* SCE which exhibited a moderate amount of tailing compared with those obtained at the bare GC electrode.

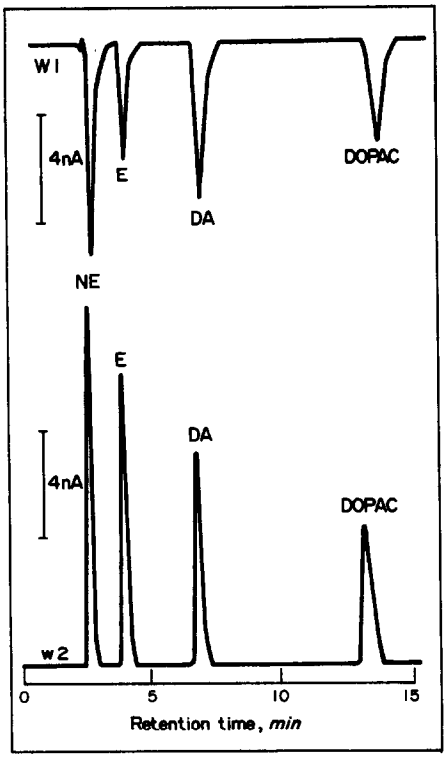

Fig. 5. Parellel–adjacent dual-electrode chromatograms of catecholamines at a bare GC (W1) and the CME (W2). Potential, 0.60 V for W1 and 0 V for W2. Flow parameters as in Fig. 3.

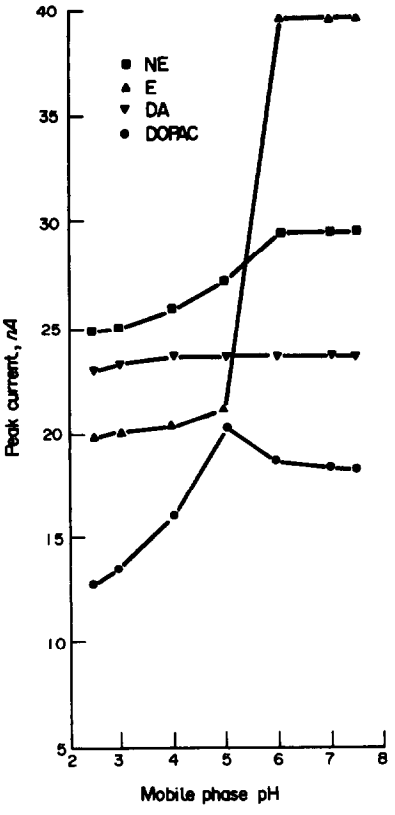

Fig. 6. Effect of mobile phase pH on the peak current in LCEC of catecholamines at the bare GC electrode. Potential, 0.60 V *vs.* SCE. Analyte concentration: 1 ppm for NE and E, 1.5 ppm for DA and 2 ppm for DOPAC. Other conditions as in Fig. 3.

The effects of the mobile phase pH on peak current with the LCEC of catecholamines at the bare GC and the CME are shown in Figs. 6 and 7, respectively. With the bare GC electrode, the current response of epinephrine at higher pH (>6) was double that at lower pH (2.5). Increasing pH had less effect on current response for norepinephrine and negligible change for dopamine. This is due to the dramatic effect of pH on the electrode mechanism involving ECE reactions.[1] Higher pH favoured the indoline form of the epinephrine molecule which has the known high rate of nucleophilic addition, resulting in a net four electron transfer and thereby the detector response may double. All these observations were consistent with previous work.[1] DOPAC exhibited maximum current response at pH 5.0. Lowering the pH is disadvantageous for DOPAC oxidation due to a more positive half-wave potential,[1] whereas higher pH is also unfavourable for DOPAC oxidation probably due to the lower heterogeneous electron transfer rate constant at higher pH.

With the CME, however, the case is quite different. As shown in Fig. 7, catecholamines (except for NE) exhibit maximal current response at pH 5.0. This unique pH dependence was ascribed to the altered electrode mechanism involved at the CME compared with that on the bare GC electrode. It should be noted that the response sensitivity was greatly improved with the CME in the LCEC of catecholamines.

Series dual-electrode configuration. Figure 3(B) shows the hydrodynamic voltamperograms of catecholamines at the downstream CME in a series dual-electrode configuration, monitoring the upstream CME at constant potential of 0.60 V *vs.* SCE. It is clearly seen that the anodic plateau response levels were lower than those at the upstream CME [Fig. 3(A)], indicating that the latter depleted a significant portion of the analyte in the diffusion layer before the mobile phase arrived at the downstream detector. However, the cathodic current response levels dramatically increased at the downstream CME in a series arrangement, reaching maximal response levels at an identical potential of 0 V. The enhancement of current responses should

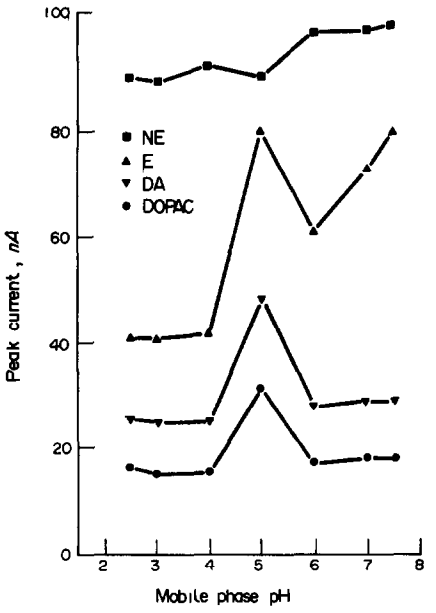

Fig. 7. Effect of mobile phase pH on LCEC of 1 ppm each of catecholamines at the CME. Potential, 0.50 V *vs.* SCE. Flow conditions as in Fig. 3.

be ascribed to the reduction of catecholamine oxidation products upstream.

Figure 8 shows dual-electrode chromatograms of catecholamines with generation (oxidation)–collection (reduction) mode, using bare GC electrodes, PB modified electrodes and EPGCs as working electrodes, respectively. The current measurements at the CMEs and EPGCs, both anodic and cathodic, were much higher than those obtained at bare GC electrodes. The effective collection efficiency (*Ne*) (determined from the ratio of the current at the downstream electrode to the current at the upstream electrode measured under given experimental conditions) for catecholamines was no more than 30% with bare GC electrodes (see Table 1). *Ne* values, however, were greatly increased at EPGCs due to the improved reversibility of catecholamines in the electrode process, as mentioned above. With CMEs, extremely high collection efficiencies were readily obtained, with the maximal value of 91% for NE, resulting from the total contributions of the complexation reaction between the analytes and Fe(II) ion sustained at the CME surface and the reduction of catecholamine oxidation products upstream.

Figure 9 shows the series dual-electrode chromatograms of catecholamines with the same oxidative–reductive mode, using EPGC (or CME) and CME (or EPGC) as generating and collecting electrodes, respectively. It was interestingly found that extremely high *Ne* values were always obtained with the CME as collecting electrode, whether the CME or EPGC was used as the generating electrode, indicating that it was the reduction of upstream oxidation products of catecholamines that contributed a significant portion to the high collection efficiencies, and not the upstream complexation reaction between the analytes and Fe(III) ion sustained on the CME surface.

Table 1 summarizes the effective collection efficiencies of catecholamines obtained with the series oxidative–reductive operation mode, using various electrodes in the upstream–downstream arrangements. It is essential that the CME be used as the collecting electrode in order to obtain highly enhanced effective collections.

Using the PB modified electrodes as generating and indicating detector in a series configuration and the oxidative–reductive mode (at constant applied potentials of 0.60 and 0.0 V *vs.* SCE), LCEC of catecholamines gave linear response range over 3 orders of magnitude, with a correlation coefficient greater than 0.99, and detection limits (S/N = 3) of 10 pg (for NE) and 50 pg (for DOPAC), readily obtained, which are much lower than those obtained at the interdigitated microarray electrode.[21]

In the past few years, a number of investigations have appeared[30–36] concerning the preparation, electrochemical properties and analytical applications of chemically modified electrodes based on the mixed-valence hexacyanides (Prussian blue and its analogues). Li and Dong[31] and Neff[32] prepared thin adherent films of PB on platinum substrate by controlled current electrolysis and studied the electrochromism of the resultant PB CMEs. Cox and co-workers[33,34] and Kulesza *et al.*[35] designed PB analogue CMEs for the electrocatalysis and determination of inorganic ions and organic compounds, including ruthenocyanide CMEs[33,34] and a nickel ferrocyanide CME.[35] All these PB CMEs and analogues were reported to possess good stability under pH less than *ca.* 5.5; higher pH conditions would destroy the films sustained on the electrode surfaces.[31] Recently, Hou and Wang[36] applied the simple adsorption procedure to the glassy carbon electrode to construct a PB/GC CME and used it in flow amperometry by electrocatalytic oxidation for hydrazine. It was found that such a PB/GC electrode was not stable in flow system at high

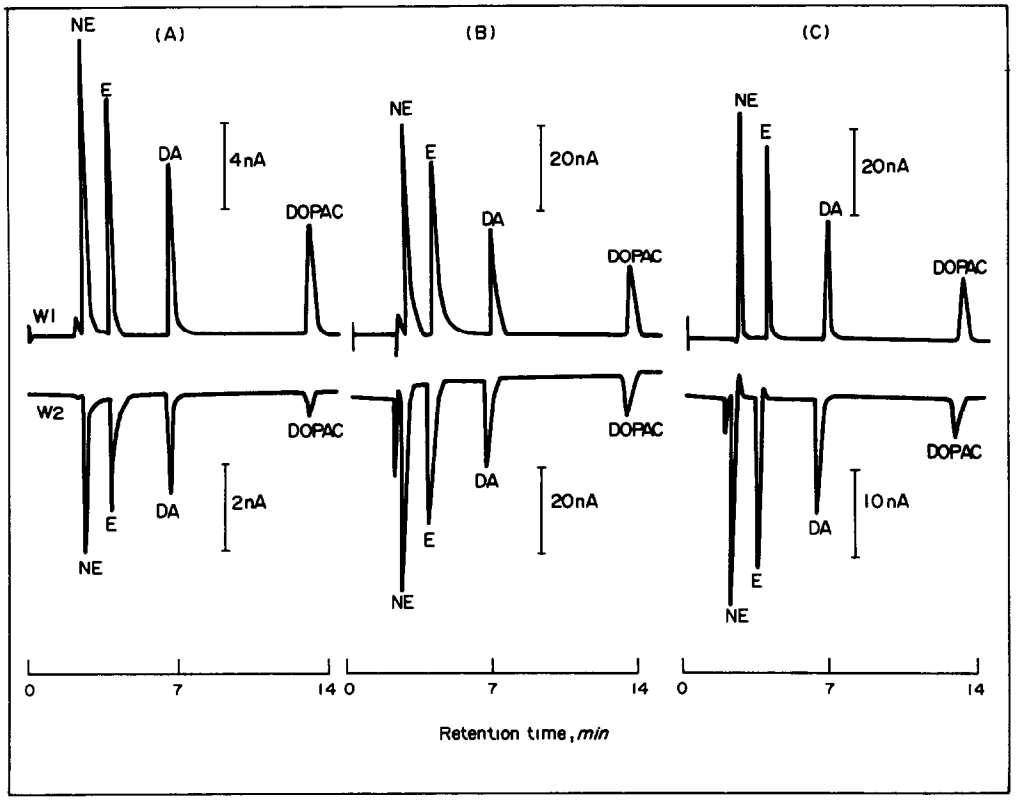

Fig. 8. Series dual-electrode chromatograms of 1 ppm each of catecholamines with bare GC electrodes (A), CMEs (B) and EPGCs (C) as working electrodes. Potential, 0.60 V for upstream W1, 0.0 V (B and C) and −0.20 V (A) for downstream W2. Other conditions as in Fig. 3.

positive applied potentials (0.9 V and beyond). In view of the fact that electrocatalysis is the fundamental point of all these previous works,[33-36] and not the case in our research, from an analytical point of view the stability of the PB CME designed should be our primary concern. It should be noted that the PB/GC CME made in this work possesses favoured stability over those mentioned above.[30-36] This is evidenced by three factors: (*a*) the CME permits hundreds of potential cycles with the anodic scan limit up to +1.5 V *vs.* Ag/AgCl, without any obvious changes in the peak potentials and peak currents; when used in a flowing stream, the cathodic and anodic peak currents of catecholamine responses retained more than 90% of their initial levels after two days of continuous service, even with high positive applied potentials (1.0 V and beyond); (*b*) the CME can be normally operated over a wide pH range (typically 1.5–8.0), examined by batch (CV) and flow (FIA) experiments. This makes the CME completely compatible with conventional reversed-phase liquid chromatography systems. Finally, the CME appears to possess excellent chemical and mechanical stability, as immersing the electrode in concentrated nitric acid for several minutes or submitting it to an ultrasonic water bath and polishing for a long period of time (typically more than 10 min) could not completely destroy the CME examined by cyclic voltammetry in a blank supporting electrolyte.

Table 1. Effective collection efficiencies for catecholamines with series dual-electrode LCEC*

	Upstream W1 Downstream W2	Bare GC Bare GC†	CME CME	EPGC EPGC	EPGC CME	CME EPGC
Ne (ic/ia)	NE	0.27	0.91	0.47	0.88	0.35
	E	0.26	0.82	0.44	0.79	0.35
	DA	0.30	0.80	0.51	0.82	0.50
	DOPAC	0.12	0.58	0.34	0.59	0.16

*Potential: 0.60 V for W1 and OV for W2 *vs.* SCE.
†Potential: −0.20 V *vs.* SCE.

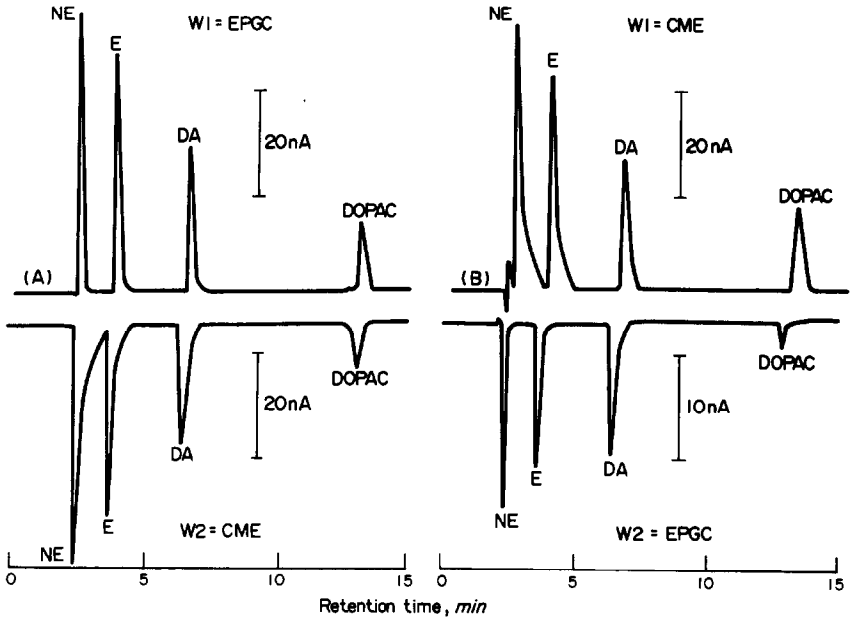

Fig. 9. Series dual-electrode chromatograms of 1 ppm each of catecholamines with EPGC and CME as generating and collecting electrodes (A) and vice versa (B). Potential: 0.60 V for upstream W1 and 0.0 V for downstream W2. Flow conditions as in Fig. 3.

This confirms that modification readily occurred in depth at the GC surface. When a fresh electrode surface is needed, the old CME surface could be effectively depleted by performing several potential cycles between −0.40 and +1.5 V *vs.* Ag/AgCl in 0.1*M* potassium hydroxide.

(*Received* 20 *March* 1989. *Revised* 6 *June* 1991. *Accepted* 22 *July* 1991)

Summary—Determination of fluoride in hydrometallurgical zinc-plant processing products and solutions with a fluoride-ion electrode is described. Various types of buffers were tested, to find a suitable common buffer for use in analysis of all types of substances generated at the zinc plant. The method involves decomposition of samples either by fusion with sodium hydroxide or by leaching with perchloric acid to bring fluoride into solution. The fluoride concentration is measured directly with a fluoride-specific electrode. In standard addition tests 100% recovery was obtained when a citric acid/sodium nitrate buffer was used. Validation tests gave satisfactory results.

In an integrated hydrometallurgical zinc plant various process solutions flow to the main circuit so that maximum recovery of zinc and various valuable by-products is achieved. Fluoride build-up in these process solutions has been found to occur, depending on the operating conditions of the plant. It has been observed that a high concentration of fluoride will cause difficulties[1] in removal of the zinc deposit from the aluminium cathode, and corrosion[2,3] of the cathode and anode, resulting in reduced life of the electrodes and in effluents from the bleed-off process that can cause environmental hazards. It is therefore essential to determine the fluoride levels accurately at various stages in the process, for effective quality-control operation of the plant as well as to provide a clean environment.

The determination of fluoride in zinc plant products and solutions has changed with the change in technology in this field. During the 1960s the fluoride was separated by the Willard and Winter steam-distillation method[4] and then determined spectrophotometrically by means of its decolourization of the zirconium–Alizarin complex. Though this is a standard reference method, it is tedious, requires constant watch on the temperature range and control, and produces a large volume of distillate.

After the introduction of the fluoride-specific electrode, the steam distillate could be analysed directly for fluoride after addition of TISAB (total ionic-strength adjustment buffer) as for water samples. Later, various decomposition/dissolution[5–8] methods were adopted to bring the fluoride into solution for potentiometric measurement with the fluoride electrode.

At Hindustan Zinc Limited, the aim has been to find a single buffer system suitable for determination of fluoride in all types of sample. Depending on the nature of the sample, the sample preparation step involves either leaching with 2*M* perchloric acid or fusion with sodium hydroxide in a zirconium crucible followed by extraction with water. The solution is then buffered and measured, with a single-point standard addition to provide the calibration data. Highly acidic process solutions are brought to an appropriate pH before addition of the buffer and measurement. A citric acid/sodium nitrate buffer has been found the most suitable for analysis of all types of complex materials arising in the zinc plant operation. The method is simple, rapid, reliable and accurate.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade.

Standard fluoride solution (0.1 mg/ml). Weigh 0.221 g of sodium fluoride, previously dried at 120° for 2 hr. in water, and dilute accurately to 1000 ml.

Sodium citrate/potassium nitrate buffer (Buffer I). Dissolve 294 g of sodium citrate dihydrate

and 20.2 g of potassium nitrate in 600 ml of water. Adjust the pH to 5.5 with 5*M* hydrochloric acid, dilute exactly to 1000 ml with water.

Sodium chloride/sodium citrate buffer (Buffer II). Dissolve 58 g of sodium chloride in 500 ml of water, add 0.3 g of sodium citrate dihydrate and 57 ml of glacial acetic acid, adjust the pH to 5.5 with sodium hydroxide, dilute exactly to 1000 ml with water.

TISAB (Buffer III). Dissolve 58 g of sodium chloride in 500 ml of water, add a slurry of 5 g of diaminocyclohexane-*N,N,N',N'*-tetra-acetic acid, and 125 ml of 6*M* sodium hydroxide to dissolve the acid. Add 57 ml of glacial acetic acid, adjust the pH to 5.5 with 6*M* sodium hydroxide and dilute to exactly 1000 ml with water.

Sodium citrate/sodium nitrate buffer (Buffer IV). Dissolve separately, in 100 ml portions of water, 20 g of citric acid, 68 g of sodium nitrate and 28 g of sodium hydroxide. Mix these solutions, along with 24 ml of glacial acetic acid, adjust the pH to 5.5 with 6*M* sodium hydroxide or hydrochloric acid, and dilute exactly to 1000 ml with water.

Perchloric acid, 2M.

Apparatus

A Metrohm model E 510 precision pH-meter, fluoride-ion electrode (6.0502.050), silver chloride electrode (6.0711.100), a swing-out magnetic stirrer with built-in speed regulator (2.504.0014) and Teflon-coated paddles (6.1903.000) were used.

Sample preparation

Sulphide concentrates. To a 1.000-g sample in a 50-ml nickel/zirconium crucible add 5 g of sodium hydroxide pellets. Place the crucible in a cold muffle furnace and raise the temperature slowly to 500°. Keep the sample at this temperature for 30 min. Cool, digest the fusion cake with 30–40 ml of water, adjust the solution to pH 5.5 with acetic acid, filter through a Whatman No. 41 filter paper into a standard flask. Make up to the mark and mix.

Roasted products and other leached residues. To a 1.000-g sample in a 100-ml polythene beaker add 50 ml of 2*M* perchloric acid, and stir on the magnetic stirrer at controlled speed for 30 min. Filter the solution into a standard flask and make up to volume.

Highly acidic process solutions. Treat with zinc oxide powder to bring to pH 5.5, and filter. Use the filtrate for fluoride estimation.

Other types of process solution. For solutions at pH 4.0–5.5 no preliminary treatment is necessary.

Measurement

To a known volume (10 ml) of prepared sample solution add 25 ml of buffer, stir on the magnetic stirrer and measure the fluoride content potentiometrically with the fluoride electrode. Add a known volume of standard fluoride solution and measure again. From the data thus obtained, calculate the concentration of fluoride in the sample.

RESULTS AND DISCUSSION

The method was tested by analysing various important types of sample generated at the zinc smelter plant. Tables 1–3 show the results, together with those obtained by the standard reference spectrophotometric method. Table 4 shows the results of recovery experiments. The method can be applied to fluoride sample concentrations between 1 μg/g and 6 mg/g, and to even higher concentrations by suitable dilution of the sample solution.

The value of 4.10% for the standard reference sample of zinc–tin–copper–lead ore (MP-1) is slightly higher than the provisional official value[9] of 4.04%. The higher value and the better response may be due to a more effective fusion technique obtained by use of the citric acid/sodium nitrate buffer.

Different sample preparation techniques were used to bring fluoride into solution, depending on the nature of the sample. For sulphide concentrates a fusion technique similar to that reported by Rajan *et al.*[10] was adopted. For oxide and other leached residues a simple acid leaching technique has been found useful for bringing the fluoride into solution. Though fusion can also be applied, we prefer the leaching technique because it gives complete dissolution effectively. The pH of the solution should be adjusted to 5–5.5 before addition of the buffer acid. All the potentiometric measurements have to be made at pH 5.5.

Zinc oxide powder was used to neutralize highly acidic plant solutions. It is preferred to other neutralizing agents such as sodium hydroxide or sodium carbonate, because it has effective neutralizing capacity without any precipitation of zinc at pH 5–5.5, and it also provides the same matrix with no loss of fluoride.

The Ag/AgCl electrode is used as reference electrode and is found to provide satisfactory results.

Various buffers were tested for their efficiency in measurement of fluoride and elimination of interferences. It was found that the sodium citrate/sodium nitrate/sodium acetate buffer was more effective than the other types of buffer tested. When this buffer was used, the response was very fast with minimum time needed for stabilization, 100% recovery of standards was obtained, and the system was effective in the presence of interfering elements such as Al^{3+}, Fe^{3+}, and soluble silica. A maximum of 5 min was needed for stabilization of the potentials whereas with the other buffers 15 min or more was needed and the recovery of a standard addition varied between 85 and 95%. Use of this buffer gave more accurate results than those obtained with the citrate/DCTA buffer,[11] and also quicker stabilization and response.

THE STABILITY OF THE METAL COMPLEXES OF CYCLIC TETRA-AZA TETRA-ACETIC ACIDS

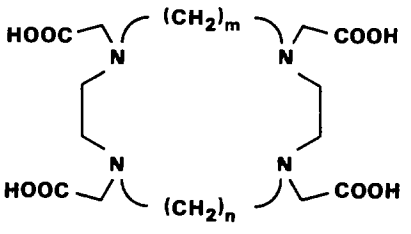
SILVIA CHAVES, RITA DELGADO and J. J. R. FRAUSTO DA SILVA
Centro de Química Estrutural, Instituto Superior Técnico, Lisbon, Portugal

(*Received* 25 *April* 1991. *Revised* 12 *July* 1991. *Accepted* 26 *July* 1991)

Summary—The stability constants of the complexes formed by three tetra-aza macrocyclic complexones (DOTA, TRITA and TETA) with Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} were determined with an automated titration instrument with data acquisition and the calculations were performed with the Superquad program, confirming and extending the range of values previously available. Both 1:1 and 2:1 metal-to-ligand complexes were now considered including their protonated species.

The results show that DOTA is a powerful but unselective ligand whereas TETA, although not so powerful as DOTA, is an interesting selective ligand for pairs of metal ions, *e.g.*, Cd^{2+} and Pb^{2+}.

In a previous paper[1] we reported the results of a study of the complexation properties of a series of *N*-acetate derivatives of tetra-aza macrocycles (**I–III**).



I—$m = n = 2$—1,4,7,10-tetra-azacyclododecane-1,4,7,10-tetra-acetic acid (DOTA);

II—$m = 3$; $n = 2$—1,4,7,10-tetra-azacyclotridecane-1,4,7,10-tetra-acetic acid (TRITA);

III—$m = n = 3$—1,4,8,11-tetra-azacyclotetradecane-1,4,8,11-tetra-acetic acid (TETA).

They are all strongly complexing ligands, particularly DOTA, which was reported to give the most stable Ca^{2+} complex in aqueous solution.[2,3] In our paper we confirmed this finding and extended the work to include the other alkaline-earth metal ions and a group of transition metals, namely Co^{2+}, Ni^{2+} and Cu^{2+} as well as Zn^{2+}. We have demonstrated that although the stabilities of the complexes of the alkaline-earth ions decrease steeply with the increase of the size of the tetra-aza ring of the ligands, the stability constants of the complexes that DOTA forms with these ions are 10^4–10^6 orders of magnitude higher than those of the classic complexones, *e.g.*, EDTA, whereas the stability constants of the complexes of the three ligands with the transition metal ions are very close and of the same order of magnitude of those formed by the linear complexones. This was in agreement with the suggestion that in the cyclic complexones not all donor atoms are able to coordinate to the transition metals[4] and with the X-ray structures of the Cu^{2+} and Ni^{2+} complexes of ligands **I** and **III**.[5–7] In contrast, for the complexes of the alkaline-earth metal ions, the stability constants are critically dependent on the size of the internal cavity of the ligand, but all potential donor atoms may be implicated, as shown by the X-ray structures and NMR studies of similar metal complexes, namely the complexes of some trivalent lanthanides.[8–11]

Subsequently to this work we determined the thermodynamic functions corresponding to the formation of the complexes of the alkaline-earth and transition metal ions in aqueous solution,[12] studied the protonation sequence of these ligands[13] and carried out a ^1H NMR study of the conformation in solution of some lanthanide(III) complexes of the ligand **II**.[14] The results of these studies confirmed the conclusions tentatively presented in our first paper.

The interest in this group of ligands and other similar *N*-functionalized tri- and tetra-azamacrocycles has been steadily growing in the last few years due to their potential usefulness in various fields, *e.g.*, analytical methods[1,15] and medical applications with their Gd^{3+} complexes as magnetic resonance imaging contrast

agents,[16,17] the ^{67}Ga, ^{111}In, ^{99m}Tc and ^{55}Co complexes in radioimmunoimaging and the ^{90}Y and ^{67}Cu complexes in radioimmunotherapy.[18–20] Notwithstanding, it does not seem that other determinations of stability constants of complexes of these ligands have been carried out, with the exception of those of some lanthanide ions[21,22] and that of yttrium.[23,24] This omission limits the evaluation of analytical and other possible applications, hence we decided to complete our first report by studying the formation of the complexes of Mn^{2+}, Fe^{2+}, Cd^{2+} and Pb^{2+}. To ensure the consistency of the results, we have repeated the determinations of the protonation constants and of the formation constants of the complexes of Co^{2+}, Ni^{2+}, Cu^{2+} and Zn^{2+} in the same experimental conditions, but with an automated titration equipment with data acquisition, followed by the calculations with the Superquad program.[25]

EXPERIMENTAL

Reagents

Ligands **II** and **III** were synthesized in our laboratories.[1] DOTA was supplied by Guerbet (Aulnay-sous-Bois, France). Analytical grade metal nitrates were used and the metal content of the solutions checked by titration with EDTA. The CO_2-free potassium and tetramethylammonium hydroxide solutions were prepared as described in a previous paper;[26] tetramethylammonium nitrate, necessary for the work with DOTA, was prepared by neutralizing the hydroxide with nitric acid.

Dimethyl sulphoxide, for the study of the protonation constants of DOTA, was purified by fractional distillation, discarding the first 20% of the distillate. This procedure ensures desiccation analogous to that obtained with molecular sieves.[27]

Equipment

A Crison Digilab 517 measuring instrument was used together with an Ingold U1330 glass electrode and a Radiometer K401 saturated calomel reference electrode with a Wilhelm-type salt bridge containing the inert-salt solutions (0.1*M* potassium nitrate or Me_4NNO_3).[26] Titrations were carried out in a thermostated cell at $25.0 \pm 0.1°$ and the ionic strength of the solutions was kept at 0.10*M* with potassium nitrate or Me_4NNO_3. A nitrogen atmosphere was maintained above the working solution to avoid any contact with carbon dioxide.

Determination of the constants

The protonation and the stability constants were determined from the potentiometric titrations with the Superquad program.[25]

As referred in our previous papers,[1,12] the reactions of metal complexation are sufficiently rapid for the automatic titration to be feasible. The equilibration is too slow only in the case of nickel, hence we have taken the data from our previous work obtained by batch ("out-of-cell") titrations.[28–30] In the case of cobalt automated titrations were still possible but with large intervals between each addition of base (5–10 min in the case of DOTA). For the other metal ions the intervals were 2–3 min and the mixture of metal and ligand were left to equilibrate for 1–2 hr before the titration was started.[1,12]

The results were obtained from a minimum of three titrations for which the $C_M:C_L$ ratios were 1:2, 1:1 and 2:1. The errors quoted are the standard deviations given directly by the program running with the data of three or more titration curves (minimum 200 points).

RESULTS AND DISCUSSION

The results obtained in the present work are summarized in Table 1 and may be compared with the values presented previously.[1] For the protonation constants the agreement is excellent for the three ligands. Since the value of log K_1 of DOTA previously published[1] raised some doubts because it is too high to be accurately determined by a direct potentiometric technique in aqueous solutions, we have repeated its determination in five different mixtures of DMSO/H_2O with the same instrumental set-up and extrapolated the straight line obtained to zero fraction of DMSO when log K_1 *vs.* X_j[31] is plotted (X_j being the mole fraction of the DMSO in the solution). The equation for the straight line is $\log K_1 = 12.14 + 4.631X_j$. The value now obtained, $\log K_1 = 12.1 \pm 0.2$ (*cf.* Table 2), is very close to the 12.09 previously reported and was therefore adopted.

As to the formation constants of the metal complexes, the agreement is, generally, quite good, particularly since a larger number of experimental data was dealt with, and a fuller description of the systems was achieved, including species that were not taken into account in our first paper, namely those involving the coordination of two metal ions to the same molecule of the ligand, already found in the

solid state,[5-7] *i.e.*, M_2H_iL ($i = 0$–2) species, for which the formation constants obtained are quite reasonable. The formation of these species is almost negligible when the metal is not in considerable excess, as can be seen in a species distribution diagram such as that of Fig. 1 for the Cu^{2+}/DOTA system.

The availability of data for an extended series of ions allows a better comparison of the coordination tendency and capacity of each member of the series. We have already commented on the fact that the Irving–Williams natural order of stability does not appear to be followed in the cases of DOTA and TRITA and less so for the complexes of other polyoxa–polyaza cyclic complexones,[26,32] but Fig. 2 illustrates the differences more clearly.

Besides the "anomalous" behaviour of the above-mentioned compounds, which is fairly common for these constrained ligands,[26,32] other interesting features are apparent, namely the appreciable difference in stability of the TETA complexes of Cd^{2+} and Pb^{2+}, compared with the corresponding complexes of DOTA and TRITA, and the almost invariant value of the stability constants of the Mn^{2+}, Fe^{2+}, Co^{2+},

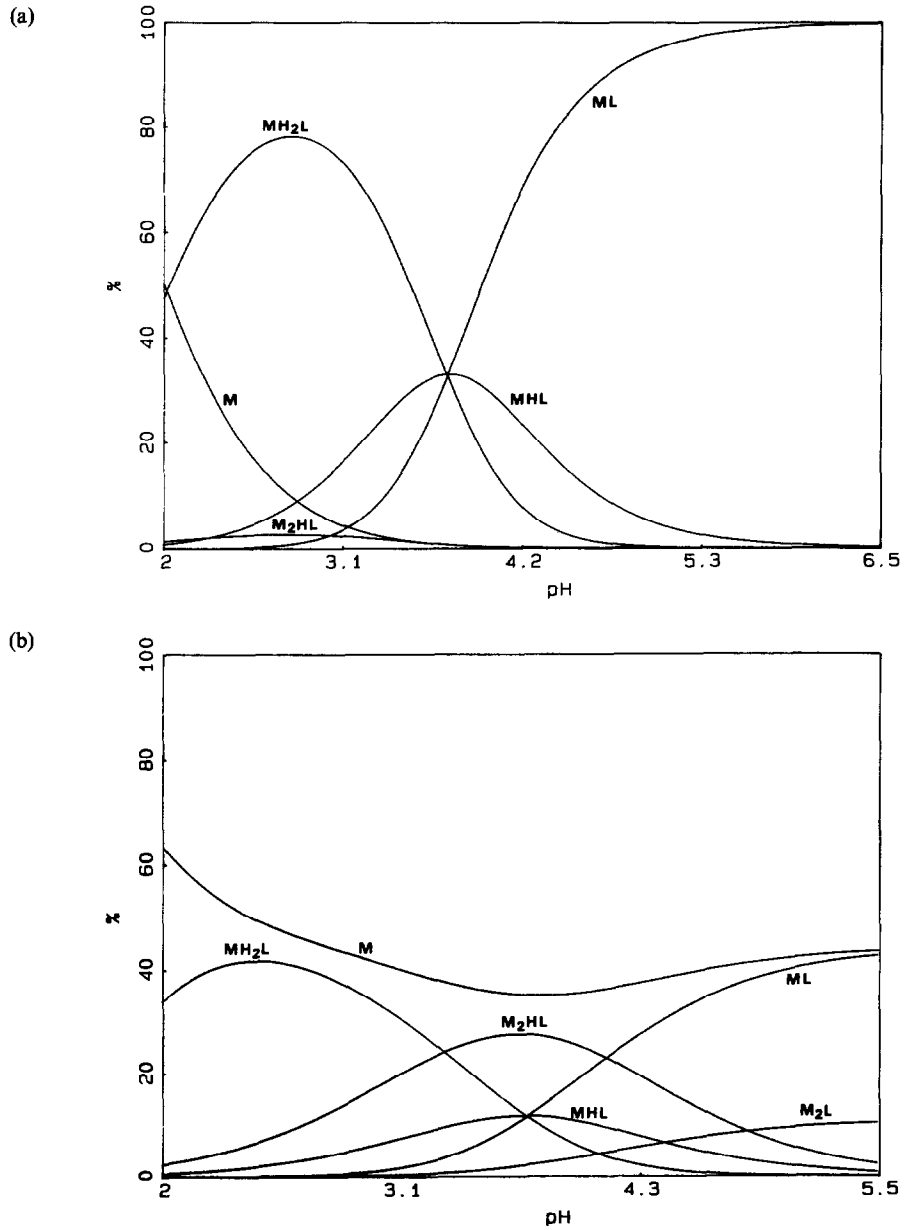

Fig. 1. Calculated distribution of the equilibrium species for the Cu^{2+}/DOTA system as a function of pH. $T = 25.0°$, $\mu = 0.1M$. (*a*) $C_{Cu} = C_{DOTA} = 8.33 \times 10^{-4}M$ (*b*) $C_{Cu} = 1.67 \times 10^{-3}M$, $C_{DOTA} = 8.33 \times 10^{-4}M$.

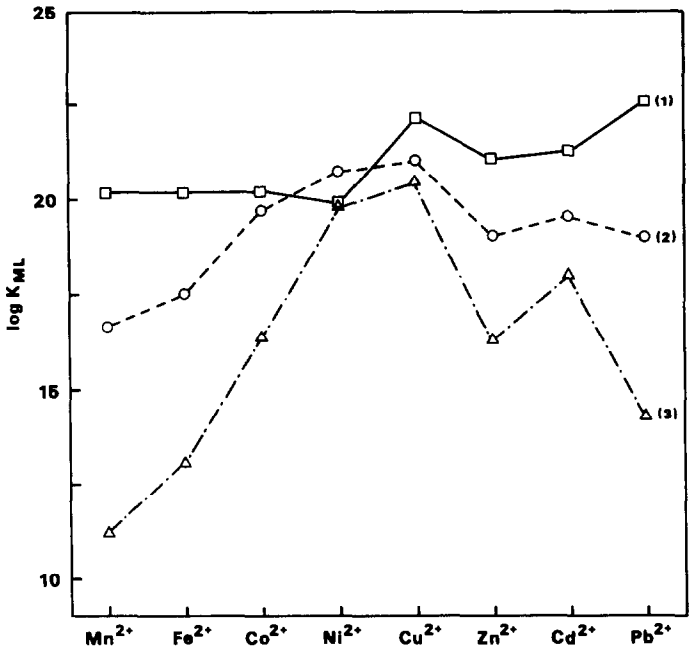

Fig. 2. Stability constants of the metal complexes of the tetra-aza macrocyclic complexones (log K_{ML}) along the first transition series metal ions, Zn^{2+}, Cd^{2+} and Pb^{2+}. (1) DOTA; (2) TRITA; (3) TETA.

Ni^{2+}, complexes of DOTA, not too different, either, from those of Zn^{2+} and Cd^{2+}.

Indeed, it seems that this ligand acts like a rigid "cage" of such conformation (*i.e.*, orientation of the lone-pair of electrons of the nitrogen atoms,[12] that the size of the transition metal ion, Zn^{2+} or Cd^{2+} does not make much difference; the ligand is quite unselective.

For the TRITA and particularly the TETA complexes, the increased flexibility of the ligand molecules allows a better discrimination of the metal ions; TETA behaves like a normal acyclic complexone and follows the Irving–Williams' series, but the selectivity ratio of its cadmium to lead complexes, contrary to the usual trend for the complexone type of ligands, is so large (4 log units) that it may allow useful analytical and other applications. The same may be said for the pairs Ni^{2+}, Co^{2+} and Cu^{2+}, Zn^{2+}, although the orders of stability are the normal ones and high selectivity ratios not so uncommon.

GRAVIMETRIC DETERMINATION OF FLYASH CONTENT IN BLENDED CEMENT

SAU-MO FAN, WAI-MING FOK and SHIU-FAI LUK*
Laboratory, China Cement Company Ltd, Tap Shek Kok, Tuen Mun, N.T., Hong Kong

(*Received* 20 *May* 1991. *Revised* 27 *August* 1991. *Accepted* 28 *August* 1991)

Summary—A simple gravimetric method is devised to determine the percent flyash in flyash blended cement. Insoluble residue of the sample was determined by the British Standard method. The flyash content was calculated by taking the insoluble residue in ordinary Portland cement and flyash to be 0.46% and 70.74%, respectively. The accuracy and precision are good and the standard deviation of the method is less than 1% for three determinations.

Flyash blended cement is formed by blending ordinary Portland cement (OPC) with flyash (FA). Such blending improves the sulphate resistance and reduces the water demand as well as the heat of hydration. It also offers the advantages of reduced cost and a reduction in the amount of flyash to be disposed by the power plant.

The ASTM suggests no method to determine the amount of flyash in the blended cement. According to the British specification (BS 6588:1985) the percent flyash is required to be reported to the nearest 1%. This method is based on the titration of soluble calcium oxide in the sample.[1] Its accuracy is limited by the variation of calcium oxide in both OPC and FA. As original samples of OPC and FA are not available, it has to be assumed that the calcium oxide in OPC and FA is 64.5% and 2%, respectively. Other methods include gamma ray spectrometry,[2] natural radioactivity measurement[3], leaching by picric acid[4] and EDTA titration in alkaline medium.[5] Instruments involved in these methods are too specialized. The picric acid method is not suitable for samples with high ash content and the EDTA method takes a long time to complete the extraction. In this paper a method is proposed based on the determination of the insoluble residue of the sample. Results indicate that the accuracy is comparable to that of the BS method and is less affected by the variation in the quality of the OPC.

*Author for correspondence.

EXPERIMENTAL

Analytical-reagent grade chemicals and demineralized water were used throughout the procedure.

Procedure

A 1.000-g sample was accurately weighed into a 250-ml beaker and 10 ml of demineralized water was added. Then 10 ml of concentrated hydrochloric acid was added and the solution was diluted to 50 ml with hot demineralized water. The beaker was covered and the solution kept at boiling for 15 min to digest the sample. The solution was cooled and filtered through a low retention ashless filter paper. The residue was washed several times with hot demineralized water to remove the soluble salt.

The filter paper was then transferred to the original beaker and 100 ml of 1% sodium hydroxide was added. The mixture was covered and heated to boiling. After 15 min, several drops of 0.1% methyl red indicator was added. The solution was neutralized with 12*M* hydrochloric acid and was further acidified with 4–5 drops of hydrochloric acid. The mixture was then filtered through low retention ashless filter paper and the residue was washed several times with hot 2% ammonium nitrate solution.

The residue in the combined filter papers was then transferred to a preweighed platinum crucible and heated to 400° for 15 min and then to 900° for another 45 min. The crucible was cooled in a desiccator and weighed. Then the mass of insoluble residue was calculated. The

percent flyash in the sample was calculated from the following relationship:

Mass (g) insoluble residue in flyash + Mass (g) insoluble residue in OPC = Mass (g) insoluble residue in blended cement − Mass (g) blank

$$A \times \frac{\%FA}{100} + C \times \frac{(100 - \%FA)}{100} = \frac{W - b}{m} \times 100$$

From which may be derived:

$$\% \text{ flyash} = \frac{\left(\frac{W \times 100}{m}\right) - B - C}{A - C} \times 100$$

W = mass (g) of insoluble residue
m = mass (g) of sample used
A = % insoluble residue of flyash, taken as 70.74%
b = mass (g) blank
B = % insoluble residue found in the blank determination (=[b/m] × 100)
For simplicity it is taken as 0.07 ± 0.03% (by the average of 20 determinations)
C = % insoluble residue of OPC, taken as 0.44%

RESULTS AND DISCUSSION

The calcium oxide contents of OPC & FA sampled from a market and a cement plant during the past six months are shown in Table 1. For 10% flyash in blended cement the calculated deviation of % FA caused by one standard deviation of calcium oxide in OPC can be as high as 1.0%, thus the BS method is not always an accurate method. On the other hand, flyash is known to be high in insoluble residue. Flyash samples from two power plants with coal sources from Australia and China were found to have insoluble residue values of 70.36 ± 4.79 and 75.63 ± 3.30%, respectively. This is a great contrast to that of cement (Table 1). Determining the insoluble residue in a sample may be a reliable alternate means to determine the flyash content. As seen from Table 1, the variation of insoluble residue for cement is much less than the calcium oxide, which is revealed from both manufactured and market samples. A similar calculation as above shows that the deviation of flyash content caused by one standard deviation of insoluble residue in OPC is about 0.5%, which is less than that calculated by calcium oxide. Taking cement standard NBS 634 (%FA = 0) as an example, its calcium oxide content is 62.58%. By the BS method, the calculated flyash content will be around 3% but in case of insoluble residue, its flyash content is expected to be less than 0.5%. Hence to determine the flyash content by means of insoluble residue measurement is expected to have better accuracy where it is less affected by the variation of composition in OPC.

More than 40 samples of blended cement were prepared with flyash from the two power plants and analysed by the proposed method. In the plot of insoluble residue *vs.* percent flyash, the correlation is found to be 0.9961. Therefore a linear relationship exists between the insoluble residue and the flyash content, it is feasible to determine the flyash in blended cement by insoluble residue measurement. To compare the accuracy and precision of the method with the BS method, blended cement samples prepared by mixing different sources of flyash (Australia, China, United States) with ordinary Portland cement were analysed by both methods. The results are summarised in Table 2. It is shown that the source of flyash does not have significant effect on the accuracy. The BS method is more affected by the variation of the calcium oxide content as shown by samples 13–15 in Table 2. By the matched pairs technique, the calculated t value was found to be 1.71, which shows that there is no significant difference between two methods. In fact from Table 2, the average difference of results of the proposed method and the known values is smaller. With

*Flyash used for samples 10 and 11 were flyash standard SRM 1633a and ASCRM 010, respectively.

†CaO in OPC component of samples 13, 14 and 15 were 62.0, 66.6, 63.2, respectively.

triplicate analyses, the standard deviation is less than 1% (Table 2). In addition its accuracy and precision is better than that by gamma spectrometry.[2] The time required is less than the EDTA extraction method and the skill required by this method is less demanding than for the instrumental methods.

CONCLUSION

The proposed method to determine the flyash content in blended cement is an alternative method to the classical method. It does not involve any special instrumentation. It is more accurate than the BS method and is less subject to variation of the chemistry of the OPC, as shown in the previous calculation and result. Since insoluble residue is required to be determined in concrete laboratories, the procedure is expected to be well established. The technique should be easily mastered by technicians.

(*Received* 13 *March* 1991. *Revised* 4 *July* 1991. *Accepted* 4 *July* 1991)

Summary—A simple, rapid and highly selective method for determination of quercetin in the presence of other flavonoids was developed. The method is based on the oxidation reaction of quercetin in neutral aqueous solution with *N*-bromosuccinimide (NBS) in the presence of phenol to give a violet chromogen measurable at 510 nm. Beer's law was valid within a concentration range of 2.5–30 μg/ml with a good correlation coefficient ($r = 0.9990$). All variables were studied to optimize the reaction conditions. The method is highly selective for quercetin. Other investigated flavonoids do not interfere. Mixtures of flavonoids were also analysed through native UV measurements of absorbance readings at 370 nm and then at 510 nm after adopting the proposed procedure. The method could also be utilized for the quantitative determination of quercetin in some plant extracts. Moreover, the proposed procedure could be considered as a good tool to follow the hydrolysis of quercetin glycosides.

The quantitative analysis of flavonoids by ultraviolet absorption is well known.[1–6] Other methods for their determination include fluorimetry,[7] polarography,[8] densitometry[9] and HPLC.[10–15] Few colorimetric methods have been reported for their determination.[16–21] Most colorimetric methods cannot be used to distinguish between the different flavonoids. When interfering flavonoids are to be present, quercetin must first be isolated chromatographically[1] but this requires an empirical correction for adsorption of quercetin.

Recent studies have shown that, flavonoids have mutagenic activity.[22–24] Quercetin is the most mutagenic; it also acts as a carcinogenic agent towards rats.[25]

There has been a need for a selective colorimetric method which could best be utilized in detecting and distinguishing between quercetin and other flavonoids without the need for any pretreatments or prior separation. *N*-Bromosuccinimide (NBS) has been previously used for the analysis of hydroxy compounds.[26,27] However, no report is available on its use for quantitative determination of flavonoids.

In the present work, the applicability of NBS for the quantitative determination of quercetin in the presence of other flavonoids has been investigated and has resulted in a selective, simple and rapid spectrophotometric method.

EXPERIMENTAL

Apparatus

Uvidec-320 (Jasco, Tokyo, Japan) and SP 1750 (Pye-Unicam) spectrophotometers were used.

Reagents

A 0.2% w/v solution of freshly recrystallized *N*-bromosuccinimide (NBS, obtained from Aldrich, Germany) was prepared in distilled water, the solution was freshly prepared before use and standardized iodometrically.[28]

Phenol, a 1% w/v solution was prepared in methanol. Flavonoids were obtained from Fluka, Koch Light, Aldrich, Eastman Organic Chemicals and Sigma. Solutions containing 0.5 mg/ml of quercetin were prepared in methanol and diluted quantitatively with the same solvent to obtain dilutions between 20–300 μg/ml.

Solvents used were of analytical reagent grade.

*Author for correspondence.

Procedures

Quercetin. Transfer 1 ml of working quercetin solution into a 10-ml standard flask, add 1 ml of phenol solution and 1 ml of NBS solution and make up to volume with distilled water. Mix and measure the absorbance at 510 nm against a reagent blank.

Quercetin and kaempferol. Into 2 sets of 10-ml standard flasks, transfer 0.5-ml aliquots (to the first set) and 1-ml aliquots (to the second set) of a mixture containing different proportions from quercetin and kaempferol (Table 3). Dilute the first set to volume with methanol, mix and measure the absorbance at 370 nm. To the other set, add 1 ml of phenol solution followed by 1 ml of NBS solution. Make up to volume with distilled water, mix and measure the absorbance at 510 nm against a reagent blank.

Stoichiometric study. A series of 5-ml quantities of mixtures containing master equimolar solutions ($2 \times 10^{-4} M$) in different complementary proportions (from 0:5 to 5:0 inclusive) were made up in 10-ml standard flasks containing 1 ml of phenol solution. After the flasks have been made up to volume with water, absorbances were measured at 510 nm against a blank treated in the same manner.

Monitoring of the hydrolysis of quercetin glycosides (Rutin). Into a 50-ml round-bottom flask, weigh accurately 18 mg of rutin (equivalent to 7.5 mg quercetin), dissolve in 5 ml of methanol, add 2.5 ml of distilled water and 7.5 ml of hydrochloric acid to produce a final solution of 5*N*. Reflux the resulting solution and at different time intervals, withdraw a 1-ml volume, transfer to a 50-ml separating funnel, extract with ethylacetate (three times, each of 10 ml). Pass the collected organic layer over anhydrous sodium sulphate and evaporate ethylacetate under reduced pressure. Dissolve the residue in methanol to produce 5 ml in a 5-ml standard flask and use 1 ml from this solution for the procedure for quercetin.

Determination of quercetin in plant. A 30-g sample of either leaves and stems, or flowers (dried and ground to 40 mesh) of *Cassia didymobotrya* Fres. was heated under reflux with 100 ml of 70% ethanol for 2 hr. The extract was concentrated to 25 ml and extracted with ethylacetate. After evaporation of the solvent under reduced pressure, the residue was dissolved in methanol to produce 10 ml in a 10-ml standard flask. Apply the procedure for quercetin, using 1 ml of the final extract solution in the blank.

RESULTS AND DISCUSSION

Optimization of conditions

Addition of an aqueous solution of NBS to a methanolic solution of different flavonoids resulted in the formation of an instantaneous violet colour only with quercetin, the other investigated flavonoids fail to give any coloured product. The violet colour is developed immediately at room temperature and in the presence of phenol remains stable for at least 15 min. Higher temperatures produce lower absorbance values. No increase in the absorbance reading (0.540 at 510 nm) was obtained upon increasing the temperature from 20 to 30° while a further 10°-increase decreases the absorbance by 6.9%. After that a regular 10° increase in the temperature up to 80° produces a 4% decrease in the corresponding absorbance readings. The absorption spectra for the quercetin reaction product exhibits three absorption peaks at 305, 375 and 510 nm (Fig. 1). Quercetin and NBS both have negligible absorbances at 510 nm.

A 1.0-ml volume of 1.5–3 mg/ml NBS was found to be optimum. Use of 1.0 ml of 5–15 mg/ml phenol solution in the total volume of 10 ml gives maximum absorbance readings. Various reducing substances such as phenol, hydrogen peroxide, salicylic acid, salicylamide, sulphanilamide, sodium nitrite and aniline sulphate were tested to try to increase the stability of the colour formed. Phenol was found the best as it gives the highest absorbance readings as well as the higher stability time. This effect might be explained on the basis of interacting the excess NBS with phenol thus preventing its destructive effect on the formed chromogen.

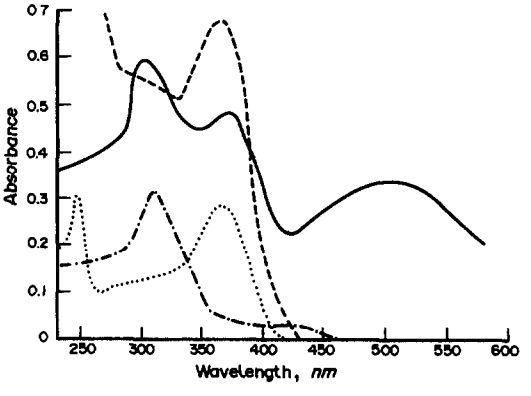

Fig. 1. Absorption spectra of: (---) quercetin, 12.4 μg/ml; (···) kaempferol 3.2 μg/ml (——) quercetin–NBS (12.4 μg quercetin and 20 mg NBS/ml and (-·-·-·) kaempferol–NBS (3.2 μg kaempferol and 20 mg NBS/ml).

The violet colour is not developed in acidic or alkaline media and the effect of pH was so studied. Tests with acetate and phosphate buffers, showed that, the maximum colour intensity and stability were obtained with phosphate buffer of pH 7 but this system was still inferior to the phenol procedure, with regard to colour intensity and stability.

Dilution of the developed coloured product by different solvents brings about bathochromic shifts with dimethylsulphoxide dimethylformamide, methanol, ethanol, n-propanol and isopropanol relative to water whereas absorption intensity was only slightly influenced (Table 1). Water was used throughout this work as it is the cheapest. These findings are in agreement with the fact that, in n-π^* transition peaks, a hypsochromic shift occurs with increasing polarity of the solvent (expressed as dielectric constant). This is due to stabilization of the ground state through hydrogen bonding.[29]

Stoichiometry

As assessed by the continuous molar variation method[30] quercetin was found to interact with NBS in a ratio of 1:4.

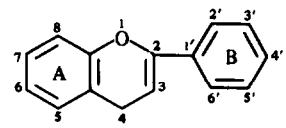
Reaction mechanism

The reaction does not seem to depend only on the catechol function, since rutin (which has the same catechol function as quercetin but sugar moiety at C-3 and luteolin (which lacks the 3-hydroxyl group) does not form such colour with NBS. Also a hydroxyl group at C-5 is necessary, as quercetin-5-glucose gives no such colour. Kaempferol failed to give a positive response indicating the necessity for orthodihydroxyl groups at C-3′ and 4′ in addition to the 3-, 5- and 7-hydroxyl groups. Morin (which has hydroxyl groups at C-3, 5, 6, 2′ and 4′) produces no such colour under the specified reaction conditions indicating that *m*-dihydroxyl groups at ring B (see structure below) are not suitable for such interaction. In conclusion, hydroxyl groups at C-3, 5, 7, 3′ and 4′ are necessary for this reaction.

Table 1. Effect of diluting solvents on the absorption intensity of the developed colour

Solvent	Absorbance*	λ_{max}†	Dielectric constant (E)‡
Water	0.540	510	78.3
Dimethylsulphoxide	0.560	518	47.0
Dimethylformamide	0.294	522	37.0
Methanol	0.459	525	33.0
Ethanol	0.490	525	25.0
n-Propanol	0.540	528	21.8
Iso-Propanol	0.523	532	19.9

*Final concentration 20 μg/ml.
†Average of three determinations.
‡Reference 33.



Quercetin = 3,5,7,3',4' - pentahydroxyflavone
Kaempferol = 3,5,7,4' - tetrahydroxyflavone
Rutin = 3-glucose-rhamnose quercetin
Luteolin = 3-deoxy - quercetin
Apigenin = 3-deoxy-kaempferol
Isorhamnetin= quercetin-3'-methylether
Morin = 3,5,6,2' and 4'-pentahydroxyflavone

Evidence for the oxidation of 3-, 5-, 3′- and 4′-hydroxyl groups in the proposed procedure is the failure of aluminium chloride alone or with hydrochloric acid to induce any bathochromic shifts when added to the reaction product indicating the absence of these hydroxyl groups (*cf.* quercetin gives bathochromic shifts due to the presence of 3-, 5-, 3′- and 4′-hydroxyl groups).[31]

Unfortunately, all trials made to isolate the formed chromogen were unsuccessful as it is destroyed during different isolation steps even under reduced pressure.

From the aforementioned observations as well as similar reports on the oxidation of catecholamines[26,27] it could be concluded that a polyquinone structure of quercetin may be formed.

Determination range

At 510 nm, a linear correlation was obtained between absorbance of the coloured product and concentration of quercetin over the range of 2.5–30 μg/ml with good correlation coefficient and small intercept, the regression equation was:

$$A_{510} = 0.019 + 0.026\ C_Q\ (r = 0.9990, n = 9)$$

The molar absorptivity was 8.14×10^3 l. mole^{-1}. cm^{-1}.

Selectivity of the colour reaction

Selectivity of the method was checked by examining the effect of NBS on various

flavonoids having hydroxyl groups in different positions such as kaempferol, rutin, isorhamnetin, luteoline, apigenin and morin.

No violet colour was produced with any of these compounds inspite of their observed interaction with NBS as shown in Fig. 1, for kaempferol as an example.

Precision

The mean of 10 replicate analyses of a solution of quercetin at a concentration of 20 μg/ml was assayed with a coefficient of variation of 1.02%. This level of precision is adequate for quality control analysis of quercetin in natural sources.

Analysis of mixtures

Eleven synthetic mixtures containing 2.5–20 μg kaempferol/ml and 2.5–25 μg quercetin/ml with a quercetin/kaempferol ratio of 0.125–10 were subjected to analysis with the proposed procedure and the results are shown in Table 2 with a mean recovery of $98.88 \pm 0.88\%$ for kaempferol and $99.54 \pm 0.45\%$ for quercetin.

The method depends upon the fact that, under the specified reaction conditions, only quercetin reacts with NBS to give a coloured product measurable at 510 nm. The other flavonoids give zero absorbance at this wavelength. Measurements at 370 nm determine the total flavonoids.

Concentration of quercetin could be directly calculated from the regression equation derived from the NBS-reaction product ($A_{510} = 0.019 + 0.026\ C_Q$). On the other hand, concentration of other flavonoids—calculated as kaempferol—could be calculated through measurement of the native absorbance at 370 nm before carrying out the reaction, then at 510 nm after the reaction, and, using the following equation:

$$A_k = 2A_{370} - 2.08A_{510} = 0.004 + 0.086\ C_k$$

from which,

$$C_k = \frac{(2A_{370} - 2.08\ A_{510}) - 0.004}{0.086}$$

where C_k is the concentration of flavonoids other than quercetin (calculated as kaempferol) in μg/ml, $2A_{370}$ is the total absorbance of the solution at 370 nm, 2.08 is a factor relating the absorbance of quercetin at 370 and 510 nm before and after the reaction, A_{510} is the absorbance of the quercetin reaction product, 0.004 and 0.086 are the intercept and slope of the regression equation of kaempferol at 370 nm respectively.

Table 2. Determination of synthetic mixtures of kaempferol and quercetin

Mixture taken, $\mu g/ml$		Recovery, % ± SD*

7.5	12.5	98.72 ± 0.60	99.94 ± 1.18
5.0	15.0	99.15 ± 0.68	99.37 ± 0.83
5.0	20.0	98.79 ± 0.91	99.00 ± 0.75
5.0	25.0	99.25 ± 0.53	99.57 ± 0.68
2.5	17.5	99.18 ± 1.22	99.43 ± 0.55
0	20.0		99.39 ± 0.71
Mean %		98.88	99.54
±SD		0.88	0.45

*Average of five determinations.

Table 3. Monitoring the hydrolysis of rutin and its subsequent determination as quercetin

Time, *hr*	Quercetin produced, % ± SD*
0.5	22.76 ± 2.32
1.0	40.08 ± 2.51
1.5	66.17 ± 2.13
2.0	83.36 ± 1.87
2.5	98.14 ± 0.93
3.0	97.34 ± 2.17

*Average of three determinations and calculated with reference to quercetin treated in the same manner as rutin.

Hydrolysis of quercetin glycosides

The proposed procedure would be valuable as a tool for quantitative monitoring of the hydrolysis of quercetin glycosides. When rutin is subjected to hydrolysis with 5*N* hydrochloric acid under reflux for 4 hr a gradual increase in the concentration of quercetin was observed, Table 3.

Analysis of plant extracts

To check the validity of the proposed procedure, assay of quercetin in *Cassia didymobotrya* Fres. in which quercetin has been described[32] was carried out. Quercetin could be determined quantitatively in ethylacetate extract without the need for preseparation steps and without interference from other constituents. Interference from any trace absorption from the extract could be eliminated by taking the same volume of extract in the blank and the results obtained are shown in Table 4.

Accuracy of the method was confirmed by the good recovery of added quercetin to the plant extracts (Table 4).

Table 4. Determination of quercetin in *Cassia didymobotrya* Fres.

Extract	Quercetin		
	Found, *mg*	Added, *mg*	Recovery, % ± SD*
Leaves and stems	1.86	2.0	99.59 ± 1.56
Flowers	2.37	2.5	99.18 ± 1.99

*Results based on three determinations per sample.

In conclusion, the proposed procedure is simple, time saving and selective for quercetin, moreover, it could be considered as a new highly-selective shift reagent for quercetin in the presence of other related flavonoids as well as a stability-indicating assay for quercetin glycosides.

In addition, it reports a good method for the selective analysis of quercetin in the presence of other flavonoids.

SIMULTANEOUS SPECTROPHOTOMETRIC DETERMINATION OF THYMOL BLUE, SEMI-METHYLTHYMOL BLUE AND METHYLTHYMOL BLUE

S. KICIAK* and M. A. MEHDI

Department of Physical Chemistry, Institute of Chemistry and Technical Electrochemistry, Politechnika Poznańska, PL-60-965, Poznań, Poland

(*Received* 11 *September* 1989. *Revised* 17 *August* 1991. *Accepted* 29 *August* 1991)

Summary—A direct spectrophotometric method for the simultaneous determination of Thymol Blue, Semi-Methylthymol Blue (SMTB) and Methylthymol Blue (MTB) in mixtures in the presence of other components usually found in synthetic SMTB and commercial MTB is presented. The method for selecting the most advantageous conditions for the spectrophotometric determination of the three dyes in different mixtures is given. A graphical version of the method is useful for monitoring syntheses of SMTB and MTB.

The mixtures obtained in the syntheses[1,2] of Methylthymol Blue (MTB) and Semi-Methylthymol Blue (SMTB) usually contain Thymol Blue (TB) and colourless substances such as formaldehyde, acetic acid and iminodiacetic acid (IDAA).[2–5] The last three compounds do not interfere in the spectrophotometric determination of the three dyes. A method for determination of MTB, SMTB and TB is needed for control of the synthesis of MTB and SMTB, the separation of MTB, SMTB and TB, and for monitoring the ageing of MTB in SMTB reagents.

The analysis of two-component mixtures of MTB and SMTB (transformed into the acid form) by potentiometry, reported by Yoshino and co-workers[3,4] gives good results only in the absence of other acids such as acetic acid, iminodiacetic acid and Thymol Blue in the acid form. These authors used the method only for analysing relatively pure MTB and SMTB reagents.

The spectrophotometric method given for simultaneous determination of MTB and SMTB by Kosenko and Mal'kova[6] utilizes the difference in the molar absorptivities of the aluminium MTB and SMTB complexes at 475 and 590 nm at pH 5.0, but does not take into consideration the presence of TB in mixtures of MTB and SMTB. Such mixtures containing TB are often met in analytical practice and particularly in the mixtures obtained during synthesis of MTB or SMTB. TB has a relatively high molar absorptivity at 475 nm and pH 5.0 and does not absorb at 590 nm. Its presence can therefore cause positive errors in determination of SMTB and relatively smaller negative errors in determination of MTB (Fig. 1).

The results of spectrophotometric determinations of *o*-Cresol Red, Semi-Xylenol Orange and Xylenol Orange,[7–10] and the initial results of

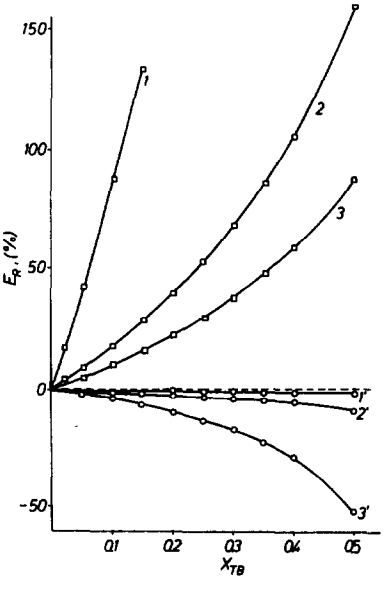

Fig. 1. Relative error (E_R) of SMTB (□) and MTB (○) determination *vs.* molar fraction of TB (x_{TB}) for ratio of molar concentrations $C_{SMTB}/C_{MTB} = 1/9$ (curves 1 and 1'), 1/1 (2 and 2') and 9/1 (3 and 3').

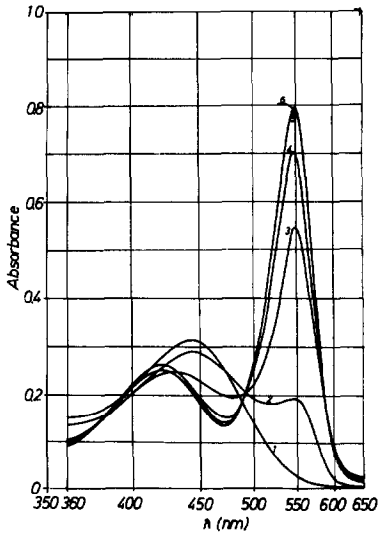

Fig. 2. Absorption spectra of $2.0 \times 10^{-5}M$ MTB for different sulphuric acid concentrations: $1.0M$ (curve 1), $4.0M$ (2), $5.5M$ (3), $7.0M$ (4), $10.0M$ (5) and $12.0M$ (6).

experiments with TB, SMTB and MTB in dilute sulphuric acid suggest that a corresponding determination of TB, SMTB and MTB is possible.

EXPERIMENTAL

Apparatus

The absorption measurements were made with a Zeiss-Jena spectrophotometer (Specord M40) with 1-cm cells. The potentiometric experiments were done with a Mera (Poland) type N517 pH-meter.

Reagents

MTB (Merck) containing ~90% of the dye was purified by extraction in a dilute sulphuric acid–1-butanol system. A mixture containing ~35% of SMTB, obtained from E. Krzyżanowska of the Organic Chemistry Department, Technical University, Poznań, was purified in small quantities (~25 mg) in the way given by Yoshino and coworkers[3,4] and in greater amounts by extraction in a water–butanol system. The latter method will be reported in a subsequent paper. The resulting MTB or SMTB were over 99.5% pure and free from TB. A commercial sample of TB was recrystallized from ethanol. All other reagents were of analytical grade.

Standard solutions of the three dyes ($0.001M$) were prepared in $0.01M$ sulphuric acid for MTB and SMTB, and in 1:1 v/v ethanol–$0.01M$ sulphuric acid mixture for TB.

Procedure

Dissolve 10–50 mg of the sample (accurately weighed) in 5 ml of water or ethanol, and dilute it to the mark with water in a 50-ml standard flask (solution I). Dilute 1 ml of this solution to 50 ml with $5M$ sulphuric acid (to obtain solution II) and measure its absorbance at 548 nm (1-cm path-length). Dilute x ml of solution I to the mark with water in a 50-ml standard flask to obtain solution III, the value of x being 25.0, 10.0, 5.0 and 2.0 when the absorbance of solution II is <0.3, 0.3–0.8, 0.8–1.5 and >1.5 respectively. Add 5-ml aliquots of this solution, with cooling) to 20.0 ml of 1.25, 5.0 and $8.75M$ sulphuric acid in 25-ml standard flasks, and make up to the marks with water, to obtain three solutions, designated S_1, S_4 and S_7, the subscript indicating the molarity of sulphuric acid in the solution. Measure the absorbances of these solutions at 548 nm (1-cm path-length cells). Calculate the concentrations of the components as shown below. The molar absorptivities of pure samples of the three dyes should be determined with the equipment used, and substituted for those quoted, if there is a difference.

RESULTS AND DISCUSSION

Molar absorptivities of TB, SMTB and MTB in sulphuric acid

The absorption spectra of MTB (Fig. 2), SMTB (Fig. 3) and TB (Fig. 4) in sulphuric acid have two peaks, at wavelengths depending on

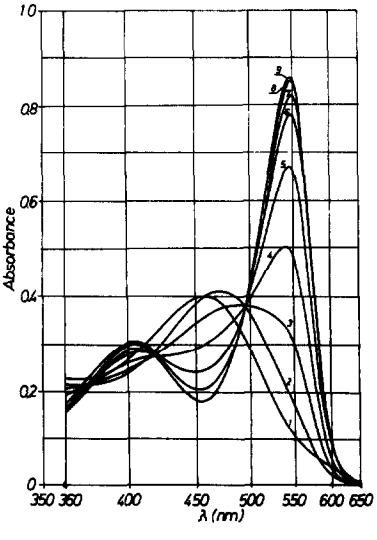

Fig. 3. Absorption spectra of $2.2 \times 10^{-5}M$ SMTB for different sulphuric acid concentrations: $0.001M$ (curve 1), $0.2M$ (2), $1.0M$ (3), $2.0M$ (4), $3.0M$ (5), $4.0M$ (6), $5.0M$ (7), $7.0M$ (8) and $10.0M$ (9).

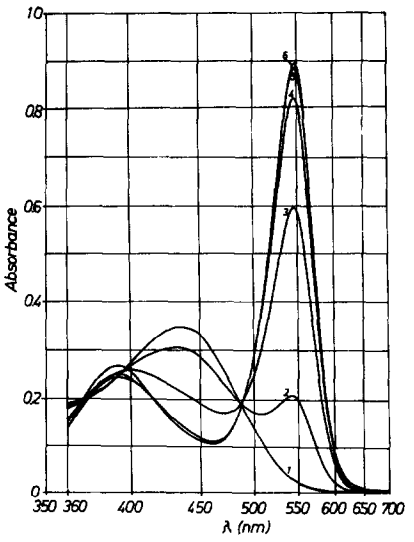

Fig. 4. Absorption spectra of $2.35 \times 10^{-5}M$ TB in buffer solutions of pH 4.0 (curve 1), 2.0 (2) and for different sulphuric acid concentrations: $0.05M$ (3), $0.5M$ (4), $4.0M$ (5) and $7.0M$ (6).

the acidity. The one near 435 nm is greatest at low concentrations of the acid, and is blue-shifted and decreased in magnitude with an increase in the acid concentration. The shift is relatively large, so the absorbance at 435 nm is not suitable for determination of the dyes. The peak at about 548 nm does not change position with an increase in the sulphuric acid concentration, but changes considerably in amplitude. The molar absorptivities of MTB, SMTB and TB differ very much from each other over almost the whole acidity range from pH 4 to $10M$ sulphuric acid (Fig. 5), and this is utilized for determination of the three dyes.

In accordance with the detailed potentiometric and spectrophotometric investigations conducted by Yoshino and co-workers[2-4] symbolic formulae such as H_6MTB, H_4SMTB and H_2TB can be assigned to the undissociated (yellow) molecules of MTB, SMTB and TB. Red protonated molecules, H_3TB^+, H_5SMTB^+, H_7MTB^+ and H_8MTB^{2+} are formed in acidic media. H_3TB^+ begins to form at pH 2, H_5SMTB^+ requires more concentrated sulphuric acid ($>1M$) and the protonated forms of MTB form if the concentration of sulphuric acid exceeds $4M$.

The blue-shifts of curve 1 (Fig. 2) for MTB and curve 1 (Fig. 3) for SMTB can be ascribed to the beginning of formation of the anionic forms of the dyes.

The ranges of sulphuric acid concentration in which the greatest changes in the spectra take place are 0.005–$1.0M$ for TB, 2–$4M$ for SMTB and 4–$7M$ for MTB.

Two-component systems

System TB–SMTB. To select the optimum concentration of sulphuric acid for the simultaneous determination of TB and SMTB the molar absorptivities at the absorption maximum (548 nm) were determined precisely and their differences ($\Delta\epsilon$) were plotted against sulphuric acid concentration (Fig. 6). It can be seen that the optimum acid concentration (greatest value of $\Delta\epsilon_{548}$) is $\sim 1.0M$.

In contrast, very small values of $\Delta\epsilon_{548}$ were obtained for $7M$ and greater concentrations of the acid. Therefore the second sulphuric acid concentration chosen for use in determination of TB and SMTB was $7.0M$.

The molar absorptivities of TB and SMTB in $1M$ and $7M$ sulphuric acid (at 548 nm) are $\epsilon_{TB_1} = 36.0 \times 10^3$, $\epsilon_{SMTB_1} = 13.0 \times 10^3$, $\epsilon_{TB_7} = 37.6 \times 10^3$ and $\epsilon_{SMTB_7} = 35.4 \times 10^3$ l.mole^{-1}.cm^{-1}. Beer's law is obeyed and the absorbances of TB and SMTB are additive over the concentration range $0.5–25 \times 10^{-6}M$, so for a path-length of 1 cm the absorbances A_1 and A_7 (in $1M$ and $7M$ sulphuric acid) are

$$A_1 = 36.0 \times 10^3 C_{TB} + 13.0 \times 10^3 C_{SMTB} \quad (1)$$

$$A_7 = 37.6 \times 10^3 C_{TB} + 35.4 \times 10^3 C_{SMTB} \quad (2)$$

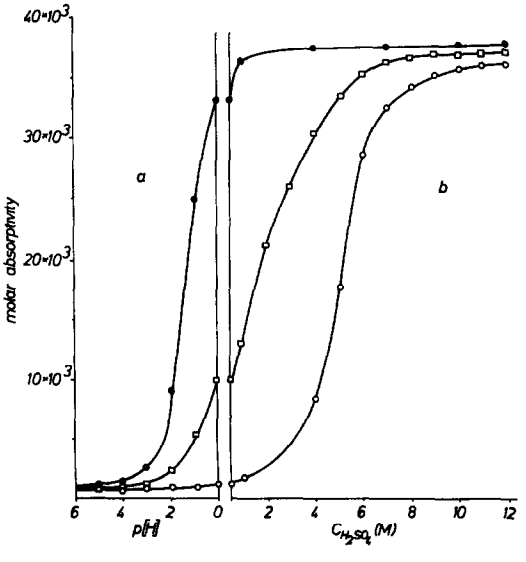

Fig. 5. Molar absorptivities (at 548 nm) of TB (●), SMTB (□) and MTB (○), (a) *vs.* p[H] (below pH = 2, calculated as p[H] = $-\log 0.5C_{H_2SO_4}$), (b) *vs.* sulphuric acid concentration.

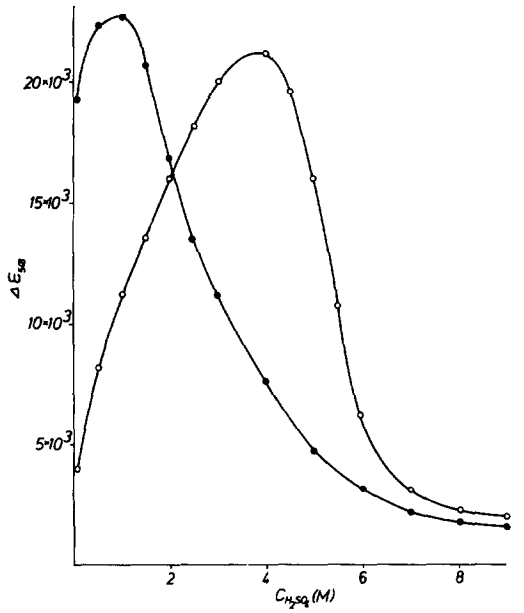

Fig. 6. Differences of molar absorptivities at 548 nm ($\Delta\epsilon_{548}$) *vs.* sulphuric acid concentration: $\Delta\epsilon = \epsilon_{TB} - \epsilon_{SMTB}$ (●) and $\Delta\epsilon = \epsilon_{SMTB} - \epsilon_{MTB}$ (○).

Rearranging gives

$$C_{TB} = (45.06A_1 - 16.55A_7) \times 10^{-6}M \quad (3)$$

$$C_{SMTB} = (45.82A_7 - 47.86A_1) \times 10^{-6}M \quad (4)$$

Table 1 shows the same experimental results for given TB and SMTB concentrations.

It is necessary to remark that even a small amount of MTB causes significant errors in determination of SMTB and TB. For example, for a mixture containing 10 μmole of TB, 10 μmole of SMTB and 0.4 μmole of MTB, from the absorbances of 1 and 7*M* sulphuric acid solutions of the mixture, the results obtained are 10.55 μmole of SMTB and 9.82 μmole of TB. In such a case better results

Table 1. Results for simultaneous spectrophotometric determination* of TB and SMTB

Taken†, μM		Found‡, μM	
TB	SMTB	TB	SMTB
2.0	18.0	$1.9_5 \pm 0.1_6$	$18.1_2 \pm 0.1_7$
5.0	15.0	$4.9_7 \pm 0.1_7$	$14.9_7 \pm 0.2_2$
10.0	10.0	$10.1_0 \pm 0.1_3$	$10.0_2 \pm 0.2_1$
15.0	5.0	$14.9_6 \pm 0.1_4$	$5.1_4 \pm 0.1_6$
18.0	2.0	$18.2_3 \pm 0.1_1$	$2.0_8 \pm 0.1_8$

*Absorbances measured at 548 nm in 1 and 7*M* sulphuric acid media.
†With error of $\pm 0.05\mu M$.
‡Means and standard deviations for 5 measurements.

Table 2. Results for simultaneous spectrophotometric determination* of SMTB and MTB

Taken†, μM		Found‡, μM	
SMTB	MTB	SMTB	MTB
2.0	18.0	$2.1_2 \pm 0.0_9$	$17.8_8 \pm 0.1_2$
5.0	15.0	$4.9_6 \pm 0.0_8$	$14.9_6 \pm 0.0_9$
10.0	10.0	$10.0_4 \pm 0.1_5$	$9.9_5 \pm 0.1_2$
15.0	5.0	$15.1_3 \pm 0.1_8$	$5.1_0 \pm 0.1_7$
18.0	2.0	$18.2_0 \pm 0.1_6$	$1.9_9 \pm 0.1_1$

*Absorbances measured at 548 nm in 4 and 7*M* sulphuric acid media.
†With error of $\pm 0.05\mu M$.
‡Means and standard deviations for 5 measurements.

can be obtained by using a solution in 4*M* instead of 7*M* sulphuric acid, and then

$$C_{TB} = (50.54A_1 - 22.24A_4) \times 10^{-6}M \quad (5)$$

$$C_{SMTB} = (61.58A_4 - 63.29A_1) \times 10^{-6}M \quad (6)$$

The results for the same mixture are then 10.12 μmole of SMTB and 9.98 μmole of TB.

System SMTB–MTB. It is similarly shown (Fig. 6) that 4*M* and 7*M* are the optimum sulphuric acid concentrations for simultaneous determination of SMTB and MTB. In this case the molar absorptivities at 548 nm are $\epsilon_{SMTB_4} = 29.6 \times 10^3$, $\epsilon_{MTB_4} = 8.2 \times 10^3$, $\epsilon_{SMTB_7} = 35.4 \times 10^3$ and $\epsilon_{MTB_7} = 32.4\,1.\text{mole}^{-1}.\text{cm}^{-1}$. Beer's law is obeyed and the absorbances are additive in the same range of dye concentration $0.5 - 25.0 \times 10^{-6}M$ as that for the TB–SMTB system, so

$$C_{SMTB} = (48.45A_4 - 12.26A_7) \times 10^{-6}M \quad (7)$$

$$C_{MTB} = (44.26A_7 - 52.94A_4) \times 10^{-6}M \quad (8)$$

Typical values for C_{SMTB} and C_{MTB} are given in Table 2.

System TB–MTB. This system is not met in practice (SMTB is always also present)—so it will not be described except for the equations:

$$C_{TB} = (29.49A_1 - 1.64A_7) \times 10^{-6}M \quad (9)$$

$$C_{MTB} = (32.77A_7 - 34.22A_1) \times 10^{-6}M \quad (10)$$

Three-component system (TB, SMTB, MTB)

Figures 5 and 6 show that in sulphuric acid solutions of TB, SMTB and MTB the dominant influence on the change of absorption at 548 nm is the concentration of the acid: for TB up to 1*M*, for SMTB up to 4*M* and for MTB up to 7*M*. Therefore solutions with these concentrations of sulphuric acid were chosen for the simultaneous determination of the three dyes.

Table 3. Results for simultaneous spectrophotometric determination* of TB, SMTB and MTB

10.0	5.0	5.0	$10.0_2 \pm 0.1_8$	$5.0_8 \pm 0.2_2$	$4.9_2 \pm 0.1_8$
10.0	8.0	2.0	$9.9_6 \pm 0.2_3$	$7.9_0 \pm 0.2_8$	$2.1_1 \pm 0.2_1$
16.0	3.0	1.0	$16.1_5 \pm 0.2_9$	$3.0_1 \pm 0.3_2$	$1.1_2 \pm 0.1_7$
16.0	2.0	2.0	$15.9_1 \pm 0.2_7$	$2.0_8 \pm 0.2_0$	$2.1_4 \pm 0.2_4$
16.0	1.0	3.0	$16.0_8 \pm 0.2_3$	$0.9_8 \pm 0.1_9$	$2.9_6 \pm 0.1_8$
18.0	1.0	1.0	$18.2_0 \pm 0.3_0$	$1.0_6 \pm 0.1_8$	$1.0_8 \pm 0.2_0$

*Absorbances measured at 548 nm in 1.0, 4.0 and 7.0M sulphuric acid media.

†With error of $\pm 0.05 \mu M$.

‡Means and standard deviations for 5 measurements.

The additional molar absorptivities at 548 nm needed are $\epsilon_{TB_4} = 37.0 \times 10^3$ and $\epsilon_{MTB_1} = 1.8 \times 10^3$ l.mole^{-1}.cm^{-1}.

Beer's law is obeyed and the absorbances of the three dyes are additive from 0.5–25μM, so for a path-length of 1 cm the absorbances of the 1, 4 and 7M sulphuric acid solutions are

$$A_1 = 36.0 \times 10^3 C_{TB} + 13.0 \times 10^3 C_{SMTB} + 1.8 \times 10^3 C_{MTB} \quad (11)$$

$$A_4 = 37.0 \times 10^3 C_{TB} + 29.6 \times 10^3 C_{SMTB} + 8.2 \times 10^3 C_{MTB} \quad (12)$$

$$A_7 = 37.6 \times 10^3 C_{TB} + 35.4 \times 10^3 C_{SMTB} + 32.4 \times 10^3 C_{MTB} \quad (13)$$

Rearranging gives

$$C_{TB} = (52.03A_1 - 27.81A_4 + 4.15A_7) \times 10^{-6} M \quad (14)$$

$$C_{SMTB} = (-69.20A_1 + 85.40A_4 - 17.75A_7) \times 10^{-6} M \quad (15)$$

$$C_{MTB} = (15.30A_1 - 61.05A_4 + 45.44A_7) \times 10^{-6} M \quad (16)$$

Some results thus obtained for synthetic mixtures of TB, SMTB and MTB are collected in Table 3. Results obtained for some commercial samples of MTB and for mixtures obtained during synthesis of SMTB are collected in Table 4.

Graphical method for the three-component system (TB, SMTB and MTB)

A graphical version of the method for the three-component system has also been worked out, and is very useful for monitoring the changes during synthesis of SMTB or MTB. In

*Time elapsed from start of synthesis.

†Equivalent concentration of pure MTB.

‡Mean of three determinations.

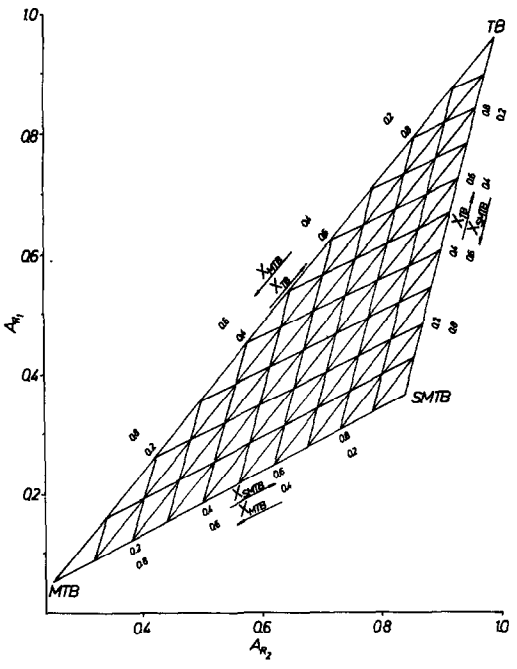

Fig. 7. Dependence of molar fractions of TB, SMTB and MTB on relative absorbances, $A_{R_1} = A_1/A_7$ and $A_{R_2} = A_4/A_7$ where A_1, A_4 and A_7 are the absorbances at 548 nm for 1, 4 and 7*M* sulphuric acid solutions.

this version the absorbance ratios are used (see Appendix for derivation):

$$A_{R_1} = \frac{A_1}{A_7} = \frac{36.0 - 23.0\,X_{SMTB} - 34.2\,X_{MTB}}{37.6 - 2.2\,X_{SMTB} - 5.2\,X_{MTB}} \quad (17)$$

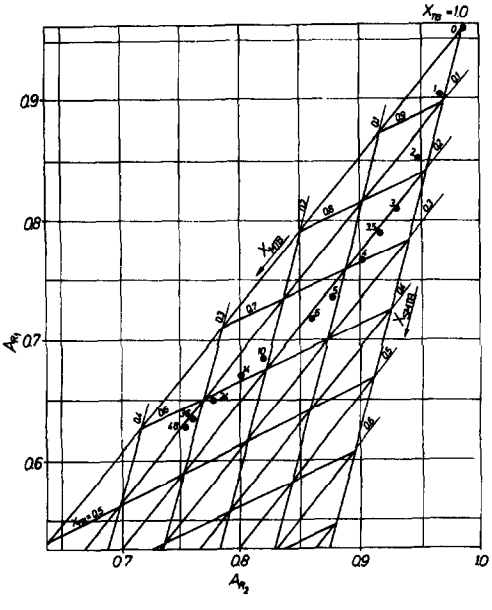

Fig. 8. Dependence of molar fraction of TB, SMTB and MTB on relative absorbances A_{R_1} and A_{R_2}. Changes in the composition of the mixture during the synthesis of SMTB are shown by the points (●) numbered with the time (hr) elapsed from the beginning of the reaction.

$$A_{R_2} = \frac{A_4}{A_7} = \frac{37.0 - 7.4\,X_{SMTB} - 28.8\,X_{MTB}}{37.6 - 2.2\,X_{SMTB} - 5.2\,X_{MTB}} \quad (18)$$

Equations (17) and (18) allow construction of Fig. 7. From which the composition of the mixture can be directly read by using only the relative values of the absorbances without calculation of the concentrations of the three dyes.

Figure 8 shows an example of use of the graphical version of the method for observation of progress during synthesis of SMTB. It is easy to see that the largest molar fraction of SMTB in the mixture is obtained 4 hr from the beginning of the synthesis.

APPENDIX

It follows from the equations for A_1, A_4 and A_7 that

$$A_{R_1} = \frac{A_1}{A_7} = \frac{(36.0\,C_{TB} + 13.0\,C_{SMTB} + 1.8\,C_{MTB}) \times 10^3}{(37.6\,C_{TB} + 35.4\,C_{SMTB} + 32.4\,C_{MTB}) \times 10^3}$$

and

$$A_{R_2} = \frac{A_4}{A_7} = \frac{(37.0\,C_{TB} + 29.6\,C_{SMTB} + 8.2\,C_{MTB}) \times 10^3}{(37.6\,C_{TB} + 35.4\,C_{SMTB} + 32.4\,C_{MTB}) \times 10^3}$$

The molar fractions of TB, SMTB and MTB are:

$$X_{TB} = \frac{C_{TB}}{\Sigma C_i}, \quad X_{SMTB} = \frac{C_{SMTB}}{\Sigma C_i}$$

and

$$X_{MTB} = \frac{C_{MTB}}{\Sigma C_i}$$

where $\Sigma C_i = C_{TB} + C_{SMTB} + C_{MTB}$ and $X_{TB} + X_{SMTB} + X_{MTB} = 1$.

Division of the numerators and denominators of both equations by ΣC_i gives

$$A_{R_1} = \frac{36.0\,X_{TB} + 13.0\,X_{SMTB} + 1.8\,X_{MTB}}{37.6\,X_{TB} + 35.4\,X_{SMTB} + 32.4\,X_{MTB}}$$

and

$$A_{R_2} = \frac{37.0\,X_{TB} + 29.6\,X_{SMTB} + 8.2\,X_{MTB}}{37.6\,X_{TB} + 35.4\,X_{SMTB} + 32.4\,X_{MTB}}$$

Because $X_{TB} = 1 - X_{SMTB} - X_{MTB}$, we obtain

$$A_{R_1} = \frac{36.0 - 23.0\,X_{SMTB} - 34.2\,X_{MTB}}{37.6 - 2.2\,X_{SMTB} - 5.2\,X_{MTB}}$$

and

$$A_{R_1} = \frac{37.0 - 7.4\,X_{SMTB} - 28.8\,X_{MTB}}{37.6 - 2.2\,X_{SMTB} - 5.2\,X_{MTB}}.$$

STUDIES ON THE EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF Ni(II), Fe(II), Fe(III) AND V(IV) WITH BIS(4-HYDROXYPENT-2-YLIDENE)DIAMINOETHANE

F. I. NWABUE* and E. N. OKAFO†
Department of Pure and Industrial Chemistry, University of Nigeria, Nsukka, Nigeria

(*Received* 24 *March* 1989. *Revised* 10 *September* 1991. *Accepted* 18 *September* 1991)

Summary—The extraction of Ni(II), Fe(II), Fe(III) and V(IV) with bis(4-hydroxypent-2-ylidene)-diaminoethane from various acids and buffer solutions has been studied. The golden yellow Fe(II) and wine-red Fe(III) complexes have maximum absorption at 445 and 435 nm respectively, and the yellow–green Ni(II) chelate shows two maxima, at 373 and 560 nm. The blue–green V(IV) chelate also has two maxima, at 580 and 660 nm. These characteristics can be used for the determination of these species. Iron, nickel and vanadium have been separated and determined in the presence of one another and of many other elements.

Since the work of Combes on the preparation of a tetradentate β-ketoamine complex of copper,[1] a considerable literature has appeared on the subject. Much of it concerns the synthesis and structural elucidation of β-ketoamine analogues,[2–4] and the gas chromatographic,[5–7] thermogravimetric[5] and spectrometric[8–10] determination of some of their metal complexes. Although these compounds have not found much use either as metal extractants or as spectrophotometric reagents, they have been noted[11–13] as promising for the purpose.

We have found bis(4-hydroxypent-2-ylidene)-diaminoethane (BHPDE) to be suitable for the extraction and spectrophotometric determination of iron, vanadium and nickel in the presence of each other and of many other elements.

EXPERIMENTAL

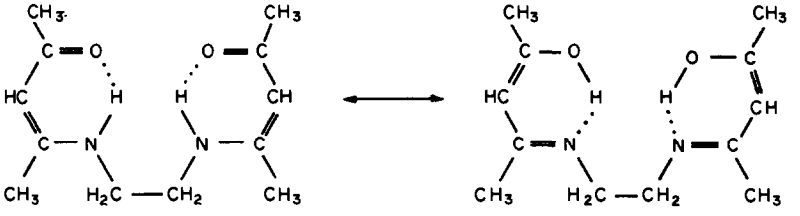
Reagents

All reagents and solvents used were of analytical grade. All aqueous solutions were prepared in distilled demineralized water. Working solutions were prepared by dilution as required.

Standard iron solution (0.1 mg/ml). Iron(II) and iron(III) solutions were prepared by dissolving the requisite amounts of ferrous or ferric ammonium sulphate (as appropriate) in dilute sulphuric acid, and were standardized by the permanganate method.[14]

Standard nickel solution (0.1 mg/ml). Prepared from nickel sulphate hexahydrate.

Standard vanadium(IV) solution (0.1 mg/ml). Freshly prepared from vanadyl sulphate pentahydrate.



BHPDE

*Author for correspondence.
†Department of Foundation and Remedial Studies, University of Jos, Makurdi Campus, Makurdi, Nigeria.

Synthesis of BHPDE. Ethylenediamine (6.00 g) is added gradually with stirring to 20.0 g of acetylacetone in a 250-ml beaker, both liquids having previously been chilled in an ice–salt mixture for 30 min. If the ethylenediamine solidifies during the cooling, it should be liquefied by very gentle warming. The reaction is exothermic. Initially a whitish solid forms, but as more ethylenediamine is added the reaction mixture becomes hot and deep golden yellow. Stirring is continued until crystallization starts, leading to a cream-coloured cake. The product is recrystallized twice from carbon tetrachloride, to give whitish crystals (96% yield, m.p. $108 \pm 1°$). The reagent is used as a freshly prepared 0.1 g/ml aqueous solution, dissolution being effected by warming.

Buffer solutions. Clark and Lubs buffers[15] for pH 1–10, and as described by Kolthoff *et al.*[15] for pH 11–13, were prepared.

Protonation and acid dissociation constants of the reagent

A 0.01*M* aqueous solution of the reagent gave a pH value of 8.3 ± 0.1. The protonation constants were determined by titration of the reagent with 0.01*M* hydrochloric acid, as log K_1, 4.40 ± 0.10 and log $K_2 = 3.20 \pm 0.15$. These values suggest stepwise protonation of the two nitrogen sites in the ligand, H_2B, to give H_3B^+ and H_4B^{2+} respectively. The acid dissociation constants were obtained by titration with 0.01*M* sodium hydroxide, and were found to be $pK_{1D} = 9.70 \pm 0.10$ and $pK_{2D} = 10.80 \pm 0.10$, corresponding to the formation of HB^- and B^{2-} respectively.

Measurement of distribution ratios

Equal volumes (5 ml) of the aqueous and organic phases were shaken mechanically [for 3 min for iron(II), 10 for vanadium and iron(III), and 20 for nickel at pH 13, but 60 at pH 5] in glass-stoppered bottles at $28 \pm 1°$. The phases were centrifuged and separated, and analysed spectrophotometrically after acid decomposition.

Iron was determined with 1,10-phenanthroline after reduction with hydroquinone,[16] nickel with dimethylglyoxime,[16] and vanadium with oxine after reduction with solid sodium dithionite.[17]

Colour stability

The stability of the colour of the complexes was studied at room temperature ($28 \pm 1°$). Maximum absorbance of the chloroform extract was obtained after 10 min standing of the aqueous phase before extraction. The absorbance of the iron(II) and iron(III) complexes was constant for at least 3 days, while that of the nickel(II) and vanadium(IV) complexes was stable for up to 1 day.

Temperature effect. The temperature was varied from 18 to 40°: the absorbance is at a maximum and constant between 24 and 30°. All determinations were done at room temperature ($28 \pm 1°$).

Phase volume ratio. Variation in volume of the aqueous phase from 3 to 40 ml had little or no effect on the absorbance of the chloroform extract or on the extraction efficiency: a working volume of 5 ml is recommended for ease of manipulation.

Recommended procedures for iron, vanadium and nickel

Iron. To 2 ml of sample solution containing 5–30 μg of iron(II), add 0.25 ml of 0.1*M* perchloric, sulphuric or hydrochloric acid, and 0.5 ml of 5 mg/ml hydroquinone solution to reduce any iron(III) to iron(II); for iron(III), add 0.25 ml of 0.1*M* perchloric acid or 0.5 ml each of 0.1*M* nitric acid and potassium nitrate but no hydroquinone. Add 1 ml of BHPDE solution, make up to about 5 ml with water, let stand for 10 min, shake with 5 ml of chloroform for 3 min, and measure the absorbance of the extract at 445 nm for iron(II) or 435 nm for iron(III), against a reagent blank.

Vanadium. Adjust 2 ml of sample solution containing 50–500 μg of vanadium(IV) to pH 10–11 with dilute ammonia solution and buffer. Add 1 ml of BHPDE solution, make up to about 5 ml with water, let stand for 10 min, shake with two 5-ml portions of chloroform for 10 min each time, and measure the absorbance of the combined extracts at 660 nm against a reagent blank.

Nickel. Adjust 2 ml of sample solution containing not less than 15 μg of nickel to pH 13 with dilute ammonia and sodium hydroxide solutions. Add 1 ml of BHPDE solution, make up to about 5 ml with water, let stand for 10 min, shake with 5 ml of chloroform for 20 min and measure the absorbance of the extract at 375 nm against a reagent blank.

Separation of iron from nickel or vanadium

Extract the iron from acid solution, then the nickel at pH 13, or vanadium at pH 10–11.

Separation of nickel and vanadium

Extract the nickel at pH 5 (triple extraction is needed) and then the vanadium at pH 10–11.

Determination of iron, nickel and vanadium together

Extract the iron from acid solution, then the nickel after adjustment of the pH to 5 (triple extraction) and finally the vanadium at pH 10–11.

Analysis of plant matter

Samples of *colocasia antiquorum* prepared from the air-dried pulp of the edible cormel were used as a model.

Ash (at 400–450°) a weighed sample sufficient to give about 0.1 g of ash. Dissolve the ash in 2*M* hydrochloric acid, dilute to a convenient volume, and then evaporate an aliquot to dryness. Take up the residue in dilute acid and determine the iron and nickel as already described.

RESULTS AND DISCUSSION

Figure 1 shows the extraction of iron(II), iron(III), nickel(II) and vanadium(IV) into chloroform with BHPDE as a function of pH. There is quantitative extraction of iron(II) in the pH range 2–5, but at pH 1 the extraction is negligible. At above pH 5 the extraction decreases, suggesting formation of an unextractable hydroxo species, which becomes more pronounced at above pH 12. The extraction of iron(III) increases from zero at below pH 1 and reaches a maximum of about 90% in the pH range 3–5. Quantitative extraction at pH 3 would be expected from the results obtained with unbuffered acid media, as shown later in Fig. 3. The shortfall could be attributed to complexation by the phthalate in the buffer at pH 3–5, as well as to hydrolysis at above pH 4.[18] This was confirmed by increase of the extraction up to 100% at pH 3–4 when phthalate was replaced by tartrate in the buffer. The partial extraction observed at above pH 11 could be due to formation of extractable complexes formed with HB^- or B^{2-} or with hydroxyl ions. The extraction of nickel(II) into chloroform, which attains equilibrium slowly at pH below 9, probably owing to kinetic factors, is incomplete at low pH but becomes quantitative and much faster at pH above 11. Vanadium(IV) is not extracted at all over the pH range 1–5, but

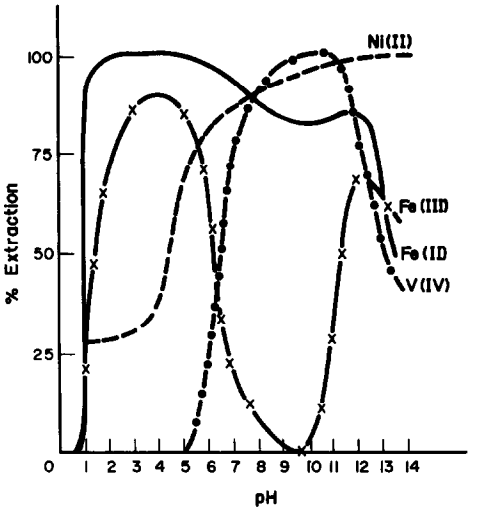


Fig. 1. Extraction of —— Fe(II), ×——× Fe(III), ●——● V(IV), and --- Ni(II) from aqueous pH buffer with an equal volume (5 ml) of 20-mg/ml BHPDE/$CHCl_3$ solution at 28 ± 1°.

its extraction increases gradually with pH > 5, becoming quantitative at pH 10–11 before decreasing sharply at higher pH. The decrease could be due to formation of the hydrous oxide,[18] $VO(OH)_2$.

The extraction of iron(II) and iron(III) from unbuffered acid media with 2% BHPDE and an equal volume of chloroform is shown in Figs. 2 and 3 respectively. Iron(II) is quantitatively extracted from all four acids when these are present in the concentration range 0.001–0.005*M*. At higher acidity a sharp decrease in extraction is observed at 0.005*M*

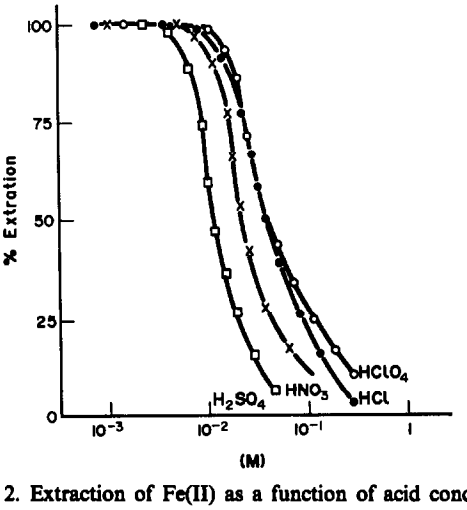

Fig. 2. Extraction of Fe(II) as a function of acid concentration: ●——● HCl, ×——× HNO_3, O——O $HClO_4$, □——□ H_2SO_4. Equal volumes (5 ml) of aqueous phase and 20-mg/ml BHPDE/$CHCl_3$ solution, contact time of 3 min, at 28 ± 1°.

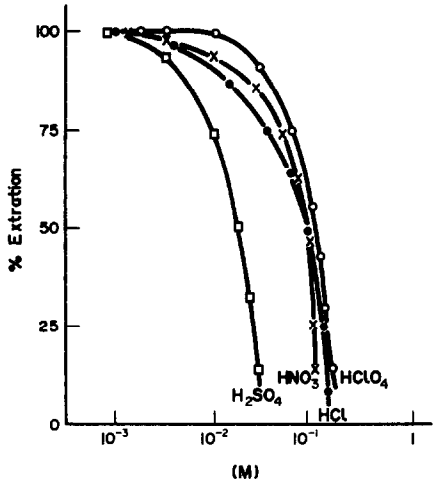

Fig. 3. Extraction of Fe(III) as a function of acid concentration: ●——● HCl, ×——× HNO_3, ○——○ $HClO_4$, □——□ H_2SO_4. Equal volumes (5 ml) of aqueous phase and 20-mg/ml BHPDE/$CHCl_3$ solution, contact time 10 min, at 28 ± 1°.

for sulphuric and nitric acids, and 0.01M for hydrochloric and perchloric acids, as a result of protonation of the ligand, H_2B, according to the equations:

$$H_2B + H^+ \rightleftharpoons H_3B^+; \quad \log K_1 = 4.40 \qquad (1)$$

$$H_3B^+ + H^+ \rightleftharpoons H_4B^{2+}; \quad \log K_2 = 3.20 \qquad (2)$$

At >1.0M acid concentration, an unextractable pinkish complex is formed but was not investigated.

The extraction of iron(III) from various acids follows a trend similar to that of iron(II) for perchloric acid, and for the other acids quantitative extraction is achieved only at 0.001M acid concentration. The extraction of iron(II) and iron(III) shown in Figs 2 and 3 shows a general decrease with increasing acidity of the aqueous phase, according to the equation:

$$M^{n+} + mH_3B^+ + nX^- \rightleftharpoons M(H_2B)_m^{n+} \cdot nX^- + mH^+ \qquad (3)$$

Hence the extraction constant is given by

$$K_{ex} = \frac{[M(H_2B)_m^{n+} \cdot nX^-][H^+]^m}{[M^{n+}][H_3B^+]^m[X^-]^n} \qquad (4)$$

where $X^- = NO_3^-$, Cl^-, ClO_4^- or HSO_4^-.

Hence

$$\log D = m \log[H_2B] + n \log[X^-] + m \log K_1 + \log K_{ex} \qquad (5)$$

Plots of log D *vs.* log[H_2B] at pH 4–6 and at constant ionic strength 0.1, maintained by chloride, perchlorate or nitrate ion, are linear with slopes of 2 and 1 for iron(II) and iron(III) respectively. Similar plots of log D *vs.* log[X^-] at 0.1M H_2B concentration and pH 4–6 are also linear, with slopes of 2 and 1 for iron(II) and iron(III) respectively. These results suggest formation of ion-association complexes of the type $[Fe^{II}(H_2B)_2^{2+}] \cdot 2X^-$ and $[Fe^{III}(H_2B)(OH)_2^+] \cdot X^-$ as the predominant species at low acidity, whereas at high acid concentration the equilibrium in equation (3) shifts to the left, preventing complex formation. The log K_{ex} values obtained from these plots are 13.85 and 6.05 for iron(II) and iron(III) respectively.

The extraction of nickel(II) and vanadium(IV) from unbuffered acid media is low, but increases with increasing pH according to the equations:

$$M^{n+} + xH_2B \rightleftharpoons M(HB)_x^{(n-x)+} + xH^+ \qquad (6)$$

$$M^{n+} + xH_2B \rightleftharpoons MB_x^{(n-2x)+} + 2xH^+ \qquad (7)$$

Hence

$$\log D = x \log[H_2B] + y\text{pH} + \log K_{ex} \qquad (8)$$

where $y = x$ and $2x$ for equations (6) and (7) respectively.

Plots of log D *vs.* log[H_2B] at constant ionic strength 0.1 and 0.15 are linear with a slope of 1 in the pH range 5–10 for nickel and vanadium, and 2 in the pH range 11–13. This suggests the extraction of $Ni(HB)_2$ and $VO(HB)_2$ complexes at pH below 10 and of NiB and VOB at pH

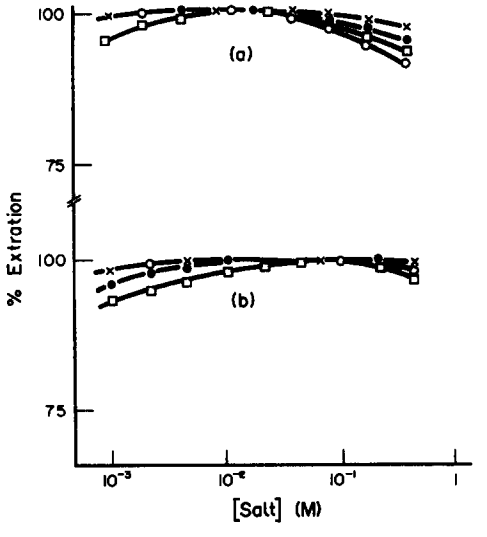

Fig. 4. Effect of added salts on the extraction of (A) Fe(II) and (B) Fe(III) from 0.05M HCl, HNO_3, $HClO_4$ and 0.01M H_2SO_4; ●——● NaCl, ×——× KNO_3, ○——○ $NaClO_4$, □——□ Na_2SO_4. Equal volumes (5 ml) of aqueous phase and 20-mg/ml BHPDE/$CHCl_3$ solution, contact time 3 min for Fe(II), 10 min for Fe(III), at 28 ± 1°.

above 11. The log K_{ex} values obtained on the basis of equation (7) are −20.82 and −20.18 for nickel and vanadium respectively.

Other extraction variables

The extraction of iron(II) and iron(III) with a 20-mg/ml BHPDE solution in chloroform is not quantitative from 0.05*M* acid, as shown in Figs 2 and 3. Under these conditions, the addition of various amounts of the sodium salts of the corresponding acids, and of sodium sulphate to 0.01*M* sulphuric acid results in quantitative extraction, as shown in Fig. 4 for iron(II) and iron(III). For both iron species this is consistent with the equilibrium suggested in equation (3).

The extraction of iron(II) from 0.005*M* hydrochloric acid is influenced by the presence of various complexing agents as shown in Fig. 5. Cyanide (0.001–0.1*M*) and trace amounts of oxalate, fluoride and thiocyanate ions have negligible effects on the extraction, even though partial masking is observed as the concentrations of fluoride and thiocyanate ions are increased, and complete masking of iron(II) is achieved at oxalate concentrations above 0.1*M*. At 0.001*M* concentration EDTA masks about 50% of the iron(II), but at higher concentrations only about 40%.

The stripping of iron(II), iron(III), nickel(II) and vanadium(IV) with various acids from chloroform extracts was studied. Two back-extractions of iron(II) and iron(III) with 3*M* hydrochloric acid (equilibration for 2 min) gave quantitative recovery, but equilibration for 3 min was needed for the complete recovery of nickel(II) and vanadium(IV) with 1*M* hydrochloric or sulphuric and 4*M* hydrochloric acid respectively.

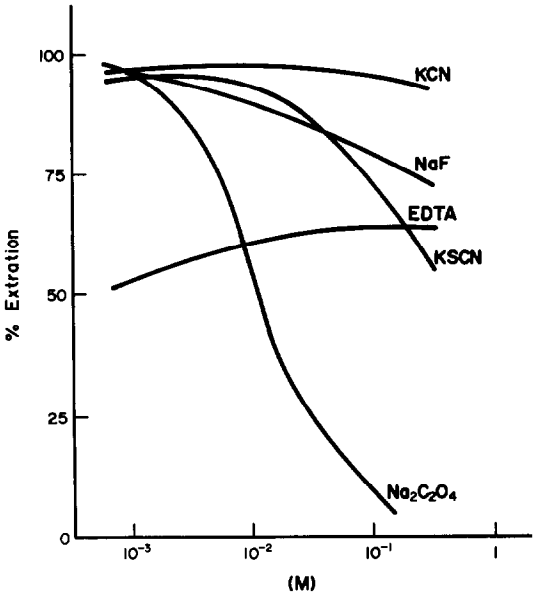

Fig. 5. Effect of complexing agents on the extraction of Fe(II) from 0.005*M* HCl with an equal volume (5 ml) of 20-mg/ml BHPDE/$CHCl_3$ solution, contact time 3 min, at 28 ± 1°.

Spectral studies

The absorption spectra of BHPDE and of chloroform extracts of its iron(II), iron(III),

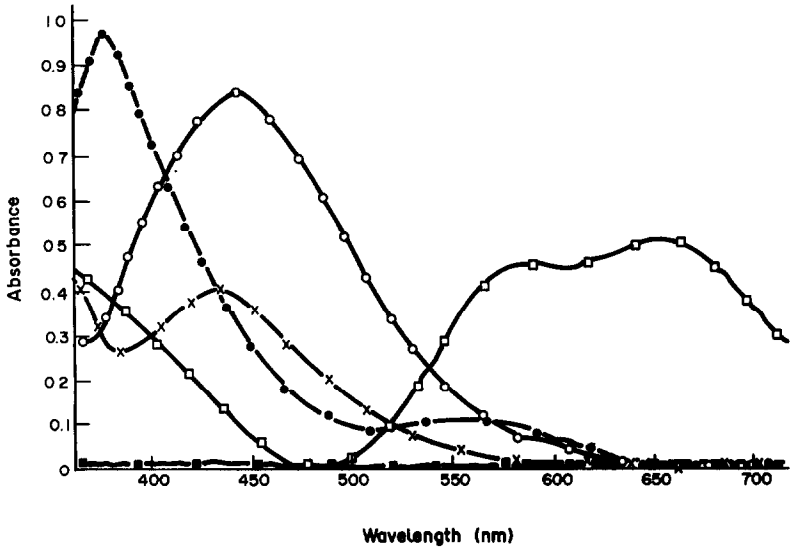

Fig. 6. Absorption spectra of chloroform solutions of BHPDE and its complexes: O——O Fe(II), ×——× Fe(III), ●——● Ni(II), □——□ V(IV), ■——■ 20-mg/ml BHPDE solution.

nickel(II) and vanadium(IV) complexes, measured against a reagent blank, and also those of the copper(II), mercury(II), palladium(II) and gold(III) complexes (which are also extracted) are shown in Fig. 6. The spectra of the golden yellow iron(II) and wine-red iron(III) complexes are similar, with maxima at 445 and 435 nm respectively. The yellow–green nickel(II) chelate shows two maxima, at 375 and 560 nm, as does the blue–green vanadium(IV) chelate (at 580 and 660 nm). The molar absorptivities of these two complexes are highest at 375 nm (Ni) and 660 nm (V), and these wavelengths are therefore used for their determination. Of the co-extracted complexes, only the violet–blue copper(II) complex shows an absorption maximum in the visible region at 540 nm.

Choice of solvent

Chloroform, carbon tetrachloride, benzene, toluene, methyl isobutyl ketone (MIBK) and n-butyl acetate were tried as solvents. BHPDE is readily soluble in chloroform, but sparingly in the rest. Iron(II) and vanadium(IV) are quantitatively extracted by all six solvents, and iron(III) by all except n-butyl acetate and MIBK. Nickel(II) is quantitatively extracted only into chloroform and toluene. Chloroform gives a clean separation and the highest absorbance for all the complexes and is therefore used in all the determinations.

Reagent concentration

The effect of varying the concentration of the BHPDE solution was examined over the range 1–50 mg/ml. Complete extraction of iron(II), iron(III) and vanadium(IV), without variation in absorbance, was obtained with 17.5–25-mg/ml reagent, corresponding to about 550–800-fold molar ratio of reagent to metal, and the range for nickel was 15–25 mg/ml. A 20-mg/ml solution (600-fold molar ratio to metal) is recommended. The order of addition of the reagents is not critical.

Spectral data

Table 1 summarizes the calibration and other data. The use of hydroquinone in the iron(II) determination ensures complete reduction of any iron(III) to iron(II).[16] For freshly prepared iron(II) solutions hydroquinone has no effect on the absorbance during the determination, whereas for solutions kept for more than one day, a lower absorbance is observed if no hydroquinone is present. The decrease is due to the presence of iron(III) [from aerial oxidation of iron(II)], which forms a complex having lower molar absorptivity at 445 nm.

Effect of diverse ions

The separation factors of various metal ions with respect to iron(II) and iron(III), nickel(II) and vanadium(IV), for extraction with 20-mg/ml BHPDE/$CHCl_3$ solution are given in Table 2. Alkali and alkaline earth metal ions, Mn(II), Ti(III), Ti(IV), La(III), Nb(V) and W(VI) are not extracted under the conditions used. Copper is quantitatively co-extracted with vanadium and iron, and palladium, mercury and gold are quantitatively co-extracted with iron. Vanadium and nickel are not co-extracted with iron, and can be separated from it in very dilute acid solution. Vanadium and nickel are co-extracted with each other under the conditions used for vanadium. However, vanadium is not extracted below pH 5, whereas nickel is about 70% extracted at this pH. A triple extraction of nickel at this pH gives practically complete separation from vanadium. These separation methods were tested with mixtures of iron and vanadium or nickel, and of vanadium and nickel. Recovery was quantitative and the results were reproducible, as shown in Table 3.

The effect of some ions in the determination of iron(II), nickel(II) and vanadium(IV) by the recommended photometric procedures was examined. Chloride, sulphate, perchlorate, nitrate, alkali and alkaline earth metal ions in up to 5000-fold amount (w/w), and Zr(IV),

Table 1. Spectral data for the complexes with BHPDE

Parameter	Fe(II)	Fe(III)	Ni(II)	V(IV)

Composition of the complex

Job's method indicates a 1:2 and 1:1 metal:ligand mole ratio for the iron(II) and iron(III) complexes respectively. For the nickel-(II) and vanadium(IV) complexes a 1:2 mole ratio is observed in the pH range 5–10 and a 1:1 ratio at pH 11–13. This supports the $Fe^{II}(H_2B)_2.2X^-$, $Fe^{III}(H_2B)(OH)_2.X^-$, $Ni(HB)_2$, $VO(HB)_2$, NiB and VOB stoichiometries postulated from the log–log plots of

distribution ratio *vs.* ligand concentration at constant ionic strength. The structure suggested for the extracted iron(II) complex is octahedral, probably distorted, in which the two neutral BHPDE molecules lie in an equatorial plane, with two water molecules *trans* to each other. It is possible, of course, that the complex is not an ion-association species, but a mixed-ligand compound, in which case the two X^- ions would occupy the *trans*-positions on the octahedron. The structure of the iron(III) complex is more difficult to predict: it could be an ion-association complex analogous to that proposed for iron(II), or a mixed-ligand complex $Ni(HB)_2$ and NiB are possibly octahedral and square complexes with the ligand exhibiting terdentate and quadridentate co-ordination respectively. These geometries have been reported[11,19] for some copper(II) complexes prepared with analogous reagents in non-aqueous solvents. A square pyramidal structure is suggested for both the $VO(HB)_2$ and the VOB complexes.

Applications

The recommended procedures were tested with synthetic solutions and the pulp of the cormel of an edible cocoyam species, *Colocasia antiquorum*, in which 0.053–0.054% iron and 0.330–0.332% nickel were found present in air-dried samples. The relative standard deviations for seven replicates were 0.8 and 1.0% for iron and nickel respectively. The results agreed with those obtained by the 1,10-phenanthroline and dimethylglyoxime methods,[16] (0.052–0.054% iron and 0.331–0.334% nickel, relative standard deviations 1.1 and 1.2% for seven replicates). The results for the synthetic solutions are given in Table 5.

SPECTROPHOTOMETRIC DETERMINATION OF VANADIUM IN DIFFERENT OXIDATION STATES WITH PYROGALLOL

N. IRANPOOR, N. MALEKI, S. RAZI and A. SAFAVI
Department of Chemistry, College of Sciences, Shiraz University, Shiraz, Iran

(*Received* 23 *August* 1989. *Revised* 17 *August* 1991. *Accepted* 29 *August* 1991)

Summary—Determination of vanadium at low concentrations is easily performed with pyrogallol as a ligand which forms a bluish-violet complex with vanadium(III), (IV) or (V). The colour of the bluish-violet complex (λ_{max} = 580 nm) contrasts well with the colour of both pyrogallol and vanadium. The complexes are stable for several hours. Beer's law is obeyed over the range 0–14 μg/ml vanadium at pH 6. The apparent molar absorptivity at 580 nm is $(7.75 \pm 0.25) \times 10^3$ l.mole^{-1}.cm^{-1}. The effects of diverse ions on the determination of vanadium have been fully studied. Only Mo(VI) and W(VI) interfere seriously. The method is selective, sensitive and can be applied to the determination of total vanadium in a variety of samples.

Although there are a number of methods proposed for the spectrophotometric determination of vanadium,[1–7] only a few are sufficiently selective to be useful[4] and most can determine only one oxidation state. Determination of total vanadium often requires converting all the oxidation states to a single state.

Reagents with suitably located nitrogen and/or oxygen donor atoms can be useful chelating agents for vanadium determination.[4] It has been proposed[8] that pyrogallol forms a complex with V(V) and this was made the basis for determination of up to 2 μg/ml of V(V). During our studies on the use of organic reagents in analysis, we observed that pyrogallol gives a bluish-violet complex with vanadium in oxidation states (III), (IV) and (V) at pH 6. This observation led us to develop the method described below.

EXPERIMENTAL

Reagents

*Pyrogallol solution, 1*M. Prepared on the day of use (to minimize aerial oxidation) by dissolving 12.6 g of pyrogallol (Merck) in triply distilled water and diluting to 100 ml.

Vanadium(V) solution, 1000 μg/ml. Prepared by dissolving 2.296 g of ammonium metavanadate (Merck) in distilled water and diluting to one litre, and standardized.[9,10]

Vanadium(IV) solution, 1000 μg/ml. Prepared by dissolving 1.776 g of vanadyl sulphate monohydrate (Merck) in distilled water and diluting to 500 ml, and standardized.[9,10]

Vanadium(III) solution, 1000 μg/ml. Prepared by dissolving 1.545 g of vanadium trichloride (Merck) in 500 ml of distilled water, and standardized.[9,10]

Standard stock solutions of other metal ions (10 mg/ml) were prepared by dissolving the nitrate or chloride in water or dilute hydrochloric acid.

An acetic acid–sodium acetate buffer solution (pH 6) was used.

Apparatus

The absorption spectra were recorded on a Varian Cary-118 instrument, with one-cm glass cells. The absorbances at a fixed wavelength were measured with a Bausch and Lomb Spectronic 70 spectrophotometer.

Procedure

A known volume of sample containing 10–350 μg of vanadium (in oxidation state III, IV or V) is placed in a 25-ml standard flask, 5 ml of buffer (pH 6) and 10 ml of 1*M* pyrogallol solution are added, and the solution is made up to the mark with distilled water and mixed. The absorbance at 580 nm is measured against a reagent blank solution.

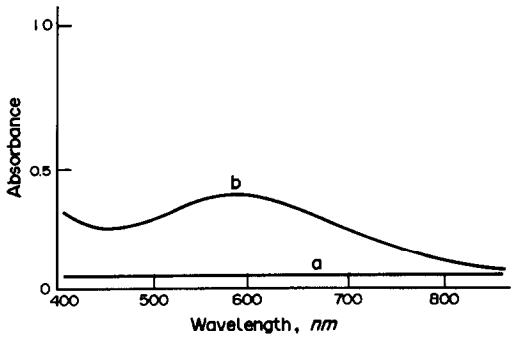

Fig. 1. Absorption spectra of (a) pyrogallol, (b) pyrogallol–vanadium complex (10 μg/ml vanadium).

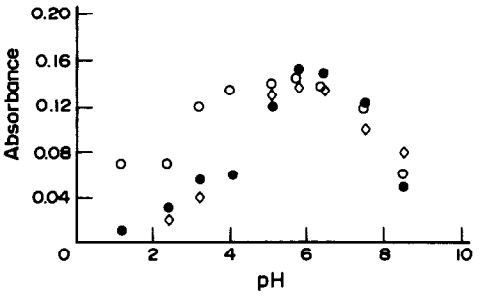

Fig. 2. Effect of pH on complex formation: (○) V(III), (●) V(V), (△) V(IV).

RESULTS AND DISCUSSION

The absorption spectra of the complex and the reagent blank are shown in Fig. 1. As neither vanadium nor the ligand show absorption at 580 nm, this wavelength was chosen for absorbance measurement of the complex.

Optimization of conditions

The absorbances of the complexes at 580 nm were found to be maximal in the pH range 5–6.5 (Fig. 2). The absorbances were found to be practically unaffected by changes in temperature or ionic strength.

A final pyrogallol concentration of at least 0.4*M* was found necessary for practically complete complexation.

Beer's law and molar absorptivity

The formation of the complex is instantaneous and its absorbance remains constant for at least 6 hr irrespective of the vanadium oxidation state. The calibration graph is linear with the regression equations

$$A = 0.043 + 0.115\,[\mathrm{V(V)}]$$
$$A = 0.016 + 0.116\,[\mathrm{V(IV)}]$$
$$A = 0.040 + 0.113\,[\mathrm{V(III)}]$$

where the concentration is expressed in μg/ml. Beer's law is obeyed for vanadium concentrations up to 14 μg/ml in the final solution, and the molar absorptivity is $(7.75 \pm 0.25) \times 10^3$ $\mathrm{l.mole^{-1}.cm^{-1}}$ for all three vanadium oxidation states. The detection limit (defined as the concentration corresponding to the average absorbance of the blank plus 3 times its standard deviation) was found to be 47 ng/ml vanadium in the final solution. By this method the three oxidation states of vanadium can be determined without a preliminary oxidation or reduction step. The analytical figures of merit for determination of vanadium by the proposed method and some other spectrophotometric methods are compared in Table 1.

Composition of the complex

The ratio of vanadium to pyrogallol was determined by the mole ratio[11] and continuous variation methods.[12] The results obtained show the formation of a 1:2 (metal:pyrogallol) complex. This is the case for all three oxidation states of vanadium at ph 6. It is assumed that

vanadium(III) is oxidized to vanadium(IV) by dissolved oxygen and that vanadium(V) is reduced by the pyrogallol [the maximum in the Job plot occurs at a mole fraction of 0.74 for pyrogallol, corresponding to a 1:2 complex and reduction of two V(V) by one pyrogallol molecule].

Interferences

The criterion for interference was a change of ±2% in the absorbance of 10 μg/ml vanadium(V) in the presence of a large excess of pyrogallol.

The effects of various anions and complexing agents on the absorbance of the complex were studied, as shown in Table 2. No interference was observed from 10^4 μg/ml concentrations of most of the common anions and complexing agents studied. Only sulphide and cyanide interfere with the determination of vanadium. Sulphide interference is removed by precipitation of zinc sulphide. Cyanide forms a precipitate with Fe(II).[13] These precipitates were filtered off before the addition of pyrogallol.

Table 4. Results for determination of total vanadium

Taken, μg/ml			Total vanadium found, μg/ml
V(III)	V(IV)	V(V)	
1.0	1.0	1.0	2.90
1.0	1.0	1.6	3.61
1.5	1.0	1.0	3.24
1.0	1.0	2.0	4.00
1.0	2.0	1.0	3.91
1.0	2.0	1.5	4.45
2.0	2.5	2.5	7.02

The tolerance limits for various cations in the determination of 10 μg/ml vanadium(V) were studied. Levels of 2000 μg/ml of Mg(II), Ca(II), Sr(II), Ba(II), Zn(II), Cd(II), Hg(II), Co(II), Cu(II), Cu(I), Ni(II), Pd(II), Al(III), Tl(I), La(III), Mn(II), Ce(III), Te(IV), Sb(III), Y(III) did not show any interference. Au(III), Ag(I), Pb(II), Fe(II), Fe(III) and Cr(III) at concentrations >500 μg/ml interfered with the determination. Their effects were removed by adding 5–10 ml of saturated ammonium thiocyanate solution to the test solution (Table 3). Fe(III) and Fe(II) complexes of thiocyanate can be extracted into MIBK. The interfering effects of Zr(IV) and Th(IV) can be removed by the addition of ammonia solution to give pH 8. The precipitated hydroxides are separated before adjustment of the pH to 6 and addition of pyrogallol. Hg(I) and Bi(III) are removed from the solution by precipitation with saturated sodium fluoride solution.[14] Although Sb(III) does not have any interfering effects, Sb(V) interferes seriously. The effect of this interference is easily removed by the addition of sodium dithionite to the solution to reduce Sb(V) to Sb(III) prior to the addition of pyrogallol. Of the 30 metal ions studied, only molybdenum and tungsten are found to interfere.

Determination of total vanadium

Since pyrogallol reacts with the three oxidation states of vanadium(III, IV, V) to give the same complex, which absorbs at $\lambda_{max} = 580$ nm, attempts were made to determine total vanadium in mixtures of the three forms. The result in Table 4 shows that the recommended procedure can be applied to the determination of total vanadium wthout any pretreatment.

Table 5. Analysis of samples by the proposed method

(*Received* 4 *March* 1991. *Revised* 29 *March* 1991. *Accepted* 12 *April* 1991)

Summary—A flow-injection analysis technique based on stop flow coulometric titrations is described, utilizing a gradient chamber, reagent generation chamber, and detector flow cell integrated into a single unit. The use of stop flow allowed for automated sample dilution up to a factor of 100 times. The system has been used to titrate samples of sodium hydroxide in the range 5×10^{-4}–$4M$, and nitric acid ranging from 5×10^{-3}–$15M$. Analyses over the entire range of concentrations yielded a relative standard deviation of less than 3%. A correlation coefficient of 0.999 was obtained for all comparisons with manual titrations. Remote spectrophotometric detection was performed with optical fibers. No frit or membrane is required to separate the generating and counter electrodes within the system, yet the advantages of conventional coulometric titration, which eliminate the problems of reagent and calibration solution handling, storage or degradation, are retained.

Flow-injection analysis (FIA) titrations represent a well known and widely used technique, especially in the field of industrial process monitoring.[1–5] This technique has gained acceptance due to its relative simplicity and good accuracy. Although these titrations are often used in FIA, the area of coulometric titration has gained very little attention. Feher and co-workers coulometrically generated a reagent which was subsequently merged with a carrier stream to perform triangle titrations of phenothiazine compounds.[6] Ruttinger and Spohn incorporated a coulometric titration cell and a flow through detector into a single component.[7] Ilcheva and Dakahev reported a coulometric detection cell for use in an FIA system.[8] Liang described a method of performing Karl Fischer titrations coulometrically in a close loop system.[9] In this paper we describe a novel stopped flow technique which is applicable to a wide variety of chemistries and incorporates a method of automated dilution. A gradient chamber and a detector flow cell are integrated into a single unit, allowing for detection at the site at which dilution and chemical reaction occurs (Fig. 1).

In conventional FIA titrations a pair of equivalence points, located on the leading and trailing edge of a dispersed sample zone, is identified (Fig. 2). The distance between these points (measured in time, Δt) at a constant flow-rate (Q) has been shown to be a function of the concentration of the sample,[1] such that

$$\Delta t = (V_m/Q) \ln 10 \log \{C_s^0/(C_T^0 n)\} + (V_m/Q) \ln 10 \log \{S_v/V_m\} \quad [1(a)]$$

where V_m is the volume of the mixing chamber, C_T^0 is the concentration of the titrant, C_s^0 is the concentration of the injected sample, n is the stoichiometric factor of the reacting components, and S_v is the volume of the injected sample (Fig. 1). In a system with a carrier of constant concentration, and a fixed sample and flow volume, the peak width (Δt) is related to the sample concentration (C_s) by the equation

$$\Delta t = (k_1) \log C_s + k_2 \quad [1(b)]$$

where k_1 and k_2 are constants. Thus, in conventional FIA titrations the peak width is directly proportional to the logarithm of the sample concentration.

The relationship described above is due to the concentration gradient produced by the zone dispersion within a mixing chamber, the volume (V_m) of which dominates the volume of the flow system. By injecting a sample, the concentration of which (C_s) is much higher than that of the titrant (C_T) in the carrier stream, the elements of the dispersal zone are gradually neutralized, until an equivalence point is reached at the leading and the trailing edge of the dispersal

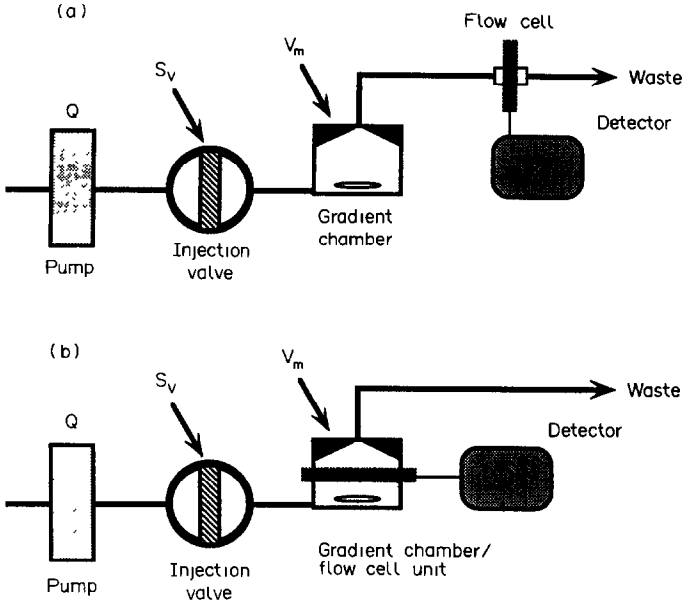

Fig. 1. FIA system for titration. In a conventional FIA titration system (1A) detection occurs downstream of the gradient chamber. For the stop flow coulometric titration technique, detection occurs at the gradient chamber (1B) where titrant is produced and chemical reaction takes place. Q = volumetric flow-rate, S_v = sample volume, V_m = chamber volume.

zone (Fig. 2). This approach, though widely used, has two disadvantages: (1) the distance between the points (Δt) is a logarithmic function of the sample concentration; and (2) the bulk of the injected sample (shaded area, Fig. 2) remains untitrated. It was Pardue and Fields[10,11] who first pointed out the second disadvantage, which seriously limits the accuracy and operational range of the flow-injection titration, since it necessitates the use of a diluted (and therefore less stable) titrant when extending to less concentrated samples.

It is proposed here to eliminate the above disadvantages by introducing a combination of stopped flow with the coulometric technique.

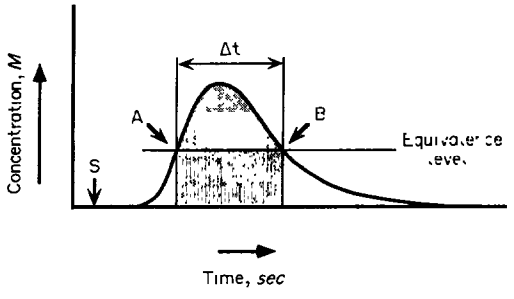

Fig. 2. Conventional FIA titration. The dispersed zone contains two equivalence points (A and B). The distance between them (Δt) is the measured parameter and is proportional to the logarithm of the sample concentration. The shaded portion of the zone represents the portion of the sample which is not titrated.

By stopping the flow at a suitable delay time following sample injection the sample zone will be arrested within the mixing chamber. If the detection and coulometric reagent generation are performed within the mixing chamber, all sample material will be reacted, as in conventional titrimetry. In addition, by selecting an appropriate delay time, a desired trailing section of the dispersal zone can be captured within the chamber, thus allowing automated dilution prior to titration, *i.e.* a selected portion of the injected sample is titrated.

In a coulometric titration,[12] reagent is produced by the application of a current at an appropriate electrode to an electrolyte. Through control of the current and time a precise amount of reagent is produced at a specified rate. The amount of reagent produced may be calculated with Faraday's Law of Electrolysis, which states that the quantity of electricity passed through a cell is directly proportional to the quantity of chemical change that occurs at the cell electrode.[13] The mathematical expression of this law, when applied to a constant current system, is

$$N = Q/nF = it/nF \qquad [2(a)]$$

where N = moles of substance, Q = total charge passed (coulombs, C), n = number of electrons transferred per molecule (equivalents, eq), i = current (amps), t = time (sec), and F = Faraday's constant (96,485 C/eq). By

measuring the time required to reach the titration endpoint and knowing the value of the constant current applied, the amount of reagent generated and reacted to reach the endpoint can then be calculated. Thus the measured parameter, Δt, the time from the initiation of electrolysis to the titration endpoint, is directly proportional to the sample concentration, as seen by rearrangement of equation [2(a)] to

$$\Delta t = NnF/i = C_s S_v nF/i = kC_s \quad [2(b)]$$

where k is a constant.

In this study the electrolysis of water was used to generate reagent for acidobasic titrations. The half reactions which occur are, at the anode

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^-$$

and, at the cathode

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^-$$

When a very large degree of mixing of a segment of a flow system is required, it may be achieved by using a mixing chamber. The chamber allows for the homogeneous dispersion of a flow segment into a much larger portion of the system fluid. This is achieved through the use of an externally driven mechanical stirring mechanism inside the chamber.

The gradient chamber has long been implemented in FIA systems.[1] Previously, the gradient chamber was used to form a reproducible concentration gradient at the outlet of the chamber. This implies that the portion of the sample remaining in the gradient chamber at a specific time is reproducible. Therefore, instead of placing a detector downstream of the gradient chamber, detection at the chamber itself would allow for detection of the homogeneous zone of the system and would result in a simplified system where the mixing chamber and detector flow cell are integrated into a single component. The dilution possibilities presented by the concentration gradient are retained through the use of stop flow, which provides the ability to isolate a predetermined portion of the sample within the chamber by stopping the flow at a specific time.

An FIA system has been viewed as following the tanks-in-series model,[14] introduced by Dankwerts.[15] The volume of the mixing chamber (V_m) completely dominates the system volume, and therefore the system behaves as a single mixing tank while the volume of the injected sample (S_v) is small. At any time t after the point at which the entire sample has entered the chamber (t_0), the concentration of a component of the fluid (C) is represented by the equation

$$C = (1/T_i)e^{-t/T_i} \quad (3)$$

where T_i is the mean residence time of a component of fluid in the tank. For a gradient chamber, the mean residence time is dependent upon the volume of the chamber and the volumetric flow-rate, such that

$$T_i = V_m/Q \quad (4)$$

Previously in FIA, equation (3) was used to model the concentration of an analyte at the effluent of a gradient chamber.[1] In the present case, however, the portion of the sample remaining inside the gradient chamber will be titrated. A representation of the area under the curve of the concentration profile produced (Fig. 3) is therefore needed. The area under this

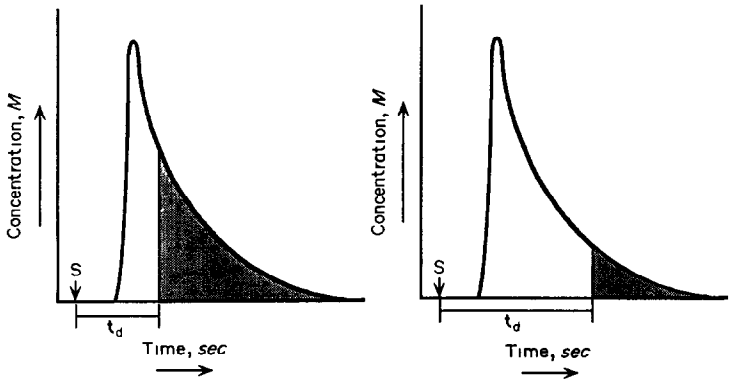

Fig. 3. Detector response to sample concentration within a gradient chamber. Response after all the sample has entered into the chamber conforms to a single tank in the tanks-in-series model. By selecting an appropriate delay time (t_d), a desired trailing section (shaded) of the zone may be arrested within the chamber and analyzed, thus providing a method of automated dilution.

curve can be integrated for any time interval after time = t_0, as

$$\int_t^{\infty} (1/T_i)\, e^{-t/T_i}\, dt \qquad [5(a)]$$

which yields the equation

$$C_t = e^{-t/T_i} \qquad [5(b)]$$

The dilution which occurs in the system can be described by the inverse mole ratio (X^{-1}), introduced by Whitman and Christian,[16] which is defined as

$$X^{-1} = n^0/n_{det} \qquad (6)$$

where n^0 is the number of moles injected and n_{det} is the number of moles detected.

By defining n as a product of molar concentration and volume, then at a constant sample volume (S_v), X^{-1} can be redefined as the ratio of molar concentrations

$$X^{-1} = C^0 S_v / C_{det} S_v = C^0/C_{det} \qquad (7)$$

By substituting equation [5(b)] into equation (7), where $C^0 = C_t$ when $t = 0$ and $C_{det} = C_t$ when $t \geq t_0$, the result is

$$X^{-1} = C^0/C_{det} = e^{-0/T_i}/e^{-t/T_i} = e^{t/T_i} \qquad (8)$$

Thus the portion of a sample remaining in the gradient chamber and the inverse mole ratio can be easily calculated at any time during which the response curve follows the given model. The degree of dilution obtained can be predetermined by calculation and controlled through the use of the stop flow technique.

EXPERIMENTAL

Reagents

The carrier for all titrations was an aqueous solution of 0.5M Na_2SO_4 (Mallinckrodt) containing bromothymol blue (BTB) (Merck) as the indicator at a concentration of 0.04% (w/v). For titrations of base, the carrier was made slightly basic with sodium hydroxide and for titrations of acid it was made slightly acidic with nitric acid. This was done to prevent any neutralization of the sample by the carrier. Appropriate dilution of concentrated nitric acid (J. T. Baker) with demineralized water was used to prepare nitric acid samples for titration. Appropriate dilution of a 5M sodium hydroxide (J. T. Baker) solution with demineralized water was used for all sodium hydroxide samples. Potassium acid phthalate (Allied Chemical) was used as a primary standard for manual titrations. For experiments determining the effects of flow-rate and chamber volume the carrier was 0.01M sodium borate (J. T. Baker) and 0.40% (w/v) BTB was injected as sample.

Apparatus

A single line FIA manifold (Fig. 4) was used in all experiments. The pump was an Alitea C4-XV peristaltic pump with a remote controller. A Rheodyne Type 5701 pneumatic actuator was used with a Rheodyne Type 50 4-way injection valve furnished with a 19-μl sample loop.

The PTFE tubing connecting the mixing chambers and the chamber containing the counter electrode had an inner diameter of 1.3 mm, while all other tubing had an internal diameter of 0.82 mm.

Stirring in the gradient chamber was performed by means of a TRI-R model MS-7 magnetic stirrer. The gradient chamber was 10-mm inner diameter glass tubing with end caps constructed of PTFE, equipped with a miniature stirring bar (Fig. 5). The net chamber volume could be varied by adjustment of the end cap positions.

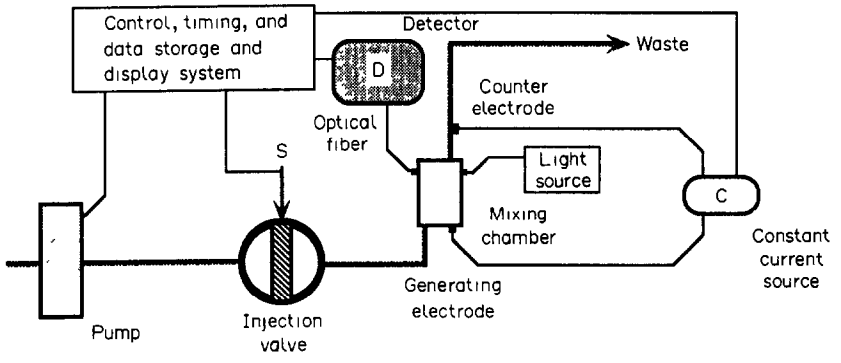

Fig. 4. Stop flow coulometric titration system. Light is transmitted from the light source, across the gradient chamber, and to the detector via optical fibers. The injection valve, pump, and constant current source are controlled by computer.

The generating and counter electrodes were 1.2-mm diameter platinum wire. The 3.4-cm generating electrode was coiled at the bottom of the mixing chamber (Fig. 5), with a total surface area of 1.3 cm^2. The counter electrode was placed in a separate chamber downstream of the mixing chamber. The connecting tubing was 4 cm long. The electrodes were connected to a laboratory built constant current source with four current settings (0.78–3.90 mA, current densities of 0.60–3.0 mA/cm^2). Current was continuously measured with a Dynascan 2830 Digital Multimeter connected in line in the constant current source circuit. Current was switched by a relay between the electrodes and a variable resistor which was used as a "dummy cell" in order to have continuous current flow in the current source.

The detector was a Bausch & Lomb Spectronic Mini 20 spectrophotometer. The output was directed to an electronic low-pass filter and a linear amplifier and then through the DACA interface board to the computer where the transmittance signal was converted to absorbance. A Volpi Intralux 4000 external light source with a variable intensity control was used. Light was directed from the external light source via a 45-cm long, 5.56-mm diameter optical fiber bundle (Volpi), across the chamber, and collected and directed to the spectrophotometer via a 45-cm long, 3.18-mm diameter optical fiber bundle (Twardy) (Fig. 5).

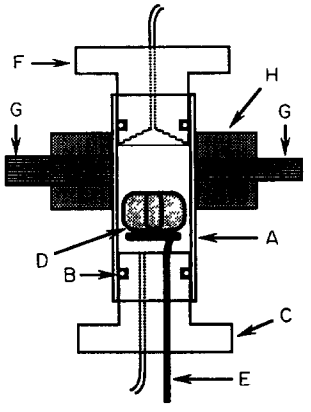

Fig. 5. Integrated flow cell, gradient chamber, and reagent generation chamber. The body of the chamber (A) is 10 mm i.d. glass tubing. The PTFE end caps (C & F) are sealed with O rings (B). The chamber is mounted vertically with the inlet cap (C) on the bottom. The star-shaped stirring bar (D) rests atop the coiled generating electrode (E). The outlet cap (F) is domed to prevent any air bubbles which may enter the chamber from becoming trapped. Light is transmitted across the chamber and collected by optical fiber bundles (G) which are held in place by the chamber mounting bracket.

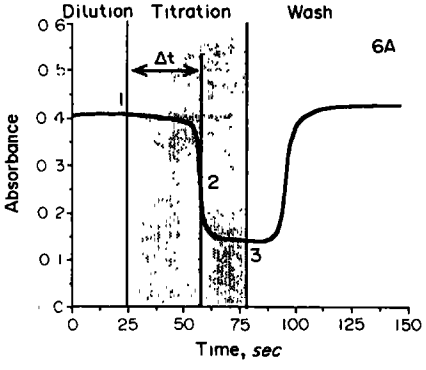
The pump controllers, injection valve actuator, and constant current source were controlled and data were collected with an IBM Data Acquisition and Control Adapter (DACA) in conjunction with an IBM XT computer.

General procedure

The following steps were performed for each titration: (1) a sample or blank (H_2O) was injected into the carrier containing electrolyte and indicator; (2) at a specified delay time the flow was stopped, causing a selected portion of the sample to be arrested in the chamber; (3) at that time a current was applied, electrochemically producing reagent for the titration; (4) a titration endpoint was reached and the current stopped; (5) after sufficient time for the endpoint to have been reached, the flow was resumed to flush out the chamber. This automated sequencing was controlled by an IBM XT computer with the



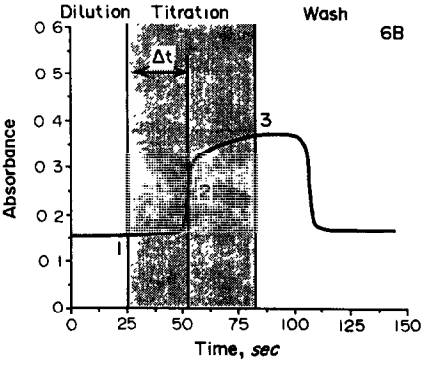


Fig. 6. FIA profiles of titrations of 0.0500M sodium hydroxide (6A) and 0.0600M nitric acid (6B), at a current of 0.78 mA each, with Sv = 19 μl, Vm = 0.930 ml, and Q = 4.23 ml/min. At the delay time after injection (25 sec) at which the desired dilution has been obtained (X^{-1} = 4.78), the flow is stopped and current is applied to begin titration (1). After an endpoint (2) is reached and titration is completed, current is turned off and flow is resumed to flush the chamber (3). The titration curve, corresponding to that obtained in conventional titrations, is indicated by the shaded area. The time from start of reagent production to the inflection point (Δt) is the parameter measured from the FIA profile.

general FIA control software of Clark *et al.*[17] This software could also display the first derivative of the FIA profile, which was used to determine the titration curve inflection point, and thus Δt. The FIA profiles for an acid and a base titration are shown in Fig. 6. The end-point was detected at a wavelength of 620 nm.

RESULTS AND DISCUSSION

The initial set of experiments was performed to determine the parameters of the single mixing tank model for our system and to enable the calculation of the dilution achieved at any specific delay time. Samples of BTB dye ($S_v = 19$ μl) were injected into a 0.01M borax carrier stream, at different flow-rates (2.83–4.88 ml/min), with a chamber volume of 0.900 ml, and at a carrier stream flow-rate of 2.9 ml/min with various chamber volumes (0.64–1.10 ml). The area under the absorbance profile at various delay times where $t_d > t_{max}$ was ratioed with the area at the peak maximum (t_{max}) to give X^{-1},

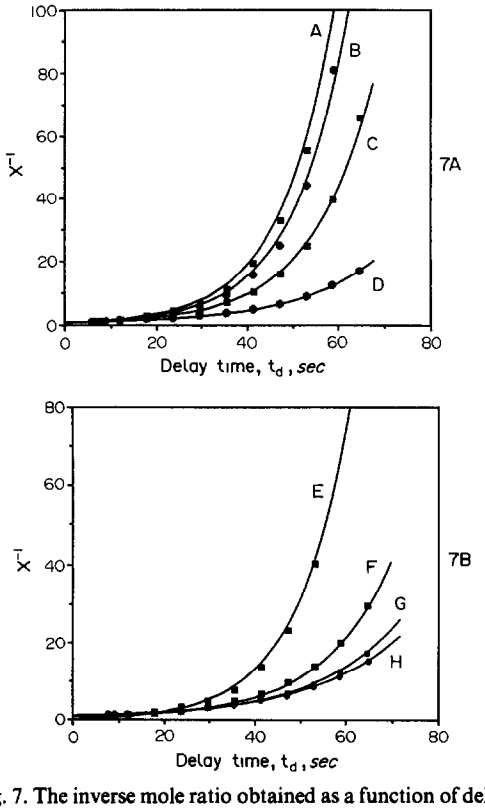

Fig. 7. The inverse mole ratio obtained as a function of delay time for various values of volumetric flow-rate and chamber volume. In 7A the chamber volume was 0.900 ml with flow-rates of (A) 4.88 ml/min, (B) 4.24 ml/min, (C) 3.95 ml/min and (D) 2.83 ml/min. In 7B the flow-rate was 2.83 ml/min with chamber volumes of (E) 0.635 ml, (F) 0.780 ml, (G) 0.900 ml, (H) 1.10 ml.

Table 1. Comparison of the mean residence times calculated ($T_{i,cal}$) with the mean residence times experimentally determined ($T_{i,exp}$)

Q, ml/min	Vm, ml	$T_{i,cal}$, sec	$T_{i,exp}$, sec
4.88	0.900	11.1	11.3
4.24	0.900	12.7	12.5
3.95	0.900	13.7	14.0
2.83	0.900	19.1	19.8
2.83	1.10	23.2	22.8
2.83	0.900	19.1	19.8
2.83	0.780	16.5	16.8
2.83	0.635	13.6	13.4

which was then plotted against delay time for each combination of flow-rate and chamber volume (Fig. 7). The equation of each of the resulting curves was of the form

$$X^{-1} = k_1 e^{k_2 t_d} \tag{9}$$

The mean residence time, which is $1/k_2$ [as seen from equation (8)], from each curve ($T_{i,exp}$) was in close agreement with the values calculated from the measured values of the flow-rate and the chamber volume ($T_{i,cal}$) (Table 1). The value of k_2 is dependent upon the flow-rate and the chamber volume. Each equation also included a constant, k_1, which was a factor to correct for the time required for the trailing portion of the injected sample to enter the gradient chamber, where the detection profile deviates from the ideal of the model, which assumes that the entire sample is in the mixing tank at time zero. The value of k_1 is dependent upon the flow-rate, the chamber volume, the sample volume and all other factors governing the dispersion of the sample zone prior to entering the chamber. It is thus observed that the shape of the X^{-1} curve does follow the single tank of the tanks-in-series model and, after all of the sample has entered into the chamber, is dependent only upon the chamber volume and the system flow-rate. Thus the amount of dilution obtained at a specific stop time can easily be predicted and controlled by adjustment of either of these two parameters.

Once determined for a given set of conditions (V_m, Q, S_v, *etc.*), the equation defining X^{-1} can be used to determine the degree of dilution obtained at a delay time after all the sample has entered into the chamber. The X^{-1} is used in conjunction with Faraday's law to calculate the amount of analyte in the injected sample, obviating the need for standards.

For all further experiments the flow-rate was 4.23 ml/min and the chamber volume of 0.930

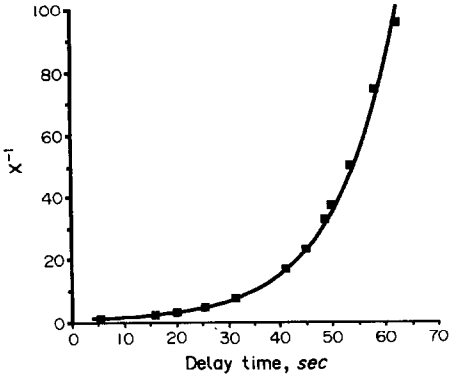

Fig. 8. The inverse mole ratio obtained as a function of delay time for the titration of 0.0200*M* NaOH. The system flow-rate was 4.23 ml/min and the chamber volume was 0.930 ml.

ml was used. Demineralized water was used as a blank for all titrations. Current values ranged from 0.7 to 4 mA. It should be noted that at high current densities, generating electrode reactions involving gases, as here, may result in increased noise levels if the gas solubility level is exceeded, which would allow bubble formation. Bubble formation was observed at currents of approximately 20 mA.

Samples of 0.0200*M* sodium hydroxide ($S_v = 19$ μl) were injected and titrated with various delay times. The resulting X^{-1} values were plotted versus their respective delay times (Fig. 8). The equation of this plot had the form of equation (9), demonstrating compliance with the given model. The greatest portion of the sample arrested in the chamber was 92%, or an X^{-1} of 1.086, at a delay time of 5.02 sec.

The results of a series of titrations performed on the described system were compared with the corresponding manual titrations. For the manual titrations, a sodium hydroxide solution was standardized against potassium acid phthalate and was used as a titrant for all acid samples. For titrating all base samples, a nitric acid solution was standardized with respect to the sodium hydroxide secondary standard solution. Titrant solutions were standardized daily prior to use.

Titration of samples ranging in concentration from 5×10^{-4}–$8 \times 10^{-2}M$ sodium hydroxide was performed with a stop time of 5.25 sec. A linear relationship was obtained from plotting the results against the equivalent manual titration, with an intercept of 1.9×10^{-3}, a slope of 0.989 and $R^2 = 0.999$.

Additional samples at concentrations up to 4.14*M* sodium hydroxide were titrated using

Table 2. Experimental data of the coulometric titration of nitric acid (see Fig. 6). For all samples: $S_v = 19$ μl, $V_m = 0.930$ ml, $Q = 4.23$ ml/min. t_d = delay time, Δt = titration time, i = current, Conc. = concentration, rsd = relative standard deviation

t_d, sec	Δt, sec	i, mA	Conc, M	rsd, %
5.27	14.97	0.785	0.00760	1.1
5.27	37.78	2.28	0.0539	1.2
5.27	44.70	3.84	0.110	0.6
16.79	37.28	3.59	0.182	0.3
28.51	27.11	3.58	0.420	1.9
40.23	19.18	3.85	0.851	1.6
50.00	14.02	3.84	1.43	0.5
50.00	21.83	3.88	2.24	1.3
62.50	6.38	3.85	3.44	1.8
62.50	8.59	3.87	4.66	2.8
62.50	14.45	3.78	8.65	1.9
62.50	17.24	3.80	9.16	1.9
62.50	19.95	3.83	10.7	2.8
62.50	23.37	3.82	12.5	2.9
62.50	27.28	3.83	14.6	2.5

various stop times such that the entire analysis time, including flushing the chamber, was 180 sec. The time allotted to flush the chamber was 70 sec for all titrations, which was slightly greater than five times the mean residence time for the flow-rate and the chamber volume used. When compared with the manual titration results, the resulting plot was again a straight line with an intercept of 1.5×10^{-2}, a slope of 1.033 and with $R^2 = 0.999$.

By changing polarity of the constant current source, hydroxide ions were produced in the mixing chamber, allowing titrations of an acid. Samples with concentrations up to 14.7*M* nitric acid were titrated (Table 2), with no physical modification of the system. The analysis time was increased to 240 sec for samples with concentrations greater than 5.0*M*. The delay time for all samples with concentrations greater than 3.0*M* was 62.50 sec. When the results were compared with manual titrations, the plot was linear with an intercept of -5.39×10^{-2}, a slope of 0.999 and with $R^2 = 0.999$.

Multiple analyses (≥ 3) were performed for all samples. The relative standard deviation was less than 1.5% for samples with a delay time of 5.02 sec and was less than 3% for samples at a delay time of 62.5 sec. The relative standard deviation tended to increase with an increase in delay time (Table 2). This occurs since any error in stopping the flow had a greater effect on the portion of the sample arrested within the chamber for those samples with the larger delay times, as can be seen in Fig. 8. All comparisons

between the manual and coulometric titrations produced correlation coefficients of 0.999.

CONCLUSIONS

A stop flow coulometric titration technique has been developed and tested. It has been shown to be capable of accurately performing titrations over a wide range of sample concentrations with good precision. The concentration profile produced within the gradient chamber has been shown to follow the tanks-in-series model, allowing for sample dilution of a preselected degree through the use of stop flow. For the first time an actual titration curve is an integral part of an FIA profile (Fig. 6).

The stop flow coulometric titration system has several advantages which enhance its appeal for application in process analysis. In industrial processes analyte concentrations are often very high or may vary over a wide dynamic range. The stop flow coulometric titration system can be used to perform a wide range of dilutions without the need for physical reconfiguration.

The direct proportionality of the measured parameter (Δt) to the concentration of the portion of the sample analyzed, instead of the logarithm of the sample concentration, enhances the precision of the analysis.

The system is mechanically simple, another advantage for use in the industrial environment. It is a single line system, incorporating only one valve and one pump. The gradient chamber, reagent generation chamber, and the detector flow cell are combined into a single component, and the system contains no frits or membranes which are prone to fouling.

The titrant is produced within the system during analysis, thus eliminating the problems of reagent handling, storage and stability. Since unstable reagents can also be produced by electrolysis, a wide range of chemistries can be exploited. Also, calibration solutions are not needed once the system has been characterized, since titrant is produced by electrolysis and the amount of titrant produced for any given current over a given period of time can be calculated. By varying the intensity of the constant current, reagent can be produced at different rates.

The system has been shown to be easily automated and controlled by computer software. The stop flow coulometric titration technique has been demonstrated to be precise and versatile. In the future, a variety of chemistries and detection schemes will be investigated with the aim to exploit them for both laboratory and process control applications.

Summary—This paper describes an investigation of turbomixers as replacements for mixing coils in FIA. The turbomixer is a device that will efficiently mix three streams simultaneously. Although the traditional FIA gradient is not produced, the data shows that the reproducibility of a turbomixer continuous flow system is comparable to a standard FIA system.

For almost two decades, research with continuous flow analysis has followed three basic approaches to automation: segmented flow, non-segmented flow and discrete analysis. Non-segmented or flow-injection analysis (FIA) has become particularly popular because of its ease of operation, speed and flexibility in automating a variety of methods and/or techniques. The basic cornerstones of flow injection are sample injection, reproducible timing and controlled sample dispersion. The most intriguing of the three and the least analytically exploited is the control concept of controllable dispersion and the sample gradient. There have been numerous papers describing the virtues of using the gradient.[1–3] In fact, the gradient has been used to perform many operations and methods unique to FIA.

In reality, few analyses utilize the potential of the gradient. In many cases, the gradient does not offer any significant advantage in terms of increased sensitivity or detectability. Why then should the gradient be formed in situations where it is not needed? This work supports the view that the gradient need not be formed to a large extent in non-segmented systems to be analytically useful in FIA.

For discussion purposes, it is important to recall why the gradient exists in an FIA system. Unlike air-segmented analyzers where the primary objective is to limit dispersion or sample carryover from one segment to a succeeding segment, the objective in FIA is to control the extent and reproducibility of sample zone spreading inside a reaction manifold. Traditionally, this has been accomplished with tubing coils of various lengths and diameters. Thus, dispersion is largely dependent on the physical design of the manifold. The coils also perform two additional functions: (*a*) their shapes help to create mixing currents and (*b*) they create a time delay necessary for some reaction chemistries to develop a measurable product.

The degree of mixing inside an FIA system has been discussed in detail and with very little agreement between practising FIA users. However, if generation of the gradient is not a priority, the primary issue becomes one of how to provide optimal mixing as rapidly as possible.

In retrospect, classical stopped-flow kineticists have been using rapid mixing techniques for several decades and have designed numerous systems to achieve their objectives. It appears that the incorporation of a design we call "turbomixer" provides excellent mixing. These turbomixing cells were incorporated into several non-segmented continuous flow manifolds. This paper presents the observations made comparing classical FIA mixing and turbomixing in non-segmented continuous flow manifolds.

EXPERIMENTAL

All flow rates were generated with standard peristaltic pumps. The turbomixers were fabricated in-house as previously described,[4,5] with

the dimensions given previously,[4,5] using 90° angle jets. The four jet ports may or may not be used, depending on the chemistry. The chemistries tested, except chlorite ion and chlorate ion analysis used standard/accepted protocols. Reagents, concentrations and flow rates were as described previously.[6] The FIA conditions established for chlorite ion and chlorate ion analyses were as described in the literature.[7] Table 1 gives all the dimensions for the manifolds. The turbomixer was simply substituted for the usual FIA reaction coils and manifolds or tees in mixer experiments. Tecator 5020 and 5023 FIA and Spectrophotometer units were used throughout the study. Tecator chemifold three and five were the manifold blocks used in these experiments.

RESULTS AND DISCUSSION

The turbomixer used here was termed a ball mixer by Berger and co-workers.[4,5] The ball is at the confluence of a curved Y mixer, and turbulence is created on the downstream side of the ball, moving back against the ball as the flow increases.[4]

The chemistries tested were chosen to show the relationship between complete mixing and chemistry. The glycerin data is included to show that complete mixing is indeed accomplished with the turbomixing system. A relatively fast ozone chemistry with indigo trisulfonate is presented as a baseline to measure doable, easy to automate chemistries. Nitrite ion measurement with the sulfanilamide/NED chemistry are included to better understand chemistries where measurement requires the formation of an intermediate prior to the formation of a measurable reaction product. Total Kjeldahl nitrogen (TKN) data were gathered to investigate the effect that turbomixing has on neutralizing a highly acidic acid digestion matrix prior to raising the pH of the system for determining the digested organic nitrogen content. *Ortho*-phosphate measurements were made for two reasons: (*a*) to determine if turbomixing prior to heat addition has an effect on product development and (*b*) to investigate whether turbomixing would provide a needed lower detection limit for this chemistry. The oxychlorine measurements were carried out as part of an on-going investigation to improve methods for measuring very low concentrations of disinfection by-products associated with the use of chlorine dioxide for water treatment. These tests require tight pH control, excellent mixing and time for product development as the chlorate ion measurement is second order with respect to acid.

The data presented compare standard FIA manifolds, turbomixing manifolds, and turbomixing manifolds incorporated into a stopped-flow FIA program. For these experiments all stopped-flow experiments mean that the sample plug was stopped external to the flow cell. These conditions were chosen since reaction coils in standard FIA manifolds act both as mixers and time delay devices. The turbomix data demonstrate the mixing capability while the turbomixer stopped-flow data represent optimized

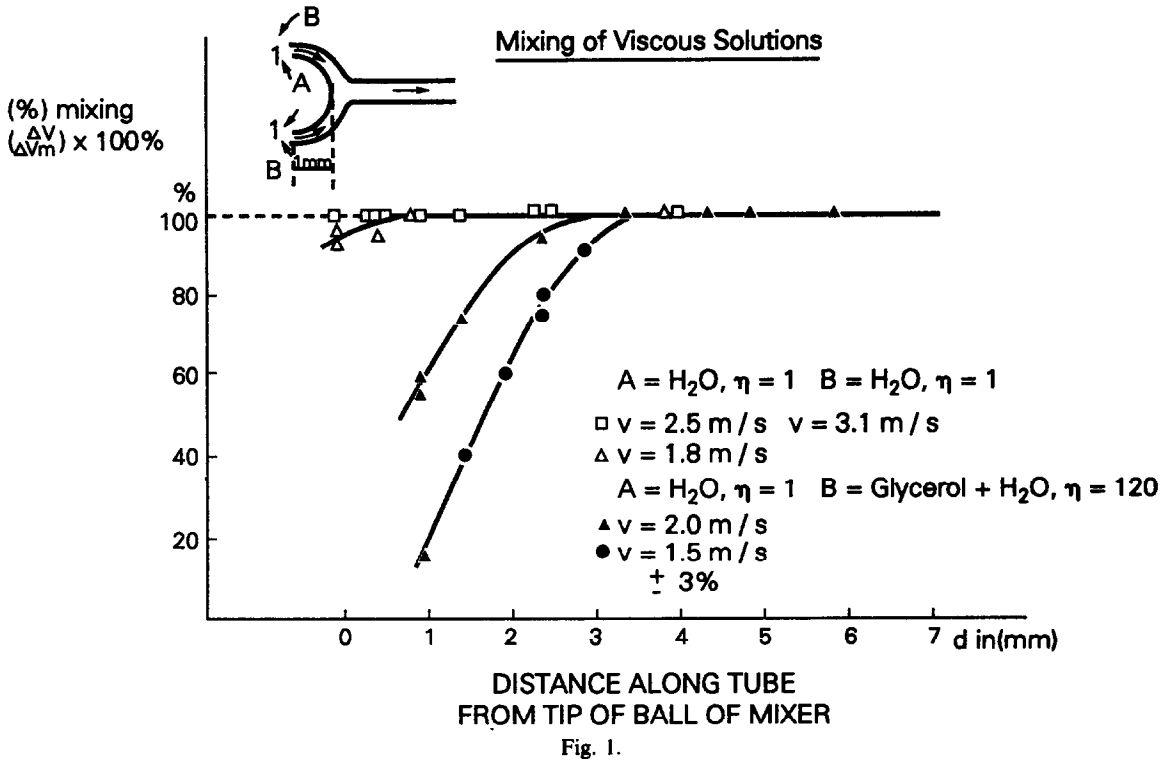

Fig. 1.

reaction conditions. The data in Table 1 represent the best available detection limits and sensitivities obtained for the conditions tested.

Mixing data—glycerin

A good test of mixing is whether the mixer can homogenize two very different solvents. In particular, solvents with viscosity differences seem to be the most difficult to mix in a FIA manifold. The turbomixers have been tested with water and glycerin.[5] Figure 4 (from reference 5) shows that complete mixing is accomplished within the first three millimeters of the turbomixer.

Fast chemistry—ozone

The reaction between ozone and potassium indigo blue is extremely fast. The working range tested was 0.01–1 mg/l. If turbomixers are to provide improved detection limits, it will most likely be observed in a fast reaction where physical mixing is the slow step. The data in Table 2 shows that the turbomixer does provide improved detection limits compared to a straight FIA system. The precision and y-intercepts are comparable. Since the selectivity of the indigo reaction is related to the amount of time the indigo is in contact with the interferent, the selectivity enhancement created by kinetic discrimination is improved by a factor of five.

Chemistries involving intermediate formation—nitrite ion

Nitrite ion data were gathered over the 1–100 mg/l. range. The data clearly show that a time delay is required to form the diazo intermediate by reacting sulfanilamide under acid conditions with nitrite ion before fully developing the measurable product as indicated by the slope and method detection limit values. All three arrangements can be used but the turbomix/stopped-flow combination provides improved sensitivity and correlation. The high RSD calculated with the turbomix set-up could be a result of the absence of time delay (needed for intermediate formation) normally incorporated with coil arrangements.

Complex matrix chemistry—TKN

TKN measurements by gas diffusion were gathered over the 1–10 mg/l. range for the 40-μl injection loop and 0.2–2 mg/l. for the 200-μl injection loop volumes, respectively. Turbomix with stopped-flow was not tested. For both loop volumes the slopes are relatively constant, indicating that both manifolds are efficient in neutralizing the acid matrix. The data also show that the smaller sample volume tends to give

better precision data. This is understandable since the amount of acid contained in a 40-μl volume of digest is 5 times less than that in a 200-μl sample injection volume.

Temperature dependent chemistry—phosphorus

Ortho-phosphorus was measured over the 0.01–1 mg/l. range with ascorbic acid phosphomolybdate chemistry. In this experiment, the four parts of one mixer took the place of two coils. The reduction by ascorbic acid is temperature dependent. The data clearly indicate that turbomixing with or without stopped-flow has no analytical advantage. If the chemistry was measured without temperature control, it is highly possible that data similar to that of the nitrite ion would be generated.

Higher order reaction—chlorite and chlorate ions

The chlorite ion measurement chemistry involves the reaction between iodide ion and chlorite ion at pH 1.5. The manifold requires two reagents, a pH buffer followed by the addition of potassium iodide. The resulting iodine is detected spectrophotometrically at 360 nm.

The stopped-flow system maintained flow for 7 sec with a 10-sec stop period before the resumption of flow. The y-intercepts increased slightly between the FIA system and turbomixer and turbomixer stopped-flow systems. This effect is probably due to an impurity in the reagent which increases the background iodine measurement. The correlation coefficient for the calibration curves were comparable. The relative standard deviations at the 1.2 mg/l. level were all under 1.2%, which is acceptable. The detection limits based on three times the signal to noise ratio were 0.017, 0.015 and 0.004 mg/l. respectively. The lower detection limit value of the turbomix/stopped flow data does not give higher detection limits based on the larger y-intercept that is seen in standard FIA manifolds.

Chlorate ion measurement uses the KI chemistry described for chlorite ion except for the pH adjustment. The chlorate manifold requires the use of 12*M* hydrochloric acid to promote the reaction. This chemistry was the slowest chemistry tested. The FIA manifold requires over 3 meters of coil to reach the desired detection limits, indicating that time delay is important.

The chlorate data are shown in Table 2. The stopped flow period was 15 sec after injection with a duration of 4 sec. The *y*-intercepts are comparable for the FIA and the turbomixer stopped-flow but significantly lower for the turbomixer only system. The sensitivity increases from the FIA to the turbomixer stopped-flow. The relative standard deviations at 1.2 mg/l. ranged from 0.5–1.2%. The detection limit was slightly better for the turbomixer only system.

The data presented in Table 1 show that the use of mixing coils and the creation of dispersion is not a prerequisite for non-segmented continuous flow analysis. In fact, when dispersion coefficients are measured for turbomix stopped-flow manifolds, values between 1.5 and 3 are typical even for reactions requiring dispersion coefficients of 5–9 under normal FIA conditions.

Turbomixers remove the need for circular, serpentine or knotted coils in FIA systems. Further, the mixers can be made of Teflon or other materials, making them ideal for organic solvents and process control applications.

CONCLUSIONS

The need to create a gradient and dispersion in non-segmented continuous flow analysis systems was eliminated in the chemistries tested in this study. Turbomixing in situations where the sample and reagent are mixed instantaneously has proven to be an effective way to perform automated analysis. Time delays created by reaction coils are simply handled by stopped-flow periods. In these experiments the optimal FIA flow-rate conditions were used to make the comparison. No attempt was made to optimize the conditions for the turbomixers. In reality the optimized turbomixers do offer improved analytical performance for some chemistries. The potential for turbomixers in extraction and fast reactions with chemiluminescence is not presented but experiments have shown significant improvements associated with their use. The lower detection limits are related to the improved slopes. Lower noise was not seen. Sample throughput is about 10% higher for turbomixers. The combination of stopped flow and turbomixers are perfect for the FIA systems of the future where peristaltic pumps will not be the pump of choice. The alternative low cost pumps will need less flow line restriction (*i.e.*, less tubing length).

SPECTROPHOTOMETRIC METHOD FOR DETERMINATION OF SULFIDE WITH IRON(III) AND NITRILOTRIACETIC ACID BY FLOW INJECTION

MICHAEL D. KESTER, PAUL M. SHIUNDU and ADRIAN P. WADE*

Laboratory for Automated Chemical Analysis, Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z1

(*Received* 14 *April* 1991. *Revised* 26 *June* 1991. *Accepted* 26 *June* 1991)

Summary—A manual colorimetric method for determination of sulfide has been adapted to flow injection, systematically optimized, and more fully characterized. Its intended application is for measurement of sodium sulfide reagent strength in pulp process streams, and sulfide contamination in effluent from Kraft pulp mills. In the flow-injection method developed, a sample solution containing sulfide is reacted with a mixture of iron(III) and nitrilotriacetic acid under ammoniacal conditions. The absorbance of the intensely-colored green product of this reaction is measured at 636 nm. Excess sulfite is present as a color stabilizer. A linear dynamic range of 20–100 ppm sulfide is readily achieved; the relative standard deviation is less than 1.2% ($n = 10$) throughout this range, and 0.37% ($n = 10$) midrange at 60 ppm. The usable dynamic range is 8–250 ppm sulfide. Long-term stability of the method is ensured by periodically performing an automatic cleaning cycle using a hydrochloric acid wash solution. This prevents tube discoloration and removes any precipitates which are formed under strongly alkaline conditions. The sample throuhput rate is at least 30/hr, given alternate acid wash cycles.

Production of pulp and paper is one of Canada's most important industries. The most common process by which wood chips are converted into pulp for high quality, high brightness papers is the Kraft process.[1] The principal chemical reagent solution for this pulping process contains high concentrations of sodium hydroxide and sodium sulfide, and is known as "white liquor". Wood chips are digested in this liquor at elevated temperature (160–180°) to remove lignin. During reaction, the concentrations of hydroxide and sulfide decrease, while organics and dissolved solids in the liquor greatly increase. It is vital to the economy of the process that reagent chemicals are recovered from the resulting "black liquor", and re-used. This involves their chemical regeneration in another part of the pulp mill. Adequate process control requires that the liquors are analyzed for sodium sulfide and sodium hydroxide at several points in the digestion and recovery process. Presently, both analyses are typically performed by manual titration of the liquor with hydrochloric acid;[2] this results in a doubly inflected plot (pH *vs.* equivalents of acid added). The titration procedure is a slow and tedious procedure which requires considerable human skill, and the quality of results obtained is highly operator dependent. Thus, there was an obvious need for development of a semi-automated method for analysis of sulfide in several streams in a Kraft pulp mill, which would be suited to on-line and at-line process-control measurements. This would improve accuracy and precision, and decrease reagent consumption. Further uses in monitoring mill effluent can be readily envisaged.

Flow injection[3] (FI) is a fast and very versatile methodology for automated chemical analysis. Its advantages and capabilities were compatible with the aforementioned analytical requirements. At least four flow-injection methods for sulfide appear in the literature. These are based on colorimetry (methylene blue method[4]), potentiometry (silver sulfide ion selective electrode[5]), atomic-absorption spectrophotometry (AAS) (precipitation as cadmium sulfide and detection by AAS[6]) and, more recently, gas diffusion (conversion to hydrogen sulfide and subsequent colorimetric detection[7]).

An alternative manual colorimetric method for sulfide determination, reported by Rahim and West,[8] appeared to be particularly suited to the highly basic nature of Kraft mill streams, and was of special interest to us. It was known[8] that their method could tolerate 100-fold molar

*Author for correspondence.

excess levels of key potential interferents such as chloride and sulfate. It involves reaction of iron(III) and nitrilotriacetic acid (NTA) with sulfide under ammoniacal conditions. Sulfite is present in excess to maintain constant ionic strength and provide color stabilization. Rahim and West suggest that the green complex formed is a colloidal basic form of Fe(OH)S. This chemistry will be discussed in more detail below and reference will be made to literature which indicates that other reaction products may also be possible under these conditions.

Preliminary evidence suggested that the iron(III)/NTA method could be more sensitive than the methylene blue procedure. Furthermore, it was felt that several questions regarding the nature of this chemistry could be uniquely addressed by use of an automated flow-injection analyzer.[9] We decided to adapt the iron(III)/NTA chemistry to flow injection, systematically optimize the method, and multivariately characterize the reaction in an automated manner.[10]

EXPERIMENTAL

Reagents

Stock solutions of 10 and 20% w/v sodium sulfite were prepared by dissolving 100.0 or 200.0 g, respectively, of anhydrous sodium sulfite (BDH Inc., Toronto, Ontario) in one litre of distilled water. These were freshly prepared each day as required, due to the possibility of oxidation of sulfite to sulfate.

A stock solution of 1000 ppm sulfide was prepared by dissovling 0.7490 g of analytical-reagent grade sodium sulfide nonahydrate (BDH Inc., Toronto) in 100 ml of 10% w/v sodium sulfite solution. This was prepared fresh daily and standards of lower concentration were made by appropriate dilution with 10% w/v sodium sulfite solution.

A solution containing 3.98m*M* iron(III) and 10.0m*M* NTA was prepared for the preliminary experiments. First, 1.92 g of ammonium ferric sulfate dodecahydrate (BDH Chemicals Ltd., Poole, England) was dissolved in 25 ml of distilled water containing 1 drop of 1*M* sulfuric acid. Then, while heating, 1.91 g of NTA (Fisher Scientific Co., Toronto) was dissolved in 25 ml of 1*M* sodium hydroxide. These two solutions were mixed, while stirring, and diluted with distilled water to 100 ml in a standard flask. Automated optimization studies required an iron(III)/NTA solution which contained 4.00m*M* iron(III) (1.93 g/25 ml) and 40.0m*M* NTA (7.64 g/25 ml). This was made in the same way. Experiments carried out at optimized conditions required a more concentrated solution which contained 6.98m*M* iron(III) and 69.8m*M* NTA. First, 1.68 g of ammonium ferric sulfate dodecahydrate was dissolved in 80 ml of distilled water containing 1 drop of concentrated sulfuric acid. Then, while warming, 6.67 g of NTA was dissolved in 50 ml of 1*M* sodium hydroxide. This solution was diluted with distilled water to *ca.* 400 ml and the iron(III) solution was then added slowly, while the solution was stirred. Using this procedure, it was possible to prepare this solution without precipitation, and the solution was found to be stable for at least one month.

Ammonia solutions were prepared by diluting 6, 10, 17 and 25-ml aliquots of concentrated ammonia (Analytical Reagent, BDH Inc.) to 100 ml with distilled water. Solutions of sodium hydroxide (AnalaR, BDH Inc.), nitrate (Analytical Reagent, BDH Inc.), chloride (Reagent grade BDH Inc.) and thiosulfate (Analytical Reagent, BDH Inc.) were prepared in distilled water from the solids, as needed. A cleaning solution (hydrochloric acid, 50% v/v) was prepared by slow addition of 50 ml of concentrated hydrochloric acid (Analytical Reagent, BDH Inc.) to 50 ml of distilled water. Early experiments used a less effective cleaning solution containing 10% v/v hydrochloric acid and 30% v/v nitric acid (iron oxides form in the presence of strong oxidizing agents such as nitric acid or dichromate).

Apparatus

Manual experiments. Absorption spectra were obtained with a diode-array spectrophotometer (Hewlett-Packard 8452A, Hewlett-Packard, Palo Alto, CA) which was controlled by a 12-MHz Intel 80286-based computer (NORA Systems, Vancouver, B.C.). The computer was equipped with an Intel 80287 math coprocessor, 40 Mb hard drive and EGA color graphics adapter card. Communication was across a Hewlett-Packard Interface Bus (HP-IB). Data acquisition software was as provided by Hewlett-Packard. Experiments used a standard quartz cell (Hellma, Model 110-QS, Fisher Scientific, Vancouver, B.C.) with a 1-cm pathlength.

Flow-injection experiments. Polytetrafluoroethylene tubing (0.5 mm i.d.) and 1/4″ inert, low pressure fittings (Omnifit, New York, NY) were used throughout.

The automated flow injection analyzer which was used for the majority of the studies has been described in detail elsewhere.[9] Its principal detector is the same diode-array spectrophotometer as used above. Specialized data acquisition routines used were written in-house and have been described elsewhere.[11] The several types of pumps interfaced to the computer include five independent stepper-motor driven, variable-speed peristaltic pump heads (Type mini-micro 2/6, Ismatec, Chicago, IL) and two high-precision variable speed peristaltic pumps (Models C-4V and C-6V, Alitea U.S.A., Seattle, WA). Sample injection is via 1–3 six-port air-driven, solenoid-actuated injection valves (Type 5020P, Rheodyne Inc., Cotati, CA), each equipped with a 70-μl sample loop. The quartz flow cell (Type P 5061-3394, Hewlett-Packard, Richmond, B.C.) used was of 30-μl volume and 1-cm path length.

A simplified flow-injection analyzer was then constructed and used for coil length optimization, sulfide calibration curves, interference studies and analysis of real samples. All components were controlled by another computer which was identical to that used for the automated analyzer. The control software for this apparatus was a modified version of that used for the automated analyzer detailed above, and is discussed elsewhere.[9–11] Stream propulsion was by three high-precision, variable speed peristaltic pumps (Models C-4V or C-6V, Alitea USA). Samples were injected with a six-port, air-driven solenoid-actuated injection valve (Type 5020P, Rheodyne) equipped with a 70-μl sample loop. A second six-port valve of the same design was used as a switching valve for the cleaning solution. Both valves could be triggered either manually or by computer, using custom-built electronic controllers.[9] The flow-through cell was of quartz, and had a 30-μl volume and 1-cm pathlength. The photometric detector used with this analyzer was a two-channel design based on the work of Patton *et al.*,[12] and was built in-house. Its output, the log of the photoresistor voltage ratio (sample to reference), was read by a Data Acquisition and Control Adapter (DACA) board (IBM Instruments; from Mendelson Electronics, Dayton, OH). The detector design was modified so as to provide a five-fold increase in the output voltage over the original design. This maximizes measurement precision by providing an optimal match between the detector output voltage level and the 0–10 V dc input required by one of the DACA's 12-bit analog-to-digital convertors. The detector's light sources were two bi-color light-emitting diodes (LED's) (Cat. No. 276-012, Radio Shack, Richmond, B.C.), one for the sample channel and the other for the reference channel. The color emitted by the LED's, red (635 nm) or green (565 nm), is selected according to the polarity of the applied potential. The emission spectra for similar diodes have been published[13] and indicate a bandwidth of 30–40 nm. Initially the LED's were powered by a 6 V lantern battery and a simple circuit incorporating one double-pole, double-throw (DPDT) switch to reverse the polarity, one 10 kΩ variable resistor to control the brightness of both LED's and one 200 Ω current-limiting resistor in series with each diode. The most recent detector modification has been to add circuitry to power and control the LED's, without external batteries. Analyzer control software was written in this laboratory in Microsoft QuickBASIC® version 4.0. This sampled the detector log-ratio output at a rate of 5 Hz and with 12-bit (1 part in 4095) resolution, and displayed a plot of peak shape on the screen in real-time. The data were subsequently stored on disk for later processing.

Further data processing was undertaken with a commercial spreadsheet (Lotus 123), a graphing program (SigmaPlot version 4.0, Jandel Scientific, Corte Madera, CA) and a three-dimensional plotting program (SURFER version 3.0, Golden Software, Golden, CO).

Procedures

Preliminary manual studies. These studies were to determine the order of addition of reagents (which inevitably determines the flow-injection manifold) and confirm the wavelength of maximum absorption (λ_{max}). Initially, the manual experiment as described by Rahim and West[8] was attempted. To each of six 50-ml standard flasks was added 0.2–1.2-ml aliquots of the 1000 ppm sulfide standard. Then 20 ml of 20% sodium sulfite solution, 1 ml of concentrated ammonia solution and 0.5 ml of the iron(III)/NTA composite solution were added in sequence, with mixing between each step. The solutions were diluted to the mark with distilled water. Aliquots from these solutions were transferred to a 1-cm quartz cell and a full UV-visible absorption spectrum from 190 to 820 nm was taken with the diode array spectrophotometer. The λ_{max} was found to be 636 nm.

The effect of the iron(III)/NTA ratio was then ascertained. Composite iron(III)/NTA solutions

were prepared where NTA ranged from equal to 10-fold molar excess relative to iron(III). The iron concentration was maintained at 2.5m*M* in all ten composite solutions while the NTA concentration was varied from 2.5–25m*M*. The absorbance (at 636 nm) of each solution was measured in a 1-cm quartz cell with the diode-array spectrophotometer.

Baseline noise and solvent effect on flow injection manifold. Once the preliminary investigations were complete, an initial manifold [Fig. 1(a)] was assembled on the automated flow injection analyzer.[10] The baseline noise was studied by varying the reaction coil length and inserting post-pump damping coils. The effects of potential color-formation enhancers were studied with sodium sulfide dissolved in: 0.5*M* sodium chloride, 0.01*M* sodium hydroxide, 10% (w/v) sodium nitrate, and 10% (w/v) sodium sulphite. The effect of distilled water was also tested.

Automated simplex optimization. Simplex optimization[14] is an efficient way to search for the values of several experimental variables which produce a maximum response. Optimization was carried out, without operator intervention, on the automated flow-injection analyzer in the same manner as has been reported previously.[10] The method used was the composite modified simplex.[15,16] Initially, we attempted to optimize all three (variable) concentrations simultaneously [sulfite, ammonia and iron(III)/NTA]

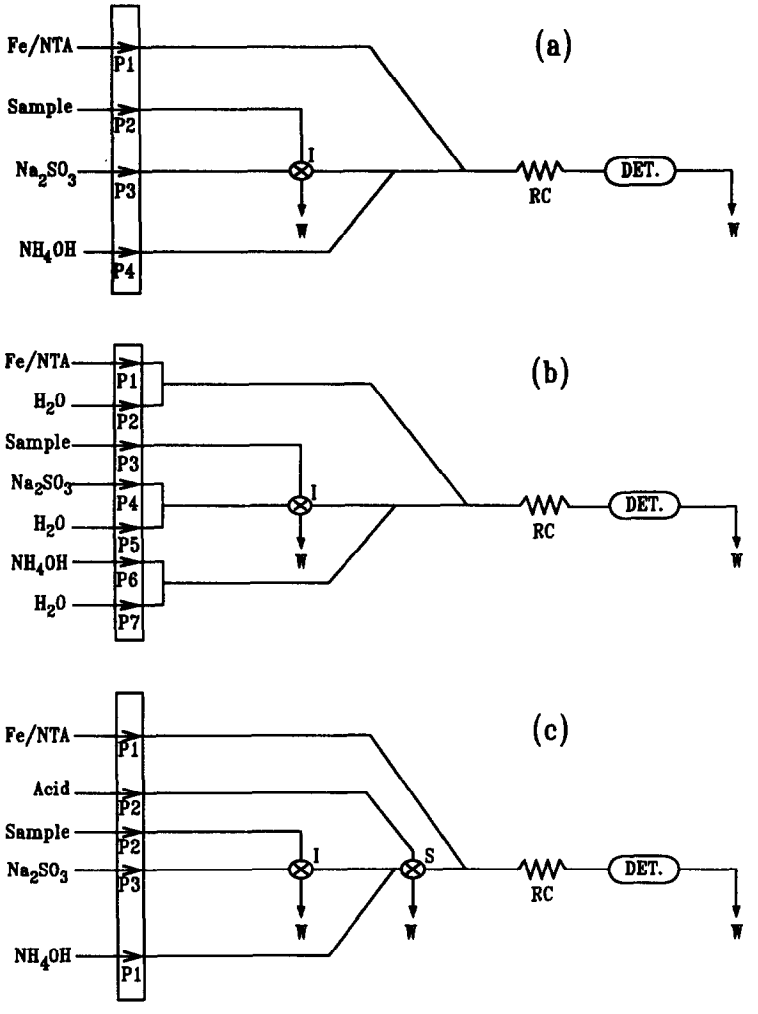

Fig. 1. Schematic diagram of the flow-injection manifolds used. Shown are variable speed pumps (P1 to P7), sample injection valve (I), wash switching valve (S), reaction coil (RC), detector (DET), and the waste lines (W). (*a*) Manifold used for preliminary flow-injection experiments. The reaction coil was 1.0 m in length. (*b*) Manifold used for automated simplex optimizations. The reaction coil was 1.0 m in length. (*c*) Simplified optimized flow-injection manifold. Flow-rates used were P1 = 0.5 ml/min, P2 = 4.5 ml/min (maximum rate), and P3 = 0.8 ml/min. The reaction coil was 80 cm in length.

while measuring absorbance at 636 nm. The automated analyzer specified reaction conditions by use of appropriate flow-rates and the stock solutions. The flow manifold used is shown in Fig. 1(b). Several optimizations were carried out. In each, the variable flow-rate reagent streams were "buddied"[10] to distilled water streams to give predetermined total flow-rates, but variable reagent concentration. In this way, each of the reagents could assume a concentration that ranged from full strength down to zero while maintaining a constant total flow-rate (and sample residence time) through the manifold. The absorbance recorded was the average of duplicate experiments at each set of conditions. On completion of each optimization, the reagent flow-rates which resulted in the largest response were reported.

Automated response surface mapping using grid search. For chemical systems with two variables, response surface mapping[10] provides a useful means of characterizing the effects of these variables, and their interactions, on the system response(s). Reagent flow-rates for iron(III)/NTA and ammonia solutions were each varied independently in seven steps from 0.1–1.0 ml/min, using a regularly-spaced square experimental design of 7 × 7 points (a total of 49 experiments, with each in duplicate). The sulfite flow-rate was kept constant. Response surface maps of these data were produced using the SURFER® graphics program.

Simplified manifold. Once optimum conditions had been established, a simplified analyzer and manifold [Fig. 1(c)] were constructed for routine analysis. The concentrations of the reagents were those determined to be optimum in the previous studies. A second automated valve (S) was placed immediately before the reaction coil to allow flushing of the manifold with acid. This removed any high pH precipitates automatically. When engaged, the valve allowed the acid cleaning solution to pass through the coil while briefly diverting the reagents to the waste bottle. A two channel pump simultaneously refilled the sample loop and propelled cleaning solution through the reaction coil and flow cell. When this pump stopped, valve s was switched back to allow pasage of the reagent stream, and the baseline absorbance reading was allowed to re-equilibrate before injection of the next sample by valve i. A calibration curve was produced for 6, 8, 10, 12, 14, 16, 18, 20, 40, 50, 60, 80, 100, 250, 500, 750 and 1000 ppm S^{2-}. In each case, the mean and sample standard deviations were calculated from 10 replicate peaks.

Coil length optimization. For this, the flow-manifold shown in Fig. 1(c) was used at the flow-rates and reagent concentrations found to be optimal. Some 20 different coil lengths were used, in the range 10–300 cm. The detector output was adjusted manually to read 0.2 V before each injection. A response surface map and contour plot was obtained which showed the effect of reaction coil length on peak shapes obtained for 50 ppm S^{2-}. The response readings were plotted in analog-to-digital convertor (adc) units and were directly proportional to absorbance.

Time dependence of absorption spectra. Manual experiments were carried out to determine the time dependence of absorption spectra, both with and without sulfide present. For this, 5.0 ml of 17% ammonium hydroxide, 8.0 ml of 10% sodium sulphite, 2.0 ml of 100 ppm S^{2-} in 10% sulfite and 5.0 ml of 6.98m*M* iron(III)/69.8m*M* NTA solution were mixed, in that order, and transferred to a 1-cm quartz cell within 30 sec of adding the iron(III)/NTA reagent. The blank contained all reagents except for sulfide. Visible spectra were recorded at a rate of one per minute for 40 min (400–800 nm; spectra taken relative to distilled water). The results were plotted as three-dimensional surfaces and contour plots.

RESULTS AND DISCUSSION

Reaction chemistry

Complete characterization of the reaction mechanism and kinetics is beyond the scope of this present study. However, some discussion of the chemical form of reagent and reaction product(s) is warranted.

It is known that under acidic conditions (pH 0.5–3.5), six coordinate iron(III) forms a 1:1 complex with tetradentate NTA.[17–20] As the pH is raised to 3.5–7.0, progressive hydrolysis[17,18,20,21] and subsequent olation[18,21] of the complex are known to occur. As the pH is raised above 9 the complex becomes unstable,[17,20] and precipitation occurs. From this we infer that formation of iron(III) sulfide complexes which retain the NTA is unlikely at high pH.

Initially the iron(III)/NTA reagent solution is at *ca.* pH 3: therefore the iron(III)/NTA complex then exists primarily in its monomeric form. The flow manifold designed for this study merges this acidic reagent stream with a highly

basic stream (pH ≈ 12) of ammonium hydroxide and sodium sulphite. This then meets the injected "sulfide plus sulfite" sample. This process has the effect of quickly raising the pH of the iron(III)/NTA reagent solution from pH 3 to approximately pH 11 in the presence of sulfide. Hydrolysis and olation may now occur if the reaction kinetics are suitably fast. However, the instability of the iron(III)/NTA complex at this pH is likely to result in rapid release of hydrolyzed iron(III) by the NTA. This would allow immediate reaction with sulfide, and explain the instantaneous color formation which is observed.

It has been shown[22] that, at pH 6.5, iron(III) and HEDTA (a similar ligand to NTA) can form an intensely colored soluble dimeric iron-sulfur complex which is bridged by one sulfide ion in the presence of H_2S. Thus, the presence of iron(III)/NTA dimer has also been suggested. However, we feel this is unlikely at pH 11, as the iron(III)/NTA complex itself is unstable.

Other researchers have suggested that a variety of reaction products can exist at elevated pH's. Morozov and Rozanov[23] reported that iron hydroxide reacted with sulfide at pH 9.5 (in the presence of sodium) to eventually precipitate as $Na_x[Fe^{III}(OH)_yS_z]$. In this x, y and z were dependent on relative reagent concentrations. They found that, in the absence of sodium, mixtures of this nature remain as a colloidal solution. Coagulation is observed when sodium chloride is added. The charged hydroxothioferrite is the likely cause of the transient green color in our reaction mixture. Precipitation of the ammonium or sodium salt of the hydroxothioferrite could follow soon afterwards [in addition to $Fe(OH)_3$ and possibly Fe_2S_3]. Morozov and Rozanov[23] also reported that the ratio of S/Fe in this complex increases if sulfide is limiting. This would explain the deviation from Beer's law which we observe at low sulfide concentrations.

The possibility of sulfide reduction of iron(III) to iron(II) via the formation of zero-valent sulfur can be ruled out as this redox effect has been shown to be minimal at high pH.[23–25] Moreover, a deep green solution has been noted under basic conditions by combining ferric chloride, potassium hydroxide, and sulfide;[24] elemental analysis of this solution and the co-existent precipitate revealed that no ferrous iron or zero-valent sulfur was present. Other workers[23] have shown that iron(III) is reduced by sulfide only if the pH is lower than 9.5. Reduction of iron(III)–NTA by sodium sulphite has been studied[25] and has been shown to decrease steadily from pH 5 to pH 8. Again, this suggests minimal formation of iron(II) at the high pH of our final reaction mixture.

From the above, we presently conclude that the (colloidal) color body is an initially soluble form of hydroxothioferrite of variable composition. Subsequent precipitation of the sodium or ammonium salts of this ion is likely. Formation of the black ferric sulfide is seen in manual experiments, but this occurs significantly later than formation of the intense dark green color (which is instantaneous). We note that, in the absence of sulfide, excess iron(III) precipitates as ferric hydroxide. This is via replacement of NTA with hydroxide when the iron(III)/NTA reagent is merged with the basic stream of sodium sulfite and ammonia.

Preliminary manual studies

It was found that the method would only work when the reagents were mixed in the order listed by Rahim and West[8] [*i.e.*, sulfide, sulfite, ammonia and then iron(III)/NTA]. A spectrum from 190 to 820 nm confirmed that maximum absorbance is at 636 nm, and absorption by the reagent is (initially) minimal in this region. Color formation was strongest and occurred instantaneously only if iron(III)/NTA was added last. From this we concluded that a flow manifold in which all reagents were merged (or otherwise combined) before sample injection was not feasible.

The effect of iron(III)/NTA concentration ratio was then determined. The iron(III) reagent was kept in at least 5-fold molar excess relative to sulfide. Under these conditions, the same amount of color development was achieved for an equal to ten-fold excess of NTA relative to iron(III). Thus the iron(III)/NTA ratio is not critical to color formation within this range. However, it was felt that free iron(III) could result in precipitation of ferric hydroxide (or sulfide or hydroxosulfide when a sulfide-containing sample plug passes through) and, to help avoid this, NTA was kept in a 10-fold molar excess relative to iron(III) for all subsequent experiments.

Baseline noise characteristics

Figure 2 shows peak shapes obtained with different coil lengths in the initial manifold [Fig. 1(a)]. The baseline noise observed was significant and periodic. From this it was

assumed that the peristaltic action of the pumps was responsible for the fluctuating response at the detector. The noise magnitude decreased as longer coil lengths were used. However, long reaction coils result in a low sample throughput rate, increased dispersion and decreased sensitivity. Rather than use a long reaction coil, the noise was minimized by lengthening the lines between the pumps and the merging tees to one meter for all subsequent experiments. The baseline noise thereafter was minimal.

Evaluation of potential color formation enhancers

The presence of 10% sodium sulfite was known to enhance color formation. Various other sodium compounds, and water, were evaluated to see if they produced the same effect.

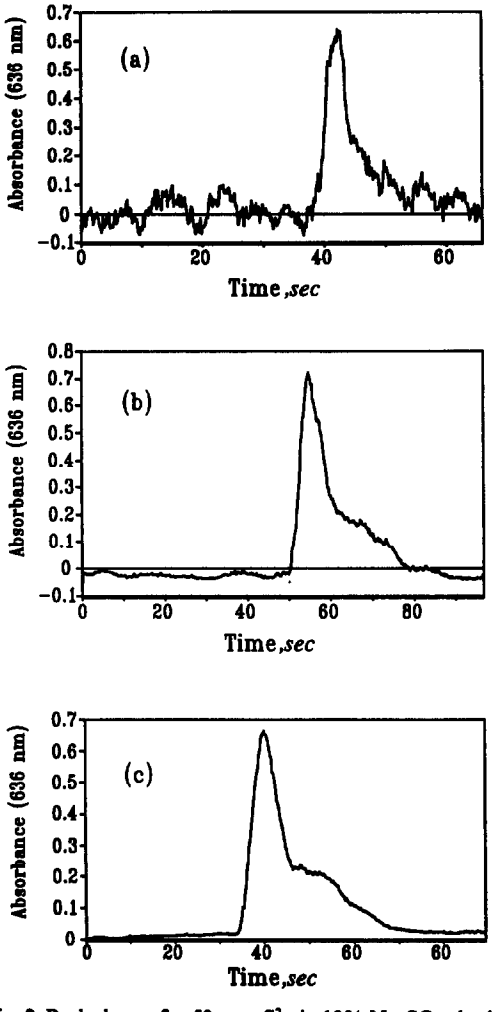

Fig. 2. Peak shapes for 50 ppm S^{2-} in 10% Na_2SO_3 obtained with the manifold shown in Fig. 1(a). The reaction coil length used was (*a*) 0.2 m, (*b*) 1.0 m and (*c*) 2.0 m. Reagent streams were 20% w/v sodium sulfite, 3.98m*M* iron(III)/10.0m*M* NTA and 25% v/v NH_4OH, each flowing at 1.0 ml/min.

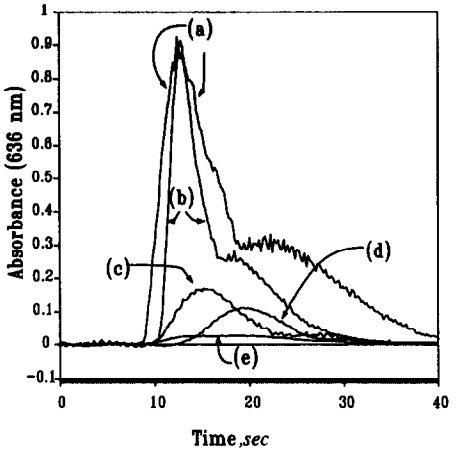

Fig. 3. Peak shapes for solutions containing 50 ppm S^{2-} and concentrations of selected sodium salts. These were obtained with the manifold shown in Fig. 1(*a*). Reagent streams were 20% w/v sodium sulfite, 3.98m*M* iron(III)/10.0m*M* NTA and 25% v/v NH_4OH (each flowing at 1.0 ml/min). The salt solutions used were: (*a*) 10% w/v sodium nitrate; (*b*) 10% w/v sodium sulfite; (*c*) 0.5*M* sodium chloride; (*d*) 0.01*M* sodium hydroxide, (*e*) water.

The peaks shown in Fig. 3 indicate that both 10% sodium sulfite and 10% sodium nitrate enhanced the peak absorbances. Water, 0.01*M* sodium hydroxide and 0.5*M* sodium chloride provided no such enhancement. The peaks for sulfite and nitrate exhibited distinct "tailing", which was proven in subsequent experiments to be due to refractive index fluctuations over the injection zone. The carrier stream being used was of 20% sodium sulfite; thus, in both cases a sulfite concentration gradient existed across the dispersed sample zone. The refractive index fluctuations caused by this gradient resulted in light scattering, which was confirmed by recording transmission spectra (190–820 nm) at a rate of 1 Hz as a sodium sulfite concentration gradient passed through the cell of the diode-array spectrophotometer. As would be expected for a scattering phenomenon, these spectra showed that transmitted radiation decreased at all wavelengths (despite the solution appearing optically colorless). Peak tailing completely disappeared when the sulfite concentration gradient was removed. In all subsequent studies, sample and carrier stream contained equal concentrations of sulfite and the observed peak heights were smaller since they no longer had a contribution from light scatter.

Automated optimization studies

Simplex methods[15,16] have been widely used in chemistry and successfully applied in flow-

Table 1. Simplex optimization of flow-injection method for sulfide

	Optimization A	Optimization B
Ammonia		
Maximum rate (ml/min)	1.0	1.0
Initial rate (ml/min)	0.3	0.3
Optimum rate (ml/min)	0.48	1.0
Iron(III)/NTA		
Maximum rate (ml/min)	1.0	1.5
Initial rate (ml/min)	0.3	0.3
Optimum rate (ml/min)	1.0	1.5
Maximum absorbance found	0.284	0.258
Experiment # (optimum conditions)	8	8
Total # of experiments performed	16	13
Total flow rate (ml/min)	3.5	4.0
Absorbance corrected to total flow rate of 3.5 ml/min	0.284	0.295

Both optimizations used 25 ppm sulfide in 10% sulfite solution.
Peak absorbance values listed are average values from two injections.
The sulfite flow rate was maintained at 1.5 ml/min.
Stock solution concentrations used were sulfite 10%, ammonia 25% and 4.00m*m* iron(III)/40.0m*M* NTA.

injection analysis.[9,10] Simplex optimization involves sequentially evaluating the responses obtained under sets of experimental conditions predicted by its algorithm. Values of several system variables are changed simultaneously.

Figure 1(a) shows the optimization manifold assembled on the automatic flow-injection analyzer. Initially, an attempt was made to optimize all three reagents [iron(III)/NTA, NH_4OH and sulfite] simultaneously. Unfortunately, interference due to the aforementioned sulfite concentration gradient resulted in unsatisfactory results.[26] Hence, a two-variable simplex optimization was attempted by maintaining a constant sulfite concentration (10% w/v). Table 1 shows the results from two such optimizations. Optimization A concluded that it was best to run iron(III)/NTA at its maximum rate (1.0 ml/min), therefore, the maximum allowable rate was increased to 1.5 ml/min for optimization B. At the high concentrations predicted by optimization B (maximum of both reagents), a brown precipitate was observed on the walls of the tubes and flow cell. This was principally of $Fe(OH)_3$ but could also contain small amounts of the black Fe_2S_3, and possibly the other species discussed above. The precipitate was easily removed by flushing the system with acid. It was assumed that the peak height measurements obtained under these conditions contained a contribution from the precipitate, and so simplex optimization was not pursued further. At this stage in the method development it was felt that better system characterization could be achieved by univeriately optimizing the sulfite concentration, and then undertaking a more detailed automated surface mapping study of the remaining two variables.

Optimization of sulfite concentration

A limited univariate study (Fig. 4) determined that the optimum concentration for sulfite was greater than 5% (w/v). A 10% (w/v) sulfite concentration was used in all experiments thereafter. This level was considered as optimal since

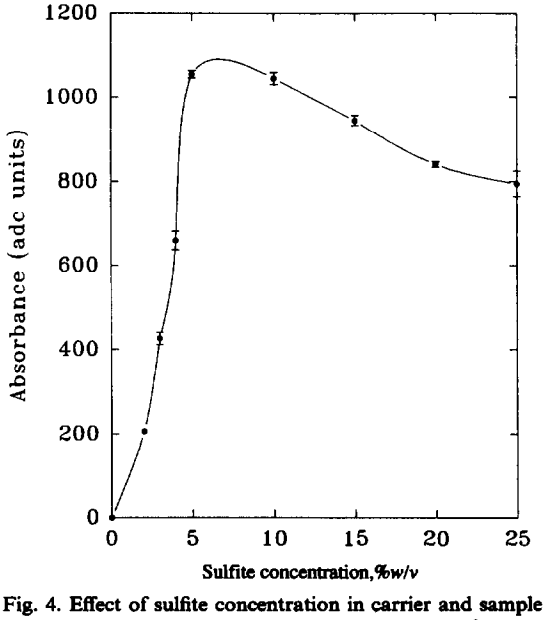

Fig. 4. Effect of sulfite concentration in carrier and sample solutions on absorbance at 636 nm for 50 ppm S^{2-}. The sulfite concentration was varied from 0 to 25% w/v. The carrier was at 0.8 ml/min. Other streams were 6.98m*M* iron(III)/69.8m*M* NTA and 17% NH_4OH, each flowing at 0.5 ml/min.

it was far enough removed from the steep absorption decrease at values below 5% sulfite, and higher concentrations would incur increased reagent costs without improving analytical performance.

Automated response surface mapping

A response surface map and a contour plot were produced by allowing the 8.00m*M* iron(III)/80.0m*M* NTA and 25% ammonia flow-rates to vary independently over the range 0.1–1.0 ml/min in seven steps. The surface map obtained (Fig. 5) confirms the findings of simplex optimization B in that maximum absorbances are obtained when the reagents are flowing at or near their maximum allowed rates. Again, precipitation was observed under these conditions. The increased absorbance found in the highest corner of the surface map was from precipitation and not increased green color complex formation. Values of 0.85 ml/min of the 8.00m*M* iron(III)/80.0m*M* NTA and 0.66 ml/min of 25% ammonia were chosen as optimum, since they lie on a high plateau, but are not in the region where most precipitation occurs (the back corner). In terms of concentration, these correspond to 6.98m*M* iron(III), 69.8m*M* NTA and 17% ammonia—and it is these concentrations which were used in all later studies, and for routine analysis. Such a choice ensured high method sensitivity and minimal effects due to small changes in the concentrations of the reagents.

Simplified flow-injection manifold

With the required concentrations of all three reagents now optimized, a simplified flow-injection manifold was assembled as shown in Fig. 1(c). In order to improve the sensitivity by decreasing the system's sample dilution factor, the pump speeds were changed so that the injection stream (sodium sulfite) ran slightly faster (0.8 ml/min) than the merging reagent streams (0.5 ml/min). The concentrations of reagents were then adjusted to match the optimum found above. An additional valve was incorporated into the manifold immediately before the reaction coil to facilitate automatic cleaning of the reaction coil and flow cell. This resulted in long-term stable operation of the system and excellent repeatability. As well, this allowed efficient removal of any lingering substances introduced from real sample matrices.

Coil length optimization

Figure 6 shows a three-dimensional surface map and contour plot that are made from 20 compiled peaks that resulted from coil lengths of 10–300 cm. These surfaces exhibit several important features. As coil length decreases, peak width decreases, time to peak maximum decreases, and baseline noise increases (note the instability in the lower right hand corner of the contour plot). Since both ammonia and the iron(III)/NTA reagent are merged with the sample carrier stream, the color forms

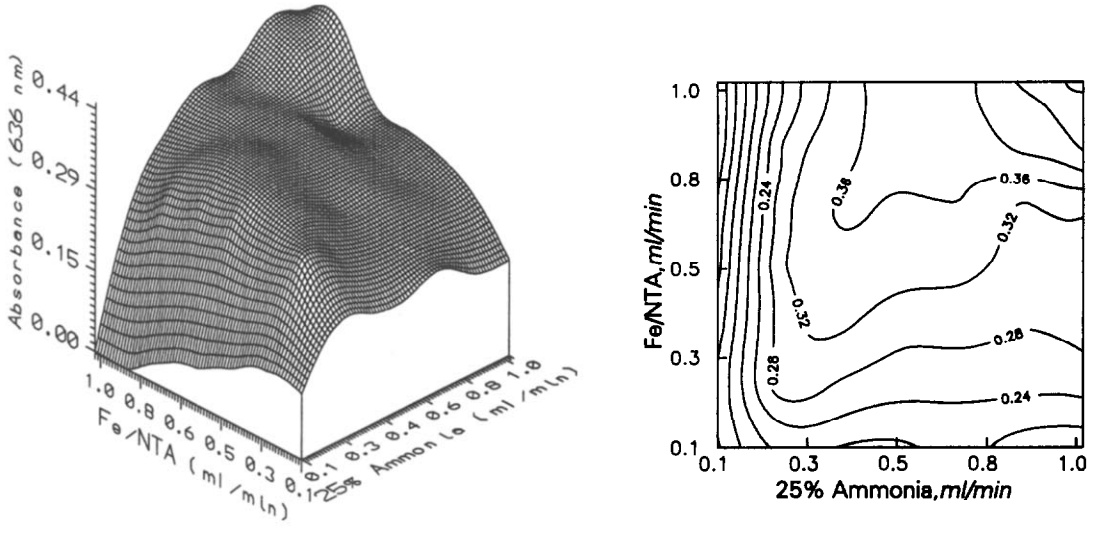

Fig. 5. Absorbance response surface map and contour plot for 50 ppm S^{2-} in 10% Na_2SO_3. This was produced by the automated flow injection analyzer using the flow manifold as shown in Fig. 1(*b*). Reagent streams were 10% Na_2SO_3 (fixed 1.5 ml/min) 8.0m*M* iron(III)/80.0m*M* NTA (variable) and 25% NH_4OH (variable).

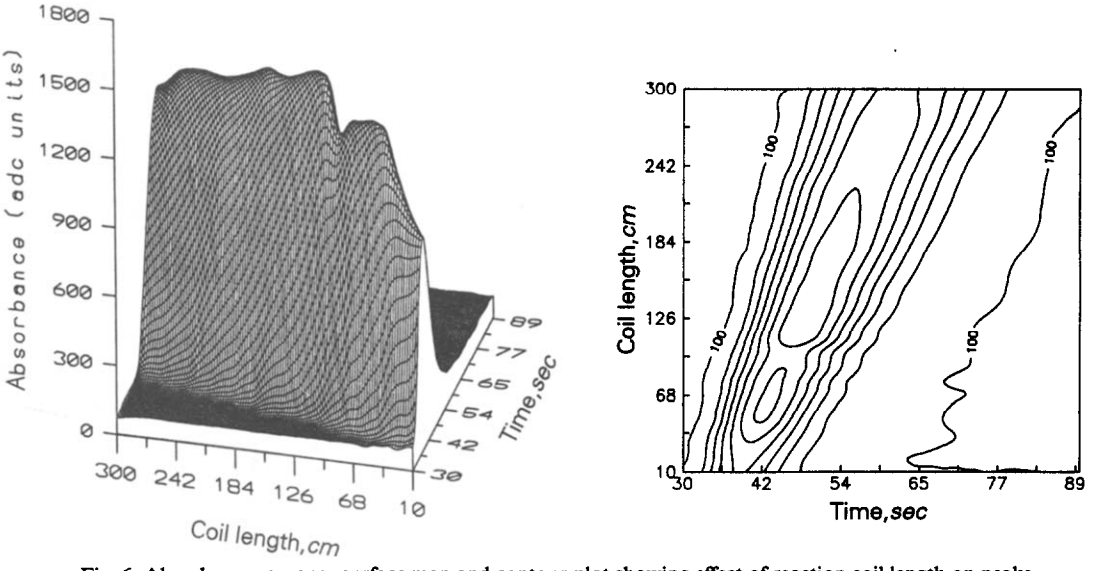

Fig. 6. Absorbance response surface map and contour plot showing effect of reaction coil length on peaks obtained for 50 ppm S^{2-}. The plot is composed of 20 peaks, observed at 636 nm. There are 300 data points across each peak, sampled at a rate of 5 Hz. The flow manifold used was as shown in Fig. 1(*c*). The flow rates and reagent concentrations were found to be optimal. Coil lengths used were 10–300 cm, in 10-cm increments from 10–130 cm, and then in 25-cm increments from 150–300 cm.

instantaneously. Without an intermittent acid wash, a gradual build-up of precipitate is seen for the longest tube lengths.

In addition to these expected observations, and the expected skewed Gaussian peak shape, there is an unexpected dip in peak height at *ca.* 100 cm. This effect is not an artifact, since it appears over 4–5 compiled peaks, which were recorded with a coil length resolution of 10 cm. Its origin posed something of a puzzle, and one possible interpretation is discussed below.

The reaction rate for precipitate formation is significant, but is much slower than that for the sulfide color body. The increased peak height seen for coil lengths of 120 cm or greater cannot be due to unassisted precipitation, since the geometry of the flow system is such that this would be seen at all times, especially for the longer coil lengths. Thus, clearly, the signal observed can only have been caused by the presence of sulfide in the sample zone (see our comments re sulfide-containing precipitates).

An 80-cm reaction coil was chosen as optimum for subsequent analytical use of the manifold, since this has low baseline noise, avoids the dip and minimizes the possibility of precipitate formation. However, before proceeding with this, further discussion of the kinetics of color body formation and precipitation is appropriate.

Time-dependence of absorption spectra

Figures 7(a) and (b) show the time-dependent absorption spectra of the reaction mixture (with and without sulfide) in a standard 1-cm cell, over a period of 40 min. When sulfide is present [Fig. 7(a)], the colored body is seen to form rapidly. Its largest absorbance maximum is at 636 nm, and it exhibits smaller maxima at 434 nm and 532 nm. At longer times, absorption was found to increase across the entire visible spectrum, a behavior typical of precipitate formation (where light is absorbed at all wavelengths, and scattered). The data shown in Fig. 7 confirmed that formation of the precipitate was the much slower of the two processes, but dominates at times greater than 3 min.

Figure 7(c) shows that the 636 nm absorbance rises rapidly over a period of *ca.* 1 min. At times between 1 and 3 min a small decrease in absorbance is seen. The absorbance increased rapidly over the next 20 min and readings became much more noisy. Thereafter, absorbance was seen to decrease as the precipitate began to settle to the bottom of the cell. After several hours the solution above the precipitate was clear.

These results suggest that the kinetic effects observed in the flow system are of the same nature to those seen under static conditions, but operate faster. This is likely because of the much greater degree of mixing which occurs

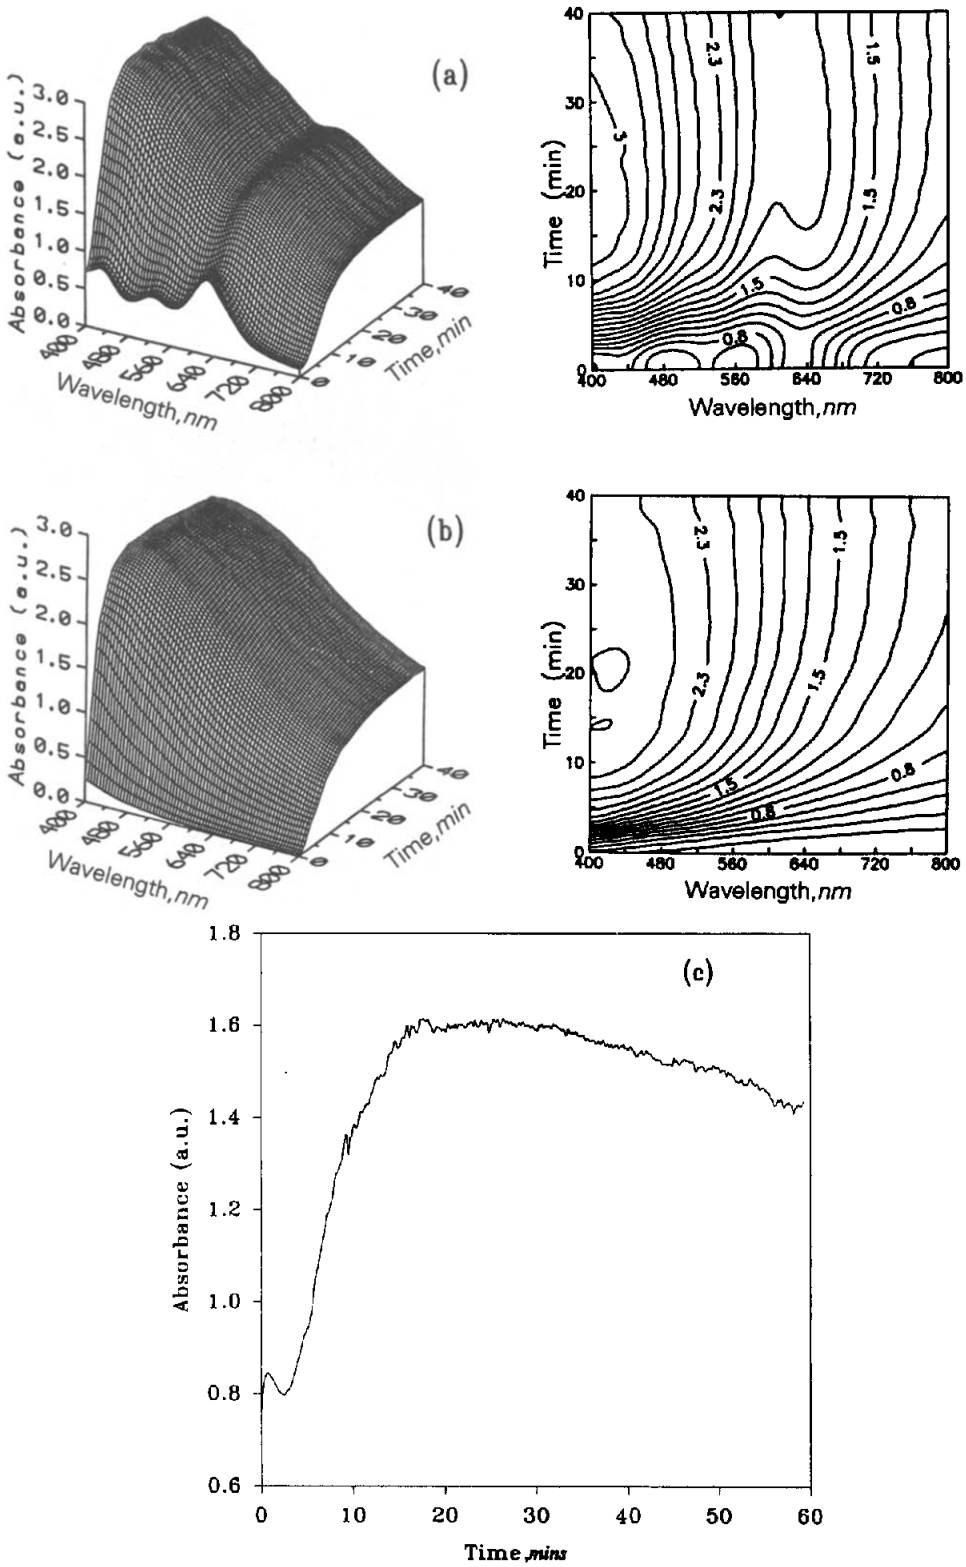

Fig. 7. Time dependence of reagent mixture absorption. Reagent solutions were comprised of 8.0 ml of 10% Na_2SO_3, 5.0 ml of 17% NH_4OH, and 5.0 ml of 6.98m*M* iron(III)/69.8m*M* NTA, and either (i) 2.0 ml of 100 ppm S^{2-} in 10% Na_2SO_3 or (ii) 2.0 ml of 10% Na_2SO_3. (*a*) Time-resolved absorption spectra (400–800 nm) for reagent mixture (i) (with sulfide), shown as 3D surface and contour plot; (*b*) Time-resolved absorption spectra (400–800 nm) for reagent mixture (ii) (without sulfide), shown as 3D surface and contour plot; (*c*) Absorbance of reagent mixture (i) at 636 nm. Measurements were taken at a rate of 0.1 Hz for 60 min.

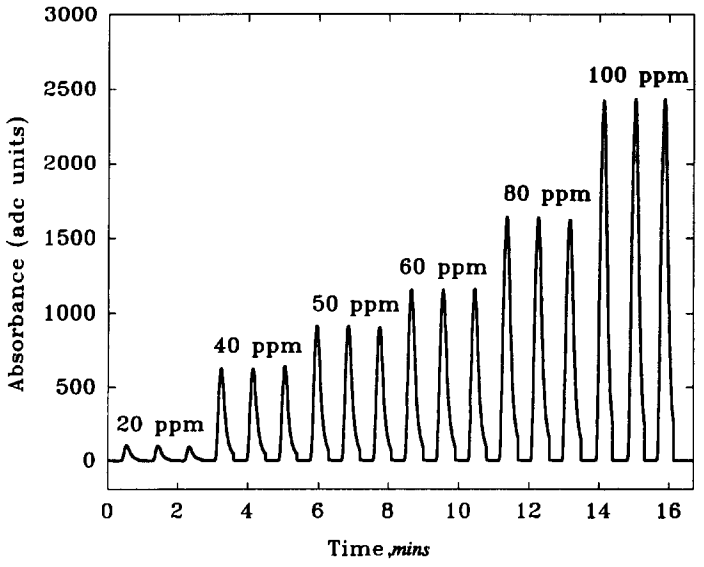

Fig. 8. Typical replicate calibration peaks for 20–100 ppm S^{2-}, obtained using the optimized manifold [Fig. 1(c)]. Reagent streams were 10% Na_2SO_3 (0.8 ml/min), 6.98m*M* iron(III)/69.8m*M* NTA (0.5 ml/min), and 17% NH_4OH (0.5 ml/min). The figure has been reconstructed from multiple data files. Tails of the peaks appear truncated in the figure as data acquisition for each peak is terminated shortly after the peak maximum is detected.

within the small bore tubing at the flow-rate used. Furthermore, it is possible that the hydroxothioferrite formed may itself have a colloidal nature.[8] Formation of the colloid would explain the small drop in product absorbance at 3 min [Fig. 7(c)], and subsequent action of the colloidal particles to increase the rate of formation of the colloid salt and/or ferric hydroxide, ferric sulfide (or hydroxothioferrites) would perhaps explain the behavior seen for coil lengths of 120 cm and above. In any case, use of the 80-cm coil length and total flow-rate of 1.8 ml/min avoids these problems.

Analytical performance

Figure 8 shows typical replicate peaks obtained at several points within the linear dynamic range of the developed method. The response is linear over the range 20–100 ppm; this range of concentration has a slope of 28.2 adc units per ppm, an intercept of −508 adc units, and a correlation coefficient of 0.996. The precision of the system is good; the relative standard deviation was less than 1.2% ($n = 10$) at all concentrations from 20–100 ppm, and was 0.37% ($n = 10$) midrange at 60 ppm. At lower concentrations, the calibration curve is unusual in that the slope decreases with decreasing concentration (Fig. 9). This effect most likely results from an uncharacterized chemical equilibrium at low sulfide concentration, possibly due to a change in the stoichiometry of the reaction product as previously mentioned. For the

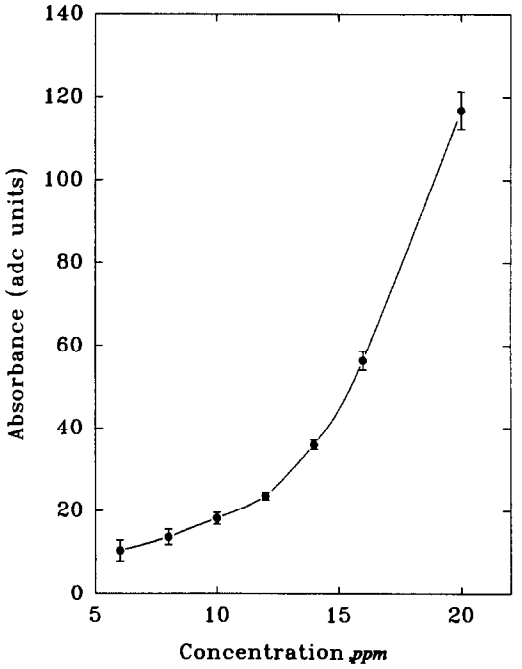

Fig. 9. Calibration curve and error bars (±1 sec) which were obtained from injections of 6–20 ppm S^{2-} ($n = 10$), using the optimized manifold [Fig. 1(c)]. Reagent streams were 10% Na_2SO_3 (0.8 ml/min), 6.98m*M* iron(III)/69.8m*M* NTA (0.5 ml/min), and 17% NH_4OH (0.5 ml/min). Beyond this range the curve is highly linear from 20 to 100 ppm S^{2-}, and then shows a negative (asymptotic) deviation from linearity at higher concentrations.

Table 2. Evaluation of effects of potential interferents

Potential interferent	Concentration of interferent	$[S_{2-}]$, *ppm*	Peak height, *adc units*	RSD, %
None	—	0	0.0	0.00
None	—	50	276.7	0.60
Cl^-	542m*M*	0	9.8	8.90
Cl^-	542m*M*	50	283.8	0.34
$Na_2S_2O_3$	156m*M*	0	−26.7	2.70
$Na_2S_2O_3$	156m*M*	50	258.0	0.39

Chloride was tested at (*ca.*) its concentration in sea water. Thiosulfate was tested at a 100-fold molar excess relative to sulfide. All samples were made up in 10% sulfite. In each case, 10 replicate injections were considered.

calibration plot shown in Fig. 9, quantitation would only be accurate to about 8 or 10 ppm since the slope decreases rapidly beyond this point. The usable dynamic range was 8–250 ppm sulfide. This may be extended somewhat (at the expense of measurement precision) if the amplifier gain is reduced.

Interference studies

Rahim and West[8] reported that the following anions did not interfere at 100-fold molar excess relative to sulfide: SO_3^{2-}, SO_4^{2-}, SeO_4^{2-}, NO_3^-, CO_3^{2-}, ClO_3^-, Cl^-, Br^-, I^-, CH_3COO^-, PO_4^{3-} and OH^-. They also reported that oxalate, citrate, tartrate and chromate could be tolerated at less than 10-fold molar excess. The interference of $Na_2S_2O_3$ (at 100-fold molar excess), and chloride at the concentration at which it is found in sea water (*ca.* 350-fold molar excess), were found to be acceptable (Table 2). Refractive index fluctuations over the sample zone were the major source of interference.

Real samples

Table 3 shows data collected on liquor and waste water samples obtained from facilities where Kraft pulping is practiced. Peak shapes were exactly as expected. Baseline noise and other causes of peak height irreproducibility were minimal, as indicated by the relative standard deviation values obtained ($n = 10$). The developed method had more than adequate sensitivity for the real samples, including the dilute pulp wash water taken from an intermediary stream. The liquor samples all required substantial dilution in order to ensure that they fell within the linear dynamic range of the method. The pulp wash water sample was analyzed as received.

Further work

This method will be applied to a variety of sample matrices obtained from different sampling locations at different mill sites. On-site performance comparisions of this with other methods should be made. On-line application of the method will require development of an automated sample dilution stage. Flow injection manifolds for such purposes have appeared in the literature.[27,28] The kinetics and chemical interactions of the colored product formed warrant further spectrochemical attention.

Table 3. Real sample data for pulp liquors and wash waters

Sample	Source	Dilution ratio	Peak height, *adc units*	$[S^{2-}]$ *ppm*	RSD, %
Blank (10% sulfite)	UBC Chemistry Department	None	0.0	0.0	0.00
Green liquor # 1	Prince George, B.C.	1:500	131.7	13,300	1.77
Green liquor # 2	Prince George, B.C.	1:250	395.5	17,900	0.46
Green liquor # 3	Paprican, Vancouver, B.C.	1:100	714.1	12,600	0.56
Dilute pulp wash water	Paprican, Vancouver, B.C.	None	240.6	45.2	0.73

Samples were as provided by industry, without details of actual source or any prior pretreatment. With the exception of the dilute pulp wash water, all samples were diluted with 10% sodium sulfite. In each case, 10 replicate injections were considered.

CONCLUSIONS

A flow-injection method for determination of sulfide has been developed, optimized and characterized. Use of an automated flow-injection apparatus allowed problems caused by refractive index effects and precipitation to be rapidly determined and eliminated.

Although the actual chemistry is complex, the analytical method developed is fast, relatively simple to use, and is well suited to the needs of the pulp and paper industry. The precision was good, and the detection limit and sensitivity adequate for the type of samples for which it was designed.

The time-dependence of this reaction makes it better suited to flow injection than as a manual analysis, since the reproducible timing from injection to detection afforded by flow injection circumvents most of the problems associated with precipitation.

AUTOMATED MEASUREMENT OF DYE COVERAGE IN PHOTOGRAPHIC NEGATIVES BY FLOW-INJECTION ANALYSIS

TERRENCE P. TOUGAS* and KATHLEEN M. HOBBS
Polaroid Corporation, Waltham, Massachusetts 02254, U.S.A.

(*Received* 24 *May* 1991. *Revised* 21 *June* 1991. *Accepted* 22 *June* 1991)

Summary—A system was designed to automate the determination of three image dyes in an instant photographic material. The method involves extracting negative samples with dimethylsulfoxide and filtering the extract, followed by quantitating the dye coverage (dye per unit area of negative) through a spectrophotometric flow-injection procedure. Significant spectral overlap exists among the dyes, and as a result calculation of coverage requires solving three simultaneous equations. A microcomputer and data acquisition system were employed for controlling the detector and flow-injection system, acquiring and integrating the detector response, calculating coverage, producing and displaying control charts, and automatically transferring results to a VAX based corporate database. In addition to automating sample preparation and measurement steps as much as possible, the goal of this project was to automate the data manipulation and transfer steps.

In general, the process of performing a routine chemical determination is a set of well-defined sequential steps. For a given determination, the process might include; (*a*) generating a request for measurement, (*b*) obtaining the appropriate sample(s), (*c*) preparing the samples, (*d*) performing the measurements, (*e*) analyzing the data (including data quality assurance), (*f*) reporting the results and (*g*) archiving the results. The decision to automate a determination generally rests with an analysis of the benefits of automation relative to the cost. The consequence of the sequential nature of the determination process is that any step might be the rate determining step. Any analysis in consideration of automating a determination should examine all steps. In general the greatest benefit will be realized by focusing the automation effort on these slow steps. Different technologies are required for automating the various aspects of a determination. As chemists, we tend to focus on the chemical steps, *i.e.*, sample preparation and measurement, but the overall automation problem requires strategies involving information management and computer networking, as well as novel chemistries and chemical instrumentation.[1]

The present work arose from a need to automate the determination of three image dyes coated on a photographic negative. Samples are generated by a pilot coating operation that supports product development. In this particular case, the photographic material is part of an instant integral film. There are three major subsystems in this type of film; photographic negative, receiving sheet and reagent pod.[2] After exposure the entire film structure is ejected from the camera between a pair of rollers. The rollers serve to break a seal on the reagent pod, and spread reagent between negative and sheet. This initiates the development process which ultimately results in the transfer of image dyes from the negative to the receiving sheet.

There is a need to routinely monitor dyes coated on negatives as an amount per unit area (coverage). These dyes are responsible for the final photographic image and the amount of dyes coated is crucial to the quality of the image. The actual measurement is used for, among other things, process control during a coating run. Thus, rapid turnaround of results is essential. The manual spectrophotometric determination is a time intensive and tedious operation. Previous to this work, a robot based system was used to automate this determination. When this system failed after several years of use, the issues surrounding automating this determination were re-examined. As a result, we have replaced this manual/robotics procedure with an automated procedure based on flow-injection analysis (FIA), and integrated this automated chemical procedure with an evolving computer

*Author for correspondence.

network composed of hardware and software from many different vendors.

EXPERIMENTAL

Dye spectra were obtained individually with a conventional spectrophotometer (AVIV model 14DS) with a 1-cm cell. Dyes were dissolved in dimethylsulfoxide (DMSO) to concentrations similar to those expected in the negative extracts. Dimethylsulfoxide (HPLC grade) was used throughout as extraction solvent for negative samples and carrier stream for FIA experiments. Samples were prepared for measurement by extracting 8.65 cm^2 of coated negative with 10 ml if DMSO. The negative extracts were filtered through 0.45-μm glass microfiber filters (Xydex, Autovial Syringeless Filters) into sampling vials for FIA with Xydex Processor (automated filtration station capable of filtering 18 samples simultaneously).

System

A requirement for the flow-injection system (FIS) was that it be integrated with the computing environment illustrated in Fig. 1. All the users of analytical information have access to a corporate-wide VAX-based network of minicomputers. The strategy within the analytical group was to connect microcomputers via a Novell based local area network (LAN) to each other and the corporate network. In this configuration, a microcomputer potentially serves as (*a*) a laboratory automation system (LAS), and (*b*) a terminal to both VAX and HP minicomputer, and a local computing resource. With respect to this work, LAS denotes a system for instrument control, data acquisition and data reduction. A decision was also made to implement an Oracle based laboratory information management system (LIMS) in a client-server configuration within the LAN. An additional requirement for the LAN was that it should integrate with an HP-1000 used to automate a chromatography laboratory.

Based on the above requirements, an FIS was configured with an HP Vectra QS/16 as the microcomputer-LAS, a Control Equipment Corporation (now part of Leeman Laboratory) AMI-103 FIA and an Applied Biosystem 783a UV/Vis detector. The AMI-103 has a pressure driven pumping system which results in pulseless flow and excellent flow stability. Crucial to the present work are two features of this system. The AMI-103 can be controlled either through a keyboard on the unit or by an external computer via an RS-232 port. A consequence of the pressure driven design is that wetted parts are all chemically inert (Teflon, glass). This proved important since the carrier stream was DMSO. Previous experiences with peristaltic pumps and this solvent were unsatisfactory because of chemical incompatibility with the pump tubing. The detector was a conventional HPLC detector equipped with the optional preparatory cell (3-mm pathlength) and tungsten lamp. The features of this detector critical to this work were: (*a*) control of wavelength and sensitivity by an external computer (RS-232) and (*b*) operability to at least 700 nm. Figure 2 provides an overview of the hardware and

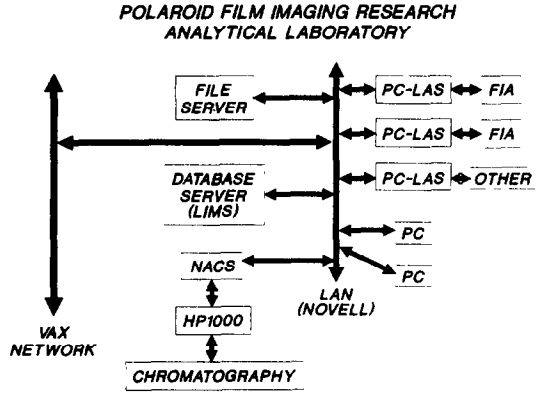

Fig. 1. Analytical laboratory computing environment designed for laboratory automation with MS-DOS microcomputers (PC) based laboratory automation systems (PC-LAS). NACS: Novell Asynchronous Communications Server, HP1000: Hewlet-Packard HP1000 minicomputer used as LAS for a chromatography laboratory.

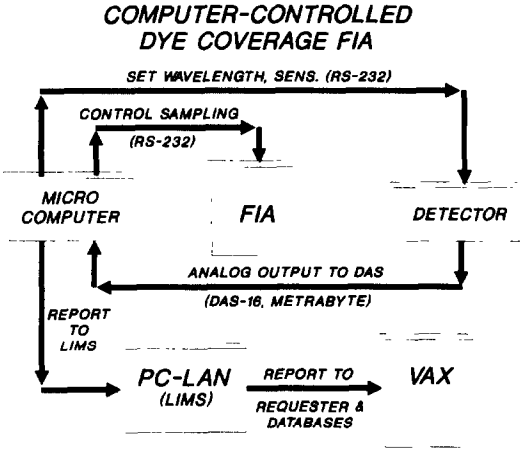

Fig. 2. Overview of equipment used to automate dye coverage determination. Illustrated are electronic paths among the computer, flow-injection system, detector local area network and wide area network.

its relationship to the computing environment. Serial communication is used to control both the flow-injection system and the detector. The analog signal from the detector is digitized (Metrabyte DAS-16) and analyzed within the local PC. Calculated results and reports are output to the LAN or VAX environments.

Operation of the flow-injection system

The operator controls the entire dye coverage determination through a microcomputer system. An MS-DOS batch file controls the overall process by executing the appropriate software (Fig. 3). Sample information is entered into a spreadsheet (Quattro Pro). This information is used by the computer to control the flow-injection system and the detector. The analog signal from the detector is digitized and converted to a concentration of analyte. The calculations require solving a set of three simultaneous equations which compensates for spectral overlap of the three dyes. This is done automatically with routines written in Asyst. The coverage information produced in Asyst is automatically passed to a Quattro spreadsheet, where a report is generated (printed locally) and transferred electronically to the LIMS. The LIMS is used to transfer chemical information based on the coverage data to VAX nodes on the corporate network. Data quality assurance is supported through automatic generation of control charts and flagging spurious controls in the reports.

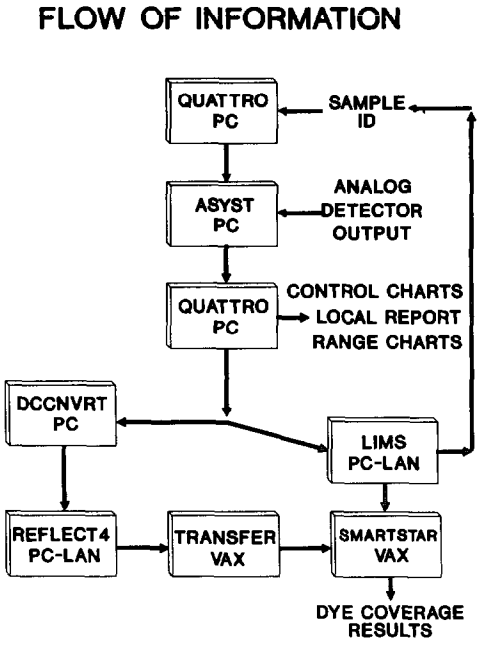

Fig. 3. Overview of software used to automate dye coverage determination. Illustrated is flow of data/information from one process to another, ultimately populating a corporate-wide database and transferring reports electronically to the individual requesting the determination. Shaded arrows indicate final configuration. DCCNVRT is a PASCAL program used to convert a report from Quattro to the format required by Smartstar database.

RESULTS AND DISCUSSION

The manual and robotics methods for dye coverage used absorbance measurements at 459, 554 and 608 nm. As can be seen in the visible spectra (Fig. 4), the former two values correspond to maxima for the yellow and magenta dyes, respectively. In the case of the cyan dye, an intense absorbance maximum occurs at about 678 nm. The dynamic range of the absorbance detector allows the use of the latter wavelength in conjunction with the other two. As a result 459, 554 and 678 nm were selected for subsequent work. The advantages

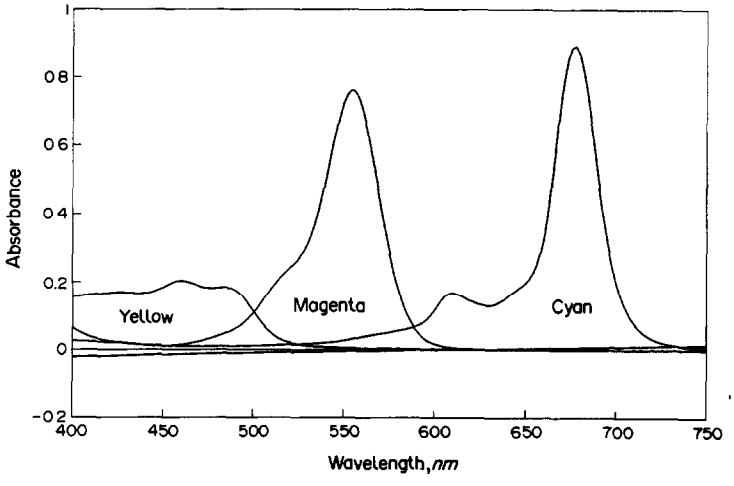

Fig. 4. Visible spectra of three image dyes determined by dye coverage methods.

are increased sensitivity and less spectral overlap with the magenta dye.

The standard negative sample is a disk with area of 8.65 cm^2 punched from a larger section of negative. Extraction and dissolution of the dyes is performed with dimethylsulfoxide (DMSO). Two aspects of the sample preparation were examined. These were the issue of filtering sample extracts *vs.* centrifuging, and the time required for complete extraction of the image dyes. The former issue arises because the centrifugation step in the manual procedure is time consuming and imposes constraints with respect to batch size. A study was performed to compare centrifuging samples extracted in DMSO to filtering these same extracts through 0.45-μm glass microfiber filters. The results indicate (based on *t*-tests) that there is no significant difference between the absorbance of sample extracts filtered *vs.* those centrifuged. On this basis, filtering was adopted for sample preparation.

The optimum time for complete extraction of the negative was examined by extracting three different negative sections for 5, 15 and 30 min and then determining dye coverage by FIA. The results were compared to results obtained by the manual method where samples were extracted for 1–2 hour, and the ratio of these results was defined as the percent extracted. These samples ranged in age from 4 days to 2 years. Previous work had indicated that 30 min was sufficient time for extracting a freshly coated negative. The purpose of this study was to see if the age of the negative had a significant impact on extraction of the dyes. The results of this study are summarized in Table 1. They indicate that 30 min is sufficient for complete extraction for the fresh and 8 month old negative. The cyan result for the 2 year old negative was 94.4%, indicating there may be incomplete extraction of this dye in the old negative.

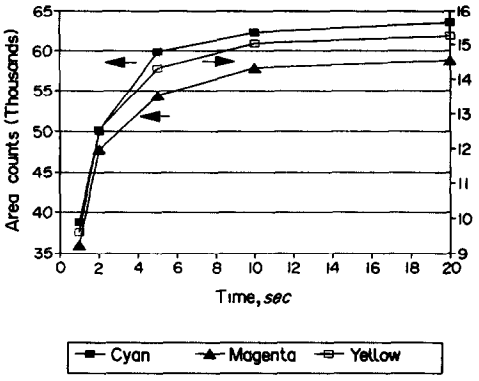

Fig. 5. Flow-injection response (peak area) to image dyes as injection time is varied.

The experimental variables which can be controlled in FIA include manifold dimensions, flow rates, carrier stream(s) and injection volume.[3] Conditions for low dispersion and minimum analysis time were selected because of the need for rapid sample turnaround. Since the extraction of sample required DMSO, this solvent was selected for the carrier stream. Two instrumental variables (injection time and sampling time) were optimized by measuring response (peak area) as a function of each variable. Sampling time is the length of time sample is pumped through the loop prior to injection and injection time is the length of time the carrier stream is flushed through the filled sample loop. In both cases, the response should reach some limit as the variables are increased. Each was varied up to a maximum of 20 sec. In the case of injection and sampling time, the response of a standard mixture was examined. The operating values selected were values well into this limiting plateau of response. Figures 5 and 6 illustrate the results of these studies. Final operating conditions were: carrier flow-rate, 1.5 ml/min; sample loop volume, 100 μl; sampling time, 12 sec; sampling flow-rate, 4 ml/min; injection time, 12 sec. This yielded a sampling

Table 1. Study of extraction efficiency *vs.* time for fresh and aged negative

	Time extracted, *min*	% Extracted relative to 2 hr Cyan	Magenta	Yellow
Fresh negative (4 days after coated)

frequency of 80 inj/hr. In principle, either peak height or area is proportional to concentration. Since it is practical to obtain either in this system, the precision of these two modes of measurements was considered. A control negative was extracted and injected repeatedly. The results in Table 2 indicate that the precision of peak areas is significantly better than of peak height. As a result, peak area has been adopted as the mode for measurement.

Precision was evaluated both in an overall sense and in an attempt to quantitate individual contribution to method variability. The FIA procedure has been in use in its working environment for over a year. As part of the standard operating procedure, a sample of negative used as a laboratory control is analyzed with every batch of samples. Recently, control limits was established for this control sample. A comparison of these statistics with the control limits established for the manual procedure form a good basis for comment on the overall precision of the new procedure. Table 3 compares the precision (as a sample standard deviation) of the FIA method to the manual method. Data used to estimate precisions were collected over about a two-week period for each case (manual and FIA). They therefore include any contributions due to daily set-up of instruments or any other day-to-day factors. Note that all results (both manual and FIA) are reported as the mean of duplicate determinations. Thus the quoted standard deviation is really a standard error. While in all three cases the estimated precision is slightly larger for the FIA, an *F*-test indicates that the differences are not statistically significant. One must also keep in mind the newness of the FIA method and anticipate that the precision will improve with increasing experience. The laboratory control was run twelve times by FIA and nineteen times by the manual method over a period of two weeks. The results for the three dyes are contained in Table 4. A comparison of means via *t*-test suggests that there is no significant difference in the results from either method.

The use of a single standard solution assumes not only that the response is linear, but also that the intercept is zero in the concentration-response curve. If a non-zero intercept exists, then accuracy will be a function of the concentration difference between sample and standard. To evaluate the correctness of these assumptions, a control negative extract was spiked with various levels of a standard dye solution. The experiment was repeated for each image dye. Knowing the coverage of the control and the amount of dye spiked into the extract, the amount found by the FIA dye coverage method was compared to a calculated coverage. The latter is the hypothetical coverage

Table 4. Comparison of laboratory control results: accuracy of FIA *vs.* manual dye coverage

		Cyan		Magenta		Yellow	
	Count	Mean, mg/m²	S.D.	Mean, mg/m²	S.D.	Mean, mg/m²	S.D.
FIA	12	425.5	9.2	356.5	8.8	1011	33
Manual	19	423.7	10.6	354.9	6.6	1021	16
$t_{v,0.05}$		0.474		0.588		0.920

corresponding to the concentrations of dyes in the spiked extracts. The results of this study are contained in Fig. 7 as a plot of calculated *vs.* measured dye coverages. They indicate a slight bias at the extremes of the conditions tested. The conclusion reached is that for the best accuracy, standard and sample concentrations should be as close as possible.

An analysis of our laboratory operations related to this determination showed that the operators spent most of their time calculating results, preparing and distributing reports, and updating control charts. This was true of either the manual or the robotics version of the determination. It was clear that major time savings could be realized by automating these operations. These aspects of the project were solved with several different software packages in the MS–DOS environment. These included a spreadsheet program (Quattro Pro) used as the operator interface, data acquisition/reduction software (Asyst), communications software (Reflections 4), and database/data management software (Oracle). The result was a system which automated all of the above operations.

CONCLUSIONS

The FIA procedure for determining dye coverage has many advantages over the manual and robotics procedures. These include: (*a*) reduced labor requirements (>70%), (*b*) decreased solvent consumption (65%), (*c*) high sample throughput (80 inj/hr), (*d*) automation of data handling and quality control procedures, and (*e*) 1/3–1/4 the cost of a robotics system. It was optimized and in its present form is equivalent to the older procedures with respect to accuracy and precision. With existing hardware and software, it is practical to integrate flow-injection systems into electronic based information networks.

CROSS-CORRELATION IN FLOW-INJECTION ANALYSIS WITH PARALLEL FLOW STREAMS AND AMPEROMETRIC DETECTION

R. E. McKEAN* and D. J. CURRAN†
Department of Chemistry, University of Massachusetts, Amherst, MA 01003, U.S.A.

(*Received* 9 *April* 1991. *Revised* 21 *May* 1991. *Accepted* 21 *May* 1991)

Summary—Cross-correlation was implemented for flow-injection analysis by using two parallel flow lines, each with amperometric detectors, and driven by peristaltic pumps. One flow line was used to generate the reference signal for an analog correlator circuit and the other to generate the analyte signal. Cross-correlation was performed by multiplying these signals together at a time delay of zero, followed by low pass filtering. Using dopamine as a test system, improvements in signal-to-noise ratios of about two orders of magnitude were found for the correlation signal over the direct measurement of the electrode current.

Electrochemical detectors are well known for their excellent detection limits in flow-injection analysis. Further improvement in their performance in this regard can be pursued in terms of approaches which reject noise. Correlation techniques[1–4] are powerful methods to improve signal-to-noise ratios and their use in flow-injection analysis is developed in this work.

Correlation approaches have been used in inductively coupled plasma atomic-emission spectrometry,[5–8] infrared absorption spectroscopy,[9,10] flame spectrometry,[11,12] interferometry in the UV–VIS region,[5,13] chromatography[14–26] and electrochemistry.[27–34] Much of this work has focussed on improving selectivity or providing peak identification. An example of the latter is the work of Mann and co-workers who cross-correlated IR spectra of lipid samples with a reference spectrum containing only the peaks of interest.[9,10] Betty and Horlick used cross-correlation to improve the selectivity of ICP–AES spectra.[6] Blanc *et al.*[27] analysed noise generated at an electrochemical interface by an autocorrelation method similar to that of Brown and Twiss.[35] Van Rooijen and Poppe[36] used cross-correlation to identify the predominant noise source in coulometric and amperometric detectors used in HPLC and FIA. A strong correlation was found between the measured noise and the working electrode area.

We report here on the use of cross-correlation in real time, to improve the electrochemical response of a thin layer amperometric detector used in flow-injection experiments. Two independent flow-injection systems were constructed in parallel. A high concentration of analyte was injected into one stream to produce the necessary reference signal and the sample of interest was injected into the other stream. The two detector responses were then cross-correlated by an analog correlation circuit and the correlation output was plotted on a strip chart recorder.

When two signals are similar but their noise components are different, correlation can be utilized to extract the coherence of the two signals while discriminating against the noise. The correlation function is expressed by equation (1):

$$R_{xy}(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{+T} V_x(t)V_y(t \pm \tau)\,dt \quad (1)$$

where the time averaged or time integrated product of two power signals, $V_x(t)$ and $V_y(t)$, is evaluated at relative displacements (τ) and $R_{xy}(\tau)$ represents the correlation function. Cross-correlation was used at a single time displacement in this work and time averaged continuously by a first order low pass filter.

EXPERIMENTAL

Instrumentation

A schematic diagram of the experimental set-up is shown in Fig. 1. Teflon tubing was used throughout the FIA system (0.05 cm i.d.) and

*Present address: Rhone-Poulenc Rorer, 680 Allendale Road, Building No. 10, King of Prussia, Pennsylvania 19406, U.S.A..
†Author for correspondence.

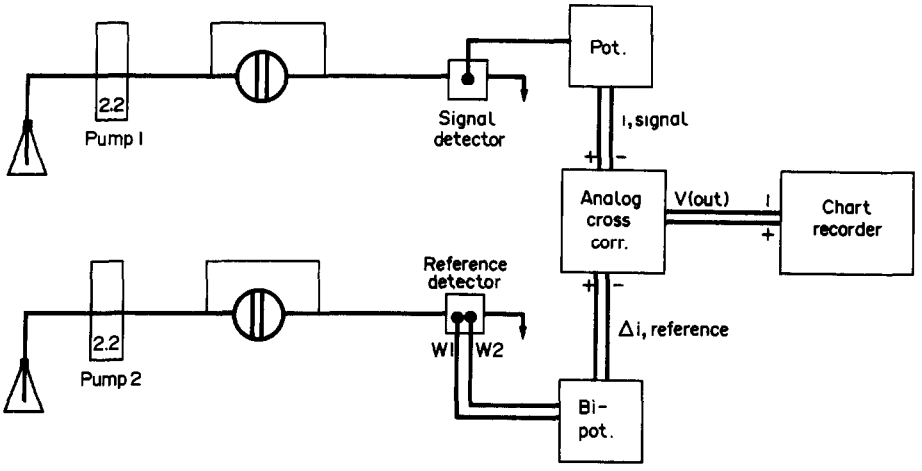

Fig. 1. Diagram of the instrumentation for parallel stream flow-injection analysis with cross-correlation in real time. The outputs from the potentiostat and the bipotentiostat are cross-correlated with analog circuitry and the correlation signal measured on a strip chart recorder.

connectors were flangeless low pressure fittings (Upchurch Scientific Inc., Oak Harbor, WA). The length of tubing connecting the injector to the detector was 30 cm for both flow systems. Two Rainin Rabbit peristaltic pumps (Rainin Instruments, Woburn, MA) were used to avoid the cross-correlation of synchronized pump noise, which occurs when a two channel pump is used. The flow-rate of each pump was set at 2.2 ml/min. A piece of silicone rubber tubing (0.15 cm i.d., Rainin, Woburn, MA) was placed after the pump to act as a pulse dampener. Low pressure Teflon injection valves (Rheodyne, type 5020, Berkeley, CA) were pneumatically actuated simultaneously with a Rheodyne 5701 and 38-931 assembly (Berkeley, CA) and control circuitry constructed in the laboratory.

A single carbon electrode thin layer amperometric detector (Bioanalytical Systems, West Lafayette, IN) was used in the sample stream and a dual carbon electrode thin layer amperometric detector (MF-1000, Bioanalytical Systems) was used in the reference stream. These detectors contain stainless steel auxiliary electrodes and silver–silver chloride reference electrodes. An applied potential of +600 mV was used in all experiments for each working electrode. Both electrochemical cells, two waste containers and a battery operated potentiostat were placed in a metal tool box which served as a Faraday cage. There was no electrolytic contact between the two flow streams.

The single electrode cell voltage was controlled by a conventional adder type potentiostat constructed in the laboratory. Battery power was used to eliminate the ac ripple present in line-operated power supplies. The applied potential was also battery supplied. The working electrode current was measured with a Keithley 427 current-to-voltage converter (Keithley Instruments Inc., Cleveland, OH). Additional functions available with the Keithley 427 are: current nulling capabilities and a second order low pass filter. Due to the low power consumption, and small electrochemical currents, nine volt batteries were employed to power operational amplifiers. High quality operational amplifiers (Burr-Brown Corp., OPA128JM, Burlington, MA) were used to achieve minimum noise and low power consumption.

The circuit shown in Fig. 2 was used to operate the dual electrode electrochemical cell and calculate the difference current between the upstream electrode and the downstream electrode when both working electrodes were held at the same potential. This is a modification of a circuit for a bipotentiostat reported by McClintock and Purdy.[37] Operational amplifiers 5 and 8 were used to supply a nulling current.

A diagram of the cross-correlation circuit is shown in Fig. 3. All resistors were 1.4 mΩ 1% precision resistors and the low pass filter capacitor was 0.94 μF. Power was provided by a Philbrick Research PR-300 ± 15 V power supply. Operational amplifiers were Burr-Brown OPA128JM (Burlington, MA) and the multiplier was an Analog Devices AD534J (Norwood, MA). Data were recorded on a dual pen strip chart recorder (Microscribe 4500, Fisher Scientific, Medford, MA).

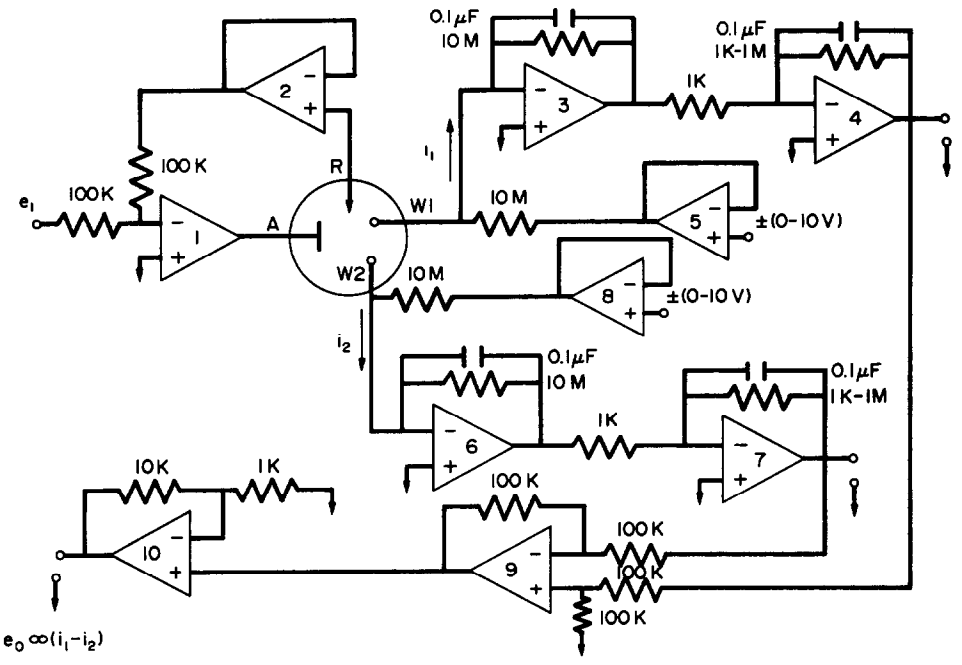

Fig. 2. Circuit digram of the bipotentiostat.

Reagents

A carrier solution of 0.1*M* sodium acetate (reagent grade, Fisher, Fairlawn, NJ) was adjusted to pH 5.1 with hydrochloric acid (Fisher, Fairlawn, NJ). Dopamine was purchased from Sigma (St. Louis, MO). Demineralized water was further purified with a Barnstead Nanopure System (Boston, MA). All dopamine solutions were prepared in 0.1*M* acetate buffer.

RESULTS AND DISCUSSION

A complete correlation operation requires multiple time delays, which is difficult to implement in real time. As a compromise a single time delay was selected. It is clear that the maximum correlation response will occur between the reference signal and the measurement signal in an FIA experiment at a time delay of zero, since the correlation process involves a multiplication and time averaging. All measurements were therefore made with zero time delay.

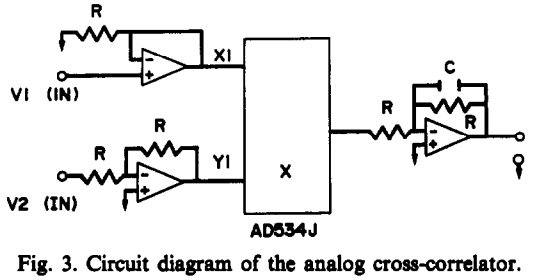

Fig. 3. Circuit diagram of the analog cross-correlator.

A zero mean baseline is necessary for the reference signal. To achieve this, a dual electrode amperometric cell with a series electrode arrangement was employed to subtract the downstream electrode current from the upstream electrode current. Figure 4 shows the

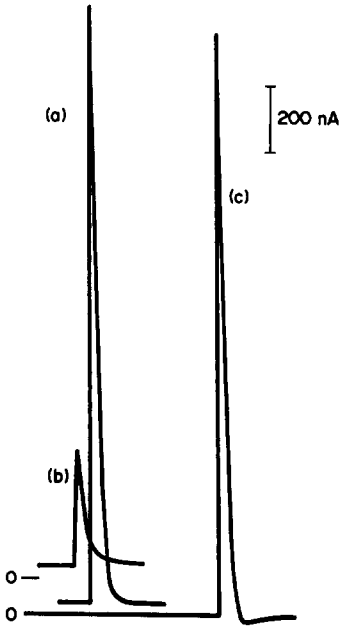

Fig. 4. Current-time response curves under bipotentiostatic control for the series electrode arrangement to illustrate peak height and background current. Zero current baseline is indicated by (0). (*a*) Upstream electrode, (*b*) downstream electrode, (*c*) difference current [(*a*) − (*b*)]. Each electrode was held at +600 mV *vs.* Ag/AgCl.

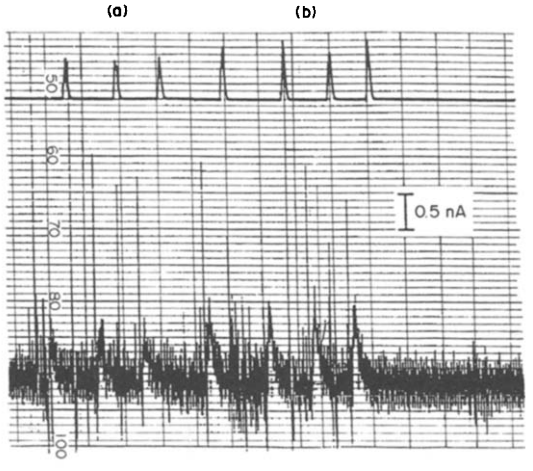

Fig. 5. Strip chart recording of noisy electrode current response signal (bottom) and cross-correlated signal (top), for injections of (*a*) 7.4n*M* and (*b*) 15n*M* dopamine in pH 5.4, 0.1*M* acetate buffer carrier solution.

response for an injection of 10μM dopamine at (*a*) the upstream electrode; (*b*) the downstream electrode and (*c*) the difference current.

For clarity, the (*a*) and (*b*) curves have been displaced on the horizontal (time) and vertical (current) axes and do not show their true time relationship. Note that both signals (*a*) and (*b*) have a nonzero baseline. After subtraction of the downstream current from the upstream current, the baseline current was reduced to zero. The advantage of this technique over simply nulling the background current is that the difference current compensates for drifting baselines while a nulled baseline cannot. Because the collection efficiency is not high, a small current is subtracted from a large current leading to a substantial difference current. The difference current can also be ampified by operational amplifiers 10 (Fig. 2), to increase the magnitude of the reference signal.

By maintaining the same flow-rate of 2.2 ml/min in each FIA system and using 30 cm of tubing between each injector and its corresponding detector, simultaneous injections of dopamine resulted in simultaneous detection. One-hundred μl of 10μM dopamine were injected into the reference stream and the same volume of dopamine with concentrations ranging from 7.4 to 240nM were injected into the sample stream. The direct electrochemical response, without cross-correlation, showed severe baseline noise as illustrated by the lower stripchart recording shown in Fig. 5. The correlated output, recorded simultaneously, is shown in the upper trace in Fig. 5. The reduction in baseline noise is very evident and the peaks are recovered nicely from the noise. The correlated response signal was converted to current and plotted versus concentration. The result was linear with a correlation coefficient of 0.997. It is important to note that the experimental configuration was such that cross-correlation of the noise was accomplished, but the choice of time constant for the low pass filter was such that the signal was not time averaged. In fact, correlation was implemented recursively, with a time constant of 1.3 sec over the entire FIA experiment. As seen in Fig. 5, the cross-correlated signal retains a peaked shape. Had the

$Noise_{rms}$ = 0.3 nA.

signal also been time averaged, the data would appear in the form of the integral of the peaks shown in the upper trace of Fig. 5.

Signal-to-noise ratios (S/N) were determined by dividing the mean peak height of three replicates by the root mean-square (rms) noise. The rms noise of the baseline current, as measured at the output of the current-to-voltage converter was 0.3 nA, while that at the correlator output was 0.003 nA after converting the voltage outputs of the respective circuits to current. Table 1 shows the data for triplicate determinations for both the I/E converter output and the correlator output, along with the calculated means, standard deviations and signal-to-noise ratios. The improvement in relative standard deviation and S/N of the correlation results over the electrode current measurements is substantial. The electrode current signal for the lowest concentration is essentially buried in noise (S/N = 1.4), but the correlation result for the same concentration had a S/N of 180. The improvement in S/N for the lower concentrations studied is over two orders of magnitude.

Choosing a S/N of 3 to correspond to the detection limit, the correlation results should yield a detection limit of 0.12nM dopamine, or about 2 picograms for 100-μl injections. This is over two orders of magnitude better than the detection limit for the measurement without cross-correlation. Attempts to achieve these detection limits in practice were inhibited by two problems which were identified. The first is the presence of false response peaks due to the pressure surge created when the injection valve is turned. Their shape and timing is identical to that of analyte peaks and they produce a blank response when carrier stream solution is injected into the carrier stream. Peak heights for these blanks had an average value of 0.031 nA which would correspond to an apparent concentration of 0.83nM. The second problem relates to the use of a reference signal obtained in real time. The precision of the reference peak maximum is subject to the experimental variation inherent in the injection and measurement process. The experimental variability in the reference signal manifests itself in the precision of the correlation signal. Solutions to these problems have been investigated. The false peak has been separated in time from the analyte peak and computer storage and playback of the reference peak were used. The detection limit was improved by a factor of four. Details will be presented elsewhere.

CONCLUSIONS

It has been demonstrated that cross-correlation techniques produce improvements in S/N of over two orders of magnitude for flow-injection analysis with amperometric detection. The correlation operation was performed in real time in the analog domain. Its implementation is simple, straightforward and inexpensive. In addition, the approach is not limited to electrochemical detectors and could be applied to any type of flow stream detector.

ANALYTICAL DATA

SPECTROPHOTOMETRIC DETERMINATION OF THE ACIDITY CONSTANTS OF 2-AMINO CYCLOPENTENE-1-DITHIOCARBOXYLIC ACID AND SOME OF ITS DERIVATIVES

M. B. GHOLIVAND and A. SAFAVI*
Department of Chemistry, Shiraz University, Shiraz, Iran

(*Received* 3 *June* 1991. *Accepted* 9 *August* 1991)

Summary—The acidity constants of 2-amino cyclopentene-1-dithiocarboxylic acid (ACDA) and some of its derivatives have been determined spectrophotometrically, at 25° and at different mole fractions of ethanol in water. In all solvent mixtures used, the acidity constants vary in the order ACDA > *N*-methyl-ACDA > *N*-ethyl-ACDA > *N*-butyl-ACDA.

Recently, there has been increasing interest in the compounds of 2-amino cyclopentene-1-dithiocarboxylic acid (ACDA) and its derivatives.[1,2] These compounds act as ligands to form different complexes with metal ions.[3–7] The importance of these complexes lies in the fact that they are used as models of sulphur metal proteins.[1] Moreover, there are reports on the use of some of these compounds as antifungal substances.[8]

Evaluation of the acidity constants of organic reagents is of great value in planning analytical work,[9] *e.g.*, the acidity constants can be employed in the design of titration procedures and in examining the possibility of the separation of mixtures of compounds by extraction. The complexing properties of a molecule depend on the number and steric disposition of its donor centres as well as on its acid–base properties. The study of the analytical behaviour of ACDA and its derivatives has been undertaken in this laboratory. In this paper we report the acidity constant of some of these compounds in mixed solvents.

EXPERIMENTAL

Chemicals

Hydrochloric acid (Merck) and sodium hydroxide (Merck) were used without any purification. ACDA and its derivatives were synthesized according to the work of Takashima and Yokoyama[10] and Bordas *et al.*[11] These compounds were further recrystallized from methanol.

Apparatus

A Corning 130 pH meter and a Cary 118 spectrophotometer with a temperature control were used.

Procedure

The procedure of Asuero *et al.* was used.[12] In this procedure the absorbance of $9.8 \times 10^{-5}M$ ACDA was measured in highly acidic and basic media, and at pH values close to p*K*a, in different mole fractions of ethanol in water. A similar procedure was used for *N*-methyl-2-amino cyclopentene-1-dithiocarboxylic acid (*N*-methyl-ACDA), *N*-ethyl-2-amino cyclopentene-1-dithiocarboxylic acid (*N*-ethyl-ACDA) and *N*-butyl-2-amino cyclopentene-1-dithiocarboxylic acid (*N*-butyl-ACDA). All experiments were performed at 25°.

RESULTS AND DISCUSSION

Water, with its particular relevance to the biological systems, is the best solvent for determination of acidity constants. But owing to the low solubility of ACDA and its derivatives in aqueous media, the acidity constants were also

*Author for correspondence.

0	6.18	6.39	6.50	*
0.07	6.24	6.40	6.82	*
0.17	6.54	6.77	7.20	7.44
0.32	7.28	7.50	7.61	7.71
0.55	8.16	8.23	8.31	8.44

*The acid was not soluble.

determined in mixed solvents. Ethanol was chosen as the non-aqueous solvent, because the structure of ethanol is very similar to the water structure. The pKa values of mentioned compounds were determined and are shown in Table 1. The variation in pKa values of 2-amino-cyclopentene-1-dithiocarboxylic acids containing different substituents on nitrogen atoms can be explained in terms of factors such as inductive effect due to alkyl substituents, strain factors associated with bonding at the nitrogen atom, and various degrees of solvation of ligand and the ligand anion.

As can be seen from Table 1, the presence of electron releasing groups such as methyl, ethyl and butyl decreases the acidic properties of these acids. This is expected since by replacing one of the hydrogen atoms of the NH_2 group by alkyl groups, the electron releasing property of the amino function to the ring is increased and this inductive effect results in a larger negative charge on the sulphur atoms, which attracts the proton. Thus addition energy is required for the dissociation of the acid, making ΔG° less negative and, hence, larger values of pKa are obtained. Therefore, the ionic property of the S—H bond in four acids varies in the order ACDA > *N*-methyl-ACDA > *N*-ethyl-ACDA > *N*-butyl-ACDA.

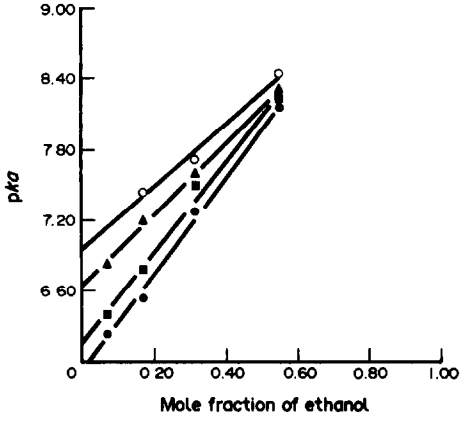

Fig. 1. Variation of pKa values of acids with X_{EtOH} in binary mixtures for ACDA (●), *N*-methyl-ACDA (■), *N*-ethyl-ACDA (▲) and *N*-butyl-ACDA (○).

The data shown in Table 1 clearly illustrate the important influence of the nature of the solvent in the dissociation reaction. The acidity constants of four acids decreases rapidly with increasing the mole fraction of ethanol in the mixed solvents. It has been shown that the solvating ability[13] (as expressed by the Gutmann donicity scale) and dielectric constant of the solvent play a fundamental role in dissociation reactions. Water is a solvent of high solvating ability [*i.e.*, donor number (DN) = 33[14] and dielectric constant (ϵ) = 78] which can dissociate the acid and stabilize the produced anion and hydrogen ion. Thus it is expected that addition of ethanol with lower donor number and dielectric constant (DN = 18.5, ϵ = 24.3) to water, decreases the extent of interaction between the ligand anion and proton with solvent, and this decreases the acidity constant of the acids.

It is interesting to note that there is actually a linear relationship between the pKa value of each acid and the mole fraction of ethanol (X_{EtOH}) in the binary mixed solvents used (Fig. 1).

It is clear that, the dissociation of an uncharged acid in a solvent requires the separation of two ions of opposite charges. The work required to separate these charges is inversely proportional to the dielectric constant of the solvent. The energy required for dissociation is supplied by solvation of the ions and also an additional energy is supplied by the proton transfer from acid to the solvent molecule. If the dielectric constant and the solvating ability of the solvent is decreased, more energy will be required to separate the anion and cation and consequently the extent of dissociation of acid will be lowered. Therefore, the increase in pKa value of each acid is due to increasing the mole fraction of ethanol in the binary mixed solvent.

Another interesting point that is seen in Fig. 1 is the differentiating property of water. Water is an amphiprotic solvent that acts as differentiating solvent. By addition of ethanol to water the basicity of mixed solvent will be increased, so that the solute acids become much stronger

proton donors than the protonated solvent. The dissociation reaction then goes to completion, and the acid is said to be levelled to the strength of the solvated proton. Therefore, although transfer of the proton is complete, because of lower dielectric constant of the mixed solvent, the equilibrium involves an ion-pair rather than the solvated ions. This causes an increase in the levelling effect of solvent by increasing the mole fraction of ethanol, or decreasing the dielectric constant of the binary mixed solvent. This is clearly shown in Fig. 1.

APPLICATION OF HYDRIDE GENERATION TO ATOMIC-ABSORPTION SPECTROMETRIC ANALYSIS OF WINES AND BEVERAGES: A REVIEW

C. BALUJA-SANTOS* and A. GONZALEZ-PORTAL
Department of Analytical Chemistry, Nutrition and Bromatology, Faculty of Chemistry, University of Santiago de Compostela, Santiago 15706, Spain

(*Received* 4 *February* 1989. *Revised* 14 *September* 1991. *Accepted* 27 *September* 1991)

Summary—The use of hydride-generation systems for atomic-absorption spectrometry and other spectrometric methods for the determination and control of As, Sb, Bi, Pb, Sn, Se and Te in wines and beverages is reviewed.

Methods based on atomic-absorption spectrometry (AAS) and inductively-coupled plasma atomic-emission spectrometry (ICP/AES) are widely used for chemical characterization of wines and beverages, investigation of their adulteration, and study of the changes that take place during vinification and the preparation of beverages. Of more than 20,000 papers published on these techniques in less than 25 years, over 300 are concerned with their application to the major, trace and ultratrace elements in wines and beverages, and of these over 100 are devoted solely to the determination of calcium and magnesium.[1]

The analytical potential of hydride generation systems in atomic-absorption spectrometry (HG–AAS) is apparent from earlier reviews,[2–8] systematic studies of interferences,[9,10] and papers on hydride generation and atomization mechanisms.[11,12] However, of the more than 600 articles published on this subject since 1970, very few are devoted to the application of HG–AAS to wines and beverages.

The aim of the present review, based in part on a paper presented in 1986 at the International Viticultural and Oenological Congress (OIV) in Santiago (Chile),[13] is to describe the hydride-generation technique, decide which of the various spectrometric methods are best fitted for use with hydride-generation systems, and compare the results obtained by their use with those of other techniques used in the analysis of wine and beverages, with special attention to determination of As, Sb, Bi, Pb, Sn, Se and Te.

*Author for correspondence.

FUNDAMENTALS

Covalent hydrides are volatile compounds in which hydrogen is bound to elements of Groups IIIb–VIb. So far, only eight of these elements are determined by atomic-absorption or emission photometric methods by means of the hydrides: Ge, Sn, Pb, As, Sb, Bi, Se and Te.

Levels of As, Sb, Bi, Pb, Sn, Se and Te in wine

According to Bowen's classification,[14] As, Sb, Bi, Pb, Sn, Se and Te are elements of unknown biological function that are regarded as toxic because they accumulate in the human organism. In fact, many of the elements found at very low concentrations in living beings have toxic effects at concentrations that are only slightly higher than normal. The problems posed by these elements for oenology, toxicology and physiological biochemistry are similar.

The mineral elements contained in wine depend on numerous factors, including kind of soil, variety of grape, climatological conditions, pollution and viticultural practices. The primary natural mineral content is to be distinguished from the secondary contaminants derived from the use of pesticides and fertilizers or acquired during vinification (in spite of the overall reduction in mineral content during this process). Table 1 summarizes the levels of various elements in man and in wine.

Table 1. Levels of certain elements in wines

Element	Level in man, *mg*	Level in wine, *mg/l.* Primary	Secondary	Limit[a]
As	1	—	1[b]	0.2
Sb	8	—	(A)	—
Bi	—	None	3[c]	—
			0.1–0.2[d]	
Pb	100–400	0.1	0.4–1.0 (B)	0.4
Sn	17	0.1–0.9	(C)	0.2
		0.3 (mean)	0.2–0.7[e], 0.1[f]	
Se	3.15	—	1.0	—
Te	(?)[h]		(D)	—

[a] Limit fixed by Office Internationale de la Vigne et du Vin (OIV).

[b] Higher levels are considered dangerous. Possible sources of As include additives such as citric or tartaric acid, agar-agar, bentonite or tannins.[15]

(A) In contact with old rubber hose, Sb levels rose tenfold after 3 hr and more than 60-fold after 48 hr.[16]

[c] A problem with Australian wines.[17]

[d] Fortified Spanish wine.[18]

(B) Contamination from lead alloys, plastics, paints and ambient air.[19]

(C) The source of tin may be tinplate containers[20,21] or the storage of wine in untreated PVC bottles.

[e] Average level measured in 8 Moselles.[21]

[f] Wine and brandy from Moldavia.[23]

[g] Selenium levels higher than about 100 μg can produce symptoms of chronic poisoning.[24]

[h] Probably 550–600 μg.

(D) The source of Te in wine is contamination.

Methods used in the analysis of wine and beverages

Among the most widely used techniques for the determination of mineral elements in wine and beverages are atomic-absorption spectrometry (AAS) and electrothermal AAS (ET–AAS), but it is generally necessary to subject samples to pretreatments that vary from one element to another. The choice of method is influenced by the desired selectivity and sensitivity, the number of samples to be analysed, the interferences present, the need to use standards or reference methods, and the cost of apparatus. A general discussion of these factors has been published elsewhere.[1] Table 2 offers a comparative summary of various methods used.

Hydride generation

Initially, "nascent" hydrogen produced by metal–acid reactions was used to generate hydrides for quantitative analysis; the most widely employed are listed in Table 3. However, these reactions all have some drawback, such as low reaction rate, presence of excess of hydrogen, or (last but not least) the small number of hydrides generated, which limits the number of elements that can be determined in a single sample.

To avoid these problems, Braman *et al.*[28] introduced use of sodium borohydride (also called sodium tetrahydroborate), which has been found applicable to determination of eight elements.[29–31] The stability of stock solutions of $NaBH_4$, which was initially a problem, was increased by using a 0.45 μm filter to remove the cloudy carbonaceous precipitate produced by alkalization with potassium hydroxide[32] or sodium hydroxide.[33] To avoid interference

Table 2. Comparative summary of the methods for analysis of wines and beverages

Method	No. of elements determinable	Cost factor	Selectivity	Sensitivity, μg	Precision, %
POL or VOL	30	1	poor	1.0	3
S (vis–UV or F)	60	0.5	poor	0.1	1
AES	60	—	medium	1.0	2
AAS	60	1	good	0.1	1
ET–AAS	60	2	good	0.0001	3
ICP	75	6	good	0.01	2
XRF	80	4	medium	1.0	10
SSMS	80	10	good	0.001	5
NAA*	75	1.5	medium	0.001	5

POL or VOL = polarography or voltammetry.
S (vis–UV or F) = spectrophotometry in the vis–UV region or by fluorescence.
AES = atomic-emission spectrometry.
AAS = atomic-absorption spectrometry.
ET–AAS = electrothermal atomic-absorption spectrometry.
ICP = inductively coupled plasma.
XRF = X-ray fluorescence spectrometry.
SSMS = spark-source mass spectrometry.
NAA = neutron-activation analysis.

Table 3. Metal–acid reactions for hydride generation

Metal	Acid	No. of hydrides generated	Rate of reaction	Reference
Zn*	HCl	2	Slow	25
$Zn/TiCl_3$	H_2SO_4 and/or HCl	2	Slow	26
$Mg/TiCl_3$	H_2SO_4 and/or HCl	5	5–10 min	26
Al†	HCl	3	—	27

*Prior reduction of As(V), Se(VI) and Se(VI) with $SnCl_2$–KI.
†For As determination, prior reduction with $SnCl_2$–KI.

from nickel in the determination of arsenic and selenium, use of sodium cyanoborohydride ($NaBH_3CN$) has been proposed,[34] but the risk of release of HCN and the consequent need for strict safety measures make this method inadvisable for routine work, and the $NaBH_4$ reaction is currently the most widely used. Most authors recommend storing the reductant solution in glass containers under refrigeration.

A wide variety of designs have been proposed for the hydride-generation apparatus.[7,35–37]

Collection of the hydride

Various systems have been devised for collection of the hydrides generated and their transport to the atomizer.

Liquid-nitrogen trap. This was the first system employed.[38] The hydride is collected in a U-tube which is then closed with a stopcock to prevent back-diffusion. One end of the U-tube is then connected to the premix chamber of the instrument used, and the other to a nitrogen or argon flow to carry the hydride to the atomizer. This technique was further developed by Braman *et al.*[39] and modified by Crecelius,[40] but is sometimes considered too slow for routine work.

Absorption solutions. Madsen[41] proposed generating AsH_3 (by reduction with zinc in sulphuric acid) in a 125-ml conical flask and collecting it in 5 ml of 0.01*M* silver nitrate in a 10-ml measuring cylinder. The absorption solution is then aspirated into an argon–hydrogen flame in an AAS apparatus. For sampling in the field, the hydrides of As, Sb, and Se can be absorbed on solid supports impregnated with silver nitrate or mercuric chloride, which are then transported to the laboratory for analysis.[42]

The balloon method. The collector described by Fernandez and Manning[43] has been modified for use as a closed system.[44] This has become the most popular method of hydride collection and has been commercialized by Perkin–Elmer. Its main drawback is the frequency with which the balloon must be changed; the useful life of a balloon has been variously estimated as 50,[44] or as few[45] as 15–20 determinations.

Other collector systems. Glass or plastic[46] flasks have been used as an alternative to balloons.

Direct introduction. It is not always necessary to collect the hydride released, though this is the procedure followed in the only commercial system currently available. Many authors have used systems in which collection of the hydride is not required.[28,30,46,47]

Atomization techniques

Tubes heated by flames. This is the most widely used method. The air–acetylene flame employed by Holak[38] has been replaced by the argon–hydrogen flame, which is currently the most highly recommended of all the various methods of heating the tube by a flame or electrically. To aid combustion for atomization of the hydride, Siemer and Hagemann[46] added a small quantity of oxygen to the stream of hydrogen used to carry the hydride (released by $NaBH_4$) to the silica tube. Thompson and Thomerson[30] were the first to employ a special open tube having the advantages of not requiring a collector and of removing virtually all background absorption by the flame. Both air–acetylene and argon–hydrogen flames were tried, better sensitivity being obtained with the latter. The tube is fixed to the head of the burner.

Electrically heated tubes. Chu *et al.*[45] used an electrically heated tube as an alternative to a flame. The carrier gas used was argon. The absence of a flame reduces background absorption, and the relatively great length of time for which the atoms to be determined remain in the tube considerably improves the sensitivity relative to that of flame techniques. This system is used for the determination of arsenic. The great advantage of these atomizers is the ease with which the temperature can be controlled

Table 4. Atomization systems

Method	Reductor	Carrier gas	Flame	Elements	Reference
AFS*	$NaBH_4$	Argon	$Ar-H_2$	As, Bi	50
AFS*	$NaBH_4$	Argon	$Ar-H_2$	Bi	51
AFS†	Zn powder	Argon	$Ar-H_2$	Sb, As, Se, Te	52
DC-arc	$NaBH_4$	Helium	—	As, Sb	53
MIP	Zn	Argon	—	As‡	53, 54
MECA	$NaBH_4$	§	—	As, Sb	55
ICP	$NaBH_4$	#		As	56

AFS = atomic-fluorescence spectrometry (*undispersed system; †dispersed system).
DC arc = arc or plasma spectrography.
MIP = microwave induced plasma.
MECA = molecular emission cavity analysis.
ICP = inductively coupled plasma.

provide the optimal temperature for each hydride.

A detailed investigation was made of the system to optimize the sensitivity for the individual elements. The stability of the hydrides was also investigated and decided which hydrides should be introduced directly into the cell (Sb, Pb, Te, Sn) or could be collected in a gasometer and subsequently transferred to the cell (As, Bi, Se).[48]

Deterioration of the inner surface of the silica tube has been observed.[34,49]

Other atomization systems. Table 4 summarizes other systems employed, which range from atomic-fluorescence spectrometry (AFS) to the inductively-coupled plasma (ICP) and microwave-induced plasma (MIP) techniques. The latter two are particularly valuable for multielemental analysis, since they considerably widen the working range.

Light sources

The most commonly used light source is the hollow-cathode lamp (HCL), but it is not advisable for the determination of As or Se, for which the signal-to-noise ratio in single-beam apparatus is rather small. For these elements, Fernandez[31] has obtained good sensitivities and detection limits with an electrodeless discharge lamp (EDL) in conjunction with $NaBH_4$, a balloon collector and an argon–hydrogen flame. The AFS and ICP techniques naturally need no light source.

Automatic systems

Various articles on the design and application of automatic and semi-automatic systems have been published.[47,57] Two groups may be distinguished: methods which use a peristaltic pump and those in which the reagent is transported under pressure. Those in the former group are the more highly automated because they involve less manipulation, but those in the latter group have the advantage of allowing very strict control of the hydride generation conditions.

Flow-injection analysis

The flow-injection hydride generation methods coupled with AAS are characterized by high efficiency, low sample and reagent consumption, and improved tolerance of interferences.[58-60] High throughput, of over 200 samples/hr, is feasible with relative sensitivities and detection limits comparable with those of conventional HG–AAS methods but consuming only μl volumes of sample. Such samples have to go through tedious preconcentration procedures to achieve 10–50-fold enrichment before the hydride-generation determination. Ion-exchange preconcentration has been combined with flow-injection HG–AAS to produce an efficient system for ultratrace determination of hydride-forming elements.[61]

Sample preparation

It is usually necessary to subject samples to wet or dry ashing. The methods used are summarized in Table 5.

Dry ashing. This is not the most usual method, since As, Sn, Sb, and Se tend to undergo loss through volatilization. Tam and Lacroix[62] have none the less obtained 100% recovery for As and Se determined by HG–AAS, from samples subjected to dry ashing

Table 5. Methods of sample preparation

Method	Elements	Remarks
Dry ashing		
$Mg(NO_3)_2$	As, Sb, Se	HCl solution
MgO	As, Se	HCl solution
Wet digestion		
$HNO_3 + H_2SO_4$	As, Sb	
$HNO_3 + HClO_4$	Se, As, Sb	
$HNO_3 + HClO_4 + H_2SO_4$	Se, As, Se	Often utilized

with a magnesium nitrate and oxide mixture as an alternative to wet ashing by digestion with a mixture of nitric, perchloric and sulphuric acids. The optimal Mg^{2+} concentration in the ashing aid is 0.6–6.0 mg/ml; higher concentrations lead to low results.

Wet digestion. Because of the volatility of the chlorides of the elements to be determined, the samples are decomposed with nitric acid, sulphuric acid, hydrogen peroxide and/or perchloric acid. Each of these reagents has its advantages and drawbacks, and normally they are used in combination. Among the reviews on the preparation of samples, that of Gorsuch[63] is particularly noteworthy, and for the digestion of biological samples that of Nève *et al.*[64]

Bomb digestion. Digestion with acid in a Teflon bomb considerably reduces losses. Alkaline media are not used for HGS work, nor is hydrofluoric acid, which gives rise to fluoride complexes of As, Sb and Sn. The bomb method is limited by the volume of sample and by the critical nature of the volume of acid and the temperature and duration of heating.

Microwave oven. Digestion by microwave oven, first used by Koirtyohann and colleagues at the University of Missouri[65] and later popularized by Kingston and Jassie,[66] is one of the most recent methods. The technique has a wide range of applications, and has excellent speed and reproducibility.[67]

Wine and beverage sampling. The preparation of samples of wines and beverages for analysis by HG–AAS is not particularly difficult. It is generally sufficient to subject the sample to degasification and acidification, followed by reduction of the analyte with potassium iodide (for As or Sb) or hydrogen (for Se and Te). The mineralization of wines and beverages has been comprehensively discussed by Baluja-Santos *et al.*,[1] Godden and Thomerson,[7] and others.[68–73]

Interferences

The interferences affecting HG–AAS may be classified in two groups, those arising during preparation of the hydrides and those arising during atomization.

Factors causing interferences during hydride generation

Oxidation state. The initial oxidation state of the element to be determined has a considerable influence on the absorption signal. The signals produced by Se(VI) and Te(VI), for example, are negligible compared with those of Se(IV) and Te(IV). After boiling for 15 min with 3:1 v/v nitric acid–hydrochloric acid mixture and subsequent cooling and dilution, Te(VI) is completely reduced to Te(IV) by the hydrochloric acid, but application of the same procedure to Se(VI) reduces only 50% of the selenium.[30]

As and Sb can be reduced to hydrides from both their (III) and (V) oxidation states. The selective determination of As(III) in presence of As(V) by suitable adjustment of the acidity before addition of $NaBH_4$ has been proposed by Aggett and Aspell[37] and Nakashima.[74]

Concentration of acid. When $NaBH_4$ is used as the hydride generation agent, the absorption signals of the As, Bi, Se and Te hydrides remain constant when the acid concentration is increased.[31] These findings have been corroborated by other studies, except that the Te signal has been observed to increase when the acid concentration is increased from 1 to 4*M*.[75]

When the acidity is maintained at pH 4–5, As(III) can be determined in presence of As(V), and total arsenic determined after increasing the acidity to 5*M* (hydrochloric acid).[37,74,76]

Pettersson and Olin[77] studied the reduction of Se(VI) to Se(IV) in 4, 5, and 6*M* hydrochloric acid at temperatures between 50 and 95° with continuous-flow hydride-generation AAS. Their results indicate that the addition of chloride to an acid digest should be limited to a concentration of about 2.5*M*.

Organic bonds. As with biological media, in analysis of wines and beverages it is necessary to take into account bonds between the element to be determined and organic groups. Fernandez and Manning consider that when the sample may contain such bonds, a preliminary oxidation is necessary.[43]

Factors causing interferences during atomization

Interference by other elements may produce a signal that is greater or smaller than the true signal of the element to be determined. Among other isolated results, it may be noted that Braman *et al.*[28] found that Cu and Ag interfere

Table 6. Interferences observed for the determination of hydrides generated with sodium borohydride (argon–hydrogen flame). (Reproduced by permission from A. E. Smith, *Analyst*, 1975, **100**, 300; Copyright Royal Society of Chemistry.)

	Interference (suppression of signal)

*Results for tin are not quoted because of the high blank.

with arsine and stibine generated in alkaline media with NBH_4, and nitric acid has been found to cause considerable interference in the determination of antimony.[7]

The most comprehensive study of interferences in hydride-generation work was made by Smith,[9] who investigated the effects of 48 elements on the determination of As, Sb, Bi, Ge, Se and Te by hydride generation with $NaBH_4$ and AAS with an argon–hydrogen flame. Table 6 summarizes his results. In another valuable study, Pierce and Brown[10] found significant differences between the results of manual and automatic hydride generation when they compared the effects of various anions, cations and acids on the determination of As and Se in a system with a graphite atomization furnace.

Verlinden and Deelstra[78] studied the effects of other hydride-forming elements on the determination of selenium, and found them to be in the order Bi < As < Te < Ge < Se < Sn.

Castillo *et al.*,[79] studied the interference by 27 ions.

Elimination of interferences

For the determination of As by HG–AAS with an argon–hydrogen flame, Kirkbright and Taddia[80] have developed a method for the elimination of interferences from Cu, Ni, Pt and Pd, by means of thiosemicarbazide and/or 1,10-phenanthroline. Co-precipitation with lanthanum hydroxide has been used to remove interference from the matrix metal in the determination of As, Sn, Se and Te.[81] It has been proposed that interference from nickel may be

*The method did not give satisfactory results, mainly owing to ethanol interference, which substantially reduces the lead signal.

eliminated by using $NaBH_3CN$ to generate the hydrides,[34] but this method involves a high risk of poisoning for personnel.

Speciation

The determination of the particular form of an element in its natural environment, *speciation*, is the most fascinating and rapidly developing area of application of atomic spectroscopy to have emerged in recent years.

Knowledge of the speciation in some types of samples is important because to relate the toxicity, bioaccumulation and transport of a particular element to its oxidation state, the nature of the ligand needs to be considered.[82] As an example, different forms of arsenic greatly vary in toxicity: arsenite > arsenate > monomethylarsonic acid > dimethylarsinic acid > arsenobetaine. Branch *et al.*[83] have stated that arsenite is the most toxic; arsenobetaine[84,85] is relatively non-toxic.

Organotin compounds are used as biocides, mainly in antifouling paints and wood preservatives; tributyltin oxide and its derivatives are commonly used for this purpose. These materials are both irritant and toxic.[24] Krull and Panaro[72] have discussed the speciation of methyltin species in beverages. The speciation of selenium present in beers has been described by Robberecht *et al.*[73]

Optimal conditions for the use of HG–AAS

When using hydride generation in the analysis of wines and beverages, the following points should be borne in mind.

(*a*) Organic matter should be totally oxidized, and the elements to be determined should be present in a single appropriate oxidation state.

(*b*) Interferences and other sources of error should be guarded against as carefully as possible. Factors to be considered include the acids and oxidizing agents employed, the "cross effect" of interfering ions,[86] the delay involved in collecting the hydride, the concentration of $NaBH_4$ used, the aging of stock solutions and the storage of samples.

(*c*) All operating conditions should be carefully optimized. The acidity, for example, is critical in the determination of Pb, Sn and Se, temperature in that of Ge, and hydride collection-time in that of Pb, Se and Te.

Table 7 lists the sensitivities of spectroscopic methods with and without use of hydride-generation systems. Table 8 summarizes the optimal conditions for the determination of As, Sb, Bi, Pb, Sn, Se and Te with hydride generation.

CONCLUSIONS

The procedures that should be followed in order to avoid errors and reduce interferences when using hydride-generation systems in AAS may be summed up in the following ten points. (*i*) Samples should be highly diluted. (*ii*) High acidities or a mixture of acids should be used. (*iii*) The quantity to be measured is the area of the absorption peak. (*iv*) Hydride collection-time should be optimized. (*v*) The hydride should be collected at low temperature (liquid-nitrogen bath) and then rapidly released. (*vi*) Interferences should be eliminated by addition of masking agents, precipitation, or other means. (*vii*) Hydrides should be collected in suitable absorbents and determination performed whenever possible by ET–AAS with a graphite furnace. (*viii*) The residence time in the optical path of the detector should be optimized. (*ix*) Blanks should be used. (*x*) The standard-addition method should be used.

The hydride-generation technique can give correct results if the proper digestion and hydride-generation conditions are used. A summary of their principal applications to analyse wines and beverages is given in Table 9.

(*Received* 11 *July* 1991. *Revised* 7 *October* 1991. *Accepted* 7 *October* 1991)

Summary—A simple continuous flow generation of volatile bromine is described for the determination of low concentrations of the element by atmospheric-pressure argon microwave induced plasma (MIP) surfatron. Bromine is continuously generated by mixing the bromide with sulphuric acid and hypochlorite solutions. The bromine vapour is separated from the aqueous phase by a gas–liquid separator and is desiccated by passing it through concentrated sulphuric acid. The detection limit attained was 2 μg/l. and the precision was $\pm 0.7\%$ (at the 80 μg/l. level). The proposed determination is very selective if oxidizing/reducing agents are absent. The procedure has been tested for bromide determination in two drug preparations. Good agreement between the experimental results and the certified values has been obtained.

Since McCormack *et al.*[1] introduced microwave induced plasma (MIP) for the element selective detection in gas chromatography, MIPs operated at relatively low paper levels (< 150 W), with helium or argon as the plasma support, have provided sensitive excitation for non-metals and some metals in the vapour phase.[2–5] Unfortunately the low kinetic temperature of such plasmas is inadequate for direct aspiration of liquid solutions into the MIP which should be desolvated before atomization/excitation of the elements of interest. In spite of this fact we are witnessing a revival of interest in MIP as excitation source, particularly for the analysis of non-metals, using both the TM_{010} Beenakker cavity[6–7] and surfatron type devices as those first proposed by Moissan *et al.*[8,9] It appears that the surfatron type coupling is more easily tuned and more resistant to detuning by solvent and solute loading than are conventional resonant-cavity devices.[10]

The determination of bromide by MIP–AES has been reported on several occasions[11–15] using different approaches for sample introduction: chemical generation of hydride or bromine,[11,14] electrothermal vaporization[12,15] and gas-chromatography techniques.[16] However, to the best of our knowledge, only one publication deals with the detection of bromide using a surfatron-MIP:[13] a glass-frit nebulizer is used for sample introduction along with a desolvation system to reduce the amount of water vapour entering the plasma. The detection limit reported was 4 μg/ml at 889.8 nm, in the NIR spectral region where most promising analytical lines appear.

We are reporting here on the improvement of Ar-MIP surfatron detection capability for bromide just by continuous chemical generation of bromine swept into the MIP by the Ar plasma gas. The technique is applied to the determination of bromide in some real samples.

EXPERIMENTAL

The basic configuration of the instrumentation used has been published elsewhere.[17] The different components of our instrumental set-up are listed in Table 1.

Relevant details of the main components of our Ar-surfatron-MIP analytical system are as follows:

Sample introduction device

The bromide samples were introduced into the plasma as chemically generated bromide. The bromine was produced in a continuous mode using a gas–liquid continuous separation

Table 1. Description and specifications of the major components of the analytical system

Instrument component	Description and specification
Microwave generator	Microtron 200 Mark III, 2450 ± 25 MHz 0–200 W, (Electro Medical Supplies, Wantage, U.K.)
Microwave Launcher	Surfatron. The microwave power is supplied to the surfatron through a coaxial line using an N-type connector
Monochromator	Jobin-Yvon THR-1000s, 1-m focal length, Czerny-Turner mount with a grating of 1200 grooves/mm. Reciprocal linear dispersion of 0.83 nm/mm in the range 500–1000 nm.
Optical arrangement	Surfatron and monochromator mounted on the same optical rail. Plasma viewed axially and imaged 1:1 on the entrance slit with a fused silica lens.
Read-out system	R-212 Hamamatsu PMT. Jobin-Yvon Spectralink system controlled by a Computer.
Argon flow control	Brooks R-2-25C.
Discharge tubes	Fused silica capillary 1 mm i.d.

system previously described for arsenic determinations and iodine generation.[17,18] The sample solution (or blank solution), the oxidant (hypochlorite) solution and the diluted sulphuric acid solution are pumped via a three channel peristaltic pump and generation, separation and desiccation of bromine formed occurs in a continuous manner, according to Fig. 1 scheme.

Surfatron-MIP source

The experimental measurements were carried out with the MIP set-up described previously.[17] The plasma was produced within 1-mm i.d. silica fused capillary tubes through the propagation of a surface wave at 2.45 GHz. The generator microwave power was coupled to the wave through a surfatron.[19] The plasma tube was surrounded by a cylindrical metallic waveguide, coaxial with it, and enclosing it completely. Forward and reflected power levels were measured with an external thermistor.

The optical resolution/detection system

The optical resolution/detection systems used have been described elsewhere.[17]

Reagents

A 1000-μg/ml stock solution of potassium bromide was prepared by direct dissolution of 1.000 g of the salt in a 1000-ml flask with redistilled water. A $4.32 \times 10^{-3}M$ solution of

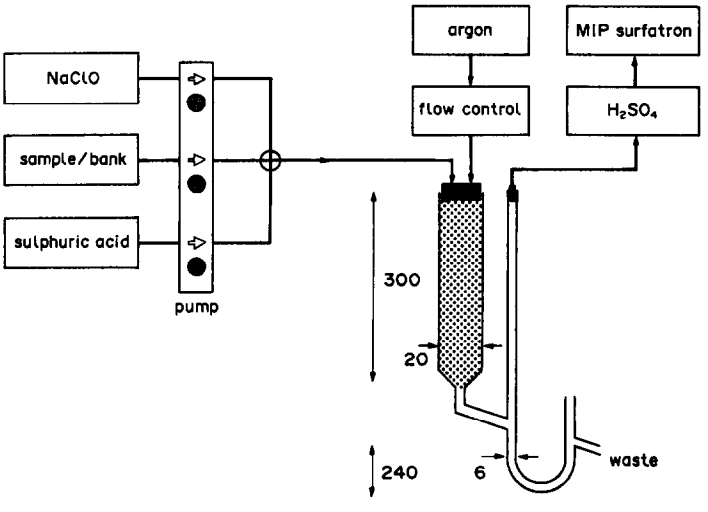

Fig. 1. Diagram of the gas–liquid continuous separation device (lengths in nm).

sodium hypochlorite, was prepared by diluting 2 ml ($7 \pm 2\%$ of active chlorine) in 250 ml of redistilled water. A $3M$ solution of sulphuric acid was also used. The salts used for interference studies were all of analytical reagent grade.

General procedure

The solution containing the bromide sample (0.020–20.000 μg/ml bromide) and the $4.32 \times 10^{-3}M$ hypochlorite and sulphuric acid solutions are pumped with the aid of a peristaltic pump towards a "T-piece" (Fig. 1). The corresponding optimum flows are 3.80 ml/min for the sample and 1.23 ml/min for the reagents. The bromine, dissolved in the resulting solution, goes into the gas-liquid continuous separator where a mild stream of argon (the plasma gas) carries the volatile Br out of the aqueous solution (which is discarded via the "U" tube). The bromine volatile species and the argon plasma gas are desiccated by passing them through concentrated sulphuric acid before entering the microwave plasma formed in the discharge tube by the surfatron device.

The operating conditions are summarized in Table 2. The atomic emission at 827.24 nm of bromine was then measured for the optimization of bromine generation conditions and of instrumental set-up parameters.

Under the operating conditions shown in Table 2, the bromine emission signal begins to rise from the baseline rather slowly. Thus, only after stabilization (around 10 min), the emission intensities are integrated for 0.5 sec. Longer integration intervals did not improve the S/N ratio.

Table 2. Optimum operating conditions for the determination of bromine with the 827.244 nm emission line

Plasma	
Forward Power	100 W
Reflected Power	< 5 W
Generator frequency	2450 MHz
Inner Diameter (Plasma Tube)	1 mm
Argon flow rate	0.5 l./min
Monochromator	
Photomultiplier voltage	1200 V
Integration time	500 msec
Slit Widths (entrance and exit)	50 μm
Sequential scanning (bandpass)	<0.03 nm
Bromine generation	
H_2SO_4 concentration	$3M$
NaClO concentration	$4.32 \times 10^{-3}M$
H_2SO_4 solution flow	1.23 ml/min
NaClO solution flow	1.23 ml/min
Sample solution flow	3.81 ml/min

RESULTS AND DISCUSSION

Wavelength selection

There are several emission lines lying in the UV-visible or IR regions which have been recommended for bromine determination by MIP–AES at atmospheric pressure.[11,12,14,20–22] Among published analytical lines, we have selected those in the long wavelength region, where the sensitivity of the detector of our instrument is still adequate. Thus the 889.80 nm, 827.24 nm and the 888.90 nm emission lines were tested. We verified the signal to background ratios of bromine at the above-mentioned emission lines in our analytical system with continuous generation of bromine. The atomic line at 824.27 nm was finally selected for subsequent measurements because it produced the most intense emission and highest signal to background ratio for bromine.

Bromine generation conditions

The conditions for optimum chemical generation of bromine in a continuous mode from potassium bromide solutions were studied by using a 10 μg/ml solution of the salt as reference and then following the general procedure proposed previously.

Three different oxidant systems for chemical generation of bromine were investigated, namely: (a) $KBrO_3$–H_2SO_4, (b) H_2O_2–H_2SO_4 and NaClO–H_2SO_4. The latter system proved to be the most efficient for bromine generation. It was faster and the intensity of emission observed was 5 times higher than that obtained with the other oxidant systems. Once selected the most convenient method for chemical vapour generation of bromine, optimum concentrations and flows of sulphuric acid and sodium hypochlorite solutions were investigated by following a univariant search. The results observed in these experiments using flows of 1.23 ml/min have been plotted in Fig. 2 (sulphuric acid) and Fig. 3 sodium hypochlorite. As shown in Figs 2 and 3, optimum concentrations for sulphuric acid are above $1M$ (a plateau is observed above $1M$ sulphuric acid concentrations), while for sodium hypochlorite solutions, the emission intensity of bromine was constant above $0.5 \times 10^{-3}M$. Concentrations of $3M$ sulphuric acid and of $4.3 \times 10^{-3}M$ sodium hypochlorite were finally selected.

Optimum flows of sample and reagents were also investigated with selected reagent concentrations in order to obtain maximum intensity

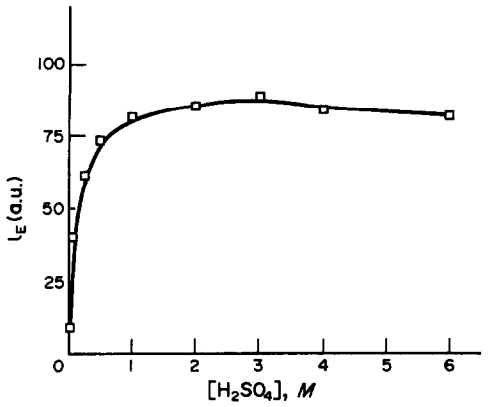

Fig. 2. Optimization of the analytical signal. Effect of the H_2SO_4 concentration. Sample and reagents flows 1.23 ml/min. Concentrations of 10 μg/ml KBr and of $1.08 \times 10^{-3}M$ NaClO.

of bromine emission at 827.24 nm. The flow-rates of each of the three channels of the peristaltic pump were varied from 0.27 to 3.80 ml/min (the same flow-rates for the three channels in each experiment). The results observed for the emission intensity of a solution of 4 μg/ml of bromide, using $3M$ sulphuric acid and $4.3 \times 10^{-3}M$ sodium hypochlorite solutions, versus the flow-rates (of sample reagents) have been plotted in Fig. 4. As shown by Fig. 4, higher flows led to higher emission signals. The observed emission, however, tends to level off at flows higher than 2.5 ml/min of sample and reagents (Fig. 4).

In a second optimization experiment, sulphuric acid and oxidant solution flow-rates were fixed at 1.23 ml/min (intermediate level of emission intensity of Fig. 4) and sample solution flow-rates were varied from 1.23 to 3.81 ml/min. The results obtained generating bromine from 4 μg/ml potassium bromide solution show a linear increase in the analytical signal with sample solution flow-rate. We selected for subsequent experiments the reagents and sample flow-rates detailed in Table 2.

Temperature effect in bromine separation

To test the possibility of a faster separation/volatilization of bromine, and thus to attain a quicker signal stabilization, a study of the effect of the bromine separation temperature was carried out. A heating mantle connected to an electrical unit (allowing for control and measurement of the temperature with a precision of $\pm 1°$) was wrapped around the gas–liquid separator to investigate the effect of heating on the bromine generated signal. The results obtained are shown in Fig. 5, which

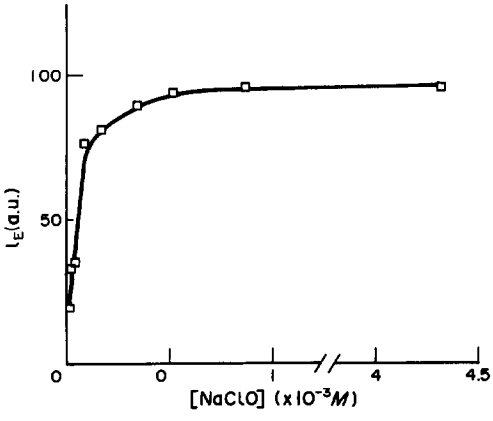

Fig. 3. Optimization of the analytical signal. Effect of the NaClO concentration. Sample and reagents flows 1.23 ml/min. Concentrations of 10 μg/ml KBr and of $3M$ H_2SO_4.

documents how temperature increases brought about an enhancement of emission intensities (due to an increased inflow of bromine into the plasma). Unfortunately, as described previously,[17] the increasing water load deteriorates the desiccator properties of concentrated sulphuric acid (see Fig. 1) in a few minutes. Therefore, working above 70° causes serious instability of the plasma which can eventually be extinguished. As improvements in bromine generation with higher temperatures are not dramatic, room temperature is recommended for bromine generation in routine operation.

Optimization of instrumental parameters

The most critical MIP instrumental parameters (including microwave power, internal diameter of quartz discharge tube and Ar plasma gas flow) affecting the bromine atomic emission have been optimized with a univariant search.

The microwave power was varied from 25 to 200 W at fixed values of the inner diameter of the plasma tube and the argon flow-rate given in Table 2. As can be seen in Fig. 6, the emission intensity turned out to be constant above 150 W. It has to be pointed out, however, that at microwave power values above 100 W, a higher reflected power and background were observed degrading reproducibility of our measurements. Therefore, a 100 W microwave power was finally selected (see Table 2).

It is well known that the internal diameter of the quartz discharge tube has a great influence on the geometry of the MIP plasma: big tube diameters originate filament-like plasmas (resulting in poor sample excitation due to inadequate contact between the sample and the plasma). Thus, we tested three different discharge tubes having 4.5, 3 and 1-mm internal diameters. Results showed that the most favourable one for atomization/excitation of bromine in our Ar plasma was the 1-mm i.d. tube.

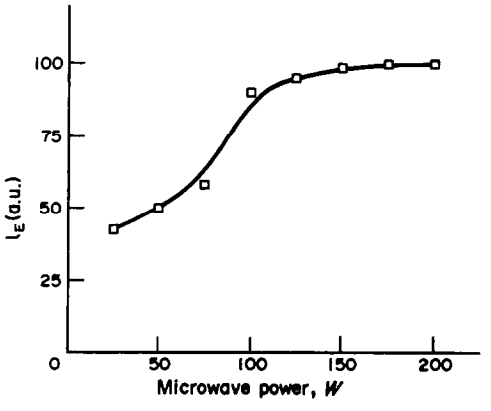

Fig. 6. Effect of microwave power on the intensity of the bromine emission. Concentration of 4 μg/ml KBr. Other experimental conditions as in Table 2.

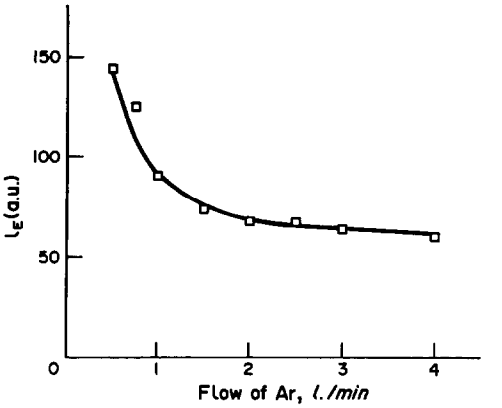

Fig. 7. Effect of the variation of plasma gas flow on the analytical signal. Concentration of 4 μg/ml KBr. Other experimental conditions as in Table 2.

The influence of plasma gas flow-rate on the analytical signal was studied by varying the plasma Ar flow between 0.5 and 4.0 l./min. The results obtained have been plotted in Fig. 7. As could be expected, increasing the flow-rate of Ar gave a decreasing bromine emission intensity because the time of residence for the analyte in the plasma decreases accordingly. A compromise value of 0.5 l./min Ar flow-rate was selected.

Analytical characteristics

Optimum conditions finally selected according to results from the above mentioned experiments are summarized in Table 2. Using such optimum conditions and the proposed general

				R.S.D.	1.21%

procedure we evaluated the detection limit attainable for bromine in our instrumental set-up. The limit of detection (3σ IUPAC criterion) was 2 μg/l. of bromide at room temperature. If the determination was carried out at 70° the detection limit became 0.8 μg/l.

The linear range observed (intensity of emission, I_E, *vs.* potassium bromide concentration) extended from the detection limit up to 20 mg/l. potassium bromide (regression coefficient 0.9999).

The precision of the proposed method was evaluated by analysing eleven replicates of a solution containing 80 μg/l. potassium bromide. The observed standard deviation was $\pm$ 0.7%.

Interference studies

In order to evaluate the extent of potential interferences particularly in the generation of bromine aqueous samples (containing 5 μg/ml potassium bromide and various amounts of foreign anions which would be compatible with bromide in aqueous solution and could be present in real samples) were analysed for Br^- by following the recommended procedure. Results obtained are summarized in Table 3 and they show that the proposed method is very selective for bromide analysis as the presence of different types of anions do not interfere.

Applications

The analytical performance of the proposed method for the determination of low levels of bromide was tested by analysing bromide in two drug preparations: "Magnesium Pyre" ($MgCl_2$ 500 mg, $MgBr_2$ 20 mg, MgF_2 0.5 mg, MgI_2 0.1 mg, Excp. c.s.) and "Otogen" (KBr 175 mg, Li_2CO_3 20 mg, KI 15 mg, Tiamine 0.2 mg, Excp. c.s.).

For sample preparation, three tablets of each drug preparation (Magnesium Pyre and Otogen) were weighed and finely ground to assist its final water dissolution. The resulting solutions were filtered and made-up to 500 ml in a standard flask, with diluted sulphuric acid (3*M* final concentration) before their final aspiration into the continuous bromine generator system.

Recovery studies were conducted along with actual analysis of the samples. To do so, 1, 2 and 5 ml of the 500-ml sample solution were delivered in three different 100-ml standard flasks and made-up to volume with 3*M* sulphuric acid (final magnesium bromide concentration in each standard flask should then be 0.041, 0.103 and 0.205 mg/l. for the "Magnesium Pyre" sample and 0.52, 1.04 and 2.6 mg/l. for the "Otogen" sample).

Good agreement between the expected amount of magnesium bromide and potassium bromide (values reported in the drug vials) and the MIP-Surfatron found values was observed as shown by Table 4. At the same time, the recoveries observed (tied to the accuracy of expected values, taken as "true" values) and the good precision for different dilutions demonstrate the excellent performance of the proposed method for this type of sample.

CATALYTIC DETERMINATION OF IODIDE BY CONTINUOUS ADDITION OF CATALYST TO A REFERENCE SOLUTION WITH PHOTOMETRIC PROBE MONITORING

G. López-Cueto,* J. M. Santiago and N. Grané
Analytical Chemistry Division, Faculty of Science, University of Alicante, Spain

(*Received* 15 *March* 1991. *Revised* 11 *July* 1991. *Accepted* 26 *July* 1991)

Summary—Probe photometry is proposed as a simple monitoring technique for catalytic determinations by continuous addition of catalyst to a reference solution. The approach has been tested on the catalytic determination of iodide which, in the concentration range of 10–100 ng/ml, can be determined with a relative error usually lower than 4–5% and relative standard deviations of 4.6 and 4.0% for 9.98 and 79.92 ng/ml, respectively. Two alternative techniques of measuring the analytical signal (the intersection time) are suggested to improve the reproducibility: the "initial signal preadjustment" and the "two-intersection point" techniques. The method has been applied to determination of iodide in table salt samples.

Kinetic catalytic methods are comparative methods, as are many other instrumental methods of analysis, because their application requires comparison of some kinetic parameter with a calibration plot. This may be avoided by continuous addition of catalyst to a reference solution.[1] This is a new unconventional method of catalytic analysis, one of its main features is that reaction kinetics are monitored in two different solutions: the sample solution, that contains the analyte (catalyst) and the reference solution, to which a standard solution of catalyst is added at a constant rate. Theory for a second-order catalysed reaction (first-order in both the catalyst and one of the reagents)[1] predicts that, once the kinetic curves from both the sample and the reference solutions have been recorded together on the same coordinate axes, they cross at a certain time, designated as the intersection time (t_x), which is the analytical variable to be measured. From here, two approaches may be followed to obtain the concentration of analyte: either the comparative procedure, based on an empirical calibration curve, or the pseudostoichiometric procedure, in which the concentration of analyte $[C]_x$ is calculated directly from the following non-empirical equation, which is valid provided dilution in the reference solution is negligible:

$$[C]_x = \frac{m[C]_s}{2V_0} t_x \qquad (1)$$

where the parameters m (addition rate), $[C]_s$ (concentration of the standard solution of catalyst) and V_0 (initial volume of the reference solution) are known. A certain formal similarity can be found between this approach and the null-point method developed by Malmstadt *et al.*[2–4] Nevertheless the foundations of the two types of method are very different, the principal difference being that, while the null-point method refers to an equilibrium situation, the method of continuous addition of catalyst to a reference solution is kinetic in nature.

In a previous paper,[1] the theoretical basis of the new method was reported and the method was tested by using the iodide-catalysed Ce(IV)–As(III) reaction.[5–9] Reaction kinetics were monitored amperometrically by means of a rotating disk platinum electrode. Amperometry is a suitable technique to take continuous measurements from a reaction medium, but a source of error arises from the poor reproducibility of currents measured with solid electrodes. This drawback was partially overcome by normalizing both the sample and the reference kinetic curves,[1] that is to say, by dividing the current measured at each time by its initial value. This procedure is, nevertheless, cumbersome and time-consuming, and therefore some simple alternatives have been searched for.

*Author for correspondence.

Photometric techniques are usually more reproducible than solid-electrode amperometry, a foreseeable feature of the use of these techniques is that kinetic curves do not need to be normalized. Continuous photometric monitoring of the reaction kinetics in the sample and reference solutions may be easily followed by using a fibre-optic probe.

In this paper the predictions above have been examined by using a fibre-optic probe photometer for the catalytic determination of iodide by continuous addition of catalyst to a reference solution. In order to test the reliability of this operating method, the method has been applied to iodide determination in table salt samples.

EXPERIMENTAL

Reagents and solutions

Ceric sulphate ($2.5 \times 10^{-2}M$) in $1.8M$ sulphuric acid, $0.100M$ As(III) (prepared from arsenious oxide), $1.8M$ sulphuric acid and $1.023 \times 10^{-2}M$ potassium iodide (standardized by titration with silver nitrate) were used.

All reagents were of analytical grade. Demineralized distilled water was used throughout.

Apparatus

Photometric monitoring of the reaction kinetics was carried out with a E-616 Metrohm photometer provided with a fibre-optic probe that allows measurements to be taken in the reaction vessel. The analog output for connecting the strip chart recorder (a E-536 Metrohm potentiograph) gives transmittance rather than absorbance values, so that kinetic plots were recorded as transmittance–time curves. A Metrohm EA 876-20 temperature-controlled titration vessel was used as the reaction cell. The temperature was kept constant at $25.0 \pm 0.1°$ with a Haake K circulation bath and a 620/3 Crison probe thermometer. The catalyst solution was continuously added to the reference solution by means of an E-655 Metrohm Dosimat electronic burette. A 2–10 ml Brand Dispensette dispenser was used for the sample addition to the sample cell.

Procedure

All the reagents must be maintained at $25.0 \pm 0.1°$ before preparing the solutions. To prepare the reference solution take, directly in the reaction cell (kept at $25.0 \pm 0.1°$), 10 ml of the arsenic(III) solution, 13 ml of the sulphuric acid solution, 25 ml of demineralized water, and 2 ml of the cerium(IV) solution. Start the continuous addition of a potassium iodide standard solution ($[C]_s$ from 2.948×10^{-5} to $1.018 \times 10^{-4}M$) with an addition rate m from 1.083×10^{-3} to 1.000×10^{-2} ml/sec. The reaction rate is monitored by continuously measuring the transmittance at 410 nm. Both the recorder and the electronic burette must be switched on simultaneously. This has been easily achieved because the E-655 Metrohm burette operates in a synchronous way with the E-536 Metrohm potentiograph.

To prepare the sample solution, the same volumes of As(III), sulphuric acid and Ce(IV) solutions have to be taken, plus $(25 - V_s)$ ml of demineralized water and V_s ml of the analyte solution (containing 4.356×10^{-8}–$1.102 \times 10^{-6}M$ iodide). The addition order has to be the same as in the preparation of the reference solution. The recorder will be switched on at the same time as the sample solution is added. The temperature is maintained constant at $25.0 \pm 0.1°$.

Once obtained, superpose together the reference and the sample curves and measure the intersection time t_x, that is to say, the time elapsed until the curves cross.

Determination of iodide in table salt. The required amount of dry sample (about either 1 g for iodized salt or 20 g for non-iodized salt respectively) was weighed accurately, dissolved in demineralized water and diluted to a final volume of 500 or 100 ml, respectively. Finally, a 20-ml aliquot was transferred to the sample cell, which contained the above cited volumes of arsenic(III), sulphuric acid and cerium(IV) solutions, and 5 ml of demineralized water. On the other hand, a $4.104 \times 10^{-5}M$ potassium iodide standard solution was continuously added to the reference solution at a rate of 1.667×10^{-3} ml/sec.

RESULTS AND DISCUSSION

Testing of the sample and the reference curves

According to the theory derived in a previous paper,[1] the transmittance–time curves for the sample and the reference solutions (provided the uncatalysed reaction is sufficiently slow and dilution of the reference solution is negligible) may be written respectively as:

$$T_s = T_0^{[\exp(-k_d[C]_x t)]} \qquad (2)$$

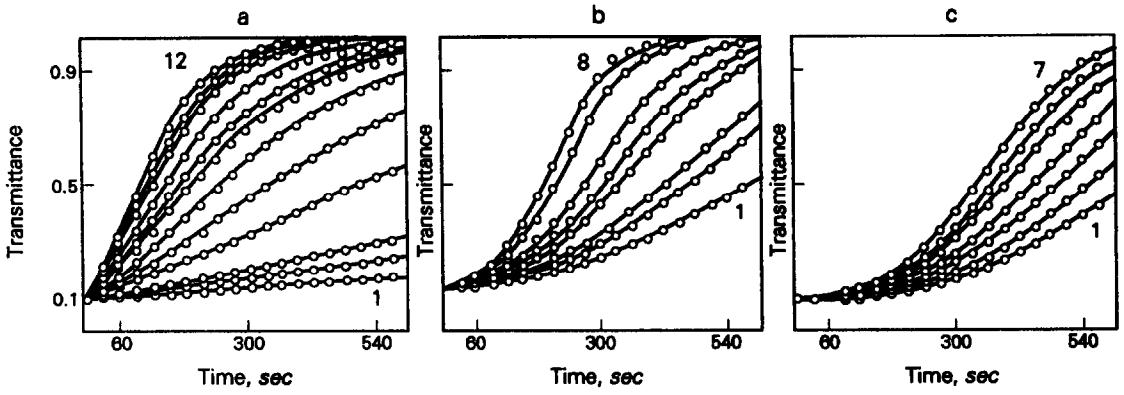

Fig. 1. Experimental (○) and simulated (——) transmittance–time curves. Ce(IV), $10^{-3}M$; As(III), $10^{-2}M$; H_2SO_4, $0.54M$; T, 25°; V_o, 50 ml. and

$$T_r = T_o^{[\exp(-k_c(m[C_s]/V_o)t^2)]} \qquad (3)$$

where T_s and T_r are, respectively, the sample and the reference transmittance, T_o is the transmittance measured at zero time and k_c is the rate coefficient (second-order constant) for the catalysed reaction. According to the equations (2) and (3), straight lines will be obtained by plotting $\ln(-\log T)$ *vs.* t and $\ln(-\log T)$ *vs.* t^2 for the sample and the reference solutions, respectively.

A series of 12 sample curves for $[C]_x$ in the range 4.356×10^{-8}–$1.102 \times 10^{-6}M$ were obtained and linearized in the indicated way. By plotting the measured slopes *vs.* the $[C]_x$ values a straight line was obtained, from whose slope the pseudo-second order rate constant k_c was measured $k_c = (1.195 \pm 0.012) \times 10^4$ $1.\text{mole}^{-1}.\text{sec}^{-1}$).

On the other hand, two series of reference curves have been obtained. In the first one, different values of $[C]_s$ from 2.948×10^{-5} to $1.078 \times 10^{-4}M$ have been used and m was kept constant. In the second one, $[C]_s$ was kept constant and different values of m from 1.083×10^{-3} to 1.000×10^{-2} ml/sec were used. Values of $(1.189 \pm 0.011) \times 10^4$ and $(1.194 \pm 0.003) \times 10^4$ $1.\text{mole}^{-1}.\text{sec}^{-1}$, for k_c are obtained from each of the series, and are in good agreement with those obtained from the sample curves.

In Fig. 1, experimental and simulated curves are compared for both sample and reference solutions. As can be seen, experimental curves fit fairly well to the theoretical equations.

Determination of iodide

Catalytic determination of iodide in pure solutions has been carried out by measuring the intersection time t_x from the crossing between the sample and the reference curves obtained separately, and then by applying the pseudo-stoichiometric procedure, that is to say, by using equation (1) directly. This is why the analytical results are shown by means of tables of the "taken–found" type. The results obtained by this "standard" technique for the t_x measurement are shown in Table 1. Relative standard deviations of 4.6 and 4.0% were obtained for 9.98 and 79.92 ng/ml iodide, respectively (ten determinations). Alternatively, linear calibration curves are obtained when the intersection times (all obtained by using the same

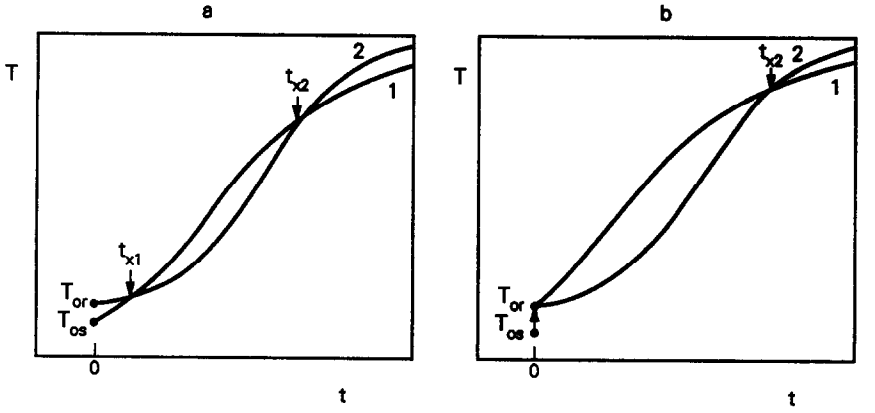

Fig. 2. Schematic drawing of crossing of (1) the sample and (2) the reference curves in (a) the two-intersection point technique and (b) the initial signal preadjustment technique.

reference curve) are plotted *vs.* the iodide concentration of standard iodide solutions, so that the comparative procedure could also be used.

To overcome the effect of possible random differences in the initial transmittance values between the two solutions, two alternative t_x measurement techniques were introduced, from which a somewhat higher precision can be expected. The "initial signal preadjustment" technique uses a sample solution that contains a cerium(IV) initial concentration higher than the one of the reference solution, so that the initial transmittance of the sample solution is lower than that of the reference solution. The reference curve is recorded first. Afterwards, the reaction is started in the sample solution, but at the beginning of the reaction the recorder remains switched off. As the reaction proceeds in the sample solution, its transmittance increases and, just when it reaches the initial value of the transmittance of the reference solution, the recorder is switched on [Fig. 2(a)].

The "two-intersection point" technique also requires that the sample solution must contain initially a cerium(IV) concentration higher than the reference solution, so that the superposition of the sample and the reference curves yields two intersection points [Fig. 2(b)]. Because the initial transmittances are not now equal, equations (2) and (3) will then be transformed into

$$T_s = T_{os}^{[\exp(-k_c[C]_x t)]} \tag{4}$$

and

$$T_r = T_{or}^{[\exp(-k_c(m[C_r]/V_o)t^2)]} \tag{5}$$

where T_{os} and T_{or} are the initial transmittance values of the sample and the reference solutions, respectively. The sample and reference transmittance values will be equal in each of the two intersection points. If t_{x1} and t_{x2} symbolize the values of the two intersection times, the following relationships can be obtained by equating (4) and (5):

$$[C]_x = \frac{m[C]_s}{2V_o} t_{x1} - \frac{B}{k_c}\frac{1}{t_{x1}} \tag{6}$$

and

$$[C]_x = \frac{m[C]_s}{2V_o} t_{x2} - \frac{B}{k_c}\frac{1}{t_{x2}} \tag{7}$$

where

$$B = \ln\frac{\log T_{or}}{\log T_{os}}$$

Finally, by solving the system of equations (6) and (7) for $[C]_x$, it can be deduced that

$$[C]_x = \frac{m[C]_s}{2V_o}(t_{x1} + t_{x2}) \tag{8}$$

According to this last expression, when two intersection points are produced, the analytical variable is the sum of the two measured intersection times.

Results of iodide determinations obtained by the pseudostoichiometric procedure by using both the initial signal preadjustment and the two-intersection point techniques are shown in Table 2. Iodide concentrations lower than about 25 ng/ml are difficult to determine by the two-intersection point technique, because the two points are very close and the measurements of the intersection times become poorly precise. Relative standard deviations of 0.9 and 1.6% (ten replicate) have been obtained for the initial signal preadjustment (69.73 ng/ml) and the two intersection point (56.93 ng/ml) techniques, respectively.

The variances of the three different techniques for measuring the intersection time have been compared by applying the F-test. The variance of the standard technique is proved to be significantly higher than the variances of both the initial signal preadjustment and the two intersection point techniques at the 95% confidence level, although no significant difference has been found between the variances of these latter measurement techniques.

Since a single-beam photometer has been used, it can be expected that the differences in the initial transmittance values between the sample and the reference solutions are due to fluctuations in the power supply voltage to a certain extent. In order to avoid such fluctuations, a voltage stabilizer was used and the standard technique to measure the intersection time was applied. A series of determinations of different amounts of iodide was carried out. Relative errors of 4.1 and 0.36% were found for 13.55 and 138.6 ng/ml iodide, respectively. A relative standard deviation of 0.9% was obtained for 70.90 ng/ml (ten replicates). A statistical comparison between these results and those obtained by the initial signal preadjustment and by the two-intersection point measurement technqiues showed that their variances are not significantly different (99% confidence level). It can be seen, therefore, that the use of a voltage stabilizer allows us to obtain results as precise as obtained by the initial signal preadjustment and the two-intersection point techniques.

Determination of iodide in table salt

According to Dubravčić,[10] an excess of chloride may interfere with the catalytic determination of iodide because chloride exerts a low catalytic effect on the cerium(IV)–arsenic(III) reaction. As a previous test, it has been proved that chloride concentrations up to at least $7 \times 10^{-3}M$ do not affect the reaction kinetics significantly.

The proposed method has been applied to the determination of iodide in several samples of both iodized and non-iodized table salt (theoretical contents in the range from 0.01 to 6 ng/100 ml of iodine). Table 3 shows the results obtained by applying the pseudostoichiometric procedure to three samples of iodized and one sample of non-iodized table salt, before and

Table 3. Catalytic determination of iodide in table salt samples

		0.0098	0.0085	0.018	0.0082	96.5

after spiking with standard potassium iodide. Satisfactory recoveries between 96.5 and 102.8% were achieved.

It may be concluded that photometric probe monitoring proves to be a valuable alternative to amperometric monitoring for catalytic determinations by continuous addition of catalyst to a reference solution. Unlike amperometric monitoring with a rotating disk platinum electrode, normalization of the experimental kinetic curves is not necessary when photometric monitoring is used, owing to the higher signal reproducibility. Moreover, the simplicity, robustness and low price of the photometric instrumentation which may be used in these determinations is another point to be borne in mind.

DETERMINATION OF TOTAL INORGANIC IODINE IN SEAWATER BY CATHODIC STRIPPING SQUARE WAVE VOLTAMMETRY

GEORGE T. F. WONG* and LING-SU ZHANG
Department of Oceanography, Old Dominion University, Norfolk, VA 23529–0276, U.S.A.

(*Received* 13 *June* 1991. *Revised* 15 *August* 1991. *Accepted* 26 *August* 1991)

Summary—A method has been designed for the reduction of iodate to iodide in seawater and subsequent determination of total dissolved iodine as iodide by cathodic stripping square wave voltammetry. The pH of the sample is lowered to about 1–2 and iodate is reduced to iodide with sodium sulfite under this acidic condition. The pH of the sample is then raised to 8–9 before the concentration of iodide is measured.

Dissolved inorganic iodine is found in seawater primarily as iodate and iodide.[1–3] The concentration of total iodine in seawater is about 0.5μM.[4] In estuarine waters, the concentration of total iodine generally decreases with decreasing salinity, reaching undetectable concentrations at times.[5–7] Total iodine in seawater has been determined directly without any preconcentration step by converting one of these two forms of inorganic iodine to the other form and then measuring total iodine either as iodide or iodate.[4] In most reported studies, the detection limit is about 20nM.

Recently, a method has been described for the direct determination of iodide in seawater by cathodic stripping square wave voltammetry (CSSWV) and the detection limit can reach 0.1nM.[8] In this method, iodide is deposited onto the surface of a hanging mercury drop electrode (HMDE) as mercurous iodide under an applied potential for a specified period of time. This deposited mercurous iodide is later reduced by a cathodic potential scan and it gives rise to a current peak at about −0.33 V. The magnitude of the current peak is related to the concentration of iodide in the solution. However, before the deposition of the iodide from the sample, oxygen, which gives rise to an interfering current peak, must first be quantitatively removed from the sample by bubbling it with an inert gas such as nitrogen or argon. This step is frequently the most time consuming step in the analytical scheme. We have reported that, instead of bubbling the sample with an inert gas, sulfite may be used as an effective agent for removing the oxygen from the sample chemically at the natural pH of seawater while leaving the speciation of dissolved inorganic iodine unchanged.[9] As a result, the time required for analyzing a sample for iodide may be reduced by a factor of two. We have also observed that while sulfite does not reduce iodate at the pH of seawater, it reduces iodate to iodide readily under acidic conditions. Thus, CSSWV can also be used for the determination of total inorganic iodine in seawater after iodate has been reduced to iodide with sulfite. The resulting method is simple, fast and reliable. With the low detection limit, the required sample volume can be reduced to a milliliter or less, if necessary. Furthermore, if total inorganic iodine is determined as iodate by oxidizing all iodine species to iodate with an oxidizing agent such as hypochlorite,[10] some as yet unknown fraction of organic iodine, if it is present, may also be oxidized to iodate and be included as inorganic iodine.[11] In the voltammetric method, since a reduction rather than an oxidation step is used, it is less likely that organic iodine will be destroyed and be included as part of the inorganic iodine. We have also investigated the optimization of the operational parameters that may affect the determination of iodide or total inorganic iodine in seawater by CSSWV. Our results are reported in this paper.

EXPERIMENTAL

Apparatus

A Princeton Applied Research Model 384B polarographic analyzer system, equipped with a

*Author for correspondence.

Model 303A static mercury drop electrode (SMDE) in the HMDE mode, a Model 305 stirrer and a digital plotter, was arranged as described by Luther *et al.*[8] and used for square wave voltammetry. A platinum wire acted as the auxiliary electrode. The Ag/AgCl reference electrode supplied with the instrument was not used as the reference electrode in order to avoid any reaction between iodide and silver. This electrode was isolated from the sample in an empty reference electrode jacket. In its place, a standard calomel electrode was used as the reference electrode through a salt bridge in a Model K0065 reference electrode bridge tube filled with a 1*M* sodium carbonate solution. A small hole was drilled near the top of each glass polarographic cell for adding various reagents to the sample since the port for adding reagent had already been occupied by the reference electrode bridge tube.

Reagents

Nitrogen was purified by passing it through an alkaline pyrogallol trap.[12] The Triton X-100 was prepared from a Fisher brand concentrated stock solution.

All other chemicals used were of ACS reagent-grade.

Procedures

Pipette 5 ml of seawater into a 50-ml standard flask and dilute to volume with distilled, deionized water. Pipette 5 ml of this diluted seawater to a polarographic cell which contains 0.05 ml of a 0.2% Triton X-100 solution and a small magnetic stirring bar. Position the cell in the polarographic analyzer. Blanket the solution in the cell with a positive pressure of purified nitrogen to prevent the dissolution of atmospheric oxygen into the sample. Add 0.2 ml of 1*M* sodium sulfite and 1 ml of 2*N* sulfuric acid to lower the pH of the sample to 1–2. Stir the solution for about 30 sec and then add 1 ml of 1 + 4 ammonium hydroxide to raise the pH of the sample to about 8. Stir the mixture for about 30 sec. Analyze the sample by CSSWV under the following settings: deposition potential, −0.15 V; deposition time, 60 sec; equilibration time, 5 sec; scan range, −0.15 to −0.6 V; scan increment, 2 mV; pulse height, 20 mV; frequency, 100 Hz; mode, square wave voltammetry; drop size, large; reference electrode, standard calomel electrode via a salt bridge. The concentration of iodide in the sample is estimated by the method of standard internal addition by recording the height of the current peak of iodide after consecutive additions of 0.1 ml of a standard 2000n*M* potassium iodide solution to the sample. A reagent blank, if present, should be corrected for. The reagent blank is determined by substituting distilled deionized water for the sample. It is usually less than 5n*M*.

RESULTS AND DISCUSSION

Reduction of iodate with sulfite

The reduction of iodate by sulfite follows the stoichiometry of:

$$IO_3^- + 3SO_3^{-2} = I^- + 3SO_4^{-2}$$

The concentration of iodate in seawater is no more than 0.5μM.[4] After the dilution of the sample and the addition of reagents, the concentration of iodate in the analyte is reduced to 35n*M* or less. The added sulfite will also react with oxygen dissolved in the analyte.[9] Even if the analyte is saturated in oxygen with respect to the atmosphere, its concentration of oxygen should only be in the order of several hundred micromoles per liter. In the proposed procedure, the concentration of sulfite in the analyte is about 28m*M*. Thus, a large excess of sulfite is maintained to ensure that the iodate is reduced quantitatively to iodide and oxygen is absent from the analyte.

While sulfite does not reduce iodate to iodide at basic pH, it will do so readily under acidic conditions. The effect of pH on the reduction of iodate to iodide by sulfite was studied by adding sulfite to a NaCl-KBr-$NaHCO_3$ solution (0.375*M* in sodium chloride, 1m*M* in potassium bromide and 5m*M* in sodium hydrogen carbonate) with a known concentration of iodate, adjusting the pH of the solution to a specified value by adding 1*M* hydrochloric acid and/or 1*M* sodium hydroxide, allowing the reduction to occur for 30 sec, raising the pH to about 9 by adding 1*M* ammonium hydroxide and then determining the concentration of iodide formed by CSSWV. (Seawater is about 0.5*M* in sodium chloride, 0.8m*M* in Br^-, 2m*M* in HCO_3^- and 10m*M* in K^+.) The concentration of added iodate in the solution analyzed ranged from 25 to 100n*M*. The recovery of iodate as iodide at various pH values is shown in Fig. 1. Above a pH of about 7.5, there was no detectable formation of iodide. Below this pH, the recovery of iodate as iodide increased with decreasing pH. Quantitative recovery was achieved at pH below

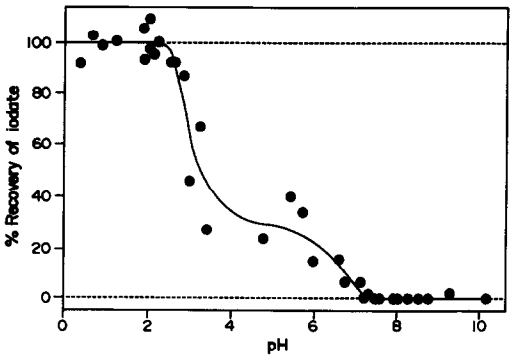

Fig. 1. The effect of pH on the reduction of iodate to iodide with sodium sulfite.

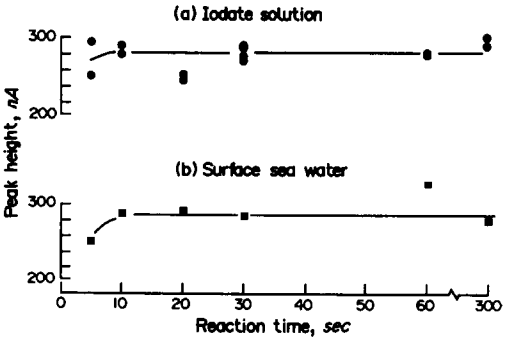

Fig. 2. Time required for the reduction of iodate to iodide (*a*) in a 519n*M* iodate solution and (*b*) in surface seawater with sulfite at a pH of 1.8.

2.3. We have chosen a pH of 1–2 for the reduction of iodate to iodide with sulfite.

The time required for the reduction of iodate to iodide with sulfite in the NaCl–KBr–$NaHCO_3$ solution and in surface seawater were studied at a pH of 1.8. Sulfite was added to the sample and the pH of the sample was adjusted to the prescribed value. After a specified amount of time ranging from 5–300 sec, 1 ml of 1 + 4 ammonium hydroxide was added to raise the pH to about 9 to stop the reaction. The peak height of the current peak of the iodide formed was then measured and the results are shown in Fig. 2. Within the analytical uncertainty, a constant peak height was reached after the reaction was allowed to proceed for 10 or more seconds. We have chosen a reaction time of 30 sec to ensure that the reaction is complete.

During the reduction of iodate to iodide, volatile iodine species with intermediate oxidation states such as molecular iodine and hypoiodous acid may be formed. Potentially, these iodine species may be lost to the atmosphere by volatilization. This possibility was tested by comparing the concentration of added iodate found in sub-samples of the NaCl–KBr–$NaHCO_3$ solution that were undisturbed, stirred with a magnetic stirrer or bubbled with nitrogen while sulfite was allowed to react with iodate at a pH of about 1. The results are shown in Table 1. The concentrations of iodate determined as iodide by these three methods for treating the sub-samples were indistinguishable from each other within experimental uncertainty.

The pH of the solution must be raised to above 7 before the concentration of total dissolved inorganic iodine can be determined as iodide by CSSWV because sulfite gives rise to a sharp current peak at about −0.6 V[13] under acidic conditions (Fig. 3). With the large amount of excess sulfite present, the residual current of the current peak of sulfite can mask the peak of iodide at −0.33 V. At pH above 7, the peak of sulfite disappears. Renard[14] suggested that the current peak of sulfite is due to the bisulfite ion. The pK_2 of sulfurous acid in a pure solution is 7.21.[15] Its value in seawater is not well known. However, it is expected to be lower as the ionic strength of seawater is high. Thus, the concentration of bisulfite may become minimal at pH above 7. We have adopted a pH of 8–9 in our analytical

scheme to insure that the interference by sulfite may be circumvented.

Optimization of voltammetric parameters

A number of adjustable operational parameters are involved in CSSWV. Luther *et al.*[8] have studied some of them for the determination of iodide in seawater. In their study, sulfite was not added to the sample. In the presence of a large excess of sulfite, we have shown that the optimal depositional and initial stripping potential for the determination of iodide should be changed from -0.1 to -0.15 V.[9] This depositional and initial stripping potential should also be used for the determination of total iodine as iodide.

The dynamic range of the method, which can be controlled by the length of the deposition time, was studied. The results are shown in Fig. 4. At each given concentration of iodide, the peak height of the current peak of iodide increased with increasing deposition time [Fig. 4(a)]. The increase was especially pronounced at deposition times that were shorter than 35 sec. Thus, at these short deposition times, the peak height may vary significantly if the deposition time cannot be controlled with a high degree of accuracy and precision. As a result, the precision of the method will be lowered. At deposition times of longer than 50 sec, the increase in peak height was minimal. In order to maximize the sensitivity and precision of the method, a deposition time of 60 sec was chosen. At each deposition time, the peak height increased with increasing concentration of iodide. The highest concentration below which a linear relationship between peak height and concentration was observed decreased with increasing deposition time from about 150n*M* at 45 sec of deposition time to 75n*M* at 80 sec of deposition time [Fig. 4(b)]. At the proposed deposition time of 60 sec, the peak height was linearly related to concentration up to about 130n*M*. Given that a calibration curve is constructed for each sample by internal additions in 3 to 4 stepwise increases in the concentration of iodide of about 25n*M* in each step, the concentration of iodide in the analyte should not exceed about 75n*M* so that the concentration of iodide in the analyte plus the added iodide does not exceed 130n*M*. The

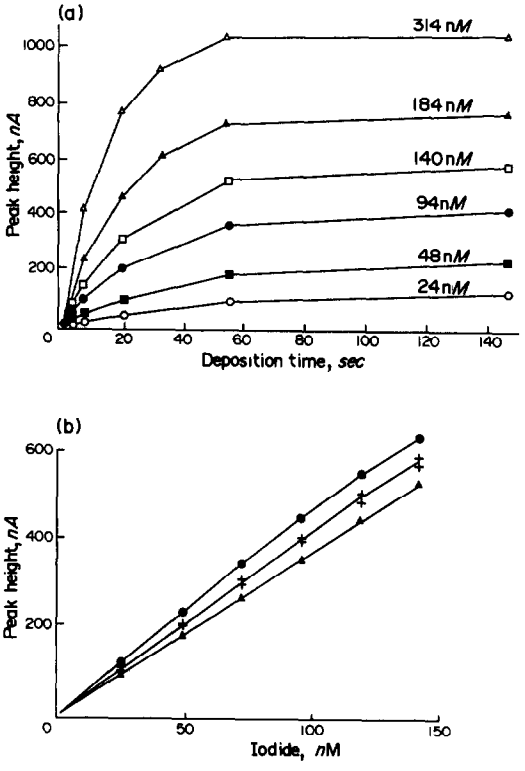

Fig. 4. (*a*) The influence of deposition time on the height of the current peak of iodide at various concentrations of iodide. (*b*) The relationship between peak height and the concentration of iodide at deposition times of 45 sec (▲), 60 sec (+) and 80 sec (●). Duplicate runs were made at a deposition time of 60 sec.

concentration of total inorganic iodine is usually about 0.5μM. A ten-fold dilution before the analyses would bring the concentration of the analyte within the dynamic range of the method. Since only 5 ml of the diluted seawater is needed for each analysis, even 0.5 ml of sample would be sufficient for the analysis. If this method is used for the determination of total inorganic iodine in other kinds of natural waters with substantially different concentrations, the dilution step and the deposition time should be adjusted accordingly to bring the concentration of total iodine in the analyte to within the dynamic range of the method. The concentration of iodide in seawater may range from less than 10nM to 300nM.[4] In most cases, it can be analyzed directly by CSSWV by varying the deposition time between 30 and 180 sec as described by Luther *et al.*[8] With a deposition time of 180 sec, a detection limit of 0.1nM can be reached.[8] However, at the high end of the concentration range, a dilution of the sample before it is analyzed may yield more precise results than shortening the deposition time alone.

Recovery and intercomparison of results from three independent methods

Aliquots of the NaCl–KBr–$NaHCO_3$ solution containing various known concentrations of added iodide, iodate or both iodide and iodate together were analyzed by the proposed method and the results are summarized in Table 2. In three solutions that were analyzed in duplicate, the concentration of added iodide ranged from 19.6 to 58.7nM and the amount of iodide recovered as total iodine averaged to 102 ± 3%. In the case of iodate, four solutions were analyzed in duplicate. The concentration of added iodate varied between 18.8 and 56.4nM and the averaged recovery of iodate as total iodine was 100 ± 3%. When both iodate and iodide were added, the average recovery in five analyses was 99 ± 3%. The recoveries in all cases were quantitative within the analytical uncertainties.

Five samples of seawater collected at various depths from the Sargasso Sea were stored frozen and later analyzed in a shore-based laboratory in triplicate according to published methods for iodide by CSSWV,[8] for iodate by differential pulse polarography (DPP),[16] and for total dissolved iodine by DPP.[10] They were also analyzed in triplicate for total inorganic iodine by the method described here. The results are shown in Table 3. The standard deviation of the triplicates determined by CSSWV ranged from 1.3 to 6.9% (one standard deviation). The concentrations agreed well with those determined by DPP or by summing the concentration of iodide and iodate. There was no detectable systematic difference between the concentration given by CSSWV and the other two methods. In all cases, the values obtained by CSSWV and one of the other two methods agreed to within ±3% of the mean value of the results from the two methods compared.

(*Received* 24 *May* 1991. *Revised* 2 *August* 1991. *Accepted* 23 *September* 1991)

Summary—This work describes the detection of sulphur dioxide with a piezoelectric crystal, at a resonance frequency of 9 MHz, covered with an active coating containing trioctylmethylammonium dichromate which irreversibly bonds sulphur dioxide in an oxidation–reduction reaction. The decrease in the vibration frequency of the crystal is directly proportional to the mass of sulphur dioxide bonded. The detector works on the basis of integration of the decrease in the frequency over a given time interval (at least 10 min), resulting in a high measuring sensitivity. The calibration curve is linear for sulphur dioxide concentrations from a few to 500 $\mu g/m^3$. Partial exhaustion of the capacity of the active coating, occurring after prolonged use, appears as nonlinearity of the detector concentration response. This nonlinearity can be compensated by a simple mathematical correction that permits the lifetime of the active coating to be lengthened by several orders of magnitude.

The ever-increasing interest in environmental protection throughout the world has led to the need for reliable, inexpensive methods of studying pollution of the atmosphere. This work, dealing with determination of the sulphur dioxide concentration in the air with piezoelectric phenomena, is a contribution to this effort.

The piezoelectric phenomenon, constituting a connection between the mechanical and electrical properties of substances, can be used to determine small mass increases in special types of microscales. Quartz piezoelectric crystals with suitable mechanical properties have been used most widely for this purpose. Sauerbrey[1] first described the dependence between the mass on the oscillating crystal surface and the change in the resonance frequency of the crystal. The above principle has been employed in a number of procedures for measuring gaseous pollutants and aerosols, but their use in practice has been complicated by a number of difficulties. Gases can be detected with piezoelectric resonators consisting of a thin quartz plate, on both sides of which fine metallic, circular electrodes are vacuum-plated. The surfaces of these electrodes are covered with a layer that, ideally, selectively absorbs the test gas. The increased mass of the electrode coating leads to a decreased resonance frequency of the crystal which is thus a measure of the amount of gas absorbed. The type of interaction between the active coating and the detected gas determines the character of the frequency response of the detector. Most of the detectors so far described utilize reversible sorption and desorption of the detected gas on the active electrode surface, leading to establishment of equilibrium between the amount of sorbed analyte and its instantaneous concentration in the gas phase.[2,3] The requirements of high detector sensitivity and simultaneous reversibility are in a certain sense contradictory and the use of reversible detectors to measure the concentrations of gaseous pollutants in the atmosphere is thus limited. An irreversible detector is better suited for highly sensitive measurements, involving irreversible sorption of the analyte from a gas stream passing through the measuring cell and thus integration of the frequency response over a certain time interval. This approach has the disadvantage of gradual exhaustion of the active electrode surface, which must thus be periodically renewed.

The composition of the active coating strongly affects the detector function. A number of substances[2–8] have been proposed for the detection of sulphur dioxide. Study of the

*Author for correspondence.

literature led us to the conclusion that the most promising substance would be a homogeneous coating with the consistency of a highly viscous liquid that would react with sulphur dioxide throughout its volume while retaining its original properties and high reactivity. Consequently, we studied two high-molecular mass amines that are employed in analytical chemistry in the extraction of anionic metal complexes, trioctylamine and trioctylmethylammonium chloride (TOMA). These substances are clear, highly viscous oils that behave as liquid ion exchangers and can be combined with various anions. About 20 different coatings were prepared from these substances, several of which exhibited acceptable activity. The complex of TOMA with dichromate ions had by far the best properties (TOMA–Cr_2O_7). This is a dark yellow substance with the consistency of honey, and is soluble in a number of organic solvents. It reacts readily with sulphur dioxide, with reduction of chromium(VI) to chromium(III). The reduced substance is green and stable to oxidation. The detailed study of the reaction mechanism was not performed but in the reduced coatings the presence of chromium(III) was established. In the experiments with greater volumes of the active substance it was confirmed that due to the sulphur dioxide diffusion the reaction passes throughout the whole volume of the substance. The bonding of sulphur dioxide in the coating is completely irreversible and the frequency response of the detector corresponds directly to the mass of the sorbed sulphur dioxide.

This work deals with the use of TOMA–Cr_2O_7 for the determination of sulphur dioxide in an irreversible detection system.

EXPERIMENTAL

The detectors consisted of AT-type quartz crystals with a characteristic resonance frequency of 9 MHz and a negligible temperature dependence in laboratory conditions. The active coatings were prepared from a 5% (vol.) solution of TOMA in carbon tetrachloride, shaken manually in a separating funnel with a four-fold volume of a saturated aqueous solution of potassium dichromate. The separated organic phase containing TOMA–Cr_2O_7 was diluted five-fold with carbon tetrachloride and sprayed onto both the electrodes of the crystal. The thickness of the coating was adjusted electronically by controlling the spraying time. The crystals were dried in a drying box at 70° for one hour. The measurements were carried out in teflon cells[2] of commonly used design with a volume of about 1.5 ml, in which the analysed gas was introduced by two inlets directed against both electrodes of the crystal plate. The oscillator frequency was read with a counter with a precision of ± 1 Hz (gate time 1 sec) and the whole measuring apparatus was computer-controlled.

A sulphur dioxide mixture with defined concentration for model experiments was prepared with standardized sulphur dioxide permeation sources (Chemoprojekt, Prague) or in a mixing apparatus.[9] The carrier gas was technical nitrogen which was not purified. The sulphur dioxide concentration was controlled analytically with the standard colorimetric method of West and Gaeke.[10]

Real atmospheric samples were measured with two identical measuring cells in series or in parallel; a membrane filter with a pore diameter of 0.4 μm (Synpor, Synthesia, Czechoslovakia) was placed at the entrance to the sampling unit to remove aerosol particles.

RESULTS AND DISCUSSION

Determination of the optimal amount of the active coating and the gas flow rate through the measuring cell

The amount of the active coating used should ensure the highest possible sensitivity and lifetime of the detector and also its reliable and reproducible functioning. It follows from Fig. 1 that the capacity of the active coating, *i.e.*, the amount of sulphur dioxide that a given coating can absorb, increases linearly with the amount of the active substance. The mass of the coating is directly proportional to the decrease in the resonance frequency of the crystal occurring after application to the electrode, and is thus expressed in the figures in terms of frequency units. Figure 2 depicts the dependence between the mass of the active substance and the detector sensitivity. It can be seen that the detector sensitivity increases with increasing mass of the active substance up to a frequency decrease of about 20 kHz, after which it no longer increases. The maximal load on the electrodes, *i.e.*, about 100 μg, corresponds to a frequency decrease of 40–45 kHz[4] (the crystal ceases to oscillate at larger loads) and the maximal amount of sulphur dioxide which the active coating can absorb corresponds to a frequency decrease of

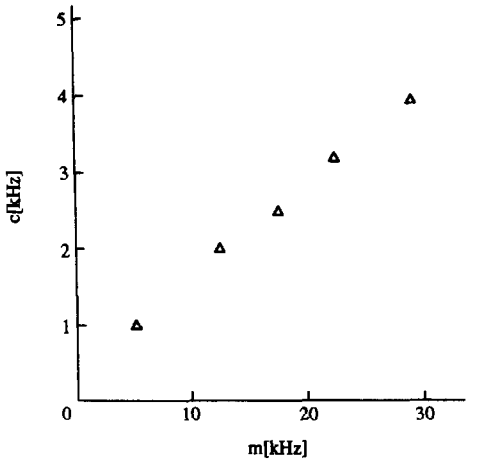

Fig. 1. Effect of the mass of the active coating, m, on its capacity, c, *i.e.*, the maximum mass of SO_2 that the given coating can absorb. Both the mass of the coating and the mass of SO_2 are expressed in terms of the frequency decrease on the crystal. Gas flow-rate through the measuring cell was 200 ml/min, SO_2 concentration was about 43 $\mu g/m^3$.

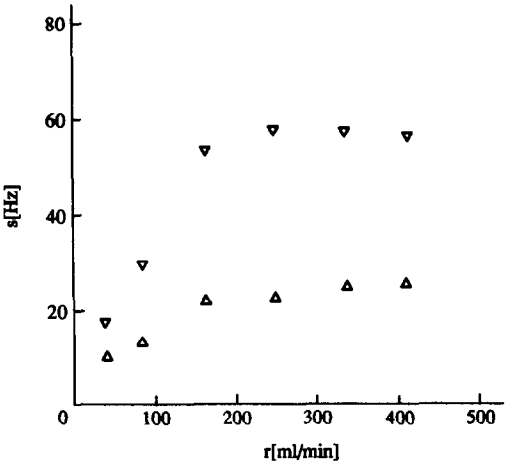

Fig. 3. Effect of the gas flow-rate through the measuring cell, r, on the detector sensitivity, s, *i.e.*, on the frequency decrease over a time interval of 10 min, for the SO_2 concentrations △: 50 $\mu g/m^3$; ▽: 100 $\mu g/m^3$.

about 5 kHz. Consequently the optimal amount of the active substance was considered to be that corresponding to a frequency decrease of 30 kHz, when a high sensitivity was ensured, with a sufficient reserve for reliable detector functioning. It also follows from Fig. 2 that the reproducibility of the active coating weight (up to ±10%) does not affect the detector sensitivity.

The experiments were carried out at a gas flow-rate of 200 ml/min, see Fig. 3, which was supposed to be the most suitable in regard to sufficient detector sensitivity for claims on the pump performance in the case of a portable instrument development.

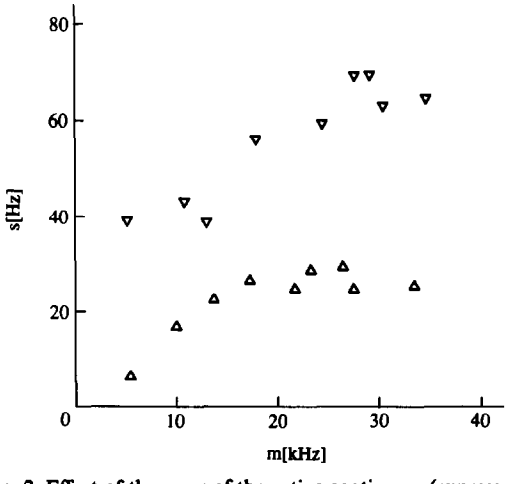

Fig. 2. Effect of the mass of the active coating, m (expressed in terms of frequency decrease), on the detector sensitivity, s, *i.e.*, on the frequency decrease over a time interval of 10 min. Gas flow-rate through the measuring cell was 200 ml/min, SO_2 concentration △: 50 $\mu g/m^3$; ▽: 200 $\mu g/m^3$.

The dependence of the detector response on the sulphur dioxide concentration

It was found that this dependence is linear in the studied concentration range up to 500 μg SO_2/m^3 and can be approximated by a straight line given by the relationship

$$f = 0.30c + 9, \quad (1)$$

where f is the frequency decrease over a time interval of 10 min (Hz). The sulphur dioxide concentration is then given by

$$c = 3.33f - 30 \quad (2)$$

where c is the concentration in $\mu g/m^3$. The correlation coefficient of the equations is equal to 0.998. It thus follows that the detector sensitivity is sufficient for measuring the sulphuric dioxide concentration in the atmosphere and that the piezoelectric crystal can reproducibly detect concentrations at the level of several μg SO_2/m^3, *i.e.*, of the order of units of ppb; this sensitivity has also been confirmed by other model experiments. The intercept of the straight line on the ordinate was observed in all the experiments with coated and even with uncoated crystals when the nitrogen or purified air were used as the carrier gas. This constant change in frequency can be explained by an increase in the crystal load but its true nature is so far not clear.

The analytical accuracy and the precision of the piezoelectric detector

The exact assessment of the measuring accuracy and precision in detectors of atmospheric pollutants is a relatively complex problem. It is difficult to compare the performances of the individual detectors because of their different operating conditions, sampling requirements and calibration procedures.

The variations in the frequency response of piezoelectric detector are basically a consequence of the lack of uniformity of the individual manufactured crystals and of the variations in the detector temperature. In model experiments, the measurements will also reflect errors in the preparation of a defined sulphur dioxide concentration in the gas dilution apparatus. The use of the common spectrophotometric method of West and Gaeke[10] as a standard procedure for checking sulphur dioxide concentrations is not completely satisfactory, especially at low concentrations where a long sampling time (up to several tens of hours) is necessary. In our work the evaluation of the piezoelectric detector performance was based on the used certified permeation devices (Chemoprojekt, Prague) that were employed in model experiments. The overall precision of the measuring system in the range from tens to hundreds of μg SO_2/m^3 over a time interval of 10 min is approximately $\pm 10\%$ as can be seen in Table 1. The precision can be improved by increasing the measuring time interval.

The detector lifetime and measuring procedure

One of the drawbacks of irreversible detectors is the gradual depletion of the capacity of the active coating, leading to a decrease in the detector sensitivity. Consequently, the change in the detector response with time was studied. Figure 4 depicts the changes in the detector response for a given constant sulphur dioxide concentration over 24 hr. It follows from the dependence for various sulphur dioxide concentrations that a linear detector response can be expected only in the beginning, up to a frequency decrease resulting from sorption of sulphur dioxide of about 500 Hz, where the slope of the tangent to the curve is directly proportional to the sulphur dioxide concentration. However, the detector sensitivity is still sufficient in the curved region and the use of a suitable mathematical approximation to the dependence of the detector sensitivity on time permits a several-fold lengthening of the detector lifetime. The approximation was carried out with a rational fractional function in the form

$$y = k_1 \cdot x/(k_2 + x), \tag{3}$$

where y is the frequency decrease from the beginning of the measurement to time $t = x$ (given in minutes).[11] The coefficient k_1 corresponds to the maximal sorption capacity of the active coating, expressed as the frequency decrease and given by the mass of the coating alone. Fraction k_1/k_2 equals the slope of the frequency decrease df/dt and corresponds to the experimentally established values for the frequency decrease in the linear response region. The validity of the approximation function was confirmed in 24-hr experiments for various sulphur dioxide concentrations. The results are

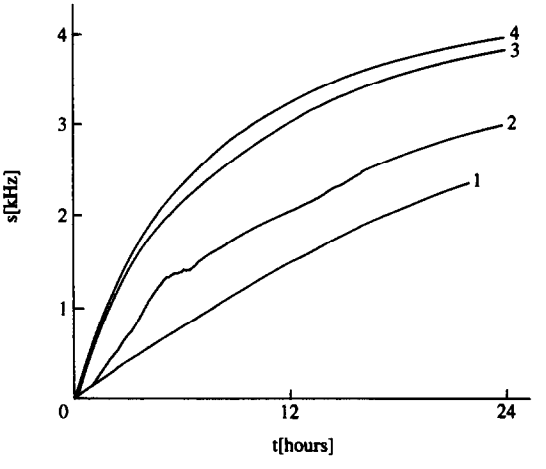

Fig. 4. The time dependence of the detector sensitivity, s, *i.e.*, of the frequency decrease over a time interval, for SO_2 concentrations: 1–47 $\mu g/m^3$, 2–116 $\mu g/m^3$, 3–370 $\mu g/m^3$, 4–428 $\mu g/m^3$. Gas flow-rate through the measuring cell was 200 ml/min.

given in Table 2. It can be seen that coefficient k_1 actually expresses the experimentally established sorption capacity of the coating. The only exception was the detector response for a concentration of 47 μg SO_2/m^3, where the detector response was almost linear over the whole 24-hr period and thus the calculated k_1 value is subject to a considerable computing error and is not in agreement with the expected sorption capacity. Nevertheless the k_1 computed for higher concentrations can be applied for the whole range of the studied concentrations (10–500 μg SO_2/m^3). Fraction k_1/k_2 is directly proportional to the sulphur dioxide concentration. The relationship between the frequency decrease f and the sulphur dioxide concentration c,

$$f = 0.27c + 19, \tag{4}$$

$$c = 3.70f - 70, \tag{5}$$

calculated on the basis of the above approximation is in relatively good agreement with the experimentally obtained calibration equations given above [equations (1) and (2)].

The practical importance of this approximation lies in the fact that the relative change in the detector sensitivity can be determined during its entire lifetime. It was experimentally confirmed that this sensitivity change is dependent solely on the total mass of sulphur dioxide that has already been absorbed by the coating, which is quantitatively reflected in the overall frequency decrease recorded during the detector lifetime. Thus, when we know the resonance frequency of the crystal with fresh coating, the change in sensitivity can be easily compensated, for instance by a series of correction coefficients to the detector response. The tangent of the frequency decrease corrected in this way corresponds to the value of the tangent that would be obtained if measurements were carried out in the linear response region and is proportional to the sulphur dioxide concentration read off the linear calibration graph. The values of the correction coefficients for the practically exploitable frequency interval are given in Table 3. The simple compensation of the sensitivity loss outlined above demonstrates the general approach and can be modified.

It can be found theoretically that the crystal can be used for continuous measurement at a concentration of 20 μg SO_2/m^3 for approximately 110 hr and at a concentration of 150 $\mu g/m^3$ for approximately 30 hr.

Table 2. The values of the coefficients of the approximation function related to the SO_2 concentration

Average	5300		
Standard deviation	±280		
Relative deviation	±5.3%		

Experimentally established sorption capacity equaled to 5200 Hz frequency decrease.

*This value was not included in calculation of the average.

Practical monitoring of the sulphur dioxide concentration does not usually necessitate continuous measurement; it is usually sufficient to carry out the measurements at given time intervals. The measuring interval and frequency must be selected according to the expected variations in the sulphur dioxide concentration and the requirements of the measuring instrument. This method has been tested on model samples and it has been found that it is useful to alternate measurement on the test and on a blank reference gas, leading to considerable lengthening of the detector lifetime.

Continuous measurement over 100 hr was carried out to determine whether any other time-dependent processes occur in the crystal active coating that would affect its sensitivity and lead to its ageing. The sensitivity of the crystal to a mixture with a defined sulphur dioxide concentration was then tested. The crystal response corresponded to that expected on the basis of the degree of exhaustion of the coating and thus the crystal sensitivity was not affected by any processes of ageing of the active coating and the lifetime of the detector is given by the amount of sorbed sulphur dioxide alone.

Table 3. Values of correction coefficients

Overall frequency decrease (Hz)	Correction coefficient	Overall frequency decrease (Hz)	Correction coefficient
0	1.00	1800	2.30
200	1.08	2000	2.59
400	1.17	2200	2.94
600	1.27	2400	3.36
800	1.39	2600	3.88
1000	1.52	2800	4.53
1200	1.67	3000	5.36
1400	1.85	3200	6.44
1600	2.06	3400	7.89

Interferences

Orientative measurements were carried out to determine the effect of gases that could interfere in the determination of sulphur dioxide by reaction with the active coating. Those investigated were HCl, H_2S, CO, CO_2, NH_3, NO_x, $CH{\equiv}CH$, C_4H_{10} and O_3. As expected, these gases did not interfere even at high concentrations, as they cannot undergo redox reactions with the active surface.

The greatest interference in the measurement of sulphur dioxide was produced by changes in the test gas humidity. As it was not possible in model experiments to ensure a constant humidity of the test gas without affecting the sulphur dioxide concentration, real atmospheric samples were measured, using a method with a reference crystal. These reference crystals were resonators whose active coating was saturated in sulphur dioxide. It was found that the response of the reference crystal was completely independent of the sulphur dioxide concentration but depended very strongly on the humidity of the atmosphere. The sulphur dioxide concentration was found as the difference between the frequency decrease of the measuring and reference crystals over the given time interval according to the calibration dependence. We know of course that the problem of removing the humidity interferences is very complicated and the use of the method suggested is limited especially when fast changes of humidity in the atmosphere occur. Practical use of the piezoelectric detector will necessitate more detailed study of this question.

CONCLUSIONS

The above experiments have demonstrated that the detection method employing irreversible reaction of the analyte with the active coating of the piezoelectric crystal can be used to measure the sulphur dioxide concentration in gases. The method has been tested on model experiments for sulphur dioxide concentrations of 10–500 $\mu g/m^3$. The detector is simple, inexpensive, and exhibits high sensitivity and a wide measuring range with sufficient selectivity and a relatively short measuring time. The whole measurement can be automated. The integration method of measurement is a disadvantage, as it is accompanied by a limited capacity of the active coating. The lifetime of the active coating depends on the procedure employed and the measured sulphur dioxide concentrations. After depletion of the active surface, the crystal must be exchanged. The depleted coating can be readily washed off with a suitable solvent, *e.g.*, CCl_4 or $CHCl_3$, and application of a new coating makes the crystal ready for use again.

The applicability of this method for measurement in the atmosphere is complicated by humidity interferences. The suggested compensation method with the reference crystal is not completely satisfactory and the problem of humidity requires further study.

ELECTROCHEMICALLY-CONTROLLED GENERATION OF SMALL AMOUNTS OF CARBON MONOXIDE

FRANTIŠEK OPEKAR* and JAN LANGMAIER

UNESCO Laboratory of Environmental Electrochemistry, J. Heyrovský Institute of Physical Chemistry and Electrochemistry, Czechoslovak Academy of Sciences, Dolejškova 3, 182 23 Prague 8, Czechoslovakia

(*Received* 10 *June* 1991. *Accepted* 14 *September* 1991)

Summary—The generation of carbon monoxide is based on oxidation of carbon at a temperature of 920–950° by electrolytically generated oxygen. The rate of production of CO is a linear function of the oxygen generating current over a range of 5–60 mA and corresponds to the theoretical value. By the method described it is possible to obtain CO concentrations from 0.0075 to 2.5% in an inert gas (nitrogen, argon and helium).

Permeation devices containing liquefied gases are very advantageous for calibrating gas analysers, testing sensors and have many other uses when a continuous supply of small amounts of gases and vapours is required. Carbon monoxide cannot be liquefied under the conditions permitting the preparation and use of these permeation devices. A permeation device containing gaseous CO under pressure has been described.[1] The CO permeates through a hole in a pressure vessel covered by a silicone rubber membrane. However, the production from this source varies with variation in the CO pressure in the vessel, *i.e.*, with the time of the use of the source. Therefore, gaseous mixtures containing defined amounts of carbon monoxide are mostly prepared by the method of volumetric gas dilution.[2,3]

Many gases can be generated electrolytically, usually at a constant current.[4,5] An advantage of this approach is the fact that the gas is only generated when required and that the rate of its production (and thus also its concentration in a carrier gas) is readily controlled through the magnitude of the generating current. The production rate can be determined from Faraday's law for a given generating current, provided that the current efficiency is known.

In this work carbon monoxide generation by oxidation of carbon with electrolytically generated oxygen at an elevated temperature is described. The oxidation takes place under conditions analogous to those for oxygen determination in elemental analysis of organic substances (the Unterzaucher method).[6]

EXPERIMENTAL

The apparatus used is shown in Fig. 1. The carrier gas (helium, argon or nitrogen) was supplied from a pressure cylinder, at flow-rates from 0.3 to 1.0 ml/sec adjusted by valve 1 and measured by flowmeter 2.

The electrolysis cell was made of plexiglass and contained separate anodic and cathodic compartments (3 and 4). The two compartments, with volumes of *ca.* 5 ml, were conductively connected by an ion-exchange membrane (5) (Nafion 117). Perchloric acid (1*M*) was used as electrolyte. A glass tube (3 mm in internal diameter) was cemented in the upper part of the anodic compartment and provided with a gas inlet and outlet, so that the carrier gas only passed over the meniscus of the electrolyte solution and thus its humidity was not much increased. A 0.2-mm platinized platinum wire served as the anode (6); the part immersed in the electrolyte was *ca.* 5 mm long. The position of the meniscus in the tube was adjusted with a syringe (7) containing the electrolyte solution. Cathodic compartment 4, containing the platinum cathode (8) was open to the atmosphere. Oxygen was generated by a constant current of 0 to 60 mA, produced by the galvanostat (9).

Carbon was oxidized in a reaction tube made of sintered corundum (400 mm long, with a bore of 5 mm and a wall thickness of 1 mm) heated to a working temperature of 920–950° by an

*Present address: Department of Analytical Chemistry, Charles University, Albertov 2030, 128 40 Prague 2, Czechoslovakia.

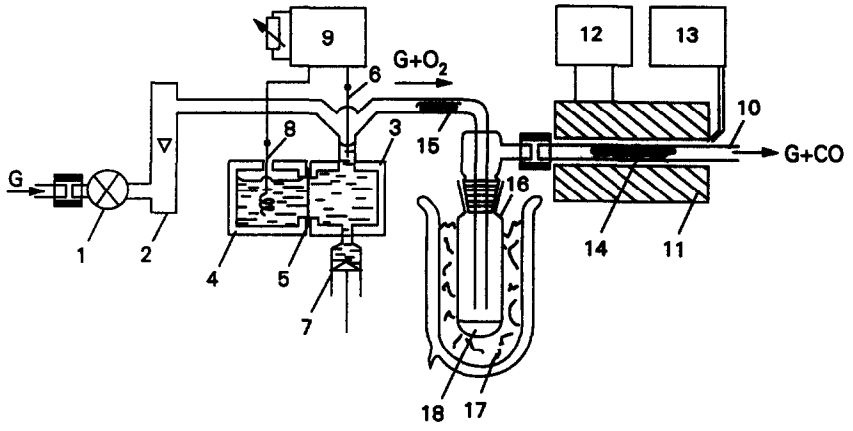

Fig. 1. A scheme of the apparatus for the CO generation. For description see the text (G = He, Ar or N_2).

electric oven (11). The temperature was adjusted by the regulating transformer (12) and measured with a thermometer (13) with a Pt–Pt/Rh thermocouple.

The reaction tube was packed into a 50-mm length with pieces of carbon (14) of 0.5–2 mm size, obtained by crushing spectrographic electrodes (Electrocarbon Topolčany, Czechoslovakia). The carbon particles were fixed in the tube with glassy carbon wool wads. After heating the reaction tube to the working temperature, the apparatus was ready for operation within an hour. A constant stream of carrier gas was passed through the apparatus when standing overnight. After a long period without operation, the apparatus can be filled with an inert gas at a small overpressure,[6] to keep out air, but this procedure is not absolutely necessary. If air enters the apparatus, the only consequence is a somewhat longer time required for preparation of the apparatus for operation and it is advisable to employ a special procedure for heating the reaction tube, see below.

The gas from the electrolyser passed through the glass wool filter (15) prior to entering the reaction tube, in order to remove any electrolyte droplets, and was dried by freezing in trap 16, cooled with dry ice in chamber 17 and by passage over a layer of phosphorus pentoxide (18).

The individual parts of the apparatus were connected by glass tubes. To prevent penetration of atmospheric oxygen, only the three joints that could be disassembled were used in the apparatus. The gas supply from the pressure cylinder and the connection of the cold trap to the reaction tube were attained by placing the tubes close together and covering the joint with thick tygon tubing. A ground-glass joint was used in the cold trap, permitting removal of the trapped moisture and replenishment of the phosphorous pentoxide packing.

Carbon monoxide was determined by gas chromatography.[7]

RESULTS AND DISCUSSION

The dependence of the CO production on the reaction tube temperature at a constant oxygen concentration in the carrier gas is plotted in Fig. 2A. This dependence was analogous to when other forms of carbon were used (*e.g.*, graphite, several kinds of active charcoal and glassy carbon wool). When using the spectrographic carbon electrode, the background production, *i.e.*, the production of CO at zero generating current, was lowest at a given

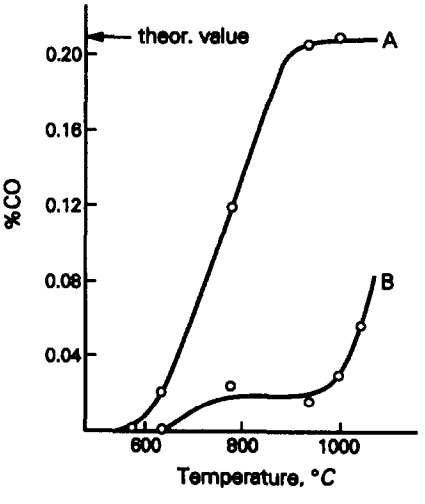

Fig. 2. Temperature dependence of the CO production (helium carrier gas, 0.6 ml/sec, spectrographic carbon electrode). A—generating current of 10 mA (the background production subtracted); B—background production.

working temperature, as can be seen in Fig. 2B. It is obvious from Fig. 2 that the optimal reaction temperature lies between 920 and 950° for the given experimental arrangement, as the production of CO is virtually 100% and the background production is low.

It has been found that the background production primarily stems from reaction of the carbon with the reaction tube walls. It is higher than the value corresponding to the oxygen content in the carrier gas which was below 5 vppm. The background production was unaffected by: using two cold traps (elimination of the carrier gas humidity), disconnecting the electrolysis cell (elimination of oxygen diffusion through the electrolyte solution), placing the reaction tube inside an auxiliary tube filled with an inert gas (elimination of possible diffusion of oxygen through the reaction tube walls at higher temperatures). On the other hand, the background production depended on the kind of carbon used and it was somewhat higher when a quartz reaction tube was employed.

To attain a constant background production more rapidly when preparing the apparatus for operation, especially when atmospheric oxygen has penetrated the apparatus, heating the reaction tube at a higher temperature (*ca.* 1150°) is recommended, for about 20 min, followed by decreasing the temperature to the working value.

The rate of production, R, of carbon monoxide (ng/sec) is a linear function of the oxygen generating current, I (mA). The equation of a regression straight line obtained from seven measurements within an interval of 5–60 mA has the form, $R = a.I + b$, where $a = (149.7 \pm 1.7)$ $ng.sec^{-1}.mA^{-1}$ and $b = (92.2 \pm 45.4)$ ng/sec, with a standard deviation of 31.9 ng/sec and a correlation coefficient of 0.999. The theoretical rate of production, obtained from Faraday's law assuming a 100% current efficiency and a 100% conversion ($O_2 = 2CO$), is $R_{theor} = 145.1\ I$ ng/sec. Slope a corresponds to (103.2 ± 1.1)% of the theoretical value. Intercept b expresses the value of the background production; here it is equivalent to the production at a generating current of about 0.6 mA.

The carbon monoxide concentration, C_{CO} (vppm), in the carrier gas flowing at a velocity of v (ml/sec) can be found for various generating currents I (mA) from the relationship, $C_{CO} = 125\ I/v$ (for 20° and 101.3 kPa). The CO production was constant over the studied flow-rates, 0.3–1.0 ml/sec. The highest CO concentration for $I = 60$ mA and $v = 0.3$ ml/sec is 25,000 vppm (2.5%). The lowest concentration is determined by the background production value, here *ca.* 75 vppm (0.0075%) for $v = 1.0$ ml/sec.

At generating currents higher than 60 mA, the contact between the anode and the electrolyte solution was periodically disconnected owing to intense evolution of oxygen. The electrolysis cell would have to be designed differently for higher generating currents.

With a change in the generating current, the rate of change in the outlet CO concentration is determined virtually only by the transport delay in the apparatus.

ELECTROCHEMICAL INVESTIGATION OF ACID–BASE PROPERTIES OF ORDERED LIQUID SYSTEMS

ALAIN BERTHOD* and OSCAR SALIBA
Laboratoire des Sciences Analytiques, Universite de Lyon 1, U.A. CNRS 435, 69622 Villeurbanne cedex, France

(*Received* 15 *October* 1990. *Revised* 8 *April* 1991. *Accepted* 1 *July* 1991)

Summary—Acid–base properties of ordered media were investigated via potentiometry, polarography and electrochemical probes. Electrochemical probes have a pH-dependent reduction potential and their oxidized and reduced forms have a different affinity for aqueous and organic phases. Solutions of anionic, cationic and nonionic surfactants were investigated. One anionic and one cationic surfactant stabilized emulsion were studied. A water–dodecane–pentanol–anionic surfactant microemulsion and a water–heptane–butanol–cationic surfactant were also investigated for several compositions. In micellar solutions and emulsions, it was possible to standardize and use the classical glass electrode for pH values in the range 1–12. The hydrogen electrode was required in the microemulsion systems. The reduction of electrochemical probes was studied by polarography. It is shown that in the ordered media studied, the aqueous phase played the most important role in micellar solutions and in O/W emulsions, as far as acid–base properties were concerned. In microemulsions, the acid–base properties of the aqueous phase were very different to those of water. The alizarin probe could be reduced at a "local" pH of about 12 when the aqueous phase pH was only 6.

Ordered systems are defined as liquid systems with some micro-organization. These systems contain surfactant molecules. A surfactant molecule is composed of two parts of very different polarity, a hydrophilic part (polar or ionic head) and a hydrophobic part, most often a hydrocarbon chain. The two main properties of such molecules are the trend to adsorb at any interface and the ability to form micelles. In order of increasing complexity, the studied systems were: micellar solutions that are two component mixtures (water + surfactant), six emulsions, that are three component mixtures (water + hydrophobic oil + surfactant), and two microemulsion systems that are four component mixtures (water + oil + surfactant + a long chain alcohol or cosurfactant[1]). The surfactants used were anionic, cationic and nonionic surfactants non-sensitive to pH changes. Carboxylate surfactants (soaps) were excluded because they are salts of a weak acid. For example, sodium stearate is a soap which is protonated to stearic acid when the pH is lowered. Stearic acid is a wax without any surfactant property.

In ordered media, the pseudo-phase model[2] is very useful for explaining many results. The ordered medium is separated in two pseudo-phases: the aqueous phase and the organic phase. The interface between the two phases is stabilized by adsorbed surfactant. Figure 1 shows an oversimplified view of the pseudo-phase representation of the three ordered media used in this work. In micellar media, normal and reversed micelles exist with diameters in the low nanometer range. An emulsion can be oil in water (O/W) or water in oil (W/O) type. Emulsion droplet diameters range from a tenth of a micrometer to some tens of a micrometer. Due to light scattering by these droplets, an emulsion has a milky appearance. The structure of a microemulsion is complex. An L1 water-rich microemulsion corresponds to an O/W system. The L1 microemulsion structure has a water phase in which oil droplets are suspended. The oil droplet diameter is smaller than 100 nanometers. An L2 oil-rich microemulsion corresponds to a W/O system. The L2 microemulsion structure has an oil phase in which water droplets are suspended (Fig. 1). In intermediate compositions, bicontinuous systems (Fig. 1) can exist.[1] The droplets are smaller than visible wavelengths and so a microemulsion is transparent. Any composition change can induce a change in the physico-chemical structure of the ordered medium. Addition of one drop of water can turn a clear L1 microemulsion into a turbid

Simplified view of the physicochemical structures of liquid ordered systems. 1—Normal and reverse micelles (lifetime in the microsecond range); 2—W/O and O/W emulsion droplets (lifetime ranging from few seconds to the year); 3—L1, bicontinuous, and L2 microemulsion structures (lifetime in the microsecond range). Hatched area: aqueous phase. ⊂⊃ Surfactant molecule.

W/O emulsion. Phase maps are used to understand the physicochemical structure of emulsions and microemulsions. Another important point to know is that the lifetime of a micelle or a microemulsion droplet is in the microsecond range, with continuous destruction–formation producing a macroscopically stable system. The lifetime of an emulsion droplet ranges from seconds to years depending on the emulsion stability.[1-3]

Ordered systems are widely used. Their main interest is the aptitude for associating apolar and hydrophilic molecules in the same medium in fields as different as paints and dyeing, pharmaceutical and cosmetics, pesticides and fertilizers, and enhanced oil recovery.[2-5] In many applications of these systems, the acidic strength must be known. Usually, to measure the pH of an ordered medium, a glass electrode is used.[6,7] Alternatively, the pH of the aqueous phase is measured before the preparation of a W/O emulsion or microemulsion.[8] Several theories have shown that the pH of the aqueous phase can be different from the interphase pH.[9,10] In experimental studies, the known concentrations often refer to the total volume of the studied system. We thought it might be useful to study the acid–base properties of ordered systems considered as solvents.

This work presents a theoretical approach to the acid–base properties of ordered systems by using the classical pseudo-phase model described, for example, by Fendler and Fendler.[3] Experimental results obtained in micellar solutions, O/W emulsions and microemulsions are presented. All experiments were performed by using potentiometry and polarography. To get an insight into some "local" pH values occurring in ordered media, we have used electrochemical probes. These are electroactive apolar organic molecules which need protons to be reduced. They are localized in the apolar phase of ordered systems. Their half-wave reduction potentials, $E_{1/2}$, are pH-dependent. This experimental $E_{1/2}$ value can be related to the "local" pH of the solubilization site of the electroactive probe.

EXPERIMENTAL

Chemicals

Sodium dodecylsulphate (SDS) ($C_{12}H_{25}SO_4^-$ Na^+, m.w. 288.3), cetyltrimethylammonium bromide (CTAB) ($C_{16}H_{33}N(CH_3)_3^+$ Br^-, m.w. 364.5) and polyoxyethylene 23 dodecylether (Brij 35) ($C_{12}H_{25}(OC_2H_5)_{23}OH$, m.w. 1200) were surfactants supplied by Merck. Pentanol, butanol and heptane were from Prolabo (Rhone-Poulenc, France). Dodecane was purchased from Fluka. All chemicals were analytical grade and were used without further purification. All solutions were prepared with demineralized, distilled water.

Table 1 introduces the electrochemical probes that were obtained from Rhone Poulenc. These quinones need two electrons and two protons to be reduced to the corresponding hydroquinones. Alizarin is also a diphenol whose phenol functions are ionized at elevated pHs (Table 1). Vitamin K3 has no ionizable functions.

Apparatus

Potentiometric measurements were performed with a digital reading pH-meter/millivoltmeter (Solea-Tacussel, Villeurbanne, France). The glass electrode was a TBC 112/HS or a TBC 170/HS (Tacussel). The hydrogen electrode was home-made by covering a platinum wire with platinum-black and working

Table 1. The electrochemical probes

Electrochemical probe	2-Methyl-1,4-naphthoquinone	1,2-Dihydroxi-anthraquinone
Common name	Vitamin K3 Menadione	Alizarin
M.w.	172.2	240.2
Water solubility (M)	8.6×10^{-4}	2.5×10^{-6}
Electrochemical reduction	Quinone + $2H^+ + 2e \rightarrow$ Hydroquinone	
pH properties	not ionizable	$AH_2 \rightarrow AH^- + H^+$ $pK_1 = 6.4$ $AH \rightarrow A^{2-} + H^+$ $pK_2 = 11.7$

with hydrogen bubbling under atmospheric pressure. The platinum-black coverage was obtained by electroreduction of a chloroplatinic acid glycol solution in a platinum crucible. The reduction time was 15 min, the reduction current was 300 μA. When the response of the hydrogen electrode became slow, it was cleaned with an abrasive paste and a new platinum-black coverage was performed. The reference electrode was a saturated calomel electrode (SCE) with a double junction RDJ/C8 (Tacussel). The junction was filled with a gel of agar-agar (2%) and 0.1M sodium chloride. The gel junction between the sample and the SCE was made necessary to minimize any leakage of electrolyte solution in the sample, to avoid any precipitation that would disrupt the junction, and to avoid any junction potential change during an experiment.

Polarographic measurements were performed with a PAR-174 polarographic analyser (Princeton Applied Research). The working electrode was a dropping mercury electrode, the counter electrode a platinum wire and the reference electrode the SCE described above. Emulsions were prepared with an Ultra-Turax homogenizer (Cole Palmer). All solutions were deaerated by bubbling with nitrogen saturated in water vapour (micellar solutions), oil and water vapours (emulsions) or oil, alcohol and water vapours (microemulsions). All experiments were performed in a thermostatic bath at 25°. All pH values referred to H^+ concentrations in the aqueous phase volume. Other concentrations are given in moles per litre of ordered medium (total volume).

Titration in an ordered medium

To avoid any change in the composition of the ordered system under investigation, the following procedure was used for titration. A 30-ml sample of the ordered medium was prepared including the electrochemical probe (10^{-5}–$5 \times 10^{-4}M$) and divided in two parts to perform acid–base titration. For example, if a study with increasing pH values had to be performed, the first part (10 ml) was made acidic by addition to pure acid to get a proton concentration of 0.1 moles/(litre of aqueous phase). The second part (20 ml) was made basic by addition of a concentrated base, to get a hydroxide concentration of 0.1 moles/(litre of aqueous phase). Using microsyringes and adding the basic ordered medium to the acidic one, it was possible to increase the pH without modifying the composition, that is to say without producing any structure change.

pK_s Determinations

The autoprotolysis constant or ionic product, K_s, in a given ordered medium was determined with a procedure established for K_s measurements in non-aqueous solvents.[11] First, a dilution of the ordered medium containing sodium chloride 0.1M, with the same medium, but containing 0.1M hydrochloric acid, was performed from $-\log [H^+] = 5$ to $-\log [H^+] = 1.2$. The curve $E_A = f(-\log [H^+])$, potential of the pH sensitive electrode (glass or hydrogen electrode) *vs.* the calculated pH ($= -\log [H^+]$), was drawn [Fig. 2-(1)]. The equation is

$$E_A = -A \log [H^+] + B = A\,\mathrm{pH} + B \quad [1(a)]$$

A similar dilution of the same composition of ordered medium, with sodium chloride in the aqueous phase, by the corresponding ordered medium, but with sodium hydroxide in the aqueous phase, was performed from $-\log [OH^-] = 5$ to $-\log [OH^-] = 2$ [Fig. 2-(2)]. The equation is

$$E_B = -D \log [OH^-] + F = D\ \mathrm{pOH} + F \quad [1(b)]$$

The coefficients A and D are the slopes of the straight lines and B is the theoretical electrode potential at $\log [H^+] = \mathrm{pH} = 0$. The term F is the theoretical potential at $\log [OH^-] = \mathrm{pOH} = 0$ (Fig. 2). In all studied cases, the

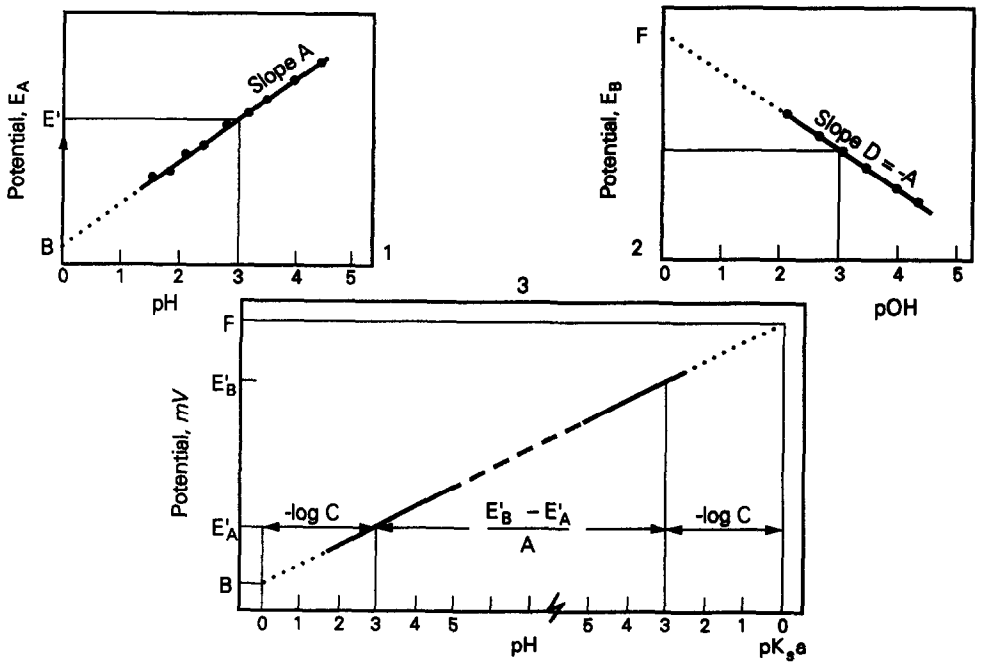

Fig. 2. The pK_s determination. 1—The acid standardization line: electrode potential versus $pH = -\log [H^+]$. 2—The basic standardization line with $pOH = -\log [OH^-]$. 3—Combining both curves allows the pK_s determination. A geometrical illustration of equation (7) is given with $C = 10^{-3}M$ ($pH = pOH = 3$).

absolute values of the slopes of the two curves were similar if not equal:

$$|A| = |D| \tag{2}$$

Because the signs of A and D were different, we wrote [Fig. 2-(2)] $A = -D$. Combining activity and concentration, the ionic product (or autoprotolysis constant) of water, K_s, is defined as:

$$K_s = [H^+]\,[OH^-] \tag{3}$$

and

$$pK_s = -\log K_s = -\log [H^+] - \log [OH^-] = pH + pOH \tag{4}$$

Theoretically, when the pH moves from $pH = 0$ to $pH = pK_s$ (or $pOH = 0$), the electrode potential moves from B (mV) to F (mV). In Fig. 2-(3), we plotted together the two curves obtained in acidic media [Fig. 2-(1)] and in basic media [Fig. 2-(2)]. These two curves were obtained with the same electrodes, so they belong to the same E *vs.* pH curve, with the unique slope A. Since the potential B corresponds to $pH = 0$ and the potential F corresponds to $pH = pK_s$, we can write

$$pK_s = \frac{F - B}{A} \tag{5}$$

The ionic strength was constrained to 0.1 and the pH ranged from 1 to $(pK_s - 1)$. For a concentration $[H^+] = [OH^-] = C$, the electrode potentials in acid and basic medium were E'_A and E'_B, respectively [Fig. 2-(3)]. Using equations [1(a)], [1(b)] and (2) [Fig. 2-(2)], we form

$$E'_B - E'_A = 2A \log C + F - B \tag{6}$$

and, with equation (5),

$$pK_s = \frac{E'_B - E'_A}{A} - 2 \log C \tag{7}$$

RESULTS AND DISCUSSION

Theory

In any medium the acidic strength is defined as the solvated proton activity. In experimental studies, people usually take a litre of say an emulsion, and add say 0.1 mole of an acid to make a $0.1M$ acidic emulsion. This means that with ordered media, the known concentrations refer to the whole volume of the system. The problem is that in an ordered system, the whole system is not of the same concentration because of the microheterogeneous nature illustrated by Fig. 1. By electrochemical investigations in ordered media, we have shown that ions are excluded from the oil phase and are mainly

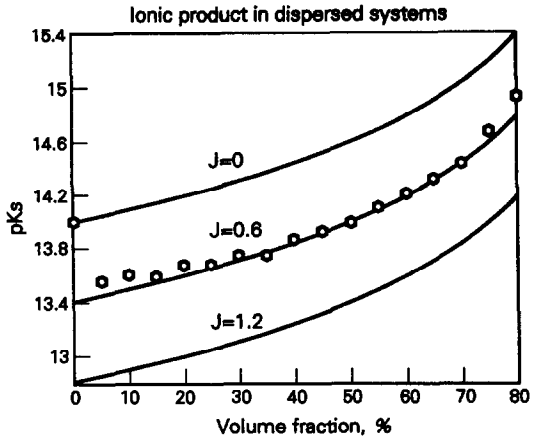

Fig. 3. Theoretical pK_s values of an organized medium plotted versus the organic volume fraction, ϕ, using equation (12) with the J values 0, 0.06 and 1.2. Open hexagons correspond to the experimental results of Ref. 15.

located in the aqueous phase with some ion-exchange with the interphase or with the micelle surface.[12–14] Hydroxide (OH^-) and hydronium (H_3O^+) ions are very hydrophilic ions and are mainly located in the aqueous phase.

Introducing $[H^+]_a$, the hydronium concentration in moles per litre of aqueous phase, and ϕ, the volume fraction of organic phase from which H^+ and OH^- ions are excluded, it is clear that the $[H^+]_a$ concentration in the aqueous phase is higher than the $[H^+]$ concentration in the total medium. The concentrations in aqueous phase (volume fraction $1-\phi$) and in the whole system are linked by:

$$[H^+]_a = [H^+]/(1-\phi) \qquad [8(a)]$$

The hydroxide ions are equally excluded out of the organic phase

$$[OH^-]_a = [OH^-]/(1-\phi) \qquad [8(b)]$$

The ionic product (autoprotolysis constant) of water in the ordered media [equation (3)] can be expressed by equations [8(a)] and [8(b)],

$$K_s = [H^+]_a[OH^-]_a(1-\phi)^2 \qquad (9)$$

The important question in ordered media studies with the pseudo-phase model is whether or not the aqueous phase of ordered systems behaves like water. The ionic product $[H^+][OH^-]$ corresponds to the autoprotolysis constant, $K_s a$, of water whose value is 10^{-14} mole^2/l.^{2} at 25°. If the aqueous phase of a given ordered system behaves like pure water, the ionic product $[H^+]_a[OH^-]_a$ should also be equal to 10^{-14}. To emphasize the acid–base behaviour of the aqueous phase of ordered media, we introduce a J value such that

$$[H^+]_a[OH^-]_a = 10^{-14+J} \qquad (10)$$

If $J = 0$, the aqueous phase behaves like water. If not, the aqueous phase cannot be regarded as pure water. Ion-exchange phenomena or electrical interactions with the organic interphase and/or modification of the aqueous phase by cosurfactant solubilization may act on the ion localization in the aqueous phase inducing non-zero J values.

The pK_s value is defined as

$$pK_s = -\log K_s \qquad (11)$$

with equations (9), (10) and (11), we form

$$pK_s = 14 - J - 2\log(1-\phi) \qquad (12)$$

Let us develop the example of a concentrated emulsion ($\phi = 0.8$) whose aqueous phase has a pure water behaviour ($J = 0$). The emulsion pK_s value is 15.4. It means that when 0.01 moles of acid is added to a litre of such an emulsion, the proton concentration is $[H^+] = 0.01M$, and the apparent hydroxide concentration is $[OH^-] = 10^{-13.4} = 3.8 \times 10^{-14}M$. However, the actual proton concentration in the aqueous phase is $[H^+]_a = [H^+]/(1-\phi) = 0.05M$ (pH = 1.3), that is five times more concentrated than in the whole emulsion. If this emulsion is a cosmetic product, such a high acidity of the water phase may have disastrous effects.

Figure 3 presents three theoretical curves obtained by using equation (12) with the three J values, 0, 0.6, 1.2. The points represent the pK_s data measured by Bahri and Letellier[15] in a microemulsion system of water–toluene–SDS–pentanol. For $\phi > 5\%$, our equation (12) seems to fit their experimental results with $J = 0.6$. It must be noted that the J value is not necessarily a constant for any composition of a given ordered system. In any system, a low ϕ value means a water-rich composition. The limit, $\phi = 0$, corresponds to water. Then, for any system

$$\lim_{\phi \to 0} J = 0. \qquad (13)$$

Micellar solutions

In all anionic, cationic and nonionic micellar solutions containing 1% w/w surfactant, the J values were nil. Given the high water content of such solutions (>99% v/v), the aqueous phase plays the predominant role as far as acid–base properties are concerned[16] (Table 2). However,

Table 2. Slope and intercept of the curves $E = f(\text{pH})$ for the reduction of Vitamin K3 in micellar media

Medium	Electrolyte	ϕ	Slope, mV/pH	Intercept mV at pH = 1	Correlation coefficient	J

*Extrapolated value. The bromide ions restricted the working potential range with the mercury electrode. Oxidation of mercury, enhanced by bromide ions, occurred at −0.1 V(SCE), that corresponded to a pH value of about 4 for the half-wave potential of Vitamin K3 reduction.
All pH values refer to the aqueous phase volume = $(1 - \phi) \times$ total volume.

the study of an oil-soluble electroactive compound (Vitamin K3) showed the importance of the micellar phase. The half-wave reduction potential of Vitamin K3 was linearly related to the aqueous pH with a slope of about 55 mV/pH (Table 2). The electrolyte, used to buffer the ionic strength, seems to have some influence. With sodium chloride, and titrating with sodium hydroxide and hydrochloric acid, as described in Experimental, the straight lines $E = f(\text{pH})$ were shifted toward less acidic values compared to the water line. For example, for a pH value of 1, the Vitamin K3 reduction occurred at a half-wave potential of 0.061 V(SCE) in a SDS 1% solution. The corresponding value in water was 0.086 V(SCE) (Table 2).

If the micelle binding constants of the oxidized and reduced forms of alizarin are different, a potential shift must be observed. This is the first explanation of the observed results. However, such a potential shift should not be dependent on the salt used to buffer the aqueous phase. Table 2 shows a 40-mV potential difference when sodium phosphate or sodium chloride were used in CTAB solutions.

Micellar ion exchange is the second parameter that can be responsible for potential shifts. The pH value at the probe location during the reduction step is called "local" pH. In the case of CTAB, the cationic surface of the micelles attracts some hydroxide ions inducing a "local" pH higher than the bulk pH. The opposite should be observed in the case of anionic SDS micelles. This is not the case. The ion-exchange process is more complex. Quina and Chaimovich[17] introduced an affinity constant $K_{x/y}$ to quantify the affinity of the ion x for the micelle surface when competing with the ion y. If $K_{x/y}$ is higher than 1, x ions have more affinity for the micelle surface than y ions. They determined $K_{H/Na}$ to be 0.8 for SDS micelles,[18] which means protons have less affinity for the SDS micelle surface than sodium ions, which can explain our results.

When a phosphate buffer was used (0.1M phosphoric acid) titrated with sodium hydroxide, the CTAB line shift disappeared, but the SDS line shift remained unchanged (Table 2). These observations are a further point showing the role of the ion-exchange process on the ionic micellar surface.[9,10,17,18] Phosphate ions had a high affinity for the cationic micelles. The CTAB micelle surface was buffered by the phosphate ions. These ions have no affinity for the

Table 3. Compositions, acid-base properties and slope of $E = f(\text{pH})$ for alizarin reduction in heptane-water emulsions

#	Composition: Heptane, % w/w	Water, % w/w	Surfactant, % w/w	ϕ	pK_a	J	Slope, mV/pH
1	49	50	SDS 1%	0.592	14.7	0.1	62.8

*Too low currents.
The confidence limits on the pK_aa and pK_a values were 0.1 unit. The accuracy on the slope determination was 3%.
All pH values are referred to the aqueous phase volume $(1 - \phi)$.

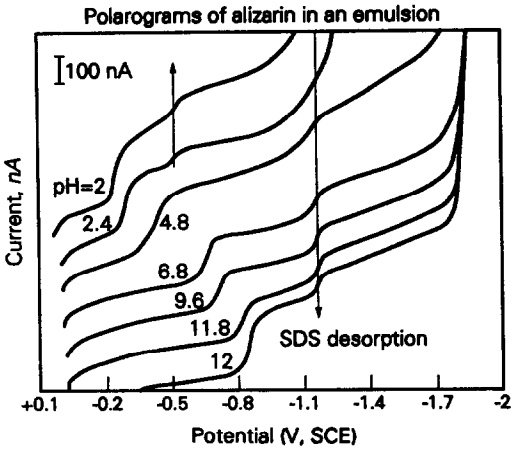

Fig. 4. D.c. polarograms of alizarin ($10^{-4}M$) in an emulsion of water (50% w/w), heptane (49% w/w) and SDS (1% w/w). The first arrow shows a wave appearing in acidic media at −0.53 V(SCE) due to a rearrangement of the SDS layer adsorbed on the mercury electrode. The second arrow shows a pseudowave [−1.2 V(SCE)] due to the desorption of SDS out of the mercury electrode (see text and Ref. 21). Mercury drop time: 1 sec. Potential scan rate 10 mV/sec.

anionic SDS micelles whose surface was not buffered. The ion-exchange process could not occur with nonionic Brij 35 micelles as observed on the data of Table 2 (no potential shift).

With the assumption that the reduction potential of Vitamin K3 was only dependent on the pH value, 0.061 V(SCE) corresponded to a pH of 1.45 in water (Table 2). In the 1% SDS solution, the "local" pH, at the Vitamin K3 location during the reduction step, seems to be 0.45 pH unit higher than the aqueous bulk pH. The 0.048 V(SCE) value in CTAB solution with sodium chloride at pH = 1, corresponded to a pH of 1.76 in water. In CTAB micelles, Vitamin K3 seems to be located in an environment with a "local" pH about 0.75 unit higher than the aqueous bulk pH.

Emulsions

Water–heptane emulsions were prepared with a homogenizer. SDS and CTAB could stabilize such emulsions for more than five hours. Water–heptane emulsions, prepared with the emulsifying agent Brij 35, were stable for only 30 min. Alizarin (Table 1) was more soluble in water–heptane emulsions than Vitamin K3, and gave reproducible results. Compositions and acid–base properties of the studied O/W emulsions are listed in Table 3.

Figure 4 shows a typical set of polarograms obtained in an emulsion with a 60% v/v organic phase content (emulsion # 1). The half-wave reduction potential was shifted toward more negative values as the pH increased from 2 to 12. The slopes of the curves $E_{1/2} = f(\text{pH})$ were not significantly different in water (Table 2) from those in emulsions (Table 3). Arrows on

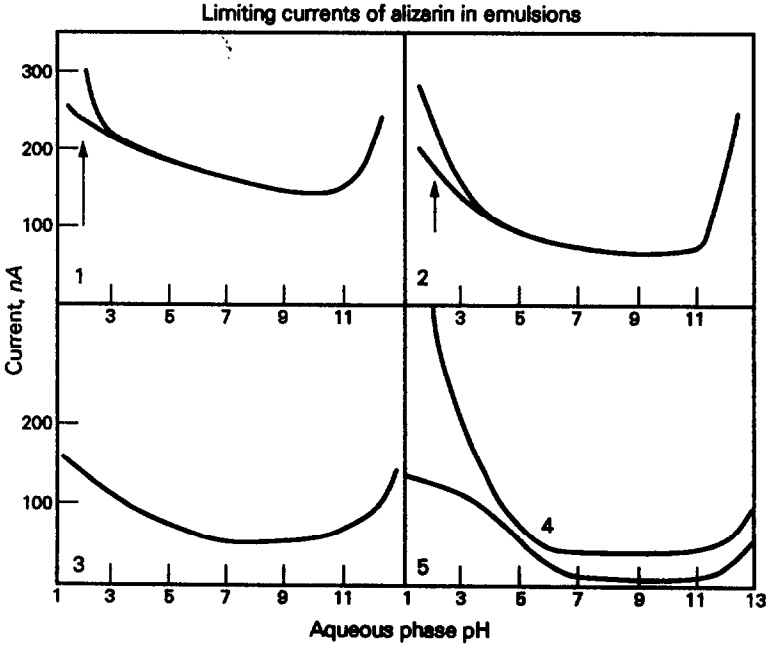

Fig. 5. Limiting currents of alizarin ($10^{-4}M$) reduction in emulsions. The figures correspond to the emulsion compositions given in Table 3. For emulsions # 1 and # 2, the arrow corresponds to the appearance of a rearrangement wave due to the electrode-adsorbed SDS layer (see Fig. 4 and Ref. 21).

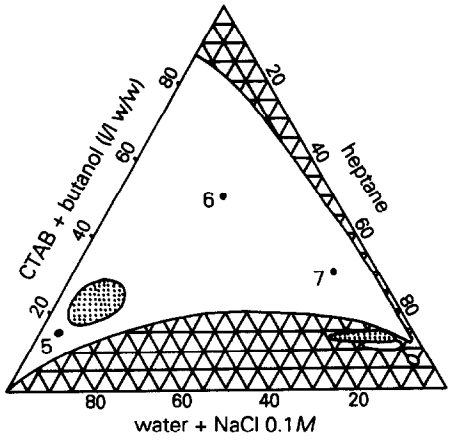

Fig. 6. Phase map of the cationic microemulsion system. Dotted areas correspond to liquid-crystal phases. ●: points studied in this work (see Table 4).

Fig. 4 point out two pseudo-waves due to SDS surfactant adsorbed onto the mercury electrode. At −0.53 V(SCE), a rearrangement of the adsorbed SDS layer induces a change in the alizarin limiting diffusion current. At −1.2 V(SCE), the mercury electrode becomes negative enough to repel adsorbed anionic SDS ions.[21] This produced the second non-pH-dependent wave shown in Fig. 4.

Figure 4 shows that, at constant alizarin concentration, the limiting diffusion current is pH-dependent. At −0.9 V(SCE), the reduction current was higher at pH 2.0 than at pH 7.0. This change was observed for all emulsions studied. Figure 5 presents the limiting diffusion current *vs.* pH for the five emulsions of Table 3. The higher the water content, the lower the reduction current. The reduction current of alizarin ($10^{-4}M$), in the water-rich CTAB emulsion # 6, was so low that it was not possible to obtain reproducible results.

The release of the oil-soluble alizarin was linked to the oil-phase volume as studied by Georges and co-workers.[13,19] The limiting current was dependent on the ionic state of alizarin. At high pH values (>11.5), the two phenol groups of alizarin were ionized and the dianion gave high reduction current due to a high diffusion coefficient. At intermediate pH values, the monoanion existed and seems to have a lower diffusion coefficient than the dianion. The alizarin molecule, existing at low pH values (<6), gave high reduction currents in both studied emulsion systems.

The J values, in SDS and CTAB emulsions, were very low, which means the acid–base properties of such emulsions are mainly those of the aqueous phase. The heptane phase excludes the hydroxide and hydronium ions in the aqueous phase. To be reduced at the mercury electrode surface, alizarin must leave the oil phase (heptane droplets) and the reduction process must take place in the water phase, or in a water-rich surfactant layer adsorbed on the electrode, according to a chemical–electrochemical (CE) process as already described.[13,19] Given the straight lines $E = f(\text{pH})$ (Table 3), during the reduction process, the pH environment of alizarin was proportional or equal to the aqueous phase pH over the whole pH range studied (from pH 1 to pH 13) with both an anionic and cationic surfactant.

Microemulsions

In micellar solutions and emulsions, the classical glass electrode gave correct, stable and reproducible responses. That was not the case in microemulsions: the signals produced by the glass electrode were very unstable and non-reproducible. Furthermore, the glass-electrode response was strongly dependent on the stirring of the microemulsion. The use of the hydrogen electrode was necessary.[20] Two microemulsion systems were investigated. The phase map of the system water–dodecane–SDS–pentanol can be found in the literature.[20,22] The phase map of the system water–heptane–CTAB–butanol was established for this study and is presented in Fig. 6. Seven compositions in both microemulsion systems were studied (Table 4).

The results obtained in the microemulsion were very different from those obtained in micellar solutions and emulsions. Table 4 shows that the J values differ significantly from zero. The lower the water content, the higher the J value. The aqueous phases of microemulsion systems do not behave as pure water. Previous studies[4,5] have shown that, in microemulsion systems, a considerable fraction of the water is bound water, especially in low water content microemulsions. Also, a significant amount of cosurfactant (pentanol and butanol in SDS and CTAB systems, respectively) can be dissolved in the aqueous phase. However, given the proportionality of the hydrogen electrode response to the proton concentration in the aqueous phase (slope between 57.1 and 58.3 mV/pH for the H_2 potential E *vs.* pH[20]), the aqueous phase still played the most important role in acid–base properties.

A typical set of polarograms in a microemulsion (# 3) is shown in Fig. 7. Figure 8 shows the limiting current of alizarin plotted *vs.* pH for the four anionic microemulsions studied. There was only one polarographic wave in microemulsion compositions # 1, # 5 and # 6, over the pH range 1–13. In microemulsion

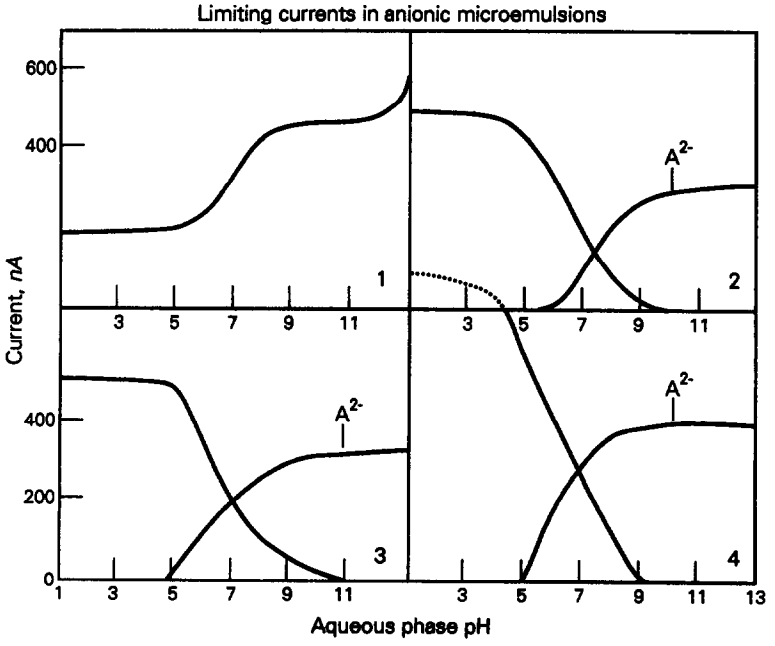

Fig. 8. Limiting currents of alizarin ($5 \times 10^{-4}M$) reduction in microemulsions. The figures correspond to microemulsion composition given in Table 4.

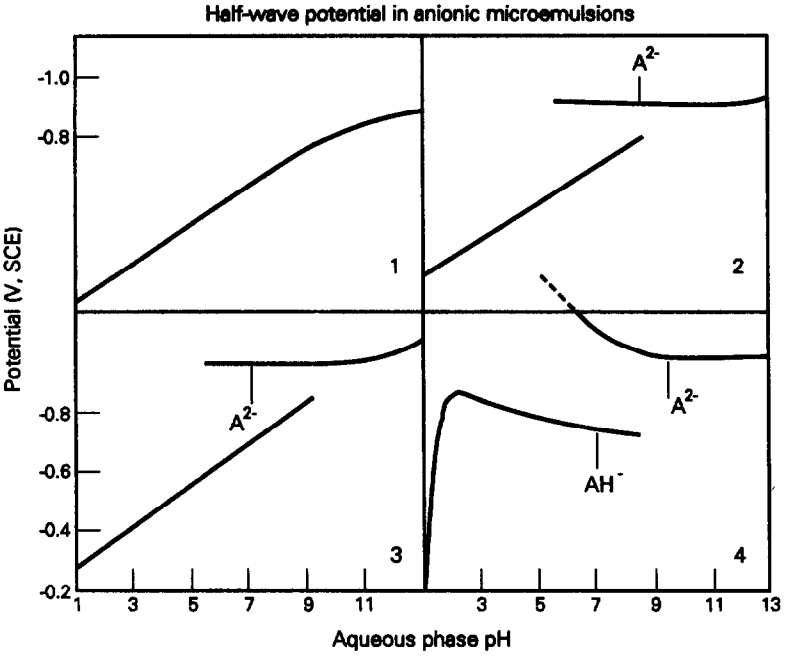

Fig. 9. Half-wave potential of alizarin reduction in anionic microemulsions. Compositions 1–4 given in Table 4.

compositions # 2, # 3, # 4 and # 7, at intermediate pH values, the reduction of alizarin occurred with two polarographic waves. Only the first wave was pH dependent. The second wave appeared at pH values higher than 5 (Fig. 7). Between pH 5 and 9, the two waves were present. Above pH 9, only the second wave remains.

It is interesting to note that the alizarin reduction occurred following a similar pattern in both cationic and anionic microemulsions of similar physico-chemical structure. In water-rich microemulsions (compositions # 1 and # 5, Table 4), the reduction process occurred in one step whatever the aqueous pH. This reduction pattern was similar to the one observed

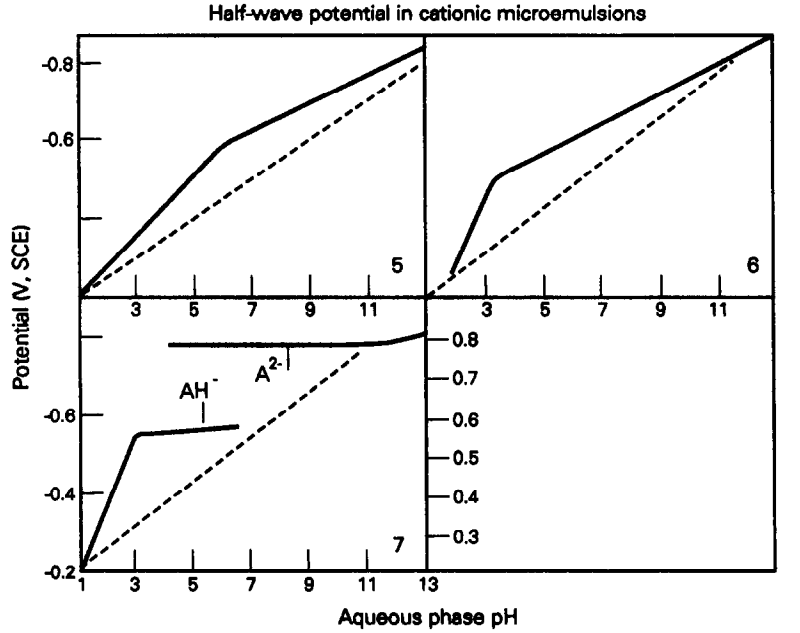

Fig. 10. Half-wave potential of alizarin reduction in cationic microemulsion. Compositions 5–7 given in Table 4. The dotted lines indicate a theoretical slope of 59 mV/pH.

in classical O/W emulsions (Fig. 4). The L1 structure of microemulsion # 1 and # 5 was the closest to the O/W emulsion structure (Fig. 1). However, the dynamic nature of the microemulsion droplets (lifetime in the microsecond range) with continuous destruction–creation, differs fundamentally from the static nature of emulsion droplets. The two L2 structure microemulsions (compositions # 4 and # 7, Table 4) gave a similar reduction pattern. Such similarities between very differing microemulsion systems allow the rejection of surfactant adsorption as a possible explanation for the two waves observed. It seems that the solute is responsible for the two waves. Alizarin has pH-dependent forms: AH_2 at low pH values, AH^- at intermediate pHs, and A^{2-} at elevated pH values (Table 1). Figures 9 and 10 show the half-wave potential of the polarograhic waves plotted *vs.* the aqueous phase pH for the SDS and CTAB microemulsion systems, respectively.

Water-rich microemulsions # 1 and # 5. In these L1 systems, the alizarin reduction occurred in one step. The limiting diffusion current was constant at low pH values, and increased from pH 6 to 9 (Fig. 8). A pH of 5 corresponds to the first ionization ($pK_{a1} = 6$) of alizarin. Above pH 10, the limiting current did not increase anymore. The J values were low, 0.6 and 0.3 in SDS and CTAB L1 systems, respectively. The aqueous phase of L1 systems has acid–base properties similar to those of water.

Oil-rich microemulsions # 4 and # 7. In these L2 oil-rich microemulsions, the alizarin reduction occurred following different routes: at high pH values (pH > 9) there was only one non pH-dependent step that seems to correspond to the dianion reduction (labelled A^{2-}, Figs 9 and 10). At intermediate pH values (4 < pH < 9), the alizarin reduction occurred in two non pH-dependent steps that may correspond to the dianion and monoanion reduction. The dianion was reduced at a constant potential [−0.98 V(SCE) and −0.78 V(SCE) for SDS # 4 and CTAB # 7, respectively] between pH 5 and 13. The monoanion, AH^-, was reduced at a constant potential [0.75 V(SCE) and 0.56 V(SCE) for SDS # 4 and CTAB # 7 systems, respectively].

We note that a pH increase induced an increase in the second wave and a simultaneous decrease of the first wave (Figs 8, 9 and 10). If the attribution of the first and second non-pH-depending waves to AH^- and A^{2-}, respectively, is correct, is seems logical to think that a pH increase depletes the AH^- form to convert it to A^{2-}. The polarity change is likely to induce a change in the probe location. The polar A^{2-} form of alizarin was certainly not located in the oil phase.

Assuming the alizarin reduction potential can be linked to a pH value, the constant potential −0.98 and −0.75 V(SCE) for A^{2-} and AH^-, respectively, in the SDS microemulsion # 4, corresponded to pH 13 and pH 7, respectively. In the CTAB microemulsion # 7, −0.78 and −0.56 V(SCE) corresponded to pH 12 and pH 7, respectively. It seems that the "local pH" at the A^{2-} dianion location was around 12 and the "local pH" at the AH^- monoanion location was around 7 even if the aqueous phase pHs of both systems were as low as 3.

Intermediate microemulsion compositions # 2, # 3 and # 6. These compositions contain a large amount of active blend surfactant–alcohol. They probably have the bicontinuous structure (Fig. 1). In anionic systems # 2 and # 3, two waves were observed, a pH-dependent and a non pH-dependent wave (Fig. 7). Since the non pH-dependent wave occurred at elevated pH values, it was attributed to the A^{2-} alizarin form reduction. The potentials of the non-pH-dependent waves were −0.85 and −0.95 V(SCE) in microemulsion # 2 and # 3, respectively. These potentials corresponded to pH values around 11. In the cationic system # 6, only one pH depending wave was observed (Fig. 10). Although the physicochemical structure of microemulsions # 2 and # 6 were similar, the acid–base properties were different. The pentanol–SDS active blend may act differently from the butanol–CTAB active blend as far as acid–base properties are concerned.

For cationic microemulsions, # 5, # 6, and # 7, the dotted lines in Fig. 10 represent the theoretical reduction potential proportional to the aqueous phase pH (59 mV/pH unit). The actual reduction potential was higher than this theoretical potential. This can be explained if the "local" pH, at the alizarin reduction location on the mercury electrode, was higher than the aqueous phase pH. It seems that the positively charged interphase was richer in anionic hydroxide ions than the aqueous phase. Electrostatic interactions and ion-exchange with bromide ions may explain this hydroxide ion enrichment.

CONCLUSION

The aqueous phase plays the most important role in acid–base properties of micellar solutions and O/W emulsions. The J value is an empirical parameter introduced to compare the acid–base properties of the aqueous phase of an ordered medium with water. If $J = 0$, the aqueous phase behaves as pure water. If J is different from zero, aqueous phase cannot be assimilated to water.

From an analytical point of view, it must be pointed out that the glass electrode can be used in ordered liquid systems. However the pH value obtained corresponds to the aqueous phase pH. The classic indicator dyes or coloured papers, used for pH determinations, must not be used in ordered media: most often a micellar effect shifts the pKa values of the dyes. Surfactants can also induce spectral changes. That is why the use of a pH indicator paper can lead to errors as high as 3 pH units when plunged into an ordered media.[16,20] Before using a glass electrode in a microemulsion system, its response must be checked (stability and reproducibility).

Summary—A hydride generation atomic-absorption spectrometric (AAS) method with flow-injection (FI), aimed at developing a practical routine assay for the determination of tin in food digests, is described. In order to modify the sample matrix and to achieve optimized and reproducible conditions for the hydride generation reaction, the analyte is initially converted into its chlorostannate-complex thereby allowing it to be separated and preconcentrated on-line on an incorporated micro-column packed with a strongly basic anion exchanger and subsequently to be eluted by diluted nitric acid under strictly controlled conditions. Optimum acidic conditions for the FI hydride generation AAS system was found to be 0.01–0.05*M* nitric acid. At a consumption of 2.7-ml sample volume, aspirated by time-based injection, the procedure resulted in an enrichment factor of 3.5 and yielded a detection limit of 0.08 μg/l. (3σ) at a sampling frequency of 72/hr. The precision was 2.5% rsd at the 10 μg/l. level. Potential interferents, such as Ni(II), Co(II), Zn(II) and Fe(III) could, at a Sn level of 10 μg/l., be tolerated at an excess of 1000 times without impairing the assay, while a 100–1000-fold excess of Cu(II) decreased the signal by 10–15%. Recoveries in the range 94–102% were obtained for canned food sample digests spiked with 10 μg/l. Sn.

Recently, the performance of hydride generation atomic-absorption spectrometric (HGAAS) methods has been enhanced significantly through the application of flow-injection (FI) techniques. Sample and reagent consumption are decreased substantially, while the absolute sensitivities are increased. Because of the inherent precise and reproducible timing of flow-injection systems, FI-HGAAS methods are generally also much more tolerant to interferents compared to batch HGAAS procedures.[1] The application of the technique has been quite successful for the assay of a number of hydride forming elements including selenium, arsenic, bismuth, and antimony in waters, environmental and metal samples.[1] However, to the authors best knowledge, so far no application of the technique for the determination of tin has been reported. Difficulties in the HGAAS determination of tin in the batch mode, owing to the strong influence of acidity on the sensitivity, have been described by several groups.[2–4] Thus, in contrast to most of the other hydride forming elements where a fairly wide range of acidity can be tolerated without impairing the hydride generation process, formation of stannane requires rigorously controlled conditions. In fact, preliminary experiments in the present study revealed that the effects of the acidity were even more crucial in the FI mode; this obviously being the reason for the lack of successful reports on the determination of tin by FI–HGAAS.

In this investigation an attempt was made to optimize the acidity conditions for the determination of tin [*i.e.*, Sn(II) and Sn(IV)] by FI–HGAAS. On-line ion-exchange separation was used to modify the acid matrix of the sample in order to obtain optimal acidity conditions for the ensuing hydride generation procedure and, as an added benefit, to allow sample preconcentration. Thus, tin was collected in the form of anionic chlorostannate-complexes in 2*M* hydrochloric acid medium on a strongly basic anion exchanger and subsequently eluted by diluted nitric acid before being mixed with

the borohydride reductant. In this manner, the acidity level of the hydride generation procedure could reproducibly and repeatedly be maintained. Sources of potential interference are discussed and quantified, and the practical applicability of the method is demonstrated by the assay of tin in canned food digests.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Model 2100 atomic-absorption spectrometer was used with the Model FIAS-200 flow-injection system and hydride generation accessories. A tin hollow cathode lamp was used at a wavelength of 286.3 nm and operated at 30 mA. The temperature of the quartz atomizer cell was set to 900°, and the argon carrier flow was fixed at 90 ml/min as recommended by the instrument manufacturer. The injection valve of the instrument was modified by drilling an extra channel on the rotor so that four channels remained open at both loading and injection positions (cf. Fig. 2). The signals were processed with a time constant of 0.5 sec in the peak height mode, and recordings from the graphic screen were printed out by a Model FX-850 printer.

The ion-exchange column used for preconcentration was made by packing 90 mg of 80–100 mesh Dowex 1-X8 strongly basic anion exchange resin into a conical plastic Eppendorf pipette tip. The construction of the conical column was as described previously.[5] According to the manufacturer, the exchange capacity of the ion-exchanger (Cl-form, wet) is 1.33 meq/ml or 1.9 meq/g. In a later stage in this study, a larger column reactor (3 mm i.d. and 45 mm long[6]), was also used to obtain better recoveries for some samples. The latter column accommodated about 140 mg of resin.

All reaction coils and connections were made with 0.7 mm i.d. PTFE tubing.

Reagents

All reagents were of analytical grade and demineralized water was used throughout. Sodium borohydride solutions [0.2% (w/v)] were freshly prepared twice every day. The appropriate volume of 2.0*M* sodium hydroxide, made by diluting Titrisol standards (Merck, Darmstadt), was added to the borohydride solution to create the necessary base concentrations for maintaining optimum acidity in the final reaction mixture (for details see Results and Discussion). Hydrochloric, nitric and sulphuric acid eluents and carrier solutions were made by dilutions of 2*M* Titrisol acid standards (Merck, Darmstadt).

Standard series solutions for tin used in the preconcentrations were prepared by two-stage dilutions of a 10 mg/l. stock solution of Sn(II) (made from $SnCl_2$ $2H_2O$) in 2*M* hydrochloric acid (diluent) [the signal outputs for Sn(II) and Sn(IV) are identical; hence, the use of the Sn(II) salt for preparing the standards was merely dictated by convenience]. Tin solutions (10 μg/l.) used to study the effects of acidity for various acids were made in acid solutions with concentrations identical to those in the carrier solution. When solutions of low acidity, that is, of below 0.1*M*, were studied, dilutions were made shortly before the experiments to avoid loss of tin through hydrolysis.

Operational procedures

Studies on the effects of acidity. The FI manifold shown in Fig. 1 was used for the study of

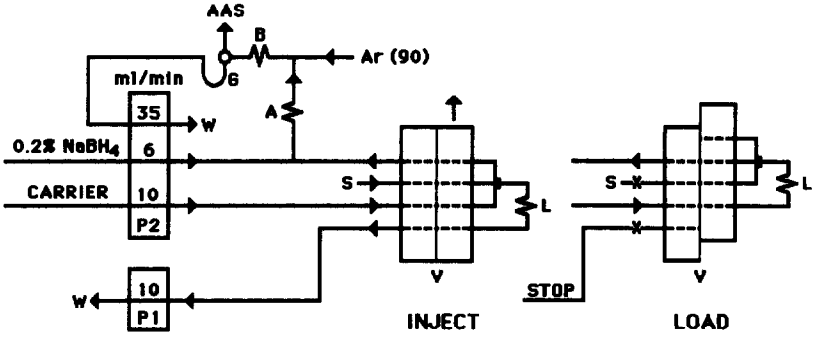

Fig. 1. FI manifold for the study of acid conditions in hydride generation AAS. L, sample loop; V, injection valve; P1, P2, peristaltic pumps; W, waste; G, gas-liquid separator; Ar, argon gas flow 90 ml/min; S, sample; A, B, 0.7 m i.d. 30 cm PTFE coils; AAS, atomizer cell, heated to 900°. Sample solution was aspirated for 10 sec corresponding to a total sample volume of 1.67 ml.

effects of the acid concentration in the carrier stream and sample solutions. The sample loading time and injection times were 10 and 15 sec respectively. The sodium hydroxide concentration in the borohydride solution during this study was maintained at 0.01*M* in all cases. The neutralization effect of this solution was taken into account when computing the acid concentration in the final reaction mixture.

On-line ion-exchange preconcentration. The FI on-line ion-exchange preconcentration manifold is shown in Fig. 2. In the loading sequence, the sample in 2*M* hydrochloric acid was propelled by pump 1 through the column at 8 ml/min, entering the column at the narrow end, and delivered to waste. Simultaneously the acid eluent was pumped through the by-pass on the rotor into the hydride generation system. In this stage the baseline for the final readout was established. At the end of the loading period, normally 20 sec, the valve was actuated automatically, directing the eluent flow to the column and entering from the wider end. The absorbed chlorostannate-complex was eluted into the hydride generation manifold and merged with the borohydride reductant solution, both eluent and reagent being propelled at 11 ml/min by pump 2. After passing through a 30 cm length of reaction coil (A), the stannane formed was stripped from the solution by a steady argon carrier flow of 90 ml/min. The gas-liquid mixture was guided into the gas-liquid separator where the waste was pumped out at a flow-rate of 35 ml/min. The separated hydride was transported by the carrier gas together with the evolved hydrogen into the atomizer cell and the absorption signal recorded. The elution sequence was 30 sec. During this stage the sample line operated by pump 1 was programmed to pump at a reduced rotation speed (30 rpm) to expel the previous sample in the pump tube to waste and to introduce the next sample.

Sample pretreatment. The canned food samples were treated by a nitric–hydrochloric acid digestion procedure according to details described previously.[7] Homogenized sample (5 g) was dried in an oven at 120° in a 250-ml flask. Concentrated nitric acid (30 ml) was added, the mixture was gently heated on a hot-plate to initiate digestion, and then boiled down to about 5 ml. Hydrochloric acid (25 ml) was added, and gently boiled down to 10–15 ml. The digest was cooled, transferred into a 100-ml standard flask and diluted to volume with water. In order to satisfy the analytical range of the hydride generation determination and conditions for the ion exchange, 10 ml of digest was taken and diluted further to 100 ml with 2*M* hydrochloric acid. In the spiking experiments, aliquots of tin-standards were added to the food samples prior to initiating the wet digestion procedure.

RESULTS AND DISCUSSION

Effects of types of acid species, and their concentration, on the HGAAS signal response for tin

At a preliminary stage in this work an attempt was made to find the acid matrix conditions which could ensure sensitive and reproducible determination of tin directly in the sample solution. Such conditions have been approached to a reasonable extent in batch methods. In one case, this involved almost complete removal of acid in a food digest, except for a very small amount of residual sulphuric acid, and then making up the solution in 0.12*M* hydrochloric acid, which gave optimum sensitivity for the subsequent HGAAS determination of tin.[3] In another application of the batch HGAAS method by Legret and Divet for the determination of tin in sediments, it was found that in

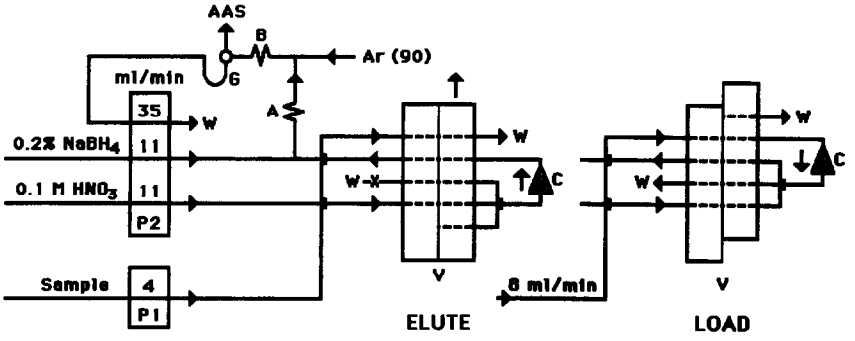

Fig. 2. FI manifold for on-line ion-exchange separation hydride generation AAS. Symbols are the same as for Fig. 1. C, conical column. Aspirated sample volume 2.67 ml. For details, see text.

nitric acid medium the signal output varied merely 10% within a wide range of acid concentrations extending from 0.05—0.6*M*, whereas variations of 50% or more were observed for hydrochloric and sulphuric acids of similar strengths.[2] Thus, using a 0.4*M* nitric acid medium it was feasible for these authors to determine tin reproducibly.

When the effects of various concentrations of hydrochloric, nitric, and sulphuric acids were studied with the FI manifold in Fig. 1, more pronounced influences from the acids were observed. The results are shown in Fig. 3, and are compared to results obtained in the batch mode for hydrochloric and nitric acids in a boric acid medium.[4] Since a reliable method would necessitate that a region of stable and reproducible signals could be established, these results appear to constitute a major disadvantage of the FI approach, because an absolutely precise control of the final acidity would be very difficult to achieve. The situation seemed to be especially unfortunate for the hydrochloric and sulphuric acids where virtually no stable region of influence on sensitivity could be found. Although control of nitric acid in the 0.01*M* range in the final reaction mixture may be feasible, with careful balancing of the flow-rates and of the acid/base concentrations in the carrier, sample and reagent solutions, the procedure would obviously lack the robustness of a good routine analytical method.

An attempt was therefore made to use buffering systems to control the pH of the reaction mixture in the 1.5–2.5 pH range. However, when oxalic acid and malonic acid buffer systems were used instead of the strong acids, the signals for tin decreased drastically, that is, to 10–20% of those obtained with the strong acids at identical molar concentrations. The use of boric acid together with the strong acids, recommended in the batch mode,[4] was also tested in the FI system, but produced no improvements in the performance. Nitric acid medium within the 0.01–0.05*M* range therefore appeared to be the best condition achieved in this study. However, hydrolysis of tin(IV) is reported to be rapid in solutions with less than 0.7*M* hydrochloric acid or 0.1*M* sodium hydroxide, producing insoluble hydrolysis products which polymerize and are difficult to redissolve.[8] For this reason, samples should not be expected to be stored in acid concentrations lower than 0.7*M* for extended periods, which is obviously in contradiction with the requirements of the FI hydride generation procedure.

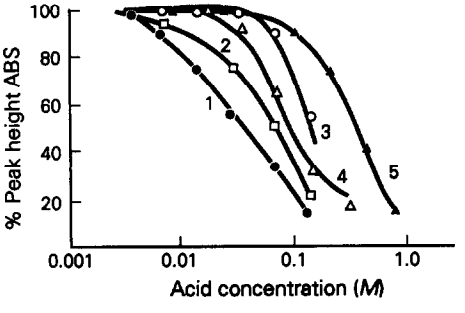

Fig. 3. Effect of acid concentrations on the Sn-signal expressed in % peak heights with peak absorbance at 0.003*M* acid concentration taken as 100% for all the acids studied, using the FI-HGAAS system in Fig. 1. 1, HCl; 2, H_2SO_4; and 3, HNO_3. Curves 4 and 5 are for HCl and HNO_3 respectively, obtained by batch procedures in boric acid medium [reconstructed from relative sensitivity (%) data in ref. 5].

Therefore a method was sought in this work for on-line modifying of the acid matrix of the sample solutions by using an incorporated ion-exchange column which, in addition to preconditioning the samples for the hydride generation process, potentially would also provide the extra advantage of removing interferences as well as effecting an enhancement in sensitivity through preconcentration.

The optimization of experimental parameters for on-line ion-exchange preconcentration HGAAS determination of tin

Ion-exchange separation and preconcentration of tin has been used successfully in combination with flame AAS in the determination of tin in copper.[9] The operation was performed off-line in the batch mode with a column packed with a Dowex 1-X8 strongly basic anion exchanger. The sample was prepared in 2*M* hydrochloric acid before being passed through the column. The tin retained as the chlorostannate-complex-anion was later eluted with 1*M* nitric acid and determined by flame-AAS. In the present work the anion-exchange preconcentration system was adapted for on-line use in a FI system, using the same ion-exchange material, resulting in the FI manifold shown in Fig. 2.

According to experiences gained in using similar anion-exchange columns for the on-line preconcentration of selenium,[10,11] a sample loading rate of 8 ml/min seemed to be a good compromise between concentration efficiency (preconcentration factor achieved in unit time) and retention efficiency (percentage of analyte collected on the column).[6] This was therefore

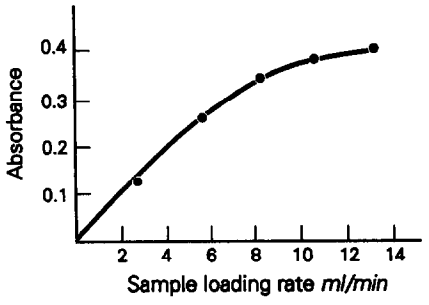

Fig. 4. Effect of sample loading flow-rate on peak absorbance. FI–HGAAS system in Fig. 2. 10 μg/l Sn; 0.1*M* HNO_3 eluent; loading period 20 sec.

used as a starting point for the optimization of other parameters. The preliminary choice was later confirmed using the optimized conditions as shown in Fig. 4. With a 20-sec loading period, the 8 ml/min loading rate appeared to be the upper limit for maintaining a close to linear relationship between loading time and signal. The lowering of the slope of the curve beyond this point implies a substantial increase of break-through due to insufficient time for arriving at ion-exchange equilibrium. Although better enrichment factors could definitely be achieved with loading rates higher than 8 ml/min, the tolerance to interferences may be considerably weaker, and is therefore not recommended.

Intuitively it might be expected that the chlorostannate-complex of Sn(IV) would be differently withheld on, and eluted from, the column as compared to that of Sn(II). However, this was found not to be the case, as verified by injecting standards of the two species. Entirely identical results were obtained, which validates the preparation of standards from Sn(II) salts.

The elution flow-rate was considered to be the most important experimental parameter in the preconcentration system because it not only influenced the rate of release of the analyte, and hence the peak width and height of the elution peak, but also the hydride generation reaction itself. The feasibility and necessary compromise in combining the on-line preconcentration with the hydride generation system have been discussed previously.[10,11] As 1*M* nitric acid was used successfully in the batch mode as an eluent,[9] this was used as a starting concentration for optimization of eluent flow-rate. The borohydride reductant flow was always made identical to that of the eluent flow-rate. This was found to be convenient in controlling the final acidity of the reaction mixture which was maintained as close as possible within 0.025–0.05*M* nitric acid (*cf.* Fig. 3), through adjustments of the sodium hydroxide concentration in the borohydride solution. While lower reductant flow-rates with higher borohydride and acid concentrations were feasible, the sensitivity was not improved although the sample was less diluted, becuase in the hydride generation system the total mass of hydride produced rather than the analyte concentration determines the magnitude of the absorption signal.[1,12] Furthermore, adjustments of acidity, using higher base concentration with lower flow-rates would become more critical and difficult to control.

As seen in Fig. 5, the recorded peak signal became increasingly higher with increase in eluent flow-rate up to a flow-rate of 11 ml/min (Fig. 5), after which a gradual drop in signal was observed. The 11 ml/min was therefore taken as the optimum eluent flow rate.

Subsequently, the effect of the acid concentration in the eluent was investigated. In these experiments the concentration of sodium hydroxide in the borohydride solution was adjusted to maintain an acid concentration of 0.05*M* in the reaction mixture, while the concentration of nitric acid in the eluent stream was gradually decreased from 1.0*M*. Surprisingly, it was found that the peak height increased and the peak width decreased with a decrease in acid concentration. This tendency continued when using demineralized water or dilute alkaline solutions as eluent (Fig. 6). This phenomenon implies that the release of the chloro-complex might be effected through mechanisms other than ion-exchange. Presumably, uncharged hydrolysis products might be formed with the decrease in acidity, giving rise to the formation

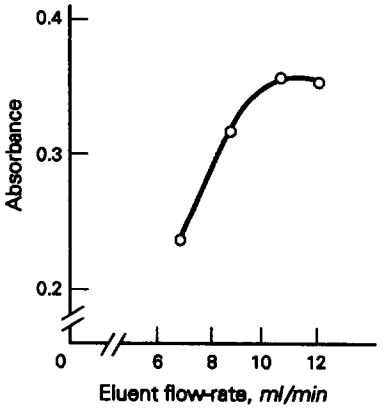

Fig. 5. Effect of 0.2*M* HNO_3 elution flow-rate on peak absorbance. FI-HGAAS system in Fig 2. 10 μg/l. Sn; loading period 20 sec.

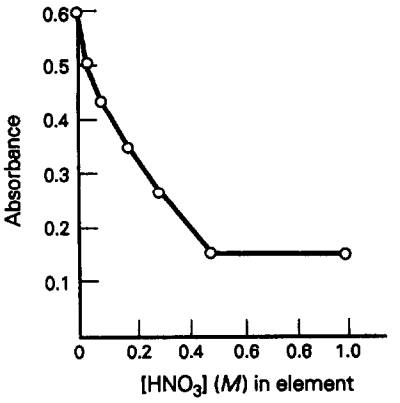

Fig. 6. Effect of nitric acid concentration on peak absorbance. FI–HGASS system in Fig 2. 10 μg/l. Sn; 20 sec loading.

of a colloidal solution which could be readily eluted. An explanation for the response under alkaline eluent conditions is that the acid conditions for the hydride generation reaction may be provided by the residual acidified sample solution remaining in the column following sample loading.

The low acidity of the eluent created, in fact, an extremely beneficial condition for optimizing the acid concentration of the hydride generation reaction. Thus the control of acid concentration within 0.025–0.05*M* proved to be quite simple by using a 0.1*M* nitric acid eluent and merging with a reductant containing 0.05*M* sodium hydroxide. Eluents with lower acid concentrations, although producing higher sensitivities, are generally not recommended since alkaline concentrations in the borohydride would also have to be decreased to maintain the acid conditions for reduction.

An alkaline concentration which is too low would affect the stability of the reductant. In fact, with a sodium hydroxide concentration of 0.05*M* in the borohydride reagent, it is strongly recommended to make this solution freshly every day and to protect it from the ambient air by means of a carbon dioxide trap. Furthermore, with eluents of lower acidity the acid conditions for reduction would be predominated by the acid in the above mentioned residual sample in the column following sample loading. This residual sample bolus forms an acid concentration gradient which presumably overlaps eluted analyte. Under hydride generation conditions, where gases are produced in this overlapping gradient of acid, hydride generation will not be very reproducible. This may explain the increase of noise in the baseline signal at lower acid concentrations for the eluent (particularly below 0.01*M*).

The effect of increasing the sample loading time was investigated with the optimized conditions, that is 0.1*M* nitric acid as eluent and 0.05*M* sodium hydroxide in the borohydride solution. The relationship between time and absorbance was not linear above a loading period of 20 sec. Although higher enrichment factors may be achieved by increasing the loading time, one has to be careful of enhanced interference effects when working with real sample solutions. The increase in loading time naturally also would imply a decrease in the sampling frequency. A relatively short loading period of 20 sec is therefore recommended.

Characteristic data for the performance of the ultimately adopted on-line preconcentration HGAAS system (*cf.* Fig. 1) are reproduced in Table 1, with a 20-sec loading period and using the optimized reagent concentrations. The good reproducibility shows an effective control over the acid conditions through the ion-exchange matrix modification.

In on-line ion-exchange procedures, the column design and capacities both strongly influence the performance of the methods.[6] The conical column used in this study appears to provide a reasonable compromise between sensitivity, sampling frequency, and tolerance of interferences. However, the anion exchanger exhibited non-ideal kinetic properties in the release of the adsorbed complex, producing elution curves with relatively long tailing (the time to reach peak maximum was *ca.* 6 sec while total elution required an additional *ca.* 20–25 sec). This tailing phenomenon was further enhanced when larger column capacities, such as the 3 × 45 mm columns, were used for separation, although that slightly better recoveries could be achieved (*cf.* analysis of practical samples where spiking experiments with the smaller columns generally yielded slightly less than 100% recovery). Within the concentration range of standards used (0–15 μg/l.), both column sizes yielded strictly linear calibration

Table 1. Characteristic data of the on-line preconcentration FI–HGAAS system

Enrichment factor	3.5
Analysis cycle (sec)	50
Sampling frequency (samples/hr)	72
% r.s.d. ($n = 10$) (10 μg/l.)	2.5
L.o.d. (μg/l.) (3σ)	0.08
Calibration curve (0–15 μg/l.): $A = 0.030 + 0.032\,C$ ($r = 0.997$)	

curves. The sensitivity of the larger column was *ca.* 20% lower than that of the short one, whereas the tolerance to interferences was better, but the back pressure was somewhat increased. However, an elution period of more than 1 min was necessary for complete elution of the analyte using the larger column, which lowered the sampling frequency, compared to that of the smaller conical column. If indeed the recovery is solely to be ascribed to the incorporated column, an alternative approach for improving recoveries would be by decreasing the sample load by diluting the sample digest or shortening the loading period, with some sacrifice in sensitivity.

Evaluation of potential interferences

In the proposed procedure there are potentially three types of interferences which should be considered, that is, (1) chlorocomplexes of other metal ions (and possibly also the presence of certain anions) which might compete with the stannate-complex ions for the sites on the ion-exchanger; (2) chlorocomplexes of metal ions which are retained on the column and which, when eluted along with the stannate ions, might interfere in the hydride generation process itself; and (3) chlorocomplexes of metal ions which are so tightly bound to the active sites of the ion-exchanger that they prevent the regeneration of the column from cycle to cycle.

It is well known that Cu(II) and Ni(II) are potential interferents for hydrides, particularly in batch procedures, because, being reduced to oxidation state zero by the borohydride, they act effectively as catalyst for the degradation of the hydrides formed so that these are at risk of being decomposed before they reach the measuring cell. It is precisely in order to eliminate, or at least to suppress, this type of side reaction that FI with its inherent accurate timing has proven itself such an ideal vehicle for hydride generating procedures. Considering the stability constant of the chlorocomplexes of these two species and the acidity/chloride concentration prevailing in the 2*M* hydrochloric acid matrix used, it should not be anticipated that they would consititute any serious problems. Indeed it was verified experimentally, that up to 1000 times excess of Ni(II) and 100 times of Cu(II) could be tolerated without any significant adverse effect on the readout (*cf.* Table 2). Thus, these two constituents do not appear to have a negative influence on either the ion-exchange process or on the hydride generation itself.

Table 2. Effect of various potentially interfering species on the recovery of Sn. All samples contained 10 μg/l. Sn and were measured with interferents added at 1, 5 and 10 mg/l. levels. If results for the two first levels are not reported, it signifies that the recovery was 100 ± 2%. All measurements are an average for $n = 5$

Ionic interferent added	Concentration, *mg/l.*	Recovery, %
Cu^{2+}	1	91
	5	85
	10	84
Ni^{2+}	1	95
	5	96
	10	97
Co^{2+}	10	101
Zn^{2+}	10	98
Fe^{3+}	10	102
MoO_4^{2-}	10	96
PO_4^{3-}	10	104

Furthermore, the levels of tolerance should amply suffice for the intended use of the analytical procedure, that is, for the determination of tin in food digests. Iron(III), which is ubiquitously expected in canned foods, forms stronger chlorocomplexes than Cu and Ni, but is not known to interfere seriously in the hydride generation process as such. When tested experimentally, it was indeed verified that this species readily could be tolerated at a 1000 times excess. The same was true for Zn(II) at the same concentration level, although with chloride it forms highly stable complexes and therefore could be expected to create difficulties particularly in regeneration of the column. However, the diluted nitric acid eluent appears to very effectively reconstitute the column so that no additional wash cycle is needed, which from a practical viewpoint is very convenient. The possible interference of two species of anions, that is, molybdate and phosphate were also tested, and neither of these gave, at the 1000 excess level tested, rise to any adverse effect.

Practical performance of the optimized on-line preconcentration HGAAS system

The practical feasability of the proposed system was tested on three canned food digests. Since standard reference biological materials with certified tin values were not available, the specificity and accuracy of the method was tested by spiking the sample digests. As shown in Table 3, the recoveries were between 94 and 102%, which demonstrates the general reliability of the method.

Table 3. Recoveries of canned food sample digests spiked with 10 μg/l. Sn

Sample	Sn found in digest, μg/l.	Sn found in sample, mg/kg	Recovery, %	rsd, % ($n = 3$)

(*Received* 18 *June* 1991. *Revised* 2 *September* 1991. *Accepted* 4 *September* 1991)

Summary—The determination of mercury(II) ions can be achieved by monitoring the decrease in the oxidation peak of the tetraphenylborate ion in the presence of this metal ion at a carbon paste electrode. The reaction between mercury(II) and the tetraphenylborate ion results in the formation of diphenylmercury, thus providing the method with good selectivity over other metal ions. Using anodic stripping voltammetry in a neutral electrolyte, a linear dependence of the decrease of peak height was observed on increasing the mercury(II) concentration in the range 1×10^{-6}–8×10^{-9}*M* mercury(II). Zinc(II), cadmium(II), lead(II), nickel(II), cobalt(II), tin(II), potassium(I) and ammonium(I) ions did not interfere at a 1000-fold concentration excess. Iron(III) and chromium(III) did not interfere at a 250-fold and 50-fold concentration excess, respectively. Following masking procedures, copper(II), bismuth(III) and silver(I) did not interfere at a 100-fold concentration excess. The method can be used to determine the concentration of mercury(II) in natural waters contaminated by this metal.

Mercury(II) and organomercury compounds are very harmful for most living organisms even in very low concentrations, and considerable attention has therefore been devoted to the determination of mercury(II) in environmental samples. The voltammetric approaches to mercury(II) determination usually involve the use of solid graphite electrodes,[1] where the mercury(II) ion is plated on the surface of the electrode and then stripped off by imposition of an anodic scan.[2] Gold electrodes, in association with either stationary or flow systems, have also often been exploited for the analysis of mercury(II) in environmental samples.[3–6] Since a number of sensitive reactions of organic compounds with Hg(II) are known, chemically modified solid electrodes have been used to determine Hg(II) by differential pulse voltammetry, often in connection with an accumulation step.[7–10] The use of a carbon-paste electrode (CPE) has also been reported for the determination of mercury(II) in the presence of copper(II) by Ulrych and Ruegsegger.[11] The CPE has the advantages of surface renewal and very low background currents, mainly in positive potential ranges.[1] This approach suffers, however, from interferences from other metal ions forming intermetallic compounds.[1] An approach to incorporate various ligands into the paste has been exploited to improve the selectivity of the determination step compared to using an unmodified CPE.[12,13]

In potentiometry, the reaction between mercury(II) and the tetraphenylborate ion has been previously exploited.[14] A carbon paste ion-selective electrode containing sodium tetraphenylborate has been described for the determination of the potassium(I), rubidium(I) and tetralkylammonium(I) ions, respectively.[15] The electrochemical behaviour of sodium tetraphenylborate (NaTPB) has been previously reported by Turner and Elving.[16] The electrochemical oxidation in aqueous solutions proceeds in three steps:

$$B(Ph)_4^- = B(Ph)_2^+ + Ph - Ph + 2e^- \quad (1)$$

$$B(Ph)_2^+ + H_2O = B(Ph)_2OH + H^+ \quad (2)$$

$$B(Ph)_2OH + 2H_2O = B(OH)_3 + Ph - Ph + 2H^+ + 2e^- \quad (3)$$

*Author for correspondence.

NaTPB may be chemically oxidized with iridium(IV), cerium(IV), and iron(III) to form similar products.[17] Turner and Elving[16] demonstrated that two waves were obtained corresponding to these changes. The first wave was well-defined and pH-independent, whereas the second wave arose at more positive potentials, and was deformed and pH-dependent. The electrochemical activity of NaTPB has also been successfully applied in the amperometric titration of potassium(I).[18] If mercury(II) is present, the following reaction with NaTPB occurs:

$$3Hg^{2+} + 2B(Ph)_4^- + 4H_2O = 3(Ph)_2Hg + 2PhB(OH)_2 + 4H^+ \quad (4)$$

and insoluble diphenylmercury is formed. Commonly occurring heavy metals, such as silver and copper, also react with NaTPB, forming insoluble silver(I) tetraphenylborate [$AgB(Ph)_4$] and copper(I) tetraphenylborate [$CuB(Ph)_4$], respectively.[19] It is required therefore to mask these ions prior to determination of mercury(II).

EXPERIMENTAL

Chemicals and reagents

All chemicals were of analytical reagent grade unless stated otherwise. The supporting electrolytes and other solutions were prepared from doubly-demineralized water obtained by passing distilled water through a Millipore Milli-Q water purification system. Dilute solutions ($\leq 1 \times 10^{-3} M$) of NaTPB, Hg(II), and other ions were prepared fresh daily.

Apparatus

All measurements were carried out using an EG&G Princeton Applied Research Model 264A polarographic analyser connected to an XY-recorder (Lloyd Instruments, Model PL-3). The electrochemical behaviour of NaTPB was monitored by cyclic voltammetry and differential pulse anodic stripping voltammetry (DPASV). A three-electrode cell involving a CPE as the working electrode, a Ag/AgCl reference electrode, and a Pt-wire counter electrode were used for all investigations. During the accumulation step a mechanical stirrer (Heidolph, Model RZR 1) was used. Oxygen was removed by bubbling of nitrogen gas through the electrolyte solution for 10 min. Sample volumes of metal ion solutions were introduced into the cell with an Oxford-sampler system micropipette.

Fabrication of carbon paste electrode

The paste was prepared by thorough mixing of 2.50 g of graphite powder (Aldrich Chemical Co., Ltd) and 1.50 ml of Nujol oil (Aldrich). The electrode body was fabricated from a plastic pipette, which had both ends removed. The paste was packed carefully into the pipette tip to avoid possible air gaps, which often enhance electrode resistance. The contact was made with a copper wire, which was passed through a glass tube. The glass tube served also as a piston for extrusion of the paste. The paste was then smoothed on wax paper.

Determination of mercury(II) in natural waters

To a 20-ml sample of river or sea water was added 100 μl of 0.001M NaTPB and 5 ml of 0.5M sodium sulphate. The current responses of NaTPB were then recorded for each sample. To check the reproducibility, five succesive scans were carried out. The same procedure was then employed for a reference solution containing 20 ml of distilled water + 5 ml of sodium sulphate + 100 μl of 0.001M NaTPB, using the same electrode surface. Subsequently, successive additions of known concentrations of mercury(II) were introduced into the reference solution to obtain the dependence between peak heights and the concentration of mercury(II) (calibration plot). Finally, the NaTPB peak heights of samples were compared with a calibration plot obtained for the reference solution.

RESULTS AND DISCUSSION

Cyclic voltammetry of tetraphenylborate ion at the CPE

The cyclic voltamperogram of NaTPB obtained with the CPE in 0.1M sodium sulphate electrolyte is shown in Fig. 1. In accordance with the results of Turner and Elving,[16] two peaks were observed. However, the second peak was badly formed, because its peak potential lay at high positive potentials, where the CPE showed a large background current. The first peak was therefore further investigated for analytical purposes. The choice of sodium sulphate supporting electrolyte was made since it gave rise to lower background currents than other acidic or basic electrolytes investigated. The first well-defined peak was pH-independent, but using a CPE, its potential occurred at a more positive potential ($E_p = +0.53$ V *vs.* Ag/AgCl) than Turner and Elving had reported

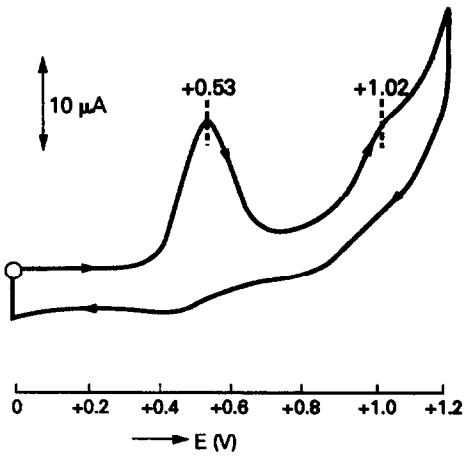

Fig. 1. Cyclic voltamperogram of tetraphenylborate ion obtained at a carbon-paste electrode. Supporting electrolyte, 0.1M Na_2SO_4; scan-rate 20 mV/sec. Concentration of NaTPB, $1 \times 10^{-5}M$. Arrows indicate scan direction.

($E_p = +0.20$ V *vs.* SCE) with the pyrolytic graphite electrode.[16] The favourable response of the CPE was obtained at a scan-rate of 20 mV/sec. Lower values resulted in lower sensitivity and higher values showed distorted curves.

Anodic stripping voltammetry

The sensitivity of the NaTPB response was enhanced by using anodic stripping voltammetry in conjunction with stirring the solution. It was found that the NaTPB peak height was essentially independent of deposition time, and for deposition times longer than 10 sec, the peak size became constant. This can be explained by the fact that NaTPB adsorbed on the electrode surface forms a compact film due to the surfactant properties of the tetraphenylborate ion.[16,19] Hence, from this it was thought that the anodic stripping detection of NaTPB itself could be a sensitive approach for the indirect determination of mercury(II).

Dependence of NaTPB peak on the presence of mercury(II)

In the presence of mercury(II), the oxidation peak of NaTPB rapidly decreases and disappears completely at high relative concentrations of mercury(II). This is illustrated in Fig. 2(A) for a $1 \times 10^{-6}M$ concentration of NaTPB in the presence of 8.3×10^{-8}–$6.7 \times 10^{-7}M$ mercury(II). It was shown that this decrease was

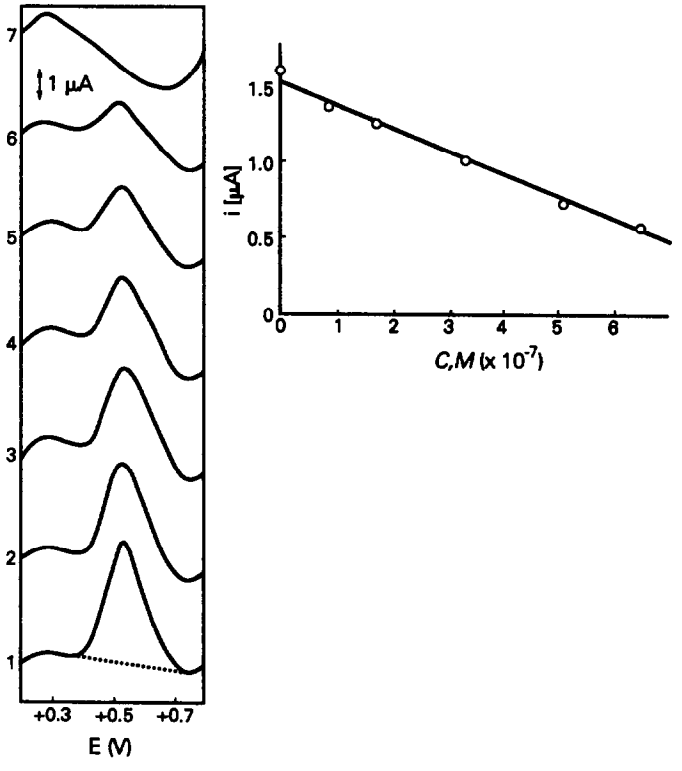

Fig. 2. (A) Effect of varying concentration of mercury(II) upon DPSAV behaviour of tetraphenylborate ion, (B) resultant calibration plot for concentration range $8.3 \times 10^{-8}M$–$6.7 \times 10^{-7}M$ mercury(II). (1) $1 \times 10^{-6}M$ NaTPB, (2–6) successive additions: 25, 50, 100, 150, 200 and 300 μl of $1 \times 10^{-4}M$ mercury(II). Supporting electrolyte, 0.1M Na_2SO_4; scan-rate 20 mV/sec. Deposition time, 10 sec; initial potential, +0.20 V. Dotted line represents base-line for evaluation.

essentially linear [Fig. 2(B)]. Despite the fact that background currents varied slightly during successive scans, especially in the lower concentration ranges, a good reproducibility was obtained for this oxidation peak. For instance, the standard deviation for twenty successive scans of $1 \times 10^{-7}M$ NaTPB was found to be 7%, whereas the standard deviation for ten successive scans of $1 \times 10^{-6}M$ NaTPB was less than 4%. It was also observed that medium exchange of solutions containing the same amount of mercury(II) had practically the same response size even in different electrolytes. The fact that the response of the NaTPB peak was reproducible during these medium exchanges is important for practical applications, which will be discussed later. In order to use this reaction for practical analyses, it is necessary to choose a suitable ratio between the concentrations of NaTPB and mercury(II). Approximately, a 10-fold excess of NaTPB against mercury(II) concentration was found to be optimal for concentrations in the range 1×10^{-8}–$1 \times 10^{-6}M$ mercury(II).

Interferences from other ions

During optimization of the voltammetric parameters for detection of mercury(II), the possibility of interferences from some heavy metals was investigated. As expected, the formation of the oxidation peak and the resultant peak decrease owing to the presence of mercury(II), was not influenced by heavy metals such as zinc(II), lead(II), cadmium(II), nickel(II), cobalt(II) and tin(II) in 1000-fold excess in concentrations, because their anodic reactions proceed in a more negative potential range than the oxidation of NaTPB. Iron(III) interferes at a 250-fold excess in concentration and chromium(III) ions interfere at a 50-fold excess, owing to their anodic oxidations proceeding near to the peak potential of NaTPB. Any incidental anodic redepositions of such metal ions were particularly restricted by the choice of a positive initial potential ($E_i = +0.20$ V). It was then noticed that the anodic peaks due to copper(II) and bismuth(III) at the CPE were small and badly formed, and that these ions influenced the peak of NaTPB at a 100-fold excess in concentrations when mercury(II) was analysed. This again supports the assumption about a coverage of the electrode surface by the compact film, which hinders other redox processes.[20] The undesirable interference of bismuth(III), whose anodic detection at the CPE is considerably sensitive,[21] was suppressed by the choice of a neutral electrolyte, where the bismuth(III) ion irreversibly hydrolyses. However, large difficulties were observed due to the interference of silver(I), if a $0.1M$ sodium sulphate electrolyte was used. This can be overcome if either $0.05M$ sodium sulphate + $0.05M$ sodium bromide or $0.05M$ sodium sulphate + $0.05M$ sodium chloride electrolytes were chosen, probably owing to the formation of both silver chloride and silver bromide precipitates, respectively. A similar paper[23] using the same masking procedure has appeared more recently. The effectiveness of this masking procedure can be seen in Fig. 3. The first set of voltamperograms 1–4 represents interferences from Ag(I) ions in $0.1M$ sodium sulphate electrolyte, where, due to the presence of these ions, the peak of NaTPB rapidly decreases. If $0.05M$ sodium sulphate + $0.05M$ sodium chloride or

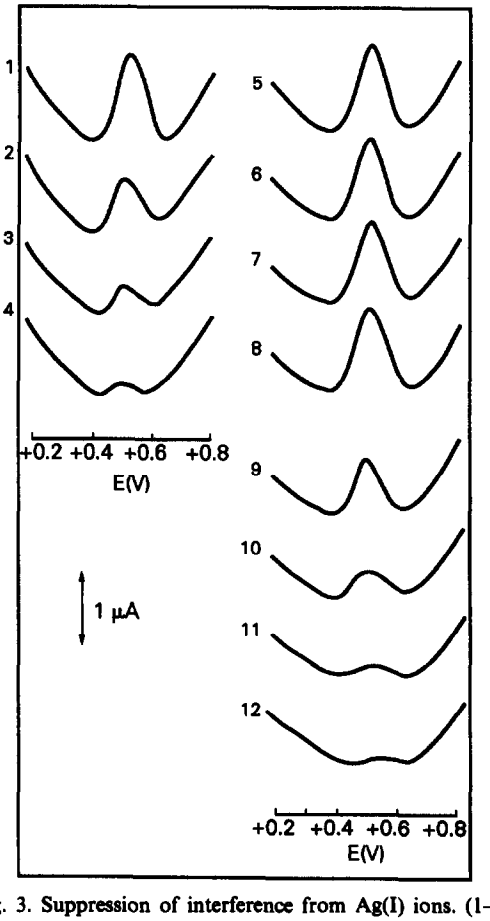

Fig. 3. Suppression of interference from Ag(I) ions. (1–4) $0.1M$ Na_2SO_4 electrolyte; successive additions: 0, 50, 100 and 200 μl $1 \times 10^{-4}M$ silver(I). (5–8) $0.05M$ Na_2SO_4 + $0.05M$ NaCl electrolyte; successive additions: 0, 50, 100 and 200 μl $1 \times 10^{-3}M$ silver(I). (9–12) Successive additions: 50, 100, 150 and 200 μl $1 \times 10^{-4}M$ mercury(II). Experimental conditions: see Fig. 2.

0.05*M* sodium sulphate + 0.05*M* sodium bromide electrolytes were used, silver(I) ions did not interfere (voltamperograms 5–8), although their concentration had been 10-fold higher than in the sulphate electrolyte. However, after successive additions of mercury(II) ions, the oxidation peak of NaTPB diminished immediately (voltamperograms 9–12). No oxidation of bromide ions was observed in the potential range studied. Potassium(I) and ammonium(I) ions, whose reactions with NaTPB are often employed in potentiometry,[15,22] did not interfere with the decrease of the NaTPB peak even in a 1000-fold excess.

A determination employing this approach would, however, be affected by the presence of strongly oxidizing agents, such as chromate or permanganate anions, or bromine water, which oxidize the tetraphenylborate ion. No interferences of organic compounds have been investigated in this work.

Analytical applications

The usable concentration range in which the decrease of NaTPB peak in the presence of mercury(II) could be employed was investigated. For appropriate NaTPB concentrations in both 0.1*M* sodium sulphate and 0.05*M* sodium sulphate + 0.05*M* sodium chloride electrolytes, the decrease in response of NaTPB due to mercury(II) was proportional in the range 1×10^{-6}–$8 \times 10^{-9}M$. The detection limit was estimated as $6 \times 10^{-9}M$ mercury(II) (by means of 3:1 current-to-noise ratio) using an appropriate amount of NaTPB in connection with highest-possible analyser sensitivity. A calibration plot for the concentration range of 8.3×10^{-8}–$6.7 \times 10^{-7}M$ mercury(II) (correlation coefficient, $r = 0.989$) was linear as shown in Fig. 2(B). Similar plots for both concentration ranges of 8.3×10^{-7}–$5 \times 10^{-6}M$ Hg(II) ($r = 0.994$) and 8.3×10^{-9}–$6.7 \times 10^{-8}M$ Hg(II) ($r = 0.984$) were also obtained (not shown). For the latter concentration range it was observed that due to high background currents, relatively distorted voltamperograms were obtained.

The determination of mercury(II) was then carried out in both river and sea water. However, as expected, this method is not sensitive enough to determine the concentration of mercury(II) at its base level in these matrices, which has been quoted to be extremely low (*e.g.*, in sea water about $1 \times 10^{-11}M$).[4] Hence, the determinations were carried out in "spiked" water samples. No pretreatment of samples to remove any matrix component was carried out. The results of these analyses are given in Table 1.

Both water samples were made $5 \times 10^{-7}M$ in mercury(II), assuming that the original content of these ions was negligible compared to the concentration that was spiked in. Peak heights were computed in a manner as shown in Fig. 2A. The standard deviations for both reference and sample solutions were less than 4% in all cases.

The responses of the NaTPB peak in both river and sea water samples were essentially the same size, and the difference between the results shown in Table 1 can probably be explained due to the effect of the different organic and inorganic constituents in each matrix. The calibration plots for reference solutions were linear, with correlation coefficients from 0.983 to 0.995. Original river and sea water samples yielded the same size of peaks as for reference solutions. The procedure of successive additions was also applied for solutions of samples, and it was observed that linear calibration plots had practically the same slopes. These observations and results have confirmed that the method employing the indirect determination approach reported in this paper can be used for practical analysis; its application would, however, be limited to heavily polluted water systems.

CONCLUSIONS

The oxidative voltammetric behaviour of NaTPB at the CPE has been shown to be dependent upon the presence of mercury(II). As a linear response was obtained for mercury(II) over a wide concentration range, this approach was first examined for the indirect determination of mercury(II) in aqueous solution. This method can be used for the determination of mercury(II) in the concentration range between 1×10^{-6}–$1 \times 10^{-8} M$. This is superior to the detection limits offered by potentiometric methods of analysis,[15,22] and is similar to those reported by other authors using stripping voltammetry.[8–10]

This indirect determination is, however, accompanied by a poorer precision compared to common direct methods.[8,10,12] However, on the other hand, a simple preparation of working electrode (compared to either the fabrication of modified solid electrodes[7,8] or expensiveness of gold electrodes), together with the exploitation of very short deposition times (in contrast to other procedures[7,8]) can be advantageous. Even so, the considerable sensitivity and selectivity towards mercury(II) can be useful for routine analysis. It was found that the electrochemical behaviour of the tetraphenylborate ion was practically not affected by the presence of other metal ions such as zinc(II), cadmium(II), lead(II), nickel(II), cobalt(II), tin(II), iron(III), copper(II), bismuth(III) and potassium(I) ions. The interference of the silver(I) ion was overcome by application of an appropriate masking procedure. The determination is unfavourably affected by the presence of higher concentrations of chromium(III), and particularly, by the presence of strongly oxidizing agents.

This method can also be used as a relatively simple and quick method to determine mercury(II) in polluted and industrial waste water.

Summary—Dithioerythritol (DTE) is frequently employed as a reducing agent or a protective reagent for thiol groups in biological assays. Owing to its known inhibiting properties in enzyme catalysis reactions, lead is also commonly used in such experiments, and often simultaneously with DTE. Given the potential affinity of these two reactants, their measured individual effects may well depend on their interactions in the medium used. Any quantitative assessment of these interactions necessitates, however, that the complex equilibria between lead and DTE be investigated beforehand. To test this hypothesis, the formation constants of lead(II) complexes with DTE under physiological conditions (37°, NaCl 0.15M) have been calculated from the results of glass electrode potentiometry, with the help of the MINIQUAD and ESTA computer programs. The pK values for dissociation of DTE have been found equal to 8.926 ± 0.003 and 9.840 ± 0.003. The following lead–DTE species have been characterized: ML (12.774 ± 0.037), MLH_{-1} (2.858 ± 0.037), M_2LH_{-1} (13.349 ± 0.025) and M_6L_5 (86.586 ± 0.099); the log $*\beta$-values are given in the parentheses. Appropriate computer simulations effectively show that the interactions of the two reactants are indeed quite significant within the concentration ranges commonly used in *in vitro* biological assays. They should thus be taken into account in interpretation of the effects observed.

Dithioerythritol (DTE), the erythro isomer of 2,3-dihydroxy-1,4-dithiobutane, has as low a redox potential as dithiothreitol (DTT) (−0.33 V at pH 7), and is thus capable of maintaining monothiols completely in the reduced state as well as of reducing disulphides quantitatively.[1] DTE has thus gained wide acceptance as a reducing agent or protective reagent for —SH groups in biochemical systems.[2,3] Owing to its capacity to inhibit certain enzyme catalysis reactions, lead is also frequently used in biological assays, and often simultaneously with DTE. Since, like some transition metal ions,[4] lead is expected to display some affinity for DTE, the individual effects attributed to each of these reactants may, to some extent at least, be affected by interactions between the two of them when both are present in the system. It was thus of interest to test this possibility on quantitative grounds. However, any reliable assessment of these interactions required that the formation constant of the lead–DTE complexes be determined under appropriate conditions.

Accordingly, in parallel to a study on lead(II)–DTT co-ordination with respect to lead/5-aminolevulinic acid dehydratase/DTT interactions,[5] the present work reports a quantitative investigation into proton– and lead(II)–DTE complex equilibria under physiological conditions (37°, NaCl 0.15M). First, the stoichiometries and stabilities of all the species potentially formed between lead(II) and DTE were determined, then distribution profiles for each of these two reactants were simulated for concentrations commonly used in *in vitro* biological investigations.

EXPERIMENTAL

Reagents

Dithioerythritol and lead(II) chloride were purchased from Aldrich Chemical Co. Fresh solutions were systematically prepared every day by dissolving the crystals in doubly-demineralized water distilled from potassium

†Author for correspondence.

permanganate, and kept under a nitrogen atmosphere.

Carbonate-free sodium hydroxide solutions were prepared by diluting BDH standard volumetric concentrates with freshly distilled water of the above quality under a constant flow of nitrogen. The alkali titre and absence of carbonate were periodically checked by use of appropriate Gran plots[6] and Merck *p.a.* potassium hydrogen phthalate. The hydrochloric acid used to acidify initial solutions to be titrated was a Prolabo R. P. Normapur product. The sodium chloride used as background electrolyte was a Merck *p.a.* reagent.

Potentiometric measurements

Potentiometric titrations were performed with use of a Beckman 4500 mV-meter equipped with Ingold glass and calomel electrodes. The electrode system was calibrated on the concentration scale in the presence of 0.15*M* sodium chloride at 37°; the corresponding pK_w determined was 13.22.

The titration vessel consisted of a thermostated Ingold Cell System in which anaerobic conditions were imposed by constant passage of nitrogen through the solution. Successive aliquots of sodium hydroxide were added by means of a Radiometer Autoburette.

The initial solution to be titrated was made sufficiently acidic for all donor groups to be substantially protonated. Proton–ligand as well as metal–ligand concentration ratios were varied over the largest possible range so as to favour the characterization of all possible complexes. Each experiment was repeated at least twice.

Table 1 summarizes the corresponding analytical data.

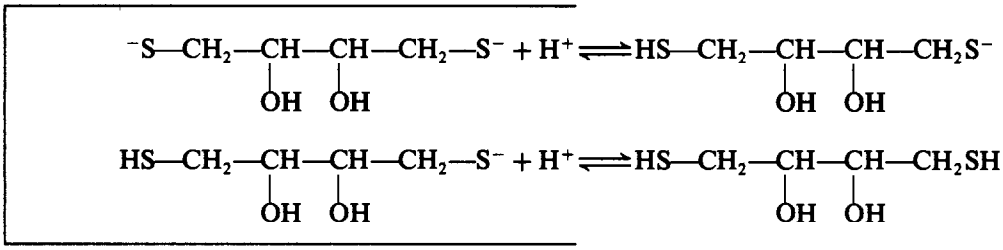
Calculation techniques

Estimates of the stability constants derived from protonation and formation curves were refined with MINIQUAD[7] and with the optimization module of the ESTA program library.[8] A first selection between the possible sets of constants was made by comparing numerical goodness-of-fit parameters (sum of squared residuals, Hamilton *R* factors). The ultimate discrimination among the several sets displaying almost equally favourable numerical fits was made on graphical grounds, based on pseudo-experimental curves calculated with the simulation module of the ESTA library.[9] The final constants were refined with MINIQUAD.[7]

Distribution profiles of Pb^{2+} ions and DTE under the concentration conditions commonly used in biological investigations were plotted by means of the SPEC module of the ESTA library.[9]

RESULTS AND DISCUSSION

The DTE molecule displays only two active protonation sites in water, which correspond to the thiol groups according to the following equilibria:



The corresponding protonation constants shown in Table 2 are in good accordance with those reported by Zahler and Cleland[10] (9.0, 9.9) and by Loechler and Hollocher[11] (9.14, 9.94) though determined under different experimental conditions.

Figure 1 shows the experimental protonation curves obtained in the presence of different concentrations of lead, put in perspective by the reference protonation curve calculated from the two constants above. Figure 2 shows the corresponding experimental formation curves obtained over the whole range of concentrations investigated.

As can be seen from Fig. 2, complex formation is not expected to be limited to simple mononuclear species in this system; otherwise all the experimental curves obtained would have indeed been statistically regular and superimpossible regardless of the reactant concentrations. In the present case, on the contrary, all the curves are "tail-shaped" above average coordination numbers of *ca.*1, except for the 2:1 metal–ligand ratio experiment, where there is a "curl back" near 0.5. Since formation curves are

*To be understood as $-\log [H^+]$ (see text).

deduced from apparent free ligand concentration calculated by supposing the existence of only simple mononuclear complexes, the shifts observed with respect to Bjerrum's theoretical definition are characteristic of species not explicitly considered. Thus, the present "tails" may *a priori* express: (*i*) the formation of metal–ligand hydroxo species, (*ii*) the additional deprotonation of ligand side-chain hydroxyl groups in one or several complexes formed at lower pH, or (*iii*) the formation of metal hydroxides.

Metal hydrolysis is taken into account in the calculations, the corresponding constant (extrapolated from Sylva and Brown's work[12]) being kept constant during the refinements. In addition, its influence can be directly appreciated by simulating the formation curves as they would have been if metal hydroxides were the only species present in solution. In this respect, the comparison of Fig. 2 with Fig. 3 suggests that strong lead–DTE complexes exist before hydrolysis becomes predominant at very high pH-values, where pseudo-experimental points tend to coincide with experimental ones.

Regarding the formation of hydroxo complexes or the possible deprotonation of hydrated lead–DTE species formed at lower pH values (both phenomena being strictly equivalent from the chemical point of view), MLH_{-1} and

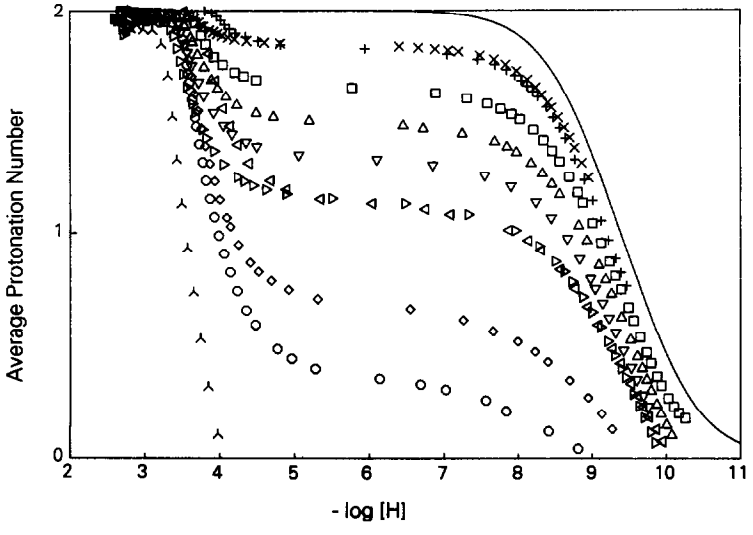

Fig. 1. Experimental protonation curves for DTE in the presence of various lead concentrations. Experiments are given in the order of Table 1 with the following symbols: +, ×, □, △, ▽, ◁, ▷, ◇, ○, ⅄. The solid line represents the reference curve calculated from protonation constants in Table 2.

M_2LH_{-1} were easily selected on numerical as well as graphical grounds (Fig. 4). However, taking these two species into account in the set of constants likely to describe the experimental data proved insufficient for satisfactory graphical fits to be obtained.

The systematic deviations observed near the two bends of the inflexion at average co-ordination numbers of about 1 may indicate the existence of polynuclear complexes. As was done in the parallel study of lead–dithiothreitol (DTT) equilibria,[5] corresponding constants were successively introduced in the refinement, in accordance with Sillen's "core + links" theory.[13] Of all the species tested during this research, which led us to consider more than 50 different combinations of constants involving M_2L_2, M_3L_3, M_4L_4, M_5L_5, M_6L_6, M_3L_2, M_4L_3, M_5L_4, M_6L_5 and their hydroxo counterparts, several polynuclear complexes gave rise to similarly acceptable goodness-of-fit parameters, but only two of these, namely $M_3L_2H_{-1}$ and M_6L_5, led to satisfactory graphical comparisons.

A priori, the formation of such polynuclear complexes may stem from the known ability of sulphur to accept electrons from a metal by π-bonding.[14] The size of the donor atom may also be a facilitating factor. In this regard, the two species above may respectively result

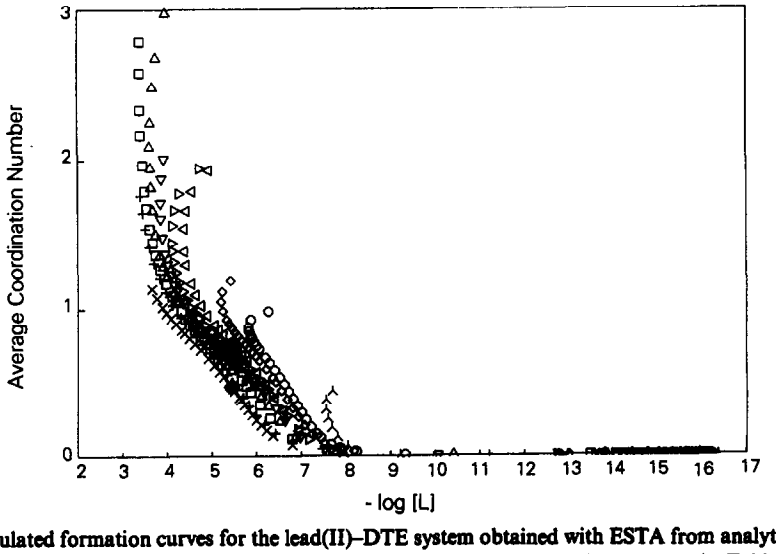

Fig. 3. Simulated formation curves for the lead(II)–DTE system obtained with ESTA from analytical data in Table 1, supposing the exclusive formation of hydroxides (see hydrolysis constants in Table 2). Key to symbols as for Fig. 1.

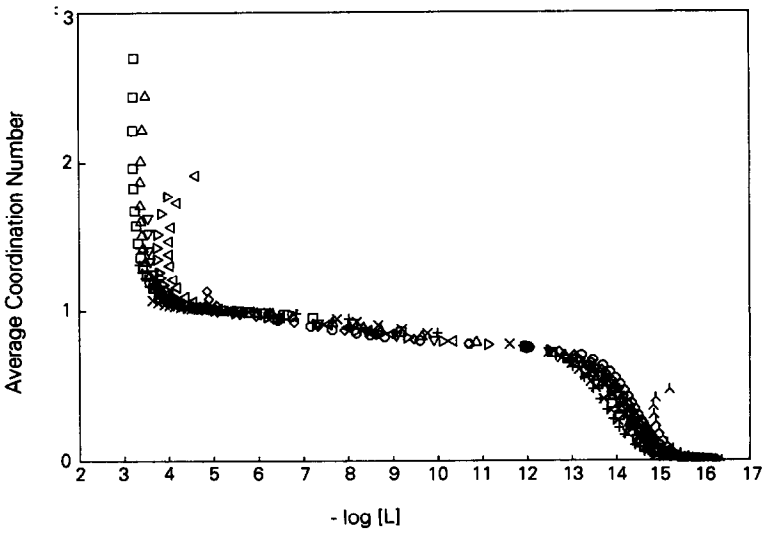

Fig. 4. Simulated formation curves for the lead(II)–DTE system obtained with ESTA from analytical data in Table 1, supposing the formation of ML (12.63), MLH_{-1} (2.71), M_2LH_{-1} (13.44), and lead hydroxides (see hydrolysis constants in Table 2). Key to symbols as for Fig. 1.

from a favourable displacement of the hydroxyl ions of the $M_3(OH)_5$ and $M_6(OH)_8$ species by deprotonated DTE molecules.

The final selection of the "best" set of constants was made extremely difficult by the fact that, like the goodness-of-fit parameters, simulated formation curves resulting from the addition of $M_3L_2H_{-1}$ or M_6L_5 to the basic model (ML, MLH_{-1} and M_2LH_{-1}) were very similar. Table 2 reports the two corresponding possibilities, with stability constants ultimately refined with MINIQUAD.

Considering, however, that (*i*) the *S* and *R* values are slightly more favourable in the case of M_6L_5, (*ii*) the graphical coincidence between the experimental and simulated formation curves is slightly better with M_6L_5 (Fig. 5) than with $M_3L_2H_{-1}$ (curve not shown here), (*iii*) the standard deviations of the constants for ML, MLH_{-1} and M_2LH_{-1} are significantly lower

Table 2. Formation constants (mean ± standard deviation) for the lead(II)–DTE complexes at 37° in 0.15*M* aqueous NaCl: the general constant is $\beta_{pqr} = [M_qL_pH_r]/[M]^q[L]^p[H]^r$; *S* is the sum of squares, *R* the Hamilton *R*-factor,[7] and *N* the total number of experimental observations used in the calculations. log*β values given in parentheses

†Lead-hydroxide equilibria were taken into account in these determinations. The following formation constants (extrapolated from Sylva and Brown[12] for the present experimental conditions) were used in the calculations:

MH_{-1} (−8.0)
M_3H_{-4} (−24.5)
M_3H_{-5} (−32.5)
M_4H_{-4} (−21.1)
M_6H_{-8} (−44.8)

For definition of *β see J. Bjerrum, G. Schwarzenbach and L. G. Sillén (eds.), *Stability Constants of Metal Ion Complexes*, Part II, *Inorganic Ligands*, p.xiii, Chemical Society, London, 1958.

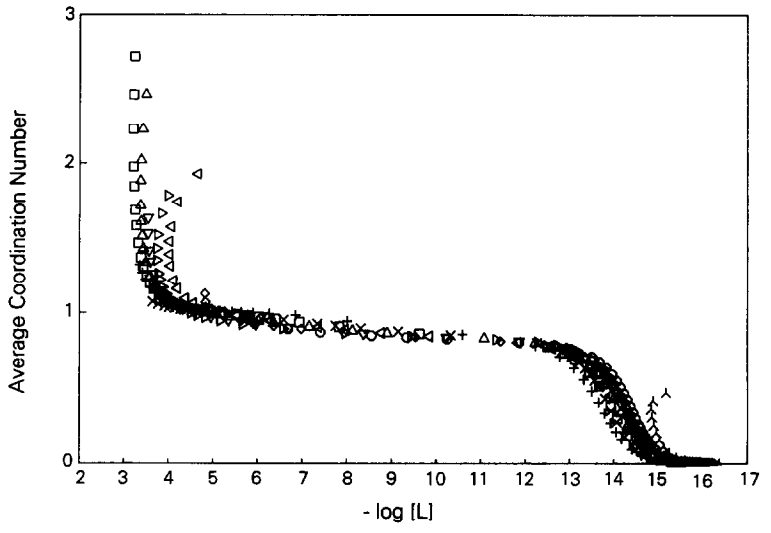

Fig. 5. Simulated formation curves for the lead(II)–DTE system obtained with ESTA from analytical data in Table 1 and formation constants in Table 2 (model with M_6L_5). Key to symbols as for Fig. 1.

with M_6L_5 than with $M_3L_2H_{-1}$, (*iv*) all species distribution percentages obtained from MINIQUAD calculations over the experimental conditions reported in Table 1 are almost exactly the same with use of M_6L_5 and $M_3L_2H_{-1}$, (*v*) M_6L_5 may well result from the dimerization of $M_3L_2H_{-1}$, the co-ordination of an additional ligand molecule at the expense of two hydroxyl ions being a supplementary factor inducing stability, we finally chose M_6L_5 as the most likely species.

As an application of the selected constants, Fig. 6 shows the distribution profile of lead from pH 2 to 11 under concentration conditions chosen within the range commonly used for *in vitro* biological systems. As can be seen, the concentration of free Pb^{2+} ions becomes negligible at pH 6 and above. This indicates that a strong competition is to be expected from DTE with respect to the lead–enzyme interactions involved in the biological process. In other words, DTE appears as a very potent agent for restricting the inhibitory capacity of lead towards the enzyme system. In contrast, the distribution of the free and protonated forms of DTE is not significantly influenced by the presence of lead at such concentration ratios (simulations not shown here).

The overall influence of DTE complexation on the distribution of lead can be still better appreciated from Fig. 7, where variations of the concentration of free Pb^{2+} ions are plotted as a

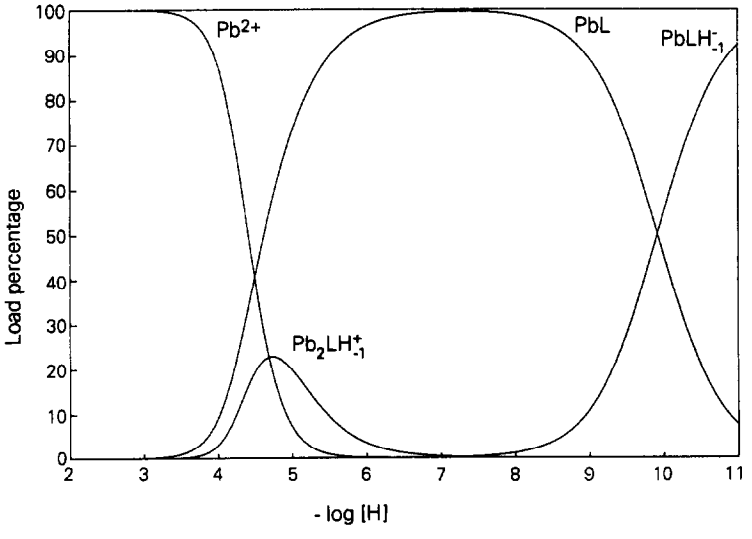

Fig. 6. Simulated distribution of Pb^{2+} ions in the presence of DTE with $C_{Pb} = 5\mu M$ and $C_{DTE} = 1mM$.

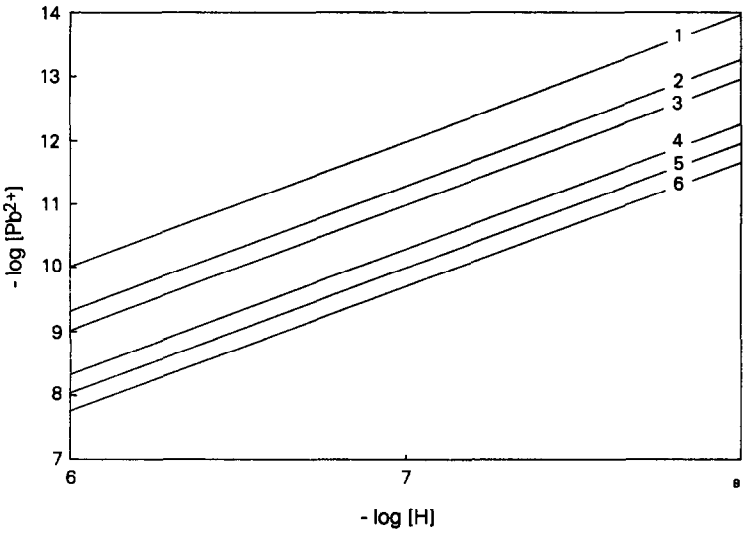

Fig. 7. Variation of the free concentration of lead in the presence of 1m*M* DTE as a function of total lead concentration within the pH range 6–8 (curves 1, 2, 3, 4, 5, 6 correspond to $C_{Pb} = 0.1$, 0.5, 1, 5 and 10μM, respectively).

function of total lead concentration within the pH interval 6–8. The family of curves drawn on this figure gives direct access to the maximum free lead concentrations present in solutions used for enzyme assays.

EXTRACTION AND SEPARATION STUDIES OF TELLURIUM(IV) WITH TRIS-(2-ETHYL HEXYL) PHOSPHATE

G. S. DESAI and V. M. SHINDE*
Analytical Laboratory, The Institute of Science, 15 Madam Cama Road, Bombay 400 032, India

(*Received* 13 *May* 1991. *Revised* 28 *August* 1991. *Accepted* 28 *August* 1991)

Summary—A method is proposed for the extraction of microgram levels of tellurium(IV) from halide media with tris-(2-ethyl hexyl) phosphate dissolved in toluene as extractant. The optimum conditions have been evaluated from a critical study of acid concentration, extractant concentration, period of equilibration and effect of solvent. Tellurium ion from the organic phase is stripped with water and determined spectrophotometrically with stannous chloride. The method affords binary separation of tellurium from copper, bismuth, gold and selenium and is applicable to the analysis of alloy samples and synthetic mixtures. The method is fast, accurate and precise.

Tellurium is an important component of thermoelectric couples used for power generating and cooling. The compound Bi_2Te_3 is widely used in the preparation of semiconductors. The addition of tellurium to stainless steel increases its machinability. Tellurium has also been used in the ceramics industry for the manufacture of glasses and porcelains of various colours. In view of this, separation of tellurium from associated elements is desired. Very few extraction methods of tellurium(IV) are available in the literature. Solvent extraction methods, using polar solvents such as tributyl phosphate (TBP), methyl isobutyl ketone (MIBK), trioctylphosphine oxide (TOPO) and di-(2-ethyl hexyl) phosphoric acid have been reviewed by Havezov and Jordanov[1] and by Sekine and Hasegawa[2] in their monographs. A novel extractant, tris-(2-ethyl hexyl) phosphate (TEHP), has been used as an extractant for the extraction of uranium(VI)[3] and thorium(IV)[4] in our laboratory. An extension of this work has shown that TEHP could also be used for the extraction of tellurium from halide media. The method is rapid and provides separation of tellurium from copper, bismuth, gold and selenium.

EXPERIMENTAL

Apparatus

Absorbance measurements were made on a Spectronic 20 (Bausch and Lomb) and pH was measured on a Control Dynamics digital pH meter with combined glass electrode.

*Author for correspondence.

Reagents and chemicals

A stock solution of tellurium(IV) was prepared by dissolving 0.435 g of sodium tellurite in distilled water and diluting to 250 ml. The solution was standardized gravimetrically[5] and diluted as required to obtain working solutions. A 70% (v/v) solution of tris-(2-ethyl hexyl) phosphate (TEHP) (97%, Aldrich) dissolved in toluene was used as an extractant. A 20% (m/v) solution of stannous chloride in 2*M* hydrochloric acid was used for the determination of tellurium.[6] All other reagents used were analytical reagent grade.

General extraction procedure

To an aliquot of solution containing 100–200 μg of tellurium(IV), add hydrobromic or hydrochloric acid so that the solution concentration is in the range 3.5–7.0 or 6.0–8.5*M*, respectively, in a total volume of 10 ml. Transfer the solution into a separating funnel and extract with 5 ml of 70% TEHP in toluene for 15 sec. After separating the aqueous layer, strip tellurium from the organic phase with 5 ml of water and estimate spectrophotometrically with stannous chloride at 400 nm.[6]

RESULTS AND DISCUSSION

Extraction conditions

The extraction of tellurium(IV) was studied at various concentrations of hydrobromic (1.0–7.0*M*) and hydrochloric acid (2.0–8.5*M*) with different concentrations of TEHP (20.0–70.0%). The results showed that 70% TEHP in toluene

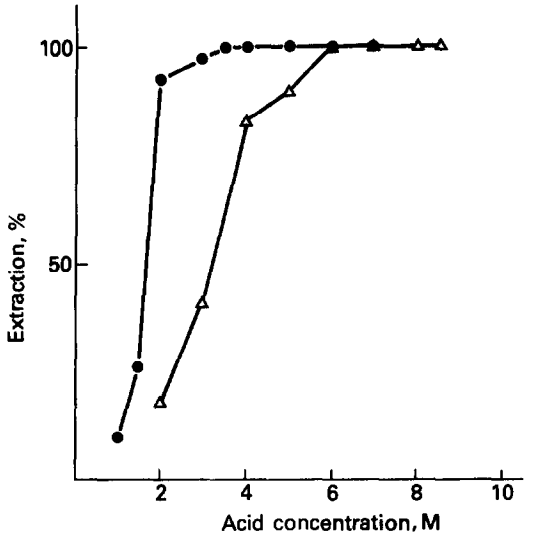

Fig. 1. Extraction behaviour of tellurium(IV) as a function of hydrobromic acid (●) and hydrochloric acid (△) concentration.

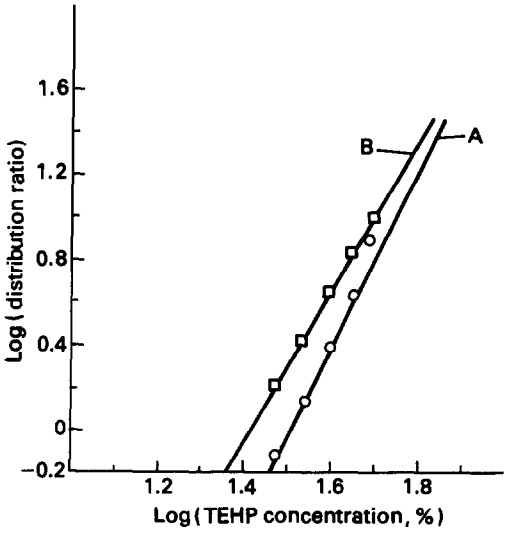

Fig. 2. Plot of log (distribution ratio) *vs.* log (TEHP concentration, %) at 4*M* hydrobromic acid concentration (A) and 6*M* hydrochloric acid concentration (B).

extracts tellurium quantitatively either from 3.5–7.0*M* hydrobromic acid or 6.0–8.5*M* hydrochloric acid (Fig. 1).

Period of extraction

Variation of the shaking period from 5 to 60 sec showed that a 15-sec equilibration time was adequate for quantitative extraction of tellurium from bromide or chloride media. However, prolonged shaking had no adverse effect on the extraction.

Effect of organic phase

The suitability of several solvents such as benzene, toluene, xylene, chloroform and carbon tetrachloride for the extraction of tellurium from bromide or chloride media, using the proposed method was investigated. It was found that a 70% (v/v) solution of TEHP in toluene, xylene or benzene provides quantitative extraction of tellurium. The extraction of tellurium was incomplete if TEHP is dissolved in other solvents. Inert diluents such as toluene, xylene, benzene, *etc.*, do not participate in the actual extraction process. However, TEHP causes solvation of the tellurium–chloro or bromo complexes and promotes extraction.

Nature of extracted species

The nature of the extracted species was established with log-log plots. The log-log plot of distribution ratio *vs.* TEHP concentration (at 4.0*M* hydrobromic acid or 6.0*M* hydrochloric acid) gave a slope of 2.2 and 1.7, respectively, indicating a molar ratio of 1:2 with respect to the extractant (Fig. 2). Hence, the extracted species is either an ion-association complex $H_2TeX_6 \cdot 2TEHP$ or solvated halo salt $TeX_4 \cdot 2TEHP$, where X stands for Cl^- or Br^- and TEHP represents tris-(2-ethyl hexyl) phosphate.

Effect of foreign ions

Varying amounts of foreign ions were added to a fixed amount of tellurium(IV) (200 μg) to study their interference in the recommended procedure in bromide and chloride media. The tolerance limit was set at the amount required to cause $\pm 2\%$ error in tellurium recovery. The results are reported in Table 1.

Binary separation of tellurium(IV) from copper(II), bismuth(III), gold(III) and selenium(IV)

The method permits separation and determination of tellurium(IV) from binary mixtures containing either copper, bismuth, gold or selenium.

Tellurium is separated from copper and selenium by its extraction with 70% TEHP in toluene from 6*M* hydrochloric acid. Under this condition both copper and selenium remain quantitatively in the aqueous phase where they are determined sepectrophotometrically with 1-(2-pyridylazo)naphth-2-ol (PAN)[7] and 3,3′-diaminobenzidine,[6] respectively. Tellurium is stripped from the organic phase with water and estimated spectrophotometrically with stannous chloride.

Table 1. Effect of foreign ions on the extraction of 200 μg of tellurium(IV) from 4*M* HBr or 6*M* HCl with 70% tris-(2-ethyl hexyl) phosphate dissolved in toluene

FE(III)	2000	1500			

Tellurium and bismuth are separated by extracting bismuth from 0.2*M* hydrobromic acid solution with 70% TEHP as an extractant. Tellurium remains in the aqueous phase quantitatively; the extracted bismuth is subsequently stripped with 0.2*M* nitric acid and determined spectrophotometrically with thiourea.[8]

Similarly gold and tellurium are separated by extracting gold from 0.5*M* hydrobromic acid solution with 25% TEHP in toluene. The unextracted tellurium is estimated in the aqueous phase while the extracted gold is estimated spectrophotometrically in the TEHP phase itself by measuring the absorbance of the yellow–orange complex at 400 nm.

While Bi(III) and Au(III) do not interfere in the Te(IV) extraction or determination from 3.5–7.0*M* hydrobromic acid, the above procedure allows their separation and separate determination.

The recovery of tellurium and that of the added ions was ⩾99.0%. The results are reported in Table 2.

Analysis of synthetic mixtures

The proposed method was applied to the extraction and determination of tellurium from bromide media in various synthetic mixtures. The results are reported in Table 3.

Analysis of alloys

Since standard alloy samples containing tellurium were not available, we analyzed synthetic alloy and leaded brass (BCS 385) samples,

BCS—British Chemical Standard.

to which a known amount of tellurium had been added. The tellurium was recovered from bromide media by the proposed method. The procedures are given below.

A 30-mg sample of synthetic alloy was dissolved in 3 ml of *aqua regia* and diluted to 100 ml with water. A 1-ml aliquot of this solution was taken for the extraction and determination of tellurium by the proposed method.

A 50-mg sample of leaded brass (BCS 385) was dissolved in 3 ml of concentrated nitric acid and evaporated to almost dryness. The residue was taken up in water and the precipitated metastannic acid was filtered off. To the filtrate solution, 2 mg of tellurium was added and the solution diluted to 25 ml with water. An aliquot of 2.5 ml of filtrate containing 200 μg of tellurium was taken for extraction and determination of tellurium by the proposed method. The results of the analysis are reported in Table 4.

The method is selective and permits rapid separation and determination of micro amounts of tellurium. The average recovery of tellurium was $\geqslant$99.0%. Each determination took a total of 15–20 min.

COLOUR REACTION OF GOLD WITH 5-(4-SODIUM SULPHONATEPHENYLAZO)-8-AMINOQUINOLINE AND ITS ANALYTICAL APPLICATION

(*Received* 28 *May* 1991. *Accepted* 24 *July* 1991)

Summary—The synthesis of 5-(4-sodium sulphonatephenylazo)-8-aminoquinoline (SPAQ) is described, and a simple, rapid, selective and sensitive new spectrophotometric method for determination of gold is developed. SPAQ reacts with gold(III), and in the presence of cetyl trimethyl ammonium bromide cationic surfactant and upon making the solution alkaline, forms a blue-green 1:3 (metal:ligand) with an absorption maximum at 605 nm. Beer's law is obeyed over the concentration range 0–2 μg/ml gold. The molar absorptivity and Sandell's sensitivity of the method are 1.48×10^5 l.mole^{-1}.cm^{-1} and 0.0013 μg/cm^2, respectively. The interference of various ions has been studied and the method has been used for the determination of microamounts of gold in ores and anode slimes.

Both 8-hydroxy- (8HQ) and 8-mercaptoquinoline (8MQ) are well-known reagents widely used as chelating agents in analytical chemistry.[1] However, the 8-amino derivative of quinoline (8AQ) has received little analytical attention, resulting in only a few published papers.[2,3] Because 8AQ has (N,N) as its chelating atom, it is more selective than 8HQ(N,O) and 8MQ(N,S). In recent years, some 8-aminoquinoline derivatives have been synthesized and used in the fluorimetric analysis of copper[4] and cobalt,[5] and spectrophotometric determination of platinum.[6]

Gold may usually be determined with various chromogenic agents such as diethyldithiocarbamate,[7] 8-mercaptoquinoline,[8] 2-quinolylaldoxime,[9] thiomides,[10] aniline,[11] ethylxanthate,[12] 2-pyridinealdoxime,[13] anthranilic acid,[14] di-2-thienyl ketoxime,[15] chromophryozole[16] or phenothiazine.[17] In most of the methods, the sensitivity is very poor and the colour fades after a few minutes. In some instances the complex is formed only after heating for a long time and requires extraction with an organic solvent, whereas others suffer from interferences from other metal ions. A thorough survey of the literature showed that no previous attempt has been made to employ 8-aminoquinolines for the spectrophotometric determination of gold. Hence, in this paper, 5-(4-sodium sulphonatephenylazo)-8-aminoquinoline (SPAQ) is proposed as a reagent for the spectrophotometric determination of gold(III) in aqueous solution. Various parameters such as pH, reagent concentrations, equilibration time and interference of foreign ions have been studied. This method has been applied to the determination of gold(III) in ores and anode slimes. The reagent has been found to be sensitive and selective compared with other chromogenic agents.

EXPERIMENTAL

Apparatus

A 751GW spectrophotometer (Analytical Instruments Factory, Shanghai) with 1-cm pathlength cells, wavelength range 200–1000 nm, was employed for all absorbance measurements.

Reagents

Synthesis of SPAQ. Sulphanilic acid (2.1 g) was dissolved in 2 ml of ice-cold concentrated hydrochloric acid, 10 ml of ice-cold distilled water and slowly diazotized with a solution of 0.8 g of sodium nitrite in 8 ml of water. The diazotized solution was then added dropwise

*Author for correspondence.

with stirring to an ice-cold solution of 8AQ (1.6 g) in 50 ml of 2*M* acetic acid, 2*M* sodium hydroxide being added to keep the pH constant, and the mixture was left for 1.5 hr, with stirring in the ice-bath, then neutralized with sodium hydroxide and filtered. The red precipitate was recrystallized and salted out with sodium chloride several times from water to give needle-shaped crystals (decomposed above 325°) with a yield of 76%. Elemental analysis was as follows: calculated, C 48.87, H 3.53, N 15.20, S 8.68%; found, C 49.11, H 3.50, N 15.15, S 8.70%. The data obtained from thermogravimetry, infrared and nuclear magnetic resonance spectra confirmed the structure of SPAQ to be as shown in Fig. 1. The acid dissociaton constant of SPAQ was obtained by Perisic-Janjic's method,[18] the pK_{a3} value being 3.65 ± 0.03.

Colour reagent solution. A 0.0368 g amount of SPAQ was dissolved in 500 ml of distilled water ($2.0 \times 10^{-4}M$). The solution is stable for one year at least.

Standard gold(III) solution, 100 μg/ml. A stock solution of gold(III) was prepared by dissolving the requisite amount of pure gold in *aqua regia*. A working standard solution, 5 μg/ml, was prepared by diluting this solution.

Cetyltrimethyl ammonium bromide (CTMAB) solution (0.2%). Prepared by dissolving the substance in water.

Sodium hydroxide solution, 0.5% in water. All other reagents were of analytical grade.

Procedures

Determination of microgram amounts of gold. Take a known volume of solution containing not more than 50 μg of gold(III) in a 25-ml standard flask, add 3.0 ml of CTMAB solution, 4.0 ml of SPAQ solution and 2.5 ml of sodium hydroxide solution, in that order, dilute to the mark with distilled water, mix and let stand for about 15 min. Measure the absorbance at 605 nm against a reagent blank prepared similarly but without gold.

Determination of gold in anode slimes. Take 0.1 g of sample into a beaker, add 10 ml of concentrated hydrochloric acid and 5 ml of concentrated nitric acid to dissolve the sample by heating on a boiling-water bath, evaporate the solution mixture to incipient dryness, add 4 ml of concentrated hydrochloric acid and evaporate until nitrogen dioxide ceases to evolve. Allow to cool to room temperature (about 25°), add 10 ml of 0.1*M* hydrochloric acid to dissolve the soluble salts, filter off the residue and wash it with distilled water three times, collect the filtrate and washings and dilute to 50 ml. (For most accurate results, the residue should be fused with Na_2O_2 and combined with the main solution.) Pipette out 1.0 or 4.0 ml of the solution, add 1 ml of 5% sodium fluoride solution to mask iron(III) and complete the determination as above.

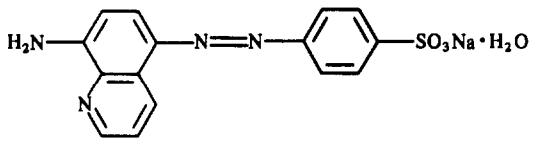

Fig. 1. Structure of SPAQ confirmed by data obtained from TG, IR and NMR spectra.

Determination of gold in ores. A 5–10 g amount of sample is transferred into a 200-ml beaker and 50 ml of concentrated hydrochloric acid is added. The beaker is covered and heated gently to dissolve the sample. About 50 ml of distilled water is added and the mixture is filtered. The residue is dissolved in *aqua regia* and heated twice to incipient dryness with distilled water to reduce the acidity. If the residue does not completely dissolve, fusion may be required as above. *Aqua regia* dissolution fails to extract all gold present in ores that have high sulphide content, high organic content, and some "Black Shale" materials. Also, it may be necessary to add sodium chloride to avoid precipitation of gold. The solutions are then transferred into 50-ml calibrated flasks and diluted to the mark with distilled water. Take 3 ml of the solution in a 25-ml standard flask, add 1 ml of 5% sodium fluoride solution, complete the determination as above.

RESULTS AND DISCUSSION

Reactivity of SPAQ

The reactivities of SPAQ with various metal ions at pH 4, 7 and 10 were investigated. In acidic medium, SPAQ reacts with gold(III), palladium(II), iridium(III), rhodium(III), platinum(IV), silver(I) and copper(II) to give coloured or precipitable complexes; in alkaline solution, the reagent is found to react with mercury(II), cobalt(II), nickel(II), gold(III) and palladium(II) to give coloured complexes, and reacts with copper(II) to give a fluorescent complex ($\lambda em/\lambda ex = 370$ nm/325 nm). The study suggested the usefulness of the synthesized SPAQ for the determination of gold, and there-

fore the conditions for this colour reaction were examined in subsequent studies.

Absorption spectra

Absorption spectrum of the reagent blank shows a maximum absorption at 459 nm. The Au–SPAQ–CTMAB system shows a maximum absorption at 605 nm, where the reagent blank gives almost zero absorption (Fig. 2). Hence in all instances the absorption was measured at 605 nm against a corresponding reagent blank.

Reaction conditions

The optimum pH for the Au–SPAQ–CTMAB system is in the strongly alkaline region and addition of 1.0–5.0 ml of sodium hydroxide solution to an approximately neutral test solution was found to give essentially a constant absorbance, addition of 2.5 ml is recommended. See below for order of reagent addition.

In the absence of surfactant or the presence of nonionic or anionic surfactants, the coloured system gives a low absorbance but the presence of a cationic surfactant, the absorbance increases markedly. Various cation surfactants enhance the absorbance in the following order: CTMAB > cetyl pyridinium bromide > tetradecyl dimethylbenzyl ammonium chloride > *N*-cetyl pyridinium chloride > tetradecyl pyridinium bromide. CTMAB is the best additive, 2.0–6.0 ml of 0.2% CTMAB solution gives good results; a volume of 3.0 ml is recommended.

In order to study the influence of cationic surfactants on the reaction of the metal ion with

the reagent, we synthesized a series of reagents which have a methoxyl (CH_3O-), acetyl (CH_3CO-), nitro (-NO_2), carboxyl (-COOH), or arsono-group (-AsO_3H_2) instead of a sulphonyl-group (-SO_3H_2) on the benzene ring, separately. The reactivity of gold(III) with the reagents which have the different substitute-groups was investigated. It was found that cationic surfactant only affects the complexation reaction between gold(III) and the reagents which have an anionic substitute-group (-SO_3^-, -AsO_3^{2-} or -COO^-), with an increase in the absorbance of the solution, but does not affect the reaction of the metal ion with the reagents which have a nonionic substitute-group (CH_3O-, CH_3CO- or O_2N-). This therefore, suggests the ion-association between the anionic group of the reagent and cationic surfactant is advantageous to the colour reaction.

Maximum and stable absorbance is attained with 2.0–5.0 ml of $2 \times 10^{-4} M$ SPAQ solution, and use of 4.0 ml is selected as optimal.

At room temperature, the maximum absorbance is obtained 10 min after the mixing of the components, and is stable for 48 hr at least. The order of addition of reagents seriously affects the system, however. Addition in the order Au(III), sodium hydroxide solution, CTMAB solution and SPAQ solution produces metal hydroxide precipitation. The order

SPAQ	605	1.48×10^5	Aqueous		This work

Au(III), CTMAB, SPAQ and sodium hydroxide solution gives the best result.

Analytical characteristics

A calibration graph was constructed under the optimum conditions described above. The system obeys Beer's law over the concentration range 0–50 μg of gold in 25 ml of final solution. The molar absorptivity and Sandell's sensitivity of the method are 1.48×10^5 l.mole^{-1}.cm^{-1} and 0.0013 μg cm^2, respectively. The standard deviation for ten replicate determinations of 20 μg of gold was 0.015 μg.

The composition of the complex was established by Job's method of continuous-variation and the molar-ratio method, and found to be 1:3 (metal:ligand).

Interferences

The influence of 34 diverse ions on the determination was examined. The ions tested were added individually to a solution containing 20 μg of gold(III). A maximum error of 2% in the absorbance reading was considered tolerable. The tolerance limit of foreign ions is given in Table 1. The interference from Fe^{3+} can be eliminated by masking with sodium fluoride, and the interference of Cu^{2+} and Hg^{2+} was eliminated by masking with EDTA. Thus the data in Table 1 indicate the reasonable selectivity of the method in the presence of associated ions.

Applications

In order to confirm the usefulness of the proposed spectrophotometric method, it has been applied to the determination of microamounts of gold in ores and anode slimes. The results are shown in Table 2, along with the value found by atomic-absorption spectrometry.

CONCLUSION

The comparison (in Table 3) of the SPAQ method with others shows the proposed method for spectrophotometric determination of gold is sensitive, simple and rapid, it does not require heating and extraction with organic solvents, and may be used to determine microamounts of gold in small samples directly in aqueous solution.

SPECTROPHOTOMETRIC DETERMINATION OF PLATINUM IN GLASS AFTER EXTRACTION WITH POLYURETHANE FOAM

DIPALI KUNDU and S. K. ROY*
Central Glass and Ceramic Research Institute, 196 Raja S.C. Mullick Road, Calcutta 700 032, India

(*Received* 21 *July* 1989. *Revised* 7 *August* 1991. *Accepted* 19 *August* 1991)

Summary—A spectrophotometric method has been developed for determination of trace amounts of platinum in glass. The method is based on the extraction of platinum(II) from 1*M* hydrochloric acid containing 0.2*M* stannous chloride and $4 \times 10^{-4}M$ dithizone onto polyurethane foam, elution with acetone (containing 3% v/v concentrated hydrochloric acid) and measurement of the absorbance of the eluate at 530 nm. Beer's law is obeyed up to 10.0 μg/ml Pt. The minimum platinum level in the eluate that can be determined by this method is 0.1 μg/ml.

Platinum vessels are often used when melting special types of glasses, which results in traces of platinum being introduced into the glass matrix and affecting the expected properties of the glass. Therefore, determination of platinum in such glasses is often necessary for evaluation and quality control. The most commonly applied spectrophotometric method[1] involves reduction of Pt(IV) to Pt(II) with stannous chloride in fairly concentrated hydrochloric acid medium and extraction of the yellow-orange Pt(II)–$SnCl_2$ complex with diethyl ether, ethyl acetate and similar solvents.

Numerous spectrophotometric methods are available,[2] in which various reagents have been used, including dithizone.[3–5] Marczenko and co-workers[6,7] have reported two methods for the separation and spectrophotometric determination of palladium and platinum by extraction with chloroform containing dithizone.

Bowen[8] pioneered the work on the extraction of metals from aqueous solution by polyurethane foam. Moore and Chow[9] have reported a method in which iridium and platinum are extracted from organic solvents with polyurethane foam. The extraction of platinum and palladium from thiocyanate solution with polyether-type polyurethane foam has also been reported.[10] Koch and co-workers[11–13] have made a critical study of the extraction of the Pt(II)–$SnCl_2$ complex by polyurethane foam. Here we describe the extraction of platinum(II) from aqueous medium containing stannous chloride and dithizone by polyurethane foam, and its use for spectrophotometric determination of platinum.

*Author for correspondence.

EXPERIMENTAL

Apparatus

A Spectromom 360 spectrophotometer was used.

Reagents

All reagents used were of analytical grade. The solutions were prepared with doubly distilled water.

Standard platinum solution. Dissolve 0.63 g of hexachloroplatinic acid in water, add 2 ml of 2*M* hydrochloric acid, dilute accurately to 250 ml and standardize the solution. Store the solution in a polythene bottle. Prepare a working solution (10 μg/ml Pt) by further dilution with water.

Stannous chloride solution. Dissolve 23 g of stannous chloride dihydrate in 16.7 ml of concentrated hydrochloric acid by heating, cool, and dilute to 100 ml with water.

Dithizone solution. Dissolve 0.060 g of dithizone in 100 ml of methanol and store the solution in a dark bottle. Standardize the solution by extractive titration with standard silver solution.[6]

Eluent. Add 3 ml of concentrated hydrochloric acid to 97.0 ml of acetone and store in a glass bottle. Freshly prepared solution should be used.

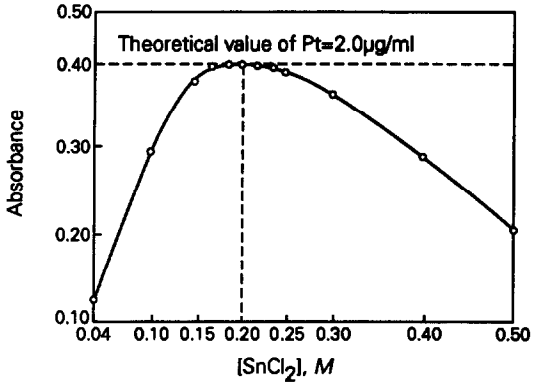

Fig. 1. Effect of stannous chloride concentration on the extraction of platinum dithizonate: $[H_2Dz] = 3.5 \times 10^{-4}M$, $[HCl] = 1.0M$.

Foam preparation[14]

Cut a sheet of polyether-based polyurethane foam into small cylindrical pieces (each ~2 cm long and ~0.5 cm in diameter, and weighing ~0.01 g). Soak the pieces in $3M$ hydrochloric acid for 24 hr, occasionally squeezing them with a plunger. Wash them several times, first with water, in a syringe, then with acetone, dry them at room temperature, place them in a vacuum desiccator for a few hours and finally store them in a plastic container in the dark.

Preparation of sample solution

Weigh accurately 1 g of sample (−200 mesh and dried at 110°) in a Teflon dish. Add 10 ml of concentrated hydrofluoric acid and 5 ml of concentrated nitric acid. Place the basin on a heated sand-bath and evaporate the acid until the residue is just moist. Repeat the acid treatment and evaporation twice more. Then add 5 ml of concentrated hydrochloric acid and evaporate the solution nearly to dryness, and repeat this twice more. Finally add 8.5 ml of concentrated hydrochloric acid and 20 ml of water, and heat to dissolve the residue. Transfer the solution to a 100-ml standard flask and dilute to the mark with water.

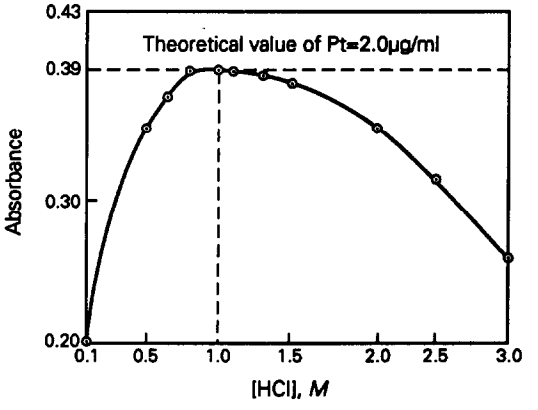

Fig. 2. Effect of hydrochloric acid concentration on the extraction of platinum dithizonate: $[SnCl_2] = 0.2M$, $[H_2Dz] = 3.5 \times 10^{-4}M$.

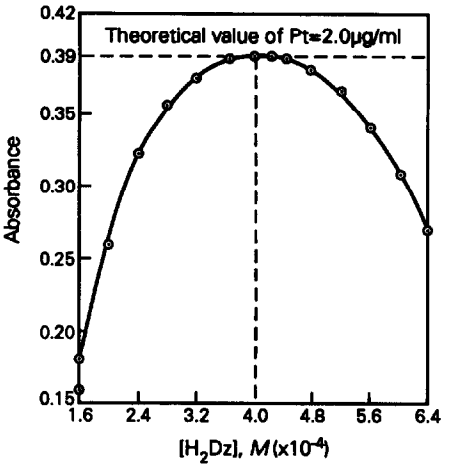

Fig. 3. Effect of dithizone concentration on the extraction of platinum dithizonate: $[SnCl_2] = 0.2M$, $[HCl] = 1M$.

Procedure

Transfer 5 ml of sample solution to a 50-ml glass beaker. Add 7.5 ml of $2M$ hydrochloric acid and 5 ml of $1M$ stannous chloride, dilute to 20 ml with water and after allowing the mixture to stand for 25–30 min, add 5 ml of the dithizone solution. Extract the platinum dithizonate onto the polyurethane foam by placing 6 pieces of foam in the solution. Squeeze the foam with a glass plunger 15 times every 15 min over a period of an hour. Transfer the foam chips into a disposable 5-ml plastic syringe. Wash the foam first with water to remove acid, then with ammonia solution (1 + 9) to remove excess of dithizone and finally with water, by repeated

operation of the syringe. Elute the platinum dithizonate in the same way, with small portions of the hydrochloric acid–acetone mixture (to give a total volume of 10 ml), transferring the eluate into a 10-ml standard flask. After allowing 1 hr for full colour development, measure the absorbance at 530 nm against a reagent blank to which the whole procedure has been applied.

Calibration

Prepare a calibration graph to cover the range up to 5 μg/ml Pt, by the same procedure.

RESULTS AND DISCUSSION

Platinum(IV) in 0.1–4*M* hydrochloric, sulphuric or perchloric acid does not form a dithizonate, nor does Pt(II) if produced by reduction of Pt(IV) with ascorbic acid or sulphite. With stannous chloride as the reductant, however, a brown-yellow Pt(II) dithizonate is rapidly formed and can be extracted with suitable solvents.[6] The stannous chloride first reduces Pt(IV) to Pt(II) and then reacts (as $SnCl_3^-$) with the latter to form a labile Pt(II) complex[6] which can react with dithizone to form a Pt(II)-dithizonate complex that can be quantitatively sorbed on polyurethane foam and eluted with acidified acetone under the optimized conditions.

To optimize the concentration of stannous chloride a series of 25-ml solutions containing 20 μg of Pt(IV), $4 \times 10^{-4}M$ dithizone, 1.0*M* hydrochloric acid and different amounts of stannous chloride were equilibrated with foam chips according to the procedure given. It was found (Fig. 1) that the yield of platinum dithizonate was maximal at 0.17–0.22*M* stannous chloride concentration, and hence formation of the platinum chlorostannate(II) complex was also maximal with this reagent concentration.

The hydrochloric acid concentration was similarly optimized, by equilibrating a series of 25-ml solutions containing 20 μg of Pt(IV), 0.2*M* stannous chloride, $4 \times 10^{-4}M$ dithizone, and various amounts of hydrochloric acid, with foam chips, and the extraction of platinum dithizonate was found to be maximal and quantitative at 0.8–1.1*M* hydrochloric acid concentration (Fig. 2).

The optimal concentration of dithizone was similarly found and was in the range $3.8–4.5 \times 10^{-4}M$ (Fig. 3). The decrease in absorbance at higher dithizone concentration is attributed to competition for adsorption sites on the foam.

In all these experiments, the equilibration time for quantitative extraction of platinum dithizonate by the foam was found to be 1 hr and the elution was quantitative only with acidified acetone and not with acetone alone. The optimum eluent composition was found to be 2.8–3.2 ml of concentrated hydrochloric acid diluted to 100 ml with acetone (Fig. 4).

This observation suggests that the sorbed species is not neutral $Pt(HDz)_2$, because if it were, acetone should be able to elute it. From the reports[11–13] that the species sorbed by polyurethane foam from a solution containing platinum(II) and stannous chloride is mainly $Pt(SnCl_3)_5^{3-}$ and the observation that a complex of this type is involved in the formation of $Pt(HDz)_2$,[6] it seems a distinct possibility that an anionic mixed-ligand complex such as $Pt(HDz)_2SnCl_3^-$ or $Pt(HDz)_2Cl^-$ may be the species sorbed. Furthermore, from the report

that $Pt(SnCl_3)_5^{3-}$ is not readily desorbed from the foam,[12] a hot ethanolic hydrochloric acid solution being required for desorption, it seems likely that the elution with acidified acetone involves ion-exchange and/or ligand displacement. A test for tin in the final eluate proved negative, which suggests that $Pt(HDz)_2Cl^-$ may be the species finally eluted from the foam. As the mechanism was not of direct interest in the work, however, the matter was not pursued further.

From the observations above, a spectrophotometric method has been developed for the determination of traces of platinum. Beer's law is obeyed from 0.1 to 10.0 μg/ml Pt. The molar absorptivity is 3.80×10^4 l.mole^{-1}.cm^{-1} at 530 nm.

Silver, mercury and copper also form dithizonates in acidic media and can be extracted with polyurethane foam, but silver does not form any dithizonate complex in the presence of chloride, so silver has no effect on the method. Mercury(II) and copper(II) are reduced to their lower oxidation state by stannous chloride, and it was observed that mercury up to 25 μg/ml and copper up to 0.5 μg/ml (Table 1) can be tolerated under the experimental conditions. However, copper(I) can be displaced from its dithizone complex by platinum and a decomposition time of 1 hr is sufficient for thus eliminating the adverse effect of up to 10.0 μg/ml Cu (Table 1). After the mixture has stood for 1 hr only the platinum complex is extracted onto the polyurethane foam.

The method developed has been applied to some synthetic and laser glass samples. The results are presented in Tables 2 and 3.

DEVELOPMENT OF FIELD SCREENING METHODS FOR TNT, 2,4-DNT AND RDX IN SOIL

THOMAS F. JENKINS and MARIANNE E. WALSH
U.S. Army Cold Regions Research and Engineering Laboratory, Hanover, New Hampshire, U.S.A.

(*Received* 13 *June* 1991. *Revised* 8 *September* 1991. *Accepted* 10 *September* 1991)

Summary—Simple field-screening methods are presented for detecting 2,4,6-TNT, 2,4-DNT and RDX in soil. A 20-g portion of soil is extracted by manually shaking with 100 ml of acetone for three minutes. After the soil settles, the supernatant is filtered and divided into three aliquots. Two aliquots are reacted with potassium hydroxide and sodium sulfite to form the red-colored Janowsky complex when 2,4,6-TNT is present or the blue–purple complex when 2,4-DNT is present. The third aliquot of the extract is passed through a strong anion exchange resin to remove nitrate and nitrite. Then the extract is acidified and RDX is reduced with zinc to nitrous acid, which is reacted with a Griess reagent to produce a highly colored azo dye. Concentrations of TNT, 2,4-DNT and RDX are estimated from their absorbances at 540, 570 and 507 nm, respectively. Detection limits are about 1 μg/g for 2,4,6-TNT and RDX and about 2 μg/g for 2,4-DNT. Concentration estimates from field analyses correlate well with laboratory analyses.

One of the most serious environmental problems facing the Army is the presence of soil contaminated with residues of high explosives and propellants at sites where the munitions were formerly manufactured, stored, used or demilitarized. The residues TNT (2,4,6-trinitrotoluene) and RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine) are most commonly encountered in munition-contaminated soils because these explosives were extensively produced and used by the military. A major impurity in production grade TNT[1] is 2,4-DNT (2,4-dinitrotoluene), which is a component of several propellant compositions. These compounds do not rapidly decompose in the environment, and, since they leach through the unsaturated zone in water, they pose an immediate problem to ground water.[2] Thus contaminated soil must be located and treated or isolated. Though laboratory methods for determining munitions residues in soil and water have been developed,[3,4,5] reliable field methods are also desirable. Use of field methods would enable efficient identification of zones of high contamination during initial surveys and the interface between clean soil and contaminated soil during clean-up. These methods can also be used for selection of samples for in-depth laboratory examination. The objective of this work was to develop rapid field methods based on simple color-forming reactions for the detection of 2,4,6-TNT, 2,4-DNT and RDX.

As early as 1891 Janowsky[6] observed that colored reaction products were formed when polynitroaromatic compounds reacted with alkali such as potassium hydroxide. Meisenheimer[7] and Jackson and Earle[8] independently proposed a quinoidal structure to explain this phenomenon. In general, Jackson–Meisenheimer anions for dinitroaromatics are blue to purple in color and those from trinitroaromatics are red.[9]

When sulfite ion is present along with hydroxide, addition of sulphite to the aromatic ring can also occur.[10] This anion is more stable than the anion formed from hydroxide alone,[11] with stabilities extended from about 30 min for the hydroxide[12] complex to at least six hours.[11]

When the base catalyzed reaction takes place in a ketone solution such as acetone (Janowsky reaction), addition of the carbanion can also occur, with resulting production of a Janowsky complex (Fig. 1).[13]

These reactions have been used analytically for a number of applications. Yinon and Zitrin[14] give examples of their use for forensic detection of TNT in post-blast debris. Heller *et al.*[15] used the reaction of strong base with TNT as the basis of a field kit for detection of low levels of TNT in water. The use of this kit was later extended to estimation of TNT in soil extracts.[16] In general, their kit provides a field method to detect the presence of TNT in soil, but is less useful for estimating concentration.[17] These

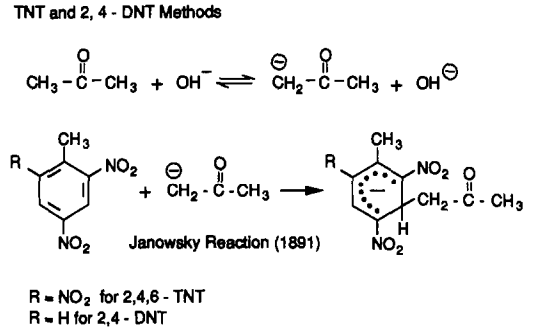

Fig. 1. Reactions used for colorimetric determination of 2,4,6-TNT and 2,4-DNT.

color-forming reactions have not been used to detect 2,4-DNT in soil.

Colorimetric chemical methods have also been developed for RDX for forensic applications.[14] These procedures generally rely on sequential reactions where RDX is first converted to nitrous acid with the Franchimont reaction (Fig. 2). The nitrous acid is used to nitrosate an aniline derivative such as sulfanilic acid and the resulting diazo cation couples to a naphthylamine to form a highly colored azo dye (Griess Reaction). Several pairs of reagents may be used to produce azo dyes.[18] A reagent containing procaine and *N,N*-dimethyl–naphthylamine was initially used for the procedure described in this paper. This choice was based on the work of Wyant,[19] who tested several reagents and found this combination to be best in terms of detection capability and shelf life. However, this liquid reagent was cumbersome to work with in the field since it is sensitive to sunlight. Also, we were concerned about the possible cancer risk associated with *N,N*-dimethylnaphthylamine. Subsequently, we found

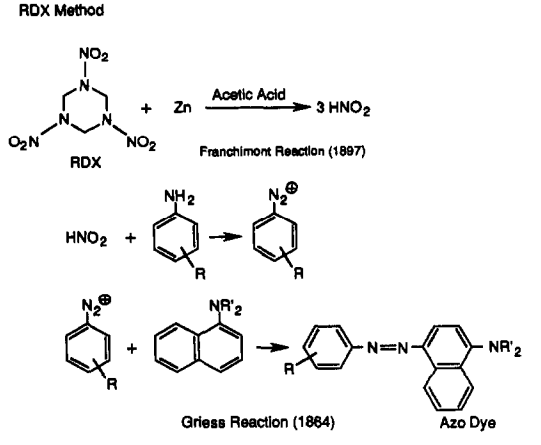

Fig. 2. Reactions used for colorimetric determination of RDX.

that a Hach NitriVer3 powder pillow, which is specifically designed for the determination of nitrite in the field, and distilled water can be substituted for the liquid Griess reagent. The powder pillow contains sodium sulfanilate, 4,5-dihydroxy-2,7-naphthalene–disulfonic acid disodium salt, potassium phosphate monobasic, potassium pyrosulfate and *trans*-1,2-diaminocyclohexanetetra acetic acid trisodium salt. The authors are not aware of a field method for RDX in soil based on the reaction sequence shown in Fig. 1.

Procedure

For these soil methods[20–22] about 20 g of wet soil is shaken with 100 ml of acetone to extract the munition residues, and the extract is filtered with a disposable syringe filter. The methods then depend on the production of colored reaction products (Fig. 3) when three aliquots of these extracts are subjected to two simple reaction sequences. For TNT and 2,4-DNT, portions of the extract are reacted with a strong base and sodium sulfite (Fig. 1). The main difference between the two procedures is the contact time with the reactants before filtration; 3 min for TNT and 30 min for 2,4-DNT. For extracts containing only TNT, a reddish colored Janowsky complex is produced. For those containing only 2,4-DNT (or 2,4- and 2,6-DNT), a bluish–purple complex is produced. If 2,4-DNT is present as a minor component and TNT is present at much higher concentration, DNT will not be detectable with this procedure. The DNT procedure is, however, capable of detecting the presence of DNT in soils contaminated with several types of single-based propellants in which 2,4-DNT is a major component. Several other polynitroaromatics also produce colored complexes and hence are potential interferences.[9] For RDX another portion of the extract is passed through a disposable anion exchange cartridge to remove any nitrate or nitrite. Then the extract is acidified and reacted with powdered zinc. This converts RDX to nitrous acid, which is detected by adding a Hach NitriVer3 powder pillow (Fig. 3) and distilled water. The development of a pink color is indicative of the presence of RDX or one of several other military explosives which are potential interferences (HMX, nitroglycerine, PETN or nitrocellulose).

The intensities of the colors produced by these reactions can be measured with a battery-operated spectrophotometer. The absorbances at 540 nm for TNT and 507 nm for RDX are

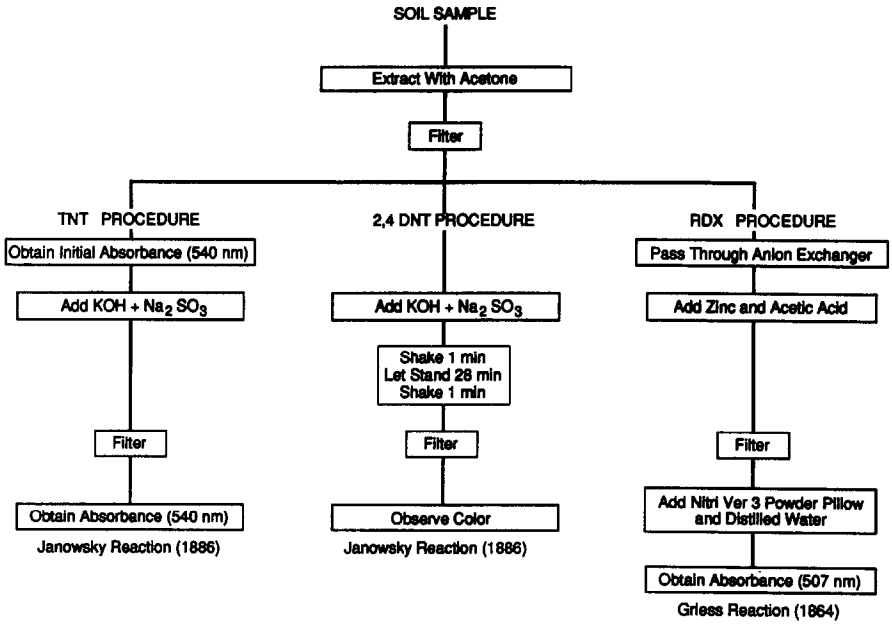

Fig. 3. Flow diagram for colorimetric field methods for 2,4,6-TNT, 2,4-DNT and RDX.

linearly related to concentration. Daily calibration is obtained with a single standard at 2 mg/l. Detection limits are about 1 μg/g for both TNT and RDX.[20,21] The linear range extends to 50 μg/g for TNT and 20 μg/g for RDX, respectively, for undiluted extracts. The absorbance for the 2,4-DNT complex (570 nm) is dependent on the water content of the extract, thus the method is only semiquantitative. The detection limit was 2 μg/g for a standard soil over a moisture content range of 10–50% (wet weight basis).[22]

EXPERIMENTAL

Analytical standards

Analytical standards for TNT and RDX were prepared from Standard Analytical Reference Material (SARM) obtained from the US Army Toxic and Hazardous Materials Agency (USATHAMA), Aberdeen Proving Ground, Maryland. Test solutions of 2,4-DNT were prepared from reagent grade 2,4-DNT (Eastman Organic Chemicals). Standard materials were dried to constant weight in a vacuum desiccator in the dark and standard solutions were prepared in HPLC grade acetone.

Soils

Soils used for laboratory extraction studies included field-contaminated and uncontaminated soils from a number of present and former military installations in ten different states. Interference tests utilized a humus-rich commercial potting soil obtained locally and uncontaminated soils obtained from a variety of military installations.

Soil extraction

Munition residues were extracted by manually shaking a 20-g soil subsample for 3 min with 100 ml of acetone and filtering the extracts with Millex-SR disposable syringe filters.

Generation of the Janowsky complexes for TNT and 2,4-DNT tests

For the TNT test, a pellet of potassium hydroxide and about 0.2 g of sodium sulfite were added to 25 ml of acetone soil extracts. Samples were manually shaken for 3 min, then filtered through a Millex-SR filter unit into a cuvette. The absorbance was measured at 540 nm. Unless the extracts contain a large amount of water, the solid reactants do not completely dissolve.

A similar procedure is used for the 2,4-DNT test except that two pellets of potassium hydroxide and about 0.75 g of sodium sulfite were added, the samples were shaken for one minute, allowed to stand for 28 min, and then shaken again for one minute prior to filtration. Absorbance was read at 570 nm.

Production of an azo dye from RDX

Acetone soil extracts were passed through an Alumina-A strong anion exchange cartridge

Table 1. Absorbance maxima and molar absorptivities for colored products from TNT, 2,4-DNT and RDX field screening tests

Analyte	Absorbance maxima (λ_{max})	Concentration of standard, *mg/l.*	Molar absorptivity $\times 10^{-4}$, *l. mole*$^{-1}$. *cm*$^{-1}$	Color
2,4,6-TNT	462	2.1	2.7	Red
	540		1.77	
2,4-DNT	570	2.9	1.12	Blue→purple
RDX	507	4.0	1.67	Pink

(Supelco, Inc) at 5 ml/min to remove any nitrate and nitrite which could be present. A 5-ml aliquot was acidified with 0.5 ml of glacial acetic acid and reacted with 0.3 g of zinc dust in the barrel of a syringe fitted with a disposable filter unit. This solution was rapidly filtered into a vial containing 20 ml of distilled water. The contents of a Hach NitriVer3 powder pillow were added. The sample is shaken briefly and allowed to stand for 10–15 min. Absorbance is read at 507 nm.

Spectrophotometers

Spectrophotometers were used to measure absorbance at various wavelengths in the visible region of the spectrum. A Coleman Junior II (Model 6/20) (bandpass 20 nm) was used for laboratory tests and either a Hach DR/2 or DR/2000 (bandpass 12 nm) was used in the field. Path length for the cuvettes was either 19 or 25 mm.

RESULTS AND DISCUSSION

Absorbance spectra and molar absorptivities

The visible absorbance spectra of the colored products produced from standards of TNT, 2,4-DNT and RDX (Figs 1 and 2) were obtained from 400–700 nm.[20–22] The absorbance maxima and molar absorptivities are given in Table 1.

The color-forming reactions used for these field screening methods are not specific for TNT, 2,4-DNT and RDX. Other polynitroaromatics such as 1,3-dinitrobenzene (DNB) and 1,3,5-trinitrobenzene (TNB) and polynitrophenols such as picric acid also give colored anions when reacted with strong base. During site clean-up activities, however, the ability to detect these other compounds as well as TNT and 2,4-DNT would be quite useful. Similarly, the same azo dye produced from the RDX test is also produced when other nitramines such as HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine) and tetryl (2,4,6-trinitrophenylnitramine) or nitrate esters such as NG (nitroglycerine), PETN (pentaerythritol tetranitrate) and NC (nitrocellulose) are treated under similar conditions. Table 2 lists munition-related compounds detected by these screening procedures.

Effects of variable concentrations of water in acetone extracts

In the field, soil extracts will be obtained by manually shaking 20 g of soil with 100 ml of

acetone. Since the soil will be moist in most cases, water will be a component of the soil extracts. In addition to a small amount of dilution, the presence of water may affect the kinetics of these reactions. To investigate this effect, standard solutions of TNT, 2,4-DNT and RDX were prepared with water added to simulate the extracts that would be obtained from soils with moisture contents ranging from 0–100% (wet weight basis). For all three analytes, little or no color formed when no water was present (Fig. 4). Over the range of moisture contents (10–75%) that should include the large majority of surface soils from potentially contaminated sites, absorbance varied little for the TNT and RDX solutions. However, absorbance for the 2,4-DNT standard significantly declined for water contents greater than 10%. Based on this variability, determinations for 2,4-DNT will be semi-quantitative while the corresponding procedures for TNT and RDX may be used quantitatively.

Reagent contact time

Experiments were conducted to determine if reagent contact time had an effect on measured absorbance. Contact time with potassium hydroxide and sodium sulfite was varied from 1 to 18 min for TNT and from 1.5 to 60 min for 2,4-DNT, after which solutions were filtered and absorbances measured. All experiments were conducted at laboratory temperature ($22 \pm 2°$).

Maximum absorbance for TNT was obtained after 3 min of continuous shaking.[20] Exposure to the reagents for periods longer than 8 min resulted in reduced absorbance at 540 nm. Thus a 3-min reaction time was selected.

For 2,4-DNT solutions, the time at which maximum absorbance was obtained depended on the water content of the solutions. In general, the absorbance obtained after 30 min of intermittent shaking was at least 90% of the maximum.[22] An additional experiment was performed to compare various shaking protocols. We found that if the solution was shaken initially for one minute, allowed to stand for 28 min, then shaken again for one minute just prior to filtration, the absorbance obtained was not significantly different from protocols that required more shaking.[22]

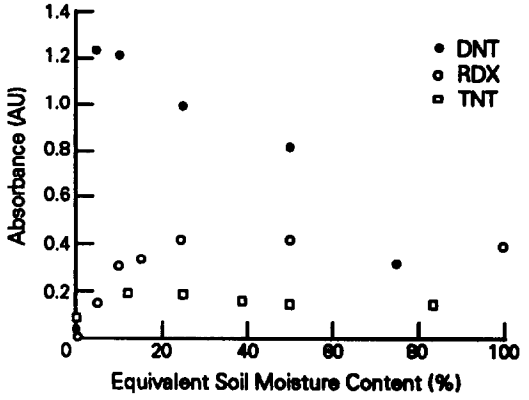

Fig. 4. Dependence of measured absorbance on water content of soil extracts.

Development of the azo dye from RDX is a two-step procedure. First, the RDX is reacted with zinc dust and acetic acid to produce nitrous acid. The nitrous acid then reacts with a Griess color reagent to produce the azo dye. The length of time the RDX is allowed to react with the zinc dust and acetic acid was found to be critical.[21] Reaction kinetics are fast when water is present in the acetone extract.[21] Contact times exceeding 30 sec resulted in less nitrous acid production, presumably because the nitrous acid was further reduced. Once the nitrous acid is produced, the solution must be filtered to remove the zinc dust. Because of the fast kinetics, this filtration is conveniently performed by reducing the RDX in the barrel of a syringe fitted with a disposable filter unit. Once the filtered solution is added to the color developing solution, full color development takes about 15 min.

For all three tests, the colors of the final solutions were stable for at least one hour.[20–22]

Potential interferences (other than munitions-related compounds)

Experiments with a variety of blank soils indicated that the color of acetone extracts will vary from colorless to yellow depending on the amount of humic matter present. Background absorbances for the yellow extracts is greatest over the range 400–500 nm,[20] and for this reason TNT determinations are made at 540 nm rather than at 462 nm, despite the lower molar absorptivity at 540 nm (Table 1). After soil extracts are reacted with potassium hydroxide and sodium sulfite for 3 min, the absorbance at 540 nm approximately doubles; thus an initial absorbance measurement must be made on aliquots of acetone extracts subjected to the TNT screening procedure and the DNT procedure as well, if used quantitatively. The initial absorbance is doubled and subtracted from the final absorbance to estimate TNT concentration.

As will be discussed later, heavy metal cations such as copper were found to interfere with 2,4-DNT determinations. These cations could form complexes with either the unreacted DNT[23] or the Janowsky complexes (Fig. 5).

For the RDX test, background absorbance from humic material is not a problem. Once the acetone extract is acidified and mixed with the color-forming reagent, the humic material precipitates and may be removed by filtration. Experiments with a wide variety of blank soils showed that background was negligible in all cases.[21]

Since the RDX test measures nitrous acid concentration, soil samples containing nitrite or nitrate would give a false positive if the nitrite and nitrate are not removed prior to reaction of RDX with zinc. This is accomplished by passing the extract through a disposable 3-ml strong anion exchanger (Supelco Alumina A). Experiments indicate that over 98% of the nitrate in a 9.8-mg/l. test solution was removed with this procedure.[21]

Extraction efficiency of field procedure

For a field method to provide accurate estimates of analyte concentration in the soil, the extraction step must be rapid. Previous extraction studies indicated that long extraction times were required when acetonitrile or methanol were used as the extraction solvent for nitroaromatics and nitramines.[24]

In order to determine how rapidly acetone will extract TNT, 2,4-DNT and RDX from soil,

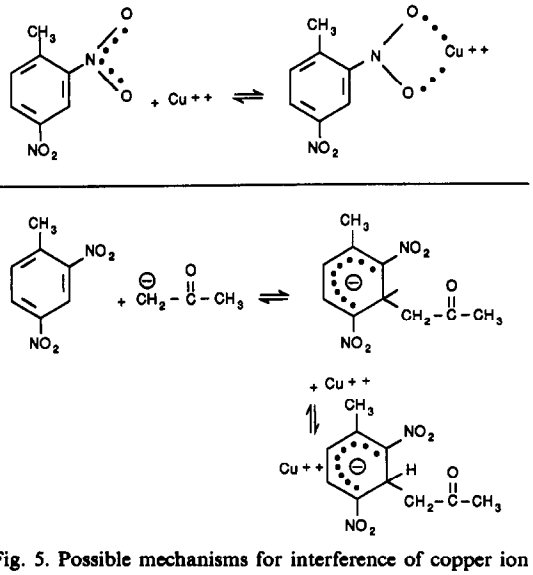

Fig. 5. Possible mechanisms for interference of copper ion with the 2,4-DNT method.

field-contaminated soil samples from 14 different sites were extracted with acetone, with 3 min of manual shaking. An aliquot of the extract was removed and the remaining soil/acetone slurries placed in an ultrasonic bath for 18 hr. Both sets of extracts (3 min and 18 hr) were analyzed by RP–HPLC as described elsewhere.[3,20] The results are presented in Table 3. The average recovery after 3 min of manual shaking with acetone for TNT was 96% and for RDX was 98% of that obtained with the more exhaustive procedure, indicating that acetone is an excellent extraction solvent with respect to its extraction kinetics for these two analytes over a wide concentration range.[20,21] The average recovery for 2,4-DNT was only 80.5%, with one low recovery (40.1%) for the soil with highest 2,4-DNT concentration.[22] Overall, the extraction efficiencies for all three analytes are sufficient for a field screening method.

Comparison of analyte concentration estimates

The field screening procedures were first tested in the laboratory with previously air-dried field-contaminated soils. Prior to extraction, the soils were wetted to simulate the moisture that would normally be present under field conditions. Estimates of analyte concentrations obtained by the colorimetric field procedure were correlated against those obtained by the standard RP–HPLC method. The colorimetric results for TNT were correlated with both the TNT estimate by HPLC and the sum of TNT and TNB. The best correlation was found with the sum of TNT plus TNB and resulted in a slope of 1.15 and an R^2 of 0.985 (Fig. 6). A paired t-test indicated that the concentration estimates for TNT from the colorimetric method and the sum of TNT and TNB by the HPLC procedure were not different at any level of significance.[20] Thus it appears that the colorimetric results are best represented as the sum of TNT plus TNB. The slope of 1.15 indicates that, in general, the colorimetric procedure gives a slightly greater estimate for TNT than can be accounted for by TNT and TNB (Fig. 6). One interpretation of these results is that other TNT degradation products such as trinitrobenzoic acid, trinitrobenzyl alcohol, and trinitrobenzaldehyde,[25] which are not identifiable by RP–HPLC analysis of the extracts, also form colored Janowsky complexes, thereby producing positive interference.

While we do not believe that the 2,4-DNT procedure can be used quantitatively in the field

since calibration depends on water content, we tested the method in the lab with air-dried soils wetted such that the moisture content was 10%. This moisture content was chosen since absorbance would be close to maximum, based on the previous experiment on the effect of water content. Only five soils were available that were contaminated primarily with 2,4-DNT. These soils were collected from explosive ordnance disposal sites. Results are given in Table 4. The field procedure severely underestimated the concentration of 2,4-DNT in one sample from Eagle River Flats, Alaska. This particular sample was also contaminated with copper (347 μg/g). As discussed previously, copper is a potential interferant since it may complex with 2,4-DNT or the Janowsky complex. Correlation between estimates for the remaining four samples was excellent (>0.999); however, the field procedure underestimated 2,4-DNT concentration by 15–25%.

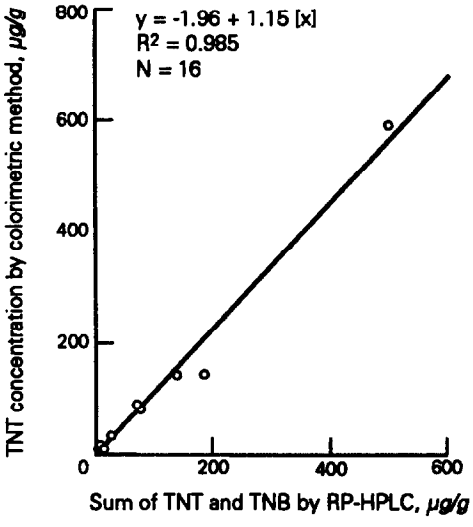

Fig. 6. Correlation of concentration estimates for TNT, using the field method with the sum of TNT and TNB by RP-HPLC.

To further explore the potential for false negatives, a series of soils from a number of Army installations that had been previously determined to be free of munitions residues were spiked with 2,4-DNT and analyzed by the field screening procedure. In all cases 2,4-DNT was easily detected, but as observed earlier, the measured concentrations were consistently lower than anticipated by up to 30%.[22] The magnitude of interference observed for the

Eagle River Flats sediment was not observed in any of these soils.

Eleven field-contaminated soils were used to compare the RDX concentrations estimated by the field method with those obtained by RP–HPLC analysis. The results from the field method were correlated with those obtained by the HPLC method for both RDX alone and the sum of RDX and HMX. The best correlation was obtained with RDX plus HMX and resulted in a slope of 0.9 and an R^2 of 0.995 (Fig. 7). Paired t-tests indicated that the estimates of RDX concentration obtained by the field procedure were not significantly different (0.05 significance level) from those obtained by the HPLC procedure for RDX alone or for the sum of RDX and HMX.

Estimation of detection capability

The reporting limits of TNT and RDX concentrations with these field procedures were established with the method of Hubaux and Vos[26] as adapted by the US Army Toxic and Hazardous Materials Agency.[27] The calculated certified reporting limits were 0.72 and 1.4 μg/g for TNT and RDX, respectively.

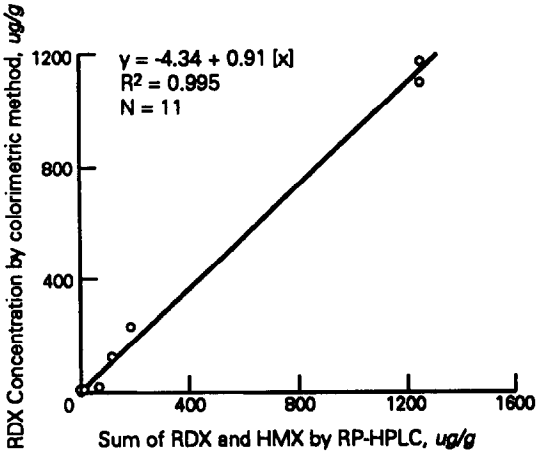

Fig. 7. Correlation of concentration estimates for RDX, using the field method with the sum of RDX and HMX by RP–HPLC.

The reporting limit for 2,4-DNT was 2 μg/g based on a certification procedure for methods that simply screen for contamination.[27] For the certification procedure four soils were spiked at a chosen concentration, in this case 2 μg/g. These soils, along with four soil blanks, were processed according to the method. After color development, four individuals were asked to distinguish the soil spikes from the blanks. Certification was performed three times, each at a different soil moisture content (10, 25 and 50% wet weight basis). In all cases, the soil spikes could be distinguished from blanks with 100% accuracy at 2 μg/g.

Field testing

Both the TNT and RDX procedures have been field tested and the concentration estimates obtained in the field compared with those obtained on separate subsamples processed by the standard RP–HPLC procedure.[3] Results are presented in Table 5.

The TNT procedure was initially tested at Umatilla Army Depot, Oregon. Since TNT concentrations were expected to be very high, a smaller subsample of soil was used and the extracts diluted before reaction with potassium hydroxide and sodium sulfite. This field test was conducted before the importance of reagent contact time was understood. Contact times of 10 min were used. Except for one sample, the results of laboratory analysis were higher than those obtained with the field method. This sample had a TNT concentration an order of magnitude higher than any of the other samples and was not included in this correlation. Correlation analysis was conducted comparing the field and laboratory results on the remaining 10 samples. This analysis resulted in an R^2 value of 0.865 which was significant at the 99% confidence level. The slope of the best fit relationship was 0.627, indicating the field procedure, on the average, gave results only about 63% as high as the laboratory results.

*Not corrected for moisture.
†NT = not tested.

Two factors may have contributed to the low results for the field method. First, an excessively long reagent contact time prior to filtration was used for the samples. Thus the absorbance would have been reduced relative to its maximum value. Second, the TNT concentrations in the Umatilla soil were much higher than those in the other field-contaminated soils tested, and the percentage extracted in the short extraction time used by the field method could have been reduced compared to the 18-hr extraction with acetonitrile used in the laboratory procedure. Nevertheless, the field results were encouraging for a first test.

The RDX method was field tested in Newport, Indiana. Correlation between estimates for all 11 samples yields a correlation coefficient of 0.95. However, the slope of the best fit relationship is only 0.36. This low value for the slope is strongly influenced by the last data point, where the estimates of RDX concentration were 4300 and 12,000 μg/g for the field and laboratory procedures, respectively. If the comparison is made with only those soils that had absorbances for the field procedure within the linear range (less than 0.7 absorbance unit) without dilution of the acetone extract, the R^2 value is 0.94 and the slope is 0.95. We feel this comparison is justified since for a field screening test we wish to distinguish the boundary between uncontaminated and contaminated soil, making accuracy at the lowest concentrations most important.

The TNT and RDX methods were also field tested at Eagle River Flats, Alaska, and Camp Shelby, Mississippi. Forty samples were screened at Eagle River Flats; all gave negative tests. The samples were subsequently analyzed by RP–HPLC and no explosive residues were detected in any sample. Some practical information was gained from this field test. Both potassium hydroxide and sodium sulfite are hygroscopic and should be protected from moisture under humid conditions by keeping reagent bottles tightly closed. Low ambient temperatures caused two problems. First, glacial acetic acid freezes at 16.6°. Second, reagent contact times for the TNT procedure had to be extended. The optimum time which depends on temperature was determined by observing the color development in a spiked sample.

At Camp Shelby, 22 samples were screened. Three samples gave positive indications for the presence of TNT, but no TNT was observed in these three samples by RP–HPLC. All three contained 2,4-DNT, as did some of the other samples, one of which was observed to give a purple color in the field TNT test. Nineteen of the soils gave a positive field screening response

for the RDX test. RDX was only detected by RP-HPLC in one of these soils. However, the RDX tests will also give a positive response for NC. NC is the primary component of single, double and triple base propellants. 2,4-DNT is an additive of single base propellant and its widespread presence at this site probably indicates the NC is present as well at even higher concentrations. In fact, propellant grains were observed scattered about the area. However, the soils were not analyzed for NC, since there is no reliable analytical technique to determine this compound in soil. So the explanation for false positives for the Camp Shelby samples must remain speculation. It should be pointed out that soils from this site were taken from areas which served as both an explosive ordnance disposal area and an artillery impact area and could have traces of a wide variety of munition compounds.

CONCLUSIONS

Simple field screening methods were developed for detecting 2,4,6-TNT, 2,4-DNT and RDX in soil. The procedure involves the extraction of munition residues from a soil subsample with acetone. Three portions of the extract are then reacted to two sets of reagents that form colors in the presence of nitroaromatics or nitramines. Concentration estimates obtained by this colorimetric procedure compared favorably with those obtained by the standard laboratory procedure. Field tests were conducted and the methods were found to be suitable for use under field conditions.

FIBER-OPTIC FLUOROMETER SIGNAL ENHANCEMENT AND APPLICATION TO BIOSENSOR DESIGN

CLAIRE KOMIVES and JEROME S. SCHULTZ*
Center for Biotechnology and Bioengineering, University of Pittsburgh, Pittsburgh, PA, U.S.A.

(*Received* 3 *March* 1991. *Revised* 13 *June* 1991. *Accepted* 16 *June* 1991)

Summary—Fiber-optic fluorescence spectroscopy is currently the focus of active research because of the high sensitivity of fluorimetry and capacity for remote analysis with optical fibers. It is shown here that a further increase in sensitivity can be achieved by placing a mirror within a few fiber diameters of the distal end of the optical fiber in a solution of flourophore. A potentially four-fold signal enhancement results which is due to an increase in the excitation intensity as well as the reflection of the collected emitted light. The enhancement is shown to be dependent on the pathlength and concentration of the fluorophore, as well as the numerical aperture and core diameter of the optical fiber. The limit of detection of the fluorometer, which incorporates a mirror, is nanomolar dye concentrations, with the maximum response in path lengths of dye that are in the order of 6 fiber diameters. This principle can be applied to the design of optical sensors for continuously monitoring the concentration of specific biochemicals, and a conceptual design for such a sensor is described. A mathematical model is presented which describes the fluorescence output signal of a fiber-optic flourometer which incorporates a mirror.

Fluorescence spectroscopic methods are well known as highly sensitive, specific techniques for chemical analysis. The coupling of fluorescence to fiber-optic technology offers the possibility of remote analysis. While fiber-optic fluorometers have only recently become commercially available, they seem to have a bright future as an analytical tool with a broad range of applications.

An obvious use of fluorescence for concentration measurements is that of fluorescently labeled compounds. A number of reviews have shown the versatility of this method for chemical sensing.[1-3] These have principally described sensors utilizing excitation or emission wavelength selectivity. Betts *et al.*[4] have demonstrated the multi-dimensional capacity of fiber-optic fluorescence analysis with the measurement of fluorescence lifetimes and other parameters. Their results showed a 10-fold loss in sensitivity due to the use of optical fibers over direct laser excitation.

An additional loss in sensitivity can result from certain sample configurations with which signal capture must be compromised for the benefit of other parameters, such as response time. Deaton[5] has shown that the effective pathlength (L_E) for a fiber-optic fluorometer with distal light collection is a function of the fiber radius (a) and numerical aperture (NA), and the refractive index of the external fluid (n_{ext}):

$$L_E = 1.303a \cot \Theta \tag{1}$$

where

$$\Theta = \sin^{-1} \frac{NA}{n_{ext}} \tag{2}$$

This presents a constraint on the sample configuration. The use of a graded-index lens at the distal end can provide a means of controlling the collection efficiency of the fiber.[1,6]

Our work has involved a method of increasing the signal with reduced sample volume, by placing a mirror at the distal end of the optical fiber in the solution of the fluorophore. White[7] demonstrated that using *two* concave mirrors in a fluorescence spectrophotometer can increase the sensitivity by a factor of 3.8. One mirror reflects the excitation light, effecting a double pass of light through the sample cuvette, and the second mirror reflects the emitted light, which is collected at 90° from the excitation light source. The use of a single optical fiber for both collection and transmission obviates the complex structure required by two such mirrors, and we will show that a *single* mirror can serve both purposes. A plane mirror was used in these studies to provide for ease of fabrication. We will show that the signal enhancement is

*Author for correspondence.

dependent on the distance of the mirror from the optical fiber, because of dispersion of the light rays.

Also, as a way of achieving a greater understanding of the enhancement, we developed mathematical models of the signal intensity as a function of distance of the optical fiber from a mirror or from a non-reflecting surface. A similar analysis for a fiber optic lever displacement transducer was developed by Cook and Hamm.[8] Their model is for the case of separate fibers for excitation and collection and is not for fluorescence based sensors. A preliminary and simplified model of the fraction of fluorescence collection which is a function only of the core diameter, w, and the pathlength of the solution of fluorophore, l, was done by Schultz.[9] This model only accounts for the centerline rays.

$$1 - \frac{l/w}{\sqrt{1 + (l/w)^2}} \qquad (3)$$

A similar approach to the analysis presented here was taken by Deaton.[5] His work, which did not include a mirror in the distal cuvette, involved an analytical solution of the power flux at the fiber face as a function of pathlength of fluorophore solution, fiber numerical aperture and core radius. A more complete analysis of the transfer function between the optical fiber and a fluorophore solution has recently been published by Modlin and Milanovich.[10] Figure 1 shows a comparison of the model described here as well as those of Schultz[1] and Deaton.[2] The principle difference between our model and that of Deaton is that ours can accomodate loss of light transmission due to absorption of light. At the low concentration used in Fig. 1(a), the light absorption is not significant.

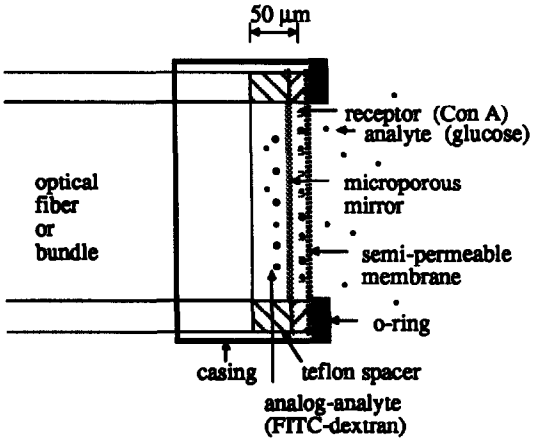

Fig. 2. Conceptual design competitive binding optical sensor with a porous mirror. Con A bioreceptor is immobilized in Region I. Bound fluorescently-labeled dextran in this region is shielded from the excitation beam by a porous opaque mirror. Displaced fluorescently-labeled dextran in Region II provides a fluorescence signal which increases with increasing glucose concentration.

In previous communications we have discussed the application of the concepts presented here to the construction of a sensor which utilizes a reflective surface to enhance the signal of a fluorescence-based sensor.[11,12] Previously, reflective surfaces to enhance response had only been reported for absorbance-based sensors.[13,14] Our concept for a distal cuvette sensor which functions analogously to that reported earlier (Mansouri *et al.*[15]) is illustrated in Fig. 2.

In this new configuration, the excitation light emanates from the optical fiber in the direction of the oncoming analyte, and therefore a means

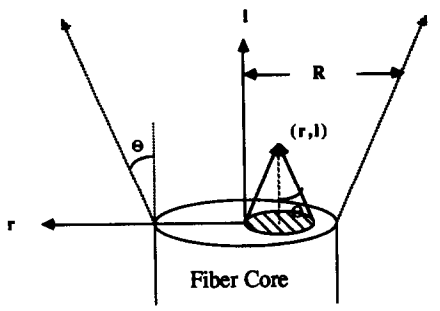

Fig. 3. Excitation from an optical fiber. Illumination from a point (r, l) is from light emanating from shaded region and at angles 0 to Θ as seen by the point (r, l).

of blocking its view of the dye bound to the receptor proteins is necessary. This is accomplished by placing a reflective porous barrier between the dye-bound layer and the optical fiber. This spacer permits the passage of analyte analog, while blocking the light. When the sensor is not in contact with the analyte, the fluorescent labeled analyte analog is bound to the immobilized receptors and the reflective membrane will return most of the excitation light to the optical fiber. When the sensor is placed in a solution of analyte, a competitive reaction takes place between the analyte and the analyte analog for the receptor sites. The free analyte analog is able to diffuse through the reflective membrane into the view of the optical fiber.

THEORY

The signal output of fluorescence-based optical sensors is due to emission photons which are captured and transmitted by the optical fiber to a detector and converted to an electrical signal. The intensity of the fluorescence is dependent upon the excitation intensity, which is not radially uniform in the case of an optical fiber. The rays emitted from a multimode optical fiber disperse in a cone of light. The intensity over

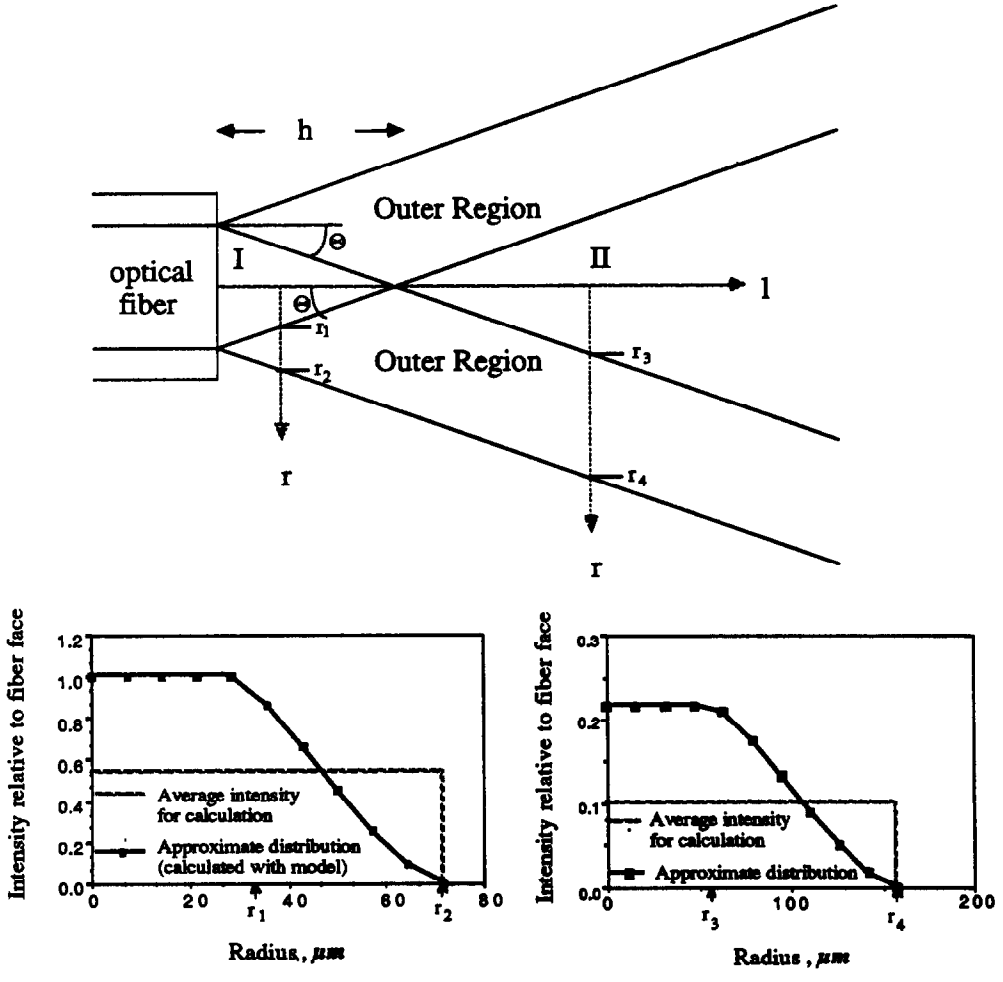

Fig. 4. Regions of different efficiency and excitation intensity.

any cross section of the light cone is assumed to be uniform. It is also assumed that the light intensity across the core of the optical fiber is uniform and any fluctuations in the refractive index are ignored. This assumption is fine for the model, because these fluctuations are irregular, and do not significantly affect the regional distribution.[16]

The amount of fluorescent light from any point (r, l) within the light cone which contributes to the fluorescence signal must be determined. A dye molecule at any point (r, l) can be excited by rays within a cone determined by the NA of an ideal optical fiber, as described in Fig. 3. Although the fluorescence emission is at 360 steradians from the molecule, only those within the same cone will contribute to the signal. Figure 4, adapted from the work of Deaton,[5] shows the regions of collection efficiency in the light cone. Within region I, the emission cone is complete, that is, the entire base overlaps the core of the optical fiber. Outside region I, only a portion of the base of the cone overlaps the fiber core. This simple concept is the basis for modeling the fluoresence signal with and without the mirror.

The same diagram that shows the regions of collection efficiency in the light cone can also be used to describe the actual light distribution in the cone, as described by Hirschfeld.[17] Region I has a uniform light distribution, with the intensity equal to that at the core of the optical fiber. The light is uniform across the cross section of region II, and it decreases in intensity with distance from the core, proportionate to the ratio of areas of the core circle and the emission cone base. Outside regions I and II, the intensity decreases radially to zero at the radius of the light cone; as shown in Figs. 4(a) and 4(b). These curves (solid lines) can be used to represent both the excitation intensity and the collection fraction distributions.

The collection efficiency of any point within the distal cone can be described by two overlapping circles, which is illustrated in Fig. 5. The shaded region is the overlap of the core face and the emission cone base. The core circle has a constant radius of a, and the emission circle has a variable radius of ρ. The distance between the centers of the circles is r. The angle, Θ, is assumed to be the same for the excitation and emission light cones for simplicity in the model. This is an approximation because the He–Ne laser light source is highly collimated while the fluorescence emission light is not. As a result,

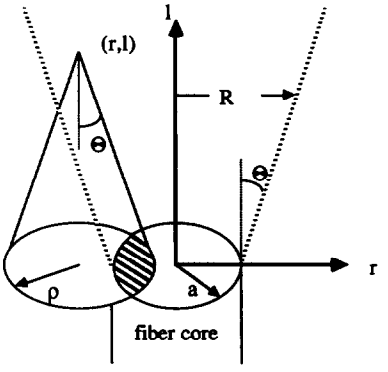

Fig. 5. Overlap of emission cone and fiber endface.

the emission cone is somewhat wider than the excitation cone, which has been described by Glass *et al.*[18]

By simple geometry, the following can be described:

$$\rho = l \tan \Theta \tag{4}$$

$$R = \rho + a \tag{5}$$

where R is the radius of the excitation cone at point 1, also defining ρ by equation (4). The length of the Region I cone, h is

$$h = \frac{a}{\tan \Theta} \tag{6}$$

The fraction of fluorescence energy returning to the fiber core which contributes to the output signal can be described by one of five sets of equations, depending on the point location which is illustrated in Fig. 6. The physical significance of regions III–V is the same, but the geometry for computation varies slightly. Regions III and IV are similar in that at least

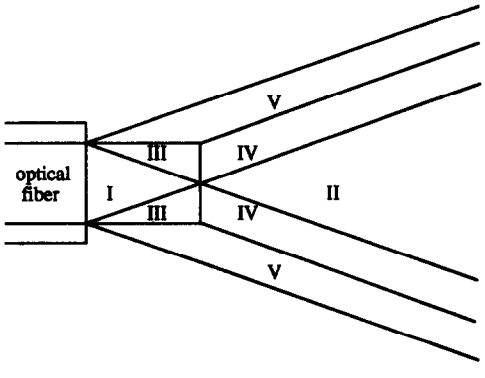

Fig. 6. Five regions for calculating collection fraction. The calculational algorithm used in the model is partitioned into five elements, one for each of these five regions.

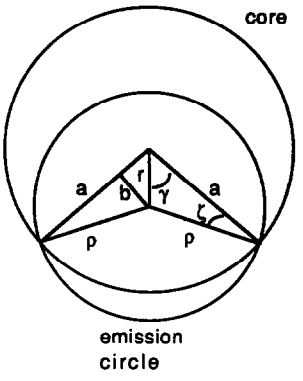

Fig. 7. Overlap region for calculation of region III collection fraction.

one of the centers of the circles are within the overlapped area. The equations are identical in format, with an exchange of a and ρ.

Figure 7 illustrates the overlapping circles. The fractional overlap in region III is calculated as,

$$\text{area}_{\text{region III}} = \frac{a^2\zeta + \rho^2(\pi - \gamma - \zeta) - ab}{\pi\rho^2} \quad (7)$$

where b is the perpendicular height of $\Delta a\rho p$. The angles, γ and ζ can be calculated from the law of cosines

$$\zeta = \cos^{-1}\left(\frac{a^2 + r^2 - \rho^2}{2ar}\right) \quad (8)$$

then,

$$b = r \sin\zeta \quad (9)$$

and

$$\gamma = \sin^{-1}(b/\rho) \quad (10)$$

Region V is similar in computation and is shown in Fig. 8. The same equations apply whether $a > \rho$ or $\rho > a$. The fractional area is calculated by

$$\text{area}_{\text{region V}} = \frac{a^2\gamma + \rho^2\zeta - rb}{\pi\rho^2} \quad (11)$$

Once again with the law of cosines,

$$\zeta = a\cos^{-1}\left(\frac{\rho^2 + r^2 - a^2}{2r\rho}\right) \quad (12)$$

Within region I, since the entire emission cone overlaps the fiber core, the fractional area is taken as unity for any increment which falls within the boundaries. In region II, as the entire core circle overlaps a portion of the emission cone, the area value is related to the ratio of areas of the two circles:

$$\text{area}_{\text{region II}} = a^2/\rho^2 \quad (13)$$

In each region, the collection fraction is a ratio of the overlap area to the area of the emission cone base.

The program is designed to calculate the fluorescence intensity as a function of distance of the fiber from the absorbing or reflective surface, based upon experimental values. The input values are NA, a, power (P), n_{ext}, molar absorptivity (ϵ), fluorescence quantum efficiency (ϕ_f), and dye concentration (c). Aside from ϵ and ϕ_f, which are provided with the dye, the others are measured experimentally.

A trapezoidal type algorithm is used with cyclindrical coordinates. Figure 9 illustrates a finite incremental segment for summation. Differential distance increments Δl are used as 10 μm, which is not greater than one tenth of the core diameter of the fibers used. The radius is divided into ten sections, the size of which increases with distance from the core because the total radius, R, over the cross section of the light cone increases with distance. For simplicity, the model curve for an absorbing surface will be referred to as the incident curve, because the

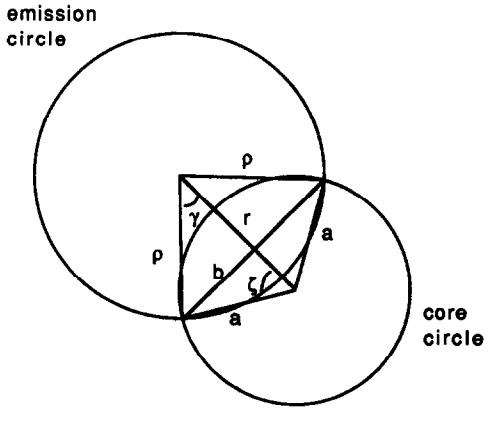

Fig. 8. Overlap region for calculation of region V collection fraction.

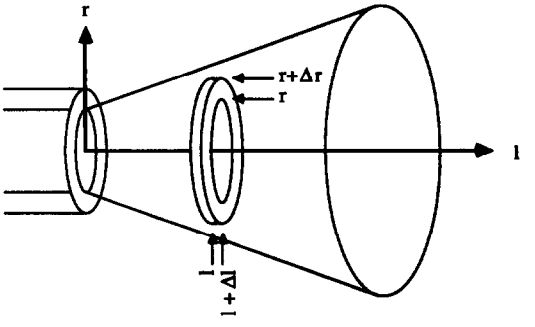

Fig. 9. Finite volume segment for summation in the model.

signal is due only to the light that is incident on the mirror or absorbing surface. The model curve for the case with a mirror will be referred to as the enhanced curve.

The entire incident curve, from $l = 0$ to the mirror, at a distance, D, is calculated each time D is incremented. When D is at the final distance, the values are stored in an array for output. The initial calculations are of constants dependent on the input variables.

$$\text{initial intensity } I_0 = P/\pi a^2 \tag{14}$$

$$\text{cone half angle } \Theta = a \sin(\mathrm{NA}/n_{\text{ext}}) \tag{15}$$

Because the model integrates by stepping through increments of 1, the reduction in light intensity at each increment can be determined by the light transmitted. The factor, α, is defined for a given dye and concentration, using the distance increment, Δl, as the pathlength:

$$\alpha = 10^{-\epsilon c \Delta l} \tag{16}$$

The length of region I cone, h, is found from equation (6).

The outermost loop is for setting D, which is initialized at 10 microns. For each value of D, the initial intensity of the incident ($I_{0,\mathrm{f}}$) and reflected ($I_{0,\mathrm{F}}$) cones is set.

$$I_{0,\mathrm{f}} = I_0 \tag{17}$$

$$I_{0,\mathrm{F}} = I_0 \alpha^{(2D-10)/\Delta D} \tag{18}$$

At each pathlength, the excitation intensity is found from the power at the fiber face divided by the area of the cross section of the light cone.

$$I_0(l) = P/\pi R^2 \tag{19}$$

In the case of the incident cone, the light intensity begins at I_0 and decreases with distance from the fiber core by the factor, α. The reflected intensity increases with distance from the core, by the same factor, α, with each increment. The intensity of the reflected cone at the core is less than the initial incident intensity by a factor of α raised to the power of twice the number of increments between the core and the mirror, as expressed by equation (18). The summations of the fluorescence signal contributions Δf and ΔF, of the incident and reflected cones, respectively, are set to 0.

At each distance, $1 + \Delta l$, the calculation begins with the incident cone, by determining $\rho(1)$ and R(1), with equations 4 and 5. The size of the radial increment is one tenth of the total radius of the cone.

$$\Delta R(l) = R(l)/10 \tag{20}$$

and the radius of the region I, II cone

$$r_{\text{regionI,II}}(l) = |a - \rho(l)| \tag{21}$$

Beginning with $r = \Delta R$, the program determines which of the 5 regions the point is in, considering first the incident cone. The program tests for region I as

$$a - \rho \leqslant 0 \tag{22}$$

and for region II as

$$a - \rho > 0 \tag{23}$$

The boundaries for the other regions

$$\text{region III } l < h \text{ and } r \leqslant a \tag{24}$$

$$\text{region IV } l \geqslant h \text{ and } r \leqslant \rho \tag{25}$$

$$\text{region V } l \leqslant h \text{ and } r > a$$

$$\text{or } l > h \text{ and } r > \rho \tag{26}$$

At each radius an incremental radial area, ΔA, is calculated

$$\Delta A = 2r\Delta R - \Delta R^2 \tag{27}$$

and both the excitation intensity and collection fraction are considered uniform in this area, with the excitation intensity being

$$\Delta I(l) = I_0 \frac{a^2}{R^2} \tag{28}$$

The fluorescence intensity is calculated with equation (29)

$$\Delta L_f = [1 - \alpha]\phi_f \Delta I(l) \text{area}_{\text{region}x} \tag{29}$$

and the contribution to the power at the fiber face which is transmitted to the detector,

$$\Delta f = \Delta I_f \Delta A \Delta l \tag{30}$$

The value is stored in an array, as well as the collection fraction for each of the 10 radial increments.

Placing a mirror in the field of view of an optical fiber results in a double pass of the excitation light as well as the reflection of the fluorescence emission light. The reflected cone is shown in Fig. 10. The additional signal produced by reflecting the light can be modeled by considering the contributions of a second, virtual molecule at a point $(r, 2D - l)$. In fact, by evaluating a parameter,

$$L = 2D - l \tag{31}$$

the equations used to calculate the light distribution without the mirror are repeated,

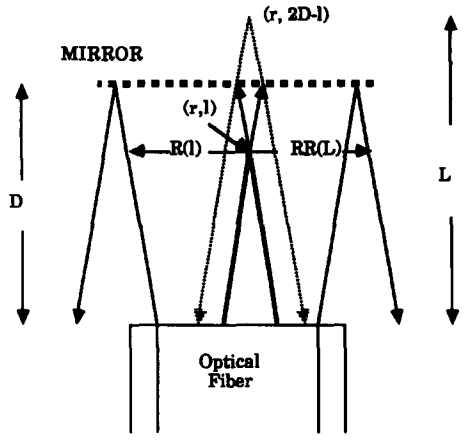

Fig. 10. Distal light distribution with a mirror.

substituting L for l. The only other difference is the number of intervals for calculation. In order to sum the contributions generated with and without the mirror, the corresponding areas to which the values refer must be identical. Since the radius of the reflected cone is larger than the radius of the incident cone, more intervals are needed in the former case

$$\Delta RR(L) = \Delta R(l) = \frac{R(l)}{10} \tag{32}$$

so the number of increments,

$$\text{index} = \frac{RR(L)}{\Delta RR(L)} \tag{33}$$

The other parameters are determined analogously to equations (4), (5) and (21) as follows:

$$\rho(L) = L \tan \Theta \tag{34}$$

$$RR(L) = \rho(L) + a \tag{35}$$

$$r_{\text{region I,II}}(L) = |a - \rho(L)| \tag{36}$$

The total enhanced signal curve is a sum of four contributing sources, as outlined in Fig. 11. The four curves represent the (a) direct excitation (top curve), and (b) the three components which are a result of the mirror. The lowest curve shows the additional fluorescence collected directly by the optical fiber due to the increased intensity of the excitation light reflected from the mirror. The middle two curves are nearly identical. One represents a contribution of the reflected excitation light and the fluorescence which is reflected back off the mirror before being collected by the optical fiber, and the other is due to fluorescence reflected off the mirror which is a result of direct excitation light. The three lower curves show a peak value which demonstrates the optimum of the dispersion of the excitation light and the increase in intensity due to the mirror.

This summation is accounted for in the model by using the sum of the incident and reflected light as the total excitation intensity:

$$\Delta I_{\text{total}} = \Delta I(l) + \Delta I(L) \tag{37}$$

and the sum of the two fractions of collection as the total contribution to the signal:

$$\text{area}_{\text{total}} = \text{area}_{\text{region } x}(l) + \text{area}_{\text{region } x}(L) \tag{38}$$

The enhanced fluorescence signal is then found

$$\Delta F = [1 - \alpha]\phi_f \Delta I_{\text{total}} \text{area}_{\text{total}} \Delta A \tag{39}$$

With the enhanced curve, moving the mirror affects the intensity distribution at each cross section. Therefore, it is necessary to sum both

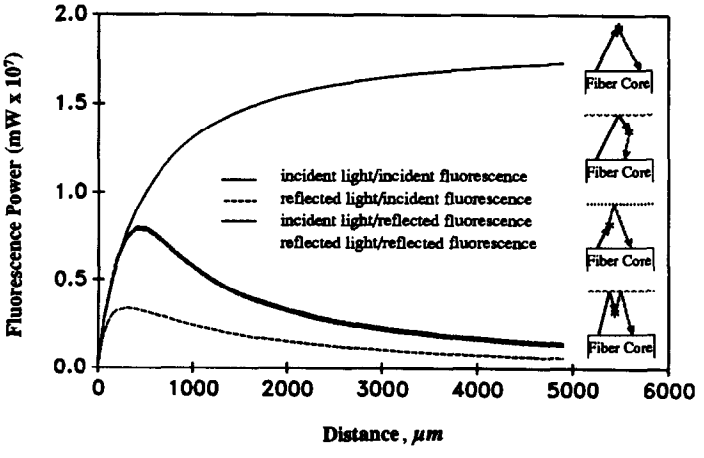

Fig. 11. Calculation of four sources of emitted light contributing to the enhanced signal.

across the radius and through the entire distance of fluorophore for each point of the curve.

$$F_{\text{enhanced curve}} = \sum_{l=0}^{D} \sum_{r=0}^{RR} \Delta F \qquad (40)$$

In the case of the incident curve, the values are summed as the calculation progresses away from the fiber core, because moving the fiber away from the black surface does not change the light distribution. The source code is a C program available from the authors.

EXPERIMENTAL

Reagents

The dye is cyanine based Cy5-18 acid obtained from Dr. Alan Wagonner at Carnegie Mellon University. The molar absorptivity is reported to be approximately 200,000 $1 \cdot \text{mole}^{-1} \cdot \text{cm}^{-1}$ at 648 nm, which was used as the basis for concentration measurements. The fluorescence quantum efficiency of the dye is 0.25. The dye was chosen because of its long excitation wavelength which results in very low ambient light interference, as well as reduced contributions to background from glass optical components. In addition, the excitation wavelength is in a range that permits the use of light emitting diodes (LED's) and other low cost light sources. The dye is completely water soluble, to make it particularly appropriate for use as a label for bioassay. Four concentrations of dye were used in the experiments which were 10^{-3}, 10^{-4}, 10^{-5} and $10^{-6}M$.

Apparatus

The schematic of the experimental set-up is shown in Fig. 12. The light source used was a Uniphase Model 1303p helium neon laser with a 2.0 milliwatt output. Filters were obtained from Omega Optical (Brattleboro, VT). Only one focusing lens, with a numerical aperture of 0.4 was used as part of the coupler which is a Newport F-915T multimode coupler. The detector was an Oriel 70680 photomultiplier tube (PMT) with an accompanying Model 7070 power supply/current amplifier. The signal was monitored with a Standford SR510 lock-in amplifier. Optical fibers were obtained from General Fiber Optics.

Procedure

Three fibers were tested and the apparent NA of each fiber was determined by measuring with a micrometer the diameter (dia) of the circle of light at a given distance (l) from the fiber endface aimed at a smooth surface in air. The diameter and distance translates into the fiber NA:

$$\text{dia} = 2(l \tan \Theta + a) \qquad (41)$$

and

$$\sin \Theta = NA/n_{\text{ext}} \qquad (42)$$

where a is the core radius of the optical fiber and n_{ext} is that of air which is 1.0. In all cases the apparent NA was less than the manufacturer specifications. An attempt at mode scrambling was made by subjecting the fiber to

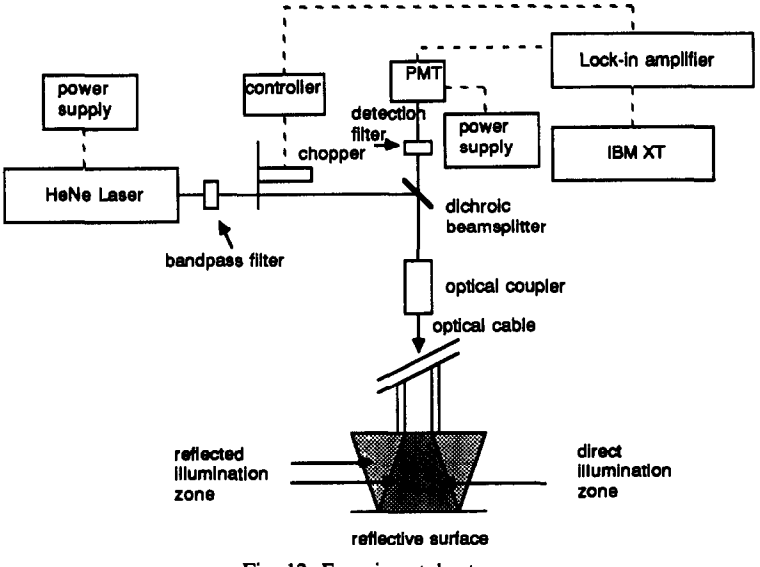

Fig. 12. Experimental set-up.

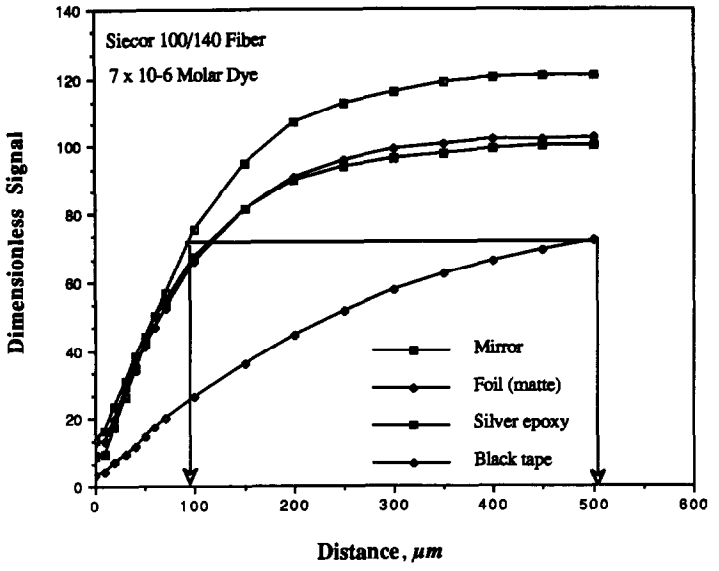

Fig. 13. Comparison of signal enhancement with various reflective surfaces and a black surface. Siecor 100/140 silica fiber, dye concentration $-7 \times 10^{-6} M$.

microbending, but the result was an unsteady power throughput.

The intensity *vs.* distance curves were acquired by measuring the PMT output with the fiber first placed in contact with the non-reflecting surface or mirror, which was then moved away from the fiber in defined increments by using a translation stage (Newport Model 416-B metric stage). In order to assure that the fiber initially was exactly at the surface, the fiber end was viewed through the side of the container of dye, using a horizontal 50× microscope. At each position the signal intensity was measured in milliwatts, but in order to compare the behavior of the system for different concentration levels, relative signal intensities are reported in most figures. The relative intensity is obtained by normalizing each intensity by the asymptotic leveling off intensity obtained when the surface was at very large distances from the fiber. These final intensities are given in millivolt units in each of the figures. A front surface silver mirror was used for reflecting the light, and black plastic electrical tape was used as the non-reflecting surface.

To determine the effect of the optical quality of the mirror on the signal enhancement, one experiment with dull aluminum foil and another with a silver epoxy coated surface was performed. The results as shown in Fig. 13 indicate that for distances less than about 60 μm, the quality of the reflector is not important. For each fiber tested, the signal as a function of distance in plain water was measured to estimate the contribution to background by the optical fiber. A comparision of the background values can be found in Fig. 14. In spite of the increase in background at very short pathlengths with the mirror in place, the limit of detection for the fluorometer was in the order of nanomolar concentrations of the dye.

RESULTS AND DISCUSSION

The experiments were performed to evaluate the effect of optical fiber numerical aperture and diameter on the signal enhancement. The goal was to reach a qualitative understanding of these factors to guide the selection of fibers for specific applications such as the use in

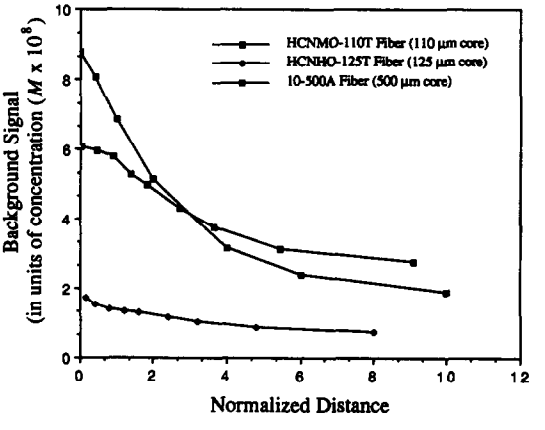

Fig. 14. Comparison of background signal values for various optical fibers. Dimensionless distance = actual distance/fiber diameter.

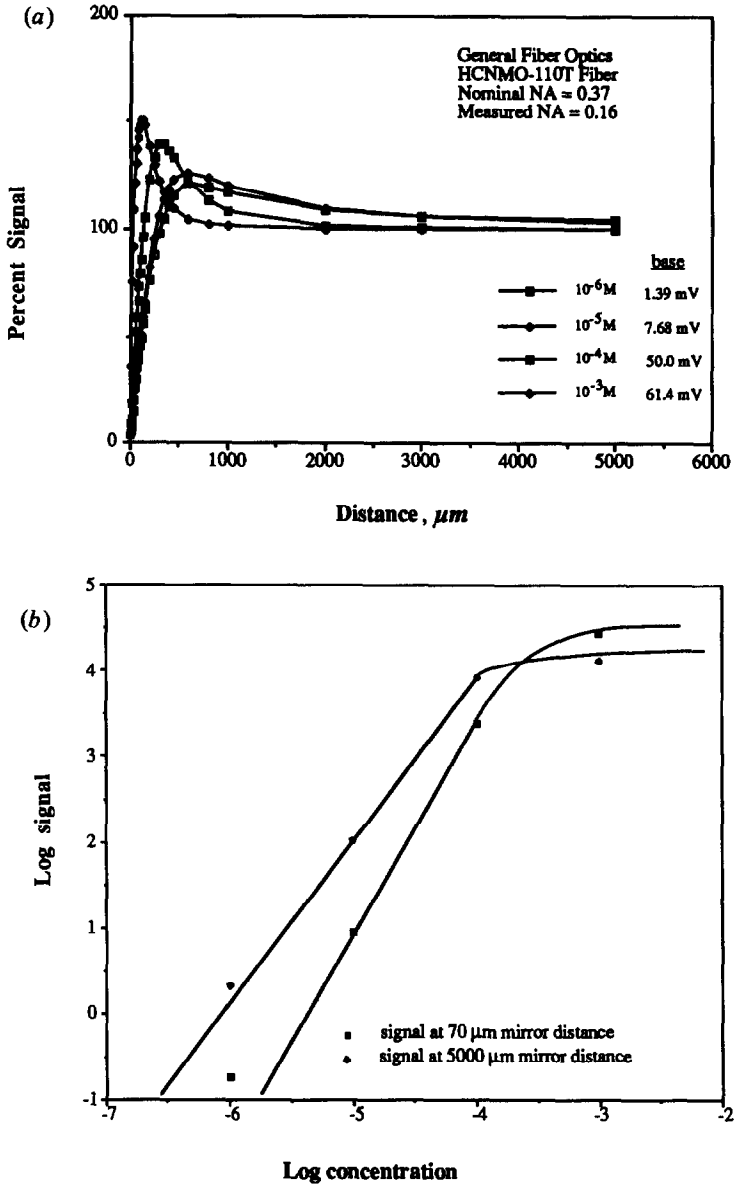

Fig. 15. (*a*) Percent signal as a function of fiber/mirror separation. "Base" signal is the actual PMT output when the mirror is placed 1 cm from fiber surface. (*b*) Log signal *vs.* log concentration.

new sensor configurations. Nominal numerical apertures chosen were 0.37 and 0.48, based on the manufacturers specifications. A silica core fiber with a numerical aperture higher than 0.48 was not available in 100 μ core diameter, so for a 0.58 NA, a 500 μm-plastic core fiber was tested. The actual measured cone half angle was used to calculate an apparent numerical aperture for the fiber with equation (41). The low measured apparent numerical apertures (0.16, 0.08, and 0.11, respectively) were likely to be a result of the highly collimated He–Ne laser light source, in addition to the short lengths of fibers that were tested (<10 meters).

Experimental results

Figure 15 shows the normalized signal plotted as a function of distance of the fiber from the mirror, for the Fiberguide Industries HCNMO-110T hard plastic clad silica fiber. The base signal values listed in the index of the figure are the actual PMT readings when the mirror is placed 1 cm from the fiber surface. Also in this figure is a plot of the log of the base signal values and of the signal values at 70-μm distance as a function of the log of the concentration. This shows the increase of the nonlinearity as the pathlength of the dye increases, which is due to the high extinction coefficient of the dye

(200,000). The response for all the fibers described similar curves, as the apparent NA's were similar. The exception was the response for the 500-μm fiber for which the response did not level off until about 20-mm separation distance between the fiber and mirror because the effective pathlength of a fiber-optic fluorometer increases proportionately with core diameter as described in equation (1).

The degree of absorption of incident light and self absorption of the fluorescent light is most visible at the high concentrations of dye. The base signal values can be compared for the different concentrations with the same fiber, but cannot be compared from fiber to fiber, as the output power and signal attenuation varies from fiber to fiber. The use of relative values for comparing the experimental results is necessary for several reasons. Physical factors such as variations in power loss across the filters, the fiber transmission efficiency and light coupling efficiency at the proximal end of the fiber are factored out of the relative responses.

Employing a mirror for enhancing a signal with a fiber-optic fluorometer will be the most advantageous for applications which require a small sample volume. From the model curves (Fig. 11), it can be seen that a potentially 4 × enhancement can be achieved at very short distances (<2 fiber diameters) and better than 3 × enhancement expected until about 4 fiber diameters. At high numerical apertures, the curves would level off and the degree of enhancement would reduce at smaller mirror displacements, because of higher dispersion of the light rays.

Signal enhancement with the mirror in place is dependent on concentration. Because the illumination and collection efficiency are the greatest closest to the fiber endface, the steepest response curves were obtained with higher solution concentrations showing the highest absorbance. Distances of the peak enhancement are shorter in high concentrations because of the reduced pathlengths due to higher light absorption. As a result, the degree of enhancement due to the mirror is indirectly related to the dye concentration.

Comparison of experimental results with mathematical model

Figure 16 shows a comparison of experimental results with model calculations (solid line) for the General Fiber Optics HCNHO-125T fiber. The dotted line represents the model calculations at a higher assumed numerical aperture of 0.12, which shows a closer resemblance to the experimental results. Figure 17 shows a similar comparison for the General Fiber Optics 10–500A fiber.

The use of the measured apparent numerical aperture in the model gives a much closer prediction of the experimental data than is obtained with the manufacturers rated numerical aperture for the fiber. The same approach was used by Deaton.[5] The measured numerical aperture is only valid for the excitation light cone, but is used in the model for the collection solid angles as well. The discrepancy between the experimental and model fit numerical apertures is probably due to this assumption.

Figure 18 shows a comparison of the experimental results with the model prediction with the General Fiber Optics HCNHO-110T fiber at dye concentrations of $10^{-4}M$ 100× greater

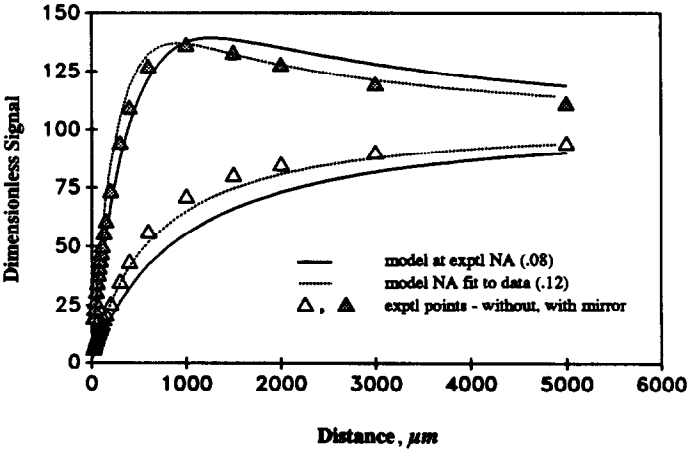

Fig. 16. Percent signal *vs.* distance from optical fiber. General Fiber Optics HCNHO-125T fiber dye concentration $10^{-6}M$, nominal NA 0.48.

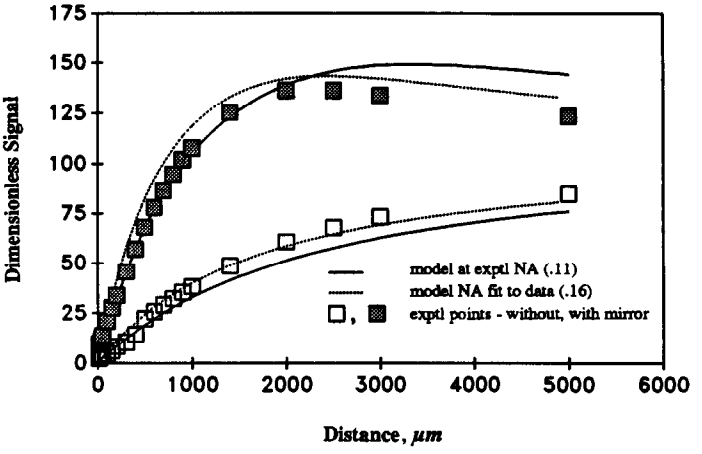

Fig. 17. Percent signal *vs.* distance from optical fiber. General Fiber Optics 10–500A fiber, dye concentration $10^{-6}M$, nominal NA 0.58.

than the previous two examples. The model curve was calculated with the measured numerical aperture of 0.16, rather than the manufacturer's nominal rated NA of 0.37. This example shows that the model is the poorest at high dye concentrations, as is expected considering that self-absorption is not accounted for in the calculations. Self-absorption is particularly significant with this dye, because of the overlap of the excitation and emission curves,[19] which at high dye concentrations affects the effectiveness of the mirror to reflect light back into the fiber.

CONCLUSION

Placing a mirror at the distal end of an optical fiber, which is used for excitation and collection of fluorescent light, results in an enhancement in the detected signal. This enhancement is potentially four-fold because of the increased excitation light as well as the reflection of the fluorescence emission light. Experimentally, a better than three-fold enhancement was achieved. The enhancement is higher for low concentrations of fluorophore, where the reduction of light transmission due to absorption is less significant. The principle can be used for constructing a continuous, reversible affinity sensor which may show some improvements over other designs.

A mathematical model was developed that successfully described the fluorescence signal as a function of distance of a mirror and non-reflecting surface from the optical fiber. A general, qualitative agreement with the data is achieved. While the model cannot be used *a priori*, it can provide a reliable estimate of trends once some fluorescence measurements are

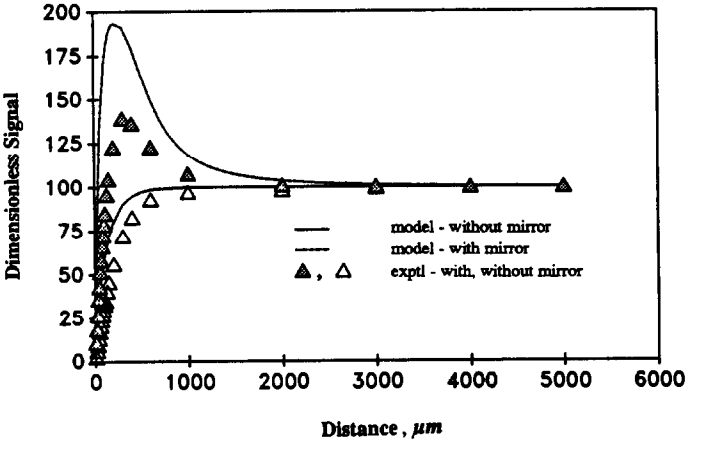

Fig. 18. Percent signal *vs.* distance from optical fiber. General Fiber Optics HCNMO-110T fiber, dye concentration $10^{-4}M$ nominal NA 0.37.

made with a specific fiber-dye combination and an apparent numerical aperture can be measured. The model accounts for the dependence of the enhancement on the diameter and numerical aperture of the fiber, as well as the concentration, fluorescence quantum efficiency, and molar absorptivity of the dye.

NOMENCLATURE

Symbol	*Explanation*
a	fiber radius (cm)
$\text{area}_{\text{region } x}$	collection fraction based on the ratio of the overlap area of emission cone base and fiber core divided by the area of the emission cone base
ΔA	incremental area for summation in sample volume (cm^2)
c	concentration (moles/liter)
D	fiber/mirror separation (cm)
F	power of fluorescence at fiber face (milliwatts)
Δf	incremental power at fiber face (milliwatts)
F_T	flux of fluorescence power at fiber face (milliwatts)
I	intensity in light cone (milliwatts/cm^2)
ΔI	incremental intensity (milliwatts/cm^2)
l	axial distance from optical fiber (cm)
L	distance of virtual molecule from fiber (cm)
L_E	effective pathlength (cm)
NA	numerical aperture
n_{ext}	refractive index of external fluid
P	light power emanating from optical fiber (mW)
r	radial variable of light cone
$r_{\text{region,I,II}}$	radius of region I,II
R	radius of light cone (cm)
RR	radius of reflected light cone (cm)
ΔR	finite radial increment
x	variable to denote one of region I–V
V	sample volume
w	fiber diameter (cm)
α	fraction of light transmitted
ϵ	molar absorptivity (liters/mole/cm)
ϕ_f	fluorescence quantum efficienty (dimensionless)
γ	angle of triangle $\Delta a\rho r$
ρ	radius of emission cone base (cm)
Θ	half angle of light cone
$\omega(r, l)$	collection efficiency from a point (r, l)
ζ	angle of triangle $\Delta a\rho r$

Summary—The use of carbon paste electrodes modified with $[Ru(bpy)_2(PVP)_{10}Cl]Cl$ for the mediated detection of nitrite is described. This surface modifier substantially lowers the overpotential for nitrite oxidation, hence permitting its determination at a lower potential. Various electrode characteristics were optimized, including the modifier loading and the monitoring potential, using batch amperometry. Standard calibration curves yielded slopes of 0.30 $\mu A/\mu M$ over the linear range 5×10^{-8}–$5 \times 10^{-4} M$ nitrite with a detection limit of $3 \times 10^{-8} M$ (1.38 ppb) nitrite. The modified electrode response was shown to be relatively stable over a period of 5 days with a signal diminution of 8%. Electrode-to-electrode precision was measured as 11.4%. Flow-injection studies indicated the suitability of this electrode as a detector in flowing streams.

The design of chemically modified electrodes (CMEs) for electroanalysis has been the subject of increasing research since their inception over 15 years ago,[1] and it was the objective of this work to develop a CME for the determination of nitrite.

In recent years there has been growing concern about the role of the nitrite ion as an important precursor in the formation of N-nitrosamines, many of which have been shown to be carcinogens.[2] The occurrence of nitrite salts in the environment and their use as food preservatives is widespread; therefore it is important that sensitive and accurate methods be available for the determination of the nitrite ion.

A large number of analytical methods have been developed for the determination of this ion based principally on spectrophotometric methods,[3–5] but these have limited sensitivity and dynamic range, frequently depend on unstable colours, and involve long reaction times. Cox and Kulesza[6] reported a voltammetric procedure with a platinum electrode modified with iodine, but this method was limited by poor sensitivity. A more sensitive CME for the detection of nitrite was described by Kalcher[7] who used a carbon paste electrode modified with an anion exchanger, but this electrode suffered from long analysis times. More recently, several sensitive polarographic methods have been reported in the literature[8,9] for the detection of *nM* levels of nitrite. Methods based on solid electrodes are more desirable, however, for sensing and flow applications.

Redox polymers containing ruthenium sites have been studied extensively in recent years.[10–13] These studies showed that various metallopolymers of ruthenium act as redox catalysts for a number of substrates. The mediation by the Ru(II/III) couple has been shown to enhance the sensitivity of oxidation processes, and recently a glassy-carbon electrode coated with a Ru-containing polymer has been shown to be effective for the mediated oxidation of nitrite.[14] However, it was reported that in a flowing system, the response from this CME was not found to be stable due to the slow removal of the polymer film from the electrode surface, making their practical application difficult. This instability was alleviated to some extent by treatment with UV light or by coating with other polymer layers.[15]

The purpose of the present study was to investigate the application of carbon paste electrodes modified with the same ruthenium polymer, *i.e.*, $[Ru(bpy)_2(PVP)_{10}Cl]Cl$ where bpy = 2,2′-bipyridiyl and PVP = poly(4-vinylpyridine), for the amperometric detection of nitrite.

EXPERIMENTAL

Chemicals and Reagents

Throughout this work analytical grade chemicals and demineralized water (obtained by passing distilled water through a Millipore water purification system) were used. Standard solutions of sodium nitrite were prepared daily in 0.1*M* sodium nitrate electrolyte and carrier solution. The preparation of $[Ru(bpy)_2(PVP)_{10}Cl]CL$ has been reported elsewhere.[16]

Apparatus

Cyclic voltammetry was performed with an EG & G Model 362 scanning potentiostat in conjunction with a Linseis LY17100 X-Y plotter to record the voltamperograms. A 10-ml homemade three-electrode cell was employed incorporating the modified electrode in addition to a Ag/AgCl reference electrode and a platinum wire auxilliary electrode. For batch amperometry, the detection system used was a Metrohm 641 VA detector. To achieve mass transfer, a 1-cm stirring bar was placed in the cell and rotated with an IKAMAG RET-G magnetic stirrer. A stirring rate of 600 rpm was used for all studies.

Flow-injection analysis was performed with a Waters 501 HPLC pump with an EG & G Model 400 electrochemical detector equipped with a homemade thin layer carbon paste cell (3-mm diameter), a Ag/AgCl reference electrode and a stainless steel auxilliary electrode. Sample injections were made through a Rheodyne injection valve (20 μl loop).

Procedures

The modified carbon paste (usually Nujol: graphite powder: Ru-polymer in a 40:55:5 ratio) was prepared by thoroughly mixing the required amounts for at least 30 min. Portions of the resulting mixture were then packed into either a glass tube (4 mm i.d.) or into the flow-injection cell base. The surface was smoothed on filter paper. Electrical contact in the glass tube electrodes was established via a copper wire which was inserted into the back of the carbon paste mixture.

Saliva was collected by expectoration into small vials. At least 1 ml was collected from each subject. No sample pretreatment was carried out on the samples which were diluted with 0.1*M* sodium nitrate supporting electrolyte.

RESULTS AND DISCUSSION

Cyclic voltammetry

Preliminary experiments to investigate the nature of the Ru-polymer in the carbon paste matrix and to confirm the retention of its ability to mediate nitrite oxidation were performed by cyclic voltammetry. Well defined oxidation and reduction responses associated with the surface bound Ru(II/III) couple were observed in 0.1*M* sodium nitrate (Fig. 1, curve A). This supporting electrolyte was used as it had been found to be optimum in a previously reported study with this polymer.[14] A linear dependence of the cathodic and anodic peak currents on scan rate was obtained up to 40 mV/sec, indicating the essential surface behaviour of the electrodes, as in the case of certain polymer modified electrodes.[17]

The addition of nitrite to the solution resulted in an electrocatalytic oxidation at the same potential as that observed for the Ru(II/III) system (Fig. 1, curve B). Using an unmodified carbon paste electrode, the oxidation of nitrite results in a broad response at 1.05 V (Fig. 1, curve C). The corresponding response on the modified electrode occurred at 0.78 V indicating a significant reduction in the overpotential of the nitrite oxidation.

As the Ru(II/III) couple is always present, the analytical signal for nitrite must be recorded on top of a substantial background current. Detection with conventional voltammetric techniques

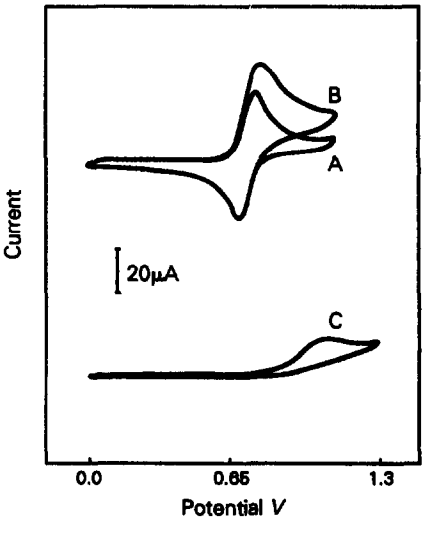

Fig. 1. Cyclic voltamperograms for (A) 5% (w/w) Ru-polymer CME; (B) same as (A) with the addition of $2 \times 10^{-4}M$ nitrite. Curve (C) is the response at an unmodified electrode for $2 \times 10^{-4}M$ nitrite. Scan rate: 100 mV/sec; electrolyte: 0.1*M* $NaNO_3$.

are therefore not recommended. Optimization of the analytical parameters for the mediated reaction were therefore performed with either constant potential batch amperometry or flow-injection analysis.

Batch amperometry in stirred solution

The effect of Ru-polymer loading in the carbon paste was investigated by constant potential batch additions (at 0.8 V) to determine the optimum composition. Calibration curves were constructed in the range 5×10^{-6}–$5 \times 10^{-4}M$ nitrite. Slopes of 0.2, 0.3, 0.3 and 0.25 $\mu A/\mu M$ and correlation coefficients of 0.9995, 0.9996, 0.9997 and 0.9991 were obtained for loadings of 2.5, 5, 10, 20% (w/v) modified electrodes, respectively. A loading of 5% (w/w) Ru-polymer was chosen as increased loadings did not result in an increased response. The decrease in sensitivity at the 20% loaded electrode may be attributed to a decrease in the conductivity of the electrode matrix caused by the high loading of the polymer. Furthermore, as the mediation was assumed to be a surface phenomenon, any Ru-polymer in the electrode not situated on the surface would not contribute to the measured current.

Hydrodynamic voltammetry was then attempted with a 5% (w/w) loaded modified electrode for batch additions of $1 \times 10^{-4}M$ nitrite. The potential of the electrode was increased in 50-mV steps and a two-plateau shaped response was observed (Fig. 2, curve A). The first wave is a result of the mediated current for the oxidation of nitrite at the Ru-polymer at the surface of the modified electrode. The second wave presumably arises due to the response of nitrite at the bare sections of carbon paste at the surface of the modified electrode. This wave is therefore lower in current due to the reduced surface area of carbon particles in the modified

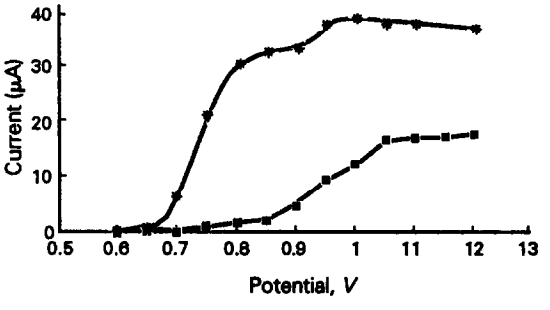

Fig. 2. Hydrodynamic voltamperograms obtained at (A) modified, and (B) unmodified electrode for $1 \times 10^{-4}M$ nitrite. Electrolyte: $0.1M$ $NaNO_3$; stirring rate: 600 rpm.

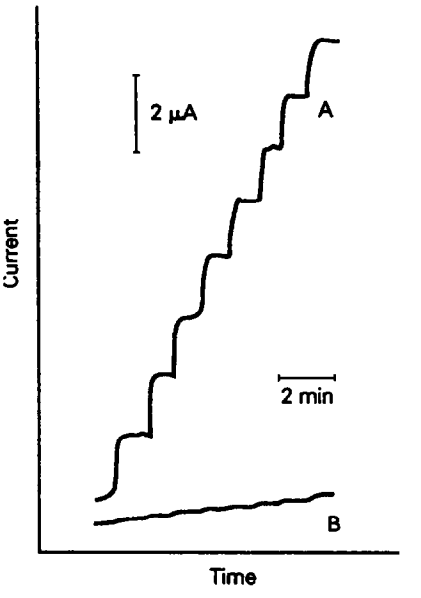

Fig. 3. Batch additions of $5 \times 10^{-6}M$ nitrite (final cell concentration) at (A) modified, and (B) unmodified electrode with constant potential detection at 0.8 V. Other conditions as in Fig. 2.

versus the unmodified electrode (Fig. 2, curve B). A potential of 0.8 V was selected for subsequent investigations in order to maximize the analytical response and minimize interferences obtained at higher potentials.

The response of the modified and unmodified electrodes to batch additions of $5 \times 10^{-6}M$ nitrite are shown in Fig. 3. From this one can see the fast response times needed to achieve a steady state current for the modified electrode. In addition, one can see the large increases in signal obtained for the modified electrode in comparison to the unmodified electrode at the monitoring potential of 0.8 V. The increase in sensitivity of the modified over the unmodified electrode was nearly 20-fold. A calibration curve constructed in the range 5×10^{-8}–$5 \times 10^{-4}M$ nitrite displayed excellent linearity with a slope of 0.30 $\mu A/\mu M$ and a correlation coefficient of 0.9999 ($n = 12$). The signal-to-noise characteristics (S/N = 3) resulted in a detection limit of $3 \times 10^{-8}M$ nitrite. To determine the surface to surface precision, 10 independently prepared electrodes were constructed and they yielded calibration curves with slopes of *ca.* 0.30 $\mu A/\mu M$ with a standard deviation of $\pm 11.4\%$.

The long-term stability of the modified electrode to the oxidation of nitrite was investigated over a 5-day period. The electrode exhibited a current diminution of only 8% during this

period, in contrast to that reported by Barisci *et al.*[14] who reported a 50% response reduction after only 8 hr for the same polymer chemisorbed on the surface of a glassy-carbon electrode. Obviously the carbon paste matrix provides a more stable fixture for the polymer.

Flow-injection analysis

When these Ru-polymer modified electrodes are used in a stationary cell with complex samples, their practical application is hampered by responses for easily oxidized species at the monitoring potential of 0.8 V. Consequently, this approach suffers from lack of selectivity. This drawback can be alleviated by using the modified electrode in a flowing system with a view to employing ion chromatographic separation with electrochemical detection.

For flow studies, 0.1M sodium nitrate was again used as the supporting electrolyte. The effect of flow-rate on the magnitude of response was investigated over the range 0.3 to 1.5 ml/min. Appreciable peak broadening was observed at low flow-rates *i.e.*, peak widths of 22 and 6 sec were obtained at 0.3 and 1.5 ml/min, respectively. A flow-rate of 1 ml/min was selected as the optimum rate as the compromise between sensitivity and sample throughput.

Typical flow-injection responses for nitrite at both the modified and unmodified surfaces are shown in Fig. 4. The linear range was found to be 2×10^{-7}–$1 \times 10^{-3}M$ nitrite. Calibration curves constructed yielded a slope of 0.032 $\mu A/\mu M$ with a correlation coefficient of 0.9998 ($n = 12$). A detection limit (S/N = 3) of $8 \times 10^{-8}M$ nitrite was calculated. These results indicate an attractive detection system for ion chromatographic determination of nitrite.

The short-term stability was ascertained by monitoring the current response for a series of 100 replicate injections of $2 \times 10^{-4}M$ nitrite over a 90-min period. The RSD of these 100 injections was 2.9%, demonstrating the short term stability of the modified electrode in flowing streams.

Determination of nitrite in saliva

The application of the Ru-polymer CME to the determination of nitrite in saliva was then investigated. Using flow-injection analysis, levels in samples taken from two volunteers were determined to be $2.05 \times 10^{-5}M$ (0.94 ppm) and $4.45 \times 10^{-5}M$ (2.05 ppm) nitrite. For both samples, known amounts of nitrite were added to check recovery which was estimated as

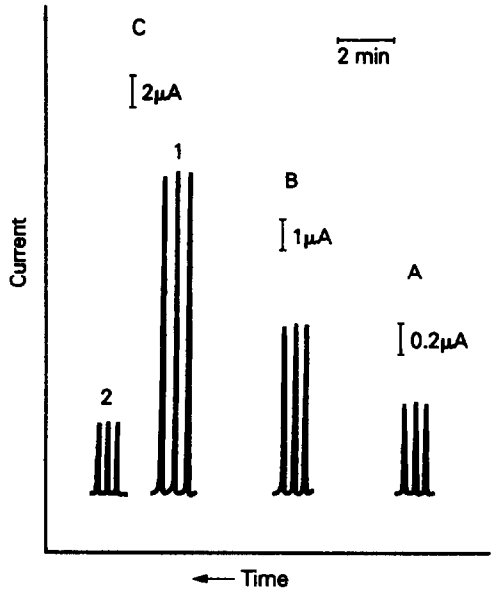

Fig. 4. Flow-injection response at the Ru-polymer modified electrode of (A) $3 \times 10^{-5}M$, and (B) $2 \times 10^{-4}M$ nitrite. (C) is the response for $8 \times 10^{-4}M$ at (1) modified, and (2) unmodified electrode. Constant potential operation at 0.8 V; electrolyte: 0.1M $NaNO_3$; flow rate: 1 ml/min.

$98 \pm 3\%$. The nitrite levels found in each sample were within the range previously reported for human saliva.[18]

CONCLUSIONS

In conclusion, the Ru-polymer modified carbon paste electrodes have been demonstrated to be both sensitive and stable for the determination of nitrite, offering a substantial decrease in overpotential for nitrite oxidation. The detection limit and dynamic linear range are only bettered by polarographic methods.[8,9] As previously mentioned, however, techniques based on mercury are generally undesirable for many practical applications, including flow analysis.

CHARACTERIZATION OF THE POLYPYRROLE FILM–PIEZOELECTRIC SENSOR COMBINATION

STEPHEN J. VIGMOND, KRISHNA M. R. KALLURY, VIDA GHAEMMAGHAMI and MICHAEL THOMPSON*

Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, Ontario, M5S 1A1, Canada

(*Received* 27 *February* 1991. *Revised* 14 *May* 1991. *Accepted* 16 *May* 1991)

Summary—Polymerization of pyrrole onto the electrode surfaces of thickness-shear-mode acoustic wave sensors at various levels of oxidation has been performed with electrochemical methods. The resulting films of polypyrrole have been characterized by scanning electron microscopy and X-ray photoelectron spectroscopy. Frequency decreases for the polypyrrole—coated sensors exposed to methanol, toluene and ammonia have been evaluated in terms of the various interactions occurring at the polymer surface.

Conducting films produced from polypyrrole have found extensive application in chemical sensor,[1–3] battery,[4] protective coating[5] and electrochromic device[6] technologies. The polymer is usually synthesized by electrochemical procedures which allow facile conversion between conductive and neutral insulating forms.[7] Preparation conditions such as concentration of reactants, nature of the solvent, reaction temperature, type of anion and applied potential are known to affect the conductivity of the polymer[8,9] which is derived from positively charged sites present along the backbone chain. These charges are compensated by the incorporation of one anionic species per three or four pyrrole units. Increase of the degree of oxidation tends to result in the pairing up of positively charged sites forming bipolarons which are thought to be responsible for conduction by an electron hopping mechanism. Transition between the oxidized and neutral forms of polypyrrole can be effected by application of an appropriate potential which results in incorporation or removal of counteranions by diffusion.

Changes in conductivity of the polymer caused by adsorption of various species from the gas phase have been employed to develop a chemical sensory strategy. For example, Bartlett and Ling-Chung[1] monitored reversible changes in the presence of a number of different saturated vapors. In the case of methanol, transient responses were interpreted in terms of a sorption model rather than a diffusion-limited mechanism.[10] The interaction of polypyrrole with several alcohols was studied by Josowicz *et al.*[11] who detected measurable changes in the electron work function of polymer-coated suspended gate field effect transistor devices.

Gustafsson *et al.*[12] studied the interaction of oxidized polypyrrole with ammonia. While low concentrations of ammonia produced a reversible increase in the resistance (approx. 15% change in the presence of 27 ppm ammonia in argon), concentrations of ammonia greater than 1 atm or the presence of water led to a permanent increase in resistance. The irreversible increase in resistance was attributed to nucleophilic attack by ammonia or hydroxide on the polymer leading to loss of conjugation and ring opening. Other gas phase studies indicate that the neutral polymer shows selectivity towards electron-accepting species through an oxidative incorporation of the gaseous molecule.[13]

Analogous experiments to the above have been performed in the solution phase. For example, Ikariyama and Heineman[14] monitored electro-inactive anions in a flow-injection system by cycling the polymer between its neutral and oxidized states. Other studies have involved the use of polypyrrole as an overlayer to simply entrap selective reagents such as enzymes near an electrode surface.[15]

In order to ascertain the applicability of polypyrrole films in chemical sensor configurations, the current work examines the nature of interactions of the basic polymer in its various oxidation states with organic species.

*Author for correspondence.

Scanning electron microscopy can be used to detect macroscopic changes in the polymer and x-ray photoelectron spectroscopy is sensitive to changes in the chemical environment of the material. While quartz microbalances have previously been used to study the mechanism of polypyrrole formation,[16] their ability to indicate the relative degree of interaction with certain chemical probes are being utilized in this study to determine the nature of these interactions. A major advantage in employing the thickness-shear-mode (TSM) acoustic wave sensor as the transduction device is that responses can be obtained from both the neutral and oxidized forms of polypyrrole. The chemical sensors described thus far monitor the resistance change of the oxidized form in the presence of the analyte; the polypyrrole films have no appreciable sensitivity in the neutral form. However, as the TSM sensor responds to changes of mass at the surface, the state of the polymer will not limit its use. Chemical changes may then be correlated to mass changes which will enable monitoring the flux of the counterions and solvent into and out of the polymer film.

EXPERIMENTAL

Reagents

Pyrrole (Aldrich) was distilled under vacuum before use while tetrabutylammonium perchlorate (Fluka) and ACS grade acetonitrile, methanol and toluene (BDH) were used as supplied. Helium and 4% ammonia were obtained from Matheson. 9 MHz gold-coated piezoelectric crystals from Oklahoma Crystal Manufacturing Co. were utilized as working electrodes in the polymerization of pyrrole with a combined platinum and Ag/AgCl electrode from Metrohm as the counter and reference electrode, respectively.

Apparatus

Scanning Electron Microscopy (SEM) was performed with a Hitachi S-570 SEM. Electrical contact from the sample holder to the underlying gold electrode was made with graphite paste. The crystals were cleaved for introduction into the SEM by scoring them with a diamond tip and then mounting them onto the holders with the scored side down.

All X-ray photoelectron spectra (XPS) were acquired with a Leybold Max 200 XPS system employing an unmonochromatized Mg X-ray source with an analysis area of 2 mm by 4 mm. The survey spectra and quantitative atomic measurements were obtained with a pass energy of 192 eV. The relative elemental surface compositions were calculated from satellite-subtracted spectra with sensitivity factors derived from Scofield Factors [C(ls) = 1.00, N(ls) = 1.66, O(ls) = 2.32, Cl(2p) = 2.50]. The high resolution spectra were acquired with a pass energy of 48 eV and then deconvoluted with software provided with the spectrometer. Oxidation of pyrrole solutions was achieved with a polarographic analyzer (model 473) from ECO Instruments.

Probing of the polypyrrole films by interacting with gas species was performed with the gas flow-through train described previously.[17] Frequency measurements were made with a universal frequency counter (Hewlett-Packard Model 5334B).

Procedures

Polymerization of pyrrole and deposition on sensors was performed by mounting piezoelectric crystals in the cell depicted in Fig. 1. Although only the contact to the upper electrode is required to apply a potential for coating, the cell was designed to allow the measurement of resonance frequency without removal of the device from the cell. A solution consisting of 0.1*M* pyrrole and 0.1*M* tetrabutylammonium perchlorate in acetonitrile was deoxygenated by nitrogen gas bubbling before use in the electrochemical deposition. The latter was performed for one minute per side at 1.0 V. Oxidation or reduction of the resulting polymer films was achieved with the same equipment with the exception that the solution was 0.1*M* tetrabutylammonium perchlorate in acetonitrile. All potentials reported are with respect to the Ag/AgCl electrode.

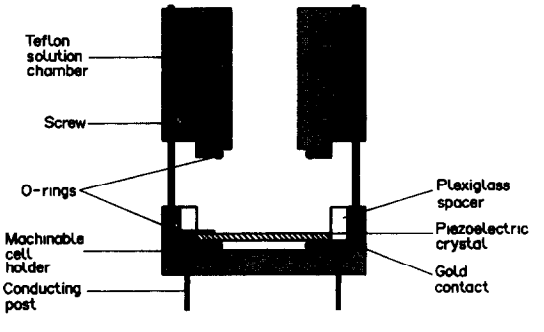

Fig. 1. Schematic of cell employed for polymerization of pyrrole.

In gas phase probe experiments a frequency reading was obtained for the polymer-coated crystal in a helium flow of 30 ml/min. Methanol and toluene were introduced into the flow-through train by diverting the helium flow over a 50-ml reservoir of the appropriate solvent contained in a solvent trap. A frequency decrease was observed which stabilized in about five minutes. The concentration of these analytes in the gas phase was determined by collecting the vapors in a liquid nitrogen-cooled trap for several hours. Ammonia was supplied as a 4% mixture in helium so the pure helium flow was interrupted before the ammonia was introduced into the system at the same flow rate. After the frequency readings had stabilized in the presence of the probe molecule for about two minutes, the pure helium flow was restored and the frequency reading would return to the initial value.

RESULTS AND DISCUSSION

Polypyrrole deposition

With a view to making meaningful comparisons between different sets of experiments, the same coating procedure was followed throughout. The crystals were coated one side at a time in order to produce a visually even coating; dipping both sides at once into the polymerization solution resulted in a non-uniform potential distribution over the electrode surface causing preferential polymerization at the electrode edges and at the solution-atmosphere interface. For the probe experiments, ensuring that the polymer coating occurred in the center of the piezoelectric crystal was necessary for maximum sensitivity. Although the perchlorate ion is the desired counteranion, some chloride ion from the reference electrode was also incorporated into the polymer occasionally.

The coating procedure, in general, lowered the frequency of the crystal by about 25,000 Hz which, for a 9 MHz crystal, roughly corresponds to 25 μg of coating. The initial and final measurements were made in air. The electrochemical deposition normally yields the polymer in its oxidized, doped state which is reported to incorporate about one perchlorate anion per three pyrrole rings. Using the modified Scofield parameters to correct area measurements derived from the XPS spectra, the as-prepared polymer was found to exhibit a lower value for this ratio than expected; the chlorine intensity is 27% that of the nitrogen signal and appears at a binding energy of 208 eV which is consistent with the perchlorate structure. Measurement of the potential of a circuit involving this polymer-coated crystal (with respect to a silver/silver chloride reference electrode) in 0.1*M* TBAP in acetonitrile yields a value of $+0.50 \pm 0.05$ V.

Upon reduction of the polymer at -1.5 V for 10 min, the frequency change (which is proportional to the mass added to a crystal) increases by 10–15%. Low resolution XPS analysis indicates complete chlorine elimination from the surface. However, if the initial polymer contains 27 mole per cent perchlorate anions (with respect to the number of pyrrole rings), removal of all the chlorine from the polymer should result in a frequency rise of about 30%. The much lower value recorded must be due to the diffusion of the perchlorate anion only from the upper layers of the surface (XPS signals arise only from the top 60 Å of the surface) or some exchange between anions and solvent to moderate the mass loss. The potential of the circuit involving this polymer ranges from about 0.0 to $+0.2$ V.

The polymer can also be reduced by chemical means. Treatment with zinc dust in a 1:1 acetic acid: water solution or simply extracting the polymer in a Soxhlet apparatus for six hours with acentonitrile was found to remove all observable chlorine from the XPS spectra. The resulting surfaces show potentials between -0.15 and $+0.15$ V. However, the frequency enhancement of the chemically-modified surfaces now ranges between 15 and 20%, which is significantly greater than that seen by electrochemical reduction. This additional mass loss may constitute evidence for the removal of some smaller oligomers from the polymer during the reaction in aqueous acetic acid or in the heated acetonitrile of the Soxhlet extraction.

While the electropolymerization produces a polymer in the oxidized state, subsequent application of a potential of $+1.0$ V to the polymer in 0.1*M* TBAP in acetonitrile appears to further enhance this state. This process is found to typically decrease the frequency by $\sim$5–10%. Its XPS spectrum shows the atomic composition of chlorine to be 60% that of the nitrogen but the total chlorine intensity is approximately equally divided between peaks at 208 and 200 eV. This lower binding energy signal is in the range of the chloride Cl(2p) binding energy peak. A recent paper has reported the incorporation of 45 mole percent of perchlorate and up to 55 mole percent of chloride as determined by

elemental analysis.[18] As in the reduction case discussed earlier, the frequency decrease is much smaller than expected for a corresponding mass increase of about 30%. The measured potential for this surface is found to increase to between +0.55 and +0.65 V.

Scanning electron microscopy

The macroscopic structure of the polymer on the crystal surface was studied by SEM. No obvious differences could be detected between the as-prepared polymer and those that had been either oxidized at +1.0 V or reduced at −1.5 V. A respresentative micrograph is shown in Fig. 2. The upper two pictures show the surface of an as-prepared polypyrrole film at two different magnifications. The films appeared rough and cracked, very similar to the underlying gold electrode (not shown), although the cracks seen in the gold surface become some-

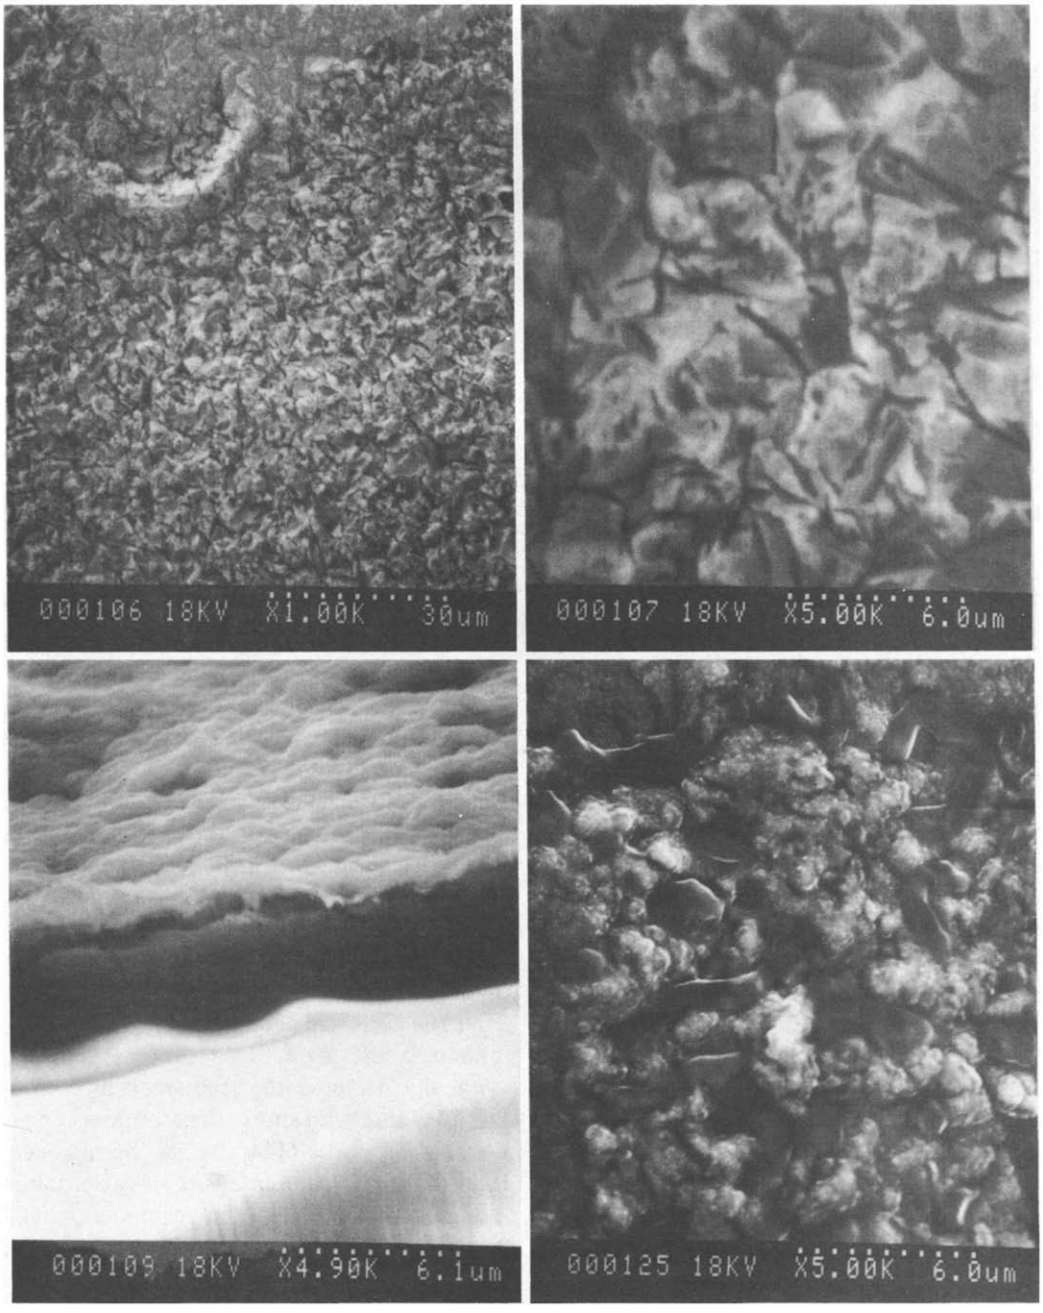

Fig. 2. Scanning electron micrographs of polypyrrole. Upper two micrographs are from the same surface, and the lower left constitutes a corresponding side view. The picture at the bottom right is from a polymer surface which has been lightly coated with gold.

what filled in. A view of the edge of the crystals indicated that the coatings are about one-half of a micrometer thick and variations in surface topology are predominantly the result of the gold layer underneath (lower left in Fig. 2). The polymer is the light coloured layer seen on top of the dark gold band.

Although literature reports indicate that the texture of the film is affected appreciably by factors such as thickness and presence of counteranion,[18,19] the micrographs of this work depict a much more angular surface than hitherto reported for polypyrrole. Most of the documented SEM show globular structures on the surface which are attributed to the polymer building up from localized sites, the accepted growth mechanism. However, we are able to observe similar structures only after vapor deposition of a thin film of gold onto the surface (20 mA current, 60 sec) which fills in the cracks and forms islands on the surface (lower right in Fig. 2). The gold deposited onto a polypyrrole surface seems to preferentially self-adhere causing the formation of globules.

XPS of the surface of polypyrrole films

The N(ls) spectra of the as-prepared, oxidized and neutral forms of the polymer are shown in Fig. 3. The spectrum of the former is in agreement with that published in previous work.[20,21] A major N(ls) signal occurs at a binding energy of 399.5 eV, together with significant enhancement on the high binding energy side of the peak. The higher binding energy peaks have been ascribed to nitrogen atoms present in the vicinity of the charged site on the polymer. Accordingly, positive charge delocalization over several atoms can result in increased charge on nitrogen atoms which have been postulated to range from one-sixth to a single charge. No significant peak is observed on the low binding energy side.

Further oxidation of the polymer in 0.1*M* TBAP causes a two-fold increase in the relative intensity of the higher binding energy nitrogen peak. This observation agrees well with the increased amount of chlorine that becomes incorporated into the polymer as discussed earlier. A small peak (about 5%) can now be detected on the low binding energy side of the main signal.

Reduction of polypyrrole at −1.5 V produces a material for which the XPS spectrum exhibits larger (~15%) and symmetrical enhancements on both sides of the main N(ls) photoline. Such

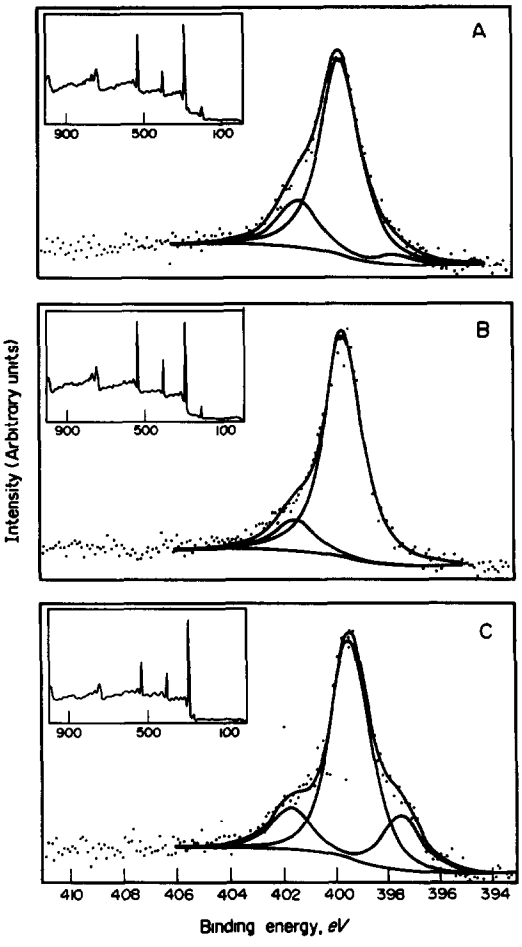

Fig. 3. Nitrogen (1s) region of XPS spectra of polypyrrole in oxidized (A), as-prepared (B) and neutral forms (C).

a spectrum can be attributed to a structure wherein a large proportion of the pyrrole units are involved in a hydrogen-bonded network, the shifts being a result of electron donation from one nitrogen to another. This interpretation derives support from a recent scanning tunneling microscopic study of polypyrrole in which the results were believed to arise from a helical structure for the oxidized polymer with the counteranions being held like spacers between the coils.[22] If the same model is extended to the current investigation, the loss of the anions would allow the nitrogen moieties of the pyrrole rings to interact and thereby produce the two smaller peaks that are observed. Application of a subsequent oxidizing potential reverts the material back to the oxidized form indicating a reversible redox system. While a similar nitrogen spectrum may be obtained by the application of potentials down to 0.0 V. (against a silver/silver chloride electrode), reductions of the oxidized polymer with either zinc or sodium

dithionite do not produce these enhancements. These conditions produce a polymer displaying a smaller enhancement on the high binding energy side in the N(ls) region of the spectrum along with the loss of the chlorine signal.

Interaction with gas phase probes

An alternative approach for the analyses of polypyrrole in different surface states involves adsorption of chemical probes from the gas phase. The analytes were chosen in the present work to demonstrate the effect of different types of interaction; *viz.* methanol for its capacity to hydrogen-bond, ammonia for its Lewis base behaviour and toluene as an aromatic representative. It should be noted that while most previous studies have focussed on an examination of the effect that various species have on the conductivity of the oxidized polymer, our protocol allows the monitoring of the degree of interaction of the chosen analytes with polypyrrole prepared at various levels of oxidation.

The magnitude of the frequency decrease occurring upon the introduction of the probes will be subject to several experimental parameters. The first is the amount of polymer present on the piezoelectric crystal; due to the porosity of the material and its thickness, the analyte is able to permeate the polymer and interact with the entire material. If only a surface interaction were to take place, simple approximations lead to an estimated frequency of about 20 Hz for these probes, which is very close to the change observed when an uncoated, gold piezoelectric crystal is employed. Yet another obvious factor is the concentration of the probe available to the polypyrrole. With the experimental configuration used, the concentrations of toluene and methanol are functions of their vapor pressure and the flow rate used while the ammonia concentration is fixed at the level at which it is supplied. By collecting the toluene and methanol vapors in a liquid nitrogen trap, their respective concentrations were determined to be 10 ± 5 ppm and 95 ± 10 ppm. However, our criterion is the change in the degree of interaction for the films as their states are altered.

Values from a typical run for each of the chemical probes are recorded in Table 1 and presented graphically in Fig. 4. The three sets of data have been normalized in the graph with respect to the frequency decrease observed for the interaction of polypyrrole after being held at a potential of 0.0 V. (versus the Ag/AgCl electrode) since this may be assumed to be an intermediate oxidation state. Therefore, changes arising from the extreme oxidizing and reducing potentials should become more pronounced with either an increased or decreased degree of interaction. The order of the potentials listed in Table 1 and recorded along the x-axis of the graph is the order that was followed experimentally. While the same qualitative results are obtained if the cycle is reversed, *i.e.*, applying a positive potential to the polymer before negative potentials, differences may be observed. These differences may arise from the polymer adopting different conformations upon reduction and oxidation which then relax either at a different rate or through an alternate mechanism upon reversing the potential so different structures may be possible for the polymer after being held at the same potential. A similar hypothesis has been put forth to explain differences in cyclic voltammetry and conductivity measurements of thin conducting polymers in forward and reverse directions.[23]

Table 1. Frequency decreases for piezoelectric sensors as a function of gas phase probe and oxidation state of polypyrrole overlayer, ± 3 Hz

Polymer appl. potential, *V*	Probe		
	NH_3	$C_6H_5CH_3$	CH_3OH
As prepared	830	1453	1425
−1.0	513	1411	1460
−1.5	439	1413	1568
0.0	400	1354	1343
+1.0	625	1178	1302
+1.4	1006	1091	1548

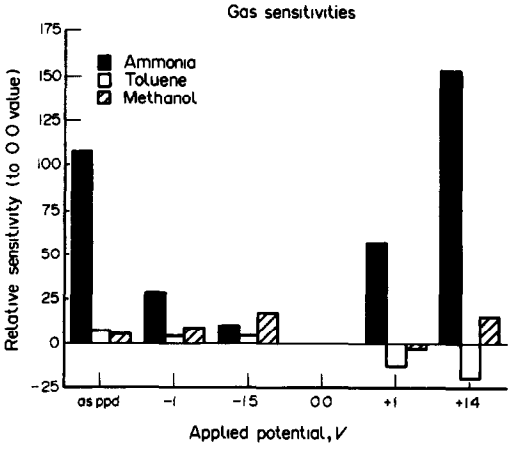

Fig. 4. Relative frequency decreases following the introduction of methanol, toluene and ammonia. Decreases after 0.0 V potential is the standard for each run. Actual frequency shifts are recorded in Table 1.

It can be seen that the polymer behaves quite differently towards the three analytes as its oxidation state is cycled from as-prepared to neutral and finally back to an oxidized state. The potentials measured with the polymer in the electrochemical circuit after the as-prepared, −1.0, −1.5, 0.0, +1.0 and +1.4 V, potentials are applied, usually correspond to about +0.5, +0.05, −0.05, 0.0, +0.5 and +0.6 V respectively. The least predictable values correspond to the surfaces subjected to the least extreme potentials.

The largest difference occurs in the presence of ammonia. The interaction of the oxidized polymer is about twice that observed with the neutral form. Gustafsson *et al.*[12] believed that the interaction is a result of either electron donation to the polymer or proton abstraction by the ammonia. In agreement with the results of these authors, the ammonia interaction was found to be reversible and was stable over tens of minutes.

The variations between the oxidized and neutral forms of polypyrrole with toluene and methanol are only in the range of about 10 to 20%. The preferred oxidation state for interaction with toluene is the neutral state. This effect was found to steadily diminish over a period of tens of minutes, in agreement with the conductivity results of Bartlett and Ling-Chung.[1] Similar experiments with methane indicate analogous behaviour; although there is a smaller preference seen with the neutral state for methane, the interaction must be weak as the frequency is seen to rise almost immediately after its initial decrease on exposure to the gas. The interaction with methanol is found to be the strongest at the most extreme oxidation states, usually after applying potentials of +1.4 and −1.5 V. The methanol-polypyrrole interaction is stable over periods of at least 300 min.

The mass responses of polypyrrole with the probe molecules show that several types of interactions are possible. The strongly basic ammonia shows a strong preference for the oxidized polymer while the neutral, aromatic toluene interacts most strongly with the neutral form, possibly through weak π-overlap. With the removal of the perchlorate anion between the polymer coils the rigid toluene structure may gain a parallel access to the neutral pyrrole rings. Methanol, being both a hydrogen bond acceptor and donor, shows enhancement after applying the extreme oxidizing and reducing potentials. Therefore, controlling the characteristics of this polymer may eventually lead to a minor degree of selectivity with polypyrrole-based sensors, which are generally nondiscriminating in the devices described in the literature so far.

The mass responses observed are also a function of other factors. Although no differences can be detected between the oxidized and neutral states of the polymer on the SEM scale, changes in the density of the film are possible, as has been observed with other polymers. While polyazulene is reported to shrink in going from the oxidized to the neutral form,[24] due to loss of counterions, polythiophene films expand upon reduction,[25] indicating a complex solvation pattern for this polymer. Besides the influence of solvent molecules known to be present, the hydrogen bonding network produced by electrochemical reduction indicates that intramolecular interactions may limit the accessibility of functionalities being presented to the analyte molecules.

CONCLUSIONS

Our studies demonstrate a complex behaviour for polypyrrole which needs to be rationalized to enable the optimization of prepared polymers for specific applications. The varying interactions of the probe molecules with respect to the oxidation state of polypyrrole indicate factors such as nature of the interaction and accessibility to the functional group control the behaviour of the polymer. The piezoelectric mass balance monitored the degree of solvation of polypyrrole as the state of the polymer was altered. The strong retention of acetonitrile seen here supports the observation of Vork and Janssen that polypyrrole retains acetonitrile even in vacuum conditions.[26] The presence of solvent molecules is certain to moderate the possible intra- and intermolecular interactions the material may experience, as has been stated by Blackwood and Josowicz.[27] The difference in the products obtained by chemical and electrochemical reductions of polypyrrole may arise from the reaction solvents used. The strongly hydrogen bonding aqueous acetic acid may not allow an intramolecular hydrogen bonding network to form as observed for the electrochemically reduced product in acetonitrile by XPS.

The results presented here from the SEM, XPS and chemical probe experiments are an attempt to obtain a fundamental understanding of the interactions polypyrrole may experience

in an effort to gain greater control of the physical characteristics of the polymer. The knowledge may then be more directly applied to specific applications in chemical sensor technology in order to generate more sensitive and selective films. While polypyrrole is now being used to entrap selective reagents in voltammetry-based sensors, studies on the stability and dynamics of this material will expand its applicability to a wide range of devices.

BOOK REVIEWS

Basic Measurement Techniques for Light Microscopy: S. BRADBURY, Oxford University Press, Oxford, 1991. Pages viii + 97. £9.95 (softback).

This, the latest (no. 23) in a series of excellent little handbooks from the Royal Microscopical Society, satisfactorily fulfils the author's intention to guide light microscopists to the various available techniques for the measurement of the size of microscopic objects. The emphasis is on simpler methods but there are also brief references to more recent digital and image analyser techniques.

The first chapter includes a very readable history of the origins and development of techniques and accessories; the final chapter provides a very short introduction to automated and electronic methods of linear measurement. In between there is a remarkably thorough coverage of a wide range of techniques. Chapters on approximation or comparison methods and on linear measurements by use of projection and drawing equipment precede the largest section, on linear measurement by using scales in the microscope. In general this chapter is clear in its treatment of its topics and its final section on sources of error in measurements is particularly valuable but there are disappointments also. First, figures spread over two or three pages have components that are large and clear but the legends and related text are then awkwardly remote. Secondly, in the section on the calibration and use of the graticule-containing eyepiece, the text paragraph immediately after the description of the determination of the micrometer value is alarmingly incomprehensible. However, these are small blemishes and perhaps negligible in the context of the wealth of information provided and the lucid manner of presentation in the whole. A short chapter on angular and depth measurements introduces interferometer systems but the larger topic of interference microscopy is scheduled to be the subject of another monograph.

This handbook, which includes over 90 literature references, given by chapter, will be an asset to those who wish to use the light microscope to measure biological materials, soil or smoke particles, droplets, crystals, etched surfaces, microcircuits and other microscopic objects.

J. A. HODGSON

Chromatographic Analysis of Pharmaceuticals: J. A. ADAMOVICS (editor), Dekker, New York, 1990. Pages vii + 661. $125.00 (U.S. and Canada), $150.00 (elsewhere).

Chromatographic Analysis of Pharmaceuticals is volume 49 in the chromatographic science series of monographs published by Marcel Dekker.

The first section of the book, which occupies about one third of the total, is divided into three parts—regulatory considerations, sample treatment (pretreatment and robotics), and chromatographic techniques (TLC, GC, headspace analysis and HPLC). These topics are dealt with in a precise and competent manner and the deliberate omission of theory (only a small number of very basic equations are included) makes for easy, as well as interesting, reading.

The final two thirds of the book is devoted to applications and this section establishes the volume as a handy reference source. Here the text is dominated by a single table which extends, without a break, over 319 pages. This table is a listing of the chromatographic methods that have been used to test over 1300 pharmaceuticals, their excipients and impurities. The table headings are: compound formulation (e.g., bulk, tablets, solution etc.), mode (e.g., TLC, GC, HPLC) sample pretreatment, sorbent and temperature, mobile phase, detection method, comments and reference source. In total the book contains about 2000 literature references up to the year 1988.

The book is an important addition to the literature because chromatographic analysis is the main technique used for the analysis of pharmaceutical substances in bulk and in formulations. The numerous applications quoted make this text a necessity for all those involved in the analysis of pharmaceuticals.

(*Received* 22 *August* 1991. *Revised* 22 *October* 1991. *Accepted* 14 *November* 1991)

Summary—Ion mobility spectrometry (IMS) was used as a flow-injection detector to quantitatively examine the ionization chemistry of aniline in hexane. A 5-μl sample was vaporized at 15–90-sec intervals in a flowing air stream and analyzed with an IMS equipped with acetone reactant ion chemistry, ambient temperature drift tube and membrane-based inlet. Precision was 3–11% relative standard deviation for 1–100 ppm aniline in hexane with 90-sec injection intervals and detection limits were *ca.* 0.5 ppm with 5-μl injections. Matrix effects with amine and organic solvent mixtures were observed and corrected for low and medium proton affinity interferences with standard addition methods. Pronounced fouling of the IMS occurred when a continuous water flow was introduced for aqueous flow injection–IMS. Continuous water monitoring without degraded IMS performance was possible by sampling air flow through a Silastic tube immersed in an aqueous sample.

Aromatic amines are substances which exhibit toxicity toward aquatic life[1] including fish,[2,3] *Daphnia magna*[4,5] and microbes in estuary water.[6] Consequently, aniline and certain aniline derivatives are classified as priority organic pollutants and the discharge of waste effluents containing aniline is regulated. Effective techniques for determining aniline and like compounds are gas or liquid chromatography which exhibit low detection limits and high specificity.[7] Other methods of identification or low level detection for these compounds include flow-injection analysis (FIA) with chemiluminescence detection,[8] electrochemical thermospray mass spectrometry[9] and ion mobility spectrometry (IMS).[10] The principal concern of the present work is instrumentation suited for continuous monitoring of aqueous effluents that are simple mixtures. The high proton affinities of aniline and other aromatic amines suggest that IMS may be suited to monitoring these compounds in aqueous industrial effluents. In positive polarity and with acetone reagent ion source chemistry, IMS exhibits little interference from common solvents making this analyzer attractive for routine applications.[11] Previously, aromatic amines were examined with both IMS and IMS/mass spectrometry[10] and mobility spectra were comprised principally of MH^+ ions. Such minor fragmentation favored possible application of IMS to effluent wastes when comprised of simple chemical mixtures. A last aspect of IMS, required for full assessment of potential usefulness, is that of quantitative response characteristics for IMS toward aniline alone and in moderately complex matrices.

In IMS, vapors are drawn into a reaction region where analyte is ionized through proton or electron transfers from a reservoir of charge, the reactant ions.[12] Ionization is based on competitive charge exchange and unequivocal response occurs when the target analyte has a proton affinity larger than that for any component in the sample matrix. Otherwise, response can become confusing even for simple mixtures.[13] Matrix effects in IMS can be alleviated somewhat though alternate reagent ion chemistry causing insensitivity to potential interferences and adding selectivity to response.[11] Ion separations in an ion drift region provide a second dimension of selectivity in IMS. Product ions are injected into a weak electric field where ions acquire constant velocities due to cross-

*Author for correspondence.

sectional areas of collision. Nonetheless, response in IMS is fundamentally governed by the original ion creation step which is limited by competitive ionizations; thus, if a product ion is not formed in the ion source, regardless of cause, a peak corresponding to that substance will not be observed in the mobility spectrum.

In the present work, IMS was used as a FIA detector with a chemically benign solvent (hexane) to evaluate the response characteristic and quantitative behavior of IMS configured for operation in harsh field environments.[12] A second portion of effort involved assessment and circumvention of water fouling in this instrument for continuous monitoring of aqueous stream as would be expected in industrial applications.

EXPERIMENTAL

Instrumentation

A flow injection–IMS set-up was assembled from a heated injector of a gas chromatograph and a hand-held IMS device, an Airborne Vapor Monitor (Graseby Ionics, Ltd, Watford, UK). Parameters of the IMS set-up were: reaction region, 12 mm; drift region, 39 mm; diameter of drift tube, 12 mm; field strength, 244 V/cm; ion source, 10 mCi ^{63}Ni; drift gas flow, air *ca.* 200 ml/min; drift tube temperature, ambient at 22–25°; drift tube pressure, ambient at 660–670 mm Hg; and nozzle air flow for sampling, 0.5 l./min. Air flow through the injector was *ca.* 5 ml/min and the injector temperature was 100°. Mobility spectra were acquired through digital signal averaging with an AT-compatible computer equipped with an interface board and software, the Advanced Signal Processor (Graseby Ionics, Ltd). Voltage from a portion of the mobility spectrum was taken from the signal processing board to a Hewlett–Packard model 3390A recording integrator to allow continuous monitoring and integration of aniline product ion intensities. The observation window for drift times for the aniline peak was *ca.* 0.1–0.2 msec wide and was centered on the drift time for aniline, 8.74 msec. Other parameters for signal collection were: number of waveforms, 32; points per spectrum, 512 and scale expansion factor, 0.25. The integrator parameters were: attenuation and threshold, both 9; chart speed, 1 cm/min; area reject, 10,000; and peak width, 0.5.

Preliminary studies of IMS as a flow-injection detector for aqueous streams were made by using a minipump (Milton Roy Co.) connected to the injector through *ca.* 1 m of 1-mm ID stainless steel tubing. A needle at the end of this tubing was inserted into the injector through a septum. For continuous monitoring of water, an inlet was constructed with 2 m of Silastic brand (0.012″ ID × 0.025″ OD) medical-grade tubing (Dow Corning Corp., Midland, MI). This tubing was wrapped in a 4-cm wide band around a 1-cm OD test tube and inserted into a 3-cm ID test tube. Aqueous solution was placed into the space between the test tubes and the Silastic tubing was loosely inserted into the IMS nozzle. Bottled air was passed through the Silastic tubing at 50 ml/min and into the IMS nozzle. This inlet attachment was kept at constant temperature in a model 1220 water bath (VWR Scientific).

Reagents and materials

The following solvents were obtained in high commercial purity and used without further treatment: hexane and acetone (Chromopure, Burdick & Jackson Co., Muskegon, MI), benzene (B&J Brand, Burdick & Jackson Co.), and ethyl acetate and methylene chloride (Fisher Scientific, Pittsburgh, PA). Aromatic amines included aniline, *m*-toluidine and *o*-toluidine (Aldrich Chemical Co., Milwaukee, WI, >99.5%) and benzylamine and *N*,*N*-dimethylaniline (Sigma Chemical Co., St. Louis, MO).

Procedures

General. A 5-μl liquid sample was delivered with a 10-μl syringe (Hamilton Co., Reno, NV) to the injector during continuous signal processing with the IMS. Intervals between analyses were 15–90 sec for restoration of inlet and IMS cleanliness. Several parameters were examined to determine optimum operating conditions and to access the reliability of IMS as a flow-injection detector. The first three studies involved ion chemistry with aniline in hexane. The last three studies were directed toward practical monitoring of effluents for which aqueous solutions were used.

The particular details of each of these studies are given below.

Clearance study and response curve. Five microliters of aniline in hexane at concentrations from 0 to 100 ppm were delivered ($n = 5$) at intervals in the range 15–90 sec. A response curve was prepared from peak areas. Later, a sleeve of borosilicate glass tubing, 25 mm long by 20 mm OD and 1–2 mm wall thickness was placed over the injector-nozzle region to diminish cross flows and turbulence.

Chemical interferences. Effects from common organic solvents were measured with 3 μl of 5 ppm aniline in selected solvents. The solvents were acetone, methylene chloride, benzene and ethylacetate in ratios (v/v) with hexane from 0.5 to 50%. Injections were made in triplicate at 90-sec intervals.

Three microliters of 5 ppm aniline and 3 μl of other aromatic amines in hexane were co-injected. These amines were *N,N*-dimethylamine, benzylamine, *m*-toluidine and *o*-toluidine at concentrations of 1, 10, 25, 50 and 100 ppm. Triplicate determinations were made at 60-sec injection intervals.

Standard addition methods. Three solutions were prepared with aniline in hexane at 10 ppm with matrices comprised of three potential interferences. The matrices included compounds with low to strong proton affinities at concentrations below the saturation level for the IMS ion source. The constituents were: low interfering solution—acetone, benzene, and methanol at 3% (v/v) each; medium interfering solution—ethylacetate, ethylether, and n-propanal at 1% (v/v) each; and strong interfering solution—pyridine, *N,N*-dimethylaniline and diethylamine at 30 ppm each. Five-point standard addition curves were made with each matrix and the experimental value for aniline compared to the actual value. In replicate determinations, the upper value for the highest addition was increased from 1 to 100 ppm aniline.

Effect of water on IMS performance. A calibration curve for 5 μl of aniline at 0–200 ppm in water was prepared with IMS with heated injector. Subsequently, demineralized water was introduced continuously at flows of 10–300 μl/min into the injector and the IMS was recalibrated.

Continuous monitoring of water. Solutions of aniline from 1 to 200 ppm in water were introduced into the Silastic tubing-inlet attachment and the temperature was controlled over the range 25–75°. The aniline peak height was monitored on the recording integrator for 15–25 min. At intervals of 0–96 hr, stability of response in the IMS was determined by analysis of 5 μl of 1 ppm aniline in hexane with the heated injector.

RESULTS AND DISCUSSION

Mobility spectra for aromatic amines

Mobility spectra for the reactant ion peak (RIP) and aniline with acetone (Ac) reagent ion chemistry in the hand-held IMS device are shown in Fig. 1. The RIP is a protonated dimer,

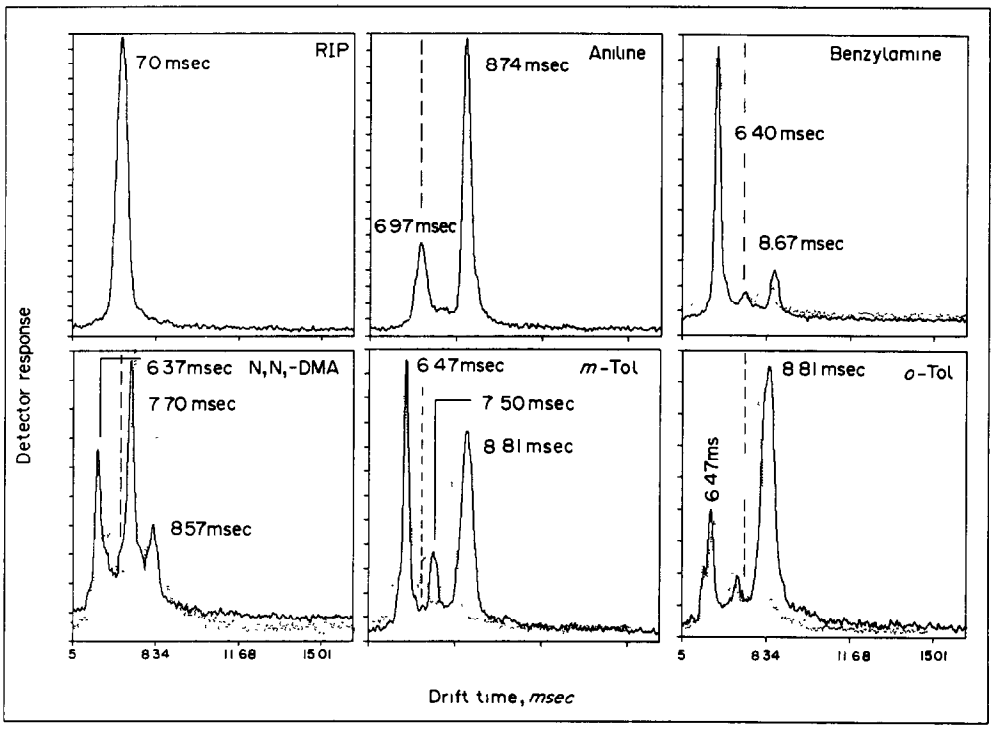

Fig. 1. Ion mobility spectra for aniline and aromatic amines in hexane with acetone ionization chemistry. Spectra were obtained in positive polarity with vapors from individual amines. The spectra made with dotted lines are for equal mixtures of aniline and the corresponding amine.

Ac_2H^+,[14] with a drift time of 7.0 ± 0.1 msec or a reduced mobility, K_o, of 1.83 $cm^2\ V^{-1}\ sec^{-1}$. The mobility spectrum for aniline contained a single symmetrical peak at a drift time of 8.74 msec, largely consistent with previous findings of a MH^+ product ion from water-based ionization chemistry. However, the K_o value was 1.32 $cm^2\ V^{-1}\ sec^{-1}$ versus 1.93 $cm^2\ V^{-1}\ sec^{-1}$ reported previously.[10] This difference is consistent with the formation of cluster ions such as MH^+*Ac arising from the Ac_2H^+ reactant ion.[14] Mobility spectra are also shown in Fig. 1 for other aromatic amines which may be considered environmental pollutants individually, or as matrix components, may be potential interferences in monitoring aniline. Reduced mobilities (in $cm^2\ V^{-1}\ sec^{-1}$) of 1.48, 1.49, 1.45 and 1.45 for benzylamine, *N,N*-DMA, *m*-toluidine, and *o*-toluidine, respectively were also lower than reported values of 1.78 for benzylamine and 1.81 for *N,N*-DMA. Such values are suggestive again of solvated ions of the kind MH^+*Ac seen earlier.[14] While ion identities are not known exactly, the results demonstrated the usefulness of this IMS as a FIA detector for aniline and portend possible chemical interferences for aniline determination (see above).

Clearance, reproducibility and response curve

The membrane-equipped inlet, ambient temperature drift tube and recirculated drift gas flows were expected to contribute to slow response for polar molecules like aniline and to memory effects lasting minutes after an exposure. These concerns were addressed in studies summarized in Table 1 where peak areas and percent relative standard deviations (%RSD) from repetitive determinations are listed for injection intervals of 15–90 sec. The %RSD ranged from 13 to 125 with a median of 21%, much greater than the expected 8–10% RSD.[11] This was associated with 13 m/min air flow in the fume hood causing turbulence at the injector-IMS nozzle region. A leak-tight connection was not employed initially to join injector and IMS nozzle due to concerns over membrane rupture in the IMS inlet from uncertain pressure gradients. A loose fitting sleeve was placed over the injector-nozzle to serve as a wind baffle and the deviations were reduced to 11% RSD or less (Table 1).

Memory effects in this IMS were visible in the mobility spectrum as a persistent product ion, seen as elevated peak areas at low injection intervals in Table 1, and as a rising offset or baseline voltage in the continuously monitored signal (not shown). The time for complete restoration to original reactant ion intensity was dependent upon concentration and ranged from *ca.* 5 sec at low levels to *ca.* 60 sec at 100 ppm. Concentrations below 20 ppm allowed injection intervals of 30 sec without serious memory effects (Table 1). An injection interval of 90 sec provided ample time for restoration of RIP intensity at concentrations from 1 to 100 ppm and was used in further studies.

Table 1. Peak areas from plots of aniline product ion intensity versus time in flow-injection ion mobility spectrometry

Aniline concentration, *ppm*	Peak area ($\times 10^6$) (% RSD) Interval for injection, *sec* 15	30	60	90	90[1]
0	0.83 (13)	1.6 (104)	0.84 (13)	1.1 (34)	*
0.4	2.8 (23)	5.4 (49)	2.5 (20)	2.0 (29)	*
1	6.8 (19)	5.2 (23)	4.6 (27)	3.6 (8.0)	26 (9.1)
5	19.6 (21)	14.9 (16)	16.0 (19)	10.9 (22)	83.3 (11.4)
10	32.6 (29)	32.9 (21)	30.4 (20)	26.1 (13)	151 (7.6)
20	*	35 (21)	41.9 (16)	46.6 (13)	240 (9.1)
40	*	49 (33)	40.4 (15)	37.6 (21)	356 (5.7)

*Baseline drift due to residual aniline was too severe for integration or recognition of a peak in flow injection IMS.

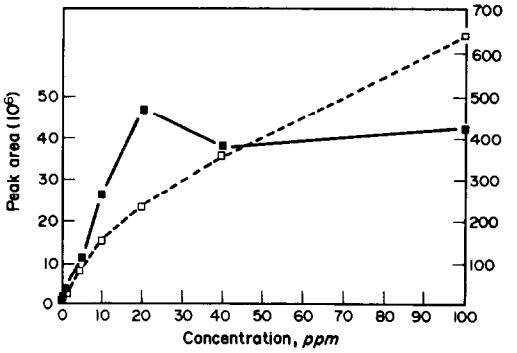

Fig. 2. Response curves for quantitative determination of aniline in hexane with IMS as detector for FIA. The curves are for interface configurations without (solid line) and with the injector-IMS nozzle sleeve to damp turbulence and cross flows.

Calibration curves, from values in Table 1, are shown in Fig. 2 for the 90-sec intervals and resembled previous response curves in IMS.[15] Such curves are comprised of a narrow linear range and a flat response at concentrations above the linear region. The narrow linear range with a saturated region originates with the comparatively slow kinetics of reactant ion formation from the beta-emitting ion source. This causes an effective limited reservoir of charge available for ionization of neutral analyte vapors.[16] The cause for differences between calibration curves with and without the sleeve (Fig. 2) are outside experimental error. The additional area is reasonable since mass transfer should be improved with a sleeve that reduces dilution from air flow in the fume hood. The sleeve-equipped interface eventually became flat at 200 ppm and the reason for this large working range is unknown.

Organic solvent interferences

The presence of various organic solvents in industrial effluents may degrade both the qualitative and quantitative response in IMS. Interfering vapors may either compete for charge hence masking the presence of the aniline, or overlap drift times hence confusing spectral interpretations. Alternatively, solvents in an ambient temperature cell can form ion-solvent clusters which lead to ambiguity through shifts in drift times for product ions.[14] These reactions will cause a decline in the certainty of a positive response or a false negative if no product ion is created or if the peak falls outside an observation window in the signal processing software. The magnitude of such effects should be governed by either proton affinities or polarities of prospective interferences.

Mobility spectra for four common organic solvents with low or medium proton affinities are shown in Fig. 3. Methylene chloride, with

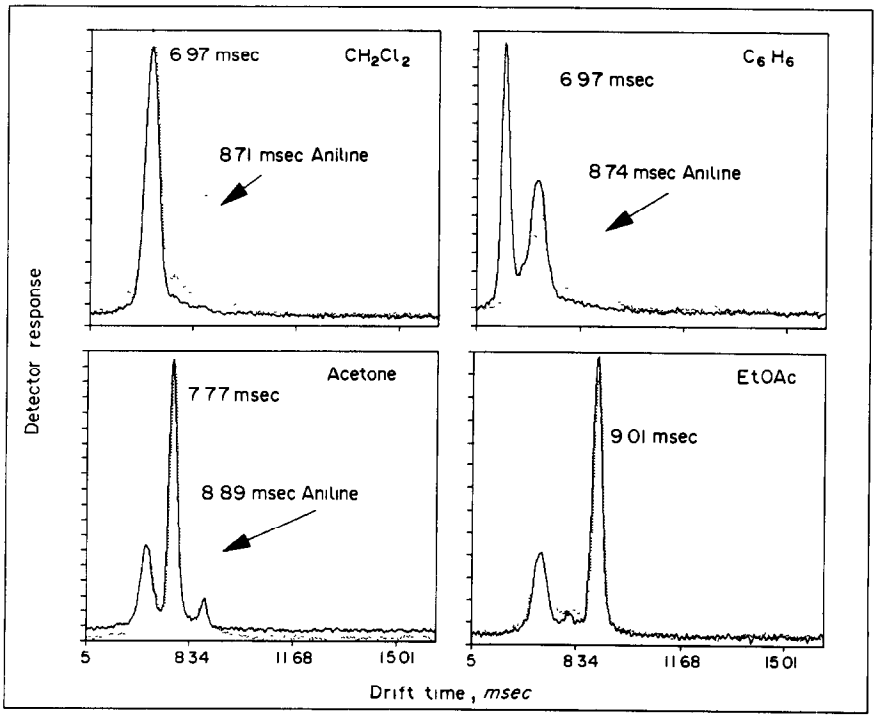

Fig. 3. Ion mobility spectra for organic solvents expected to be encountered in analysis of non-aqueous streams for aniline. Mobility spectra were obtained in positive polarity. Mobility spectra shown as dotted line spectra were for mixtures of 5 ppm aniline in an equal mixture of solvent with hexane.

low proton affinity, exhibited no product ions in positive polarity. Benzene, with weak proton affinity ($G^{\circ}_{300} = 19$ kcal/mole),[17] showed a weak response with an acetone reactant ion chemistry where the proton affinity of acetone is $G^{\circ}_{300} = 7.2$ kcal/mole. Acetone formed a cluster ion with drift times longer than that for the RIP through ion-molecule equilibria in the IMS drift region.[18] Only ethyl acetate (EtOAc) with a moderate proton affinity, *i.e.*, $G^{\circ}_{300} = 3.4$ kcal/mole, showed significant ionization from the RIP. Of these solvents, only benzene has been mass identified[18] as M^+, though acetates are known to form MH^+ and M_2H^+ product ions.[19]

Solvents in equal mixtures with hexane affected IMS spectra for 5 ppm injections of aniline as shown in Fig. 3 (dotted lines). Additionally, solvents influenced quantitative response at levels below 50% (v/v) as suggested in Fig. 4 though effects arose through different chemical events, not all of which are well described. Ethylacetate dominated aniline in the ionization step by virtue of concentration, even though proton affinities favored aniline ($G^{\circ}_{300} = -6.7$ kcal/mole) over ethylacetate. This occurred at 0.5% ethylacetate in hexane and virtually saturated the source so trends in response beyond 5% (v/v) were within experimental error. Benzene exhibited comparable interference even though the proton affinity for benzene is comparatively low. Evidently, benzene vapors were at levels sufficient to compete for protons through collisional ionizations. At low levels for acetone, no effect was obvious, at 25% and greater for acetone in hexane the signal associated with the mobility spectrum region for aniline increased. This was caused not

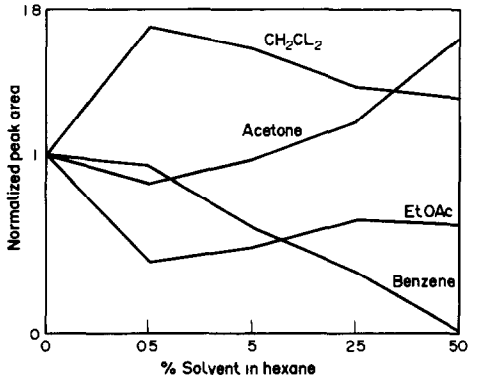

Fig. 4. Influence of organic solvents on FIA–IMS response to aniline. The normalized axis is peak area for aniline with the solvent divided by peak area for aniline at 5 ppm in hexane.

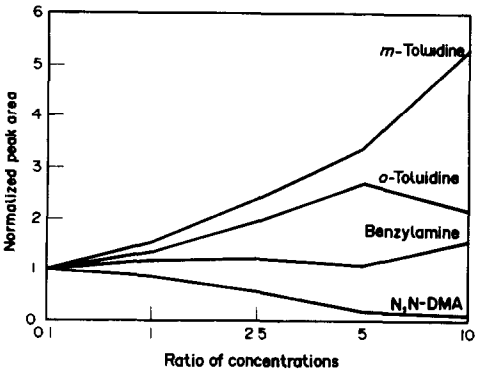

Fig. 5. Influence of aromatic amines on FIA–IMS response to aniline. The normalized axis is peak area for aniline with the solvent divided by peak area for aniline at 5 ppm in hexane.

by an aniline product ion but by the migration of an acetone product ion[14] into the mobility window used for aniline monitoring. In such a situation, only inspection of the mobility spectrum could avert an error in monitoring or analyses. The interference from methylene chloride was unexpected and the cause is unknown. These results suggest that solvent interferences can occur with this IMS configuration and matrix effects must be considered in quantitative monitoring. Previously,[20] Dam showed that similar complications in air monitoring by IMS could be corrected partially with standard addition methods (see above).

Aromatic amine interferences

Aromatic amines, with proton affinities larger than those for common organic solvents, should present serious interferences with aniline determinations by FIA or in continuous flow monitoring. The effects of concentratioon for four aromatic amines on the peak area of aniline are shown in Fig. 1 as dotted lines. The four aromatic amine compounds showed drift times near aniline and had proton affinities comparable to or greater than that for aniline. Toluidines were not well-resolved from aniline in the mobility spectra and were within the monitoring window. Appropriated charge combined with that for aniline to give enhanced apparent aniline product ion intensity. All of the aromatic amines, except *N,N*-DMA, yielded product ions at drift times different from aniline but close enough to enter the monitoring window and give false positives. In contrast, *N,N*-DMA ($G^{\circ}_{300} = 12.4$ kcal/mole) competed for charge in the ion source and caused a slight decrease in peak area for aniline (Fig. 5). Benzylamine was

not an interferent at ratios of 10:1 and below. Clearly, compounds with strong proton affinities if present in samples for FIA–IMS will cause substantial errors in aniline determinations.

Standard addition methods

Standard addition in IMS monitoring of flowing streams with variable matrices was demonstrated for airborne toxic vapors at an industrial site[20] and was deemed successful for improving accuracy in quantitative determinations. Issues here include both the type of matrix, *i.e.*, proton affinities of components and the concentration range of additions. Results from standard addition experiments are shown in Table 2 and provide clues into the general suitability of this IMS configuration for FIA measurements or for effluent stream monitoring. A total of 10% (v/v) of low proton affinity solvents, benzene ($G^{\circ}_{300} = 19.0$ kcal/mole), methanol (G°_{300} 19.3 kcal/mole) and acetone caused appreciable errors in direct measurements of aniline at 10 ppm. Standard addition methods resulted in low errors so long as a suitable range of additions was employed. Small increments should be expected to cause large uncertainty in the slope of the extrapolation. Large concentrations where source saturation occurs should extend the IMS into non-linear response also causing error. When the ion source is not saturated (10 ppm addition for a total of 20 ppm aniline) the error was low. A matrix which contains strong proton affinity interferences represents a debilitating condition (Table 2) for an IMS without a pre-separation inlet and no useful information was gleaned from the error figures. Medium interfering mixtures with moderate proton affinities, EtOAc, ethylether ($G^{\circ}_{300} = 3.7$ kcal/mole), n-propanal ($G^{\circ}_{300} = 10.9$ kcal/mole) were expected to provide an illustration of the strength of standard addition methods. Results were suggestive of source overload since the lowest concentration range (1 ppm total addition) gave a reasonable error of 23%. These results are considered only preliminary and it is encouraging that the quantitative IMS response is possible in low and possibly medium strength interferences given suitable concentrations of interferences.

Table 2. Errors from determination of aniline at 10 ppm in interfering matrices

Range of addition	Low interference	Percent error between measured versus known Medium interference	Strong interference
0–1 ppm	3.4×10^{2}	23	37
0–10 ppm	7×10^{-1}	1.9×10^{2}	8.8×10^{3}
0–50 ppm	52	1.8×10^{2}	3.0×10^{3}
0–100 ppm	1.3×10^{2}	3.5×10^{2}	1.6×10^{3}

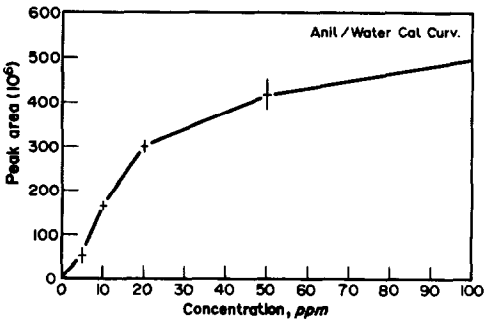

Fig. 6. Calibration curve for aniline in water by FIA–IMS.

Ion mobility spectrometry of aniline in aqueous solutions

When injections of aniline in water were made in the IMS with small volumes at intervals of *ca.* 90 sec, the performance of the IMS did not change perceptibly illustrating that water provided no dramatic interference in ionizaton and suggesting that the membrane inlet was functional. Mobility spectra were good quality and the linear range extended to 100 ppm (Fig. 6). This expanded linear range may originate with a water layer on the membrane of the inlet lowering membrane efficiency for aniline. This effect was also expected from the increased memory effect with water injections as shown in Fig. 7 where even low concentrations required long restoration times of clean ion source conditions. The effects of continuous water flow on

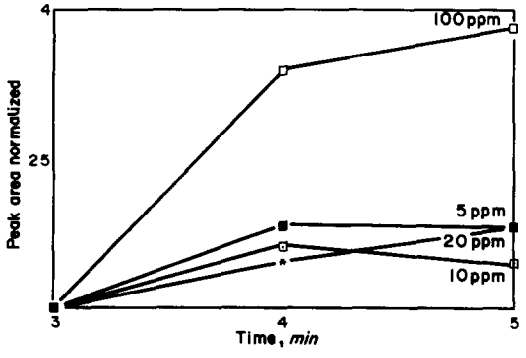

Fig. 7. Memory effect for injections of aniline during delivery of water continuously to the injector-IMS. Various flow-rates of water are given in the figure. The top bar is for aniline peak heights from FIA–IMS analysis taken intermittently during the time of the Silastic tube studies.

hand-held IMS were catastrophic (Fig. 8) for chemical measurements regardless of flow-rates from 10 to 300 μl/min. Clearly, the technology for this membrane based inlet as configured for military applications was not directly transferable to monitoring aqueous streams following volatilization of sample in a heated zone.

Two solvent-free approaches to isolating volatile organic compounds (VOCs) from water have been described and involve either removing water from a wet volatilized flow[21,22] or extracting VOCs from water into a gas flow.[23–25] Water was successfully removed from a wet nitrogen stream containing sample through the use of a Nafion drying tube.[21,22] However, aniline was not detected in the dried effluent from the Nafion and this approach was regarded as unpromising for polar compounds. The alternate approach of isolating VOCs from water via a permeable tube had previously been used with mass spectrometry[23–25] and concern existed that such behavior might be related to the mass spectrometer vacuum. A Silastic tube swept with air was effective in continuously detecting aniline in water from 1 to 200 ppm as shown in Fig. 9. The response was somewhat sluggish but certainly proportional to aqueous compositions and extraction efficiency was very sensitive to water temperature necessitating a temperature-controlled unit for future designs. A positive benefit of this attachment was the absence of water fouling of the IMS (Fig. 8) during the course of these experiments. Terminal studies are needed to establish the duty cycle for sieve packs used for recirculated IMS drift although three years of experience suggest an upper time limit of 90 days is the best condition.

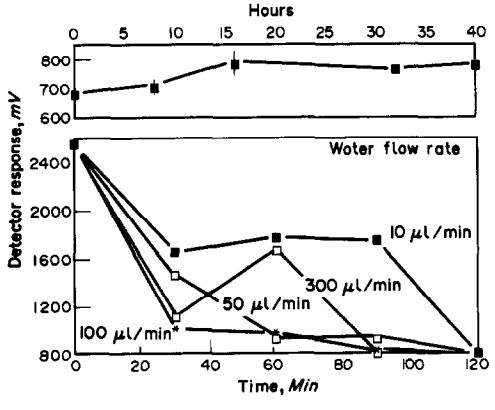

Fig. 8. IMS response to aniline during exposure to continuous flow of water. Top frame shows IMS response to aniline during studies with Silastic.

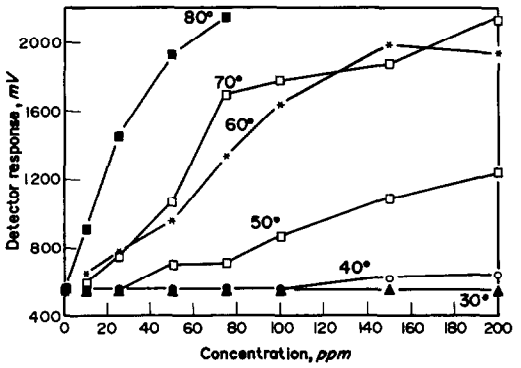

Fig. 9. Response of IMS as continuous flow monitor of water with Silastic tube inlet. Limit of detection (not shown) was *ca.* 0.1 ppm for upper temperatures.

CONCLUSIONS

Flow-injection studies showed that an ion mobility spectrometer was a quantitative detector for aniline with a precision of *ca.* 10%, a linear range of 1–100 ppm, and replicate analysis times of 90 sec or less. The susceptibility of response to potential solvent or chemical interferences suggests that use of IMS must be limited to chemical mixtures where competitive charge exchange does not alter response characteristics. Interest in IMS as a fixed aqueous waste stream monitor developed from the low cost, small size and field configurations. However, possible adaptation of a hand-held IMS for direct sampling of an aqueous stream was thwarted by water permeation of the inlet membrane which caused fouling of ion source chemistry. This can be circumvented by the use of Silastic membranes and preliminary findings supported further development of IMS as an effluent waste stream monitor.

ESTIMATION OF THE METHOD EVALUATION FUNCTION FOR THE DETERMINATION OF HYDRIDE-GENERATING ARSENIC COMPOUNDS IN URINE BY FLOW-INJECTION ATOMIC-ABSORPTION SPECTROMETRY

ANN J. L. MÜRER,* ANNE ABILDTRUP, OTTO M. POULSEN and JYTTE MOLIN CHRISTENSEN
Danish National Institute of Occupational Health, Department of Chemistry and Biochemistry, Lersø Parkalle' 105, DK-2100 Copenhagen, Denmark

(*Received* 11 *July* 1991. *Revised* 27 *September* 1991. *Accepted* 22 *October* 1991)

Summary—A direct flow-injection atomic-absorption spectrometric (FIA–AAS) method for the assessment of inorganic arsenic compounds and their metabolites was developed and statistically evaluated by the estimation of the method evaluation function (MEF), which provides detailed information on the analytical performance of the method, *i.e.*, the average combined uncertainty and the magnitude of potential systematic errors. The method evaluation study demonstrated that the use of standard addition was a necessity to obtain an acceptable method performance at low concentrations typical for low dose exposure. In contrast the use of calibration curves resulted in a method with reduced sensitivity and high systematic error. The developed method, using standard addition, had a limit of detection (2.9 μg/l.) sufficiently low for the determination of hydride-generating arsenic species in urine from non-exposed and low exposed persons. Organoarsenicals such as arsenobetaine and arsenocholine are not detected by this method. Hence, the contribution of these compounds derived from a diet containing seafood does not affect the monitoring of inorganic arsenic compounds after occupational or environmental exposure. The high capacity of the FIA–AAS system (three minutes per sample measured by standard addition) together with the low limit of detection makes this method suitable for biological monitoring of inorganic arsenic exposure even though standard addition is required.

As inorganic arsenic compounds are well known carcinogens,[1] assessment of environmental and occupational exposure is of medical and political importance. Occupational exposure to inorganic arsenic compounds occurs in industries involved in such things as wood preservation, glass production and manufacturing of lead accumulators. In 1985 arsenic pentoxide was among the 15 most widely used compounds in Danish industry.[2] Environmental exposure occurs in relation to either an ongoing industrial pollution[3] or a previous pollution of waste sites for example.[4]

During the last five years, assessment of airborne exposure has been supplemented by biological monitoring.[3-5] The good correlation between airborne concentrations of inorganic arsenic and the urinary excretion of inorganic arsenic and its metabolites monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA), together with the convenience of collecting urine samples, makes urine the preferred biological material in biological monitoring.[4] The short half-life of the hydride-generating arsenic compounds means that only the exposure of the last few days is reflected in the urinary concentration measured.[6]

So far hydride-generating atomic-absorption spectrometry, using a MHS-10 system has been used for biological monitoring of the sum of inorganic arsenic and its metabolites.[7] However, the analytical capacity of this method is high only when calibration curves are used, assuming that no systematic error is introduced when different urine samples are analysed.

Whenever analytical results are associated with large consequences, *i.e.*, evaluation of health risk in relation to occupational or environmental exposure, documentation of the quality of the method should be mandatory. The method evaluation design developed at our institute[8-11] validates the analytical method by estimating the method evaluation function (MEF) resulting in a simultaneous estimation of the total errors of the analytical method, includ-

*Author for correspondence.

ing the within and between run uncertainties, and the systematic errors.

In order to enable the assessment of low dose occupational and environmental exposure of inorganic arsenic compounds, the aim of the present study was to develop a fast, automatic and direct flow-injection hydride-generation atomic-absorption (FIA–AAS) method for the measurement of inorganic arsenic compounds and their metabolites in urine. The experimental design mentioned above for method evaluation was modified to evaluate the method.

EXPERIMENTAL

Reagents

Demineralized water (18 mΩ) purified through a Millipore Purification System S.A. (Millipore Waters, Taastrup, A.B. Denmark) was used for all aqueous solutions. Unless otherwise stated all chemicals were of analytical reagent grade.

A 1000-μg/ml dimethylarsenic acid (DMA) stock solution was prepared by dissolving $(CH_3)_2AsO(OH)\cdot 3H_2O$ (Sigma no. C-0250, Dorset, United Kingdom) in water. This stock solution was used to prepare both the five different standards for standard addition and the method evaluation function (MEF) samples.

Pure samples of arsenite, arsenate, monomethylarsonic acid, dimethylarsenic acid, arsenocholine and arsenobetaine (all 1.00 g of the compound per litre) were from the ongoing intercomparison study on arsenic species organized by BCR.[12]

The reagents for flow-injection analysis and hydride-generation were: antifoaming agent tri-n-butylphosphate (BDH no. 30488, United Kingdom), argon used as carrier gas, sodium borohydride 0.5% (Fluka no. 71320, Buchs, Switzerland) in 0.04% sodium hydroxide (Merck no. 6498, Damstadt, Germany) used as a reductant and 2% hydrochloric acid (Merck no. 937, Damstadt, Germany) as an acidic carrier solution for the hydride generation.

Sample preparation for method evaluation

Three different urine pools were collected, two pools from unexposed persons (pool A and pool B) and one pool (C) from a slightly exposed person resident in a polluted area (9.3 μg/l. As in urine). All persons were requested to abstain from consuming seafood for three days before sampling.

For each of the three urine pools ten different method evaluation function (MEF) samples were prepared by spiking with a defined volume of the DMA stock solution to obtain concentrations in the linear range of the method (0–45 μg/l. As in urine). The samples were stored at −5°. The order of analysis of the MEF samples was randomly selected. Only two concentration levels from each urine pool were determined each day. Each MEF sample was determined twice on different days. A total of 57 MEF samples were measured.

Apparatus

The employed apparatus was a Perkin–Elmer 1100 B AAS equipped with an EDL Power Supply, autosampler AS 90, Flow-Injection Analysis FIAS 200 (all from Perkin–Elmer, Germany). The arsines were determined at 197.3 nm in a heated (900°) quartz cell.

The following modifications of the equipment were made in order to optimize the method:

(1) An enlarged gas/liquid separator with an inner cubic content of 8.29 cm^3 instead of the standard separator of inner cubic content 3.29 cm^3. This modification was necessary as proteins present in the urine samples produced large amounts of foam in the system disturbing the measurements in the AAS when using the standard separator.

(2) Three metres of mixing tube (inner diameter of 0.8 mm) with 20 knots giving coils with a diameter of 35 mm was used to improve the mixing resulting in a more optimal signal as compared with the signal obtained when no knots were used.

(3) A sample loop (inner diameter approximately 0.9 mm) containing 80 μl. This size is big enough to produce a signal with a low detection limit, and in combination with the previous described modifications, it is small enough to avoid problems with the foam producing proteins in the urine.

Procedure

Figure 1 outlines the basic design of the optimized FIA–AAS system.

It is of importance that the pH of the reaction mixture has reached a constant low pH (pH < 1) before reaching the gas/liquid separator to obtain optimum hydride generation. A final adjustment of the concentrations of reagents, the number of knots on the mixing tube and the flow-rates of the FIA-system was done by

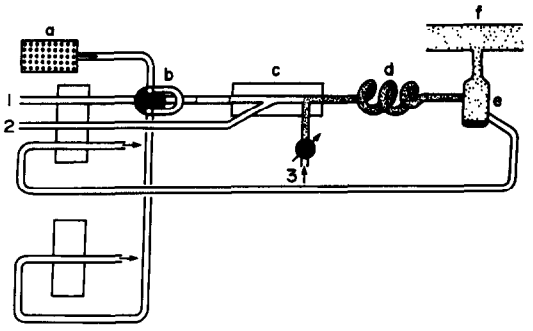

Fig. 1. The prediluted samples (a) were injected through the injection valve (b) into the carrier stream (1). $NaBH_4$ (2) was added in the chemifold (c) and the mixture was passed through the knotted mixing tube (d). Argon (3) was admitted (85 ml/min) to carry the developed arsines from the gas/liquid separator (e) to the heated quartz cell (f).

running a pH-indicator solution through the tubes and observing the colour change throughout the transparent system.

The concentration of hydride-generating arsenic compounds (arsenite, arsenate, MMA and DMA)[7] in urine was determined by using standard addition with five different concentrations of As (as DMA) ($x + 0$ μg/l., $x + 10$ μg/l., $x + 20$ μg/l., $x + 30$ μg/l. and $x + 40$ μg/l.) and weight regression analysis (3, 2, 1, 1 and 1) of the standard addition curves. In addition calibration curves with the same concentrations of DMA in urine were prepared for estimation of the arsenic concentration of the MEF samples. New samples for calibration were prepared each day with different batches of urine. Hence only two MEF samples from each urine pool (A, B and C) were measured on each calibration curve. This design includes matrix differences of the urine in the method evaluation.

Peak areas were recorded in all cases as recommended by Norin and Vahter.[7]

Statistics

Method evaluation was carried out as described previously.[8–11] The principles of the method evaluation design are as follows:

Any chemical method can be characterized by its method evaluating function (MEF) which is the estimated result of the chemical analysis, $E(Y|\mu)$, as a function of the true value of the analyte, μ. The equation of MEF is:

$$\text{MEF}(\mu) = E(Y|\mu) = \alpha + \beta\mu$$

The method evaluation is performed by statistical analysis of the MEF. The underlying theory is based on the assumption that the analytical method is in statistical control, *i.e.*, the distribution of Y given μ can be approximated by a normal distribution. Test for normal distribution is performed as described by Miller and Miller.[13] When the assumption is correct the standard deviation (SD) of Y given μ is an expression of the combined uncertainty of the method.

Linearity of the MEF plot is tested with the pure error lack of fit test.[14] The systematic error (the accuracy) is then the combination of the so-called zero point error (α) and the proportional error ($\beta - 1$). Ideally, an analytical method should be without any systematic error (*i.e.*, $\alpha = 0$ and $\beta = 1$). In practice it is, however, not possible to assure $\alpha = 0$ and $\beta = 1$ for all values of μ. When a least square regression analysis of the MEF is performed and the standard deviation of α and β is calculated, the accuracy of the measurements is validated by testing if $\alpha = 0$ and $\beta = 1$ using a T-test.[15] If the uncertainty of the method increases profoundly with increasing true value (μ) (*i.e.*, the relative standard deviation increases more than 50% over a 15-fold range of concentration[16]) weight regression analysis should be used to estimate the value and standard deviation of α and β, respectively.

RESULTS AND DISCUSSION

The method evaluation design originally developed for analytical methods, using calibration curves was used with the following modifications:

The concentration of hydride-generating arsenic compounds in the 57 MEF samples were determined using both calibration curves (C) and standard addition (S), respectively. For each of the three urine pools the average endogenous background values were estimated. These endogenous background values were subtracted from the spiked values of the 57 MEF samples prior to the final statistical treatment of MEF.

Plots of the MEF of S(ABC) (MEF plot of values obtained by standard addition on all samples from pool A, B and C) and the MEF of C(ABC) (MEF plot of values obtained by the use of calibration curves on all samples) is presented in Fig. 2. The results of the method evaluation are presented in Table 1.

The n-score test of all MEF presented in Table 1 revealed that in no case did the distribution of the MEF points around the line of

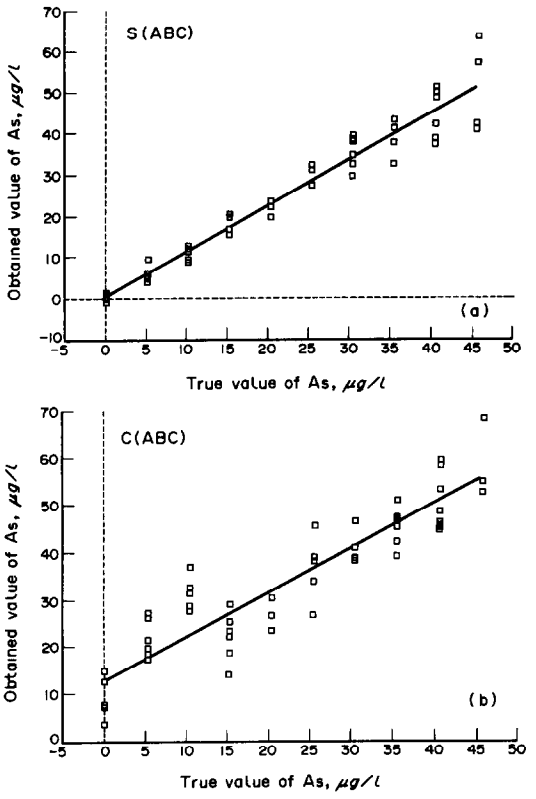

Fig. 2. The obtained values of the MEF samples are plotted against the true values. S(ABC) values are obtained using standard addition on all samples from pool A, B and C. C(ABC) values are obtained using calibration curves on all samples from pool A, B and C.

regression deviate from the normal distribution. The pure error lack of fit test for linearity showed that the use of standard addition results in a linear MEF [P = 0.980 for S(ABC)]. In contrast, the MEF obtained by using calibration curves significantly deviated from linearity [P = 0.0003 for C(ABC)]. In principle, it is not valid to perform the test for systematic errors in the case of C(ABC) since the MEF is non-linear. For the sake of comparison the values of α and β are, however, included in Table 1 and validated for both C(ABC) and S(ABC). The tests for systematic errors (α and β) revealed that MEFs using standard addition had no zero point error (*i.e.*, α was not significantly different from zero), whereas the MEF based on calibration curves had a profound zero point error. The reversed pattern was seen with respect to the proportional error, where standard addition resulted in a significant proportional error (*i.e.*, β was significantly different from one), whereas the use of calibration curves produced no significant proportional error. Weight regression analysis of S(ABC) did not result in estimates of α and β significantly different from the estimates obtained with unweighted regression analysis (Table 1). The employed weights were the inverse of the squared true values multiplied with 25 ($25/\mu^2$), hence the weight at $\mu = 5$ μg/l. was one. The same weight was used at $\mu = 0$ μg/l.

Table 1. Method evaluation parameters

MEF	α	SD_α	β	SD_β	$SD(Y\|\mu)$
S(A)	0.45	1.82	1.076	0.070	3.91
S(B)	1.21	1.44	1.093	0.060	3.88
S(C)	−0.14	1.82	1.194	0.070	4.73
S(ABC)	0.40	0.92	1.123	0.036	3.99
S_w(ABC)	0.14	0.27	1.145	0.032	0.99*
C(ABC)	12.8	1.4	0.949	0.056	6.12

*The SD $(Y|\mu)$ at weight = 1.

The FIA–AAS method using standard addition (S) was statistically evaluated for each of the three batches of urine alone [S(A), S(B) and S(C)] and in combination [S(ABC)]. S_w(ABC) denotes the MEF parameters obtained by weight regression analysis of the MEF plot. In addition the method using calibration curves was evaluated for all three batches in combination [C(ABC)]. $SD(Y|\mu)$ is the combined uncertainty of the method. SD_α and SD_β are the standard deviation of the estimated intercept (α) and slope (β) of the regression line.

The limit of detection, 2.9 μg/l., of the method was determined as three times the standard deviation of ten measurements of samples at a concentration level of 3.7 μg/l. This value is in accordance with the limit of detection obtained by estimating the MEF, using weight regression analysis (3 × 0.99 μg/l. ≈ 3.0 μg/l.).

Using the described method a single determination is done in 40 sec, meaning that a complete determination of a sample, using five standard additions lasts 3.3 min in total.

No certified reference urine materials is available with concentrations of hydride generating arsenic compounds in a range relevant for low dose exposure. In order to study both accuracy and the molar sensitivity of the developed FIA–AAS method, different arsenic species samples were prepared by spiking water and a pool of urine with 40 μg/l. of either arsenite, arsenate, MMA, DMA, arsenobetaine or arsenocholine, all from the ongoing BCR programme.[12] The arsenic concentration was measured by using standard addition with the DMA stock solution. The recovery of arsenite, MMA and DMA was not significantly different from 100%. By contrast, the sensitivity to arsenate was reduced by approximately 20%, and no signal was obtained for the organic compounds, arsenobetaine and arsenocholine.

Biological monitoring of environmental and occupational exposure to inorganic arsenic compounds often requires an analytical method with high capacity.[4] So far hydride-generating AAS, using a MHS-10 system has been used for monitoring the sum of inorganic arsenic and its metabolites.[7] However, the analytical capacity of this method is high only when calibration curves are used. The present MEF study demonstrated that the use of calibration curves may result in a method with a non-linear MEF. As indicated in Fig. 2 the non linearity originates from the three lowest concentrations of the MEF samples, which appears to be outside the linear range of the method. A possible contamination of these samples can be excluded since the same samples showed no bias in the method evaluation using standard addition. The bias may partly be explained by the fact that hydride-generating systems in general have a tendency to produce non-linear standard curves,[4] which produce overestimated values at the low concentrations when linear regression analysis is used to estimate the calibration equation. Consequently, non-linear regression analysis may reduce this bias. When the MEF is estimated for the MEF samples with As concentrations above 10 μg/l. a linear MEF is obtained. However, this MEF has both a zero point error ($\alpha = 4.75$) and a significant proportional error ($\beta = 1.18$) in addition to a fairly high uncertainty [$SD(Y|\mu) = 5.26$]. Consequently, the use of calibration curves resulted in an inferior FIA–AAS method as compared with the method based on standard addition. Only the latter is suited to the assessment of low dose arsenic exposure with an acceptable performance. The use of standard addition in combination with FIA–AAS gives a sufficient high capacity and the developed FIA–AAS method has been used at our department for biological monitoring of environmental and occupational exposure.[17]

The standard deviations of Y given μ in Table 1 represent the average uncertainty of the method with respect to the linear range studied. Since the uncertainty increases with increasing concentration of the arsenic compound (see Fig. 2) the average uncertainty is well above the uncertainty used for the calculation of the limit of detection (*i.e.*, three times the standard deviation at a very low concentration close to the expected limit of detection). When weight regression analysis was used to estimate MEF, the estimated standard deviation of Y given μ (at weight = 1) was in accordance with the uncertainty used for calculation of the limit of detection. These results add further weight to the usefulness of the method evaluation function design.[8–11]

The method evaluation study demonstrated a significant systematic proportional error ($\beta = 1.12$) of the FIA–AAS method using standard addition. The DMA concentration of the stock solution used for preparation of both the method evaluation samples and for the standard addition solutions was confirmed by using the BCR DMA standard solution. Consequently, it is not likely that the proportional error is due to a calibration error, so the proportional error must be considered an expression of the recovery of the method. The above mentioned explanation may still apply, *i.e.*, the standard addition curves of the FIA–AAS method tend to be non-linear, *i.e.*, the standard addition point at the highest concentration of the standard added is nearly always situated below the line of regression (data not shown). When least square regression analysis is used on this type of non-linear standard addition curves the concentration of the hydride-generating arsenic compounds will be overestimated. Part compensation for this tendency is obtained by the use of weight regression analysis on the standard addition curves. When the developed FIA–AAS method is used for measurements on urine samples the remaining systematic error is corrected by dividing the measured values by 1.12. An identical correction (measured conc/1.12) has been described by others.[4]

Recently, Larsen[12] published an optimized Zeeman–AAS method for determination of arsenite, arsenate, MMA, DMA, arsenobetaine and arsenocholine in aquatic solutions with the same molar sensitivity. Since this method measures both arsenocholine, arsenobetaine and the hydride-generating arsenic compounds it may be attractive to use this in combination with our FIA–AAS method in order to estimate the contribution of the organoarsenic compounds in urine. It should, however, be emphasized that the applicability of the Zeeman–AAS method has not yet been documented on biological samples.

The developed FIA–AAS method had a recovery of arsenite, MMA and DMA in urine not significantly different from 100%, whereas a reduced sensitivty to arsenate was observed. This result is in accordance with Buratti *et al.*[18] but in disagreement with Norin and Vahter,[7]

who showed the same sensitivity for MMA, DMA and arsenate. The reduced sensitivity to arsenate may be considered acceptable since this inorganic species represents only approximately 1% of the total urinary excretion of arsenic compounds.[6]

The developed FIA–AAS method does not measure the two organoarsenic compounds, arsenobetaine and arsenocholine. Consequently, a contribution of these compounds originating from a diet containing seafood is not likely to be measured. However, since seafood on some occasions does contain substantial amounts of hydride-generating arsenic compounds a restricted diet is requested by routine prior to assessment of occupational and environmental inorganic arsenic exposures.

POTENTIOMETRIC STUDY OF COMPLEX FORMATION EQUILIBRIA OF α-OXOOXIMES WITH COPPER(II) AND NICKEL(II) IONS

A. IZQUIERDO,* M. GRANADOS and J. L. BELTRAN
Departament de Química Analitica, Universitat de Barcelona, 08028 Barcelona, Spain

(*Received* 29 *March* 1991. *Revised* 8 *July* 1991. *Accepted* 26 *July* 1991)

Summary—Complex formation equilibria between copper(II) and nickel(II) with phenylglyoxal 2-oxime (HPGO) and 1-phenyl-1,2-propanedione 2-oxime (HPPO) have been studied in 50% (v/v) ethanol–water solution containing 0.5*M* sodium nitrate as constant ionic medium at 25°, using glass electrode potentiometry. The emf data obtained have been analysed with MINIGLASS and SUPERQUAD programs. Formation constants for the $Cu(PGO)^+$, $Cu_2(PGO)(OH)^{2+}$, $Cu_2(PGO)_2(OH)^+$, $Ni(PGO)^+$, $Ni_2(PGO)_3^+$, $Ni_2(PGO)_4$, $Ni_2(PGO)_2(OH)_2$, $Cu_2(PPO)(OH)^{2+}$ and $Cu_2(PPO)_2(OH)^+$ complexes are reported.

α-Oxooximes are analytical reagents widely used in spectrophotometry for metal ion determination,[1] but little attention has been paid to the complexation and distribution equilibria related to these systems.[2–6] Most of the literature about α-oxooxime metal complexes deals with the composition and structure of solid complexes.[7–11] These studies point out that α-oxooximes act as bidentate ligands, via carbonyl and oximic groups, forming five or six-membered chelate rings.

Complexation between Cr(III), Mn(II), Fe(III), Co(II), Ni(II) and Cu(II) and some α-oxooximes were studied by Bhargava and Tyagi[2] in 75% methanol–water mixtures and they identified only monomeric species (ML, ML_2 or ML_3). In the study about complexation between lanthanum(III) ions and α-oxooximes, Manku[3] also reports the formation of monomeric species. Nevertheless, in previous studies on solvent extraction of divalent ions with α-oxooximes,[5,6] we have found that polynuclear complexes can be formed. Moreover, some studies on solid complexes of these systems have also pointed out the existence of polynuclear species.[7,8]

In order to ascertain the possible formation of polynuclear complexes between α-oxooximes and divalent metal ions, we have studied the complexation equilibria between copper(II) and nickel(II) with phenylglyoxal 2-oxime (HPGO) and 1-phenyl-1,2-propanedione 2-oxime (HPPO). This work was carried out by means of glass electrode potentiometry at 25° and 0.5*M* sodium nitrate ionic strength. Because of the low solubility of the ligands in water, 50% (v/v) ethanol–water mixtures were used. The acid–base equilibria of the ligands in these conditions had been determined previously[12] and the dissociation constants are: $pK_{HPGO} = 8.77 \pm 0.02$ and $pK_{HPPO} = 10.07 \pm 0.02$.

EXPERIMENTAL

Reagents and solutions

Phenylglyoxal 2-oxime (Aldrich), 1-phenyl-1,2-propanedione 2-oxime (Aldrich), nitric acid (Merck AR), copper nitrate (Merck AR) and nickel nitrate (Merck AR) were used without further purification. Sodium nitrate (Probus AR) was purified by recrystallization in water. Sodium hydroxide solutions free from carbon dioxide were prepared by dilution of a concentrated solution of sodium hydroxide (Merck AR) according to Kolthoff *et al.*[13] These solutions were kept under a CO_2-free atmosphere and standardized by titration with potassium hydrogenphthalate. Nitric acid solutions were standardized volumetrically with tris(hydroxymethyl)aminomethane, copper(II) stock solution was standardized iodimetrically and nickel(II) stock solution was standardized as bis(dimethylglyoximate)nickel.[14] All these solutions were made 50% (v/v) ethanol–water by mixing doubly distilled freshly boiled water and ethanol (Merck AR). The ionic strength was kept at 0.5*M* with sodium nitrate. A flow of nitrogen (previously

purified with vanadous perchlorate and barium hydroxide) was bubbled continuously through the solution in the potentiometric cell.

Apparatus

A Radiometer PHM64 pH meter equipped with a combined Ross pH-electrode (Orion 81-02) was used. The titrand (sodium hydroxide solution) was added with a Metrohm 655 Multi-Dosimat automatic burette with a 10.0-ml exchanging unit. Sample solutions were titrated in a double-walled vessel maintained at 25 ± 0.1° by circulating water and were stirred magnetically under a continuous flow of nitrogen. The potentiometric assembly was controlled by an HP 9816 microcomputer via an HP 3421A data acquisition control unit.[15]

Infra-red spectra (potassium bromide pellets) were recorded on a Perkin–Elmer 1330 spectrophotometer.

Procedure

The electrode system was calibrated in terms of hydrogen ion concentration from strong acid–strong base titrations by the Gran method.[16] The value of the ionic product of the medium is $-\log K_w = 14.165 \pm 0.015$. In this medium, the liquid junction potential, $E_j = j_{OH}[OH^-]$, must be taken into account in basic solutions: $j_{OH} = 282 \pm 5$ mV/*M*. In acidic medium, the liquid junction potential is negligible in the working range.

Complexation equilibria have been studied at several metal concentrations and different ligand-to-metal ion concentration ratios. The experimental conditions of the titrations performed are listed in Table 1. Taking into account the errors in the preparation of solutions (from glassware, weighing of ligands and the standardization of metal ion stock solutions), the errors in the concentrations listed are within 0.2–0.3% of its value. In all the systems studied the titrations were performed up to pH values at which the formation of precipitates began and unstable emf measurements were obtained.

The numerical analysis of all the experimental emf data was carried out with the computer programs MINIGLASS[15] and SUPERQUAD.[17] When SUPERQUAD was used, the errors in the titrant volume added and the measured emf value, were taken as 0.02 ml and 0.2 mV, respectively, according to the specifications of automatic burette and potentiometer used.

RESULTS AND DISCUSSION

Copper(II) complexation equilibria

The results obtained in the complexation study between copper(II) ions and HPGO or HPPO are given in Table 2. In the calculation of the confidence range of the logarithms of these formation constants, as well as those corresponding to the nickel(II) complexes, we

have taken into account the standard deviations in the constants given by the computer programs, and the standard error deviation from the error propagation law, on the basis of the errors in concentration of reactants and in the measured emfs.

From the values of the constants obtained, the distribution of species which contain copper(II) as a function of pH was evaluated for both systems (Figs. 1 and 2). In the copper(II)–HPGO system titrations can only be performed up to pH values around 5, because above this value precipitates are formed in the solutions. In the copper(II)–HPPO system precipitation takes place around pH 4.5. The formation curves are not superimposed in either system (Figs. 3 and 4), which points to the existence of protonated or polynuclear species or hydroxocomplexes.

In the copper(II)–HPGO system the best fit of the experimental data has been found with the model containing the monomeric 110 and the dimeric 21-1 and 22-1 species, expressed as mlh, where m, l and h are the stoichiometric coefficients for metal ion, deprotonated ligand and hydrogen ion, respectively. Although the 110 species is formed only to a maximum of 10%, its inclusion in the postulated model gives an improvement of the fitting.

In the copper(II)–HPPO system the proposed model is very similar and it is composed by the species 21-1 and 22-1. The 110 species is rejected by the programs. The 22-1 species is formed to a slight extent (less than 10% and not in all the titrations performed) before precipitation occurs, but its inclusion in the model improves the fitting significantly.

Elemental analysis of precipitates obtained from different ligand:metal ratios gives, in both systems, results that are between the theoretical values corresponding to the neutral species $[CuL_2]_x$ and $[CuL(OH)]_y$ (Table 3). As the ligand:metal ratio increases the results approach the values corresponding to $[CuL_2]_x$ species.

A comparison of the IR absorption spectra of the insoluble complexes and those of the pure ligands shows variations of some IR bands due to complexation. The most characteristic are the

lowering of νC=O and the shifting of νN—O to higher frequencies, indicating coordination through these groups.[3,8–10] A strong broad band appears around 3300 cm^{-1}, corresponding to νO—H. This band was described by Danilewicz *et al.*[7] in the IR spectra of a complex of copper(II) and HPPO obtained from a ligand:metal ratio of 1:1. The stochiometry of this complex is Cu(PPO)(OH); it has been proposed that this compound is a dimer or indeed a polymer of higher order.

Some of the species detected in the potentiometric study appear to be previous steps to the formation of this kind of complex. $[CuL(OH)]_x$, but the neutral species have not been detected, probably because of their low solubility in common solvents.[7]

The complexing behaviour of HPGO and HPPO is very similar, both ligands showing a trend towards dimeric species, which is in accordance with the fact that they have the same active coordination centres against metal ions. On the other hand, in the copper(II)–HPGO system complexation begins at a pH lower than

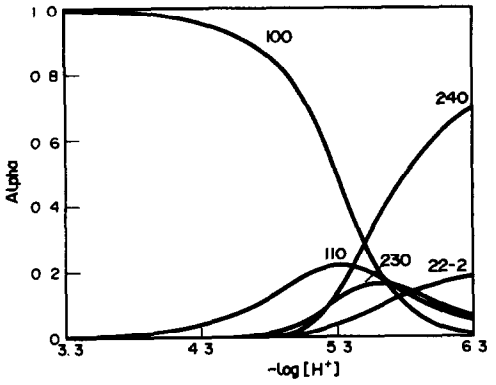

Fig. 5. Species distribution diagram for Ni(II)–HPGO complexes. $[Ni^{2+}] = 2.4mM$, $[HPGO] = 47.5mM$.

that in the copper(II)–HPPO system, as can be expected from the pK_a values of these reagents.

Nickel(II) complexation equilibria

It was not possible to carry out the complexation study betwen nickel(II) and HPPO because in the experimental conditions (ligand:metal ratio between 5 and 25) stable emf readings were only obtained at pH < 6, where complexation

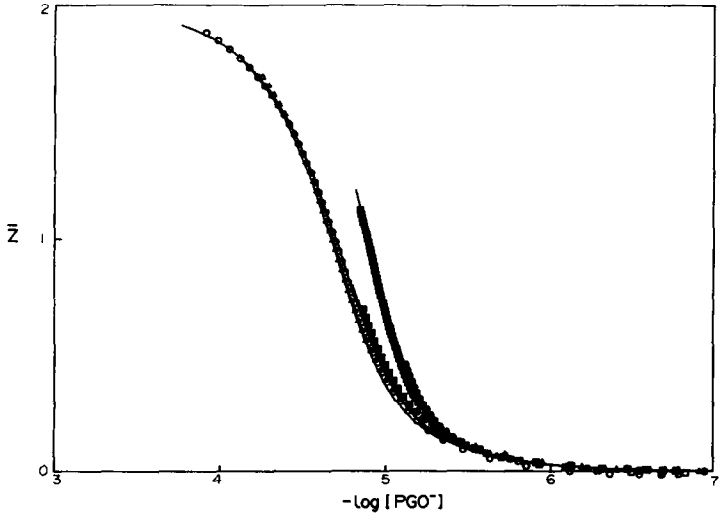

Fig. 6. Experimental formation curves for the Ni(II)–HPGO system. Symbols are: (▲) titr. 15, (□) titr. 16, (●) titr. 17, (○) titr. 18, (■) titr. 19 and (△) titr. 20. Solid lines are the theoretical curves after the constants given in Table 4.

does not take place; at pH values higher than 6 precipitation occurs and emf values become unstable.

The results obtained in the complexation study between nickel(II) and HPGO are shown in Table 4. The species distribution as a function of pH for this system, calculated from the values of the constants obtained, is shown in Fig. 5. In this system titrations can be performed up to pH values around 6, before precipitation takes place. The formation curves (Fig. 6), like those of the copper(II) systems, are not superimposed. The best fit of experimental data was found with the model containing the species 110, 230, 240 and 22-2.

While in some α-oxooximes–copper(II) systems hydroxocomplexes have been described[7,18] no references exist about hydroxocomplexes of nickel(II) and this class of ligands, but the inclusion of the 22-2 species in the model proposed is necessary in order to attain good fit with the experimental data in the higher pH range. Furthermore the existence of other polynuclear species (230 and 240) must be taken into account. Species 230 seems to be a previous step leading to the formation of the neutral species 240, which has been previously described by Thakkar and Haldar.[8] The inclusion of the species 120 resulted in a very slight improvement of the fitting, but this species was found to be formed only to a maximum of 5% in some titrations and therefore was not considered further. Because the model includes basically dimeric species, the 220 complex was also considered, but was rejected by the programs. Furthermore, an attempt was made to replace 110 by 220 in the model but the fitting was found to be less acceptable.

Elemental analysis of precipitates obtained from different ligand:metal ratios gives undefined stoichiometries, similar to that reported by Taylor and Ewbank for this system.[19] The results obtained (Table 5) are between the corresponding values of $[NiL_2]_x$ and $[NiL(OH)]_y$ complexes. As in the copper(II) systems, when the ligand:metal ratio increases, the results approach that of $[NiL_2]_x$ complexes. By means of the potentiometric studies two neutral species (240 and 22-2) have been identified. Thus the solids obtained must be mixtures of $[NiL_2]_x$ and $[NiL(OH)]_y$, with x and y equal to or higher than 2.

Table 5. Elemental analysis of the insoluble nickel(II)–HPGO complexes

Ligand:metal ratio	%Ni*	%C†	%H†	%N†
2	25.3	44.41	3.37	6.42
5	24.3	44.90	3.26	6.73
10	23.3	45.16	3.51	6.88
$[Ni(PGO)_2]_x$	16.55	54.13	3.38	7.89
$[Ni(PGO)(OH)]_y$	26.24	42.91	3.13	6.26

*Determined by titration with EDTA after mineralization of the precipitate with sulphuric acid.
†Analysed by automated microanalytical techniques.

The IR absorption spectra of the insoluble complexes, compared with the spectra of the pure ligand, show the same main features as those reported for the copper(II) systems—shifting to lower frequencies of νC=O, shifting to higher frequencies of νN—O and a broad band in the region of 3300 cm^{-1} corresponding to νO—H.

Complexation between nickel(II) and HPGO shows similar behaviour to that observed in the copper–α-oxooximes systems studied: a trend towards formation of dimeric species and hydroxocomplexes, although the latter are formed in smaller proportions.

PREPARATION OF A POLYPYRROLE–LEAD DIOXIDE COMPOSITE ELECTRODE FOR ELECTROANALYTICAL APPLICATIONS

D. VELAYUTHAM* and M. NOEL
Central Electrochemical Research Institute, Karaikudi, India 623 006

(*Received* 22 *April* 1991. *Revised* 12 *August* 1991. *Accepted* 13 *August* 1991)

Summary—A constant potential electrolytic method for the preparation of a new polypyrrole–lead dioxide composite electrode on glassy-carbon substrate is described. The method involves constant potential electrolysis (CPE) of 1*M* potassium nitrate containing 2m*M* lead acetate at +1.100 V *vs.* SCE for about 10 min, followed by addition of 25m*M* pyrrole and subsequent CPE at +0.800 V for about 2–3 min. The choice of experimental conditions for the preparation and mechanical stability, open circuit potential (ocp) response, background current levels and typical voltammetric response of Mn^{2+} in 1*M* sulphuric acid are also presented and discussed.

In spite of the fact that lead dioxide electrodes find wide application in electrochemical synthesis and electrochemical energy conversion,[1] basic studies on these electrodes are mainly confined to the nucleation growth process of lead dioxide crystallites.[2] Very few results concerning electroanalytical applications have been reported. Lead dioxide coated platinum electrodes have been used for the estimation of EDTA,[3,4] Ca^{2+}, Mg^{2+} and Zn^{2+} ions,[5,6] hydrogen peroxide,[7] polyphosphates[8] and sulphite anions.[9] In addition lead dioxide coated on Au and graphite,[10] wax bound carbon,[6] carbon paste,[11] and glassy-carbon (GC) substrates[12,13] have also been recommended for analytical applications. A recent report also recommends direct electrochemical oxidation of a solid lead electrode.[14] However, none of these electrodes have found wide spread application in electro analysis. A careful review of all the literature cited above and also some preliminary investigations in this laboratory have indicated that the electrodes prepared by such conventional means lack longterm stability, leading to mechanical peel off, as well as gassing through edges[9] and cracks.[13]

Recently, a slightly modified procedure involving constant potential electrolysis (CPE) with very low concentrations of Pb^{2+} ions ($<5mM$) have been proposed for preparing very thin lead dioxide films on gold substrates.[15–19] When efforts were made to adapt a similar procedure on GC substrates, the same type of stability problems mentioned above were encountered. Hence a novel method of preparing a stable lead dioxide electrode by codepositing lead dioxide along with a comparatively small proportion of polypyrrole (PP) was considered. Some of the preliminary results obtained in the fabrication and characterization of such a composite electrode are presented here.

EXPERIMENTAL

A 5-mm diameter GCE (Tokai Electrode Mfg. Co., Japan) fixed into a glass tube with epoxy resin was polished, cleaned and activated by electrochemical cycling as described earlier.[20] Care was taken to clean the GCE coated with lead dioxide after every experiment in 1:1 H_2O_2/HOAc mixture and 1:1 HCl/H_2O mixture[21] before usual surface pretreatments.

A typical H-type electrochemical cell with a Pt counter electrode and a luggin capillary connected SCE reference electrode was used. Nitrogen gas was used for deaeration. The experiments were carried out at 25 ± 1°. All AR chemicals and triply distilled water were used throughout.

A BAS 100 A electrochemical analyser was employed for CPE as well as CV measurements. A Jeol (Model 35 CF) scanning-electron microscope was used for surface characterization.

*Author for correspondence.

Preparation of polypyrrole–lead dioxide composite film

The main technical difficulty towards achieving the desired composite film lies in selecting the right experimental conditions in which simultaneous deposition of both lead dioxide and polypyrrole can occur at the same electrode potential. It is already well established that polypyrrole formation in aqueous solution will lead to an electronically insulating layer if the deposition potential exceeds +0.850 V *vs.* SCE.[22] In perchloric acid and nitric acid media electrodeposition of lead dioxide can begin only beyond +1.6 V *vs.* SCE.[2,23] On the other hand, in alkaline potassium hydroxide media, the electrodeposition of lead dioxide begins much earlier, *i.e.*, +0.400 V *vs.* SCE. Hence, a fairly neutral pH range alone seems to be suitable for further consideration towards development of a polypyrrole–lead dioxide composite electrode.

Another important requirement is the necessity of selecting the proper counter ion for maintaining good electronic conductivity of the polymer film. Since acetate anion does not belong to the established group of counter ions for conducting polymer films, nitrate ion as additive was chosen to serve this purpose.

With the two choices mentioned above it was indeed found that a reasonably close electrodeposition potential could be achieved for both polypyrrole and lead dioxide in the pH range close to 7.0. A typical cyclic voltamperogram of lead dioxide deposition on GC under these experimental conditions is presented in Fig. 1. In the first sweep lead dioxide deposition begins as low as +1.1 V due to nucleation overvoltage requirements. But in the subsequent sweeps where lead dioxide nuclei already exist on the surface, the electrodeposition process occurs as low as +0.8 V (Fig. 1). In this voltammetric experiment the potential was never allowed to decrease below zero voltage and move to the

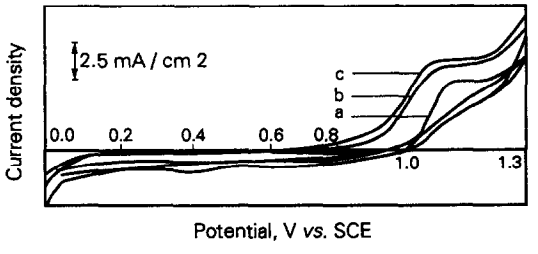

Fig. 1. Typical multisweep CV curves of deposition of PbO_2 on the glassy-carbon electrode in 1*M* KNO_3/0.1*M* $Pb(OAc)_2$; (a), (b) and (c) represent 1st, 5th and 11th cycles. pH = 6.9. V = 5 mV/sec.

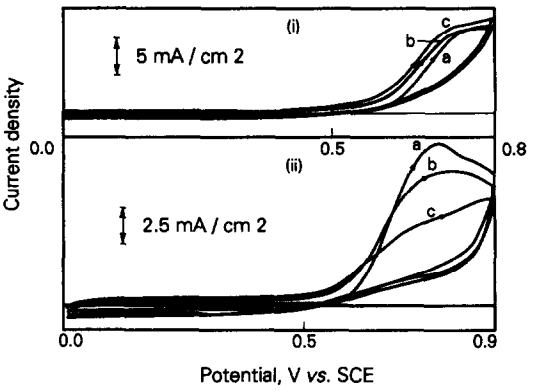

Fig. 2. The effect of the anodic potential limit on multisweep CV curves of pyrrole on the glassy-carbon electrode in 1*M* KNO_3/50m*M* pyrrole. V = 5 mV/sec; (a), (b) and (c) represents 1st, 2nd and 3rd cycles.

negative region, to ensure that the electrodeposited lead dioxide does not become reduced to Pb^{2+} and hence get stripped.

Under the same solvent-supporting electrolyte system (1*M* potassium nitrate) pyrrole also undergoes electrochemical oxidation in the usual potential range (Fig. 2). It may also be noted that during multisweep cyclic voltammetry if the anodic limit is held below +0.8 V, the polypyrrole formed remained conductive and in all subsequent sweeps the anodic current increased slightly [Fig. 2(i)]. On the other hand if the anodic limit exceeds +0.8 V, the polypyrrole film passivates and hence the anodic current decreases with increasing numbers of sweeps in multi-sweep voltammetry [Fig. 2(ii)]. This observation agrees very well with the earlier report on polypyrrole formation[22] from aqueous solutions. The passivation at more positive potentials is probably connected with overoxidation of the polypyrrole conjugated system and the resultant decreasing electronic conductivity.

In consideration of the above facts, a number of CPE experiments were carried out to optimize the conditions for preparing a polypyrrole–PbO_2 composite, parameters such as the concentration of Pb^{2+} ions and pyrrole, the relative proportions of these constituents, the anodic potential, the deposition time and the total charge passed for the deposition of composite were optimized to obtain a mechanically stable and electrochemically active composite electrode.

Some typical optimization experimental conditions and results obtained in the deposition processes are presented in Table 1. Pb^{2+} (2m*M*) and a 10-min deposition time was found to give

Table 1. Typical results of the constant potential electrolysis of Pb^{2+} and pyrrole (PY) showing the stability of the PbO_2, polypyrrole (PP) and PP–PbO_2 composite film electrode

Expt No.	$C_{Pb^{2+}}$, mM	C_{py} mM	Deposition time, min		Deposition charge, mC		Nature of deposit
			PbO_2	PP + PbO_2	PbO_2	PP + PbO_2	
1	5	—	4	—	85–90	—	PbO_2 deposit non uniform and unstable
2	2	—	10	—	85–90	—	PbO_2 deposit uniform but peels off during polarisation
3	1	—	30	—	15–20	—	PbO_2 deposit too low

*Optimized condition for the preparation of PP–PbO_2 composite film electrode.

Note: (1) In all the experiments studied above PbO_2 deposition carried out at +1.1 V followed by addition of pyrrole and further deposition at +0.8 V *vs.* SCE.

(2) Polarisation study was carried out in 1.0*M* H_2SO_4 from 1.4 V to 1.8 V *vs.* SCE.

uniform deposits at an optimum deposition rate (experiments 1–3). For polypyrrole deposition, 25m*M* pyrrole solution and a deposition time of 10 min were found to be optimum. At lower concentrations of pyrrole, the deposition is non-uniform and at higher concentrations it becomes highly porous and unstable (experiments 4 and 5). Comparison of experiments 4 and 6 would indicate that, in the presence of 2m*M* Pb^{2+}, charge due to PP–PbO_2 composite deposition decreases substantially, even with increasing deposition time. This requires further optimization of concentration of pyrrole as well as composite deposition time. From these studies, conditions described in experiment 9 are selected to be the optimum for a mechanically stable as well as electrochemically active composite electrode. The experimental procedure for this process may be described in detail as follows.

Potassium nitrate (1*M*) containing 2m*M* $Pb(OAc)_2$ is taken in the working electrode compartment, deaerated with nitrogen for 15–20 min. The activated GC was then inserted and CPE was carried out at +1.1 V for about 10 min to achieve an overall deposition charge of 80–90 millicoulombs. The electrode is then taken out and washed with distilled water. Then 25m*M* pyrrole is added and the electrolyte stirred for 2–3 min taking care to keep the electrolyte under nitrogen atmosphere. The electrode is then inserted and CPE at +0.800 V is further carried out for a period of 2–3 min. During this period simultaneous deposition of polypyrrole as well as lead dioxide takes place and an overall electrodeposition charge of 10 mC is passed (a considerably larger concentration of pyrrole compared to Pb^{2+} always seems to be required; there appears to be some blocking effect for polypyrrole formation on lead dioxide crystallites especially when Pb^{2+} is simultaneously present in the solution). The electrode is then taken out, washed with triply distilled water, allowed to dry in the open air and then stored in a desiccator.

Characterization of polypyrrole–lead dioxide composite electrode

The electrodeposition of lead dioxide and polypyrrole–lead dioxide composite could be easily distinguished by using a metallurgical microscope of ×100 and ×450 magnification. This method was conveniently employed during the preparation and characterization studies. A typical set of SEM photographs containing these two deposits are shown in Fig. 3(a) and (b), respectively. It may be noticed that the lead dioxide layer before addition of pyrrole contains distinct spherical particles without any covering film. The overall deposit also has a bright appearance [Fig. 3(a)]. After polypyrrole–lead dioxide composite deposition the individual lead dioxide particles are submerged on a

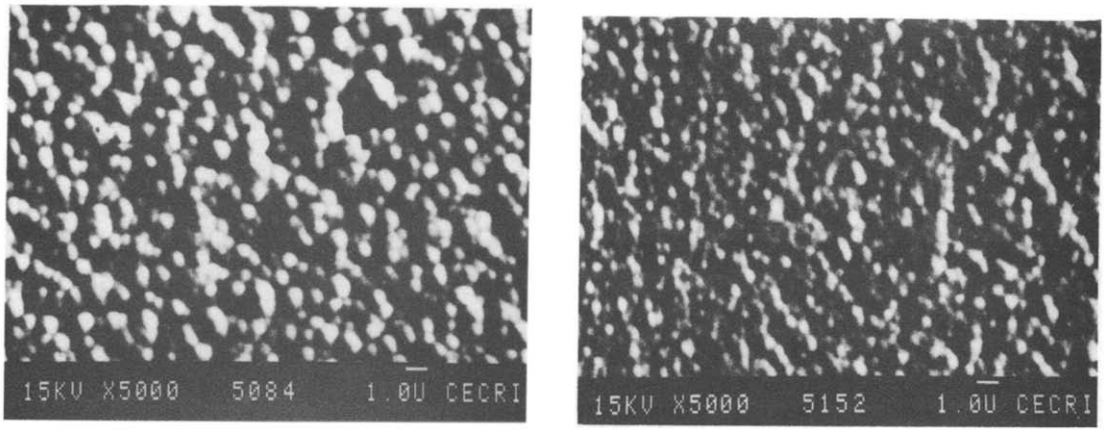

Fig. 3. Scanning electron micrographs of PbO_2 deposited on the glassy-carbon electrode. (a) GCE/PbO_2 (1*M* KNO_3/2m*M* $Pb(OAc)_2$, CPE at +1.100 V for 10 min). (b) GCE/PbO_2/polypyrrole (CPE of electrode from Fig. 3(a) after adding 25m*M* pyrrole at +0.800 V for 3 min).

continuous polypyrrole layer [Fig. 3(b)]. The composite also loses its brightness and shiny nature.

The rest potential of the lead dioxide electrode, as well as the polypyrrole–lead dioxide composite electrode, were also continuously monitored in 1*M* sulphuric acid at 24-hr intervals. During the first measurement, both the electrodes give rest potential values of $+1.4 \pm 0.02$ V, suggesting that both electrodes behave essentially like lead dioxide electrodes. However, the pure lead dioxide electrode does not remain stable to give a reproducible rest potential response for one day. The electrode slowly decomposes and the glassy-carbon surface is exposed. On the other hand the polypyrrole–lead dioxide composite remains stable and gives reproducible responses for about 10 days.

The anodic background currents from the rest potential region for lead dioxide as well as polypyrrole–lead dioxide composite electrode in 1*M* sulphuric acid at different sweep rates are presented in Fig. 4(a) and (b) respectively. As may be noticed from the figure, the background current values are very similar. Once again however pure lead dioxide electrode breaks down mechanically after a few cycles whereas the composite electrode shows remarkable stability. Although mechanical instability of pure lead dioxide material has also been reported earlier[24] the exact cause of this property is not known. Non-adherence of lead dioxide crystallites with the substrate, weak interactions between lead dioxide crystallite grain boundaries, effect of occluded oxygen gas bubbles and mechanical break down during oxygen evolution are some of the likely causes for the breakdown. However, in the PP–lead dioxide composite, lead dioxide particles are held in between.

The voltammetric responses of 5m*M* Mn^{2+} in 1*M* sulphuric acid at different sweep rates are presented in Fig. 5(a). It can be seen that the peak current increases with sweep rate (V). However, quantitative evaluation of peak current values becomes impossible because of the

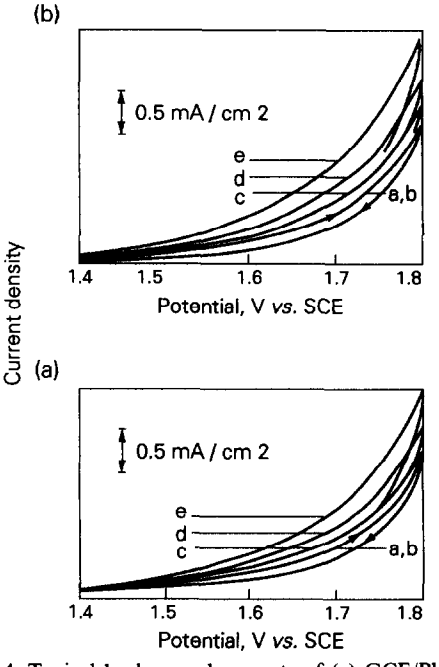

Fig. 4. Typical background currents of (a) GCE/PbO_2 (b) GCE/PbO_2/polypyrrole composite electrode in 1*M* H_2SO_4 V = 10, 20, 40, 80 and 160 mV/sec from (a)–(e) respectively.

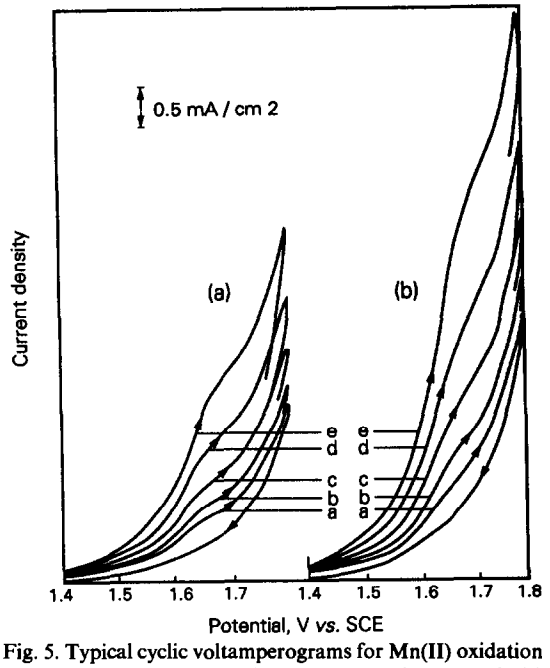

Fig. 5. Typical cyclic voltamperograms for Mn(II) oxidation in 1M H_2SO_4 on polypyrrole–PbO_2 composite electrode (a) 5mM Mn^{2+} (b) 10mM Mn^{2+}, V = 10, 20, 40, 80 and 160 mV/sec from (a)–(e) respectively.

closeness of the peak current to the continuously increasing background current. One may however notice that the peak currents are actually concentration dependent by comparing Figs. 5(a) and 5(b) for 5mM and 10mM Mn^{2+}, respectively, under identical sweep rate conditions. In this figure the I – E curves for the negative scan direction are not shown, except for the slow sweep rate for the sake of clarity. A pure lead dioxide electrode also showed quite similar responses, at least for a few voltammetric cycles, but once again mechanical break down prevents checking the reproducibility of the results. Some voltammetric responses for the same redox system for pure lead dioxide electrodes on Au[17] and stainless steel substrates[19] have been reported. At least on GCEs such reproducible responses on pure lead dioxide electrodes over long periods (say 10 days or more) could not be obtained in the present study.

Voltammetric responses of 25mM dimethyl sulphoxide (DMSO) at different sweep rates on PP–lead dioxide composite electrode are presented in Fig. 6. The peak current (i_p) and peak potential (E_p) responses for this system could be quantitatively evaluated; i_p is directly proportional to $V^{1/2}$ indicating diffusion controlled nature of the process. As indicated in the inset of Fig. 6, the peak current is also found to increase linearly with concentration of DMSO. From the $E_p - E_{p/2}$ values the transfer coefficient αn_a was calculated to be equal to 0.69. Using Nicholson and Shain's expression for irreversible charge transfer[25] and the diffusion coefficient value of the closely related molecule 2-mercapto ethanol to DMSO ($D = 1.3 \times 10^{-5}$ cm^2 sec^{-1}) from the literature,[26] the number of electrons (n) involved in the oxidation of DMSO was calculated to be 2.0 ± 0.1. This suggests that DMSO is oxidized to dimethyl sulphone[18] in an irreversible diffusion controlled charge transfer process. Hence in this case PP–lead dioxide composite electrode can be used effectively for quantitative estimation of DMSO in millimolar concentration range. More detailed work on this as well as a number of other redox systems which can be analysed using this electrode is in progress in this laboratory.

CONCLUSION

The present experimental results clearly indicate that a stable and electrochemically active polypyrrole–lead dioxide composite electrode can be easily prepared in aqueous solution

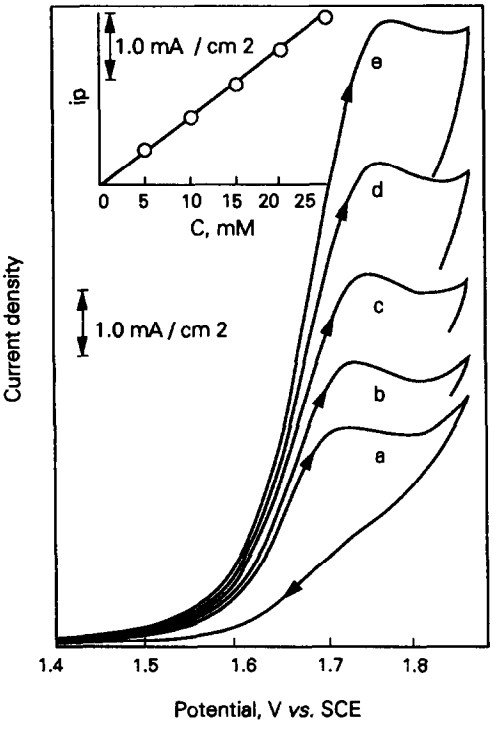

Fig. 6. Typical cyclic voltamperograms for DMSO oxidation in 1M H_2SO_4 on polypyrrole–PbO_2 composite electrode: C_{DMSO} = 25mM, V = 10, 20, 40, 80 and 160 mV/sec from (a)–(e) respectively.

under potentiostatic conditions, in 1*M* potassium nitrate solution with millimolar concentration of $Pb(OAc)_2$ and pyrrole. The porous and electronically conducting polypyrrole matrix containing electrochemically active lead dioxide particles serves as a mechanically stable electrode system without any decreasing electrochemical activity. Further investigations to establish the long-term stability and electrocatalytic properties of this electrode are in progress. The most important and interesting conclusion from this work however is the fact that one can actually think of a variety of polymer–oxide composite electrodes for catalytic effects and analytical applications.

SALTING-OUT SURFACTANT EXTRACTION OF PORPHYRINS AND METALLOPORPHYRIN FROM AQUEOUS NON-IONIC SURFACTANT SOLUTIONS

WILLIAM J. HORVATH and CARMEN W. HUIE*
Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13902-6000, U.S.A.

(*Received* 4 *September* 1991. *Revised* 8 *November* 1991. *Accepted* 8 *November* 1991)

Summary—A number of cloud point temperature-depressing electrolytes have been investigated for the separation of a non-ionic surfactant (Triton X-100) from aqueous solutions and the corresponding extraction of the organic solutes into the smaller volume surfactant-rich phase using the salting-out method. High extraction efficiencies and preconcentration factors were obtained at room temperature for the extraction of several hydrophilic and hydrophobic metal-free porphyrins (uroporphyrin, coproporphyrin, protoporphyrin and hematoporphyrin) and one metalloporphyrin (iron-protoporphyrin) that were dissolved in the aqueous non-ionic surfactant solutions. Possible mechanisms responsible for the efficient extraction of these important biological molecules into the surfactant-rich layer are discussed.

Non-ionic surfactants containing polyoxyethylene functional groups are known to form neutral adducts with a variety of reagents such as sodium picrate[1] and ammonium tetrathiocyanato-cobaltate(II).[2] It has been postulated[3] that the metal cations within these adducts are coordinated to the polyoxyethylene groups via the unpaired electrons of the regularly spaced oxygen atoms; subsequent interaction of these cationic complexes with the anions form net neutral adducts, which can then be concentrated by extraction into organic solvents. This extraction process has been exploited as a sensitive method for the determination of non-ionic surfactants at low levels.[4] Recently, it has been shown[5] that aurocyanide ion-pairs with alkali metal ions can be extracted efficiently into organic solvents with the aid of a common long-chain polyoxyethylene non-ionic surfactant (Triton X-100) and interestingly, the experimental results agree favorably with those obtained from molecular mechanics calculations.

It is known[6] that many aqueous non-ionic surfactant solutions will separate into two liquid phases upon heating above a characteristic temperature (*Tc*) referred to as the cloud point. Watanabe and Tanake[7] have applied this unique property of non-ionic surfactants for the efficient extraction of metal chelates without the use of any conventional organic solvents. Advantages include experimental conveniences, lower cost, ease of waste disposal, and perhaps more importantly, enhanced analytical sensitivity due to the fact that the metal chelates can be easily extracted from the bulk aqueous medium into a much smaller solution phase mostly containing the surfactant. In their experiment it was necessary to use an uncommon non-ionic surfactant (PONPE-7.5) with cloud point temperature near that of room temperature in order to obtain high extraction efficiencies. When a common non-ionic surfactant (Triton X-100) with a *Tc* of $\sim 70°$ was used instead, leakage of surfactant and metal chelates back into the aqueous medium occurred when the temperature of the solution gradually fell towards room temperature, resulting in loss of extraction efficiency.

A large number of salting-out agents have been investigated by Matkovich and Christian[8] for the separation of acetone from aqueous solutions and its use for extraction of metal chelates. More recently, Jenkins *et al.*[9,10] have demonstrated the use of a salting-out solvent extraction method for preconcentration of organic solute from water into a smaller volume of organic phase. Schott and Royce[11] have shown that electrolytes can either cause salting out or salting in of non-ionic surfactants, resulting in the lowering or increasing of the magnitude of *Tc*, respectively. Several mechanisms

*Author for correspondence.

have been proposed for the effects of electrolytes on *Tc* of aqueous non-ionic surfactant solutions. For example, some electrolytes can depress *Tc* by the process of dehydration, while others can decrease *Tc* by enhancing self-association of water molecules. A large number of electrolytes have been classified as having either salting-out or salting-in properties and are ranked according to their salting strength.[11–13] However, to the best of our knowledge, surfactant extraction and preconcentration of organic solutes by the salting-out method has not been reported.

In this paper separation of aqueous non-ionic surfactant (Triton X-100) solutions into two liquid phases by the addition of relatively large amounts of cloud point-depressing electrolytes and the corresponding extraction of the organic analytes (porphyrins and metalloporphyrin) into the smaller volume phase rich in surfactant was performed. High extraction efficiencies and preconcentration factors were obtained at room temperature. Possible mechanisms responsible for the efficient extraction of the analytes into the surfactant-rich phase are mentioned.

EXPERIMENTAL

Reagent

Analytical grade Triton X-100 (a branched *p*-octylphenol with an average of 9–10 ethylene oxide units) and research grade bovine hemin were obtained from Sigma (St Louis, MO, U.S.A.). Sodium and potassium hydroxide, sodium and potassium sulfate, and ammonium sulfate were all of analytical grade and obtained from Fisher (Pittsburgh, PA, U.S.A.). Hematoporphyrin(IX), uroporphyrin(I), coproporphyrin(III) and protoporphyrin(IX) were all purchased from Porphyrin Products (Logan, UT, U.S.A.).

Apparatus

Measurements of porphyrin fluorescence spectra for the determination of extraction efficiency were takien with a SLM 800 photon-counting spectrofluorometer (Amico, Urbana, IL, USA). The bandwidths of the excitation and emission monochromators were set at 16 nm. The excitation wavelength of all the measurements was set at the Soret band at ~400 nm. Emission spectra were obtained by scanning the monochromator from 550 to 700 nm and the intensity of the fluorescence peak maxima of the various porphyrins situated between 610 and 630 nm were recorded. The sample solution was placed in a 1-cm pathlength quartz cell. Measurements of the non-fluorescent bovine hemin (iron–protoporphyrin) samples for determining extraction efficiency were performed with a Spectraspan 7 direct current plasma instrument (Applied Research Laboratories, Valencia, CA, USA, Model 112100). The emission monochromator was set at the iron line of 2599.4 Å for all measurements.

Procedure

To prepare the sample solutions, appropriate amounts of porphyrins were first dissolved in doubly distilled demineralized water (DDDW), and then an appropriate volume of Triton X-100 was added to the aqueous sample solution and stirred until completely dissolved. Each aqueous Triton X-100 solution was portioned into 20-ml aliquots and poured into a 60-ml separating funnel. To initiate the extraction process, an appropriate amount of a particular salting-out electrolyte was added to the separating funnel and the solution was thoroughly shaken to accelerate the dissolution of the electrolyte. At this point, separation of the aqueous Triton X-100 solution into two distinct phases can be effected in one of two ways. The fastest way is to place the sample solutions in a high-speed centrifuge and separation of the two phases will take about 10 min with the centrifuge set at 4000 rpm. If a high-speed centrifuge is not available, separation of the two phases can be effected by simply letting the solution stand in the dark at room temperature for a couple of hours. Heating the solution can speed up the separation; however, we avoided heating the sample solution because thermally labile solutes such as porphyrins can decompose under high temperature. Once the separation of the two phases was completed, the bottom layer (aqueous phase) was drained from the separating funnel into a standard flask and then filled with DDW up to 20 ml. The top layer (surfactant phase) remaining in the separating funnel was also diluted back up to 20 ml with DDW. It should be noted that extra care should be taken in draining the bottom layer from the funnel since the top layer is relatively thin compared to the bottom layer. In our experiment this process was facilitated by illuminating the sample solution with a hand-held ultraviolet lamp. The top layer appeared as a brightly-colored ring above the bottom layer,

thus making it easier to physically separate the two layers. Extraction efficiency for each sample solution was obtained by determining the concentration of the porphyrin present in both the top and bottom layers using the fluorescence technique. Since fluorescence spectra of porphyrins are dependent on the pH, ionic strength and surfactant concentration,[14] fluorescence calibration curves for both top and bottom layers were obtained by using a series of standards prepared by adding appropriate amounts of porphyrins into blank surfactant and aqueous phases. These blanks (top and bottom layers) were prepared in the same manner as the sample solutions except that porphyrin was not present in the DDDW prior to extraction but was added to the surfactant and aqueous phases after the two phases were separated. The procedures for the extraction of bovine hemin (iron-protophyrin) and preparation of the standards were identical to that of the metal-free porphyrins. However, extraction efficiencies were determined by using a plasma emission method. In calculating the extraction efficiencies for iron-protoporphyrin it was assumed that all the iron present in the extract was associated with the iron-protoporphyrin spiked into the blanks and sample solutions. Average extraction efficiencies and precision (standard deviation) of the measurements calculated from five repeated extractions for each sample solution are presented in Tables 1–3.

RESULTS AND DISCUSSION

Porphyrins and metalloporphyrins are highly significant biological molecules. Their unique chemical and physical properties have been harnessed by nature for carrying out important processes such as photosynthesis and transportation of oxygen in living systems. Interestingly, these molecules have found significant application in medicine; of particular importance is the use of hematoporphyrin derivatives and other porphyrin-related molecules in the detection and photodynamic therapy of tumors.[15] Table 1 shows the extraction efficiencies (*E*%) of hematoporphyrin (a mixture of dicarboxylic acid porphyrins) as a function of concentration and the type of electrolyte. The hydroxide anion has been determined to be one of the most effective *Tc* depressing electrolytes. It salts out aqueous non-ionic surfactant by promoting self-association among water molecules via hydrogen bonding, thereby tightening the structure of water and lowering its solvating power. On the other hand, phosphate anion salts out the non-ionic surfactant by competing with the surfactant for water of hydration,

thereby reducing the amount of water available for the hydration of the polyoxyethylene functional groups of the non-ionic surfactant and lowering the *Tc*.[11-13] Table 1 indicates that both the hydroxide and phosphate anions are very effective in causing separation of the Triton X-100 from aqueous solution once a certain threshold concentration of the electrolyte was added to the aqueous non-ionic surfactant solution. It can be seen that high *E*% values of hematoporphyrin from the aqueous medium into the surfactant phase were obtained when an electrolyte containing more than 5*M* hydroxide or 1.5*M* phosphate anion as the salting-out agent was added to the solutions. Also, it is interesting to note that the *E*% calculated from determining the hematoporphyrin concentrations in the top layer were slightly higher when using sodium hydroxide as the salting-out electrolyte as compared to potassium hydroxide; however, the corresponding *E*% values calculated with the bottom layer were very similar. From these data it is not clear whether or not different cations have an effect on the *E*% of hematoporphyrin. The role of cations in the formation of complexes and in the salting-out processes needs more detailed investigation in future experiments.

Figure 1(a) and (b) compare the *E*% of hematoporphyrin obtained with and without the addition of *Tc*-depressing electrolyte, respectively, as a function of time that the surfactant and aqueous phase sit together after separation of the two phases. It can be seen from Fig. 1(a) that with the addition of 10*M* potassium hydroxide, high *E*% was obtained for hematoporphyrin at room temperature immediately after the solution was separated into two phases (time = 0) and the *E*% stayed relatively constant when the two phases were allowed to sit together over a time period of 48 hr in the dark. Without the addition of any electrolytes, phase separation was performed by simply heating the surfactant solution above its *Tc* at ~70°. As shown in Fig. 1(b), the initial *E*% at time = 0 was significantly lower (~85%) and this value dropped exponentially as a function of time, suggesting that an appreciable fraction of the surfactant phase redissolved into the aqueous phase as the temperature of the solution approached room temperature. It should be noted that when compared to the solution in which no *Tc*-depressing electrolyte was added, a phase inversion occurred with the addition of large amounts of electrolytes, *i.e.*, the surfactant-rich phase was the top layer and the aqueous phase, which was the denser medium, became the bottom layer.

Table 2 shows the *E*% of hydrophobic and hydrophilic porphyrins with the addition of various salting-out electrolytes. As expected, protoporphyrin—having similar structure as hematoporphyrin in which two carboxylic acid groups are present in the periphery of the porphyrin ring—was also found to be extracted efficiently into the surfactant phase with

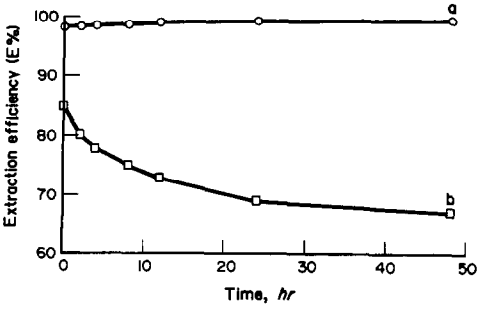

Fig. 1. Extraction efficiencies of hematoporphyrin (200 μg/l.) by Triton X-100 dissolved in aqueous solutions (1% v/v) as a function of time that the surfactant and aqueous phases sit together after separation (a) with the addition of 10*M* KOH and (b) without the addition of any electrolytes.

either hydroxide or phosphate added as the *Tc*-depressing electrolyte. It should be noted that protoporphyrin is an essential precursor of heme, the prosthetic group of hemoglobin. To investigate the $E\%$ of the present method for the extraction of metalloporphyrin, bovine hemin (iron-protoporphyrin) was spiked into the aqueous non-ionic surfactant solution and extracted by the same procedures as for metal-free porphyrin. As shown in Table 2, it was found that an average $E\%$ of ~96 and 99% were obtained with hydroxide and sulfate as the salting-out electrolyte, respectively.

Coproporphyrin and uroporphyrin—having four and eight carboxylic acid groups in the porphyrin ring, respectively—are also biologically important molecules since they are major components of total urinary porphyrin contents. In clinical laboratories porphyrins present in urine are usually measured after employing extraction procedures designed to separate out the "uroporphyrin" and "coproporphyrin" fractions.[16] Urine samples are considered abnormal when the total urinary porphyrin concentrations are greater than the threshold level between 100 and 200 μg/l. As in the case of hematoporphyrin and protoporphyrin it can be seen from Table 2 that the coproporphyrin also shows high $E\%$ with the addition of various electrolytes; however, the $E\%$ was found to be dramatically lower for the extraction of uroporphyrin with the addition of hydroxide or phosphate anion as the salting-out agent. This is not surprising since the eight carboxylic acid groups of uroporphyrin were likely to be ionized completely under the high basic environment of concentrated hydroxide and phosphate solutions, resulting in a significant increase in the aqueous solubility of uroporphyrin as compared to hydrophobic porphyrins such as proto- and coproporphyrins. It is interesting to see from Table 2 that the $E\%$ of uroporphyrin was significantly increased when using sulfate anion as the *Tc*-depressing electrolyte. This may be explained partly by the fact that since sulfate is less basic than either hydroxide or phosphate anion, ionization of the eight carboxylic groups would be less complete. This could result in the lowering of the aqueous solubility of uroporphyrin and in more effective complexation of uroporphyrin by the non-ionic Triton X-100; furthermore, sulfate anion is known to be a more effective *Tc*-depressing electrolyte when compared to phosphate in salting out non-ionic surfactant since it is more efficient in competing with the surfactant for hydration with water molecules.[11]

Table 3 shows the $E\%$ of hematoporphyrin as a function of the concentration of Triton X-100 and hematoporphyrin. Firstly, it can be seen that high recovery of hematoporphyrin is possible for a surfactant concentration of 1%; however, at a surfactant concentration of 10%, a significant drop in $E\%$ was found. It is possible that at higher surfactant concentrations, appreciable fractions of surfactant remain dissolved in the aqueous phase, leading to lower $E\%$. On the other hand, at a surfactant concentration of 0.2%, only a slight drop in $E\%$ was observed. Surfactant concentrations lower than 0.2% were not investigated in our experiment because the volume of the surfactant-rich phase at these concentrations were so small that it was experimentally difficult to separate the surfactant and aqueous phases. Secondly, it can also be seen from Table 3 that a preconcentration factor as high as 94.3 can be achieved with high $E\%$ at a surfactant concentration of 1%. Preconcentration factors higher than 100 can also be achieved with high $E\%$ at a surfactant concentration of 0.2%; however, it was difficult to determine the degree of preconcentration since the volume of the surfactant-rich phase was too small to be measured accurately. Lastly, Table 3 also shows that high $E\%$ can be obtained for a large concentration range of hematoporphyrin from 2 to 2×10^4 μg/l., which could be an important advantage for the extraction of porphyrin present in a variety of biological materials containing a wide range of porphyrin concentrations.

It has been known for a long time that strong interactions exist between surfactants and porphyrins.[17] For porphyrins dissolved in an aqueous surfactant solution above its critical micelle concentration, it has been postulated[18] that the porphyrin species is solubilized by the surfactant in such a manner that a doughnut-like structure is formed. In this porphyrin-micelle complex the pyrrole rings are embedded in the interior of the doughnut (hydrocarbon region of the micelle), with the porphyrin nitrogen situated in the inner ring of the doughnut coming into contact with the aqueous phase; the outer surface of the doughnut is covered with the surfactant head groups. Such a structure has been shown[18] to possibly favor the rate of formation of various metalloporphyrin complexes by attracting ions to the vicinity of the central pyrrole nitrogen atoms according

to the charge of the surfactant head groups. Complexes with a number of monovalent cations are known,[17] *e.g.*, Na_2, K_2, Li_2 complexes, in which one of the cations is likely to be situated slightly above and the other slightly below the plane of the porphyrin nucleus. In our experiment it is possible that a similar doughnut-like complex may form between the porphyrins and Triton X-100 surfactant in which the porphyrin species is immersed in the hydrophobic region (long-chain hydrogen and phenyl component) of this non-ionic surfactant; the long-chain polyoxyethylene functional groups lie in the outer surface of the doughnut. Furthermore, for the extraction of ions by extractants containing the polyoxyethylene functional groups, it has been postulated[3] that the so-called "cation-chelation" mechanism prevails in which the cation is coordinated to the oxygen within a helical structure formed by the polyoxyethylene chain and the co-extracted anion lies outside the helix. It is therefore also possible that the doughnut-like porphyrin-micelle complex in our experiment may be further stabilized by the chelation of the cations from the electrolytes, *e.g.*, Na^+, K^+, with the polyoxyethylene functional groups and resulting in concomitant interaction of this moiety with the porphyrin nucleus.

In summary, this work has shown that excellent extraction efficiencies and high preconcentration factors can be obtained for a large concentration range of porphyrins and metalloporphyrin dissolved in aqueous non-ionic surfactant solutions by effecting separation between the surfactant and aqueous medium, and taking the solubilized analytes into the surfactant phase upon the addition of cloud point-depressing electrolytes. A logical extension of this work might involve the use of the present method for the extraction of other important porphyrins or porphyrin-related molecules such as chlorophylls or the application of similar extraction procedures for the determination of trace amounts of clinically important porphyrins such as coproporphyrin and uroporphyrins. For example, the present salting-out extraction method could potentially be used as a simple and convenient approach for the preconcentraton and separation of urinary or serum coproporphyrin from uroporphyrin into a much smaller volume surfactant-rich phase for the differential diagnosis of diseases associated with impaired heme synthesis or metabolism without the use of any conventional organic solvents. Current extraction methods employed for the separation of coproporphyrin and uroporphyrin present in urine or serum are usually too time-consuming and inconvenient for routine use in the clinical laboratory.[16,19] Furthermore, it is important to gain some insights into the fundamental mechanisms responsible for the efficient extraction of porphyrins and metalloporphyrin by using non-ionic surfactant such as Triton X-100 and into the effects of electrolytes (both cations and anions) on the formation of complexes and salting-out processes. Work is in process in our laboratory to pursue these goals.

(*Received* 22 *August* 1991. *Accepted* 21 *September* 1991)

Summary—Extraction of promethium(III), uranium(VI), plutonium(IV), americium(III), zirconium(IV), ruthenium(III), iron(III) and palladium(II) has been carried out with a mixture of octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) and tributyl phosphate (TBP) in dodecane. The effects of nitric acid, TBP and CMPO concentrations on the extraction of these metal ions have been studied. The nature of the species of the above metal ions extracted into the organic phase has been suggested.

Bidentate organophosphorous reagents, as a class, are most important for the extraction, separation and recovery of trivalent actinides and lanthanides from high level waste (HLW) solutions of the PUREX process. Encouraged from the early work of Siddall[1,2] on the extraction of americium(III) from acidic solutions by dialkyl-*N*,*N*-dialkylcarbamoylmethylphosphonate, various bidentate compounds have been prepared. Of these dihexyl-*N*,*N*-diethylcarbamoylmethylphosphonate (CMP) and octyl(phenyl)-*N*,*N*-diisobutylcarbamoylmethylphosphine oxide (CMPO) are the most promising reagents for extraction of trivalent actinides and lanthanides from nitric acid solutions and their easy and efficient stripping. Using CMPO as the extractant, the main emphasis has been on the extraction and recovery of americium(III) from nitric or hydrochloric acid solutions employing diethyl benzene, carbon tetrachloride, tetrachloroethylene or normal paraffinic hydrocarbons as the diluents.[3–7] Also, the extraction behaviour of neptunium and plutonium from nitric acid solutions with a mixture of CMPO and tributyl phosphate (TBP) in dodecane has been reported.[8,9] In a recent communication, extraction of europium(III) from nitric and hydrochloric acid solutions with CMPO alone or a mixture of CMPO and TBP in mesitylene or dodecane diluents has been reported.[10] No reports are available on the extraction of promethium(III) from nitric acid solutions with bidentate organophosphorous reagents. Since ^{147}Pm, a low energy β emitter, can be recovered in large quantities from HLW solutions of the PUREX process, a programme has been initiated to deploy different potential extracting agents for the extraction, removal and recovery of promethium(III) from nitric acid solutions. In this connection, in a recent communication we have reported the extraction of promethium(III) by CMP alone as well as its mixture with TBP in benzene.[11] In the present study, besides the extraction of promethium(III), we have undertaken studies on uranium(VI), plutonium(IV), americium(III), zirconium(IV), iron(III), ruthenium(III) and palladium(II) from nitric acid solutions by a mixture of CMPO and TBP in dodecane.

EXPERIMENTAL

Materials

CMPO was prepared by a modified three step procedure suggested by Horwitz and coworkers.[12] It was purified by successive treatments with macroporous cation (H^+) and anion (OH^-) forms of ion exchange resins.[12] The purity of CMPO was checked by IR and ^{1}H, ^{13}C and ^{31}P NMR spectroscopy. To confirm that the CMPO prepared is the solvent extraction (SX) grade (contains $\leqslant$0.02 wt% of acidic

impurities), D_{Am} at pH 2.0 (HNO_3) with 0.2*M* CMPO + 1.2*M* TBP in dodecane was determined and found to be very low (0.016).[13]

Tributyl phosphate (Bharat Vijay Chem., India) was purified by contact with a dilute solution of sodium hydroxide, washing with water and drying over anhydrous sodium sulphate. Dodecane (~93% C-12, sp. gr. 0.751, refractive index 1.42 and aromatics (<0.1%, distillation range 160–210°) was obtained from Transware Chemia Handelsgeselschaft, Hamburg, Germany and was used as such. All other chemicals used were of A.R. grade.

Radioactive tracers

The radioactive tracers ^{241}Am, ^{233}U, Pu (mainly 239) and ^{147}Pm were purified and prepared by standard procedures.[14–16] The tracers ^{95}Zr, ^{59}Fe and ^{103}Ru were procured from the Board of Radiation and Isotope Technology, Department of Atomic Energy (India) and their radiochemical purity was checked by taking γ-spectra. A ^{109}Pd stock solution was prepared by irradiating ammonium tetrachloro palladate in the Apsara research reactor of Bhabha Atomic Research Centre and dissolving it in 6*M* hydrochloric acid. A 25-μl portion of this solution was added to 1 ml of the aqueous phase for the extraction studies. The radioactive tracer solutions of ^{233}U, Pu (mainly 239) and ^{147}Pm were assayed by liquid scintillation counting and ^{95}Zr, ^{59}Fe, ^{103}Ru, ^{241}Am and ^{109}Pd (as ^{109}Ag, which is in secular equilibrium with ^{109}Pd) were counted with a well-type γ-scintillation counter, using a sodium iodide (Tl) detector.

Extraction of the metal ions by CMPO + TBP at various nitric acid concentrations

A 1-ml aliquot of aqueous phase (varying nitric acid concentrations from 0.01 to 6.0*M*) containing one of the radioactive tracers ^{233}U, Pu (mainly 239), ^{241}Am, ^{147}Pm, ^{95}Zr, ^{59}Fe, ^{103}Ru or ^{109}Pd was mixed with an equal volume of 0.2*M* CMPO + 1.2*M* TBP in dodecane (earlier pre-equilibrated with respective nitric acid solutions). The solutions were shaken for 1 hr by slow rotation in a temperature controlled bath at 25 ± 0.1°. This time was more than sufficient for attaining the equilibrium. The solutions were allowed to settle, centrifuged and pipetted for radioassay. In cases where the *D* (distribution ratio) values were very high or very low, at least three cycles of removing the phases and centrifuging was done before taking the samples for counting.

Extraction of metal ions at a fixed concentration of CMPO and varying TBP concentrations

A 1-ml aliquot of the aqueous phase (3.0*M* nitric acid) containing one of the above mentioned tracers was mixed with an equal volume of organic solution containing a fixed 0.2*M* concentration of CMPO and varying concentrations of TBP(0.6–1.4*M*) in dodecane. After shaking, the solutions were allowed to settle, centrifuged and aliquots were taken for radioassay as mentioned above.

Extraction of metal ions at a fixed concentration of TBP and varying CMPO concentrations

A 1-ml aliquot of the aqueous phase (3.0*M* nitric acid) containing one of the above-mentioned radioactive tracers was mixed with an equal volume of the organic phase containing a fixed 1.2*M* TBP concentration and a varying (0.01–0.2*M*) concentration of CMPO in dodecane. After settling, the solutions were processed as above for radioassay.

RESULTS AND DISCUSSION

Figure 1 gives the plots of log *D vs.* nitric acid concentration at 0.2*M* CMPO + 1.2*M* TBP in dodecane for the extraction of Am(III), Pm(III), U(VI), Pu(IV), Zr(IV), Fe(III), Ru(III) and

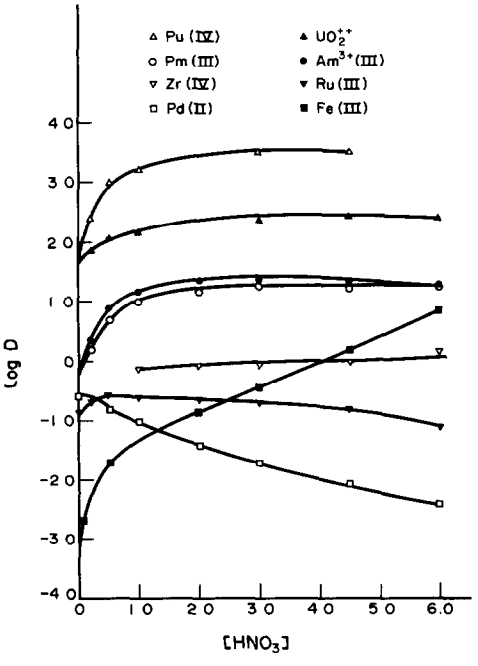

Fig. 1. Acid dependency on the extraction of Pm(III), Am(III), Pu(IV), U(VI), Zr(IV), Ru(III), Fe(III) and Pd(II) with 0.2*M* CMPO + 1.2*M* TBP in dodecane at 25°.

Pd(II). The results show that there is practically no difference in D values for americium(III) and promethium(III). Further, the D values do not show much variation for 2–6M nitric acid. This could be explained by the "intramolecular buffering effect".[7] Similar extraction behaviour was observed in the case of U(VI) and Pu(IV) as well. The order of extraction of promethium(III), americium(III), uranium(VI) and plutonium(IV) was found to be Pm(3.0) ~ Am(3.0) ≪ U(3.2) ≪ Pu(4.0). This could be explained on the basis of effective ionic charge for these metal ions (given in parentheses). The extraction of fission products such as zirconium(IV), ruthenium(III) and palladium(II) are much lower as compared to the actinides and promethium(III) reported in this study. Amongst these three, the order of extraction Pd < Ru < Zr could be explained on the basis of the ionic charge of these metal ions. In the case of zirconium(IV) the D values remain almost constant in the acidity range 1–6M nitric acid. In the case of ruthenium(III), the D values initially increase between the acidity range of 0.01–0.5M and then they start decreasing between 0.5 and 6.0M nitric acid, while in the case of palladium(II) there is a continuous decrease in the D value from 0.01 to 6.0M nitric acid. The decrease in the D values of palladium(II) and ruthenium(III) is possibly due to the formation of unextractable species. In the case of iron(III) the D value increases with increasing nitric acid concentration. Here, with increasing acidity, less iron(III) is in the hydrolysed form, and the formation of the extractable iron(III) nitrate species increases. It is clear that in the acidity range of about 2M (likely to be encountered in the HLW solutions) the extraction of plutonium(IV), uranium(VI), americium(III) and promethium(III) are much higher as compared to those of fission products and iron(III). From these studies it could be concluded that promethium(III) along with the actinides americium(III), uranium(VI) and plutonium(IV) could efficiently be extracted from HLW solutions of PUREX origin by 0.2M CMPO + 1.2M TBP in dodecane leaving behind most of the fission products present therein.

Figure 2 shows the plot of log D *vs.* log[TBP] at a fixed concentration of CMPO (0.2M) and 3.0M nitric acid for the metal ions studied here. In the case of plutonium(IV), uranium(VI), americium(III), promethium(III) and zirconium(IV), the straight lines are almost parallel to the x-axis indicating thereby that

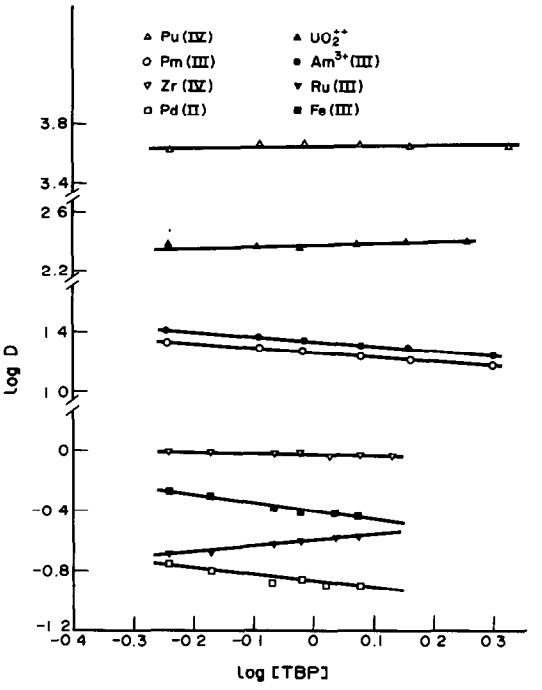

Fig. 2. Plots of log D *vs.* log [TBP] for Pm(III), Am(III), Pu(VI), U(VI), Zr(IV), Ru(III), Fe(III) and Pd(II) at 0.2M CMPO and 3.0M HNO_3, at 25°.

TBP is not one of the moieties in the species extracted in the organic phase. However, in the case of iron(III) and palladium(II), the D values were found to decrease with increasing TBP concentration, a negative slope of ~0.5 was obtained for both these metal ions. In the case of ruthenium(III), the D values slightly increased with increasing TBP concentration. The straight line in Fig. 2 shows a positive slope of 0.5. Further detailed study is needed in the case of iron(III), ruthenium(III) and palladium(II).

Figure 3 gives the plots of log D *vs.* log[CMPO] at fixed TBP (1.2M) and nitric acid (3.0M) concentrations. The concentration of CMPO was varied between 0.1 and 0.2M for the metal ions promethium(III), americium(III) and iron(III). The straight lines are obtained with a slope of 2.5. Similar lower slopes than the expected value of 3.0 have been reported in the case of americium(III) and europium(III) at CMPO concentrations higher than 0.1M in diethyl benzene or xylene when extracted from 0.5M nitric acid.[4] The non-ideality of the organic phase has been suggested as the reason for the lower stoichiometry of the extracted species by the slope analysis method at high concentrations of CMPO.[6] Under our experimental conditions the equilibria for the uptake of

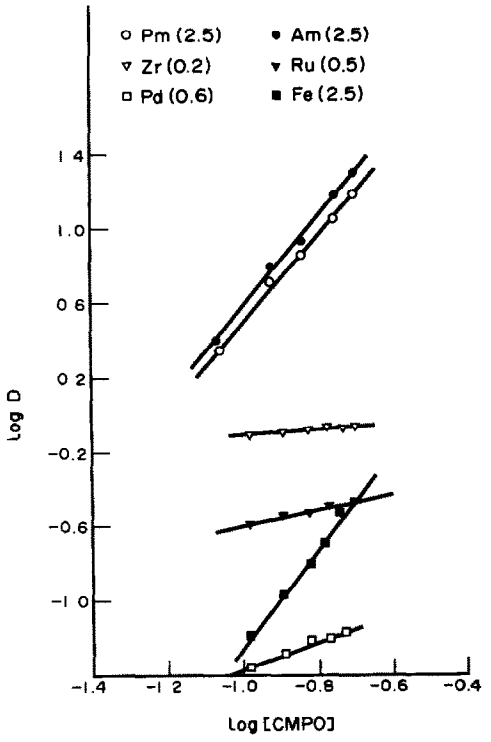

Fig. 3. Plots of log *D vs.* log [CMPO] for Pm(III), Am(III), Fe(III), Ru(III), Zr(IV) and Pd(II) at 1.2*M* TBP and 3.0*M* HNO_3, at 25°.

M(III) ions (M = Am, Pm and Fe) by CMPO may be written as:

$$M^{3+}(a) + 3NO_3^- (a) + 3CMPO \cdot (HNO_3)_{n(o)} \rightleftharpoons M(NO_3)_3(CMPO)_3 \cdot (HNO_3)_{m(o)} + (3n - m)\ HNO_{3(a)} \quad (1)$$

where (a) and (o) represent the aqueous and organic phases, respectively.

Under similar experimental conditions to the above, the plots of log *D vs.* log[CMPO] gave straight lines with a slope of 0.6 for palladium(II), 0.5 for ruthenium(III) and 0.2 for zirconium(IV). In these cases, the species formed is most probably $M(NO_3)_x \cdot (CMPO).(HNO_3)_m$ (where $x = 2$ for Pd, 3 for Ru and 4 for Zr).

It can be seen from Fig. 4 that in the CMPO concentration range 0.14–0.2*M* for uranium(VI) and 0.04–0.06*M* for plutonium(IV) the straight lines are obtained with slopes of 1.4. Here it may be suggested that the species formed are $M(NO_3)_x \cdot (CMPO)_2 \cdot (HNO_3)_m$ [where $x = 2$ for

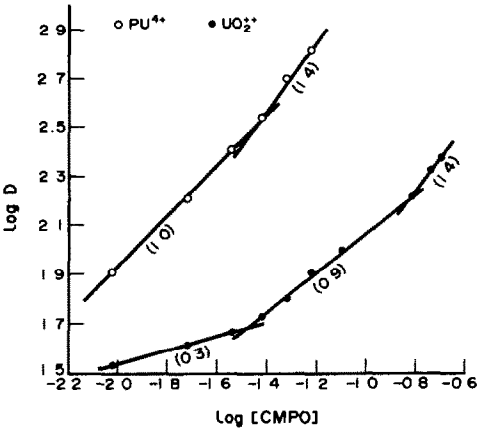

Fig. 4. Plots of log *D vs.* log [CMPO] for U(VI) and Pu(IV) at 1.2*M* TBP and 3.0*M* HNO_3, at 25°.

uranium(VI) and 4 for plutonium(IV)]. However, in the lower concentration ranges of CMPO, where slopes lower than 1.4 are obtained for both the ions, formation of species containing less than two CMPO moieties may be suggested.

EXTRACTION OF AROMATIC ACIDS AND PHENOLS BY POLYURETHANE FOAM

P. FONG and A. CHOW
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

(*Received* 9 *April* 1991. *Revised* 16 *August* 1991. *Accepted* 26 *August* 1991)

Summary—The extraction of several aromatic acids and phenols including salicylic acid, 8-hydroxyquinoline, 1-amino-2-naphthol-4-sulphonic acid and cinnamic acid in the presence of various protonated alkylamines, ammonia and alkali metal cations from aqueous solution by polyurethane foam has been investigated. These compounds are extracted only in the neutral form by a solvent extraction mechanism. The mechanism has been confirmed by the salting-out effect and pH studies. With the exception of 8-hydroxyquinoline, the compounds are more extractable by polyether foam than by polyester foam, suggesting that hydrogen bonding is stronger with the polyether foam.

Considerable progress has been made in recent years in the use of polyurethane foam for separation and preconcentration purposes. Both inorganic and organic substances can be extracted from different media. Several reviews[1–7] dealing with the extraction by polyurethane foam have appeared.

Considerable work has been done on the extraction of inorganic compounds by the foam, but only a few papers have discussed the extraction mechanism. Bowen[8] concluded that the extraction is not due to surface adsorption because of the relatively high capacity measurement (0.5–1.8 mole/kg) for species on the foam. A solvent extraction mechanism was suggested since the compounds extractable by the foam are also extractable by diethyl ether. Gesser and co-workers[9,10] extended this idea to describe the foam as a polymeric analogue of diethyl ether. This mechanism has been widely accepted by many workers to describe the extraction of various species, *e.g.*, $GaCl_4^-$,[9] $FeCl_4^-$,[10] $SnCl_5^-$,[11] $SbCl_4^-$[12] and $Rb(SCN)_6^{3-}$.[13,14]

Hamon *et al.*[15] proposed the cation chelation mechanism to account for the extraction of anionic metal complexes. According to this mechanism, the extraction of anionic metal complexes is facilitated by the efficient complexation of the cation with the crown-ether type of configuration in the foam. Polyether- and polyester-type polyurethane foams are referred to as polyether and polyester foams, respectively. The poly(ethylene oxide) portion of polyether foam which adopts a helical structure with inwardly-directed oxygen atoms is considered to be responsible for the specific interaction between the cation and the foam. It was observed that polyether foam demonstrates similar cation selectivity to 18-crown-6. Polyester foam does not readily assume such a helical structure, and hence the interaction with the cation is not as strong in comparison to polyether foam. As a result of this, polyether foam is a better extractor than polyester foam. Many extraction systems[16–21] involving inorganic compounds have been explained by this mechanism.

Polyurethane foam has been successfully applied to concentrate various organic contaminants from water such as chlorinated organic compounds and aromatic hydrocarbons (PAH). In 1971, Gesser *et al.*[22] used polyurethane foam packed in a column for the concentration of polychlorinated biphenyls. Foams were used as an alternative to activated carbon for the determination of trace organic contaminants in water by Gesser *et al.*[23] Musty and Nickless[24] reported the quantitative extraction of chlorinated insecticides by foam at pHs between 6 and 9, and they noted that the foam was superior to activated carbon since the material recovered from activated charcoal is often different from the original form due to catalytic effects. Afghan *et al.*[25] demonstrated that polyurethane foam is capable of concentrating PAH at parts per trillion levels in natural waters and has a concentrating ability similar to other sorbents such as XAD-2 and C18-bonded phase packing. Gough and Gesser[26] reported the retention and recovery of phthalate esters by the foam.

Table 1. Effect of salts on the extraction of salicylic acid from aqueous solution by polyurethane foam

Salt	Concentration ($\times 10^{-3}M$)	Distribution coefficient, *l./kg*		Equilibrium pH	
		Polyester	Polyether	Polyester	Polyether
None	0.00	96.9 ± 3.2	218 ± 4	3.20	3.25
sec-Butylamine	0.50	83.9 ± 1.2	185 ± 1	3.30	3.40
sec-Butylamine	0.99	65.6 ± 2.6	139 ± 4	3.50	3.60
iso Butylamine	0.99	67.3 ± 3.8	149 ± 2	3.45	3.55
sec-Butylamine	1.98	31.9 ± 0.8	51.9 ± 0.8	3.90	4.05
Ethylamine	1.06

NaCl	2.0	150 ± 4	332 ± 8	2.80	2.85
KCl	2.0	125 ± 3	284 ± 8	3.05	3.10
$MgCl_2$	1.0	137 ± 3	256 ± 5	2.50	2.55
$BaCl_2$	1.0	111 ± 3	234 ± 7	2.65	2.75

Conditions: $2.9 \times 10^{-3}M$ salicylic acid, 0.300 g of foam, 100-ml solution, 24 hr extraction time.

Recent work by Schumack and Chow[27] studied the mechanism of the extraction of simple aromatic compounds by polyurethane foam. Comparison with identical extractions into diethyl ether and the salting-out effect observed suggest that the basic extraction mechanism is an ether-like solvent extraction mechanism. It was noted that compounds containing a phenolic or carboxylic group have larger distribution coefficients due to hydrogen bonding with the foam. The hydrogen bonding is prevented by the presence of a strong electron-donor group *ortho* to the hydrogen bonding group as in *o*-nitrophenol or salicylaldehyde where intramolecular hydrogen bonding can take place. It was concluded that hydrogen bonding is stronger with polyether foam relative to polyester foam.

Chow *et al.*[28] investigated the extraction of many organic dyes by polyurethane foam from aqueous and 50% aqueous methanol solutions. It was found that the extraction of neutral dyes can be explained by a simple solvent extraction mechanism, but the extraction of anionic dyes is consistent with the cation chelation mechanism.

It appears that many organic compounds are extracted by an ether-like solvent extraction mechanism, however, other extraction systems involving inorganic complex anions can be explained by the cation chelation mechanism. The extraction of salicylic acid, 8-hydroxyquinoline, 1-amino-2-naphthol-4-sulphonic acid and cinnamic acid was studied in this work. These compounds were chosen because they are quite hydrophobic and are likely to be extracted by the foam. Furthermore, they contain carboxylic acid and phenol groups which can dissociate to form the anions at appropriate pH. The extraction of these anions in the presence of some chelatable cations proposed in the cation chelation mechanism can then be investigated. The objective of the present study was to determine whether the extraction takes place by solvent extraction, cation chelation or by other mechanisms.

EXPERIMENTAL

Apparatus

UV absorbance measurements for the determination of the organic compounds were obtained with a Varian 634S spectrophotometer. A Fisher Accumet Model 520 pH-meter was used. The alkylamine concentration was determined by using a Hewlett-Packard 5710A gas chromatograph with a flame ionization detector and a 6-ft × 2-mm ID column packed with GP Carbopack B/4% Carbowax 20*M*/0.8% KOH.

Reagents

All chemicals were of reagent grade and water was purified by reverse osmosis and a Barnsted Nanopure II® system before use. The polyether foam (# 1338M) was obtained from G. N. Jackson Ltd (Winnipeg, Manitoba). The polyester foam (DiSPo) was obtained from Canlab (Winnipeg, Manitoba).

Procedure

Foam plugs of approximately 0.4 g each were cut from a polyurethane sheet. These plugs were soaked in 1*M* hydrochloric acid for 24 hr with occasional squeezing to remove any possible inorganic contaminants and washed with water

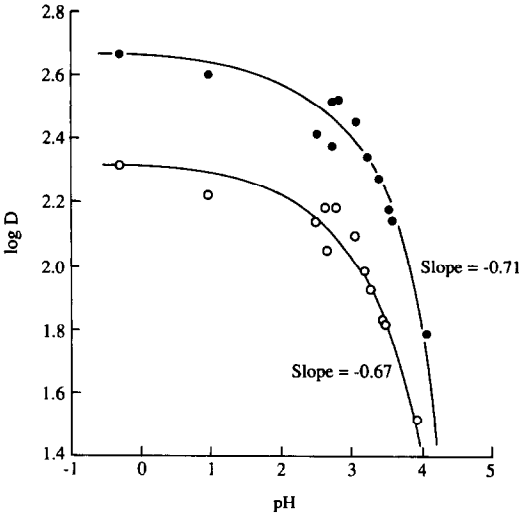

Fig. 1. Plot of log D *vs.* pH for the distribution of salicylic acid between foams and aqueous solution. Conditions: $2.9 \times 10^{-3}M$ salicylic acid, 0.300 g of foam, 100-ml solution, 24-hr extraction time, (●) polyether foam, (○) polyester foam.

until they were acid free. They were then extracted with acetone in a Soxhlet apparatus for 6 hr to remove organic contaminants and finally air dried in a 60° oven.

The sample solution (100 ml) and the foam plug (0.300 ± 0.005 g) were placed in a Pyrex glass cell. The foam was squeezed by means of a glass plunger operated by an automatic squeezer[29] in order to bring fresh solution into contact.

The % extraction and distribution coefficient (D) were calculated with:

$$\% \text{ extraction} = (1 - C'/C_0) \times 100$$

C_0 = concentration in solution before extraction
C' = concentration in solution after extraction

$$D = \frac{\% \text{ extraction}}{(100 - \% \text{ extraction})} \times \frac{\text{volume of solution (l)}}{\text{weight of foam (kg)}} \quad (1)$$

RESULTS AND DISCUSSION

To determine whether the alkylamines are extractable by polyurethane foam, the extraction of various amines including methylamine, ethylamine, isopropylamine, isobutylamine, n-butylamine, sec-butylamine and t-butylamine in $0.1M$ sulphuric acid was studied. No detectable amounts of the amines were extracted by either polyether or polyester foam after 24 hr extraction. These results suggest that the sulphate ions are too hydrophilic to form ion-pairs with these amines. Thus, the effect of the protonated amines on the extraction of various organic compounds which are more hydrophobic than sulphate was examined. It was expected that any ion-pair formation of the organic compounds with the protonated amines should result in the extraction of the amines as well as in the increase of the extraction of the organic compounds.

Extraction of salicylic acid

To determine the extractability of salicylic acid, solutions (100 ml) containing $2.9 \times 10^{-3}M$ of this acid were extracted with polyether and polyester foams (0.300 g). The initial pH of the solution was 3.15. Extraction equilibrium was reached within 1 hr. The distribution coefficients were 96.9 and 218 l./kg for polyester and polyether foams respectively (Table 1).

The extraction of salicylic acid in the presence of the amines was studied and the results are given in Table 1. Although salicylic acid is extractable, no extraction of the amines was observed. This result indicates that no ion-pair formation between salicylate and the protonated amines occurs. Salicylic acid extraction decreases with increasing amounts of added amine. In the presence of the same amount of amine, the extraction coefficients for salicylic acid are about the same for both sec-butylamine and *iso*butylamine. As the total amount of amine becomes greater than the amount of salicylic acid present, the pH increases markedly to 9.6 and no salicylic acid extraction was obtained. This observation suggests that the amount of amine added rather than the nature of the amines is important in the extraction of salicylic acid.

An increase in the amount of amine added increases the pH of salicylic acid solution and decreases the distribution coefficient of salicylic acid (Table 1). It is likely that the decrease of salicylic acid extraction is due to pH change. Therefore, the extraction of solutions of $2.9 \times 10^{-3}M$ salicylic acid in 0.1 and $2M$ hydrochloric acid solution with 0.300 g of foam was also studied. Figure 1 shows the relationship between log D and pH, and it includes the results of the extraction in the presence of various amines, alkali and alkali earth metal chlorides from Table 1. Two regions are apparent from the graph. These are the plateau of

Table 2. Effect of salts on salicylic acid extraction at pH 1

Salt	Concentration *M*	Distribution coefficient, *l./kg* Polyester	Polyether
None	0.0	164 ± 6	398 ± 14
LiCl	2.0	341 ± 9	818 ± 41
NaCl	2.0	312 ± 3	791 ± 29
KCl	2.0	260 ± 1	626 ± 23
$MgCl_2$	1.0	325 ± 8	780 ± 20
$BaCl_2$	1.0	275 ± 2	658 ± 18

Conditions: $2.9 \times 10^{-3}M$ salicylic acid, $0.1M$ HCl, 0.300 g of foam, 100-ml solution, 24-hr extraction time.

approximately zero slope below pH 2 and the linear segment with respective slopes of −0.71 and −0.67 for polyether and polyester foams. For the extraction of an acid of which the molecular species is extractable, slopes of 0 and −1 below and above the pK_a of the acid, respectively, would be expected. The pK_a value for salicylic acid is 2.75.[30] The slopes of the straight lines are approximately equal to 0 and −1 for pH values below 2 and above 3, respectively. The deviation of the values of the slopes from the theoretical values probably occurs because the pH of the data points is close to the pK_a value of salicylic acid. The results suggest that salicylic acid is extracted by a simple solvent extraction mechanism in which only the neutral molecular species is extractable.

According to the cation chelation mechanism, the presence of the potassium ion should facilitate the extraction of the anion more than the other alkali metal ions because of the better fit of this ion into the central cavity of the oxygen-rich helix in the polyether foam. Therefore, the effect of various alkali metal chlorides ($2M$) and alkaline earth metal chlorides ($1M$) on salicylic acid extraction was studied. Table 1 demonstrates significant increases in salicylic acid extraction in the presence of LiCl, NaCl, KCl, $MgCl_2$ and $BaCl_2$ by both polyester and polyether foams. The following order of extraction: $Li^+ \approx Na^+ > K^+$, $Mg^{2+} > Ba^{2+}$ was observed. The extraction of salicylic acid increases with increasing charge density on the cation. This order is different from that for a cation chelation extraction system where K^+ produces a greater increase for anion extraction than Na^+ and Li^+. This effect is consistent with a solvent extraction mechanism with the salts acting as salting-out agents. Added ions increase the extraction of an organic compound into the organic phase by reducing the number of water molecules available to solvate the organic compound because some water molecules are used to solvate the ions. Ions with higher charge density are expected to exert a greater effect. The charge density for the cations studied is $Li^+ > Na^+ > K^+$ and $Mg^{2+} > Ba^{2+}$. Thus the influence of the salts can be explained by the salting-out effect on a solvent extraction system.

To confirm the salting-out effect of the salts, an extraction was carried out in $2.9 \times 10^{-3}M$ salicylic acid solution containing $0.1M$ hydrochloric acid. At pH 1, 99% of the salicylic acid is in the neutral form as opposed to 50% at pH 2.75. Comparing the results of Tables 1 and 2, the added salts increase the extraction of salicylic acid more in a solution of pH 1 than at high pH owing to the increased amount of neutral salicylic acid. The effect of the salts remains the same for the sequence $Li^+ > Na^+ > K^+$ and $Mg^{2+} > Ba^{2+}$.

It can be concluded that salicylic acid is only extractable in the neutral form. The protonated alkylamine cations are too hydrophilic to affect the extraction of salicylate anions from aqueous solution by either polyester or polyether foam.

Extraction of 8-hydroxyquinoline

8-Hydroxyquinoline is more hydrophobic than salicylic acid. To evaluate the extractability of 8-hydroxyquinoline, solutions (100 ml) of $1.0 \times 10^{-3}M$ 8-hydroxyquinoline were extracted with 0.300 g of foam for 1 hr. In addition, extractions of 8-hydroxyquinoline in the presence of $1.0 \times 10^{-3}M$ methylamine and n-butylamine were also studied to determine whether the amines are extractable. Table 3 shows the amines have no effect on the extraction of 8-hydroxyquinoline. Both methylamine and n-butylamine were found to be non-extractable. The pK_a values for 8-hydroxyquinoline are 5.02 and 9.81.[30] At pH 6.4, the major species is the molecular form, therefore, no extraction of the amines was found. To ionize the (—OH) group of 8-hydroxyquinoline, a pH above 11 is required; however, at pH 11 undissociated amine is predominant. These difficulties prevent a proper investigation and no further studies on this compound were carried out.

Extraction of 1-amino-2-naphthol-4-sulphonic acid (ANS)

Solutions (100 ml) of $1.0 \times 10^{-3}M$ ANS containing methylamine or butylamine ($1.0 \times 10^{-3}M$) were extracted with 0.300 g of foam for 6 hr. Table 3 shows that methylamine and butylamine have no effect on the distribution coefficient (D) of ANS.

Table 3. Effect of amines on the extraction of 8-hydroxyquinoline and 1-amino-2-naphthol-4-sulphonic acid (ANS) extraction

Compound	Amine	Concentration, *M*	Distribution coefficient, *l./kg*	
			Polyester	Polyether
8-Hydroxyquinoline	None	0.0	173 ± 3	165 ± 3
	Methylamine hydrochloride	1.0×10^{-3}	170 ± 4	164 ± 3
	n-Butylamine	1.0×10^{-3}	156 ± 4	158 ± 2
	Hydrochloric acid	1.0×10^{-3}		
1-Amino-2-naphthol-4-sulphonic acid	None	0.0	9.3	30.8
	Methylamine hydrochloride	1.0×10^{-3}	8.1	28.2
	n-Butylamine	1.0×10^{-3}	11.1	32.1
	Hydrochloric acid	1.0×10^{-3}		

Conditions: (i) $1.0 \times 10^{-3}M$ 8-hydroxyquinoline, 0.300 g of foam, 100-ml solution, 1-hr extraction time, pH = 6.4. (ii) $1.0 \times 10^{-3}M$ ANS, 0.300 g of foam, 100-ml solution, 6-hr extraction time, pH = 3.5.

The pK_a values for ANS shown as (1) in Fig. 2, could not be found in the literature, however the (—SO_3H) group is expected to be completely ionized. The pK_a for 1-naphthylamine, (2) in Fig. 2 is 3.92.[30] In the presence of the (—SO_3H) group, the pK_a for the (—NH_2) group would be lowered. Thus at pH 3.5, the forms of ANS (3) and (4) may be present in comparable amounts. Since there is no change of *D* with the addition to the amines, it is clear that the extraction of the possible ion-pair between the amine cation and (4) does not occur. Thus, the neutral molecule (3) must be the extractable species.

The effect of potassium chloride and ammonium chloride on the extraction of ANS was studied. To verify that (3) is the extractable species, the extraction of ANS in $0.1M$ hydrochloric acid was also carried out. Table 4 demonstrates that there is no significant change of *D* for ANS with the addition of ammonium chloride and potassium chloride up to $0.1M$. Thus, ANS is too hydrophilic to extract K^+ and NH_4^+ from aqueous solution. However, *D* increases in $0.1M$ hydrochloric acid which can be the result of the increased formation of the neutral species (3) at pH 1. This result is consistent with a solvent extraction mechanism.

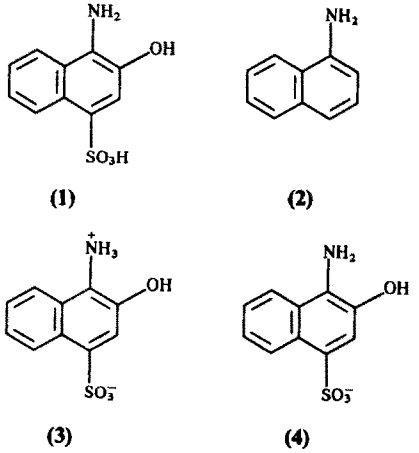

Fig. 2. Various forms of 1-amino-2-naphthol-4-sulphonic acid and 1-naphthylamine.

Extraction of cinnamic acid

Solutions (100 ml) of $1.0 \times 10^{-3}M$ cinnamic acid at pH 3.9 were extracted with 0.300 g of foam for 24 hr. Distribution coefficients of 195 and 343 for polyester and polyether foams respectively were obtained. Extraction of cinnamic acid in $1.0 \times 10^{-2}M$ potassium hydroxide was also carried out. The pH of the solution was above 12 and no detectable amount of cinnamic acid was extracted. The pK_a value for cinnamic acid is 4.44,[30] and therefore at pH 12, cinnamic acid is fully ionized. Therefore, the results indicated that dissociated cinnamic acid is not extractable. At pH 3.9, 77.6% of cinnamic acid is in the neutral form. Thus, only the undissociated cinnamic acid is extractable.

Table 4. Effect of salt and pH on 1-amino-2-naphthol-4-sulphonic acid (ANS) extraction

Salt	pH	Concentration, *M*	Distribution coefficient, *l./kg*	
			Polyester	Polyether
NH_4Cl	3.5	1.0×10^{-3}	9.0	29.2
NH_4Cl	3.5	0.1	4.7	25.3
KCl	3.5	1.0×10^{-3}	7.7	30.3
KCl	3.5	0.1	8.6	29.5
HCl	1.0	0.1	30.8	66.9

Conditions: $1.0 \times 10^{-3}M$ ANS, 0.300 g of foam, 100-ml solution, 6-hr extraction time.

Table 5. Comparison of the distribution coefficients of various organic compounds extracted by polyester and polyether foams

Compound	Distribution coefficient, *l./kg*		
	Polyester	Polyether	$D_{Polyether}/D_{Polyester}$
Salicylic acid	96.9 ± 3.2	218 ± 4	2.2
8-Hydroxyquinoline	173 ± 3	165 ± 3	1.0
Cinnamic acid	195 ± 3	343 ± 4	1.8
1-Amino-2-naphthol-4-sulphonic acid	9.3	30.8	3.3

Conditions: (1) salicylic acid: $2.9 \times 10^{-3}M$ salicylic acid, 0.300 g of foam, 100-ml solution, 24-hr extraction, pH = 3.2. (2) 8-hydroxyquinoline: $1.0 \times 10^{-3}M$ 8-hydroxyquinoline, 0.300 g of foam, 100-ml solution, 1-hr extraction time, pH = 6.4. (3) cinnamic acid: $1.0 \times 10^{-3}M$ cinnamic acid, 0.300 g of foam, 100-ml solution, 24-hr extraction time, pH = 3.9. (4) 1-amino-2-naphthol-4-sulphonic acid (ANS): $1.0 \times 10^{-3}M$ ANS, 0.300 g of foam, 100-ml solution, 6-hr extraction time, pH = 3.5.

Water is a solvent with a high dielectric constant. Ions in aqueous solution are well solvated and so it is difficult for ions to form ion-pairs in aqueous solution. Ion-pair formation is facilitated in solvents with low dielectric constant. To determine whether ionized cinnamic acid is extractable in a low dielectric constant solvent, extractions of $1.0 \times 10^{-3}M$ cinnamic acid with $1.0 \times 10^{-2}M$ sodium hydroxide and potassium hydroxide in 50% v/v dioxane solution at pH 10.4 were carried out. No extraction of the cinnamic acid was observed. It is apparent that cinnamic acid is too hydrophilic to form ion-pairs with Na^+ or K^+ even in 50% dioxane solution.

Hydrogen bonding

Schumack and Chow[27] examined the extraction of a wide variety of organic compounds by polyether and polyester foams. It was concluded that a solvent extraction mechanism is responsible for the extraction of these organic compounds. It was also found that compounds containing a (—OH) hydroxyl group are generally more extractable by polyether foam than by polyester foam. Hydrogen bonding between the (—OH) group on the organic compound and polyurethane foam can account for this observation because polyether foam is able to form stronger hydrogen bonds than polyester foam. In addition, when hydrogen bonding is prevented by placing a strongly intramolecular hydrogen bonding group adjacent to the (—OH) group as in the case of *o*-nitrophenol, salicylaldehyde or *o*-methoxyphenol, the extraction by polyester and polyether foams is about the same.

The various organic compounds used in this study all contain the (—OH) group. The distribution coefficients (*D*) for these compounds under different conditions with polyester and polyether foams are summarized in Table 5. With the exception of 8-hydroxyquinoline, the compounds are more extractable by polyether foam. It is possible that intramolecular hydrogen bonding takes place in 8-hydroxyquinoline which prevents hydrogen bonding between it and the foam. For salicylic acid, there are two groups per molecule able to form hydrogen bonds as opposed to one group for cinnamic acid. The higher $D_{polyether}/D_{polyester}$ ratio for salicylic acid could be ascribed to greater hydrogen bonding between the compound and the foam. Although there are two groups per molecule capable of hydrogen bonding for salicylic acid and ANS, the $D_{polyether}/D_{polyester}$ ratio for ANS is somewhat higher than the salicylic acid. it is possible that the ($—NH_3^+$) group can have an ion–dipole interaction with the foam in addition to hydrogen bonding, resulting in higher extraction for ANS. Considering the lower *D* values for ANS compared with those for salicylic acid, the relatively higher error of *D* for ANS may result in the higher $D_{polyether}/D_{polyester}$ ratio. Overall, the results obtained in this work are consistent with those previously reported.[27]

CONCLUSION

The study of the extraction of salicylic acid, 8-hydroxyquinoline, 1-amino-2-naphthol-4-sulphonic acid and cinnamic acid shows that these compounds are extracted in their neutral form by a simple solvent extraction mechanism. This conclusion is supported by the salting-out

phenomenon and the pH effect. The anionic species are too hydrophilic to facilitate the extraction of alkylamine and alkali metal cations from aqueous solution. Although a simple solvent extraction mechanism is involved, these compounds, except 8-hydroxyquinoline, are more extractable by polyether foam than polyester foam. This result can be attributed to the stronger hydrogen bonding of the organic compound with polyether foam since all these compounds contain a (—OH) group which is capable of forming hydrogen bonds with the foam. For 8-hydroxyquinoline, it is possible that intramolecular hydrogen bonding in the compound prevents the intermolecular hydrogen bonding with the foam resulting in about the same extraction for both types of foam.

Summary—Near-infrared dyes can be derivatized with appropriate functional groups for use as analytical probes for numerous applications. A dye derivatized with pH-sensitive functional groups may show spectral changes when the pH of its environment is changed. These dyes are valuable to the researcher since they absorb and fluoresce at long wavelengths where interference is minimal and their absorption maxima permit the use of semiconductor lasers. In this paper we have evaluated the sensitivity to pH of a *bis*-carboxylic acid derivative of a near infrared dye to illustrate its potential as a probe for determining pH. The dye has an absorption maximum at 795 nm in aqueous solution, a region where several commercially available laser diodes have their output maximum. The analytical utility of near-infrared laser diodes for pH determination has also been evaluated.

The pH determination of aqueous solutions is an important aspect of analytical chemistry.[1] In the past many dyes have been evaluated as potential acid/base indicators for the determination of solution pH.[2–4] The analytical detection method preferred for this purpose is fluorescence, which offers enhanced selectivity and sensitivity. An appropriate pH indicator must therefore fluoresce in either its molecular or ionized state, or exhibit fluorescence differences between these forms.

Fluorescent indicators are particularly useful in determining the pH of biological samples which have significant absorbance.[5,6] In particular, the near-infrared (NIR) region of the spectrum has proven useful in the study of biological samples because their absorbance in this region is minimal and does not interfere with the absorbance or fluorescence of an NIR chromophore.[7,8] Indeed, the analytical applications of NIR chromophores have increased dramatically over the last few years. Their advantages include a strong absorption band in the NIR spectral region (600–1000 nm) and large molar absorptivities which facilitate low detection limits. Additionally, due to the relatively low interference in this spectral region, considerable selectivity can be achieved. When semiconductor lasers are used as the excitation source, the advantages of the NIR region are further enhanced.[8,9]

Spectrophotometry is a convenient and rapid analytical tool for pH determination and many studies have attempted to develop and characterize suitable dyes for pH determination using spectrophotometry.[10,11] Although many pH indicator dyes have been evaluated, few NIR absorbing dyes have been investigated for this purpose. The polymethine cyanine dyes are excellent candidates for pH determination. Their absorption and fluorescence maxima generally fall in the 600–1000 nm region, determined by the length of the polymethine chain. Additionally, laser diodes may be used for the NIR dye excitation since their output wavelengths closely match the dye absorption and fluorescence maxima. The output wavelength of the 680-nm laser diode is very close to that of the dicarbocyanine dyes and the tri-carbocyanine dyes can be used with laser diodes of 780-nm output wavelength.[12] Once a dye with the appropriate absorbance and fluorescence characteristics is chosen, it can be easily modified to fit the analytical application. By combining the use of laser diodes with the analytical possibilities afforded by NIR pH-sensitive chromophores, the development of a multitude of analytical techniques is possible.

The absorption and fluorescence properties of many NIR chromophores have been evaluated in the past; including their use as laser dyes,[13] potential sensitive probes,[14] and covalent and non-covalent labels.[15] However, their use as pH indicators has not yet been evaluated, primarily

*Author for correspondence.

because suitable dyes were not available. An appropriate pH indicator dye must have pH sensitive functional groups that can change from the ionized to the non-ionized form as the concentration of the hydrogen ions changes. A change in the ionization of the functional group may influence the conjugation of the π system of the indicator molecule resulting in spectral changes which can be used for determining pH. To date, there are no commercially available NIR dyes that contain these functional groups. However, routine synthetic steps can be followed to introduce pH sensitive functional groups, carboxyl, amino, or phenol(-OH), into NIR dyes.[12]

We report here the pH dependence of the absorption and fluorescence characteristics of a new NIR pH sensitive dye, a *bis*-carboxylic acid derivative of 2-{4′-chloro-7′[2″-(1″-ethyl-3″,3″-dimethyl indolenine)]-3′,5′-(1′″,3′″-propanediyl)-1′,3′,5′-heptatrien-1′-yl]-1-ethyl-3,3-dimethyl indolenine bromide (Fig. 1). These studies may serve as a framework for the development of a new class of NIR dyes that can be used as pH probes utilizing laser diode excitation.

EXPERIMENTAL

Reagents and chemicals

The chemical structure of the pH sensitive dye used in this study is depicted in Fig. 1. It is a *bis*-carboxylic acid derivative of 2-{4′-chloro-7′-[2″-(1″-ethyl-3″,3″-dimethyl indolenine)]-3′,5′-(1′″,3′″-propanediyl)-1′,3′,5′-heptatrien-1′-yl]-1-ethyl-3,3-dimethyl indolenine bromide which has been prepared in our laboratory as follows: 4.65 g of *p*-hydrazinobenzoic acid and 9 ml of 3-methyl-2-butanone were refluxed in ethanol for 45 min. Workup of this reaction mixture included cooling to 0° to give the hydrazone. The hydrazone was refluxed in glacial acetic acid under a nitrogen atmosphere for 4 hr. The reaction mixture was then cooled and poured into ice cold water followed by ether extraction. Acetic acid was removed by washing with water several times. The analytically pure 2,3,3-trimethyl-5-carboxy-3-H-indole has a mp of 210–211°. Reaction of the 3-H indole with 2 g of ethyl bromide in 15 ml of acetonitrile under pressure gave the quaternary salt. Subsequent transformation of this bromide into the final dye was conducted according to cyanine dye synthesis procedures.[16,17] Crude dye was crystallized twice from ethanol, and the product was heated at 60° under reduced pressure of 0.1 mm Hg for 12 hr producing the analytically pure dye sample that is shown in Fig. 1. The dye structure is fully consistent with the proton NMR spectrum ($CDCl_3$).

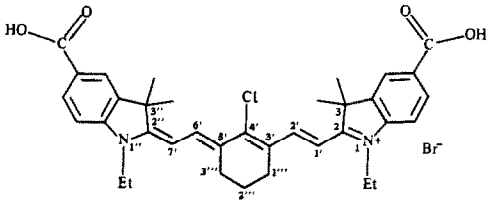

Fig. 1. Chemical structure of the pH sensitive NIR dye used in this study.

Chemicals used in the dye synthesis were obtained from Aldrich Chemical Company (Milwaukee, WI). Spectrophotometric grade methanol was also obtained from Aldrich. Hydrochloric acid, sodium hydroxide and buffer components were obtained from Fisher Scientific (Pittsburgh, PA).

Method

Stock solutions ($10^{-3}M$) of the pH sensitive NIR dye were prepared in spectrophotometric grade methanol. For the pH studies solutions were prepared by pipetting the required amount of dye stock solution dissolved in methanol into a 50-ml standard flask. The standard flask was then filled with demineralized water or 0.05M Tris buffer and briefly sonicated. The final solutions contained less than 0.05% v/v methanol which had no effect on the dye spectra or pH. The dye preparation is simplified by diluting from a stock solution in methanol, compared to removing methanol from the stock solution with dry nitrogen gas. The concentration of the final dye solution was $4 \times 10^{-6}M$ unless otherwise stated.

Solution pH was varied for two separate sets of dye solutions in order to evaluate dye behaviour at different ionic strengths. The low ionic strength solutions were prepared by slowly adding appropriately diluted hydrochloric acid or sodium hydroxide to the dye solutions. Minute quantities of acid or base were used to avoid spectral changes caused by dilution. The high ionic strength solutions were prepared in 0.05M buffers. For both sets of solutions, the pH was monitored continuously with glass pH electrodes.

Instrumentation

Absorbance spectra were obtained on a Perkin–Elmer Lambda 2 UV/VIS/NIR spectrophotometer, interfaced to a Zenith 286 computer

to store spectra and control the spectrophotometer. Each spectrum was recorded with a PECSS program. All data were obtained at room temperature, using solutions in equilibrium with air. Solution pH was measured with an Orion Research Model 701A Digital Ionanalyzer. Fluorescence spectra were recorded on an SLM 8000 spectrofluorometer interfaced to an IBM PS/2. The instrument was modified to accommodate an NIR laser diode excitation source.[18] A 30-mW laser diode was used with a 782-nm output wavelength; the optical and electronic design of this modification has been discussed previously.[18] Dye pK_a values were obtained with the Schott Model 250 autotitrator and Model T90/10 autoburet interfaced to a 286 computer.

RESULTS AND DISCUSSION

Representative absorption spectra of the pH sensitive NIR dye in methanol is shown in Fig. 2. The dye maximum is at 795 nm, comparable to the output wavelength of the commercially available laser diodes. Dye spectra were similar in both aqueous and methanol solutions except for a minor spectral shift of the NIR absorption maxima. The dye molar absorptivities in methanol and in water at different wavelengths are summarized in Table 1 indicating values typical of most cyanine dyes. The relatively high molar absorptivities typical of most cyanine dyes, enhances their detection limits. In the case of spectrophotometric pH probes, a high molar absorptivitiy allows the use of lower dye concentrations which minimizes interference resulting from dye acid/base equilibria.

Several indicator dyes work on the premise of ionization of pH sensitive groups, amino, phenol, hydroxyl or carboxyl. Changes in these groups may influence the π system of the indicator

Table 1. Molar absorptivity values for the NIR pH sensitive dye

Solvent	$\epsilon_{298\,nm}$	ϵ_{NIR}
Water	13,050	150,000 (795 nm)
Methanol	11,200	166,000 (803 nm)

molecule resulting in changes in the absorption and fluorescence spectra. Since the carboxylic groups are directly attached to the aromatic nuclei of the NIR dye described in this study, we presume that the conjugation and the charge distribution in the molecule is dependent on the ionization of these carboxylic groups. We chose to prepare a *bis*-carboxylic acid derivative of the NIR dye 2-{4′-chloro-7′-[2″-(1″-ethyl-3″,3″-dimethyl indolenine)]-3′,5′-(1‴,3‴-propanediyl)-1′,3′,5′-heptatrien-1′-yl]-1-ethyl-3,3-dimethyl indolenine bromide (Fig. 1) rather than the monosubstituted analogue, for two reasons. First, it is much easier to prepare a symmetrical cyanine dye and second, due to the presence of two carboxylic groups, a much larger perturbation of the π system of the molecule is expected upon ionization of the carboxylic groups. Two distinct pK_a values were also expected for the NIR dye acid. The presence of two carboxylic groups in the dye molecule should widen the pH range where changes in the spectral properties are expected. This should also increase the emission or excitation spectral shift upon ionization of the carboxylic groups.

The pK_a values of the dye acid were determined with automated titrators using $0.039M$ sodium hydroxide. Titration curves showed pK_a values of 4.90 and 6.80, respectively, for the two carboxylic groups. These values are in good agreement with pK_a values for carboxylic acid derivatives of other heterocyclic compounds.[12] The non-ionized form of the indicator dye depicted in Fig. 1 is cationic. The relatively low pK_a value of the first carboxylic group can be explained by the positive charge of the dye molecule. Since the molecule is symmetrical, including the positive charge distribution between the quaternary nitrogens, either carboxylic group may be ionized first. Once the first carboxylic group is fully ionized, the neutral zwitterionic form will predominate. Ionization of the second carboxylic group is more difficult because of the lack of a net positive charge.

We expect that the ionization steps result in changes of the π system of the NIR dye molecule. The relative influence of the two ionization steps on absorption spectra of the NIR indicator dye may be estimated by the

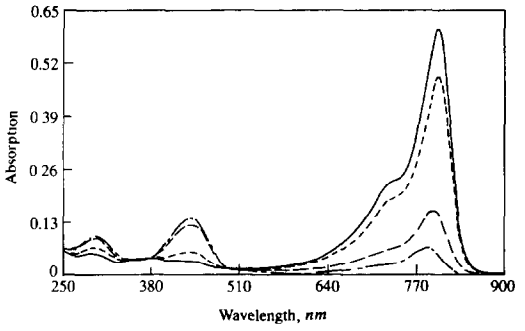

Fig. 3. Typical absorption spectra of the NIR dye in pH 7 (——), 8 (– – –), 9 (—·—) and 9.7 (———) solutions.

Henderson–Hasselbach equation if we compare the dye spectra at different pHs.

Typical absorption spectra of the NIR dye acid in the low ionic strength solution (water) at different pHs are shown in Fig. 3. These changes in the absorption spectra were repeatedly observed when the pH of the same solution was varied by addition of acid or base, indicating the hydrogen ion concentration was the primary determining factor. These experiments showed spectral reproducibility and stability of the NIR dye in its aqueous environment as the pH was increased and decreased repeatedly. Photostability of this NIR dye has been evaluated. The dye solution was continuously illuminated at its absorption maximum for about two hours. No change in absorption or fluorescence was observed during this period.

Spectral changes with pH of the dye in the higher ionic strength buffer solutions (0.05*M* Tris) resulted in almost identical spectra and therefore are not shown here. As can be seen from Fig. 3, at higher pH values, an absorption peak at 435 nm appears and increases with increasing pH. At corresponding pH values, the NIR peak at 795 nm decreases with increasing pH. According to the Henderson–Hasselbach equation, the first carboxylic group will be approximately 90% ionized at $pH = pK_{a1} + 1$ and the second carboxylic group will be 90% ionized at $pH = pK_{a2} + 1$.

Figure 4(a) shows a plot of NIR dye absorbance at 435 nm and 4(b) at 795 nm for each pH value from 2 to 12. Both Figs. 4(a) and 4(b) show that at pH 6, where the first carboxylic group is about 90% ionized, very little spectral change is observed, indicating that the first ionization step probably has little influence on the distribution of positive charge between the quaternary nitrogens. This positive charge distribution usually has a large influence on the spectral properties of polymethine cyanine dyes.[12]

The second ionization step results in much more pronounced changes in the dye absorption spectra. At pHs above 8.5 we expect most of the dye molecules to be fully ionized. Figure 3 shows that significant NIR absorption is still present at pH 8.5, indicative of other possible factors influencing the molar absorptivities of the dye molecule at the second ionization. This phenomena is interesting when you consider that the molar absorptivity of the dye remains unchanged when the first carboxylic group is ionized. This difference in molar absorptivities between the mono- and di-ionized form of the NIR indicator dye further emphasizes the extent of perturbation in the π system upon the second ionization step. This also indicates that the quaternary nitrogens probably have much less influence on these spectral changes since they are very basic.[12]

Both the 435-nm or NIR peaks can be used for determining the pH of the environment around the dye molecule. Figure 4(a) can be used as a calibration curve for determining the pH, using the 435 nm absorption peak. Figure 4(a) indicates that this peak is not present in the dye spectra in acidic solutions. In basic solutions

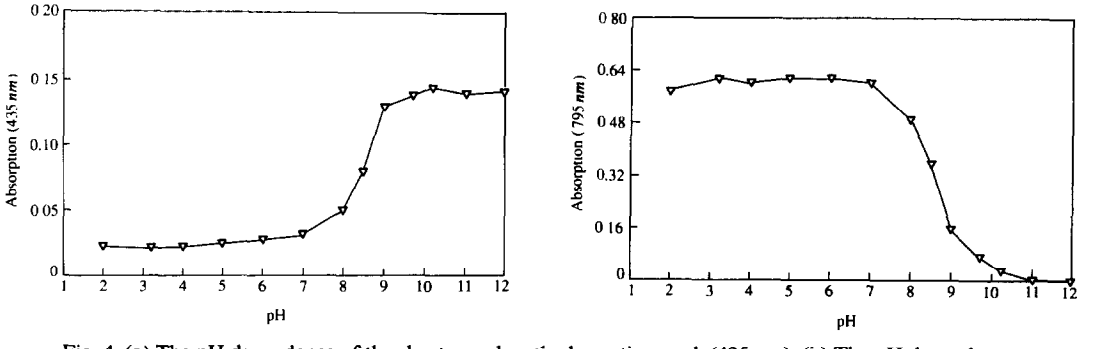

Fig. 4. (a) The pH dependence of the short wavelength absorption peak (435 nm). (b) The pH dependence of the NIR absorption peak (795 nm).

however, the 435-nm absorption peak appears and the intensity of the peak increases with increasing basicity of the solution and levels off at pH 10. The appearance of this short wavelength absorption peak corresponds to a decrease in the NIR peak [Fig. 4(b)], clearly indicating that the presence of negatively charged carboxylate groups disrupts the delocalization of the positive charge between the quaternary nitrogen atoms. Although this phenomenon may be used for pH determination, the 435-nm peak is in the region of higher interference and therefore, may be less useful for this purpose.

The NIR peak at 795 nm, however, may be more useful for pH determination. This dye could be suitable for measuring the pH, using laser diodes or other NIR light sources. Although the intensity of the NIR absorption peak remains unchanged in acidic solutions, at pH 7 and higher the intensity of this peak decreases due to ionization of the carboxyl groups. The NIR peak intensity gradually decreases as the solution pH increases and becomes insignificant above pH 10.

Since the chromophore is fluorescent in both aqueous and non-aqueous media, the NIR fluorescence of this dye may also be used for determining the pH of solutions. The absorption maximum of the NIR dye acid is in the region where inexpensive consumer laser diodes have their output maximum (785–795 nm). As indicated by several earlier studies,[9,18] laser diodes are excellent excitation sources for fluorescence measurements. The fluorescence of this dye has also been evaluated with a laser diode modified SLM 8000 fluorometer which has been described earlier.[18] A representative fluorescence spectrum for the dye is shown in Fig. 5. The NIR fluorescence intensity of the NIR dye acid was determined using a laser diode excitation source of 782 nm, 30 mW in aqueous solutions of different

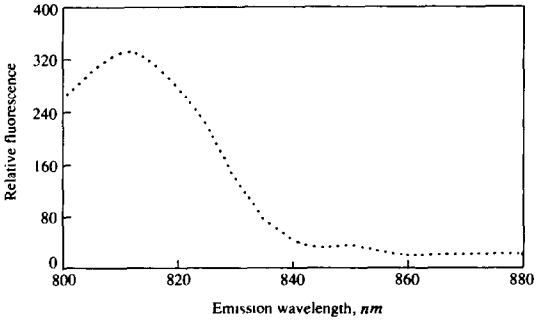

Fig. 5. Fluorescence spectra of the NIR pH sensitive dye at pH = 4.1 (Excitation: 795 nm).

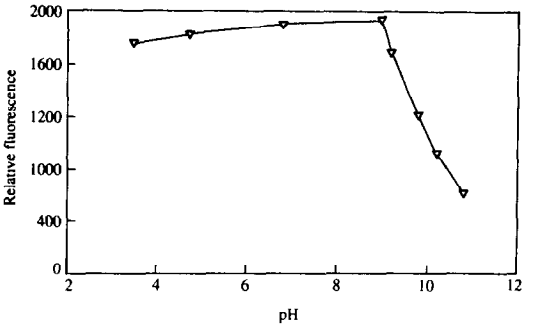

Fig. 6. Solution pH determination with NIR laser diode excitation (λ_{ex} = 782 nm, λ_{em} = 820 nm).

pHs. Fluorescence intensity was measured at 820 nm, using a 10-nm band width interference filter. The calibration curve obtained (Fig. 6) indicates that NIR laser diode induced fluorescence may be used for determining pH in solutions. A comparison between Figs. 4(b) and 6 reveals that the NIR absorbance or fluorescence changes occur at different pH values; the NIR absorbance begins to decrease at pH 7 and the fluorescence begins to decrease at pH 9. This difference is expected since fluorescence is characteristic of the excited state of the molecule while absorption is characteristic of the ground state of the molecule. The fluorescence enhancement above pH 4 may be attributed to the first ionization step. Although the absorption spectra do not show significant changes until the second ionization step occurs, fluorescence properties of the dye may be influenced by changing charge distribution.

CONCLUSIONS

A new NIR cyanine dye has been shown to be sensitive to changes in pH. The NIR absorption and fluorescence characteristics of this dye could be useful in actual samples since interference is negligible in near-infrared fluorometry. The laser diode used in these studies has an output wavelength of 782 nm, at room temperature and as mentioned, laser diodes with different output wavelengths may be used to match the varying spectral characteristics of different dye structures. The dicarbocyanine dyes which have an absorption band that closely matches the output maxima of 680-nm laser diodes, may also be useful for this purpose. Their heterocyclic nuclei may influence the absorption maxima of the dye. However, the heterocyclic nuclei have a greater influence on the pK_a values and therefore on the useful pH range. It is clear

that additional studies are required for determining the exact role of the heterocyclic nuclei on the useful pH range. Numerous other possibilities for designing appropriate dye structures exist. Other functional groups may be used in the NIR dye molecule to achieve pH sensitivity. For example, NIR dyes with aromatic amino groups are expected to be indicators in the acidic pH region, while phenolic groups may be used to extend the useful pH range to more basic pHs. The introduction of additional charge into the dye molecule may also be used to fine-tune the pH range desired.

Although the use of NIR dye solutions and laser diodes for determining pH may be useful when low interference is desired, immobilized dye attached to the end of fiber optic should give greater versatility for the method. Using different dyes with different absorption maxima and pK_a values, a large pH range may be achieved if multi-laser diode excitation is utilized. Other NIR dyes that have spectral pH dependence closer to their pK_a values may be developed for physico-chemical applications, for example in the determination of pK_a.

TITRIMETRIC DETERMINATION OF FLUORIDE IN SOME PHARMACEUTICAL PRODUCTS USED FOR FLUORIDATION

BILJANA F. ABRAMOVIĆ* and FERENC F. GAÁL
Institute of Chemistry, Faculty of Sciences, University of Novi Sad, Trg Dositeja Obradovića 3, 21000 Novi Sad, Yugoslavia

SRETEN D. CVETKOVIĆ
Military Medical Centre, Herceg Novi, Yugoslavia

(*Received* 9 *September* 1991. *Revised* 28 *October* 1991. *Accepted* 31 *October* 1991)

Summary—Two titrimetric methods were developed for the determination of fluoride contents in some pharmaceutical preparations used for fluoridation. One of the methods is catalytic controlled-current potentiometry involving two identical platinum indicator electrodes and thorium nitrate as titrant. The reaction between hydrogen peroxide and potassium iodide in the presence of acetate buffer (pH 3.6), which is catalysed by the excess of thorium nitrate, served for the end-point indication. The other method is the automatic potentiometric titration involving a fluoride-selective electrode and lanthanum nitrate as titrating agent. In both procedures, special attention was paid to sample pretreatment and to determination of optimal experimental conditions. Fluoride contents in the range 16–32 μg/ml are determined with a relative standard deviation less than 1.34%. The results are compared to those obtained by standard methods described in the United States Pharmacopeia XXI and recommended by the manufacturer of the preparations.

Fluorine compounds, both organic and inorganic, have their specific use in modern medical practice. The most important of these compounds are synthetic fluorinated corticosteroids, neuroleptics, anaesthetics, uroanesthetics, cytostatics and antirheumatics. Besides, fluorine compounds are used in the prevention of caries.

Although fluorine preparations for caries prevention have been in use in Yugoslavia for a long time they have not been treated in Farmakopeja SFRJ, Ph. Jug. IV.[1] The only reference is concerned with pure sodium fluoride, but the titrimetric method recommended therein is not suitable for the determination of fluoride in these preparations because of the necessity to use a relatively large amount of sodium fluoride (50 mg/probe). A similar situation applies to the British Pharmacopoeia 1980.[2] However, the United States Pharmacopeia XXI[3] contains several monographs on fluoride preparations used in caries prevention. The recommended method for fluoride determination is direct potentiometry with a fluoride-selective electrode. The application of this method,[4,5] together with spectrophotometry[6] and isotachophoresis[7] for determination of fluoride content in pharmaceutical preparations have also been described in the literature.

As a continuation of our studies on the determination of pharmacologically active components in pharmaceutical preparations,[8–10] the present article describes the development of a simple, relatively fast and sufficiently accurate analytical method for the determination of fluoride content in fluoridation preparations which could be performed even in a modestly-equipped laboratory. For this purpose a catalytic titrimetric method with thorium nitrate as titrant was employed with the use of controlled-current potentiometry to follow the course of the titration.[11] Besides, for the same purpose we used the potentiometric titration with lanthanum nitrate as titrating agent.

EXPERIMENTAL

Chemicals and solutions

All chemicals used were of analytical purity. Solutions were prepared with doubly distilled water.

*Author for correspondence.

The fluoride content was determined in the following pharmaceutical preparations: Fluonatril tablets (Belupo 1, Ludberg), 0.55 and 2.21 mg of sodium fluoride per tablet; NAF tablets (Bosnalijek, Sarajevo) 0.55 and 2.21 mg of sodium fluoride per tablet; Aminfluorid solution (Belupo 2, Koprivnica) 12.140% of *N,N,N'*-tri-(2 - hydroxyethyl) - *N'* - octadecyl - 1,3 - diaminopropane-dihydrofluoride (I) and 1.135% of 1-amino-9-octadecen hydrofluoride (II) (which corresponds to a total fluoride content of 1.000%), and Aminfluorid gel (Belupo 2, Koprivnica) 3.032% of I, 0.287% of II, and 2.210% of sodium fluoride (total fluoride content 1.250%).

Standard thorium nitrate and lanthanum nitrate solutions (0.01*M*) were standardized against a known amount of fluoride by potentiometric titration with the fluoride-selective electrode.

Potassium iodide solution, $1.8 \times 10^{-2}M$, hydrogen peroxide solution, $5.5 \times 10^{-2}M$ and acetate buffer, pH 3.6, were prepared as described previously.[11]

Solutions for direct potentiometric measurements were prepared according to the US Pharmacopeia XXI.[3]

Apparatus

The course of catalytic titrations was monitored by a controlled-current potentiometric ($I = 2\ \mu A$) method with two identical indicator electrodes. The laboratory-constructed indicator electrodes[12] used in fluoride determination in the model solution were made of platinum (Pt), graphite (C) and glassy carbon (GC). To determine fluoride contents in the investigated preparations, use was made of a platinum indicator electrode couple. Titration curves were recorded on a chart recorder (Goerz-Electro Servogor 2S RE-571) at a rate of 30 mm/min.

For automatic potentiometric titrations with the electrode couple fluoride-selective electrode (Radiometer F-1052F) and SCE (Radiometer K-401), a Radiometer pHM 26 coupled to a Radiometer TTT 60, was used.

The titrant was added continuously by means of a Radiometer ABU 12 piston burette (volumes of 2.50 and 25.00 ml). The rate of titrant addition was 0.282 ml/min in catalytic titrations and 0.035 and 0.35 ml/min, respectively, in automatic titrations.

The comparative direct potentiometric method was performed with a Radiometer pHM 62 Standard pH meter and the above fluoride-selective electrode in combination with a saturated calomel electrode.

Analysis of tablets

After homogenization of 250 of the tablets to be analysed by grinding in a mortar, the procedure used in catalytic potentiometric ($I = 2\ \mu A$) titration was as follows. A 50-mg amount (for a sodium fluoride content of 2.21 mg/tablet which corresponded to the mass of one tablet), or 100 mg (if sodium fluoride content was 0.55 mg/tablet, which corresponded to the mass of two tablets) of the homogenized powder was placed in a 70-ml plastic reaction vessel and 10.0 ml of water were added. After heating the mixture on a water bath for 30 min and cooling to room temperature, the following solutions were added: 16.0 ml of ethanol, 4.0 ml of acetate buffer, 0.5 ml of hydrogen peroxide and 0.5 ml of sodium iodide. The solution was titrated with the standard thorium nitrate solution.

In automatic potentiometric titrations the following procedure was used. The homogenized powder was weighed as in the previous case and placed into a 70-ml reaction vessel. Then, 10.0 ml of water and 25.0 ml of ethanol were added and the solution titrated with the standard lanthanum nitrate solution. Before starting the titration, the "proportional band" on the titrator was set at the value 1 and the appropriate end-point potential.

The procedure in comparative direct potentiometric determination was the one described in the US Pharmacopeia XXI.[3]

Analysis of Aminfluorid solution and Aminfluorid gel

In both catalytic and automatic potentiometric titrations, the following procedure was used. To 100 mg of the sample placed in a 70-ml reaction vessel 10.00 ml of water was added and the reaction mixture homogenized by stirring with a magnetic stirrer. Further procedure was identical to that used in fluoride determination in tablets.

The procedure in comparative direct potentiometric determinations was similar to that in the analysis of tablets.

In the neutralization titrations the following procedure was used. About 3.00 g of Aminfluorid solution (*i.e.*, about 5.00 g of Aminfluorid gel), was dissolved in 40 ml of ethanol in a 70-ml plastic vessel. After adding several drops of phenolphthalein solution, the solution was titrated with the 0.1*M* standard ethanolic

potassium hydroxide solution to a light-rose colour.

The end-point of the catalytic titration in all cases was determined graphically from the intersection of straight-line interpolations before and after the equivalence point. The results were corrected for the blank.

RESULTS AND DISCUSSION

Optimization of conditions

As already mentioned, the most suitable method for titrimetric determination of fluoride content in model solutions was the controlled-current ($I = 2$ μA) potentiometry, using two identical platinum indicator electrodes.[11] However, it was interesting to examine the effect of the nature of indicator electrodes on the shape of titration curves and on the results of these determinations. For this purpose we compared the performance of three electrode pairs made of platinum, spectral graphite and glassy carbon (Fig. 1). As can be seen, the largest change in the potential is observed in the case of glassy-carbon electrodes (curve 2). However, the pair of platinum electrodes was chosen because the corresponding titration curve (curve 1) is characterized by the most pronounced potential change around the equivalence point.

As the fluoride content in the analysed tablets was 2–4 times lower than in the model solution,[11] it was necessary to examine the possibility of using catalytic titrations for the determination of these lower quantities of fluoride. It was found that for the investigated range of quantities of sodium fluoride (Table 1) the resulting titration curves were suitable for the end-point determination, but the results thus obtained were not satisfactory.

An analysis of these results showed that in all cases, irrespective of the quantity determined, the same absolute error was observed, which was in agreement with our earlier observations.[11] A probable explanation of this could be the difference in experimental conditions in recording a catalytic titration curve for the sample and the corresponding curve for the blank. Because of that we have investigated the possibility of employing the standard addition method in which, instead of titrating the blank, a probe containing a certain amount of sodium fluoride was titrated both alone and in combination with the probe of the sample. The content of fluoride in the analysis was obtained from the difference between the results of the two titrations. The recoveries thus obtained agreed well with the expected ones.

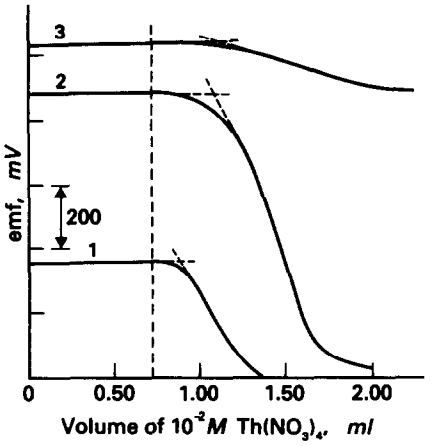

Fig. 1. Effect of nature of indicator electrode on the shape of catalytic constant-current potentiometric titration curve of 1.202 mg of sodium fluoride: (1) [Pt(+)/Pt(−)]; (2) [GC(+)/GC(−)]; (3) [C(+)/C(−)]. The dotted line indicates the equivalence point.

The possibility of employing the calibration graph method has also been investigated. The obtained plot was linear in the investigated range of concentrations, so that it could be represented by the following equation:

$$y = 64.09x + 9.98 \qquad r = 0.99999$$

where y is the length of the titration curve to the equivalence point (mm) (the blank subtracted)

Table 1. Results of catalytic titrimetric determination of sodium fluoride in model solutions ($n = 6$)

	Procedure			
	Direct		Standard addition	Calibration curve
NaF taken, *mg*	Found, %	RSD, %	Found, %	Found, %

1.202	114.0	0.55	99.2	99.8
1.801	109.8	0.61	100.8	99.8
2.404	107.8	0.31	100.2	100.1

and x is the amount of sodium fluoride (mg) under the given experimental conditions.

It comes out from the above equation that only amounts of sodium fluoride higher than 16 mg can be determined by the direct method with a relative error less than 1%. On the other hand, the results obtained by the calibration graph method are also satisfactory (Table 1). Because of that, this method was employed to determine fluoride contents in the investigated preparations.

In the course of establishing optimal experimental conditions for determination of fluoride by automatic potentiometric titration it was found that the amounts of 1.20–12.00 mg of sodium fluoride could be determined without any difficulty as to the accuracy of the results.

In view of the slow attainment of a steady potential at the fluoride-selective electrode in the solutions with low fluoride concentrations it was necessary to find an optimal rate of titrant addition. For this purpose, the accuracy and precision of determination were tested for the titrant addition rate in the range 35–282 μl/min. It appeared, however, that this effect was rather small provided the standardization of the lanthanum nitrate solution was carried out under the same conditions as the sample analysis, which is understandable. In view of the highest precision obtained, all further determinations were carried out at the lowest rate of titrant addition, although such titrations lasted a relatively long time (60 min).

Because of the presence of certain amounts of fillers in the analysed tablets, which are not completely soluble in the water–ethanol mixture used in the titration, it was also necessary to optimize the procedure of sample (tablets) pretreatment. For this purpose, several pretreatment procedures of Fluonatril tablets were employed (Table 2). As can be seen, according

Table 2. Effect of mode of preparation of Fluonatril tablets on the results of catalytic titration of fluoride. Declared content of F^-: 1.00 mg/tablet ($n = 6$)

Method of sample preparation	F^- found, *mg*	RSD, %	F-ratio†
A	1.006	0.66	4.10
B	1.007	1.27	
C	1.001	0.92	
D	0.991	0.57	

After adding water, ethanol and buffer, the sample was stirred on a magnetic stirrer for 5 min (A), 30 min (B) and 60 min (C). For D, 10.0 ml of water were added to the sample and the mixture was heated for 30 min in a water bath; †$F_{0.05,3,20} = 3.10$; $F_{0\,01;3;20} = 4.94$.

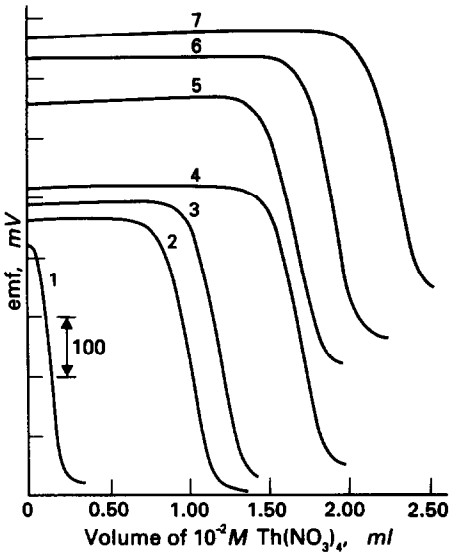

Fig. 2. Catalytic potentiometric [Pt(+)/Pt(−)] ($I = 2$ μA) titration curves obtained in determination of fluoride in: (1) blank; (2) 0.09916 g of Fluonatril tablets with 0.25 mg F^-/tablet; (3) 0.10035 g NAF tablets with 0.25 mg F^-/tablet; (4) 0.05047 g NAF tablets with 1.00 mg F^-/tablet; (5) 0.04940 g of Fluonatril tablets with 1.00 mg F^-/tablet; (6) 0.09184 g of Aminfluorid gel; (7) 0.13368 g of Aminfluorid solution.

to one-way analysis of variance there was a significant difference between all the mentioned methods. On comparing these results with those obtained by the other two methods (Table 3), Procedure D was chosen as the optimal one.

Applicability of methods

Typical catalytic titration curves of the analysed samples are presented in Fig. 2.

Some of the results of determination of fluoride content in the analysed preparations are given in Table 3. As none of the above pharmacopoeias[1-3] contains the monograph for the determination of fluoride content in Aminfluorid solution and gel, the neutralization titration (the procedure recommended by the manufacturer) and the direct potentiometry (as in the determination of fluoride in tablets[3]) were used as comparative methods. A relatively low fluoride content found by the neutralization titration of Aminfluorid gel is understandable if it is borne in mind that only 0.25% of fluoride is present in the form of hydrofluoride.

As can be seen from Table 3, if the fluoride content in the product is higher (1 mg F^-/tablet) then, the application of all the above procedures yields a satisfactory agreement of the results. However, if the fluoride content is lower, as in the case of Aminfluorid solution and gel, and especially with tablets containing 0.25 mg F^-/tablet, such an analysis shows a highly significant difference between all the mentioned methods. This is probably a consequence of a higher content and different nature of the filler because it can also react in some way with the titrant. For this reason, the titrant standardization should be performed in the presence of an appropriate amount of the filler in the solution.

On the basis of all the above, it can be concluded that catalytic controlled-current and automatic potentiometric titrations are equally suitable for the determination of fluoride content in the preparations used for fluoridation. However, a certain advantage can be given to catalytic titrations because no strict reproducibility of the potential changes is required, as is the case with the automatic titrations. Similarly, on comparing the titrimetric methods with the direct potentiometric method, it can be concluded that the former ones have a certain advantage because of a somewhat simpler preparation procedure.

(*Received* 21 *May* 1991. *Revised* 25 *July* 1991. *Accepted* 23 *September* 1991)

Summary—Water sorption on an ion exchanger can be described by formation of several hydrates. The general least squares program WSLET based on the "pit-mapping" approach has been written for evaluating such equilibria. It is written in FORTRAN 77 for use on personal computers. Besides finding the best values for the equilibrium constants of the various hydrates the program also searches for best values of the stoichiometric indices by using the so-called ESI-method. The program is provided with least-squares procedures and blocks for statistical analysis of the residuals as well as for data simulation. It has been tested with data on the strong base resin Dowex 1 as well as on simulated data. In the present paper an illustrative example is given together with data simulation. It is found that in most cases WSLET helps to find a better fit than earlier models quite efficiently, showing the advantage of the ESI method in combination with least-squares methods.

Ion exchangers are part of the basic arsenal in analytical chemistry. The water content related to the crosslinking of resins has a profound influence on their properties. Knowledge of the water uptake is thus of practical interest.

Recently, Kellomäki[1,2] tried to fit water sorption data onto resins with the BET isotherm. He found that only the beginning of the isotherm could be fitted to this equation. Similar results were found by Soldatov *et al.*[3] They compared four isotherm equations and found that only the model described below gave an acceptable fit over the whole range of the isotherm.

It has been shown elsewhere[4] that water uptake can be described by a chemical model, where water molecules are added stepwise to an ion exchanger similar to ordinary complex formation. The method has been applied to water sorption on salts of the liquid ion exchanger dinonylnaphthalene sulphonic acid (HD)[5,6] as well as the solid anion exchanger Dowex 1.[7]

However, not all possible species are formed and the search for the "best model" is tedious. For that reason the program WSLET has been constructed permitting a more efficient search for the species formed. In the evaluation of the data pocket calculators and computer programs, such as LETAGROP, have been used. Recently, a new method for treating such data was suggested by Zargarov.[8] This method is rather tedious, however, in its present form. It was felt that a computer program containing the ESI block might considerably speed up the calculations. In the ESI method the stoichiometric indices are also estimated together with the equilibrium constants in order to get a faster appreciation of the possible species present, using non-linear regression. This is done in the WSLET program described in this paper together with some examples of both experimental and simulated data. The program also contains a block for statistical analysis of the residuals, which is lacking in LETAGROP. A preliminary report of the program with examples has been reported elsewhere.[9]

THEORETICAL

The model

Consider the reaction

$$RX(s) + mH_2O(g) \rightleftharpoons RX(H_2O)_m(s) \quad (1)$$

Here RX stands for the ion exchanger in a certain salt form. The number of water molecules per ion exchanging group, W, is defined by

$$W_{exp} = [H_2O]_{iex}/s_0 \quad (2)$$

$[H_2O]_{iex}$ = Water sorbed by the ion exchanger.
s_0 = Ion exchange capacity of sample on the same concentration scale as $[H_2O]_{iex}$.

From equilibrium analysis

$$W_{calc} = \sum_1^n mk_m\alpha^m \Big/ \left(1 + \sum_1^n k_m\alpha^m\right) \quad (3)$$

n = number of species present.
k_m = equilibrium constant of reaction (1) for formation of $RX(H_2O)_m$.
$\alpha = \{H_2O\}$ = water activity.

Besides comparing W_{exp} with W_{calc} on a plot $W = f(\alpha)$ the distribution of the various hydrates is of interest.

Three different distribution functions can be recognized. The fraction of resin present in each hydrate, α_m, is defined by

$$\alpha_m = [RX(H_2O)_m]/s_0$$
$$= k_m\alpha^m \Big/ \left(1 + \sum_1^n k_m\alpha^m\right) = k_m\alpha^m/S \quad (4)$$

The fraction of unhydrated exchanger is given by $1/S$. The contribution of each hydrate to the maximal water uptake β_m (*i.e.*, for $\alpha = 1$ or the highest water activity reached) is given by

$$\beta_m = m\alpha_m \Big/ \sum m\alpha_m \quad (\alpha \to 1) \quad (5)$$

The contribution of each hydrate to the total water uptake at a given water activity, γ_m, is given by

$$\gamma_m = m\alpha_m \Big/ \sum m\alpha_m \quad (6)$$

The fractions α_m and γ_m are those used in equilibrium analysis.

The program

The program WSLET (Water Sorption data evaluation program using ABLET[13] searches for the combination of m- and k-values giving the best possible fit to the experimental isotherm

$$W = f(\alpha)$$

by searching for the minimum in the residual squares sum, U, defined by

$$U = \sum_1^n (W_{exp} - W_{calc})_i^2 \quad (7)$$

W_{calc} is computed from equation (3) with current m- and k-values.

The program is written in FORTRAN 77 for use on personal computers. From the many minimizing procedures available[10] the well-known pit-mapping approach[11] in the ABLET form[12] is used. This approach is described in detail elsewhere.[13] It has been modified for use on PCs. The structure of the program is similar to POLET[14] and other programs of the ABLET family.[13]

The simultaneous estimation of stoichiometric indices and equilibrium constants (ESI) was suggested earlier[14,15] and quite successfully applied in potentiometry,[11] spectrophotometry[16] and kinetics.[17] The parameters to be determined are k_1, m_1, k_2, m_2, *etc.*, and estimates of these quantities must be given in this order in the input. The minimization procedure can either be controlled by the operator or automatically by the program. Input data should be prepared as described in the manual.[18] The organization of data is similar to other programs of the ABLET family. (The manual and the program can be purchased from E.H. in Stockholm for 20 US dollars.)

Some statistical criteria

Before the program is applied to experimental and simulated data the criteria for the goodness of fit will be given. These criteria use statistical analysis of the residuals. Besides the residual squares sum, U, defined by equation (7) above they are:

$$\text{Residual mean} \quad |r| = \sum |r_i|/n \quad (8)$$

$$\text{Mean residual} \quad r_m = \sum r_i/n \quad (9)$$

$$\text{Variance} \quad m_{r,2} = \left(\sum r_i^2\right)\Big/n - \left[\left(\sum r_i\right)\Big/n\right]^2 \quad (10)$$

$$\text{Standard deviation} \quad s(W) = \sqrt{m_{r,2}} \quad (11)$$

The Hamilton R-factor in per cent, $R(\%)$, is defined by

$$R(\%) = 100\sqrt{\sum r_i^2 \Big/ \sum y_{exp}^2} \quad (12)$$

The summations in equations (8)–(12) are taken from $1 \to n$ as in equation (7). The weighting factors are set to unity.

In the following equations (7), (11) and (12) are used to illustrate the fit. Also other statistical parameters for a more detailed fitness test are available in the program: chi-square, kurtosis, skewness, *etc.*

EXAMPLES

Water sorption by Dowex 1 in fluoride form

Sosinovich *et al.*[7] studied among other systems the water uptake by Dowex 1 with 4% DVB in fluoride form. In Table 1 the results of the calculations are given. Run 1 gives the

Table 1. Results of the calculations with the data given in reference [7]

Water sorption by Dowex 1 in sulphate form

Sosinovich *et al.*[7] also studied that the water sorption on Dowex 1 with 4% DVB in sulphate form. The results of these calculations are shown in Table 2. First in run no. 1 the model from ref. 7 is given. Run 2 gives the same model computed with WSLET. A better fit is found. In run 3 the same model is used but here also the m-values are allowed to vary. Values close to integers are found with the exception of $m = 5$, where the exact value is $m = 5.41 \mp 0.4$. The highest m changes from 30 to a value close to 27. The value $m = 5.4$ may be due to the presence of two hydrates. For that reason the model with m-values of 2, 5, 6, 12 and 27 was tried in run 4.

Table 3. Simulated data for formation of $RX(H_2O)_m$ with $k_2 = 393$, $k_5 = 6960$ and $k_{10} = 23200$; s (inst = ∓ 0.100)

Search for model on simulated data

Water sorption data were simulated for a system with $m = 2$, 5 and 10 and constants $k = 393$, 6960 and 23,200. These values are close to those for the fluoride system discussed above. The theoretical values were loaded with noise, having the standard deviation s(inst), on various levels. Data for $s(\text{inst}) = \mp 0.01$ are given in Table 3.

Table 4 gives the results of the computation. First, in runs no. 1–5 the effect of experiment uncertainty is shown. The standard deviations of the k-values increase with increasing s(inst), but even for $s(\text{inst}) = \mp 0.10$ values close to the theoretical ones are obtained. For $s(\text{inst}) = \mp 0.10$, which is slightly higher than the experiment uncertainty in W, it is shown in runs 6–10 that false models give a poorer fit than the correct one for the same s(inst).

In runs 9 and 10 one additional false species with $m = 12$ and 13 have been added. As might have been expected the standard deviation for that species is much larger than the constant itself and should thus be excluded in an ordinary search. In run 11 the advantage of the direct search is demonstrated. The initial values for m were 1, 2, 3 or 2, 5, 15. After some cycles both gave m-values 2.2, 5.2 and 10.1, *i.e.*, the correct model after rounding off to the nearest integers. Thus, the correct model can be found rather direct. After rounding off to nearest integers the equilibrium constants of the model are computed.

CONCLUSIONS

The WSLET program makes it easy to search for the best possible model to a certain set of data. The calculations on simulated data show that false species are likely to be eliminated as long as the experiment uncertainty is not too high.

It is advisable to try m-values around those found by the ESI method in order to make certain the model arrived at is the best possible one under the circumstances. The model finds primary hydration species ($m < 10$) and secondary species ($m > 10$). That not all possible hydration numbers are to be expected is obviously due to the restrictions imposed by the three-dimensional network of the ion exchanger. Since a limited number of experimental points are available, the model arrived at can only be said to be the best possible with the experimental material available, using the fitness criteria mentioned above.

(*Received* 16 *July* 1991. *Revised* 1 *October* 1991. *Accepted* 2 *October* 1991)

Summary—An ion-exchange phase absorptiometric method with Arsenazo III has been developed for the determination of uranium(VI). A flow cell with 0.1 ml of anion exchange resin was employed to achieve a detection limit for uranium of 0.16 μg/l. in 100 ml of a seawater sample. The sensitivity is about 300 times higher than for corresponding solution spectrophotometry.

For the determination of uranium in seawater, it is usually necessary to separate and/or concentrate uranium from a solution containing large amounts of background electrolytes. Among a number of preconcentration techniques reported, methods using ion-exchange or chelating resins[1–8] have sometimes proven to be more effective. However, the uranium species sorbed on the solid phase has usually been eluted for succeeding measurement, leading to an undesirable dilution of the uranium.

Ion-exchanger phase absorptiometry,[9–12] based on the direct absorptiometric measurements of adsorbed analytes on ion exchange resins, has been conveniently used for the determination of trace amounts of components present in natural waters: this method does not need any such preconcentration and/or undesirable dilution by elution. Neodymium[11] and cobalt(II)[12] have been successfully determined recently by this method, the sensitivities being 260 and 1000 times higher than conventional solution spectrophotometries, respectively. In this study ion-exchanger phase absorptiometry has been applied to uranium determination using Arsenazo III as a colouring agent.[13] The present method is highly sensitive and directly applicable to uranium analysis of sea-water without any other means of preconcentration.

EXPERIMENTAL

Reagents

Analytical grade Bio-Rad AG 1-X2 anion exchange resin (100–200 mesh, Cl^- form) was used in the original wet state. EDTA solution ($2 \times 10^{-3} M$) was prepared by dissolving an appropriate amount of disodium salt of EDTA (Dojindo, Japan). Arsenazo III was purchased from Dojindo, Japan. All chemicals were of analytical grade.

Apparatus

The attenuances† of the ion exchanger were measured with a double-beam Nippon Bunko spectrophotometer, Model UVIDEC-320 and a perforated metal disc with an attenuance of 2.0 was used to balance the light intensities.

A small-volume flow cell was supplied by Nippon Quartz Glass Co. This cell was black-sided with a 0.5-cm path length and 0.035-ml

*Author for correspondence.

†In ion-exchanger phase absorptiometry, the contribution of light scattering in a measurement is considerable, so the term "attenuance" is preferable to "absorbance", although attenuance has essentially the same meaning as absorbance.

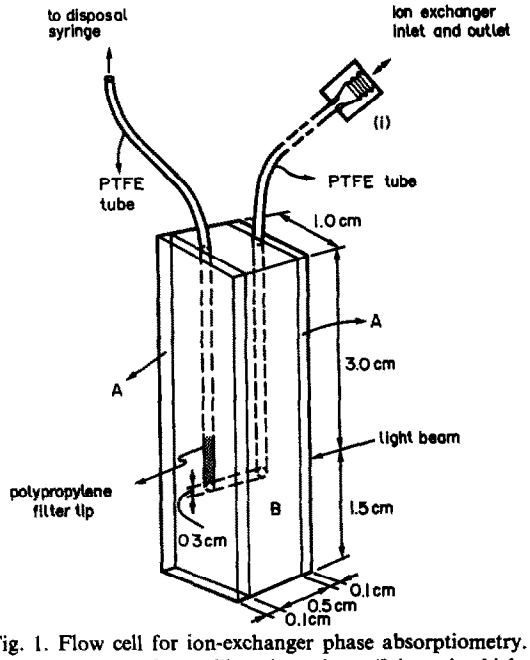

Fig. 1. Flow cell for ion-exchanger phase absorptiometry. Two transparent fused silica glass plates (0.1 cm in thickness), A, are pasted on both sides of black cell glass, B, of 0.5-cm thickness.

cell volume. The cell was fitted with a polypropylene filter tip, as shown in Fig. 1, to retain the ion exchange resin.

Procedure for the determination of uranium(VI) in seawater

To 100 ml of seawater sample, 1 ml of 0.5*M* formate buffer solution (pH 3.2), 2 ml of 0.002% Arsenazo III, 1 ml of $2 \times 10^{-3}M$ EDTA were added. Then, 0.10 ml of anion exchanger slurry was collected with suction in a fused-silica tube (0.15 cm i.d., 6.0 cm in length), fitted on one side with a polypropylene filter tip and connected with a disposable syringe [Fig. 2(A)], and then poured into the solution with a small amount of water. The mixture was stirred for 60 min at room temperature. After settling, the resin beads were collected in the fused-silica tube mentioned above and transferred to a flow cell with a syringe [Fig. 2(B)]. The attenuances at 665 and 800 nm were measured against air as reference. The difference in attenuances (ΔA) at 665 nm and 800 nm, was used for the determination of uranium by means of a calibration graph.

Distribution measurement

The pH of about 230 ml of a water sample containing 1.05×10^{-6} moles of uranium(VI), C_1, and 0.13 moles of sodium chloride was adjusted to 3.3 with formate. Then 5×10^{-6} moles of Arsenazo III and 2×10^{-6} moles of EDTA were added and the total solution volume was adjusted to 250 ml. After a short mixing period, 0.81 ml of Bio-Rad AG 1-X2 was added. After one hour equilibration, the solution and the ion-exchanger were separated and the attenuance, ΔA_1, of the ion-exchanger phase was measured. To the filtrate a further 0.81 ml of Bio-Rad AG 1-X2 was added and the solution was stirred for one hour. The exchanger attenuance, ΔA_2, was again measured and the distribution ratio, D, was calculated from

$$D = \frac{\text{mmoles of uranium sorbed per ml of exchanger}}{\text{mmoles of uranium per ml of solution}}$$

$$= \frac{(C_1 - C_1 \cdot \Delta A_2/\Delta A_1)/0.81}{(C_1 \cdot \Delta A_2/\Delta A_1)/250}$$

$$= 309(\Delta A_1/\Delta A_2 - 1) \qquad (1)$$

ΔA_1 and ΔA_2 were found to be 0.87 and 0.024, respectively, giving 1.1×10^4 as the value of the distribution ratio.

RESULTS AND DISCUSSION

Enhancement of sensitivity with a flow cell of small volume

For an ion-exchanger layer prepared with V ml of ion exchanger which was previously equilibrated with V' ml of solution containing a sample component at $C_o M$, the net absorbance, A, of the ion exchanger phase due to the sorbed coloured complex can be expressed as:

$$A = \varepsilon C_o \, l \, \frac{V'}{V} \, \frac{1}{1 + 1/VD} \qquad (2)$$

where ε and l are the molar absorptivity of the complex and the light path length in cm in the ion exchanger phase, respectively. The distribution ratio of the complex between the solid and solution phase is represented by D. This equation means that, if D is sufficiently large as in the case of the present system, higher sensitivity can be attained by using a large amount of sample volume and/or a small amount of ion exchanger within the limits of the resin capacity: the resin capacity measured by acid–base titration was 0.0554 ± 0.0003 meq for 0.1 ml of the ion exchanger aliquoted with the device mentioned below. Therefore, a small amount of ion exchanger slurry could increase

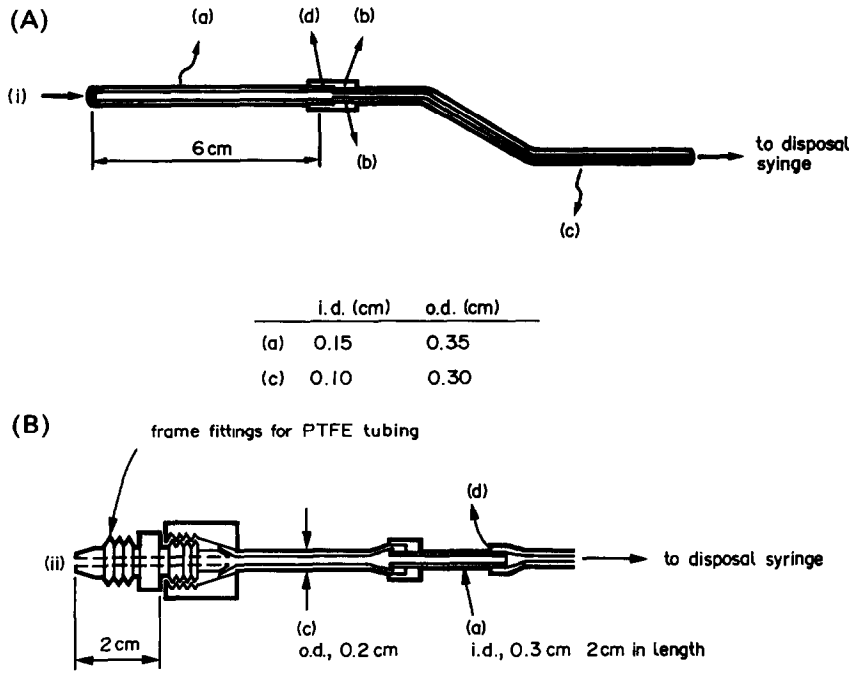

Fig. 2. Capillary fused silica tube; (A) for measuring a constant amount of ion-exchanger slurry; (B) for collecting colour-developed ion-exchanger beads; (a): fused silica tube; (b): silicone rubber tube; (c): PTFE tube; (d): polypropylene filter tip

the sensitivity if it could be handled reproducibly. To achieve this reproducibility, the fused-silica tube apparatus shown in Fig. 2(A) was designed. Ion exchanger was collected into the tube from the left (i) and water was discarded with a disposal syringe. The ion exchange resin could then be added to a sample with a small amount of water. After equilibration, the ion exchanger was collected from the inlet (ii) and then introduced into the flow cell by connecting the frame fitting [Fig. 2(B)] to nut (i) of the flow cell. The relative standard deviation of the resin amounts collected by using this resin aliquoting method was 0.5% for 6 repeated measurements.

Optimization of conditions

Absorption spectra in the anion exchanger. Arsenazo III forms a 1:1 complex with uranyl ion in the pH range 1.5–2.0 in an aqueous solution. The purplish red colour complex has a maximum absorption at about 650 nm with a molar absorptivity of 4.4×10^4 $l.mole^{-1}.cm^{-1}$ in the presence of a large excess of Arsenazo III.[13] This complex is easily sorbed on an anion exchanger, together with free Arsenazo III, because of its high anionic charge. Absorption spectra of the complex in an anion exchanger and solution are shown in Fig. 3. In order to make the contribution of free Arsenazo III low, the attenuance measurements of the complex in anion exchanger phase should be done at the longest wavelength possible. Therefore 665 nm was selected as the wavelength for the determination of uranium(VI).

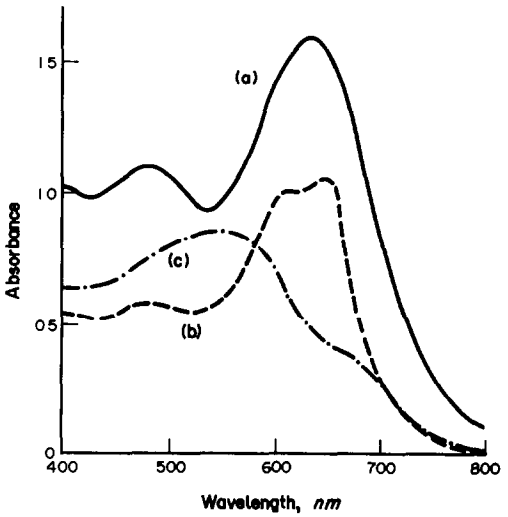

Fig. 3. Absorption spectra of uranium(VI)–Arsenazo III complex in anion exchanger and aqueous solution. (a) Spectrum in anion exchanger phase: U(VI): $5.25 \times 10^{-3}M$; Arsenazo III: $1 \times 10^{-3}M$; resin: 0.80 g; solution volume: 250 ml, pH 3.3. (b) Spectrum in solution: U(VI): 5.25×10^{-5}mM; Arsenazo III: 1.0×10^{-5} mM; pH 3.3. (c) Spectrum in anion exchanger phase (Arsenazo III in excess): U(VI): 5 μg; Arsenazo III: 1.3×10^{-4} mmoles; resin: 0.10 g; solution volume: 250 ml; pH 3.3.

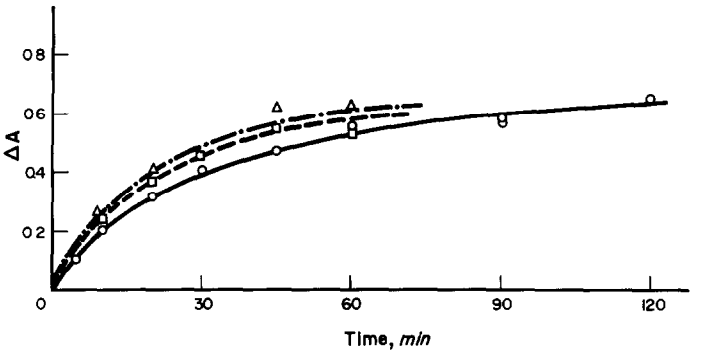

Fig. 4. Effect of colour development on stirring time. Sample: 100 ml, pH 3.2, 0.25 μg U(VI), 0.05 moles of NaCl; resin: 0.10 ml; cell length: 0.5 cm. —○—○— 20°; --□--□-- 40°; —-△—-△—- 56°.

Stirring time and temperature dependence. The dependence of colour development on stirring time at different temperatures is shown in Fig. 4. Attenuance reached a constant value within one hour of stirring and colour development did not accelerate appreciably at higher temperatures. Accordingly, the solution-ion exchanger mixture was stirred for one hour at room temperature. The distribution ratio of the complex was 1.1×10^4, and 92% of the uranium in the sample solution could be recovered.

pH Dependence of colour development in anion exchanger. The UO_2–Arsenazo III complex is strongly sorbed on an anion-exchanger in the pH range 2.5–5.0. Free Arsenazo III is also sorbed in this pH range but the reagent has a low constant absorption at 655 nm, as shown in Fig. 5. Therefore the pH of the sample solution was adjusted to 3–4.

Dependence on sodium chloride concentration. The effect of sodium chloride concentration on colour development is shown in Fig. 6. ΔA gradually increased with sodium chloride concentration up to 0.4*M* and reached a constant value at 0.6*M*, while ΔA for the reagent blank is almost constant at 0.25. The apparent ΔA increase may be due to contraction of the ion-exchanger and the same phenomenon was

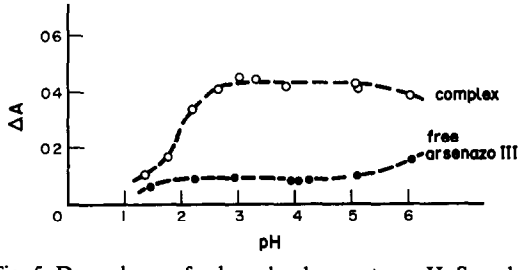

Fig. 5. Dependence of colour development on pH. Sample: 40 ml, pH 3.2, 0.8 μg U(VI), 2.1×10^{-8} moles of Arsenazo III; resin: 0.10 ml; stirring time: 30 min; cell length: 0.5 cm.

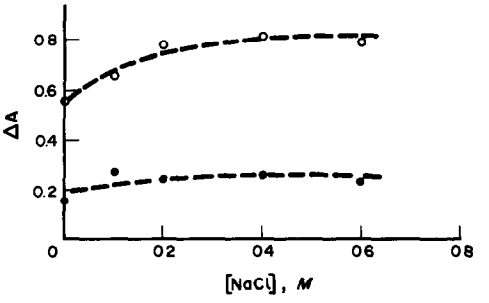

Fig. 6. Effect of sodium chloride concentration. Sample: 40 ml, pH 3.2, 0.4 μg U(VI), 2.1×10^{-8} moles of Arsenazo III; resin: 0.10 ml; stirring time: 60 min; cell length: 0.5 cm. ○---○; ΔA for sample. ●---●; ΔA for reagent blank.

observed in the determination of cobalt by ion-exchanger phase absorptiometry.[12] Consequently, uranium in seawater may be conveniently analysed without dilution of the salt matrix because sensitivity at 0.6*M* sodium chloride concentration is 40% higher than that in the absence of sodium chloride.

Table 1. Effects of foreign ions on the determination of uranium(VI)

Type	Foreign ion amount, *mg/l.*	A*	U found, *μg/l.*	Relative error, %
Mg	1300	0.556	10.2	+2
Ca	1100	0.535	9.8	−2

	1.0×10^{-3}†	0.575	10.5	+5

Solution: 100 ml, 1 μg U(VI), pH 3.2 (formate, 5.2×10^{-8} moles of Arsenazo III, 0.055 moles of NaCl; Resin, Bio-Rad AG 1-X2 (Cl^- form, 100–200 mesh), 0.1 ml; Stirring time, 60 min.

*$A = \Delta A - \Delta A$ (for the blank). †*M*.

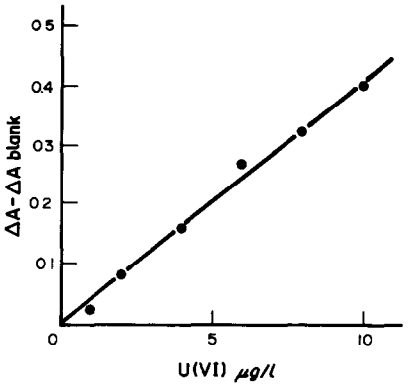

Fig. 7. Calibration curve for the determination of U(VI). Sample: 100 ml, pH 3.2, 0.05 moles of NaCl, 2.1×10^{-8} moles of Arsenazo III; resin: 0.10 ml; stirring time: 60 min; cell length: 0.5 cm.

Effect of foreign ions

Table 1 shows the effect of foreign ions on the determination of uranium. Below the concentration levels present in the seawater no heavy metals except uranium(VI) can complex with Arsenazo III in these experimental conditions, therefore no coexisting ions interfered. All the sample solutions contained $2 \times 10^{-5}M$ EDTA in order to mask foreign ions such as iron(III) present in seawater. Further increase in EDTA concentration at least up to $5.0 \times 10^{-4}M$ did not interfere with the uranium determination. Therefore this procedure may also be applied to other solution systems which contain foreign ions up to $5 \times 10^{-4}M$.

Calibration curve

A calibration curve for uranium(VI) is shown in Fig. 7. The linearity holds up to 10 μg/l. of uranium, but the curve became convex at more than 10 μg/l. of uranium(VI).

Sensitivity and detection limit

The uranium concentrations giving a final absorbance of 0.1 were $7.7 \times 10^{-9}M$ for the present method and $2.3 \times 10^{-6}M$ for conventional solution absorptiometry,[13] corresponding to about 300 times enhancement by the present method.

The detection limit was measured in a matrix of a 100-ml blank solution containing 0.055 moles of sodium chloride. For 6 determinations, ΔA was 0.315 ± 0.004. The detection limit (the concentration corresponding to an attenuance equal to twice the magnitude of the error) was 0.29 μg/l.

*$A = \Delta A - \Delta A$ (for the blank).

Determination of uranium(VI) in seawater

Seawater samples were analysed by the standard-addition method in order to check the recovery of added uranium. As shown in Table 2, the recovery of the spiked uranium was quantitative. In coastal seawater from Mitoma, Fukuoka (open sea), the uranium content was found to be 3.5 ± 0.3 μg/l. The content was in accord with those reported previously.[3,4]

Recently, ion-exchanger phase absorptiometry has been extended to flow analysis.[14,15] Using this method, trace levels of a target element can be determined in water only in fairly small volumes. However, the present system could not be applied to flow analysis, because the uranium–Arsenazo III complex is difficult to be desorbed from the ion exchanger.

ON THE STABILIZATION OF NIOBIUM(V) SOLUTIONS BY ZIRCONIUM(IV) AND HAFNIUM(IV)

E. SØRENSEN and A. B. BJERRE
Risø National Laboratory, DK-4000 Roskilde, Denmark

(*Received* 12 *November* 1990. *Revised* 27 *September* 1991. *Accepted* 2 *October* 1991)

Summary—Niobium cannot be separated from zirconium or hafnium when these elements occur together in solution with common anions such as chloride and sulphate. This is ascribed to the co-polymerization of niobium(V) and the hydrolysed ionic species of zirconium(IV) and hafnium(IV) to form colloidal particles. In hydrochloric acid the particles are positively charged, whereas in sulphate solution the Zr- and Hf-sulphate complexes confer a negative charge. The two cases are considered separately.

During some work on recovery of zirconium and niobium from a complex zirconium ore, a crucial point was the separation of these elements. This was accomplished by means of solvent extraction,[1] but only after we had studied the classical precipitation method based on hydrolysis of the niobium. Weiss and Landecker[2] stated that the precipitation is complete from perchloric acid solution, and Silverman[3] used this principle for determining niobium in steel. However, we have found that in the presence of certain elements such as titanium and zirconium, the expected reaction does not take place at all.

Marignac[4] has shown that on hydrolysis of a solution containing niobium and titanium, some niobium remains in solution and some titanium is precipitated. This effect has been termed "loss of individuality".

Schoeller[5] mentions that zirconium may prevent the precipitation of Nb_2O_5.aq, and Chekmarev *et al.*[6] conclude from extraction data that niobium and hydrolysed zirconium probably form mixed-metal compounds in solution.

As the information available seems rather vague we have investigated the relationship between zirconium and niobium in solution. The chemical similarity between zirconium and hafnium made it natural to include the latter in the investigation, and it was then possible to use radioactive ^{181}Hf as a tracer (zirconium has no radioactive isotopes convenient for the purpose). During the work we found a marked difference in behaviour between the systems in chloride and sulphate media. Consequently the two cases were examined separately.

Since the above-mentioned Zr–Nb ore also contained tantalum, which is even more inclined than niobium to hydrolyse, the behaviour of tantalum was also considered.

EXPERIMENTAL

Preparation of solutions

Nb in hydrochloric acid. $KNbO_3$ (1 g) was dissolved in 10 ml of water, and the solution was poured slowly, with vigorous stirring, into a beaker containing 20 ml of concentrated hydrochloric acid. The mixture was heated to boiling, then water was added until the solution was completely clear (about 30 ml was needed). This solution was transferred to a Visking dialysis tube and allowed to dialyse against a large volume of 0.2*M* hydrochloric acid. After 24 hr, a clear solution of $(Nb_2O_5.nH_2O)_x$ remained in the tube.

Nb in sodium hydrogen sulphate solution. Nb_2O_5 (0.2 g) was fused with 20 g of sodium hydrogen sulphate in a silica crucible. After the crucible had cooled to about 50°, a few ml of saturated sodium hydrogen sulphate solution were added, followed by small additions of water with stirring and heating until all was dissolved. The resulting solution was clear and nearly saturated with sodium hydrogen sulphate.

Turbidimetry

The absorbance of the solutions gave a reproducible measure of their stage of polymerization. With a Zeiss spectrophotometer, the absorbance was measured in 1-cm cells at 400 nm.

Methods of separation

Dialysis. The Visking dialysis tube (Union Carbide) is made from cellulose. A 1/2-in. bore tube with 24-Å pores was used. A practically stationary state of dialysis was reached after 3 days. The 24-Å pores retain particles with M.W. larger than $\sim 10^4$.

Precipitation. Hydrosols are often coagulated by addition of organic solvents such as alcohol or acetone. This applies to the solution of Nb_2O_5 in hydrochloric acid. $ZrOCl_2$ and $HfOCl_2$, in the concentration range used, are still fully soluble after addition of acetone in 2:1 v/v ratio to the aqueous solution, so this offers a method for their separation from the polymers. The sulphates of zirconium and hafnium are only slightly soluble in acetone–water mixture, so for the sulphate system this method is of no avail.

Analysis

Tagging with the radioactive isotopes ^{95}Nb and ^{181}Hf allowed us to determine the distribution of these elements by gamma-counting with a well-type NaI crystal. The precipitates were ignited and weighed, and with knowledge of the amount of starting material, it was possible to calculate the composition of the products obtained.

RESULTS AND DISCUSSION

Behaviour of niobium in hydrochloric acid

Measurement of stability by turbidimetry. First the stability of pure niobium solutions in dilute acid was established. The experimental solution, which at room temperature remains clear for weeks, was heated at 95° with various concentrations of hydrochloric acid. The degree of stability was measured by the time elapsed before turbidity just became visible. The results shown in Table 1 agree reasonably well with the finding by Nabivanets[7] that $Nb_2O_4^{2+}$ ions tend to polymerize at hydrogen-ion concentrations below 2*M*.

Table 1. Time elapsed before turbidity is just visible in 0.03 *M* Nb_2O_5 solutions at 95°

[HC], *M*	Min
0.5	5
1.0	15
1.5	90
2.5	200

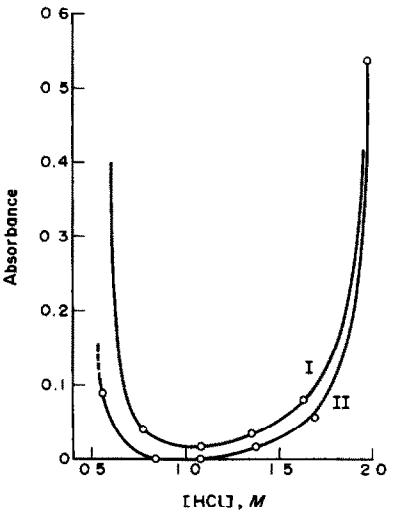

Fig. 1. Absorbance of solutions of Nb(V) and Zr(IV), 0.028*M* in Nb, in varying concentrations of hydrochloric acid after heating at 95° for 6 hr. The respective unheated solutions were used for reference. Curve I corresponds to the atomic ratio Zr/Nb = 0.50. Curve II corresponds to the atomic ratio Zr/Nb = 0.62.

If $ZrOCl_2$ or $HfOCl_2$ was added to the niobium solution before this was heated, the stability was greatly changed. Solutions were prepared with various acidities and two different ratios of [Zr] or [Hf] to [Nb]. The solutions were heated for 6 hr at 95°, then the absorbances were measured. The results seen in Figs. 1 and 2 show that the solutions stay clear over an acidity range which becomes wider the greater the [Zr]/[Nb] ratio. The effect is similar with hafnium, but the stability range is somewhat narrower.

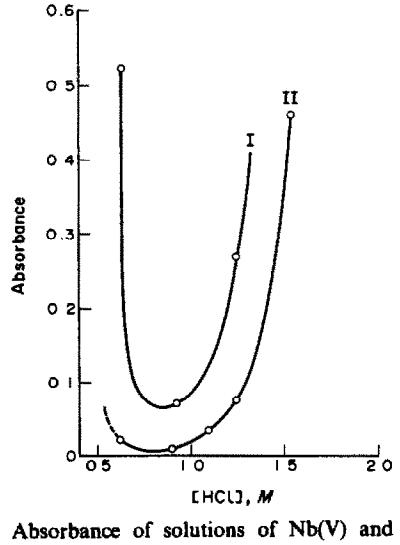

Fig. 2. Absorbance of solutions of Nb(V) and Hf(IV), 0.0275*M* in Nb, in conditions similar to those for Fig. 1. Curve I, Hf/Nb = 0.50. Curve II, Hf/Nb = 0.62.

At the upper acidity limit the solutions are turbid but fairly stable; at the lower limit the colloidal particles coagulate. The precipitate contains Zr or Hf ions even though these are normally completely soluble at the relevant acid concentration.

The hypothesis that hydrolysed species of Zr(IV) and Hf(IV) co-polymerize with Nb(V) is supported by the following experiments.

Separation of the polymers by dialysis. Some $HfOCl_2$ containing radioactive ^{181}Hf was mixed with Nb_2O_5 solution to give an atomic Hf/Nb ratio of 0.35 (6.5 g/l. HfO_2, 11.7 g/l. Nb_2O_5). This low ratio was chosen in order to make the effect of co-polymerization more perceptible. The hydrochloric acid concentration was 1.7*M*. Portions were subjected to four different treatments.

(1) No heating.
(2) Heating to 95° within 3 min, then cooling to 25° in 1 min.
(3) Rapid heating to 95° and keeping at 95° for 36 min followed by fast cooling.
(4) Like (3) but keeping at 95° for 60 min.

The samples were then placed in Visking tubes and dialysed for 3 days against an equal volume of pure 1.7*M* hydrochloric acid. The ratio of [Hf] inside the tube to that outside ($[Hf]_{in}$:$[Hf]_{out}$) was then determined for each sample, by gamma counting (see Table 2).

Hafnium ions pass freely through the Visking membrane, as shown by the 1:1 distribution ratio found for the unheated sample. After heating at 95° the hafnium is more or less retained within the dialysis tube, depending on the duration of heating. This retention is ascribed to an association with the colloidal particles of Nb_2O_5.aq. Assuming the concentration of free hafnium ions on both sides of the membrane will be the same, and remembering that the volumes are equal, we find that the fraction of hafnium associated with the colloidal particles is given by

$$\frac{[Hf]_{in} - [Hf]_{out}}{[Hf]_{in} + [Hf]_{out}}$$

(see right-hand column, Table 2).

Table 2. Equilibrium ratio of [Hf] in the inner and outer liquid after dialysis of differently treated mixtures with Nb_2O_5 in hydrochloric acid solution

Treatment	$[Hf]_{in}/[Hf]_{out}$	Per cent of Hf trapped
No heating	1.0	0
Heating to 95° within 3 min, followed by cooling to 25° in 1 min	1.3	13
Heating at 95° for 36 min	2.9	49
Heating at 95° for 60 min	5.0	67

Precipitation of the polymer by addition of acetone. Some $HfOCl_2$ containing ^{181}Hf was mixed with Nb_2O_5 solution to give an atomic ratio of Hf to Nb of 0.4 (4.2 g/l. HfO_2, 6.6 g/l. Nb_2O_5). The hydrochloric acid concentration was 0.85*M*. The mixture was heated to 95° and samples were taken after 10, 34 and 60 min. Each sample was added to twice its volume of acetone; the precipitates were collected and analysed, with the results shown in Table 3.

In an analogous experiment, solutions with the same Nb_2O_5 content but different Hf/Nb ratios were all heated to 95° for 60 min before precipitation by addition of the acetone. The compositions of the precipitates are shown in Table 4.

There is indication that for a given time of heating the Hf/Nb ratio in the precipitate approaches that of the solution when the Hf-level is diminished, as seen also from Table 3, but the absolute amount of precipitate decreases with increasing initial ratio of Hf to Nb.

General properties of the polymer. Both the silky residue left by gentle evaporation of a dilute hydrochloric acid solution containing Nb(V) and Zr(IV), and the coagulated solid obtained by addition of acetone, can be redissolved in water. When ammonia is added

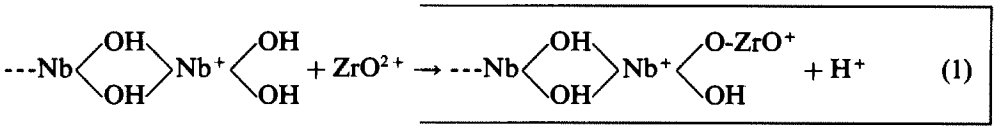
to the solution a "hydroxide" is formed, which can be redissolved with hydrochloric acid. Electromigration experiments confirmed that the niobium was contained in positively charged particles.

Discussion. It has been demonstrated that in niobium solutions with hydrochloric acid concentrations of less than 2*M*, hydrolytic polymerization proceeds until turbidity or eventually a precipitate is produced. The inhibitory effect of ZrO^{2+} or HfO^{2+}* is assumed to be due to a reaction of the type



(1)

by which the colloidal particles are studded with ZrO^+ or HfO^+. The resulting increase in charge density leads to stabilization of the sol.

The precipitate formed by addition of excess of ammonia is soluble in hydrochloric acid, indicating that most of the bonds are similar to those occurring in the zirconium or hafnium hydroxides.

The upper and the lower acidity limits of the stability interval in Figs. 1 and 2 are set by decreasing charge on the colloidal particles, but for different reasons. High $[H^+]$ leads to a gradual rupture of the —O— bridges, whereby ZrO^{2+} or HfO^{2+} is split off.

The solution becomes more and more turbid, but remains fairly stable. At low $[H^+]$ the positive charges are neutralized by hydrolysis, and coagulation occurs within a narrow range of $[H^+]$. Since the coagulated material cannot be redissolved in acids, it is assumed to be a polymer of Nb_2O_5.aq. The co-precipitated Zr and Hf are trapped in the structure by occlusion and are thus also made insoluble. Comparison of Figs. 1 and 2 shows that the stability interval of the Hf compounds is shifted towards lower $[H^+]$, in accordance with the slightly more electropositive character of Hf.

The results of the dialysis experiment, shown in Table 2, confirm that the HfO^{2+} ions are caught by the colloidal particles, and further show that the process continues for more than 60 min at 95°. This is confirmed by the precipitation experiment (Table 3). Here the sorting of particles by size is brought about by the acetone–water solvent. The amount of Nb precipitated is seen to increase with heating time, which suggests that the particles grow during the heating period. Table 4 shows that a higher Hf/Nb ratio leads to a smaller amount of Nb being precipitated. This indicates more efficient coverage of the larger surface area presented by the smaller particles.

Behaviour of niobium in sodium hydrogen sulphate solution

Stabilization of niobium solution by precipitation of hydroxide and redissolution. If the $NaHSO_4$-saturated solution of Nb is diluted, it polymerizes immediately. Simple addition of zirconium or hafnium salts will not prevent this polymerization. If, however, $ZrOCl_2$ or $HfOCl_2$ is mixed with the $NaHSO_4$-saturated Nb solution and the mixture is poured into an excess of ammonia solution, then the precipitate formed can be dissolved in sulphuric acid to form a stable solution. The same behaviour is obtained if Nb_2O_5 and ZrO_2 are fused with sodium hydrogen sulphate and the cooled melt is dissolved.

The solution of Nb_2O_5 in sodium hydrogen sulphate was divided into eight equal samples to which were added varied amounts of $ZrOCl_2$ or $HfOCl_2$. After homogenization of the mixtures, ammonia solution was added to each, and the

*The symbols ZrO^{2+} and HfO^{2+} are used for convenience to designate the more complex positive ions that actually occur.

resulting precipitates were collected, washed, and redissolved in 2 ml of 2*M* sulphuric acid. Finally 2 ml of 2*M* sodium sulphate were added, and water to give a final volume of 8 ml.

After heating of these mixtures at 95° for 6 hr it appeared that stabilization was obtained for Zr/Nb > 3 and Hf/Nb > 2. Figure 3 shows the plot of absorbance *vs.* Zr/Nb and Hf/Nb.

Separation of the polymer by dialysis. Excess of sulphate, (Hf, Zr)O^{2+} and H^+ can be removed by dialysis. If this is done stepwise, alternated with heating periods, stable solutions are obtained up to approximately pH 1.8, the highest value at which a solution of zirconium sulphate remains clear.[8]

These solutions of pure colloidal Nb and Zr or Nb and Hf sulphate will coagulate on addition of only a slight amount of free H^+ unless the sulphate concentration is simultaneously increased. It appears that in the case of Zr the ratio $[H^+]/[SO_4^{2-}]$ must be less than 1.2, and in the case of Hf less than 1.0 if the solutions are to stay clear for 6 hr at 95°.

General properties of the polymer. Evaporation at room temperature leaves a clear glass that breaks into scales with a conchoidal fracture. The glass redissolves easily in water, from which it may again be precipitated by addition of acetone. This property is not as useful as in the chloride case, since zirconium sulphate, and sulphates in general, are also precipitated from aqueous solutions by acetone. Electromigration shows that the colloidal particles are negatively charged.

Discussion. The positively charged $[Nb_mZr_n(OH)_x(H_2O)_y]^{5m+4n-x}$ particles will, on addition of sulphate, form negatively charged sulphate complexes, and the presence at the same time of positively charged particles leads to coagulation. Therefore a particular method of preparation must be employed.

In the concentrated sodium hydrogen sulphate solution, Nb and Zr or Hf ions are prevented from coming into close contact by the complexing sulphate ligands. On dilution, Nb will hydrolyse first and polymerize without being protected by Zr or Hf. When excess of ammonia is added, co-polymerization becomes possible. When the redissolved precipitate is aged at suitable concentrations of H^+ and SO_4^{2-} a co-polymerized Zr or Hf sulphate is formed, which presumably surrounds the Nb_2O_5 particles.

Since aggregation is prevented by maintaining a negative charge on the particles, it is evident that sulphate ions act as a stabilizer, whereas hydrogen ions have the reverse effect.

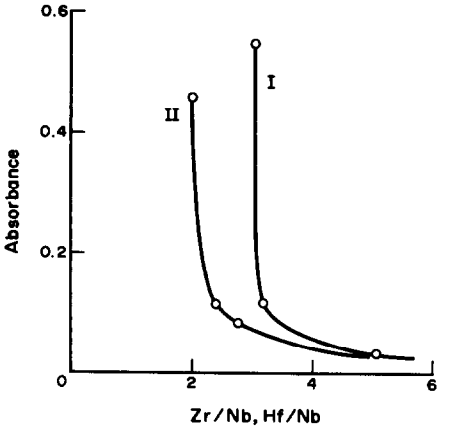


Fig. 3. I, Absorbance of sulphate solutions of Nb(V) and Zr(IV), 0.0235*M* in Nb, at pH = 1.8, at varying values of the atomic ratio of Zr to Nb. II, Absorbance of solutions of the corresponding Hf compound.

A higher sulphate concentration is required in the case of Hf, probably because the stability constant of hafnium sulphate is lower than that of zirconium sulphate. On the other hand, there seems to be no obvious reason for the marked difference between the atomic ratios Zr/Nb and Hf/Nb that are just sufficient to stabilize the respective solutions (Fig. 3).

Behaviour of niobium in carbonate solutions

It is well known that ZrO^{2+} forms soluble carbonate complexes. This is also true for the Zr–Nb compounds, although they are less stable and can be prepared only with a limited yield.

Samples (20 ml) from the chloride and sulphate solutions, each containing 10 mg of Nb_2O_5 and 100 mg of ZrO_2, were added to 20 ml of 1*M* sodium carbonate. In the chloride solution, a precipitate was seen immediately, and in the sulphate solution, after a few seconds. The same experiments with 20 ml of ammonium bicarbonate solution yielded a precipitate from the chloride solution after 1 hr, but not before 24 hr from the sulphate system. Tagging with radioactive ^{95}Nb made it simple to determine the niobium distribution after precipitation. Table 5 shows that in all cases a considerable fraction of the niobium remained in the solution.

Table 5. Percentage of Nb left in solution after precipitation with the reagents quoted, and standing for 24 hr

	Fraction of original Nb in solution, %	
Anion	Sodium carbonate	Ammonium bicarbonate
Cl^-	15	32
SO_4^{2-}	36	50

Discussion. The failure to precipitate Nb by carbonate, a reaction which is otherwise complete even in the presence of complexing agents, appears to give strong evidence for a masking effect exerted by ZrO^{2+} on colloidal Nb_2O_5.

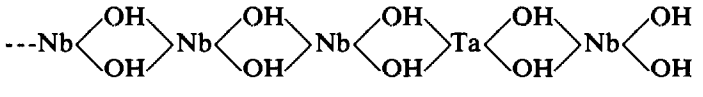
The transformation into the carbonate form takes place more completely when the particles are negatively charged beforehand, as in the sulphate solution. Further, the solubility is higher in ammonium bicarbonate solution than in sodium carbonate solution because of the lower hydroxide concentration.

Tantalum compounds

An attempt was made to prepare solutions of Ta stabilized with Zr analogously to those of Nb, but they always appeared to be turbid, probably because Ta has a greater tendency to hydrolyse than Nb. However, with Ta, Nb and Zr in atomic ratio 0.2:1:5 clear stable solutions can be obtained both in dilute hydrochloric acid and sulphate media.

The oxides are fused with sodium hydrogen sulphate and the cooled melt is dissolved as described above for the preparation of solutions in sodium hydrogen sulphate. Conversion into the chloride form is accomplished by precipitation with ammonia solution, collection, and then addition of just enough hydrochloric acid to dissolve the precipitate.

It has been known for a long time[5] that in mixtures of Nb and Ta a certain amount of one of these elements can be masked by the other. Lassner and Püschel[9] indicate the following scheme for formation of a heteropolymer:



An increase in the proportion of Ta leads to turbid solutions. It may be expected that colloidal particles of the composition shown require a higher ZrO^{2+} concentration to prevent more extensive polymerization than do those of pure Nb_2O_5.aq.

CONCLUSIONS

In solutions containing weakly complexing anions, Nb_2O_5.aq adsorbs ionic species of Zr(IV) and Hf(IV). As a result, the niobium species are stabilized and to a certain extent assume the behaviour of Zr and Hf compounds in an $[H^+]$-domain where they would otherwise undergo hydrolytic precipitation. In the presence of sulphate, complex formation causes a negative charge on the particles; for this reason the solution is sensitive to H^+ unless it is stabilized by an excess of SO_4^{2-}.

The higher the Zr/Nb ratio, the more Nb loses its chemical individuality; thus it becomes able to behave like Zr in carbonate solution and in phase distribution equilibria (solvent extraction).

Tantalum, when masked by niobium, behaves in a similar manner.

IMPROVED SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM(VIII) WITH 4-(2-PYRIDYLAZO) RESORCINOL IN MIXED SURFACTANTS

ITSUO MORI,* YOSHIKAZU FUJITA, MINAKO TOYODA and YUKI HASEGAWA
Osaka University of Pharmaceutical Sciences, 2-10-65, Kawai, Matsubara-city, Osaka 580, Japan

(*Received* 26 *November* 1990. *Revised* 10 *September* 1991. *Accepted* 21 *September* 1991)

Summary—The colour development between 4-(2-pyridylazo)-resorcinol(PAR) and osmium(VIII) in the presence of cationic and nonionic surfactants in a weakly acidic medium was more stable and reproducible than in the absence of surfactant (PAR-alone method). An improved spectrophotometric determination of osmium(VIII) with PAR was investigated in the presence of mixed surfactants of *N*-hexadecyltrimethylammonium chloride (HTAC) and Brij 58 [poly(oxyethylene)lauryl ether] as cationic and nonionic surfactants at pH 6.0–7.2. The calibration graph was linear in the range 0–110 μg/10 ml osmium(VIII), and the apparent molar absorptivity was 2.4×10^4 l.mole^{-1}.cm^{-1} with a Sandell sensitivity of 0.0079 μg/cm^2 osmium(VIII).

Although the spectrophotometric determination of osmium with 4-(2-pyridylazo)resorcinol (PAR) as a water-soluble agent has been reported,[1–3] the PAR–osmium(VIII) complex in the absence of surfactant was unstable and poor in sensitivity. The effectiveness of various coexisting surfactants in improving the stability or sensitivity has been recognized in a number of spectrophotometric or fluorophotometric methods.[4–10] In this paper, the colour formation reactions between PAR and osmium(VIII) in the presence of various surfactants (simple or mixed micellar media) were systematically investigated with a view to obtaining more reproducible and sensitive spectrophotometric measurement of osmium(VIII).

EXPERIMENTAL

Reagents and apparatus

Standard osmium(VIII) solution ($5.0 \times 10^{-4}M$) was prepared by dilution of $1.0 \times 10^{-3}M$ stock osmium(VIII) solution (prepared by dissolving osmium tetraoxide in $5.0 \times 10^{-1}M$ sodium hydroxide solution). A $1.0 \times 10^{-3}M$ PAR solution was prepared according to a previous report,[10] and a 1.0–5.0% HTAC (*N*-hexadecyltrimethylammonium chloride) or Brij 58 [poly(oxyethylene)lauryl ether] solution was prepared by dissolving HTAC or Brij 58 in water. A Sörensen phosphate buffer solution (M/15 Na_2HPO_4–KH_2PO_4, pH 6.0–7.2) was used for the pH adjustments. All other reagents were of analytical grade without further purification.

Shimadzu Model UV-260 and 240 recording spectrophotometers with 1.0-cm quartz cells were used for recording absorption spectra and absorbance measurements.

Standard procedure

A sample solution containing up to 110 μg of osmium(VIII) was placed in a 10-ml standard flask. A 1.0-ml portion of 5.0% Brij 58 solution, 1.0 ml of 1.0% HTAC solution, 2.5 ml of phosphate buffer solution (pH 6.5) and 1.5 ml of $1.0 \times 10^{-3}M$ PAR solution were added (Solution A). The solution was diluted to the mark with water, mixed well, kept at 50° for 30 min, and then cooled in water for 5 min. The absorbance of Solution A was measured at 540 nm against the reagent blank (Solution B) treated in the same way.

RESULTS AND DISCUSSION

Colour reaction between PAR and osmium(VIII), and absorption spectra

The colour reaction systems between PAR and osmium(VIII) in the presence (single

*Author for correspondence.

surfactant or combinations) or absence of surfactants were respectively investigated in aqueous solution at room temperature or 50°. The colour developments in the presence of small amounts of surfactant (less than the CMC values) or absence of surfactant were generally unstable, and less sensitive in comparison with those in the micellar media with large amounts of surfactants. In particular, the colour development in a combination of cationic and nonionic surfactants (mixed micellar media) was very stable and more reproducible than that in the absence of surfactants (PAR alone method) or presence of a single surfactant.

Figure 1 shows the absorption spectra of the PAR–osmium(VIII) complex solution (Solution A) and PAR solution (Solution B) in the presence or absence of a HTAC–Brij 85 mixture.

A slight bathochromic shift based on the coexistence of large amounts of cationic surfactant was observed, and the maximum difference of absorbances between Solutions A and B was obtained at 540 nm, with an increase of about 20% in the presence of the mixed surfactants (micellar of cationic and nonionic surfactants).

Figure 2 shows the stability of the PAR–osmium(VIII) complex solution in the presence of HTAC alone and HTAC–Brij 58 mixture.

Effects of pH and surfactants

For the colour development between PAR and osmium(VIII), a maximum and constant absorbance at 540 nm was obtained at pH 6.0–7.2 with a Sörensen phosphate buffer solution, and the optimum amount of buffer solution was 1.5–3.0 ml per 10 ml.

The effects of surfactants, single or surfactant combinations, were examined in terms of stability and sensitivity of the colour reaction. Nonionic surfactants {Brij 35 [poly(oxyethylene)hexadecylether], Brij 58, Triton × 100, Tween 20 [poly(oxyethylene)-sorbitanmonolaurate], PVA [poly(vinyl)alcohol, $n = 200$]}, cationic surfactants [HTAC, HPC (hexadecylpyridinium chloride), Zephiramine [Zp, benzyldimethyltetradecylammonium chloride], anionic surfactants [SDS(sodium dodecylsulphate)] and an amphoteric surfactant [LS(sodium *N*-lauroylsarcosine)] were studied. As shown in Table 1 and Fig. 2, the use of the surfactant-combination of HTAC as cationic surfactant and Brij 58 as nonionic surfactant was most effective, and the colour development was stable and reproducible. The optimum amounts of surfactants were $\geqslant$0.5 ml of 5.0% Brij 58 solution and $\geqslant$0.5 ml of 1.0% HTAC solution in a final volume of 10 ml, *i.e.*, 0.25% Brij 58 and 0.05% HTAC, as shown in Fig. 3. Accordingly, further investigation was carried out on the mixed micellar media of final 0.5% Brij 58 and 0.1% HTAC.

Osmium(VIII), $2.5 \times 10^{-5}M$; PAR, $1.5 \times 10^{-4}M$; pH: 6.5.
*0.1%.
†0.5%.
Reference, reagent blank.

Effect of PAR concentration

The recommended amount of PAR was a final concentration in the range $1.0–2.0 \times 10^{-4}M$; 1.5 ml of $1.0 \times 10^{-3}M$ PAR solution in 10 ml was used for further investigation.

Effect of temperature

The relationship between reaction temperature and reaction time was examined at the following conditions: room temperature, 40°, 50° and 60° for 10–40 min. Maximum and constant absorbance was obtained by standing at 50° for 30 min, and cooling to room temperature (10–25°) in water for 5 min.

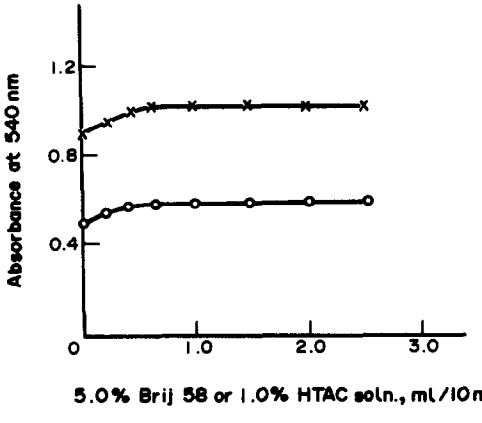

Fig. 3. Effect of Brij 58 and HTAC concentrations PAR, $1.5 \times 10^{-4}M$; pH, 6.5; —×—: effect of Brij 58 in the presence of 0.1% HTAC; Os(III), $5.0 \times 10^{-5}M$; —○—: effect of HTAC in the presence of 0.5% Brij 58; Os(III), $2.5 \times 10^{-5}M$; Reference, reagent blank

Calibration graph and reproducibility

The calibration graph was linear in the range 0–110 μg of osmium(VIII) in a final volume of 10.0 ml. The relative standard deviation (R.S.D.) for 50 μg of osmium(VIII)/10 ml was 0.9% ($n = 5$). Table 2 shows the apparent molar absorptivities (ε) and Sandell's sensitivities in the presence or absence of surfactant No. 1 (proposed method—stable and reproducible) and Nos. 2–6 (single surfactant or non-micellar media—unstable and irreproducible).

Effect of foreign ions

As shown in Table 3, the coexistence of such elements as copper(II), cobalt(II), iron(III), palladium(II) and mercury(II) showed positive error owing to reaction with PAR, but aluminium(III) and zirconium(IV) up to 10-fold excess over osmium(VIII) were permitted. Anions such as sulphate, bromide, nitrate, fluoride and chloride did not interfere, but oxalate ion caused a slight interference at high concentrations. On the other hand, cyanide ion gave a negative error at a 1/10 molar ratio to osmium(VIII). The interferences of iron(III), cobalt(II) or aluminium(III) at high concentrations could be masked by addition of large amounts of ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA) or sodium fluoride. In the second case, large amounts of

*0.1%.
†0.5%.
Methods No. 2–6 were unstable and irreproducible.

NTA gave a negative error, but its interference could be compensated by preparing a calibration graph in the presence of NTA. Therefore, the assay of osmium(VIII) together with foreign ions such as iron(III) was investigated. Firstly, the amount of osmium(VIII) was found by measuring the absorbance at 540 nm of Solution A in the presence of NTA [PAR–osmium(VIII)–iron(III)–NTA complex] and using the osmium(VIII) calibration graph in the presence of NTA. Secondly, the amount of iron(III) was calculated by measuring the absorbance at 540 nm of Solution A [PAR–osmium(VIII)–iron(III) complex], and by using the iron(III) calibration graph prepared with iron in the presence of the determined amount of osmium(VIII). [Note that it should be possible also to determine the iron from the increase in absorbance in the absence of NTA and comparison against an iron(III) calibration curve in the absence of osmium.]

Composition of the complex

The molar ratio of PAR to osmium(VIII) in the presence of HTAC and Brij 58 mixed micellar media was estimated to be 1:1 by the molar ratio and Job's continuous variation methods. The molar ratio was identical to that in the absence or presence of HTAC or Brij 58 alone.

CONCLUSION

The colour reaction between PAR and osmium(VIII) in the presence (single or combinations of surfactants) or absence of surfactants was systematically investigated, and the mixture

of HTAC and Brij 58, the mixed micellar cationic and nonionic surfactant combination, was most effective in terms of sensitivity, stability and reproducibility. Therefore, an improved, simple spectrophotometric method for the determination of osmium(VIII) with PAR is proposed. The method is more sensitive and reproducible than the PAR-alone method.[1,3]

A RAPID SPECTROPHOTOMETRIC METHOD FOR DETERMINATION OF FLUORIDE IN SILICATES WITH THE ZIRCONYL–XYLENOL ORANGE COMPLEX

P. SAHU,* J. D. PANDA and B. C. SINHA†
Dalmia Institute of Scientific and Industrial Research, Rajgangpur-770017 Orissa, India

(*Received* 15 *April* 1989. *Revised* 12 *September* 1991. *Accepted* 20 *September* 1991)

Summary—A critical study has been made of the effect of acid concentration and of polymerized and depolymerized zirconyl ions on the formation of ZrO–XO complexes and their stabilities. At an optimum acidity of 0.5–0.6*M* hydrochloric acid, most of the common cations occurring in silicates do not interfere. Maximum colour development is almost instantaneous for the depolymerized ZrO–XO complex, but takes a few hours for the polymerized complex; the colour is stable for several hours. The absorbance is highest for the depolymerized ZrO–XO complex and decreases with an increase in polymerization of the zirconyl ions. Dissolved oxides of nitrogen affect the stability of the ZrO–XO complex but can be eliminated with urea. A simple, rapid and sensitive spectrophotometric method has been worked out for use of this complex in determination of fluoride in silicates, without separation, after fusion of the sample with sodium hydroxide at 450–550°.

Among the available methods for determination of small amounts of fluoride, the spectrophotometric and ion-selective electrode methods are most widely used. In silicate analyses, the sample is usually decomposed by fusion with sodium carbonate[1–6] or sodium carbonate plus zinc oxide at 900°,[7] and fluoride is then separated by distillation, pyrohydrolysis or ion-exchange before its determination. It has been reported[8] that there is some loss of fluoride during fusion of samples at 900°. Low-temperature fusion with sodium hydroxide has been recommended for use in the determination of fluoride by the ion-selective electrode method.[9] It has been reported that with alkaline fusion the same results are obtained with or without separation of the fluoride.[10–12] However, there are practically no studies on spectrophotometric determination of fluoride after alkaline fusion at low temperature, without a separation step.

Several reagents[2,4,7,13–27] have been used for direct and indirect spectrophometric determination of fluoride. Xylenol Orange (XO) which forms an intensely coloured complex with zirconium even in 1*M* nitric or hydrochloric acid[28] has been successfully utilized for determination of zirconium.[29–33] The bleaching of the ZrO–XO complex by fluoride has been used for determination of fluoride in mineral water,[33] wastewater,[27] bone and teeth[20] and uranium oxide.[22] However, at pH $\geqslant$ 2 cations such as Al^{3+}, Fe^{3+}, TiO^{2+}, which are invariably present in significant amounts in silicates or ceramic materials, interfere seriously by forming stable complexes with fluoride and with XO. In the spectrophotometric methods based on the ZrO–XO complex and its bleaching, the effect of polymerization of zirconyl ions has seldom been studied or discussed. Sinha and Das Gupta[28] reported the polymerization of zirconyl ions on aging or boiling in $<1M$ hydrochloric or nitric acid, and suggested quantitative depolymerization by boiling in 2–3*M* hydrochloric or nitric acid (preferably the latter) for accurate direct titration with EDTA. Sinha[34] later reported that depolymerization of zirconyl ions is also essential in the indirect determination with EDTA. It is very likely that quantitative depolymerization of zirconyl species is essential in any spectrophotometric method based on the ZrO–XO complex or its bleaching, since the characteristics of the two systems will be different. Cabello-Tomas and West[35] reported that the reaction between slightly aged $ZrOCl_2$ solution and XO is catalysed by substoichiometric amounts of F^-, SO_4^{2-}, PO_4^{3-}, AsO_4^{3-}, citrate or oxalate, and this was used for spectrophotometric determination (at 15°) of 0.005–0.05 ppm fluoride. They also reported that maximum colour took 90 min to develop and it remained constant for 60 min.

*Author for correspondence.
†Consultant and retired scientist from Central Glass and Ceramics Research Institute (CSIR) Calcutta, India.

The present investigation concerned the effect of polymerization of zirconyl ions on the quantitative formation of ZrO–XO complexes and their stabilities, and application of the results to derive a rapid, sensitive and accurate method for direct spectrophotometric determination of fluoride in silicates and other ceramic raw materials and products, after low-temperature alkaline fusion of samples.

EXPERIMENTAL

Apparatus

A Systronic type 103 spectrocolorimeter was used.

Reagents

All reagents used were of analytical grade.

Zirconium nitrate stock solution (0.9 mg/ml Zr). Dissolve 0.66 g of $ZrO(NO_3)_2 \cdot 2H_2O$ in 35 ml of 8*M* nitric acid. Boil for 5 min to depolymerize the zirconyl ions[28] and dilute to 250 ml. Standardize by EDTA titration in 1*M* nitric acid with XO as indicator.[28]

Working depolymerized zirconyl solution (0.036 mg/ml Zr). Boil 10 ml of stock solution with 60 ml of 4*M* nitric acid for 5 min, cool, and dilute to 250 ml.

Partly polymerized zirconyl solution (0.036 mg/ml Zr). Bring a mixture of 10 ml of stock solution and 50 ml of water just to the boil, cool, and dilute to 250 ml.

Highly polymerized zirconyl solution (0.036 mg/ml Zr). Boil 10 ml of stock solution with 50 ml of water for 10 min, cool, and dilute to 250 ml.

Stock fluoride solution (1 mg/ml F^-). Dissolve 2.211 g of sodium fluoride (dried at 110° for 3 hr) in water and dilute to 1 litre. Dilute 5 ml to 500 ml to obtain a 10 μg/ml fluoride working solution.

Xylenol Orange indicator. Dissolve 0.5 g of XO in water, add one drop of hydrochloric acid (1 + 1), dilute to 250 ml with water and filter.

Procedure

Fuse 4–5 g of sodium hydroxide in a nickel crucible and cool. Weigh 0.2–0.5 g of sample (containing up to 2 mg of fluoride) into the crucible and fuse the mixture for about 20 min at 450–550°. Cool the melt, extract it with 50 ml of hot water, then rinse the crucible and remove it. Add 20–30 ml of concentrated hydrochloric acid and boil the solution at 200–300° for 5–10 min. Add 20 ml of 50-mg/ml zinc nitrate solution, with stirring, add a few drops of phenalphthalein indicator and then 5*M* sodium hydroxide dropwise until a faint pink colour is obtained, transfer into a 250-ml standard flask and dilute to the mark. Filter a portion of the solution through a dry filter paper and pipette 5–10 ml of the filtrate (containing 10–40 μg of fluoride) into a 100-ml standard flask. Add 10 ml of hydrochloric acid (1 + 1), then exactly 3 ml of dilute zirconium solution (0.036 mg/ml Zr), with shaking, and let the solution stand for about 10 min. Dilute the solution to about 70 ml, add 5 ml of 100-mg/ml urea solution and exactly 2 ml of Xylenol Orange indicator, and make up to volume. Measure the absorbance at 535 nm against a blank prepared by diluting 10 ml of hydrochloric acid (1 + 1), 5 ml of the urea solution and exactly 2 ml of Xylenol Orange indicator to volume in a 100-ml standard flask. Prepare a calibration curve in the same way with 0, 1, 2, 3 and 4 ml of 10-μg/ml fluoride solution.

RESULTS AND DISCUSSION

Effect of acid concentration

Figure 1 shows that the absorbance of the depolymerized ZrO–XO complex increases with increase in hydrochloric acid concentration to a constant maximum at 0.3–0.6*M* acid, then decreases sharply with further increase in acidity. In this optimum range of acid concentration, particularly at 0.5–0.6*M*, most other cations (including Al^{3+} and TiO^{2+}) form hardly any coloured complex with the protonated XO. The fluoride complexes of these cations also do not form (owing to practically complete protonation of the fluoride). However, because of the large difference in the relative strengths of

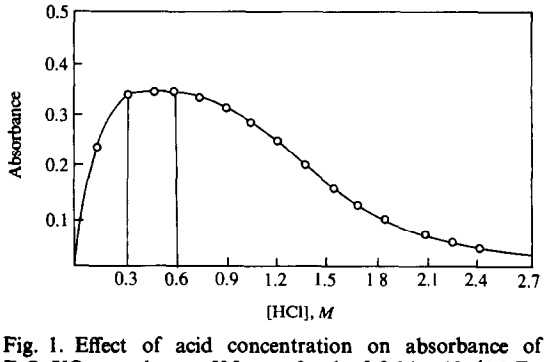

Fig. 1. Effect of acid concentration on absorbance of ZrO–XO complex at 535 nm: 3 ml of $3.94 \times 10^{-4}M$ Zr, 2 ml of $2.97 \times 10^{-3}M$ XO and appropriate volumes of hydrochloric acid (1 + 1), diluted to 100 ml.

Table 1. Tolerance limits for various ions in determination of 10 μg of fluoride

Ion	Ion:F molar ratio	Ion	Ion:F molar ratio

Cu(II)	237	Borate	2000
La(III)	5	Silicate	200

HF and XO, at this high acidity fluoride can decompose the ZrO–XO complex.

The tolerance limits for a number of ions in the method are given in Table 1. It shows that several elements will interfere at the levels present in the type of sample for which the method was designed, and must therefore be eliminated, or reduced in concentration to below the tolerance level. This can be done by the treatment with zinc nitrate and sodium hydroxide, as discussed below.

Effect of polymerization of zirconyl ions

Figure 2 shows that depolymerized zirconyl ions form the ZrO–XO complex instantaneously

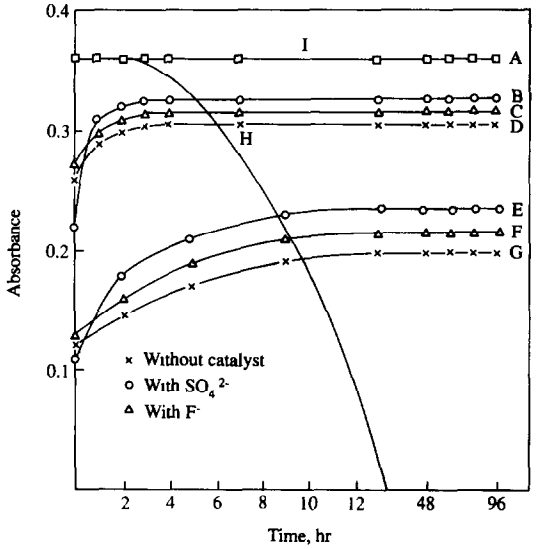

Fig. 2. Effect of depolymerized and polymerized zirconyl ions on formation and stability of the XO complex in 0.5–0.6*M* hydrochloric acid at room temperature (30 ± 2°). A, in absence of oxides of nitrogen or after their removal with urea; B, C and D, less polymerized ZrO–XO complexes; E. F and G, highly polymerized ZrO–XO complexes; H, depolymerized ZrO–XO complex in presence of oxides of nitrogen.

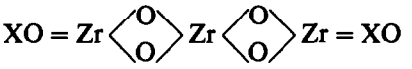
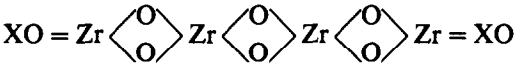
and the colour is stable for some days (curve A). However, if the solution contains a little dissolved oxides of nitrogen the absorbance decreases sharply after about 3 hr (curve H). This adverse effect of oxides of nitrogen can be removed with urea (curve A is again obtained).

The absorbance of the XO complexes with polymerized zirconyl ions increases with time to a constant value, the rate and the final absorbance being dependent on the degree of polymerization. Substoichiometric amounts of sulphate or fluoride slightly increase the rate of reaction as well as increasing the absorbance (curves B, C, E and F), in accordance with the observations by Cabella-Tomas and West.[35] However, the maximum absorbance is much lower than that of the depolymerized ZrO–XO complex. It has been reported that zirconyl ions form complexes in which Zr:XO is 1:1,[30] 1:2,[31] 2:1,[36] and it is possible that the 1:1 complex may actually be a 2:2 complex. Since the molar absorptivity will be essentially a function of the XO moiety in the complex, that of the 1 : 1 and 2 : 2 complexes should be similar but those for species such as



and



and higher polymers will be progressively lower, as indicated by the curves in Fig. 2.

Xylenol Orange

To test the quality of XO available in the market, six samples, three each from BDH and Merck, with different batch numbers, were obtained. Their molar absorptivities were found to range from 4.2×10^4 to 1.4×10^5 $l.mole^{-1}.cm^{-1}$, indicating the variation in purity of the reagents. However, a linear relationship was found between zirconium concentration and the absorbance of the XO complex, and between fluoride concentration and decrease in absorbance of the ZrO–XO complex, with different sensitivities. The purest of these reagents was used in the present study.

Decomposition of silicate samples

A preliminary study to eliminate the separation of fluoride by distillation was made by precipitating silica along with the R_2O_3 group

elements, according to the method of Huang and Johns[7] for decomposition of the sample by fusion with sodium carbonate and zinc oxide at 900°, but did not yield satisfactory results. Besides loss of fluoride during the decomposition, as reported by Troll and Farzaneh,[8] it was found that the filtrate often became turbid on acidification, owing to formation of colloidal silicic acid. Fusion with sodium hydroxide and zinc oxide also failed to yield satisfactory results, owing to incomplete separation of silica. The difficulty has been overcome by fusion of the samples with sodium hydroxide at 450–550°, extraction with water and hydrochloric acid, addition of zinc nitrate solution, and precipitation of silica and the R_2O_3 group at pH ~ 8. On acidification the filtrate gave a clear solution, analysis of which (Table 2), clearly showed satisfactory removal of most of the other constitutents.

Applications

The method has been applied to a variety of simulated and natural samples. The results (Tables 3 and 4) clearly show that the fluoride found, though slightly higher than that obtained by the distillation method, compared very favourably with the actual amounts of fluoride taken or the standard values, indicating better accuracy of the method. The slightly lower values obtained by the distillation method are attributed to incomplete recovery of the fluoride.

The method is simple, accurate and reasonably rapid, since it does not involve a distillation. The determination of fluoride in cement and other silicates can easily be completed within 2 hr.

(*Received* 21 *May* 1991. *Revised* 25 *July* 1991. *Accepted* 6 *September* 1991)

Summary—A new spectrophotometric method for resolving ternary mixtures is proposed. The method is based on the simultaneous use of the first derivative of ratio spectra and measurements of zero-crossing wavelengths. The ratio spectrum is obtained by dividing the amplitudes of the absorption spectrum of the mixture by a standard spectrum of one of the components giving the first derivative of the ratio spectrum. The concentrations of the other components is then determined from their respective calibration graphs established by measuring the ratio derivative analytical signal at the selected zero-crossing points. The method has been applied to resolving ternary mixtures of the isomers salicylaldehyde, 3-hydroxybenzaldehyde and 4-hydroxybenzaldehyde. Previously, we also resolved the binary mixture of salicylaldehyde and 3-hydroxybenzaldehyde. The method compares favourably with other spectrophotometric methods.

One of the classic analytical problems is the simultaneous determination of two or more compounds in the same sample, without previous chemical separation. In this way, derivative spectrophotometry is an analytical technique of great utility and offers greater selectivity than normal spectrophotometry.[1,2] Also mixtures have been resolved by using a multicomponent analysis program.[3,4] Blanco and co-workers[5,6] reported a method called multi-wavelength linear regression analysis (MLRA).

The resolution of binary mixtures of compounds with overlapped spectra by derivative spectrophotometry is frequently made on the basis of zero-crossing measurements.[1,7] In general, this technique is not suitable for ternary mixtures of compounds with overlapped spectra and in the case of binary mixtures it is often necessary to use a wavelength with low sensitivity in the measurements. Recently, Salinas *et al.*[8] developed a new spectrophotometric method for resolving binary mixtures. The method is based on the use of the first derivative of the ratio spectra. The absorption spectrum of the mixture is obtained and divided (amplitudes at each wavelength) by the absorption spectrum of a standard solution of one of the components, and the first derivative of the ratio spectrum is obtained. The concentration of another component is then determined from a calibration graph. This method permits the use of the wavelength of greatest sensitivity as the signal of measurement, a maximum or a minimum.

However, this method shows some limitation because in the wavelength range where the absorbance of the standard solution used as divisor is zero (or below the baseline) the noise is strongly exalted. In consequence, the useful wavelength range must be selected and, if noise is now slightly exalted, a smoothing function (prior to derivation) can be used as in classical derivative spectrophotometry. In experimental practice, we have observed that there are some mixtures which cannot be treated by this method.

The approach taken has now been extended to resolving ternary mixtures by simultaneous use of the zero-crossing method and Salina's method.

With the aim of testing this method, it has now been applied to the simultaneous determination of three isomer compounds with overlapped spectra, salicylaldehyde (SA), 3-hydroxybenzaldehyde (3HBA) and 4-hydroxybenzaldehyde (4HBA).

At first, it is necessary to resolve the different binary mixtures. In previous papers,[9,10] we have studied the SA and 4HBA, and 3HBA and 4HBA binary mixtures, and new methods for resolving their mixtures were described.

In this paper, the last binary mixture (SA and 3HBA) is studied and chemical and instrumental parameters are optimized. On the other hand, the SA, 3HBA and 4HBA ternary mixture is studied and several mixtures are resolved by using the proposed method for ternary mixtures. The results obtained were compared with those obtained by derivative spectrophotometry, and, in the case of binary mixtures, also by the method of Blanco and co-workers.[5,6]

THEORY

Consider a mixture of three compounds, M, N and P. If Beer's Law is obeyed for all compounds over the whole wavelength range used and the path-length is 1 cm, the absorption spectrum of the mixture is defined by the equation:

$$A_{m,\lambda_i} = \epsilon_{M,\lambda_i} C_M + \epsilon_{N,\lambda_i} C_N + \epsilon_{P,\lambda_i} C_P \qquad (1)$$

where A_{m,λ_i} is the absorbance of the mixture at wavelength λ_i, ϵ_{M,λ_i}, ϵ_{N,λ_i} and ϵ_{P,λ_i} are the molar absorptivities of M, N and P at wavelength λ_i and C_M, C_N, and C_P are the molar concentration of M, N and P, respectively.

If equation (1) is divided by the corresponding equation for the spectrum of a standard solution of one of the components (*e.g.*, M of concentration C_M°) and the first derivative of the result is obtained, the following equation can be written:

$$\frac{d}{d\lambda}\left[\frac{A_{m,\lambda_i}}{\epsilon_{M,\lambda_i} C_M^\circ}\right] = \frac{C_N}{C_M^\circ}\frac{d}{d\lambda}\left[\frac{\epsilon_{N,\lambda_i}}{\epsilon_{M,\lambda_i}}\right] + \frac{C_P}{C_M^\circ}\frac{d}{d\lambda}\left[\frac{\epsilon_{P,\lambda_i}}{\epsilon_{M,\lambda_i}}\right] \qquad (2)$$

If $C_N = 0$, we have the binary mixture of M and P, and the equation in this case is:

$$\frac{d}{d\lambda}\left[\frac{A_{m,\lambda_i}}{\epsilon_{M,\lambda_i} C_M^\circ}\right] = \frac{C_P}{C_M^\circ}\frac{d}{d\lambda}\left[\frac{\epsilon_{P,\lambda_i}}{\epsilon_{M,\lambda_i}}\right] \qquad (3)$$

Equation (3) indicates that the "derivative ratio spectrum" of the binary mixtures is dependent only on the values of C_P and C_M° and is independent of the value of C_M in the binary mixture.

A calibration graph is obtained by recording and storing the spectra of the solution of pure P at different concentrations, and the spectrum of a standard of pure M of concentration C_M°.

The stored spectra of the solutions of pure P are divided by the standard spectrum of M of concentration C_M° by use of "Data Leader Software".

The ratio spectra thus obtained are then differentiated with respect to wavelength and the derivative values for a given wavelength are plotted against C_P for a given calibration graph. M can be determined by an analogous procedure. This is the basis of the method of Salinas *et al.*[8] A new method can be developed from this for resolving ternary mixtures, by simultaneous use of the zero-crossing method and Salinas's method.

Equation (2) indicates that the derivative ratio spectrum of the ternary mixture is independent of the value of C_M and dependent of the value of C_N, C_P and C_M° in the ternary mixtures.

The content of N and P can be resolved by the zero-crossing method by measuring at adequate wavelengths and by use of calibration graphs.

Two calibration graphs are obtained by recording and storing the spectra of solution of pure N and pure P at different concentrations and the spectrum of a solution of pure M of concentration C_M°. The amplitudes of the spectra of N and P are then divided, wavelength by wavelength, by the corresponding amplitudes for M°. The "ratio spectra" thus obtained are then differentiated with respect to wavelength. The derivative values

$$\frac{C_N}{C_M^\circ}\frac{d}{d\lambda}\left[\frac{\epsilon_{N,\lambda_i}}{\epsilon_{M,\lambda_i}}\right]$$

are plotted against C_N for a given wavelength corresponding to zero crossing of the ratio spectrum of P (in this wavelength

$$\frac{d}{d\lambda}\left[\frac{\epsilon_{p,\lambda_i} C_P}{\epsilon_{M,\lambda_i} C_M^\circ}\right] = 0)$$

to give a calibration graph. The calibration graph for P is obtained by plotting derivative values

$$\frac{C_P}{C_M^\circ}\frac{d}{d\lambda}\frac{\epsilon_{P,\lambda_i}}{\epsilon_{M,\lambda_i}}$$

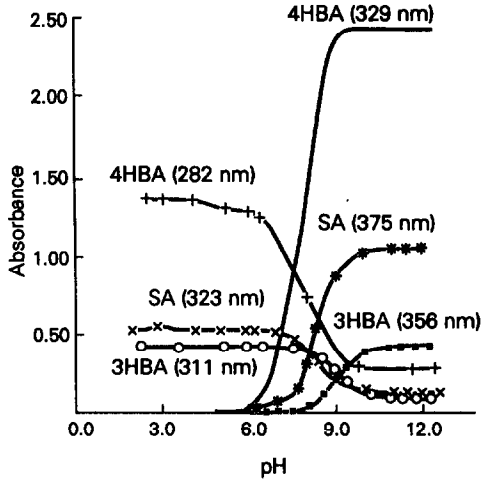

Fig. 1. Influence of pH value SA (20 ppm); 3HBA (20 ppm); 4HBA (10 ppm).

against C_P at λ_i corresponding to zero crossing of the ratio spectrum of N (at this wavelength

$$\frac{d}{d\lambda}\left[\frac{\epsilon_{N,\lambda_i} C_N}{\epsilon_{M,\lambda_i} C_M^\circ}\right] = 0).$$

Application of the method to the sample containing M, N and P and use of the calibration graphs, will then give the values of C_N and C_P in the ternary mixtures.

M can be determined by an analogous procedure. If we use a spectrum of standard solution of N or P of concentration C_N° or C_P° we can determine M and P in the presence of N, or M and N in the presence of P.

EXPERIMENTAL

Apparatus

A Beckmann Instrument DU-50 spectrophotometer connected to an IBM PC-286-XT fitted with Beckmann Data Leader Software and an Olivetti DM-282 printer was used for all the measurements and treatment of data.

Solutions

All solvents and reagents were of analytical reagent-grade. Salicylaldehyde, 3-hydroxybenzaldehyde and 4-hydroxybenzaldehyde ethanol –water 1:1 solutions were prepared from the Merck products. Sodium hydroxide solution 0.2*M* was prepared by dissolving 8.0 g of sodium hydroxide (Merck) and diluting to one litre.

Procedure

Samples were prepared in 25-ml calibrated flasks containing 2–20 ppm salicylaldehyde and/or 2–30 ppm 3-hydroxybenzaldehyde and/or 1–10 ppm 4-hydroxybenzaldehyde, plus 2 ml of 0.2*M* sodium hydroxide. They were diluted with water and ethanol to the mark (the resulting final solution is 10% in ethanol). The absorption spectra were recorded with 1-nm resolution against water and stored in the IBM PC 286-XT.

The stored spectra of the binary mixtures, salicylaldehyde and 3-hydroxybenzaldehyde and of the ternary mixtures were divided by a standard spectrum of salicylaldehyde of 10 ppm. The ratio spectra were smoothed through the use of 15 experimental points and the first derivates calculated with $\Delta\lambda = 4$ nm.

In the binary mixtures we can determine 3-hydroxybenzaldehyde by measuring at $^1DD_{290}$ (derivative divided spectrum at 290 nm).

In the ternary mixtures we can determine 3-hydroxybenzaldehyde by measuring at 304 nm ($^1DD_{304}$) and 4-hydroxybenzaldehyde at 295 nm ($^1DD_{295}$). The concentration of 3-hydroxybenzaldehyde was proportional to the amplitude of the minimum at 240 nm and to the amplitude at 304 nm, and 4-hydroxybenzaldehyde to the amplitude at 295 nm.

On the other hand, stored spectra of binary as well as ternary mixtures were divided by a standard spectrum of 3-hydroxybenzaldehyde of 15 ppm concentration. In the same way as we have previously described we obtained the first derivatives from smoothed ratio spectra. Now, we can determine salicylaldehyde by measuring at 394 nm ($^1DD_{394}$) in binary mixtures and by measuring at 398 nm ($^1DD_{398}$) in ternary mixtures. The concentration of salicylaldehyde was

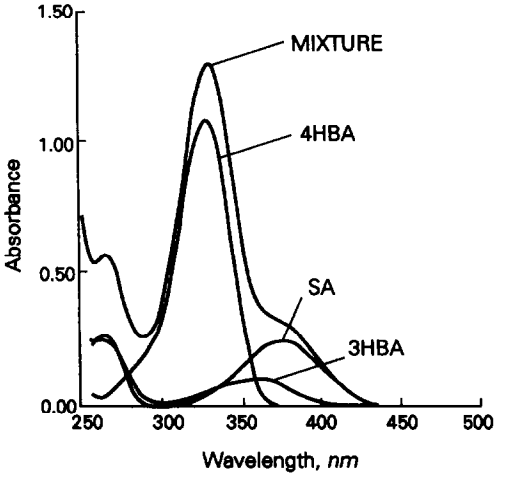

Fig. 2. Absorption spectra of SA (5 ppm), 3HBA (7 ppm), 4HBA (5 ppm) and their mixture.

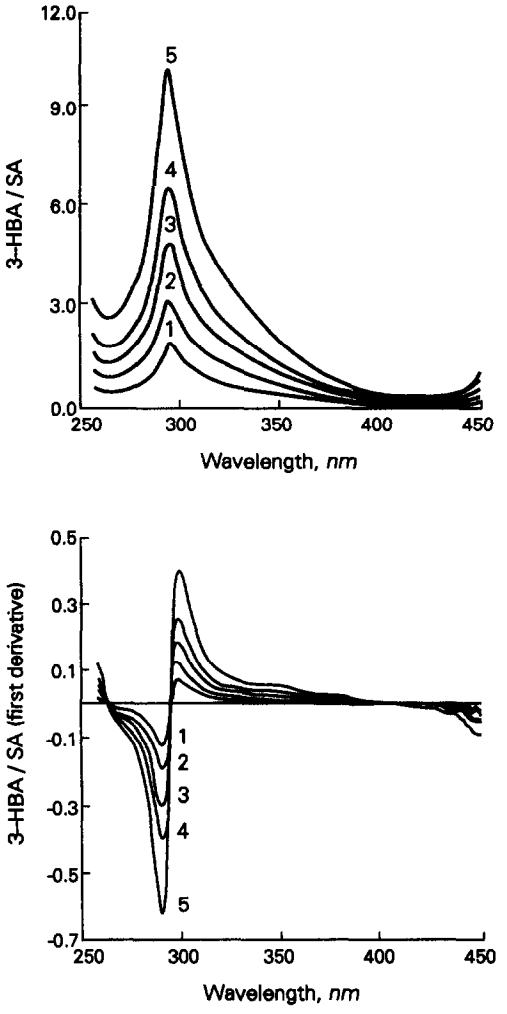

Fig. 3. Ratio spectra and first derivatives for different concentrations of 3HBA when SA was 10 ppm 1 (5 ppm), 2 (10 ppm), 3 (15 ppm), 4 (20 ppm), 5 (30 ppm).

proportional to the amplitudes at 394 nm and 398 nm.

RESULTS AND DISCUSSION

With the aim of testing theoretical considerations in an experimental system, we have chosen three isomer compounds which have overlapped spectra. The ternary mixture selected was salicylaldehyde (SA) and its 3-hydroxybenzaldehyde (3HBA) and 4-hydroxybenzaldehyde (4HBA) isomers. We emphasize that this mixture has been selected exclusively and with the sole purpose of testing the method described.

The UV spectra of SA, 4HBA and 3HBA, showed two absorption maxima for all pH values studied (2–13). In order to establish suitable pH values for use throughout, a range of values were examined between pH 2 and 13 (Fig. 1). Only small changes were experienced between pH 2 and 5 and between pH 11 and 13. Therefore pH values of 12 and 4.5 must be considered suitable for use throughout. However, for the pH value of 4.5 the results obtained were not acceptable and the method is only developed at pH = 12.

These compounds are soluble in ethanol –water. The ethanol content of the medium slightly affects the absorbances of the three compounds; 10% was selected as optimum. Under these conditions, SA, 3HBA and 4HBA solutions were stable for 2 hr at least.

Figure 2 shows the absorption spectra of SA, 3HBA, 4HBA and their mixture in basic medium (pH = 12). The spectra of three compounds overlap sufficiently to demonstrate the resolving power of the proposed method for the ternary mixture and for the binary mixture of SA and 3HBA.

Binary mixture of SA and 3HBA

Figure 3 shows the ratio spectra of different 3HBA standards (spectra divided by the spectrum of a 10-ppm SA solution) and their first derivatives were calculated. The first derivative amplitudes at a given wavelength are proportional to the 3HBA concentration.

Table 1. Results obtained for different binary mixtures of SA and 3HBA by use of the proposed method

Composition mixture		15 ppm 3HBA (divisor)		10 ppm SA (divisor)	
		$^1DD_{394}$		$^1DD_{299}$

20.00	2.00	19.98	99.9	2.68	134.0

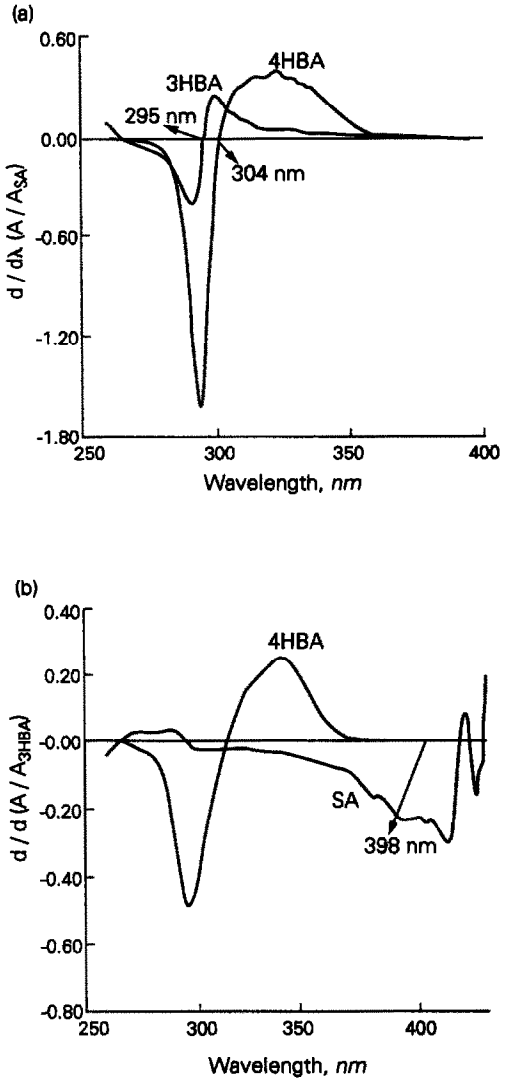

Fig. 4. First derivative of the ratio spectra of (a) 3HBA and 4HBA (10 ppm) of SA as divisor) (b) 4HBA and SA (15 ppm 3HBA as divisor).

Due to the extent of the noise levels on the ratio spectra, a smoothing function was used on the basis of the Savitzky and Golay method[11,12] and 15 experimental points were considered as optimum.

The influence of $\Delta\lambda$ for obtaining the first derivative was tested; $\Delta\lambda = 4$ nm was considered as suitable. The concentration of divisor (SA in this case) can be modified, and different calibration graphs are then obtained. We selected an SA concentration of 10 ppm. The calibration graph was established by measuring at 290 nm corresponding to a minimum ($^1DD_{290}$) and it gave a straight line up to 30 ppm SA.

For determining the other component (SA) an analogous procedure was followed. We obtained the ratio spectra of different SA standards (spectra divided by the spectrum of a 15 ppm 3HBA solution) and their first-derivatives were calculated. The ratio spectra were smoothed with experimental points and the first derivatives were calculated with $\Delta\lambda = 4$ nm. The concentration of the divisor (3HBA) was 15 ppm.

The calibration graph was obtained by measuring at 394 nm ($^1DD_{394}$) and it gave straight lines up to 20 ppm SA.

Several mixtures of SA and 3HBA were prepared and resolved by the proposed method. The results are summarized in Table 1. In all cases recovery between 96.0 and 101.0% were obtained for determining SA. The determination of 3HBA is possible when the ratio SA/3HBA $\leqslant 6$, with recovery between 93.0 and 110.0%.

Ternary mixtures of SA, 3HBA and 4HBA

After developing the methods for resolving SA, 3HBA and 4HBA in their possible binary mixtures, SA and 3HBA are described in this paper while SA–4HBA and 3HBA–4HBA have been described previously.[9,10] We developed the new method for resolving the ternary mixture.

We did not have to establish the experimental optimum conditions because it was made in binary mixtures. We only needed to select the adequate wavelength to determine each component.

Table 2. Results obtained for differents ternary mixtures of SA, 3HBA and 4HBA by using the proposed method

Figure 4 shows the first derivative of the ratio spectra of (a) 3HBA and 4HBA (10 ppm SA as divisor) and (b) 4HBA and SA (15 ppm 3HBA as divisor).

Taking into account the zero crossing method, 4HBA can be determined by measuring at 295 nm (zero-crossing of 3HBA/SA) and 3HBA can be determined at 304 nm (zero crossing of 4HBA/SA), with SA as divisor [Fig. 4(a)]. SA can be determined by measuring at 398 nm in the first derivative of the ratio spectra with 3HBA as divisor [Fig. 4(b)].

The calibration graphs were obtained at wavelengths selected previously and gave straight lines up to 20 ppm SA, up to 30 ppm 3HBA and up to 10 ppm 4HBA.

Several mixtures of SA, 3HBA and 4HBA were prepared and resolved by the proposed method. The results obtained are summarized in Table 2. In all cases good recovery values were obtained.

Comparative study

The binary mixtures were also resolved by using the method of Blanco and co-workers,[5,6] and classical derivative spectrophotometry (first and second orders). SA can be determined by measuring at 345 nm in the first derivative mode ($^1D_{356}$) and at 381 nm in the second derivative mode ($^2D_{381}$). 3HBA can be determined by measuring at 375 nm in the first derivative mode ($^1D_{375}$) and at 350 nm in the second derivative mode ($^2D_{350}$).

Various values of the experimental points were tested for smoothing the absorption spectra and 15 points were selected as optimum. We also optimized the value of $\Delta\lambda$ to obtain the first and second derivative smoothed spectra and 4 nm and 28 nm were selected as optimum respectively.

Table 3 shows the results obtained for the mixtures of SA and 3HBA by the first and second derivative mode and by the method of Blanco and co-workers[5,6] (by using 10 ppm SA and 15 ppm 3HBA as divisors).

We also tested the derivative spectrophotometry method (first to fourth orders) for resolving the ternary mixtures. We couldn't

3HBA	$^1D_{375}$	0.1577	±0.77	2.40
	$^2D_{350}$	0.1574	±0.67	0.00
	$^1DD_{290}$	0.8460	±3.74	1.70
Ternary mixture				
SA	$^1DD_{398}$	0.1140	±0.94	0.48
3HBA	$^1DD_{304}$	0.2440	±1.25	1.99
4HBA	$^1DD_{295}$	0.0293	±0.45	0.04

find, in the same order of derivative spectra, the appropriate wavelengths for the simultaneous determination of the three compounds. Therefore 4HBA can be determined by measuring at 299 nm in the first derivative order, SA can be determined at 396 nm in the third derivative order ($^3D_{396}$) and 3HBA can't be determined by this method.

Table 4 summarizes the different calibration graphs of SA and 3HBA in binary mixtures and SA, 3HBA and 4HBA in ternary mixtures, and their linear regression coefficients which are very good.

To check the precision of the methods, replicated samples were measured ($n = 10$) containing SA (10 ppm), 3HBA (10 ppm) and 4HBA (5 ppm) individually (Table 5); in addition determination limits were calculated for each of the compounds.[13,14]

CONCLUSION

The proposed method permits the resolution of ternary mixtures of compounds which have overlapping spectra, as in the case of isomers studied, SA, 3HBA and 4HBA while derivative spectrophotometry for resolving the same mixtures does not provide good results.

(*Received* 3 *May* 1991. *Revised* 1 *August* 1991. *Accepted* 1 *August* 1991)

Summary—A highly sensitive spectrophotometric method for the determination of 0.03–1.0 μg of arsenic is described. After extraction as AsI_3 into benzene, it is selectively stripped into water. Both the arsenic(III) and iodide present in the aqueous phase are made to react with iodate in acidic medium in the presence of chloride to form the anionic chloro complex, ICl_2^-. The determination is completed after extraction of ICl_2^- species as an ion-pair with Rhodamine 6G into benzene and measuring the absorption of the extract at 535 nm. The coefficient of variation is 1.5% for 10 determinations of 0.5 μg of arsenic. The method has been applied to the determination of arsenic content in plant materials, high purity iron, copper base alloys and inorganic arsenic levels of natural waters.

The widely used methods for the spectrophotometric determination of trace amounts of arsenic are based on the formation of molybdenum blue[1] and the reaction of arsine with silver diethyldithiocarbamate.[2] Methods based on the formation of an ion-pair between arsenomolybdate and a large dye cation have been described to improve the sensitivity and selectivity of the determination.[3–5] None of these methods, however, are sufficiently sensitive to establish the arsenic levels of natural waters without resorting to a preconcentration step.

The ability of arsenic(III) to react with potassium iodate in the presence of chloride in an acidic medium to form the anionic chlorocomplex is well known[6] and has been applied to the spectrofluorimetric determination of 0.3–1.5 μg of arsenic(III) after extraction of the anionic complex as an ion-pair with Rhodamine B into benzene.[7] The presence of ions that are oxidized by iodate however interferes seriously in the determination. Since iodide can also react with potassium iodate to form the anionic chlorocomplex[6] similar to arsenic(III), it seemed worthwhile to examine whether the formation of the anionic complex and its interaction with a cationic dye could be put to advantage for the spectrophotometric determination of both arsenic(III) and arsenic(V) after extractive separation as arsenic triiodide into benzene. Such an approach, besides improving the selectivity (since relatively few ions extract into benzene from iodide media), would also provide considerable enhancement in sensitivity arising due to reaction of iodide, in addition to arsenic(III) present in arsenic triiodide with potassium iodate to form the anionic chloro-complex. Detailed examination disclosed that the reaction with potassium iodate in acidic chloride containing medium after selectively stripping the arsenic triiodide into water and subsequent interaction of the anionic iodine complex with Rhodamine 6G can form the basis for the spectrophotometric determination of arsenic. The resulting ion-pair, after extraction into benzene, had maximum absorption at 535 nm, and arsenic concentration as low as 0.03 μg in a final volume of 25 ml can be determined with this procedure. The method was found suitable for the rapid determination of arsenic concentration of natural waters and applicable to the determination of arsenic in plant materials, high purity iron and copper base alloys without prior separation of arsine.

*Author for correspondence.

EXPERIMENTAL

Apparatus

Absorbances were measured with a Carl Zeiss PMQ II spectrophotometer with 10-mm quartz cells.

Reagents

Standard arsenic(III) solution, 1.0 mg/ml. Prepared by dissolving 0.1321 g of arsenious oxide in 10 ml of 1*M* sodium hydroxide, adding 7.5 ml of 1*M* sulphuric acid and diluting to volume with water in a 100-ml standard flask. A suitable volume of this solution was diluted to obtain working standards.

The following solutions were prepared by dissolving appropriate amounts of the reagents in distilled water.

Potassium iodate solution, 0.01%.

Rhodamine 6G solution, 0.02%.

Sodium chloride solution, 15%.

*Saturated sodium chloride solution, ~5*M.

*Potassium iodide solution, 2*M.

*Sodium hypophosphite, monohydrate solution, 2*M.

*Sulphuric acid, 2.5 and 12.5*M.

Benzene (thiophene free[8]). Used for extraction.

*Di-*isopropyl *ether solvent.* Di-*iso*propyl ether containing 0.015 weight per cent peroxide was prepared by equilibrating 50 ml of the solvent rendered free from peroxide[9] with 50 ml of 0.5*M* sulphuric acid containing 0.3 weight per cent of hydrogen peroxide for 5 min. It was prepared fresh every week, stored in a brown bottle and kept in a refrigerator.

Procedure

Separation of arsenic. Transfer a portion of the sample solution into a 125-ml separating funnel. Add enough sulphuric acid and sodium chloride to make their concentration 3*M* (4*M* for sample volumes greater than 30 ml) and 2*M* respectively. Add 1 ml of 2*M* sodium hypophosphite solution followed by sufficient potassium iodide to provide an overall concentration of 0.3*M*. Shake the solution for 2 min with 10 ml of benzene (separate the aqueous layer and repeat the extraction with 10 ml of benzene if the initial sample volume used is >30 ml).

Collect the organic phase(s) in a 60-ml separating funnel, treat with 2 ml of di-*iso*propyl ether solvent (4 ml if the extraction is performed twice) containing 0.015% peroxide, mix well and allow to stand for 15 min. Then extract with 10 ml of water for one minute and discard the organic layer.

Determination

Transfer an aliquot of the stripping agent containing not more than 1.0 μg of arsenic into a 25-ml standard flask. Add 2 ml each of 2.5*M* sulphuric acid, 0.01% potassium iodate solution and 0.02% Rhodamine 6G solution followed by 4 ml of 15% sodium chloride solution. Dilute to volume with water and allow to stand for 5 min. Transfer the made up solution into a 60-ml separating funnel and extract with 5 ml of benzene for one minute. Separate the organic layer into a dry test tube and add about 1 g of anhydrous sodium sulphate. Measure the absorbance of the extract at 535 nm in 10-mm cells against a reagent blank run through the entire procedure. Establish the concentration of arsenic by reference to a calibration graph prepared with 0.03–1.0 μg of arsenic, following the above procedure.

RESULTS AND DISCUSSION

Extractive separation of arsenic as arsenic triiodide

Although arsenic can be extracted from an iodide medium into a variety of solvents, the extraction into hydrocarbon solvents as arsenic triiodide from a highly acidic medium (>8*N*) has been shown to be highly selective.[10–13] It was found that from solutions of lower acidity, extraction becomes quantitative in the presence of sodium chloride as a salting-out agent. Using simplex optimization,[14] it was established that for quantitative extraction the overall concentration with respect to sulphuric acid, potassium iodide and sodium chloride should be 3, 0.3 and 2*M* respectively.

A single equilibration for two minutes with 10 ml of benzene was adequate for quantitative extraction which remained unaffected up to an aqueous phase volume of 30 ml. Beyond this volume, the extraction was incomplete and repetition of the extraction on the aqueous phase was not effective. Increasing the concentration of potassium iodide up to 0.6*M* showed no marked improvement in the recovery of arsenic. For quantitative extraction of arsenic from aqueous volume up to 100 ml, it was found necessary to equilibrate the solution twice with 10 ml of benzene each time, after raising the acidity to >4*M* with respect to sulphuric acid. A single equilibration for one minute with 10 ml of water was found adequate for stripping the arsenic from the organic layer.

Determination with Rhodamine 6G

Preliminary studies under conditions found optimal (hydrochloric acid—1.5*M*, IO_3^-—

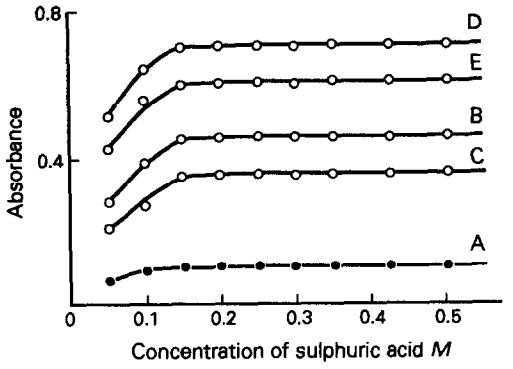

Fig. 1. *Effect of acidity.* A. 2 ml of 0.01% KIO_3, 5 ml each of 0.01% Rhodamine 6G and 15% NaCl, "x" ml of 2.5*M* H_2SO_4, diluted to 25 ml, extracted with 5 ml of benzene measured against benzene at 535 nm in 10-mm cells. B. As in (A) with 5 μg of As(III). C. As in (B) but measured against (A). D. As in (A) with 5 μg of I^-. E. As in (D) but measured against (A).

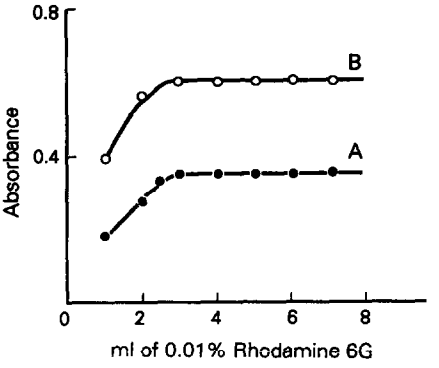

Fig. 3. *Effect of Rhodamine 6G concentration.* A. 5 μg of As(III) with "x" ml of 0.01% Rhodamine 6G, 2 ml each of 2.5*M* H_2SO_4 and 0.01% KIO_3, 5 ml of 15% NaCl, total volume 25 ml, extracted with 5 ml of benzene, measured against respective reagent blank. 0.025m*M* and Rhodamine B—0.025m*M*) for the spectrofluorimetric determination of arsenic[7] showed that the colour when extracted into benzene gradually faded on standing. This was overcome by using Rhodamine 6G instead of Rhodamine B, the use of which stabilized the colour of the extract that absorbed maximally at 535 nm for 75 min. Acidification with sulphuric acid in the presence of sodium chloride was preferred to hydrochloric acid because in the former the blank was low and reproducible, due to lower levels of impurities.

Variation of the acidity of the reaction medium as shown in Fig. 1, revealed that the ion-pair extraction remained maximal and constant when the overall acidity was greater than 0.15*M* for both arsenic(III) and iodide. The influence of potassium iodate, Rhodamine 6G and sodium chloride on the extraction of the ion-pair into benzene are shown in Figs. 2, 3 and 4, respectively. Based on these experiments an overall concentration of 0.2*M* sulphuric acid, 0.04m*M* (0.0008%) potassium iodate, 0.035m*M* (0.0016%) Rhodamine 6G and 0.04*M* (2.4%) sodium chloride were chosen as optimum for the determination of both arsenic(III) and iodide. Although the presence of sodium chloride and Rhodamine 6G in excess of the recommended concentration caused a slight increase in blank value, the net absorbance due to reaction with arsenic(III) and iodide remained unaffected.

The formation of the ion-pair in both instances was found to be almost instantaneous and mixing the phases for about 30 sec was found to be sufficient for its quantitative extraction into benzene. Benzene, toluene,

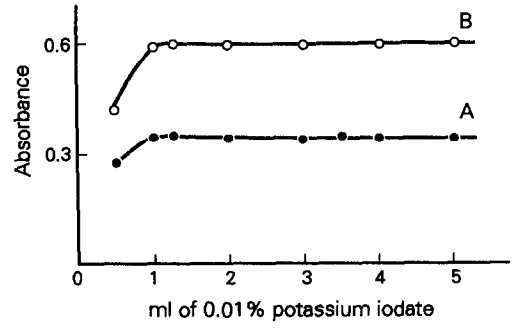

Fig. 2. *Effect of potassium iodate concentration.* A. 5 μg as As(III) with "x" ml of 0.01% KIO_3, 2 ml of 2.5*M* H_2SO_4, 5 ml each of 0.01% Rhodamine 6G and 15% NaCl solution, total volume 25 ml, extracted with 5 ml of benzene measured against respective reagent blank. B. As in (A) with 5 μg of I^- instead of As(III).

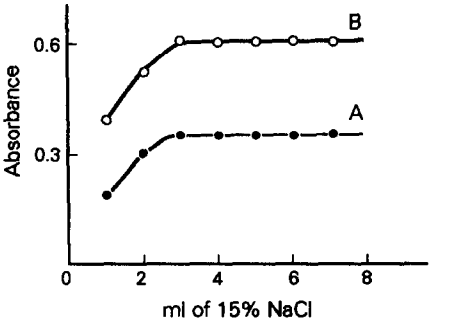

Fig. 4. *Effect of sodium chloride concentration.* A. 5 μg of As(III) with "x" ml of 15% NaCl, 2 ml each of 2.5*M* H_2SO_4, 0.01% KIO_3 and 0.02% of Rhodamine 6G, total volume 25 ml, extracted with 5 ml of benzene, measured against respective reagent blank. B. As in (A) with 5 μg of I^- instead of As(III).

xylene, hexane, cyclohexane, carbon tetrachloride, chloroform, and *iso*amyl acetate were investigated as extraction solvents. However, only benzene proved to be satisfactory, as the extraction of the ion-pair was found to be maximum in this solvent.

When independently checked, linear calibration curves passing through the origin were obtained for arsenic(III) and iodide in the range 0.15–11.0 μg and 0.1–6.0 μg, respectively. The molar absorptivities were found to be 2.6×10^4 $l.mole^{-1}.cm^{-1}$ for arsenic(III) and 7.6×10^4 $l.mole^{-1}.cm^{-1}$ for iodide.

Extractive separation and determination of arsenic

As the optimal conditions for the determination of arsenic(III) and iodide were found to be identical, it was decided to apply the method for the determination of arsenic, after its extraction as arsenic triiodide into benzene and stripping into water. Difficulties were encountered because the blank was intensely coloured, evidently due to co-extraction of hydroiodic acid. As washing the benzene layer with acid solution was found to be ineffective in removing the hydroiodic acid, the use of a dilute solution of hydrogen peroxide was considered for washing purposes. The use of a 0.3 weight per cent solution of hydrogen peroxide in 5*M* sulphuric acid was effective in minimizing the blank value, but the results were not reproducible. Blank values comparable to the normal blank resulted only when the hydrogen peroxide concentration in the wash liquid was increased above 1.0%, but this resulted in a considerable decrease in the sample absorbance also. In this instance the absorbance of the sample extract corresponded to that of arsenic alone, indicating the oxidative loss of the iodide that remained associated with arsenic.

Addition of organic solvents containing peroxide to the benzene layer after the separation of the aqueous layer was examined next. The solvents examined included, *iso*amyl acetate, cyclohexanone, di-*iso*propyl ether, *iso*butyl methyl ketone and mesityl oxide. After adding 1 ml of the solvent, the benzene layer was mixed and allowed to stand for 15 min before stripping with water. In all instances, there was a considerable reduction in the blank. As the addition of di-*iso*propyl ether containing 0.022 weight per cent peroxide was found to be most effective among the solvents examined it was used, with an optimal amount of peroxide, for destroying the co-extracted hydroiodic acid.

In order to establish the optimal range of peroxide in di-*iso*propyl ether that would be effective for produding low and reproducible blanks, the solvent was first rendered free from peroxide[9] and then varying amounts of peroxide were introduced by equilibrating for five min with an equal volume of 0.5*M* sulphuric acid containing 0.1–1.0 weight per cent hydrogen peroxide. After equilibration the solvent was found to contain peroxide in the range 0.005–0.035 weight per cent.

The effect of the addition of 2 ml of each peroxide containing ether to the benzene extract was examined separately. After the addition of ether, the extracts were allowed to stand for 15 min before stripping into water for completing the determination. The results, shown in Fig. 5, clearly indicate that the addition of 2 ml of ether containing peroxide in the range 0.012–0.026 weight per cent effectively reduces the blank value without affecting the sample. When the recommended procedure was followed for the preparation of peroxide containing ether, it was found to contain 0.015 weight per cent. After the addition of 2 ml of this solvent to the benzene extract, a standing time of 10 min was found to be adequate (Fig. 6) to destroy the co-extracted hydroiodic acid, and the recovery

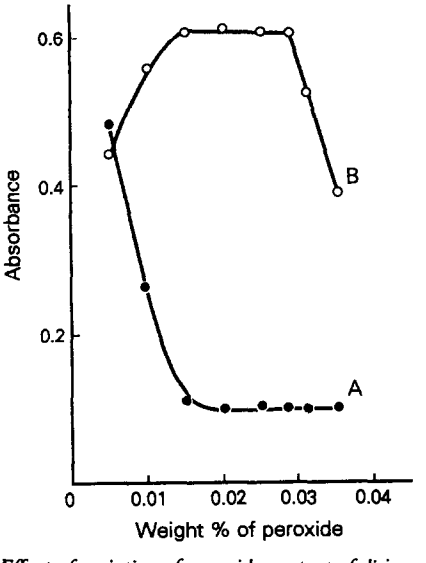

Fig. 5. *Effect of variation of peroxide content of di-*iso*-propyl ether.* A. 10 ml of benzene extract, 2 ml of di-*iso*-propyl ether solvent, standing time 15 min, before stripping and colour development. Measured against benzene. B. As in (A) using benzene extracts obtained with 1 μg of arsenic, measured against (A).

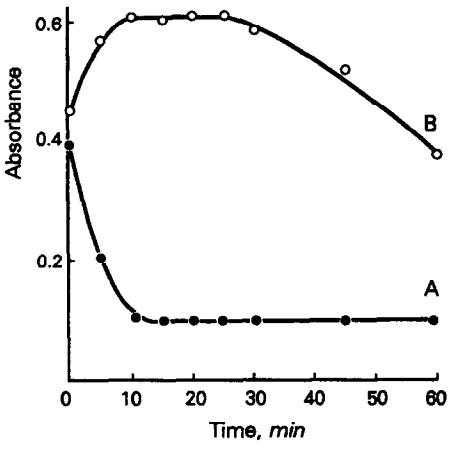

Fig. 6. *Influence of standing time after the addition of di-*iso*-propyl ether solvent on the stability of AsI_3 in the benzene extract.* A. 10 ml of benzene extract, 2 ml of di-*iso*-propyl ether solvent (0.015%), standing time × min before stripping and colour development. Measured against benzene. B. As in (A) with benzene extracts obtained with 1 μg of arsenic, measured against (A).

of arsenic remained unaffected up to a standing time of 25 min before stripping into water.

When the procedure described in the Experimental section was followed, 1.0 μg of arsenic(III) gave an absorbance of 0.62 ± 0.02 compared to the expected value of 0.66 [0.07 for 1 μg of arsenic(III) and 0.59 for 5.0 μg of associated iodide]. The calibration graph was linear over the range 0.03–1.0 μg of arsenic. From the slope of the calibration plot the molar absorptivity was established to be 2.37×10^5 $l.mole^{-1}.cm^{-1}$. The Sandell sensitivity was found to be 8×10^{-5} $\mu g/cm^2$.

The precision of the proposed procedure was checked by establishing the concentration of 10 samples containing 0.50 μg of arsenic. The mean recovery was found to be 0.497 μg with a coefficient of variation of 1.5%.

Nature of the extracted species

The equilibrium shift method[15] was employed to establish the ratio of arsenic to iodide. The slope of the straight line obtained by plotting log *D vs.* log $[I^-]$ was found to be 2.98, indicating that arsenic was extracted into the benzene layer as arsenic(III) triiodide, which conforms to the findings reported in the literature.[13]

When the benzene layer was equilibrated with water, both arsenic(III) and the associated iodide were readily stripped into water. The stripping, when reacted with iodate in acidic medium, leads to the formation of iodine as shown in the following equations:

$$5AsO_3^{3-} + 2IO_3^- + 2H^+ \rightleftharpoons I_2 + 5AsO_4^{3-} + H_2O \quad (1)$$

$$5I^- + IO_3^- + 6H^+ \rightleftharpoons 3I_2 + 3H_2O \quad (2)$$

In the presence of chloride, the excess iodate[6] present in the solution can further oxidize the generated iodine and stabilize it as ICl_2^- species in accordance with

$$2I_2 + IO_3^- + 6H^+ + 5Cl^- \rightleftharpoons 5ICl + 3H_2O \quad (3)$$

$$ICl + Cl^- \rightleftharpoons ICl_2^- \quad (4)$$

The overall reaction for the formation of ICl_2^- from AsO_3^{3-} and iodide can be represented as

$$2AsO_3^{3-} + IO_3^- + 2H^+ + 2Cl^- \rightleftharpoons 2AsO_4^{3-} + ICl_2^- + H_2O \quad (5)$$

$$2I^- + IO_3^- + 6H^+ + 6Cl^- \rightleftharpoons 3ICl_2^- + 3H_2O \quad (6)$$

While the reaction with iodide can give rise to only ICl_2^-, the possibility of the formation of ICl_4^-, due to the reduction of the iodate to I^{3+} state and stabilization as ICl_4^- can also be expected in the case of arsenic(III) in accordance with

$$AsO_3^{3-} + IO_3^- + 4H^+ + 4Cl^- \rightleftharpoons AsO_4^{3-} + ICl_4^- + 2H_2O \quad (7)$$

As both ICl_2^- and ICl_4^- can form ion-pairs with Rhodamine 6G and extract into benzene, investigations were carried out to establish the nature of species responsible for the extraction of the ion-pair in the determination of arsenic(III) with iodine solution in benzene and completing the determination under conditions optimal for the determination of arsenic(III). Though this experiment would not give direct evidence for the formation of ICl_4^-, it would provide indirect evidence of whether the formation of ICl_2^- was responsible for the observed colour.

Experiments with iodine solution in benzene showed a linear relationship with an increasing amount of iodine and the absorbance of 0.20 produced by 2.0 μg of iodine was identical to that produced by 2.94 μg of arsenic(III). Since, 2.0 μg of iodine would result from 2.94 μg of arsenic(III) [equation (1)], it was felt reasonable to conclude that the ICl_2^- species was responsible for the observed absorbance with arsenic(III). Had ICl_4^- been the species, as evident from equation (7), 1.47 μg of arsenic(III) would have been adequate to produce the observed absorbance.

Table 1. Determination of arsenic in various materials

*Molybdenum blue method.
†Average value of three determinations.

Another evidence in support of the formation of ICl_2^- species in the case of arsenic(III) was obtained by establishing the stoichiometry of the species extracted as an ion-pair into benzene. The combined ratio of the anionic chloro-complex and the dye cation was established by determining the ratio of arsenic(III) to Rhodamine 6G by the continuous variation and mole ratio methods. Both methods showed that for maximum extraction of the ion-pair, the medium should contain 2 moles of arsenic(III) and 1 mole of Rhodamine 6G. Since 2 moles of arsenic(III) would yield 1 mole of ICl_2^- species [equation (5)] and 2 moles of ICl_4^- species [equation (7)], it was concluded that ICl_2^- species and the monovalent Rhodamine 6G cation interact in a 1:1 ratio for the formation of the ion-pair. If ICl_4^- were to be the species, the arsenic(III) and Rhodamine 6G would have reacted in a 1:1 ratio.

Effect of interfering metal ions

The presence of one milligram amounts of various ions which are known to react with iodide were examined in the determination of 0.5 μg of arsenic by the proposed procedure. The ions examined included Ag^+, Bi^{3+}, Cd^{2+}, Cu^{2+}, Fe^{3+}, Ge^{4+}, In^{3+}, MoO_4^{2-}, Tl^+, TeO_2^{2-}, Sb^{3+}, SeO_3^{2-}, Sn^{4+} and Zn^{2+}. The determinations were carried out in the presence of sodium hypophosphite solution to prevent the liberation of iodine. Although 1 ml of 2*M* sodium hypophosphite was adequate, the addition of larger volumes would be necessary in the presence of excessive amounts of iron(III) and copper(II). The excess hypophosphite had no effect on the recovery of arsenic.

Only antimony(III) at all concentration levels and germanium(IV) in excess of 100 μg were found to cause positive interference in the determination of arsenic. The influence of antimony(III) could be overcome by extracting off as antimony(III) triiodide into a 1:1 mixture of cyclohexanone–isobutyl methyl ketone from 0.5*M* sulphuric acid and 0.25*M* potassium iodide. The inclusion of this step also eliminated the difficulties arising due to dispersion of copper(I) iodide in the organic layer when copper(II) in excess of 1 mg was present with arsenic.

Application of the method to real samples

Table 1 presents the results of the analysis of several arsenic containing samples with and without added standard by the proposed procedure. The water samples were filtered immediately after collection and acidified with sulphuric acid to ~pH 1. The solid samples were brought into solution with 1:1 sulphuric acid and hydrogen peroxide.[16,17] After evaporating almost to dryness to decompose excess

peroxide, the residue was dissolved in 10 ml of water, filtered if necessary, and made up to known volume with water. Suitable aliquots were subjected to determination following the procedure given under 'Experimental'. As no standard samples were available, the arsenic content of brass,[17] plant materials[18] and water[19] was also established following the standard molybdenum blue method after separation of arsenic. The results summarized in Table 1 clearly show that the method developed works satisfactorily for the analysis of traces of arsenic in various materials.

CONCLUSION

The method described provides a simple and reliable means of determining trace amounts of arsenic by spectrophotometry. It is more sensitive ($\epsilon = 2.37 \times 10^5$ $1.mole^{-1}.cm^{-1}$) than those based on the formation of Molybdenum Blue ($\epsilon = 2.5 \times 10^4$ $1.mole^{-1}.cm^{-1}$) and reaction with silver diethyldithiocarbamate ($\epsilon = 1.4 \times 10^4$ $1.mole^{-1}.cm^{-1}$). It is superior to the fluoresence method based on the use of Rhodamine B in that the colour system is quite stable and can find use for the determination of both arsenic(III) and arsenic(V) in the range 0.03–1.0 μg. The method also has the advantage of virtual freedom from interferences from extraneous ions and can therefore find use for the rapid and precise determination of trace amounts of arsenic in natural and synthetic samples.

TECHNICAL NOTE

ELEMENTAL ANALYSIS OF BOVINE LIVER BY INDUCTIVELY COUPLED PLASMA ATOMIC EMISSION SPECTROMETRY BY USING A SIMPLE DISSOLUTION PROCEDURE

T. N. Asp and W. Lund
Department of Chemistry, University of Oslo, Box 1033, N-0315 Oslo, Norway

(*Received* 31 *May* 1991. *Revised* 5 *September* 1991. *Accepted* 23 *October* 1991)

Summary—A simple digestion with nitric acid followed by filtration of the undigested lipids was found to be suitable for the decomposition of bovine liver, prior to multielement determination by inductively coupled plasma atomic emission spectrometry. Using reference materials, accurate results were obtained for cadmium, copper, iron, manganese, molybdenum and zinc.

The determination of metals in bovine liver by inductively coupled plasma atomic emission spectrometry (ICP–AES) requires dissolution of the sample. Many different decomposition methods can be used for this purpose.[1] Decomposition with a single acid or acid mixtures is performed either on a hot plate, in a microwave oven or under pressure in Teflon-lined steel bombs. Dry ashing is done either in a temperature-programmed muffle furnace, or by low temperature ashing in a low pressure oxygen plasma. Also solubilization with tetramethyl ammonium hydroxide may be used. De Boer and Maessen[2] compared all of these methods for the decomposition of bovine liver prior to ICP–AES analysis, and showed that in skilled hands, most of the methods gave accurate results for at least some elements. Dahlquist and Knoll[3] have compared wet and dry ashing of bovine liver for ICP–AES analysis, and found that wet ashing gave poorer detection limits because of the dilution, whereas dry ashing gave rise to element losses. Other workers have also used dry ashing[4] or low temperature ashing[5] for multielement analysis of bovine liver and other biological tissues by ICP–AES.

Apparently, there is not one decomposition method that stands out as the method of choice. However, the methods differ much with respect to the reagents used and the equipment and time needed for the digestion. An acid mixture which includes perchloric acid will normally ensure a complete mineralization of the biological material, but the use of perchloric acid should be avoided whenever possible, for safety reasons. Dry ashing in a muffle furnace usually requires heating for 10–30 hr, and the choice of a suitable crucible material and temperature programming is often essential. In addition, the use of an ashing aid such as magnesium nitrate is not to be recommended for dry ashing in combination with ICP–AES, because a high concentration of magnesium gives rise to an enhanced background and a depression of the emission signals.[6–8] The use of a microwave oven, high pressure bombs and low temperature ashing all require special equipment.

For routine analysis, an attractive decomposition procedure would be one that utilizes standard equipment, has a short digestion time, low reagent consumption and a low dilution factor. The last point is important because of the moderate detection limits of ICP–AES.

The suitability of a simple procedure based on heating with nitric acid was investigated in this work. A low dilution factor was considered essential, in order to determine trace metals like cadmium. Bovine liver is not a difficult matrix to dissolve, but some fat usually remains after treatment with nitric acid. Low values have been reported for copper and iron in bovine liver, using extraction with cold nitric acid.[2]

EXPERIMENTAL

Apparatus

A Perkin–Elmer ICP 5500B sequential inductively coupled argon plasma atomic emission spectrometer was used. The plasma generator, operating at 27.12 MHz, and the torch box was identical with those of the Perkin–Elmer ICP 6500, but the data system was a Model 3600 computer with a PR-100 printer. An all-quartz torch was used instead of the demountable torch. A peristaltic pump and a cross-flow nebulizer were used for sample introduction.

Materials

All reagents were of analytical-reagent grade. Multielement standard solutions were prepared from 1000 ± 0.5 ppm single-element standards (Spectrascan, Oslo). The bovine liver materials analysed were SRM 1577a from the National Institute of Standards and Technology (NIST; Gaithersburg, USA) and NSC-2 from Czechoslovakia.[9]

Digestion procedures

Procedure A (recommended). To a 0.5-g sample, add 10 ml of 65% nitric acid in a beaker and boil on a hot plate until *ca.* 1 ml of acid remains (1–2 hr). Transfer to a 10-ml standard flask and dilute to volume with water. Filter through a filter paper (Black Ribbon) before the ICP analysis.

Procedure B. Same as procedure A, except that the solution, including the water used for washing the beaker is filtered, before dilution to 10 ml in a standard flask.

Procedure C. To a 0.8–1.0-g sample, add 7 ml of nitric acid and 7 ml of water in a beaker and let it stand for 24 hr at room temperature. Filter the solution (and the washings) through a filter paper into a 25-ml standard flask and dilute to volume.

Procedure D. Same as procedure A, except that the remaining solution (*ca.* 1.5 ml) is finally diluted to 10 ml with methanol instead of water, and the filtration is omitted.

Procedure E. To a 1-g sample, add 16 ml of an acid mixture consisting of 9 ml of nitric acid, 6 ml of perchloric acid (70%) and 1 ml of sulphuric acid (95.5%). Heat on a water bath by slowly increasing the bath temperature to 100°, then continue the digestion on a hot plate until *ca.* 1 ml of acid remains. Cool, transfer to a 25-ml standard flask and dilute to volume with water.

Measurements

The plasma conditions used in this work were: plasma power 1.0 kW, plasma gas flow-rate 15 l./min, nebuliser gas flow-rate 1 l./min and viewing height 18 mm. The wavelengths used for the emission measurements were (in nm): Cd: 228.80, Cu: 324.75, Fe: 261.19, Mn: 257.61, Mo: 281.62, Zn: 213.85. Background correction was used for cadmium, manganese and molybdenum. The instrument was standardized with two multielement standard solutions. For each digestion procedure, the standards were matrix-matched with the samples, with respect to the concentration of acids. Also, three blank digestions were carried out for each procedure. Of the resulting solutions, one was run as a blank, while the other two were run as unknowns (control). The blank values were usually less than 10% of the sample concentrations.

RESULTS AND DISCUSSION

The two bovine liver materials SRM 1577a and NSC-2 were analysed. NSC-2 was obtained from Czechoslovakia and had a certified value only for cadmium.[9] The results obtained, using the digestion procedures A, B, C and E (see Experimental) are given in Tables 1–3. The two sets of results reported for procedure A in Tables 1 and 3 refer to digestions carried out at different dates. Each value given represents

the mean of the results from three parallel digestions. The corresponding standard deviations are also given. The standard deviations for repeated ICP-analyses of each sample solution are not shown, but these were generally lower than the standard deviations for parallel digestions.

From the Tables it can be seen that only procedure A gave results in agreement with the certified values for all metals and both samples studied. For copper and iron in NSC-2, the results should be compared with those obtained by procedure E, due to the absence of certified values.

The concentration of cadmium (Tables 1 and 3) was close to the detection limit. When the detection limit was determined experimentally,[10] a value of 4 μg/l. was obtained, based on three times the standard deviation of the background signal. This corresponds to 0.08 μg/g dry liver, when procedure A is used. For the other elements, the detection limits were of little interest, because these were at least a factor of 0.002 lower than the actual concentrations in the liver material, except for molybdenum, where the factor was *ca.* 0.05.

All samples were apparently dissolved completely, after being boiled with nitric acid for 1–2 hr (procedure A). However, when the digest was cooled, some fat appeared on the surface, and some was also formed when the digest was diluted with demineralized water. For this reason, the solution was filtered before the ICP analysis. From Tables 1 and 3 it can be seen that the filtration must be done after the sample has been diluted to volume (procedure A). If the digest is filtered before the final dilution to 10 ml (procedure B), low results are obtained, because of adsorption losses during the filtration. It was found that the adsorption losses could be minimized by a more thorough washing of the filter paper, but the resulting larger dilution factor prevented the quantitative determination of cadmium in this case.

Low results were also obtained with procedure C, indicating that treatment with diluted nitric acid at room temperature for 24 hr does not release all metal. The method is similar to the extraction procedure used by De Boer and Maessen,[2] who also obtained low results for copper and iron. Obviously a high temperature is more efficient than a long time for releasing these metals. Somewhat better results were obtained when concentrated nitric acid was used instead of the 1 + 1 diluted acid in procedure C, but the values were still low.

To avoid the formation of fat, attempts were made to dilute the solution to volume with methanol instead of water (procedure D). It was found that the resulting solution (85% methanol) could be handled by the ICP-instrument, provided a more narrow injection tube (0.85 mm), a higher power (1.3 kW), and an auxiliary gas flow (1 l./min) were used. However, the methanol depressed the emission signals, and caused a high and structured background around the three most useful

cadmium lines (214.44, 226.50 and 228.80 nm). Therefore, cadmium could not be determined in the samples diluted with methanol. In addition, the plasma was unstable and carbon was deposited in the injection tube. Therefore, the use of a methanol–water mixture as solvent appears to be unattractive for the determination of trace metals in biological material by ICP–AES.

BOOK REVIEW

Principles and Practice of Chromatography: B. RAVINDRANATH, Ellis Horwood, Chichester, 1989. Pages 502. £67.70.

This book is divided into four unequal parts. The first part—Basic Principles—is 62 pages long and consists of an overview and some theoretical concepts. The second part—Gas Chromatography—is a little longer (100 pages) and deals with basic instrumentation, separation and detection systems. The third part—Liquid Chromatography—is the longest (200 pages) and is broken up into three sections. The first section—Principles and Methods—includes work on size-exclusion chromatography (SEC), hydrodynamic chromatography (HDC), field-flow fractionation (FFF), counter-current chromatography (CCC), ion-exchange chromatography (IEC), suppressor ion chromatography (SIC), and hydrophobic (interaction) chromatography (HIC). The second section is on HPLC and the third section is headed "Planar Chromatography" and includes some work on HPTLC. Part 4—Applications—is 80 pages long and is divided into chemical, biological and biomedical, industrial, and miscellaneous subsections. The last includes some environmental applications. The references cover the period up to 1987.

The book is well written and the diagrams are good. It is quite comprehensive and is to be recommended.

SURFACE ENHANCED RAMAN SPECTROSCOPY ON COPPER HYDROSOLS

MARTIN J. ANGEBRANNDT and JAMES D. WINEFORDNER*
University of Florida, Gainesville, Florida 32611, U.S.A.

(*Received* 1 *August* 1991. *Revised* 7 *November* 1991. *Accepted* 14 *November* 1991)

Summary—Surface enhanced Raman spectroscopy (SERS) allows the detection of trace quantities of molecular species adsorbed onto a surface. The potential use of silver colloids as substrates for analytical SERS measurements is demonstrated. Detection limits and other analytical figures of merit for pyridine, *p*-aminobenzoic acid and *p*-nitrobenzoic acid are presented.

It has been established that the Raman scattering cross section can be increased by up to six orders of magnitude by bringing the molecule close to a surface.[1,2] Copper, gold and silver surfaces have generated the largest enhancements.[3,4] Because of this enhancement, Raman spectrometry can compete more effectively as a trace analysis technique with other molecular spectroscopies, such as fluorescence and phosphorescence. The advantage of surface enhanced Raman spectrometry (SERS) over these techniques is two-fold. First, not all molecules fluoresce or phosphoresce, whereas all molecules have vibrational modes accessible to SERS. Secondly, a SERS spectrum provides a wealth of information, allowing one to identify the molecule and/or differentiate it from a similar molecule. These provide the impetus for the development of SERS as a trace analytical technique. Reviews by Garrell[5] and Campion and Woodruff[6] have focussed on the application of Raman techniques to analytical problems.

Silver and gold colloids were first used as SERS substrates in 1979 by Creighton *et al.*[7] Most research on SERS has involved silver colloids as the substrate. Silver colloids are easily produced, provide fresh surfaces for adsorption of analyte molecules, and are easily excited by the 514.5 nm line of an argon ion laser. Silver hydrosols have been used for the quantitative analysis of drugs[8–10] and nitrogen containing heterocycles.[11,12]

Silver hydrosols have also been adapted for use with flow-injection analysis[13–15] and HPLC[16,17] systems; on line measurements increase reproducibility, thus lowering limits of detection. SERS has also been adapted to both paper[17,18] and thin layer chromatography[19] in an effort to further increase the detection power as well as the identification power of these separation techniques.

Copper colloids were first evaluated[20] for SERS in 1983; other studies[21–23] have also shown useful SERS spectra could be obtained with copper colloids. In this study, the SERS enhancement of pyridine by a citrate stabilized copper hydrosol was investigated. A later study found there was competitive adsorption between pyridine and citrate onto the silver colloid surface.[24] To minimize this interference, an unprotected copper colloid was used in the present study. The chemical enhancement mechanism should play a larger role with copper colloids than with silver colloids. However, the strength of the SERS signal also depends upon the number of analyte molecules in contact with the surface. The present work involves the investigation of copper colloids for use as an analytical SERS substrate. The colloidal surface is prepared by a simple borohydride reduction of cupric nitrate. These results illustrate the future of SERS on copper colloids for qualitative and quantitative analytical use.

EXPERIMENTAL

Apparatus

The instrumental set-up involved conventional 90° excitation–observation measurements. A Spectra Physics 2040 argon ion laser was used to pump a Spectra-Physics model

*Author for correspondence.

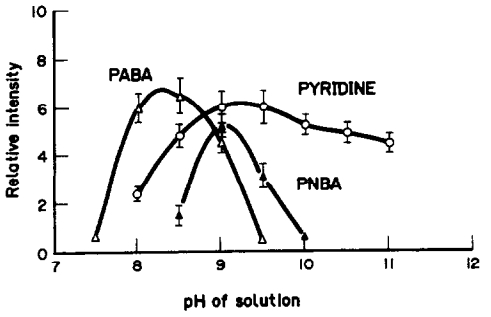

Fig. 1. The relative SERS intensity of the most intense band of the analytes as a function of pH. A 10 μg/ml solution and the 1010 cm^{-1} band were used for the pyridine curve. A 50 μg/ml solution was used for the evaluation of the 1397 cm^{-1} band of PABA and the 1387 cm^{-1} band of PNBA. Excitation is at 660 nm (150 mW).

375 dye laser (Spectra-Physics, Mountain View, CA). DCM (Exciton, Dayton, OH) was used to produce the necessary wavelengths. All measurements were made relative to the 200 mW of 660-nm exciting radiation. The stability of the output power and lasing frequency were continuously monitored with both a power meter and a 0.3-m McPhereson model 218 monochromator (McPhereson, Acton, OH) with a R928 Hamamatsu photomultiplier tube. The laser beam was directed through the sample twice and the scattered radiation collected at 90°. A 0.22-m Spex model 1680B double monochromator (Spex, Edison, NJ) with slits set for 6 cm^{-1} resolution was used for wavelength discrimination. The Raman scatter was detected with a thermoelectrically cooled (R636 Hamamatsu) photomultiplier tube. The photoelectron pulses were amplified and counted with a Stanford model 440 photon counter with a 1-sec acquisition time. The data was collected on an IBM PC. The Raman bands used for quantitative measurements were 1010, 1397 and 1387 cm^{-1} for pyridine, *p*-aminobenzoic acid, and *p*-nitrobenzoic acid respectively.

Chemicals and procedure

A 30-ml volume of a $2 \times 10^{-3} M$ cupric nitrate solution was added dropwise to 70 ml of a fresh $1.4 \times 10^{-2} M$ sodium borohydride solution at room temperature with stirring. Volumes (50 μl–200 ml) of analyte (1–200 μg/ml) were added to 100 ml of the above colloidal solution. The pH of the solution was then adjusted to maximize the SERS signal as shown in Fig. 1, using a small amount of nitric acid. The pyridine solutions were prepared in Barnstead distilled water. The PABA and PNBA solutions were prepared in 50:50 methanol:water solutions, using sonication if necessary. A portion of this pH adjusted solution was then placed in a standard 1×1 cm^2 cuvette. Measurements began 2.0 min after the first two reagents were completely combined. All glassware had been cleaned thoroughly with concentrated nitric acid and then rinsed repeatedly with Barnstead water. Pyridine, *p*-nitrobenzoic acid (PNBA), methanol and sodium borohydride were obtained from Kodak (Rochester, NY). Cupric nitrate and *p*-aminobenzoic acid (PABA) were obtained from Fisher Scientific (Pittsburgh, PA). The solutions of PABA and PNBA were prepared in 20% (v/v) methanol. All chemicals were analytical reagent grade or equivalent and were used without further purification.

RESULTS AND DISCUSSION

Pyridine (the major SERS peaks are given in Table 1) was chosen as the test compound for the initial optimization because it is soluble in water, has a large Raman cross section, adsorbs strongly to colloidal surfaces and SERS from pyridine has been observed previously on copper colloids. The enhancement factor for the pyridine 1010 cm^{-1} band, corrected for prefilter and post filter effects was calculated to be 1.8×10^5, which is in good agreement with previous results.[20] Pyridine proved a good choice, because of the relatively small effect that pH had upon its SERS signal relative to those of the other analytes (Fig. 1). The pH (~8.5) for the observation of the maximum SERS signal from pyridine differed from the pH previously observed for the copper electrode[25] and the copper colloid[20] studies. The pH for peak SERS signals for our system is 1.5 units higher than the study with the copper electrode,[25] where a

pH of 7.0 was used; the copper colloids undergo dissolution at approximately pH 7.0. The surface potential of the colloid in our case was controlled by the adsorbed species and the ionic strength, rather than with a potentiostat. The largest difference between these colloidal systems is the use of citrate as a protecting agent; citrate covers the colloid surface changing both the surface charge of the colloid and the partitioning of the pyridine between the bulk phase and the surface. In addition, there is competition between citrate and pyridine for the colloidal surface. PABA and PNBA exhibit a rather narrow pH range (optimum pH ~ 8.0 for PABA and pH ~ 9.5 for PNBA) over which appreciable SERS signals were obtained. The major SERS peaks (550–1900 cm^{-1}) for PABA and PNBA are given in Table 1; peaks agree well with those measured by other workers[26–29] obtained at silver electrodes and with silver-colloids.

Absorption spectra taken over a time period of about 15 min indicated colloidal particle sizes between ~20 and 100 nm and indicated considerable temporal instability of the copper colloids. As a result of the poor colloid stability, it was difficult to obtain reliable Raman spectra with wavelength scanning. Others[20,22–24] have obtained greater stabilities; however, in these cases, citrate was used to stabilize the colloids. Unfortunately, citrate competes with the analytes for the available surface sites and thus smaller enhancement factors should result with the previous citrate method. In addition, the time required for the citrate stabilized copper colloids[20,22–24] to reach maximum enhancement was 2–4 times as long as for our colloids (~13 min in our case). The present copper colloids protocol should therefore find more analytical use in flow-injection systems where timing and flow rates can be carefully controlled.[13,14] Nevertheless, we have evaluated the copper colloid system for *para*-aminobenzoic acid (PABA) and *para*-nitrobenzoic acid (PNBA) as well as pyridine (PY). The time-dependent SERS signals (1606 and 1397 cm^{-1}) for PABA are shown in Fig. 2.

The copper colloid system has a much lower background from Mie scatter than that observed with silver colloidal system because of the longer wavelength used for the former. Unfortunately, the SERS signals are also smaller, so that the signal to background ratio is not improved. An additional problem as stated above is that our copper colloid solutions

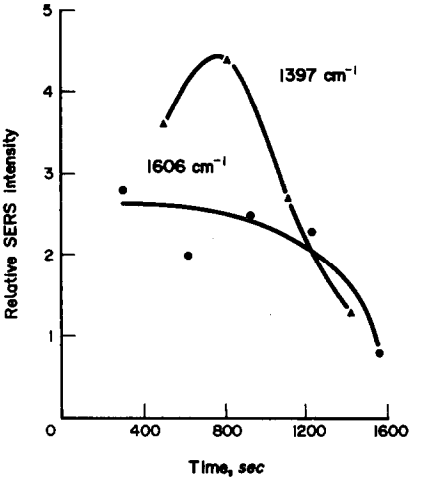

Fig. 2. Intensities of the 1606 cm^{-1} (filled triangle) and 1397 cm^{-1} (filled circle) SERS bands of PABA as a function of time. Conditions are the same as those in Fig. 1.

cannot be prepared more than 15 min ahead of time, whereas the silver colloid can be made stable for weeks.[7,16]

The colloidal copper surface has a linear dynamic range of 1–1.5 orders of magnitude (see Fig. 3) with an RSD of 15%. This limited dynamic range (LDR) is common with colloidal systems, since the signal is dependent on the adsorption isotherm. The limited LDR is the greatest disadvantage of colloidal based SERS. The limits of detection for PY, PABA, and PNBA are estimated to be 1.5 μg/ml ($1.9 \times 10^{-5} M$), 2.5 μg/ml ($1.8 \times 10^{-5} M$), and 13 μg/ml ($7.8 \times 10^{-5} M$), respectively. These results represent the first reported detection limits for SERS with copper colloids.

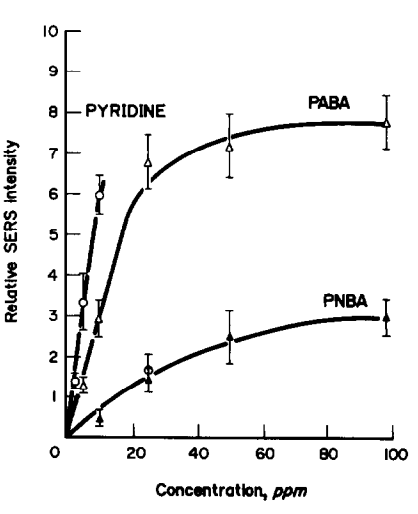

Fig. 3. Calibration curves for pyridine, PABA and PNBA. Conditions are as stated in Fig. 1 (excitation wavelength, laser region, peak pH values and Raman peaks).

DETECTION OF LOW MOLECULAR WEIGHT ALDEHYDES IN AQUEOUS SOLUTION BY MEMBRANE INTRODUCTION MASS SPECTROMETRY

TARUN K. CHOUDHURY, TAPIO KOTIAHO* and R. GRAHAM COOKS†
Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 25 *September* 1991. *Revised* 5 *November* 1991. *Accepted* 6 *November* 1991)

Summary—Membrane introduction mass spectrometry (MIMS) is used to detect low molecular weight aldehydes in aqueous solutions. The best sensitivity was obtained by aqueous phase derivatization of aldehydes with *O*-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine (PFBOA) and electron capture detection. This negative chemical ionization mass spectrometry procedure allowed the measurement of C_1–C_6 aldehydes at low concentrations in mixtures. The characteristic ion signals in the mass spectrum of the mixture were verified by examining the full mass spectra and product ion MS/MS spectra of the derivatives of individual aldehydes. A reaction scheme is proposed to explain the fragmentation pattern of the molecular anions ($M^{-\cdot}$) of the derivatives. The processes observed include loss of HF to form $(M–HF)^{-\cdot}$ ions which then competitively fragment by elimination of H(R)CN and NO$^{\cdot}$ to produce ions of *m/z* 178 and $(M–50)^{-\cdot}$, respectively. Multiple reaction monitoring was applied to establish the lower limits of detection. Formaldehyde could be detected without preconcentration at 1 ppb with S/N = 3/1. The detection limits of acetaldehyde, propanal and butanal were found to be 10 ppb and that of pentanal and hexanal were found to be 20 ppb. Response curves *vs.* concentration are linear in the ppb range. This method is not as readily applicable to the corresponding ketones.

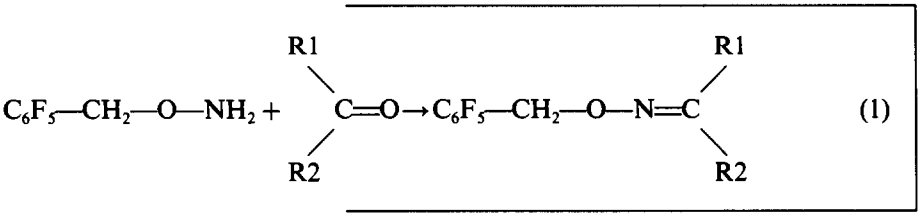
Low molecular weight carbonyl compounds are often present in drinking water,[1] where one of the major sources is the ozonation process used during water purification.[1] In addition to its use as a disinfectant, ozone is used to control odor, color and to reduce the iron and manganese content of water.[2] Carbonyl compounds are also formed naturally by the photodissociation of dissolved organic compounds in water.[3] In addition, industrial effluents can be a direct source of carbonyl compounds which are major by-products of some industrial processes and of such materials as industrial surfactants.[4] Of the low molecular weight carbonyl compounds, formaldehyde is of special interest because of its toxicity. Formaldehyde is mutagenic for some bacteria, fungi and yeasts[5] and has also been proven to be carcinogenic to rats and mice during long term inhalation exposure, even at low concentrations (2 ppm).[5] Due to these facts, safety levels of 0.11 mg/l. for adults[6] and 0.030 mg/l. for children[7] have been proposed for formaldehyde in drinking water. The high reactivity of carbonyl compounds with nucleophiles is an additional factor which makes the qualitative and quantitative analysis of these compounds in drinking water desirable.

Various analytical techniques have been applied for the detection of carbonyl compounds in ozonated water. Sievers *et al.*[8] used gas chromatography (GC) and gas chromatography/mass spectrometry (GC/MS) to study the products of secondary treated domestic waste water. They concentrated their samples with a polymeric sorbent (Tenax) prior to gas chromatographic analysis with a flame ionization detector or mass spectrometric detection. They were able to measure sub ppb levels of low molecular weight aldehydes. Kobayashi *et al.*[9] used GC with a flame ionization detector to quantify the low molecular weight carbonyl compounds in aqueous solutions as their pentafluorophenyl hydrazone derivatives at 200 ppb–8 ppm levels. Yamada and Somiya[10] used *O*-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine (PFBOA) to derivatize carbonyl compounds and GC with electron capture detection (ECD) to measure low ppb levels of the PFBOA derivatives. Glaze *et al.*[1] modified the aqueous-phase derivatization method for the detection of carbonyl compounds by using a high resolution

*On leave from Technical Research Center of Finland, Chemical Laboratory, Biologinkuja 7, 02150 Espoo, Finland.
†Author for correspondence.

capillary GC together with electron capture detection (ECD) or mass spectrometric detection (MS) with electron impact ionization. The reported detection limits were in the low ppb range for both detection modes.

PFBOA is an excellent derivatizing agent for carbonyl compounds since it reacts with them in aqueous solution to form the corresponding oximes (reaction 1).



Also the high fluorine atom content of PFBOA derivatives of carbonyl compounds suggests that very low detection limits might be achieved if electron capture detection is used with negative chemical ionization mass spectrometry. The first results of this type are presented here. Another advantage of electron capture negative ion chemical ionization mass spectrometry is the improvement in selectivity and sensitivity.[11-13] Moreover, the stability and volatility of the PFBOA derivatives suggest that membrane introduction mass spectrometry could be an excellent analytical method to analyze these compounds directly from aqueous samples.

Membrane introduction mass spectrometry (MIMS) is a successful analytical technique for the introducton of volatile non-polar organic molecules from aqueous solution.[14] The use of semipermeable membranes as a selective barrier which allows permeation of dissolved gases, but not the liquid phase, was first introduced by Hoch and Kok[15] to monitor dissolved gases produced by photosynthesis. Since then, MIMS has been used increasingly for the detection of trace organic compounds and for monitoring reaction products.[16-26] In most of these experiments, the membrane was placed externally to the mass spectrometer. This kind of experimental arrangement can suffer from poor response time, memory effects and analyte dilution because of condensation along the transfer line between the membrane and the ion source of the mass spectrometer. These problems can be reduced by sweeping the permeate into the mass spectrometer with an inert gas.[18] Alternatively, they are eliminated by the flow-through method which uses a direct insertion membrane probe (DIMP).[27-29] The DIMP places the membrane within the ion source of the mass spectrometer and allows the sample to be transported directly into the heated ion source. These probes have been successfully used for detection of a variety of organic compounds in water at parts-per-billion levels[29,30] and for on-line monitoring or organic reactions and fermentation products of bioreactors.[31-35]

This paper reports the application of membrane sample introduction, in combination with negative ion mass spectrometry, to measure quantitatively low molecular weight aldehydes in aqueous solutions. The PFBOA derivatives of the aldehydes were introduced into the mass spectrometer, using the membrane introducton probe and characterized by their negative ion electron capture spectra. Detection limits were also of interest and were measured with multiple reaction monitoring.

EXPERIMENTAL

The experimental arrangement used is shown in Fig. 1. A tandem mass spectrometer with a sheet membrane mounted in a direct insertion membrane probe (S-DIMP), already described in previous publications,[29-32] was used for this study. The membrane chosen was a dimethyl vinyl silicone polymer (ASTM: VMQ Dow Corning) with a thickness of 0.25 cm. The membrane probe used is provided with a programmable temperature control system which was used to maintain the membrane at a tem-

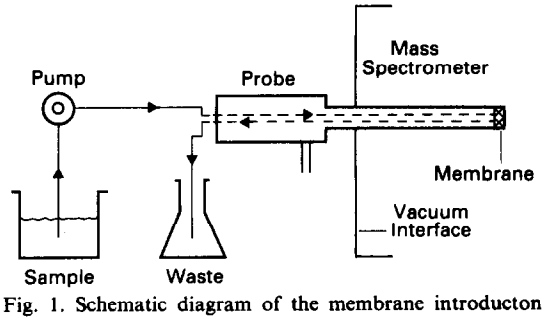


Fig. 1. Schematic diagram of the membrane introducton apparatus used in this study.

perature of 70° as read by a thermocouple located within the probe. A methanol–water (1:1) mixture was continuously pumped through the membrane interface at a rate of 1 ml/min with a peristaltic pump (Ismatec, Switzerland: model 7618-30). Methanol was used in the mixture in order to keep the sample introduction system clean. Sample plugs of 0.2-ml volume were injected into the methanol–water flow stream with a six-port liquid injector. The mass spectrometer used (Finnigan Corporation, San Jose, California, Model TSQ 4500) was operated with an INCOS data system. Negative ion chemical ionization was performed with isobutane as chemical ionization (CI) reagent to moderate electron energies and facilitate electron capture. The reagent gas pressure was 0.4 torr. Tandem mass spectrometry (MS/MS) product spectra were recorded in order to confirm the identity of the ions present in the mass spectra. In order to record the product spectra, a 20-eV collision energy and 1 mtorr of argon collision gas (*i.e.*, multiple collision conditions, approximately 80% beam attenuation) was chosen.

A stock solution containing 100 ppm each of C_1–C_7 aldehydes was made by dissolving the appropriate quantity of the compounds in methanol and diluting with distilled water. The stock solution was diluted successively with distilled water in order to make a series of solutions in the concentration range of 1 ppb–10 ppm for the measurement of detection limits. A 100-ppm solution of each of the compounds was prepared separately in order to study the mass spectra and MS/MS product ion spectra of individual aldehydes. *O*-(2,3,4,5,6-Pentafluorobenzyl)-hydroxylamine hydrochloride (PFBOA), supplied by Aldrich Chemical Company, Milwaukee, Wisconsin, was 99% pure. It was dissolved in distilled water in order to make a 1-mg/ml solution. The PFBOA derivatives were prepared by the method of Glaze *et al.*[1] To 5 ml of the aqueous sample was added 2 drops of 0.1*M* sodium thiosulphate and 0.5 ml of PFBOA solution. The mixture was shaken and allowed to react for a few minutes. Finally 1 drop of concentrated sulphuric acid was added before injection of the derivatized solution into the methanol–water flow stream.

RESULTS AND DISCUSSION

Electron impact (EI) spectra of the underivatized aldehydes examined in methanol at 100 ppm, were first recorded by MIMS. In the EI mass spectrum of formaldehyde, the molecular ion peak (*m/z* 30) was not readily observed because of the strong signals due to oxygen gas (*m/z* 32) and nitrogen gas (*m/z* 28). Similarly, in the EI mass spectrum of acetaldehyde, the signal due to carbon dioxide made it difficult to identify the molecular ion peak (*m/z* 44). For propanal a distinct molecular ion peak was observed at *m/z* 58 in the EI mass spectrum, but, it was not possible to detect sub ppm levels. For the other aldehydes (C_4–C_7), only fragment ions and no molecular ion peaks were observed. Since much better signal intensity and characteristic peaks for each of the aldehydes were observed by negative ion chemical ionization mass spectrometry of the PFBOA derivatives, this method was used to develop an analytical procedure for direct analysis of aldehydes in water samples.

Figure 2 shows the negative ion chemical ionization mass spectrum of a mixture of PFBOA derivatives of the C_1–C_7 aldehydes. The base peak at *m/z* 181 and the peak at *m/z* 197 both arise from the derivatizing group and are due to the pentafluorobenzyl anion $C_6F_5CH_2^-$ and the pentafluorobenzyloxy anion $C_6F_5CH_2O^-$, respectively. The second most intense peak at *m/z* 178 is due to successive loss of the neutral molecules HF and HCN (or RCN) *i.e.* ($M^{-\cdot}$–HF–H(R)CN). The loss of HF must involve a fluorine atom from the aromatic ring and is proposed to involve the cyclization shown in scheme 1. Further loss of HCN (or RCN) yields the quinoid anion radical shown.

The intact molecular ions of the PFBOA derivatives are of very low abundance compared to the base peak, *e.g.*, that for formaldehyde (*m/z* 225) is ~4% of the base peak. The peaks for the molecular anions are at *m/z* 239, 253, 267, 281 and 295 for the derivatives of acetaldehyde, propanal, butanal, pentanal and hexanal have less than 1% of the base peak abundance. The molecular ion peak for hepatanal (*m/z* 309) is of negligible intensity. Different ion source temperatures in the range 60–200° were used in order to check the effect of ion source temperature on the ion abundance. But, there was no noticeable change of signal intensity with the change of temperature indicating that the reactions shown in scheme 1 are ionic processes without contributions from thermal dissociation of the neutral PFBOA derivative. The $(M–HF)^{-\cdot}$ peaks at *m/z* 205, 219, 233, 247, 261, 275 and 289 for formaldehyde, acet-

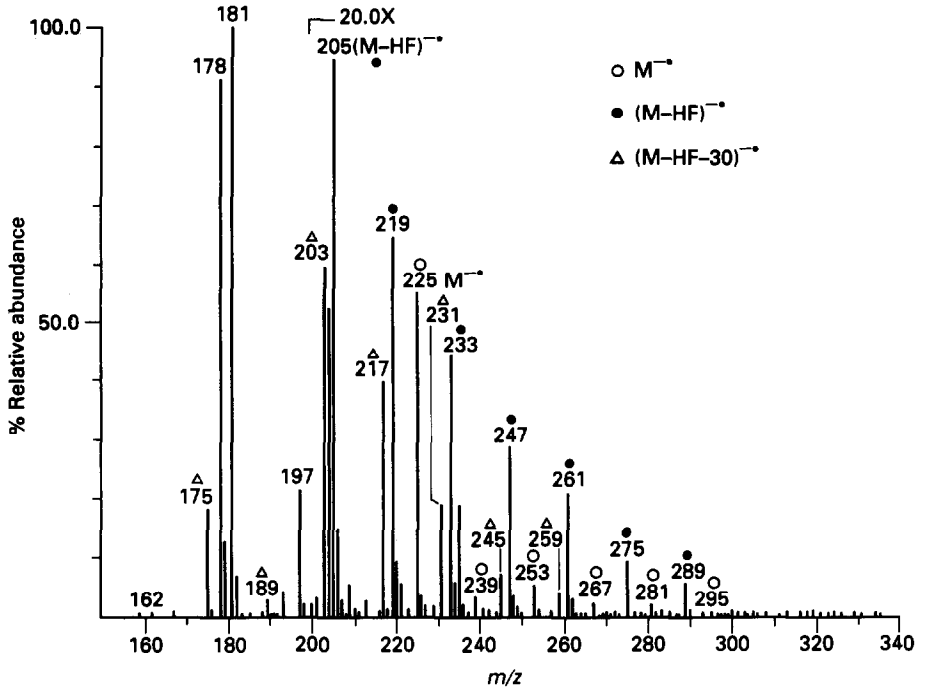

Fig. 2. Negative ion chemical ionization mass spectrum of PFBOA derivatives of a mixture containing 100 ppm of C_1–C_7 aldehydes.

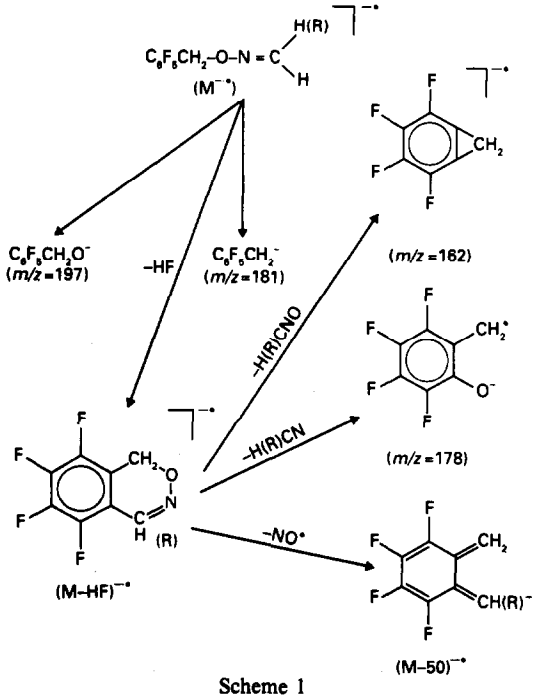
aldehyde, propanal, butanal, pentanal, hexanal and heptanal, respectively, are significantly more abundant than the corresponding molecular ion peaks. As we go from m/z 205 towards m/z 289, the peak intensity decreases, indicating that as the size of the molecule increases the rate of permeation through the membrane decreases.



Scheme 1

Another factor that may be partly responsible for this observation is the higher reactivity of the smaller aldehydes towards the derivatizing agent. Similar results were observed by Glaze *et al.*[1]

In order to confirm the identity of the characteristic peaks in the mixture, mass spectra and product MS/MS spectra for each of the compounds were examined individually. The product MS/MS spectra of the molecular anion radicals for formaldehyde, acetaldehyde and propanal derivatives are shown in Fig. 3(a), (b) and (c), respectively. The product MS/MS spectra for the other aldehydes (C_4–C_7) are similar to these three. Each of the product ion spectra displays $(M–HF)^{-\cdot}$, m/z 181 ($C_6F_5CH_2^-$) and m/z 178 [$M^{-\cdot}$–HF–H(R)CN] peaks, in addition to their molecular ion peaks. A minor peak in the MS/MS spectra which is of considerable intensity in the mass spectra is ($M^{-\cdot}$–HF–30) occurs at m/z 175 for formaldehyde, 189 for acetaldehyde, 203 for propanal, 217 for butanal, 231 for pentanal, 245 for hexanal and 259 for heptanal. The origin of these peaks was confirmed by examining the product MS/MS spectra of ($M^{-\cdot}$–HF) for each of the compounds. As an example, the product MS/MS spectra of the ($M^{-\cdot}$–HF) ions of butanal, pentanal and hexanal derivatives are shown in Fig. 4(a), (b) and (c), respectively, and they are seen

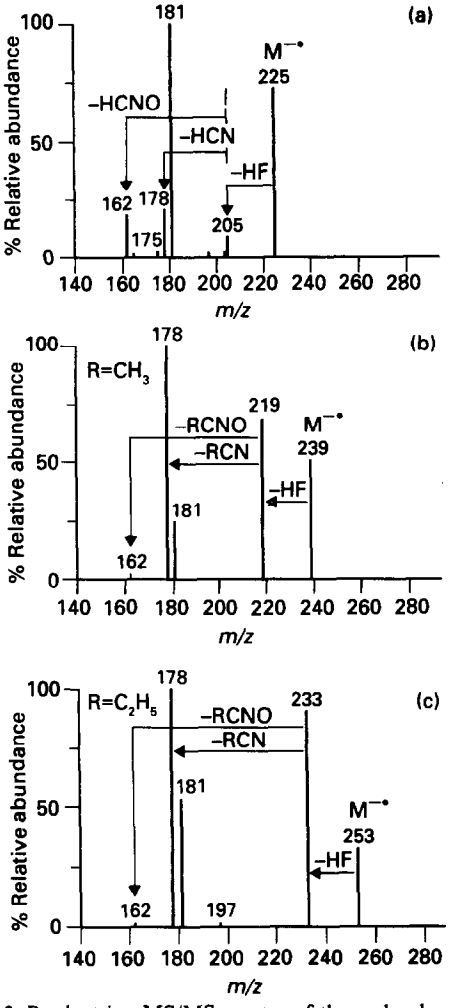


Fig. 3. Product ion MS/MS spectra of the molecular anion radicals of (a) formaldehyde, (b) acetaldehyde and (c) propanal; collision energy 20 eV and collision gas (argon) pressure 1 mtorr.

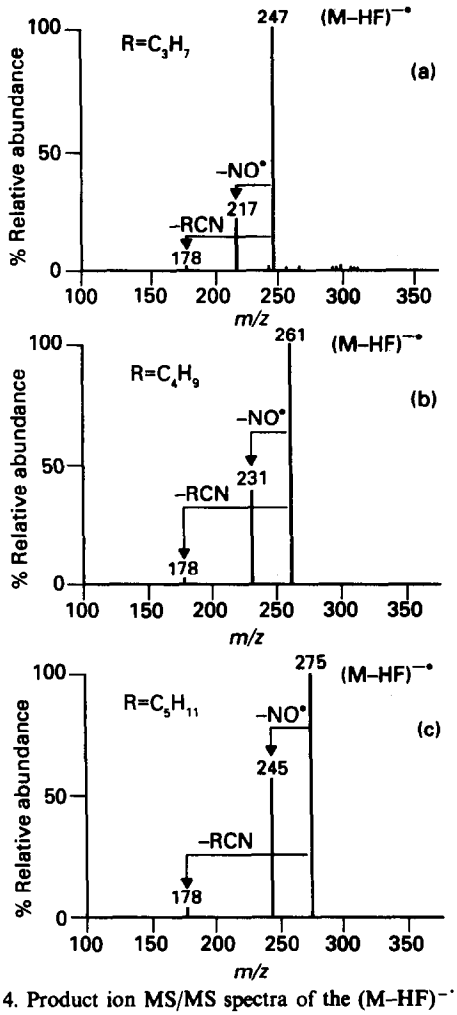

Fig. 4. Product ion MS/MS spectra of the $(M-HF)^{-\cdot}$ ions for (a) n-butanal, (b) n-pentanal and (c) n-hexanal; collision energy 20 eV and collision gas (argon) pressure 1 mtorr.

to be dominated by an ion due to loss of 30 daltons. These peaks are assigned to the loss of NO from ($M^{-\cdot}$–HF) ions and yield closed shell quinoid anions as shown in Scheme 1. The alternative possibility, that 30 corresponds to CH_2O loss, is consistent only with the data for the PFBOA derivative of formaldehyde itself but not with that for the higher aldehydes. The ($M^{+\cdot}$–30) ion peaks observed by Glaze *et al.*[1] for the PFBOA derivatives of formaldehyde, acetaldehyde and propanal were assumed to be due to the loss of NO from the molecular ions. In our negative ion electron capture mass spectra and MS/MS spectra no ($M^{-\cdot}$–NO) ion peak was observed. The characteristic ion peaks for each of the aldehydes are shown in Table 1.

Table 1. Characteristic ions for PFBOA derivatives of aldehydes

	$M^{-\cdot}$	($M^{-\cdot}$–HF)	($M^{-\cdot}$–HF–30)	Peaks from derivatizing reagent
Formaldehyde	225	205	175	197, 181, 178
Acetaldehyde	239	219	189	197, 181, 178
Propanal	253	233	203	197, 181, 178
n-Butanal	267	247	217	197, 181, 178
n-Pentanal	281	261	231	197, 181, 178
n-Hexanal	295	275	245	197, 181, 178
n-Heptanal	309*	289	259	197, 181, 178

*Observed in the mass spectrum of the individual compound but not observed in the mass spectrum of the mixture.

Table 2. Detection limits measured by multiple reaction monitoring

	Ion selected with first quadrupole	Ions monitored	Detection limit
Formaldehyde	225	225, 205, 178, 181	1 ppb
Acetaldehyde	239	239, 219, 178, 181	10 ppb
Propanal	253	253, 233, 178, 181	10 ppb
n-Butanal	267	267, 247, 178, 181	10 ppb
n-Pentanal	281	281, 261, 178, 181	20 ppb
n-Hexanal	275	275, 178, 181	20 ppb
n-Heptanal	289	289, 178, 181	1 ppm

Another characteristic feature of the fragmentation patterns is the appearance of a significant amount of ion m/z 162 in the product MS/MS spectra of the molecular ion of the derivatives, especially in the case of formaldehyde, whereas in the full mass spectra, the intensity of the signal for m/z 162 is very small. Due to the addition of internal energy supplied to the parent ion in the collision region during the MS/MS experiment an additional fragmentation route opens up leading to the production of m/z 162 ions. This reaction channel dominates over the direct decomposition channel of the molecular ion to produce m/z 197 which appears as quite an intense signal in the mass spectra.

In order to test the capability of the method to distinguish between isomers, mass spectra and product MS/MS spectra of n-butanal and isobutanal were compared. Some differences were observed but they were sufficiently small to make it difficult to distinguish the isomers in mixtures.

In order to measure detection limits for the aldehydes, multiple reaction monitoring was used. For formaldehyde, $M^{-\cdot}$ (m/z 225) of the PFBOA derivative was selected by using the first quadrupole, and the characteristic product ions m/z 205, 178 and 181 were monitored to establish the detection limit. The detection limit of formaldehyde was found to be 1 ppb with S/N = 3/1. The detection limits for other aldehydes were established in a similar way. The molecular ions selected with the first quadrupole and the product ions monitored during an MS/MS experiment to measure the lower limits of detection of the aldehydes are listed in Table 2. Table 2 also lists the detection limit for each of the aldehydes. The detection limit for acetaldehyde, propanal and butanal was found to be 10 ppb and that of pentanal and hexanal was 20 ppb. Linearity up to 100 ppb was observed for the C_1–C_6 aldehydes. Figure 5 shows the range of linearity for each of the aldehydes. For heptanal, it was possible to detect below 1 ppm but, it was hard to establish the linear dynamic range. As the size of the aldehyde molecule increases, the reactivity towards the derivatizing agent decreases and at the same time the ease of passage of the derivative through the membrane decreases. This is also evident from Fig. 2 which shows that the intensity of the characteristic peaks of the derivatized aldehydes decreases with the increase in molecular weight.

An alternative method of achieving low detection limits is to employ $(M–HF)^{-\cdot}$ ions as precursors for aldehydes in multiple reaction monitoring. Some experiments, in which $(M–HF)^{-\cdot}$ ions on C_2, C_5 and C_6 aldehydes were selected as precursor ions in multiple reaction monitoring, were therefore done and comparable detection limits were observed. The greater abundance of the parent ions is offset by the slightly higher noise level observed in $(M–HF)^{-\cdot}$ ions than $M^{-\cdot}$ ions.

An attempt was made to use the tandem mass spectrometer equipped with the DIMP to detect the PFBOA derivatives of ketones in a mixture of aldehyde and ketone derivatives. When examined independently, the derivatives of acetone, 2-butanone and 2-pentanone passed through the membrane. The mass spectra of the ketones showed peaks for $(M^{-\cdot}–HF)$ ions in addition to the characteristic ions due to the

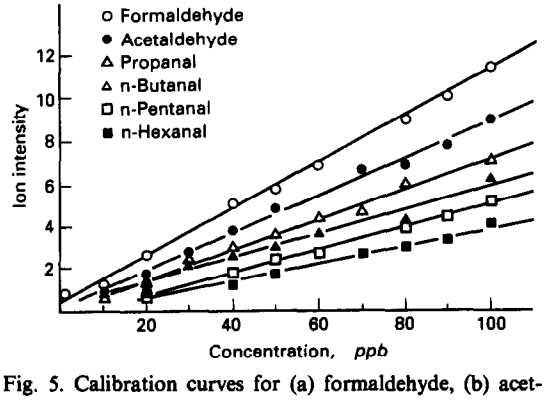

Fig. 5. Calibration curves for (a) formaldehyde, (b) acetaldehyde, (c) propanal, (d) n-butanal, (e) n-pentanal and (f) n-hexanal. The data were collected by multiple reaction monitoring.

derivatizing agent at m/z 181 and 197. Ketones generally took longer to undergo derivatization and, their detection limit was about 1 ppm. However when a mixture of derivatives of aldehydes and ketones was examined, the mass spectrum showed only the peaks for aldehydes. For example, in an experiment on a mixture of formaldehyde ($M^{-\cdot}$, m/z 225), acetaldehyde ($M^{-\cdot}$, m/z 239), acetone ($M^{-\cdot}$, m/z 253), 2-butanone ($M^{-\cdot}$, m/z 267) and 2-pentanone ($M^{-\cdot}$, m/z 281), the negative ion spectrum showed only the characteristic signals for formaldehyde and acetaldehyde and no signals for the ketones. This is not because of a failure to derivatize the ketones but due to preferential membrane transport of the aldehyde derivatives over the ketone derivatives in the presence of each other.

CONCLUSIONS

Sample introducton via a direct insertion membrane probe was used to detect low molecular weight aldehydes directly from an aqueous solution containing a mixture of C_1–C_7 aldehydes. Electron impact ionization of the underivatized aldehydes is unable to detect sub ppm levels of these compounds. Derivatization with PFBOA and ionization by electron capture allows the measurement of much lower concentrations of the aldehydes. A fragmentation scheme is proposed to explain the identity of the ion signals observed in the mass spectra and MS/MS product spectra of the derivatives. The molecular ions ($M^{-\cdot}$) produced via electron capture in the ion source of the mass spectrometer lose HF to produce $(M–HF)^{-\cdot}$ ions which, in the mass spectra, show significantly more intense signals than do the corresponding molecular ions. The $(M–HF)^{-\cdot}$ ions undergo further dissociation to produce ions m/z 178 and $(M–HF–30)^{-\cdot}$ which also appear as intense signals in the mass spectra. The use of multiple reaction monitoring helps to measure the detection limits of each of the aldehydes to the low ppb level. Calibration curves were linear up to 100 ppb. The method is less satisfactory for the corresponding ketones when a silicone membrane is used as an interface.

(*Received* 25 *July* 1991. *Revised* 19 *November* 1991. *Accepted* 19 *November* 1991)

Summary—The slotted quartz tube has been applied to flow-injection flame atomic-absorption spectrometry (FI–FAAS) showing several important advantages. The tube life was improved by a factor of 5–6 compared to conventional continuous aspiration. Flow impact systems were found not to be necessary in the applications so that larger enhancement factors may be achieved without sacrifice in precision. For 1.0 mg/l. copper, 1.0 mg/l. lead, 0.1 mg/l. cadmium and 1.0 mg/l. gold sensitivity enhancement factors of 3.1, 5.5, 5.3 and 4.0 were obtained with precisions of 1.3%, 1.1%, 1.6% and 1.7% RSD ($n = 11$) respectively. Application of the slotted quartz tube FI–FAAS method to the determination of heavy metals in urine has shown improved tolerance to interfering matrices. Recoveries obtained by spiking undiluted urine samples with 0.1 mg/l. copper and lead, and 0.01 mg/l. cadmium were in the range 100–102%.

In 1977, Watling first reported the application of a slotted quartz tube to improve the sensitivity of flame atomic-absorption spectrometry (FAAS) for a number of volatile elements.[1] In most applications sensitivity may be enhanced by a factor of 3–5 due to an increase in the residence time of the analyte atoms in the light path of the atomic-absorption spectrometer. Despite the simplicity of the approach, the application of the technique has been rather limited. One of the principle reasons for this seems to be the relatively short life time of the quartz tube, particularly when the samples contain substantial amounts of alkaline metals. It has been reported that the lifetime of the quartz tube may be prolonged by coating the tube with aluminium oxide.[2] This may be easily achieved by conventionally nebulizing an aluminium nitrate solution on the heated quartz tube for 10–15 min.[2] Later, Brown *et al.* conducted a critical comparison of the lifetimes of uncoated tubes and tubes coated with aluminium oxide, aluminium metal and lanthanum oxide.[2] The study revealed that the coating procedure prolonged the tube lifetime for more than one-fold. However, even with the coating treatment, the tubes lasted for only 240–360 samples containing 1% sodium chloride (w/v) using conventional continuous sample introduction. In order to further extend the tube lifetime, Brown and Taylor suggested discrete sampling (100-μl aliquots) of urine samples,[3] which increased the lifetime of an uncoated tube more than one-fold. However, deterioration of the sensitivity and precision were also observed, and hence could not always be recommended.

The flow-injection (FI) technique has been used successfully for the introduction of micro-samples in FAAS. It was shown recently that under optimized conditions of carrier flow-rate, nebulization rate and with careful control of sample dispersion in the sample loop and transport conduit, as low as 70-μl sample volumes may be introduced, giving almost the same sensitivity and precision as conventional continuous sample introduction.[4] As smaller sample volumes may shorten the exposure of the quartz tube to detrimental effects, flow-injection sample introduction appears to be a reasonable approach for further increasing the lifetime of the slotted quartz tube without sacrificing sensitivity and precision. The feasibility and performance of such a combination are studied in this work.

cadmium, lead and gold lamps were operated at 15, 6, 10, and 10 mA with wavelengths set at 324.8, 228.8, 283.3, and 242.8 nm, respectively. The spectral bandpass was 0.7 nm for all the elements studied. The instrument was operated either with a flow spoiler or impact bead system, or without any impact system, as specified separately for the individual experiments. Results were evaluated in the peak height mode with a time constant of 0.5 sec. Flame conditions were as recommended by the instrument manufacturer. Three different designs of slotted quartz tubes were used in this study. The dimensions of the narrower slotted quartz tubes were mainly those given by Taylor and Brown,[5] which were 8 mm i.d., 10 mm o.d. and 130 mm long, with either a single slot along the axis measuring 50 mm long (tube A), or two slots on opposite sides of the tube, with the lower slot measuring 50 and the upper slot measuring 40 mm long (tube B). The slot widths were not given in reference 5; a slot of 0.7 mm was used in this study as recommended by Liu *et al.*[6] The dimensions of the wider slotted tube (tube C) were those following a design of Burns *et al.*[7] The tube was 15 mm i.d., 18 mm o.d. and 130 mm long, with a lower slot measuring 3 mm wide and 110 mm long. Six holes, of 6 mm diameter and 9 mm apart were made on the tube 180° opposite the slot. The tubes were fixed directly above the burner, using a holder made of 3-mm diameter aluminium wire which was clamped on the back wall of the burner compartment. The arrangement was made to facilitate the ignition of the burner. The burner head could then be moved out of the light beam, in which the slotted tube was positioned, and cleared out a space for the ignitor to function without disturbing the tube position. Fine adjustments were made so that the tube slot (or slots) were aligned exactly over, and in the central section of the burner slot. Experiments were conducted to optimize the gap width for the three tube designs in respect to sensitivity and precision. The optimum gap width between the tube and the burner was 4 mm for the tubes A and B, and 10 mm for tube C, and these were used for further experiments.

A Perkin–Elmer FIAS-200 FI system was used for sample introduction. The FI manifold was as described previously.[8] The transport conduit was a 20-cm long, 0.35-mm i.d. Tygon tubing, and the sample loops were 0.5-mm i.d. Micro-line tubing (Thermoplastic Scientifics, Sterling, NY, U.S.A.), knotted into a 3-dimensionally disoriented configuration to limit the dispersion.[4] The instrument was programmed to operate with a sample loading period of 10 sec and an injection period of 5 sec. The demineralized water carrier stream had a flow rate of 6.0 ml/min, and the nebulizer free uptake rate was 8.0 ml/min.

The aluminium coatings were applied by conventionally nebulizing an aluminium sulphate solution containing 0.5% (w/v) aluminium for 15 min with the quartz tube in the operation position. Experiments were conducted to compare the lifetimes of coated and uncoated quartz tubes under FI conditions by repeatedly introducing samples in batches of 99 at a time, the tubes were cooled down to room temperature between batches. The tests were carried on until complete breakdown of the quartz tubes occurred.

All reagents were of analytical reagent grade, and demineralized water was used throughout. The test solutions were prepared from 2-step dilutions of 1000 mg/l. stock solutions of the analyte elements. An aqueous solution containing 0.5% Al (w/v) in the form of aluminium sulphate was used for coating the quartz tubes. Urine samples were acidified with 10% hydrochloric acid (v/v) to contain 0.1% hydrochloric acid (v/v) immediately after collection; no further dilutions were made for the AAS determinations.

RESULTS AND DISCUSSIONS

Studies on various experimental parameters

The impact systems in the spray chamber of an atomic-absorption spectrometer are considered mandatory for good precision in conventional FAAS. Although some impact systems, such as the flow spoiler, produces significantly lower sensitivity than using an impact bead or without impact systems, the detection limits do not become poorer due to the better precision. This is because of the more favourable droplet size distribution of the aerosol, after excluding a bigger fraction of the larger droplets. The situation might be somewhat different when a slotted quartz tube is used in the flame, or when FI sample introduction is used with carrier flow-rates lower than the free nebulizer uptake rate. In the former case, the longer residence time of the dried aerosol particles in the heated quartz tubes, and additional collision of the particles on the heated tube walls may provide a better opportunity for any

Table 1. Effect of spectrometer impact system on the sensitivity and precision of 0.100 mg/l. cadmium with conventional FAAS, FI–AAS and slotted quartz tube FI-AAS

Method	Performance	Impact system		
		Flow spoiler	Impact bead	None
Conventional	Characteristic concentration (*mg/l.*)	0.041	0.032	0.027
	RSD, % ($n = 11$)	1.8	2.3	3.5
FI–AAS	Characteristic concentration (*mg/l.*)	0.043	0.033	0.028
	RSD, % ($n = 11$)	1.5	1.3	1.6
Conventional introduction and slotted tube	Characteristic concentration (*mg/l.*)	0.012	0.008	0.006
	RSD, % ($n = 11$)	1.4	2.0	2.8

	RSD, % ($n = 11$)	1.5	1.4	1.5

undissociated larger particles to atomize; the tube may also act as a damping system to lower the short term flickering noise of the flame. In the latter case, nebulization efficiency is enhanced with lower carrier flows, which was also assumed to produce more favourable droplet size distributions. In both cases improvements in precision have been reported.[1,8] The improvement in droplet size distribution may also obviate the need for impact systems in the spray chamber, as has been shown previously.[8] Therefore, a comparison was made in this work to assess the function of the flow spoiler and impact bead systems with FI sample introducton, and with a slotted quartz tube flame atomizer, using cadmium as a model element. The results shown in Table 1 again demonstrate the favourable precision of flow-injection sample introduction without using impact systems, whereas the improvement in precision by applying slotted tubes were less pronounced. Although an improvement in precision could be observed with the slotted tube with or without impact systems using conventional sample introduction, the effect was no more noticeable in the FI mode. It seems that the impact system could not be dispensed with when samples are introduced conventionally, even using the slotted tube. In the FI mode, however, the impact systems only produced deteriorating effects on the sensitivity, with no improvement in the precision, regardless of the presence or absence of the slotted tube, at least under the experimental conditions adopted in this work. Thus, the best performance may be expected when the slotted tube is used in the FI mode without any impact systems, and the latter was removed from the spray chamber for all further studies.

The gap width between the slotted quartz tube and the burner seems to be an important parameter affecting the enhancement factor, particularly for copper. In this work, a preliminary study was made with FI sample introduction, using the narrow bored slotted tubes (A and B). The results in Table 2 show a significant decrease in enhancement factors with an increase in the gap width between the tube and burner, even from 2 to 4 mm, using a single slotted tube (tube A). The dual slotted narrow tube (tube B) behaved similarly. In fact, the

Table 2. Effect of gap width between burner and slotted tube on sensitivity enhancement factors and reproducibility, using FI sample introduction without impact system

Analyte element	Enhancement factor*			RSD, % ($n = 11$)		
	Tube A		Tube C	Tube A		Tube C

Concentration of test solutions Cu, 1.00; Pb, 1.00; Cd, 0.100; Au, 1.00 mg/l. Sample volume, 200 μl for Cu and 100 μl for all other elements.

*Enhancement factors derived from comparison of the slopes of the calibration curves obtained by FI introduction using the slotted tube without impact system and that obtained in the conventional mode using a spoiler impact system and without the slotted tube.

enhancement effect for copper was completely lost with a 4-mm gap; the enhancement factor would have been unity if compared to peak height obtained by flow-injection without impact systems. However, despite the higher enhancement factors of the smaller gaps, distances closer than 4 mm cannot be recommended, at least when the burner system used in this study was allowed to heat the tube continuously, owing to danger of overheating the burner head. The sensitivity enhancement effect for some elements, such as copper, can only be fully exploited, using more efficiently cooled burners. However, studies using the wide bored slotted tube (tube C) with a large gap of 10 mm between the tube and burner produced sensitivities and precisions which were almost identical to those of the narrow bored tube with a 2-mm gap. Therefore this latter design is recommended to prevent overheating of the burner head.

Previous studies on FI micro-sample introduction in FAAS showed that with careful control of sample dispersion, the steady state signal obtained by conventional nebulization may be approached with about 70 μl of sample.[4] With the slotted tube, however, a longer time (*i.e.*, a larger sample volume) is necessary to reach the steady state signal (see Fig. 1), the length of time depending on the analyte element. Therefore larger sample volumes had to be used to achieve a near steady state peak height signal. As larger samples containing substantial amounts of alkaline metals will inevitably shorten the lifetime of the tube (see later section), a compromise was made by using a sample volume of 100 μl for cadmium, lead and gold, achieving more than 90% of the steady state signal. For copper, however a larger sample volume of 200 μl was necessary to reach the same percentage.

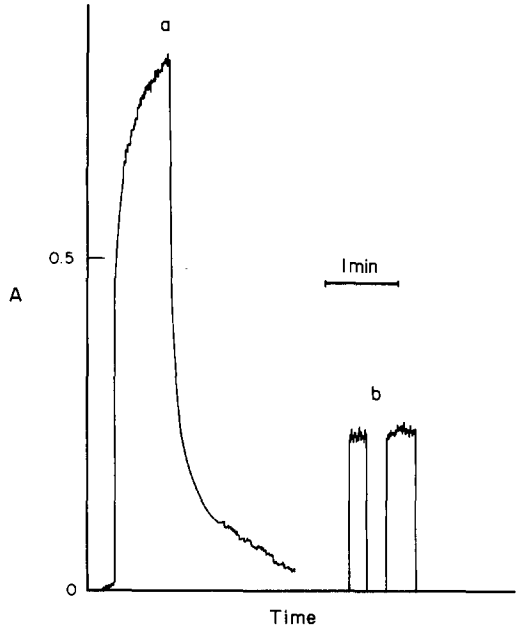

Fig. 1. Graphic recordings of 5 μg/ml Cu solution introduced in conventional FAAS mode (a) with slotted quartz tube and (b) without slotted quartz tube.

The model 2100 atomic-absorption spectrometer used in this study is an instrument with a single beam optical system, but capable of performing background offset correction in the double beam mode by automatically moving the burner in and out of the beam for each measurement as a standard mode of operation. Preliminarily, this feature was thought to be advantageous for increasing the lifetime of the quartz tube, as the heating period was shortened by moving the flame out of the tube during the sample loading period. This was not completely verified in the later experiments presumably because of the harmful effects created by frequently heating and cooling the quartz tubes and because the increase in lifetime of the quartz tube was not significant. Unexpectedly, however, when the burner was moved below the tube 2 sec before the injection of the sample, the enhancement factors for cadmium and copper were improved by 46, and 53%, respectively. Although the phenomenon still requires explaining, the beneficial effect may well be exploited when higher sensitivities are desired for these elements. However, to facilitate comparison, all data presented in this work were collected in the single beam mode, *i.e.*, without moving the burner.

Performance of aluminium oxide coated slotted quartz tubes with FI sample introduction

The sensitivity enhancement factors and the precisions of the aluminium oxide coated slotted quartz tube for copper, lead, cadmium and gold, using FI sample introduction are shown in Table 2 and are compared to those obtained under conventional slotted tube FAAS conditions. The enhancement factors for copper, lead, cadmium and gold with FI sample introducton with slotted tube C were 50, 20, 20 and 60% higher than those for conventional sample introduction, respectively, while precisions were marginally better in the FI mode. The reason for the better performance in the FI mode is that a flow spoiler was used in the conventional mode to ensure acceptable

precision, whereas no impact systems were necessary in the FI approach. The enhancement factors would have been similar if the comparisons were made against conventional sample introduction without an impact system; however, the precision in the conventional mode would have been significantly worse.

The small sample volumes injected (less than one-tenth of that consumed in conventional mode) allowed high sampling frequencies of over 360 samples/hr. Figure 2 shows the recordings from the graphic screen for the determination of cadmium in 1% sodium chloride matrix with and without the slotted tube. Besides the higher sensitivity for the slotted tube, it is also interesting to note a suppression of the background from the matrix. The phenomenon does not seem to have been reported previously, and may be associated with a more complete dissociation of molecular species in the sample matrix, but a closer study may be necessary to explain it fully.

Lifetime of the slotted quartz tube using FI sample introduction

The lifetimes of coated and uncoated slotted quartz tubes with FI sample introduction of samples containing 1% sodium chloride are shown in Table 3. Uncoated quartz tubes were reported to be quickly devitrified by sodium atoms in the flame, presumably through migration of the atoms into the hot quartz, forming sodium silicates, which on cooling, contracted and eventually destroyed the tube.[9] Coating of the tubes with a refractory oxide film by conventionally aspirating 0.5% lanthanum (as nitrate), aluminium (as nitrate), or vanadium (as ammonium vanadate) on the heated tube substantially increased the lifetime of the tubes.[2,9] In this work a comparison was made between aluminium oxide coated tubes and uncoated tubes. A comparison was also made between tubes coated by continuously nebulizing aluminium sulphate solution for 10–15 min, as recommended by other workers[2] and using a more dilute coating solution (0.1% Al) as a carrier stream after the preliminary coating. The latter procedure was expected to provide a steady regeneration of the film when it was gradually consumed with extended use. The difference in lifetime of the two alternatives was, however, not significant, and the carrier stream approach was discontinued due to an accumulation of aluminium oxide on the burner slot, which then required frequent cleaning. It has been reported that the tube lifetime could also be prolonged by using discrete micro-volume sampling (pulsed nebulization) instead of conventional continuous nebulization.[2,3] Although specific data on the effect were not given, it may be drawn from the related data that about 800 samples containing 1% sodium chloride may be

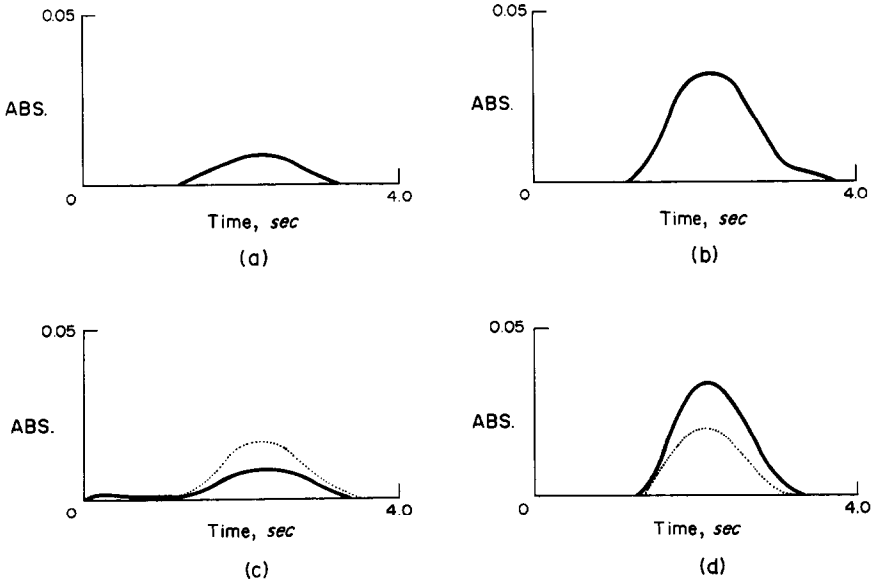

Fig. 2. Graphic recordings of FI–FAAS. Determination of 50 μg/l. Cd in (a) and (b), simple aqueous solutions; and (c) and (d), 1% NaCl solution; (a), (c), without slotted quartz tube; and (b), (d), with slotted quartz tube. No impact system was used. Carrier flow-rate, 6 ml/min; nebulizer free uptake, 8 ml/min. Sample volume, 100 μl. Solid lines, analyte absorption signals; dotted lines, background absorption signals.

Table 3. The lifetime of slotted quartz tubes in the analysis of samples containing 1% sodium chloride, in number of samples analysed

Tube coating	Continuous nebulization	Pulsed nebulization	FI
Aluminium oxide	240 (ref. 3)	(~800)	1900–2100
Uncoated	140 (ref. 3)	320 (ref. 3)	910

analysed by using coated quartz tubes with discrete introduction of 100 μl-samples. However, pulsed nebulization was found to degrade both the sensitivity and precision of the results,[3] the benefits gained by using the slotted quartz tube were therefore at least partially lost.

As shown in Table 3, the improvement in the lifetime of the slotted tube using FI sample introduction is quite significant, even when compared to conventional pulsed nebulization. Approximately 2000 samples containing 1% sodium chloride analysed with a single aluminium oxide coated quartz tube appears to be the longest lifetime reported thus far for slotted quartz tubes. The reason for the improvement is presumably the stronger washing action of the carrier stream which has previously been shown to be very effective in decreasing the accumulation of salts on the burner slot.[10] This would in turn decrease the exposure of the quartz tube to the corrosive matrix salts.

In contrast to conventional pulsed nebulization, FI sample introduction did not produce deteriorating effects on the sensitivity and precision of the determinations for the elements studied in comparsion to conventional continuous sample introduction. In fact, a slightly higher sensitivity may even be achieved in some cases, a phenomenon which has been observed and discussed previously.[8] The increase in the tube lifetime, which was reported to be 240 samples with aluminium oxide coated tubes (1% sodium chloride sample) with conventional sample introduction[2] is thus much more meaningful than using conventional discrete sampling.

Application of the slotted quartz tube to the determination of copper, cadmium, and lead in urine samples by FI–FAAS

The determination of heavy metals in serum and urine has been a main field of application of the slotted quartz tube technique in recent years.[2,3,5,6,9] While simple aqueous standards may be used for the analysis of diluted serum samples, the determination of lead, cadmium and copper in urine samples required the use of "urine equivalent" standards to achieve good recoveries.[2] The observed matrix effect in urine samples was thought to be at least in part due to changes in the aspiration rate. With FI sample introduction, such effects may be minimized by using a pump-propelled steady carrier flow. With this in mind, we attempted to use simple aqueous standards for the FI analysis of original urine samples. The recoveries obtained by spiking the urine samples with 0.1 mg/l. copper and lead, and 0.01 mg/l. cadmium were 100, 102 and 101% respectively, which demonstrate yet another advantage of the FI approach.

CONCLUSIONS

FI sample introduction significantly improves the lifetime of the slotted quartz tube atomizer used for FAAS by a factor of 5–6, compared to conventional continuous aspiration, without loss in sensitivity and precision, thus overcoming one of the main disadvantages of the slotted quartz tube technique. Impact systems were not found to produce better precision with FI sample introduction either with or without the slotted quartz tube, but higher sensitivities may be achieved without impact systems. Application of the FI method to the determination of heavy metals in urine has shown improved tolerance of interfering matrix effects and significantly higher sample throughputs.

The sensitivity enhancement effects of the slotted quartz tube technique may not be as impressive as FI on-line column preconcentration procedures for FAAS where 20–30 fold enhancements could be achieved under normal FAAS sampling frequencies and sample consumption levels.[11] However, preliminary studies on applying the two techniques simultaneously have shown that the enhancement effects of the two techniques are completely multiplicative. It is therefore reasonable to anticipate the achievement of enhancement factors of 100 or more with sampling frequencies of 120 samples/hr in the near future. Work on the above is now under development.

A DUAL-WAVELENGTH LIGHT-EMITTING DIODE BASED DETECTOR FOR FLOW-INJECTION ANALYSIS PROCESS ANALYSERS

JIALIN HUANG, HANGHUI LIU, AIMIN TAN, JINHUA XU and XINNA ZHAO

Centre for Process Analytical Chemistry, Department of Chemistry, Central South University of Technology, Changsha, Hunan 410083, People's Republic of China

(*Received* 5 *August* 1991. *Revised* 1 *November* 1991. *Accepted* 1 *November* 1991)

Summary—In this paper, a small dual-wavelength light-emitting diode (LED) based detector for FIA process analysers is designed. The detector's optical parts include a flow cell, a dual-wavelength LED and a photodiode. Neither mirrors nor lenses are used. The optical paths for the different light beams are almost the same, distinguishing it from previously reported LED based detectors. The detector's electronic components, including a signal amplifier, an A/D and D/A converter, and an Intel 8031 single-chip microcomputer, are integrated on one small board. In order to obtain response signals of approximate intensity for the two colours, the D/A converter and a multiplexer are used to adjust the emission intensity of the two colours respectively. Under microcomputer control, light beams are rapidly electronically modulated. Therefore, dark current and intensity of the two light beams are measured almost simultaneously; as a result, the effect of drift is negligible. While a solution of absorbance 0.875 was measured repeatedly, an RSD (relative standard deviation) of 0.24% could be reached. Furthermore, such a detector with a red/yellow LED has been coupled with the FIA technique for the determination of $10^{-6}M$ levels of cobalt.

In industrial process analysis the use of dual-wavelength spectrophotometric methods for the analysis of samples with turbidity, for simultaneous multicomponent determination and for high concentration analytes, offers obvious advantages;[1–3] and also increases the sensitivity and accuracy of the analysis.

Conventional dual-wavelength spectrophotometers used in the laboratory consist of two monochromators to obtain two paths of monochromatic light of different wavelengths and is equipped with modulator and demodulator. Both the optical system and the electric circuit are complicated. Lenses, mirrors and many mechanical moving parts are needed. Recent use of a photodiode array[4–6] is a practical instrumental improvement. Such spectrophotometers have good properties but the cost is high.

For industrial on-line process analysis, the environment is severe and the task is usually specific and not very complicated. A reliable and inexpensive dual- (or multi-) wavelength spectrophotometer of rugged simple construction is desirable.

Since commercially available light-emitting diodes (LED) emit visible radiation over a narrow wavelength range with high light intensity, short response time and a very long life time, its use as a light source for spectrophotometers is increasing.[4] The application of LEDs for photometric detection in FIA has recently been reported and reviewed.[7,8] When monochromatic light of different wavelengths is needed, LEDs of different colours may be selected. Sometimes, a combination of LEDs may be used.[8]

The purpose of this work is to employ a multi-colour LED as the light source in conjunction with a single photodiode as detector,[9] thus a compact rugged dual-wavelength spectrophotometer is designed and constructed, which can be used in connection with a flow-injection analysis system as a process analyser for industrial purposes.

EXPERIMENTAL

Apparatus

Dual-wavelength LED based photometer. A block diagram of the dual-wavelength LED based detector is shown in Fig. 1.

A dual-wavelength LED is employed as the light source. Light beams of different wavelengths emitted from the LED use the same optical path and share a common photodiode detector. This configuration greatly simplifies

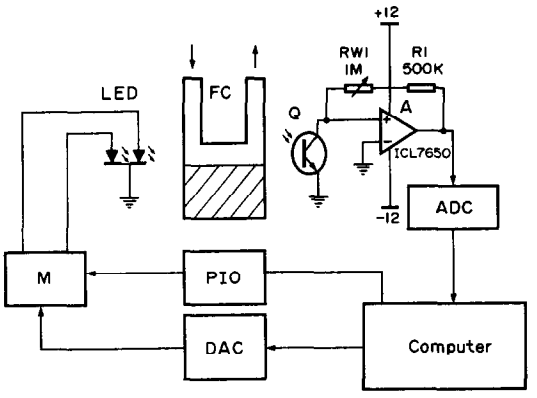

Fig. 1. A block diagram of the dual-wavelength LED based detector: FC is a common Hellma flow-cell with 10 mm of optical length and 1.5 mm of diameter; Q is the photo-transistor, 3DU80A; A is the amplifier, ICL7650; ADC is a 12-bit analogue to digital converter, AD574; DAC is an 8-bit digital to analogue converter, DAC0832; M is an analogue multiplexer, CD4051; computer is an Intel 8031 single-chip microcomputer.

the instrumentation and enhances the detector's stability.

The detector's electronic control system consists of current/voltage converter, A/D converter, D/A converter, electronic analogue multiplexers and a microcomputer. Under the control of the microcomputer, the electronic analogue multiplexers change the colour of the LED with very high speed, giving forth alternate light beams with different wavelengths, which falls onto the photodiode detector after being absorbed by the solution in the flow cell. The current generated is then converted into voltage which is digitized by the A/D converter at the rate of 1000 times per second. Then, the computer proceeds to process the data and display the results on the recorder. Under the control of the computer, the change of wavelengths of the light beam can be accomplished with extremely high speed (in milliseconds) so that the absorbance of the sample solution at different wavelength can be simultaneously or almost simultaneously obtained, which can be applied either for the elimination of the disturbances of background turbidity or for the simultaneous determination of multiple components.

Owing to the fact that the light intensities of different colour from the multi-colour LED may be different, and considering that the sensitivity of the detector towards light with different wavelengths may be different, for each wavelength, the 100% transmittance must be calibrated. Usually a double-beam instrument is used, of which one optical path is for calibration and the other path is for determination. Such a double-beam instrument is far more complicated than the single-beam instrument. In our work, we calibrate and compensate the difference electronically and automatically with the aid of the computer.

The detector's electronic part, including a signal amplifier, an A/D converter, a D/A converter, and an Intel 8031 8-bit single-chip microcomputer, is integrated on one small board. Prisms or gratings, lenses and mirrors *etc.*, are not needed. The detector thus constructed is compact, simple, inexpensive, robust and suitable for use with a FIA system. Different multi-colour LEDs can be easily incorporated in different applications.

The flow-injection system used was a FIA-21A instrument (Xin Tong Co., China) which has two 4-channel peristaltic pumps and one six-port rotary valve.

Reagents and solutions

The solutions employed include 1.6×10^{-5} g/ml bromothymol blue + 0.01*M* Borax,[10] 1% NaAc + 0.01% 5-Cl-PADAB,[11] 4% sulphuric acid, and 100 μg/ml cobalt stock solution. All the reagents employed are of analytical grade.

RESULTS AND DISCUSSION

Absorbance measurement and precision

While in operation, the LED diodes are switched on and off sequentially and as a result the signal observed (Fig. 2) is pulse like. Absorbance at the two wavelengths are calculated according to the following equation:

$$A = \log [(I_o - I_d)/(I - I_d)] \qquad (1)$$

where A is the absorbance, I_d is the dark current, I_o and I are the light intensities observed before and after being absorbed by the sample.

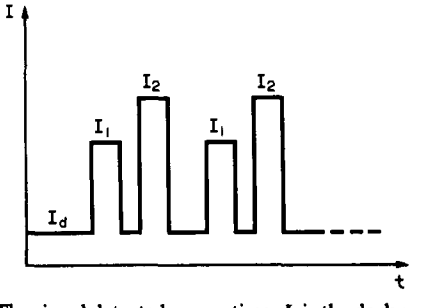

Fig. 2. The signal detected versus time. I_d is the dark current; I_1 and I_2 are the currents observed when different LEDs are switched on.

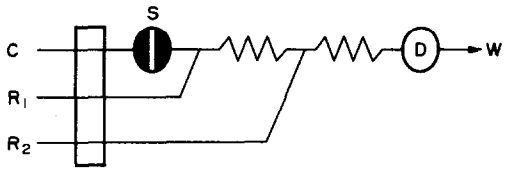

Fig. 3. FIA manifold for the determination of cobalt: C is H_2O; R_1 and R_2 are 1% NaAc + 0.01% 5-Cl-PADAB and 4% H_2SO_4 respectively; D is the LED-based photometer; W is the waste; S is the injection port.

The absorbances measured for a series of bromothymol blue solutions by using a red/green dual-wavelength LED with the emission maxima at 630 nm and 565 nm are summarized in equations (2) and (3).

$$A = 0.0194 + 4.909 \times 10^4\ C \text{ (for 630 nm)} \quad (2)$$

$$A = 0.0016 + 5.475 \times 10^4\ C \text{ (for 565 nm)} \quad (3)$$

where A is the absorbance and C is the concentration of bromothymol in g/ml. The regression coefficients of equations (2) and (3) are 0.9994 and 0.9999, respectively. In order to demonstrate the precision, a blank and a dye solution of absorbance 0.794 at 630 nm and 0.875 at 565 nm were measured 11 times. For the blank, the standard deviation of absorbance at 630 nm and 565 nm was 0.0009 and 0.0007, respectively; for the dye solution, the standard deviation of absorbance was 0.0020 at 630 nm and 0.0021 at 565 nm, with a resulting RSD of 0.25% and 0.24% for red and green colours, respectively.

Coupling with FIA for the determination of 10^{-6}M levels of cobalt

A red/yellow dual-wavelength LED (with the emission maxima at 665 and 585 nm) was selected as the light source for the determination of cobalt by the spectrophotometric method with 5-Cl-PADAB as the complexing reagent.[11] The FIA system designed for sample handling is shown in Fig. 3.

A series of standard cobalt solutions were prepared and measured with the above mentioned instrument. The results are shown in Table 1.

Effect of solution turbidity on the determination of cobalt. Solutions of cobalt ($3.224 \times 10^{-5}M$) with a different degree of turbidity were measured under the same conditions as mentioned above. The results are shown in Table 2. The peak heights at 665 nm show the absorbance caused by solution turbidity; the peak heights at 585 nm show the absorbance of the coloured sample and the turbidity.

Table 2 shows that although the turbidity is different for the above three samples, the difference in peak heights between the two wavelengths remains basically the same, which means that the disturbance of turbidity on the determination of cobalt in this case can be overcome.

CONCLUSION

A dual-colour LED based photometer has been designed and constructed. The experimental test shows that it has the following advantages:

The instrument is simple, compact and rugged; it is composed mainly of electronic devices, with no lenses, no mirrors, no sophisticated optical parts and no mechanical moving parts; in connection with a FIA system, it provides a cost-effective, robust process analyser for industrial purposes.

The study of the simultaneous determination of two components in turbid samples for on-line analysis for industrial purposes with this instrumentation is under progress in our laboratory.

Table 1. Absorbance of cobalt solutions

Conc. of Co M	8.484×10^{-4}	1.697×10^{-5}	2.543×10^{-5}	3.394×10^{-5}
Difference of peak heights between 665 and 585 nm	0.0554	0.1046	0.1526	0.1958
Relative standard deviation	2.0%	1.0%	1.2%	1.1%
Regression coefficient		0.9996		

Table 2. Effect of sample turbidity ([Co] = $3.224 \times 10^{-5}M$)

Sample No.	1 (no turbidity)		2		3	
Peak height (585 nm)	0.185	0.187	0.213	0.213	0.258	0.260

DETERMINATION OF AQUEOUS OZONE FOR POTABLE WATER TREATMENT APPLICATIONS BY CHEMILUMINESCENCE FLOW-INJECTION ANALYSIS. A FEASIBILITY STUDY

HYUNG-KEUN CHUNG, HARVEY S. BELLAMY and PURNENDU K. DASGUPTA*
Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 15 *August* 1991. *Revised* 15 *September* 1991. *Accepted* 20 *September* 1991)

Summary—The feasibility of determining aqueous ozone by chemiluminescence flow-injection analysis (CL–FIA) was studied for applications in potable water treatment. The ozonated water sample is injected into a pure water carrier and mixed with a dye reagent in front of a photodetector. Many reagents undergo fast CL reactions with aqueous ozone. Most of these reactions display considerable selectivity for ozone over other oxidants of importance in water treatment. Even when there is steady-state response to another oxidant, significant discrimination against the interferents is possible by taking advantage of the much faster kinetics of the CL reaction with ozone. A simple design of a Siemens-type ozone generator and preparation of standard ozone solutions are also described.

A large number of organic compounds have been reported to exhibit chemiluminescence (CL) when they react with high concentrations of gaseous ozone.[1] The CL reaction between gaseous ozone and ethylene[2] constitutes the reference method for ambient ozone measurements.[3] CL occurs when O_3(g) reacts with Rhodamine B/gallic acid in solution;[4] Rhodamine B has also been utilized for the development of solid phase reagent systems.[5,6] The CL resulting from passing O_3(g) over a fiber pad saturated by a continuously flowing solution of Eosin Y, Rhodamine B, or fluorescein permits detection of very low [O_3] levels.[7] CL analysis based on direct mixing of aqueous indigo-5,5′disulfonate and O_3(g) reportedly provides a limit of detection (LOD) of 0.4 ppbv.[8]

Aqueous O_3 has also been determined by CL reactions albeit less frequently than O_3(g). The CL reaction between O_3(aq) and luminol[9] was the basis of an early instrument. Despite refinements,[10] this reaction is not specific for ozone. Takeuchi and Ibusuki used Rhodamine B/gallic acid[11] and more recently indigo disulfonate[12] for the determination of aqueous ozone. With photon counting equipment, an LOD of 6 ng/l., suitable for direct measurement of O_3(aq) in cloudwater, was reportedly possible with the latter reagent.

Because of health concerns regarding the formation of halogenated organic compounds from the use of chlorine and related oxidants, ozone is increasingly being used as the primary oxidant in potable water treatment.[13–15] In the US, there are approximately 40 water treatment plants currently utilizing ozone with another 20 under design or construction.[15] The levels to be measured are higher than those in atmospheric applications but it is necessary to discriminate the O_3 from secondary oxidants resulting from O_3 (notably H_2O_2 and MnO_4^-) and other added oxidants (*e.g.*, Cl_2). We report here an inexpensive means of generating aqueous ozone at concentrations involved in drinking water treatment and on a feasibility evaluation of selective measurement of ozone by CL–FIA.

EXPERIMENTAL

Instrumentation

All measurements were performed with a programmable timer controller FIA system consisting of a multichannel peristaltic pump (Minipuls 2, Gilson Medical Electronics, Middleton, WI), an electropneumatically actuated dual loop sample injection valve (loop volumes 1 and 0.2 ml, Dionex Corp., Sunnyvale, CA), and a homemade flow-through reaction cell installed in front of an end-on type 4283B photomultiplier tube (PMT) typically operated at 1200 V. One pump channel was used to

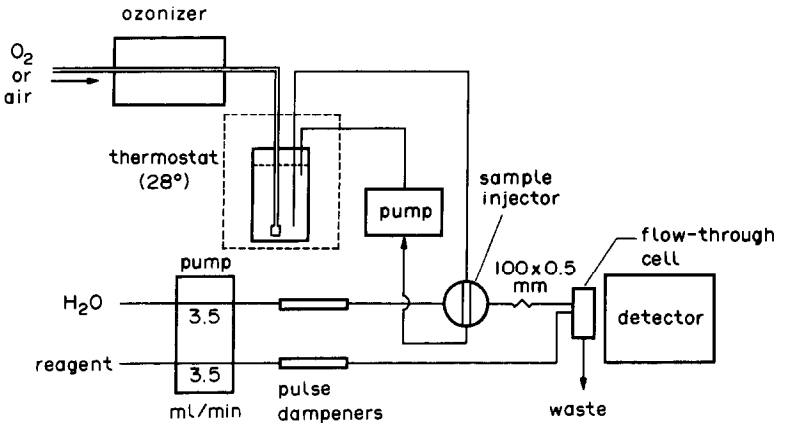

Fig. 1. Schematic diagram of the CL–FIA system.

aspirate aqueous ozone solutions into the sample loop from the sample reservoir. All tubing in the analytical conduit was polytetrafluoroethylene (PTFE), 0.5 mm in bore. Ozone solutions are unstable; the length of tubing between the aqueous ozone generator/reservoir and the valve was minimized and a high pumping rate (10 ml/min) with a ceramic/fluorocarbon pump (Fluid Metering Inc., Oyster Bay, NY) was used to avoid decomposition. Figure 1 shows a schematic diagram of the measurement system.

A Siemens-type ozone generator was constructed from a neon sign transformer (9 kV, 30 mA). A snugly fitting stainless steel tube was inserted in a 30 cm × 8 mm i.d. glass tube which was in turn inserted into a 25 cm × 16 mm i.d. glass tube wrapped in aluminium foil. Polypropylene tees at each end (9.5 mm i.d.) allow the inner tube to pass through via seals made by PTFE sleeves. Feed gas (air or O_2) was metered in (FC-280, Tylan General, Torrance, CA) and the product O_3 exited through the T-ports. The electrical field applied across the steel tube and the aluminum foil results in silent discharge in the annular space between the two concentric glass tubes. The O_3 output, controlled by a variable input voltage from a variable voltage transformer, was monitored with a photometer (1003 AH, Dasibi Corp., Glendale, CA; factory-modified with a 0.75-mm pathlength flow cell).

Solutions

Aqueous O_3 was prepared by continuously bubbling ozone in high purity water contained in a temperature-controlled vessel. The absorbance due to O_3(aq) at 258 nm was continuously monitored by circulating the solution through an absorbance detector (model 757, ABI, Ramsey, NJ; modified with a flow cell made from 3-mm square quartz tubing to avoid frequent problems with trapped bubbles) via PTFE lines.

Water used in the preparation of reagent solutions and the carrier stream of distilled demineralized water were determined to be free from ozone demand. All test reagents (Aldrich chemical or J. T. Baker) were used without further purification; the reagents were typically used at a concentration of $1 \times 10^{-4}M$.

RESULTS AND DISCUSSION

Preparation of aqueous ozone standards and gaseous ozone generation

Since O_3(aq) is readily decomposed, preparation of standards for calibration are non-trivial; the toxic nature of O_3(g) at high concentrations also mandate that experiments be conducted in a well ventilated hood. The best approach is to continuously equilibrate pure water (acidification can be used to increase the stability of the dissolved O_3)[16] with a stable concentration of O_3(g). To determine the concentration of O_3(aq), a value of 3100 $l.mole^{-1}.cm^{-1}$ was used for ϵ_{258}; a critical survey of literature data has indicated that this value is subject to a maximum error of $\pm 5\%$.[17] In potable water treatment, concentrations up to 5 mg/l. (*ca.* $100\mu M$) O_3(aq) need to be determined in the gas contact chambers. Based on a Henry's law constant of $0.015M$ atm^{-1} at 293 K,[18] the O_3(g) concentration necessary to make such a solution approaches the per cent level. Necessary generators are commercially available but the design reported here is simply constructed at a fraction of the cost. The generator provides a

stable O_3(g) output; the performance characteristics are summarized below.

The i-V relationship in the primary coil of the high voltage transformer is shown in Fig. 2. The point of departure from the initial linear relationship also indicates the experimentally observed onset of significant O_3 production. The relationship between the discharge energy, which we assume to be the product of the voltage and the difference between the total current and the linearly voltage dependent inductive current in the transformer (extrapolated straight line in Fig. 2), and the O_3 output is shown in Fig. 3. Two separate regions clearly exist regarding the efficiency of O_3 production. It is noteworthy that the slope (efficiency of O_3 production) in the higher current regime is five times larger for O_2 than for air suggesting that the efficiency is linearly related to pO_2. The mass of O_3 generated is essentially independent of the flow rate; Fig. 4 shows that the concentration of ozone generated is inversely proportional to feed gas flow rate with a near-zero intercept (the gas phase O_3 photometer is known to suffer from negative errors at very high concentrations; the departure of the highest concentration point from the lower linear portion is likely an artifact).

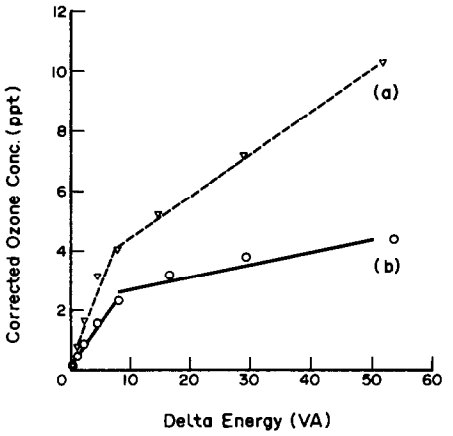

Fig. 3. Dependence of ozone output on discharge energy. Feed gas was (a) O_2(g) and (b) air at 200 standard cm^3/min.

Design of the chemiluminescence cell

The CL reaction of O_3 with most test reagents occurs on a time scale faster than it is commonly possible to achieve complete mixing in a FIA system; the half-life for the O_3-indigodisulfonate CL reaction, for example, is <1 msec.[12] It is therefore necessary to initiate the CL reaction directly in front of the PMT and in a controlled manner to obtain good signal reproducibility. Three types of reaction cells (Fig. 5) were studied for the reaction between O_3(aq) and indigotrisulfonate (ITS). In cell 5(a), the analyte and the reagent enter at the center of the cell via separate opaque tubes. The entrance bore is 0.3 mm and the streams are mixed at a right angle to achieve as rapid a mixing as possible. The stream then travels through the maze-like channel (V-shaped groove 0.3 mm deep, 0.5 mm wide, 21 cm total length, volume 16 μl) while CL occurs and is registered by the PMT through the Plexiglas window. A similar entrance geometry is used for cell 5(b) except that a much larger inner volume (100 μl) was used and the geometry was not constrained to facilitate hydrodynamic mixing. In cell 5(c), analyte enters into a relatively low velocity stream of the reagent and the total view volume in front of the PMT is large (800 μl). In all cases, the mixer windows are directly positioned in front of the end-on PMT and the same flow-rates were used for both the carrier stream and the reagent. Interestingly, all the tested cells produced

essentially the same CL signal height, indicating that the CL reaction is being controlled by diffusional mixing. However, the best RSD (<1.5%) was observed with cell 5(a); typical RSD values were 2–3% for cell B and >4% for cell C. Additionally, cell 5(a) is preferred because a lower residence volume is desirable for kinetic discrimination against slower

reacting interferents. A typical system output at the 1.8-mg/l.O_3(aq) level is shown in Fig. 6. The dual loop arrangement can effectively provide two independent calibration ranges without changing the instrument gain.

Effectiveness of different test reagents

In order to generate CL, the excited intermediate produced by the ozone–substrate reaction must luminesce itself or transfer its energy to another molecule that can. The situation is simplified if the substrate is itself fluorescent. Therefore a number of organic compounds that fluoresce in dilute aqueous solutions were evaluated for the determination of aqueous ozone by CL–FIA. Table 1 shows the relative CL signals obtained with different reagents. For our experimental arrangement, the calculated LOD (based on the S/N = 3 criterion) for the most thoroughly studied ITS reaction system was 2 μg/l.; this is acceptable for the determination of residual ozone in water treatment applications. Chromotropic acid, Rhodamine B and Eosin Y, all of which produced more intense CL than ITS, may yield more sensitive determination systems. However, when Rhodamine B and Eosin Y solutions were used in the system for a continued period, adsorption of the reagent on the view window occurred, resulting in a gradual decrease in sensitivity and deterioration of the run-to-run reproducibility. For the Rhodamine B system, the addition of a surfactant (Triton-X-100, 0.1% w/v) was studied. It increased the CL signal by *ca.* 30% but did not solve the adsorption problem.

Effect of pH and salinity

The effects of varying pH and salinity in a real water sample on the system response are important. Using 0.1*M* phosphate and acetate buffers at pH 2 and 4.7 respectively for the ITS reagent, the CL signal increased by 60% at the higher pH. With 0.1*M* sodium chloride to add salinity, the CL signal for this system was higher by a factor of *ca.* 5 at pH 7 compared to pH 2. Interestingly, the colorimetric response (bleaching of indigo) determined by a parallel system[17] was independent of the reagent pH. The salinity did not affect the magnitude of the signal as much as it affected the precision of replicate injections—whether it is due to any real chemical reasons or Schlieren effects from imperfect mixing needs to be investigated. The importance of appropriately buffering the reagent was, however, evident.

Effect of potential interferents

While further studies and field validation will be necessary before a CL–FIA method can be recommended for the determination of O_3(aq), a major incentive to pursue this route is the fact that for many of the reagents, on a short time measurement scale (*e.g.*, <1 sec), the effect of potential slower reacting interferents are either nonexistent or can be minimized. For chromotropic acid, Rhodamine B, and Eosin Y as reagents, H_2O_2, Cl_2 (as OCl^-) at concentrations <10 mg/l. and MnO_4^- at a concentration <1 mg/l. showed no measurable response in the present measurement system with cell 5(a).

With ITS, significant response was found only with MnO_4^-; based on a colorimetric FIA study,[17] the decolorization reaction of ITS by MnO_4^- is 20% complete in 1.6 sec while the reaction with ozone is 100% complete. However, the CL reaction for the ITS–MnO_4^- system appears to be faster, CL presumably precedes decolorization. On an oxidant equivalents basis (note that ozone is a 4-electron oxidant for indigo), MnO_4^- produced $\geq 65\%$ of the ozone response in a reaction cell with a calculated residence time <150 msec. Therefore significant interference from MnO_4^- may result from waters with significant Mn content (albeit such Mn concentrations do not occur frequently) if ITS is chosen as the reagent. However, the other three reagents mentioned above produce negligible CL with MnO_4^- and may more conveniently form the basis for sensitive analytical methods immune to interferences from oxidants other than ozone.

QUANTITATIVE COMPARISONS USING LIQUID CHROMATOGRAPHY WITH DUAL-LABEL RADIOACTIVITY MEASUREMENTS FOR EVALUATION OF ISOTOPE AND IMPURITY EFFECTS

LAWRENCE C. THOMAS
Department of Chemistry, Seattle University, Seattle, Washington 98122, U.S.A.

(*Received* 1 *July* 1991. *Revised* 1 *November* 1991. *Accepted* 15 *November* 1991)

Summary—Dual-label methods with radiometric measurements with liquid chromatography are evaluated for assessing effects of impurities and isotopic composition in reaction experiments. The procedure is suitably sensitive to detect interferences caused by effects of impurities in reactants, isotope exchange during reaction and effects of kinetic differences due to differing masses of the differently labeled forms. The methods show marked improvements in data quality for comparisons of product formations and relative product abundances in multiple-pathway reaction systems. The results from computer simulations for the procedures are shown to be relatively unaffected by large variations in uncertainties in pretreatment steps and volume measurements. Moreover, these methods yield much better quantitative results than do commonly used corresponding conventional comparisons, and the benefits are corroborated by results from experiments with microsomal reactions.

Radioactivity measurements for chromatography can be used to obtain quantitative information in experiments involving multiple reaction pathways. Radiochemical detection of reaction products separated by chromatography can provide good selectivity, low limits of detection and freedom from many interferences.[1] However, several factors plague radiometric chromatography procedures for reaction product evaluations and can cause large uncertainties in data and results.[2–5] Typically, those procedures require both availability and careful characterization of appropriate reference materials for every measured component. Unfortunately, for complex systems such as metabolism studies, several reaction product analytes may be measured for each sample and appropriate pure standards may not be available for them all. Moreover, identities of the products are not always known, which precludes use of either conventional internal- or external-standard methods.

In related work,[2,5] compounds labeled with two different radioactive isotopes were separated by HPLC for special dual-label procedures which mimic internal-standard methods. In those studies biologically generated radiolabeled reference solutions were used and their components separated along with differently labeled respective coeluting metabolites from samples from biological experiments. The dual-label approaches allow for compensation for variations in extraction efficiencies, variable losses during concentration of extracts, imprecisions of volume measurements and uncertainties in specific activities of dosage compounds. Moreover, the procedures greatly obviate difficulties caused by unavailability of pure reference compounds and do not necessarily require eluate identifications.

Similarly, as done herein for characterizing isotope effects and impurity interferences, one may use a combined solution of differently labeled forms of the same compound, with concurrent exposure of the two forms in the same reaction system via addition of an aliquot of the mixed reactant solution.[3] The two forms thereby concurrently react under identical conditions. The respective reaction products may then serve as mutual internal standards in dual-label HPLC procedures for quantitative comparisons to evaluate: (a) effects of impurities on reaction product formation experiments, (b) effects of isotope exchange upon those experiments, and (c) effects of kinetic differences between the forms which may be caused by their different respective masses.

Improvements from the dual-label method for assessing isotope or impurity interferences in reaction experiments have been estimated for a

few selected circumstances,[3] but no detailed evaluations of data-quality enhancements offered by the dual-label techniques have been done. In this work, computer simulations are used for detailed theoretical studies of improvements provided by use of the dual-label quantitative comparisons for evaluating isotope effects and impurity interferences, and the results from simulations are corroborated by laboratory experiments.

THEORY

A main advantage of the dual-label procedure for assessing interferences is that selected special ratios, described below, yield well-defined theoretically predictable results which may be tested statistically.[2,3,5] One may concurrently react in the same solution both an X-labeled test compound and the same compound which is labeled differently, *e.g.*, Y-labeled, perhaps one or both of unknown concentration. If the two differently labeled reactant compounds are chemically identical their respective reaction products will typically also be identical, except for their respective radioactivities; this equivalence is a reasonable assumption unless isotope exchange occurs during reaction, or if kinetics are affected as a result of differences in isotopic masses. Moreover, if the reaction products are pretreated together in the same solution prior to measurement, the pretreatments will typically have equivalent extraction/concentration/dilution efficiencies, E, for the two forms of each reaction product i, *i.e.*, $E_{X,i} = E_{Y,i}$. Thus, if V_t is the volume of the sample solution from the reaction mixture, V_{ss} is the volume of the prepared subsample used for chromatographic separation, and M is the mass of specified analyte in the original sample, then

$$M_{X,i} = (A_{X,i} V_t)(E_{X,i} V_{ss} S_{X,i})^{-1}$$

and

$$M_{Y,i} = (A_{Y,i} V_t)(E_{Y,i} V_{ss} S_{Y,i})^{-1}$$

where $A_{X,i}$ and $A_{Y,i}$ are corrected measured radioactivities, respectively, for the X-labeled and Y-labeled forms of eluate component i from volume V_{ss}, and $S_{X,i}$ and $S_{Y,i}$ are respective specific activities for the labeled component i.

Intrasample comparisons

To evaluate isotope or impurity effects for reaction systems, special intrasample ratios can be defined for X- *vs.* Y-labeled reaction products. For this, V_t is identical for both labeled forms of each reaction product taken together from the same sample solution. Similarly, V_{ss} is the same or both forms of each product. Accordingly, a ratio of respective masses can be calculated and $M_{X,i} M_{Y,i}^{-1} = (A_{X,i} S_{Y,i})(A_{Y,i} S_{X,i})^{-1}$ for any component i. Furthermore, separated reaction products, i *vs.* j, derived from the same reaction experiment can then be compared,

$$Q_{i,j} = (M_{X,i} M_{Y,i}^{-1})(M_{X,j} M_{Y,j}^{-1})^{-1} = (A_{X,i} A_{Y,j}) \times (A_{Y,i} A_{X,j})^{-1} (S_{Y,i} S_{X,j})(S_{X,i} S_{Y,j})^{-1}$$

If relative specific activities for components i *vs.* j are known, then Q_{ij} may be calculated from radioactivity data in combination with those appropriate $S_{Y,i}/S_{Y,j}$ and $S_{X,i}/S_{X,j}$ ratios. Moreover, if there is no isotope exchange during reaction $S_{Y,i} = S_{Y,j}$ and $S_{X,i} = S_{X,j}$, and so, $Q_{ij} = (A_{X,i} A_{Y,j})(A_{Y,i} A_{X,j})^{-1}$. Thus, Q_{ij} may be computed from corrected measured radioactivity data of the dual-label chromatogram only, without knowing specific activities.

If there has been neither isotope exchange nor differences in kinetics, nor contributions to the specified components due to impurities, then $Q_{ij} = 1$; that is, the relative isotopic composition for all components is the same. If isotope effects or impurities cause interferences, then Q_{ij} may be significantly different than unity, and one may test Q_{ij} statistically for each i,j pair via replications and a null hypothesis that the measured reaction products are unaffected by impurities or isotope effects.

Intersample comparisons

Similarly, one could compare intersample Q-ratios to ascertain intersample differences due to impurities or isotope effects; for compound i, $Q_{12,i} = (M_{X,i,1} M_{Y,i,1}^{-1})(M_{X,i,2} M_{Y,i,2}^{-1})^{-1}$ for comparisons for samples 1 *vs.* 2, both resulting from reactions of identical aliquots of the same test solution containing both X- and Y-labelled reactant. Conveniently, $S_{X,i,1} = S_{X,i,2}$ and $S_{Y,i,1} = S_{Y,i,2}$ for those intersample comparisons, thus $Q_{12,i} = (A_{X,i,1} A_{Y,i,2})(A_{X,i,2} A_{Y,i,1})^{-1}$, which can be readily calculated from radioactivity data only and can be tested statistically for $Q_{12,i} = 1$, as above, and does not require specific activity data.

Likewise, intrasample comparisons can be extended to comparisons of two or more component concentration ratios relative to the same

components in intersample sets of measurements, *e.g.*, $Q_{ij,1}/Q_{ij,2} = Q_{ij,12}$. This might correspond to comparing products of two reaction pathways and, of course, $Q_{ij,12} = 1$ if the reaction product profiles are unaffected by impurities or isotope effects. Again, the Q-ratio can be calculated from radioactivity data only without knowing specific activities, and can be tested statistically.

EXPERIMENTAL

Reagents

All organic solvents used were Mallinckrodt ChomAR. Radiolabeled compounds were purchased from Amersham Corporation. Water used was distilled in all-glass apparatus and other chemicals were reagent grade quality.

Apparatus

An Altex HPLC system with two Model 110 pumps, a Model 420 control module and a Beckman Model 171 dual-channel flow-through radioactivity counter with a 150-μl flow cell volume, interfaced to an Equity I+ computer and an Epson Model 800 printer was used. Separations were done at 1 ml/min eluant flow through an Altex 4 mm i.d. × 25 cm length stainless column packed with 5 μm octadecylsilyl reverse phase column material. Eluted fractions were collected every 30 sec in scintillation vials by a Pharmacia FRAC-100 fraction collector after automatic mixing with Beckman Ready-Flow II scintillation cocktail, added at 4.0 ml/min, in the Model 171. Collected fractions were counted on a Beckman Model 5000 liquid scintillation counter (LSC) and corrected for energy overlaps according to conventional procedures. Labware used was treated with dimethyldichlorosilane in hexane, and washed with water and acetone prior to use.

Computer simulations. An Epson Equity II+ computer with EGA graphics, a 20-Mbyte hard disk, an Intel 80287 mathematics co-processor and an Epson LX 810 printer were used for mathematical modeling of dual-label chromatography separations and measurements. Computer programs were written in Microsoft's Quickbasic 4.0 (listings available from author upon request).

Procedure for computer simulations

Chromatograms from the simulations were generated for specified enzymatic reaction rates of aryl hydrocarbon hydroxylases (AHH), using relative metabolite concentrations from others' data compilations.[6] For rats metabolizing benzo(a)pyrene (BaP), relative concentrations in Table 1 were used, with other minor reaction products[6] ignored.

Efficiencies of component recoveries from extractions, reduction of extract volumes and dilutions to appropriate volume were taken from other work with reasonable standard deviations[2,6] (see Table 1). No differences in these efficiencies were assumed for the differently labeled forms, consistent with their nearly identical chemical properties.[2,3] Random variations in these efficiencies were generated by an accepted procedure.[7] Variations in volume measurements for the diluted extract, the added reference solution and the subsample taken for HPLC were generated with reasonable standard deviations for volume measurements[8] and random gaussian deviations.[7]

Masses for each respective reaction product in subsamples taken for HPLC were calculated from assumed but varied AHH activities in the respective reaction systems, uncertainties in pretreatment recoveries, uncertainties in volumes and the volumes used. Mass *vs.* time relations for components separated by HPLC were calculated from respective injected masses, assumed

Table 1. Metabolite retentions, percentage of metabolites and uncertainties due to pretreatments used for simulations

Metabolite	Retention, *min*	% Met*	E/C/D Eff† ± (SD × *n*) (%; *n* = 1, 2 or 3)
9,10 BaP Dihydrodiol	16	8%	0.4 ± 0.05 n
7,8 BaP Dihydrodiol	24	6%	0.4 ± 0.05 n
1,6 BaP Dione	31	7%	0.5 ± 0.05 n
3,6 BaP Dione	34	8%	0.5 ± 0.10 n
6,12 BaP Dione	38	7%	0.8 ± 0.10 n
9-Hydroxy BaP	45	11%	0.8 ± 0.10 n
3-Hydroxy BaP	54	40%	0.9 ± 0.05 n
BaP	65		0.9 ± 0.05 n

*Percentage of total metabolites.
†Extraction/Concentration/Dilution efficiency.

HPLC peak widths at half-maximum of 1.0 min and presumed gaussian peak shapes. The radioactivities of the two labeled forms eluting from the column were calculated over all 1-sec intervals throughout the separation duration. These interval radioactivities were then summed into consecutive 30-sec intervals to simulate contents of collected fractions (see Fig. 1).

Radioactivities were assumed to be for ^{3}H- and ^{14}C-labeled compounds for these calculations. The simulated measured radioactivity for each fraction was calculated from the contained masses, specific activities, appropriate counting efficiencies for the relative amounts of solvents and mixed scintillation cocktail, and imposed random variations in counting according to accepted procedures, with appropriate compensation for energy overlaps.[7,9] Histograms simulating counted elution fractions were generated and integrated measured radioactivities for each labeled form of each separated metabolite were calculated by conventional methods.[9] Those data were saved for later computations and statistical analyses.
