On the basis of the data obtained we have developed two methods for determination of chromium, and applied them to steels and some selected soils. The comparatively low tolerance ratios for sodium and calcium restrict the soil analysis application to soils of podzolic type.

Analysis of soils

The methods were applied for the determination of chromium in five soil samples: lessive cinnamonic, pseudopodzolic, gray forest, brown, and black.

Sample preparation. Weigh 4 g of the soil into a platinum crucible, then heat it for 3 hr in a muffle furnace at 550°. After cooling, transfer the sample into a platinum basin, add 2 ml of doubly distilled water, 1 ml of concentrated sulphuric acid and 10 ml of concentrated hydrofluoric acid, and heat on a sand-bath until vapours of SO_3 appear. Dissolve the residue in 5 ml of doubly distilled water acidified with hydrochloric acid to pH 3.[46] Raise the pH of the solution to ~10 by addition of concentrated ammonia solution to precipitate the iron and aluminium. Filter off the precipitate with a suitable filter paper and wash it with three 3-ml portions of doubly distilled water. Evaporate the filtrate to ~20 ml, cool, acidify the solution to pH 3 with hydrochloric acid, transfer it into a 25-ml standard flask and dilute to the mark with water. Take a 2.5-ml or other suitable aliquot of this solution and oxidize the chromium(III) to chromium(VI)[23] by adding 5 ml of 1M sulphuric acid and 1.5 ml of 1-mg/ml potassium permanganate solution and boiling for 3 min. Cool, then add 0.1 ml of saturated thiourea solution and 0.5 ml of 100-mg/ml potassium nitrite solution, and dilute to volume in a 25-ml standard flask. Take an aliquot of this solution for analysis. Run a reagent blank.

Table 2. Determination of chromium in soils and steels

Soil*	Cr, 10^{-4} %			RSD† %	
	INT	TV	Atomic absorption	INT	TV
Black	9.35	9.33	9.37	0.5	0.7
Pseudopodzolic	5.82	5.80	5.80	0.5	0.5
Lessive cinnamonic	4.15	4.18	4.17	0.7	0.5
Gray forest	3.72	3.69	3.70	0.7	0.6
Brown	3.51	3.54	3.53	0.7	0.5

Steel	Certified chromium content, %	Chromiun found, %		RSD† %	
		INT	TV	INT	TV
38 × 2CO in 14a	1.84	1.83	1.83	0.5	0.4
CO-C 37	17.6	17.6	17.6	0.6	0.7

*The soils contained 0.018–0.049% sodium and 0.015–0.041% calcium.
†Relative Standard Deviation.

Determination of chromium. Add to the aliquot sample solution 1.2 ml of 1.2*M* hydrochloric acid and 2 ml of $1 \times 10^{-4}M$ INT (or 0.9 ml of 1.2*M* hydrochloric acid and 1 ml of $1 \times 10^{-4}M$ TV) and 2 ml each of saturated solutions of ascorbic acid and ammonium fluoride, and dilute to 10 ml with water. Shake the solution for 1 min with 3 ml of dichlorethane. Filter the extract through a dry filter paper and measure the absorbance at 250 nm (for INT) or 230 nm (for TV). Correct for the absorbance of the blank.

The concentration of Cr(VI) is determined from a calibration graph.

Analysis of steels

Two standard samples were studied: 38 × 2 CO-C 14a contains (%) C 0.364, Si 0.50, Mn 0.305, Cr 1.84, Ni 0.162, W 0.292, V 0.208, Cu 0.128, Al 0.56, S 0.0058, P 0.0074, and CO-C 37 contains (%) C 0.05, Si 0.5, Mn 1.35, Cr 17.6, Ni 12, Cu 0.2, Nb 1.2.

Dissolve a 0.1-g sample in 30 ml of a 1:3 v/v mixture of 1:1 v/v nitric acid and 1:1 v/v hydrochloric acid; add 10 ml of concentrated sulphuric acid and evaporate the solution until vapours of SO_3 appear. Transfer the solution into a 100-ml standard flask and dilute to the mark with distilled water. Take a suitable aliquot and oxidize the Cr(III) to Cr(VI) as described for soil samples. Complete the analysis as described for soils.

Results

The results of the soil and steel analyses are given in Table 2 and the accuracy of the methods was checked by atomic-absorption spectrometry. There was good agreement between the results obtained by the three methods.

SPECTROPHOTOMETRIC DETERMINATION OF CHROMIUM (VI) WITH METHYLENE BLUE

M. KAMBUROVA

Department of Chemistry, Higher Institute of Agriculture, 4000 Plovdiv, Bulgaria

(*Received* 24 *October* 1991. *Revised* 9 *March* 1992. *Accepted* 17 *April* 1992)

Summary—The interaction of Cr(VI) and the thiazine dye Methylene Blue has been examined. The ion-associate formed is extractable into 1,2-dichlorethane. The optimum conditions have been established, and values obtained for the conditional extraction constant K'_{ex}, distribution constant K'_D and association constant β'. A sensitive and selective method for determination of microquantities of Cr(VI) in soils and alloys is suggested.

The determination of microquantities of chromium in soils and other naturally occurring materials is of particular importance in connection with the growing interest in environmental problems. It is known that an increase in the content of this element in soils makes them infertile, and that the toxic effect depends, to some extent, on the chromium oxidation state.[1] On the other hand, it has also been established that the introduction of chromium salts into soils has some positive effects, such as an increase in sugar content and yields, favourable changes in chemical composition, and activation of some biochemical processes.[2–5] Obviously, the concentration and oxidation state of chromium, like those of other microelements, are of great significance for its physiological action.

The reagents suggested for determination of chromium include: diantipyrylmethane,[6] diphenylcarbazide,[7] diantipyrylstyrylmethane,[8] Chromethylpyrazole and Chrompyrazole I,[9] triphenyltetrazolium chloride,[10] *N*-*m*-tolyl-*p*-methoxybenzohydroxamic acid,[11] antipyrine basic dyes,[12] Chrome Azurol S,[13,14] α-methyl-2,4-dihydroxybenzylidene-2-aminoaniline,[15] bis-(2,4-diaminophenyl)phosphonate,[16] (1-naphthylmethyl)triphenylphosphonium,[17] 2, 2′-bipyridyl[18] and 3-hydroxyflavone.[19] The most sensitive and selective of these is diphenylcarbazide, but V(V), Mo(VI), Fe(III) and Hg(II) interfere with the Cr(VI) determination.

The goal of the present work was to use the thiazine dyestuff Methylene Blue (MB) for determination of microquantities of chromium by an extraction photometric method.

EXPERIMENTAL

Reagents

Methylene Blue (MB), 1×10^{-4} and $1 \times 10^{-5}M$ solutions; potassium chromate, 1×10^{-4} and $1 \times 10^{-5}M$ solutions; hydrochloric acid, $1{,}2M$; perchloric acid, $9M$; 1,2-dichlorethane. Analytical-reagent grade or equivalent chemicals were used.

Apparatus

Zeiss VSU 2-P and Specord UV-VIS spectrophotometers were used, with 1-cm path-length cuvettes.

Procedures

Calibration. In a 100-ml separatory funnel place 1.5 ml of $1.2M$ hydrochloric acid, 1 ml of $1 \times 10^{-4}M$ Methylene Blue, and a known volume of chromium(VI) solution containing up to ~5 μg of chromium. Dilute to 10 ml with distilled water and shake with 3 ml of dichlorethane for 1 min. Transfer the organic layer through a dry filter paper into a 1-cm cuvette and measure the absorbance at 295 nm against a reagent blank similarly prepared.

Determination of chromium in soils. Weigh a 4-g sample into a platinum crucible and heat it at 500–550° for 3 hr. Cool the crucible, add 2 ml of doubly distilled water, 1 ml of concentrated sulphuric acid and 10 ml of concentrated hydrofluoric acid, and evaporate until fuming has ceased. Cool, and dissolve the residue in 5 ml of doubly distilled water acidified to pH 3 with hydrochloric acid.[20] Add concentrated ammonia solution to precipitate iron and aluminium at

pH 10, filter off the precipitate, and wash it with three 3-ml portions of doubly distilled water, then evaporate the filtrate and washings to about 20 ml. Cool the solution, acidify it to about pH 3 with hydrochloric acid, and make up to the mark in a 25-ml standard flask. Take a 2.5-ml or other suitable aliquot of this solution and oxidize the chromium(III) to chromium(VI)[21] by adding 5 ml of 1*M* sulphuric acid and 1.5 ml of 1-mg/ml potassium permanganate solution and boiling the mixture for 3 min. Cool, then add 0.1 ml of saturated thiourea solution and 0.5 ml of 100 mg/ml potassium nitrite solution, and dilute to volume in a 25-ml standard flask. To a suitable aliquot of this solution add 1.5 ml of 1.2*M* hydrochloric acid, 1 ml of $1 \times 10^{-4}M$ Methylene Blue and 2 ml each of saturated solutions of ascorbic acid, tartaric acid and ammonium fluoride (to mask any interfering ions). Dilute to 10–12 ml with water and shake for 1 min with 3 ml of 1,2-dichlorethane. Filter the organic phase through a dry paper into a 1-cm cuvette and measure the absorbance at 295 nm against a reagent blank run by the same procedure. Prepare a calibration graph with chromium(VI) standards similarly treated.

Determination of chromium in steels. Dissolve a 0.1-g sample of the steel in 30 ml of a 1:3 v/v mixture of 1:1 v/v nitric acid and 1:1 v/v hydrochloric acid. Cool, add 10 ml of concentrated sulphuric acid and evaporate until SO_3 fumes appear. Cool, take up the salts in water, and dilute to volume in a 100-ml standard flask. Oxidize a suitable aliquot as described above for soil samples. To a suitable aliquot of the resultant solution add 1.5 ml of 1.2*M* hydrochloric acid, 2 ml of $1 \times 10^{-4}M$ Methylene Blue and dilute to ~10 ml with saturated ammonium fluoride solution (to mask any interfering ions). Extract the ion-associate and complete the determination as for soil analysis.

RESULTS AND DISCUSSION

The solubility of the ion-associate in various organic solvents was investigated. The most effective for extraction of the compound was found to be 1,2-dichlorethane. The absorption spectra of the ion-associate and the dye in 1,2-dichlorethane and chloroform are given in Fig. 1. The absorption spectrum of the associate in dichlorethane has maxima at 230 and 295 nm. At 230 nm the dye also absorbs strongly, so 295 nm was selected as the working wavelength. The absorption spectrum of the associate in chloroform has only one maximum, at 245 nm.

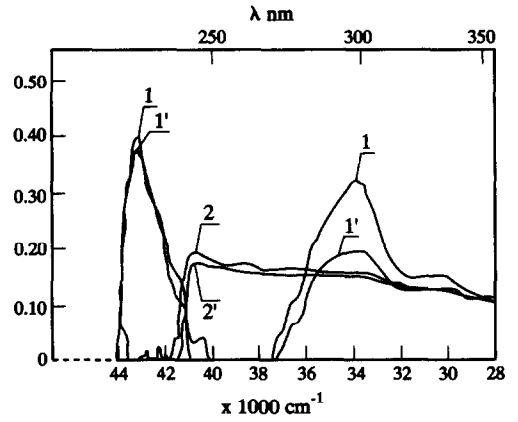

Fig. 1. Absorption spectra of $MB^+ \cdot CrO_3Cl^-$ in (1) $C_2H_4Cl_2$ and (2) $CHCl_3$, and of MB in (1′) $C_2H_4Cl_2$ and (2′) $CHCl_3$; $C_{Cr(VI)} = 4 \times 10^{-6}M$, $C_{HCl} = 0.18M$, $C_{MB} = 4 \times 10^{-6}M$.

The ion-associate formed from the cation of the dye (MB^+) and Cr(VI) in hydrochloric acid medium may be ascribed the formula $MB^+ \cdot CrO_3Cl^-$, in agreement with earlier reports.[22–25]

The Job,[26] Bent and French,[27] and Asmus[28] methods all showed that the extracted species was a 1:1 ion-associate of the dye cation and the chlorochromate anion. Equilibrium between the two phases, aqueous and organic, was reached in 30 sec. The ion-associate is stable for over 36 hr. Its molar absorptivity was determined by the method of Komar[29] and Klotz and Ming[30] and found to be $(8.33 \pm 0.04) \times 10^4$ l · mole^{-1} · cm^{-1} at 295 nm.

To find the optimum conditions for extraction of the ion-associate, the influence of pH and the concentrations of Methylene Blue and chromium(VI) was studied.

The acidity of the aqueous phase is a major factor in the determination. The influence of hydrochloric, sulphuric, nitric and perchloric acids on the extraction equilibrium was investigated. Only in the presence of hydrochloric or perchloric acid was the ion-associate extracted. Figure 2 indicates that not only the concentration but also the nature of the acid has an effect on the extraction equilibrium. Maximum absorbance is achieved in hydrochloric acid medium, in the acid range 0.18–0.6*M*. A higher concentration of the acid causes some reduction of Cr(VI) to Cr(III) and a decrease in light-absorption by the organic phase.

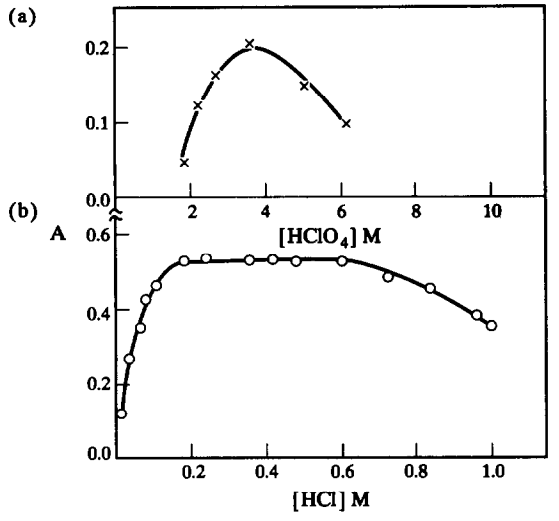

Fig. 2. Investigation of the influence of acidity on the extraction of Cr(VI) with Methylene Blue: $C_{Cr(VI)} = 5 \times 10^{-6}M$, $C_{MB} = 1 \times 10^{-5}M$; (A) $HClO_4$, (B) HCl.

Table 1. Effect of diverse ions on determination of 2 μg of chromium

Foreign ion	Limiting amount, *mg*
Ni(II)	55
K(I)	40
V(V)	32.5*
Sr(II)	30
W(VI)	30*
Fe(III)	3.5*
Mo(VI)	3*
Cu(II)	2
Cd(II)	1
Mn(II)	1
Zn(II)	1
Al(III)	1*
Pb(II)	0.5
Co(II)	0.2
Na(I)	0.2
Ca(II)	0.08
Hg(II)	interferes at any level

*In the presence of ascorbic acid, ammonium fluoride and tartaric acid as masking agents.

Optimization of the concentration of Methylene Blue is essential in the determination of chromium; for 0.2 μg/ml Cr(VI) the absorbance of the extract is maximum with MB concentration $\geq 1 \times 10^{-5}M$ and for 0.5 μg/ml Cr(VI),[MB] $\geq 2.5 \times 10^{-5}M$ is necessary (Fig. 3).

Beer's law is obeyed over the Cr(VI) concentration range from 0.01 to 0.54 μg/ml in the 10 ml of aqueous phase.

Interferences

The data in Table 1 show that mercury(II) must be absent from the test solution, and that calcium and sodium must be present in only small amounts, which places a restriction on the types of sample that may be analysed for chromium by the proposed method. Several potentially interfering ions can easily be masked with suitable reagents. The method offers better selectivity than the diphenylcarbazide method with respect to vanadium(V), molybdenum(VI) and iron(III).

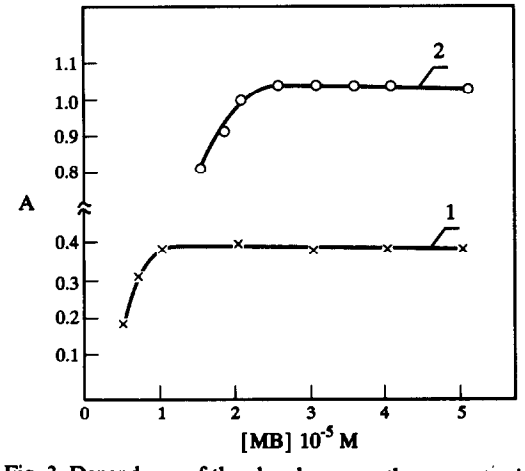

Fig. 3. Dependence of the absorbance on the concentration of Methylene Blue: (1) $C_{Cr(VI)} = 0.2$ μg/ml; (2) $C_{Cr(VI)} = 0.5$ μg/ml; $C_{HCl} = 0.18M$.

Extraction equilibria

The following equilibria should be taken into account for the system of chromium(VI), Methylene Blue, hydrochloric acid, water and 1,2-dichlorethane.

1. Formation of the ion-association complex in the aqueous phase, and the corresponding equilibrium constant:

$$\beta = \frac{[MB^+ \cdot CrO_3Cl^-]}{[MB^+][CrO_3Cl^-]}. \qquad (1)$$

2. Distribution of the complex between the aqueous and organic phases, and the corresponding distribution constant:

$$K_D = \frac{[MB^+ \cdot CrO_3Cl^-]_{org}}{[MB^+ \cdot CrO_3Cl^-]}. \qquad (2)$$

3. The entire extraction process and the corresponding extraction constant:

$$K_{ex} = \frac{[MB^+ \cdot CrO_3Cl^-]_{org}}{[MB^+][CrO_3Cl^-]} = K_D\beta. \qquad (3)$$

The system is much more complicated than this, however, since the formation constant for

CrO_3Cl^- and the distribution constant for $MB^+ \cdot Cl^-$ between the organic and aqueous phases also need to be taken into account, and in consequence the constants listed above are apparent (or conditional) constants.

A conditional constant was obtained for the distribution coefficient of the ion-associate by taking 5 ml of $1 \times 10^{-4}M$ Methylene Blue, 1.5 ml of $1.2M$ hydrochloric acid and various amounts of chromium(VI), diluting to 15 ml with water and shaking the mixture for 1 min with 3 ml of 1,2-dichlorethane in a separatory funnel, then diluting the extract to volume in a 25-ml standard flask with 1,2-dichlorethane. The absorbance (A) was measured, against a reagent blank prepared in the same way (without chromium present), in 1-cm cuvettes at 295 nm. For each solution containing chromium an exact duplicate was prepared, and this was extracted with three 3-ml portions of dichlorethane, the extracts being combined and diluted to volume in a 25-ml standard flask; the absorbance (A_{max}) was then measured against the reagent blank already prepared. As a constant amount of Methylene Blue is used, the change in absorbance is due to the ion-associate. The value of the conditional distribution coefficient $D'_{MB/Cr}$ is then given by

$$D'_{MB/Cr} = A/(A_{max} - A).$$

The results were evaluated by plotting log $D'_{MB/Cr}$ against log $C_{Cr(VI)}$ (Fig. 4). According to the model used by Aleksandrov *et al.*,[31] the intercept of the horizontal part of the curve on the ordinate gives log K'_D and the intercept of the extrapolated slope of the curve gives log K'_{ex}

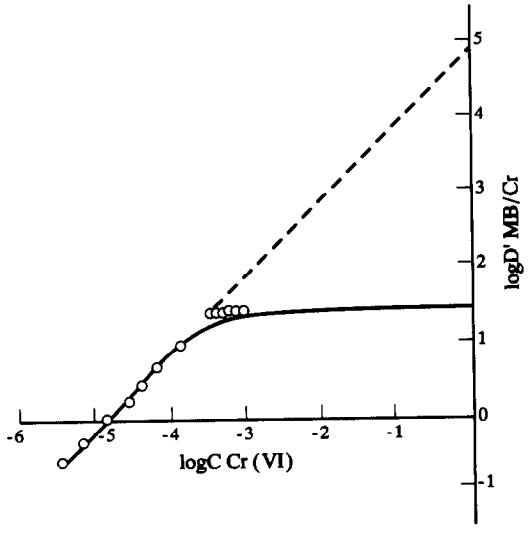

Fig. 4. Determination of $D'_{MB/Cr}$, K'_D and K'_{ex}.

Table 2. Determination of chromium in selected soils and steels

Soil*	Cr, 10^{-4}% Methylene Blue method	Atomic absorption	RSD*, %
Leached chernozem	2.40	2.38	0.6
Podzolized black	2.50	2.54	0.5
Brown	3.53	3.54	0.5
Gray forest	3.70	3.67	0.6

Steel	Certified chromium present, %	Chromium found, %	RSD, %
38 × 2 CO-C 14a	1.84	1.85	0.4
CO-C 37	17.6	17.6	0.5

*The soils contained 0.024–0.036% sodium and 0.019–0.030% calcium.
†Relative Standard deviation (based on 3 determinations).

(where primes indicate conditional constants). From equation (3) the value of β' can then be obtained. The theoretical curve can be calculated[31] from

$$D'_{MB/Cr} = K'_D\beta'[Cr]/(1 + \beta'[Cr]) \quad (4)$$

and is also shown in Fig. 4. The slope of 45° confirms that a 1:1 ion-associate is formed. The conditional constants obtained were

$$K'_{ex} = (7.94 \pm 0.22) \times 10^4;$$

$$K'_D = 26.99 \pm 0.08;$$

$$\beta' = (2.94 \pm 0.09) \times 10^3.$$

Applications

Soil analysis. As is evident from Table 1, the method is applicable only to soils with sufficiently low calcium and sodium contents, *e.g.* soils of bodzol type. As a test of its validity the method was applied to some selected soils, and the chromium was also determined by atomic-absorption spectrometry. The results are shown in Table 2.

Steel analysis. An advantage of the method for steel analysis is that it is applicable to steels containing large amounts of vanadium or molybdenum relative to chromium, in contrast to the diphenylcarbazide method, where these elements interfere. Typical results are given in Table 2.

SPECTROPHOTOMETRIC DETERMINATION OF MERCURY IN SOILS WITH TRIPHENYLTETRAZOLIUM CHLORIDE

M. KAMBUROVA
Department of Chemistry, Higher Institute of Agriculture, 4000 Plovdiv, Bulgaria

(*Received* 18 *June* 1991. *Revised* 19 *September* 1991. *Accepted* 7 *October* 1991)

Summary—The formation of the acidocomplex of mercury(II) with triphenyl-tetrazolium chloride is studied spectrophotometrically in water–organic media. The composition of the complex is established as TTC:Hg:I = 1:1:1. The molar absorptivity $\epsilon_{255} = (6.45 \pm 0.12) \times 10^4$ l mole$^{-1} \cdot$ cm^{-1} is determined. The selectivity of the reaction is studied and the method for determination of mercury(II) 0.1–0.8 μg/ml is shown. Extraction investigations of the system discussed were carried out. The characteristic values for the extraction equilibrium and the equilibrium in the aqueous phase was determined: extraction constant $K_{ex} = 3.16 \times 10^4$, distribution constant $K_D = 20.67$, and association constant = 1.53×10^3. A rapid and sensitive extractive–photometric method for determination of mercury(II) in soil was developed. The determination was carried out without preliminary elimination of mercury.

Getting into soil, mercury has a negative effect upon the development of crop plants. This necessitates some more detailed studies of this chemical element in soils. Various methods for determination of mercury have been published.[1] They require expensive equipment and highly qualified analysts.[2,3] Atomic absorption spectrophotometry[4–11] and analyses with some other reagents are used.[12–29]

No data about determination of mercury with tetrazolium salts can be found in the literature. The tetrazolium salt (triphenyltetrazolium chloride) we suggest is a new reagent for determination of microquantities of mercury(II). It is known that mercury has an extremely high affinity towards iodide ion. Hg(II) forms stable acidocomplexes with I^-. This can be used in developing an extraction–photometric method for determination of mercury. The nature of the interaction between the acidocomplex of Hg(II) with the cation of the tetrazolium salt should be studied. The present paper represents the conditions needed for determination of mercury with triphenyltetrazolium chloride (TTC). This is an extremely simple and direct extraction for determination of microquantities of mercury.

The goal is to develop an extraction–photometric method using TTC for determination of mercury, superior, in some respects, to the existing methods. For example, no preliminary isolation or concentration of mercury is required as in some of the other methods.[19,20,29] To be superior in sensitivity to methods reported in the literature[16,17,24,27,28] the organic extract needs to be stable for a long time, and not only for a few hours as it is in the method of Mudakavi and Ramaswamy.[25]

EXPERIMENTAL

Apparatus

Spectrophotometer VSU 2-P, Carl Zeiss Jena, DDR, $\lambda = 255$ nm, 1 cm light path cuvette; Specord UV–VIS, DDR.

Reagents

2,3,5-Triphenyltetrazolium chloride (TTC) ($5 \times 10^{-4}M$, Merck), mercury acetate, p.a.—2 μg/ml Hg(II), $1 \times 10^{-5}M$ Hg(II); Sulphuric acid, p.a.—$2M$; Potassium iodide, p.a.—$1 \times 10^{-3}M$, Chloroform, merk.

Procedure

Sulphuric acid 1 ml $2M$, KI 1 ml $1 \times 10^{-3}M$ and TTC 0.5 ml $5 \times 10^{-4}M$ are added to an aliquot of the sample solution containing 1–8 μg of mercury in a separating funnel. It is diluted to aqueous phase volume of 10 ml with distilled water and extracted with 3 ml of chloroform for 30 sec. The organic layer is then transferred through filter paper into a 1-cm cuvette and recorded on a photometer VSU 2-P spectrophotometer at 255 nm. A blank, containing the same solutions without mercury, is prepared.

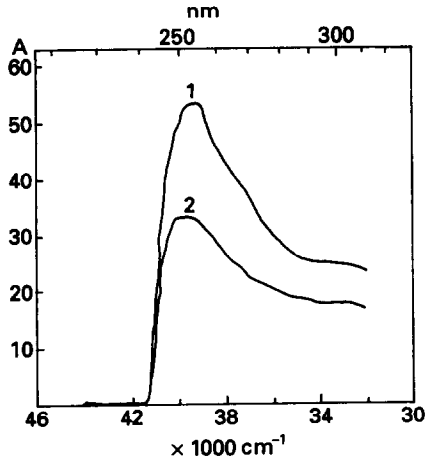

Fig. 1. Absorption spectra in chloroform of ion-association complex (1) and triphenyltetrazolium chloride (2); $C_{Hg(II)} = 0.2$ μg/ml, $C_{H_2SO_4} = 0.2M$, $C_{KI} = 5 \times 10^{-5}M$, $C_{TTC} = 5 \times 10^{-5}M$.

RESULTS AND DISCUSSION

The light absorption of the solutions of mercury acidocomplexes with TTC reaches its maximum immediately after mixing and does not change for 2 days. To clear out the possibility of extracting the ion associate a number of different types of solvents were tested: hydrocarbons (benzene and toluol), ketones, ethers, alcohols, chloroform, dichlorethane and tetrachlorethane. The studies showed that the associate is best dissolved in chloroform. The absorption spectra of equimolar solutions of tetrazolium salt and ion-association complex in sulphuric acid show that the absorption maxima are around 255 nm (Fig. 1). The absorption additivity, without a significant shift in the absorption maximum, is an indication of a formation of an ion-association complex.

The stoichiometric coefficients of the associate formation were established by various methods.[30] The ratio $Hg:I^-$ in the complex was established by the isomolar series and molar ratio methods. The ratio $TTC:[HgI_3]^-$ was proved by the methods of Bent–French, molar ratios, isomolar series and the method of Assmuss. The pH remained constant and optimal ($0.2M$ sulphuric acid) in all the assays. The results for the light absorption of the extracts at 255 nm showed that the associate was formed at a ratio $TTC:Hg:I = 1:1:3$.

The ion-associate of Hg(II) was completely extracted in a single extraction of only 5 sec. The molar absorptivity of the associate, calculated by the method of Komar–Tolmatchov,[30] was $\epsilon_{255} = (6.45 \pm 0.12) \cdot 10^4$ l mole^{-1} · cm^{-1}. This indicates the high sensitivity of the given reaction. The detection limit is 0.1 μg/ml Hg(II). Under optimum reaction conditions ($C_{TTC} = 2.5 \cdot 10^{-5}M$, $C_{H_2SO_4} = 0.2M$), the Beer's law was obeyed in the concentration range of 0.1–0.8 μg/ml Hg(II).

The effect of the acidity of the solution on the extraction of the ion associate of mercury is given in Fig. 2. The optimum acidity of the extraction was over a rather wide range: pH 1–9 and 0.1–4.5M H_2SO_4. At pH > 9, a hydrolysis occurs and the light absorption of the ion associate decreases. The effect of various acids (H_2SO_4, HCl and HNO_3) on the extraction equilibrium was studied. The light absorption of the extracts showed constant and maximum values when using H_2SO_4 (0.1–4.5M) or HCl (0.1×10^{-1}–$3.8 \times 10^{-1}M$).

A large excess of potassium iodide is needed for formation and extraction of the mercury complex with I^-. The chloroform extracts

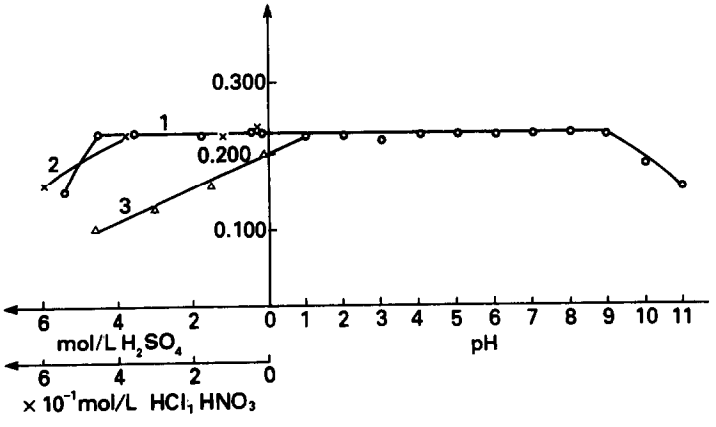

Fig. 2. The influence of acidity on the extraction of Hg(II) using TTC: 1—H_2SO_4, 2—HCl, 3—HNO_3; $C_{Hg(II)} = 2 \times 10^{-6}M$, $C_{TTC} = 2.5 \times 10^{-5}M$, $C_{KI} = 5 \times 10^{-5}M$.

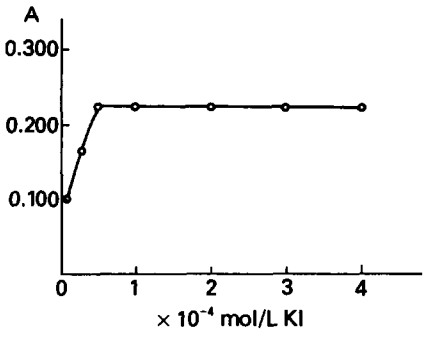

Fig. 3. Dependence of the absorbance change on the concentration of KI; $C_{Hg(II)} = 2 \times 10^{-6}M$, $C_{H_2SO_4} = 0.2M$, $C_{TTC} = 2.5 \times 10^{-5}M$.

have maximum value at a concentration of KI $> 0.5 \times 10^{-4}M$ (Fig. 3).

The extraction also depends strongly on the reagent TTC. A complete extraction of mercury(II) was achieved at a 10-fold excess of TTC (Fig. 4).

The effect of some ions upon the extraction–photometric determination of mercury(II) under optimum conditions was studied. The ratios of the accompanying ions at which the deviations in the results reached $S_r = 0.02$ ($n = 3$) are given in Table 1. The results obtained show the possibility of extractive–photometric determination of Hg(II) in the presence of numerous ions without separating Hg(II) from the accompanying ions. When an extraction with chloroform is used, Hg(II) could be determined in the presence of various amounts of the ions mentioned because the complexes they form cannot be extracted in chloroform. Ascorbic acid and NaF were used to eliminate the interference of Fe(III), Mo(VI) and W(VI). The determination is only interfered with by S_2O_3.

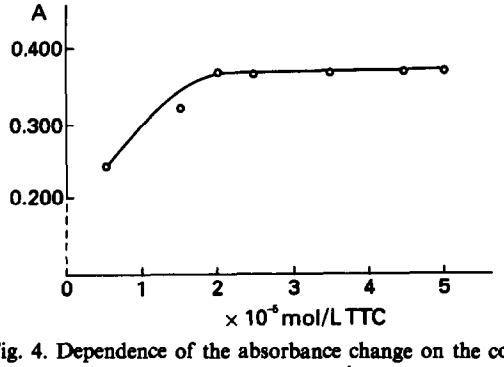

Fig. 4. Dependence of the absorbance change on the concentration of TTC; $C_{Hg(II)} = 4 \times 10^{-6}M$, $C_{H_2SO_4} = 0.2M$, $C_{KI} = 1 \times 10^{-4}M$.

A study of the extraction equilibrium

The values characterizing the extraction equilibrium K_{ex}, K_D, β were determined by a chemical model.[31]

We consider the equilibrium in the extraction system of triphenyltetrazolium chloride–mercury iodide–chloroform.

1. The formation of the ion associate in aqueous phase is characterized by the corresponding equilibrium constant

$$\beta = \frac{TTC[HgI_3]}{[TTC^+] \cdot [HgI_3^-]}. \quad (1)$$

2. Distribution of the ion associate between the aqueous and the organic phases and the corresponding distribution constant

$$K_D = \frac{\{TTC[HgI_3]\}_0}{TTC[HgI_3]}. \quad (2)$$

3. The entire process of the extraction in the system considered is described by the corresponding equilibrium constant which is regarded as the extraction constant

$$K_{ex} = \frac{\{TTC[HgI_3]\}_0}{[TTC^+] \cdot [HgI_3^-]} = K_D \cdot \beta. \quad (3)$$

Table 1. Effect of foreign ions $C_{Hg(II)} = 0.33$ μg/ml, $C_{KI} = 8.33 \times 10^{-5}M$, $C_{H_2SO_4} = 0.16M$, $C_{TTC} = 4.10 \times 10^{-6}M$

*In the presence of maskings reagents.

The distribution coefficient determined at a constant concentration of TTC and variable concentration of Hg(II) in the system studied gives the form:

$$D_{TTC} = \frac{\Sigma(TTC)_0}{\Sigma(TTC)} = \frac{\{TTC[HgI_3]\}_0}{[TTC^+] + TTC[HgI_3]}. \quad (4)$$

The following solutions are introduced into 100-ml separating funnels: 1 ml of $5 \times 10^{-4}M$ TTC, 1 ml of $2M$ H_2SO_4, 5 ml of $1 \times 10^{-3}M$ KI and the corresponding amounts of Hg(II). The volume of the aqueous phase is brought to 10 ml with distilled water. It is extracted with 3 ml of $CHCl_3$ for 30 sec. After the stratification of the two phases the organic phase is transferred through filter paper into a standard flask of 25 ml and is diluted up to the mark with chloroform. The light absorption of the organic phase is measured at $\lambda = 255$ nm with a 1-cm light path cuvette.

To determine the distribution coefficient of tetrazolium salts TTC, the absorptions obtained are compared to the one obtained after three times the extraction of the aqueous layer:

$$D_{TTC} = A/(A_{max} - A)$$

A—light absorption for a single time extraction
A_{max}—light absorption for three times extraction.

The experimental data are represented graphically by log D_{TTC}/log $C_{Hg(II)}$ (Fig. 5). The distribution constant is determined graphically by extrapolation of the straight line parallel to the x-axis up to the point of intersection with the y-axis. Using this graphical dependence we can also determine the extraction constant K_{ex} and the association constant β. They are determined by the slope of the figure up to the point of its intersection with the ordinate axis. The slope of the straight line (Fig. 5) is 45°. It means that the molar ratio of the reacting ions TTC^+ and $[HgI_3]^-$ is 1:1.

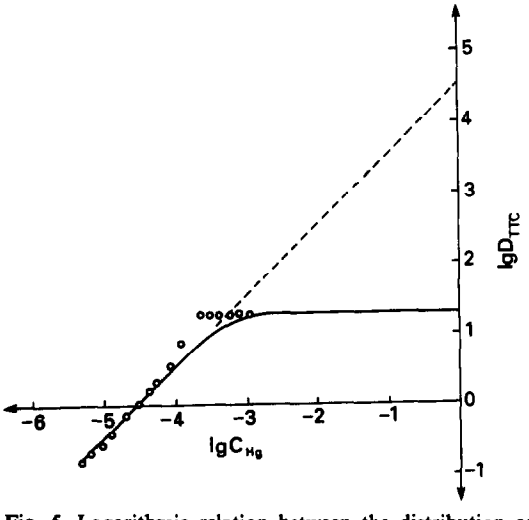

Fig. 5. Logarithmic relation between the distribution coefficient of TTC and the concentration of Hg(II).

The check-up for the fidelity of the experimental data has been performed according to the following formula:

$$D_{TTC} = \frac{K_D \cdot \beta \cdot [Hg]}{1 + \beta[Hg]}. \quad (5)$$

A curve is built, by the values calculated for D_{TTC}, where $C_{Hg(II)}$ is arbitrary changed and β and K_D are found experimentally. The curve obtained in this way is shown in Fig. 5. A good agreement is seen between the experimental data and the theoretical curve.

The ion associate $TTC[HgI_3]$ is characterized by the following equilibrium constants determined graphically:

$$K_D = 20.67 \pm 0.10$$

$$K_{ex} = 3.16 \times 10^4 \pm 0.08 \times 10^4$$

$$\beta = 1.53 \times 10^3 \pm 0.21 \times 10^3.$$

Determination of mercury in soils

The method was applied to determination of microquantities of mercury in various types of soils. The samples were collected from a depth of 0–20 cm.

Dissolving the sample. A 2-g weight of soil, 5–7 ml of conc. H_2SO_4 and an excess of $KMnO_4$ are placed into a flask equipped with a reflux condenser. The crystals of $KMnO_4$ are added slowly in small portions, while stirring. It is heated until vapours of SO_3 are evolved. After cooling down, 10 ml of distilled water are added. The excess of $KMnO_4$ and manganese oxides are eliminated by adding H_2O_2. Iron is isolated by precipitation as hydroxide. After filtration the solution is transferred into a standard flask of 25 ml and the volume is brought to the mark with distilled water. Aliquots of this solution are taken for analysis.

Extraction and determination of mercury. The following solutions were transferred into separating funnels: 12 ml of the corresponding type of soil solution and 1 ml of $2M$ H_2SO_4, 1 ml of $1 \times 10^{-3}M$ KI, 0.5 ml of $5 \times 10^{-4}M$ TTC and 5 ml of a saturated solution of NaF (to mask the interfering ions). Extracted with 3 ml of $CHCl_3$ for 30 sec. Then the organic phase was recorded

Table 2. Content of mercury in soil samples

*Relative error.
†Relative Standard Deviation.

at $\lambda = 255$ nm. A blank, containing the same solutions without the corresponding type of soil, is prepared. The concentration of mercury was determined by a standard curve.

The results for mercury(II), obtained using triphenyltetrazolium chloride, were compared to those obtained by the dithizone method (Table 2). The results of both methods show a good agreement. The method with TTC we developed, is sensitive, selective and rapid. Moreover, the reagent used in this method does not suffer the lack of stability which is the case for the dithizone extraction of mercury.

IODNITROTETRAZOLIUM CHLORIDE—A NEW ANALYTICAL REAGENT FOR DETERMINATION OF CHROMIUM

M. KAMBUROVA
Department of Chemistry, Higher Institute of Agriculture, 4000 Plovdiv, Bulgaria

(*Received* 25 *April* 1991. *Revised* 25 *July* 1991. *Accepted* 2 *August* 1991)

Summary—The extraction of chromium (VI) with iodnitrotetrazolium chloride (INT) was studied spectrophotometrically. The basic spectrophotometric characteristics of the ion associated formed were determined. Using different methods it was found that the ratio between chromium and INT was 1:1. The molar absorptivity of the associate is $\epsilon_{250} = (3.70 \pm 0.08) \times 10^4$ l · mole^{-1} · cm^{-1}. Performing the reaction in acid medium (0.1–1.1*M* hydrochloric acid) allowed the determination of chromium in the presence of large amounts of W(VI), Mo(VI), Fe(III) and V(V). Hence INT is suggested as a sensitive and selective reagent for extractive–spectrophotometric determination of microquantities of chromium(VI).

Tetrazolium salts appear as highly sensitive reagents for extractive–spectrophotometric determination of a number of elements, *viz.* Co(II), Zn(II), Au(I), Sb(V), Nb(V), Mo(VI), W(VI), Re(VII), Tl(III), Ga(III).[1–11] The methods for determination of chromium with tetrazolium salts are particularly interesting. In earlier studies we have established that under certain conditions triphenyltetrazolium chloride[12] and tetrazolium violet[13] form ion-association complexes with chromium, which are extractable in organic solvents.

The known methods of determination of chromium are of low sensitivity.[23,24] The most sensitive and selective is the method with diphenylcarbazide.[21] It is the best reagent for determination of small amounts of chromium. A disadvantage of this method appears to be the labour-consumption of the preparatory works. Another disadvantage is the instability of the aqueous solution of diphenylcarbazide and its preparation in acidified acetone.

In the present work we show the possibility of using iodnitrotetrazolium chloride (INT) for determination of chromium to demonstrate that in the determination of microquantities of chromium, the tetrazolium salt is superior to diphenylcarbazide in some respects. The reagent we used is available and has good chemical–analytical parameters. The complexation and extraction of chromium(VI) with this tetrazolium salt was studied as well as the effect of various factors upon the extraction of the ion associate of chromium. Its basic chemical–analytical characteristics were determined. The possibility of using INT as a reagent for spectrophotometric determination of microquantities of chromium(VI) is demonstrated in assays of this species in steel and soil samples.

EXPERIMENTAL

Reagents

Iodnitrotetrazolium chloride (INT), Fluka, $1 \times 10^{-4}M$; potassium chromate, *p.a.* $1 \times 10^{-4}M$ Cr(VI); hydrochloric acid, *p.a.* 1.2*M*; 1.2 dichlorethane, *p.a.*

Apparatus

A Carl Zeiss VSU 2-P spectrophotometer (Jena, DDR) was used with 1-cm light path quartz cells with measurement at 250-nm. A Specord UV–VIS (DDR) was also used.

Procedure

Corresponding amounts of the solution containing chromium, 1.2 ml of 1.2*M* hydrochloric acid and 2 ml of $1 \times 10^{-4}M$ INT are introduced into separating funnels. The mixture is diluted with distilled water to an aqueous phase volume of 10 ml and extracted with 3 ml of dichlorethane for one minute. The organic layer is then transferred through filter paper into a 1-cm cell and measured at $\lambda = 250$ nm. A blank is prepared in a similar manner, without the presence of chromium.

RESULTS AND DISCUSSION

With chromium, in hydrochloric acid medium, Iodnitrotetrazolium chloride forms an ion associate with chromium in hydrochloric acid medium of composition INT $H[CrO_3Cl]$. This composition has been confirmed in earlier reports.[14-18]

Our studies showed that the ion associate of Cr(VI) with INT was quantitatively extracted into dichlorethane. In other solvents, such as chloroform, benzene, nitrobenzene and ether, the compound is not extractable.

The analysis of the absorption spectra of the ion associate obtained from the interaction of Cr(VI) and INT showed that the compound had maximum light absorption at $\lambda = 230$ nm and $\lambda = 250$ nm (Fig. 1). The intensity of the second maximum was considerably higher. We therefore chose 250 nm as a working wavelength.

The maximum extraction of chromium as an ion associate in the organic phase was reached after extraction for 30 sec. The ion associate is stable for five days.

The molar ratios of the constituents in the associate were established by the method of equilibrium shift.[19] The tangent of the slope angle was 1, *e.g.*, the ratio INT:Cr = 1:1. This ratio was confirmed with the method of Asmuss.[20] Under optimal conditions the molar absorptivity had the value of $\epsilon_{250} = (3.70 \pm 0.08) \times 10^4\ l \cdot mole^{-1} \cdot cm^{-1}$.[20] The light absorption of the associate depended linearly on the concentration of chromium in the range 0.02–0.3 μg/ml. From these data it is seen that the reaction of chromium with INT is highly sensitive.

The basic parameters studied which characterize the qualities of INT as a reagent are concentration parameters.

To establish the optimal conditions for extraction and complexation we studied the relationship between light absorption and the concentration of the tetrazolium salt (Fig. 2). The optimal concentration of INT for formation and extraction of the associate was found to be [INT] $\geqslant 2 \times 10^{-5} M$.

The stability and character of the compound formed depend considerably on the acidity of the aqueous phase. The effect of the acids upon the extraction of the ion associate of chromium is given in Fig. 3 where it can be seen that the nature of the acids studied (HCl, H_2SO_4, HNO_3 and $HClO_4$) contributes substantially to the maximum extraction of chromium as an ion associate. The best results were obtained in hydrochloric acid medium in the range 0.1–1.1M hydrochloric acid.

When the acidity of the aqueous phase is high, the extraction of the ion associate decreases because of the reduction of Cr(VI) to Cr(III).

The effect of foreign elements and complexing substances was studied during the determination of 2 μg of Cr(VI). It was found that most of the studied ions did not interfere with the determination of chromium as an ion associate. The experimental data are given in Table 1. Hg(II), Al(III), Ca(II), Na(I) and Br^- all interfered in the determination. Sodium fluoride, tartaric acid and ascorbic acid were used as

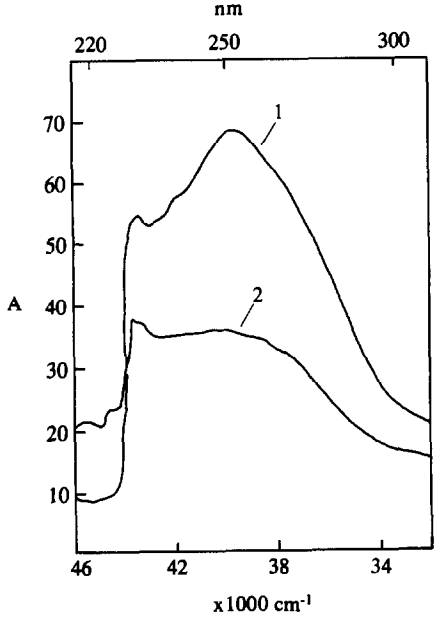

Fig. 1. Absorption spectra in dichlorethane of the ion-association complex of Cr(VI) with INT(1) and INT(2).

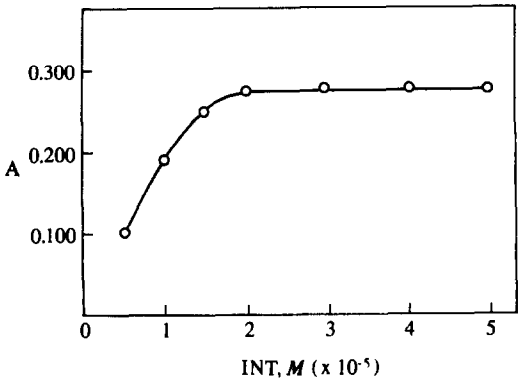

Fig. 2. Dependence between light absorption and the concentration of INT; $C_{Cr(VI)} = 0.3$ μg/ml, $C_{HCl} = 0.14M$.

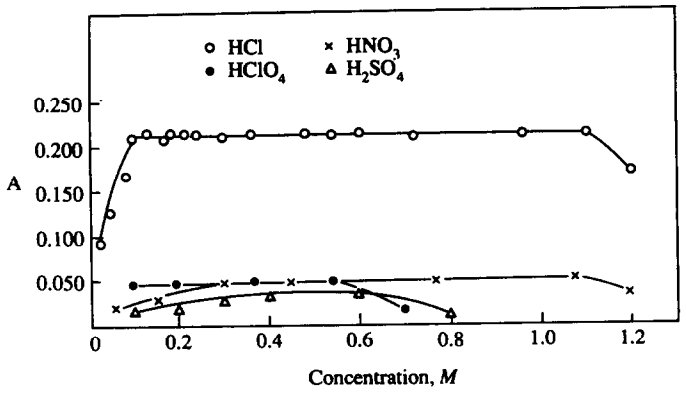

Fig. 3. Dependence between light absorption and pH of the solution; $C_{INT} = 1 \times 10^{-5} M$, $C_{Cr(VI)} = 7 \times 10^{-6} M$.

masking reactions. The method with INT for determination of chromium was found to be selective in the presence of W(VI), Mo(VI) and Fe(III).

On the basis of the data obtained we developed a method for determination of chromium. The sensitivity of the method according to Sandell[21] is $W_S = 0.0014$ $\mu g/cm^2$. Its practical applicability was demonstrated by application to analysis of steels and soils containing chromium.

Application to determination of chromium in steels

Sample dissolution. Steel (0.1 g) is weighed and dissolved in a 30-ml mixture (1:3) of HNO_3(1:1) and HCl(1:1). Concentrated sulphuric acid (10 ml) is added and the mixture is evaporated until SO_3 vapour is noticed. The solution is transferred into a 100-ml standard flask and is diluted to the mark with distilled water.

Table 1. Effect of foreign ions

N	Foreign ion,	μg	Chromium(VI) Taken, μg	Found, μg	$C_M/C_{Cr(VI)}$
1	K(I)	8000	2	1.98	4000

*In the presence of maskings reagents.

The oxidation of Cr(III) to Cr(VI) is performed with potassium permanganate in a sulphuric acid medium.[21]

Determination of chromium. Aliquots of the prepared solution of alloyed steel, 1.2 ml of 1.2*M* hydrochloric acid, 2 ml of $1 \times 10^{-4} M$ INT are introduced into separating funnels. Saturated solutions of 2 ml of sodium fluoride and 2 ml of ascorbic acid are introduced (to mask the interfering ions). The solutions are extracted with 3 ml of dichlorethane for 1 min. The organic layer is then transferred through filter paper into 1-cm cell and measured at $\lambda = 250$ nm.

The quantity of chromium in the aliquot is determined by a standard curve. The results of the chromium determination in steels are given in Table 2.

Application to analysis of soils

The method was applied to the determination of chromium in five soil samples: lessive cinnamonic, pseudopodzolic, gray forest, brown and black soil.

Sample dissolution. A 4-g soil sample is weighed and introduced into a platinum crucible, heated for 3 hr in a muffle furnace at 550°. After cooling, the sample is transferred into a platinum bowl and 2 ml of bidistilled water, 1 ml of concentrated sulphuric acid and 10 ml of hydrofluoric acid are added. It is evaporated on a sand bath until SO_3 vapour is evolved. The dry residue is dissolved in bidistilled water acidified with hydrochloric acid.[22]

Table 2. Determination of chromium in steels

N	Steel	Content of chromium by certification list, %	Chromium found, % (*n*)
1	38 × 2I–O CO–C 14a	1.84	1.83 ± 0.02 (5)
2	CO–C 37	17.6	17.58 ± 0.01 (5)

38 × 2I–O CO–C 14a (%): C—0.364; Si—0.50; Mn—0.350; Ni—0.162; Cr—1.84; W—0.293; V—0.208; Cu—0.128; Al—0.56; S—0.0058; P—0.0074; CO–C 37 (%): C—0.05; Si—0.5; Mn—1.35; Cr—17.6; Ni—12; Cu—0.2; Nb—1.2.

Table 3. Determination of chromium in soils

N	Soil	$Cr \times 10^{-4}$ %		Relative error, %
		Iodnitrotetrazolium chloride	Atomic absorption	
1	Lessive cinnamonic	4.35	4.37	0.45
2	Pseudopodzolic	5.62	5.62	0.00
3	Gray forest	3.10	3.12	0.64
4	Brown	3.11	3.12	0.32
5	Black	9.35	9.37	0.21

After the precipitation of iron and aluminium the solution was transferred into a 25-ml standard flask and diluted up to the mark with bidistilled water. Aliquots from this solution were taken for analysis.

Determination of chromium. Hydrochloric acid (1.2-ml, 1.2*M*), 2 ml of $1 \times 10^{-4}M$ INT and equal volumes of saturated solutions of ascorbic acid and ammonium fluoride are added to the sample solution. A 10-ml portion of the aqueous phase is extracted for 1 min with 3 ml of dichlorethane. A blank is run in parallel in the absence of soil sample.

The concentration of Cr(VI) is determined with a standard curve. The accuracy of the method was checked with an atomic absorption method. The experimental data (Table 3) show good agreement between the results obtained by the two methods.

The method with iodnitrotetrazolium chloride can be successfully applied to the determination of chromium in various objects. Its features are high accuracy, selectivity and sensitivity.

ANNOTATION PAPER

INTERFERENCE BY VOLATILE NITROGEN OXIDES IN THE DETERMINATION OF MERCURY BY FLOW INJECTION COLD VAPOR ATOMIC ABSORPTION SPECTROMETRY

INGE ROKKJÆR, BOY HOYER* and NINA JENSEN
Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Aarhus C, Denmark

(*Received* 11 *May* 1992. *Revised* 7 *July* 1992. *Accepted* 3 *August* 1992)

Summary—The determination of mercury by the title method with sodium tetrahydroborate as reducing agent can be interfered with by volatile nitrogen oxides which inhibit the reduction of mercury by scavenging the reducing agent. The nitrogen oxides are formed as reduction products of nitric acid during sample decomposition. The interference effect was encountered in the determination of mercury in sewage sludge digests, and the main symptom was poor reproducibility of the shape of the mercury peak. The area of the mercury peak is more resistant to the interference than the peak height. The nitrogen oxide interference did not cause any systematic error in the mercury determination when calibration was done by standard addition. The interference can be easily remedied by purging the sample with argon.

The coupling of flow injection (FI) with cold vapor atomic absorption spectrometry (CVAAS) for the determination of mercury has many significant advantages in comparison with the conventional batch CVAAS technique. These advantages include[1] lower sample and reagent consumption, higher sample throughput, ease of automation and superior resistance to metals which cause solution-phase interferences (*e.g.* Ni, Cu and Ag). When sodium tetrahydroborate is employed as reducing agent in FI–CVAAS it is generally used in lower concentration than in batch CVAAS,[1,2] and the determination of mercury by the latter technique is therefore more susceptible to interferences from sample constituents which scavenge the reducing agent. The present paper describes an interference of this type which was encountered in the determination of mercury by FI–CVAAS in digests of sewage sludge. The interference effect could be attributed to volatile nitrogen oxides which were formed during the decomposition of the sample.

To the authors' knowledge, the interference from nitrogen oxides in the determination of mercury by batch CVAAS has only been described in one paper,[3] and the interference therefore appears to be rare in this technique. Stuart[4] and Wigfield *et al.*[5] have previously shown that the peak area is generally less susceptible to matrix effects and interferents than the peak height in the determination of mercury by batch CVAAS.

*Author for correspondence.

EXPERIMENTAL

Apparatus

All atomic absorption measurements were made with a Perkin–Elmer ZL 4100 spectrometer equipped with a 16.6-cm quartz flow-through cell heated to 200°. Operating conditions were as follows: wavelength, 253.7 nm; monochromator wavelength interval, 0.7 nm; mercury hollow cathode lamp current, 6 mA. Sample introduction was performed by a Perkin–Elmer FIAS 200 flow injection system, of which a schematic diagram is shown in Fig. 1. The gas–liquid separator was a vertical tube with the sample inlet placed above the waste outlet and the gas outlet in the top.[6] The internal volume of the gas–liquid separator was 4.1 ml, and it was filled with spherical glass beads with a diameter of 3 mm. The 1-mm i.d. tube connecting the gas–liquid separator and the quartz cell was one metre long. The carrier was a 10% (v/v) hydrochloric acid

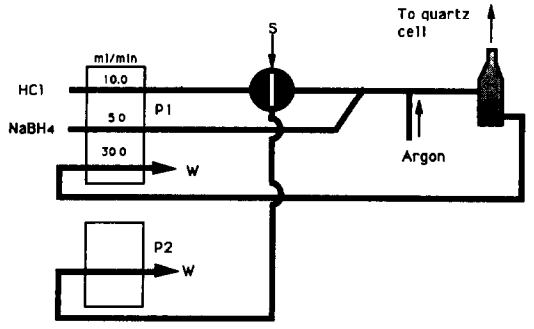

Fig. 1. Schematic diagram of flow injection system for mercury determination. P1, P2: peristaltic pumps; S: sample inlet; W: waste.

solution, while the reductant, unless stated otherwise, contained 0.2% (v/w) sodium tetrahydroborate stabilized with 0.04% (v/w) sodium hydroxide. The flow rates were as follows: carrier, 10 ml/min; reductant, 5 ml/min; waste, 30 ml/min; argon, 75 ml/min. The amalgamation accessory was a Perkin–Elmer system in which the gas from the gas–liquid separator passes through a wash bottle and a magnesium perchlorate drying filter prior to collection of mercury on a platinum-gold gauze. Mercury is subsequently liberated by rapid heating of the gauze to 600°. In the experiments with the amalgamation technique, the argon flow through the gas–liquid separator was 300 ml/min, while the collector was purged with a 75 ml/min argon stream during heating. The volume of the sample loop was respectively 500 μl in the direct flow injection measurements and 200 μl in the measurements with the amalgamation technique. The pressure digestion bomb (Berghof model DAB III) was made of stainless steel with a 250-ml Teflon insert.

Reagents and samples

Solutions were prepared from triply distilled water and Merck Suprapur chemicals except for sodium tetrahydroborate and potassium dichromate which were of Merck analytical grade with low mercury content. The anti-foaming agent was Merck no. 7743 silicone oil. Mercury standards were prepared in a stabilizing medium containing 5% (v/v) nitric acid and 0.05% (w/v) potassium dichromate. Sludge samples were supplied from a local sewage treatment plant. The type I sludge was sampled from the aerobic stage of the treatment while the type II sludge originated from an anaerobic digester. The total solid content of sludge I and II was respectively 2.8 and 4.0%.

Procedure

Sludge samples were decomposed by mixing 20 ml of concentrated nitric acid and approximately 20 g wet sludge in the pressure digestion bomb and heating it to 140° for 4 hr. After cooling, the digest was transferred to a standard flask and the volume made up to 100 ml with water. The nitric acid concentration of this solution determined by acid–base titration was $2.9 \pm 0.1M$ for both sludge types. Before mercury determination, the type II sludge digest was further diluted tenfold with water. Volatile nitrogen oxides were removed from the digests by purging with an argon stream (75 ml/min) in a sample tube (15 mm i.d.).

Quantitation of mercury was done by standard addition. It has been shown that precision is improved by use of a single, large addition with the number of measurements equally distributed between sample and spiked sample.[7] This approach was adopted in the present study, and the mercury concentration was approximately tripled by the addition. In separate experiments it was verified that the linear part of the instrument response function was not exceeded by the addition. Four replicate measurements were performed on the unspiked as well as the spiked sample. A blank signal measured in $0.1M$ nitric acid was subtracted from all absorption curves. Signals were smoothed with a 5-point Savitsky-Golay algorithm prior to peak height evaluation. The peak integration time was 20 sec unless stated otherwise. Signals were evaluated by peak height in the amalgamation technique.

RESULTS AND DISCUSSION

In Fig. 2, a series of absorption curves obtained by repetitive mercury measurements on the type I digest is shown. The technique employed is FI–CVAAS without amalgamation. Obviously, the peak shape can vary considerably between individual replicates. Although a gradual decrease of peak height is seen in Fig. 2, it was generally observed that the variations in peak shape were random. The relative standard deviation of the peak height and peak area were respectively 11.5 and 2.4% for the signals in Fig. 2 which are typical values for repetitive measurements on the type I digest. Thus, precision is substantially improved by using the peak area instead of the peak height as the analytical signal.

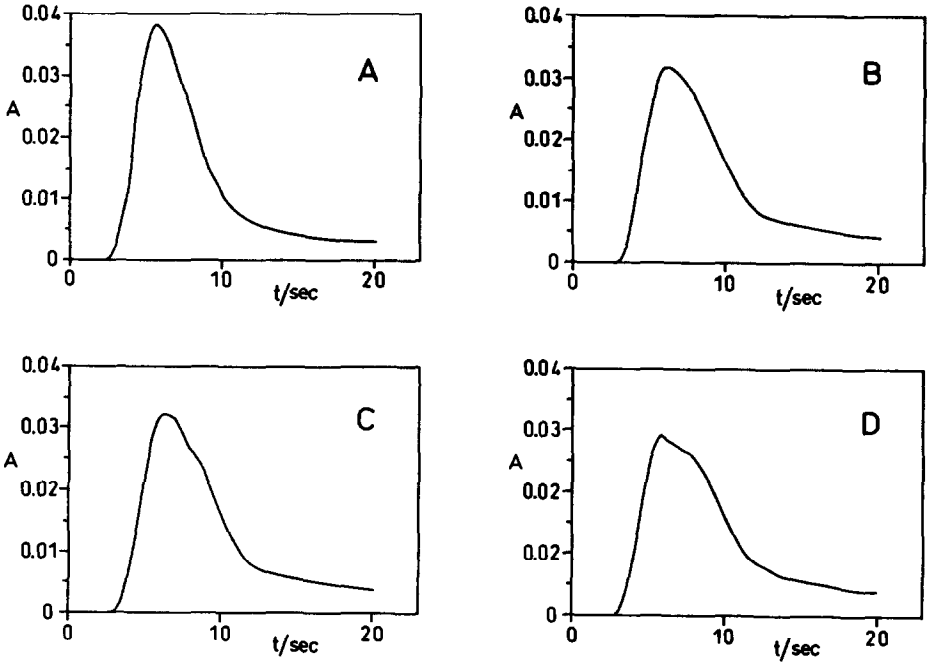

Fig. 2. Absorption peaks for mercury obtained by repetitive measurements on the type I sludge. The peak heights (absorbance) and areas (absorbance·s) are respectively: (A) 0.038, 0.203; (B) 0.032, 0.214; (C) 0.032, 0.204; (D) 0.029, 0.207.

Initially it was believed that the poor reproducibility of the absorption peak of mercury was due to segmentation of the sample stream by the formation of hydrogen gas which takes place at the confluence point of the sample and the reductant stream. From this hypothesis it follows that the shape and the reproducibility of the mercury peak should be improved by decreasing the concentration of sodium tetrahydroborate. However, as shown in Fig. 3 the

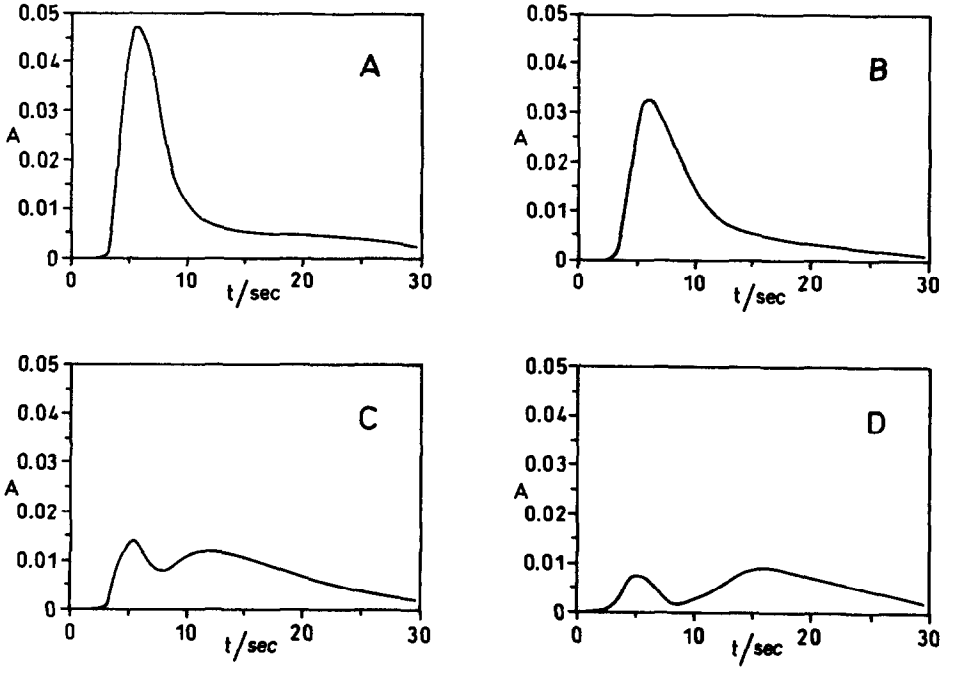

Fig. 3. Influence of the reductant concentration on the mercury signal measured in a type I digest by FI–CVAAS without amalgamation. Sodium tetrahydroborate concentration [% (v/w)]: (A) 0.2; (B) 0.15; (C) 0.1; (D) 0.05.

mercury peak was suppressed, broadened and even split when the strength of the reducing solution was decreased. In a similar experiment, a mercury standard prepared in a nitric acid medium of equal strength as the type I digest was used as sample. In this case, it was found that the concentration of sodium tetrahydroborate could be reduced from 0.2% (v/w) to at least 0.012% (v/w) without any significant change of the mercury signal. Therefore, a constituent of the type I sample matrix interferes with the reduction of mercury or the separation of the elemental mercury into the gas phase. In Fig. 4 it is shown that purging of the type I digest with argon greatly improves the shape of the mercury absorption peak, and the interferent must therefore be volatile. This is in agreement with previous work[8] which showed that nitrogen oxides generated by reduction of nitric acid during sample decomposition can inhibit the formation of the hydrides of arsenic and selenium in the hydride generation atomic absorption technique. Signal suppression by nitrogen oxides has also been reported in the determination of mercury by batch CVAAS in samples which were decomposed by a mixture of nitric, sulphuric and hydrochloric acid.[3] The decomposition was done in an open flask heated by a boiling water bath, and it would be expected that the volatile nitrogen oxides escaped under such conditions. However, concentrated sulphuric acid reacts with nitrogen oxides, *e.g.*,[9]

$$N_2O_4 + 3H_2SO_4 \leftrightarrow NO^+ + NO_2^+ + 3HSO_4^- + H_3O^+$$

and their solubility is therefore increased. This is in agreement with the fact that no interference from nitrogen oxides was observed when nitric acid was used on its own for decomposition.[3]

The extent of the interference from nitrogen oxides in the type I digest was related to the age of the digest. In one digest, which had been kept for four months in a half full bottle, no interference was observed at all, and a reduction of the concentration of sodium borohydride from 0.2% (v/w) to 0.003% (v/w) only caused a slight broadening of the mercury peak, while the integrated absorbance was unaffected. Usually, 2 or 3 days passed between sample decomposition and the FI–CVAAS measurement. In this case the degree of interference was typically as shown in Fig. 1. The mercury signal was strongly suppressed and resembled Fig. 2C when the measurement was performed immediately after the sample was transferred from the pressure bomb. These observations can all be attributed to the volatility of the interferent. In all cases, it was found that 10 min of argon

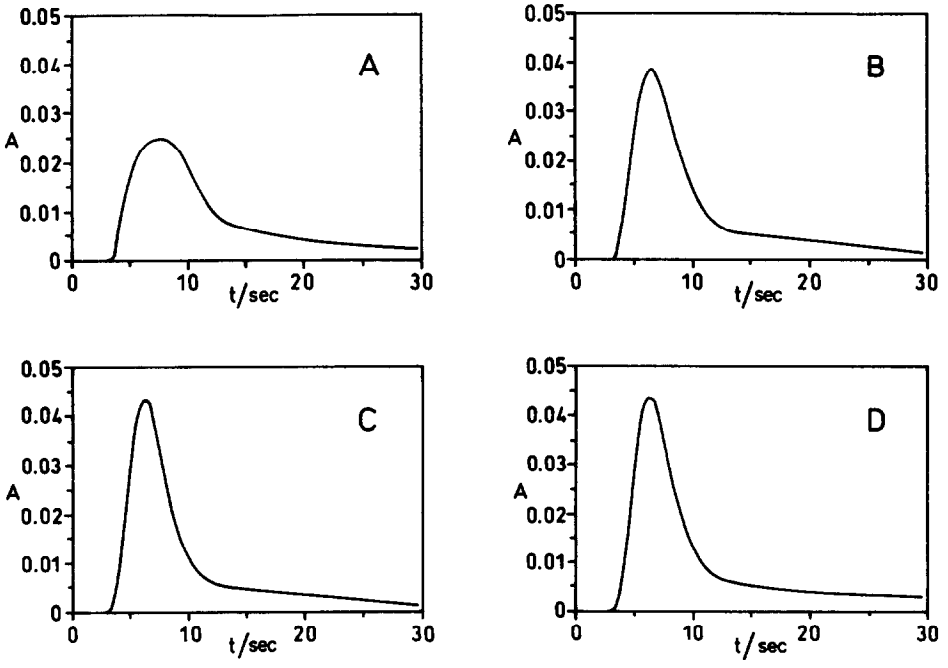

Fig. 4. Influence of the argon purging time on the mercury signal measured in a type I digest by FI–CVAAS without amalgamation. Sodium tetrahydroborate concentration: 0.2% (v/w). Purging time (min): (A) 0; (B) 2; (C) 4; (D) 6.

purging was sufficient for complete elimination of the interference. No further change of the mercury signal occurred when the purging time was increased to 60 min, and the amount of mercury lost by the purging is therefore insignificant.

The most plausible explanation[3] of the interference effect appears to be that the reduction of nitric acid during sample decomposition yields a volatile product (the interferent) which is further reduced by sodium tetrahydroborate. The rate of the latter reaction must be so fast that tetrahydroborate is consumed before the reduction of mercury is complete. Naturally, the suppression of the mercury evolution can only be complete when the interferent is in stoichiometric excess of tetrahydroborate. The scavenging of the reductant and the concomitant inhibition of mercury evolution will be most pronounced in the central part of the sample zone where the concentration of the interferent is highest. This effect explains the splitting of the mercury peak at low reductant concentrations which is seen in Fig. 3.

The main products of the reduction of nitric acid when used as oxidant in high concentration are[9] NO, NO_2, N_2O_4 and NO_2^-. On the basis of the present work it is not possible to determine which species is the actual interferent. Argon purging will also remove nitrite from the sample according to the reaction[9]

$$3HNO_2 \leftrightarrow HNO_3 + H_2O + 2NO\uparrow.$$

An attempt was made to eliminate the interference from nitrogen oxides by increasing the strength of the reductant solution, which normally contained 0.2% (v/w) sodium tetrahydroborate. However, this was not possible in practice with the digests of the type I sludge because the formation of aerosol in the gas–liquid separator became excessive, and the moisture carried into the quartz cell condensed on the end windows. Moderate foaming occurred in the gas–liquid separator when mercury was determined in the type I digest. Addition of anti-foaming agent to the carrier solution did not reduce the foaming significantly, whereas some suppression of the foaming was obtained by adding anti-foaming agent to each sample. However, this measure did not improve the reproducibility of the mercury signal, and further use of the anti-foaming agent was given up.

The data given in Fig. 2 and Fig. 5 indicate that the area of the mercury peak is less susceptible to the interference from nitrogen oxides than the peak height. In order to investigate this matter further, the results obtained by the direct FI method and the amalgamation method were compared. In the latter, the collection of mercury prior to the measurement step yields a signal which corresponds to the total quantity of mercury evolved during the reduction step, and this signal is not sensitive to variations in the shape of the mercury concentration transient emerging from the gas–liquid separator. The amalgamation method will also be affected by interference from nitrogen oxides if the evolution of mercury is inhibited to such an extent that a significant amount of unreacted, ionic mercury is pumped to waste from the gas–liquid separator. However, the measurements reported in the following were performed on digests which were at least 2 days old (see above), and purging of the digest with argon did not affect the mercury signal obtained with the amalgamation method. This result implies that the interference from nitrogen oxides is not so severe that it reduces the efficiency of the transfer of mercury from the sample to the collector. Mercury was determined in twelve separate digests of the type I sludge by the direct FI as well as the amalgamation method, and the concentration (as determined by the latter method) ranged from 4.6 μg/l. to 6.3 μg/l. When the FI signals were evaluated by peak height, the ratio $R = [Hg]_{TOT(FI)}/[Hg]_{TOT(AMALGAM)}$ ranged from 82 to 105%, with mean and standard deviation of respectively 96 and 6%. For the peak area evaluation of the FI signals, the corresponding values for R were: range, 95–105%; mean, 99%; standard deviation, 3%. Again, precision is improved by use of peak integration. A t-test showed that the mean value of R obtained by either form of signal

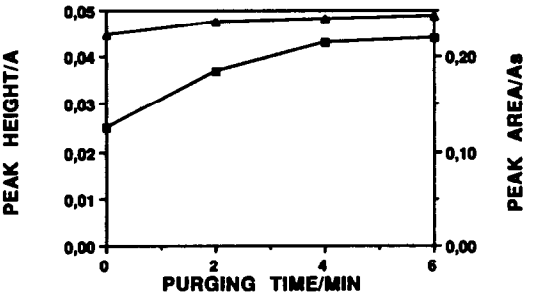

Fig. 5. Influence of the argon purging time on the peak height (■) and the peak area (▲) of the mercury signal measured in a type I digest by FI–CVAAS. Experiment conditions as in Fig. 4. Each point is the average of 3 replicates.

evaluation did not differ from 100% at a 95% confidence level. Therefore, it cannot be concluded from the data that the interference from nitrogen oxides causes systematic errors in the direct FI mercury determination. However, it must be emphasized that quantitation of mercury was carried out in a manner that yields a high precision (see above). If fewer replicates and a smaller standard addition is used, as would be expected in a routine application, the variations in peak shape can cause serious scatter of the results in the direct FI method when signal evaluation is based on peak height.

The high mercury content of the type II sludge digest necessitated a further tenfold dilution prior to measurement. In this matrix, no signal distortion was observed, and the relative standard deviation of the peak height as well as the peak area was typically 2%. For this sludge type the accuracy of the direct FI method was also verified by comparison with the amalgamation technique. Eleven digests were analysed, and the mercury content in the diluted digests ranged from 4.3 to 7.1 μg/l. The values for R (defined above) were: (a) peak height evaluation of FI signals: mean, 100%; standard deviation, 3%; (b) peak area evaluation: mean, 99%; standard deviation, 3%. In this case, there is little to choose from the two ways of quantifying the signal in agreement with the reproducible FI peak shapes.

As discussed above, the precision of the determination of mercury by FI-CVAAS without amalgamation in the type I digest was improved by evaluating the signal by peak area instead of peak height. However, it is possible that signal evaluation by peak area results in a poorer detection limit as the best signal-to-noise ratio (S/N) is found at the peak maximum. On the other hand, the noise is averaged by signal integration, and it is not possible to determine *a priori* whether it is peak height or peak area that yields the best detection limit. This matter was not investigated experimentally, but an estimate can be given as follows. If the noise level N is assumed to be independent of absorbance at low absorbance levels, one obtains:

$$(\mathrm{S/N})_{\text{peak h}} = \frac{A_{\text{peak}}}{\mathrm{N}}.$$

In practice, the peak area is evaluated by numerical integration of I absorbance readings taken with constant time interval Δt, and S/N for the peak area is approximately

$$(\mathrm{S/N})_{\text{peak a}} = \frac{\Delta t \sum_{i=1}^{I} A_i}{\Delta t \cdot \mathrm{N}\sqrt{I}}$$

if the noise is "white". Thus,

$$\frac{(\mathrm{S/N})_{\text{peak h}}}{(\mathrm{S/N})_{\text{peak a}}} = \frac{\sqrt{I} \cdot A_{\text{peak}}}{\sum_{i=1}^{I} A_i}.$$

Moreover,

$$I = \frac{\text{integration time}}{\Delta t} = \frac{20\ \text{sec}}{18\ \text{msec}} = 1110.$$

It is reasonable to assume that the shape of the signal is independent of concentration at low signal levels, or, in other words, that the ratio between peak height and peak area is constant. In a typical signal (*cf.* Fig. 2), the values for the peak height and the peak area were respectively 0.038 A and 0.20 $A \cdot s$, and

$$\frac{A_{\text{peak}}}{\sum_{i=1}^{I} A_i} = \frac{\text{peak h}}{(\text{peak area})/\Delta t} = 0.0034.$$

Therefore,

$$\frac{(\mathrm{S/N})_{\text{peak h}}}{(\mathrm{S/N})_{\text{peak a}}} = 0.11$$

which indicates that the best detection limit with the given experimental conditions is obtained by evaluating the signal by peak area. However, it must also be taken into account that $(\mathrm{S/N})_{\text{peak h}}$ is improved by the Savitsky–Golay smoothing.

In conclusion, there is a risk of interference from volatile nitrogen oxides when mercury is determined by FI–CVAAS in digests of samples which have been decomposed by nitric acid. This acid is prescribed for sample decomposition in, *e.g.*, the Danish[10] and Swedish[11] standard methods for mercury determination in waters, sludges and sediments. The interference effect is easily eliminated by purging the sample with argon. Alternatively, the nitrogen oxides can be reduced by sulphamic acid.[8] The interference is more likely to occur in FI–CVAAS than in batch CVAAS as the concentration of sodium tetrahydroborate used in the latter method is higher. For example, the concentration of sodium

tetrahydroborate in the present study was approximately 0.07% (v/w) after the merging point of the sample and reductant streams. In batch CVAAS, the concentration of sodium tetrahydroborate in the reaction vessel is typically[1,2] 0.6% (v/w) assuming complete mixing of the reductant and the sample. Both estimates disregard acidic hydrolysis of tetrahydroborate. It is also likely that the risk of interference from nitrogen oxides on the mercury determination can be decreased by use of tin(II)chloride as reductant instead of sodium tetrahydroborate. Typically, a 10% (v/w) tin(II)chloride solution is used as reductant[12] in FI–CVAAS which has a much higher stoichiometric reduction capacity than the corresponding 0.2% (v/w) sodium tetrahydroborate reductant. Consequently, it is less likely that the tin(II)chloride reductant is consumed by nitrogen oxides.

In the present work, the continuous variation of the mixture ratio between the interferent and the reductant created by the dispersion of the sample zone proved useful in the elucidation of the interference mechanism. Therefore, this article also exemplifies the diagnostic power of flow injection analysis.

(*Received* 20 *August* 1992. *Revised* 6 *November* 1992. *Accepted* 8 *November* 1992)

Summary—A rapid, precise and low cost method for saccharin determination in dietary products is proposed. Saccharin in several samples is potentiometrically titrated with mercurous nitrate solution using a silver wire coated with a metallic mercury film as the working electrode, and the end point was found using a Gran's plot. The detection limit of sodium saccharin was 0.5 mg/ml and the best pH range was from 2.0 to 3.5. Sucrose, glucose, aspartame, sodium cyclamate, sorbitol, fructose, benzoic acid, salicylic acid and lactose do not interfere even in significant amounts. The interference due to the presence of chloride and/or phosphate ions can be eliminated by previous solvent extraction of this sweetener. Recovery of saccharin from various dietary products gave from 95.2 to 103.2% of the label claim.

Saccharin (o-benzoic sulfimide, $C_6H_4COSO_2NH$) and its salts are white crystalline powders, odorless and in diluted solution are about 400–500 times[1] sweeter than sucrose. Due to their characteristics, they are widely used in medicine and several dietary products. There are several analytical procedures cited in the literature for determining saccharin such as gravimetry,[2,3] polarography,[4,5] fluorimetry,[6] ultraviolet spectrophotometry,[7,8] infrared spectrophotometry,[9] thin-layer chromatography,[10] gas–liquid chromatography,[11–13] high-performance liquid chromatography,[14,15] visible spectrophotometry using tris-(1,10-phenanthroline)-iron(II) chelate,[16] methylene blue,[17] phenothiazine,[18] phenosulphonaphthalein,[19] chlorophenothiazine,[20] azure B[21] and azure C[22] and potentiometry by using a liquid membrane electrode based on the formation of ion association between this sweetener with iron(II)-bathophenanthroline chelate.[23] Nevertheless most of these methods are time-consuming and laborious.[2–5,10,16–22] while others either need costly equipment[4–6,11–15] or have limitations in selectivity and/or sensitivity.[2,3,6–10,16–23]

In this paper, a new potentiometric method for saccharin determination in dietary products is proposed, based on the low solubility of mercurous saccharinate. Saccharin was potentiometrically titrated with $Hg_2(NO_3)_2$ solution and the remaining Hg_2^{2+} was monitored by a silver electrode coated with a metallic mercury film. After the equivalence point, a small excess of the titrant causes a potentiometric jump that was treated by a Gran's plot to give a precise and accurate end point determination. The proposed method is rapid, precise, accurate, inexpensive and does not need previous preparation to remove interferring substances. Only samples containing chloride and/or phosphate ions need be extracted with ethyl acetate in order to quantitate saccharin.

EXPERIMENTAL

Apparatus

Potentiometric measurements were carried out using a Micronal potentiometer, model B374 with 1 mV precision. The indicator electrode used was a silver wire (Aldrich, 99.9%) of 1 mm diameter and 15 mm length coated with a metallic mercury film and the reference electrode was a silver–silver chloride electrode in a 0.1*M* KCl solution with a 3.0*M* $NaNO_3$ bridge.

All potentiometric measurements were made in a 25 ml glass vessel and the temperature was kept at 25 ± 1°C by circulation of water from a

*Author for correspondence.

Veb ML W Prufgerate-Werb Medingem/Sitz Freital thermostatic bath, model U2C.

Reagents

All reagents used were of analytical grade. Saccharin stock solution was prepared by dissolving 4.580 g of saccharin (Aldrich, 99%) in 25–30 ml 0.1*M* NaOH solution and diluted to 250 ml. The reference solutions were prepared from the stock solution. The ionic strength and pH of these solutions were adjusted to 0.2*M* with sodium nitrate and to pH 3 with nitric acid.

The mercurous nitrate solution was prepared by dissolving 2.6260 g of $Hg_2(NO_3)_2$ (Aldrich, 99%) in $10^{-3}M$ HNO_3. The ionic strength of this solution was adjusted to 0.2*M* with $NaNO_3$ and the volume was made up to 1000 ml with water. This 0.005*M* solution was then standardized with 0.01*M* potassium chloride solution by potentiometric titration. A silver wire coated with mercury was used as an indicator electrode.

Sample preparation

Doce Menor powder and Assugrin liquid sweetener (Vepê Indústria Alimenticia Ltda., São Bernardo do Campo, S. P., Brazil), Sucaryl liquid sweetener (Abbott Laboratórios do Brasil Ltda., São Paulo, S. P., Brazil), Dietil liquid sweetener (Nutricia S. A., Rio de Janeiro, R. J., Brazil), and Diet Coke (Refrescos Ipiranga Ltda., Ribeirão Preto, S. P., Brazil) were purchased from a local food store.

(a) Liquid sweeteners

A volume of 1.0 ml of each liquid sweetener sample was diluted to 25.0 ml in a volumetric flask with 0.2*M* $NaNO_3$ made to pH 3 with nitric acid. Then. 5.0 ml of this solution was directly titrated with $5.4 \times 10^{-3}M$ $Hg_2(NO_3)_2$ solution.

(b) Powder sweeteners

An accurately weighed amount of 1.0–1.6 g of the solid sweetener was transferred to a 20.0 ml volumetric flask and the sample was dissolved and diluted to volume with 0.2*M* $NaNO_3$, pH 3 solution. An aliquot containing 10–80 mg of saccharin was transferred to the glass vessel and titrated as described with liquid sweeteners.

(c) Low calorie soft drinks

An aliquot of 250 ml of low calorie soft drink was transferred into a 500 ml separator funnel. An aliquot of 2 ml of concentrated HNO_3 was added and the saccharin content was extracted three times with 50, 30 and 10 ml of ethyl acetate, respectively. The layers were allowed to equilibrate for at least 3 min after each extraction. The organic phases were transferred to a 150 ml beaker and ethyl acetate was evaporated in a current of hot air. To the residue was added sufficient 0.1*M* NaOH solution to dissolve it, the pH adjusted to 3, and the solution was transferred to a 20 ml volumetric flask. The solution was made up to volume with 0.2*M* $NaNO_3$ solution and an aliquot of 5.0 ml was taken for titration as previously described.

RESULTS AND DISCUSSIONS

Life-time of the electrode

After about 10 titrations it is necessary to wash the electrode with distilled water to remove the precipitate. The mercury film must be renewed daily.

Effect of pH

The effect of the pH on the determination of $9.52 \times 10^{-3}M$ saccharin by $5.40 \times 10^{-3}M$ mercurous nitrate was studied. The optimum pH values for the titration of this sweetener was found to be from 2.0 to 3.5. There is a decrease of the potentiometric jump at a pH of less than 2.0 due either to the partial decomposition of saccharin to ammonium o-sulfobenzoic acid by acid hydrolisis[1] and/or protonation of the saccharinate anion (pKa = 1.6).[24] The decrease also occurs at a pH of above 3.5 due to the hydrolysis of mercurous cation to Hg_2O. A 0.2*M* $NaNO_3$ solution at pH 3 was then chosen for further work.

Potentiometric titration

Figure 1(a) shows a typical titration curve of 5 ml of $9.52 \times 10^{-2}M$ saccharin with $5.4 \times 10^{-3}M$ mercurous nitrate at 0.2*M* ionic strength and pH 3.0. Figure 1(b) shows the Gran's Method[25,26] applied to determine the equivalence point of this titration, using the equations for precipitation titrations in which the electrode responded to the titrant (Hg_2^{2+}). For this kind of reaction, Gran's Function, F_2, is equal to $(V_o + V) \times 10^{-mE/nK}$ before the equivalence point, and equal to $(V_o + V) \times 10^{E/K}$ after the equivalence point, where V_o is the initial volume of saccharin solution, V is the added volume of mercurous nitrate solution, E the observed EMF, K the calibration slope of the indicator electrode, and m and n are equal to 1 and 2, respectively. The precision was estimated

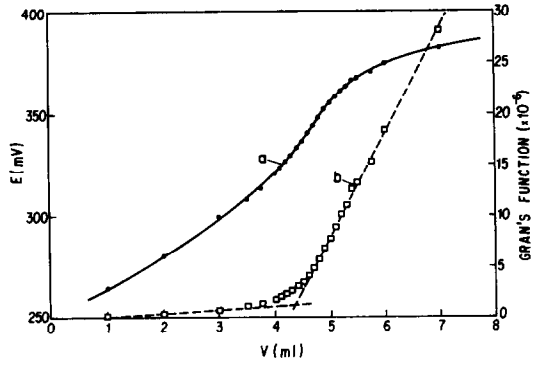

Fig. 1. (a) Typical titration curve of saccharin with mercurous nitrate at ionic strength 0.2*M*, pH 3 and 25°C. (b) Gran's method applied to determine the equivalence point of this titration.

from six titrations for 5 ml aliquots of $9.52 \times 10^{-3}M$ saccharin with mercurous nitrate. The standard deviation of the added volume of $Hg_2(NO_3)_2$ at the equivalence point and the relative standard deviation were 0.025 ml and 1.21%, respectively. The detection limit of the method performed by addition of saccharin in sugar containing soft drink (Coke) was $8 \times 10^{-4}M$.

Analytical curve

The analytical curve obtained [$V_e = 0.0285 + 0.4649m_{sac}$(mg)] from five different titrations of saccharin with $5.40 \times 10^{-3}M$ of mercurous nitrate and the good linearity ($r = 0.9993$) between the equivalence volume (V_e) and the amount of titrated saccharin (mg), demonstrated the usefulness of the proposed method.

Effect of foreign substances

Several potential organic and inorganic interferents which would be expected to exist in dietary products such as sucrose, fructose, glucose, aspartame, sodium cyclamate, sorbitol, benzoic acid, salicylic acid, lactose, citric acid, sodium chloride and sodium phosphate were investigated in a concentration range of at least 50 times higher than that of saccharin. Of those substances, only sodium chloride and sodium phosphate have strong interference, while sodium cyclamate has little interference, except at high concentrations. However, the interference due to chloride and/or phosphate ions can be eliminated with previous solvent extraction of the sweetener from aqueous medium with ethyl acetate. Figure 2 shows the effect of cyclamate concentration (0.10; 0.20 and 0.50*M*) on the titration of 1.0 ml of $9.52 \times 10^{-3}M$ of saccharin with $5.40 \times 10^{-3}M$ of mercurous nitrate. It can be seen from the curves that this method can be successfully applied to the determination of saccharin, even in the presence of cyclamate in a concentration range of 20 times that of saccharin. Nevertheless, 0.50*M* cyclamate solution (50 times) has a strong effect.

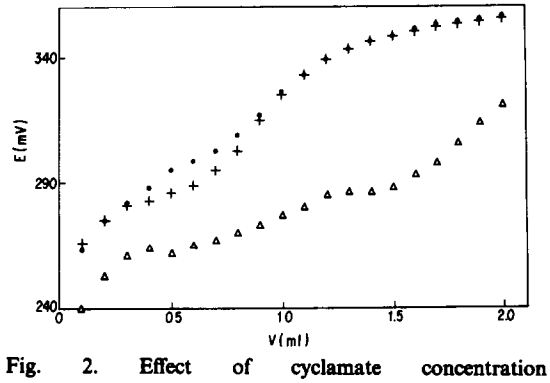

Fig. 2. Effect of cyclamate concentration (...:0.10; +++:0.20 and △△△:0.50*M*) on the determination of $9.52 \times 10^{-3}M$ saccharin with $5.40 \times 10^{-3}M$ of mercurous nitrate solution.

Determination of saccharin in dietary products

The results presented in Table 1 show a recovery of 95.2–103.2% of saccharin from three dietary products. In this study 1.89; 3.89; 5.78 and 7.74 mg/ml of saccharin were added to several diet products.

Table 2 presents a comparison between a UV spectrophotometric method, reported as one of the most used methods for saccharin determination,[7] and that proposed in this paper. Sucaryl was also analysed by the standard addition method and the result obtained is very similar to that obtained by Gran's method. The results are in close agreement with those reported and within an acceptable range of error. The adaptation of this method in flow injection analysis is underway.

Table 1. Recovery of saccharin from various dietary products

Sample	Saccharin (*mg/ml*) Added	Found	Recovery (%)
Assugrin	1.89	1.80	95.2
	3.89	3.99	102.6
	5.78	5.92	103.1
	7.74	7.62	98.5
Sucaryl	1.89	1.95	103.2
	3.89	3.78	97.2
	5.78	5.55	96.0
	7.74	7.53	97.3
Doce Menor	3.89	3.91	100.5
	5.78	5.75	99.5
	7.74	7.81	100.9

Table 2. Potentiometric determination of saccharin in dietary products using Gran's method

Sample	Saccharin content (*mg/ml*), (*mg/gl*)* or (*mg/290 ml*)†		Rel. error %	Coefficient of variation
	Spectrophotometric	Potentiometric‡		
Assugrin	57.2	55.8 ± 3.0	−2.4	5.4
Dietil	50.1	48.0 ± 1.0	−4.2	2.1
Sucaryl	58.7	61.2 ± 3.0	+4.3	4.9
Sucaryl§	58.7	59.5 ± 0.5	+1.4	1.0
Doce Menor*	24.8	26.2 ± 0.5	+5.6	1.9
Diet Coke†	15.2	15.7 ± 0.7	+3.3	4.5

‡Assay values represent the average of six ($n = 6$) determinations per sample with a confidence level of 95%.

§Determined by standard addition method.

CONCLUSIONS

The potentiometric method for determination of saccharin reported in this paper is rapid, precise and of low cost. It is suitable for routine analysis of this sweetener in various dietary products.

PRECONCENTRATION AND CATALYSIS IN REDUCTION OF ALIPHATIC ORGANOHALIDES USING SURFACTANT-COATED ELECTRODES*

HEPING ZHANG and JAMES F. RUSLING†
Department of Chemistry, Box U-60, University of Connecticut, Storrs, CT 06269-3060, U.S.A.

(*Received* 10 *August* 1992. *Revised* 16 *September* 1992. Accepted 21 *September* 1992)

Summary—Voltammetric reductions of several organohalide pollutants in films of didodecyldimethylammonium bromide (DDAB) and clay-DDAB cast onto pyrolytic graphite electrodes were examined. Direct reduction data show that the amount of accumulation in these liquid crystal films was larger for relatively nonpolar analytes such as trans-1,2-dibromocyclohexane than for chlorinated acids. The vicinal dibromides are probably taken up by hydrophobic regions of the films. Chlorinated acids were accumulated and reduced in DDAB films, but their direct reduction was partly blocked by the clay-DDAB films. Catalytic reductions using films containing metal phthalocyanines had good efficiencies for all substrates studied and shifted reduction potentials positive by 200–550 mV.

Solutions of dispersions of water-insoluble surfactants can be cast onto solid supports to make ordered films.[1–21] Results of X-ray diffraction, electron microscopy, and gel-to-liquid crystal transition temperatures close to those of bilayer vesicle suspensions of the same surfactants have been used to propose stacked, wavy multiple bilayer structures for these films.[1–15,19,20] A partially disordered structure of adjacent bilayer domains has been deduced on the basis of phase transition and electron microscopy studies of dialkyldimethylammonium films,[20] and a similar structure was proposed for phospholipid films based on electrochemistry of incorporated amphiphilic probes.[20] Surfactant films with multiple bilayer structures can also be prepared as intercalates between clay[8,17,20] or linear ionic polymer layers.[9–14]

Insoluble surfactants used for cast films typically have two or three hydrocarbon chains of 12 or more carbons. Permeability of these surfactant films is controlled by their phase. Neutral, water soluble solutes pass through films that are in the liquid crystal state, but permeability is poor in the solid-like gel phase.[8–13]

Ordered surfactant films have many potential uses in analytical chemistry.[15,16–20] They show permselectivity. Films of didodecyldimethylammonium bromide (DDAB) are impermeable to multiply charged hydrophilic cations in aqueous solution,[16] and DDAB-clay films are relatively impermeable to multiply charged anions and cations in solution.[18] Anionic redox catalysts in aqueous solutions can be introduced by ion exchange into liquid crystalline films of DDAB from aqueous solutions. Films incorporating anionic metal macrocyclic tetrasulfonates on electrodes[17] and clay-surfactant composite films containing neutral metal phthalocyanines have been used to catalyze reductions of trichloracetic acid.[18] Charge transport rates were much better for both types of films in liquid crystal phases than in solid-like gel states. Surfactant films loaded with metal phthalocyanine tetrasulfonates[19] or intercalated with clay colloids[18] gave stable signals for several weeks or more in aqueous electrolyte solutions. DDAB films without such stabilizing anions were usable for about a week.[16]

Since liquid crystal films of cationic surfactant are permeable to neutral or anionic organics, there are two components to electrochemical catalysis using them. The first is the usual electrochemical catalytic cycle. Represented in its simplest form:

$$P + e = Q \quad E^{\circ\prime}_{P/Q} \text{ (at electrode)} \qquad (1)$$

$$2\,Q + RX \rightarrow 2\,P + \text{Products (in film, rds)} \qquad (2)$$

in which the reduced form of the catalyst Q formed at the electrode reduces organohalide substrate RX at potential $E^{\circ\prime}_{P/Q}$, which is typically significantly positive of the potential of

*Part 12 of the series: Electrocatalysis in Organized Media.
†Author for correspondence.

direct, irreversible reduction of substrate RX. The current at $E^{\circ\prime}_{P/Q}$ is increased by the catalytic cycle in rough proportion to the square of the rate of the bimolecular rate-determining step (rds), equation (2). The film may also preconcentrate substrate RX. Enhanced RX concentration in the films would produce larger currents in the direct reduction than at bare electrodes, and perhaps increase rates of catalytic reductions via enhancement of the rate of the bimolecular rds.[22]

In this paper, we compare direct and catalytic reductions of several small, aliphatic organohalide molecules in DDAB and clay-DDAB films, with the aim of surveying possible voltammetric applications. DDAB was chosen because its films are liquid crystalline at ambient temperature,[8,16] and should be permeable to and perhaps preconcentrate the organohalides. In contrast, films of longer chain alkylammonium surfactants, such as dioctadecyldimethylammonium bromide, are in the solid-like gel state below 44–50°C, and show poor permeability and charge transport at ambient temperature.

Aliphatic organohalide molecules that are completely dehalogenated by reduced metal phthalocyanine catalysts were chosen. These compounds are "activated" by having a $-$COOH or another carbon-halogen group adjacent to a carbon-halogen bond attacked in the reaction.[23,24] The specific compounds studied were trichloroacetic acid, formed in water chlorination,[25] 3-chloroacrylic acid, a hydrolysis product of the soil fumigant Vorlex (1,3-dichloropropylene),[26] and two vicinal dihalides that serve as models for many aliphatic fumigants and pesticides.

EXPERIMENTAL

Chemicals

Didodecyldimethylammonium bromide (DDAB, 99+%) and cobalt phthalocyanine (CoPc) were from Eastman Kodak and used as received. Nickel phthalocyanine tetrasulfonic acid tetrasodium salt (NiPcTS), *trans*-3-chloroacrylic acid (CAA), 1,2-dibromobutane (DBB) and *trans*-1,2-dibromocyclohexane (DBCH) were from Aldrich. Trichloroacetic acid was from Janssen Chimica. Butanol was from Burdick & Jackson. Bentonite clay (Bentolite H) was from Southern Clay Products, cation-exchange capacity 80 mequiv/100 g. Other chemicals were analytical reagent grade.

Apparatus

Cyclic and square-wave voltammetry were done in three-electrode cells using a basal plane pyrolytic graphite (HPG-99, Union Carbide) cylinder as a working electrode, a platinum-wire as a counter electrode, and a saturated calomel electrode (SCE) as reference. The potentiostat was a BAS-100 electrochemical analyzer. Cells were thermostated at 25°C. PG cylinders ($A = 0.20$ cm^2) were sealed into heat shrinkable teflon tubes, as described previously.[17,19] Pyrolytic graphite (PG) electrodes were abraded to a rough finish with 400-grit SiC paper before coating.

Preparation of films

DDAB films were prepared by pipetting 10 μl of 0.1 *M* DDAB/chloroform onto a freshly abraded PG electrode, as described previously.[16] Chloroform was evaporated overnight in air. DDAB electrodes loaded with nickel phthalocyanine tetrasulfonate were prepared by soaking DDAB-PG electrodes in 1 m*M* NiPcTS solution overnight, then washing with distilled water. Clay-DDAB films and CoPc-Clay-DDAB films were cast from chloroform suspensions as described previously.[18]

Voltammetry

Procedures included compensation of the cell's ohmic drop and were described previously.[16–18]

RESULTS

Direct reductions

Scans by cyclic voltammetry after coated electrodes were equilibrated in solution for 10 min or more showed larger peak currents on DDAB coated electrodes than on bare PG [Fig. 1 (a)], as illustrated for 1,2-dibromobutane (DBB). Repetitive cyclic scans of the same equilibrated electrode gave much diminished peak currents [Fig. 1 (b)] on second and subsequent scans, consistent with the chemically irreversible reduction of DBB in the film. DBB is converted to olefin[27] which cannot be oxidized on the reverse scan to regenerate DBB. Thus, the film is depleted of DBB during the scan and an additional equilibration period is required to reload the film with analyte and regenerate the signal.

In general, the largest current enhancements were obtained with DDAB-PG electrodes and

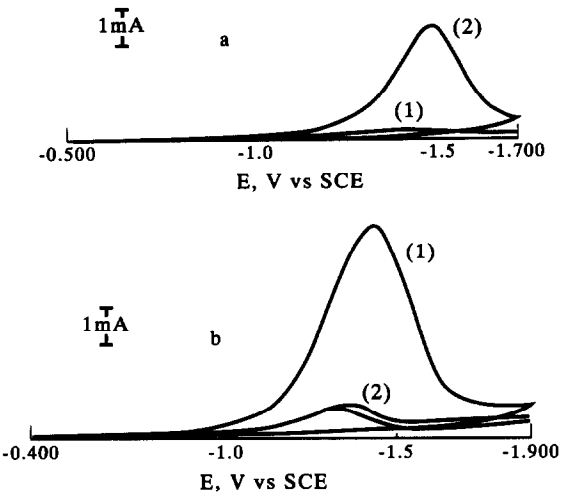

Fig. 1. Cyclic voltamperograms at 0.10 V/sec in 0.1*M* KBr solution containing 0.2 *M* 1-butanol and saturated with DBB (*ca.* 2.5 m*M*): (a) (1) bare PG electrode; (2) DDAB–PG electrode after equilibration; (b) Multiple scans on a different DDAB–PG electrode: (1) first scan; (2) scans 2–5.

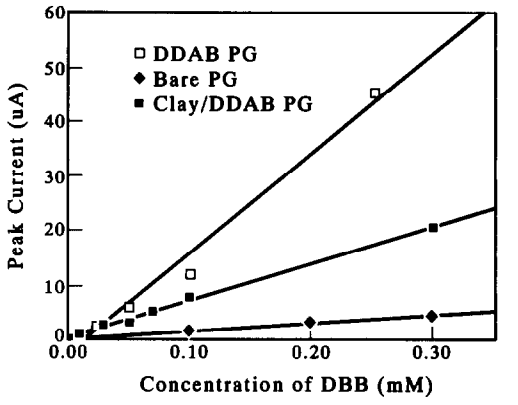

Fig. 2. Influence of concentration of DBB on peak current at 0.10 V/sec in 0.1 *M* KBr/0.2 *M* 1-butanol on bare PG, clay–DDAB–PG, and DDAB–PG electrodes.

the neutral DBB and *trans*-1,2-dibromocyclohexane (DBCH) analytes. DBCH gave the largest enhancement in peak currents compared to bare electrodes (Table 1), consistent with having the largest oil/water partition coefficient of the two dibromides.[28] Peak currents on clay–DDAB electrodes for DBCH and DBB were intermediate between those on DDAB–PG and bare electrodes.

Less dramatic current increases were found for trichloroacetic acid (TCA) and chloroacrylic acid (CAA) on DDAB electrodes (Table 1). The clay–DDAB electrodes gave smaller peak currents for these acids than bare electrodes.

Good linearity was found in plots of peak current *vs.* concentration in the 5 μM–1 m*M* range. This is illustrated for DBB in the lower concentration range (Fig. 2). Sensitivities were best for the neutral vicinal dihalides, with typical correlation coefficients of 0.994–0.998 for both types of coated electrodes.

Catalytic reductions

These reactions were done with NiPcTS–DDAB and CoPc–clay–DDAB electrodes, which had been used to catalyze reduction of trichloroacetic acid in earlier work.[17,18] All of the substrates were catalytically reduced by both electrodes.

Cyclic voltammetry of a NiPcTS–DDAB electrode clearly shows a nearly reversible, one-electron reduction peak[19] centered around −0.7 V (Fig. 3, top). The direct, irreversible reduction peak of TCA on a non-catalytic DDAB electrode can be seen at about −1.4 V (Fig. 3, middle). The use of a NiPcTS–DDAB electrode in a solution containing TCA gave a broad peak (Fig. 3, bottom) about 400 mV positive of the direct reduction. This new "catalytic" peak is larger than the peak for the NiPcTS–DDAB electrode in solutions without TCA, and has no anodic complement. This is because the reduced form of NiPcTS has reacted with TCA to regenerate NiPcTS in the film (cf. Scheme I) in a catalytic cycle. Similar results were obtained with CAA (Fig. 4), and catalytic and direct reduction peaks are of about equal heights. Catalysis shifts the peaks to more positive potentials.

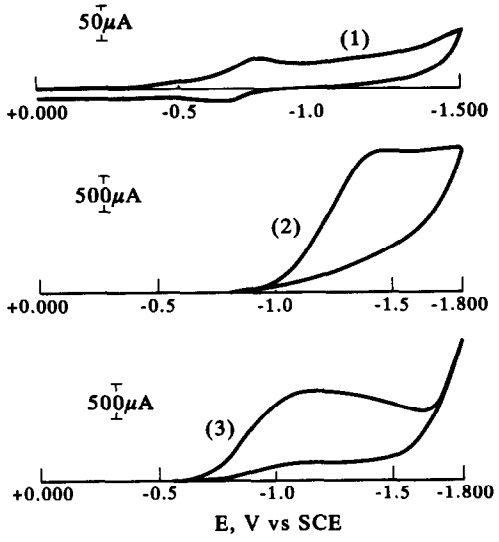

Fig. 3. Cyclic voltamperograms at 0.10 V/sec in 0.1 *M* NaCl solution: (1) NiPcTS–DDAB electrode after loading in 1 m*M* NiPcTS; (2) DDAB–PG electrode with 10 m*M* TCA in solution; (3) NiPcTS–DDAB electrode with 10 m*M* TCA in solution.

As observed previously, currents for CoPc in CoPc–clay–DDAB films are quite small.[18,20] The Co(II)/Co(I) reduction can be observed by square wave voltammetry at about −0.45 V, with a second wave due to ligand reduction at about −1.2 V [Fig. 5 (a)]. Large catalytic waves were found when these electrodes were used in solutions of any of the analytes [Fig. 5 (b)].

Electrochemical catalytic reactions can be characterized by their catalytic efficiencies, *i.e.*, the ratio of catalytic peak or plateau current (i_{cat}), to the peak current of the catalyst (i_d) in the absence of a reducible substrate. This quantity is roughly proportional to the square of the rate constant of the reaction of reduced catalyst with substrate.[22] Voltammetry with the two types of coated catalytic electrodes gave good efficiencies for all the organohalides studied (Table 2). The catalytic reductions were at potentials about 200–550 mV more positive than direct reductions of the substrates on the same electrodes (Table 2). For the vicinal dibromides,

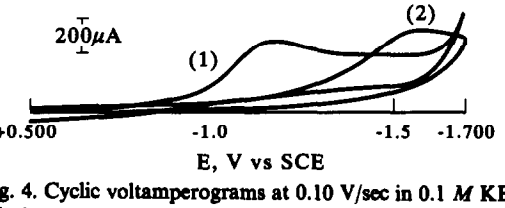

Fig. 4. Cyclic voltamperograms at 0.10 V/sec in 0.1 *M* KBr solution containing 5 m*M* 3-chloroacrylic acid: (1) NiPcTS–DDAB electrode; (2) DDAB–PG electrode.

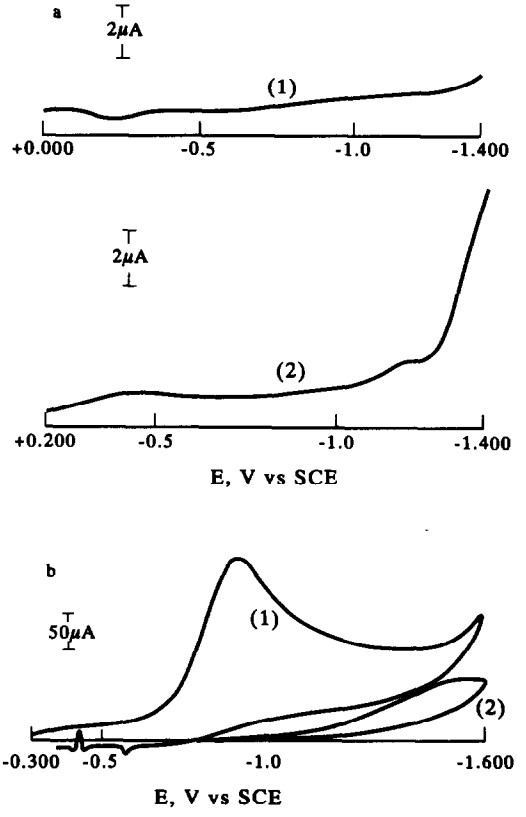

Fig. 5. Voltamperograms in 0.1 *M* KBr/0.2 *M* butanol solutions: (a) square wave voltamperograms at 15 Hz, 25 mV pulse amplitude, 4 mV step: (1) PG electrode; (2) CoPc–clay–DDAB electrode. (b) cyclic voltamperograms at 0.10 V/sec in solutions saturated in DBB: (1) CoPc–clay–DDAB electrode; (2) clay–DDAB electrode.

catalytic reductions on the CoPc–clay–DDAB electrodes were about 250 mV positive of those on NiPcTS–DDAB electrodes. Catalytic efficiencies on the two types of electrodes are not directly comparable because the peak current of the CoPc–clay–DDAB electrode is so small in the absence of a reducible substrate. Catalytic currents on the NiPcTS–DDAB electrodes were larger than on the CoPc composite electrodes.

A peak for catalytic reduction of TCA at CoPc–clay–DDAB electrodes was also found at about −0.6 V, as reported previously.[18] It is likely that this reaction, as well as those of the vicinal dibromides, involves the Co(II)/Co(I) redox couple of Co(II)Pc. Catalytic reductions at −1.1 V in these films may involve addition of two electrons to the catalyst. Reductions catalyzed by NiPcTS–DDAB films probably involve addition of electrons to the ligand of the catalyst, as found for similar reactions in microemulsions.[29]

Coated electrodes were used for several days with no gross loss in performance. However,

day to day reproducibility was not satisfactory, and such electrodes would need daily calibration in real analytical situations.

Influence of alcohol

Butanol was used in DBB and DBCH solutions to improve solubilities. Coated electrodes in solutions containing butanol may deteriorate a bit faster, but the effect was not dramatically noticeable. Also, alcohol was previously shown to increase the fluidity of surfactant films, giving larger currents for ferrocyanide incorporated into DDAB films.[16] This was also observed in the present work (Fig. 6), as illustrated for DBB. Linear increases in peak current with butanol concentration were found.

DISCUSSION

Direct reductions

Aliphatic vicinal dihalides undergo two-electron reductions at cathodes to yield olefins.[27] Halogenated carboxylic acid derivatives are reductively dehalogenated, with hydrogen replacing halogen.[30] Both are two-electron irreversible reductions. The organohalide analytes need to enter the films before being reduced. After reductions at relatively low scan rates, the films appear to be depleted of the analyte, and further equilibration is needed to restore the signal.

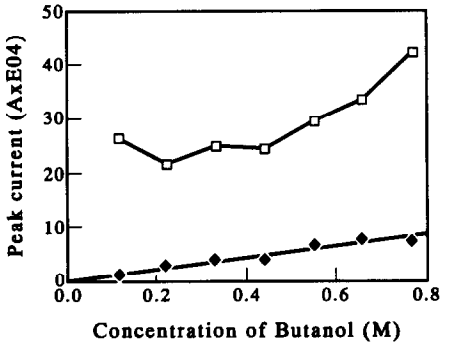

Fig. 6. Influence of butanol on peak current in 0.1 *M* KBr/0.2 *M* butanol solutions saturated in DBB (□) cyclic voltammetry at 0.10 V/sec at DDAB–PG electrodes; (◆) square wave voltammetry at NiPcTS–DDAB electrodes, 15 Hz, 25 mV pulse amplitude, 4 mV step.

Peak currents for direct reductions in the films compared to those on bare electrodes can be taken as a measure of the relative amount of organohalide accumulated during equilibration. For DDAB films, the amount of accumulation of analytes followed the order DBCH > DBB > TCA > CAA. Results for the vicinal dibromides are in line with oil/water partition coefficients, which for DBCH is an order of magnitude larger than for DBB.[28] This suggests that the vicinal dibromides reside at relatively hydrophobic sites in the DDAB films, probably in the vicinity of the hydrocarbon tails of the surfactant bilayers. Chlorinated acids could enter the films either in the anion or acid forms. Since the neutral acid forms are still quite polar, their hydrophobic interactions with the hydrocarbon tails of the surfactant are expected to be weak. The anions, on the other hand, need to compete with Br^- ions to enter the films by ion exchange.

The order of accumulation of analytes was the same for the clay–DDAB and DDAB films. Currents for TCA and CAA were smaller on clay–DDAB electrodes than on bare electrodes, indicating that access to the electrode is partly blocked by the composite film. Clay–DDAB films do not act as ion exchangers. Therefore, this blocking effect is consistent with TCA and CAA having entered the DDAB films, which *are* anion exchangers,[16] mainly by an ion exchange process.

In a practical sense, the best enhancement in sensitivity was found for the neutral DBCH and DBB, although a four-fold increase in current compared to bare electrodes was also found for TCA with DDAB electrodes. Good linearity of voltammetric peak current was found in the micromolar concentration range. Thus, these films show promise for the determination of relatively hydrophobic electroactive species in

water. Addition of butanol to the solution can be used to enhance sensitivity, although perhaps at some expense to long term stability. However, the film casting procedure is so simple that coated electrodes can be made readily by the user on demand.

Catalytic reductions

The main advantage to catalytic reductions in the films are shifts to less reducing (*i.e.*, more positive) potentials. Peak currents in the catalytic reductions were comparable to those in direct reductions, so that sensitivities would not be much better than for direct reductions. However, the positive potential shift from the catalysis might remove the peak from interfering peaks that might occur at the more reducing potential of the direct reduction of the analyte.

The low current for the CoPc–clay–DDAB electrodes in the absence of reducible substrate has been traced to crystallization of CoPc within the composite film matrix.[20] Thus, all of the catalyst in the film may not be available for reaction. On the other hand, concentrations of up to 0.3 *M* NiPcTS can be achieved in DDAB films, leading to the higher observed catalytic currents. From a practical point of view, catalytic clay-composite films may be more suitable in some situations. Even though the catalytic currents are somewhat smaller, they are measured against the background of the very low current of the composite films.

A better surfactant coated electrode for activated organohalides might be prepared with a catalyst with a much lower reduction potential. This should further decrease the possibility of encountering reducible interferences in real samples. This type of electrode, probably with a much thinner catalytic film, might also be useful on a larger scale for treatment of contaminated water. Work along these lines is currently underway in our laboratories.

CONCLUSIONS

This work shows that neutral alkyl vicinal dihalides can be preconcentrated in easily prepared liquid crystal films of insoluble surfactants and clay-surfactant composites on electrodes, giving larger voltammetric sensitivities. Trichloroacetic acid can be preconcentrated in surfactant films, but not in the composites. In practice, such electrodes would probably require daily calibration. In principle, preconcentration of neutral organohalides could also be done with appropriate polymeric coatings.[31] Similarly, phospholipid films on electrodes[32–35] should have preconcentration properties in their liquid crystal states. However, to our knowledge, preconcentration of organohalides has not been studied for polymer or phospholipid-coated electrodes.

Analytes gave signals at significantly less negative potentials by using surfactant films with incorporated catalysts, which may be useful in avoiding easily reducible interferences. DDAB films are impermeable to multiply charged anions,[16] while composite films reject multiply charged ions of both signs.[18] Thus, film permeabilities combined with catalysis may provide desirable selectivity in some analytical applications.

ORGANICALLY-DOPED SOL–GEL BASED TUBE DETECTORS: DETERMINATION OF IRON(II) IN AQUEOUS SOLUTIONS

I. KUSELMAN* and O. LEV

Division of Environmental Sciences, School of Applied Science and Technology, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

(*Received* 14 *July* 1992. *Revised* 18 *September* 1992. *Accepted* 18 *September* 1992)

Summary—A novel type of disposable sensor for the determination of iron(II) in aqueous solution is described. The iron sensor serves to exemplify a new class of disposable field tests for field analysis of water pollutants. The sensors are comprised of capillary glass tubes filled with porous sol–gel silica powder doped with *o*-phenanthroline. When a sample solution is passed through a tube detector the iron ions are complexed by the immobilized *o*-phenanthroline and a stained section of the capillary develops. Metrological characteristics of these detectors including precision and accuracy and chemical interferences by heavy metals and humic acids are discussed.

Length of stain sensors are frequently used by occupational health and indoor air practitioners for the detection of air borne pollutants.[1,2] The tube detectors are comprised of glass tubes, filled with silica powder impregnated with specific photometric reagents. Leaching of the impregnated reagents hinders their application for water diagnosis. In principle, direct chemical derivatization of silica glass by photometric reagents may be used to circumvent this obstacle and improve the stability and shelf life of these detectors. Indeed, synthesis of porous glass derivatized with several colorimetric reagents has been reported.[3–6] However, complexation capacity of such glasses is relatively low and the ability to form multiple ligand complexes with metal ions is hindered by the tight bonding of the reagents to the glass. For example, iron(II) forms—almost exclusively—a triple ligand complex with *o*-phenanthroline, while Zaytsev and Trophymchuk[6] report a two ligand complex of *o*-phenanthroline derivatized silica with divalent iron. Alterations in coordination stoichiometry affect the complexation capacity and specificity of such potential detectors. Recently, the sol–gel doping procedure has evolved as an efficient method to encapsulate organic compounds in silica glass.[7,8] The method is based on the introduction of the organic dopants with the reaction precursors during the hydrolysis/polycondensation of alkoxisilanes to form silica glass.[9] Application of this method for the preparation of colorimetric[10,11] and fluorometric sensors[12,13] and prototypes of on-line fibre optic sensors have been reported.[14,15] In a recent paper[16] we demonstrated that sol–gel technology can be used to mold organically doped silica powder for length of stain detectors suitable for water analysis. In this paper a systematic study of a representative type of water detector is undertaken, in order to evaluate potential utilization in water analysis.

Iron is a widespread pollutant, with a special relevance to the water industry because it frequently serves as a flocculation agent. Recommended[17] procedures for its aqueous determination include atomic absorption spectroscopy, inductively coupled plasma and polarographic techniques. These techniques are very sensitive but require complex analytical instruments and therefore are less suitable for field analysis. Future field instruments may rely on the evolution of electrochemical methods using modified electrodes, which promise high sensitivity and simple instrumentation.[18–20] Currently, however, most rapid field tests rely on the colorimetric determination of the orange–red chelate of divalent iron with *o*-phenanthroline under reducing conditions. This is a reliable and pH insensitive technique, which is approved by the Standard Methods.[17] However, even this technique requires a comparator and a certain level of wet chemistry. Another relevant

*Current address: National Physical Laboratory, Jerusalem 91904, Israel.

procedure for determiantion of iron(III) in aqueous solution is based on complexation of iron with soluble *o*-phenanthroline and subsequent filtration of the complex through a fixed bed of silica gel grains.[21] This technique comes a step closer to length of stain detectors but does not eliminate the need for "wet chemistry" and therefore is less amenable for field testing. In this paper we evaluate the characteristics of iron sol–gel tube detectors, that will serve to model this new class of field tests.

EXPERIMENTAL

Reagents

Analytical grade reagents and triply distilled water were used unless stated otherwise. Tetramethoxysilane was purchased from ABCR. Iron(II) stock solution (10m*M*) was prepared by dissolving the required amount of $FeSO_4 \cdot 7H_2O$ in distilled water. Hydroxylamine hydrochloride (1.3m*M*) was used to prevent oxidation of divalent iron. Sample solutions were buffered to pH = 4 by 0.1m*M* acetate buffer. Interference studies were conducted using $NiSO_4 \cdot 6H_2O$, $Zn(CH_3COO)_2 \cdot 2H_2O$, $Cr(NO_3)_3 \cdot 9H_2O$, $Hg(CH_3COO)_2$, $CdCl_2 \cdot H_2O$, $AgNO_3$, $(NH_4)_6Mo_7O_{24} \cdot 6H_2O$, $Bi(NO_3)_3 \cdot 5H_2O$ and humic acid sodium salts (Aldrich).

Glass preparation

The experiments were carried out using doped sol–gel glasses prepared according to standard sol–gel procedures:[9,22] *e.g.*, 2.5 ml of tetramethoxysilane, 3.0 ml of 0.1% *o*-phenanthroline in methanol and 2.9 ml of 0.5m*M* sodium hydroxide were mixed, allowed to gel for approximately three days and dried to constant weight (*ca.* 2.0 g) at 41° for approximately two weeks. The final concentration of *o*-phenanthroline in the dry glass is *ca.* 0.15%. After drying, the glasses were crushed in a porcelain cup, sieved by a sieve shaker and selected fractions were collected for further experiments.

Preparation of tube detectors

Glass capillaries (0.7-mm inside diameter and 10-cm length) were filled to *ca.* 75% of their length with sol–gel grains and stoppered at both ends by 3-mm filter paper to hold the glass bed in place. In some experiments plastic tubes (2-mm inside diameter and 20-cm length) were connected to the downstream side of the glass capillaries in order to hold the excess volume of solution that passed through the sensor (Fig. 1). Plastic tubes permit accurate determination of the sampled volume by a simple length measurement with no need for analytical scale and with minimal evaporation loss.

Measurement procedure

In the simplest measurement procedure one end of the tube detector is immersed *ca.* 2-mm deep in a sample solution and capillary forces drive the solution upward through the tube detectors. As the colorless front of the sampled solution advances upwards, a second red front marking the upper end of the stained portion of the sol–gel doped glass ascends (Fig. 1). The length of the stained portion of the sol–gel glass can be measured after an adequate amount of solution has passed through the sensor. Hydrostatic pressure or external pumping were applied in order to sample larger volumes through the sensor. To achieve this, the tube detectors (the capillaries connected with the plastic tubes) were dipped into vertical tubes filled with the sample solutions [Fig. 1(b)]. In some experiments a home made pumping device comprising a plastic syringe connected to a simple piston mechanism was used in order to inject the sample slowly through the detecting capillary [Fig. 1(c)]. The measuring procedure currently takes 15 min or more, depending on the sampled volume and grain size.

Interference evaluation

Evaluation of chemical interferences was conducted by repeating iron analysis in the presence of each of the interfering species mentioned in the Standard Methods[17] and comparing the results with a measurement of a blank solution containing iron with no interfering substance. All the solutions were prepared according to the reagent preparation procedures above.

RESULTS AND DISCUSSION

Calibration

A calibration curve for determination of iron can describe the length of stain formed after either constant sampling time or constant sampled volume. In practice, constant volume calibration curves are more accurate since they eliminate flow rate drifts. On the other hand, constant volume techniques require careful monitoring (or manual attendance) of the volume in order to terminate the analysis before an excess volume is sampled. A third, intermediate

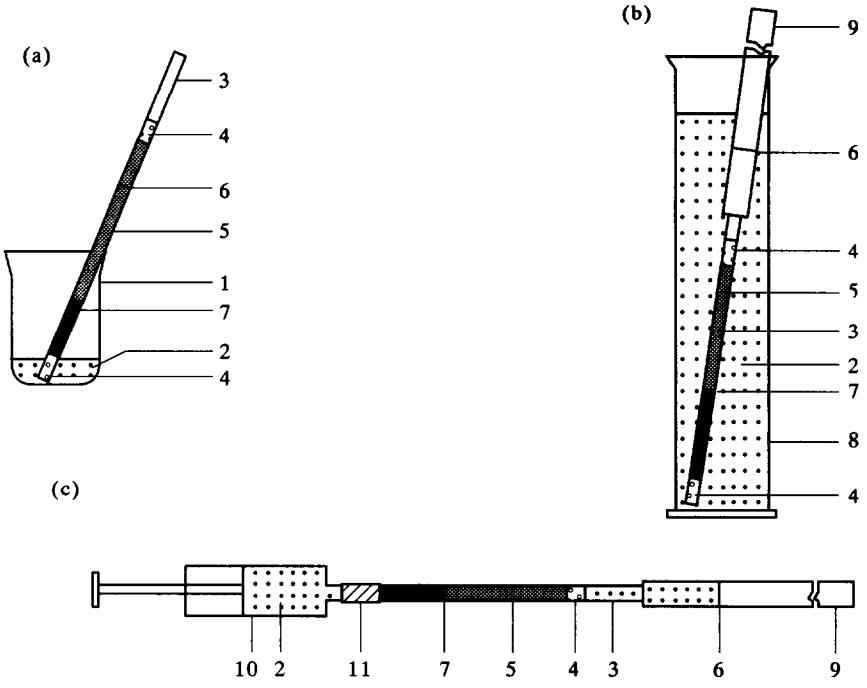

Fig. 1. Schemes of tube detectors using alternative sampling modes: a. capillary force; b. hydrostatic pressure; c. external pumping. 1. beaker, 2. sample solution, 3. capillary tube, 4. paper plug, 5. sol–gel glass powder, 6. solution front, 7. color front, 8. cylinder, 9. auxiliary (plastic) tube, 10. syringe, 11. rapid connector, 12. positioning mechanism.

procedure can be employed when the evolution of the length of stain is proportional to the sampled volume, *i.e.*, measure the length of stain after constant sampling time and correct the result for differences in the sampled volumes. The auxiliary plastic tubes (Fig. 1) are convenient tools that accumulate and measure the sampled volume. When an auxiliary tube with radius r_a filled to a level l_a, is connected to a capillary of length l_c and radius r_c, the sampled volume can be expressed as

$$V = 3.14(l_c\, r_2^c\, v_f + l_a\, r_a^2) \qquad (1)$$

where v_f represents the void fraction (dimensionless) of the packed capillaries. Now, taking $v_f = 1$, V can be approximated by:

$$V = 3.14\ (l_c\, r_c^2 + l_a\, r_a^2) \qquad (2)$$

Figure 2 depicts a typical dependence of the length of stain S (mm) propagation on the sampled volume. These experiments were conducted using capillary suction of 3.0mM divalent iron solution through a detector filled with 0.1–0.2 mm glass grains doped with 1.7% *o*-phenanthroline (sampling duration = 15 min). After an initial evolution time the front stablizes and propagation velocity becomes proportional to the sampled volume, indicating equilibrium control. Therefore, it is convenient to express the calibration curves as a relative length of stain R_l versus the concentration of the analyte: R_l is defined as the ratio (in percent) between the volume of the coloured bed and the sampled volume:

$$R_l = 100\ S\ r_c^2/(l_c\, r_c^2 + l_a\, r_a^2) \qquad (3)$$

When capillary suction is the only driving force, the sample fills only the volume of the packed bed, auxiliary tubes are not needed and equation (4) can be used directly:

$$R_l = 100\ S/l_c \qquad (4)$$

l_c now stands for the length of the packed bed section. Thus, calibration curves depicting S *vs.* C at constant l_c can be used.

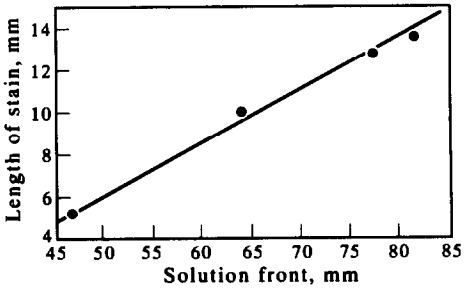

Fig. 2. Evolution of the length of stain. The sampled volume is expressed in units of length of wetted section.

Analysis of calibration data

Figure 3 (after data reproduced from[16]) depicts two calibration curves describing the relative length of stain as a function of iron concentration in two working ranges: Fig. 3(a) depicts a calibration curve of a sensor operated under capillary forces at relatively high concentrations (0.5–10.0mM) the sensor comprises glass grains (smaller than 0.1 mm) doped with 1.7% o-phenanthroline. Approximately 0.02 ml of solution were sufficient to produce such a response. Curve B depicts sensor response in the low concentration range (0.01–0.1mM). Larger samples (*ca.* 0.5 ml) were required to produce significant coloured sections and therefore hydrostatic driving force (0.05 atm) was applied. Glass powder (0.1–0.2 mm) doped with 1.0% o-phenanthroline was used. The concentration of o-phenanthroline in the glass was set as a compromise between considerations regarding the length of the coloured section (favoured by lower o-phenanthroline concentrations) and colour contrast, which becomes more intense, when higher concentrations of ligand are used. Leaching of the reagent becomes significant at exceedingly high concentrations of o-pehnanthroline and then a pretreament to wash the easily leachable molecules of dopant may be required prior to packing of the capillaries. At the level of o-phenanthroline, used in this experiment, the colour fronts were sharp, could be clearly distinguished within $+/-0.1$ cm and leaching pretreatment was not required. The size of the glass grains was determined as a compromise between resolution (favouring smaller grains) and analysis time (favouring larger grains). When large particles and a short analysis period are used intraparticle diffusion becomes significant and affects the selection of the optimal particle dimensions.

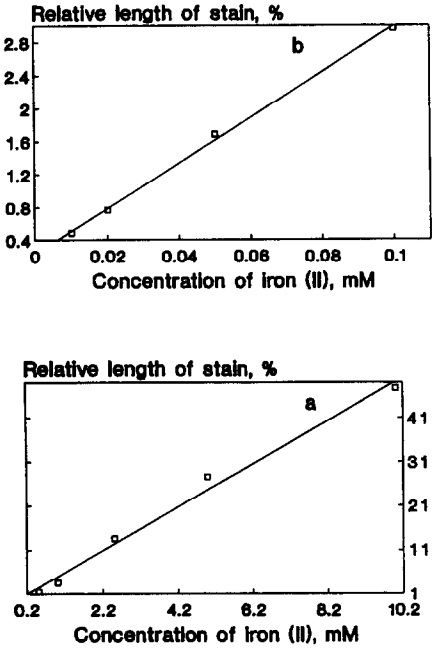

Fig. 3. Calibration curves of iron tube detectors: a. 0.5–10mM; b. 0.01–0.1mM.

The values of R_l in the high iron concentration range [Fig. 3(a)] are best fitted by

$$R_l = 0.07 + 4.91C \quad (5)$$

with standard deviation $S_{ad} = 2.2\%$ and correlation coefficient $R = 0.989$, where C represents iron concentration in mg/l. The values of R_l in the low iron concentration range [Fig. 3(b)] are best fitted by

$$R_l = 0.23 + 27.6C \quad (6)$$

with $S_{ad} = 0.06\%$ and $R = 0.998$.

Precision

Repeatability evaluation[23] in the two working ranges was based on 24 identical measurements at $C = 10$mM and 25 repeated measurements at $C = 0.1$mM. The tube detectors were prepared using the same procedure used for the preparation of the calibration curves in Fig. 3. Frequency histograms depicting the percent of measurements falling in the corresponding R_l ranges are presented in Fig. 4(a) and (b). For $C = 10$mM [Fig. 4(b)] the mean relative stain length, $R_{l,av} = 50.04\%$. The relative standard deviation of the measurements is $S_r = 1.35\%$. The histogram in Fig. 4(b) summarizes the measurements conducted at 0.1mM. Here, $R_{l,av} = 3.03\%$ and $S_r = 2.65\%$. By comparison, the reliability of visual determination using nessler tubes is approximately 5–10% and for photometric determination (using a pectrophotometer) it is approximately 3%.[17]

The histograms of Fig. 4 deviate from normal distribution and are skewed towards high R_l values. This phenomenon although barely noticeable in the high concentration range [Fig. 4(b)] is indeed significant at $C = 0.1$mM. This asymmetry can be attributed to a mechanism shift from equilibrium domination to one influenced by intraparticle diffusion. Therefore, the deviation from the normal distribution is more significant when larger grains and external driving force are used.

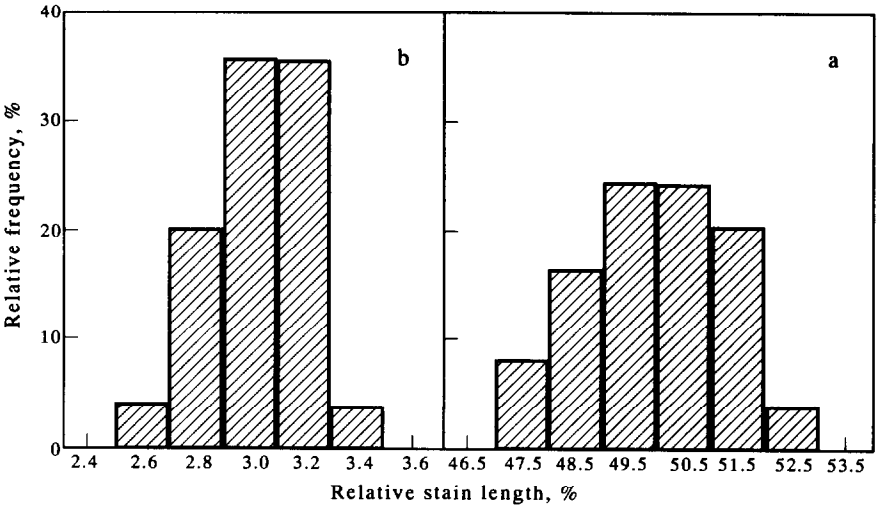

Fig. 4. Frequency histograms for iron determination by tube detectors: a. 10mM; b. 0.1mM.

Bias and accuracy

The frequency histograms of Fig. 4 can be used to estimate the bias[23] of the technique. Since the "true" concentrations of iron(II) are known ($C_t = 0.1$mM or 10mM) the sample bias (B) can be calculated by $B = C_{av} - C_t$ where C_{av} = average concentration. From Fig. 4(a) and equation (5), $C_{av} = 10.18$mM and the standard deviation of the determined concentration $S_c = 0.27$mM. By analogy $C_{av} = 0.101$mM and $S_c = 0.006$mM for Fig. 4(b) and equation (6). The relative error in the preparation of the standard solution is approximately 2%, since hydrated iron salts were used for the stock solutions (*i.e.*, the standard deviation of C_t is $S_{st} = 0.2$mM at $C = 10$mM and $S_{st} = 0.002$mM at $C = 0.10$mM). Analytical techniques are considered to be sufficiently accurate when the difference between the systematic error of analysis and the random error in the preparation of the standard solutions are insignificant relative to the random error of the analysis.[24] It has recently been demonstrated[25] that this condition is guaranteed, at 95% confidence level, for normalized standard deviation $S_{st}/S_c = 0.8$ when $B/S_c < 0.7$ and for $S_{st}/S_c = 0.4$ when $B/S_c < 0.3$. The results of Fig. 4(a) indicate that $S_{st}/S_c = (0.2/0.27) = 0.8$ (approximated to a larger value) and $B/S_c = 0.18/0.27 = 0.67$. Likewise, Fig. 4(b) indicates that $S_{st}/S_c = 0.4$ and $B/S_c = 0.17$. Therefore, in both cases the accuracy demands are easily met.

The metrological characteristics of this method are particularly encouraging since the repeated experiments (for construction of Fig. 4) were independent of the calibration experiments. These experiments were conducted using different batches of doped sol–gel glasses, prepared by two different experimenters, and in fact more than 6 months elapsed between the construction of the calibration curves and the metrological studies.

Interferences

Interferences to the colorimetric determination of iron by phenanthroline chelate are well studied,[26,27] thermodynamic chelation data are available[28,29] and detailed procedures to mask some of the interferences have been devised.[17] Tube detectors and liquid photometry employ the same chelates but since the underlying mechanism of tube detectors is more complex, different effects of interfering species are to be expected. The study included the species mentioned in Standard Methods.[17] Each interference analysis was repeated at three interference levels: identical to the molar concentration of ferrous ions; five times this concentration; and 10 or 25 times (molar ratio) larger. The results of the interference studies are described in Table 1 along with the relevant thermodynamic complexation values. In some cases (*e.g.*, copper and nickel) the tube detectors exhibit better characteristics than liquid analysis and in others (*e.g.*, chromium and zinc) the effect of interfering species is more significant than the corresponding liquid analysis.

Classification of modes of interference may help gain a better insight into the reason for the different role of competing chemical specieson tube detection and conventional liquid colorimetry (or photometry). Five different

classes of interferences may be distinguished: interferences due to complexes of iron with other ions, such as pyrosulphate and cyanide; coloured background of the solution, *e.g.*, high concentrations of humic acids; consumption of *o*-phenanthroline by other cations to form uncoloured chelates, *e.g.*, nickel and cadmium; coloured chelate formation with cations such as Cu(II) and Cu(I); precipitation of phenanthroline—mixed metal chelates forming a milky, opaque solution, *e.g.*, silver and molybdenum. In the following section, the significance of each mode of interference is discussed and exemplified by the data of Table 1.

Iron chelate with other chemical species. A pretreatment is recommended in order to release the iron ions from the competing chelate prior to the colorimetric determination. This mode of inteference affects tube detection and photometric methods in the same manner and therefore is not exemplified here.

Coloured solution. Filtration is usually recommended in order to eliminate suspended solids and colloid interferences. In the presence of dissolved coloured substances, comparative colorimetry is not recommended and instrumental analyses, using a suitable reference, may partially overcome this mode of interference. Tube detectors are less sensitive to effects of suspended interferences since interfering particles are filtered out by the glass bed. Tube detectors are also less sensitive to dissolved colours because the location of the front, and not colour intensity is measured. The low interference of humic acids (Table 1) even when their concentration is ten times larger than iron exemplifies this characteristic.

Formation of an uncoloured chelate. Addition of excess phenanthroline is sufficient to eliminate such interferences and since phenanthroline does not absorb visible light, excess phenanthroline has no effect on the background colour of the solution. Tube detectors are particularly sensitive to this mode of interference, because downstream to the colour front virtually all the phenanthroline is consumed. Competition of other metals for the same ligand may cause misleading, large colour stains. Fortunately, the tube detectors operate in a displacement chromatography mode, and therefore the competition between the cations is significant only when iron and the interfering caton have similar affinity to the ligand. When the chelate of the interfering metal (*e.g.*, nickel) with phenanthroline is more stable than ferroine it displaces the red stain to a higher position without affecting its length. When the competing ligand has a much lower affinity to phenanthroline its own band will be displaced upstream with no significant interference. This is the reason why the stable nickel–phenanthroline and the less stable cadmium–phenanthroline have relatively little effect on iron determination with tube detectors, while copper and cobalt (which have intermediate stability constants) give misleading high readings.

Formation of coloured chelates. Metals that form phenanthroline chelates that absorb light in the visual range affect the selectivity of colorimetric determination, particularly when their molar absorptivity (e) is large. For example, copper(I) with is formed during the reduction of iron(III) with hydroxylamine yields an intense red chelate with *o*-phenanthroline. Tube detectors are affected by such interferences only when the stability constants of such chelates are similar to that of ferroine. Otherwise, a displacement mechanism will separate the two colour bands.

Precipitation of mixed complexes. Bismuth, cadmium, mercury, molybdate and silver form stable metal–ligand salts with common anions such as chloride and nitrate. The resulting solution is often milky, turbid and interferes with photometric or colorimetric determination of iron. A filtration step is often necessary prior to the photometric measurement. Table 1 reveals that these interferences are often less significant for iron determination by tube detectors. The formation of a solid precipitate is hindered by the competition of the labile and stable iron chelate. However, in some cases (*e.g.*, molybdate and silver) a mixed precipitate of interfering metal/iron salts appears and diminishes the size of the coloured ferroine section (here, of course, the immobilized phenanthroline does not take part in the reaction).

The analyses and classification presented here are sufficient to explain tube detector interferences which operate under pseudo equilibrium conditions. When high flow rates and large particle sizes are used the selectivity of the tube detectors will be influenced also by intraparticle diffusion and the relative lability of the competing chelates.

CONCLUSIONS

The iron length of stain detector demonstrates the advantages and current shortcomings of tube detectors based on doped sol–gel silica sensors for water analysis. Operator convenience, easy implementation and good precision and accuracy are significant advantages, particularly for a technology in its current initial stage of development. However, techniques to mask interferences and to further reduce measurement time should be developed. Currently the disposable tube detectors still do not eliminate wet chemistry since buffering (with acetate buffer) and reduction of iron(III) to iron(II) are still required prior to the final quantitation by the tube detectors. However, these pretreatments may be performed by inserting additional precolumns comprised of modular disposable segments, before the length of stain detector. Such precolumns, may be designed to perform specific pretreatments such as iron reduction, buffering or absorption of specific interfering substances, in a similar way to flow injection analysis. Work, in these directions is currently underway.

AIR-GAP FIBER-OPTIC AMMONIA GAS SENSOR

SATYAJIT KAR and MARK A. ARNOLD*
Department of Chemistry, University of Iowa, Iowa City, IA 52242, U.S.A.

(*Received* 1 *August* 1992. *Revised* 14 *August* 1992. *Accepted* 11 *September* 1992)

Summary—A novel fiber-optic gas sensing arrangement based on an air-gap design is evaluated. In this arrangement, a small gap of air separates the internal solution from the sample. In addition, a second air-gap separates the internal solution from a fiber-optic probe which measures the fluorescence of the internal solution. A series of gas sensors for ammonia is used to investigate several critical design parameters. The length of the air-gap between the internal solution and the fiber-optic probe affects the magnitude of response. The length of the air-gap separating the internal and sample solutions has minimal effect on either magnitude or rate of response. As with membrane-type gas sensors, thickness of the internal solution and concentration of the indicator dye are the most important sensor parameters to consider when designing a fiber-optic gas sensor.

Fiber-optic ammonia sensors capable of nanomolar detection have been developed and the use of these devices to investigate neurochemical events has been proposed.[1] The utility of such a device for biomedical research depends to some extent on the dimensions of the sensing tip. Smaller sensing tips will permit greater spatial resolution, thereby enhancing the information content of the measurement.

Ammonia gas sensing electrodes based on potentiometric pH detection have been miniaturized with tip sizes as small as 10 microns.[2,3] An air-gap design was used to fabricate these sensors. The air-gap is constructed by silanizing a short region inside a drawn out glass capillary. Sensor construction is completed by placing a small volume of internal solution above this hydrophobic region and then positioning a small pH/reference electrode pair in the internal solution. Additionally, the corresponding micro-biosensors have been demonstrated by covalently attaching urease to the outer surface at the tip of the glass capillary.[4]

We have characterized a series of miniature fiber-optic ammonia sensors based on this same air-gap design. Instead of using a pH electrode to measure the pH of the internal solution, a set of optical fibers is used in combination with a fluorescent pH indicator dye. Our intention has been to identify sensor parameters that most strongly influence the analytical characteristics of air-gap fiber-optic gas sensors. Sensors with tip sizes from 0.2 to 0.5 mm have been constructed. The sensor design parameters considered in this investigation include the positioning of the internal solution relative to both the optical fibers and the sample solution, volume and length of the internal solution, and concentration of the indicator dye.

EXPERIMENTAL

Sensor fabrication

Sensor bodies were constructed from glass capillary tubes (Kimble Products, Skokie, II) in the following manner. First, the closed end of the tube was removed and then the tube was cleaned by placing it into boiling water for approximately 30 min followed by a thorough rinsing with water. Cleaned capillaries were dried in a 115° oven. Sensing tips were formed by drawing out the capillary when the glass became red-hot under a normal gas flame. In this way, two sensor bodies were produced from each capillary with tip sizes ranging from 0.2 to 0.5 mm. Tips were silanized individually by dipping each into a 4% solution of dichlorodimethyl silane in carbon tetrachloride. The solution that occupied the tip was allowed to evaporate in air. Each tip was dipped between 6 and 10 times and the treated tips were placed in an 80° oven for 1 hr. Silanized tips were stored under nitrogen.

Sensors were constructed by placing a small volume of the internal solution inside a sensor

body between the silanized region and a fiber-optic probe. Figure 1 shows the sensor tip schematically. The fiber-optic probe was constructed by packing four plastic optical fibers (Super Eska type EK-10 fibers from Mitsubishi Rayon America, New York, NY) into a narrow bore glass capillary. This capillary fit snugly in the sensor body by matching the outer diameter of the capillary with the inner diameter of the untreated end of the sensor body. The optical fibers were held in the inner capillary with an adhesive sealant. A needle was used to place a small volume of the internal solution in position. The fiber-optic probe was then placed in the sensor body until its tip butted against the tapered portion at the drawn tip. A low temperature dental wax (Sybron-Kerr, Romulus, MI) was used to seal the top of the sensor and to hold the fiber-optic probe in place. As illustrated in Fig. 1, there was a short gap between the internal solution and the tip of the fiber-optic probe. As specified below, several internal solution compositions were used throughout this investigation. Internal solution volumes were calculated from differential weights obtained by weighing the sensor body before and after placement of the internal solution.

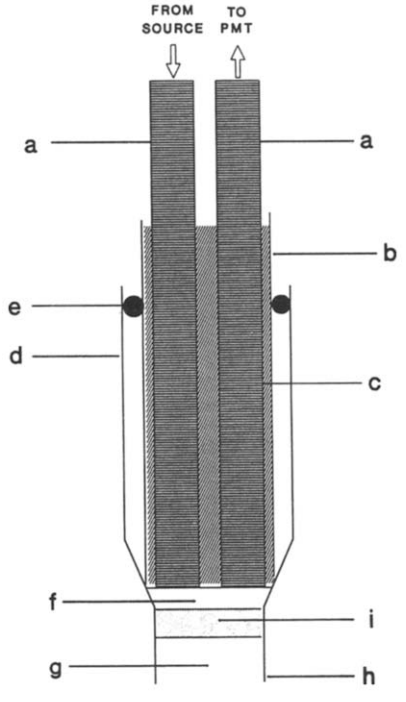

Fig. 1. Schematic representation of the air-gap fiber-optic ammonia sensor showing a, optical fibers; b, fiber-optic probe body; c, epoxy; d, gas sensor body; e, wax seal; f, air-gap; g, air-gap; h, sensor tip; i, internal solution.

Fluorescence measurements

Fluorescence from the internal solution was measured through the fiber-optic probe by using an instrumental arrangement similar to that reported previously.[1] Basically, the incident radiation was selected from a 100 watt tungsten halogen lamp by a 490 nm narrow band pass filter and then launched into two of the four plastic fibers of the fiber-optic probe. Emission was collected by the remaining fibers and directed toward the detection optics which consisted of a 540 nm interference filter and a photomultiplier tube (PMT).

Sensor calibrations

Sensors were calibrated by immersing the sensor tip in a 10.0-ml aliquot of a 0.01*M* sodium hydroxide solution that contained 0.105*M* sodium chloride. The required levels of ammonia were obtained by adding a series of microliter additions of an ammonium chloride standard solution. The steady-state sensor response was recorded after each change in the ammonia concentration. Response times were measured as the time required to achieve 95% of the final steady-state response.

Reagents

Both 5(and 6)-carboxyfluorescein (CF) and 5(and 6)-carboxy-4′,5′-dimethylfluorescein (CDMF) were used as received from Molecular Probes, Inc., Eugene, OR. All other reagents were analytical grade quality and were purchased from common suppliers. Freshly distilled-deionized water from a Milli-Q three house purification unit was used for all solutions.

RESULTS AND DISCUSSION

The position of the internal solution is a critical parameter in terms of both the magnitude and rate of sensor response. A small air gap between the fiber-optic probe and internal solution was found to be necessary to prevent the internal solution from climbing between the outer wall of the fiber-optic probe and the inner wall of the sensor body (see Fig. 1).

The size of gap between the fiber-optic probe and internal solution has important optical consequences in terms of both the intensity of the incident radiation hitting the internal solution and the efficiency of the fibers to collect the emitted radiation. Both parameters are

adversely affected by increasing this distance. As a result, a larger gap lowers the sensitivity of the measurement. For example, the effect of increasing the gap distance from 0.6 to 3.2 mm was measured for a sensor with an internal solution composed of 0.112M ammonium chloride and 1.0μM CF. In this experiment, the sensor response was measured for a zero to 10μM concentration step and the volume of the internal solution was 0.5 μl throughout. The magnitude of response decreased approximately 4-fold when the gap distance was increased, yet there was no significant difference in sensor response times.

The position of the internal solution was unstable when the chamber holding this solution was not sealed (see Fig. 1). Slight changes in ambient atmospheric pressure caused movement in the internal solution, thereby altering the sensor response. Another problem encountered with unsealed sensors was evaporation of the internal solution. Evaporation affected the sensor response in two ways. First, a decrease in the volume of the internal solution resulted in an increase in the distance between the fiber-optic probe and the internal solution which altered the fluorescence measurement. Second, evaporation altered the sensor response by concentrating the components in the internal solution. The small volumes of internal solution resulted in rather dramatic evaporation effects which demanded sealing the chamber before reproducible responses could be obtained.

The length of the air-gap region at the sensor tip was less critical than the length of the internal solution. The length of the internal solution affects both the magnitude and rate of response. These effects are illustrated by the data plotted in Fig. 2 which presents both the magnitude and rate of response measured for an ammonia concentration step from zero to 10μM. The internal solution used in this experiment was composed of 0.02M ammonium chloride and 10μM CF and the air-gap at the sensor tip was 3 mm. Increases in the length correspond to increases in the optical path length which provides higher sensitivity and larger responses. As the length approaches 2.5 mm, the response becomes insensitive to solution length, thereby defining the maximum optical path length in terms of the fluorescence measurement. Unfortunately, response times also increase as a function of solution length. Response times increased by a factor of 4.5 as the length was varied from 0.8 to 2.5 mm. Extrapolation to zero length gives the minimum response time based on the other parameters of the sensor design, most notably the length of the air-gap region. The effect of air-gap length was minimal when internal solution lengths ranged from 1 to 5 mm. Under these conditions, the rate of diffusion through the internal solution is rate limiting and controls the sensor response time. Similar results have been obtained for fiber-optic ammonia gas sensors with microporous Teflon membranes as the gas-permeable barrier.[1,5]

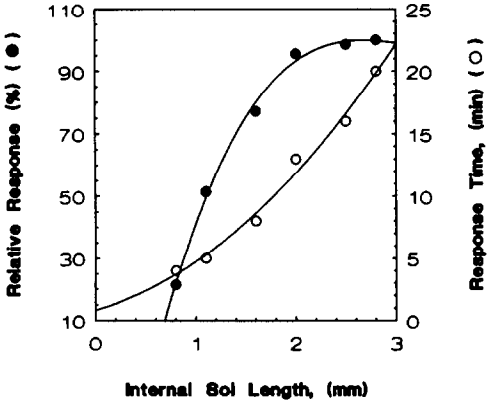

Fig. 2. Effect of internal solution length on the magnitude of response (right axis) and response time (left axis).

Both the magnitude and rate of response are also strongly influenced by the concentration of the indicator dye. These effects were examined by recording responses for a zero to 10μM concentration step as a function of the concentration of CF. Besides the indicator, the internal solution contained 0.1M ammonium chloride. As has been observed for sensors with Teflon membranes,[1,5] both the magnitude of response and response times increase as the dye concentration increases. By increasing the dye concentration from 2 to 10μM, the magnitude of the response increased by a factor of 2.5 and the response time increased from 4 to 11 min. Both effects are caused by a need for more ammonia to enter the internal solution to achieve equilibrium at higher dye concentrations.

Response curves for miniature air-gap fiber-optic ammonia sensors have the same nonlinear shape as the larger, membrane-type sensors. Figure 3 provides a sample response curve for a sensor with approximately 0.3μl of an internal solution composed of 2.0mM ammonium chloride and 0.1mM CDMF. The curve shape matches that predicted by the response function which has been derived for fiber-optic ammonia sensors.[5,6] Relative

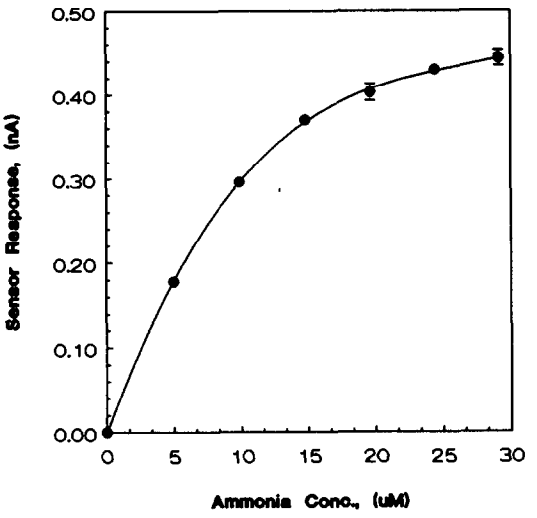

Fig. 3. Sample calibration curve for an air-gap fiber-optic ammonia sensor.

standard deviations for this sensor range were from 1 to 4% over the 5 to 30μM concentration range. Response times varied from 3 to 10 min over this same concentration range with longer response times recorded at lower ammonia concentrations. The limit of detection was calculated to be 0.5μM (S/N = 3) which is similar to that obtained for a membrane-based sensor with the same internal solution.

CONCLUSION

The response properties of fiber-optic ammonia sensors based on an air-gap design are similar to those for the larger, membrane-based sensors. The results of this investigation indicate that miniaturization is possible without adversely affecting the sensitivity, limit of detection or response time of the fiber-optic ammonia sensor. Overall, the thickness of the internal solution and the concentration of the indicator dye are the critical parameters that determine analytical performance.

VOLTAMMETRIC DETERMINATION OF INDIUM IN ALUMINA SUPPORTED CATALYSTS

P. V. C. RAO and V. J. KOSHY
Research Centre, Indian Petrochemicals Corporation Ltd, Baroda-391346, India

(*Received* 2 *June* 1992. *Revised* 14 *July* 1992. *Accepted* 2 *September* 1992)

Summary—A sensitive and rapid method for the estimation of trace levels of indium in alumina supported catalysts using square wave voltammetry (SWV) is discussed. The SWV method for indium in the alumina matrix is standardized using synthetic samples and good recoveries were obtained. Calibration graphs are linear in the range 1–5 μg/ml and the detection limit is 3.57×10^{-8} g/ml. In order to determine the accuracy of the proposed method, the results obtained have been compared with those given by atomic absorption spectrophotometry (AAS). Statistical analysis shows no significant bias between the two methods. This technique is found suitable for the estimation of indium in the range 0.1–1.0% (w/w) in the catalyst samples with an RSD < 1.5%.

Alumina supported noble metal catalysts have the ability to rearrange and transform the molecular structure of hydrocarbons: hence they have become very important in the petrochemical industry.[1] It is well known that various promoter elements are added to the alumina support in order to improve the activity and selectivity of the catalyst.[2] Indium is used as such and decreases the number of electron acceptor centres characterizing Lewis acidity of alumina by the neighbouring centre effect.[3] It is therefore important to monitor the level of indium in the catalysts during the preparation as well as usage in commercial plants.

In our laboratory, X-ray fluorescence,[4] electrothermal atomic absorption spectrometry,[5] electron probe micro analysis[6] and spectrophotometry[7] are the techniques reported for the estimation of minor constituents in catalysts. In the present study, the possibility of using square wave voltammetry for the determination of indium in alumina supported catalysts is investigated. This technique has been widely used for the estimation of indium in other matrices[8–10] but is rarely used for quantification of catalysts. In such investigations, the sensitivity and selectivity is much affected by the composition of the matrix. In the presence of large amounts of alumina, techniques based on atomic spectrometry suffer from atomization interferences.[11] The proposed voltammetric method is free from such problems and offers good sensitivity for the determination of trace levels of indium in the alumina supported catalysts.

EXPERIMENTAL

Apparatus

A Princeton Applied Research (PAR) Model 384B polarographic analyser system together with PAR 303A static mercury drop electrode were used for all square wave voltammetric measurements and the voltamperograms were recorded on a Houston DMP-40 digital plotter. Potentiostatic control of the electrode potential was established by means of a three electrode system consisting of a static mercury drop working electrode, a platinum wire counter electrode and an Ag–AgCl–KCl (satd) reference electrode. The SWVs are recorded at 10^5NA whereas the CVs are recorded at 10^3NA current settings.

A GBC model 902 atomic absorption spectrophotometer, equipped with deuterium arc background corrector, a 10 cm laminar flow air–acetylene burner, indium hollow cathode lamp and Epson LX-800 printer were used for all AAS measurements. An IBM PS/2 computer system with Lotus 1-2-3 was used for all plots and computations.

Reagents

All reagents used were of analytical grade and water purified by means of a Milli-Q system was used for preparing all the solutions. Standard

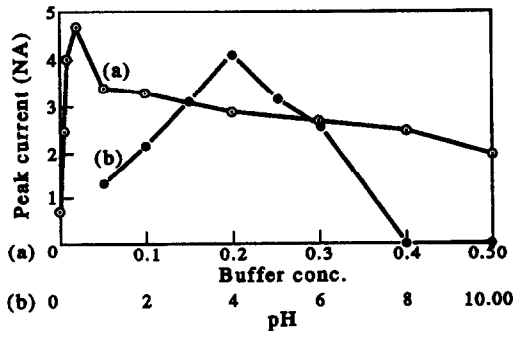

Fig. 1. Plot of buffer concentration (a) + pH (b) *vs.* peak current of indium(III) system.

In(III) solution has been prepared by dissolving 1.000 g of indium metal (99.99%) in 30 ml (2:1) hydrochloric acid by refluxing in a round-bottomed flask. After complete dissolution, the contents are cooled and transferred to a 100-ml standard flask and made up to volume with double distilled water. This solution is standardized with respect to indium AAS standard (1000 μg/ml) from Aldrich. Acetate buffer (1*M*) was prepared by mixing appropriate amounts of sodium acetate and acetic acid.

Procedure

Synthetic solutions are made by accurately weighing 1.000-g portions of finely ground powdered and dried (<200 mesh, 200° for 2 hr) γ-alumina was then taken in six separate 100-ml round bottom flasks. To each of them, the stock solution was added to achieve final concentrations of indium in the range of 0.1–1.0% (w/w). Subsequently the other concomitant solutions have been added in the following range (μg/ml): copper (10–100), zinc (10–100), Re (10–100), Sn (20–120), Li (40–120), Na (10–40), Ni (10–100) and Pd (10–100). Later, 30 ml of 2:1 hydrochloric acid was added and digested under reflux for 2 hr. After complete dissolution, the contents are quantitatively transferred to a 50-ml standard flask and the volume brought up to the mark with deionised water.

In the case of laboratory prepared catalysts also, 1.000-g portions are digested with 30 ml of 2:1 hydrochloric acid and diluted to 50 ml, as mentioned above.

Preparation of samples

To the standard or sample solution of 0.2 ml, add 1.0 ml of 1*M* acetate buffer and dilute the solution to 10 ml with water. After 4 min of deaeration, the square wave voltamperograms were recorded from −0.50 to −0.80 V (*vs.* Ag/AgCl) and the height of the peak is measured at −0.64 V. The blank substraction mode in the 384B was applied for all the samples. Each sample was then determined for indium by the standard addition method.

For atomic absorption spectrophotometric (AAS) analysis of indium, calibration solutions were prepared from their AAS standard solutions in the range 10–50 (μg/ml) using the following parameters: lamp current, 5 mA; flame, air–acetylene; wavelength, 325.6 nm; distance of the burner below optical axis, 6 mm. Matrix matching was carried out using reagent blank depending upon the sample dilution.

RESULTS AND DISCUSSION

Selection of experimental conditions

The experimental conditions have been optimized using 8 μg/ml of indium(III) in the synthetic solutions. The effects of pH and buffer concentration on the peak height are shown in Fig. 1. The optimum pH is about 4.0 and the buffer concentration of 0.1*M* was fixed for all further investigations.

Calibration

In order to ascertain the accuracy of the methods developed, synthetic solutions (S-1–S-5) of known compositions were prepared and used for voltammetric studies. A typical square wave voltamperogram of a laboratory prepared sample before and after the indium spike is shown in Fig. 2. The analysis has been carried out by the standard additions method. The regressed plots of successively spiked solutions shows good linearity as seen in Fig. 3. The

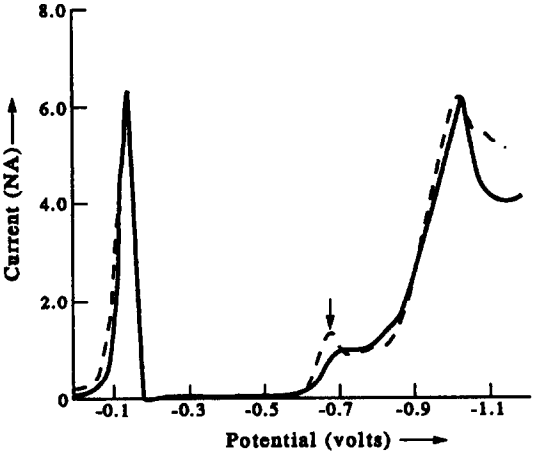

Fig. 2. Square wave voltamperogram of indium in alumina digest (—) and with an indium spike (– – –).

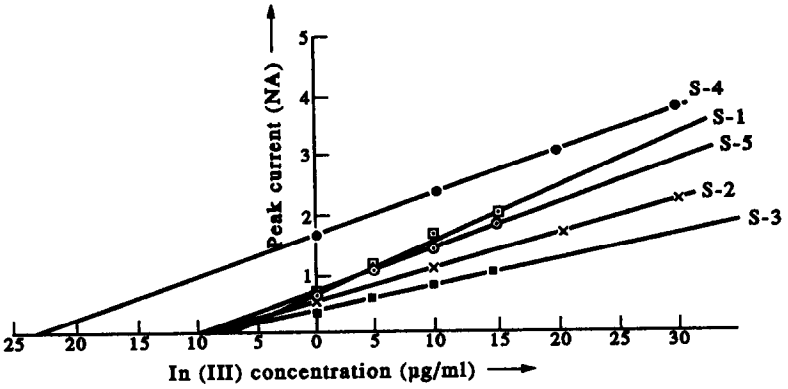

Fig. 3. Typical graphs obtained using standard addition method.

calibration characteristics of indium in synthetic solutions are given in Table 1. The percentage recovery for indium tested for different samples lies between 99 and 101%. Under the optimum conditions, the detection limit[12] of indium in the alumina matrix was found to be 3.57×10^{-8} g/ml.

Interference study

The possible interference of other concomitant elements, present as active element, promoter element or impurity, carried forward during the sample digestion processes were studied by adding increasing amounts of interferent to a fixed concentration of indium(III) solution (8 μg/ml) and measuring the peak currents under optimal conditions after each addition. The results are summarized in Table 2. It can be observed that the increase in the metal to concomitant ratio (>1:10) causes considerable interference (Pt and Sn) in the analysis of indium, but in the present study most of the catalyst compositions fall within these limits. The main interference is due to Fe(III).

Cyclic voltammetry

The cyclic voltammetry of the system was investigated wtih model 384B polarographic analyser with a static mercury drop electrode. The cyclic voltamperograms have been recorded at a scan rate of 50 mV/sec in acetate buffer: indium standard solution (a), synthetic sample (b) and catalyst digest (c) are shown in Fig. 4. Reversible peaks were obtained for indium in acetate buffer, whereas the peaks were not discernible in the case of catalyst digest, indicating the irreversible nature of indium reduction in the presence of other catalyst elements.

Sample analysis

The acquisition of data for the laboratory prepared samples was carried out by following the same procedure as that used for synthetic solutions. Recovery assays of indium in the digests of laboratory prepared samples (S-6–S-11) were carried out separately by SWV and AAS methods and the results are given in Table 3. The relative standard deviation of the order of 1.5% in indium content shows good reproducibility of the method. The results obtained by SWV and AAS were subjected to an *F*-test, and at the 95% confidence level the calculated

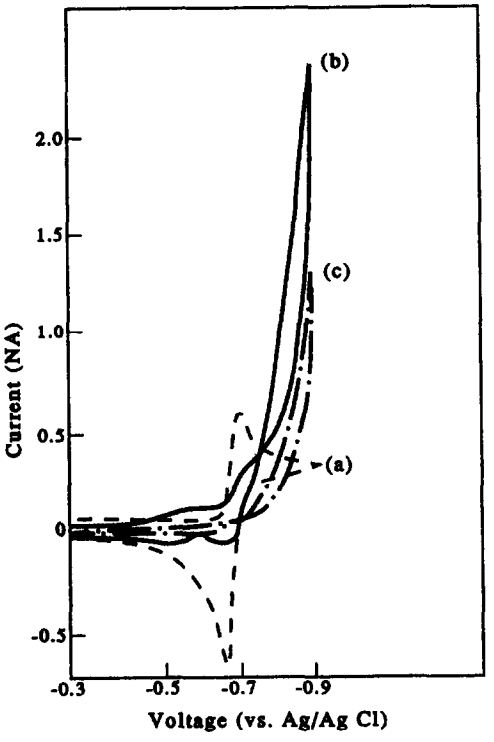

Fig. 4. Cyclic voltamperogram of indium(III) in (a) 0.1*M* acetate buffer, (b) in synthetic solution, (c) in the catalyst digest.

F-value did not exceed the tabulated value, indicating the absence of any significant error. The same method was extended to the analysis of real catalyst samples (CAT1–CAT5) and the results obtained by SWV compare well with AAS results (Table 4).

CONCLUSIONS

The results obtained indicate that the SWV method has proved its usefulness for the determination of indium in the presence of other active elements. SWV serves as an alternative for AAS method and its reliability is shown by the recovery studies performed and by the satisfactory determination in the laboratory prepared samples. The proposed method gives good sensitivity and lower detection limits compared to AAS. In addition to Fe, concomitants like Pt and Sn can cause interference at higher concentrations. In conclusion, the procedure is rapid and simple for the determination of indium in the alumina supported catalysts.

A FAST RESPONSE MEMBRANE-BASED pH INDICATOR OPTODE

TERENCE J. CARDWELL, ROBERT W. CATTRALL, LESLIE W. DEADY,* MARIA DORKOS and GREGORY R. O'CONNELL

Centre for Scientific Instrumentation, La Trobe University, Bundoora, Victoria 3083, Australia

(*Received* 15 *June* 1992. *Revised* 11 *August* 1992. *Accepted* 12 *August* 1992)

Summary—A cellulose acetate based optode membrane containing 4-dimethylamino-4′-octylazobenzene as an acid–base indicator is described. Other essential components of the membrane for a fast-responding and durable sensor are diethyl phthalate, triethyleneglycol and potassium tetrakis(4-chlorophenyl)borate. Factors affecting the sensor behaviour are discussed and an application in a flow-cell is demonstrated.

There is much current interest in the development of optical sensors (optodes) for a variety of analytical purposes. For example, a number of indicators have been immobilized in polymer films and used as pH sensors.[1] A considerable amount of work has dealt with poly(vinyl chloride) based membranes and Morf and coworkers have described the mechanisms which lead to successful optical sensors.[2] However, PVC based membranes tend to suffer from a slow response time, in the order of seconds to minutes, which is not too different from their potentiometric counterparts. A rapid colour change is essential if a film is to be used in an acid/base titration and, for repeated use, the indicator must not leach out of the membrane. Among the most successful attempts at achieving a fast response for optode membranes has been the incorporation of an unmodified "direct dye" such as Congo Red into a modified cellulose acetate film.[3]

Our work in this field is related in that cellulose acetate was found to be the best polymer from which to construct a water-permeable membrane, but we have modified a standard indicator to make it more polymer-compatible and less prone to leaching in aqueous solutions. We have also developed a simple formulation for a membrane sensor which has a fast response to pH change and which does not require an ultra-thin film. This paper reports studies on factors critical to the response time and the use of the optode in a flow system.

*Author for correspondence.

EXPERIMENTAL

4-Dimethylamino-4′-octylazobenzene

A solution of sodium nitrite (0.12 g) in water (1 ml) was added, dropwise with stirring, to a solution of 4-octylaniline (0.25 g) in water (3 ml) and concentrated hydrochloric acid (1.2 ml) at $<5°$. After 15 min at 5°, this was added, slowly with stirring, to a solution containing an excess of *N*,*N*-dimethylaniline and sodium acetate in aqueous ethanol. The yellow solid which separated was filtered, washed with water, and recrystallized from acetonitrile to give orange-yellow flakes, m.p. 80–81° (found: C, 78.6; H, 9.4; N, 12.7. $C_{22}H_{31}N_3$ requires C, 78.3; H, 9.2; N, 12.5%).

Construction of membrane

A typical composition was (weight %): cellulose acetate (Aldrich-acetate content 39.8%), 50; diethyl phthalate, 10; triethylene glycol, 34.7; dye, 0.3; sodium tetraphenylborate, 5. This mixture (100 mg) was dissolved in *ca.* 2 ml of tetrahydrofuran (which was purified by passage through a short alumina column), a coating applied to the appropriate surface and the solvent allowed to completely evaporate. In some circumstances, the membrane was heated briefly to improve the transparency. Coated in this way were a glass microscope slide and plastic coated stirrer bar (for qualitative testing), the inside of a normal 1-cm quartz cuvette (for visible spectroscopy), and the walls of a 14-mm × 2.3-mm diameter tunnel (roughened with a diamond drill to improve adhesion of the plastic) in a 7.5-mm diameter glass cylinder (for use in the flow-cell). The membrane when separated from

a glass surface was quite robust. The thickness of the membrane in both the glass cylinder and on a flat glass surface was typically *ca.* 50 μm, measured by micrometer, which is considerably thicker than the fast response examples of Porter.[3]

Spectroscopy

The membrane coated cuvette was used and gave λ_{max} values of 420 nm (free base) and 545 nm (conjugate acid). A standard spectroscopic technique[4] was applied to determine the pK of the dye in this membrane. In spite of a non-uniform coating, the membrane gave useable values within $\pm$ 1 pH unit of the pK, determined as 3.8. This compares with the value of 2.96 reported by Yeh and Jaffé,[5] obtained in 25% ethanol–sulphuric acid for the parent dimethylaminoazobenzene. The values reported by Yeh and Jaffé are not true pK_a values, since tautomeric forms are possible for the protonated species.

Flow-cell measurements

The Discontinuous Flow Analyser used has been described previously.[6] In this work, the indicator application was demonstrated by the titration of 0.1M sodium hydroxide or potassium hydroxide with 0.1M hydrochloric acid, the membrane coated glass cylinder (i.d., 2.3 mm) providing the flow channel and the optical window for a yellow LED (emission λ_{max} = 580 nm).

RESULTS AND DISCUSSION

Composition of the sensor

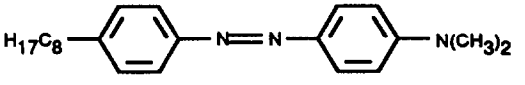
There are five necessary components of the successful sensor:

1. Cellulose acetate was the polymer support of choice for making a water-permeable membrane. Cellulose triacetate, polyvinyl acetate, polyvinyl pyrrolidone, and polyvinyl chloride were much less satisfactory. A noteworthy feature was that the optode worked with much thicker membranes than are normally specified for sensors, so that casting the membrane required no special technique.

2. Diethyl phthalate (5–20%) was included as plasticizer and this improved the transparency of the membrane. Slow drying, as from inside a cuvette, gave a more transparent membrane; one cast on a glass slide was opaque initially but gentle heat for a short time gave a clear membrane.

3. During early fabrication attempts it was noted that, if the membrane retained any of the water miscible tetrahydrofuran used to initially dissolve the components, the response time was much reduced. This essential feature has been incorporated in the final formulation by including the non-volatile triethylene glycol as "wetting-agent". About 10% by weight seemed to be necessary and up to 50% was used.

4. This first study has only considered a single indicator (I) which is a simple azo-dye to which is attached the long-chain octyl group. This was prepared by standard chemistry and the compound at 0.3% was miscible with the polymer and did not leach from the membrane on repeated use.



(I)

5. For this dye, which goes from a yellow neutral form in base to a red cationic form in acid, it was essential to have an ion-balance reagent (IBR) present and sodium tetraphenylborate (NaTPB) and potassium tetrakis(4-chlorophenyl)borate (KTKB) were each used. Without the IBR, no reaction occurred in aqueous hydrochloric acid. To maintain ionic balance in these conditions, it is necessary for an anion to be taken into the membrane with the proton and it was evident that the hydrophilic chloride anion would not transport along with the proton into this membrane. The IBR provided mobile metal cations in the membrane to exchange with the incoming protons to overcome this problem. A molar excess (with respect to the dye) was necessary for rapid response. However, too much gave an opaque/crystalline membrane, and 5% by weight (*ca.* 10-fold molar excess) was a good working amount. It emerged that the response time was affected by the nature of the IBR reagent, as described below.

The membranes with NaTPB as the IBR, though thicker than those reported previously,[3] were characterized by a rapid response to pH change in either direction. For a coated slide immersed in the appropriate solution, the colour change to red was "instant" and to yellow, marginally slower, but too fast to measure quantitatively in a batch type experiment. A more quantitative answer is available

from flow-cell experiments (below). The colour change could be quantitatively related to pH by visible spectroscopy only over *ca.* a 2-unit range about the pK value of 3.8. Thus, this dye is more appropriate for an indicator of pH change rather than for a measure of pH value.

Flow-cell application

The application of this pH-optode to use in a discontinuous flow analysis system[6] was demonstrated. The optode membrane (*ca.* 50 μm thick) was incorporated into the flow-cell of the instrument as described in the experimental section. Figure 1(a) shows a typical DFA acid–base titration curve for a membrane with NaTPB as the IBR. At A, the liquid in the flow-cell is 0.1M hydrochloric acid. At B, the titration cycle of the instrument provides a rapid flush of 0.1M sodium hydroxide and the indicator immediately turns yellow. The actual titration begins at C as acid is added and the observable colour change back to red commences at about D. The end-point E is indicated by the rapid change in the detector signal and is defined in the DFA instrumental method by taking the first derivative. The times for the colour changes can be estimated from the time-bar in the figure, which refers to the speed of rotation of the instrument cam. These times are virtually identical to the case where a water-soluble indicator is introduced separately into the flowing stream.[6]

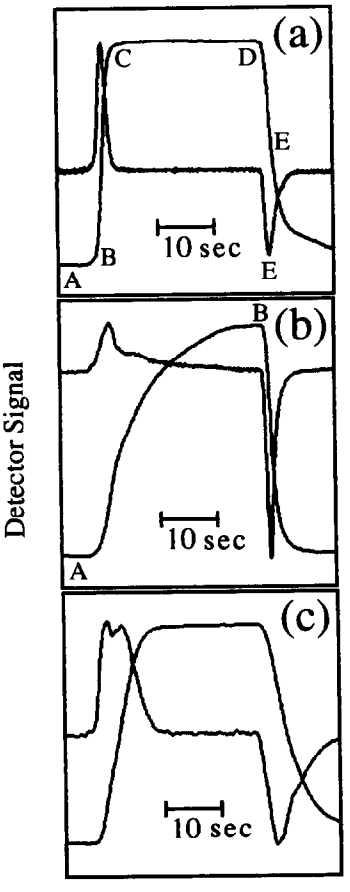


Fig. 1. DFA titration of 0.1M HCl with base. (a) Base, 0.1M NaOH; IBR, NaTPB. (b) Base, 0.1M NaOH; IBR, KTKB. (c) Base, 0.1M KOH; IBR, KTKB. The time-bars relate to the instrument cam speed.

The behaviour is ideal for the DFA application, which requires a rapid colour change at the end-point. Unfortunately, NaTPB as IBR slowly leached from the membrane and the optode ceased to function after about ten titration cycles (though the coated glass slide lasted many more batch changes of acid and base, probably because there is much less agitation of the membrane surface than in the DFA cell). This problem was overcome by the use of the less hydrophilic KTKB as IBR and there was no perceptible deterioration in the membrane performance after more than forty cycles. However, with sodium hydroxide as the base, there was now an unacceptably slow response for the acid to base change (but no effect on the reverse). This is seen in Fig. 1(b) as a very slow rise, A, in the detector signal to the maximum, B, which is reached just before the change back to the acid form.

Clearly, the movement of the various ions involved in the indicator colour change, across the membrane/solution interface, is a complex process. The tetrakis(4-chlorophenyl)borate anion apparently has a lower affinity for a sodium ion in the membrane than does the unsubstituted tetraphenylborate anion and the replacement of a proton by a sodium ion is slower. The situation, however, is also cation dependent and, when potassium hydroxide was used as the base, the response times in both directions were quite acceptable. The membrane was stable indefinitely and Figure 1(c) shows the titration sequence in these conditions after seventy cycles.

This DFA application represents an advance on the previous example using photometric end-point detection, where an indicator had to be added in reasonably high concentrations to the flow system.[6] Compound I, while being a quite satisfactory indicator for a strong acid–strong base titration, has limited potential because of its low pK_a value. We are currently investigating compounds applicable to other pH

regions and which will be compatible with the polymer system.

BOOK REVIEWS

The Kirk–Othmer Encyclopedia of Chemical Technology: Volume 4, Fourth Edition. Bearing Materials to Carbon. J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley–Interscience, Chichester, 1992. Pages: xxx + 1117. £150.00. ISBN 0-471-52672-X (v. 4).

The first three volumes of this encyclopedia have recently been reviewed in *Talanta* and the current volume continues to report on a variety of chemical topics. The chemical elements covered together with associated compounds are beryllium, bismuth, boron, bromine, cadmium and calcium. Technological aspects of the different solid state forms of carbon are mentioned at the end of the volume and carbides are dealt with in a separate section.

Several other diverse topics, as well as the expected elements and compounds, are included. Some of these are beer, benzene, biosensors, bleaching agents, butadiene, butylenes, caprolactam and carbohydrates. The standard of the previous volumes is maintained and the topics are dealt with at a level which is informative, interesting, and easy to understand. My own favourite gems in this volume include (1) the different ways of sawing logs of trees into slabs, (2) a definition of Scotch whisky, (3) the use of biopolymers in chiral chromatography, and (4) problems associated with developing artificial blood.

Other short sections cover biphenyl and terphenyls, brake linings and clutch facings, butyl alcohols and carbamic acid. The topic of biotechnology is stated to be dispersed throughout various articles but a concise overview is included in this volume. Extensive and up-to-date bibliographies are given after each article and the whole work is extremely well edited. This is an encyclopedia which every good science library should obtain.

P. J. Cox

The Elements: Second Edition, J. EMSLEY, Oxford University Press, Oxford, 1991. Pages: vii + 251. £11.95 (softback). ISBN 0-19-855568-7.

This is a marvellous book of data about all the elements up to atomic number 104. The first edition was published in 1989 and proved extremely popular. The main additions in the second edition are sections on what the author calls Environmental Properties.

The first nine pages explain the type of data provided and the sources of information. Thereafter, the data are arranged per element in alphabetical order, with two pages devoted to each element. The preliminary information given includes the atomic number, relative atomic mass, the derivation of the name and the date and place of discovery. This is followed by a section on Chemical Properties such as reactivity towards air, water, acids and alkalis, values of the atomic and ionic radii, the electronegativity and effective nuclear charge. The standard reduction potentials and oxidation states are also listed. The next section concerns Physical Properties such as the melting and boiling points, thermodynamic properties, density, thermal conductivity, electrical resistance, mass magnetic susceptibility, molar volume, crystal structure and X-ray diffraction mass absorption coefficients.

The section on Nuclear Properties contains the thermal neutron capture cross-section, the number of isotopes and isotope mass range and details about the key isotopes. Details relevant to NMR spectroscopy are also given including relative sensitivity, receptivity, magnetogyric ratio, quadrupole moments and frequency in MHz. The Electron Shell Properties listed are the ground state electron configuration, the term symbol and the electron affinity in kJ mol^{-1}. The main lines in the atomic spectrum are given along with ionisation energies for sequential loss of up to 10 electrons.

The new sections on Environmental Properties will be of interest to geologists and those involved in the life sciences. The abundance of the element in the sun, the earth's crust and the oceans are listed along with geological data concerning the principal ores, world production of the element or its minerals and an indication of the estimated reserves available. Data in the subsection on the biological role of the element includes typical levels found in human muscle, bone and blood. Normal daily dietary intake is given along with comments on the toxicity of the element and whether or not it is essential to healthy human existence.

There are 20 supplementary tables of properties of the elements in order of the element and in ranking order of property. For example, there is a table on the dates of discovery of the elements in chronological order. Other tables give the melting and boiling points of the elements in order of temperature.

The cost of the paperback version is extremely reasonable and I consider this book to be excellent value for money. Anyone who is interested in elemental properties should have a copy of this book on their library shelves. This must be one of the most concise yet comprehensive collections of data about the elements. I do not know how I managed to survive without it!

D. LITTLEJOHN

Solution Mining—Leaching and Fluid Recovery of Materials: R. W. BARTLETT, Gordon & Breach Science Publishers, Philadelphia, 1992. Pages: xxxii + 276. $29.00 £16.00. ISBN 2-88124-546-3.

Anyone who has been shown around a cyanide treatment plant for extracting gold from mining wastes by aerial oxidation assisted by complexation of the gold cannot fail to have been impressed by the simplicity and the cheapness of the process. Similarly, the recycling of leachates from old mining residue tips to extract workable levels of copper and other metals obviously makes not only economic but also environmental sense. But that the value of materials extraction by solution mining exceeded two billion dollars in the US alone in 1990, accounting for between 20% (for boron) through 35% (for gold), 75% (for uranium) to 85% (for magnesium) of that country's total production came as a big surprise to me. The author of this book has been responsible for a number of large development programmes, for recovery of copper, gold and precious metals, and boron. Based on this experience he has introduced an advanced level course on the topic for which this is the textbook.

Both surface mining, of old mining residues, and deep mining, of new deposits following initial mechanical removal of 15–25% of the ore body, are discussed. The need for the introduction of some rather formidable mathematical equations becomes clear when the last chapter, computer simulation of solution mining operations, is reached. Optimisation of a commercial process depends on a sound knowledge of the permeability of the rock, the lump sizes, the dimensions of the ore heap, the flow of the eluting acid, and the kinetics of the process.

Environmental aspects of solution mining are also discussed. Handling large amounts of cyanide solution presents obvious hazards, while slightly less obvious is the possible percolation of acid leachates into ground water. Dust and noise from mechanical mining are probably more serious threats to the environment.

This is an interesting book, though written for a rather specialised market. It is readable, well illustrated, (with both photographs and line drawings) and contains useful bibliographies at the end of each chapter. It is certainly good value for money.

I. MARR

Capillary Electrophoresis—principles, practice and applications: S. F. Y. LI, Elsevier, Amsterdam, 1992. Pages: xxvi + 582. Dfl 395.00. ISBN 0-444-89433-0.

This is a very comprehensive text which deals in detail with the several modes of capillary electrophoresis.

Chapter one is a readable introduction to the range of individual techniques associated with CE. It will be particularly useful in acquiring a basic knowledge of the different modes of use. Chapters two and three deal with injection and detection techniques in considerable detail. Both are very comprehensive and provide a wealth of information on lesser known methods as well as those more generally appreciated.

A very complete overview of column technology is given in Chapter four dealing in particular with methods of capillary coating and attributes of gel-filled capillaries. Chapter five gives an exhaustive coverage of electrolyte systems used including the functions of simple buffer systems and organic modifiers. The effects and uses of more complex additives are also well covered in particular the use of surfactants in MEKC. Chapter six is a collection of diverse methods and techniques associated with CE ranging from fraction collection through isoelectric focusing and isotachophoresis and concluding with a review of combination methods.

Chapter seven lists a multitude of CE applications. Amino-acid and biopolymer separations are comprehensively covered and the utilisation of CE in various diverse areas is reviewed. At the end of this chapter there is a very useful summary of separation conditions for different analytes in various matrices which will provide useful starting points for new applications. The review of commercial equipment which is also included in this chapter will prove invaluable for first time users of the technique. The last chapter attempts to cover recent advances and to indicate possible future developments.

This volume is a very useful addition to the literature of separation science encompassing, as it does, all aspects of this rapidly emerging family of methods. It is almost encyclopaedic in its coverage and all chapters are extremely well referenced. This will facilitate any search for original information on any aspect of CE.

SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF CADMIUM IN HIGH PURITY ZINC MATERIALS WITH IODIDE AND RHODAMINE 6G

S KARTIKEYAN, T PRASADA RAO*, C S P IYER and A. D DAMODARAN
Regional Research Laboratory (CSIR), Trivandrum 695 019, India

(*Received* 13 *August* 1992 *Revised* 18 *November* 1992 *Accepted* 21 *November* 1992)

Summary—A highly selective and sensitive spectrophotometric procedure for the determination of cadmium is developed This is based on the interaction of rhodamine 6G with tetraiodocadmate (II) anion to form a pink product which absorbs maximally at 575 nm that is stable for 24 hr when stabilized with gelatin Cadmium concentrations as low as 0 01 ppm can be readily determined The method is precise and has been applied to synthetic sea water samples and high purity zinc materials

Cadmium is one of the priority pollutants and is usually associated with zinc materials. Various methods have been described for the last one decade for trace determination of cadmium. These procedures are applicable to the determination of cadmium in river water,[1] natural water[2–5] and waste water.[6–8] Since, zinc has a relatively low tendency to form complexes with iodide ($pK_4 = -2\,3$) compared to cadmium ($pK_4 = 6.1$), this has been utilized with advantage to devise methods for cadmium after reaction with rhodamine B[6] ($\varepsilon l = 4.2 \times 10^4$ l.mole^{-1}.cm^{-1}) and pyronine G[10,11] ($\varepsilon l = 9.0 \times 10^4$ l.mole^{-1}.cm^{-1}). However, the former method is less sensitive and the latter has a drawback in the sense that pyronine G is an impure commercial dye consisting of ~80% rhodamine S and ~20% of pure pyronine[12] (where rhodamine S is the main reacting molecule). Hence, it is essential to devise a procedure to determine traces of cadmium in high purity zinc materials with a reagent of definite composition. This paper describes the studies on the interaction of anionic iodo complex of cadmium with rhodamine 6G that provides a basis for a highly selective spectrophotometric method for the determination of cadmium. This method finds application in the determination of cadmium at levels down to 1 μg/g of high purity zinc materials.

EXPERIMENTAL

Reagents

All reagents used were of analytical reagent grade unless otherwise stated. All solutions were prepared with double distilled water.

Standard cadmium solution, 500 ppm: Dissolve 0.2854 g of cadmium sulphate (3 $CdSO_4$.8 H_2O) in 250 ml of water and standardize titrimetrically using EDTA. Prepare working standards (5 ppm) by suitable dilution.

Citrate buffer solution, 0.8*M*, pH 3.5: Prepare the citrate buffer (0.8*M*) by dissolving 21.04 g of citric acid monohydrate and 29.41 g of trisodium citrate in water and adjust the pH to 3.5 using either HCl or NaOH and diluting to 250 ml.

Rhodamine 6G (BDH, Poole, U.K.) solution, 0.01%: Dissolve 0.025 g of rhodamine 6G in 250 ml of water.

Potassium iodide solution, 10%: Dissolve 10 g of potassium iodide in 100 ml of water.

Gelatin solution, 1%: Dissolve 1 g of gelatin in 100 ml of water.

Apparatus

A microcomputer based Hitachi Model 220 double beam spectrophotometer with extended program was used. An ELICO LI-120 digital pH meter was used for pH adjustment.

Procedure

Mix 2.5 ml of citrate buffer in an aliquot of sample solution containing not more than

0.6 ppm of cadmium in a 25-ml volumetric flask, mix and adjust the pH to 3.5 using HCl or NaOH under a pH meter. Mix 2 ml of potassium iodide and 5 ml of rhodamine 6G followed by 1 ml gelatin and dilute to the mark with distilled water using 10-mm quartz cells Measure the absorbance at 575 nm against a reagent blank and establish the concentration by reference to a calibration graph prepared for 0–0.6 ppm of cadmium using standard cadmium solutions, by following the above procedure

Analysis of high purity zinc materials

Dissolve 5 g of high purity zinc materials in 10 ml of 1·1 HCl and dilute to 100 ml with water. Add 2 ml of 20% solution of sodium citrate to a 10-ml aliquot and adjust the pH to 3.5, as described above. Transfer the solution to a 25-ml volumetric flask and establish the concentration of cadmium as described above.

RESULTS AND DISCUSSION

The pink ternary complex that resulted, on the addition of rhodamine 6G to the aqueous solution of cadmium containing iodide, was unstable and gradually precipitated on standing. This ternary complex (Cd–I⁻–rhodamine 6G) was found to be stable for 24 hr on the addition of gelatin.

Absorption spectra and spectral characteristics

Figure 1 shows the absorption spectra of 4 ml of $10^{-4}M$ rhodamine 6G (curve A) with 1 and

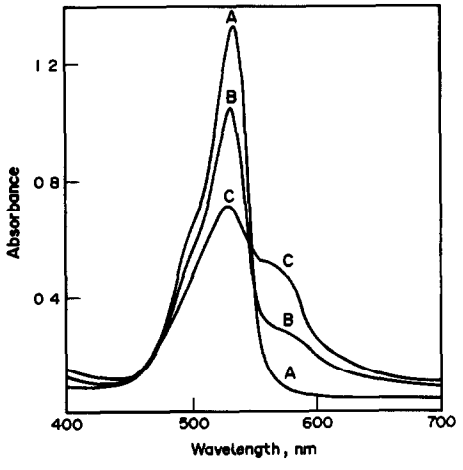

Fig 1. Absorption spectra of the cadmium–iodide-rhodamine 6G complex, width of cells, 10 mm, reference, water, pH 3 5 Curve A 4 ml of $1 \times 10^{-4}M$ rhodamine 6G + buffer and 2 ml of 10% KI solution + 1 ml of 1% gelatin in 25 ml of final solution Curves B & C as in A but with the addition of 1 and 4 ml of $1 \times 10^{-4}M$ cadmium solution

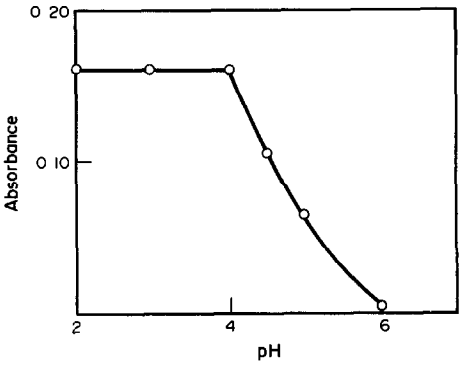

Fig 2 Effect of pH on the absorbance at 575 nm (0 2 ppm of cadmium, 2 ml of 10% KI, 5 ml of 0 01% rhodamine 6G, total volume = 25 ml, 10 mm quartz cells)

4 ml of $1 \times 10^{-4}M$ (curves B and C, respectively) amounts of cadmium in the presence of potassium iodide and gelatin. It is evident from Fig. 1 that the interaction of the iodo complex of cadmium with rhodamine 6G proceeds with a considerable bathochromic shift. the ternary complex has a maximum absorption at 575 nm compared with that of the dye at 530 nm.

Optimization of experimental conditions

It was found that the ternary complex was fully formed in the pH range 2–4 (Fig. 2) Studies at higher acidities were not considered because liberation of I_2 increases the blank value. Citrate buffer (pH 3.5) was preferred to phthalate or acetate buffer as its presence removes the interference of 200-fold amounts of Pb^{2+}, Cu^{2+}, WO_4^{2-}, Sn^{2+} and Sb^{3+}. The results of the investigation on the effect of iodide and rhodamine 6G showed that, for constant and maximum absorbance, the solution should contain at least 3 ml of 5% potassium iodide

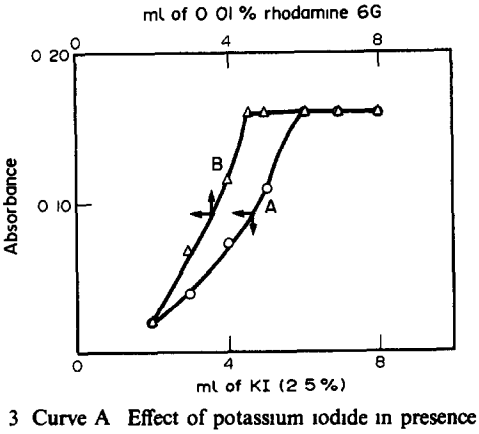

Fig 3 Curve A Effect of potassium iodide in presence of 5 ml of 0 01% rhodamine 6G Curve B Effect of rhodamine 6G in presence of 2 ml of 10% KI (0 2 ppm of cadmium, pH 3 5, total volume = 25 ml, 575 nm, 10 mm quartz cells)

Table 1 Results of interference studies

Interference	Remarks
Li^+, Na^+, K^+, Ca^{2+}, Sr^{2+}, Ba^{2+}, Pb^{2+}, Sn^{2+}, Cu^{2+}, Zn^{2+}, Fe^{2+}, Co^{2+}, Be^{2+}, Ni^{2+}, Mn^{2+}, UO_2^{2+}, Cr^{3+}, Fe^{3+}, Al^{3+}, Sb^{3+}, Tl^{3+}, La^{3+}, Ce^{4+}, Zr^{4+}, Th^{4+}, Se^{4+}, Sb^{5+}, AsO_4^{3-}, AsO_3^{3-}, VO_4^{3-}, MoO_4^{2-}, WO_4^{2-}, SO_3^{2-}, $S_2O_3^{2-}$, $B_4O_7^{2-}$, F^-, SCN^-, oxalate and tartrate	No interference
Hg^{2+}, Pd^{2+}, Bi^{3+} and Pt^{4+}	Interfere by enhancing the absorbance
NO_2^-	Interferes by oxidizing rhodamine 6G

(*cf.* curve A, Fig. 3) and 4.5 ml of 0.01% rhodamine 6G (*cf.* curve B, Fig. 3). Under these optimal conditions, the colour development was instantaneous and remains stable for 24 hr. The order of addition of reagent solutions was found not to be critical provided that the gelatin solution was added after the addition of other reagent solutions.

Calibration graph and precision

The colour system obeys Beer's law in the range 0–0.6 ppm of cadmium in a final volume of 25 ml. The molar absorptivity (*el*) at 575 nm was calculated to be 8.9×10^4 $l.mole^{-1}.cm^{-1}$. Ten replicate determinations on standard solutions that contained 5 μg of cadmium showed a mean recovery of 98.6% with a coefficient of variation of 1.39%.

Nature of the complex

The combining ratio of cadmium to rhodamine 6G was established to be 1:2 from mole ratio and continuous variation methods. These methods were unsuccessful when applied to the determination of the combining ratio of cadmium to iodide as no colour development took place when they were present in molar proportions. However, the equilibrium shift method indicates a ratio of 1:4 for cadmium to iodide. Hence, the ternary complex has the empirical composition $(Cd\ I_4)^{2-}R_2^+$ where R^+ represents the rhodamine 6G cation.

Interference studies

The interfering effects of various ions at 40 ppm level on the determination of 0.2 ppm of cadmium by the proposed method are summarized in Table 1.

The addition of 2 ml of 5% thiourea overcame the interference due to Pd^{2+} and Pt^{4+} and addition of 2 ml 5% oxalic acid eliminated the interference due to Bi^{3+}. The interference of mercury(II) was eliminated by reduction with 2.5 ml of 2% $SnCl_2$ and centrifuging of the turbid solution prior to the addition of reagent solutions. The addition of 2 ml 5% urea overcame the interference due to nitrite.

Analysis of synthetic samples

The results in Table 2 show that the presence of similar or even larger concentrations of metal ions either alone or in combination, had no effect. The method can therefore be used for the determination of cadmium in real samples such as steel and high purity zinc materials.

Table 3 presents the results of the analyses of synthetic sample solutions of various forms of sea water after overcoming the interferents as described above. The results clearly show that the method can find use in trace determination of cadmium in polluted sea water samples.

Analysis of high purity zinc materials

Table 3 shows the results of the determination of cadmium in zinc sulphate and zinc oxide samples by the proposed method. The results were compared with those obtained by atomic absorption spectroscopy. The data obtained on samples spiked with known amounts of cadmium are presented. The results show good agreement between the two methods.

CONCLUSION

The method described provides a simple and reliable means of determining trace amounts of cadmium by spectrophotometry. Though it is of similar sensitivity as that of pyronine G procedure,[10] it is superior to other methods in terms of selectivity and is readily applicable to the analysis of high purity zinc materials. The method also has the advantage of virtual freedom from 200-fold amounts of various extraneous ions and can therefore serve as an alternative to atomic absorption spectrophotometry for rapid and precise determination of cadmium in steel, in polluted sea water, waste water and high purity zinc materials.

HIGH-SPEED CHROMATOGRAPHIC ANALYSIS OF HIGH-FRUCTOSE CORN SYRUP FOR PROCESS MONITORING

DARREN R DUNPHY and ROBERT E SYNOVEC
Department of Chemistry, BG-10, University of Washington, Seattle, WA 98195, U S A

(*Received* 23 *September* 1992 *Revised* 20 *November* 1992 *Accepted* 20 *November* 1992)

Summary—High-speed chromatography is coupled with numerical methods for analyzing unresolved chromatograms and applied to a process analysis of high-fructose corn syrup A column selection process is demonstrated where a minimum amount of resolution is sacrificed in order to decrease analysis time from over 5 min to 25 sec. Two data analysis methods, linear least squares regression and the sequential chromatogram ratio technique coupled with sequential suppression, are compared for their ability to quantitate the poorly resolved chromatograms Both methods fit pure component analyte chromatograms, collected on a computer, to a sample chromatogram with unknown concentrations of each analyte For a high-fructose corn syrup sample with a nominal fructose concentration of 55%, linear least squares analysis gave a fructose concentration percentage of $57\,2 \pm 0\,9\%$ The sequential chromatogram ratio algorithm gave a fructose concentration percentage of $57\,9 \pm 0\,7\%$

Liquid chromatography involves a balance between analysis time, separation ability, and complexity of instrumentation.[1] In many applications, analysis time becomes critical. High-speed chromatography[2] (where the eluent dead-time is around 10 sec) and super-speed chromatography (where eluent dead-time is less than a second) sacrifice either resolution or instrumental simplicity. Traditional attitudes toward high-speed chromatography favor the loss of the latter over the former.[3] However, in certain applications, such as process analysis and control, it is desirable to keep instrumentation as simple as possible.[4] In such cases it is advantageous to sacrifice resolution for analysis time. Davis and Giddings have shown that as the number of components in a chromatogram increase, the probability of interference between an analyte and an unknown also increases.[5,6] This situation is essentially the same as when one sacrifices resolution while reducing analysis time. For process chromatography, however, this is less a problem, as most of the components are generally known, and chromatograms, sequential in time, are fairly constant while the process is under control. Yet, any data analysis algorithm must first support accurate qualitative analysis prior to, or in conjunction with, quantitative analysis. Quantitation remains a problem, as traditional data analysis techniques such as integration or peak height do not work well with unresolved or poorly resolved chromatograms.

Two methods that are useful for the quantitation of poorly resolved chromatograms are linear least squares regression,[7,8] and the sequential chromatogram ratio (SCR) technique.[9–11] Both are computer-based methods that fit analyte standard peaks to the chromatogram to be analyzed. Linear least squares regression, the better known of the two, is limited to cases where all components of a region of interest in a chromatogram are known. The SCR technique does not have this limitation, however, and can also be used to provide qualitative information on analyte purity and identity using a statistical value obtained from a pure analyte standard.[10] The SCR technique is not able to quantify totally unresolved analytes unless coupled with sequential suppression,[11] in which the signal contribution of an interfering component is mathematically removed.

The following paper will demonstrate the application of high-speed chromatography to an analysis important to process monitoring, where resolution is forsaken in order to decrease analysis time. For this particular application it is advantageous to go from a 5 min chromatogram to less than 30 sec. The particular analysis examined will be that of high-fructose corn syrup. Special attention will be given to the choice of an appropriate column, as the packing

material used for the separation is sensitive to high pressure The high-fructose corn syrup separation is accomplished at approximately 80°C, thus special attention to efficiently heating the high-speed column is necessary to avoid radial thermal gradients that lead to severe peak broadening.[12] The adverse effects of a radial thermal gradient in the high-speed regime is avoided by using a column with a bore that is significantly more narrow than conventional column widths.[13,14] Both linear least squares regression and the SCR technique, coupled with suppression, will be applied to analyze the poorly resolved high-speed chromatogram, obtained in less than 30 sec. Results from the analysis will show that both methods give similar results in terms of quantitative precision and accuracy.

THEORY

Given a certain resolution, R_S, the minimum analysis time required, t_R, is

$$t_R = 16R_S^2\left(\frac{\alpha}{\alpha-1}\right)^2\frac{(k'_B+1)^3}{(k'_B)^2}\frac{H}{u}, \qquad (1)$$

where k'_B is the capacity factor for the latest eluting analyte, α is the selectivity factor of the two analytes, H is the plate height, and u the linear mobile phase velocity.[2] A comparison of the resolution change between two columns, labeled with subscripts 1 and 2, differing only in analysis time but not in thermodynamics, may be made using equation (1)

$$R_{S,1} = R_{S,2}\left(\frac{t_{R,1}(H/u)_2}{t_{R,2}(H/u)_1}\right)^{1/2}, \qquad (2)$$

where column 1 may correspond to a high-speed column, and column 2 to a normal-speed column. The minimum analysis time is also equal to

$$t_R = \frac{L}{u}(1+k'), \qquad (3)$$

where L is the column length and k' is the capacity factor of the last analyte.[3] For high-speed chromatography,

$$H \approx Cu \propto \frac{d_p^2 u}{D_m}, \qquad (4)$$

where d_p is the packing material diameter, and D_m is the analyte diffusion coefficient.[2] Substituting equations (3) and (4) into equation (2) leads to the relationship between resolution, column length, mobile phase velocity and particle diameter

$$R_{S,1} = R_{S,2}\left(\frac{L_1 u_2 d_{p,2}^2}{L_2 u_1 d_{p,1}^2}\right)^{1/2}. \qquad (5)$$

For chromatography using soft packing materials such as a polymer gel, pressure becomes an important limitation. The pressure drop ΔP across a packed column is given by

$$\Delta P = \frac{\phi\eta u L}{d_p^2}, \qquad (6)$$

where u is the mobile phase velocity, ϕ is a structural parameter dependent on packing material geometry, and η the viscosity of the mobile phase.[2] For the sake of discussion, one can set the constraint that the pressure drop must be kept constant for both separations

$$1 = \frac{u_1 L_1}{u_2 L_2}\left(\frac{d_{p,2}}{d_{p,1}}\right)^2. \qquad (7)$$

This constraint keeps the instrumental performance requirements constant in terms of pump reliability. If one of the parameters is adjusted, then at least one other parameter must be changed to maintain the identity of equation (7). Thus, equation (5) must be worked within the context of equations (3) and (7), and in terms of analysis time, equation (5) becomes

$$\frac{R_{S,1}}{R_{S,2}} = \left(\frac{t_{R,1}d_{p,2}^2}{t_{R,2}d_{p,1}^2}\right)^{1/2}. \qquad (8)$$

Under the constraint of equation (7), speeding up an analysis by changing particle size is not the best method. If one increases particle size, then either the column length must be lengthened (which actually increases analysis time), or the mobile phase linear velocity must be increased. However, the velocity would have to be changed by a factor equal to the square of the particle size change, leading to an undue loss of resolution. By decreasing particle size, either the column length would have to be shortened, or the mobile phase velocity decreased, which again would increase analysis time. Although decreasing column length by an amount necessary to preserve the identity of equation (7) decreases the analysis time by a factor equal to the square of the particle size change (equation 8), resolution is not sacrificed (equation 5). Moreover, extremely short columns have limited commercial availability.

Decreasing column length and speeding up the mobile phase linear velocity is the most acceptable method of decreasing analysis time

while sacrificing a minimum of the resolution and keeping pressure drop constant. By decreasing column length by a factor of M, the mobile phase linear velocity may be increased M times (equation 7). This leads to a decrease in resolution equal to a factor of M (equation 5) and a decrease in analysis time equal to a factor of M^2 (equation 8).

The above discussion assumes that an unresolved chromatogram can be quantified. Two computer analysis methods that can be used to analyze unresolved chromatograms are linear least squares regression,[7,8] and the sequential chromatogram ratio technique.[9-11] Both methods determine the best fit of a calibration standard to an analysis. For least squares analysis of N analytes, analyte concentrations are given as a $1 \times N$ row vector $\mathbf{x}$, computed as follows

$$\mathbf{x} = \mathbf{y}\beta^T(\beta\beta^T)^{-1}, \tag{9}$$

where $\mathbf{y}$ is the response vector (expressed as a row) and β is a calibration matrix predicted by

$$\beta = X^{-1}Y, \tag{10}$$

where Y is the calibration set containing N rows for N pure component standards, and X is an $N \times N$ diagonal matrix containing the concentrations of the pure component standards.

Linear least squares regression works well when all the components of a chromatogram are known. However, if a component in a chromatogram is an unknown, or a standard for that component is not available, then this method is not usable. A technique that can analyze unresolved chromatograms even when unknowns are present is the sequential chromatogram ratio (SCR) technique. The SCR technique involves the point-by-point ratio of two chromatograms differing only in the relative concentrations of one or more analytes.[9] For a linear detector, the sequential ratio of analyte j is computed by

$$R(t) = \frac{U(t)}{S(t)} = \frac{C_{j,U}}{C_{j,S}}, \tag{11}$$

where $U(t)$ and $S(t)$ are two sequential chromatograms expressed as data vectors, recorded under the same conditions, and $C_{j,U}$ and $C_{j,S}$ are the injected concentrations of analyte j for each respective chromatogram. A plot of the sequential ratiogram will be flat where there exists a pure elution region for analyte j. If the injected concentration of analyte j is known for either $U(t)$ or $S(t)$, the concentration of j in the other chromatogram may be determined from the flat ratiogram. The sequential chromatogram ratio may also be used to provide qualitative information on peak purity, or for analyte identification. The ratio of the chromatogram with a pure component standard chromatogram of the analyte (or suspected analyte) in question is examined. The presence of a flat ratiogram, whose boundaries are determined by comparison of a flatness statistic S_w, obtained from the ratiogram in question, to S_w obtained from replicate standard runs, indicates a pure elution region of an analyte common to both the chromatogram and the standard.[10] The sequential chromatogram ratio may be used to determine concentration changes in chromatograms with resolution as small as 0.1.[9] To quantitate totally unresolved analytes, or to improve the quantification of poorly resolved analytes, it is possible to algebraically remove an interfering component using sequential suppression.[11] Sequential suppression, like the SCR technique, uses two sequential chromatograms, each containing the component to be suppressed. All that needs to be known is the concentration change of that analyte between the two chromatograms. Sequential suppression creates a third chromatogram, $S_{supp}(t)$, lacking the signal contribution of the suppressed component

$$S_{supp}(t) = S(t) - kU(t). \tag{12}$$

The suppression constant k is the ratio of concentrations of the component to be suppressed, obtained from equation (11). If $U(t)$ is a pure component standard, then the signal contributions of all other analytes are unaffected.

EXPERIMENTAL

The mobile phase pump consisted of an ISCO LC-2600 syringe pump (ISCO, Inc., Lincoln, Nebraska) with a volumetric flow rate of 0.75 ml/min for the high-speed analysis, and 0.66 ml/min for the normal-speed analysis. Note that it is not the volumetric flowrate, specifically, that defines the analysis time regime, but rather the linear flow velocity and column dead time.[2] The detector was a Bio-Rad refractive index monitor (Bio-Rad Laboratories, Richmond, CA) with a 10 μl flow cell. Sample injection was accomplished with a Rheodyne 9125 manual injection valve (Rheodyne Inc., Cotati, CA) with a 5 μl sample loop. For the normal-speed analysis, a 100×7.8 mm, 9 μm particle diameter polystyrene-divinyl benzene sulfonated ion

exclusion column in the Pb^{2+} form (Bio-Rad Laboratories, Richmond, CA) was used. The high-speed column was a 35 x 3.2 mm, 10 μm particle diameter polystyrene–divinyl benzene sulfonated ion exclusion column in the Ca^{2+} form (Alltech Associates, Inc., Deerfield, IL). Both columns were heated to 78°C in a hot water bath.

The mobile phase was 100% HPLC-grade water (J.T. Baker Inc., Phillipsburg, NJ). The fructose (Alfa Products, Danvers, MA), dextrose (J.T. Baker, Phillipsburg, NJ), and maltose (Aldritch Co., Inc., Milwaukee, WI) standards were at concentrations of 0.01, 0.0083 and 0.005 g/ml, respectively. Two high-fructose corn syrup samples, one at 55% nominal fructose concentration, and the other at 42% nominal fructose concentration, were diluted 500 times in water.

Data collection was accomplished through the use of an IBM XT personal computer (Boca Raton, FL), equipped with a DASH-16 data acquisition board (Metrobyte Corp., Taunton, MA). Data collection was performed at the rate of 250 points per sec which were box-car averaged down to 50 points per sec. The data were processed using Matlab (The Mathworks, Inc., South Natick, MA). A variance-weighted ratio algorithm was used to calculate all ratios.[9]

Each corn syrup sample was run five times All analyte standards were run four times, twice before the corn syrup samples, and twice after

RESULTS AND DISCUSSION

Before choosing a column for high-speed chromatography it is necessary to examine a conventional analysis, and compare it to the goals of the high-speed separation. Figure 1 is of a chromatogram of high-fructose corn syrup, with a total analysis time of 5.5 min. A reasonable goal is to speed up the analysis to under 30 sec, a 12-fold decrease in analysis time. Although pressure drop across the column was an important consideration, the constraint of equation (7) was not entirely necessary, but should be kept in mind, as the pressure drop of the slow separation (600 psi) was well below the recommended maximum of 1500 psi. Assuming constant volumetric flowrate, the mobile phase linear velocity was increased by a factor of 5.9 by going to a 3.2 mm i.d. column, instead of the 7.8 mm i.d. column used for the slow separation. Column diameter was decreased in this manner in order to lessen the effects of any radial thermal gradients in the heated column at the higher linear flow velocity, and thus maintain the separation efficiency.[12] Microbore columns (1 mm i.d.) easily eliminate any radial thermal gradient,[13,14] but any column with less than 3.2 mm i.d. would have lead to significant extra-column band broadening from the detector available for analyte peaks less than 10 times the detector flow cell volume. The separation efficiency achieved with the high-speed (3.2 mm i.d.) column indicated that radial thermal gradients were not significant with this column at 78°C and a linear flow velocity of 3 mm/sec. To decrease analysis time further, the column length was decreased from 10 to 3.5 cm. Thus, the column dead time was about 11 sec, which was in the high-speed regime.[2] Theoretically, at constant volumetric flowrate, all the changes in column diameter and length result in the analysis time decreasing by a factor of 17.0 (equation 3), with an increase in pressure by 2.1 times (equation 6). Also, the resolution should be $\sqrt{17.0}$ times worse, or a factor of 4.1.

Figure 2 shows two chromatograms of high-fructose corn syrup using the high-speed column, nominally at 42% fructose (HF-42)

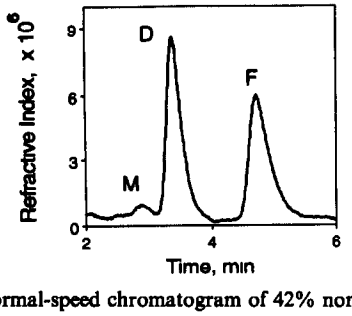

Fig. 1 Normal-speed chromatogram of 42% nominal fructose concentration high-fructose corn syrup M—maltose, D—dextrose, F—fructose. For chromatographic conditions, see text.

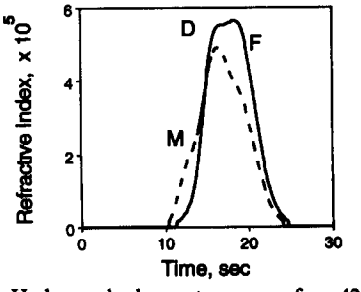

Fig. 2. High-speed chromatograms of a 42% nominal fructose concentration high-fructose corn syrup (dashed line) labeled HF-42 in Table 1 and text, and a 55% nominal fructose high-fructose corn syrup (solid line) labeled HF-55 in Table 1 and text: M—maltose, D—dextrose, F—fructose. For chromatographic conditions, see text.

and 55% fructose (HF-55). The experimental parameters, such as pressure and analysis time, are within acceptable bounds of the values predicted in the above discussion of going from a normal-speed separation to a high-speed separation. Actual agreement was not expected, as the above discussion, using equations (3), (5), (6) and (8), assume that the thermodynamics between the separations remains constant. This was not precisely the case, as the fast column packing material differs slightly in particle diameter and counterion (as reported in the experimental section). Also, by using a smaller diameter column, the thermal gradients present in the heated column were minimized. Total analysis time has been decreased by a factor of over 13, relative to Fig. 1, to under 25 sec. Resolution of the three sugars in the high-speed chromatograms was determined from injections of individual standards, shown in Fig. 3. Resolution between the fructose and the dextrose has decreased from 2.2 in the normal-speed chromatogram to 0.8 in the high-speed chromatogram; resolution between dextrose and maltose has decreased from 1.0 to 0.3. Finally, the pressure drop across the column has been increased to 1100 psi in the high-speed runs, from 600 psi in the normal speed run.

As all components of the sample mixture were known, it was possible to apply least squares regression (equations 9 and 10) to quantitate the poorly resolved chromatograms, using the analyte standards in Fig. 3. The results, shown in Table 1, agree well the nominal percentages of each sugar one might expect in a corn syrup sample, especially the fructose percentage. Precision was also good, with the standard deviation being better than 2% on average for fructose, the primary analyte of interest. By using an automated injection system, precision could be further improved to below 1%.

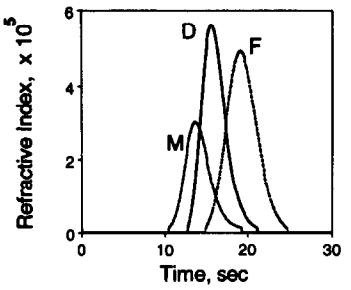

Fig 3 High-speed pure-component chromatograms for the major components of high-fructose corn syrup· M—maltose, D—dextrose, F—fructose For chromatographic conditions, see text

The SCR technique works in a similar fashion to linear least squares regression, but has the added advantage that not all of the components in a chromatogram need be known (high-fructose corn syrup can be expected to contain up to 1.5% unknown higher saccharides).[9-11] Figure 4 is a ratiogram between the HF-55 corn syrup sample and a pure fructose standard (Fig. 3), obtained from applying equation (11). The ratiogram is flat from 20 to 23 sec, indicating a pure elution region for fructose. This constitutes the qualitative analysis of fructose, and can be substantiated by applying a flatness statistic comparison of apparent pure elution regions between replicate standards and the data in Fig. 4.[10] From this flat region the ratio of concentrations between the two chromatograms may be calculated. Below 20 sec, the ratiogram rapidly increases due to a mixed elution region of fructose and dextrose. This mixed elution region in no way interferes with the analysis of fructose. Even if an unknown component co-eluted with the dextrose or maltose, it would still be possible to calculate the concentration of fructose, as a flat ratiogram would still exist. Maltose may also be analyzed by repeating the above procedure, using a pure maltose standard of known concentration.

Table 1 Quantitative comparison of the determination of the primary components in high-fructose corn syrup by linear least squares regression and the SCR technique coupled with suppression

Sample label	Nominal fructose (%)	Method of analysis*	Maltose (%)	Dextrose (%)	Fructose (%)
HF-42	42	LLSR	18.5 ± 0.2	43.4 ± 0.5	38.1 ± 0.5
		SCR	18.1 ± 0.4	42.8 ± 1.2	39.0 ± 1.2
HF-55	55	LLSR	1.9 ± 0.5	40.7 ± 0.7	57.2 ± 0.9
		SCR	1.4 ± 0.6	40.3 ± 0.4	57.9 ± 0.7

All values are the average of five runs, and are listed ±1 S.D.

*LLSR—Linear least squares regression. SCR—Sequential chromatogram ratio technique coupled with sequential suppression

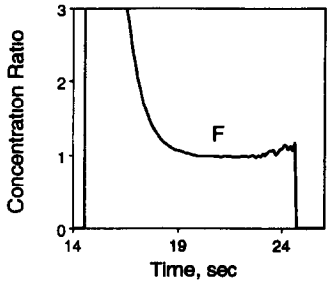

Fig. 4 Ratio of injected concentrations, obtained from applying equation (11) to the chromatograms of the 55% nominal concentration high-fructose corn syrup (Fig. 2) and the pure fructose standard chromatogram (Fig 3) The flat concentration ratio for fructose, F, is used for positive identification and quantification

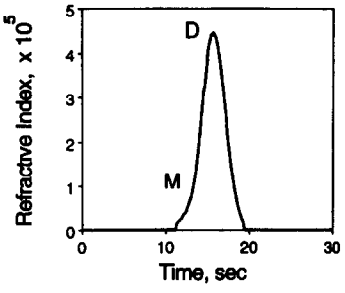

Fig 5 High-speed chromatogram of 55% nominal concentration high-fructose corn syrup after fructose has been mathematically suppressed using equation (12) and the pure component fructose chromatogram (Fig 3)

However, it is not possible to quantitate dextrose without suppression of maltose or fructose, as no pure elution region exists for this sugar as is clear from Fig. 3. One must first mathematically remove the signal contribution of either maltose or fructose, using sequential suppression. Figure 5 is the same chromatogram of the above high-fructose corn syrup (HF-55), only with the signal contribution of fructose removed, using equation (12). The suppression constant, k, was calculated from the ratiogram in Fig. 4. There now exists a pure elution region for dextrose, with which the SCR technique was applied. The results of the analysis using the SCR technique may be compared with the results of the analysis using least squares in Table 1. Again, precision could be improved with the use of an automated injection system to better than 1%. The results of the two methods are comparable with each other.

By using an appropriate data analysis method, it is possible to sacrifice resolution in order to speed up an analysis, and not give up significant accuracy or precision of the results. Linear least squares analysis is a simple algorithm which requires that all components of a chromatogram be known. The sequential chromatogram ratio technique does not have this limitation, and provides results comparable with classical least squares.

Acknowledgement—The authors would like to thank Michael J Blackburn and Cargill, Inc for providing a refractive index detector, the normal-speed column, and the high-fructose corn syrup samples

SPECTROPHOTOMETRIC DETERMINATION OF SELENIUM WITH 6-AMINO-1-NAPHTHOL-3-SULPHONIC ACID (J-ACID) AND ITS APPLICATION IN TRACE ANALYSIS

K N RAMACHANDRAN, R. KAVEESHWAR and V. K. GUPTA*
School of Studies in Chemistry, Pt Ravishankar Shukla University, Raipur, M P, 492 010, India

(*Received* 9 *September* 1992 *Revised* 18 *November* 1992 *Accepted* 18 *November* 1992)

Summary—A selective procedure for spectrophotometric determination of selenium with 6-amino-1-naphthol-3-sulphonic acid (J-acid) is described In acidic conditions selenium forms a yellow complex with J-acid which has an absorption maximum at 392 nm The molar absorptivity is $1\,48 \times 10^4$ 1 $mol^{-1}cm^{-1}$ Beer's law is obeyed for selenium in the range of 0 08–0 8 mg/l The method has been applied to the determination of trace amounts of selenium in water, polluted water, plant material and steel plant dust The proposed method is sensitive, rapid, simple and accurate

Selenium is one of the widely distributed non-metallic elements with considerable significance.[1,2] The maximum tolerance limit for human beings is 0.1 mg/m^3 in air and 4 mg/l for water.[2] Several methods based on different techniques have been reported for the determination of selenium.[3–7] Of the numerous methods reported for spectrophotometric determination of selenium, only a few of them have sensitivity, selectivity and simplicity. The most popular reagents reported include 3,3′-diaminobenzidine,[8] dithiozone,[9] o-phenylenediamine,[10] and chromotropic acid.[11] Methods using o-diamines require long reaction times, acidity maintenance, *etc.* while most of the other reported reagents are non-selective. Here, 6-amino-1-naphthol-3-sulphonic acid (J-acid) is proposed as a new reagent for photometric determination of selenium(IV). The sensitivity for the determination of selenium (IV) is superior to that of other reported reagents. The conditions of the formation of the Se (IV)–J-acid complex were studied in detail. In the pH range of 1–2.5, J-acid reacts instantaneously with Se (IV) to form a yellow 2.1 complex.

The Se–J-acid complex exhibits maximum absorption at 392 nm with a molar absorptivity of $1\,48\ (\pm 0.01) \times 10^4$ 1 $mol^{-1}cm^{-1}$. Beer's law is valid over the concentration range of 0.08–0.8 mg/l of Se (IV). The colour reaction is free from interference from more than 25 ions investigated. The proposed method has been applied to the spectrophotometric determination of trace amounts of Se (IV) in environmental samples and offers advantages of simplicity, sensitivity, rapidity and stability of the coloured solution without heating.

EXPERIMENTAL

Apparatus

Absorption spectra and the absorbance were recorded using a Varian DMS 100 S UV–visible spectrophotometer, with matched silica cells. A Systronics pH meter model No. 331 was used to measure the pH. Standard glassware was used for volumetric measurements.

Reagents

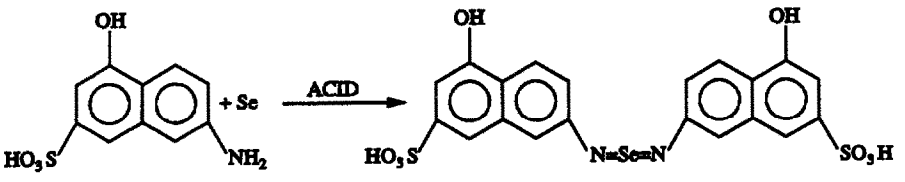
All chemicals used were of analytical reagent grade unless otherwise stated. Deionized double distilled water was used.

Standard selenium solution (100 mg/l): dissolve 100 mg of elemental selenium in 5 ml concentrated nitric acid by gently heating and evaporate to dryness and dilute with distilled water to 100 ml. Dilute further to obtain a 1 mg/l working standard solution.

J-acid (Wilson): dissolve 500 mg of 6-amino-1-naphthol-3-sulphonic acid (J-acid) in 100 ml of concentrated sulphuric acid, and store in an amber coloured bottle.

Sulphuric acid: 18M.

*Author for correspondence



J-ACID J-ACID-Se-COMPLEX (λmax, 392 nm)

Scheme 1

Acid mixture: mix 80 ml of concentrated nitric acid with 20 ml of 60% perchloric acid.

EDTA: 0.05M.

3,3′-Diaminobenzidine hydrochloride: dissolve 500 mg of the reagent in 100 ml water.

Hydroxylammonium chloride solution: dissolve 2.5 g of the reagent in 100 ml of water.

Sodium hydroxide: dissolve 10 g of the reagent in 100 ml of water.

Potassium bromide, bromine water, saturated solution of bromine in distilled water.

Recommended procedures

Procedure for the study of the colour reaction of selenium. Take a test solution containing not more than 20 μg of selenium in a 25 ml calibrated flask, add 2 ml of J-acid, mix well and successively dilute to the mark with sulphuric acid. Measure the absorbance at 392 nm against a reagent blank.

Procedure for the determination of selenium in water and polluted river water. Take an aliquot of test solution in a distillation flask, add 5 ml sodium hydroxide solution and distill the mixture under vacuum to concentrate the selenium content. Discard the distillate and then add 0.7 g potassium bromide and 10 ml sulphuric acid treated with 8–10 drops of saturated bromine water to the concentrate. Connect the condenser of the distillation flask to a receiver flask containing 10 ml of 2.5% hydroxylammonium chloride solution to collect the distillate containing $SeBr_4$. Now distil the sample under vacuum until white copious fumes of SO_3 vapours are evolved. Make the distillate to a fixed volume (25 ml). Take 10 ml of it and then follow the recommended procedure described above for determination of selenium.

Procedure for the determination of selenium in plant materials. Take 5 g of plant material in a 100 ml Kjeldahl flask, add 10 ml nitric acid and heat for 20 min. Then add 0.5 ml perchloric acid and heat for another 10 min or until the evolution of ample fumes of perchloric acid, whichever is earlier. Add 10 ml water to the cooled residue and heat for 10 min. Add 5 ml of HCl and heat for 10 min. Then dilute the contents to 50 ml after adding 10 ml EDTA solution and then follow the above recommended procedure for determination of selenium.

Procedure for determination of selenium in steel plant dust. Place the filters containing dust from the steel plant in 100 ml beaker, add 10 ml acid mixture for digestion and evaporate to 2 ml. Cool the contents and boil with 10 ml HCl for 10 min. Again cool the contents and dilute to 25 ml with water. Analyse 5 ml of the solution for selenium as recommended above.

*Tolerance limit may vary the results by $\pm$2%

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the Se (IV) J–acid complex is shown in Fig. 1. The absorption maximum of the complex is at 392 nm.

Adherence to Beer's law and sensitivity

The absorbance is a linear function of selenium concentration in the range of 0.08–0.8 mg/l of solution. The apparent molar absorptivity is 1.48×10^4 l $mol^{-1}cm^{-1}$. The Sandell sensitivity is 0.005 $\mu g/cm^2$

Reproducibility

The relative standard deviation of the sample containing 0.4 mg/l of selenium for seven replicate analyses is $\pm$ 2.26%. The percentage recovery of spiked samples is 96–98%.

Conditions for the colour development

The absorbance of the complex depends on the pH of solution as shown in Fig. 2. The maximum and constant absorbance was attained in the pH range 1–2.5.

Under the conditions employed the volumes of 0.5% J-acid required to obtain constant absorbance for 0.8 mg/l selenium was 2 ml. Hence 2 ml of J-acid solution was introduced.

The colour reaction was instantaneous and requires no heating. In the solution of pH 1–2 5 the absorbance reached its maximum immediately and remained stable for at least 24 h Normal variations in temperature have no effect on the complex.

Composition of the complex

The composition of the complex was determined by the continuous variation method and mole ratio method. The ratio of Se–J-acid was 1:2 in the complex by both methods (Fig. 3).

Effect of foreign ions

The effect of various ions on the determination of selenium was studied and their tolerance limits are shown in Table 1 It was found

Table 2. Application of the method

6-Amino-1-naphthol-3-sulphonic acid (J-acid) (Present method)	Aqueous 1–2 5	392	0.08–0 8	Te^{4+}, V^{5+}, Fe^{3+}, Cu^{2+}, do not interfere

that tellurium^{4+}, manganese^{2+}, vanadium^{5+}, iron^{2+}, iron^{3+} and copper^{2+}, which interfere strongly with most of the other reported methods did not interfere. Thus, the selectivity and sensitivity of the method is appreciable and can be applied to the determination of trace amounts of selenium.

APPLICATION

The method has been applied for the determination of selenium in several samples of water, polluted river water, plant materials and steel plant dust. The results obtained are present in Table 2 and are in agreement with those obtained by the 3,3′-diaminobenzidine method.

Comparison with other reagents

J-acid is proposed as one of the most sensitive reagents available for the spectrophotometric determination of selenium. The proposed method is simple, rapid and accurate as compared to other published methods. The sensitivities of various reagents are listed in Table 3 for comparison.

CONVECTIVE TRANSPORT IN DIFFUSIVE SAMPLERS

DWIGHT W. UNDERHILL
School of Public Health, University of South Carolina, Columbia, SC 29208, U S A

(*Received* 16 *June* 1992 *Revised* 18 *November* 1992 *Accepted* 18 *November* 1992)

Summary—Convective transport in diffusive samplers was determined by the loss of a dilute dye solution from these samplers while held in a water bath The water flow in the bath was adjusted to give the same Reynolds number had the diffusive sampler been exposed to an airborne analyte at a predetermined flow velocity By numerical analysis, estimates were made of the degree of interference of convection on sampler performance. The results indicate an enormous difference between commercial diffusive samplers with respect to the effect of convection on the transport of analyte into the sampler

Many diffusive samplers are seriously affected by ambient air currents, and experiments in which the uptake of analyte is determined at different air flow velocities are an important part of a proposed procedure to "validate" the performance of diffusive samplers.[1–5] However, because diffusive effects predominate in these samplers, determining the added effect of convection has a high experimental error. This difficulty in seeing the convective transport against a much larger background of diffusive transport could be resolved if the effect of diffusion could be reduced to where the major mode of mass transfer is convection.

By holding these samplers in a water bath, the diffusion coefficient for the analyte (in this study a dilute solution of methylene blue, a dye) is reduced to a negligible level, and the mass transport by convection can be determined independently of molecular diffusive effects. The suppression of molecular diffusion by this procedure is quite effective because the rate of diffusion of dyes in water is about 1000 times lower than that of organic analytes in air

Water bath models have been used before in studies of the airborne mass transfer of contaminants, for example to simulate the performance of an impinger, to model the transport by thermal currents of toxic matter during a fire, or to define operational parameters for local ventilation systems to exhaust ethylene oxide.[6–8] In these prior examples the major component of mass transport is convection, so that the use of a water bath model for this study, where the major component of mass transfer is diffusion, may appear novel.

THEORY

The water flow was adjusted to give the same Reynolds number had the diffusive sampler been exposed to air at a predetermined velocity. This maintains the same flow patterns around and *through* the diffusive sampler that would be observed in an atmospheric environment at the same Reynolds number. The Reynolds number (Re) is defined as:

$$Re = dV/v \tag{1}$$

where:

d = characteristic linear dimension of the flow channel in centimeters,
V = fluid velocity in centimeters per second,
v = kinematic viscosity of the flowing fluid.

Listed below are the necessary steps in applying data from a water bath experiment to the diffusive sampling of airborne contaminants.

Step 1: determining the appropriate scaling factors

At 25°C, the kinematic viscosities of air and water, v_a and v_w, are 0.155 and 0.0084 cm^2/sec, respectively. To maintain the same Reynolds number in water as in air (and hence the same flow patterns), the ratio of the flow of water to the flow of air should be the ratio of these kinematic viscosities, which is a factor of 0.0542.

Because the actual diffusive samplers, and not models, are used in these experiments, there is no need to provide scaling factors for any dimensional changes.

Step 2: determining the "exposure time"

In order to obtain the same flow of water as of air, the sampler must be in the water bath longer than in a corresponding air chamber. The ratio of the two exposure times for an equivalent amount of flow is the ratio of the kinematic viscosities, v_a/v_w, which is approximately a factor of 18. Thus to estimate the effect of convection on the sampling of an analyte from air at the same Reynolds number and for the same total flow, the time durations for the measurements in the water bath should be divided by a factor of 18.

For these results to be valid, the duration of the water bath test should be either until nearly all the dye is lost from the sampler, or for a time period significantly longer than $(v_a/v_w)L^2/D_m$, where L is the width of the air gap, and D_m is the diffusion coefficient of the analyte in air. The significance of the grouping, L^2/D_m, is that it describes the mean time required for an analyte to pass across the air gap.

Step 3: determining the eddy diffusion

After the rate of loss of an aqueous solution of methylene blue by convection from the sampler was measured, these results were used to quantify the eddy diffusion inside the diffusive sampler. To do this, the diffusive sampler was treated as consisting of a series of strips, with the mass transfer across each strip calculated using the Crank–Nicolson finite difference equation:[9]

$$\frac{C_{i,j+1}-C_{i,j}}{\delta T}=\frac{D_e}{2\delta X^2}\left\{\frac{C_{i+1,j}-2C_{i,j}+C_{i-1,j}+C_{i+1,j}}{\delta X^2}+C_{i+1,j+1}\frac{-2C_{i,j+1}+C_{i-1,j+1}}{\delta X^2}\right\} \quad (2)$$

where:

$C_{(i,j)}$ = concentration in the ith strip at the jth time in grams per cubic centimeter,
δT = time increment in seconds,
δX = width of strip in centimeters,
D_e = eddy diffusion coefficient in square centimeters per second.

It is assumed that the concentrations at the jth time are known, and the unknowns are the concentrations at the next time row, $j+1$. If this model assumes n strips, then there are n equations with $n+2$ unknowns, which can be reduced to n unknowns once the boundary conditions are defined. The two boundary equations appropriate for this model are:

$$C_{i=1}=0 \text{ (negligible dye concentration at opening)} \quad (3)$$

and

$$C_{i=n-1}=C_{i=n} \text{ (no diffusion out of back of sampler).} \quad (4)$$

Further, it is assumed that the sampler is initially evenly filled with dye, so that at time $t=0$ (*i.e.* $j=0$) the initial concentration of dye is:

$$C_{j=0}=K. \quad (5)$$

Combining equations (2)–(5) leads to a series of equations that comprise a tridiagonal matrix. A well-known numerical method leads to the solution of such matrices in a number of arithmetic operations proportional to "n".[10]

The eddy diffusion will be strongest at the exposed surface and drop off rapidly in intensity with respect to the depth in the sampler. Here it was assumed that the eddy diffusion obeyed a power function of the form,

$$D_e=aX^b \quad (6)$$

where:

X = distance from the back of the diffusive sampler

allowing us to find by trial and error the coefficients "a" and "b" for the eddy diffusion coefficient, D_e, that best give the measured outflow of dye as a function of time.

Step 4: calculating the effect of eddy diffusion on uptake

Next, the mass transport of airborne analytes by the combined effects of convection and molecular diffusion can be determined by adding the molecular diffusion coefficient to the eddy diffusion coefficient, *i.e.*

$$D=D_m+D_e \quad (7)$$

where:

D = combined diffusion coefficient,
D_m = molecular diffusion coefficient and
D_e = eddy diffusion coefficient, all in square centimeters per second

This is the same procedure used in the van Deemter equation for mass transport in a gas chromatography column.[11]

Assuming that the eddy diffusion coefficient is not constant across the sampler, then the mean diffusion coefficient across the air gap, if calculated using equation (9.15) of Crank, will be.[9]

$$D_{ave} = L\left(\int_0^L \frac{dX}{D}\right)^{-1}. \quad (8)$$

If the average diffusion coefficient, D_{ave}, differs appreciably from the molecular diffusion coefficient, D_m, then the sampling rate has been affected by the eddy diffusion, and the percent increase in the sampling rate brought about by eddy diffusion is given by the factor, $100(D_{ave}/D_m - 1)$.

Table 1 Physical dimensions of examined diffusive samplers

1	The *3M Brand Air Sampling Monitor*, #3550 is a badge type sampler in which the diffusion barrier is 3 *cm* in diameter, and 0 9 *cm* deep A thin continuous membrane is placed at the end of the diffusion barrier to reduce the effect of external convection currents.[16]
2	The *Formaldehyde Monitor*, Advanced Chemical Sensors Co is also a badge type sampler The diffusion barrier is 2 4 *cm* in diameter, and 0 5 *cm* deep As with the 3M diffusive sampler, a thin continuous membrane is placed at the end of the diffusion barrier to reduce the effects of external convection currents [15]
3	The *Gasbadge Organic Vapor Dosimeter* is a badge type sampler, having a diffusion passage 4 8 *cm* wide, 3 7 *cm* high, and 1 3 *cm* deep The convection barrier is a course ($\approx$25 openings per cm^2) light plastic screen [14]
4	The *HOMEcheck Mobile Home Odor (Formaldehyde) Test Kit* is a glass cylinder 7 *cm* high At its base the outside diameter is 2 *cm* and the inside diameter is 1 8 *cm* In use, solution is to be placed in it Its fill line is 2 *cm* over the base It has a screw top $\approx$0 5 *cm* in height The inside diameter at the screw top is 1 5 *cm* [20]
5	The *Palmes' Tube* used in these experiments was fashioned from an aluminum cylinder 7 *cm* high, closed at one end, and having an outside diameter of 1 4 *cm* and an inside diameter of 0 9 *cm* [19]
6	The *PF-1 Formaldehyde Monitor*, distributed by Air Quality Research, Inc , Berkeley, CA, is a glass cylinder 9 3 *cm* deep (measured internally), having an outside diameter of 2 5 *cm*, an internal diameter of 2 3 *cm*, and is closed at one end [21]
7	The *Pro-Tek Air Monitoring Badge* [12] is a badge-shaped diffusive sampler that is unusual in that both sides of the sampler, after the covers have been removed, can participate in the sampling process The diffusion space on either side is 0 8 *cm* wide, 6 5 *cm* in length, and 0.3 *cm* deep The actual diffusion takes place through a set of small holes ($\approx$15 cm^{-2}) placed in the plastic cover

EXPERIMENTAL RESULTS

Samplers having a high degree of flow induced convection

Many commercial diffusive samplers are shaped like film badges and are conveniently used to assess worker exposure by being attached to the worker's collar during his or her workday. Because in such samplers, the wide, thin region across which mass transport takes place is very vulnerable to the sampling rate being altered by convection, these diffusive samplers must be furnished with some means to reduce convection. The first two samplers tested, the Pro-Tek Air Monitoring Badge and the Gasbadge Organic Vapor Dosimeter, have a solid surface permeated with small holes, and a porous plastic screen, respectively, placed at the exterior of the sampler to reduce convective flow.[12-14] Figure 1 gives drawings of representative diffusive samplers. Additional details of the diffusive samplers used in these tests are given in Table 1 In our tests these diffusive samplers were filled with a dilute solution of methylene blue and placed in a water bath, 11.5 cm wide, 13 cm high, and 30 cm long (see Fig. 2). At a flow rate of 0 11 cm/sec, the loss of methylene blue was so rapid that its loss could not be quantified Even stopping the water flow, placing the closed sampler into the water bath, carefully opening the sampler and restarting the water flow, gave irreproducible results In the few seconds required to establish an even water flow in the recirculating water bath, much of the dye was lost from the samplers

Our inability, even with care, to place these diffusive samplers into a water bath and starting the flow of water without their losing a sizable fraction of the methylene blue dye contained within, indicates (even though no numerical

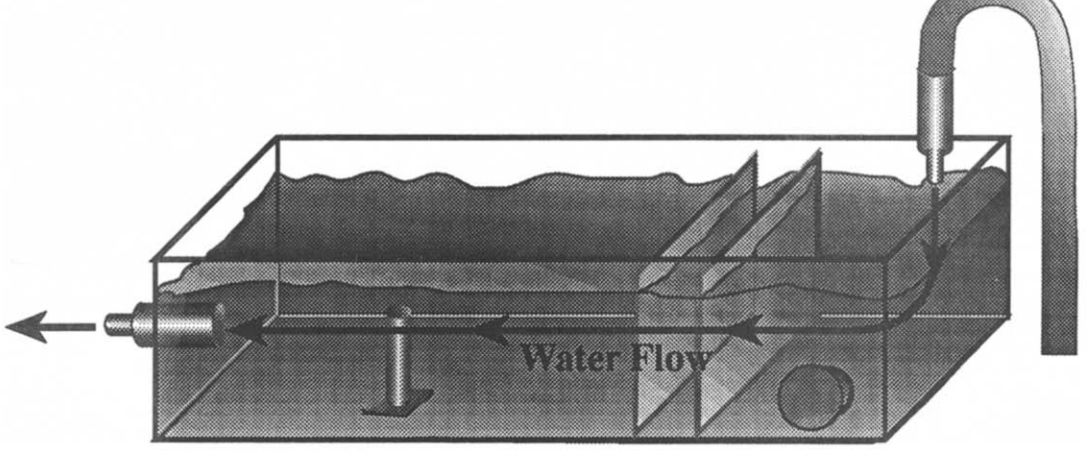

Fig 2 The test system

values could be obtained) a strong effect of convection on their performance.

In the absence of numerical data, the numerical analysis developed above could not be applied to these samplers.

Samplers having a low degree of flow induced convection

The other two "film badge" type of diffusive samplers, the Formaldehyde Monitor, Advanced Chemical Sensors Co., and the 3M Brand Air Sampling Monitor, #3550, both contain a thin plastic membrane across the exterior of the diffusive sampler.[15,16] For both samplers, under the same conditions as described above, less than 1% of the methylene blue was lost from the sampler over a 24 hr test period. In these diffusive samplers, the convective flow from the sampler was reduced by such an extent that it could not be conveniently measured. In these latter two samplers, any measurable convective effects should only be in the external air film that is found across any impervious surface placed in an air stream.

Again, no numerical values are presented for this case, but this time because the mass transfer of the dye (and presumably all convective effects as well) was blocked by a continuous membrane placed between the air gap and the ambient environment. Nevertheless this is useful knowledge, for if the external film does control any flow induced effects, then the analysis of flow effects on mass transfer is reduced to calculations involving the Schmidt and Reynolds numbers that are familiar to chemical engineers and that have already been applied successfully to the effect of the air film on the performance of diffusive samplers.[17,18]

Samplers having a moderate degree of flow induced convection

A large family of diffusive samplers are patterned after the Palmes' tube, and geometrically are essentially long tubes with an adsorbent or reactive material placed at the closed end of the tube.[19] Very often there is no wind shield placed over the open end of the sampler, for the very length of the tube is thought to provide sufficient protection against an unacceptable amount of convection.

In the tests that are described next, three of these samplers, *i.e.* a HOMEcheck Mobile Home Odor (Formaldehyde) Test Kit, PF-1 Formaldehyde Monitor, and a Palmes' tube were filled with a dilute solution of methylene blue and placed in the water bath.[20] Table 2 gives the fraction of a dilute solution of methylene blue remaining in the samplers after they were opened in the water bath, at various times and water flow velocities.

In carrying through these tests it is essential that the solution inside the sampler be at the same temperature as the water in the water bath, or else flotation effects confound the convection effects. For if the solution in the samplers were only a few degrees centrigrade warmer than the water in the bath, then a chimney effect resulted in rapid loss of solution and the subsequent results were irreproducible. To eliminate thermal effects, these tube-shaped samplers were allowed to thermally equilibrate in the bath for an hour with rubber stoppers placed over their openings, before the stoppers were lifted away and the test begun.

Note from Table 2 that the higher the flow velocity, the more rapid the loss of dye solution by convection. Note also that the wider the diameter of the sampler, the more rapid the loss. One characteristic of the Palmes' tube was a very rapid loss of a small fraction ($\approx$20%) of the dye, followed by a period of comparatively small loss.

As described earlier, these data can be analysed to give estimates of the effect of eddy

Table 2 Fraction of dye retained in diffusive samplers after being opened in water bath

Mean water velocity	Elution time, (*hr*)	Palmes' tube sampler	HOME check sampler	PF-1 Formaldehyde Monitor
Slow	1	0 699	0 890	0 858
flow·	3	0 676	0 717	0 720
0 070 *cm/sec*	10	0 633	0 692	0 670
	24	0 607	0.633	0 530
Medium	1	0 713	0 824	0 700
flow	3	0 697	0 723	0 514
0 23 *cm/sec*	10	0 681	0 497	0 133
	24	0 554	0 280	0 033
Fast	0 25	0 773	0 811	0 353
flow	1	0 753	0 747	0 273
0 70 *cm/sec*	3	0.607	0 649	0 047
	10	0 503	0 090	0 007
	24	0 444	0 005	0.000

These water flow velocities of 0 07, 0.23, and 0 7 *cm/sec* match the Reynolds number of air flow velocities of 1 26, 4 14, and 12 6 *cm/sec*, respectively As Cassinelli *et al* suggest "validating" diffusive samplers at air flow velocities of 10 and 150 *cm/sec*, these samplers were tested at the low range of possible air flow velocities in the work environment [5] However, it should be noted that both the HOMEcheck Mobile Home Odor (Formaldehyde) Test Kit and the PF-1 Formaldehyde Monitor are intended for home use in the absence of strong air currents

Table 3 Calculated percent increase in sampling rate due to added effect of eddy diffusion

Flow velocity	Palmes' tube sampler	HOME-check sampler	PF-1 Formaldehyde Monitor
Fast	15	27	121
Medium	11	17	40
Slow	11	9	14

diffusion on the sampling rate of representative analytes. It was found by trial and error that the observed loss of dye by convection from the Palmes' tube, at the lowest flow velocity, could be matched very closely ($\pm 1.2\%$) by assuming coefficients of 0.0305 cm^2/sec and 18.86 for the coefficients "a" and "b" in equation (6). The corresponding coefficients for loss assuming the same Reynolds number in air are 0.549 cm^2/sec and 18.86 (the coefficient "b" remains unchanged). Further, if it is assumed that the analyte being sampled has a molecular diffusion coefficient of 0.1 cm^2/sec in air, then from equations (7) and (8) the percent increase in the sampling rate brought about by the added presence of eddy diffusion is 11%.

Table 3 shows the results of applying this algorithm to the data in Table 2. Note that the diffusive sampler having the widest diameter would be expected to be affected the most by convection. At the highest flow velocity examined (0.7 cm/sec), the sampling rate would be expected to be affected the most by convection. At the highest flow velocity examined (0.7 cm/sec), the sampling rate would be expected to be increased by 121%, indicating that at this velocity the rate of uptake was controlled by eddy diffusion, rather than by molecular diffusion, thus invalidating the basic assumption assumed in the use of this type of sampler. This limits the use of this sampler to quiescent areas where air flow velocities are very low.

CONCLUSIONS

This work shows an enormous difference between commercial diffusive samplers with regard to convection affecting the transport of analyte. Most importantly, placing a plastic membrane impervious to flow across the face of the diffusive sampler, as was done in two of these samplers, can attenuate this effect to a very low level. Given the uncertainties caused by convection, it certainly seems appropriate that this preventative step be taken. However, should the diffusive sampler have no protective membrane, then in the design and testing of such diffusive samplers, a simple aqueous dye experiment can be used to determine the degree to which convection is likely to confound their calibration.

DETERMINATION OF NOBLE METALS IN SILICATE ROCKS, ORES AND METALLURGICAL SAMPLES BY SIMULTANEOUS MULTI-ELEMENT GRAPHITE FURNACE ATOMIC ABSORPTION SPECTROMETRY WITH ZEEMAN BACKGROUND CORRECTION*

J G. SEN GUPTA
Geological Survey of Canada, Ottawa, Ontario, Canada K1A OE8

(*Received* 27 *July* 1992 *Revised* 13 *November* 1992 *Accepted* 15 *November* 1992)

Summary—A new method has been developed for rapid determination of μg/g and ng/g amounts of noble metals in silicate rocks, ores and metallurgical samples by attacking with hydrofluoric acid and aqua regia, preconcentration by ion-exchange chromatography and measuring in a simultaneous multi-element graphite furnace atomic absorption spectrometer equipped with a polarized Zeeman background correction device which eliminated interferences from any incompletely separated common elements The method was tested for Ru, Rh, Pt, Ir, Pd, Ag and Au with three Canadian certified reference materials, and then applied to the determination of ng/g amounts of these elements in four new Canadian candidate reference materials

The quantitation of trace and ultra-trace amounts of noble metals in geological and metallurgical samples is fraught with the difficulty of not only selection of a suitable method for decomposition and preconcentration but also application of a sufficiently rapid and sensitive method for accurate determination.

Although fire assay preconcentration of noble metals involving collection in lead, tin or nickel sulphide button has found useful application in some Government and large commercial laboratories,[1] wet-chemical decomposition and preconcentration by solvent extraction or ion-exchange separation procedure is still the preferred choice of small geochemical laboratories where space limitation and high cost of fire assay equipment inhibit application of the former.

In the past, for graphite furnace atomic absorption spectroscopic (GFAAS) determination of precious metals in geological, metallurgical and meteoritic materials decomposition of samples by heating with HF–aqua only were used by several workers.[2–7] Except for the works of Kritsotakis and Tobschall[3] and Branch and Hutchison,[4] who used ion-exchange separations, preconcentration of precious metals were effected by tellurium co-precipitation.[2,6,7] Thus, Sighinolfi *et al.*[2] observed aqua regia solubilization of precious metals except platinum which was completely attacked by HF–aqua regia, their results for precious metals in HF–aqua regia digest of SARM-7 were reasonably good compared to the certified values. Kritsotakis and Tobschall[3] also obtained good results for Au, Pt, Pd, Rh and Ir in SARM-7, and, excepting Pt and Rh values which were somewhat low, their results for Au, Pd and Ir in PTM-1 and PTC-1 were comparable with the certified values.

Using sodium peroxide fusion method, Branch and Hutchison[4] noted losses of only 1% Pt and 2% Pd in the residue of a sample of PTO-1 (ultrabasic rock) after HF–aqua regia digestion. Because of these insignificant losses, these workers omitted determination of Pt and Pd in the residues after HF–aqua regia digestion of PTA-1, PTC-1 and PTM-1.[4] For vegetation samples, use of an ashing temperature of 900°C prior to treatment with HF–aqua regia improved GFAAS results for Au, Pt and Pd, which compared favorably with those of nickel sulphide fire assay/neutron activation.[7]

In the present work, a new method has been developed for determination of the noble metals which involves decomposition of samples by attack with HF–aqua regia followed by ion-exchange preconcentration and simultaneous measurement of four elements using a multi-element graphite furnace atomic absorption spectrometer equipped with Zeeman background

*Paper presented at *37th Canadian Spectroscopy Conference*, Ottawa, Ontario, 12–14 August 1991 Geological Survey of Canada Contribution NO 22992

correction device. The method was found satisfactory for determination of Ru, Rh, Pt, Ir, Pd, Ag and Au in three certified reference materials of Canadian Certified Reference Materials Project (CCRMP). Application was then made to the determination of these elements in four new candidate reference materials (two rocks, one mineralized rock and one sulphide mineral) of CCRMP.

EXPERIMENTAL

Instruments and reagents

Hitachi Model Z-9000 simultaneous multi-element atomic absorption spectrometer, fitted with a pyrolytically-coated tube (Part No. 190–6003), argon gas (UHP, 99 999%, exit pressure regulated to 44 psi and predried by passing through a Matheson Gas Purifier Model 6406) and cooling water, was used in this work. The cooling water was supplied by a Neslab Cooflow Model CFT-33 Refrigerated Recirculator and the temperature was maintained at 17°C In addition to the built-in plotter of the Hitachi Z-9000 instrument, an IBM compatible PC computer was used for data recording and storage. A Radiometer pH meter was used for all pH measurements.

Standard solutions of ruthenium, rhodium, palladium, iridium, platinum and gold (100 ng/ml each) were prepared by diluting 1000 μg/ml of the Plasma-Chem ICP standard solutions of these elements (Delta Scientific Ltd, Mississauga, Ontario Supplier) with 1*M* hydrochloric acid. A standard solution of silver was prepared by dissolving a weighed amount of silver grain (Johnson Matthey "Specpure") in hot dilute nitric acid, cooling and diluting to a definite volume. An aliquot was diluted with 1*M* nitric acid to obtain a concentration of 100 ng/ml. All silver standard solutions were stored in dark bottles inside a cupboard to prevent decomposition by light. Mixtures of calibration standards containing 10–100 ng/ml of noble metals were prepared by mixing appropriate aliquots of these stock standard solutions and diluting to definite volumes with 1*M* hydrochloric acid, and stored in nalgene bottles fitted with screw-caps.

Ultrapure water, prepared by reverse osmosis with a Millipore apparatus, and Seastar ultrapure acids were used throughout this work.

Ion-exchange columns

A series of 12 ion-exchange resin columns,[8] each 30 cm long and 1.8 cm I.D., were prepared and packed with Dowex 50W-X8 cation exchange resin (50–100 mesh). The columns were washed with 3*M* hydrochloric acid until the effluents were free from Fe^{+3} (tested with drops of 1% ammonium thiocyanate solution on a spot plate), and then with deionized water until the washings were neutral to blue litmus paper

Procedure

To a 100-ml Teflon beaker, previously cleaned by heating with HF–aqua regia, 5 g of finely powdered (−200 mesh) and homogenized sample was transferred. The sample was moistened with water and carefully treated with a total of 25 ml of hydrofluric acid (48–51%), adding a small quantity at a time and stirring with a Teflon rod and immediately covering with a Teflon cover until the vigorous reaction subsided. The bottom side of the cover and the upper inner wall of the beaker were washed with small quantity of a jet of water to dislodge adhering solid particles of the sample, using a policeman if necessary After adding 25 ml of a freshly prepared aqua regia solution and mixing, the beaker was covered and heated overnight on a steam-bath. The following morning, the cover was removed and the beaker was heated on the groove of a medium-hot iron plate until the solution was evaporated to dryness. After cooling, 25 ml of concentrated nitric acid was added, the lumps were broken with the Teflon rod and the solution was evaporated to dryness again To the residue, brought to room temperature, 1 ml of 20% (w/v) sodium chloride (Note 1) solution and 25 ml of freshly prepared aqua regia were added, the beaker was covered and heated with frequent stirring and dislodging the solid until the solution became clear The cover was removed and the solution was evaporated to incipient dryness. The residue was treated with 10 ml of concentrated hydrochloric acid, and after stirring with the rod to a syrupy liquid the solution was evaporated to dryness on the steam-bath (Note 2). The evaporation process was repeated once more with an additional 10 ml of concentrated hydrochloric acid (steam-bath).

To the residue 10 ml of concentrated hydrochloric acid was added, and after stirring with the rod the beaker was covered and heated briefly on the groove of the hot plate to dislodge the solid from the bottom. After adding 60–70 ml of water, the beaker was heated on the hot plate with frequent stirring until a clear or near clear solution was obtained (Note 3). When the solution was clear, the beaker was cooled to room

temperature and the solution was transferred to a 100-ml standard flask. The beaker was rinsed with 2% hydrochloric acid and the volume was made up to the mark with the same acid. When any undissolved material was noticed, the solution was allowed to stand several hours to settle the solid particles and then filtered through a 11-cm Whatman No. 40 filter paper. The residue and the filter paper were washed thoroughly with a hot solution of 2% hydrochloric acid until the paper was free from any stain of iron, nickel or copper. The solution was transferred to a 100-ml standard flask, the beaker was rinsed with 2% hydrochloric acid and the volume was made up the mark with the same acid. The solution was stored in a nalgene bottle fitted with a screw-cap (solution A). Any insoluble residue was separately treated by the procedure described under Results and Discussion.

Ion-exchange separation

A 40-ml aliquot of the above stock solution A was transferred to a 600-ml borosilicate beaker and diluted to ~350 ml with deionized water to attain pH 1 5 ± 0.3 (tested with a pH meter). The solution was passed through the ion-exchange column at a rate of 2 ml/min, and the effluent was collected in a 800-ml borosilicate beaker. The beaker and the column were washed with a total of 350 ml of water acidulated to pH 1.5 with hydrochloric acid, and the washings were collected in the same beaker containing the effluent. After adding 1 ml of 2% (w/v) sodium chloride solution (Note 1) to the effluent, the beaker was placed on a hot plate and the solution was evaporated to ~5 ml. The solution was transferred to a 20-ml borosilicate beaker by rinsing with hot 3*M* hydrochloric acid and evaporated first on a hot plate to ~0 5 ml, then on a steam bath to a moist residue. The salts were dissolved in hot 3*M* hydrochloric acid, the solution was transferred to a 10-ml borosilicate beaker and evaporated to near dryness (steam bath). In the case of a syrupy residue, which indicated the presence of sulphuric acid formed by oxidation of sulphides during decomposition of the sample with nitric acid, it was evaporated further to dryness on a hot plate until no more white fumes appeared. The inside of the beaker was rinsed with water and the solution was evaporated again. The residue was treated with 4 ml of aqua regia, the beaker was covered with a watch glass and heated to dissolve the salts. When the reaction subsided, the cover was removed and its bottom was rinsed with water into the beaker, and the solution was evaporated to a moist residue on the steam-bath. The salts were dissolved in 0.5 ml of 1*M* hydrochloric acid by warming briefly on the steam-bath and, depending on the concentration of the noble metals expected, the solution was transferred to a suitable standard flask (1–5 ml) and the volume was made up with the same acid. In case a white residue (hydrated TiO_2) separated out from some silicate rock samples, it was filtered out through a 4-cm glass fiber filter paper, the beaker and the paper were rinsed with small quantity of 1*M* hydrochloric acid and the filtrate was made up to a definite volume

Table 1 Instrumental parameters

Element	Wavelength (nm)	Varian hollow-cathode lamp current (mA)
Ru	349 9	8
Rh	343 5	5
Pd	244 8	5
Ag	328 1	3
Ir	208 9	10
Pt	266 0	10
Au	242 8	4

Spectral bandwidth fixed at 0 8 nm in the Hitachi Z-9000 instrument

Instrumental determination

Using the instrument operating parameters of Tables 1 and 2 and standard solutions (40 μl of each) containing the analytes in concentrations from 0 to 100 ng/ml, calibration curves were prepared for Ru, Rh, Pt and Ir (Fig. 1). Employing the instrument parameters of Tables 1 and 3 and five standard solutions (10 μl of each) of similar concentrations (except silver concentrations which ranged only from 0 to 75 ng/ml because of its much higher sensitivity than other elements), calibration curves for Ag, Au and Pd were prepared (Fig. 2).

Table 2 Temperature programme for simultaneous determination of Ru, Rh, Pt and Ir

No	Stage	Temperature (°C) Start	End	Time (sec)
1	Dry	75	75	10
2	Dry	90	90	60
3	Dry	120	130	20
4	Ash	850	850	20
5	Ash	1400	1400	10
6	Atom	3000	3000	10
7	Clean	3000	3000	5

Monitoring stage 1–7
Check stage 1–7
Carrier gas 200 ml/min
Interrupted gas 0 ml/min

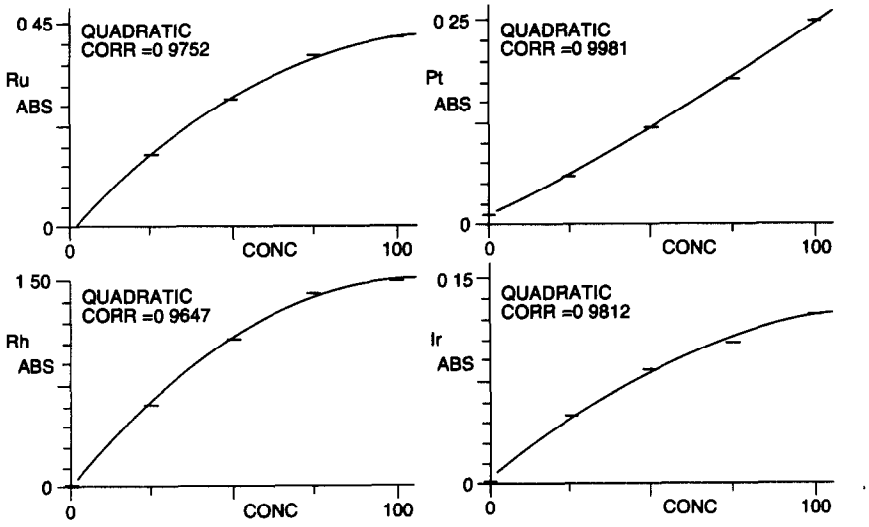

Fig 1 Calibration curves for ruthenium, rhodium, platinum and iridium at atomization temperature of 3000°C (concentration in ng/ml)

For silicate rocks and minerals, Ru, Rh, Pt and Ir were determined from 20–40 μl of a solution containing 0.5–2 g sample/ml, and Ag, Au, and Pd from 10–20 μl of a solution containing 0.2–1 g sample/ml or after suitable dilution with 1*M* hydrochloric acid, as necessary.

Table 3 Temperature programme for simultaneous determination of Ag, Au and Pd

No	Stage	Temperature (°C) Start	End	Time (sec)
1	Dry	75	75	10
2	Dry	90	90	60
3	Dry	120	130	10
4	Ash	800	800	20
5	Atom	2700	2700	10
6	Clean	2800	2800	5

Monitoring stage 1–6
Check stage 1–6
Carrier gas 200 ml/min
Interrupted gas 0 ml/min

For sulphide ores or metallurgical samples, Ru, Rh, Pt and Ir were determined from 10–40 μl of a solution containing 0.1–0.2 g sample/ml, and Ag, Au and Pd from 10–20 μl of a solution containing 0 1–0.2 g sample/ml or after suitable dilution with 1*M* hydrochloric acid, as required.

Notes

1. Sodium chloride was added to form chlorocomplexes of the noble metals to prevent their decomposition to free metals and losses to the walls of the beaker during evaporation steps.

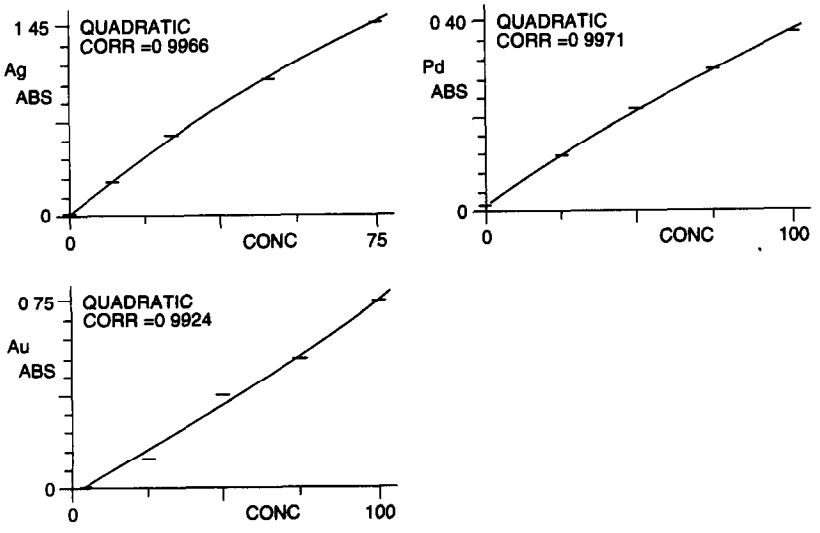

Fig 2 Calibration curves for silver, gold and palladium at atomization temperature of 2700°C (concentration in ng/ml)

2. Heating on the steam-bath instead of a hot plate prevented decomposition of the noble metal salts to free metals, particularly gold and platinum.

3. Sulphide minerals gave clear solutions at this stage.

RESULTS AND DISCUSSION

Sensitivity

The sensitivities of the noble metals on pyrolytically-coated graphite furnace in the Hitachi Z-9000 multi-element atomic absorption spectrometer are given in Table 4 and compared with those obtained previously[9] by using a Varian single-element graphite tube atomizer (Model GTA-95) in combination with a Varian AA-475 spectrometer. Compared to the Varian AA-475 coupled with GTA-95, higher temperatures are found necessary for the noble metals with the Z-9000 instrument to obtain sufficiently high sensitivities for useful analytical applications. This is probably due to the fact that Hitachi Z-9000 spectrometer has a restricted spectral bandwidth of 0.8 nm for all elements, whereas spectral bandwidth of <0.8 can be used with Varian AA-475.

For ruthenium, rhodium, platinum and iridium an atomization temperature of 3000°C, and for silver, gold and palladium an atomization temperature of 2700°C were found satisfactory in the Hitachi Z-9000 instrument.

With the Hitachi Z-9000 instrument four elements could be determined simultaneously in one firing and the instrument could be programmed for determination of up to eight elements automatically in two firings. However, in this work, based on the sensitivities and atomization temperatures, the noble metals were divided into two groups containing four elements in Group 1 and three elements in Group 2 for simultaneous determinations as follows:

Group 1—Ru, Rh, Pt and Ir.

Group 2—Ag, Au and Pd.

Table 4 Sensitivities of noble metals on pyrolytically-coated graphite-furnace in Hitachi Z-9000 simultaneous multi-element atomic absorption spectrometer

Element	Atomization temperature (°C)	Sensitivity* (pg)	
		This work†	Previous value with Varian GTA-95‡

Analyses of reference materials for noble metals

The results for noble metals as obtained in this work for three CCRMP reference materials SU-1a (Ni–Cu–Co ore), PTM-1 (noble metals bearing Ni–Cu matte) and UMT-1 (ultramafic ore tailings) are given in Table 5 and compared with the certified or other values.[9,10] For UMT-1 "recommended" values for some noble metals are now available in the "Certificate of Analysis" sheet. These and other "provisional" or "information" values for this sample are compared with the results of this work in Table 5. Good agreement is found in most cases indicating completeness of recovery.

Silver was not determined in PTM-1 because a previous work[9] showed that most of the high silver from this sample was lost by precipitation as silver chloride during sample decomposition steps.

For four other reference materials (diabase rock, gabbro rock, mineralized gabbro and massive sulphide mineral), the results of this work are compared in Table 5 with those obtained by independent method(s) and/or supplied by the Coordinator of CCRMP. Reasonably good agreement is found between the results of this work with other values, where available.

In order to test any loss of precious metals in the residues after HF–aqua regia dissolution of the samples of Table 5, the filter paper containing the residue was transferred to a porcelain crucible and after charring the paper at 450°C the residue was ignited to oxides at 800°C. After cooling, the oxides were finely ground by the tip of an agate pestle and then transferred to a zirconium crucible and intimately mixed with 5 g Na_2O_2. The crucible was covered by a zirconium lid and placed on a claypipe triangle enclosed by a chimney which was supported by a tripod stand, and the mixture was fused over a Méker burner for 2–3 min with occasional swirling. The melt was cooled to room temperature, small quantities of concentrated hydrochloric acid were gradually added and the dissolved mass was quickly transferred to a 100-ml borosilicate beaker with a jet of water. More concentrated

hydrochloric acid was added and the beaker was heated on a hot plate until the solution became clear or near clear and no more evolution of gas bubbles occurred. A very small amount of gritty matter was filtered off through a glass fiber filter paper and washed with 1*M* hydrochloric acid. The solution was diluted to 60 ml with water, 5 ml of 1 mg Te/ml solution was added and a freshly prepared stannous chloride solution was added in excess to coprecipitate any precious metals with the added tellurium. After boiling, the coagulated precipitate was filtered off through a Millipore Type HA 0.45 μm filter disk and washed with 1*M* hydrochloric acid. The disk was placed in the original beaker and decomposed by concentrated nitric acid and aqua regia as described in an earlier paper.[9] The final solution was evaporated on the steam-bath in a 10-ml beaker in the presence of 1 mg sodium chloride. The salts were dissolved in 0.5 ml of 1*M* hydrochloric acid by warming the beaker on the steam-bath, the solution was transferred quantitatively to a 1-ml standard flask and the volume made up to the mark with the same acid. A reagent blank was taken throughout the whole procedure. An aliquot of 40 μl of this solution was transferred to a new graphite tube in the Hitachi Z-9000 spectrometer and after drying and ashing as usual (*cf.* Table 2) the sample was atomized at 3000°C for determining Ru, Rh, Pt and Ir. From another aliquot of 40 μl the sample was dried, ashed and atomized at 2700°C (*cf.* Table 3) for determining Ag, Au and Pd. The amounts, if any, of these elements were quantified from calibration curves. The precious metals were found to be either nil or negligibly small in these solutions.

Acknowledgements—The author is indebted to the Coordinator of CCRMP for supplying the reference materials used in this work, and to D C Grégoire for providing ICP-MS data on some samples reported in this work

DETERMINATION OF MANGANESE, IRON AND COPPER IN SODIUM BY CHEMICAL MODIFICATION/GRAPHITE FURNACE ATOMIC ABSORPTION SPECTROMETRY

YUKIHIRO KOSHINO and AKIR NARUKAWA

Materials Analysis Laboratory, Corporate Research and Development Group, NGK Insulators, Ltd, 2-56 Suda-cho, Mizuho-ku, Nagoya-shi, Aichi 467, Japan

(*Received* 1 *September* 1992 *Revised* 13 *November* 1992 *Accepted* 15 *November* 1992)

Summary—Trace Mn, Fe and Cu in sodium were determined by chemical modification/graphite furnace atomic absorption spectrometry The sodium sample was changed into NaOH in a desiccator by room temperature water vapor generated under reduced pressure, then the NaOH was dissolved in water and HNO_3 was added to give a clear solution. The solution was analysed by chemical modification/graphite furnace atomic absorption spectrometry A nickel nitrate modifier was effective in improving integrated absorbance signals and the reproducibility of measurement Analytical results for Mn, Fe and Cu were 170, 970 and 210 ng/g and relative standard deviations ($n = 5$) were 3 5, 5 8 and 6 7%, respectively These results agreed with the values obtained from a chelating resin preconcentration/ICP-AES method

When sodium is used as a coolant for fast reactor systems, analysis of impurities in it is very important. Metal impurities in sodium are analysed by flame atomic absorption spectrometry or ICP–AES after decomposing by water vapor or alcohol and treating with HCl, but detection limits with these methods are at the microgram per gram level because a great quantity of NaCl matrix is present.

On the other hand, graphite furnace atomic absorption spectrometry (GFAAS) is a highly sensitive technique. Since it is easily influenced by the matrix, the interferences are removed by various methods, *e.g.* solvent extraction,[1,2] or ion-exchange.[3–5] However, these methods require complicated procedures. In recent years, elimination of matrix interference has been investigated using chemical modifiers. Chemical modification methods have the advantage that no complicated procedures are required and there is no concern of contamination from vessels used for separation or preconcentration of analyte elements. Chloride matrix interference is eliminated by addition of HNO_3 or NH_4NO_3 because the generated nitride can be decomposed at about 400°C before the ash step.[6,7] Mg $(NO_3)_2$ and Ni $(NO_3)_2$ are used as modifiers for the determination of Mn and Al.[8,9]

This paper describes the determination of Mn, Fe and Cu in sodium by chemical modification/GFAAS. Mg $(NO_3)_2$ and Ni $(NO_3)_2$ were investigated as chemical modifiers in accordance with previous reports.[8–11] Sodium was changed into NaOH in a desiccator by room temperature water vapor generated under reduced pressure, then treated with HNO_3. The resulting solution was analysed by GFAAS using Ni $(NO_3)_2$ modifier. Nanogram per gram levels of Mn, Fe and Cu in sodium were determined accurately.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Model Z5100 atomic absorption spectrophotometer equipped with a Zeeman background corrector, an AS-60 autosampler and a ZHGA-600 atomizer were used. A Perkin-Elmer model 7700 computer was used to control furnace conditions and the amount of solution injected. Hollow-cathode lamps of Mn, Fe and Cu were used as the radiation sources. A pyrolytic graphite coated graphite tube and pyrolytic graphite L'vov platform were used throughout. A Nippon Jarrell Ash, ICAP 575-II inductively coupled plasma atomic emission spectrometer (ICP-AES) was used in the chelating resin preconcentration experiment to check the accuracy of the established method. A Miwa Seisakusho, argon atmospheric glove box capable of maintaining the concentration of both moisture and oxygen below 1 μl/l was used to treat sodium samples. A METTLER AE-163 balance was used.

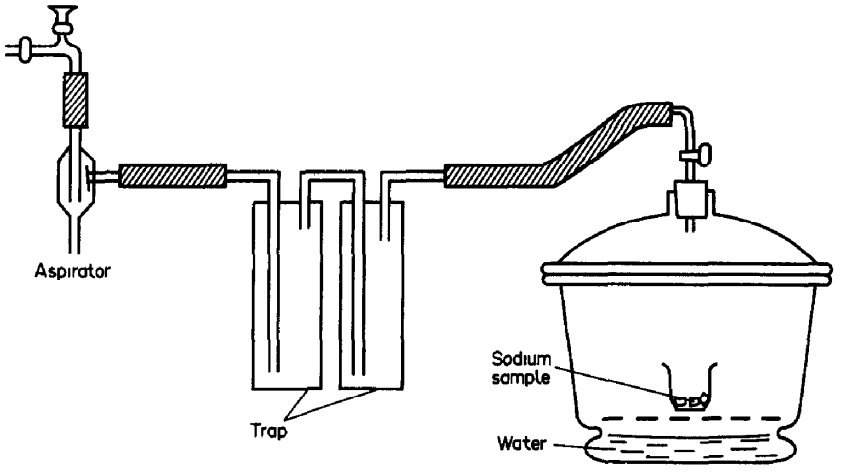

Fig. 1 Decomposition system for sodium

Reagents

Metal stock standard solutions (1000 mg/l) were prepared by dissolving 0.2500 g of high purity metals (Mn;99.99%, Cu; 99.99%, Katayama Chemical Industries Co. Ltd., Japan, Fe; 99.99%, Wako Pure Chemical Industries Co. Ltd., Japan) in 5 ml of HNO_3 and diluting to 250 ml with water. These resulting solutions were stored in polyethylene bottles. Metal–$NaNO_3$ solutions (20 ng/ml Mn, Fe and Cu, $1^m/_v$% Na) were prepared by dissolving 3.70 g of $NaNO_3$ (Merck Suprapur) in $0.2^m/_v$% HNO_3 and adding 2000 ng of Mn, Fe and Cu, then diluting to 100 ml with $0.2^m/_v$% HNO_3. These solutions contain 1.0 g of sodium in 100 ml. Calibration standards were prepared in the same manner using metal–$NaNO_3$ solutions containing 0–2000 ng of analyte elements. Mg modifier solution was prepared by dissolving 1.000 g of Mg $(NO_3)_2$ $6H_2O$ (Merck Suprapur) in water and diluting to 100 ml. Ni modifier solution was prepared by dissolving 1.000 g of Ni $(NO_3)_2$ $6H_2O$ (Kojundo Kagaku Kenkyuujo, Japan, 99.9%) in water and diluting to 100 ml. A Cica-Merck Ultra Pure HNO_3 was used. A Bio-Rad Laboratory Chelex-100 chelating resin (200–400 mesh) was used to concentrate and separate analyte metals. Distilled water was purified with Milli-Q purification system.

Analytical procedure

After removing oxidized surfaces of sodium samples using a ceramic knife and polytetrafluoroethylene (PTFE) coated tweezers in the glove box. 1 g of sample was weighed into a PTFE evaporating dish. The dish was taken out from the glove box, and placed into a desiccator containing water at the bottom. The sodium sample was changed into NaOH by water vapor generated under reduced pressure for 5 hr using an aspirator. A schematic drawing of sodium decomposition system is shown in Fig. 1. The resulting NaOH was dissolved in 20 ml of water and 3 ml of HNO_3 added, followed by dilution to 100 ml with water. Twenty microlitres of the solution and 20 μl of Ni modifier solution were injected into the furnace and the integrated absorbance signal was measured with the conditions given in Table 1. Calibration graphs are constructed by a series of calibration standards.

RESULTS AND DISCUSSION

Investigation of ash and atomization temperatures without modifier

The effect of ash and atomization temperatures on the signals for Mn, Fe and Cu were investigated without modifier. The signals

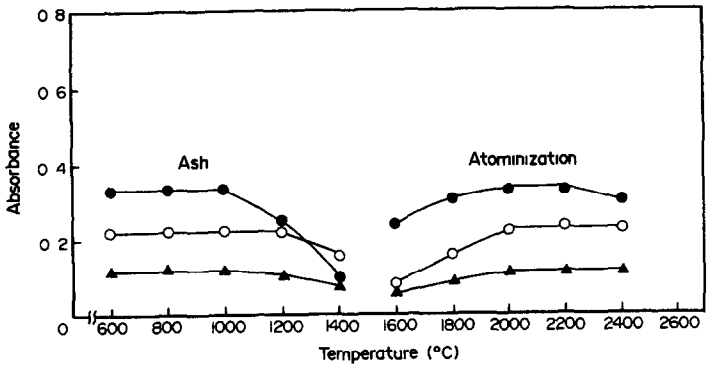

Fig. 2 Effects of ash temperature (atomization at 2000°C for Mn, 2400°C for Fe and Cu) and atomization temperature (ash at 1000°C) on the absorption signal for Mn, Fe and Cu in metal–$NaNO_3$ solution
● Mn 400 pg, ○ Fe 400 pg, ▲ Cu 400 pg

obtained are shown in Fig. 2 as a function of ash and atomization temperatures. First, ash temperature was studied. Twenty microlitres of metal–$NaNO_3$ solution was injected into the furnace, followed by application of an ash temperature of 600–1400°C, and an atomization temperature of 2000°C for Mn, 2400°C for Fe and Cu. Other conditions were according to Table 1. Signals were maximum and constant at an ash temperature of 600–1000°C for Mn and Cu, 600–1200°C for Fe. From these results, an ash temperature of 1000°C was selected for the atomization study. Second, atomization temperature was examined at 1600–2400°C. Since maximum signal was obtained an atomization temperature of 2000–2200°C for Mn (0.327), and above 2000°C for Fe (0.225) and Cu (0.114), respectively, 2100°C for Mn and 2400°C for Fe and Cu were selected as atomization temperatures.

Investigation of ash and atomization temperatures with Ni modifier

Ash and atomization temperatures using Ni modifier were investigated by injecting 20 μl of Ni modifier solution and 20 μl of metal–$NaNO_3$ solution into the furnace. Signals obtained are shown in Fig. 3. The signal for Mn was maximum and constant at an ash temperature of 600–1200°C, and an atomization temperature of 1900–2200°C. For Fe and Cu, maximum and constant signals were obtained at ash temperatures of 1200–1400°C and 600–1200°C, respectively, and an atomization temperature of 2200–2600°C for both. From these results, Ni modifier gave a higher ash temperature than only the metal–$NaNo_3$ solutions examined. The maximum absorbance for Mn, Fe and Cu was 0.630, 0.248 and 0.140, respectively. These maximum values were 1.9 times for Mn, 1.1 times for Fe and Cu in comparison to values found without Ni modifier. Mean integrated absorbances and relative standard deviations of five repeated runs on metal–$NaNO_3$ solutions in the case of with and without Ni modifier are shown in Table 2. Since the relative standard deviations for Mn, Fe and Cu using Ni modifier were within 2%, this was effective in improving the reproducibility.

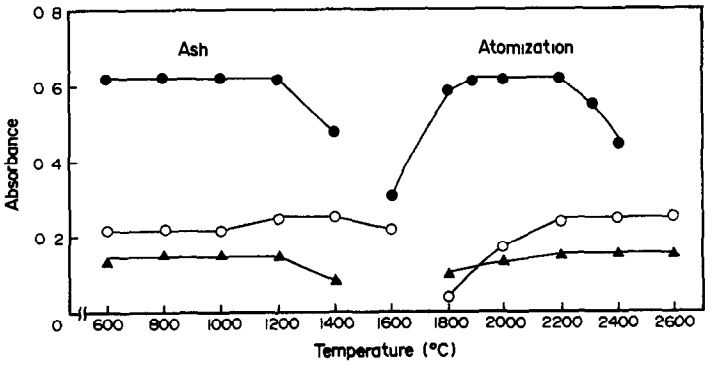

Fig 3 Effects of ash temperature (atomization at 2000°C for Mn, 2400°C for Fe and Cu) and atomization temperature (ash at 1000°C for Mn and Cu, 1300°C for Fe) on the absorption signal for Mn, Fe and Cu in metal–$NaNO_3$ solution in addition of Ni modifier ●: Mn 400 pg, ○ Fe 400 pg, ▲ Cu 400 pg.

Table 2 Effect of Ni modifier on reproducibility

NI modifier	Absorbance Mn	Fe	Cu
With*	0 655 (0 7)	0.250 (0 9)	0 135 (1 3)
Without	0 331 (3 7)	0 229 (2 2)	0 119 (4 9)

*1 m/v% $Ni(NO_3)_3$ $6H_2O$ 20 m μl was added
The amount of Mn, Fe and Cu tested was 400 pg, respectively The percentage relative standard deviation ($n = 5$) is given in parentheses

Effect of concentration of nitric acid

The effect of the concentration of nitric acid on the integrated absorbance signal was examined. Twenty microlitres of 0–3M HNO_3 metal–$NaNO_3$ solution was injected into the furnace and treated following the conditions given in Table 1. The signals were constant at a range of 0–3M HNO_3, and hence HNO_3 did not have an affect on absorption signals.

Investigation of modifiers

Some modifiers were examined for eliminating the $NaNO_3$ interference. The concentration of HNO_3 in the test solution was fixed 0.2 m/v%, because 0–3M HNO_3 did not have an affect on the signals. Twenty microlitres of modifier solution and 20 μl of metal–$NaNO_3$ solution were sucked into the autosampler, then injected into the furnace and treated following the conditions given in Table 1. Although Mg $(NO_3)_2$, Ni $(NO_3)_2$, Pd $(NO_3)_2$, NH_4NO_3, $(NH_4)_2HPO_4$ and $NH_4H_2PO_4$ were examined as modifiers, only Mg $(NO_3)_2$ and Ni $(NO_3)_2$ gave good peak profiles. Accordingly, these two modifiers were tested in detail. Peak profiles for Mn are shown in Fig. 4. Integrated absorbance signals for Mn obtained with metal–$NaNO_3$ solutions, and with added Mg modifier solution and Ni modifier solution were 0.330, 0.638 and 0.655, respectively. With Mg and Ni modifiers the Mn signal increased about 1.9 times. Since Mn forms an alloy with Mg and Ni having higher melting points in this order than Mn only, the atomization time was delayed in the order of Mg and Ni. Therefore, Mg and Ni modifiers were effective in preventing vaporization of Mn in the ash step. Mg modifier caused peak split. The reason ascribed was the disagreement of valence of Mn. The result of the same examination for Fe is shown in Fig. 5. The signals obtained with metal–$NaNO_3$ solutions, and with Mg modifier solution and Ni modifier solution were 0.224, 0.248 and 0.249, respectively. Though the increase in the signal was about 10% when Mg and Ni modifiers were used, peak split was not observed. Copper showed the same behavior as Fe. The results of these examinations show that the Ni modifier gave the largest absorption signals and good peak profiles for Mn, Fe and Cu. Further, the optimum amount of Ni modifier solution is in the range of 5–50 μl, with the largest signal found for 20 μl. From these results, ash and atomization temperatures were investigated with the optimum amount, *i.e.* 20 μl, of Ni modifier. The results are shown in Fig. 3.

Lower detection limit

The lower detection limits were 30, 50 and 50 ng/g for Mn, Fe and Cu, respectively, equal to 0.010, 0.006 and 0.004 the absorbance signal,

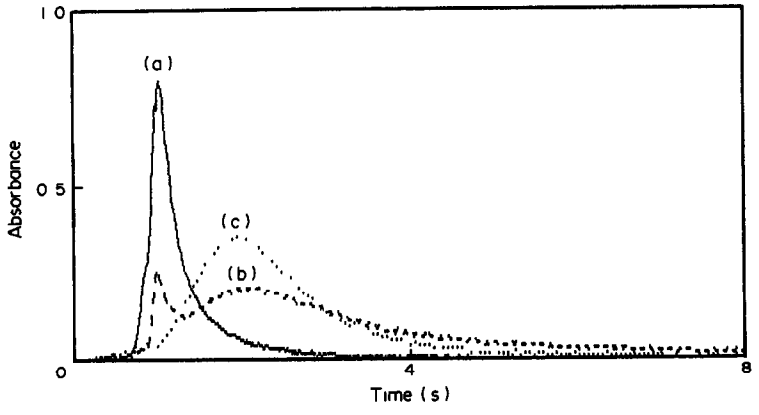

Fig. 4. Investigation of chemical modifier for Mn The amount of Mn tested was 400 pg (a) Metal–$NaNO_3$ solution 20 μl. (b) Metal–$NaNO_3$ solution 20 μl and Mg modifier 20 μl. (c) Metal–$NaNO_3$ solution 20 μl and Ni modifier 20 μl

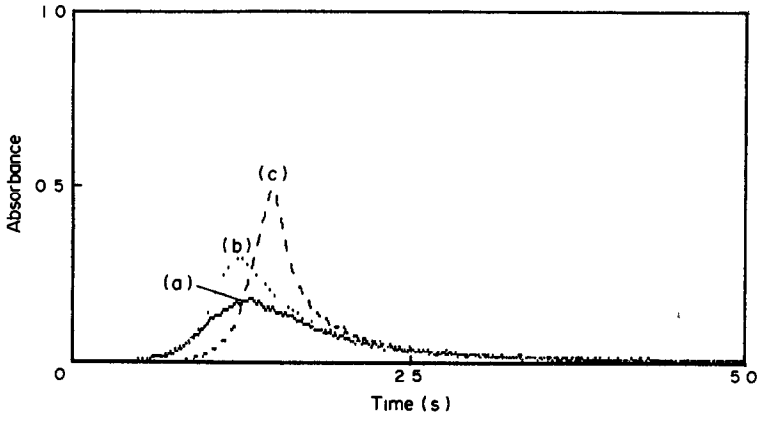

Fig 5 Investigation of chemical modifier for Fe. The amount of Fe tested was 400 pg. (a) Metal–$NaNO_3$ solution 20 μl. (b) Metal–$NaNO_3$ solution 20 μl and Mg modifier 20 μl (c) Metal–$NaNO_3$ solution 20 μl and Ni modifier 20 μl.

defined as three times the standard deviation of procedural blanks ($n = 3$).

Results of the analysis

The analytical results for Mn, Fe and Cu in a sodium sample using the proposed method and a preconcentration/ICP-AES method are summarized in Table 3. The procedure of preconcentration/ICP-AES was as follows; the NaOH generated by decomposing sodium was dissolved in 50 ml of water, and the pH was adjusted to 8.0 by adding dropwise HCl (1 + 100). The solution was passed through a column loaded in the H form Chelex-100 resin at a flow rate of 1 ml/min, then the adsorbed Mn, Fe and Cu were eluted with 20 ml of 2M HNO_3, and determined by ICP-AES. The results agreed with the values obtained from preconcentration/ICP-AES, and percentage relative standard deviations ($n = 5$) were within 10%. The time required for the determination of Mn, Fe and Cu was about 8 hr, including 5 hr sample decomposition time.

Table 3. Determination of Mn, Fe and Cu in sodium metal

Method	Found (ng/g) Mn	Fe	Cu
Proposed	170 (3.5)	970 (5.8)	210 (6.7)
Preconcentration/ ICP-AES	160	1010	200

The percentage relative standard deviation ($n = 5$) is given in parentheses.

SYNERGISTIC EXTRACTION OF COBALT(II) FROM CESIUM CONTAINING AQUEOUS SOLUTIONS WITH MIXTURES OF 4-ACYL-PYRAZOL-5-OLS AND CROWN ETHERS

B RUSDIARSO, A. MESSAOUDI and J P BRUNETTE*

Laboratoire de Chimie Minerale et Analytique, E H I C S, C N R S URA 405, 1, Rue Blaise Pascal, 67008 Strasbourg Cedex, France

(*Received* 3 *August* 1992 *Revised* 5 *October* 1992 *Accepted* 10 *November* 1992)

Summary—The synergistic extraction of cobalt(II) from aqueous solutions loaded with cesium chloride or nitrate, with mixtures of 1-phenyl-3-methyl-4-acyl-pyrazol-5-ols (HL) [acyl = benzoyl (HPMBP), para-*tert* -butyl-benzoyl (HPMB'P), stearoyl (HPMSP)] and crown ethers E = B15C5, 18C6, DC18C6, DB18C6 and DB24C8 (DC = dicyclohexano, B = benzo, DB = dibenzo), in $CHCl_3$, CH_2Cl_2 and $ClCH_2CH_2Cl$, has been studied The experimental data agree with the extracted species E_2CsCoL_3 (E = B15C5), $ECsCoL_3$ (E = DB18C6) and CoL_2E (E = DB24C8) The extraction yields follow the orders 18C6 ≥ DC18C6 > DB18C6 > B15C5 > DB24C8, HPMBP > HPMB'P > HPMSP, and $ClCH_2CH_2Cl > CH_2Cl_2 > CHCl_3$ In spite of the better complexation of potassium than cesium with "18C6" type crown ethers, the extraction of ECsCo $(PMBP)_3$ is generally higher than the EKCo$(PMBP)_3$ one Except in the case of DB24C8, loading the aqueous phase with Cs^+, K^+, Sr^{2+} or Ba^{2+} improves the synergistic extraction of cobalt

Added to acidic chelating extractants (HL) crown ethers (E) can act as neutral oxo-donor synergistic agents in the extraction of numerous metal cations (M^{m+}), *e.g.*, trivalent actinides and rare earths generally extracted with HL = HTTA (thenoyltrifluoroacetone),[1–3] HPMBP (1-phenyl-3-methyl-4-benzoylpyrazol-5-ol),[4,5] HPMTFP (1-phenyl-3-methyl-4-trifluoroacetyl-pyrazol-5-ol)[5,6] as ML_3E or ML_3E_2 species, technetium as TcO (OH).TTA.E[7] and cobalt as Co $(TTA)_2E$.[8] Likewise, in previous papers,[9,10] it has been shown that cobalt, nickel, cadmium and zinc are extracted from sodium or lithium aqueous solutions with HPMBP and crown ethers as $M(PMBP)_2E$ species, but E_eK^+,M $(PMBP)_3^-$ ion pairs were extracted from potassium solutions. The present paper deals with the synergistic extraction of cobalt(II) from cesium solutions, with mixtures of 4-acyl-pyrazol-5-ols and crown ethers. The role of cesium in the synergistic effect is compared to the role of potassium and other similar cations.

EXPERIMENTAL

Chemicals

4-Acyl-pyrazol-5-ols were prepared following Jensen's procedure.[11] Crown ethers, Aldrich chemicals of analytical grade, were used without further purification: dicyclohexano-18-crown-6 was a mixture of the *syn-cis* and *anti-cis* isomers.

Metal extraction and analytical procedure

The experimental data obtained were of type $\log D_{Co}$ *vs.* pH ($D_{Co} = [Co]_{org}/[Co]_{aq}$) at various constant extractant concentrations. The organic phases were prepared by dissolving weighted amounts of acyl-pyrazolol and crown ether in the solvent freshly washed with distilled water (extractant concentrations from 0 to 0.06*M*). Initial cobalt concentration in the aqueous phase, before contact with the organic phase, was $10^{-3}M$, and the ionic strength was fixed at 1*M* (generally $[CsNO_3] = 1M$ or $[CsCl] = 1M$, and, in particular experiments, $[CsCl] + [LiCl] = 1M$). The distribution measurements were performed in a thermostated vessel (25.0 ± 0.2°C) using a batch technique· two volumes (40 ml) of aqueous phase and one volume (20 ml) of organic phase were shaken. For each experimental point, the pH (measured with a digital pH meter and combination glass-reference electrode) was adjusted to a given value (between 3 and 5) by adding small volumes of acidic or basic solutions of suitable composition to keep constant ionic strength and cesium concentration of the aqueous phase.

*Author for correspondence

After at least 15 min shaking, time enough to reach equilibrium, the phases were separated by gravity, and equal aliquots of both phases (0.5 to 1 ml) were withdrawn and centrifuged. Cobalt concentrations were determined, after suitable dilution ($\frac{1}{10}$ or $\frac{1}{5}$), by atomic absorption measurements with a Perkin Elmer 2380 spectrophotometer (The organic aliquot was contacted with 10 or 5 ml of 0.1*M* HNO_3 to strip and dilute cobalt before determination.) Before shaking phases for a new experimental point, at another pH, the aqueous and organic phase volumes were completed up to 40 and 20 ml.

RESULTS AND DISCUSSION

Cobalt extraction from 1M CsCl (or $CsNO_3$) aqueous solutions with HPMBP and crown ethers (E) in chloroform

In the presence of dibenzo-24-crown-8 (DB24C8), a weak synergistic effect occurs, and the extraction curve (Fig. 1) is a straight line of slope 2 as in the extraction performed with HPMBP alone [extraction of Co $(PMBP)_2$ with $\log K_{2,0} = -6.88$]. The synergistic effect is more and more improved with benzo-15-crown-5 (B15C5), dibenzo-18-crown-6 (DB18C6), dicyclohexano-18-crown-6 (DC18C6, commercial mixture) and 18-crown-6 (18C6) crown ethers, and the slope 3 of the curves indicates a significant change in the extraction process. Varying $[HPMBP]_{org}$ at constant pH and $[E]_{org}$, leads to $\log D_{Co}$ *vs.* $\log[HPMBP]_{org}$ curves which are also straight lines of slope 2 (E = DB24C8) or 3 (E = "18C6" type crown ethers or B15C5) (Fig. 2). These results indicate the extraction of $Co(PMBP)_2$ moieties with DB24C8 and Co $(PMBP)_3^-$ moieties with other crown ethers. The slopes of the curves $\log D_{Co}$ *vs.* $\log[E]_{org}$ at constant pH and $[HPMBP]_{org}$ are 1, 2 and 1 for E = DB24C8, B15C5 and "18C6" crown ethers, respectively (Fig. 3). Thus, the experimental data are in agreement with the extraction of $Co(PMBP)_2DB24C8(B15C5)_2Cs^+$, $Co(PMBP)_3^-$, and ("18C6") Cs^+, Co $(PMBP)_3^-$ species. Attempts to measure the cesium concentrations in organic phases did not lead to accurate conclusions owing to its high concentration in the aqueous phase and to its possible extraction, independently of the cobalt one. Nevertheless, analogous species [Co $(PMBP)_2DB24C8$, $(B15C5)_2K^+$, $Co(PMBP)_3^-$ and ("18C6") K^+, $Co(PMBP)_3^-$] were previously extracted from 1*M* KCl aqueous medium.[9,10] Moreover, the extraction of CoL_3^- anions in B^+, CoL_3^- ion pairs with B^+ = high molecular weight ammoniums and HL = 4-acyl-pyrazol-5-ols, is rather common.[12]

Table 1 Cobalt extraction from 1M CsCl medium with 4-acylpyrazol-5-ols and crown ethers in $CHCl_3$ at 25°C

HL	E	Extracted species	$\log K^*_{i,j}$
HPMSP	B15C5	E_2CsCoL_3	−7.15
HPMB'P	B15C5	E_2CsCoL_3	−5.77
HPMBP	B15C5	E_2CsCoL_3	−5 38
HPMSP	DB18C6	$ECsCoL_3$	−8 49
HPMB'P	DB18C6	$ECsCoL_3$	−6 93
HPMBP	DB18C6	$ECsCoL_3$	−6.57
HPMBP	DC18C6	$ECsCoL_3$	−5.90
HPMBP	18C6	$ECsCoL_3$	−5 80
HPMSP	DB24C8	CoL_2E	−5.69
HPMB'P	DB24C8	CoL_2E	−4.75
HPMBP	DB24C8	CoL_2E	−4.53

$^*\log K_{i,j} = \log D_{Co} - i\log[HL]_{org} - j\log[E]_{org} - i\text{pH}$
$\Delta\log K_{i,j} \pm 0\,05\text{–}0\,10$

Taking arbitrarily $\log[Cs^+] = 0$, conditional extraction equilibrium constants have been determined. They are summarized in Table 1. No noticeable effect was observed by replacing CsCl by $CsNO_3$.

Comparison of cobalt extraction from 1M CsCl medium with those performed from other similar media (KCl, NaCl, LiCl, $SrCl_2$, $BaCl_2$)

The extraction of $Co(PMBP)_2DB24C8$ does not depend on the aqueous medium (CbCl,

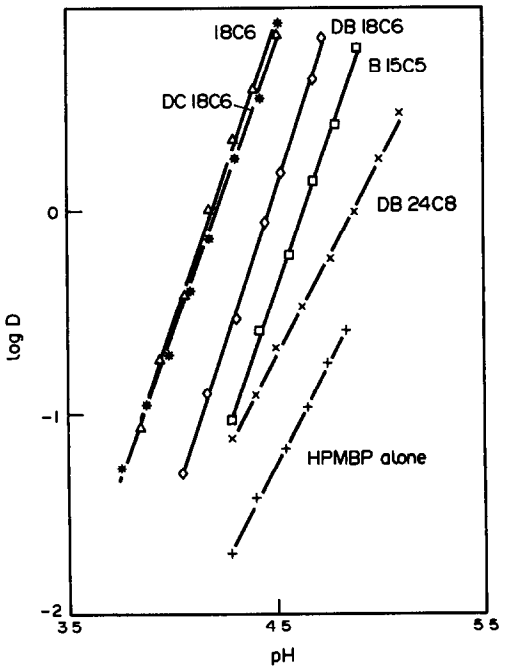

Fig 1. Distribution curves of cobalt from 1*M* CsCl aqueous medium with HPMBP (0.02*M*) and crown ethers (0.02*M*) in chloroform. pH effect

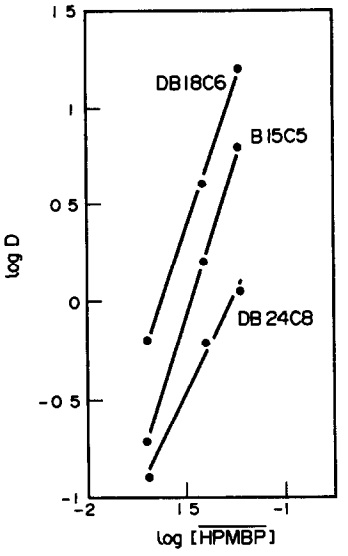

Fig 2. Distribution curves of cobalt from 1*M* CsCl aqueous medium at pH 4 4 with HPMBP and crown ethers (0 02*M*) in chloroform. [HPMBP] effect

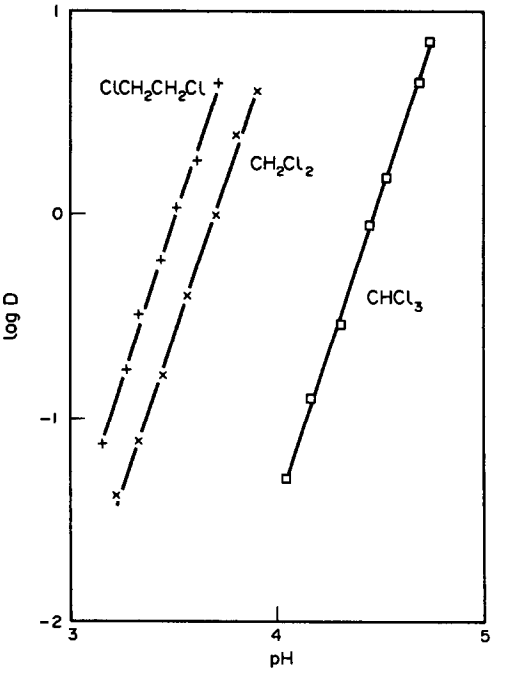

Fig 4 Distribution curves of cobalt from 1*M* CsCl aqueous medium with HPMBP (0.02*M*) and crown ethers (0 02*M*) in chloroform, dichloromethane and 1,2-dichloroethane pH effect

KCl, NaCl or LiCl): $\log K_{2,1}$ (−4.53) lies between values determined with linear polyethers, *e.g.* −4.17 with Triton X-100 and −4.82 with Butex,[13] which shows that there is no obvious cavity effect.

Like K^+[10] (ionic diameter 2.66 Å), Cs^+ (ionic diameter 3.34 Å) likely forms $(B15C5)_2Cs^+$ "sandwich" cationic complexes with B15C5 (cavity diameter 1.7–2.2 Å), which are co-extracted as ion pairs with Co $(PMBP)_3^-$ anions: the extractions performed from CsCl and KCl media ($\log K_{3,2} = -5.38$ and −5.40, respectively) are quite similar, which can be related with the close complex formation constants of Cs^+ and K^+ with "15C5" type crown ethers.[14] The extraction is higher than that performed from LiCl medium [extraction of Co $(PMBP)_2B15C5$ with $\log K_{2,1} = -4.8$].[10]

The cavity size of "18C6" type crown ethers (diameter 2.6–3.2 Å) allows the formation of

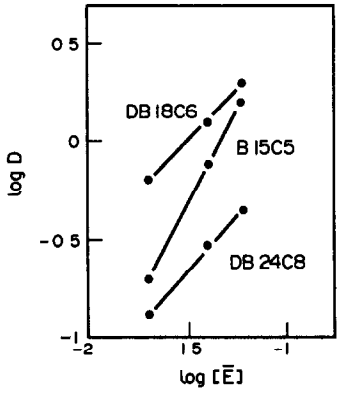

Fig 3. Distribution curves of cobalt from 1*M* CsCl aqueous medium at pH 4.4 with HPMBP (0.02*M*) and crown ethers in chloroform: [crown ether] effect.

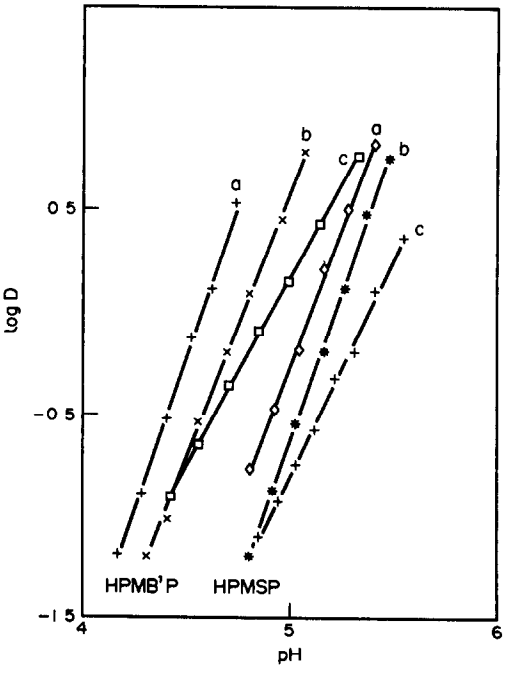

Fig. 5 Distribution curves of cobalt from 1*M* CsCl aqueous medium with HPMB'P or HPMSP (0 02*M*) and crown ethers (0.02*M*) in chloroform· pH effect (a = DB18C6, b = B15C5, c = DB24C8).

stable inclusion complexes with K^+ whereas Cs^+ is slightly too large to enter into the cavity, which leads to lower complex formation constants K_f: for example, in water, $\log K_f$ (18C6, K^+) = 2.03 whereas $\log K_f$ (18C6,Cs^+) = 0.99.[15] Thus, a better extraction of ("18C6")K^+, $Co(PMBP)_3^-$ than ("18C6")Cs^+,$Co(PMBP)_3^-$ could be expected. In fact, the opposite is observed emphasizing the better extractability (lipophilicity + ion pair stability) of the cesium containing ion pairs. The cobalt extraction from CsCl aqueous medium with HPMBP and "18C6" crown ethers is minimum with DB18C6, that is the weakest complexing agent towards Cs^+ [$\log K_f$ (DB18C6,Cs^+) = 0.83],[15] but also the least flexible ligand From LiCl and NaCl media, only Co $(PMBP)_2$DB18C8 species are extracted (40% of extracted cobalt at pH = 5, with $[DB18C6]_{org} = [HPMBP]_{org} = 0.02M$). It results in a lower cobalt extraction than those performed from 1*M* CsCl and KCl media (95 and 91%, respectively). Loading aqueous phases with Sr^{2+} or Ba^{2+} also improves cobalt extraction (80 and 65% from 0.33*M* $SrCl_2$ and $BaCl_2$ media, respectively.

Influence of cesium concentration on cobalt extraction

In order to estimate the influence which the variation of cesium concentration exercises on cobalt extraction with mixtures of HPMBP and DB18C6, extraction experiments have been performed from ([CsCl] + [LiCl] = 1*M*) aqueous solutions with increasing [CsCl] from 0 to 1*M*, the cobalt extraction is progressively improved, and the DB18C6Cs^+,$Co(PMBP)_3^-$ extraction is characterized by an increase of $\log D_{Co}$ *vs.* pH curve slope from 2 [extraction of Co $(PMBP)_2$ DB18C8 alone] to 3. At pH = 5, with $[HPMBP]_{org} = [DB18C6]_{org} = 0.02M$, the extracted cobalt ratios are 40, 48, 58, 72 and 95% at [CsCl] = 0, 0.01, 0.05, 0 1 and 1*M*, respectively.

Diluent effect (*Fig.* 4)

Replacing chloroform by 1,2-dichloroethane and dichloromethane, leads to better synergistic extractions of cobalt from 1*M* CsCl solutions. Stoichiometries of extracted species remain unchanged, *i.e.* $Co(PMBP)_2$DB24C8 ($\log K_{2,1} = -3.07, -3.33$, respectively), DB18C6, Cs^+,$Co(PMBP)_3^-$ ($\log K_{3,1} = -3.77, -4.30$, respectively), and $(B15C5)_2Cs^+$,$Co(PMBP)_3^-$ ($\log K_{3,2} = -2.55, -3.15$ respectively). The extraction order, $ClCH_2CH_2Cl > CH_2Cl_2 > CHCl_3$, is that of diluent dielectric constants.

Effect of the acyl group of 4-acyl-pyrazol-5-ols on the extraction

Among 4-acyl-pyrazol-5-ols, HPMBP is certainly the most studied as a metal extractant. Nevertheless, its unsufficient lipophilicity limits its applications Thus, it was interesting to substitute its acyl = benzoyl group with more lipophilic para-*tert.*-butylbenzoyl and stearoyl groups, which leads to the more lipophilic, but less acidic HPMB'P and HPMSP chelating acidic extractants. Slope analysis of cobalt distribution curves (Fig 5) performed with mixtures of HPMB'P or HPMSP and B15C5, DB18C6 or DB24C8 crown ethers in chloroform has shown that the extracted species have the same composition as those extracted with HPMBP The extraction constants are given in Table 1. For each crown ether, they follow the order HPMBP > HPMB'P > HPMSP which is the decreasing order of the acidic character of the compounds, that means that the lack of acidity of HPMB'P and HPMSP is not counterbalanced by an increase of lipophilicity. The variations of $\log K_{3,1}$ (extraction of DB18C6, Cs^+,CoL_3^-) and those of $\log K_{3,2}$ [extraction of $(B15C5)_2Cs^+$,CoL_3^-] between HPMBP, HPMB'P and HPMSP, are close to those observed previously in the extraction of B^+, CoL_3^- where B^+ = methyl-tri-*n*-octylammonium,[12] which can be explained mainly by the CoL_3^- complex formation: indeed, these variations are weaker (by $\frac{2}{3}$) in the extraction of CoL_2DB24C8 species that involve only two L^- per cobalt.

CONCLUSIONS

The presence of cesium in aqueous phases can strongly enhance the extraction of cobalt (II) with mixtures of 4-acyl-pyrazol-5-ols (HL) and crown ethers (E): it is the case when sufficiently stable complexes are formed between Cs^+ and crown ethers, *e.g.* 18C6,Cs^+, DC18C6,Cs^+, DB18C6,Cs^+, and $(B15C5)_2Cs^+$, which are coextracted with CoL_3^- as ion pairs In spite of the better complexation of K^+ than Cs^+ with "18C6" type crown ethers, a greater synergistic effect is achieved in extractions from cesium containing solutions. When the crown ether cavity is too large in comparison with the Cs^+ size (DB24C8), only a weak synergistic effect is observed, due to extraction of CoL_2E complexes. In all cases, extractions are higher in diluents of high dielectric constant, and with HPMBP, more acidic but less lipophilic than

HPMB'P or HPMSP. Results herein emphasize how important the aqueous phase composition is, in extraction systems involving mixtures of acidic chelating extractants and crown ethers.

SIMULTANEOUS DETERMINATION OF AMOXYCILLIN AND DICLOXACILLIN IN CAPSULES BY POTENTIOMETRIC TITRIMETRY AND HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

EZZAT M ABDEL-MOETY,* MOHAMMAD A. ABOUNASSIF, EL-RASHEED A GAD-KARIEM and NASHAAT A. KHATTAB

Pharmaceutical Chemistry Department, College of Pharmacy, King Saud University, P O Box 2457, Riyadh-11451, Saudi Arabia

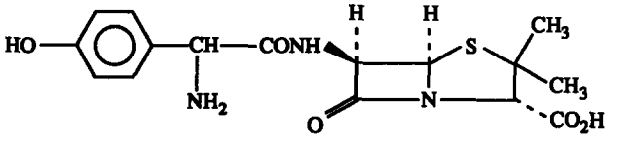
(*Received* 24 *October* 1991 *Revised* 10 *November* 1992 *Accepted* 10 *November* 1992)

Summary—Direct potentiometric titration and two HPLC conditions for the simultaneous determination of amoxycillin and dicloxacillin in their capsules have been developed One-run titration utilizing 0 05*M* acet. $HClO_4$ enables the quantification of both antibiotics The HPLC-separation could be undertaken on reversed phase, LiChrosorb RP-18 (10 μm), and LiChrospher 100 RP-18 (5 μm), columns by using mobile phases containing acetonitrile + 1% aq, acetic acid, in proportions of 47·53 or 39 61 (v/v), respectively, at a flow rate of 1 5 ml/min with UV-detection at 240 nm Recoveries of the individual drugs by the application of each described method were found to be fairly satisfactory

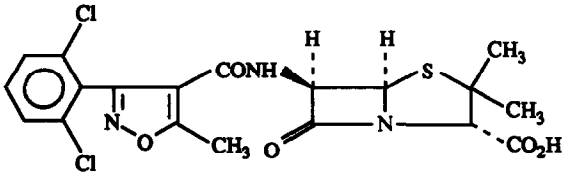
INTRODUCTION

Synergistic activity of some penicillin combinations was reported for gram-negative bacteria.[1-4] Combined penicillins provide a broader spectrum of antibacterial activity and may be advantageously prescribed in cases of β-lactamase-producing strains. Synergy between amoxycillin (I) and dicloxacillin (II) has been demonstrated against clinical isolates of some β-lactamase-producing and non-producing strains.[5,6] Pharmaceutical preparations containing both the mentioned β-lactam antibiotics are now normally found in the market.

There have been some different procedures of analysis proposed for the determination of amoxycillin, including spectrophotometric measurement of the copper chelate[7] or the penicillenic acid formed by reaction with H^+/Cu^{2+},[8] spectrofluorometry (Ex: 366 nm and EM: 430 nm) after reaction with formaldehyde, in addition to high-performance liquid chromatography (HPLC),[9] which is also the method of choice for dicloxacillin.[10] The British Pharmacopoeia 1988[11] recommends a titrimetric method for the determination of amoxycillin in bulk form using standard mercuric nitrate with potentiometric detection of the equivalent complex,



I Amoxycillin



II Dicloxacillin

*Author for correspondence.

and a colorimetric one using imidazole mercury reagent at 325 nm in the case of capsules containing the drug. No official procedure has yet been approved for dicloxacillin, although the method described for amoxycillin seems to be applicable Quantification of the individual penicillins in their binary combinations cannot be achieved by adopting the BP 1988 procedure. The applicability of the derivative spectrophotometry for simultaneous determination of amoxycillin and dicloxacillin in their mixtures and in capsules has been recently investigated.[12] Preliminary separation of amoxycillin from dicloxacillin, by dissolving in 0.1 mole/l hydrochloric acid, where only amoxycillin goes into solution leaving dicloxacillin, followed by adopting the ferric hydroxamate method[13] is recommended by one of the manufacturers for the determination of each separated penicillin [14]

The present work describes a potentiometric titrimetry and two HPLC procedures for simultaneous determination of amoxycillin and dicloxacillin in pharmaceutical formulations. The stability-indicating characteristics, *i.e* determination of the intact drug substance in the presence of its degradation product(s), and statistical evaluation of the results have been discussed.

EXPERIMENTAL

Apparatus

Potentiograph model E576, equipped with Dosimat E575 and magnetic stirrer E649 (Metrohm, Herisau, Switzerland), and combined glass–calomel electrodes were used for recording potentiometric titration curves

Varian model 5000 Liquid Chromatograph equipped with a variable Varian UV-50 detector set at 240 nm, a Rheodyne model 7125 injector with a 20 μl sample loop, and a Varian model 9176 strip recorder (chart speed 0.5 cm/min), were used. The chromatographic parameters were controlled by a Varian Data System model CDS 111L. Two different columns, namely a Hibar prepacked LiChrosorb RP-18 (10 μm), 25 cm × 4 mm ø, and a Hibar prepacked LiChrospher 100 RP-18 (5 μm), 12.5 cm × 4 mm ø (E. Merck, Darmstadt, Germany), were utilized. Eluting solvent mixtures containing CH_3CN + 1% aq CH_3COOH, 47·53 (v/v), in case of LiChrosorb, and 39.61 (v/v), in case of LiChrospher, were kept isocratic at a rate of 1.5 ml/min.

Materials

Amoxycillin trihydrate. The drug was used as supplied (Gist-Brocades, Amsterdam, The Netherlands). Purity was assessed by the BP 1988 method[11] and found to be 99.1% (the water of crystallization content 12.6%).

Dicloxacillin monohydrate. The drug was utilized without further treatment, the claimed purity was 99.6% (the water of crystallization content 3.9%) (Gruppo Lepetit, S.p.A., Milan, Italy). The reference substances and dosage formulations containing them were stored in a dry cool place in tightly closed and moisture-proof containers.

Pharmaceutical preparations

Amoclox capsules are products of Memphis Chem Co., El-Zeitoun, Cairo, Egypt, BN490013; each capsule contains 250 mg amoxycillin (as trihydrate) and 250 mg dicloxacillin (as sodium monohydrate) and Miclox 250 capsules, produced by Misr Co. Pharm. Ind., S.S.A., El-Mataria, Cairo, Egypt, BN R127; each capsule contains 125 mg amoxycillin (as trihydrate) and 125 mg dicloxacillin (as sodium monohydrate)

HiPer Solv acetonitrile for HPLC (BDH-Chemicals, Poole, U.K.), and all-glass distilled water were used for preparing the mobile phase. All other chemicals were of analytical grade

Standard solutions

Acetic acid, 0.05*M* $HClO_4$ was prepared by adding 4.2 ml $HClO_4$ (72%, w/w) to about 900 ml glacial acetic acid, followed by 32 ml acetic anhydride and then cooling to room temperature (~22°C) before completing the volume to 1l with glacial acetic acid. The moisture content was checked by the micromethod of Karl–Fischer, and was adjusted to 0.01–0.2% by adding either acetic anhydride or water. Standardization of the freshly prepared solution was carried out against 0 5 g KH phthalate to get the correction factor (f).

Analytical procedures. Potentiometric titrimetry

Authentic amoxycillin or dicloxacillin. An aliquot of the drug (50–75 mg) was weighed and dissolved in 25 ml glacial acetic acid. The titration curve was recorded using standard 0.05*M* acetic $HClO_4$. The amount C (mg) of penicillin was computed from the expressions:

$$C \text{ (mg) amoxycillin (anhydrous)} = V \times f \times 18.270 \quad (1)$$

where V is the volume of titrant (protonation of the amino group) and f is the correction factor. The equivalent factor (F) 18.270 is the amount (milligrammes) of anhydrous amoxycillin equivalent to each millilitre of the titrant. The F-value for the trihydrated base is 20.970.

$$C \text{ (mg) dicloxacillin (anhydrous)} = V \times f \times 23.516 \quad (2)$$

where, V is V_1 or V_2 which are the volumes at EP_1 (protonation of the carboxylate group) and EP_2 (protonation of the basic nitrogen in the isoxazole at the 2-position), respectively. For pure dicloxacillin, the millilitres of V_1 equals exactly that of V_2. The equivalence value 23.516 is milligrammes of dicloxacillin equivalent to each millilitre of the titrant.

Authentic binary mixtures. A mixture containing equialiquots (50 mg each) of amoxycillin and dicloxacillin sodium was dissolved in 25 ml glacial acetic acid and the titration was completed with 0.05M acetic $HClO_4$. The V_1 [end point equivalent to the sum of the amino group (amoxycillin) and the carboxylate group (dicloxacillin)] and V_2 [end point corresponding to the basic centre in the isoxazole ring at position-2 (dicloxacillin alone)] were located. The content of amoxycillin and dicloxacillin can be calculated as follows:

$$C \text{ (mg) amoxycillin (anhydrous)} = (V_1 - V_2) \times f \times 18.270 \quad (3)$$

$$C \text{ (mg) dicloxacillin (anhydrous)} = V_2 \times f \times 23.516. \quad (4)$$

Sample determination. The content of at least 10 capsules was weighed and thoroughly mixed. From the powder, aliquot portions containing about 50–75 mg of each drug were taken and dissolved in 25 ml glacial acetic acid. Recording the titration curves was undertaken by using 0.05M acetic $HClO_4$ and applying equations (3) and (4) for computing the amounts of both penicillins

Recovery experiments. To one of two equal amounts of the capsule content, an accurately weighed aliquot of the drug to be evaluated was added and mixed. Each powder, with or without addition, was dissolved separately in 25 ml glacial acetic acid. The procedure described for sample determination was followed for getting the quantities of the component drugs. The volume increases of the titrant due to the added drug could be used for determination of the recovered amount in relation to the known added amount.

HPLC methods

Standard mixtures and series. For each drug substance, 25 mg was dissolved in the mobile phase up to 100 ml to get the stock solutions, *i.e.* 250 μg/ml. Mixtures containing both drugs were prepared by mixing equal amounts of the stock solution followed by proper dilution to obtain the required concentrations. From the stock solutions, different working solutions (25–125 μg/ml) were prepared by diluting aliquots with the mobile phase. Standard plots of each antibiotic were made by injecting replicates

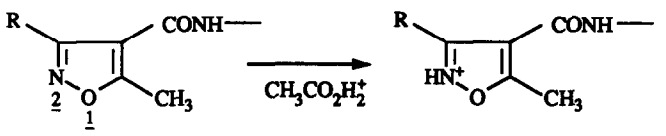
Sample preparation and determination The content of at least 20 capsules was weighed and the average content weight of a capsule was computed. Aliquots containing 25 mg of each drug were transferred into 100 ml volumetric flasks, and about 80 ml of the mobile phase added followed by mechanical shaking for 10 min before completing to volume with mobile phase. From each well-mixed solution, 3 ml portions were diluted with mobile phase into 10 ml. Triplicate injections of each sample were done alternatively with similar standard working solution in order to enable reliable sample-standard comparisons. Calculation of drug contents was undertaken either by matching the standard curves and/or adopting the following formula:

$$C \text{ (mg capsule)} = \frac{A_1 \times D \times C\% \times W_1}{A_2 \times W_2}$$

where A_1 and A_2 are the areas for amoxycillin or dicloxacillin in sample and standard, respectively, D is the dilution factor, W_1 and W_2 are the average weight (milligrammes) per capsule and the taken weight (milligrammes), respectively, and $C\%$ is the concentration (percent) of standard solution in the final dilution.

Recovery and reproductivity. Different ratios of standard to sample, namely 1:2, 2:3, 3·2 and 2:1, were prepared by diluting aliquots of the stock solutions with mobile phase. Triplicate injections of each solution mixture were done to ensure the degree of recovery of the added amounts of each drug. The reproducibility was tested by 12 consecutive injections of a standard solution equivalent to full amounts of each component based on the theoretical quantities

Chromatographic conditions. Two different HPLC-conditions, LiChrosorb RP-18 (10 μm) and LiChrosphere RP-18 (5 μm) columns



Scheme 1

utilizing different proportions of CH_3CN and 1% aq. CH_3COOH as the mobile phases, have been investigated and evaluated for their stability-indicating characteristics. The flow rate was 1.5 ml/min, the UV-detection was fixed at 240 nm, and the CDS-attenuation was 16 (5 mV/Fs) at 0.5 cm/min chart speed, in the two conditions.

RESULTS AND DISCUSSION

The application of the BP-1988[11] procedure, described for the determination of amoxycillin capsules, has been tried on specimen capsules containing amoxycillin and dicloxacillin combinations. The reaction products of the imidazole-mercury reagent with dicloxacillin exhibit overlapping maxima at the wavelength specified for amoxycillin. Even the binary mixtures containing both studied penicillin exhibit considerable UV-band overlap. At the practically justified λ_{max} for amoxycillin (227 and 274 nm), dicloxacillin exhibits considerable effective UV absorbance at about 275–280 nm, which makes the direct UV spectrophotometric determination of one penicillin in the presence of the other quite impracticable.

The potentiometric titrimetry described here depends on the fact that the amino groups of amoxycillin and the carboxylate groups of dicloxacillin are readily protonated together differentially from the dicloxacillin isoxazole basic ring, when treated with acetic perchloric acid. The direct linking of the heteroatoms N and O in the isoxazole ring of dicloxacillin has a base-weakening effect (pka 2.03), which is about 3 pka units weaker than oxazole. The lone pair of electrons on the nitrogen of 1,2-azole is not part of the aromatic sextet and is therefore available for salt formation without disruption of the aromaticity. Scheme 1 demonstrates the protonation pattern of the substituted isoxazole; The HPLC separation of the two component penicillins has been tried on the basis of finding out not only an accurate quantitative method but also one with good stability-indicating characteristics. Two different reverse-phase (RP) columns, namely LiChrosorb and LiChrospher, have revealed validity. Table 1 gives the LC parameters of the HPLC methods. Figures 1 and 2 illustrate the HPLC resolution of both penicillins and their degradation products, on the LiChrosorb and the LiChrospher columns, respectively. It is clear that the intact drug substances were resolved quite away from both of the solvent peaks and those of the degradation products. The selected chromatographic conditions seemed to be the best for indicating the drug stabilities. Table 2 collects and matches the obtained results of assay, recovery and reproducibility testing of the proposed three methods. Variations in results between the two different techniques, namely potentiometric protonation and liquid chromatography, are only in the drug assay of capsules. No clear explanation can be suggested, but it may be due to the variability of the capsules matrices or the poor stability-indicating characteristics of the potentiometric method. The high-performance liquid chromatography has achieved a pronounced advantage over some other techniques in being the most stability-indicating. Both the described HPLC methods have proved their advantage in the capability of finding the accurate contents of each

*Arithmetic mean

^+n = the average mean of at least two determinations of each encountered experiment

drug substance in the presence of its degradation products, although no justification of the decay products have been done in this study. Moreover, the quantification of both intact penicillins can be carried out simultaneously without possible interferences from the presence of the degradation fragments of both drug substances. The recovery testing of all the proposed methods indicates the good accuracy and precision. The statistical evaluations of the obtained recoveries demonstrate that there are no significant differences between the potentiometric method and each of the liquid chromatographic methods proposed in the present communication. Good reproducibilities of all the investigated methods have been observed for different replicates, as reflected in the relative low coefficient of variations.

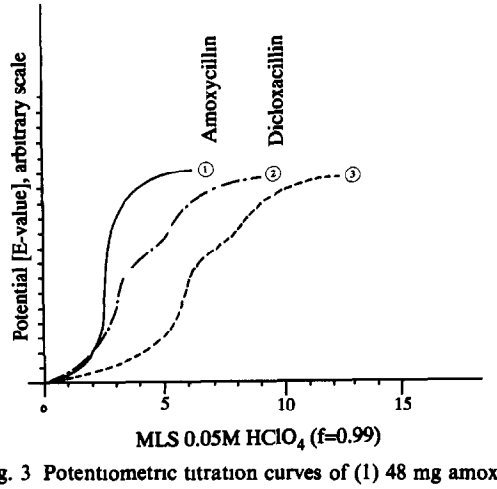

Fig. 3 Potentiometric titration curves of (1) 48 mg amoxycillin, (2) 54 mg dicloxacillin, and (3) a mixture of (1) and (2) against standard 0.05M (f = 0 99) acetic $HClO_4$.

It can be concluded that the demonstrated methods for the simultaneous quantification of amoxycillin and dicloxacillin in their mixtures and/or dosage formulations are simple, rapid and accurate. The relative cheapness of the apparatus beside the simplicity of the procedure of the non-aqueous potentiometry demonstrate its advantageous characteristics. The liquid chromatographic techniques described in the present work have the clear advantage of indicating the drug stability in addition to their high accuracy and confidence.

Summary—A new, general method of coupling calculations of equilibria with those of other chemical effects and processes is described The method, based on the use of simple empirical functions, is demonstrated by applying it to changes of ionic strength and temperature in speciation modelling

One of the most persistent criticisms of speciation models is that they are too simplistic: many systems, especially physiological or environmental systems,[1] it is said, are chemically much more complicated than we can, at present, properly simulate. Leaving aside the lack of understanding of scientific modelling often reflected by this kind of criticism, it is undeniable that equilibrium calculations are currently somewhat limited.[2] As outlined in Part I of this series,[3] they suffer from inadequacies in several thermodynamic respects, including how best to deal with changing conditions of temperature and ionic strength. Moreover, profound difficulties can arise when applications involve relationships between chemical species other than equilibrium interactions.[4,5] Kinetically-controlled systems fall into this category, as do biological or industrial processes regulated by feedback mechanisms.

The reason why speciation calculations are presently so limited is simple. Programs cannot be expanded indefinitely to cope with extra complexity. This is even though the various processes may be well understood and can be satisfactorily described in mathematical terms. The problem is to solve simultaneously multiple systems of equations that are inherently diverse, and sometimes very large. Not only is it theoretically difficult to amalgamate such different types of calculation but efforts to do so in a general way tend to overwhelm whatever computational capacity is available.

Accordingly, progress in coupling equilibrium with other calculations has been slow, despite the fact that this has been the focus of much research.[6] Resorting to brute force seems unlikely to yield, at least in the foreseeable future, the comprehensive modelling capabilities which motivated our development of JESS.[3]

This paper describes a general method for speciation calculations of complicated chemical systems which require extension beyond just solving conventional mass balance equations. As a specific case, it outlines how we have applied this method to overcome the difficulties which have hitherto restricted calculations of changing temperature and ionic strength. It should be noted that details of the algorithm used below are of secondary importance and are likely to be improved in future. Subsequent papers will detail the method's application to metal ion binding by macromolecules and to other complicated effects.

GENERAL METHOD

Partitioning the numerical computation of the solution of a heterogeneous set of non-linear equations implies an iterative approach in which successive, improving approximations are substituted into each of the equation subsets in turn. Such calculations yield a simultaneous, overall solution by convergence, *i.e.*, changes in the tentative solution produced by a full iterative cycle become negligible, as defined by some pre-determined tolerances. Whatever methods are used to improve the tentative solution from initial estimates to final values, the calculation

*Part II is *Talanta*, 1991, **38**, 1419[8]

performed in respect of each part of the iterative process should not counteract the progress made elsewhere. Otherwise, convergence becomes slow or, in the extreme, the iteration diverges

In essence, coupling calculations of equilibria with those of other chemical effects and processes can be simplified if the different types of equation can be partitioned, and evaluated separately, without compromising the chances, or the rate, of achieving convergence. This is not straightforward: attempts to evaluate equation subsets in isolation fail to converge except in special cases where the propagation of errors in any tentative solution is controlled. These well-behaved cases are, in general, difficult to derive rigorously, particularly if this must be done *a priori* Consequently, attempts to tackle complicated calculations by partitioning the system's equations are frequently unsuccessful.

A general method which helps to overcome this problem of partitioning is now being implemented in our JESS package for speciation calculations.[3] This is based on empirical expressions that we call "surrogate functions". These surrogate functions have four main characteristics:

(i) they are simple in form;
(ii) they are constructed to represent the main effects of selected subsets of equations,
(iii) their parameters are determined empirically, sometimes by optimization of data obtained from the behaviour of the subset of equations scanned over a range of conditions;
(iv) they are easily incorporated into the solution of the equations in the equilibrium calculations.

By substituting surrogate functions into other parts of a complicated calculation, the effects of their respective subset of equations can be emulated. In this way, error propagation in that stage of the iterative cycle can be substantially reduced and the likelihood of convergence failure through the partitioning of the calculation suppressed.

In addition to the simplification of calculations achieved by partitioning, there are other advantages to using surrogate functions. The most important of these is that the equation solving code can be generalized. This is because the simple form of the surrogate function can, over a suitably narrow range, stand in place of equations of considerably greater intricacy. The benefit of avoiding a tailor-made code is not only that standard, well-tried equation-solving methods can be applied but also that any subsequent alterations are much easier to implement because the highly specific segments of the program are well isolated. Another advantage of surrogate functions is that they can be applied directly to experimental data, even when the functional behaviour of the data has not been satisfactorily characterized

Much work has been done in the past on response surface analysis and experimental design.[7] There are some parallels between these approaches and surrogate functions in that both involve empirical data fitting, reduction in the number of empirical parameters and similar methods of choosing suitable functions. However, the key difference proposed here is in the use of the surrogate function to incorporate complicated effects into the solution of another, application-specific, set of equations (in this case for equilibrium modelling).

So far, we have experienced surprisingly few difficulties in implementing surrogate functions in JESS. Of course, the best way to formulate the empirical functions must be worked out in each particular case. It is necessary to decide on the variables to use, the number and the make-up of the terms to include and the number of degrees of freedom to permit. The initial range over which the surrogate function is to interpolate must be decided. Often this must be done arbitrarily in the first instance, but then information for making better choices tends to become available naturally after the first iterative cycle is complete. Significantly, the range may be narrowed as convergence approaches.

A SPECIFIC IMPLEMENTATION

The practical problems of modelling equilibria which must take account of changes in ionic strength (I) and temperature (T) were discussed in detail in Part I of this series [3] These stem mainly from the large number of correction methods available, especially for changes in ionic strength. This diversity makes it highly unsatisfactory to perform such corrections by interspersing conventional formulae within the body of the equilibrium calculations. To do so would introduce serious inflexibilities through lack of modularity in programming. It would also generate very bulky and cumbersome code. Moreover, the simulation procedure would

sometimes become prohibitively time-consuming: certain models involve many thousands of equilibrium constants and, to investigate the influence of ionic strength and temperature, would require all of them to be repeatedly recalculated.

For these reasons, JESS applies the user's choice of correction methods in a separate stage prior to the equilibrium calculations themselves. This isolates and minimizes the impact of what is necessarily a tedious step in the modelling procedure. It also permits JESS to offer a wide selection of approaches to ionic strength correction. Any desired combination of methods is possible because each reaction can be treated individually beforehand. The fact that particular methods of correction do not need to be "hardwired" into the speciation program code is therefore a tremendous advantage.

A set of computer programs has been developed to take data from any standard JESS Thermodynamic (JTH) database.[8] The information concerning how each equilibrium constant changes with respect to I and T is evaluated and expressed as a surrogate function. The surrogate functions employ a set of nine empirical parameters we call the "Constant Correction Coefficients" or CCCs. These are then passed on, via intermediate databases, to the equilibrium calculations. Thus, equilibrium constants (as $\log K$) can be obtained *at any required* I *and* T (within user-specified ranges) in an extremely efficient and flexible way during subsequent stages of the modelling procedure.

The major practical limitation of this approach is that users must nominate, at an early stage, the ranges of I and T over which they will later wish to perform their equilibrium calculations. The accuracy of the corrections is lessened if ranges are given which are either wider or narrower than those actually explored later on. However, the likely ranges of I and T are usually set by the overall context of the modelling and are mostly evident to users from the outset.

The surrogate functions for equilibrium constant correction

From the ranges of I and T specified by the user, JESS creates a two-dimensional grid of 3×3 points. A grid of nine points was considered to be adequate from two points of view. First, real changes of $\log K$ as a function of I and T are sufficiently smooth over fairly wide ranges. Secondly, in practice there will seldom exist sufficient primary data to justify a denser grid. JESS then applies the correction methods specified by the user to determine values of the equilibrium constants at each of the corresponding nine pairs of I and T values, as described below. The position of the midpoints is based on the available data and the ranges required and need not necessarily be in the middle of the ranges. A two-dimensional empirical function is then fitted exactly to the surface created by these nine points. This function can be described as follows.

At constant T, the function is

$$\log K = P_1 + \frac{P_2 I^{\frac{1}{2}}}{1 + I^{\frac{1}{2}}} + P_3 I$$

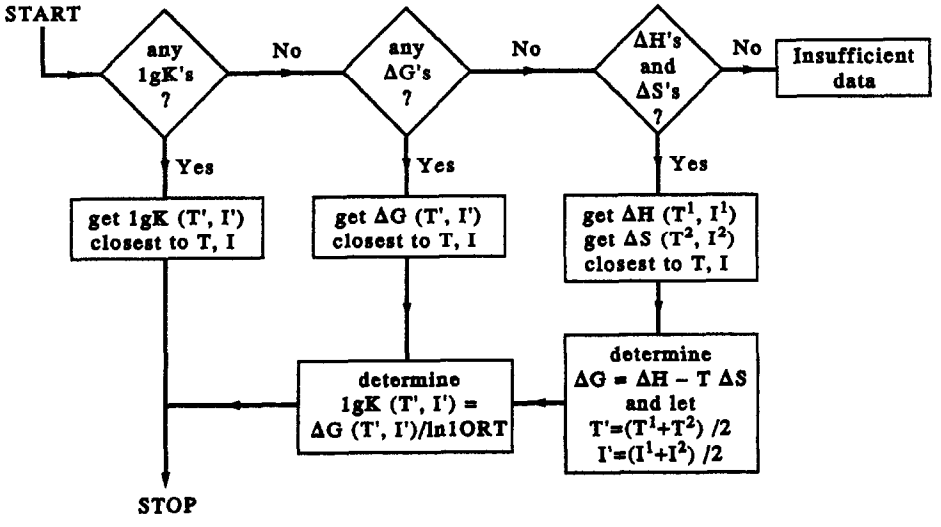

Fig. 1

This functional form was chosen to reflect an underlying theoretical model (of a Debye–Hückel type). Although it may not be accurate over large ranges it is almost certainly preferable to a simpler quadratic or cubic function.

The assumption is then made that, at constant I, each coefficient, P, is a quadratic function in T. This form was chosen because it is well known that a linear model is often adequate for modelling the change of $\log K$ with T and that by simply including a quadratic term its flexibility would be greatly enhanced. In this respect, it is relevant to note that "thermodynamics does not define [a] quantitative relationship between K and T"[9] and that a very wide variety of functional forms have been applied in the literature,[9] with little to favour any one in particular. Thus, we put

$$P_j = C_{1j}T^2 + C_{2j}T + C_{3j}.$$

Substituting the nine pairs of I and T values and their corresponding $\log K$s into these equations results in a system of linear equations which is solved to give the nine coefficients C_{ij}.

Algorithms for obtaining constants under given conditions

Although, for any given reaction, data can be stored in the thermodynamic database at many different Is and Ts, the data available are unlikely to fall precisely on the nine points required for the CCC grid. To obtain the $\log K$ for a particular grid point, the present algorithm simply selects the constant nearest to the I and T of the grid point and corrects it. The details are given in the following sections.

- Selecting the $\log K$ closest to a specified I and T
  If no $\log K$ values are found explicitly in the database, an attempt is made to determine an approximation from other thermodynamic parameters (free energy, enthalpy and entropy changes). The algorithm currently in use is shown in Fig. 1.

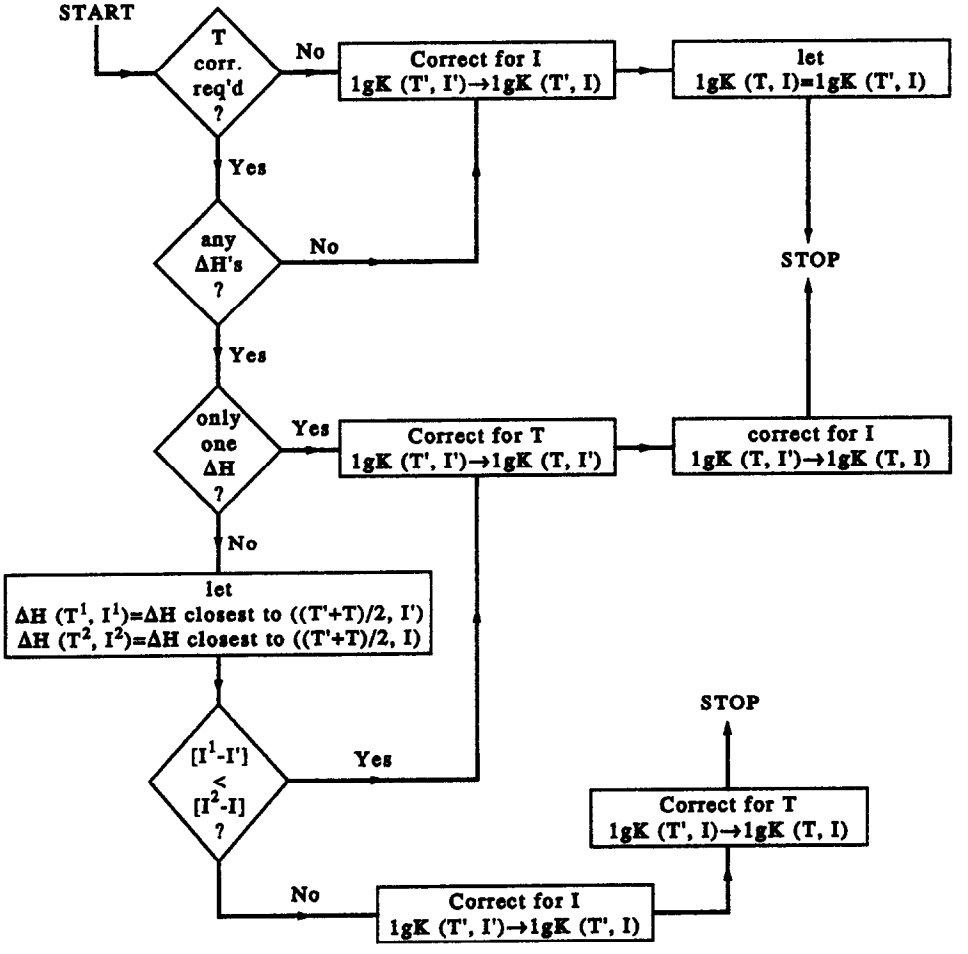

Fig. 2

If a series of constants (of any particular type) are found, the following objective function is evaluated to decide which value should be used.

$$U = |T - T'|/60 + |I - I'|$$

where I and T refer to the required conditions and I' and T' refer to the conditions under which the constant in the database applies. If the constant in the database refers to a range of conditions, I' and T' assume the upper or lower limit, whichever is closest to I and T. The constant with the lowest value of U is taken.

- Correcting a log K for I and T

Once the value of the equilibrium constant closest to the required conditions has been obtained, it is corrected using the methods selected for this purpose by the user. The user can specify activity coefficient calculation methods for individual species in the Thermodynamic database. It is possible either to invoke these or to override them with a global method. Figure 2 shows the current algorithm for correcting from (I', T') to (I, T).

RESULTS

To investigate the accuracy of interpolations using the above Constant Correction surrogate function, data for the following five reactions were examined.

$$H^+ + OH^- = H_2O \quad (1)$$

$$H^+ + F^- = HF \quad (2)$$

$$Zn^{2+} + F^- = ZnF^+ \quad (3)$$

$$H^+ + Phthalate^{2-} = HPhthalate^- \quad (4)$$

$$H^+ + Acetate^- = HAcetate \quad (5)$$

Tables 1–5 summarise the results obtained. When constants were corrected for ionic strength, the Davies equation was used to calculate the activity coefficient for all charged species:

$$-\log \gamma = \frac{Az^2\sqrt{I}}{1+\sqrt{I}} + 0.3Az^2$$

where A was calculated as in Ref. 10.

The following formula was used for uncharged species:

$$-\log \gamma = -0.1I$$

*Used in determination of CCC function

Temperature corrections were made with the following formula.

$$\ln K_2 = \ln K_1 + \frac{\Delta H}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

where R = gas constant.

Since the purpose of this exercise was to investigate how well CCC functions fit observed data (not how well constants can be corrected), the T and I ranges were chosen such that inaccuracies due to correction of constants (for T and I) were minimized. Accordingly, the following two conditions were satisfied wherever possible. First, the limits were set at points for which measured data were available. Secondly, reactions were selected such that there were sufficient intermediate points against which the interpolated constants could be directly compared These points were necessarily other than those whose data were used in the determination of the CCC function. The CCC functions, determined for each reaction (with T in °C), are given in Tables 1–5 in the Fortran format displayed by JESS.

CONCLUSION

The increasing use of chemical simulation for such purposes as optimizing industrial process streams, understanding molecular mechanisms of biochemistry and making decisions for environmental regulation must inevitably create demand for ever more sophisticated modelling capabilities. The method described in this paper based on surrogate functions is intended to facilitate such developments. How successful it will be in general is still unclear, although preliminary investigations of several possibilities appear promising.

It would seem that the surrogate function approach is particularly well-suited to correction of constants for I and T. This is probably because, on the whole, the change in a constant over quite significant (and useful) ranges can be adequately described by quite simple functions. Indeed, this provides one criterion by which to judge the suitability of any other potential application to the surrogate function method. Another is that the surrogate function should be easily incorporated into, and mathematically compatible with the solution of, the equations in the main application

The results presented here demonstrate that satisfactory interpolated values can be obtained from the proposed Constant Correction surrogate function. This is despite the fact that

particularly wide ranges of conditions were chosen. In real applications these ranges would usually be considerably smaller and thus the interpolations would probably be even more precise (assuming that satisfactory corrections for T and I were possible).

As might be expected, the deviations are greatest for interpolations at low ionic strengths when I ranges from zero to a high value ($1M$ and above). Here again, such extreme ranges would not normally be necessary in practice. One would generally know the approximate ionic strength of the system under investigation. Then, for example, one could choose ranges which were confined to one side or the other of the Debye–Hückel minimum (say between 0.0–0.3M and 0.3–3.0M for low and high ionic strength solutions, respectively). In such cases one might reasonably anticipate very satisfactory interpolations.

Finally, it is important to record that the particular methods of selecting constants described above are likely to change in the near future. For instance this will occur when, as foreshadowed,[3] we implement the JESS programs that modify observed and estimated thermodynamic values to achieve intermediate databases with better internal consistency However, we see no reason why these changes would negate the conclusions about surrogate functions that are drawn in this paper.

ION-PAIR CHROMATOGRAPHIC DETERMINATION OF CHROMIUM(VI)

A. V. PADARAUSKAS* and L G KAZLAUSKIENE
Department of Analytical Chemistry, University of Vilnius, 2734 Vilnius, Lithuania

(*Received* 18 *June* 1992. *Revised* 13 *October* 1992 *Accepted* 27 *October* 1992)

Summary—Ion-pair chromatography (IPC) with conductometric detection was investigated as a precise and selective analytical method for the determination of chromium in electro-plating solutions and waste waters. Chromatographic parameters were optimized for separation of Cr(VI) and SO_4^{2-} The analytical column (100 × 6 mm) was packed with 10 μm silasorb C_{18} (Czechoslovakia) Tetrabutylammonium butyrate (TBAB), at pH 7 0 in acetonitrile–water (18·82 v/v) mixture, was used as the eluent. Two samples of solution are taken for the analysis In the first of them the amount of Cr(VI) is determined, in the second one Cr(III) is oxidized to Cr(VI) with H_2O_2 in alkaline medium and the total amount of Cr is determined From the difference of the two obtained results the concentration of Cr(III) is calculated The detection limit of Cr(VI) is 0.1 μg/ml and the relative standard deviation (at the 1 0 μg/ml) is 4 0%. The IPC results for chromium agreed closely with these obtained by spectrophotometry

At present chromium is widely used in industry. Electroplating solutions containing Cr(III) salts, chromates or bichromates are suitable for chrome-plating and for etching and passivation of metallic details. Further, Cr(III) is less toxic than Cr(VI). Thus, when electroplating solutions and waste waters are controlled it is important to determine the concentration of both forms of chromium.

Precipitation[1,2] and titrimetric[3] analysis are used for determination of chromium in electroplating solutions most of all. However, the precipitation methods is time consuming and non-selective. Further, chemical methods of analysis are not sensitive enough for analysis of waste waters. Thus more sensitive spectrophotometry[4,5] or atomic-absorption spectrometry[6] (AAS) are used to determine chromium in waste waters. Fe(III), Cu(II), Hg(II), Mo(VI) and V(VI) interfere in the spectrophotometry determination of chromium with diphenylcarbazide. Iron can be masked with EDTA and vanadium, copper and molybdenum can be extracted into chloroform as oxine complexes, while mercury can be masked with chloride.[7,8] The additional operations prolong the analysis. AAS is non-selective for chromium forms.

Recently, ion-chromatography (IC)[9] has been very popular for anion determination in aqueous solution. Suppressed[10] and single column[11,12] IC have been used for the detection of Cr(VI), but these ions are very strongly retained in anion-exchange columns and so the chromatographic peaks obtained were very broad, which made accurate quantification difficult.

As an alternative to IC methods, is ion-pair chromatography (IPC).[13] It is more efficient and selective than IC and so is applicable to separate and determine inorganic, as well as organic and complex, ions.[14] With the help of IPC, in most cases chromium is determined as a chelate with 4-(2-pyridylazo)resorcinol using a spectrophotometric detector.[15,16] This technique is very sensitive and is used for the analysis of natural waters. However, this method is insufficiently selective because of the capability of a great number of metals to form analogous chelates.

In industrial waters it is more convenient to determine chromium in the form of CrO_4^{2-} when many of the other metals are in the form of cations and do not interfere in chromium determination. Furthermore, a conductometric detector can be used.

The objective of this study was to develop a IPC method for the determination of chromium in electroplating solutions and waste waters.

EXPERIMENTAL

Instrumentation

The work was done with an HPLC chromatograph manufactured in Russia (Tsvet 3006) and

equipped with a conductometric detector. The analytical column (100 × 6 mm) was packed with 10-μm silasorb C_{18} (Czechoslovakia)

The absorbances of standard and sample solutions were measured at 540 nm with KFK-2 photometer. The diphenylcarbazide method[5] was used.

Reagents and solutions

All chemicals were of analytical-reagent grade. The mobile phase was prepared by dissolving tetrabutylammonium hydroxide and butyric acid (TBAB) in mixtures of specified volumes of "pure for chromatography" grade acetonitrile and demineralized water. The eluent was filtered with a 0.22-μm membrane GS filter before use. Proper pH of the eluent was obtained with sodium hydroxide solution. The flow-rate was 2 ml/min

Analyte solutions were prepared by dissolving potassium chromate, chromium sulphate and potassium sulphate in demineralized water. The Cr(VI) and SO_4^{2-} standards were prepared daily from a standard stock solution. All analytes were determined on an elemental basis.

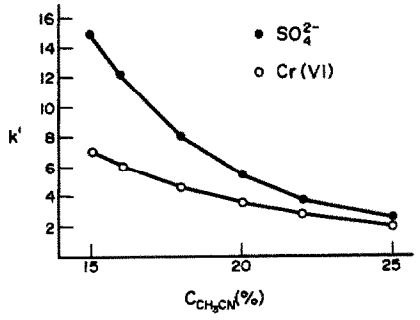

Fig. 2. Effect of CH_3CN concentration on the capacity factor (k') Eluent conditions 1mM TBAB, pH 7 0

RESULTS AND DISCUSSION

Influence of TBAB and acetonitrile concentration on Cr(VI) and SO_4^{2-} resolution

The influence of some inorganic anions which are generally present in water samples on Cr(VI) determination has been estimated first of all. According to our investigation single-charge anions F^-, Cl^-, NO_2^-, NO_3^-, $H_2PO_4^-$ at given conditions (mobile phase—1mM TBAB,75% H_2O, 25% CH_3CN, pH 7.0) are slightly retained and do not effect the determination of Cr(VI). Anions of W(VI) and Mo(VI) also do not interfere. But the selectivity of separation of SO_4^{2-} and Cr(VI) is bad, hence an optimization of the resolution of the anions has been made.

Figure 1 illustrates the effect of ion-pair reagent concentration in the mobile phase on the

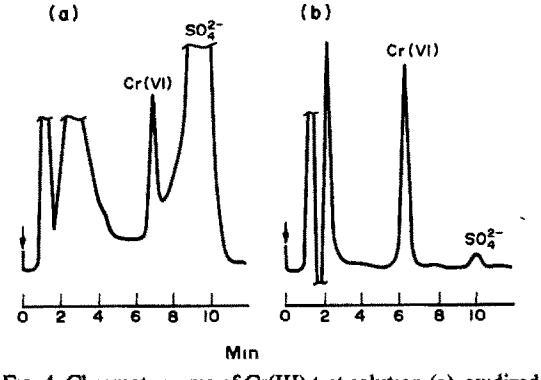

Fig 4 Chromatograms of Cr(III) test solution (a) oxidized with ammonium persulphate, (b) oxidized with hydrogen peroxide Eluent conditions 1mM TBAB, 82% H_2O, 18% CH_3CN, pH 7 0

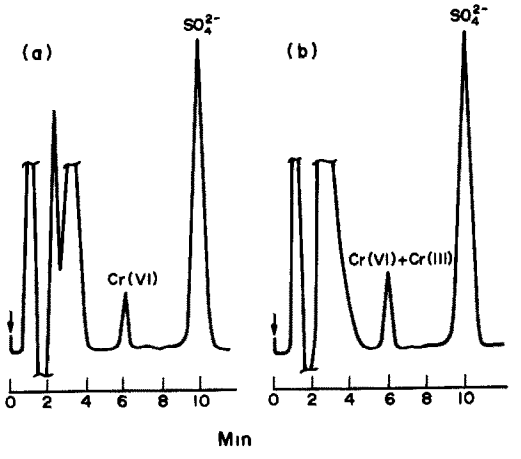

Fig 5 Chromatograms of waste water Eluent conditions as in Fig 4

retention of Cr(VI) and SO_4^{2-}. According to the results the retention and the selectivity of resolution increases with increasing TBAB concentration. The optima ion-pair reagent concentration in the mobile phase is 1.0–1.5 m*M*.

In Fig. 2 the dependence of retention of Cr(VI) and SO_4^{2-} upon CH_3CN concentration in the mobile phase is shown. The selectivity of resolution of anions tested increases with decreasing CH_3CN concentration and is optimal in the acetonitrile concentration range 15–20%.

Influence of eluent pH

Figure 3 illustrates the effect of mobile phase pH on the retention of anions tested. Retention of SO_4^{2-} ions increases with decreasing mobile phase pH. The explanation of the fact can be the decrease of mobile phase elution strength because of the protonation of the ion-pair reagent anion (butyrate) with increasing acidity (butyric acid's pK = 4.8).

There are two species of Cr(VI) in neutral medium—CrO_4^{2-} and $HCrO_4^-$ (chromic acid pK = 6.5). With increasing mobile phase acidity the equilibrium $CrO_4^{2-} + H^+ \leftrightarrows HCrO_4^-$ moves to the right, *i.e.*, the quantity of $HCrO_4^-$ ions increases. Competition of two contrary processes takes place in the system. Protonation of butyrate ions increases the retention of Cr(VI) ions. On the other hand protonation of Cr(VI) ions goes on too, therefore their charge and retention at the same time decreases. Besides that at pH < 6.5 the signal of Cr(VI) ions begins to decrease. That indicates dimerization of $HCrO_4^-$ ions with forming bichromate. Hence the dependence of Cr(VI) retention on mobile phase pH is determined by three factors: (1) protonation of butyrate ions; (2) protonation of chromate ions; (3) dimerisation of protonated chromate ions.

The optimal eluent for Cr(VI) determination is 1m*M* TBAB, 82% H_2O, 18% CH_3CN and pH 7.0.

Characteristics of Cr(VI) determination

The limit of detection of Cr(VI) was calculated as the concentration equivalent to three times the baseline noise (S/N = 3, sample injection volume of 100 μl) and is 0 1 μg/ml. The sensitivity of detection can be increased by increasing the sample loop size. The calibration plot for Cr(VI) peak area against concentration is linear in the range 0 15–20 μg/ml. Ten standard solutions containing 1.0 μg/ml Cr(VI) were analysed by the proposed method. The results had a relative standard deviation of 4.0%.

Oxidation of Cr(III) to Cr(VI)

In most cases the oxidation of Cr(III) to Cr(VI) is carried out by treating chromium with ammonium persulphate in acidic medium or with hydrogen peroxide in alkaline medium. Chromatograms of Cr(III) test solutions oxidized with ammonium persulphate (a) and with hydrogen peroxide (b) are shown in Fig. 4. If the oxidation with persulphate is carried out, a big quantity of SO_4^{2-} ions forms and the chromatographic column is overloaded. On the other hand hydrogen peroxide and it's reduction products do not interfere with the Cr(VI) determination.

Determination of Cr(III) and Cr(VI) in chromium electroplating solutions and waste waters

Two samples of solution were taken for the analysis. The first one was adjusted to pH 7–8 (if required), filtered and the amount of Cr(VI) was determined. The second one was adjusted to pH 9–10, and 0.1–0.5 ml of 30% H_2O_2 were added, the solution was boiled for 1–2 min, diluted, filtered, and the total amount of Cr(III) and Cr(VI) was determined. From the difference between the two results obtained the concentration of Cr(III) in the tested solution was calculated. Electroplating solutions were diluted 50–1000 times, and waste waters 2–5 times, or not at all. In Fig. 5 chromatograms of waste water from a television set plant are shown. Table 1 shows results of Cr(III) and Cr(VI) determination in chromium

Table 1 Cr(III) and Cr(VI) content in electroplating solutions and waste waters determined by IPC and spectrophotometric analysis

Sample	Element	Number	IPC	Spectrophotometry

COMPARISON OF PHOTOMETRY AND CONDUCTOMETRY FOR THE DETERMINATION OF TOTAL CARBONATE BY GAS PERMEATION FLOW INJECTION ANALYSIS

VLASTIMIL KUBÁŇ* and PURNENDU K. DASGUPTA†
Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 27 *October* 1992 *Accepted* 27 *October* 1992)

Summary—The experimental system involves the permeative preconcentration of CO_2 from an acidified sample through a tubular silicone rubber membrane into a suitable receptor. Procedures for measuring the CO_2 collected in the receptor by the absorbance change of an acid–base indicator incorporated in the receptor or by the conductance change of the receptor are compared. Previous theoretical considerations of the photometric system are augmented for numerical modeling and the theoretical behavior of the conductometric system is considered in detail. Experimental data generally conform to theoretical expectations. Based on either reproducibility or sensitivity, the conductometric measurement method using a solution of 1–10m*M* tris(hydroxymethylamino)methane as receptor is recommended. The interference from sulfite or sulfide can be eliminated by adding acidic permanganate to the sample, considerably more involved arrangements are necessary to eliminate interferences from cyanide.

The determination of total carbonate carbon is a crucially important measurement in a diverse variety of samples ranging from natural waters to beverages to physiological fluids. (For many real samples, total carbonate carbon is essentially the same as dissolved CO_2.) Unfortunately, specific chemistry to determine carbonate does not really exist. One reported procedure[1] utilizes the catalysis of the reaction between Cr(III) and edta by carbonate; however, even the catalyzed reaction is quite slow. This restricts the lower determination limit to $\sim 10\mu M$ and there may be interferences from chelating agents present in natural waters. Virtually all other existing procedures rely on adjustment of the sample pH to convert total carbonate to the free acid form, transport of a reproducible fraction of the CO_2 to a suitable receptor across an appropriate membrane and measurement of the transferred CO_2 via potentiometry[2], spectrophotometry[3–7] or conductometry.[8,9] Indeed, for the determination of CO_2 in biological fluids, this membrane-differentiated procedure has been in vogue since such a method was introduced for segmented flow analyzers. In many samples, most notably physiological fluids, carbonate species represent by far the dominant anions derived from a volatile weak acid and although the measurement itself is nonselective, no significant interferences are encountered. In potentiometric measurements, the transferred CO_2 changes the pH of the receptor and this pH change is directly sensed. Altogether, this measurement strategy is essentially the same as that of a potentiometric gas sensing electrode. It is obvious that the desired analytical performance parameters such as sensitivity and linear response range are dependent on the choice of the receptor. Compromises in one or the other parameter may be necessary in making such a choice, Van der Linden[10] has outlined the theoretical considerations. Photometric measurements of the pH change are less direct and further require the consideration of the choice of a suitable indicator, both in terms of its pK_a and spectral properties, as well as its concentration. These considerations have been outlined as well[10] and Cresol Red (CR) is the most commonly used indicator for this purpose. A fiber optic based fluorescence sensor using a receptor buffer and hydroxypyrene trisulfonate as the acid–base indicator has also been described.[11]

The conductometric measurement strategy is only indirectly related to a change in pH of the

*Permanent address: Department of Analytical Chemistry, Masaryk University, Kotlarska 2, CS-61137 Brno, Czechoslovakia.
†Author for correspondence

receptor. Considerations relating to the choice of a suitable buffer for conductometric sensing have never been outlined and will be considered in the next section.

Further alternatives to the above approaches are limited in scope. Precipitation as $CaCO_3$ and subsequent determination of the calcium by atomic absorption spectroscopy[12] has obvious sensitivity limitations. A polypyrrole electrode responds to carbonate[13] but it is neither completely selective nor stable in an aerobic environment.

Interferences may not be a problem in some sample types in the membrane differentiated approach, but in some others they are. Among the more common anions that can be potentially present in real samples, sulfite, sulfide and cyanide are the principal species derived from parent acids that are sufficiently volatile to be transferred across the membrane. Especially, the concurrent presence of sulfite and carbonate is common in many beverages. Linares *et al*[2] chose, for example, to determine the sum of carbonate and sulfite by potentiometry after membrane differentiated gas transfer, sulfite by an independent specific colorimetric procedure and carbonate by the difference of the two above results. Even in the absence of a specific colorimetric reaction for sulfite, it should be reasonably simple to differentiate this analyte from carbonate because SO_2 is a much stronger acid than CO_2 and by choosing a donor pH appropriately intermediate between the respective pK_a values, SO_2 transport can be vastly reduced. Differentiating CO_2 from H_2S or HCN, gases of comparable or weaker acid strength, is considerably more difficult. Adjustment of acceptor pH to limit ionization and thus discriminate against a weaker acid is of little value for gases like HCN which have a high intrinsic solubility in the unionized form.[14] To what extent it is possible to remove or minimize these interferences based on the different redox or complexing properties of these ions relative to carbonate, has not been reported.

The purpose of the present paper is to (a) delineate the theoretical considerations on the membrane-differentiated conductometric measurement technique as to the choice of a receptor, (b) compare the optimized conductometric technique with an optimized colorimetric technique and make recommendations as to the preferred procedure based on the observed results, and (c) explore the possibilities of minimizing the effects of the potential interferents.

PRINCIPLE OF THE CONDUCTOMETRIC METHOD

For simplicity, we shall consider a stationary receptor into which the CO_2 is transferred. Let us assume that the amount of the CO_2 absorbed and the receptor volume is such that there is a net increase of C_TM in total carbonate carbon in the receptor. We further assume that during the measurement cycle, the receptor solution is propelled to the detector and the peak signal is measured essentially without dispersion. There are two possible extreme compositions of the receptor: (a) water[8,9] and (b) a strong alkali such as NaOH. In the first case, the blank is negligible and the net signal may be given by:

$$S_{H_2O,net} = 1000([H^+]\lambda_{H^+} + [HCO_3^-]\lambda_{HCO_3^-} + 2[CO_3^{2-}]\lambda_{CO_3^{2-}} \quad (1)$$

where λ_i is the equivalent conductance of species i, concentrations are expressed in molar units and S is in units of μS/cm and

$$[HCO_3^-] = [H^+]K_1C_T/Q \quad (2)$$

$$[CO_3^{2-}] = K_1K_2C_T/Q \quad (3)$$

$$Q = [H^+]^2 + K_1[H^+] + K_1K_2 \quad (4)$$

K_1 and K_2 being the first and second dissociation constants of H_2CO_3. $[H^+]$ may be computed from an equation derived from the requirements of charge and mass balance:[15]

$$[H^+]^4 + K_1[H^+]^3 + (K_1K_2 - C_TK_1 - K_W)[H^+]^2 - K_1(2C_TK_2 + K_W)[H^+] - K_1K_2K_W = 0 \quad (5)$$

Figure 1(a) shows the expected signal as a function of C_T. Use of water as absorber results in high initial sensitivity and a negligible background conductance but very pronounced nonlinear response behavior. A nonlinear response behavior may be undesirable but by itself it is not the sole determinant of the utility of a method in an era where the exact response behavior can be easily stored in a computer's memory. The real problem is that the accuracy of the estimation depends acutely on the initial CO_2 content of the receptor because of the steep initial portion of the response. This initial content cannot be assumed simply from the background conductance of the receptor because in many real situations, CO_2 may not be the only adventitious impurity in the receptor water. Moreover, Fig. 1(a) assumes the efficiency of transport is independent of C_T. Because of poor ionization of CO_2 in pure water, in most real situations transmembrane transfer efficiency will decrease with increasing C_T and the overall

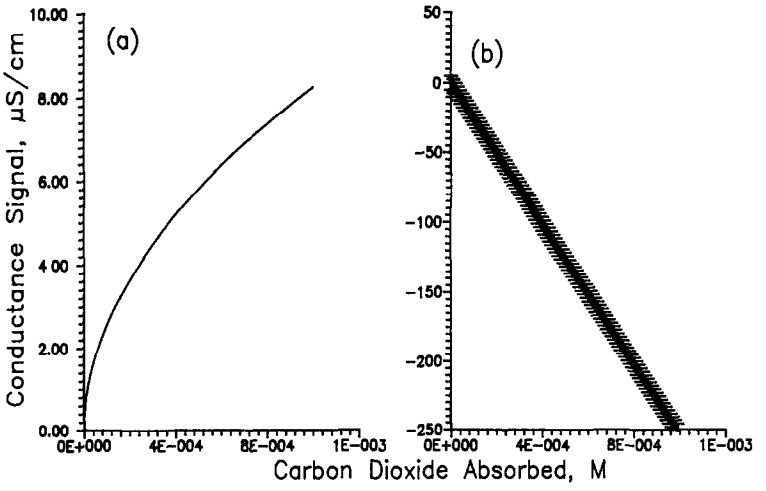

Fig 1 (a) Expected conductance signal with pure water as absorber, (b) expected conductance signal with pure NaOH as absorber

nonlinearity in response behavior would be much larger.

In contrast, the use of an absorber like NaOH results in conversion of the absorbed C_T into carbonate. If the original concentration of NaOH in the receptor is $C_{NaOH}M$, the background conductance $S_{Blank,NaOH}$ is given by

$$S_{Blank,NaOH} = 1000(\lambda_{Na^+} + \lambda_{OH^-})C_{NaOH} \quad (6)$$

When C_TM CO_2 is absorbed and $2C_TM$ NaOH is converted to Na_2CO_3 (obligatorily, $C_{NaOH} > 2C_T$), the sample conductance is:

$$S_{sample,NaOH} = 1000(\lambda_{Na^+}C_{NaOH} + \lambda_{OH^-}(C_{NaOH} - 2C_T) + 2\lambda_{CO_3^{2-}}C_T) \quad (7)$$

The net signal is therefore

$$S_{net,NaOH} = 2000(\lambda_{CO_3^{2-}} - \lambda_{OH^-})C_T \quad (8)$$

Note that not only is the net signal strictly linear with C_T, but the presence of adventitious impurities like NaCl or Na_2CO_3 in the receptor NaOH would make no difference in equation (8). It should also be noted that $\lambda_{OH^-} > \lambda_{CO_3^{2-}}$ *i.e.* S_{net} is negative. The necessity to cover some minimum range of C_T requires that some minimum concentration of NaOH be used as absorber. NaOH is highly conductive and results in a high background conductance. Consequently, although the sensitivity (slope of the calibration plot) given by equation (8) is high, the noise is also high and limits of detection are not necessarily improved. If we assume a noise equivalent of 1% of the background conductance, the situation is depicted in Fig. 1(b) for a 2mM NaOH absorber and the expected noise is shown as an error bar.

It is now obvious that a desirable absorber should have a low initial background conductance, good sensitivity and preferably linear response behavior. Can this be achieved with an appropriate buffer or weak base solution? Let us consider the solution of a weak base B with a dissociation constant K_a for its conjugate acid. The background conductance of such a receptor is shown in Fig. 2 as a function of pK_a and concentration. For clarity, the results are shown both in linear and logarithmic scales. It is obvious that too large a background conductance is detrimental in terms of achieving a good S/N. Therefore we consider next the effect of absorption of CO_2 by an absorber B with the pK_a of BH^+ being $\leqslant 9$. The conductance of the absorber solution after absorption of C_TM CO_2 is given by

$$S_{sample,B} = 1000(\lambda_{BH^+}[BH^+] + \lambda_{OH^-}[OH^-] + \lambda_{H^+}[H^+] + \lambda_{HCO_3^-}[HCO_3^-] + 2\lambda_{CO_3^{2-}}[CO_3^{2-}]) \quad (9)$$

The individual species concentrations are given by the standard acid–base equilibrium expressions:

$$[BH^+] = C_B[H^+]/(K_a + [H^+]). \quad (10)$$

where C_B is the total concentration of B and K_a is the dissociation constant of BH^+, and $[HCO_3^-]$ and $[CO_3^{2-}]$ have been given by equations (2) and (3). The relevant polynomial in $[H^+]$ can be solved by numerical iteration from the charge balance equation

$$[H^+] + [BH^+] - [OH^-] - [HCO_3^-] - 2[CO_3^{2-}] = 0 \quad (11)$$

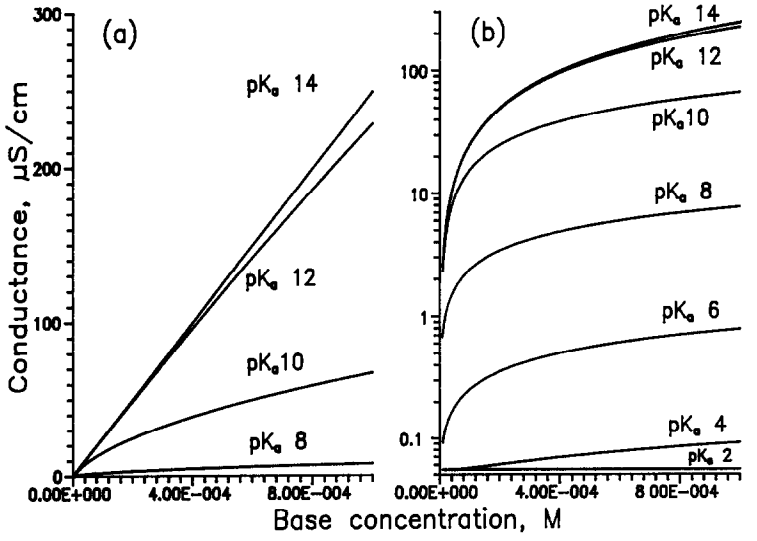

Fig. 2. Background conductance values of different base solutions as receptor as a function of pK$_a$ of the conjugate acid BH$^+$ and concentration The equivalent conductance of BH$^+$ is assumed to be 50 (a) Linear ordinate, (b) logarithmic ordinate

and the value of equation (9) can thus be computed. The net signal can be computed to be

$$S_{\text{net,B}} = S_{\text{sample,B}} - S_{\text{Blank,B}}. \qquad (12)$$

where $S_{\text{Blank,B}}$ is the value of equation (9) at $C_T = 0$. $S_{\text{sample,B}}$ is shown plotted in Fig. 3 for different pK$_a$ values, C_B was assumed to be $0.005M$ and λ_{BH^+} was assumed to be 50. The results indicate that in terms of linearity of response and background conductance, experimentation with bases with the pK$_a$ value of BH$^+$ being in the range of 6–8 may be recommended. However, it is actually inappropriate to assume that the blank receptor solution contains no absorbed CO_2. In a real situation, it is more practical to assume that the original receptor contains some initial dissolved CO_2, to the extent of $C_{T,i}$ molar To this, the sample adds additional CO_2 to the extent of C_T molar. Thus in computing $S_{\text{sample,B}}$ and $S_{\text{Blank,B}}$, respectively,

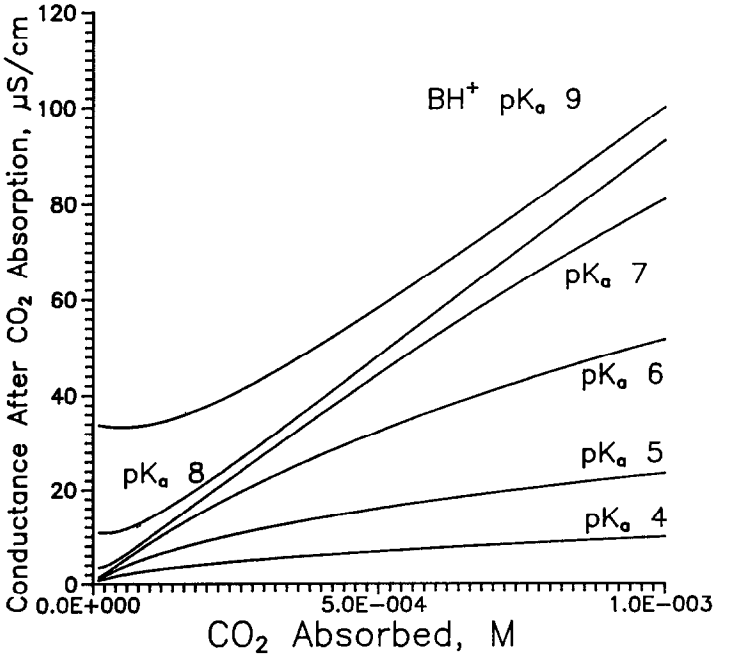

Fig. 3. Conductance of base receptor solutions upon CO_2 absorption The base concentration is assumed to be 5mM, λ_{BH^+} is assumed to be 50 and the pK$_a$ of BH$^+$ is indicated

$C_{T,i} + C_T$ and $C_{T,i}$ need to be substituted for C_T in equations (9)–(12). Consideration of Fig. 3 will indicate that the presence of some initial dissolved CO_2, up to the extent of *ca.* $2 \times 10^{-4}M$, will actually improve the linearity of response to further additions of CO_2 for receptors with conjugate acid pK_a values of $\geqslant 7$. It should also be noted that in Fig. 3 absorption efficiency has not been considered as a function of receptor pK_a. The pH of a 1mM solution of a weak base receptor varies from 8.5 to 9.5 as the pK_a varies from 6 to 8. At the low end of this pH scale, efficient absorption of CO_2 may not occur due to saturation of the solution at the membrane–receptor interface.

EXPERIMENTAL

Chemicals

Neutral Red (NR) and CR, were obtained from Aldrich Chemical and used without further purification. Buffer substances included 4-methylpyridine (4-Picoline, pK_a 6.1), bis-(2-hydroxymethyl)-imino-tris(hydroxymethyl)-methane (Bis–Tris, pK_a 6.5), 1,3-bis[tris(hydroxymethyl)methylamino]propane (BTP, pK_{a1} 6.8, pK_{a2} 9.0), morpholinopropanesulfonic acid (MOPS, pK_a 7.2), Tris(hydroxymethyl)-aminomethane (Tris, pK_a 8.1), and sodium carbonate/bicarbonate (all from Sigma/Aldrich Chemical). For unbuffered receptor solutions, carbonate free NaOH was added to 20–50μM indicator solutions to attain the desired pH or to water until the desired background conductivity was reached. For the donor stream, phthalate (0.05M, pH 4) and acetate (0.1M, pH 4.9) and 0.5M H_3PO_4 were tested.

Equipment

The manifold for the flow injection determination is shown in Fig. 4. All systems used the membrane permeation-preconcentration mode. In the colorimetric detection scheme, the sample and the modifier/conditioning reagent (0.5M H_3PO_4) are pumped together (model XV peristaltic pump, Alitea U.S.A., Medina, WA), mixed in a mixing coil MC and proceed through the jacket of a silicone membrane permeation device PU to waste. The active element of PU is a silicone membrane tube 120 mm long, 0.4 mm in i.d. and 0.6 mm in o.d.[16] PU constitutes the loop of the injection valve V and when it is switched to the inject position, the contents of PU are flushed by the receptor/indicator solution to the optical detector (Kratos Model 757). The amount of sample injected is dependent on the length of time the valve is in the load mode; except as indicated, load periods of 1 and 5 min were, respectively used to obtain the data reported here for the conductometric and photometric procedures. All conduit tubing were 0.7 mm in i.d.

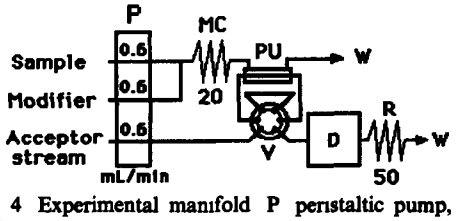

Fig. 4 Experimental manifold P peristaltic pump, MC: mixing coil, PU: silicone membrane permeation unit, V: six-port rotary valve, D: detector, R: restriction tubing, W: waste. Tubing length in cm is indicated (0.7 mm i.d.)

The conductometric detection manifold is identical, except that the membrane length was 18 cm unless otherwise noted and a model CDM-I conductivity detector (Dionex Corp.) was used. In experiments pertaining to the elimination of potential interferences, a solution of 100 mg/l $KMnO_4$ in 0.1M H_2SO_4 was used as the conditioning reagent. Depending on the quality of the H_2SO_4 used, it may be necessary to boil this solution to remove volatile acid gases before the addition of $KMnO_4$.

Software

MINSQ (Micromath Scientific Software, Salt Lake City, UT), a nonlinear least squares fitting routine that utilizes the Marquardt–Levenberg algorithm, was used for model fitting. The results were exported to GRAPHER (Golden Software, Golden, CO) for graphical presentation.

RESULTS AND DISCUSSION

Photometric determination

Based on considerations previously outlined,[6,14] the receptor pH should be minimally 2 pK_a units above that of the (first) dissociation constant of the permeant acid gas of interest. The pK_1 of H_2CO_3 being 6.3, a carbonate–bicarbonate buffer with a pH of *ca.* $\geqslant 8.3$ is therefore commonly used as receptor. Sensitivity considerations dictate that pK_{In} should not be drastically different from the receptor pH. Indeed, CR, the most common indicator used for the determination of CO_2, has a pK_{In} of 8.3. The base form of CR ($\lambda_{max} = 572$ nm)

absorbs more strongly than the acid form ($\lambda_{max} = 434$ nm). Monitoring a decrease in absorbance due to CO_2 transfer by following the absorption at 572 nm is more sensitive than monitoring an increase in absorbance at 434 nm. However, the background absorbance and baseline noise is also higher. In principle, NR has more desirable spectral characteristics for this application because the acid form ($\lambda_{max} = 530$ nm) absorbs more strongly than the base form ($\lambda_{max} = 450$ nm) and the increase in absorption due to CO_2 absorption can therefore be more sensitively monitored by measuring the acid form. However, NR has a pK_{In} of ~7, lower than that optimally desired. It has been previously reported[17] that the pK_{In} of NR is increased in the presence of anionic surfactants—the effective pK_{In} is 7.30, 7.82, 8.03 and 8.25, respectively in the presence of 1, 3, 5 and 10m*M* sodium dodecylsulfate (SDS) in a medium containing 10% ethanol. We experimented therefore with a receptor solution containing NR and 1m*M* SDS. Although the sensitivity did increase relative to a receptor without SDS, the extent was marginal (*ca.* 10%) and additional problems appeared because of vastly enhanced tendencies of bubble formation within the conduits or the permeation device. This in turn increased baseline noise and deteriorated reproducibility. It is interesting to note that the lack of a greater increase in sensitivity could be traced back to slower kinetics of the overall indicator reaction in the micellar medium. This avenue of investigation was therefore abandoned and further experiments continued with receptor buffers containing CR without any surfactant.

The high permeability of silicone membranes to carbon dioxide and oxygen is well known. When dimethylsilicone membranes were first introduced by General Electric Co., a particularly well publicized experiment showed the prolonged survival of rodents put in cages completely covered with silicone membrane, even when the latter were put under water.[18] A high permeability of the membrane to the analyte gas results in membrane limited transport only at high donor flow rates. Indeed, this is experimentally observed. As Fig. 5(a) indicates, the system does not become membrane transport limited until the donor flow is well in excess of 0.5 ml/min.

The membrane permeation system shows relatively rapid response, as indicated in Fig. 5(b). When the sample is changed from a blank to standard or vice-versa, full plateau response is attained by the second injection. The short term reproducibility of repeat injections of the same sample is excellent (rsd = 0.2%, $n = 15$). These characteristics are independent of the (colorimetric or conductometric) detection mode used.

The response of the buffer/indicator reaction system was studied at 50μ*M* indicator concentration at a constant total buffer concentration of 1m*M* (sodium carbonate + bicarbonate) with varying pH and also at a constant buffer pH of 9.0 with varying buffer concentration of

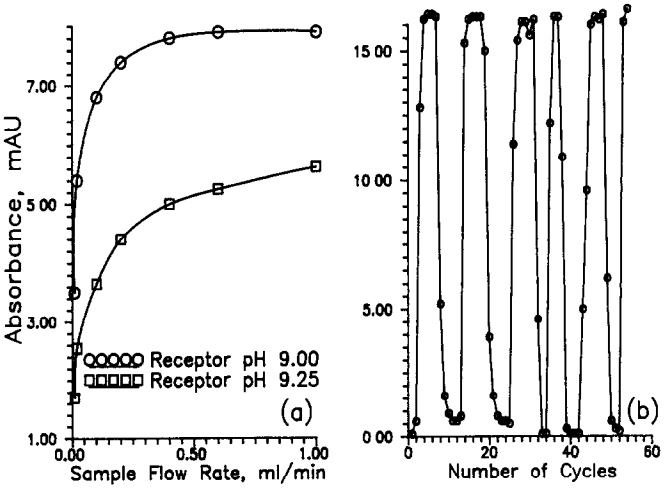

Fig. 5. Colorimetric determination system (a) Response as a function of donor flow rate, 1m*M* carbonate buffer of indicated pH, 50μ*M* CR, 3 min preconcentration of sample containing 1m*M* C_T, detection at 434 nm (b) Temporal response pattern for repeated analysis and alternation between a sample (0.25m*M* in C_T) and a blank Successive points plotted are 3 min apart Other conditions same as above

0–5mM. The results are shown in Fig. 6. The system can also be modeled numerically:

$$[Na^+] = C_{T,in}(K_1[H^+]_{in} + K_1K_2)/([H^+]_{in}^2 + K_1[H^+]_{in} + K_1K_2) + K_w/[H^+]_{in} + [In^-]_{in} - [H^+]_{in} \quad (13)$$

Where the subscript in denotes initial conditions, $C_{T,in}$ being the initial buffer concentration. The total indicator concentration C_{In} is distributed as

$$[In^-] = C_{In}K_{In}/([H^+] + K_{In}) \quad (14)$$

$$[HIn] = C_{In}[H^+]/([H^+] + K_{In}) \quad (15)$$

After the absorption of CO_2, the final concentration of total carbonate is

$$C_{T,fin} = C_{T,in} + [C_{T,analyte}]f \quad (16)$$

where a fraction f of the analyte C_T is transferred to the receptor. This fraction f can also be presumed to include the effects of dispersion in the flow injection system. $[H^+]_{fin}$ is then computed from

$$[H^+]_{fin} = C_{T,fin}(K_1[H^+]_{fin} + 2K_1K_2)/([H^+]_{fin}^2 + K_1[H^+]_{fin} + K_1K_2) + K_w/[H^+]_{fin} + C_{In}K_{In}/([H^+]_{fin} + K_{In}) - [Na^+] \quad (17)$$

and thence the absorbance signal can be computed:

$$Abs = C_{In}([H^+]_{fin}/(K_{In} + [H^+]_{fin}) - [H^+]_{in}/(K_{In} + [H^+]_{in}))\Delta\epsilon \quad (18)$$

where $\Delta\epsilon$ is the difference in molar absorptivities of the indicator in the acid and base forms, respectively at the wavelength of interest. Two of the data sets in each of Fig 6(a) and (b) were subjected to nonlinear least squares fitting with f and $\Delta\epsilon$ being adjustable parameters. Note that in each case, the two experimental data sets were treated collectively as one and the results shown are from a single fit. These results illustrate the general agreement of experimental results with theoretical expectations and also point out the problems inherent in photometric measurement of this type: nonlinear response and an acute dependence of the response on buffer concentration and its initial pH. In our experience, it is very difficult to reproduce the response behavior on a day-to-day basis, because of unavoidable CO_2 absorption by the receptor buffer. Accordingly, it is also difficult to quantitatively reproduce the results as new receptor solutions are made.

Conductometric determination

Figure 7(a) shows the results of experiments with the receptor being pure water and NaOH solutions of two different concentrations. The predicted linear response behavior was observed for the higher concentration NaOH absorber (the approximate concentration of the NaOH receptor in millimolar can be obtained by dividing the cited background conductance by 250; however, since some CO_2 contamination is unavoidable, it is more convenient to cite it in

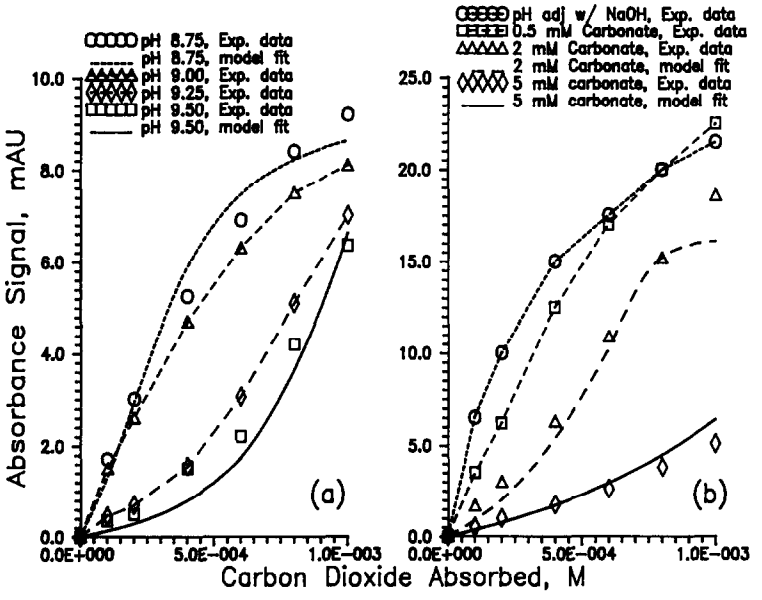

Fig. 6. Colorimetric system, conditions as in Fig 5 except 5 min preconcentration time (a) 1mM carbonate buffer, pH as indicated; (b) pH 9.0 carbonate buffer, concentration as indicated.

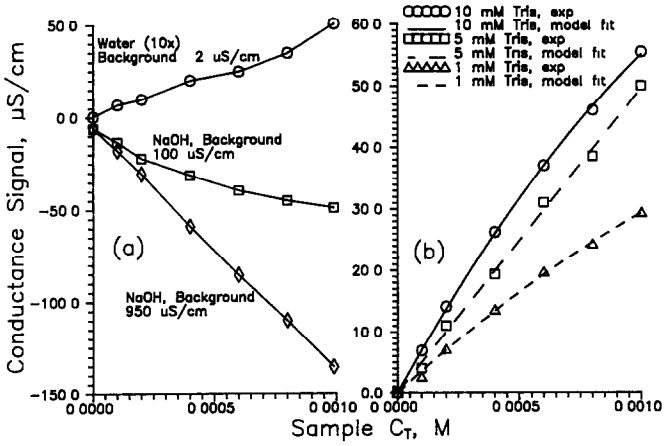

Fig 7 Conductometric system (a) Response using pure water and NaOH solutions as absorber (12 cm membrane) Note that the response is magnified by 10 for the water absorber (b) Response using different concentrations of Tris as absorber The lines shown are the best model fits to the experimental data shown as the points

terms of background conductance), over the C_T range studied but the absolute noise level was also high, as expected. With the lower concentration NaOH absorber, the response is linear only at low concentrations of C_T and even then the CO_2 already present in the absorber leads to a lower calibration slope than for the higher concentration absorber. At higher C_T values, C_T exceeds the absorber concentration and response nonlinearity becomes very pronounced. Day-to-day reproducibility of the signal with a low concentration absorber is also poor. The same problems relating to reproducibility and linearity of response also plagues the use of pure water as absorber. However, in this case even though the absolute sensitivity at higher C_T levels is quite low (note that the response is plotted with tenfold magnification), the background conductance is so low that background noise is very small; if the limit of detection was the only criterion, pure water should be the absorber of choice

Figure 7(b) shows the experimental results at three different concentrations of Tris as absorber, the most useful of the weak base absorbers studied, as detailed below. The points plotted are the experimental observations and the lines drawn represent best fit of the data to the model represented by equations (9)–(12) and (16) as modified by the allowance of a finite initial concentration of CO_2 already present in the absorber ($C_{T,i}$, *vide supra*). The CO_2 transfer efficiency through the membrane, [f, see equation (16)] and $C_{T,i}$ are the adjustable parameters the best fit values of which are obtained by the fitting procedure. It would appear that a satisfactory agreement exists between the model expectations and the observed results (λ_{BH^+} was assumed to be 40). However, the best fit values for f also consistently increase with increasing absorber concentration (that concomitantly results in higher initial absorber pH); this is not part of the model assumptions. The reason for this behavior is considered below along with the results observed for other absorbers. Meanwhile, although the absolute value of the response with a Tris absorber is substantially smaller than with NaOH, baseline noise is so much improved that relative reproducibility in the determination range tested is significantly better (rsd 0.5–1% for Tris *vs.* $\geqslant$2% for the higher concentration NaOH absorber). Comparable reproducibilities are also observed with other weak base absorbers. The response with the Tris absorbers are also very close to linear. We made no special efforts to determine limits of detection because the preconcentration protocol used in the present system can easily be extended to greater sampling periods for improving detection limits. It should be noted, however, that because of surface stagnation (*vide infra*), the relationship between the preconcentration period and the observed signal is not linear.

Figure 8(a) shows the experimental results obtained with several different receptors of different pK_a, all at a concentration of 1m*M*. Note that all the absorbers other than MOPS are of the free base type, thus the conductance is relatively low when the free base is put in solution (BTP is a diprotic base with a pK_2 of 9, the background conductance in this case is

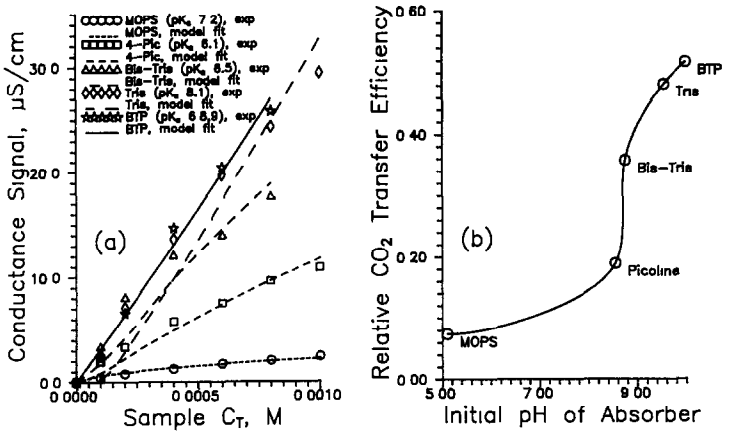

Fig 8 Conductometric system (a) Response using 1mM solutions of different weak bases (MOPS is used in zwitterionic form) as absorber (b) The best model fit values of the CO_2 transfer efficiency [f, equation (16)] as a function of the initial absorber pH

not negligible; the model equations were also modified for BTP to take into account its diprotic nature). MOPs, on the other hand, is a zwitterionic substance. The base form (*e.g.* the alkali metal salt) has a high background conductance and is not attractive. Experiments were therefore conducted with the zwitterionic form itself, even though it was recognized that this would result in a slightly acid absorber pH. Again, in most cases the experimental data (shown as the points) were reasonably fitted by the model (λ_{BH+} was assumed to be 40, 40, 35 and 30 for 4-picoline, Tris, Bis–Tris; λ_{BH+} was assumed to be 60 for BTP and the mobility of either the cationic or anionic form of MOPS was assumed to be 30). The best fit values of f are shown in Fig. 8(b) as a function of the initial absorber pH. The sigmoid dependence of the transfer efficiency on this parameter is clear. This suggests strongly that boundary layer stagnation can occur at the membrane–receptor interface. Such a dependence of f on the initial absorber pH would not have been observed if liquid phase diffusion within the receptor was sufficiently fast relative to the membrane-permeated flux of CO_2 for homogeneous equilibrium to exist in the receptor phase.

Interferences

If no measures are taken, sulfite, sulfide and cyanide all interfere in either the colorimetric or the conductometric procedure. However, the extent of response is not equal on an equimolar basis because of differences in the pK_a of the different acids as well as their different permeabilities through silicone rubber. For example, in the colorimetric procedure using 0.5M H_3PO_4 as the modifier, 1mM $NaHCO_3$ produces a signal of 15.7 mAU (3 min preconcentration, 2mM $NaHCO_3$ receptor) while the same signal is elicited by 0.68mM Na_2S. For KCN, 3.8mM produces a signal of 26 mAU and 0.75mM $NaHSO_3$ produces a much smaller signal of 2.15 mAU Similarly in the conductometric procedure using 1 mS/cm NaOH as absorber and 0.5M H_3PO_4 modifier, $NaHCO_3$, Na_2S, KCN and $NaHSO_3$ (all at 1mM concentration) respectively elicited signals of 149, 103, 17.1 and 17 μS/cm.

The use of a higher pH modifier, *e.g.* a 0.05M pH 4 potassium acid phthalate buffer, did not perceptibly reduce the signal from an $NaHCO_3$ sample. However, it was effective in reducing the interference from $NaHSO_3$ (by 75%, as measured by the colorimetric method), signals from cyanide or sulfide were predictably undiminished. It is noteworthy that the background signal was perceptibly affected when an acetate buffer (0.1mM, pH 4.9) was used as the modifier, presumably due to the permeation of volatile acetic acid. Further experiments to reduce the influence of interferents were limited to the conductometric procedure using 10mM Tris as the receptor. The interference from both sulfide and sulfite was completely eliminated using H_2SO_4–$KMnO_4$ as the modifier. However, the interference from cyanide continued unabated. Using a modifier of H_2O_2 (1 g/l) was found to be equally ineffective for cyanide. By adding an additional pumping channel to pump a metal salt [1mM $NiSO_4$ or $Fe_2(SO_4)_3$] at the same rate as the sample (0.6 ml/min) and merging this with the sample, followed by an 0.7 × 500 mm mixing coil prior to the existing

manifold shown in Fig. 4 (which then adds H_3PO_4 and so on), a study was carried out to see if the cyanide could be effectively removed by chelation. The reaction with Fe(III) was too slow to be of much utility; however, the use of Ni(II) eliminated >90% of the initial signal. Unfortunately, if sulfide is present, NiS is precipitated in the manifold, leading to complications. We find that cyanide can be effectively removed by oxidation only under alkaline conditions. To adopt this successfully in the present case, a relatively complex manifold is required. Alkaline permanganate prepared *in situ* in the manifold (the reagent is unstable; alkaline ferricyanide is ineffective and alkaline hypochlorite itself leads to volatile acid gases upon subsequent acidification), is added to the sample and this mixture is acidified before preconcentration. Details of this approach will be described in a subsequent publication addressing the measurement of CO_2 in process gases in the presence of SO_2, H_2S and HCN. It may also be noted that based on the differences between the pK of HCN and pK_1 of H_2CO_3, a two stage pH-based discrimination[14] between carbonate and cyanide is also possible. However, the required arrangement is not simple, either.

CONCLUSIONS

Measurement of total dissolved CO_2 in aqueous samples can be accomplished by a procedure involving acidification of the sample, permeation of the CO_2 through a silicone rubber membrane, and collection in a suitable receptor. Relative to the use of a photometric method utilizing an indicator solution in a carbonate–bicarbonate buffer, a conductometric procedure with a weak base receptor solution provides better day-to-day reproducibility, sensitivity and detection limits. A number of different weak bases may be useful for the purpose; based on our experience and its inexpensive availability in a pure form, Tris solutions (1–10m*M*) are recommended. The interference from sulfide and sulfite can be eliminated by using H_2SO_4–$KMnO_4$ as the sample acidifying/oxidizing agent. Significantly more elaborate efforts are required to eliminate the interference from cyanide

IODOMETRIC MICROGRAM DETERMINATION OF CHROMIUM(III) AND (VI) BY USE OF CHEMICAL AMPLIFICATION REACTIONS

A M EL-WAKIL, A B FARAG and M. S EL-NAHAS
Department of Chemistry, Faculty of Science, Mansoura University, Mansoura, Egypt

(*Received* 27 *April* 1992 *Revised* 6 *October* 1992 *Accepted* 23 *October* 1992)

Summary—A simple, rapid and sensitive method is described for the iodometric determination of microgram amounts of chromium(III), based on the oxidation of chromium(III) with periodate at pH 3 2, removal of the unreacted periodate by masking with molybdate and subsequent iodometric determination of the liberated iodate Chromium(VI) can be determined by this method after prior reduction to chromium(III) with sodium sulphite The method can also be used for the analysis of organochromium compounds

The determination of chromium(III) and (VI) in environmental and biological systems is of considerable interest.[1–3] Chromium(VI) may enter the drinking water distribution system from the corrosion inhibitors used in water pipes.[3] Chromium(III) and (VI) may also exist in very low concentrations in natural waters.[4]

Although some instrumental methods have been described [2–4] for the estimation of trace concentrations of chromium, iodometric amplification procedures, with their simplicity and sensitivity, [5–11] are still of special attraction and Besada[12] has described such a method for the determination of chromium(III).

The aim of the present study was to develop a rapid and accurate iodometric method for the determination of microgram amounts of chromium(III) and (VI) in aqueous solution and to explore the critical role of pH in the reactions used.

EXPERIMENTAL

Reagents

Unless otherwise specified, all reagents were of analytical reagent grade.

Ammonium molybdate solution. A 100-mg/ml aqueous solution of $(NH_4)_6Mo_7O_{24}.4H_2O$.

Potassium periodate solution. Prepared by dissolving 1.75 g of the recrystallized reagent in 500 ml of distilled water containing 3 ml of saturated borax solution.

*Sodium thiosulphate solution, 0.005*M. Standardized against potassium iodate solution.

Sodium sulphite solution. A saturated aqueous solution of the anhydrous salt.

Buffer solution, pH 3.2. Prepared by mixing 150 ml of glacial acetic acid with ~100 ml of water, then adjusting the pH with concentrated sodium acetate solution and diluting with water to 500 ml.

Chromium(VI) stock solution. Prepared by dissolving 0.2450 g of potassium dichromate in water acidified with two drops of concentrated sulphuric acid and diluting to volume in a 500-ml standard flask. Test solutions were prepared by further dilution.

Chromium(III) stock solution. Prepared by adding 0.5–1 ml of saturated sodium sulphite solution to a standard solution of chromium(VI), acidifying with 1 ml of 5*M* sulphuric acid, then removing the excess of sulphurous acid by boiling for 1–2 min. The pH was adjusted to around 3 with dilute sodium hydroxide solution.

Procedures

Determination of chromium(III). Transfer a known volume of chromium(III) solution (0.5–5 ml, containing 20–310 μg of Cr) to a 100-ml conical flask. Add 5 ml of potassium periodate solution, immediately adjust the pH to 3.0–3.2 by adding the buffer solution directly, and keep the solution for 0.5 hr at room temperature (20–27°). This method is easier and faster, but suffers from slightly higher blank values than those obtained by the alternative method, which is a little time-consuming, of

Table 1 Determination of various amounts of Cr(III) in aqueous media

Cr taken, μg	Cr* found, μg	Note
20 8	21 1 ± 0.8	Determination of Cr(III) after reduction of

300 0	300 1 ± 0 6	Cr(III) = 300 μg, Cr(VI) = 25–300 μg

*Average ± standard deviation (5 determinations)

adjustment to pH 3.0–3.2 with dilute sulphuric acid and/or sodium hydroxide solution and then leaving the reaction mixture for 0.5 hr at room temperature. At the end of this interval, in either case add 2 ml of the acetate buffer before adding 2 ml of the ammonium molybdate solution to mask the unreacted periodate. It should be remembered that heating increase the rate of oxidation of chromium(III) to chromium(VI) but also causes a concomitant increase in the blank values. Add a few crystals (20–40 mg) of solid potassium iodide and after a few minutes titrate the liberated iodine with sodium thiosulphate solution. Run a blank under the same conditions and apply any correction necessary.

Determination of chromium(VI). To a known volume of chromium(VI) solution (1–10 ml) containing up to 310 μg of chromium, in a 100-ml conical flask, add 0.5–1 ml of saturated sodium sulphite solution followed by 1 ml of 5*M* sulphuric acid. After about 1 min, boil the solution for 1 min to remove the excess of sulphurous acid. Adjust the pH to ~3 with dilute sodium hydroxide solution and determine the chromium(III) as above.

Analysis of chromium(III) and (VI) mixtures. Analyse an aliquot of the mixture according to the chromium(III) procedure; the volume of standard sodium thiosulphate solution required (*A* ml) is equivalent to the chromium(III). Treat another aliquot as for determination of chromium(VI), to obtain the sum of Cr(III) + Cr(VI) from the volume of standard sodium thiosulphate required (*B* ml). The volume of thiosulphate equivalent to the chromium(VI) present in the original mixture will be *B*–*A* ml.

Determination of chromium in organic compounds. Weigh accurately about 2 mg of sample, and digest it with 5 ml of saturated potassium chlorate solution and 5 ml of concentrated nitric acid, then evaporate the solution to dryness. Take up the salts in 5 ml of distilled water and follow the procedure for determination of chromium(VI).

RESULTS AND DISCUSSION

Besada[12] has published a method for iodometric determination of chromium(III), based on oxidation of Cr(III) to Cr(VI) with potassium periodate, masking the unreacted periodate with molybdate and subsequent iodometric determination of the chromium(VI) and iodate.

The oxidation of chromium(III) with periodate proceeds according to

$$2Cr^{3+} + 3IO_4^- + 4H_2O = Cr_2O_7^{2-} + 3IO_3^- + 8H^+ \quad (1)$$

which indicates that the reaction will be promoted by the use of low acidity. The iodate and

Table 2 Determination of sum of Cr(III) and Cr(VI) in aqueous media

Cr(III) + Cr(VI) taken, μg	Cr* found, μg
25 + 100	125 1 ± 0 8
50 + 100	150 5 ± 0 7
100 + 100	199.9 ± 0 8
200 + 100	299 9 ± 0 8

*Average ± standard deviation (5 determinations)

chromium(VI) liberated can oxidize iodide according to

$$IO_3^- + 5I^- + 6H^+ = 3I_2 + 3H_2O \quad (2)$$

$$Cr_2O_7^{2-} + 6I^- + 14H^+ = 2Cr^{3+} + 3I_2 + 7H_2O. \quad (3)$$

If both reactions (2) and (3) can occur, each initial chromium(III) ion leads to the liberation of 12 atoms of iodine. It has been found that reaction (1) is complete at room temperature within 0.5 hr in the pH range 3.1–5.5, but the rate of oxidation is lower at pH 2.9 and markedly decreased at pH 2.2. In addition, in reaction (2) the release of iodine for subsequent determination is remarkably slow at pH $\geq$ 4 but quantitative at pH $\sim$ 3. A comprehensive study on the critical role of pH in reaction (3) revealed some facts which are worth mentioning and should be considered in any similar investigations. Reaction (3) is strongly pH-dependent, as can be predicted from the standard redox potentials concerned, and is very slow at pH $\geq$ 2. It is quantitative and instantaneous at pH $\leq$ 1, but under these conditions the molybdate–periodate complex is at least partially decomposed,[13] and erroneously high results are obtained because of reaction of the liberated periodate with iodide. Aerial oxidation of iodide can also occur under these conditions. The blanks will be high and variable. However, reaction (3) (in acetate media) proceeds slowly at pH 2.2, taking a relatively long time for completion ($\sim$2.5 hr) and being accompanied by increased blank values, and proceeds extremely slowly at pH $\geq$ 3.1. It is interesting that in acidic media free from acetate ion and with pH adjusted with sulphuric acid, reaction (3) is even slower at pH 2.2. than the same reaction at pH 2.2. in the presence of acetate buffer. A pH around 3.2 is the best choice, giving a reasonable rate for reaction (1), meeting the recommendations of Burnel for the masking reaction[13] and allowing completion of the determination at a pH at which reaction (3) is not operative. There will then be only 9 atoms of iodine released per Cr(III) ion, but the method can be employed for the determination of chromium(III) in the presence of chromium(VI), or for the sum of the two after reduction of the chromium(VI) to the tervalent state.

Alternatively, the chromium(VI) could be directly determined iodometrically at pH $\sim$ 1 on the basis of equation (3). In the method based on reoxidation to chromium(VI), sodium sulphite was found to be the most suitable reducing agent for use in the prior reduction method, as its excess can be easily eliminated by boiling the solution. The procedures finally developed have been used for the determination of various microgram amounts of chromium(III) and/or chromium(VI), with the results shown in Tables 1 and 2.

Moreover, the proposed method has been successfully employed for the determination of chromium in organochromium compounds after their decomposition by acid digestion (or oxygen-flask combustion).[14] Representative results are given in Table 3.

The clear advantages of the proposed method are that it is not only applicable for the determination of chromium(III) in the presence of chromium(VI), but can also be used for the determination of both oxidation states in a mixture.

DETERMINATION OF TRACE THORIUM USING CATALYTIC–ADSORPTIVE STRIPPING VOLTAMMETRY OF THE THORIUM–CUPFERRON COMPLEX

ROSSI SETIADJI, JOSEPH WANG* and GILBERTO SANTANA-RIOS
Department of Chemistry and Biochemistry, New Mexico State University, Las Cruces, NM 88003, U S A

(*Received* 8 *September* 1992 *Accepted* 22 *October* 1992)

Summary—A sensitive stripping voltammetric procedure for trace measurement of thorium, based on the catalytic-adsorptive peak of the thorium–cupferron complex, is reported Optimal experimental conditions include the use of 1m*M* BES buffer solution (pH 5 5), containing 20μM cupferron, an accumulation potential of −0 80 V (*vs* Ag/AgCl), and a differential pulse potential scan The resulting stripping procedure offers improved sensitivity over a previous stripping scheme for thorium The limit of detection after 5 min preconcentration is 50 ng/l ($2 \times 10^{-10} M$), the response is linear up to $8 \times 10^{-8} M$, and the relative standard deviation at the $2\ 1 \times 10^{-8} M$ level is 4 4% Possible interferences are evaluated

Because of the importance of thorium in the nuclear industry, a sensitive and yet simple method for its determination is required. Spectrophotometric or neutron activation measurements of trace levels of thorium usually require lengthy procedures as well as expensive instrumentations.[1,2] Because of the extremely negative reduction potential of thorium, it cannot be determined by direct polarographic analysis.[3] However, indirect polarographic procedures based on complexation[4] or displacement[5] reactions have been reported. Lower detection limits can be achieved by adsorptive stripping voltammetry, based on coupling the complexation of thorium with Mordant Blue 9, with an adsorptive accumulation of the complex.[6]

The present paper describes an extremely sensitive stripping voltammetric procedure for trace measurements of thorium, based on the coupling of adsorptive accumulation and catalytic effects. This procedure relies on the role of cupferron as both a chelating agent and an oxidizing agent for thorium. A similar role of cupferron has been exploited recently for analogous measurements of trace molybdenum[7] and chromium.[8] The dual (adsorptive/catalytic) amplification effects result in improved sensitivity over a previous adsorptive stripping procedure for thorium. These improvements, as well as detailed optimization and characterization, are reported below.

*Author for correspondence.

EXPERIMENTAL

Apparatus and reagents

An EG&G PAR 264A voltammetric analyzer, a PAR 303A static mercury drop electrode and a PAR 0073 X-Y recorder were used to obtain the voltamperograms. All solutions were prepared from double-distilled water. Chemicals used were of analytical grade. The thorium and other metal atomic standard solutions (1000 mg/l.) were purchased from Aldrich. A 0.01*M* stock solution of cupferron (Aldrich) was prepared daily. An aqueous pH buffer stock solution containing 0.5*M* BES [*N*,*N*-bis(2-hydroxyethyl)-2-amino ethanesulfonic acid] (Aldrich) and 0.4*M* sodium hydroxide was prepared.

Procedure

A 10-ml volume of doubly distilled water was pipetted into the voltammetric cell. Next, 20 μl of the BES pH buffer (final concentration 1.0m*M*) and 20 μl of 0.01*M* cupferron stock solution (final concentration 20μM) were added. The pH of the solution was then adjusted to 5.50. After deaeration of the solution (by purging with nitrogen) for 8 min, an accumulation potential of −0.80 V (*vs.* Ag/AgCl) was applied to a fresh mercury drop, while the solution was stirred, for a predetermined period of time. Following the accumulation step, the stirring was stopped and after 15 sec, the background voltamperogram was obtained by ap-

plying differential pulse negative-going scan terminating at -1.40 V. A scan rate of 10 mV/sec and pulse amplitude of 50 mV were used. A known volume of thorium standard was then added and the accumulation-stripping cycle was repeated with a new mercury drop.

RESULTS AND DISCUSSION

Cyclic voltammetry

Figure 1 illustrates typical cyclic voltamperograms for 10 μg/l. ($4.3 \times 10^{-8} M$) thorium, in the presence of $2 \times 10^{-5} M$ cupferron recorded following 0 (a) and 60 (b) sec stirring at -0.80 V (*vs.* Ag/AgCl) in a medium containing 1.0mM BES buffer solution (pH 5.5). In the absence of prior accumulation, a small cathodic peak, associated with the reduction of the thorium-cupferron complex, is observed at -1.27 V. The reduction peak, observed also in the anodic branch (at a similar potential), is indicative of a catalytic process. No reductive response was observed for the free ligand under these conditions. A substantial increase of the cathodic peak is observed after the stirring period, indicating a significant accumulation onto the surface. Subsequent scans exhibit a substantial diminution of the complex cathodic peak (not shown), indicating rapid desorption of the complex from the surface. The fact that a well-defined cyclic voltammetric response is observed for μg/l. concentrations illustrates the remarkable sensitivity associated with the coupling of adsorptive accumulation and catalytic processes. Such processes can be summarized as follows.

$$[\text{Th(IV)-cupferron}]_{sol} \rightarrow [\text{Th(IV)-cupferron}]_{ads} \quad (1)$$

$$[\text{Th(IV)-cupferron}]_{ads} + e^- \rightarrow [\text{Th(III)-cupferron}]_{ads} \quad (2)$$

$$\text{cupferron}_{(red)} \qquad \text{cupferron}_{(ox)}$$

Reaction 2 corresponds to an EC mechanism which results in the catalytic-adsorptive wave. Hence, cupferron acts as both the complexing agent and the oxidizing agent, in a manner similar to that reported for analogous measurements of molybdenum[7] and chromium.[8] Such self-catalytic behavior eliminates the need for adding another oxidizing agent for performing the catalytic regeneration.

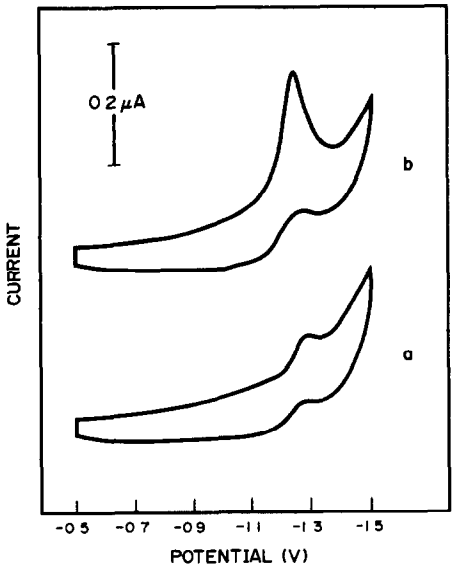

Fig 1 Cyclic voltamperograms for 10 μg/l. thorium in the presence of 20μM cupferron following 0 (a) and 60 (b) sec accumulation at -0.50 V (*vs.* Ag/AgCl) with 300 rpm stirring Scan rate, 50 mV/sec Electrolyte, 1mM BES (pH 5.5)

Optimized experimental conditions

The effective accumulation of the thorium–cupferron complex prior to the voltammetric scan can be exploited for a highly sensitive determination of thorium. Figure 2 displays stripping voltamperograms for 2.5 μg/l. of thorium following different preconcentration periods [0–120 sec, (*a*)–(*e*)]. The peak increases rapidly with increasing accumulation time, indicating an enrichment of surface concentration of the complex. The inherent sensitivity of the cupferron based procedure is indicated also from the well-defined response observed without accumulation (*a*). Figure 2 inset exhibits the resulting peak current *vs.* accumulation time plot for 2.5 (A) and 5.0 (B) μg/l. thorium. The peak current increases rapidly and linearly with the time at first and starts to level off at longer periods.

Other experimental variables affecting the adsorptive stripping response were studied and optimized. The dependence of the complex peak current on the ligand concentration is shown in

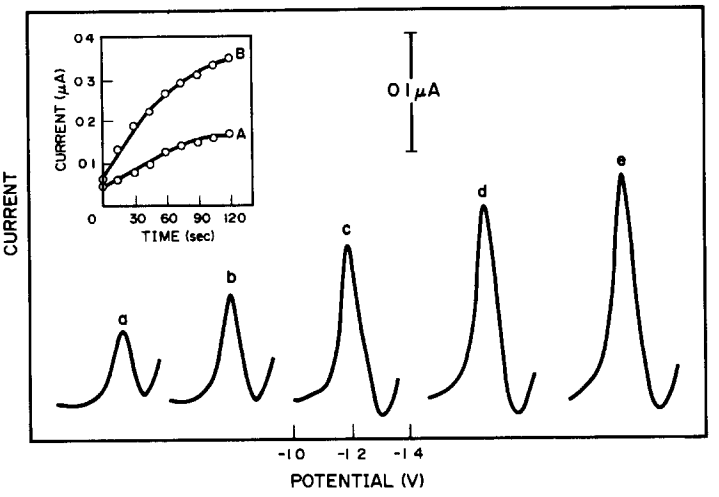

Fig 2 Voltamperograms for 2 5 μg/l thorium following 0 (a), 30 (b), 60 (c), 90 (d) and 120 (e) sec accumulation at −0 80 V Inset are the resulting current–accumulation time plots for 2 5 (A) and 5 0 (B) μg/l thorium Differential pulse waveform with 50 mV amplitude and 10 mV/sec scan rate Other conditions as in Fig 1

Fig. 3(A). The current increases linearly with the cupferron concentration up to 16μM and then it starts to level off. A concentration of 20μM cupferron was chosen for subsequent experiments. At higher cupferron concentration, high background current is observed owing to the fact that cupferron is electroactive and exhibits a well-defined peak at −1.24 V. The pH of the solution has a significant effect on the response of both cupferron and its thorium complex. Figure 3(B) illustrates the effect of pH on the stripping current. At pHs lower than 5.0, a large and stable cupferron reduction peak, which interferes with the complex quantitation, is observed. Such a peak is expected based on the known electroactivity of cupferron in acidic media.[9] Furthermore, the complex formation is slower at a more acidic solution. At pHs higher than 6.0, the response of the complex is smaller and rather unstable due to competitive hydroxide formation. All subsequent work used a 1mM BES pH buffer solution (pH 5.5). Other solutions tested, including an acetate buffer (0.25M, pH 5.5), 0.01M NH_4Cl, 0.01M PIPES, and 0.01M HEPES (all at pH 6.0), yielded inferior responses.

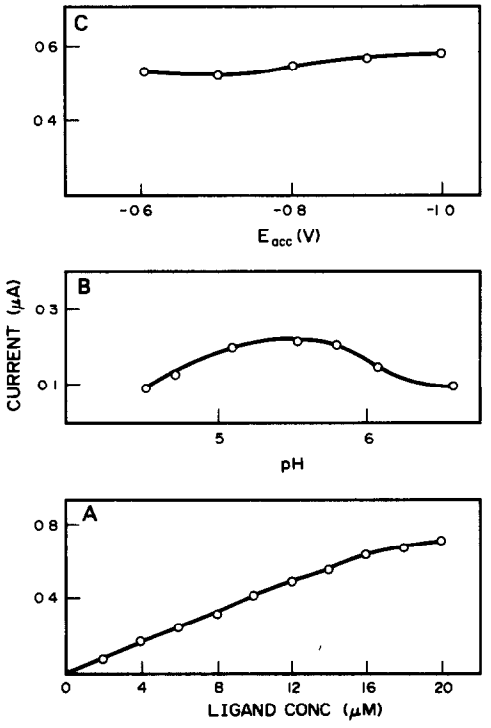

Fig. 3 Effect of cupferron concentration (A), solution pH (B), and accumulation potential on the response of 20 (A,C) and 10 (B) μg/l thorium. Accumulation time, 60 (A,C) and 30 (B) sec at −0 80 V (A,B). Other conditions as in Fig 2

The dependence of the complex peak current on the accumulation potential is shown in Fig. 3(C). The peak current increases slowly over the accumulation potential range from −0.60 to −1.00 V (*vs.* Ag/AgCl). The peak decreases rapidly at accumulation potentials higher than −1.10 V (not shown) which approach the reduction potential of the complex. Other optimal conditions include the use of differential pulse waveform with a 50 mV pulse height, 0.2 sec drop time, and a scan rate of 10 mV/sec.

Analytical performance

The analytical utility of the adsorptive stripping procedures depends on achieving a wide

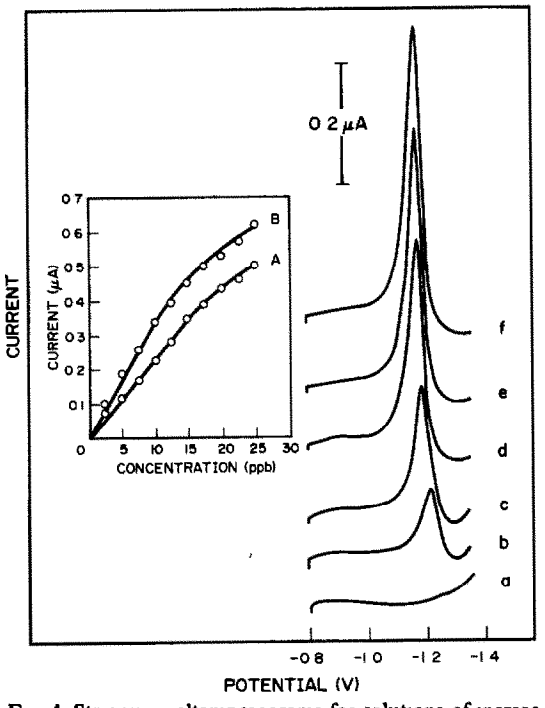

Fig 4 Stripping voltamperograms for solutions of increasing thorium concentration over the range 0–25 μg/l (a)–(f) Accumulation for 15 sec Inset are current–concentrations plots for 15 (A) and 45 (B) sec preconcentration Other conditions are as in Fig. 2

linear dynamic range, high sensitivity, good selectivity and high accuracy and precision. Figure 4 shows the voltammetric stripping response for solutions of increasing thorium concentration in 5 μg/l. steps (a)–(f). Well defined stripping peaks, which are proportional to thorium concentration, are observed following a short (15 sec) accumulation period. The resulting calibration plots, obtained with accumulation period of 15 (A) and 45 (B) sec, are also shown in Fig. 4 (inset). While the response recorded after 15 sec accumulation is linear over the range from 0 to 20 μg/l. thorium, the 45 sec data exhibit linearity only up to 15 μg/l. Both plots indicate curvature at higher thorium concentrations. The sensitivity of the procedure over the linear portion of the current–concentration plots is 21.4 and 28.7 nA l. μg^{-1} for 15 and 45 sec, respectively (correlation coefficients, 0.998). A detection limit of 0.05 μg/l. ($2.0 \times 10^{-10} M$) was estimated based on the signal-to-noise characteristics ($S/N = 3$) of the response to 0.5 μg/l. thorium following 5 min accumulation. This detection limit is lower than that of the Mordant Blue 9 stripping procedure.[6] Figure 5 compares adsorptive stripping voltamperograms for 0.5 (a) and 5.0 (b) μg/l. thorium, using cupferron (A) and Mordant Blue 9 (B) as the complexing agent. The inherent sensitivity of the cupferron-based procedure is apparent from a comparison with the azo dye based one. Notice, in particular, that the use of Mordant Blue 9 does not permit quantitation of 0.5 μg/l., while cupferron offers a well-defined response at this level.

The adsorptive accumulation of the thorium–cupferron complex results in reproducible stripping currents. The precision was estimated from 20 successive measurements of 5.0 μg/l. thorium following a 60-sec accumulation step. The mean peak current was 270.7 nA, with the range from 252.5 to 287.5 nA, and a relative standard deviation of 4.4%. Recovery experiments using river water spiked with known concentration of thorium yielded 96.4% accuracy.

No interference was observed upon adding 50 μg/l. of the following metals ions to a 5 μg/l. thorium solution: Bi(III), Cd(II), Cu(II), Fe(III), Hf(IV), Hg(II), La(III), Mn(II), Pb(II), Sb(V), and Sn(IV). Although additions of 25 μg/l. Nb(V), Te(IV), and Zn(II) resulted in the

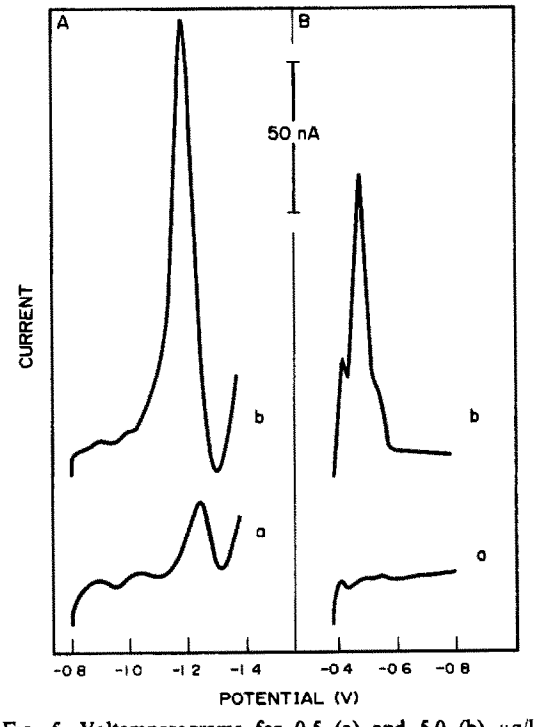

Fig. 5 Voltamperograms for 0 5 (a) and 5 0 (b) μg/l thorium, with cupferron (A) and Mordant Blue 9 (B), obtained following 5 (a) and 1 (b) min accumulation Solutions (A), 1m*M* BES pH 5 5 and 20μ*M* cupferron, and (B) 0.05*M* acetate buffer pH 6.5 and 2μ*M* Mordant Blue 9 Other conditions, (A) as in Fig. 2, (B) linear scan with 50 mV/sec, accumulation potential −0 38 V

appearance of new peaks (at −0.87, −0.97, and −0.98 V, respectively), only zinc and niobium cause *ca.* 50% diminution of the 5 μg/l. thorium peak. Al(III), Sc(III), and U(VI) resulted in overlapping peaks with thorium. Addition of 25 μg/l. Cr(VI), Ni(II), Ti(IV), V(V), W(V) and Zr(IV) caused the disappearance of the 5 μg/l. thorium peak. As a consequence, thorium should be isolated from these interfering elements prior to its determination. Severe interference from relevant ions such as Al(III), U(VI) or Ti(IV) characterize also the quantitation of thorium in the presence of Mordant Blue 9.[6]

In conclusion, under the optimum conditions, trace levels of thorium can be determined rapidly with a simple approach using the catalytic–adsorptive stripping peak of the thorium–cupferron complex. Such coupling of interfacial and catalytic processes offers higher sensitivity and a lower detection limit over a previously reported procedure. The attractive performance characteristics of the cupferron-based procedure, along with its instrumentation portability and low cost operation, should find wide applicability for measuring trace thorium in environmental and nuclear matrices. Such applications may require a prior removal of interfering elements.

USE OF *P*-DIMETHYLAMINOBENZALHYDE AS A COLOURED REAGENT FOR DETERMINATION OF GENTAMYCIN

HUAIYOU WANG,* JIANCHENG REN and YICI ZHANG†
Analysis and Test Centre, Shandong Teachers' University, Jinan 250014, People's Republic of China

(*Received* 2 *September* 1992 *Accepted* 22 *October* 1992)

Summary—Spectrophotometric determination of gentamycin is described. Gentamycin reacts with *p*-dimethylaminobenzalhyde in acetic acid/acetate buffer solution to form a Schiff base, a yellow complex, and its maximum absorption wavelength is 405 nm Effects of pH, kanamycin, streptomycin, beneylpenicillin, lincomycin and foreign ions on the determination of gentamycin have been examined. The absorbance for gentamycin from 0 to 74 40 μg/ml obeys Beer's law The linear regression equation of the calibration graph is $C = 103A - 0\,264$, with a linear regression correlation coefficient of 0.9997, and recovery from 97 to 101% The results obtained by this method agreed with those of the microbiological method This method is rapid and simple, and can be used for the determination of gentamycin in injection solutions of gentamycin sulphate

Gentamycin is a broad spectrum aligosaccharide antibiotic produced by *Micromonospora purpurea*. The present USP,[1] UP[2] and CP[3] requirements for this antibiotic estimate the total potency by a microbiological method. Wilson *et al.*[4] published a chemical method for quantitating the total potency of gentamycin after separation of impurities by TLC. However, the procedure is inconvenient. The determination of gentamycin by a colorimetric method based on gentamycin reaction with Cu^{2+} in basic medium to form an orange complex has been reported,[5,6] but the sensitivity is too low in these methods. Although the official microbiological assay estimates total potency, many foreign ions and biologically active impurities in drugs may interfere.[7]

This paper reports a rapid spectrophotometric method for estimating the total potency of gentamycin, which is based on a Schiff reaction,[8] *i.e.*, *p*-dimethylaminobenzalhyde reacts with amino of gentamycin molecule to form a Schiff base, a yellow complex. The principal advantage of this method is high sensitivity, which is two orders higher than that of the previous colorimetric method.[6]

EXPERIMENTAL

Apparatus

All the spectrophotometric measurements were made with a SHIMADZU UV-265 UV-vis recording spectrophotometer with matched 1-cm quartz cells. In order to compare all spectrophotometric measurements and ensure reproducible experimental conditions, the UV-265 spectrophotometer was checked daily. An acidimeter (Model pHS-3C, Shanghai Leici instruments factory, China) was used for pH adjustments.

Reagents

Gentamycin sulphate (624 μg/mg), kanamycin sulphate (784 μg/mg), streptomycin sulphate (741 μg/mg), beneylpenicillin (1607 μg/mg), lincomycin hydrochloride (838 μg/mg) were used as standards. (*Drugs and Biological Products Examination Bureau of China*). All reagents were of analytical-reagent grade, unless stated otherwise. Double-distilled water was used in all experiments.

Gentamycin sulphate standard solution. 1560 μg/ml. An accurately weighed 0.1250-g standard sample of gentamycin sulphate was dissolved in water, transferred into a 50-ml standard flask and diluted to the mark with water. It is stable for 5 days at 5°.

p-*Dimethylaminobenzalhyde solution*, 1% (v/w). *(Chemical Reagent Factory of Shanghai, China).* Accurately weighed 0.5000 g of *p*-dimethylaminobenzalhyde was dissolved in 25 ml of glacial acetic acid and diluted to the mark in a 50-ml standard flask with pH 4.1 acetic acid/acetate buffer solution. The solution was prepared fresh daily.

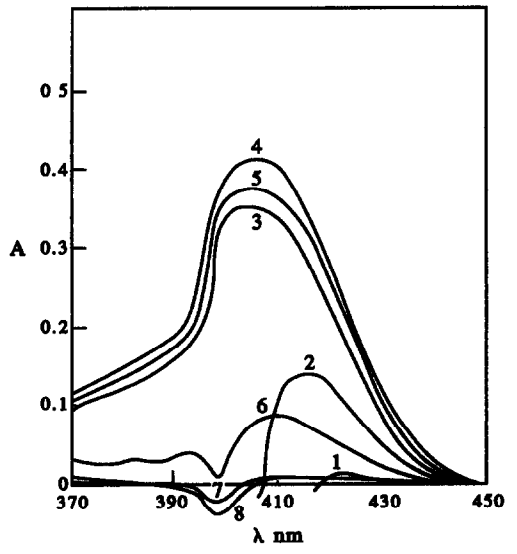

Fig 1 Effect of pH on the absorption spectrum of gentamycin complex

1 pH = 1 00	5 pH = 5 01
2 pH = 2 01	6 pH = 8 29
3 pH = 3 04	7 pH = 9 91
4 pH = 4 01	8 pH = 12 00

Procedure

A 0.50-ml portion of standard gentamycin sulphate solution was transferred into a 25-ml standard flask, and 2.0 ml of 1% *p*-dimethylaminobenzalhyde solution and 5 ml of pH 4.1 acetic acid/acetate buffer solution were added. The mixture was shaken and heated for 2 min in a boiling water bath, and then cooled to room temperature at once, diluted to the mark with water and mixed well. The absorbance of the gentamycin complex was measured at 405 nm against a reagent blank prepared with the same reagent concentration, but no gentamycin sulphate.

Absorption spectrum of gentamycin complex

A gentamycin complex solution prepared according to the procedure was scanned with the spectrophotometer and the absorption spectrum was recorded. The maximum absorption wavelength is 405 nm.

RESULTS AND DISCUSSION

Effect of pH

Comparative tests at various pH values show that the maximum absorption wavelength of the gentamycin complex changes with pH (Fig. 1). Variation of the pH from 1 to 12 was investigated. λ_{max} of the gentamycin complex is 405 nm in the range of pH 3 ~ 12, but the absorbance is different under the different pH conditions. The λ_{max} is 423 nm and 426 nm at pH 1 and 2, respectively. In addition, the absorbance spectrum was measured in the range of pH 3.7 ~ 4.5 at intervals of 0.2 pH using *p*-dimethylaminobenzalhyde prepared with glacial acetic acid. It was found that the maximum absorption wavelength is also 405 nm in the range of pH 3.7 ~ 4 5. Therefore, a pH 4.1 acetic acid/acetate buffer system was employed. The reasons for the negative absorbances at pH 9.9 and 12 are possibly due to refractive index effects or a pH-dependence of a blank constituent

Stability of gentamycin complex

According to the procedure, the gentamycin complex solution was heated for different times in a boiling water bath and the absorbance measured. The results are shown in Table 1. The colour formation of the gentamycin complex is slow at room temperature, but when heated for 2 min in a boiling water bath the absorbance reached its maximum. Heating for 2 min was selected as optimum. The absorbance of the complex remained stable for at least 8 hr at room temperature.

Effect of foreign ions

A systematic study was made of the effect of the ions commonly found, on the determination of 32.1 μg/ml gentamycin sulphate. A 500-mg/l. level of each potentially interfering ion was tested first. If interference occurred, the ratio was reduced progressively until interference ceased. The tolerance level was defined as an error not exceeding ±5% in the determination of the analyte. The results are summarized in Table 2.It is emphasized that under the selected conditions, kanamycin reacts with *p*-dimethylaminobenzalhyde to form a complex. The absorption spectra of the kanamycin and gentamycin complexes strongly overlap (Fig. 2).

Effect of amount of p-*dimethylaminobenzalhyde*

It was found that addition of 2.0 ml of 1% *p*-dimethylaminobenzalhyde was sufficient for

determining gentamycin up to 74.4 μg/ml (upper limit of linear range). Therefore, 2.0 ml of 1% *p*-dimethylaminobenzaldhyde solution is recommended.

Relationship between concentration of gentamycin and absorbance

Under the selected conditions, a linear relation was obtained between absorbance and concentration of gentamycin in the range of 0 ~ 74.40 μg/ml. The linear regression equation of the calibration graph is $C = 103A - 0.264$, with a correlation coefficient of linear regression of 0.9997.

Recovery of gentamycin

The recovery of gentamycin added to three different injection gentamycin sulphate solutions is shown in Table 3. The recovery is from 97.4 to 101%.

Analysis of sample

A 1.0-ml portion of injection solution of gentamycin sulphate was transferred into a 50-ml standard flask, diluted to mark with water and mixed well. According to the procedure, 1.0 ml of this solution was transferred into a 25-ml standard flask, reacted and measured. The results are shown in Table 4.

Reproducibility

The same batch number of gentamycin sulphate injection solutions was measured 10 times, under the previously selected conditions. The mean value was 40 7 mg/ml with a standard deviation of 0.54 and relative standard deviation of 1.3%.

KINETIC ENZYMATIC DETERMINATION OF ETHANOL/METHANOL MIXTURES BY THE STOPPED-FLOW TECHNIQUE

EVA FÓRSTER,* MANUEL SILVA, MATHIAS OTTO* and DOLORES PÉREZ-BENDITO
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(*Received* 26 *June* 1992 *Revised* 20 *October* 1992 *Accepted* 20 *October* 1992)

Summary—The analytical use of the enzymatic oxidation of alcohols by alcohol oxidase was assessed applying the stopped-flow technique for mixing sample and reagents, and the DTNB (5,5′-dithiobis-(2-nitrobenzoic acid))/*L*-cysteine system as a new chromogenic reagent The oxidation reaction was monitored by measuring the rate of absorbance decrease at 412 nm, the wavelength of maximum absorption of the reduced form of DTNB The calibration graphs for the individual determination of the alcohols were linear over the range 1.0×10^{-6}–$1\ 0 \times 10^{-5}M$, and the precision ranged between 2.1 and 4 8% A differential rate principle was applied to the determination of ethanol/methanol mixtures involving mutual kinetic effects which allowed mixtures in molar ratios between 25 1 0 and 1 0 1 0 to be accurately resolved with good precision (r s d less than 9 and 5%, respectively) Compared to the flow-injection analysis method, the proposed approach offers higher sensitivity and sample throughput, as well as the wider concentration ratio range for mixture resolution

Ethanol is a major compound in chemistry and biochemistry and a very important ingredient of various groceries and beverages as well as cosmetics, medicines, cleaning fluids, *etc.* Ethanol is commonly associated to methanol, which introduces some hazards owing to the toxic effects of the latter, so the determination of both alcohols in mixtures is of great interest. In recent years, several methods for the resolution of this mixture at very different concentration levels have been reported. Of these, gas chromatographic methods are quite commonplace, and headspace gas analysis[1,2] is particularly useful for these determinations. In general, analyses can be performed in a few minutes over wide dynamic ranges,[1,3,4] even though the sensitivity achieved is not correspondingly high (in any case lowest concentration determined from the calibration graphs was *ca.* $10^{-4}M$). These chromatographic methods have been used for the determination of methanol and ethanol in foods[5,6] and plasma.[4] Spectrophotometric methods have also been used for this purpose. Thus, methanol and ethanol reduce cerium(IV) in a $HClO_4$ medium, forming complexes at different reaction rates that can be determined spectrophotometrically.[7] Mixtures of these alcohols in ratios from 3:7 to 7:3 can thus be resolved. Also, a flow-injection system with a column of immobilized alcohol oxidase was used for the simultaneous determination of these alcohols using the *p*-rosaniline/Na_2SO_3 system as chromogenic reagent for the aldehydes formed in the enzymatic reaction.[8] The method allows the resolution of ethanol/methanol mixtures at the microgram per millilitre level in the ratio range 3.3:1.0 to 1.0:1.3.

In this work we used the above-mentioned enzymatic reaction for the determination of lower straight-chain alcohols such as methanol, ethanol, propanol and butanol, as well as for the resolution of methanol/ethanol mixtures based on the stopped-flow technique, which allows the photometric monitoring of the fast reaction between the hydrogen peroxide released in the enzymatic reaction and the DTNB (5,5′-dithiobis(2-nitrobenzoic acid))/*L*-cysteine system used as chromogenic reagent. The use of the stopped-flow technique and the DTNB/*L*-cysteine system (employed here for the first time as a developer system for this enzymatic reaction) allows for a faster determination of these alcohols at the nanogram per millilitre level. The method is also suitable for the accurate resolution of binary mixtures of methanol and ethanol subject to mutual kinetic effects and compares favourably with its flow-injection

*Present address. Bergakademie Freiberg, Department of Chemistry, 9200 Freiberg, Germany

counterpart in terms of sensitivity, alcohol concentration ratios that can be assayed and sample throughput.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade Alcohol solutions (methanol, ethanol, propanol and butanol) were prepared from standards of absolute grade (Merck) by appropriate dilution with bidistilled water. A 1.6 mg/ml alcohol oxidase (AO, candida boidinii, Sigma) solution was prepared by dissolving 16 mg of the lyophilized powdered enzyme (which features a protein activity of 4–10 units/mg) in 10 ml of 0.1*M* tris(hydroxymethyl)aminoethane (Tris) buffer of pH 8.55 A stock solution of 5,5′-dithiobis(2-nitrobenzoic) acid (DTNB) ($1.0 \times 10^{-3}M$) was prepared by dissolving 40 mg of chemical (Merck) in 100 ml of 0.1% sodium citrate. A stock L-cysteine solution ($1.24 \times 10^{-2}M$) was prepared by dissolving 37.5 mg of reagent (Merck) in 25 ml of bi-distilled water. The 0.1*M* Tris buffer (pH 8.55) was prepared by dissolving 13.28 g of sodium chloride and 12.1 g of Tris in about 850 ml of bidistilled water, the pH then being adjusted to 8.55 with 1*M* hydrochloric acid and the mixture diluted to one litre with further bidistilled water. All solutions were stored in a refrigerator in order to minimize degradation.

Apparatus

Absorbance measurements were made on a Philips PU 8625 UV–visible spectrophotometer fitted with a device for stopped-flow measurements[9] and a Netset PC-AT 16-Mhz compatible computer equipped with a PC-Multilab PCL-812PG 12-bit analog-to-digital converter for acquisition and treatment of kinetic data. The software required for application of the initial reaction-rate method was written by the authors themselves. A Hanna HI 8418 pH-meter was also used.

Procedures

Individual kinetic determinations of the alcohols. Two solutions were mixed in the stopped-flow cell by simultaneous injection from two drive syringes, one of which was filled with a solution prepared by mixing 2.0 ml of sample containing between 1.0×10^{-6}–$1.0 \times 10^{-5}M$ alcohol in the final volume, 3.0 ml of $1.0 \times 10^{-3}M$ DTNB, 2.0 ml of $1.24 \times 10^{-2}M$ *L*-cysteine and 3.0 ml of 0.1*M* Tris buffer (pH 8.55) in a 10-ml standard flask, and the other with a solution made by diluting 2.0 ml of 1.6 mg/ml alcohol oxidase with 8.0 ml of 0.1*M* Tris buffer (pH 8.55). The reaction was monitored at 412 nm and the temperature was kept constant at $25 \pm 0.1°$. The computer system recorded the full signal *vs.* time curve at a data acquisition rate of 100 msec per point and calculated the initial rate (over a period of *ca.* 2 sec) and the concentrations of the alcohols from the corresponding calibration graph.

Resolution of methanol/ethanol mixtures. Synthetic samples containing micromolar concentrations of methanol and ethanol were analysed in two kinetic runs. A volume of 1.0 ml of $2.5 \times 10^{-3}M$ ethanol was added to 1.0 ml of sample containing 2.0–$6.0 \times 10^{-6}M$ methanol and 5.0×10^{-6}–$5.0 \times 10^{-5}M$ ethanol in a final volume of 10 ml and the above-described procedure was followed for the determination of ethanol in the mixture based on initial rate measurements because methanol was not affected under these conditions. In the second experiment, two calibration graphs were constructed for methanol (initial rate and final absorbance *vs.* methanol concentration) in the range 8.0×10^{-7}–$4.0 \times 10^{-6}M$ in the presence of the ethanol concentration found in the previous experiment. Then, an aliquot of the mixture was reacted under the same conditions as for the individual kinetic determinations of the alcohols the concentration of methanol in the sample was determined from the measured initial rate or final absorbance.

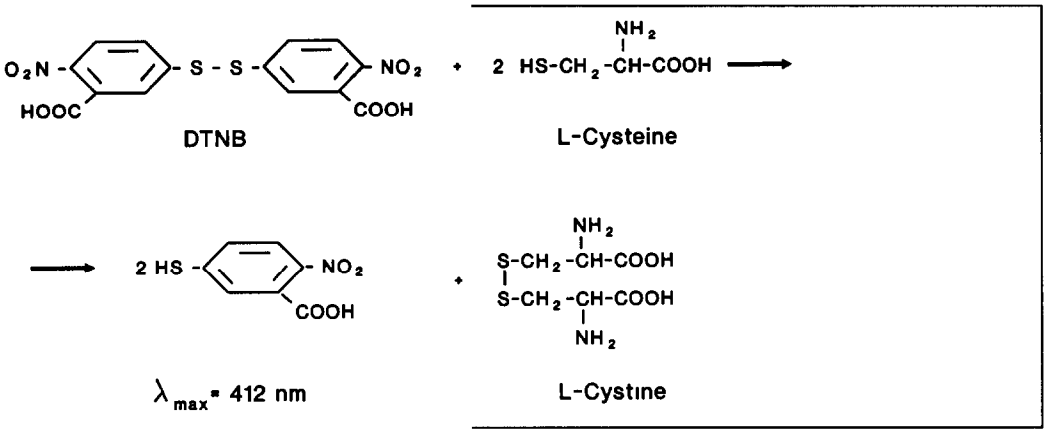
RESULTS AND DISCUSSION

The enzymatic oxidation of lower straight-chain alcohols with alcohol oxidase is widely used; the reaction is generally monitored via a coupled reaction in which the aldehyde formed in the enzymatic reaction is reacted with an appropriate reagent in order to obtain a chromogenic product.[10] The proposed method for the determination of these alcohols relies on the above-mentioned enzymatic reaction and the DTNB/*L*-cysteine system as chromogenic reagent for the hydrogen peroxide released in the enzymatic oxidation of the alcohols. This chromogenic reaction was used for the first time in this work as coupled to the enzymatic determination of these alcohols, for which the following reaction scheme is suggested. In a first step,

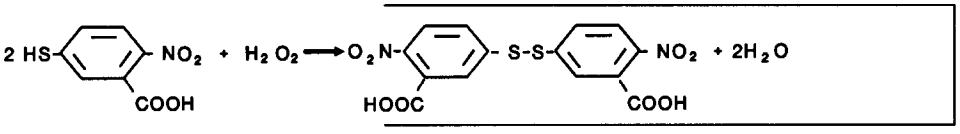
hydrogen peroxide is formed by enzymatic oxidation of the alcohols:

$$\text{R-OH} + \text{Alcohol oxidase} \rightarrow \text{R-CHO} + H_2O_2$$

and the chromogenic reagent is formed by reaction between DTNB and *L*-cysteine according to



The sulphur derivative of 2-nitrobenzoic acid (a sulphide or mercaptan) is responsible for the colour, which shows maximum absorption at 412 nm. In the final step, this compound reacts with hydrogen peroxide to yield DTNB (colourless) again.



This reaction scheme is consistent with literature data on the reversible oxidation of mercaptans.[11] In fact, these compounds can be oxidized to sulphoxides and even to sulphones by using concentrated hydrogen peroxide, whereas dilute solutions of this oxidant readily oxidize mercaptans to disulphides. On the other hand, disulphides can be reduced to mercaptans by mild reducing agents such as *L*-cysteine, so interconversion between *L*-cysteine and *L*-cystine using this sulphide/disulphide system is very important in biochemistry.

These reactions develop to completion in a few seconds, which calls for the use of the stopped-flow technique for making kinetic measurements. Figure 1 shows the stopped-flow kinetic curve (absorbance at 412 nm *vs.* time) provided by the spectrophotometer and processed by the data acquisition system which is the basis for development of the proposed kinetic method for the determination of lower straight-chain alcohols. Even though the proposed method is based on signal decrease *vs.* time measurements, reaction rates are usually positive, so all graphs and calculations in this work are conformant to this criterion.

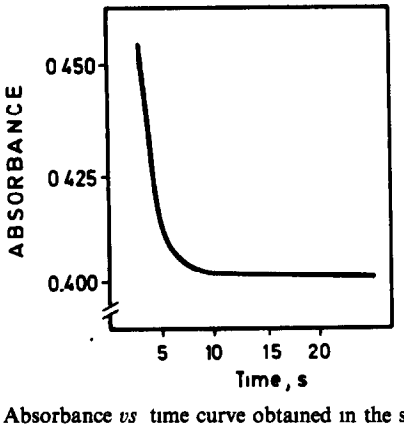


Fig 1 Absorbance *vs* time curve obtained in the stopped-flow determination of $5.0 \times 10^{-6} M$ ethanol Experimental conditions as described under Procedure

Influence of variables

The working conditions for application of the proposed method were selected by using ethanol only to examine the influence of variables on both the enzymatic and the chromogenic reaction. The conditions arrived at for ethanol were then applied to the other alcohols. In this study, all concentrations stated are initial concentrations in the syringes (twice the actual concentrations in the reaction mixture at time zero after mixing) and kinetic data (averages of three measurements) were obtained from the initial rate/concentration plots.

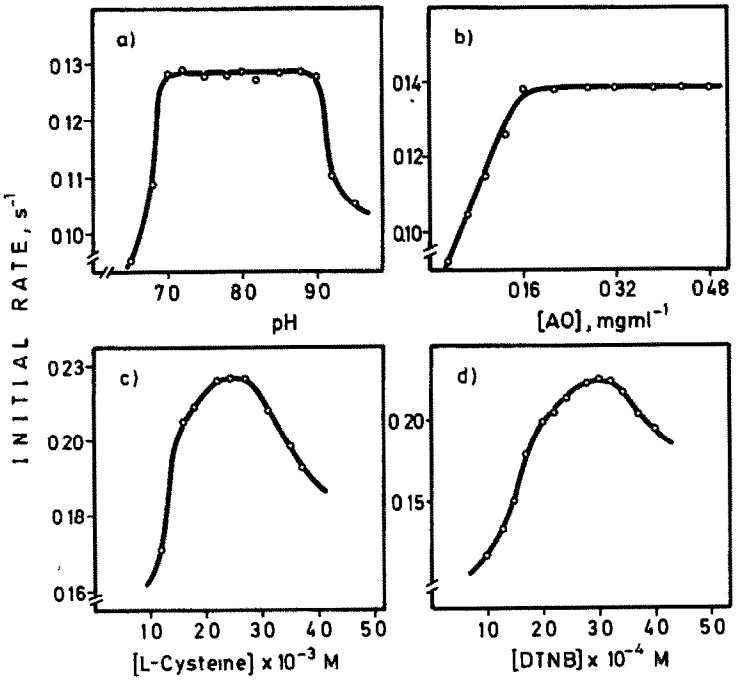

Fig 2 Effect of (a) pH, and (b) the alcohol oxidase, (c) *L*-cysteine and (d) DTNB concentrations on the kinetic determination of $1.0 \times 10^{-6}M$, (a) and (b), and $5.0 \times 10^{-6}M$, (c) and (d), ethanol (conditions described under Experimental)

The effect of the temperature on the reaction rate was examined between 15 and 45°. The absorbance *vs.* time curves show an increase in reaction rate with increase in temperature up to 20°, above which the initial rate remained constant up to 40°. At higher temperatures, the reaction rate decreased owing to the enzyme denaturation. A temperature of 25° was selected.

The influence of the pH was studied over the range 6.5–9.5. As can be seen from Fig. 2(a), a pseudo zero-order region occurred between pH 7.0 and 9.0, above which the reaction rate decreased, probably owing to the enzyme denaturation. A pH of 8.55 was chosen for further experiments, which was adjusted and kept constant by using a $0.1M$ Tris buffer. The influence of the alcohol oxidase concentration on the reaction rate was studied over the range 0.032–0.48 mg/ml [Fig. 2(b)], its dependence being of zero-order at concentrations above 0.16 mg/ml; therefore, 0.32 mg/ml alcohol oxidase was selected for further experiments in order to ensure the presence of an excess and avoid unnecessary consumption of the enzyme.

The effect of the *L*-cysteine concentration on the reaction rate at an ethanol concentration of $5 \times 10^{-6}M$ is illustrated in Fig. 2(c). As can be seen, a $2.48 \times 10^{-3}M$ *L*-cysteine solution (2.0 ml of $1.24 \times 10^{-2}M$ solution in 10 ml) yielded the maximum initial-reaction rate, so it was chosen for implementation of the proposed procedure. The influence of the DTNB concentration on the analytical signal is shown in Fig. 2(d). The initial rate increased with increasing DTNB concentration up to $2.8 \times 10^{-4}M$ and the reaction became nearly zero-order with respect to DTNB over a narrow range, $2.8–3.2 \times 10^{-4}M$, above which it started to decrease. A DTNB concentration of $3.0 \times 10^{-4}M$ was selected.

Kinetic enzymatic determination of alcohols

The initial rates derived from the absorbance *vs.* time curves for solutions containing different concentrations of the alcohols under the selected conditions, were linearly related to the alcohol concentration. The analytical features of the proposed stopped-flow methods are summarized in Table 1. As can be seen, the alcohols can be determined at the nanogram per millilitre level with good precision (between 2.1 and 4.8% as RSD). We should note the relatively large values of the intercepts in the linear regression equations. In fact, lower alcohol concentrations resulted in decreased initial rates, however, the net absorbance changes in the kinetic curves were very small, so the analytical results were quite irreproducible. The dynamic linear ranges

Table 1 Analytical figures of merit of the determination of alcohols by the stopped-flow technique

Alcohol	Dynamic linear range M	Dynamic linear range ng/ml	Linear regression equation*	Correlation coefficient ($n = 10$)	Precision† (RSD), %
Methanol	1.0×10^{-6}–1.0×10^{-5}	32–320	$IR = 5.61 \times 10^{-2} + 3.37 \times 10^{3}\ C$	0.9994	4.49
Ethanol	1.0×10^{-6}–1.0×10^{-5}	46–460	$IR = 1.34 \times 10^{-1} + 1.50 \times 10^{4}\ C$	0.9995	2.71
Propanol	1.0×10^{-6}–1.0×10^{-5}	60–600	$IR = 1.35 \times 10^{-1} + 1.62 \times 10^{4}\ C$	0.9998	2.13
Butanol	1.0×10^{-6}–1.0×10^{-5}	74–740	$IR = 2.81 \times 10^{-2} + 3.52 \times 10^{3}\ C$	0.9995	4.83

*IR = initial rate (absorbance/sec), C = molar concentration.
†Obtained from 11 samples containing $5 \times 10^{-6} M$ of the alcohol

obtained in this work allow the kinetic determination of these alcohols with a higher reliability. The analytical sensitivity to the alcohols varied from compound to compound in the following sequence:

propanol ≅ ethanol > butanol ≅ methanol.

We thus selected the ethanol/methanol couple in order to test the performance of the proposed kinetic enzymatic method in the resolution of mixtures of the alcohols.

At this point it is worth comparing the performance of the proposed kinetic enzymatic method for the determination of alcohols with others reported in the literature also based on the use of alcohol oxidase. Two recently reported methods were selected for this purpose: one in which alcohol oxidase is immobilized in a gelatin matrix and the electrode formed from the membrane is used in a continuous-flow system,[12] and the other based on a flow-injection system including a column of immobilized alcohol oxidase and using the *p*-rosaniline/Na_2SO_3 system as a coupled reaction for spectrophotometric detection.[8] Table 2 shows the performance of the methods as applied to the determination of ethanol and methanol only, compared to the proposed stopped-flow method, which offers higher sensitivity, inasmuch as it allows the determination of these alcohols at lower concentrations by at least two orders of magnitude, and lower analysis time (it was considered to be the time elapsed between insertion of the sample into the system and the end of data processing for delivery of the analytical signal). Even though the use of immobilized enzyme obviously reduces analytical cost, the low enzyme concentrations used in this procedure partly avoids the need to work in homogeneous medium (the estimated cost per analysis was $10 per 100 triplicate determinations. On the other hand, alcohol oxidase solutions prepared as described above are stable for at least 4 hr (the longest time assessed).

Resolution of methanol/ethanol synthetic mixtures

The first step in the resolution of mixtures of species involves checking whether the reaction rates of the species concerned are independent of one another or, in other words, if the presence of one component has no effect on the kinetic behaviour of the others. We thus constructed several calibration plots of initial rate *vs.* methanol concentration in the present of different fixed concentrations of ethanol. The results obtained are shown in Fig. 3. As can be seen, the initial rate decreased with an increase in the methanol concentration owing to the presence of ethanol. In summary, the occurrence of strong negative mutual kinetic effects was detected in the resolution of methanol/ethanol mixtures, consistent with previous reports.[8]

The occurrence of this mutual kinetic effect precluded use of classical differential reaction-rate methods for resolution of these mixtures, so a new methodology must be developed in order

Table 2 Comparison of the figures of merit of the proposed stopped-flow method for the determination of alcohols with those of other recently reported methods using alcohol oxidase

†Ref 8

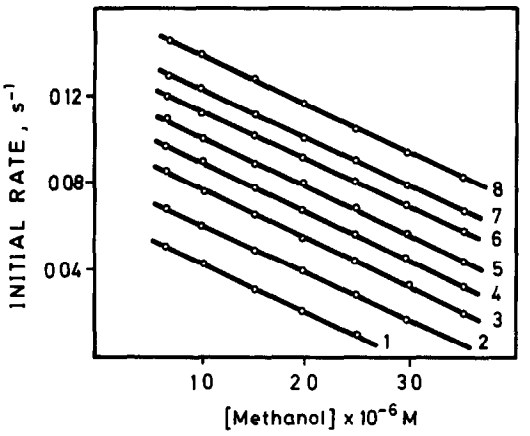

Fig 3 Calibration plots of initial rate *vs* methanol concentration obtained in the presence of the following amounts of ethanol curves (1)–(8) 1·0–8·0 × $10^{-6}M$ ethanol Reaction conditions as described under Procedure

to take account of this effect as in previously reported cases.[13–15] Even though the intercepts of the curves shown in Fig. 3 depend on the concentration of ethanol, their relationship cannot be used to assess the mutual kinetic effect because, if an unknown mixture is added with increasing amounts of methanol, a linear dependence is indeed found, yet the intercept of the straight line depends on the concentration of both ethanol and methanol in the mixture. It is therefore indispensable to establish a set of experimental conditions under which the mutual kinetic effect does not occur in order to be able to determine one of the mixture components. For this purpose, we prepared various samples of methanol containing increasing concentrations of ethanol and found that, at ethanol concentrations above 2·0 × $10^{-4}M$, methanol concentrations of the order of $10^{-6}M$ had no effect on the measured initial rate of ethanol. Under these conditions, ethanol could be determined in the presence of methanol. Thus, at a fixed ethanol concentration of 2.5 × $10^{-4}M$, the above-mentioned linear dependence held over the range 5.0 × 10^{-6}–5.0 × $10^{-5}M$ for ethanol and the straight line obtained conformed to the following regression equation

$$IR = 0.464 + 2.60 \times 10^{3}[\text{ethanol}] (r = 0.992). \quad (1)$$

Under these conditions, the resolution of methanol/ethanol mixtures can be accomplished by using the following procedure· the amount of ethanol required to obtain a concentration of 2.5 × $10^{-4}M$ in this alcohol was added to an aliquot of the unknown sample and the mixture is reacted as described for the individual determination of the alcohols. Substitution of the measured initial rate into equation (1) yields the concentration of ethanol in the unknown sample. Once such a concentration is known, a calibration graph for methanol is constructed in the presence of the determined ethanol concentration (Fig. 3). Then, a new aliquot of the unknown mixture is reacted and the measured initial rate allows the methanol contents in the sample to be determined from the previously run calibration graph. Obviously, this procedure only permits the resolution of methanol/ethanol mixtures with ethanol contents not lower than those of methanol, which is the normal situation in real samples. On the other hand, applying the proposed method to these samples would call for further investigations as

regards sample pretreatment in order to avoid potential interferences.

The results obtained for several synthetic mixtures of methanol and ethanol are summarized in Table 3. As can be seen in the table, methanol was determined from two calibration curves: initial rate and net absorbance change *vs.* methanol concentration. Equilibrium measurements resulted in smaller errors in the determination of this alcohol, so they were chosen to analyse for it in this type of sample. Thus, the determination of ethanol/methanol mixtures was feasible over the concentration ratio range 25·1–1:1. When the recommended procedure was applied to a series of 11 samples containing (a) $5.0 \times 10^{-6}M$ ethanol and $3.0 \times 10^{-6}M$ methanol; (b) $2.0 \times 10^{-5}M$ ethanol and $2.0 \times 10^{-6}M$ methanol, and (c) $5.0 \times 10^{-5}M$ ethanol and $2\,0 \times 10^{-6}M$ methanol, the average relative standard deviations (for both species) were 3.86, 5.05 and 4.61%, respectively.

Compared with other methods for the resolution of ethanol/methanol mixtures based on the same enzymatic reaction [*e.g.*, the simultaneous determination of these alcohols by flow-injection analysis[8]] the proposed stopped-flow method can be applied to higher ethanol/methanol ratios and is more precise: the flow-injection method allows the resolution of ethanol/methanol mixtures in the weight ratio range of only 3.3:1.0–1.0:1.3, with a precision (RSD) between 6.0 and 7.1%.

ASSIGNMENT OF STANDARD pH VALUES [pH*(s)] TO BUFFERS IN 50 MASS % METHANOL + WATER FROM 288.15 TO 308.15 K

H. A. AZAB

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(*Received* 26 *June* 1992 *Revised* 20 *October* 1992 *Accepted* 20 *October* 1992)

Summary—The secondary dissociation constants of *o*-phthalic and phosphoric acids have been determined in methanol + water (50 mass %) from reversible e m f measurements of the cell of the type Pt, H_2(1 atm)|M_2A(m), MHA(m), MCl|AgCl, Ag at different temperatures (288 15–308 15 K) and at different ionic strengths To minimize the unsteadiness in potential measurements palladium coated platinum electrodes have been used The large set of such e m f values has been analyzed in terms of a multi-linear regression method recommended in recent IUPAC documents The thermodynamic values $\Delta G°$, $\Delta H°$ and $\Delta S°$, for the respective equilibria, were estimated Standard pH values [pH*(s)] have been assigned to buffers in methanol + water (50 mass %) at temperatures between 288 15 and 308 15 K

The study of the dissociation equilibria of phosphoric and *o*-phthalic acids in water[1–5] has permitted the combination of a series of standard aqueous buffer solutions. The standardization of pH* measurements in mixed solvents, needs similar studies regarding the dissociation equilibria of certain adequate electrolytes in these solvents.[6,7] In the present work the second-stage dissociation constant of phosphoric and *o*-phthalic acid in methanol + water (50 mass %) have been determined as part of a program to develop standard buffer solutions.[5,8]

EXPERIMENTAL

All reagents used were of AnalaR (BDH) grade. All stock solutions were prepared in doubly-distilled air free conductivity water. Methanol + water (50 mass %) was prepared by mixing appropriate amounts of analytical grade methanol, fractionally distilled before use, with conductivity water. Owing to the low solubility of dipotassium phosphate in the given solvent, disodium phosphate was used. *o*-Phthalic acid, potassium chloride and certified ULTREX Baker potassium hydrogen phthalate were dried at 383.15 K before use. The potentiometric measurements, the preparation and standardization of the silver–silver chloride electrode were carried out as described earlier.[8] The values of the standard potential of the Ag/AgCl electrode ${}_sE°_{AgCl}$, in methanol + water H_2O (50 mass %) from 288.15 to 308.15 K have been determined and are given in Table 1. Each measured e.m.f. value was corrected to 1 atm (101,325 Pa) pressure of hydrogen from the barometric pressure and the vapor pressure of the solution, the latter being taken as the same as the vapor pressure of the solvent.[9–11] An average of about four independent cells were measured at each electrolyte molality and at each temperature The large set of such e.m.f. values has been analyzed in terms of a multi-linear regression method recommended in recent IUPAC documents.[12]

RESULTS AND DISCUSSION

Electrochemical cells without liquid junction potentials of the type:

$$\text{Pt}|H_2(1\text{ atm})|M_2A(m),\ \text{MHA(m)},\ \text{MCl(m)}|\text{AgCl}|\text{Ag} \quad (1)$$

were used to determine pK_{a_2} values of *o*-phthalic and phosphoric acid in methanol + water (50 mass %) from 288.15 to 308.15 K.

A represents the $C_6H_4(COO)_2^{2-}$ and HPO_4^{2-} anions and M^+ the Na^+ or K^+ cations.

For the equilibrium

$$HA^- \rightleftharpoons A^{2-} + H^+$$

$$K_2 = \frac{a_H^+ \cdot m_A^{2-} \cdot \nu_A^{2-}}{m_{HA^-} \cdot \nu_{HA^-}} \quad (2)$$

Table 1 Standard potential ($E°$) of the Ag/AgCl electrode in methanol + water (50 mass %) at different temperatures (288 15–308 15 K)

T, K	$E°$, V
288 15	0 1975
293 15	0 1935
298 15	0 1893
303.15	0 1850
308 15	0 1802

when the concentrations are such that $m_{Cl^-} = m_{HA^-} = m_A^{2-}$ relationship (3) can be derived[8]

$$pKa_2 + \beta I = \left(\frac{(E - E°)F}{2.303\ RT}\right) + \log m + \frac{2AI^{1/2}}{1 + Ba°I^{1/2}} \quad (3)$$

where A and B are the constants of the Debye–Hückel equation for the respective solvent which were derived for methanol + water (50 mass %) from the expressions given by Robinson and Stokes:[13]

β is the salting-out parameter and $a°$ is an "ion-size" parameter which has been assigned the widely used value of 4.4 Å. Electric permittivities (ϵ), for the solvents containing methanol were not available in the literature for temperatures other than 298.15 K.[14] However, it was observed from the data of Akerlof[15] that the relationship between the log of the electric permittivity and temperature is linear and that the gradients of the lines for various organic solvents and their aqueous mixtures are essentially parallel. This provided an acceptable method for extrapolating the measured electric permittivities for methanol + water (50 mass %). An equation for the least-squares regression line for the relationship between $\log \epsilon_{H_2O}$ and temperatures was derived from the data given by Hamer[16]

$$\log \epsilon = 0.00197\ t + 1.9431 \quad (4)$$

where t is expressed in °C.

The Debye–Hückel constants for methanol + H_2O (50 mass %) at temperatures other than 298.15 K were calculated using electric permittivities estimated from the known difference between ϵ_{H_2O} and the electric permittivity for the mixed solvent at 298.15 K by extrapolating the difference to different temperatures.

By representing the right hand side of equation (3) vs. concentration (m) graphically, a straight line intersecting the ordinates at pKa_2 is obtained.

Table 2 Experimental data obtained by electrochemical cell (1) for $KH_2PO_4(m) + Na_2HPO_4(m) + NaCl(m)$ in methanol + water (50 mass %)

Seven cell solutions containing hydrochloric acid at molalities ranging from 0.05 to 0.005 *m* were used to determine the standard potential of the silver–silver chloride electrode. The standard potential, on the molality scale was obtained by extrapolation of

$$E^\circ = E + 2k \log m - \frac{2k A m^{1/2}}{1 + B a^\circ m^{1/2}} \quad (5)$$

to $m = 0$.

This function is derived from the Nernst equation, where a Debye–Hückel expression has been included to approximate the mean activity coefficient of HCl. The term k is written for RT ln $10/F$ and the Debye–Hückel constant A and B were calculated as mentioned above.

The acidity function $P_s(a_H \cdot \nu_{Cl})$ has been obtained from the e.m.f. of the hydrogen–silver chloride cell (1) containing the standard solutions (with added chloride) in methanol + water medium.[17]

$$P_s(a_H \cdot \nu_{Cl}) = \frac{(E - E^\circ)F}{2.303RT} + \log m_{Cl} \quad (6)$$

and then pa_{H^*} by the non-thermodynamic step

$$pa_{H^*} = P_s(a_H \cdot \nu_{Cl}) + \log {}_s\nu_{Cl} \quad (7)$$

Data for the experimental measurements of e.m.f. of cell (1) at different temperatures (288.15–308.15 K) and different ionic strengths are given in Tables 2 and 3 for both *o*-phthalic and phosphoric acid in methanol + water (50 mass %). As the concentration of the supporting electrolyte increased, a salting out effect is observed. This is because the activity coefficient of the uncharged particles present in solution is changed on increasing the concentration of the dissolved salt.

The secondary dissociation constants of *o*-phthalic and phosphoric acids in methanol + water (50 mass %) at different temperatures (288.15–308.15 K) and at different ionic strengths are given in Tables 4 and 5. Values of pKa_2 at different ionic strengths have been calculated using a convenient form of the Debye–Hückel equation, such as that due to Davies.[18] Values of the thermodynamic parameters ΔG°, ΔH° and ΔS° for the second dissociation stage of *o*-phthalic and phosphoric acid have been calculated and are given in Table 6.

The need for reliable pH measurements at different temperatures in mixed solvents such as methanol and water has become increasingly apparent in different biological studies. The data obtained in the present report can be used for preparing standard buffer solution for pH*(s) measurements in methanol + water (50 mass %) at different temperatures (288.15–308.15 K) as shown in Tables 2 and 3.

(*Received* 31 *July* 1992. *Revised* 15 *October* 1992. *Accepted* 15 *October* 1992)

Summary—A new sample introduction system for the analysis of continuously flowing liquid streams by flame infrared-emission (FIRE) spectrometry has been developed. The system uses a specially designed purge cell to strip dissolved CO_2 from solution into a hydrogen gas stream that serves as the fuel for a hydrogen/air flame. Vibrationally excited CO_2 molecules present in the flame are monitored with a simple infrared filter (4.4 μm) photometer The new system can be used to introduce analytes as a continuous liquid stream (process analysis mode) or on a discrete basis by sample injection (flow injection analysis mode). The key to the success of the method is the new purge-cell design The small internal volume of the cell minimizes problems associated with purge-cell clean-out and produces sharp, reproducible signals Spent analytical solution is continuously drained from the cell, making cell disconnection and cleaning between samples unnecessary. Under the conditions employed in this study, samples could be analyzed at a maximum rate of approximately 60/h. The new sample introduction system was successfully tested in both a process analysis- and a flow injection analysis mode for the determination of total inorganic carbon in Waco tap water. For the first time, flame infrared-emission spectrometry was successfully extended to non-volatile organic compounds by using chemical pretreatment with peroxydisulfate in the presence of silver ion to convert the analytes into dissolved carbon dioxide, prior to purging and detection by the FIRE radiometer. A test of the peroxydisulfate/Ag^+ reaction using six organic acids and five sugars indicated that all 11 compounds were oxidized to nearly the same extent. Finally, the new sample introduction system was used in conjunction with a simple filter FIRE radiometer as a detection system in ion-exchange high-performance liquid chromatography. Ion-exchange chromatograms are shown for two aqueous mixtures, one containing six organic acids and the second containing six mono-, di-, and trisaccharides

Although the analytical application of gas-phase infrared emission is well documented for the case of remote sensing of pollutants in smokestack plumes[1–5] and gases in jet engine exhaust,[6] its use as a means of routine quantitative analysis in the laboratory is relatively new.[7–9] When flame/furnace infrared-emission (FIRE) spectrometry is employed in the laboratory, samples are introduced into a heated environment (such as a small flame[10] or electrically heated furnace[11,12]) where they are typically converted into small, thermally-stable, vibrationally-excited molecules.[13,14] The characteristic infrared bands emitted by these molecules are generally well resolved and can be detected with a simple infrared filter photometer.[7]

Because FIRE spectrometry is a relatively new analytical technique, much of the previous work has concentrated on improving instrumental performance.[10,11,15–19] Although it is clear from previous studies that gas-phase infrared emission from selective radiators could be useful analytically in a number of significant areas,[7] the key to the analytical success of the technique depends on the availability of a reliable means of sample introduction.[20–23] In particular, the ability to determine analytes present in continuously flowing liquid streams would be useful for applications involving process analysis,[24] flow injection analysis (FIA),[25] and high-performance liquid chromatography (HPLC).[26]

One way to introduce a liquid sample into a flame or furnace on a continuous basis is in the form of a fine spray. Although both thermospray and pneumatic nebulization show

*Author for correspondence.

some promise as means of analyzing liquid streams on a continuous basis, the sensitivity achieved by spraying aqueous samples directly into a small flame or furnace has been relatively disappointing to date.[27,28] Poor sensitivity can be attributed to cooling of the excitation source by liquid evaporation. (Evaporation of as little as 1 ml/min of an aqueous stream by a microflame or low thermal-mass furnace of the type used in FIRE spectrometry will produce a measurable depression in the excitation temperature of the source [27]) When the power to the thermospray nebulizer was increased to completely vaporize the liquid stream prior to introduction into the source, the relatively large amount of water vapor diluted the analyte and significantly increased the magnitude of the water background emission in the FIRE spectrum.[27] Regardless of the type of nebulizer used, small fluctuations in nebulizer efficiency gave rise to increased background noise resulting from changes in excitation temperature, source background, or a combination of both.[28]

Compared with FIRE-HPLC applications involving direct introduction of liquid into the source,[28] FIRE-GC applications involving direct introduction of gas-phase samples into the source have produced improved detection limits which are typically in the low ng/sec range.[10] Improved detection limits for liquid samples have been obtained in some FIRE applications[21-23] through the use of purge tubes, which permit the sparging of volatile analytes out of the liquid and into the flame. The major disadvantages with previous sparging approaches[21-23] have been, (1) the large internal volume introduced by the purge tube, (2) the relatively long time period between samples (about 3–6 min) due to disconnection of the sample purge tube for cleaning and refilling, (3) the additional purge tube and valving system required to maintain gas flow and stabilize the flame during cleaning of the sample cell, and (4) the limitation of the technique to relatively volatile, dissolved analytes.

In spite of the disadvantages associated with the earlier use of purge tubes, the improved detection limits obtained by sparging discrete samples from liquids[21-23] (compared to direct introduction of liquid into the source[27,28]), suggested that a sparging approach might be useful in improving the sensitivity of FIRE spectrometry for liquid samples. This paper reports a new sample introduction sample for FIRE spectrometry that is highly versatile and can be used to analyze liquid streams on a continuous basis. The key to this system is a specially designed purge tube which introduces less than 2 ml of internal volume and does not require disconnection between samples.

To demonstrate the potential of the new sample introduction system, the specially designed purge tube was used for the determination of total inorganic carbon (TIC) by FIRE spectrometry in both a process analysis and a flow injection analysis mode. Finally, an improved FIRE-HPLC detector, which uses the new purge tube, is described. This detector, which, in principle, should be universal for all oxidizable organic compounds, was used to monitor organic acids and sugars which had been separated by ion-exchange HPLC.

EXPERIMENTAL

FIRE radiometer

A standard, single-channel, filter FIRE radiometer of the type described previously[7] was used for these studies. The radiometer consisted of a flame excitation source, a chopper, calcium fluoride collection optics, a bandpass filter, a lead selenide detector, and a preamplifier. Signal from the preamplifier was fed to a lock-in amplifier (Model #HP3962, Ithaco, Inc., Ithaca, NY) whose output was monitored with a recorder/integrator (Model #3396A, Hewlett-Packard Corp., North Hollywood, CA). A bandpass filter with a transmission band at 4.4 μm (Part #58300, Oriel Corp., Stratford, CT) was used to select the antisymmetric stretching vibration of CO_2 from the other infrared radiation emitted by the flame.[22]

An improved two-tube burner, described previously,[10] was used as the excitation source. In this study, the inner stainless steel capillary was replaced with a nickel capillary [Part #31313, Alltech Associates, Inc., Deerfield, IL; i.d. 0.51 mm (0.020 in.); o.d., 1.59 mm (1/16 in.)] because of its superior resistance to attack by hydrochloric acid. The inner nickel capillary was centered and positioned so that its tip was 1 mm above the outer stainless steel tube (Part #2-0384, Supelco, Inc., Bellefonte, PA) using a glass wool plug. A diffusion flame was maintained on the burner by flowing hydrogen gas up the central nickel capillary and air up

the outer stainless steel tube. The flow rate of H_2 was maintained with a flow controller (Part #8148, Alltech Associates, Inc.), and air flow was controlled with a rotameter (Part #03216–18, Cole Palmer, Chicago, IL).

Purge cell

Figure 1 shows a schematic diagram of the purge cell used in this study. The lumen of the cell had an inside diameter of 10 mm, a length of 30 mm, and a total volume of 2.4 cm^3. The top portion of the cell was sealed with a Teflon® [poly(tetrafluoroethylene)] stopper, TC [Fig. 1(A)], which was fitted with an O-ring [O, Fig. 1(A)]. A length of Teflon® tubing [Part #123814, Spectrum Scientific, Los Angeles, CA; o.d., 3 17 mm (1/8 in.); i d., 0.79 mm (1/32 in)] served as the sample conduit and was passed into the cell through a hole drilled in the center of the Teflon® stopper. The bottom end of the purge cell was connected to the purge gas supply through a gas dispersion tube, G (Part #9435-09, Ace Glass, Vineland, NJ; o.d., 5 mm). The gas dispersion tube was held in place by two Nylon nuts, N (Part #NY-402-1, Swagelok Co., Solon, OH) that compressed O-rings against the dispersion tube when tightened to the two ends of a Nylon union, U (Part #NY-400-1-4, Swagelok Co.). The side arm of the purge cell (o.d., 6.35 mm; i d , 3.96 mm) was located just below the bottom of the Teflon® stopper [Fig. 1(B)]. The porous end of the gas dispersion tube, F, and the end of the Teflon® tube that served as the sample conduit were adjusted so that they were separated by about 1 mm, and the vertical distance from the top of

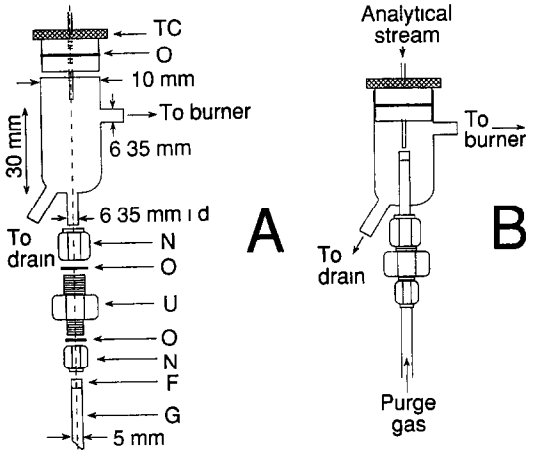

Fig 1 Schematic diagram and dimensions for the continuous-flow purge cell (A) Exploded view (B) Assembled TC, Teflon® cap, O, O-ring, N, nylon nut, U, nylon union, F, porous glass frit, G, gas dispersion tube

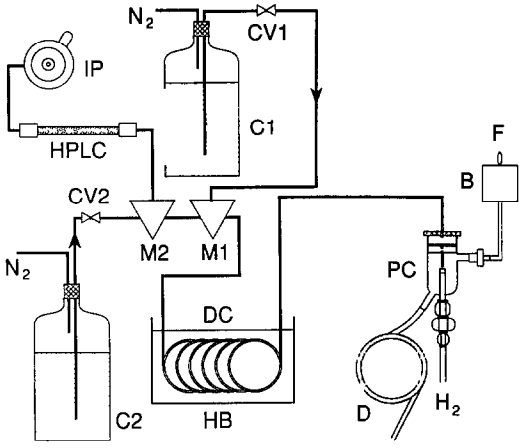

Fig 2 Schematic diagram of the continuous-flow sample delivery system configured for high-performance liquid chromatography IP, injection port of the liquid chromatograph, HPLC, chromatographic column, M1, M2, multiport valves, C1, C2, glass carboys, CV1, CV2, check valves, DC, delay coil, HB, hot bath, PC, continuous-flow purge cell, D, drain, B, two-tube burner, F, hydrogen/air flame, N_2, nitrogen gas inlet, H_2, hydrogen gas inlet Air supply for the hydrogen/air flame not shown

the gas dispersion tube to the center axis of the side arm of the purge cell was approximately 5–6 mm.

The purge cell was connected to the two-tube burner (Fig 2) by mean of Teflon® tubing [o.d., 3.17 mm (1/8 in.), i.d., 1.59 mm (1/16 in.)]. This tubing was connected to the side arm of the purge cell by means of a 1/4–1/8 in. reducing union (Part #B-400-6-2, Swagelok Co.) and to the central capillary of the burner by means of a 1/8–1/16 in reducing union (Part #B-200-6-1, Swagelok Co.).

A length of Tygon® tubing (Part #6409-18, Norton Co, Worcester, MA; o.d., 11 mm; i.d., 8 mm) was connected to a tube at the bottom of the purge cell by means of a hose clamp and allowed the spent liquid in the purge cell to drain into a waste container. The diameter of this tubing was selected so as to introduce the smallest possible volume while still allowing the liquid to drain freely A loop, formed in the Tygon® tubing and filled with solution (Fig. 2), prevented the escape of gas through the drain.

Hydrogen gas was used to purge the analytical stream. A cylinder of hydrogen gas was connected to the gas dispersion tube with Tygon® tubing (Part #6409-25, Norton Co., o.d., 8 mm; i d., 4.8 mm) which was held in place with a hose clamp.

Purge cell performance was evaluated as a function of several design parameters and operating conditions. These included the effect of

reagent- and purge-gas flow rates, reagent concentrations and three different frit porosities in the gas dispersion tube.

Sample introduction

Liquid streams were introduced into the purge cell through a length of Teflon® tubing. One end of this tubing passed through the Teflon® stopper of the purge cell, as described previously, and the other end was connected to the sample delivery system. Three sample delivery systems were studied.

HPLC mode. Figure 2 shows a diagram of the delivery system used for HPLC applications. Two separate nitrogen gas cylinders were used to pressurize two heavy-walled glass carboys (2-l. capacity, catalog #45-3203, Rainin Instrument, Woburn, MA, 5-l. capacity, catalog #45-3205, Rainin Instrument), equipped with special caps to which tubing could be connected. The pressure, which was controlled by standard, two-stage regulators, was typically maintained at 7–14 kPa above atmospheric (1–2 psig), but in no case exceeded the rating of the glass carboys (10 psig). Each outlet from the two carboys was connected to its own check valve (Part #J-6468-80, Cole Palmer) and then to its own three-way connector (Part #OM-1003, Chrom Tech Inc., Apple Valley, MN) which served as a mixer. One three-way connector (M2, Fig. 2) mixed the effluent from the chromatograph (Varian 5000 Liquid Chromatograph, Varian, Sunnyvale, CA) with the contents of carboy C2. The other connector (M1, Fig. 2) permitted addition of reagent from carboy C1 to the liquid stream. A delay coil, which could be maintained at a fixed, constant temperature by means of a hot bath, could be inserted after the two mixers. Teflon® tubing [catalog #6468-08, Cole Palmer; i.d., 0.79 mm (1/32 in.)] was used for all connections.

A sample injection loop of 20 μl (Model #00-997182-04, Varian) or 50 μl (Model #00-997182-05, Varian) volume was employed. All samples were injected onto the HPLC column manually using a 100-μl syringe (Model #00-997074-04, Varian).

Ion-exchange HPLC of a mixture of organic acids (butyric, formic, fumaric, oxalic, propionic, and tartaric) dissolved in deionized water (Continental Water System Co., Austin, TX) was performed using an ORH-801 column (Interaction Chemicals, Mt. View, CA) packed with cation-exchange polymer in the hydrogen form. The 30-cm long by 6.5-mm diameter column was maintained at 37° by means of a water jacket (Model #9502, Alltech Associates) connected to a circulating water bath (Model Type MS, Lauda, Westbury, NY). A GC-801 IonGuard® guard column (Interaction Chemicals) was connected between the injector and the analytical column. Separation was performed using 0.01*N* nitric acid (ACS reagent grade, Fisher Scientific, Pittsburgh, PA) in HPLC-grade water (Fisher Scientific) as the mobile phase at a flow rate of 0.8 ml/min.

Ion-exchange HPLC of a mixture of sugars (fructose, galactose, glucose, mannitol, raffinose, and sucrose) dissolved in deionized water was performed using a CHO-620 carbohydrate column (Interaction Chemicals) packed with a cation-exchange polymer in the Ca^{2+} form. The 30-cm long by 6 5-mm diameter column was maintained at 90° by means of the same water jacket and recirculating water bath employed in the separation of organic acids. A precolumn filter (Model #A-318, Upchurch Scientific, Oak Harbor, WA) and GC-620 IonGuard® guard column (Interaction Chemicals) were placed between the injector and the analytical column. Separation was performed using HPLC-grade water as the mobile phase at a flow rate of 0.5 ml/min.

FIA mode. In this arrangement, the separation channel, consisting of the injection port, HPLC column, and the mixer, M2, was removed, and a septum injector (Part #OM-3301, Chrom Tech Inc.) for sample introduction was interposed between the check valve, CV2, and the remaining three-way connector, M1. Samples were injected manually using either a 25- or 250-μl syringe (catalog #725SNR and #702SN, Hamilton Co., Reno, NV). Both carboys were pressurized as described previously, with flow for the carrier provided by pressurization of carboy C2.

Process analysis mode. This arrangement was similar to the FIA mode, but the septum injector was not used, and the sample was introduced continuously from a carboy Carboy C1 in Fig. 2 was replaced by three, 2-litre carboys connected in parallel, which were used for the introduction of blank, sample, and analytical standard, as desired. The three carboys connected in parallel were pressurized from a single nitrogen gas supply, and a four-way valve (Part #45-1118, Rainin Instrument), which was located ahead of the check valve, CV1, was used to select the desired solution.

Sample pretreatment

Determination of total inorganic carbon (TIC) required addition of hydrochloric acid (Fisher Scientific) to the sample stream prior to purging, while organic acids and sugars required addition of sodium peroxydisulfate ($Na_2S_2O_8$, Sigma, St Louis, MO) and a catalyst. Silver nitrate ($AgNO_3$, Thorn Smith Laboratories, Beulah, MI), cupric sulfate ($CuSO_4$, Mallinckrodt, Inc., St Louis, MO), and ferric chloride ($FeCl_3$, EM Science, Gibbstown, NJ) were each evaluated as a catalyst in the peroxydisulfate method. The effect of three different temperatures on the peroxydisulfate reaction was examined by adjusting the temperature of the hot bath (Fig. 2) to 21, 59, and 89°. Four different lengths and inside diameters of the delay coil were evaluated: 3.05 m (10 ft.) × 0.79 mm (1/32 in.), internal volume of 1.5 ml; 2.13 m (7 ft.) × 0.79 mm (1/32 in.), internal volume of 1.0 ml; 2.13 m (7 ft.) × 1.6 mm (1/16 in), internal volume of 4.3 ml; and 4 27 m (14 ft.) × 1.6 mm (1/16 in.), internal volume of 8.6 ml A delay coil was not employed for TIC determinations.

Reagents

Stock solutions of K_2CO_3 (Analytical Grade, J. T. Baker, Phillipsburg, NJ) were prepared by drying primary standard K_2CO_3 at 110° for 24 hr prior to dissolution in distilled, deionized water. A 0.25*M* solution of hydrochloric acid was prepared by dilution of the concentrated reagent using deionized water. Solutions of sodium peroxydisulfate were prepared by dissolving the solid reagent in deionized water. Solutions containing mixtures of organic acids and sugars were prepared by weighing and dilution with deionized water. Organic acids, sugars, and all reagents not already specified were obtained from typical commercial sources and used without additional purification.

RESULTS AND DISCUSSION

Purge-cell performance

The purge cell is the most critical component of the sample introduction system, and the design shown in Fig. 1 represents the best of several tested. The performance of this purge cell was evaluated using the FIA mode of sample delivery. In this procedure, carboy C1 was filled with a dilute solution of hydrochloric acid, and carboy C2 was filled with deionized water. An aliquot of standardized carbonate (K_2CO_3) solution was injected into the flowing aqueous stream using a 250-μl syringe and converted to CO_2 on mixing with the flowing hydrochloric acid stream. Dissolved CO_2 was liberated from solution at the gas dispersion tube and swept into the hydrogen/air flame by the purge gas (H_2), where it was vibrationally excited and detected by the FIRE radiometer configured in the carbon mode (4.4 μm filter)

In these studies, location of the gas dispersion tube with respect to the side arm of the cell [Fig. 1(B)] did not prove to be critical For convenience, the tube was positioned adjacent to the cell side arm, with the end of the Teflon® sample delivery tube close to, but not touching the tip of the porous frit.

Cell performance was found to vary with frit porosity in the gas dispersion tube. Figure 3(A) shows signals obtained by making replicate 250-μl injections of 12.5m*M* K_2CO_3 solution and acidifying with 0.25*M* hydrochloric acid. These results show that of the three frits tested, the 10–20 μm frit gave the best performance in terms of peak height and average RSD (4–8 μm frit: 35 mm ± 3.3%, 10–20 μm frit: 43 mm ± 3.3%; 25–50 μm frit. 30 mm ± 4.0%). As a result, a frit porosity of 10–20 μm was employed in all further studies.

The effect of hydrochloric acid concentration was also studied. According to the pK_1 and pK_2

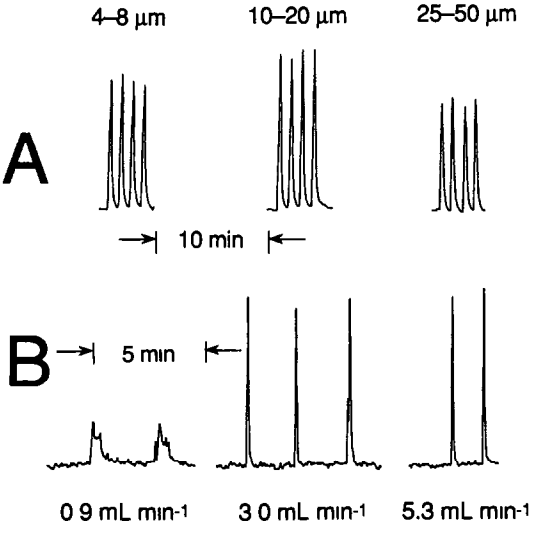

Fig 3. Peak profiles obtained with the sample delivery system configured for flow injection analysis (A) Influence of frit porosity in the gas dispersion tube Injections of 250 μl of 12.5m*M* K_2CO_3 solution mixed with 0 25*M* HCl (acid flow rate, 3.15 ml/min) (B) Influence of HCl flow rate for 10–20 μm frit porosity Injections of 25 μl of 0 241*M* K_2CO_3 solution Deionized water flow rate for (A) and (B), 5 30 ml/min

of carbonic acid (6 37 and 10.25, respectively) a final pH of less than 3.9 should be sufficient to convert all carbonate and bicarbonate in the sample into dissolved carbon dioxide. For samples with a relatively low acid-neutralizing capacity, 0.25*M* hydrochloric acid was used. For samples with a higher acid-neutralizing capacity, the concentration of hydrochloric acid was adjusted accordingly.

The influence of acid flow rate on purging efficiency was also studied. Different flow rates of hydrochloric acid were obtained by using Teflon® delivery tubes with different inside diameters and by adjusting the valve in the carboy cap. Figure 3(B) shows the injection profiles obtained from replicate 25-μl injections of 0.241*M* potassium carbonate solution followed by acidification with 0.25*M* hydrochloric acid. As can be seen from Fig. 3(B), if the flow rate of the hydrochloric acid stream was too slow, purging efficiency was poor, and serious peak broadening and distortion were evident. In general, narrow, symmetric peaks were obtained as long as the hydrochloric acid flow rate exceeded 3 ml/min

Because the purge gas (H_2) also provided fuel for the hydrogen/air flame, selection of the purge gas flow rate was an important factor affecting flame stability, as well as purging efficiency For optimal system performance, a hydrogen flow rate of about 50–70 ml/min was found to be satisfactory While higher flow rates produced stronger signals (as expected for a mass-flow rate detector), baseline fluctuations also increased Ultimately, the maximum hydrogen flow rate that could be used was limited by the internal pressure produced within the purge cell. If the flow rate produced an internal pressure much above one atmosphere, the spent liquid in the 8-mm Tygon® drain loop was expelled, allowing the purge gases to escape.

Because of the nature of the burner used, air flow rates were not particularly critical. As found in previous studies,[10] air flow rates between 100–200 ml/min produced satisfactory results. In general, both the hydrogen and air flow rates were adjusted to obtain optimal burner and purge-cell performance for each analytical application

Compared with the purge cell used in previous studies,[21–23] the new cell design (Fig. 1) offers several advantages. Since the internal free volume of the cell (internal cavity volume minus the volume of the gas dispersion tube) was less than 2 ml, flushing of the purged analyte into the flame was quite rapid, purge-cell clean-out problems were virtually eliminated, and peaks were sharp with minimal tailing [Fig. 3(A)] Since the new cell design continuously drained the spent analytical solution, cell disconnection and cleaning between samples were unnecessary. Therefore, the extra valves and reference purge cell required in the previous purge system[21–23] could be eliminated, and the total analysis time for a large number of samples was considerably shortened. Figure 3(A) shows that samples could be reproducibly injected at a rate of approximately 60/hr, compared with 10–20 samples/hr using the old purge system.[21–23]

Total inorganic carbon

Total inorganic carbon (TIC) in water is defined as the sum of all dissolved carbonates, bicarbonates and carbon dioxide present in the sample.[29] Because the level of TIC affects the pH and mineral content of the water, the measurement of TIC is important in many environmental and industrial areas including oceanography,[30] water resource management,[31] and water/wastewater treatment.[32]

Total inorganic carbon in water is typically determined indirectly from alkalinity titrations and a knowledge of the initial pH of the sample.[29] This indirect procedure depends on two measurements and can produce errors when the sample contains significant, but unsuspected levels of noncarbonate bases that increase the acid-neutralizing capacity of the water sample In contrast to alkalinity measurements, FIRE spectrometry has been shown to offer a sensitive, reproducible, accurate, and direct means of determining TIC, with few interferences.[22] In this earlier FIRE method, demountable purge tubes, requiring disconnection and cleaning between samples, were employed To demonstrate the versatility of the new sample introduction system, TIC in samples of Waco tap water was determined by FIRE spectrometry using both the process analysis and FIA modes of continuous sample delivery

FIA mode. In the FIA application, carboy C2 (Fig. 2) contained deionized water, and carboy C1 contained 0.25*M* hydrochloric acid Using this experimental configuration, a series of five replicate, 250 μl-injections of each of five standard potassium carbonate solutions was made, and the results are shown in Fig. 4(A). As can be seen from these recorder tracings, baseline stability was quite good, and replicate injections could be made with high precision (2.4%

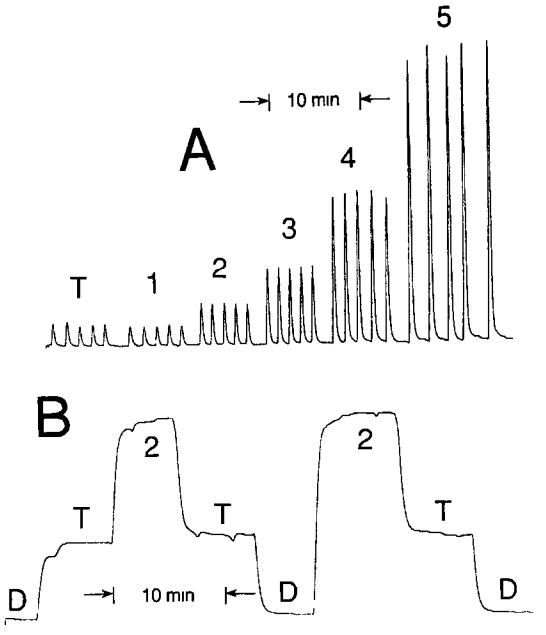

Fig 4 Peak profiles obtained with the sample delivery system configured for (A) flow injection analysis and (B) process analysis (A) Injections of 250 μl of (1) 3 12mM, (2) 6 25mM, (3) 12 5mM, (4) 25 0mM, and (5) 50mM K_2CO_3 solution, and (T) Waco tap water, each mixed with 0 25M HCl Flow rates deionized water, 5 34 ml/min, HCl, 3 59 ml/min (B) Signal obtained for continuous delivery of (D) deionized water, (T) Waco tap water, and (2) 6 25mM K_2CO_3 solution, each mixed with 0 25M HCl Flow rates deionized water plus HCl, 8.42 ml/min, Waco tap water plus HCl, 7 38 ml/min, K_2CO_3 solution plus HCl, 7 94 ml/min

average RSD for a single measurement) over the time period required for the analysis. Using this same data, a plot of average peak height vs. potassium carbonate concentration gave a highly linear calibration curve with a correlation coefficient of 0.99990. From this calibration curve, the TIC of a sample of Waco tap water was estimated from the five replicate injections, T, shown in Fig. 4(A) as equivalent to 3.1 ± 0.3mM potassium carbonate, a value which compares well with the TIC levels (2–4mM potassium carbonate) typical of the natural waters making up the municipal water supply.[22]

Process analysis mode. In this application, carboy C1 (Fig. 2) was replaced with three carboys, connected in parallel, which contained either deionized water [the blank, D in Fig. 4(B)], Waco municipal water [the sample, T in Fig. 4(B)], or a 6.25mM solution of potassium carbonate [the standard, 2 in Fig. 4(B)]. Carboy C2 (Fig. 2) contained 0.25M hydrochloric acid. Figure 4(B) shows the excellent reproducibility of the signal obtained using the FIRE radiometer when the four-way valve was repeatedly switched between blank, sample and standard.

On the basis of a single-standard calibration curve, constructed from the results shown in Fig. 4(B), the TIC of a sample of domestic water (taken on a different day) was estimated as equivalent to 2.4 ± 0.1mM potassium carbonate. The difference between the TIC values obtained from Fig. 4(A) and Fig. 4(B) undoubtedly reflects a number of factors including the natural variation in water quality and the difference between a single- and multi-point calibration procedure It should also be noted that in the process analysis mode, small differences in solution flow rate from the three carboys (blank, sample, and standard) were sometimes observed, even though the carboys were all pressurized from the same nitrogen cylinder. Since the rate of solution flow into the purge cell determines the magnitude of the signal, solution flow rate from these three carboys must be controlled as precisely as possible for good quantitative work

Nonvolatile organics

The measurement of TIC by FIRE spectrometry is made possible by the acidification step that converts non-volatile carbonates and bicarbonates to dissolved carbon dioxide, which can be readily purged from solution and excited in the FIRE source.[22] Nonvolatile organics in aqueous solution can, in principle, also be converted to carbon dioxide by chemical reaction prior to the purge step, if a suitable oxidizing agent can be found Sodium peroxydisulfate, one of the strongest chemical oxidizing agents known [$E°_{red}(S_2O_8^{2-}/SO_4^{2-}) = +2.010$ V; $E°_{red}(S_2O_8^{2-}/HSO_4^{-}) = +2.123$ V][33] was selected for this initial study, despite the fact that reactions involving this species are typically slow at room temperature and generally require a catalyst [34] Silver(I) and copper(II) are among the catalysts that have been investigated most extensively,[34] although peroxydisulfate reactions employing iron(III) chloride have also been reported.[35] In the silver catalyzed reaction, peroxydisulfate is thought to react with Ag^+ to form a higher valent silver species (Ag^{2+}, or possibly even Ag^{3+}), which subsequently oxidizes the substrate.[34] In the copper catalyzed reaction, the active oxidizing species is believed to be copper(III).[34]

The FIA mode of sample delivery was used to determine the best concentrations of sodium peroxydisulfate (carboy C2, Fig. 2) and catalyst (carboy C1) for the FIRE procedure. Of the

three metal salts investigated, silver nitrate was found to be the best catalyst for this application. In neutral media, cupric sulphate was an effective alternative to silver nitrate, especially under conditions in which silver formed an insoluble precipitate. In acid media (0.01*N* sulphuric acid), however, cupric sulphate appeared to lose much of its catalytic activity and was ineffective in promoting the oxidation of acetic, propionic, or butyric acids under the conditions employed in this study. Iron(III) chloride did not appear to exhibit any catalytic activity under the reaction conditions tested.

The effectiveness of sodium peroxydisulfate over a concentration range of 0.5–5% was also investigated. Peroxydisulfate concentrations greater than 2% caused the reaction to become so vigorous that considerable foaming of the liquid in the purge cell was produced. If the reaction occurred too rapidly, solution was forced out of the purge cell and into the Teflon® tube leading to the burner. This produced an unstable baseline and, in some cases, the flame was completely extinguished. At lower peroxydisulfate concentrations, the reaction proceeded more slowly, but a stable baseline could be obtained. A 1% sodium peroxydisulfate concentration was found to produce a reasonably rapid reaction, without excessive foaming, and represented a good compromise.

Concentrations of silver nitrate catalyst in the range from 0.1–10% were also examined. At high silver concentrations, excessive foaming in the purge cell was observed. A 0.25% silver nitrate solution was found to produce a reasonably rapid reaction rate, as well as a stable baseline, and was used for most peroxydisulfate reactions.

The peroxydisulfate reaction could also be accelerated by heating, and three different delay coil temperatures (Fig. 2) were investigated (21, 59 and 89°). At a bath temperature of 89°, the formation of bubbles could be observed in the delay coil as a result of substrate oxidation. Below 89°, no visible evidence of oxidation was observed.

Aqueous solutions of non-volatile organic acids, and mono- and disaccharides were used to test the peroxydisulfate pretreatment procedure The FIA mode of sample delivery was employed with carboy C1 containing a 0.25% silver nitrate solution, carboy C2 containing a 1% sodium peroxydisulfate solution, the hot bath maintained at 89°, and a total liquid flow rate of 10 ml/min. Samples containing individual compounds were injected sequentially into the flowing reagent stream using a 25-μl syringe. Figures 5(A) and (B) show the results obtained for the organic acids and the mono- and disaccharides, respectively. In both recordings, excellent baseline stability and peak shape are evident.

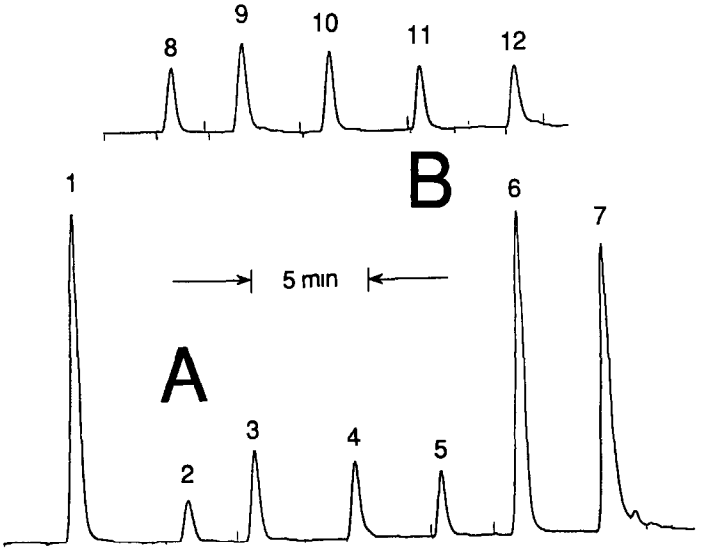

Fig 5. Peak profiles obtained for aqueous solutions of (A) carboxylic acids and (B) sugars, with the sample delivery system configured for flow injection analysis Interface conditions 1% sodium peroxydisulfate solution, 0 25% $AgNO_3$ solution; total liquid flow rate, 10 ml/min; delay coil, 3 05 m × 0 79 mm, water bath, 89°. Quantities injected. Table 1 gives the FIRE signal (peak height) obtained per mole of carbon injected into the sample delivery system. For the 11 compounds studied in this experiment, these values are fairly similar and range from a low of 1.8×10^6 mm/mole C for butyric acid to a high of 5.0×10^6 mm/mole C for acetic acid. An analysis of the numbers in Table 1 suggests that the extent of peroxydisulfate oxidation of the four aliphatic acids is a function of the chain length of the acid, with the two-carbon chain (acetic acid) giving the best results. Malic acid (a four-carbon, dicarboxylic acid) and citric acid (a six-carbon, tricarboxylic acid) may give a better response than butyric acid because the extra functional groups already make these molecules more highly oxidized

Table 1 suggests that the variation in signal per mole of carbon reflects differences in the kinetics of the oxidation process rather than thermodynamic factors, with conversion of analyte to carbon dioxide probably limited by the relatively short reaction time employed in the experiment. In this application, a 3.05 m (10 ft.) x 0.79 mm (1/32 in.) delay coil, having an internal volume of 1 5 ml, was selected to avoid excessive peak broadening. For a total reagent flow rate of about 10 ml/min and a heating coil volume of about 1.5 ml, the sample remains in the heating coil for only about 9 sec before entering the purge cell. If the extent of oxidation is governed by kinetics, the heating coil should be made as long as possible to ensure complete oxidation of the organic analyte. For process stream applications where the concentration of organic analyte may not vary dramatically with time and mixing of adjacent solution volumes is not a problem, very long coil lengths or stop flow techniques could be used to extend the reaction time of the sample.

HPLC mode

The generation of purgeable carbon dioxide by the oxidation of organic acids and sugars in a flowing liquid stream (Table 1) suggested that peroxydisulfate/Ag^+ pretreatment might be useful in the development of an improved FIRE detector for HPLC. Such a detector would be especially useful in applications involving the separation of nonvolatile organic compounds that do not have a conveniently accessible UV chromophore and are present at concentrations where changes in refractive index are small. Ion-exchange HPLC with an aqueous mobile phase was selected to avoid the large background associated with the oxidation of an organic mobile phase.

Figure 6(A) shows the chromatogram obtained for a 50-μl injection of an aqueous mixture of six sugars, separated on an ion-exchange column in the Ca^{2+} form. In this application, a 1% solution of peroxydisulfate was pumped from carboy C2 (Fig. 2) at a flow rate of 4.5 ml/min, and a 0.25% solution of silver nitrate catalyst was pumped from carboy Cl at 3.4 ml/min. The flow rate of the mobile phase (HPLC-grade water) through the ion exchange column was maintained at 0.5 ml/min. A 2 13 m (7 ft.) x 1.6 mm (1/16 in.) delay coil, having an internal volume of 4.3 ml, was immersed in a water bath at a temperature of 89°.

Figure 6(B) show the chromatogram obtained for a 50-μl injection of an aqueous mixture of six organic acids, separated on a column packed with cation-exchange polymer in the hydrogen form. In this application, a 1% solution of

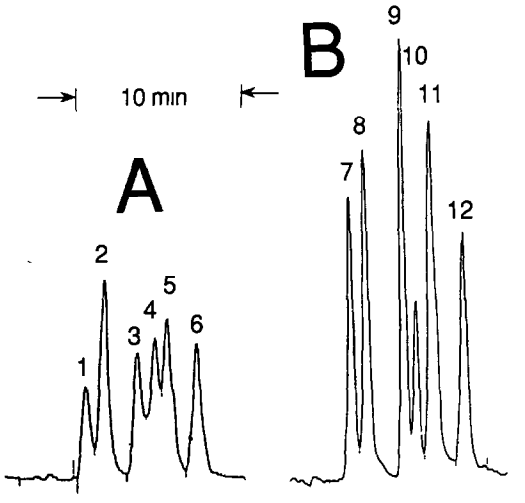

Fig 6 Peak profiles obtained for an aqueous mixture of (A) sugars and (B) carboxylic acids with the sample delivery system configured for ion-exchange high-performance liquid chromatography Sugars separated on a CHO-620 Carbohydrate column, mobile phase, HPLC-grade water, flow rate, 0 5 ml/min through the column, column temperature, 90°, 50-μl injection Interface conditions 1% sodium peroxydisulfate solution, 4 5 ml/min, 0 25% $AgNO_3$ solution, 3 4 ml/min, delay coil, 2 13 m × 1 6 mm, water bath, 89° Carboxylic acids separated on an ORH-801 Organic Acid column, mobile phase, 0 01N HNO_3, flow rate, 0 8 ml/min through the column, column temperature, 35°, 50-μl injection Interface conditions 1% sodium peroxydisulfate solution, 4 5 ml/min, 0 25% $AgNO_3$ solution, 5 7 ml/min, delay coil, 3 05 m × 0 79 mm, water bath, 89° Quantities injected (1)(96 μg raffinose, (2) 137 μg sucrose, (3) 122 μg glucose, (4) 117 μg galactose, (5) 120 μg fructose, (6) 122 μg mannitol, (7) 273 μg oxalic acid, (8) 290 μg tartaric acid, (9) 180 μg formic acid, (10) 185 μg fumaric acid, (11) 165 μg propionic acid, (12) 79 μg butyric acid

sodium peroxydisulfate was pumped from carboy C2 at 4.5 ml/min, and a 0.25% silver nitrate solution was pumped from carboy C1 at 5.7 ml/min. The flow rate of the mobile phase (0.01N nitric acid) through the ion exchange column was maintained at 0.8 ml/min. A 3.05 m (10 ft.) × 0.79 mm (1/32 in.) delay coil, having an internal volume of 1.5 ml, was immersed in a water bath at a temperature of 89°.

Figure 6 demonstrates that the FIRE-HPLC detector has good baseline stability and responds rapidly enough to follow the analytes as they elute from the column At the solution flow rates used, the carboxylic acids remained in the heated delay coil for only about 8 sec and the sugars for only about 30 sec. In the case of the sugars, a smaller diameter (1/32 in) delay coil resulted in such a short residence time in the heating bath that the signals decreased significantly The dependence of signal on residence time in the bath suggests that the extent of the reaction is controlled by the kinetics of the peroxydisulfate oxidation. A more detailed study of the parameters affecting the peroxydisulfate oxidation of organic analytes with the new purge system is currently underway in this laboratory.

While the HPLC column represents the major source of chromatographic band broadening when a UV- or RI detector is employed,[37] band broadening in the FIRE-HPLC chromatogram can also be caused by mixing with the peroxydisulfate and silver nitrate solutions, as well as by flow of the chromatographic effluent through the delay coil and other components which make up the FIRE-HPLC interface. In order to estimate the relative importance of these additional sources of band broadening, the band variances, σ^2, resulting from different components in the HPLC–FIRE interface were estimated (Table 2) from the baseline widths, W, of

several FIRE peaks assuming a Gaussian band shape.[37]

The band variance resulting from mixing with two reagents and flow through the HPLC–FIRE interface in the absence of both the delay coil and HPLC column (Table 2, row 1) was estimated from the FIRE response for injections of 50m*M* potassium carbonate solution [peaks 5, Fig. 4(A)]. In this experiment, the HPLC column and its connecting tubing had been removed, and injections were made manually through a septum located at M2 in Fig. 2. No delay coil was employed, but mixing occurred with the carrier (distilled water) from carboy C2 and with 0.25*M* hydrochloric acid introduced from carboy C1.

Peak 6 in Fig. 5 was used to estimate the band variance resulting from mixing with two reagents and flow through the HPLC–FIRE interface with the delay coil in place (Table 2, row 2). In this experiment, a 1-μl injection of 100% propionic acid was made manually through the septum injector. Mixing occurred with peroxydisulfate solution from carboy C2 and silver nitrate solution from carboy C1. A 3.05 m × 0.79 mm delay coil was used to promote the formation of carbon dioxide. Once this variance had been determined, band broadening due to the delay coil alone (Table 2, row 3) could be estimated by subtracting the band variance in row 1 from that in row 2.

Peak 11 in Fig. 6(B) (propionic acid) was used to estimate the total band variance for the complete HPLC–FIRE detector (Table 2, row 4). In this experiment, a mixture containing several organic acids was chromatographed on an ORH-801 Organic Acid column under conditions essentially identical to those recommended by the manufacturer.[38] Mixing occurred with peroxydisulfate solution from carboy C2 and silver nitrate solution from carboy C1 A 3.05 m × 0.79 mm delay coil was used to promote the formation of CO_2. Once the total variance had been determined, band broadening due to the HPLC column and the tubing which connected it to the multi-port valve M2, could be estimated (Table 2, row 5) by subtracting the variance in row 2 from that in row 4.

A comparison of the results in Table 2 indicates that band broadening in the complete FIRE-HPLC detector [including the column and delay coil (290 sec^2, row 4)], is nearly three times that resulting from the HPLC column and its connecting tubing alone (100 sec^2, row 5). Approximately half of the additional broadening results from the delay coil (90 sec^2, row 3) and approximately half from reagent mixing and flow through the remainder of the interface (100 sec^2, row 1). The band variance calculated indirectly for the HPLC column (our data, 100 sec^2, row 5) is reasonable when compared to the band variance estimated from the manufacturer's literature[38] for propionic acid under nearly the same chromatographic conditions (56 sec^2, row 6). [Some of the difference between these two values undoubtedly reflects the additional tubing required to connect the HPLC column to valve M2 (Fig. 2), as well as errors in estimating the variance in row 5 due to small differences in liquid flow rate for rows 1, 2 and 4.] The approximate agreement between the variances in rows 5 and 6 provides some verifications of the calculational procedure. These calculations have also suggested several design modifications for the FIRE-HPLC interface, which are currently being implemented in this laboratory.

CONCLUSIONS

A new liquid sampling system which employs a specially designed purge cell is described for use in continuous-flow FIRE spectrometry. The new analytical system represents a major improvement over the discrete-sampling purge system used in previous studies.[21–23] The small internal volume of the new cell promotes rapid flushing of the purge analyte into the flame, thereby minimizing problems associated with purge cell clean-out and resulting in sharp, reproducible signals. Spent analytical solution is continuously drained from the cell. Since cell disconnection and cleaning between samples is no longer necessary, total analysis time for a large number of similar samples is considerably reduced.

The new purge cell is highly versatile and was successfully tested in both a process analysis- and a flow injection analysis mode for the determination of TIC in Waco tap water. Other samples which have proven amenable to FIRE spectrometry using the new purge cell include carbonated beverages, bleaches, and volatile organic compounds (VOCs).[20] Some of these applications[20] employed a simple, single-channel FIRE photometer configured in the chlorine mode[7] (3.8-μm bandpass filter).

In this study, flame infrared-emission spectrometry was successfully extended to non-

volatile organic compounds, using chemical pretreatment with peroxydisulfate in the presence of silver ion to convert the analyte to carbon dioxide, prior to purging and detection by the FIRE radiometer. Pretreatment of six organic acids and five sugars with peroxydisulfate and silver ion at 89° for approximately 9 sec gave results which indicated that all 11 compounds were oxidized to nearly the same extent.

Chemical pretreatment avoids the introduction of large amounts of unwanted sample matrix into the flame, thereby minimizing dilution of analyte in the excitation source and reducing flame background noise. When pretreatment with peroxydisulfate and silver ion was applied to aqueous solutions of organic acids and sugars eluting from a liquid chromatograph, the FIRE radiometer could be used as a convenient detection system for ion-exchange HPLC.

(*Received* 7 *July* 1992 *Revised* 9 *October* 1992 *Accepted* 13 *October* 1992)

Summary—A variable-size simplex procedure was used to optimize the overall response of a simultaneous multi-element flame atomic absorption spectrometer Seven factors (air to fuel ratio, slit width, height above the burner head, and four hollow cathode lamp currents) were optimized for copper, iron, manganese, and zinc atomic absorption A univariate search procedure was used to determine the effect of individual factors on response The results of the optimization showed that a comprise set of operating conditions must be used when performing multi-element determinations The atomic absorption sensitivity of the multi-element determination as compared to single-element determination was reduced by a factor of no more than two

Convention flame or furnace atomic absorption spectrometry (AAS) has generally been considered to be a single-element technique. In the last decade, multi-element systems using sequential or simultaneous techniques,[1,2] including continuum sources[3] and lasers,[4] have been developed. Simultaneous multi-element AAS studies require that a single set of operating conditions, such as flame type, hollow cathode lamp current, and slit width be used for analysis. For optimum performance, a compromise in operating conditions between those of a single-element determination to a multi-element determination must be employed.

Univariate searches, which vary one factor at a time while holding other factors constant, have been used to optimize operating conditions. A drawback to this approach is that it does not take into account interactions between the factors being varied, and requires many experiments to optimize conditions. Another technique employed for system optimization is the "simplex" method A simplex is a geometric figure that has a number of vertexes equal to one more than the number of dimensions in the factor space: for example, a three-dimensional simplex is a tetrahedron.[5] Each variable being studied in the optimization process will add one dimension to the simplex. The simplex rapidly attains an experimental optimum guided by calculations and decisions that are rigidly specified.[6] The sequential simplex method as introduced by Spendley *et al.*,[7] uses a multi-factor, empirical strategy for optimizing experimental conditions.

Optimization of experimental factors in atomic absorption spectrometry was studied by Parker *et al.*,[8] and also by Borszeki *et al.*[9] They showed that by changing experimental factors, such as fuel and oxidant flow rates and burner height, the overall system response could be improved for a single element. Michel *et al.*,[10] and Sneddon[11] performed simplex optimization of experimental factors for microwave electrodeless discharge lamps. Johnson *et al.*,[12] used a simplex in the computer controlled study of pulsed hollow cathode lamps.

In this paper, a sequential simplex has been used to optimize the operating conditions for a multi-element measurement of copper, zinc, manganese, and iron using flame atomic absorption spectrometry. The factors that were varied include the slit width, hollow cathode lamp currents of each element, air to fuel ratio, and height above the burner head.

EXPERIMENTAL

Instrumentation

A Smith-Hieftje 8000 atomic absorption spectrometer (Thermo Jarrell Ash, Franklin, MA, U.S.A.) was used with an air/acetylene flame. The instrument was operated in the simultaneous mode which allows for analysis of up to four elements at a time. The system uses a galvanometer driven grating in its monochromator A galvanometer driven mirror is used to select lamps. This mechanism allows the instrument to scan the full spectrum (190–800 nm) in 20 milliseconds. Visimax II hollow cathode lamps were used. Measurements were performed with no background correction. Wavelengths for the four elements used were· 279.5 nm (manganese), 248.3 nm (iron), 324.7 nm (copper) and 213.9 nm (zinc).

Preparation of the standard

A standard solution containing 0.5 μg/ml zinc, 3.0 μg/ml copper, 4 0 μg/ml iron, and 2.5 μg/ml manganese was prepared from 1000 μg/ml certified atomic absorption solutions of zinc, copper, iron and manganese (Fisher Scientific Co, New Jersey). Concentrations were chosen by preliminary experimentation so that the signal generated was between 0.2 and 0.3 absorbance units and were based on previously established calibration curves which showed the approximate linear working range for each of the individual elements. Distilled/deionized water was used for making dilutions.

Procedure for the simplex

The simplex rules used in this study are based on the modified simplex introduced by Nelder and Mead.[13] These rules allow the simplex to expand in regions of favorable response and contract in regions of unfavorable response. An IBM^{tm}-compatible 286 computer was used for all calculations. A program was incorporated into Quattro Pro 3.0 Borland to calculate the reflection, expansion, and contraction points. Boundary conditions for the simplex were based on the operating limits of the instrument (*e.g.*, height above the burner head could not be below zero). If a new vertex contained an instrumental parameter which was beyond the boundary limits, or if the absorbance for any individual element was less than 0.1 absorbance units, a response of -1 was assigned.

The experimental factors include the air to fuel ratio, the height above the burner head, the slit width, and the hollow cathode lamp currents for each of the four elements (Mn, Cu, Zn and Fe). The system was auto-zeroed prior to each analysis. Four repeats were performed for each set of instrumental factors. The response at each vertex was taken to be the sum of the absorbance readings for each of the four elements. The best, next-to-worst and worst responses were ranked for each simplex move. The worst response was discarded in the next simplex move while a new calculated vertex was added (either a reflection, expansion or contraction) This procedure was continued until the overall response of the vertices varied by less than the experimental deviation.

Univariate experiment

Once the region of optimum response was found, a univariate search was conducted over a wide range of values for each instrumental factor. All factors were held constant at their simplex optimum value except for the factor of interest. Four repeats of each standard were conducted at the factor of interest. A sample uptake rate was maintained at 3 ml/min throughout the experiment.

RESULTS AND DISCUSSION

Simplex optimization

The simplex experiment was used to achieve the maximum overall absorbance for a simultaneous determination of the four elements listed above. The factors chosen each affect the overall absorbance of the system. The simplex was halted after 22 vertexes. Figure 1 shows improvement in overall response as the simplex increased. The coordinates for the final accepted

Operating parameters	Simplex optimum	Univariate optimum
Air/Fuel ratio (SCFH)	2 53—3 1	1.9–2.11 2 92–3 45
Slit width (nm)	0 4	0 4
Burner height (mm)	8.9–9 4	8 0–13 4
Copper lamp (mA)	2 0–3 0	2 0–5 5
Iron lamp (mA)	5.0–5 5	5 5–9 0
Manganese lamp (mA)	4 8–5.2	3 9–6 0
Zinc lamp (mA)	2 0–3 1	1.5–3.4

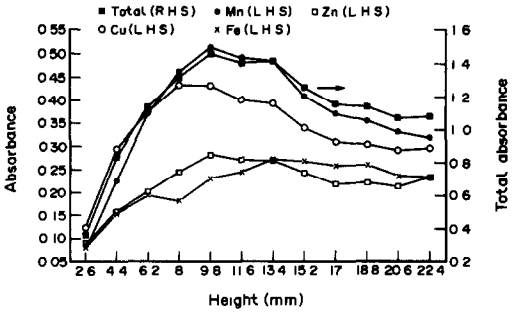

Fig 3

vertex (number 21), which produced the highest overall response, were taken as the optimum instrumental operating conditions. The eight initial vertices were based on the acceptable operating conditions for single element analysis. As such, the optimum response was achieved relatively quickly. Table 1 lists the results of optimum values which the simplex and univariate experiments obtained for each of the seven factors studied. Univariate experiments for each factor, in the region of the optimum, assisted in verifying that the optimum lay near the simplex value.

Air to fuel ratio optimization

The optimum values for the air to fuel ratio are listed in Table 1. Figure 2 illustrates the results of the univariate search for optimum air to fuel ratio. A univariate search was conducted to find the region of highest overall absorbance and the region for the maximum absorbance of the individual elements. There are two regions of optimum absorbance, the first at 3.16:1 and the second at 2:1. The two different regions of optimum occur due to the variation in absorbances for the individual elements. Copper, zinc and manganese have higher absorbances when the flame is fuel rich (lower air to fuel ratio). Iron, however, has a higher absorbance when the flame is fuel lean.

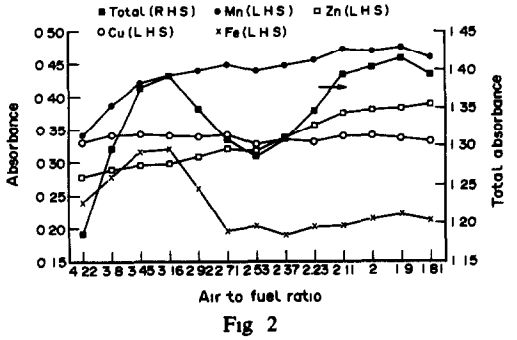

Fig 2

Height above the burner head optimization

Figure 3 shows the results of the univariate search for absorbance vs. height above the burner head. The height, given in mm, is the height from the tip of the burner head to the center of the hollow cathode lamp light. A maximum total absorbance was found at a height of 9.8 mm. Maximum absorbances for the individual elements occurred at slightly different heights above the burner head. No attempt was made to investigate potential interferences between elements which may have resulted as the height above the burner head was changed.

Slit-width and hollow cathode lamp current optimization

Five possible values of the slit width were available for the optimization: 0.08 nm, 0.15 nm, 0.4 nm, 1.0 nm and 2.0 nm. The simplex converged rapidly to the 0.4-nm slit width. At a slit width of 0.08 nm, insufficient light from the hollow cathode lamp reached the detector. While at the larger slit widths of 1 nm and 2 nm, the photomultiplier tube (PMT) used for iron became saturated with light. For the optimization of copper in a single element determination, a slit width of 1 nm is preferred. In the multi-element situation, however, this was not possible due to saturation of the PMT. These results again show that a compromise in operating conditions is required for multi-element determinations.

The range of optimum hollow cathode lamp currents is given in Table 1. Absorbances over the range of each of the lamp currents varied by less than 15%. Preferred lamp currents for individual element determinations did not vary from those of the multi-element determinations. The results for the single element determination are in agreement with those of Parker *et al.*,[8] who demonstrated that changing the lamp

Table 2. Comparison of atomic absorption sensitivity for single element determination *vs* multi-element flame AAS determination

Element	Sensitivity for single element μg/ml	Sensitivity for multielement μg/ml
Copper	0 065	0 085
Iron	0 08	0 167
Manganese	0 04	0 055
Zinc	0 015	0 016

current for calcium did not cause a statistically significant difference upon response.

Atomic absorption sensitivity

The atomic absorption sensitivity, defined as the concentration or mass which yields 1% absorption of $A = 0.0044$[14] was determined for each element individually and for the multi-element solution. Operating factors for the individual elements were determined from simplex optimization and univariate searches. For the multi-element standard, the instrumental parameters attained from the best response in the final simplex worksheet were used. Table 2 lists the atomic absorption sensitivities for the individual elements as compared to the multi-element case. In each case, the multi-element determination showed reduced sensitivity. Sensitivity was not decreased by more than a factor of two for any of the elements. The reduced sensitivity for iron in the multi-element analysis was caused by the use of an air to fuel ratio which was optimum for the other elements but which was not the optimum ratio for iron.

CONCLUSION

Multi-element atomic absorption requires a compromise in operating conditions from those of a single element determination. The modified simplex algorithm allows for rapid optimization of multi-element atomic absorption spectrometry. Once the optimum region has been attained, univariate searches can be used to verify that the simplex values are in the region of true optimum. Univariate searches can also provide some information about the effect of different operating conditions on single elements being analysed in a multi-element analysis. Using simplex optimized operating conditions, it can be seen that sensitivity is only slightly less for multi-element determinations for the elements used in this study

RESIN PHASE SPECTROPHOTOMETRY OF BERYLLIUM BY AN OPTICAL FIBER AND BERYLLON II

XU YANJUN, CHEN XINGGUO and HU ZHIDE*
Department of Chemistry, Lanzhou University, Lanzhou, 730000, People's Republic of China

(*Received* 3 *June* 1991 *Revised* 20 *June* 1991 *Accepted* 10 *October* 1992)

Summary—We have developed a resin phase spectrophotometric method to determine the amount of beryllium by detecting a change in absorbance of the resin phase 8-Hydroxynaphthalene-3,6-disulphonic acid–(1-azo-2′)-1′,8′-dihydroxynaphthalene-3′,6′-disulphonic acid tetrasodium salt (beryllon II) immobilized by a strong base anion-exchange resin on the end of a bifurcated optical fiber bundle was chosen as a material sensitive to beryllium Experiments were made using a home-made optical fiber spectrophotometer The properties of the resin phase proved to be good for continual use of 350 times during a month The reaction order between immobilized beryllon II and beryllium in solution was determined by kinetic theory and experiments This method was also used to determine the amount of beryllium in beryllium–copper alloy, the response was linear from 0.43 to 2 60 μg/ml at pH 12 5 and 676 nm. The effect of interfering ions on the determination of beryllium was studied at the same time

Many reagents have been proposed for the spectrophotometric determination of beryllium.[1] The two most important reagents for routine spectrophotometric determination of beryllium are chrome azurol S and beryllon II.[2–8] We immobilized the two colour reagents on a strong base anion-exchange resin and found that chrome azurol S and beryllon II immobilized on the resin formed colour complexes with beryllium in solution under proper conditions. The resin with beryllon II was attached to the common end of a bifurcated optical fiber bundle. We carefully studied the interaction between beryllium in solution and beryllon II in a resin phase and established a new analytical method by detecting a change of resin phase absorbance.

Our interest is in the development of new resin phase spectrophotometric methods which have a greater precision than conventional methods for the measurements of elements. In this paper we report our preliminary studies using an optical fiber spectrophotometer to assist the development of a new resin phase spectrophotometric method.

In comparison with conventional liquid phase spectrophotometry, a very small amount of colour reagent is consumed in measurements. In addition, the selectivity and sensitivity of this method is enhanced because of the separation and enrichment function of the resin.[11] In our experiments, because the resin phase with beryllon II interacts with dissolved beryllium for only a short time, there is no remarkable effect on enrichment.

Our method was based on detecting a change of absorbance in the resin phase; beryllon II was chosen as a material sensitive to beryllium. The absorbance of the Be-immobilized beryllon II complex was proportional to the beryllium concentration in solution. The method was also used to determine the amount of beryllium in beryllium–copper alloy Good results were obtained.

In general, it is convenient to establish such a method by using proper colour reagents and an optical fiber spectrophotometer.

EXPERIMENTAL

Apparatus

The optical fiber spectrophotometer is composed of a bifurcated optical fiber bundle and an ordinary spectrophotometer, Model 721, manufactured by the Shanghai No.3 Analytical Instruments Factory, China. Two arms of a bifurcated optical fiber bundle were fixed between the monochromator and the detector of the spectrophotometer.

A bifurcated optical fiber bundle is composed of many single strands of optical fiber. The effective sectional area of the bundle is 0.3 × 0.3 cm^2

*Author for correspondence

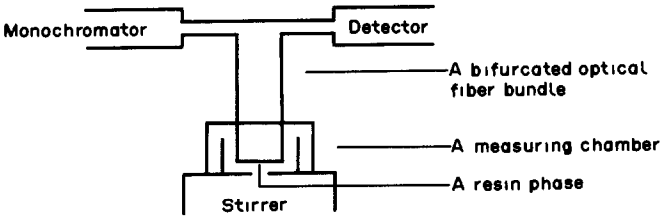

Fig 1 Measuring device

with two arms and a common end. Probe radiation is transported through one arm of the bifurcated bundle. Detected radiation is then transported through the other arm to a detector.[12] The measuring device is shown in Fig. 1.

The light source is a 10 V, 75 W tungsten lamp. The power supply voltage must be stabilized by a voltage-regulating transformer.

A pH meter, Model PHS-2, manufactured by the Shanghai No.2 Analytical Instruments Factory, China, was used to measure pH with a saturated calomel electrode (Type 232) and a glass electrode (Type 231) manufactured by the Shanghai Dian Guang Device Works, China. The solutions of various pH values were made by adding various volumes of sodium hydroxide solution to analytical solutions.

Absorbance was measured with a UV-240 spectrophotometer manufactured by Shimadzu Corporation, Japan.

Reagents

A beryllium stock solution was prepared by dissolving 0.2710 g of 99.99% pure beryllium metal in a minimum amount of concentrated hydrochloric acid and by diluting the solution to 250 ml with water. Less concentrated standard solutions were prepared by dilution from the stock solution. The 99.99% pure beryllium metal was provided by Professor Wang Huaigong of the Department of Chemistry, Lanzhou University.

Other reagents used were 5.0% EDTA solution, 10.0% sodium hydroxide solution, 10.0% ascorbic acid solution and 0.10% beryllon II solution. EDTA, sodium hydroxide, ascorbic acid and beryllon II were manufactured by the Peking Chemical Works, China.

Strong base anion-exchange resin (717) [R-N$(CH_3)_3$Cl] was manufactured by the Shanghai Resin Works, China. Its exchange capacity is 3.0 mmol/g. It possesses 7% cross-linking, the cross-linking agent being divinylbenzene (DVB). A general equivalent of 717 resin is Dowex I made in the U.S.A.

Polystyrene (average molecular weight about 10^5) was manufactured by Lanzhou Chemical Industry Company.

All reagents were analytical grade.

Procedures

Immobilization procedure. After 717 resin was ground in a grinder to 180 mesh size, the beryllon II was immobilized by soaking 1.0 g of 717 resin in a 10.0 ml, $1.8 \times 10^{-3}M$ beryllon II solution for half an hour and stirring. The resin with immobilized beryllon II was filtered through a funnel with filter paper, washed with water and dried by heating. Draw a certain amount of filtered, undiluted solution to determine the concentration of beryllon II in the filtered solution by spectrophotometry at 546 nm. The amount of beryllon II bound to the resin phase can be calculated through the change of beryllon II concentration in solution before and after adding the resin to the beryllon II solution. The amount of beryllon II bound to the resin was 1.4×10^{-5} mole/g.

A 6-ml toluene solution of polystyrene was mixed with 1.0 g of resin with immobilized beryllon II. The concentration of polystyrene in the toluene solution was 1.0 g of polystyrene in 50 ml of toluene. The 0.1 ml toluene solution

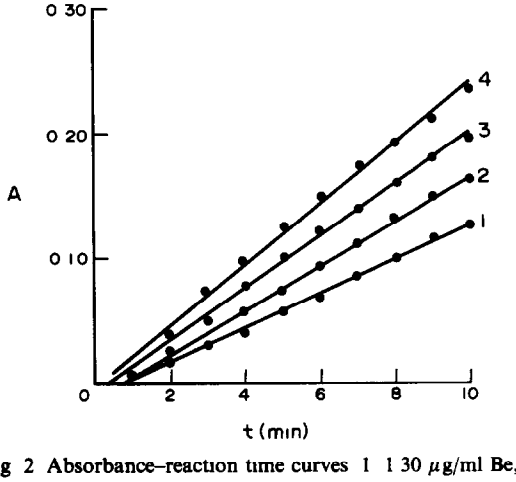

Fig 2 Absorbance–reaction time curves 1 1 30 μg/ml Be, 2 1 73 μg/ml Be, 3 2 17 μg/ml Be, 4 2 60 μg/ml Be

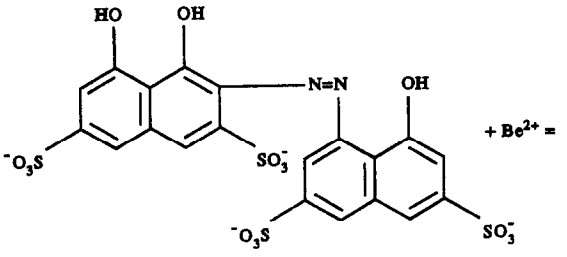
of polystyrene without resin phase was dropped to the common end of a bifurcated optical fiber bundle. After the toluene evaporated, the 0.1 ml toluene solution of polystyrene with resin phase was dropped to the common end of a bifurcated bundle. The resin phase could be used for measurement after toluene was evaporated completely About 16 mg of resin with beryllon II was attached to the common end of the bifurcated optical fiber bundle



Beryllon II was immobilized in a resin phase by combining RSO_3^- groups of beryllon II with $R\text{-}N(CH_3)_3^+$ groups of resin by electrovalent bonds.

Measurement of absorbance–time curves. Absorbance–time curves shown in Fig. 2 were measured using a home-made optical fiber spectrophotometer and beryllon II resin on the common end of the optical fiber bundle. A stirrer was used during the measurements.

Spectrum measurements. The absorption spectra of blank resin and resin–beryllon II without beryllium shown in Fig. 3(a) were obtained with a UV-240 spectrophotometer. During measurements, the blank resin and resin–beryllon II were suspended in pure glycerol.

The absorption spectrum in Fig. 3(b) were obtained with a home-made optical fiber spectrophotometer according to the analytical procedure.

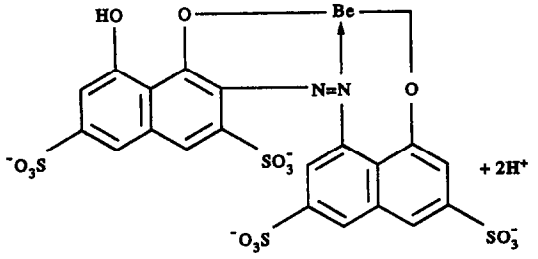
Analytical procedure A 2.0-ml volume of 10.0% ascorbic acid, 5.0 ml of 5.0% EDTA, 2.0 ml of 10.0% sodium hydroxide and a certain amount of beryllium were added to a 50-ml standard flask and diluted to the mark. The resin phase was immersed in the solution, and the absorbance was measured at 676 nm.

After detection, the resin phase was soaked in 3.0*M* hydrochloric acid for 3 min to remove beryllium in the resin phase. Because the colours of beryllon II vary with acidities in solution, the resin phase soaked in a 3.0*M* hydrochloric acid must be immersed in a reagent reference solution for 5–10 min to make beryllon II develop the color at the measuring pH value. By so doing, the zero point of a spectrophotometer can be regulated accurately before each measurement.

RESULTS AND DISCUSSION

Reaction order between beryllium in solution and beryllon II in the resin phase

By the reaction



we can obtain the reaction rate equation

$$dC/dt = K_1 C_L C_{Be} \quad (1)$$

where C is the concentration of the Be–beryllon II complex in the resin phase; t is time. C_L is the concentration of beryllon II in the resin phase; C_{Be} is the beryllium concentration in solution and K_1 is a constant. Because the concentration of the Be–beryllon II complex in the resin phase is proportional to the complex absorbance in the resin phase, we substitute the complex absorbance for the complex concentration in equation (1) and obtain equation (2)

$$dA/dt = K_2 C_L C_{Be} \quad (2)$$

where A is the complex absorbance in the resin phase. Because beryllon II is a solid, within a certain reaction time only beryllon II on the resin phase surface reacts with beryllium in solution; therefore, C_L can be considered constant during the reaction process. For the above reason, we can obtain equation (3)

$$dA/dt = K_3 C_{Be} \quad (3)$$

where $K_3 = K_2 C_L$.

In experiments, the beryllium amount in solution was considerable, up to 65–130 μg/50 ml. The amount of beryllium reacting with beryllon II in the resin phase accounts for a very small part of the total amount of beryllium in solution. So C_{Be} can also be considered constant during the reaction process. For the above reason, we can obtain equation (4)

$$dA/dt = K_4 \quad (4)$$

where $K_4 = K_3 C_{Be} = K_2 C_L C_{Be}$.

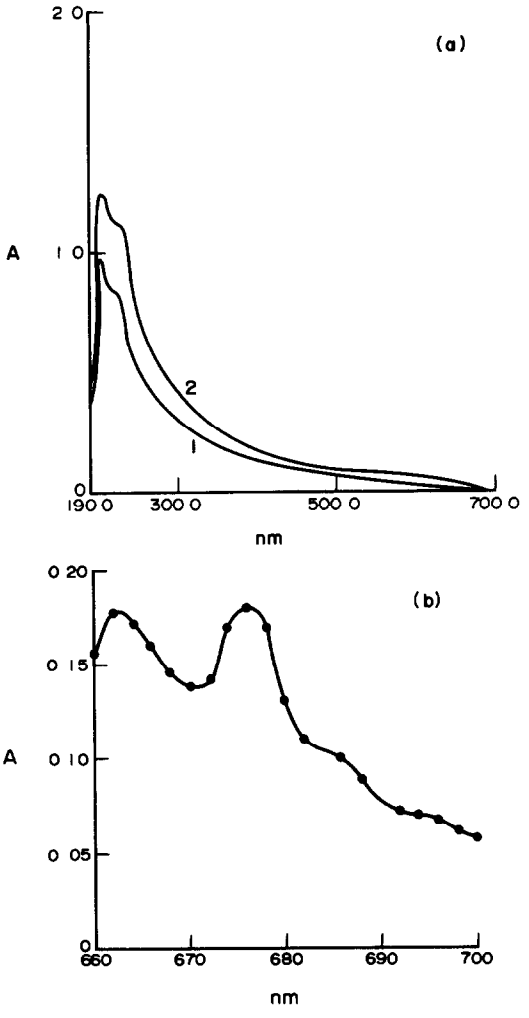


Fig 3 (a) Absorbance–wavelength curves 1 Blank resin, 2 resin–beryllon II (b) Absorbance–wavelength curve Reaction time = 5 min Be concentration = 2 17 μg/ml

Equation (4) is a rate equation of a pseudo-zero-order reaction. We integrate equation (4) to obtain equation (5)

$$A = K_4 t + B \qquad (5)$$

where B is a constant. Equation (5) is a kinetic equation of a pseudo-zero-order reaction. It shows that the Be–beryllon II complex absorbance in a resin phase is proportional to the reaction time between beryllium in solution and beryllon II in a resin phase only if the total amount of beryllium in solution is much greater than the total amount of beryllon II in the resin phase and only beryllon II on the surface of the resin phase reacts with beryllium in solution.

We conducted a series of experiments and found that the relation between the complex absorbance and the reaction time is linear, shown in Fig. 2. The change in absorbance with time was not influenced by the rate of stirring. By kinetic theory and experiments, we come to the conclusion that the reaction between beryllium in solution and beryllon II in a resin phase is a pseudo-zero-order reaction under our experimental conditions.

Because K_4 is equal to $K_3 C_{Be}$ and K_4 stands for the slopes of every curve in Fig. 2, K_4 increases with C_{Be} and can be determined by the slopes of every curve in Fig. 2. When the concentrations of beryllium in solution are 1 30, 1.73, 2.17 and 2.60 μg/ml, K_4 values in equation (5) are 0.014, 0.018, 0.021 and 0.025, respectively. In Fig 2, the Y-intercepts of curves 1, 2, 3 and 4 are 0.011, −0.015, −0.0081 and −0.0051

Figure 2 indicates that the A–t curves cannot pass through the origin because a certain time is needed for a change in beryllium concentration. Before beryllium in solution forms a complex with beryllon II in the resin phase, it must pass through the interface between the resin phase and solution. This mass transfer process takes some time. As the beryllium concentration in solution increases, the time decreases. When beryllium concentration is 1.30, 1 73, 2.17 and 2.60 μg/ml and absorbance values reach 0.1 unit, the time is 8.1, 6.5, 5 2 and 4.3 min, respectively.

Spectra

Figure 3(a) shows the absorption spectra of the blank resin and resin–beryllon II without beryllium.

Curve 1 has two absorption maxima at 204.8 and 222.3 nm. They are the E1 and E2 absorption bands of benzene rings in the resin Curve 2 also has two absorption maxima at 208.3 and 233.5 nm and we believe they are also E1 and E2 absorption bands of benzene rings in the resin. Because beryllon II was combined with resin, a red shift in absorption maxima was produced. It is reported that the absorption maxima of beryllon II in aqueous solution is 546 nm at pH 6–7.[7] After beryllon II was combined with resin, the absorption maxima at 546 nm disappears. We cannot yet explain the phenomenon.

It is reported in by Lukin and Zavarickhina[7] that the maximum absorption wavelength of the Be–beryllon II complex in aqueous solutions if 600 nm,[7] but Fig 3(b) shows that the maximum absorption wavelength of Be–immobilized beryllon II complex is 676 nm under our experimental conditions. Immobilization leads

to a maximum absorption wavelength shift from 600 to 676 nm. This red shift of the complex in the resin phase is attributed to a higher ligand concentration in the resin phase than one in the solution of a conventional wet method.[9-11] So, the Be–beryllon II complex has a higher coordination number in the resin phase.[9,11] However, no experimental evidence was provided to prove this point.

Effect of pH

Figure 4 shows the effect of pH on the absorbance of the Be-immobilized beryllon II complex. From pH 12.4 to 12.6, the absorbance of the complex is constant. At pH values higher than 12.6 and lower than 12.4, absorbance decreases rapidly. Absorbance is sensitive to a pH change. We chose pH 12.5 as a measuring pH value to obtain a higher absorbance. We cannot explain why the useful pH range is so narrow; perhaps at pH values more than 12.6, the dissolved beryllium forms a $Be(OH)_2$ precipitate while at pH values lower than 12.4, the Be-immobilized beryllon II complex on the resin phase may dissociate. In our study, no experiments were made on this aspect.

Acidity to remove beryllium from resin phase

We removed beryllium from resin phase using $1M$, $2M$, $3M$ and $6M$ hydrochloric acid. In order to ensure the removal of beryllium from the resin phase, we used $3M$ hydrochloric acid during our experiments.

Effect of ionic strength on absorbance

The effect of variation of ionic strength on the absorbance of the Be-resin–beryllon II complex was investigated adding a certain amount of sodium chloride to vary the ionic strength; it was observed that the absorbance of the Be-resin–beryllon II complex was independent of variation in ionic strength in the range 0–0.01M sodium chloride.

Calibration

Figure 2 shows that the slope of the absorbance–time curve is proportional to Be concentration in solution which means that the Be concentration can be related on the absorbance at a fixed time after the reagents are mixed. In our paper, reaction time was fixed to 5 min in sample analysis.

Since the method is used in the rate mode determining the reaction time is very important. If the reaction time is too long the resin phase

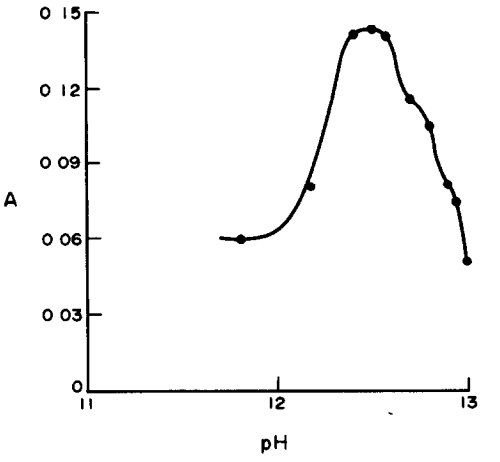

Fig 4. Absorbance–pH curve Reaction time = 5 min Be concentration = 2 17 μg/ml

is easily saturated and the linear range becomes narrow; at the same time, the analysis rate decreases. If the reaction time, is too short absorbance readings are too low and greater measuring errors occur.

In order to have a wider measuring linear range and shorter measuring time, we chose curve 2 (Fig. 5) as a calibration curve in sample analysis. Its slope is 0.0514, Y-intercept −0.0121 and correlation coefficient 0.9970. The linear range of curve 2 is 0.43–2.60 μg/ml. The reaction time of curve 2 is 5 min.

Experiments showed that response was linear from 0.43 to 2.60 μg/ml at pH 12.5. At this pH, the maximum absorption wavelength of the Be–beryllon II complex was 676 nm. By kinetic theory and experiments, we found that the reaction between beryllium in solution and beryllon II in the resin phase was a pseudo-zero-order reaction under our experimental

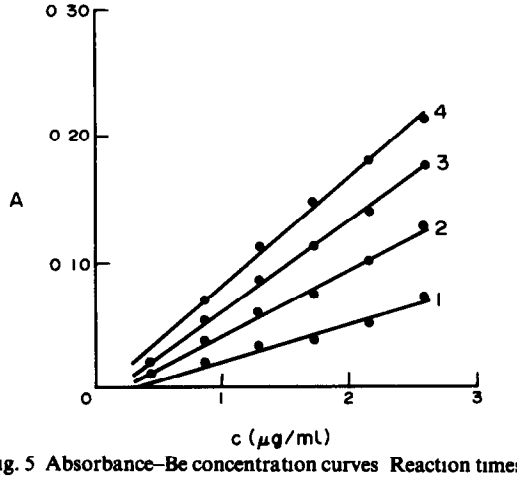

Fig. 5 Absorbance–Be concentration curves Reaction times of curves 1–4 are 3, 5, 7 and 9 min, respectively

Table 1 Effect of interfering ions on the determination of Be

Interfering ions	Concentration of interfering ions, μg/ml	Concentration of beryllium, μg/ml	Recovery rate of beryllium, %
F^-	240	2.17	104
Cl^-	400	2.17	100
NO_3^-	80	2.17	100
SO_4^{2-}	1920	2.17	93
PO_4^{3-}	760	2.17	93
Fe(III)	40	2.17	100
Co(II)	400	2.17	96
Ni(II)	800	2.17	100
Cu(II)	60	2.17	100
Mg(II)	60	2.17	103
Ca(II)	40	2.17	104

conditions. The stability of the resin phase was satisfactory for a continual use of 350 times during a month.

Effect of interfering ions

Table 1 shows the effect of interfering ions on the determination of beryllium.

Solutions of cation and anion for the interfering studies were made from the sulphates of copper(II), nickel(II), iron(III), the chlorides of cobalt(II), calcium(II) magnesium(II), sodium salts of fluoride, chloride, sulphate, phosphate and potassium salt of nitrate.

Many elements form coloured beryllon II complexes (*e.g.*, Fe^{3+}, Cu^{2+}, Mg^{2+}, Ca^{2+}, *etc.*) but in the presence of EDTA their interference is considerably masked.

Ascorbic acid was used to reduce iron(III) to iron(II) because, when a 10.0% sodium hydroxide was added, colloidal iron(III) hydroxide was formed which affected absorbance readings. Ascorbic acid can be omitted if iron is absent.

The relation between recovery rate of Be and Be concentration was not studied in our paper. Generally speaking, in a certain range of Be concentration, the recovery rate of Be does not vary with Be concentration.

Sample analysis

A beryllium–copper alloy sample solution was prepared by dissolving a 0.2518 g sample in 8 ml of 1:1 hydrochloric acid and by dropping 30% H_2O_2 as the solution was being heated. Surplus H_2O_2 was removed by heating. The sample solution was then transferred into a 100-ml standard flak and diluted to the mark.

Results of sample analysis are shown in Table 2.

Table 2 shows that the method is suitable for determining the amount of beryllium in beryllium–copper alloy and obtaining good results.

Precision was evaluated by measuring the absorbance at 676 nm four times for a sample. The Be concentration in the sample solution was determined from the second calibration curve of Fig. 5. Be content in sample and standard deviation were 2.02% and 0.03%.

This method is different from conventional resin phase spectrophotometry.[9-10] The resin phase with beryllon II need not be replaced for a long time. After beryllon II in a resin phase reacts with beryllium in solution, the resin phase is soaked in a 3.0*M* hydrochloric acid and the Be–beryllon II complex in the resin phase dissociates. Only beryllium in the resin phase comes off and beryllon II is still kept in the resin phase. In other words, after every measurement, the function of the resin phase can be entirely restored by soaking in hydrochloric acid. Because the resin phase has been attached to the common end of a bifurcated optical fiber bundle and need not be replaced, every measurement is made in the same resin phase; therefore, there

Table 2 Results of sample analysis

Be content in sample, %	Determined Be content, %	Standard deviation, % ($n = 4$)	Added Be amount, μg	Recovery rate of beryllium, % ($n = 4$)
2.12	2.02	0.03	21.68	104

is greater precision in this method than in a conventional resin phase spectrophotometric method.

POTENTIOMETRIC DETERMINATION OF IRON USING A FLUORIDE ION-SELECTIVE ELECTRODE—THE APPLICATION OF THE APPLE II-ISE INTELLIGENT ION ANALYZER

BINGYAO SUN,* YINGZHI YE, HONGWU HUANG and YAN BAI†
Department of Chemistry, Zhengzhou University, Zhengzhou, Henan, 450052, People's Republic of China

(*Received* 16 *July* 1992 *Revised* 24 *August* 1992 *Accepted* 10 *October* 1992)

Summary—A new method for determining iron is based on both nonlinear regression calibration plots and parabolic interpolation using a fluoride ion-selective electrode (ISE) and the Apple II-ISE intelligent ion Analyzer developed by ourselves The experimental conditions for determining iron are discussed The appropriate acidity of the experimental solution is pH 3, controlled by total ionic strength adjustment buffer (TISAB) that is composed of glycine (aminoacetic acid), nitric acid and sodium nitrate The suitable total concentration of fluoride is equal to the highest concentration of iron in the standard series Because the mathematical model of the method coincides with the experimental data the Apple II-ISE intelligent ion Analyzer can perform data acquisition and data processing, and the performance of fluoride electrode is excellent, the new method for determination of iron is fast and accurate This method has been used successfully in the determination of iron in mineral samples

Methods for determining iron include spectrophotometry,[1,2] titrimetry including redox titration[3] and complexometric titration,[4,5] photometric complexometric titration,[6,7] atomic absorption spectrometry (AAS),[8,9] polarized Zeeman AAS,[10] precolumn chelation liquid chromatography,[11] flow injection analysis,[12] oscillopotentiometric titration,[13] *etc.* In addition, there have only been a few reports on potentiometric methods[14,15] and kinetic potentiometric methods.[16,17] But there haven't been any reports on determining iron with a fluoride-ISE. Because several complexes can be formed from iron(III) and fluoride, the difficulty lies in establishing the stoichiometric ratio between fluoride and iron in their complexes during the analytical experiment. The stepwise stability constants are not markedly different in order of magnitude, so potential breaks at the equivalence point are not evident in potentiometric titration with fluoride as the titrant and fluoride-ISE as the indicator electrode. However it was found here that there is a smooth relationship between the potential of the fluoride-ISE and the amount of iron(III) in a standard series containing a constant quantity of fluoride. Furthermore, it was shown that the mathematical model, $y = ax^2 + bx + c$, coincides with the experimental data by the quadratic regression. Thus, both the quadratic regression calibration plot and the parabolic interpolation are satisfactory for the determination of iron.

EXPERIMENTAL

Reagents

Standard solution of iron(III) [$C(Fe^{3+}) = 0.1000M$] was prepared by dissolving reduced iron powder, that had been dried for two hours at 393 K and weighed accurately after cooling, in an appropriate amount of nitric acid. After the iron powder reacted completely it was necessary to remove the nitrogen dioxide from the solution by evaporation Then the solution was transferred to a volumetric flask, diluted to the mark with water and mixed. Dilute standard solutions of iron were prepared from the stock solution as above by diluting with water as necessary.

Total ionic strength adjustment buffer (TISAB) [$C(NaNO_3 + NH_2CH_2COOH + 0.18\ HNO_3) = 0.50M$] pH 3, was prepared by dissolving 37.5 g of glycine and 42.5 g of sodium nitrate in appropriate amounts of water, adding 6.2 ml of nitric acid during agitation, (calculated

on the basis of. $NH_3^+CH_2COOH$; $pK_{a1} = 2.35$[3], HNO_3: 66%, $\rho = 1.40$ g/cm^3), then the solution was diluted with water to 1000 ml. Other TISAB, pH 2 and pH 4, *etc.*, were prepared by altering the added amount of nitric acid.

Sodium fluoride solution [C(NaF) = 1.0M] was stored in a polyvinyl chloride (PVC) flask. Dilute sodium fluoride solutions were obtained by dilution.

All reagents used were of analytical grade and doubly distilled water was used throughout.

Apparatus

The fluoride-ISE was a Model 201 electrode (made in Jiangsu Electroanalyzer Factory), with $10^{-3}M$ sodium fluoride saturated by silver chloride as the interal solution. The reference electrode was a Model 217 double-junction saturated calomel electrode (made by Shanghai Electrophotodetector Factory) with a 1M sodium nitrate as the bridging solution. The test solution was in the PVC plastics beaker and stirred with a PVC-coated magnetic bar during the experiment. Both the stirring speed and electrode distance were kept constant throughout all measurements. The cell potentials were measured with the Apple II-ISE intelligent ion Analyzer (0.1 mV resolution), which has nine functions as follows:[18] (1) method of calibration plot; (2) single standard addition method; (3) double standard addition method; (4) Gran's method; (5) sample addition method; (6) comparison method and determination of pH; (7) determination of selectivity; (8) potentiometric titration; (9) digital potentiometer, and cannot only discriminate and acquire the equilibrium potential of electrode automatically, but also process data quickly. There are linear and quadratic regression and parabola interpolations in the method of the calibration plot. The principles of quadratic regression and parabola interpolation are explained in the following two sections.

Quadratic regression. Suppose the quadratic equation is

$$y = ax^2 + bx + c \tag{1}$$

If n pairs ($n \geqslant 3$) of data are acquired from experiments: x_i, $y_i (i = 1, 2, \ldots, n)$, then n simultaneous linear equations in three unknowns are obtained:

$$\begin{cases} ax_1^2 + bx_1 + c = y_1 \\ ax_2^2 + bx_2 + c = y_2 \\ \cdots \\ ax_n^2 + bx_n + c = y_n \end{cases} \tag{2}$$

Solving the simultaneous linear equations, we can find a, b, c and the quadratic equation by substituting a, b, c into equation (1). For the determination of iron with the fluoride-ISE, y is the potential of fluoride-ISE, x is the concentration of iron: $C(Fe^{3+})$, or its logarithm: $\log C(Fe^{3+})$.

Parabolic interpolation. Given n experimental points. x_i, $y_i (i = 1, 2, \ldots, n)$, and in order of: $y_i < y_{i+1}$, take three near-points to the point interpolated and calculate according to the formula as follows, that is, three-node Lagrange's interpolation formula:

$$\begin{aligned} x = {} & \frac{(y - y_i)(y - y_{i+1})}{(y_{i-1} - y_i)(y_{i-1} - y_{i+1})} x_{i-1} \\ & + \frac{(y - y_{i-1})(y - y_{i+1})}{(y_i - y_{i-1})(y_i - y_{i+1})} x_i \\ & + \frac{(y - y_{i-1})(y - y_i)}{(y_{i+1} - y_{i-1})(y_{i+1} - y_i)} x_{i+1} \end{aligned} \tag{3}$$

then, we can obtain x from y

For a given y, the three near-points can be selected in the following way.

$$i = \begin{cases} 2 & \text{at } y \leqslant y_2 \\ k-1 & \text{at } y_{i-1} < y \leqslant y_k \\ & \quad \text{and } |y - y_{k-1}| \leqslant |y - y_k| \\ k & \text{at } y_{k-1} < y < y_k \\ & \quad \text{and } |y - y_{k-1}| > |y - y_k| \\ n-1 & \text{at } y \geqslant y_{n-1} \end{cases} \tag{4}$$

The block diagram of the computer program for this calculation was referred to the previous work of authors.[19]

Procedure

Pipette 1.0, 2.0, ..., n ml of standard solution of iron into a series of 50-ml volumetric flasks successively, add equal volumes of sodium fluoride solution and 5 ml of TISAB solution, dilute to the mark with water and mix Transfer them in the proper order into a series of 100-ml dried plastics beakers, measure the cell potentials with Apple II-ISE Analyzer in order of decreasing iron concentration *i.e.*, increasing fluoride concentration. At the same time, enter the concentrations of iron corresponding to the various solutions. If the quadratic regression calibration plot was adopted, as soon as data acquisition was complete, the calibration plot would be displayed on the screen and printed out simultaneously on the floppy disk to use for

determining the sample. If the parabola interpolation was adopted, then the interpolation table would be arranged and written on the floppy disk.

Determination of iron in iron ore sample. The solution of mineral sample was prepared in a similar way as the standard solution of iron. Pipette an appropriate amount of sample solution into a 100-ml volumetric flask, add TISAB and an equal amount of sodium fluoride solution to the standard series and the sample. After measuring the potential, the result was displayed and printed out immediately.

RESULTS AND DISCUSSION

Effect of pH

Acidity influences both the potential response of fluoride-ISE and the complexation of iron (III) with fluoride.

Generally speaking, we should use the fluoride-ISE in the intermediate pH range 4–8.[20] If the pH is less than 4, the protonation results in the formation of hydrogen fluoride, to which the electrode is insensitive. However, it was shown that the electrode still retains good linear response of potential and the same experimental slope, $-59.3\ \text{mV} \cdot \text{pF}^{-1}$, in acidic solution by our experiments. This result is in agreement with Radic and Bralic.[21] In terms of theory, if we define C as the total concentration of fluoride and hydrogen fluoride δ_F as the fraction of concentration of fluoride, or distribution coefficient of fluoride, then:

$$[F^-] = \delta_F C = \frac{K_a}{[H^+] + K_a} C \tag{5}$$

$$a = \gamma_F [F^-] = \frac{\gamma_F K_a}{[H^+] + K_a} C \tag{6}$$

where, K_a is the dissociation-constant of hydrogen fluoride, a and γ_F are the activity of fluoride and its activity coefficient, respectively. After substituting formula (6) into the following equation:

$$E = E^0 + S \log a \tag{7}$$

we can obtain the potential of the fluoride electrode expressed in terms of γ_F, K_a, $[H^+]$ and C as follows:

$$E = E^0 + S \log \frac{\gamma_F K_a}{[H^+] + K_a} + S \log C \tag{8}$$

If the solution is sufficiently buffered, the ionic strength and pH are fixed. This can readily be realized by adding TISAB. Then, in equation (8), the second term,

$$S \log \frac{\gamma_F K_a}{[H^+] + K_a}$$

is constant. Consequently, the sum of the standard electrode potential E^0 and the second term is also constant. We can define the sum as the conditional potential and express it as $E^{0'}$, that is.

$$E^{0'} = E^0 + S \log \frac{\gamma_F K_a}{[H^+] + K_a} \tag{9}$$

substituting formula (9) into (8), a similar equation to (7) can be obtained:

$$E = E^{0'} + S \log C \tag{10}$$

Here, the linear relationship between E and $\log C$ is shown clearly. Because the conditional potential $E^{0'}$ is not a fixed constant but depends on the experimental conditions, the calibration plot will be shifted parallel when altering the experimental conditions. From the above discussion, we concluded that if necessary the fluoride-ISE can be used in acidic solution, but the experimental conditions, such as acidity, ionic strength, *etc.*, must be strictly controlled.

For the determination of iron, the acidity had to be controlled. We had prepared several standard series that contained the same total fluoride concentration, $2.0 \times 10^{-3} M$, and the same iron concentration range, $2.0 \times 10^{-4} \sim 1.0 \times 10^{-3} M$, only at different pH values. The experimental results are shown in Table 1.

The results illustrate that at pH 2 and 4 the variations of potential are less than pH 3. At pH 4 the hydrolysis and the formation of polyhydroxy complexes of iron(III) influence the complexation reactions of iron(III) with fluoride. At pH 2, the protonation of fluoride as a

Table 1. Effect of pH on potentials

$C(Fe^{3+})/M$	1.0×10^{-3}	8.0×10^{-4}	6.0×10^{-4}	4.0×10^{-4}	2.0×10^{-4}	R/mV
pH 2	103.7	94.8	86.4	78.7	71.2	32.5
3	84.7	72.3	60.7	50.2	40.7	44.0
4	53.8	49.9	44.6	37.5	28.5	25.3

*The numerical values in the table are potentials.

Table 2. The coefficients of the acid effect at different pH values (HF. $K_a = 6.8 \times 10)^4$

pH	$\alpha_{F(H)}$	$\log \alpha_{F(H)}$	$6 \log \alpha_{F(H)}$
2	15 71	1.196	7 176
3	2 47	0 393	2 358
4	1.15	0 061	0 366

side reaction is not neglected. If we introduce the coefficient for the acid $\alpha_{F(H)}$, as a coefficient for the side reaction:[22]

$$\alpha_{F(H)} = \frac{[F^{-\prime}]}{[F^-]} \tag{11}$$

$$\alpha_{F(H)} = 1 + \frac{[H^+]}{K_a} \tag{12}$$

and consider the effect of pH on the overall formation constant β_6 ignoring the other side reactions, then, from

$$\beta_6 = \frac{[FeF_6^{3-}]}{[Fe^{3+}][F^-]^6} \tag{13}$$

we can obtain:

$$\beta_6' = \frac{\beta_6}{\alpha_{F(H)}^6} \tag{14}$$

where β_6' is the conditional formation constant, the logarithmic form as follows:

$$\log \beta_6' = \log \beta_6 - 6 \log \alpha_{F(H)} \tag{15}$$

Some results calculated are arranged in Table 2. It is clear that at pH 2 the conditional formation constant β_6' is decreased by seven orders of magnitude compared to the overall formation constant β_6. But, at pH 3 the effect of acid is not serious, or can be neglected.

In summary, the optimum acidity for determining iron is pH 3.

Effect of fluoride concentration

Figure 1 shows the variation of potential when the standard series contains the same iron concentration range, $2.0 \times 10^{-4} \sim 1.0 \times 10^{-3} M$, but different total fluoride concentration, all at pH 3. The figure shows that the less the amount of fluoride the greater the variation of potential when the amount of fluoride is larger than one-fold amount. If the amount of fluoride is too much, such as seven-fold amount, the curve becomes gentle, that is, the variation of potential is not obvious. Therefore, to employ less fluoride is advantageous for increasing the sensitivity and accuracy of the determination of iron. But if the amount of fluoride is too little, less than one-fold amount, on the contrary, the variation of the potential begins to decrease and the potential response of the fluoride electrode becomes unsteady with poor reproducibility. A suitable amount of fluoride is just one-fold.

TISAB

Several buffer systems were used in the experiments. The system composed of glycine, nitric acid and sodium nitrate is better than others. Nitric acid and nitrate are better than hydrochloric acid and chloride, because chloride can complex with iron, and so influences the determination. A suitable concentration of TISAB is $0.05M$, but the effect of TISAB concentration is not as important as acidity and the fluoride concentration.

*Obtained by measuring the same standard series twice at interval of 10 hours after preparation

Range of determination

Table 3 lists the measured results of several standard series prepared in suitable experimental conditions at pH 3, with a one-fold amount of fluoride and 0.05M TISAB. The results show that the range for determining iron is $2.0 \times 10^{-5} \sim 1.0 \times 10^{-2}M$ and the optimum range is $2.0 \times 10^{-4} \sim 1.0 \times 10^{-2}M$. The measurement of potential showed that the solution can be steady for a long time after preparation.

Interferences

Every substance that can complex with fluoride will be possible interferences of the method, such as aluminium, silicon and zirconium. On the other hand, all substances being able to complex with iron except fluoride also influence the determination of iron, such as thiocyanate, oxalate and tartrate, Strictly speaking, during the determination the interferences should not be present, but it was shown in the experiments that if the interference concentrations are far less than iron, the method is not influenced.

A quadratic regression calibration plot is shown in Fig. 2. It is obvious that the mathematical quadratic regression calibration plot and parabola interpolation method have high accuracy and precision.

(*Received* 20 *July* 1992 *Revised* 7 *October* 1992 *Accepted* 8 *October* 1992)

Summary—A method is proposed for the simultaneous determination of copper and nickel by third-derivative spectrophotometry based on the absorption spectra of their complexes with cyanide ion in the ultraviolet range The method allows the determination of 0 55–5 8 μg/ml of copper and 0.55–6.8 μg/ml of nickel. The relative standard deviation for 11 determinations of 1 5 μl/ml of copper and nickel were 0.78 and 0.72%, respectively. The detection limits were 0.10 μg/ml for nickel and 0 13 μg/ml for copper The method has been applied to direct determination of copper and nickel in iron alloys and an aluminium alloy without any separation

Many methods have been reported for the spectrophotometric determination of nickel[1–5] and copper.[6–10] None of these is entirely specific for nickel and copper in the same sample.

The cyanide ion forms square tetracyanonickelate anion with nickel or copper in basic media. Buck *et al.*[11] demonstrated the potential application of ultraviolet spectroscopy for the measurement of nickel and copper.

In this paper the absorption spectra of nickel and copper complexes with cyanide ion are investigated using zero-order and derivative spectrophotometry. The suggested third-derivative spectrophotometry has been applied successfully to the analysis of copper and nickel in some iron alloys and an aluminium alloy without any separation.

EXPERIMENTAL

Apparatus

A Shimadzu UV-3000 double-beam spectrophotometer with 1.0 cm quartz cells was used.

Reagents

Stock solutions of copper and nickel, 5 mg/ml. Prepared from the sulphates. The exact concentrations were determined gravimetrically by ammonium thiocyanate and dimethylglyoxime method,[12] respectively, and further diluted as required.

Ammoniacal sodium cyanide solution containing 1.0 g of NaCN and 20 ml of concentrated ammonium hydroxide per 100 ml of solution is prepared.

All experiments were performed with analytical-reagent grade chemicals. Distilled water was used throughout.

Procedure

Transfer a known volume of sample solution containing 6.0–55 μg of copper and nickel into a 10 ml calibration flask. Add 0.15 ml of 1.0% NaCN solution, and dilute the mixture to the mark with distilled water. Record the third-derivative spectrum against a reagent blank. Determine the copper and nickel contents from the third-derivative spectrum by measuring the peak to valley signals at 242(+) nm - 234(−) nm for copper and at 271(+) nm - 283(−) nm for nickel, respectively, and comparing the value with an appropriate calibration graph.

Decomposition of sample

Dissolve 0.3 g of sample in 10 ml of hydrochloric acid (1 + 1) in a 50-ml beaker. Iron is oxidized by a few drops of concentrated nitric acid and the solution evaporated nearly to dryness. The residue is dissolved in 10 ml of

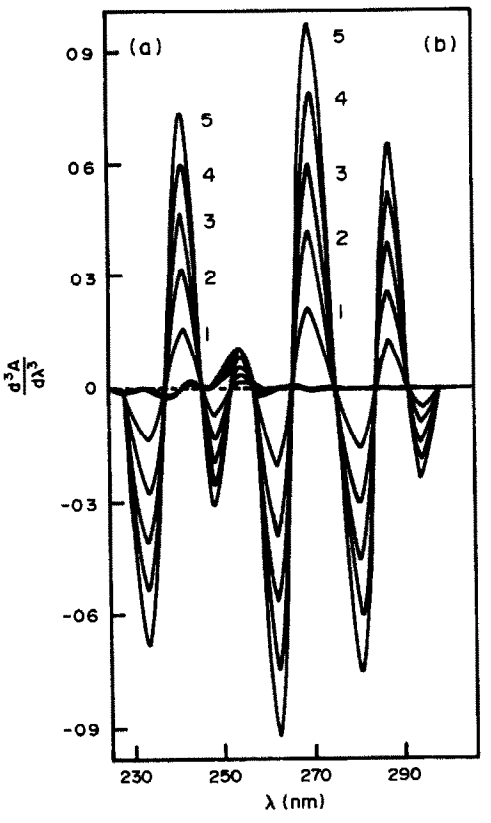

Fig 1 Calibration spectral curves $[CN^-] = 3.0 \times 10^{-3}M$, $\Delta\lambda = 6.3$ nm, scan rate = 50 nm/min, band pass = 1.0 nm, 1.0 cm cell (a) Cu, (b), Ni 1, 0.55, 2, 1.10, 3, 1.65, 4, 2.20, 5, 2.75 μg/ml

water. This solution with insoluble silicic acid is transferred to a 50-ml measuring flask. The iron (or aluminium) is precipitated by adding 25 ml of ammonium hydroxide (1 + 1) containing 5.0 g ammonium chloride and mixed thoroughly in the cold. The solution is diluted to the 50-ml mark with distilled water. Determine the copper and nickel concentrations in a suitable aliquot.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectrum of copper complex which has an absorption maximum at 238 nm; the absorption spectrum of the corresponding nickel complex has an absorption maximum at 268 nm; and both have sharp absorption patterns. However, they have slight interference on each other, when they are present in the same solution. To overcome this problem, derivative spectrophotometry can be used. The use of derivative spectra is not only simple and selective, but also improves the sensitivity.[13–15] Hence, their derivative spectras were investigated.

A study of the second-, third- and fourth-derivative spectra of the copper complex and nickel complex demonstrated that the third-derivative spectrum gave the lowest detection limits or highest sensitivity. The significant amplitudes are at 242(+) nm - 234(−) nm for copper and at 271(+) nm - 283(−) nm for nickel, respectively (Fig. 1).

Selection of optimum instrument conditions

The main instrumental parameters affecting the shape of the derivative spectra are the wavelength scan rate, the wavelength increment over which the derivative is obtained ($\Delta\lambda$) and the response time Therefore, various values of $\Delta\lambda$ were tested and 6.3 nm was selected, as the optimum, in order to give a satisfactory signal-to-noise ratio. The scan rate of the monochromator has no effect on the derivative signal obtained. Hence, a fast wavelength scan rate (*ca.* 50 nm/min) was selected The response time is automatically selected by the spectrophotometer in accordance with optical energy and the scan rate.

Optimization of reaction conditions

The effect of the cyanide ion concentration was studied. The experimental results found that the cyanide ion concentration ranges that gave the greatest derivative signals were 2.0×10^{-4}–$5.5 \times 10^{-3}M$ for copper and greater than $2.0 \times 10^{-4}M$ for nickel. So, $3.0 \times 10^{-3}M$ CN^- solution was selected.

The complexes formed quickly and the derivative absorption was stable for at least 6 h.

Calibration graphs,precision and detection limits

Using the optimum instrumental parameters and reaction conditions established above, linear calibration graphs were obtained by plotting the amplitudes measured for third-derivative spectra for copper and nickel in the concentration ranges 0.55–5.8 μg/ml and 0.55–6.8 μg/ml, respectively (in the final solution) The

*From Metallurgical Research Institute, Shandong, China
†Average of five determinations
‡Relative standard deviation ($n = 5$)

representative third-derivative spectral curves are shown in Fig. 1 The proposed procedure showed good precision, the relative standard deviation (RSD) for 11 determinations of 1.5 μg/ml of copper and nickel being 0.78 and 0.72%, respectively. The detection limits, corresponding to a signal-to-noise ratio (SNR) of 2, were found to be 0.13 μ/ml and 0.10 μg/ml for copper and nickel, respectively.

Interference studies

The effects of various cations and anions on the simultaneous determination of copper and nickel were investigated. The tolerance limit was taken as the amount that caused $\pm 5\%$ error. Cations were added as solutions of the their chlorides, nitrates or sulphates. Anions were added as solution of their sodium, potassium or ammonium salts. The results is given in Table 1.

Analytical application

The method can be applied to the determination of copper and nickel in iron and aluminium alloys. The results of analysis in comparison with certified values of several alloys are given in Table 2, indicating that the procedure provides accurate and precise results without the necessity of chemical separation.

FLUORESCENCE PROPERTIES OF 1-NAPHTHOL, 2-NAPHTHOL AND 1,2,3,4-TETRAHYDRONAPHTHOL IN AQUEOUS ALCOHOL SOLVENTS WITH AND WITHOUT β-CYCLODEXTRIN

DAN WU* and ROBERT J. HURTUBISE
Department of Chemistry, University of Wyoming, Laramie, WY 82071, U S A

(*Received* 29 *July* 1992 *Revised* 6 *October* 1992 *Accepted* 6 *October* 1992)

Summary—The fluorescence properties of 1-naphthol, 2-naphthol and 1,2,3,4-tetrahydronaphthol were obtained in binary aqueous–alcohol solvents with and without β-cyclodextrin. The fluorescence of both the molecular and anionic forms of 1-naphthol and 2-naphthol were observed in the binary solvents without β-cyclodextrin Only the fluorescence of the molecular form of 2-naphthol appeared in the binary solvents with β-cyclodextrin present, and its fluorescence was quenched with increasing amounts of β-cyclodextrin However, the fluorescence intensity of the molecular form of 1-naphthol increased with an increasing amount of β-cyclodextrin in the binary solvents The fluorescence intensity of 1,2,3,4-tetrahydronaphthol decreased with an increase in the amount of β-cyclodextrin The fluorescence results were interpreted with the Stern-Volmer equation and a modified Stern-Volmer equation

INTRODUCTION

A considerable amount of work has been carried out in investigating the interactions of guest molecules with cyclodextrins with water as a solvent.[1,2] However, very little work has been performed with binary aqueous–organic solvents. Nakajima[3] studied the effects of ethanol on the inclusion complex formation of pyrene with β-cyclodextrin (β-CD). It was found that the intensity ratio of the third vibronic band to the first vibronic band of pyrene decreased with the addition of ethanol. This implied that pyrene experienced a less polar environment in the presence of ethanol. Warner and coworkers[4,5] further investigated this phenomenon. They found that in the presence of alcohols the fluorescence intensity of pyrene was enhanced compared to that with no alcohols present. They also found that the largest increase was achieved in aqueous solution with a small amount of *t*-butanol. The intensity peak ratio also showed that with the *t*-butanol present in solution, pyrene experienced a more hydrophobic environment than in other alcohol solutions. They proposed that the alcohol molecule was a third component which participated in the complex formation. In other work, the fluorescence lifetimes of pyrene were measured in a γ-CD solution in the presence of alcohols, and the pyrene complex had a longer lifetime than the free pyrene.[6,7] Upon addition of alcohol, the lifetime and the formation constant of pyrene–γ-CD complexes were increased with respect to that in aqueous solution. Patonay *et al.*[8] also studied the quenching of pyrene in γ-CD aqueous solution. A modified Stern-Volmer equation was derived and applied to their experimental data. Nelson and Warner[9] have also investigated the fluorescence quenching of naphthalene and pyrene cyclodextrin complexes with iodide in the presence of alcohols. De la Pena *et al.*[10] considered the influence of alcohol addition on the γ-CD:pyrene complex. Hamai[11] has reported on the inclusion complexes of γ-CD with coronene in aqueous methanol, and also on exciplex formation between perylene and *N,N*-dimethylaniline in a ternary inclusion compound with γ-CD in a water–ethanol mixture. Also, Hamai[12] investigated the complexes of γ-CD with coronene in aqueous methanol. Recently, Huang *et al.*[13] reported the effects of aliphatic alcohol cosolvents on the nature of the cyclodextrin inclusion complexes of 2-anilinonaphthalene-6-sulfonic acid using steady-state and time resolved fluorescence spectroscopy.

In this work, the fluorescence properties of 1-naphthol, 2-naphthol, and 1,2,3,4-tetrahydro-

*Present address Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A

1-naphthol were investigated in binary organic–aqueous solvents with and without β-CD. It was important to investigate the fluorescence properties of these compounds without β-CD to help distinguish the change in the fluorescence properties of the model compounds in the binary solvents with and without β-CD present. In addition, by investigating two hydroxyl aromatics that are structural isomers, and a hydroxyl aromatic in which the hydroxyl group was substituted on a hydroaromatic ring, important insights were gained about the interactions of these compounds in binary solvents with and without β-CD present.

EXPERIMENTAL

Reagents

Ethanol was purified by distillation. Water was HPLC grade and obtained from Burdick and Jackson Co. (Muskegon, MI, U.S.A.) and used as received. Methanol and isopropanol (HPLC Grade) were purchased from Baker Inc. (Phillipsburg, NJ, U.S.A.) and used without further purification.

1-Naphthol (99%), 2-naphthol (99%), 1,2,3,4-tetrahydro-1-naphthol (99%) and β-cyclodextrin hydrate (β-CD) were purchased from Aldrich Chemical Co. (Milwaukee, WI, U.S.A.) and used as received.

Instrumentation

Fluorescence spectra were recorded on a Perkin-Elmer LS-5 spectrofluorimeter (Norwalk, CT, U.S.A.) which had a xenon lamp pulsed at line frequency (50–60 Hz) and f/3 Monk-Gillieson type monochromators. A 1 × 1-cm quartz cell was used for handling the sample solutions. Slits were set at 5 nm for the excitation monochromator and 3 nm for the emission monochromator for all fluorescence spectra measurements. The spectrofluorimeter was interfaced with a Perkin-Elmer 3600 data station. The data collection and manipulation were achieved by using the Perkin-Elmer computer software (PECLS). A Perkin-Elmer model 660 thermal printer was used for plotting the spectra. An ultrasonic cleaner (Cole-Parmer, Chicago, IL, U.S.A.) was used to mix the solutions.

Procedures

The model compounds were dissolved in binary solvents with different percentages of organic solvents and in the absence of β-CD for the initial set of experiments. For the other major set of experiments, the model compounds were dissolved in the binary solvents with a fixed organic solvent to water volume ratio, but with various amounts of β-CD. Different amounts of β-CD were added to a series of 10-ml standard flasks, and then the contents of the standard flasks were sonicated to ensure that all the β-CD dissolved. For all the solvent systems investigated for fluorescence, aliquots from a stock solution of a given model compound were added to the standard flasks prior to diluting with the appropriate solvent to the final volume. The stock solutions were prepared by dissolving a weighed amount of model compound in a 1 1 organic:aqueous solvent with no β-CD present and then diluting to volume. The final concentration of the model compounds used in the experiments were 3 μg/ml for 2-naphthol, 1 μg/ml for 1-naphthol and 5 μg/ml for 1,2,3,4-tetrahydro-1-naphthol.

Solution fluorescence excitation and emission spectra of the model compounds in the binary solvents in the absence and presence of β-CD were obtained with the Perkin-Elmer LS-5 spectrofluorimeter. A scan rate of 240 nm/min and response factor of 2 were used to obtain the spectra. Since the excitation and emission maxima of the model compound shifted slightly with the volume ratio changes of the binary solvents, the excitation and emission monochromators were set at the wavelength corresponding to maximum fluorescence intensities.

In order to compensate for instrumental variation and obtain accurate intensity readings, the intergradation mode of the Perkin-Elmer LS-5 was used, and a *p*-terphenyl fluorescence standard bar was employed (Wilmad Glass Co., Buena, NJ, U.S.A.). The fluorescence standard bar was rectangular shaped and had *p*-terphenyl embedded in a polymethyl methacrylate (PMMA) matrix. The excitation and emission wavelengths used for *p*-terphenyl were 295 and 338 nm, respectively. Each time the standard bar was placed in the sample holder at the same position to ensure reproducible fluorescence signals. To obtain an intensity reading, the quartz cell containing the sample solution was placed in the sample holder, and the monochromators were set at the corresponding excitation and emission wavelengths. The signal was integrated for 4 sec and the intensity reading of the sample (I_{sample}) was displayed. Then, the fluorescence standard bar was switched into the excitation light path, and the excitation and emission

monochromators were set at 295 and 338 nm, respectively. By using the integration mode, the intensity reading of the standard bar (I_{std}) was obtained. The corrected intensity was calculated by using the following equation:

$$I_{corr} = (I_{sample}/I_{std})20$$

This equation shows that all the sample readings were arbitrarily corrected to the value which corresponded to an I_{std} of 20.

RESULTS AND DISCUSSION

Fluorescence properties of 2-naphthol, 1-naphthol, and 1,2,3,4-tetrahydro-1-naphthol in binary organic–aqueous solvents in the absence of β-cyclodextrin

The fluorescence properties of 2-naphthol in water have been extensively studied.[14–16] 2-Naphthol in the lowest excited singlet state is a stronger acid than in its ground state, and it undergoes excited state ionization in water. In this work, the emission spectra of 2-naphthol in water, 0.1*N* hydrochloric acid and 0.1*N* sodium hydroxide solution were obtained so that the fluorescence spectra of the anionic and molecular forms of 2-naphthol would be available. The emission spectra of 2-naphthol in 0.1*N* hydrochloric acid and 0.1*N* sodium hydroxide were due to the emission of molecular and anionic species of 2-naphthol, respectively. The emission spectrum of 2-naphthol in pure H_2O had two major bands which corresponded to molecular and anionic forms of 2-naphthol with the band for the anionic species appearing at longer wavelengths. Because very little work has been published on the influence of binary aqueous–organic solvents on the fluorescence of organic compounds, and in particular, for compounds with similar structures, the fluorescence properties of the three model compounds were obtained in several binary solvents. Three alcohol:H_2O binary solvent systems were studied over a wide range of compositions. The solvent systems were methanol (MeOH):H_2O, ethanol (EtOH):H_2O, and isopropyl alcohol (IPA):H_2O. The fluorescence results for 2-naphthol in MeOH:H_2O solvent will be discussed as a representative example. Figure 1 gives the emission spectra of 2-naphthol in H_2O, MeOH, and MeOH:H_2O solvents. It can be seen that the intensities of emission bands changed with addition of MeOH. The pronounced change in emission spectra was due to the anionic peak gradually decreasing with an increasing content

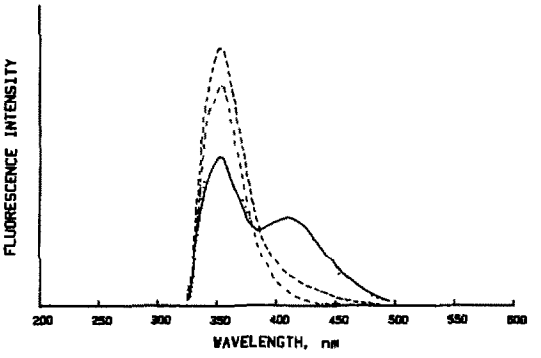

Fig 1 Representative fluorescence emission spectra of 2-naphthol in MEOH H_2O solvents in the absence of β-CD H_2O (——), MeOH H_2O (1 9) ( ), MeOH H_2O (1 1) (----), MeOH (- - -)

of MeOH. In pure MeOH, only the molecular form existed at 354 nm. Lee *et al.*[17] reported similar results for 2-naphthol in MeOH:H_2O. The excitation spectra showed red shifts of 0.5 nm and the emission spectra red shifts of 2.5 nm on changing from pure water to pure MeOH.

The relative fluorescence intensities of the molecular form of 2-naphthol and the anionic form of 2-naphthol *vs.* volume fraction of alcohol were compared, and the results for the molecular form are given in Fig. 2. The trends for intensity changes in the three alcohol:H_2O systems were similar to each other. As indicated in Fig. 2, the fluorescence intensities of the molecular form initially increased with addition of alcohols. At a IPA volume fraction of 0.5, a MeOH volume fraction of 0.7, and a EtOH volume fraction of 0.7, the intensities approximately reached maximum values, and then relative intensities decreased (Fig. 2) As more and more alcohol was added to the water, the fraction of the molecular form increased. Lee *et al.*[17] have shown that in greater than 50% methanol

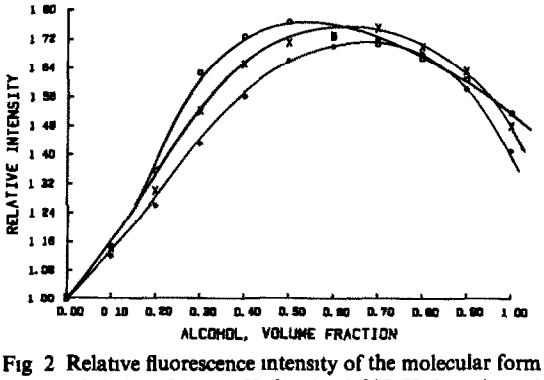

Fig 2 Relative fluorescence intensity of the molecular form of 2-naphthol in MeOH·H_2O (•), EtOH:H_2O (×), and IPA·H_2O (○) solvents *vs* volume fraction of alcohol to water

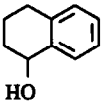
only emission from the molecular form of 2-naphthol was observed. In our work, fluorescence intensities of the anionic form in the different alcohol:water solvents decreased with addition of alcohols.

1-Naphthol undergoes excited state ionization in both neutral aqueous and acidic aqueous solutions. Excitation and emission spectra of 1-naphthol were obtained in H_2O, acidic and basic solutions. In the three types of solution, the emission band was the same and was due to the anionic form. In H_2O and acidic solution, the excitation bands corresponded to the ground state molecular form of 1-naphthol. In basic solution, the excitation peak originated from the ground state anionic form. Only in pure organic solvent could the fluorescence emission of only the molecular species be observed.

The fluorescence study of 1-naphthol was carried out in the same solvent systems as for 2-naphthol. Excitation and emission spectra of 1-naphthol in MeOH·H_2O solvents were obtained, and with increasing amounts of MeOH, the anion intensities, measured at 465 nm decreased, and intensities of molecular peaks at 328 nm increased In the solvents containing MeOH:H_2O, the emission spectra of both the molecular form and the anionic form were obtained. The excitation peak for 1-naphthol in MeOH was red-shifted by 4 nm relative to H_2O, and the emission band at 462 nm was blue-shifted by 3 nm relative to water. The spectra obtained in EtOH:H_2O and IPA:H_2O showed similar trends to that in MeOH.H_2O.

Plots of the relative fluorescence intensities of the molecular and anionic forms of 1-naphthol in the three alcohol·H_2O solvents *vs.* volume fraction of alcohol were acquired. The fluorescence intensities of the molecular form increased very slowly with larger amounts of alcohol, and then rapidly increased near a volume fraction of alcohol of 0.9. The maximum fluorescence intensity was reached in pure alcohol. The intensities from the anionic form had relatively constant values from pure H_2O to a volume fraction of alcohol of 0.3, then the intensities decreased with an increase in the amounts of the alcohol.

The fluorescence spectra of 1,2,3,4-tetrahydro-1-naphthol were obtained only in MeOH:H_2O and EtOH:H_2O binary solvents. As shown below, the structure of 1,2,3,4-tetrahydro-1-naphthol was different from 1-naphthol and 2-naphthol, in that, the hydroxyl group was bonded to an aliphatic ring. In addition, it does not undergo excited state ionization. The excitation and emission spectra of 1,2,3,4-tetrahydro-1-naphthol had one band each, and they appeared at 260 and 287 nm, respectively. The excitation bands red-shifted by 2 nm upon addition of MeOH, but the emission band did not shift. The fluorescence intensities increased with addition of alcohol. The maximum fluorescence values were obtained in a volume fraction of methanol of 0.6 MeOH:H_2O (6·4) and a volume fraction of ethanol of 0.5, and then the fluorescence intensities decreased beyond these volume fractions.



Fluorescence spectra of model compounds in organic–aqueous solvents with a fixed organic-aqueous composition in the presence of various amounts of β-cyclodextrin

The organic–aqueous solvent systems used in this part of the research were MeOH:H_2O (1:1), EtOH·H_2O (1:1) and IPA:H_2O (1·1) for 2-naphthol; MeOH.H_2O (1:9), EtOH·H_2O (1:9), and IPA.H_2O (1:9) for 1-naphthol; MeOH:H_2O (1:1) EtOH:H_2O (1:1) for tetrahydro-1-naphthol. The criteria used to select the solvents were a relatively high solubility of β-CD in the solvent and a relatively large change in the fluorescence intensity of the solute in the solvent in the presence of β-CD compared to the solute in the solvent without β-CD.

The emission spectra of 2-naphthol in EtOH:H_2O (1:1) were obtained with 0.00, 1.07, 4.54, 9 08 and 12 70 m*M* β-CD. The spectra showed only a molecular band at 355 nm, and the intensity of the 355 nm band decreased with the addition of β-CD. The emission spectra for 2-naphthol obtained in MeOH:H_2O (1·1) and IPA:H_2O (1:1) had similar spectral patterns as those obtained in EtOH:H_2O. A plot of fluorescence intensity of 2-naphthol in EtOH:H_2O *vs.* concentration of β-CD gave a straight line with a negative slope The same types of plots were also obtained with MeOH:H_2O and IPA:H_2O.

The emission spectra of 1-naphthol in EtOH:H_2O (1:9) are shown in Fig. 3. The emission spectra of 1-naphthol in all the binary solvents studied with β-CD gave molecular and anionic bands. The intensity of the molecular

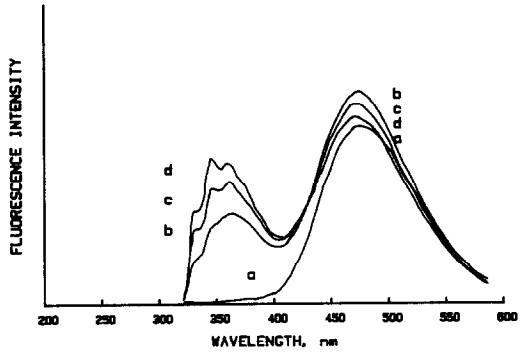


Fig 3 Fluorescence emission spectra of 1-naphthol in EtOH H_2O (1.9) with various amounts of β-CD (a) 0 00 mM, (b) 4 32 mM (c) 8 84 mM (d) 14 1 mM

form of 1-naphthol *vs.* concentration of β-CD is given in Fig. 4. As Fig. 4 shows, as the amount of β-CD increased, the fraction of the molecular form of 1-naphthol increased, and the intensity increased in a nonlinear fashion with the addition of β-CD. The intensity changes for 1-naphthol in MeOH:H_2O and IPA.H_2O were similar to that in EtOH:H_2O for the molecular species.

The fluorescence excitation and emission spectra of 1,2,3,4-tetrahydro-1-naphthol in binary solvents in the presence of various amounts of β-CD were relatively simple. There was only one emission peak, and the position of the spectra did not shift. The fluorescence intensity of this compound in EtOH:H_2O and MeOH:H_2O water decreased with the addition of β-CD, and linear relationships were obtained for fluorescence intensity *vs.* concentration of β-CD.

In summary, for 2-naphthol and 1,2,3,4-tetrahydro-1-naphthol in all the solvent systems studied, the intensities decreased with the addition of β-CD. In MeOH:H_2O, EtOH:H_2O, and IPA:H_2O the fluorescence intensity increased for the molecular form of 1-naphthol.

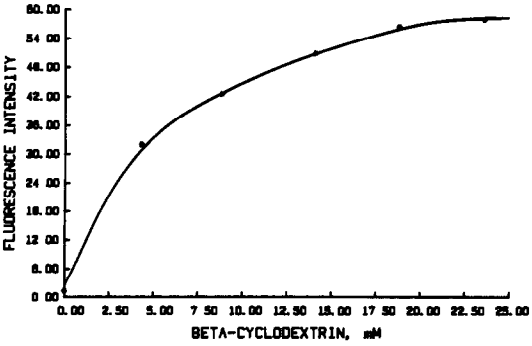

Fig 4 Fluorescence intensity of the molecular form of 1-naphthol in EtOH H_2O (1·9) *vs.* concentration of β-CD.

Fluorescence quenching of model compounds in binary solvents with various amounts of β-CD

The dynamic fluorescence quenching model is described by the Stern-Volmer equation:[18]

$$I_0/I = 1 + k_q\tau_0[Q] = 1 + K_{sv}[Q] \quad (1)$$

where I_0 and I are fluorescence intensities in the absence and presence of quencher, respectively, $[Q]$ is the concentration of the quencher, k_q is the bimolecular quenching constant, and τ_0 is the lifetime of the fluorophore in the absence of quencher. The Stern-Volmer constant is defined as K_{sv} and is equal to $k_q\tau_0$. Frequently, a plot of I_0/I *vs.* $[Q]$ gives a linear relationship, and the slope of the line is equal to the Stern-Volmer constant K_{sv}. As indicated in equation (1), if the lifetime of the fluorophor is known, the bimolecular quenching constant can be calculated.

If complex formation occurs with the ground state fluorophore and quenching results, the process is called static quenching. However, there are other mechanisms that can cause static quenching. An equation which has the same form as equation (1) is also used to describe the quenching mechanism [equation (2)].

$$I_0/I = 1 + K_s[Q] \quad (2)$$

where I_0, I, and $[Q]$ have the same meaning as in equation (1) In equation (2), K_s is the association constant of the complex in the ground state. According to this equation, a plot of I_0/I *vs.* $[Q]$ would also give a linear relationship. In this work, dynamic and static quenching could not be distinguished because lifetime measurements were not made.

As discussed earlier, the fluorescence signals of 2-naphthol and 1,2,3,4-tetrahydro-1-naphthol decreased with the addition of β-CD. Stern-Volmer plots of 2-naphthol in MeOH·H_2O, EtOH.H_2O and IPA:H_2O solvents were obtained, and all the curves gave linear relationships. The slopes of the curves were 16.4, 26.2, and 15.9 for MeOH:H_2O, EtOH:H_2O and IPA:H_2O, respectively. The linear relationships obtained for the curves indicated that either dynamic or static quenching processes were occurring. Based on the trends for the Stern-Volmer slopes, the fluorescence quenching of 2-naphthol by β-CD in the three alcohol:H_2O solvents was EtOH:H_2O > MeOH:H_2O > IPA:H_2O.

Stern-Volmer type plots of the molecular form of 1-naphthol data for water, MeOH:H_2O, and EtOH:H_2O did not represent quenching phenomena because the intensities of 1-naphthol in these solvents were enhanced. Thus, the normal Stern-Volmer plot could not be used to describe the data. However, a modified Stern-Volmer equation has been developed by Patonay *et al.*[4,8] that is useful in situations where the fluorescence signal is either enhanced or diminished. This equation was first used to explain the quenching of pyrene in β-CD solutions,[8] and it was assumed that the β-CD:pyrene complex might have a different quantum yield from the free molecular form. In their equation, Patonay and co-workers[4,8] defined the factors d and e as the quantum yield change of the cyclodextrin complex and the free molecule, respectively, and the ratio of fluorescence intensity could be expressed as:

$$(I_0-I)/I=[(1-e)+KC(1-d)]/(e+KCd) \quad (3)$$

where I_0 and I are fluorescence intensity of the compound in the absence and presence of quencher, or complexing agent, respectively. The term C is the concentration of the quencher, or complexing agent, and K is the equilibrium constant for the reaction of solute with cyclodextrin. If the quantum yield of the free molecular form does not change, which means e is equal to one, the equation (3) becomes:

$$(I_0-I)/I=[KC(1-d)]/(I+KCd) \quad (4)$$

Equation (4) can be rearranged to give.

$$I(I_0-I)=1/[K(1-d)C]=d/(1-d) \quad (5)$$

A plot of $I(I_0-I)$ *vs.* $1/C$ would give a linear relationship, and from the slope and intercept, the values of d and K can be obtained. As mentioned above this equation is not limited to describing quenching processes, but it can also be applied to cases where the fluorescence is enhanced.[4]

In this work, the fluorescence intensity of the molecular form of 1-naphthol increased in solutions with β-CD. It was assumed that the β-CD did not affect the fluorescence quantum yield of the molecular form of 1-naphthol, and thus equation (5) was valid. In addition, because only the fluorescence emission of the molecular form of 1-naphthol was measured, the fluorescence emission of the anionic form of 1-naphthol did not directly affect the fluorescence of the molecular form of 1-naphthol. The plots of $I(I_0-I)$ *vs.* $1/C$ of 1-naphthol for water, MeOH:H_2O, and EtOH:H_2O have good linear relationships with correlation coefficients of 0.995, 0.999, and 0.975, respectively. However, the same type of plot was also obtained for IPA:H_2O, and a linear relationship was not obtained. The equilibrium constants for the 1-naphthol:β-CD complex that were obtained from the plots were 1134, 859, and 171 for water, MeOH:H_2O and EtOH:H_2O, respectively. The d values were 34.3, 29.6 and 51.0 for water, MeOH:H_2O and EtOH:H_2O, respectively. The d values are rather large and indicate the substantial increase in the fluorescence intensity of the molecular form of 1-naphthol. This was due to the formation of a greater fraction of the molecular form of 1-naphthol as the amount of β-CD increased (Fig. 3). In MeOH:H_2O, the K value was larger than in EtOH:H_2O, which indicated in MeOH:H_2O more 1-naphthol reacted with β-CD than in EtOH:H_2O. This is reasonable because the association constant for EtOH with β-CD is 2.9 times as large as that in MeOH:H_2O.[19] Thus, 1-naphthol in EtOH:H_2O would not interact as readily with β-CD because EtOH would compete somewhat more effectively than MeOH for β-CD.

The Stern-Volmer plots of 1,2,3,4-tetrahydro-1-naphthol in MeOH:H_2O and EtOH:H_2O gave linear relationships, and the slopes of the plots with MeOH:H_2O and EtOH·H_2O were 47.1 and 54.5, respectively. The larger slope with EtOH:H_2O indicates more effective quenching in this solvent system and may be related to the fact that EtOH reacts more with β-CD than does MeOH.

Comparison of results

In water, the molecular and anionic forms of 2-naphthol were present. With the addition of alcohol, the extent of excited state ionization decreased, and only the molecular form emitted at relatively high concentrations of alcohol. For example, with ethanol, only the molecular form was present at 50% ethanol and greater. With 1-naphthol, only the anionic form emitted in water, and with the addition of alcohol both the molecular and anionic forms of 1-naphthol appeared, but the molecular form only started to appear in relatively large amounts of alcohol. This indicated that 1-naphthol had a greater tendency to undergo excited ionization than did 2-naphthol in alcohol water solvents. For 1,2,3,4-tetrahydro-1-naphthol it did not undergo excited state ionization, and its

fluorescence intensity reached maximum values in alcohol solvents that contained a sizeable amount of water.

Because of the very large range of solvents that could be used for the binary alcohol:water solvents, a wide range of binary solvents that contained β-CD were not investigated. Nevertheless, some very interesting results were obtained. Only the molecular form of 2-naphthol was present in the alcohol:water solvents containing β-CD, but the fluorescence intensity of 2-naphthol decreased in a linear fashion with the addition of β-CD. In contrast, the fluorescence intensity of the molecular form of 1-naphthol increased with the addition of β-CD while the fluorescence intensity of the anionic form of 1-naphthol decreased with increasing amounts of β-CD. The results obtained for the two hydroxyl aromatics indicated that they interacted differently with the alcohol:water β-CD systems. Because 2-naphthol did not show the anionic form, then it was possible that the hydroxyl group was inside the β-CD or protected from water, and thus did not undergo excited state ionization.[20,21] In the alcohol:water solvents with β-CD, 1-naphthol gave fluorescence emission from both the molecular form and the anionic forms. Thus, the hydroxyl group was not buried in the β-CD cavity and could undergo ionization with a sizeable amount of β-CD present Interestingly, 1,2,3,4-tetrahydro-1-naphthol is structurally similar to 1-naphthol, but its fluorescence intensity decreased with the addition of β-CD.

The results of this work indicate that more detailed photophysical experiments are needed to elucidate the interactions of the three model compounds with β-CD in binary alcohol:water solvents. However, the results of this work form the basis for the development of analytical methodology for the determination of mixtures of 1- and 2-naphthol in alcohol:water solvents in the presence of β-CD. In addition, the results can be used in the fluorescence detection for the separation of the hydroxyl aromatics by high-performance liquid chromatography with alcohol based mobile phases that contain β-CD.

(*Received* 20 *July* 1992 *Revised* 5 *October* 1992 *Accepted* 5 *October* 1992)

Summary—Silica fume is formed as a by-product in the manufacture of silicon from quartzite. This paper describes an analytical method for the determination of free carbon and silicon carbide in silica fume. The silicon carbide was determined after removal of free carbon, amorphous silica, crystalline silica, graphite and silicon from the fume. The free carbon content was found to vary from 2 to 8% while the silicon carbide content ranged from 1 to 5%. X-ray diffraction, thermal analysis, scanning electron microscopy and Fourier Transform infrared spectroscopy were used to validate the steps used in the analytical procedure. The purpose of determining the free carbon and silicon carbide content of the fume is to help understand the efficiency of the reduction process and mechanism of the reaction.

Silica fume is formed as a by-product in the manufacture of silicon from quartzite by reduction with charcoal, coal or coke at temperatures of up to 1780° using graphite electrodes in an electric arc furnace. While there are a few less important reactions, the following represents the main reaction sequence.[1]

Molten quartz reacts with reductant:

$$SiO_2(l) + C(s) \xrightarrow{1780^\circ} SiO(g) + CO(g) \quad (1)$$

Gaseous SiO reacts with reductant:

$$SiO(g) + 2C(s) \xrightarrow{1570^\circ} SiC(s) + CO(g) \quad (2)$$

SiC reacts with molten quartz:

$$SiC(s) + SiO_2(l) \xrightarrow{1780^\circ} Si(s) + SiO(g) + CO(g) \quad (3)$$

The silica fume forms when SiO in the vapour phase reacts with oxygen:

$$2SiO(g) + O_2(g) \longrightarrow 2SiO_2(s)$$

Any unreacted carbon reductant and intermediate SiC will be carried through in the fume. Some fragments of the quartzite burden are also carried through with the fume, together with low levels (<1%) of graphite fragments from the electrodes. Low levels (<1%) of elemental silicon may also be detected in the fume. There have been no previous attempts to analyse SiC as a minor component in silica fume or other such matrices. Julietti[2,3] has developed procedures for the analysis of SiC in silicon carbide refractories.

A knowledge of the free carbon and SiC content of the fume is of important in assessing the efficiency of the reduction process and understanding the reaction mechanism.

EXPERIMENTAL

Samples

Approximately 150 g samples were taken at regular intervals from the fume discharge line to the baghouse over two periods. They were numbered 1–12 and 13–27 corresponding to the day, month and time of sampling. All samples were dried at 110° for 1 h prior to analysis. Samples of silicon and graphite electrodes were also taken for analysis.

Reagents

Hydrofluoric acid 70% Flukka Grade. Nitric acid 70%, AR Grade. Silicon carbide, LR Grade. Quartz, AR Grade.

Instruments

X-ray Diffraction measurements were made on a Philips PW 1820 diffractometer. DTA measurements were carried out on a Stanton

Redcroft STA-780 in air at a heating rate of 20°/min. Fourier Transform Infra Red measurements were made on a BioRad FTS-40. Scanning Electron Microscopy measurements were made on gold coated samples using a Leica Cambridge Stereoscan 360.

Qualitative tests

Triplicate samples of SiC, graphite, quartz and silicon were treated with HF, HNO_3 and a HF/HNO_3 mixture to confirm the steps used in the analytical procedure. One-gram samples were dissolved in 50 ml of acid corresponding to the conditions to be used in the analytical procedure. The percentage weight losses were recorded for each test.

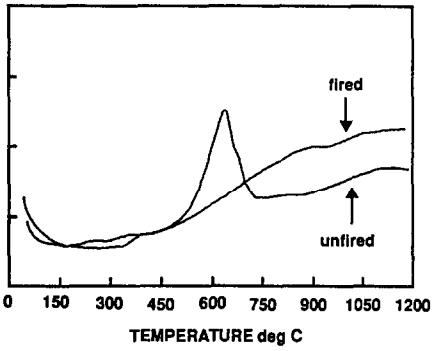

Fig 2. Differential thermograms of fired and unfired fume

Firing

One silica fume sample was heated at a series of temperatures for various periods of time to establish that there was no oxidation of SiC under such conditions. The relative intensities of the SiO_2 and SiC peaks were determined by X-ray diffraction.

Method for free carbon and SiC

A 10-g portion of silica fume sample was heated in a platinum crucible at 750° for 1 h The crucible was cooled and weighed. Two 5-g halves of sample, were treated separately with 50 ml of 1:1 HF in a Teflon beaker at 180° for 1 h and taken to dryness. A mixture of 10 ml of HNO_3 an 15 ml of HF was added and the sample again taken to dryness. A further 10 ml of HF was added to ensure the complete removal of silica. A 25 ml volume of HNO_3 was

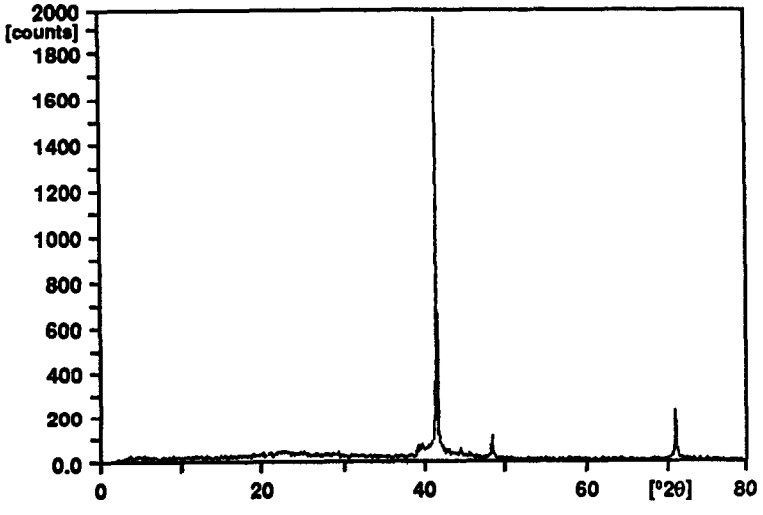

Fig 3. XRD trace of a SiC residue.

Table 2 X-ray diffraction of fired samples

Temperature (°C)	Time (min)	SiO_2 SiC Peak intensity
0	0	3 0
400	60	2 7
500	60	2 7
600	20	2 9
600	60	2 6
750	60	3 1

added, the beaker covered with a watchglass and the sample boiled for 4 h. The solution was diluted with 50 ml of deionized water and the grey residue filtered through a previously weighed 0.8 μm millipore filter paper. The paper and residue were dried at 110°, cooled and weighed as SiC. One SiC residue was sonicated for 30 min, treated with 5 ml of HNO_3 at 140° for 30 min and thermally analysed in air to check for complete removal of free carbon from the sample.

RESULTS AND DISCUSSION

Qualitative tests

The dissolution characteristics for the components of the fume are shown in Table 1.

Free carbon and silicon carbide content

The results for the free carbon and SiC content of the silica fume samples are shown in Fig. 1. The RSD for the free carbon determination was $\pm 1\%$ while that for the SiC determination was $\pm 3\%$.

The similar variation between the free carbon and SiC content is evidence for the proposed reaction mechanism. Some free carbon will be found in the fume due to incomplete reaction of the carbonaceous raw materials in equation (1). The diffusion of gaseous SiO through the highly porous carbon will result in both the complete conversion of carbon to SiC and the formation of some incompletely reacted SiC-coated carbon particles. The greater the number of these SiC-coated carbon particles, the higher will be the apparent free carbon content when the fume is fired at 750°. The results are thus evidence for equations (1) and (2) of the proposed reaction mechanism. Any carbon not oxidized at 750° will be removed during the concentrated nitric acid treatment in the analytical procedure.

Discussion of the analytical method

Differential thermograms of an unfired silica fume sample and one fired at 1000° for 1 h are shown in Fig. 2. The disappearance of the 600° exotherm indicates that all free carbon was removed by heating the sample at 750° for 1 h.

An X-ray diffractogram of a SiC residue is shown in Fig. 3. The only peaks found were those for SiC at 42°, 49° and 71° (2θ), respectively

X-ray diffraction data for the unfired and fired samples are shown in Table 2. The results

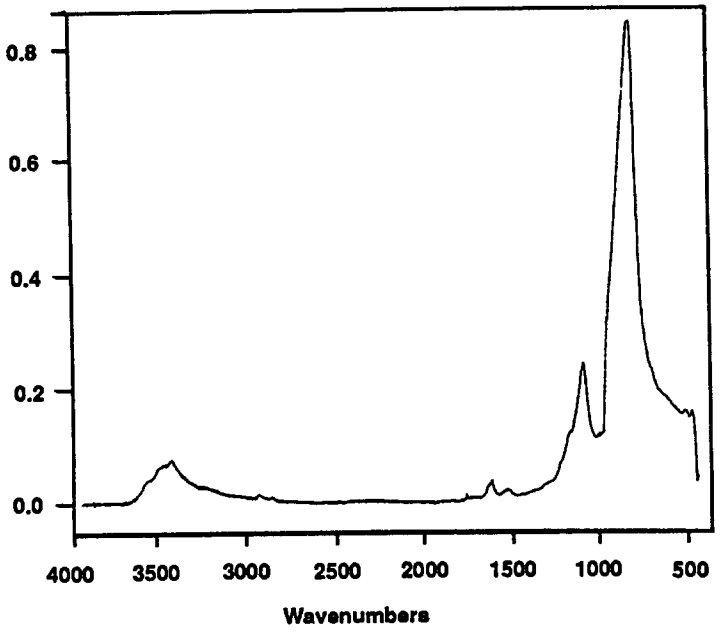

Fig 4 FTIR spectrum of a SiC residue

indicate that no significant oxidation of SiC occurred when the samples were fired at 750° for 1 h. This supports the findings of Julietti[2] and Ramanathan and Muraleedharan[4] where no significant oxidation of SiC was found below 800°.

Scanning electron microscopy studies on a typical final residue from the analytical method showed that SiC was the only phase present in the residue.

An FTIR spectrum of a SiC residue is shown in Fig. 4 where the typical antisymmetric SiC peak was revealed at 780 cm^{-1}. A small quartz peak occurred at 1080 cm^{-1} due to grinding the sample prior to analysis as reported by Falk and Karunanithy.[5]

Differential thermal analysis of a typical SiC residue in air showed no exotherm at 600° indicating that all carbon had been removed from the particles during the HNO_3 treatment.

CONCLUSION

A reliable method has been developed for the analysis of free carbon and SiC in silica fume. The free carbon and SiC content of the fume can be used as a measure of the efficiency of the furnace operation. At the time that these samples were taken, the furnace was operating much more efficiently and reproducibly during the second sampling period. The analytical results go part of the way to confirming the proposed reaction mechanism.

LIQUID–LIQUID EXTRACTION OF NIOBIUM(V) IN THE PRESENCE OF OTHER METALS WITH HIGH MOLECULAR MASS AMINES AND ASCORBIC ACID

MANJUSHA A KARVE and SHRIPAD M. KHOPKAR*
Department of Chemistry, Indian Institute of Technology, Bombay 400 076, India

(*Received* 16 *July* 1992 *Revised* 2 *October* 1992 *Accepted* 2 *October* 1992)

Summary—A novel method is proposed for the solvent extraction of niobium(V) A 0 1*M* solution of Aliquat 336S in xylene quantitatively extracts microgram quantities of niobium(V) from 0 01*M* ascorbic acid at pH 3.5–6 5 Niobium from the organic phase is stripped with 0 5*M* nitric acid and determined spectrophotometrically in the aqueous phase as its complex with TAR The method permits separation of niobium not only from tantalum(V) but also from vanadium(IV), titanium(IV), zirconium(IV), thorium(IV), chromium(III), molybdenum(VI), uranium(VI), iron(III), *etc* Niobium from stainless steel was determined with a precision of 0.42%

Solvent extraction separation of niobium with high molecular mass amines has been carried out from oxalic,[1–5] tartaric[6–8] and dicarboxylic acids.[9–11] Niobium was separated in oxalate media from tungsten, molybdenum, however titanium and zirconium showed strong interference. The separation from tartrate media needed specific diluents[7,8] such as chlorex when chloroform suppressed the extraction. Malonate media permitted group separation of niobium from tantalum while succinate[10] and glutarate[11] were not very effective. However, the systematic studies of extraction from ascorbate media are lacking. Therefore, such studies are reported in this paper. The proposed method facilitates the separation of niobium from titanium, zirconium, thorium, tantalum, chromium and molybdenum. The method was extended to the determination of niobium in stainless steel.

Apparatus and reagents

A digital pH meter with combined glass and calomel electrodes, Model GS866C spectrophotometer with matched 10-mm Corex glass cuvettes and a wrist-action flask-shaker were used.

The stock solution of niobium was prepared by fusing 0.1 g of niobium pentoxide with 5 g of potassium bisulphate in a platinum crucible. The cooled mass was extracted with 5 ml of 20% tartaric acid, and was made up to 100 ml with distilled water. The solution was standardized gravimetrically with *N*-benzoyl-*N*-phenyl hydroxyl amine.[12] It contained 1 mg/ml niobium. The diluted solution containing 30 μg/ml niobium was prepared by appropriate dilution.

Amberlite LA-1 (*N*-dodecyl (trialkylmethyl) amine), Amberlite LA-2 (*N*-lauryl (trialkylmethyl) amine), Primene JMT (a mixture of primary amines in the C_{18}–C_{22} range) (Rohm and Hass, Philadelphia, PA, U.S.A.), Aliquat 366S (tricaprylmethylammonium chloride) (General Mills Ltd., U.K.), Trioctylamine (Riedel de Haen, Hannover, Germany) were used without further purification. The exchangers were converted into the ascorbate form as per the procedure described earlier.[13]

A buffer solution of pH 5.4 was prepared by dissolving 80 g of ammonium acetate in 7 ml of glacial acetic acid and diluting to 1 l. with distilled water. TAR (4-(2-thiazolylazo) resorcinol) (Fluka AG, Buchs, Switzerland), 0.2% solution in methanol, was also used.

General procedure

To an aliquot of solution containing niobium(V), 1 ml of 0.01*M* ascorbic acid was added and its pH was adjusted to 4.5 by addition of dilute ammonium hydroxide or ascorbic acid. The resulting solution was made up to 10 ml with distilled water. The solution was transferred into a separating funnel and it was equilibrated with 10 ml of 0.1*M* Aliquat 336S in xylene. After allowing the phases to settle and

*Present address: Chemical Engineering Division, Department of Chemical Technology, University of Bombay Matunga, Bombay-400019 India

separate, niobium(V) was stripped from the organic phase with 0.5*M* nitric acid. Niobium in the aqueous phase was determined spectrophotometrically at 540 nm as its complex with 4-(2-thiazolylazo) resorcinol.[14]

RESULTS AND DISCUSSION

Extraction as a function of pH

The pH for the quantitative extraction of niobium(V) was ascertained by extracting it with 4% quantities of different liquid anion exchangers in xylene in the pH range of 1.0–8.0 (Fig. 1). The phase volume ratio was maintained at 1:1. The best pH ranges for the quantitative extraction were 3.5–6.5 (Aliquat 336S), 3.0–5.0 (Amberlite LA-1), and at 3.0 (Amberlite LA-2) and 6.0 (Primene JMT). The extraction was only 75.1% with trioctylamine. Aliquat 336S was preferred as the extractant as it permitted extraction over broader pH range.

Extraction as a function of Aliquat 336S concentration

With all other factors constant the extraction was carried out with different concentrations of Aliquat 336S (Table 1). The extraction was quantitative with 0.075–0.1*M* Aliquat 336S in xylene. Therefore 0.1*M* Aliquat 336S was used throughout the investigations.

Effect of varying ascorbic acid concentration

The best concentration of ascorbic acid for complete complexation of niobium(V) was ascertained by extracting niobium(V) with 0.001–0.05*M* ascorbic acid (Table 2). Thus 0.01*M* ascorbic acid was adequate for complete complexation of niobium(V).

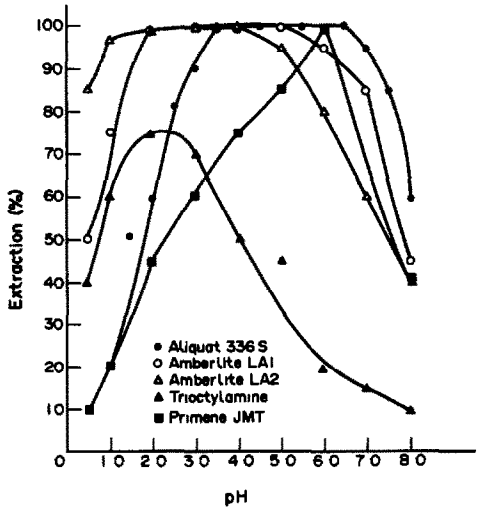

Fig. 1 Extraction of niobium(V) as a function of pH with various liquid anion exchangers

Table 1 Effect of Aliquat 336S concentration

Aliquat 336S concentration, *M*	Extraction, %	Distribution ratio, *D*
0 005	40 0	0 66
0 01	56 0	1 2
0 02	62 0	1 6
0.03	69 0	2 2
0 04	74 0	2 8
0 05	80 0	4 0
0 06	89 0	8 0
0.07	95 0	19 0
0 075–0 10	99 6	24 9

Effect of extracting solvent

Various nonpolar solvents like benzene, toluene, xylene, hexane, cyclohexane, chloroform and carbontetrachloride were tested as extractants (Table 3). The phase volume ratio was maintained at 1.1. The extraction was quantitative with toluene and xylene. Xylene alone was preferred as it was non-toxic in nature, offered clear phase separation and did not exhibit phenomenon of emulsification.

Period of equilibration

The extraction was carried out on a wrist-action flask-shaker for various periods of shaking of 1, 2, 4, 5, 7 and 10 min. The corresponding magnitude for the extraction in percentage was 40, 65, 80, 95, 99.6 and 99.6, respectively. Thus a 10-min period of equilibration was adequate.

Nature of extracted species

The probable composition of the extracted species was ascertained by plotting the graph of log *D vs.* log [Aliquat 336S] at a fixed ascorbic acid concentration and by plotting of log *D vs.*

Table 2 Effect of ascorbic acid concentration

Ascorbic acid concentration, $10^{-3}M$	Extraction, %	Distribution ratio, *D*
1 0	35.0	0 53

Carbontetrachloride	2·24	50.0	1.0

log [ascorbic acid] with a fixed Aliquat 336S concentration. The corresponding slopes were 2.9 and 3.1, respectively. Therefore, the probable species which was extracted was $[(R_4N)_3NbO(asc)_3]$. Similar inferences were noted in earlier work.[9]

Effect of stripping agents

After extraction of niobium(V), it was stripped with 10 ml of various mineral acids (Table 4). Sulphuric acid and hydrobromic acids were poor stripping agents while 0.5–7.0*M* nitric acid and 2.0–6.0*M* hydrochloric acid were satisfactory. Therefore, 0.5*M* nitric acid was used as the stripping agent.

Separation of niobium(V) from binary mixtures

Niobium(V) was extracted in the presence of various ions (Table 5). The tolerance limit was set as the amount of foreign ion required to cause ±2% suppression in the recovery of niobium(V). As the alkali, alkaline earths, aluminium(III), thallium(I, III), copper(II) and zinc(II) were not extracted they were tolerated in ratios exceeding 1:100. Gallium(III), indium(III) and molybdenum(VI) were coextracted, so niobium(V) was first stripped with 6*M* hydrochloric acid followed by stripping of these elements with 1*M* nitric acid. Titanium(IV), zirconium(IV) and hafnium(IV) were separated by stripping them first with 0.2*M* hydrochloric acid containing 0.6% hydrogen peroxide.[9] It should be noted that 0.2*M* hydrochloric acid is a poor stripping agent and in the presence of 0.6% hydrogen peroxide it quantitatively strips titanium, zirconium and hafnium but could not strip niobium. Similarly, scandium(III) and vanadium(IV) were separated by first stripping them with 0.01*M* oxalic acid–1*M* hydrochloric acid, followed by stripping of niobium with 0.5*M* nitric acid. Thorium(IV) and uranium(VI) were strongly complexed with ascorbic acid and hence could be stripped after niobium.

Table 4 Effect of stripping agents

Stripping agent, *M*	% of Stripping							
	0·5	1	2	3	4	5	6	7
HCl	80.0	85·0	99.6	99.6	99·6	99·6	99.6	80.0

H_2SO_4	10·0	20·0	25.0	30.0	25·0	21·0	20.0	20.0

Sequential separation of vanadium(IV), niobium(V) and tantalum(V)

The group separation of vanadium(IV), niobium(V) and tantalum(V) was possible in various ratios.

After extraction of the mixture, vanadium(IV) was stripped with 0.01*M* oxalic–1*M* hydrochloric acid followed by stripping of niobium(V) with 0.5*M* nitric acid. During such separation tantalum(V) was not extracted and remained behind in the aqueous phase. With various ratios of vanadium:niobium:tantalum,

1:1:1 to 1:2:1 or 2:1:1, such separations were possible.

Separation of multicomponent mixtures

Niobium(V) was separated from several multicomponent mixtures (Table 6). Thus, it is interesting to note that 6*M* hydrochloric or nitric acid strips out niobium(V) but not molybdenum(VI), thorium(IV) or uranium(VI) as they form either anionic chloro or nitro complexes and get reextracted. Further metals like chromium(III), iron(III), silver(I), nickel(II) and manganese(II) are not extracted by Aliquat 336S under any conditions and can be thus separated while 0.1*M* hydrochloric acid in the presence of 0.6% hydrogen peroxide can easily strip out titanium(IV) or zirconium(IV) but not niobium(V). Therefore these differences were exploited to develop novel separations of niobium from multicomponent mixtures. Further these separations were confirmed from the knowledge of separation factors of various ions[15] (Table 7).

Table 7 Separation factor for various metal ions

Metal	Distribution ratio, *D*	Separation factor (α)
Nb	249	—
Ga	249	1 0
In	∞	—
Sc	332 3	0 74
Ti	249	1 0
Zr	110 1	2 2
Hf	124	2.0
V	165.6	1 5
Th	332.3	0.74
U	99	2.5
Mo	249	1.0

Most of the metals after stripping were determined spectrophotometrically with appropriate chromogenic ligand.

Determination of niobium in steel (BCS No. 261)

A 0.5-g sample was dissolved in a mixture of hydrochloric and hydrofluoric acids (2:1). The solution was evaporated almost to dryness, the residue was dissolved in 2 ml of concentrated hydrochloric acid containing 2 ml of 20%

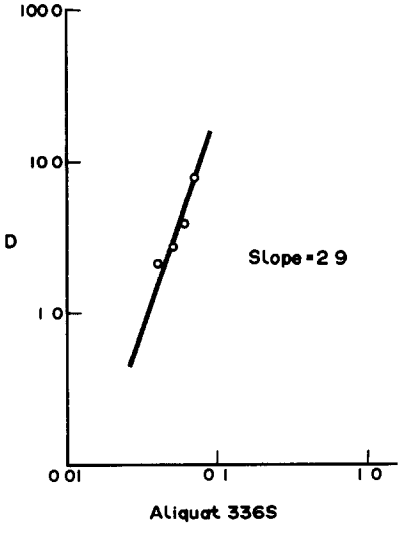

Fig 2 Distribution ratio *vs* Aliquat 336S concentration.

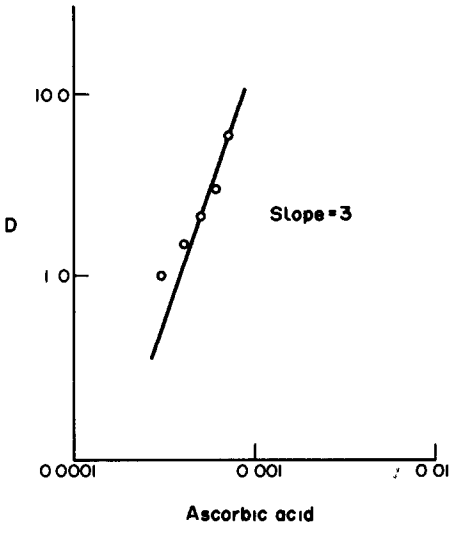

Fig. 3 Distribution ratio *vs* ascorbic acid concentration.

taric acid and the resulting solution was diluted to 50 ml with distilled water.

A known aliquot of solution was taken and was extracted as per the general procedure. Iron, chromium and molybdenum were co-extracted and were stripped with appropriate stripping agents as described earlier. The amount of niobium was found to be 0.900%, compared to the certified value of 0.920%. The precision of the determination was ±0.42% based on six determinations.

The significant feature of the proposed method is that it permits the separation of niobium from titanium(IV), vanadium(IV), tantalum(V), chromium(III), manganese(II), iron(III) and nickel(II) which are generally associated with it in steel. The method provides excellent sequential separation of vanadium(IV), niobium(V) and tantalum(V) in any ratio.

DIFFERENCE SPECTROPHOTOMETRIC ASSAY OF BENZALDEHYDE IN BENZYL ALCOHOL

ISMAIL I. HEWALA

Department of Pharmaceutical Analytical Chemistry, Faculty of Pharmacy, University of Alexandria, Alexandria 21521, Egypt

(*Received* 1 *June* 1992 *Revised* 22 *September* 1992 *Accepted* 22 *September* 1992)

Summary—A simple and rapid procedure is described for the selective determination of benzaldehyde in benzyl alcohol intended for use in the manufacture of parenteral dosage form The assay is based upon the measurement of the difference absorbance between two equimolar solutions of benzaldehyde in buffer solution pH 5 75, one of which also contains sodium bisulphite The difference absorbance which has a maximum at 248 nm is due to the different spectral characteristics of benzaldehyde and its adduct form with sodium bisulphite is proportional to concentration of benzaldehyde. The accuracy, precision, sensitivity and specificity of the procedure are discussed Application of the assay is described for different batches of benzyl alcohol The results are compared with the official (BP) GLC method

The technique of difference spectrophotometry has proved to be useful for eliminating both non-specific matrix interference and specific interference from co-formulated drugs and decomposition products in a wide variety of formulations.[1] Procedures involving alteration of pH,[2] oxidation,[3] reduction,[4] competitive condensation[5] and ester formation[6] reactions have been successfully used in pharmaceutical analysis. The use of this technique for the detection of decomposition products has been described.[7]

Benzyl alcohol is commonly used in the manufacture of parenterals. Thus, the British Pharmacopoeia monograph for benzyl alcohol stated that benzyl alcohol intended for use in the manufacture of parenteral dosage form contains not more than 0.05% of benzaldehyde and described a GC method for the determination of the contents of benzaldehyde.[8] However, the limit test in the United States Pharmacopoeia monograph of benzyl alcohol for benzaldehyde, which involves the addition of hydroxylamine hydrochloride and titration with sodium hydroxide, is not specific for benzaldehyde and is designated as a test for aldehyde.[9]

In the present paper a new difference spectrophotometric procedure is described for the assay of benzaldehyde in benzyl alcohol. The method includes the measurement of the difference in absorbance between two equimolar solutions of benzaldehyde in buffer pH 5.75, one of which contains sodium bisulphite reagent. Sodium bisulphite forms an addition product with benzaldehyde and consequently destroys its strong UV absorption. The difference absorbance spectrum possesses the characteristic UV absorption band of benzaldehyde in the range 230–300 nm with a maximum at 248 nm and is free from interference due to benzyl alcohol.

EXPERIMENTAL

Reagents

Benzaldehyde (Sigma Chemical Co. U.K.), benzyl alcohol, sodium bisulphite (BDH, U.K.), dibutyl phthalate (Sigma Chemical Co., U.S.A.), were of analytical reagent quality.

Buffer solutions were prepared using substances of analytical reagent grade according to published formulae:[10] buffers pH 2 (potassium chloride and hydrochloric acid); pH 3, 4, 5, 6 and 7 (citric acid and disodium hydrogen phosphate); pH 8, 9 and 10 (potassium chloride, boric acid and sodium hydroxide).

Apparatus

Absorption and difference absorption spectra of solutions in 1-cm silica quartz cells were recorded using a Perkin-Elmer 550 S UV-visible spectrophotometer. The spectral band width was 2 nm, the scan rate 1 nm/sec and the response (time constant) one sec. The difference absorbance values of the standard, sample and blank solutions at 248 nm were read from the digital display under non-scanning conditions.

Gas chromatography was performed on a Pye-Unicam series 304 Gas chromatograph equipped with a flame-ionization detector. A 2-m length, 2-mm internal diameter glass column packed with 3% OV-17 (Phase separation Ltd) on Gas Chrom Q (80–100 mesh; Phase separation Ltd) was used. The temperature programming procedure described in the British Pharmacopoeia[8] under the monograph for benzyl alcohol was used for determination of benzaldehyde using dibutyl phthalate as an internal standard.

Procedures

Standard solutions. A standard solution of benzaldehyde was prepared by dissolving approximately 100 mg, accurately weighed, in 100 ml of ethanol (I). A 2-ml aliquot of solution I was transferred to a 50-ml standard flask and diluted to volume with ethanol (II) A 5-ml aliquot was transferred to two 50-ml standard flasks. The content of one flask was diluted to 50 ml with pH 5.75 buffer and the content of the second was diluted to 50 ml with 0.05% w/v sodium bisulphite solution prepared in pH 5.75 buffer. The difference absorption spectrum of the sodium bisulphite untreated solution in the sample cell was recorded relative to that of the solution treated with sodium bisulphite, in the reference cell.

Test solution. A sample solution of benzyl alcohol was prepared by dissolving approximately 100 mg, accurately weighed, in 25 ml of ethanol. A 3-ml aliquot was transferred to two 50-ml standard flasks and the procedure was continued as described above for standard solution from the words "The content of one flask was diluted . . . . . ." . The concentration of benzaldehyde in benzyl alcohol was calculated from the standard solution.

RESULTS AND DISCUSSION

Development of the method

Figure 1(A) shows the UV absorption spectra of benzaldehyde in the presence and absence of sodium bisulphite and their difference absorption spectrum. The bisulphite addition product of benzaldehyde eliminates the strong and weak UV absorption band of benzaldehyde around 248 and 280 nm, respectively. The difference absorption spectrum shows a λ_{max} at 248 nm and an isosbestic point (wavelength at zero ΔA because of the equal absorptivity of sodium

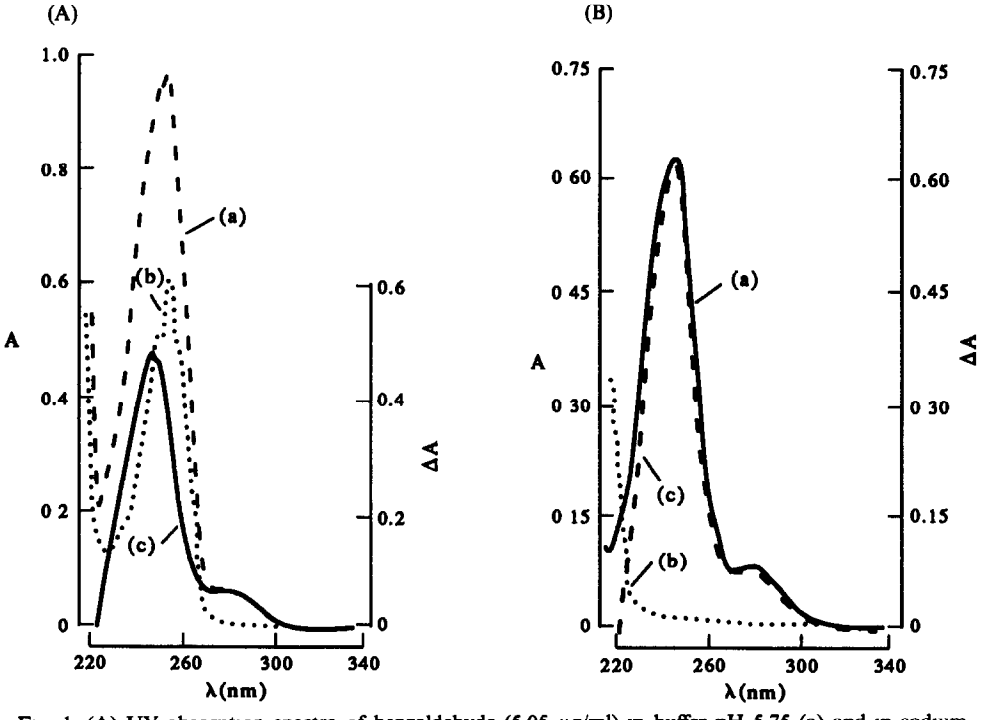

Fig 1 (A) UV absorption spectra of benzaldehyde (5.05 μg/ml) in buffer pH 5.75 (a) and in sodium bisulphite pH 5.75 solution (b) and the difference absorption spectrum (c) of solution (a) relative to solution (b) (B) UV absorption spectra of a sample of benzyl alcohol (0.353 mg/ml) in buffer pH 5 75 (a) and in sodium bisulphite pH 5 75 solution (b) and the difference absorption spectrum (c) of solution (a) relative to solution (b).

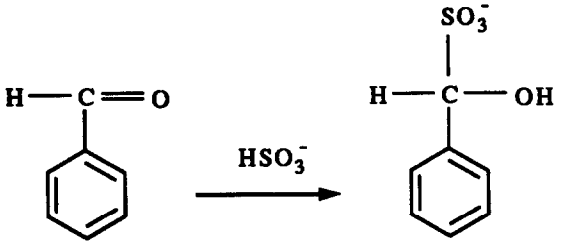
bisulphite non-treated and treated benzaldehyde) at 223 nm. The change in spectral properties of benzaldehyde by addition of sodium bisulphite is due to the destruction of dienone chromophore of benzaldehyde I to yield the diene chromophore II results from the classical addition of a nucleophile to the carbonyl system.[11]



I II

The difference absorption spectrum closely resembles the UV-absorption spectrum of benzaldehyde between 340 and 230 nm (maximum at 248 nm).

The effect of pH was investigated by measuring the absorbance at 248 nm (A_{248}) of a solution of benzaldehyde that had been buffered to various pH values in the range 1–10 using buffer and sodium bisulphite treated benzaldehyde prepared in the same buffer. Figure 2 shows that the absorbance of benzaldehyde is not dependent on pH and that the reaction is pH dependent. The reaction is almost quantitative in solution adjusted to pH values between 5.5 and 6.0 as the A_{248} was maximum and the bisulphite treated solution has an absorption reading which is almost the same as the reagent, *i.e.*, has negligible absorption.

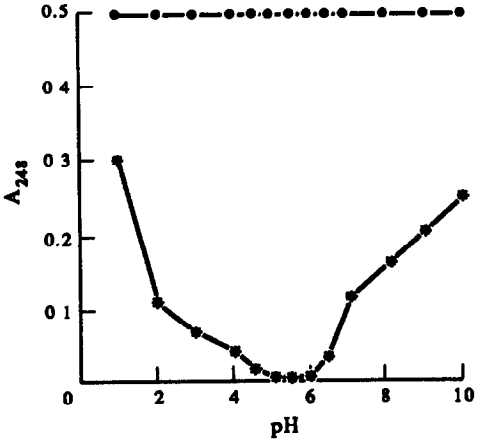


Fig. 2. The effect of pH on the absorbance of benzaldehyde (4 04 μg/ml) in the presence (—•—•—•) and absence (—·—·— — —) of sodium bisulphite

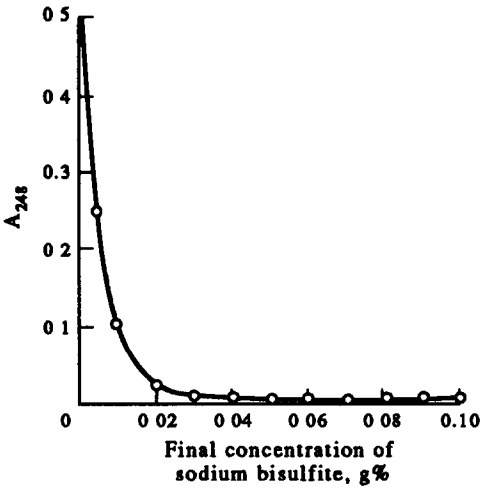

Fig. 3 The effect of concentration of sodium bisulphite on the absorbance of benzaldehyde (4 04 μg/ml) at pH 5 75

The effect of concentration of sodium bisulphite reagent was investigated and it was found that a concentration above 0.02% is enough for complete derivatization of benzaldehyde. A solution of 0.05% was chosen throughout the assay as sodium bisulphite has almost no absorption in the range up to 0.1% (0.004 absorbance units). It was found that increasing the concentration of sodium bisulphite (0.3–0.5% w/v) reduces the ΔA reading which could be due to the considerable absorption of bisulphite concentrated solution. Figure 3 shows the effect of bisulphite concentration on the absorbance of benzaldehyde at 248 nm.

Adherence to Beer's Law

Beer's law graphs for benzaldehyde showed that a rectilinear relationship exists between the measured ΔA_{248} and the concentration of benzaldehyde in the range 0–7 μg/ml. The regression equation was $Y = 0.12193\ X - 0.0012$ where Y is the ΔA_{248} in a 1-cm cell and X μg/ml is the concentration of benzaldehyde (correlation coefficient 0.9999 for $n = 6$). An almost identical line ($Y = 0.12188\ X - 0.0019$; correlation coefficient 0.9998 for $n = 6$) was obtained for a similar series of solutions of benzaldehyde containing benzyl alcohol (200 μg/ml).

Specificity, accuracy, precision and limit of detection

To assess further the specificity of the method, a series of solutions containing benzaldehyde at 10 μg/ml and increasing concentrations of benzyl alcohol (0–4 mg/ml), were assayed by the proposed procedure; the final

Table 1 Assay of benzaldehyde in standard mixtures of benzaldehyde and benzyl alcohol using the proposed method

Concentration of benzaldehyde in benzyl alcohol, added μg/g	20	50	100	200	400	500
Concentration of benzaldehyde in benzyl alcohol, found μg/g	19 70	49 40	99 90	200 10	399.80	500 20
Accuracy, %	98 50	98 80	99.90	100 05	99 95	100 04

concentration of benzaldehyde in each solution being 1 μg/ml. The ΔA of all solutions containing benzyl alcohol fell within 98.8–100.2% of that of the standard solution of benzaldehyde containing no benzyl alcohol. This confirms that the ΔA method is independent of the level of benzyl alcohol (Table 1).

The standard deviations of the difference absorbance given by a solution of benzyl alcohol (1 mg/ml) and benzaldehyde (1 μg/ml) (S_A) and a similar solution of benzyl alcohol without the addition of benzaldehyde (S_B), each assayed 10 times by the proposed procedure, were found to be 2.70×10^{-3} and 9.47×10^{-4}, respectively. The relative standard deviation, calculated from the corrected standard deviation,[12], was 0.57% and the limit of detection ($2S_B$) of benzaldehyde in benzyl alcohol corresponded to a concentration of 7.7×10^{-5}% m/m. These results show that the proposed method is accurate, precise and sensitive.

Analysis of commercial samples

In order to test the application of the method, the concentrations of benzaldehyde were measured in samples of benzyl alcohol intended for use in the manufacture of parenterals. Figure 1(B) shows the absorption spectrum of benzyl alcohol before and after treatment with sodium bisulphite and their difference absorption spectrum. The spectra illustrated that, whereas a direct measurement of A_{248} [Fig. 1(B), a)] of the solution is subject to interference from benzyl alcohol, the ΔA_{248} [Fig. 1(B), c] is selective for benzaldehyde. To prove further the absence of interference, the standard addition method was used to calculate the recovery of added benzaldehyde (2 μg/ml). The results (Table 2) show good recovery of the added benzaldehyde and consequently benzaldehyde is assayed without interference from any related substances[8] that may exist in commercial samples.

Table 2. Recovery of benzaldehyde added to diluted solutions of benzyl alcohol

	Concentration of benzaldehyde (μg/ml)		Recovery

SF = Sterilization by filtration

SA = Sterilization by autoclaving at 121° for 15 min.

The proposed procedure was applied for the determination of four different batches of commercial benzyl alcohol described for use in manufacture of parenterals. For comparison, the concentrations of benzyl alcohol were also assayed by the GLC procedure described in the British Pharmacopoeia monograph for benzyl alcohol.[8] The results in Table 3 show good agreement between the two methods and confirm that the difference spectrophotometric procedure is both accurate and selective.

Parenteral dosage forms containing benzyl alcohol are sterilized either by filtration or autoclaving. The effect of such treatment on the concentration of benzaldehyde in benzyl alcohol was investigated. The results (Table 3) show that heat sterilization increases the concentration of benzaldehyde by approximately 5% of its original content. It is recommended that samples of benzyl alcohol (pharmaceutical grade) containing relatively high concentrations of benzaldehyde (stored samples) be sterilized by filtration.

SPECTROPHOTOMETRIC DETERMINATION OF EQUILIBRIUM CONSTANTS OF TWO MUTUAL COMPETITIVE REACTIONS BY THE METHOD OF ISOSBESTIC POINTS

JIE ZHOU*, SHI-FU ZOU and WEI-AN LIANG†
Department of Chemistry, Shandong University, Jinan, Shandong, People's Republic of China

(*Received* 15 *July* 1992. *Accepted* 25 *August* 1992)

Summary—We have developed a method that makes use of dual isosbestic points in a dual ligand, single metal system that allows the determination of the equilibrium constants of complexes in which two ligands compete for the same metal ion, and one complex is colourless The competition of methyl thymol blue and citrate was used to test the model.

The method of corresponding solutions competition[1] can be used in the determination of equilibrium constants of two mutual competitive reactions and is useful in studying the chemical equilibria of complicated systems, such as speciation analyses.[2] However, the method is only applicable to the case in which two metal ions compete for the same ligand, whereas it is not suitable when two ligands compete for the same metal ion. New approaches are still required for the latter case. Based on the distribution of species in a competitive system, and making use of the characteristics of the isosbestic points found as system compositions vary, we have developed a method to determine the stability constants of complexes formed by two mutual competitive reactions. The method has been used in the system in which 3,3′-bis[*N*,*N*′-di(carboxymethyl)aminomethyl]-thymolsulphophthalein(methyl thymol blue) competes with 2-hydroxypropane-1,2,3-tricarboxylic acid (citric acid) for aluminium(III), and satisfactory results are obtained.

THEORY

Suppose that the reactions in which two ligands R and L compete for the same metal ion are as follows (the charges are omitted for simplicity)

$$M + R = MR, \quad \beta_1 = [MR]/[M][R] \qquad (1)$$

$$M + 2R = MR_2, \quad \beta_2 = [MR_2]/[M][R]^2 \qquad (2)$$

$$M + nL = ML_n, \quad \beta_L = [ML_n]/[M][L]^n \qquad (3)$$

Suppose the reaction (M + R) is a coloured reaction and the other reaction (M + L) is a colourless reaction in a competitive system. The absorption spectra of relevant species chosen in this study are shown in Fig. 1. The absorbance of the solution is expressed as

$$A = \epsilon_0[R] + \epsilon_1[MR] + \epsilon_2[MR_2] \qquad (4)$$

where ϵ_0, ϵ_1 and ϵ_2 are the molar absorptivities of R, MR and MR_2, respectively. Two isosbestic points exist in the spectra. According to earlier workers' discussion about the characteristics of isosbestic points,[3–5] we obtain $\epsilon_2 = 2\epsilon_1$ at the wavelength of the isosbestic point (λ_q). If λ_q is selected as the measurement wavelength, equation (4) becomes

$$\begin{aligned} A &= \epsilon_0[R] + \epsilon_1[MR] + 2\epsilon_1[MR_2] \\ &= \epsilon_1 C_0^R - (\epsilon_1 - \epsilon_0)[R] \\ &\quad + (C_0^R = [R] + [MR] + 2[MR_2]) \end{aligned} \qquad (5)$$

By rearrangement of equation (5), we obtain

$$\begin{aligned} [R] &= (\epsilon_1 C_0^R - A)C_0^R/(\epsilon_1 C_0^R - \epsilon_0 C_0^R) \\ &= (A_q - A)C_0^R/(A_q - A_0) \qquad [5(a)] \\ &\quad (A_q = \epsilon_1 C_0^R, A_0 = \epsilon_0 C_0^R) \end{aligned}$$

A_q is the absorbance of the isosbestic point q, A_0 is that of the reagent R at λ_q. They are constant and can be measured directly as C_0^R is fixed.

*Present address. Department of Basic Sciences, Shandong Agricultural University, Taian, Shandong, People's Republic of China
†Author for correspondence

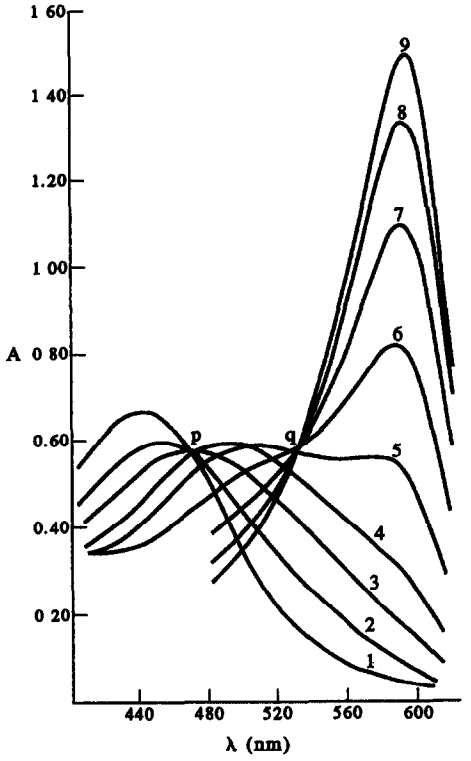

Fig 1 Absorption spectra for Al–MTB system at different C^{Al} $C_0^R = 1\ 70 \times 10^{-5}M$, pH = 4 95, 2-cm cells, with distilled water as the reference, C^{Al} ($\times 10^{-5}M$) curves 1—0 00, 2—0 40, 3—0 80, 4—1 20, 5—1 60, 6—2 00, 7—2 40, 8—2 80, 9—3 20

Therefore after the absorbance of each solution is measured, [R] is evaluated form equation [5(a)].

It should be noted, the values of [R] are almost close to zero for any of the curves across the point q, therefore, equations (5) and [5(a)] are useless under such circumstances.

After the values of [R] are obtained, from the definition of Bjerrum's function, we obtain

$$\bar{n} = (C_0^R - [R])/C^M \qquad (6)$$

$$\bar{n} = (\beta_1[R] + 2\beta_2[R]^2)/(1 + \beta_1[R] + \beta_2[R]^2) \qquad [6(a)]$$

$\bar{n}$ can be evaluated from equation (6). Substituting each pair of values ($\bar{n}$, [R]) of solutions into equation [6(a)], homologous linear equations are obtained. Two of the arbitrary equations compose simultaneous equations, and β_1 and β_2 can be evaluated.

Equation [6(a)] can be rewritten in the form

$$\frac{2-\bar{n}}{\bar{n}}[R]^2 = \frac{\bar{n}-1}{\bar{n}}[R]\frac{\beta_1}{\beta_2} + \frac{1}{\beta_2} \qquad [6(b)]$$

A linear plot of $(2-\bar{n})[R]^2/\bar{n}$ *vs.* $(\bar{n}-1)[R]/\bar{n}$ is obtained from equation [6(b)] (Fig. 2), the slope

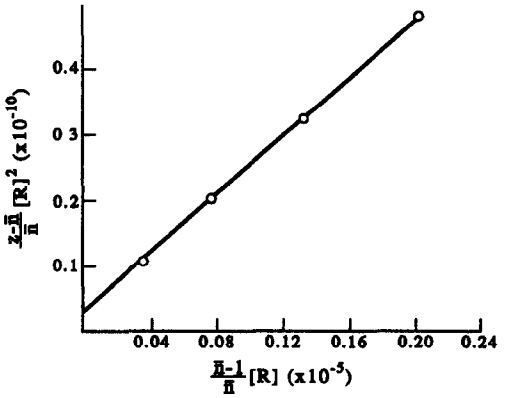

Fig 2 Graphs of $(2-\bar{n})[R]^2/\bar{n}$ *vs* $(\bar{n}-1)[R]/\bar{n}$

and the intercept of the line are β_1/β_2 and $1/\beta_2$, respectively. Thus β_1 and β_2 are evaluated.

When there is only the reaction (M + R) in a solution, equation (6) is used directly. If there is also the competitive reaction (M + L) simultaneously, equation (6) should be corrected. Because C^M is divided into two parts, ΔC^M is used in the reaction (M + L). So as to evaluate ΔC^M, we prepare two series of solutions. First, C_0^R is fixed and C^M is gradually increased, Secondly, $C_0^R + C_0^L$ is fixed and C^M is gradually increased. The absorbances of these solutions are measured as λ_q and [R] is evaluated from equation [5(a)]; the graphs of [R] *vs.* C^M are shown in Fig. 4.

In Fig. 4, a line parallel with the abscissa is drawn. It intersects with the curves *a* and *b* at a_1 and b_1. The solutions corresponding to the points a_1 and b_1 have the same [R]. From the material balance relation and the expression of equilibrium constants, we can derive that the solutions also have the same [M], [MR] and [MR_2], while C^M is different. The solutions include the following material balance equations

$$C_a^M = [M] + [MR] + [MR_2] \qquad (7)$$

$$C_b^M = [M] + [MR] + [MR_2] + [ML_n] \qquad (8)$$

$$C_a^R \text{ or } C_b^R = [R] + [MR] + 2[MR_2] \qquad (9)$$

$$C_b^L = [L] + n[ML_n] \qquad (10)$$

Subtracting equation (7) from equation (8), yields

$$C_b^M - C_a^M = \Delta C^M = [ML_n] \qquad (11)$$

Substituting equation (11) into (10), yields

$$[L] = C^L - n\,\Delta C^M \qquad (12)$$

According to the above discussion, β_1 and β_2 can be evaluated from equation [6(a)]. Whether there is the competitive reaction (M + L) or not, C_a^M has to be used in the calculation of β_1 and β_2. If the value of C_b^M at b_1 is used, ΔC^M consumed in the reaction (M + L) has to be deducted.

It is very convenient to evaluate the stability constant of ML_n by its distribution coefficient. We define

$$\delta_{ML_n} = [ML_n]/C_b^M = \Delta C^M/C_b^M \qquad (13)$$

δ_{ML_n} can be evaluated from equation (13). Substituting equations (1), (2), (3) and (8) into (13) yields

$$\delta_{ML_n} = \beta_1[L]^n/(1 + \beta_1[R] + \beta_2[R]^2 + \beta_L[L]^n \qquad [13(a)]$$

[R], β_1 and β_2 can be evaluated in advance. If n is known or evaluated by another method, substituting these known values into equation [13(a)] provides β_L.

EXPERIMENTAL

Apparatus

A Shimadzu UV-3000 double-beam spectrophotometer and a pHs-2 acidimeter were used.

Reagents

A $1.00 \times 10^{-3}M$ stock solution of aluminium-(III) was prepared by dissolving the calculated amounts of $KAl(SO_4)\cdot 12H_2L$(G.R.) in a solution of $1.0 \times 10^{-4}M$ hydrochloric acid. The working standard solutions were obtained by diluting the stock solution. A $1.213 \times 10^{-4}M$ solution of methyl thymol blue(MTB) was prepared from commercial MTB which was purified by DEAE-cellulose column chromatography,[7] and its accurate concentration was determined by a spectrophotometric method.[8] Citric acid solution (cit, $1.000 \times 10^{-3}M$), HOAc/NaOAc buffer solution (pH 5.0) and $1M$ potassium nitrate were prepared with analytical-reagent grade chemicals, respectively.

Procedure

To each of a series of 50-ml beakers, add 5 ml of buffer solution, 3.50 ml of MTB solution, 1.00 ml of cit solution, 2.5 ml of $1M$ potassium nitrate and a different volume of Al solution, respectively, dilute to 20 ml with distilled water, heat for five min in a boiling water-bath, and cool to room temperature. Transfer each of the solutions to a 25-ml standard flask, respectively, dilute to the mark with distilled water and mix, stand for 10 min and measure their absorption spectra or absorbances.

Selection of pH of solution

Based on the earlier studies, the range of pH selected was 4.5–5.0 for formation of the coloured complexes.

RESULTS AND DISUSSION

Determination of stability constants of the complexes for the Al–MTB system

When pH and C^{MTB} were fixed and C^{Al} was gradually increased, a series of solutions resulted with the absorption spectra shown in Fig. 1. Figure 1 shows Al can form two complexes with MTB. Their maximum absorption wavelengths are 492 and 585 nm, respectively. In addition, two isosbestic points exist in Fig. 1. According to the literature,[9] the compositions of the complexes with maxima at 492 nm and 585 nm are $Al(MTB)_2$ (1:2) and Al(MTB) (1:1), respectively. In the presence of a higher concentrations of Al(III), the formation of 1:1 complexes predominates, conversely, the formation of 1.2 complexes predominates. The first isosbestic point p is at 463 nm and the second isosbestic point q is at 532 nm at pH 4.95.

According to the above discussion, we measure A at 532 nm (λ_q) and evaluate [R] from equation [5(a)]. Substituting the values of [R] obtained into equation (6), we can evaluate $\bar{n}$. Then the values of $(2-\bar{n})[R]^2/\bar{n}$ and $(\bar{n}-1)[R]/\bar{n}$ are calculated, respectively. The values of relevant parameters obtained are shown in Table 1. A linear plot of $(2-\bar{n})[R]^2/\bar{n}$ *vs.* $(\bar{n}-1)[R]/\bar{n}$ is shown in Fig. 2. The values of β_1 and β_2 obtained from Fig. 2 are: $\beta_1 = 6.57 \times 10^6$ and $\beta_2 = 2.94 \times 10^{11}$, respectively.

Determination of stability constant of ML_n for Al–cit system

Similar to Fig. 1, the absorption spectra for Al–MTB–cit system at different C^{Al} are shown in Fig. 3. In Figs 3 and 1, C^{MTB} is the same. On

Table 1 Values of relevant parameters obtained for Al–MTB system at different C^{Al}($C_0^R = 1.70 \times 10^{-5}M$, $A_q = 0.600$, $A_0 = 0.175$)

$C^{Al}(\times 10^{-5}M)$	0 60	0.80	1.00	1.20
$[R](\times 10^{-5}M)$	0 932	0 720	0.528	0 360
$\bar{n}$	1 280	1.225	1.172	1 117
$(2-\bar{n})[R]^2/\bar{n}(\times 10^{-10})$	0.489	0 328	0 197	0 102
$(\bar{n}-1)[R]/\bar{n}(\times 10^{-5})$	0 204	0.132	0.077	0 038

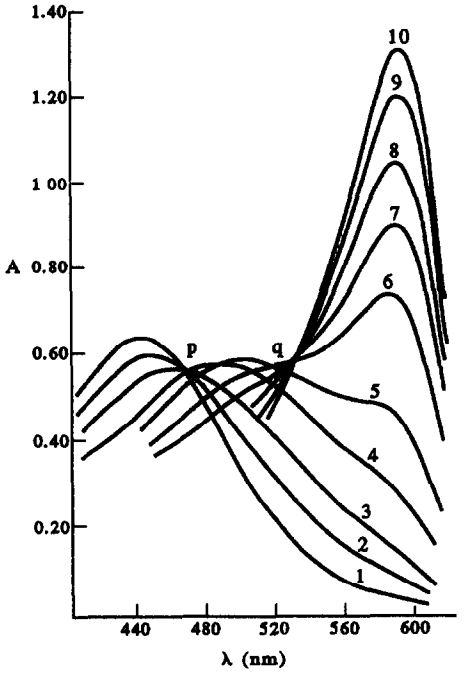

Fig. 3. Absorption spectra for Al–MTB–cit system at different C^{Al} $C^{L} = 4.00 \times 10^{-5}M$, C^{Al} ($\times 10^{-5}M$) Curves 1—0 00, 2—0.40, 3—0 80, 4—1.60, 5—3 20, 6—4 80, 7—5.60, 8—6.40, 9—7 20, 10—8.00; other conditions as for Fig 1

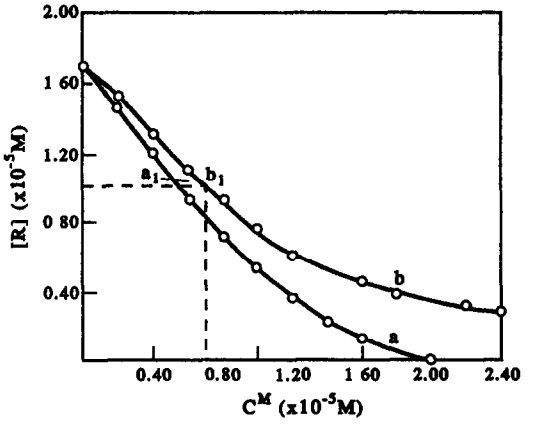

Fig 4 Graphs of [R] *vs* C^{Al} for two series of solutions corresponding to Fig 1(a) and Fig 3(b)

comparing the two figures, λ_{max} of the complexes formed between MTB and Al(III) is the same, as are λ_p, λ_q and A_q, A_p, respectively. But as C^{Al} is increased, the curves differ (the rate of change is diminished). Cit competes with MTB for Al(III) and a part of C^{Al} is consumed in the formation of the complexes Al(cit). It is preliminarily estimated that ternary complexes are not formed.

According to the report of the literature,[10] Al(III) can form 1:1 complexes (AlHL) with cit under acid conditions, so we consider n to be 1. Thus β_L can be evaluated. The absorbances of two series of solutions corresponding to Figs 1 and 3 are measured at λ_q, then [R] is evaluated from equation [5(a)] (Table 2). The graphs of [R] *vs.* C^{Al} are shown in Fig. 4. A line parallel with the abscissa is drawn at a fixed value of [R]. It intersects with the two curves at a_1 and b_1. [R] is the same at the two points a_1 and b_1, C^{Al} is evaluated from C_a^{Al} and C_b^{Al}, corresponding to a_1 and b_1. Then $[ML_n]$, [L] and δ_{ML_n} are evaluated from equations (11), (12) and (13), respectively. Thus β_L can be evaluated from equation [13(a)]. The values of relevant parameters and β_L are shown in Table 3. The average value of β_L obtained from Table 3 is 6.06×10^5 (log $\beta_L = 5.78$). Studies of the equilibrium relations for the Al–MTB system are limited. The only literature[9] we found reported log $\beta_1 = 3.88$, log $\beta_2 = 9.9$. Our results differ from them, because our experimental conditions are different from those of the literature.[9] For the Al–cit log system, after correcting our results by alpha coefficients (at pH 5, log $\alpha_{L(H)}$ and log $\alpha_{Al(OH)}$ are 1.2 and 0.4,[11] respectively), we calculated the

PRECONCENTRATION AND DETERMINATION OF Ce, La AND Pr BY X-RAY FLUORESCENCE ANALYSIS, USING AMBERLITE XAD RESINS LOADED WITH 8-QUINOLINOL AND 2-(2-(5 CHLOROPYRIDYLAZO)-5-DIMETHYLAMINO)-PHENOL

A. N. MASI and R A OLSINA

Department of Analytical Chemistry "Dr. B. Marone", Faculty of Chemistry, Biochemistry and Pharmacy, National University of San Luis, San Luis, Argentina

(*Received* 9 *December* 1991 *Revised* 17 *April* 1992 *Accepted* 23 *August* 1992)

Summary—8-Quinolinol (oxine) and 2-(2-(5 chloropyridylazo)-5-dimethylamino)-phenol (5ClDMPAP) were immobilized on the non ionic sorbents Amberlite XAD-4 and XAD-7 These loaded resins were used for the preconcentration of Ce, La and Pr High preconcentration factors were obtained in each case After the retention of these rare earths, the resins were measured as thin films by x-ray fluorescence spectrometry Up to 50 ppm of REEs can be retained on these thin films

The analytical treatment of rare earth elements is not performed on the individual elements because they form a closely related group of elements.[1] It is usually necessary to preconcentrate and separate them from the matrix, especially for trace analysis. Chemists have proposed different procedures for preliminary enrichment and separation of trace REEs such as: coprecipitation,[2] ion exchange[3–5] and solvent extraction.[6]

The rare earths have been determined by many instrumental techniques, but are affected by spectral interferences. Thus, when they are determined by these techniques, separation and preconcentration steps are necessary. X-ray fluorescence analysis is a useful and versatile method for determination of rare earths[7–9] in a variety of materials. As with other instrumental methods, XRF is subject to spectral and other modes of interferences, which can be corrected.[10]

Absorption-enhancement effects are negligible in thin film type specimens because neither primary nor analyte line x-rays are significantly absorbed in the extremely thin layer.

We propose for the preconcentration and separation of Ce, La and Pr, the immobilization of two organic reagents on the adsorbent resins: 8-quinolinol (oxine) and 2-(2-(5 chloropyridylazo)-5-dimethylamino)-phenol (5ClDMPAP). With the proper conditions, the elements of interest can be retained on these. The resins which contain the retained ions are presented to the x-ray spectrometer as thin films. This technique has many advantages in the determination of the REEs.

EXPERIMENTAL

Reagents and apparatus

The Amberlite XAD-4 (Rohm & Haas) had a specific surface area of 750 m^2/g, pore diameter 50 Å and bead size 20–50 mesh; and XAD-7 had a specific surface area of 450 m^2/g, pore diameter 80 Å and bead size 20–50 mesh.

5ClDMPAP reagent was synthesized by the technique of Shibata and Furukawa.[11] This reagent is slightly soluble in water but easily soluble in ethanol.

Ce standard solution was prepared by dissolving $Ce(NO_3)_3$ in water. La standard solution was prepared with $La(NO_3)_3$ in 0.1*M* HCL. A Pr standard solution was prepared by dissolving Pr_4O_{11} in 0.1*M* HCl.

Membrane filter papers were Millipore of 0.47-μm pore size.

All other chemicals were analytical grade and doubly distilled water was used throughout.

A Philips PW1400 x-ray spectrometer was used for Ce, La and Pr Lα line measurement. The parameters were appropriately selected.

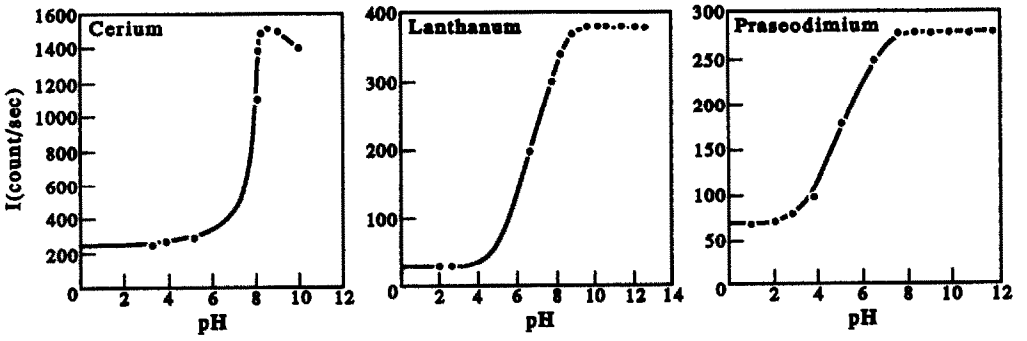

Fig 1 Retention of Ce, La and Pr on SCIDMPAP-XAD-4 as a function of pH

A Varian UV-Visible Spectrometer was used with 10-mm path length glass cells.

pH of solutions were measured in an Orion 701-A pH meter with a Ag–AgCl electrode.

The filtrations were performed in a special filtration apparatus with a vacuum pump.

Preparation of resins

The XAD resins were ground with an acetone–water mixture in a ceramic mortar and sieved with a mesh sifter to obtain 100–200 mesh grains. Then the resins were soaked with methanol–4*M* HCl (1:1) overnight and washed with water.[12]

Preparation of loaded resins

Using the optimum adsorption conditions,[13] the organic reagents were loaded on the ground resins (XAD-4 and XAD-7). One gram of each was shaken for 10 hr with solutions of 600 mg/l. 5ClDMPAP and 0.02*M* oxine both in 0.01*M* HCl.

Retention of Ce, La and Pr as a function of pH

Solutions containing 10 ppm Ce and 5% Triton were adjusted to the desired pH with sodium hydroxide or hydrochloric acid and shaken with 10-mg portions of each resin for 1 hr. Resins were filtered using a vacuum pump on Millipore paper. These papers were covered with Mylar and each analyte Lα line was recorded by an x-ray spectrometer. The same procedure was carried out with solutions of 10 ppm La and 10 ppm Pr. The graphs of retention as a function of pH are shown in Fig. 1.

Determination of critical thickness

Solutions containing 10 ppm Ce(III) were shaken with 10, 15, 20, 25, 30, 35 and 40-mg portions of loaded resins at the proper pH. Solutions were filtered on Millipore paper and then covered with Mylar. Ce lines were read with an x-ray spectrometer (Fig. 2).

Evaluation of the interelement effects in the thin film

Solutions containing a mixture of Ce and La in the ratio 1:6, 6:1 and Ce–Pr 1:6, 6:1 were prepared and Ce, La and Pr were determined by the same method.

Determination of total adsorption capacity

Each rare earth was retained at the proper pH on each loaded resin. With this purpose, 10 ml of REE solution between 0 and 80 ppm was shaken for 30 min with 10 mg of resin. Solutions were filtered on Millipore paper, covered with Mylar and REEs Lα lines were measured in an x-ray fluorescence spectrometer.

Preconcentration of Ce, La and Pr

Solutions containing 0–10 and 0–50 ppm Ce, La and Pr were shaken with 10 mg of each

loaded resin at maximum adsorption pH (7.5 in each case) for 30 min. Resins were filtered with a vacuum pump on Millipore paper. Thus, a thin film was obtained and covered with Mylar.

Calculation of enrichment coefficients

Ce, La and Pr solutions were agitated with loaded resins at maximum adsorption pH for 30 min. In filtered liquids the rare earth amounts were determined spectrometrically by the Arsenazo I[14] method (using triethanolamine buffer of pH 7.2) at 580 nm.

Determination of Ce, La and Pr by x-ray fluorescence spectrometry

Standards were measured in the x-ray fluorescence spectrometer. Measurement parameters were: 79.025° 2θ for Ce Lα, 82.930° 2θ for La Lα and 68.240° 2θ for Pr Lβ, Cr tube, 50 kV, 50 mA, LiF (200) crystal, 75–25 window width, counting time 100 sec, gas proportional-scintillation counter in tandem.

The reproducibility in the adsorption of Ce, La and Pr was assessed by repeating the same procedure, six times.

Analysis of samples

Samples containing Ce, La and Pr in different concentrations were prepared. Some were in the same proportions as the standard samples G2 and SDC-1 (USGS). A 10-ml portion of these samples was preconcentrated and determined by this method. Results are presented in Table 1.

RESULTS AND DISCUSSION

The adsorption behaviour of Ce, La and Pr as a function of pH was examined and results are presented in Fig. 1. As can be seen Ce and La adsorption begins in every case at pH 6 and is maximum at pH 8. For Pr the adsorption begins at pH 5, but the maximum retention is at pH 8. These REE cannot be separated by this method but they can be determined without interferences by preparing a thin film for measurement by x-ray fluorescence spectrometry.

In order to prepare the thin films with the loaded resins, the critical thickness was determined. Results showed that films prepared in this way allowed up to 20 mg of loaded resin (Fig 2).

The presentation of standards to an x-ray spectrometer as thin films permits determination free from interferences. Thus Ce, La and Pr together can be determined by this method, without modifying its line intensities. Under the experimental conditions the only interference detected was on measuring Pr Lα (75.42° 2θ). Because of the La Lβ_1 line (75.27 2θ), the resolution of the LiF 200 dispersing crystal did not allow a separation of these two lines. Therefore, Pr was determined by measuring its Lβ line (68.24° 2θ)

The rare earths not retained on the resins were spectrometrically determined by the Arsenazo I method. These experiments indicated that the adsorption is almost quantitative within 20 min of shaking. Consequently, all data were obtained after a shaking period

Table 2. Detection limits (in ppm) for the determination of Ce, La and Pr retained on each loaded resin

Resin	Ce	La	Pr
Oxine-XAD-4	0 36	0 42	0 71
Oxine-XAD-7	0 47	0 45	1 07
5ClDMPAP-XAD-4	0.47	0 53	0 94
5ClDMPAP-XAD-7	0 42	0 43	1 07

of 30 min to ensure complete equilibrium. Practically 100% retention of each element was obtained.

So, with these working conditions 10 mg of each resin adsorbs almost quantitatively up to 50 ppm of each element studied. Considering that 10 mg of loaded resin occupies 20 mm^3 and 10 ml of the REE solution were agitated with this quantity of resin, the enrichment factor is 500 in every case, which is highly satisfactory if the determination is made by x-ray fluorescence spectrometry.[15]

Synthetic calibration standards of individual rare earths were prepared over a concentration range between 0 and 80 ppm. The correlation found between measured intensity (corrected for background) and the concentration of an element was linear up to 50 ppm (maximum capacity of retention) in every case.

Synthetic samples with different concentrations of Ce, La and Pr were prepared due to the lack of suitable references samples with certified REE contents. In case of having these certified samples, they can be treated following Sen Gupta's procedure,[16] before performing the adsorption of the REEs on the loaded resins. The results for the determination of Ce, La and Pr in each of these samples are shown in Table 1.

The concentration at the detection limit is defined[10] as:

$$C_{DL} = (3/m)\ I_B^{1/2},$$

where:

m: is the slope of the calibration curve

I_B: is background intensity (counts/sec)

and was calculated for each case and presented in Table 2.

CONCLUSIONS

Amberlite XAD-4 and XAD-7 loaded with Oxine and 5ClDMPAP have proved to offer a simple preconcentration technique for determination of trace amounts of Ce, La and Pr by x-ray fluorescence analysis.

SPECTROSCOPIC STUDIES OF A NEAR-INFRARED ABSORBING pH SENSITIVE AMINODIENONE–CARBOCYANINE DYE SYSTEM

G PATONAY, G. A. CASAY, M. LIPOWSKA and L. STREKOWSKI
Department of Chemistry, Georgia State University, Atlanta, GA 30303, U S A

(*Received* 1 *September* 1992 *Revised* 13 *November* 1992 *Accepted* 15 *November* 1992)

Summary—Synthetic red and near-infrared absorbing dyes may be used as probe molecules in a large number of applications. Dyes exhibiting spectral changes with hydrogen ion concentration are useful as pH probes. Those dyes which have their absorption and fluorescence maxima in the long wavelength region of the visible spectral region are especially valuable because of decreased interference and semiconductor laser applications In this paper we have evaluated an aminodienone dye 1 which demonstrates pH dependent absorption and fluorescence spectra as well as solvent polarity dependence. In organic solvents the long wavelength absorption band of the dye is in the reduced interference region The absorption maximum is at 535 nm in neutral or alkaline solutions in methanol The absorption spectra undergo a strong bathochromic shift in the presence of acids (λ_{max} = 709 nm) with a concomitant change in the fluorescence spectra This pH sensitive dye was found to be especially useful for organic solvents The analytical utility of this and similar near-infrared absorbing dyes is discussed

The determination of hydrogen ion concentration (pH) is an important part of many analytical procedures. In previous years numerous dyes have been studied as to their potential for use as acid/base indicators. Sometimes only the color change is utilized, but more sophisticated methods use absorption or fluorescence spectroscopy. A large number of available weak organic acids and bases exhibit different absorption/fluorescence spectra or colors when in undissociated and ionic forms. The color changes or variations in absorption and fluorescence spectra are usually associated with the alteration in the degree of conjugation upon ionization of the functional groups present in the indicator molecule. The pH region of utility is usually determined by the pK_a of the indicator molecule.

Peterson was the first to report the use of an indicator that related the change in the absorption spectra to pH.[3] Seitz used a pH indicator based on changes in the fluorescence spectra of fluoresceinamine.[4] Fluorescence has become the preferred method because of its selectivity and sensitivity. Selectivity arises from the fact that not all chromophores that absorb will fluoresce, which is especially true in the NIR region where only a few classes of compound exhibit fluorescence. The use of fluorescent dyes as pH indicators, mostly azo or fluorescein derivatives, is well documented in the literature.[5–10] Applications include analysis of blood,[5] spinal cord tissue,[6] brain pH[7] and more.[8–10]

The utility of the indicator is often greatly enhanced if the pH change has a large effect on the fluorescence quantum yield of the indicator. Fluorescent indicators can be especially valuable in determining the pH of samples which have significant absorbance. In particular, the near-infrared spectral region of the electromagnetic spectrum has proven to be useful in the characterization of biological samples. The long wavelength red and short-wave near-infrared spectral region of 650–1000 nm exhibits minimal interference from biological matter. This attractive feature of the spectral region has intensified interest in development of new probe molecules. The analytical applications related to NIR absorbing chromophores have increased dramatically during the last few years. The use of semiconductor lasers as light sources further enhances the advantages of this spectral region.

The absorption and fluorescence properties of many pH sensitive indicators have been investigated in the past, including their use as fiber optic probes. Most of these dyes are weak acids or bases with ionizable functions such as carboxylic acid, phenol or amine. The appropriate pH indicator dye must have pH sensitive functional groups that reversibly change from the ionized to the non-ionized form with a

concomitant change in the degree of conjugation of the double bonds in the molecule as the hydrogen ion concentration changes. The use of pH indicators that are suitable for tissue and blood pH measurements in the physiological range has become of interest since their first application in the late 1970s.[1-4]

The chemistry of pH sensitive molecules has been of immense interest. One group of fluorescent dyes, however, that has not been fully investigated as pH indicators is the aminoenones.[11,12] Junek reported in 1973 the synthesis and properties of dialkyl aminomethylene substituted tetralones, indanediones and indanones.[11] In the following year he reported these dyes as a new group of pH indicators.[12] Nevertheless, few reports have addressed the use of aminoenone indicators that can be useful in the physiological range.[13,14]

We report here the spectral characteristics and the pH dependence of a new symmetrical aminodienone dye system **1** in methanol and in a series of organic solvents. The data presented reveal dramatic effects of protonation of the dye on its spectral characteristics. The dye is stable in alcohols under acidic and basic conditions and the dye spectra are dependent on the solution pH. Also, the dye exhibits high spectral sensitivity to the presence of protons in aprotic organic solvents.

EXPERIMENTAL

Reagent and chemicals

The chemical structure of the pH sensitive dye, 2,6-Bis[2′-(1″-ethyl-3″,3″-dimethylindolin-2″-ylidene)ethylidene]cyclohexanone (**1**, $C_{34}H_{40}ON_2$, MW = 492.68) used in this study, is shown in Fig. 1. We recently presented an efficient synthesis of **1** and its purification.[15] A sample of **1** used in this work was homogenous by TLC on silica gel with several mobile phases, gave good microanalytical results (C, H, N), and its 400 MHz proton NMR spectrum was fully consistent with the high purity of the dye.

For the experiments, spectrophotometric grade methanol was obtained from Baker Chemical Co. Isopropyl alcohol, dimethyl sulfoxide, dichloromethane, tetrahydrofuran, acetonitrile, hydrochloric acid, sodium hydroxide and buffer components were obtained from Fisher Scientific Co. The absorbance data were determined by using a disposable PS cuvette (Fisherbrand). The fluorescence intensity was determined in a quartz cuvette (Fisherbrand).

Method

Stock solutions of the dye (10^{-3} M) were prepared in spectrophotometric grade methanol, isopropanol and DMSO (Baker analyzed). For the pH studies, small amounts of stock solution were diluted to arrive at the desired concentrations for absorbance and fluorescence measurements. Since the dye is less soluble in water, the aqueous solutions were prepared by dissolving the dye in methanol and then diluting with water to obtain dye solutions in a methanol/water (1:9) mixture. No spectral differences were observed in the presence of up to 10% methanol.

Dye **1** is stable in methanol/water at room temperature for 24 hr. If kept in the dark at −20°C the dye solutions are stable for up to 20 days; however, they would turn orange if exposed to excessive sunlight. Dye **1** is stable in acetonitrile for 10 days, but undergoes slow

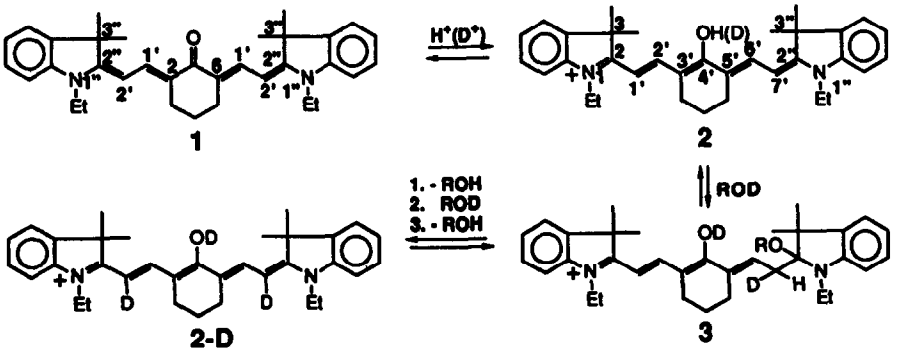

Fig. 1 Structures of a neutral form of the pH sensitive dye **1** and its protonated form **2**. A suggested mechanism for the selective hydrogen–deuterium exchange in positions 1′ and 7′ of the dye under acidic conditions is also shown. Note different numbering schemes for the disubstituted cyclohexanone derivative **1** and the cyanine dye **2**, as required by chemical names of these systems

decomposition in dimethyl sulfoxide, even in the dark. Accordingly, fresh working solutions were prepared for each experiment.

The solution pH was varied by slowly adding small amounts of hydrochloric acid or sodium hydroxide in a methanol–water mixture. The absorption spectra of the dye were taken before and after the pH measurements to examine the stability of the dye. The visual transition of color from basic (pink) to acid conditions (green) occurred at pH 3.0. Buffer solutions were used to calibrate the pH glass electrode (Fisher Scientific).

Instrumentation

Solution pH was determined by using an Orion Research Model 701A digital ionalyzer. A Perkin–Elmer Lambda 2 UV/Vis/near-IR spectrophotometer interfaced to a Zenith 286 PC was used to obtain absorption measurements. The PECSS program supplied with the instrument was used to analyze, store and retrieve data. An SLM 8000 spectrafluorometer interfaced to a PS/2 IBM PC was used for fluorescence measurements, and the fluorescence spectra were stored on floppy disks for later analysis. The pK_a values were determined using a Schott Geraete Model 250 autotitrator and model T90/10 autoburet interfaced to a PC.

RESULTS AND DISCUSSION

Absorbance

Representative absorption spectra of the pH sensitive dye **1** in methanol under acidic and basic conditions are shown in Fig. 2. Under basic conditions (dark pink solution), the dye is in a ketone form and shows a broad absorbance band with a maximum at 531 nm (Fig. 2B). The intensity of the 531 nm peak decreases with decreasing pH. At around pH 3 the dye solution turns a pale pink color. As the pH of the dye solution is decreased further, the color becomes pale green with the concomitant appearance of a narrow peak with a maximum absorbance at 709 nm (Fig. 2A). The intensity of the peak at 709 nm increases as the solution pH is lowered further while the color of the dye solution turns dark green. The change in the absorption spectra is attributed to the protonation of the oxygen atom to yield a cationic enol from **2** (Fig. 1). The formation of the enol function at the polymethine chain results in the development of a longer conjugated system. More specifically, the protonation results in the formation of a cationic cyanine dye systems **2**. This structural change is responsible for the observed, large bathochromic shift. It is known from the chemistry of the polymethine cyanine dyes that the two major determining factors in the absorption maximum wavelength are the extent of conjugation and presence of a quaternary nitrogen in the heterocyclic moiety. Those dyes that have no quaternary nitrogen, commonly referred to as dye bases, have much lower absorption wavelength maxima than a similar molecule with quaternary nitrogen in the heterocyclic terminus. The absorption of the cationic form **2** is typical for a heptamethine cyanine dye system.[16]

Two forms of the dye, thus, are an aminodienone **1** and a cationic heptamethine cyanine system **2**. The symmetrical cationic species **2** is the predominating form under acidic conditions. Dye **1** is more stable in acid conditions than in basic conditions, including light sensitivity. Under basic conditions the molecule undergoes deprotonation to form the neutral aminodienone **1**. The dye can be converted back and forth between the two forms simply by adjusting the solution pH, and these changes are fully reversible.

The dye is sparingly soluble in pure aqueous solutions; however, in the presence of a small amount of alcohol, the dye becomes soluble and it is stable in such a solvent system. The spectral behavior of the dye is markedly different in aqueous media. Under acidic conditions a broad absorbance peak with a maximum at 423 nm can be observed, while under basic conditions a very broad peak with a maximum absorbance of 484 nm is present. The molar absorptivity measured at pH 6 and pH 2, respectively, and other spectral properties of the dye are tabulated in Table 1. The different

Basic	535	7 760E + 4	484	3 438E + 4	520	6 218E + 4

*10% Methanol/90% water

spectral behavior in aqueous systems might be attributed to two factors, namely, dimerization or higher order aggregation of the molecules in a less hydrophobic environment and covalent hydration of the dye system or dye aggregate under acidic conditions (Fig. 1). However, the absorbance spectra of dye **1** at concentrations $\leqslant 10^{-8}M$ showed no dimerization effect.

The hydration would result in shortening of the dye chromophore with a concomitant blue shift in the absorption spectra, as observed. This blue shift would be especially large for hydration of the cationic form **2**, due to a facile nucleophilic addition reaction with the polyunsaturated cationic chromophore.[15,16] The changes between the aqueous and organic solutions are fully reversible, however. After the aqueous solution of **1** was extracted with dichloromethane, the spectra of the organic extract taken under different pH conditions exhibited the same behavior as the spectra of a freshly prepared solution of **1** in dichloromethane. The same results were obtained with the extracts from alkaline and acidic solutions.

The addition reaction of water to position 2(2″) of the indoline of dye **2** to give an adduct **3** (R = H) can be suggested (Fig. 1). Absorption maximum around 400 nm was estimated[17,18] for **3**, which is in reasonable agreement with the experimental value of 423 nm. With methanol the equilibrium **2** + $CH_3OH \rightleftarrows$ **3** must favor the substrate **2** because the increased steric hindrance destabilizes the adduct **3** (R = Me) in comparison to its hydroxy analog (R = H). As a result, the absorption maximum of **2** in methanol is shifted to longer wavelengths relative to the absorption in aqueous media.

Strong experimental support for the suggested addition reactions was obtained from proton NMR studies. The spectrum of **1** taken in deuterochloroform exhibited a characteristic AB pattern for H1′ and H2′ at δ 5.46 and 8.17, respectively, with a coupling constant of 13.2 Hz.[15] Upon acidification of the 1 ml sample solution in the NMR tube with 2 equivalents of HCl in 0.05 ml of methanol, a similar absorption pattern was observed at δ 8.58 and 5.79, provided the spectrum was obtained immediately following acidification of the sample. The deshielding effect is attributed to the formation of cation **2**. With deuterium chloride instead of HCl a highly selective deuteration at positions 1′ and 7′ was observed to give **2-D** (note a different numbering scheme for this compound), as evidenced by the appearance of a singlet for H2′ (6′) at δ 8.58 and lack of absorption at δ 5.79. This fast deuteration was complete within 5 min, a minimum time period necessary for obtaining the NMR spectrum. No additional changes in integration of the spectral signals were observed after the sample had been allowed to stand at 23°C for 24 hr. The facility of this acid-catalyzed hydrogen–deuterium exchange was further stressed by the isolation of non-deuterated **1** after the sample of **2-D** had been treated with silica gel, a weak acid. These results are fully consistent with the proposed mechanism (Fig. 1) in which the adduct **3** is an intermediate product for **2-D.**

The NMR signals of the samples discussed above were gradually broadened with time, and no further broadening was observed after 1 hr after the addition of acid in methanol-d_4 to the solutions in deuteriochloroform. The period of time required to reach the final line shapes at 23°C decreased with increased amount of methanol-d_4 in the solution and was 15 min for pure methanol-d_4 in the presence of 2 equivalents of acid. Unfortunately the NMR spectra in aqueous acidic methanol-d_4 could not be obtained due to low solubility of the dye under these conditions. Interestingly, the neutral dye **1** gave sharp NMR signals regardless of the concentration, time, and solvent composition.

The NMR signal broadening is indicative of a relatively slow aggregation of the hydrophobic dye molecules in a hydrophilic environment, a typical property of most carbocyanine dyes.[19] It should be noted that in all cases dye **1** was isolated quantitatively from solutions used for NMR studies.[19]

In aqueous or methanol environment, under the influence of atmospheric oxygen, especially in the presence of intense sunlight, the dye decomposes and a color change can be observed with the absorption maximum changes from 535 nm (pink) in methanol (or 484 nm in aqueous solutions) to 445 nm (orange) in 25 min. The absorbance spectra of the dye in a 50% (v/v) methanol–water solution is shown in Fig. 3. This type of light sensitivity is typical for several members of the carbocyanine dye family and can be attributed to the reaction of the molecular oxygen with the conjugated system in the presence of short wavelength radiation. Accordingly, special care was taken not to expose our solutions to excessive sunlight during experiments.

In isopropanol the dye showed properties similar those in methanol. Under basic conditions the dye gave an absorbance peak at 520 nm which is only slightly lower than the absorbance shown in methanol. In acid conditions the dye showed an absorbance band at 709 nm. These results are in good agreement with the general observation about carbocyanine dyes that alcohols are usually good solvent systems for studying electronic spectroscopic properties of cyanine dyes and there is very little variation from alcohol to alcohol

The absorption properties of the dye were also examined in dichloromethane and tetrahydrofuran. When the solution was made acidic with the addition of acetic acid, a narrow peak with an absorption maximum at 709 nm was observed. This result is consistent with the formation of a cationic dye system **2**. The intensity of this absorption increased with increased acetic acid concentration in both solvents.

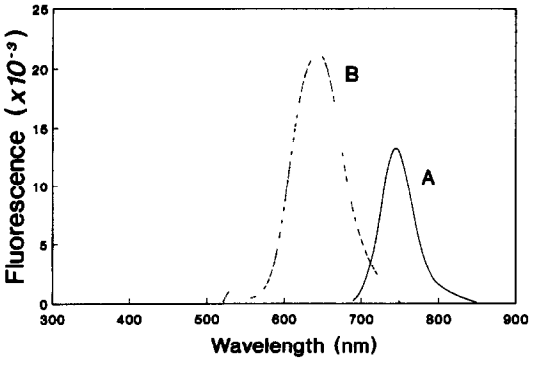

Fig 4 Fluorescence for the pH sensitive dye **1** in methanol under acidic (A), pH 2 (——) and basic (B), pH 6 5 ( ) conditions

Fluorescence

Changes in the fluorescence spectra of dye **1** in methanol were studied under acidic and basic conditions. The representative spectra under basic conditions, shown in Fig. 4(B), exhibited a broad peak with a maximum emission at 606 nm ($\lambda_{EX} = 534$ nm). The spectra under acidic conditions with an emission maxima at 743 nm, ($\lambda_{EX} = 709$ nm) is shown in Fig. 4(A). As can be seen, the emission spectra are determined by the solution pH. A plot of fluorescence intensity as a function of solution pH is shown in Fig. 5. The fluorescence emission was monitored at a constant wavelength of $\lambda_{EM} = 620$ nm ($\lambda_{EX} = 530$ nm) for the basic peak (Fig. 5B) and at $\lambda_{EM} = 740$ nm ($\lambda_{EX} = 709$ nm) for the acidic peak (Fig. 5A). The fluorescence emission intensity for dye **1** in the cationic enol form is not as intense as in the ketone form.

The fluorescence properties of the dye were found to be different in aqueous solutions compared to alcohols. Under basic conditions, the

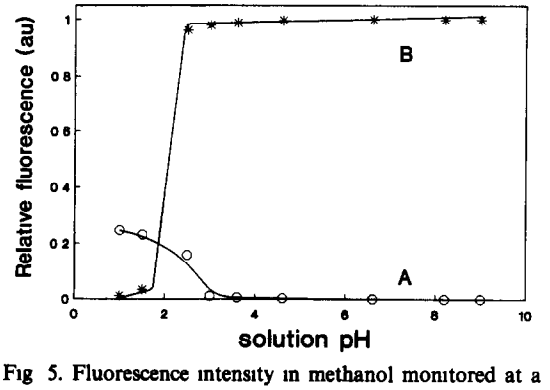

Fig 5. Fluorescence intensity in methanol monitored at a constant wavelength of $\lambda_{EM} = 620$ nm ($\lambda_{EX} = 530$ nm) for the basic peak (B) and at $\lambda_{EM} = 740$ nm ($\lambda_{EX} = 709$ nm) for the acidic peak (A)

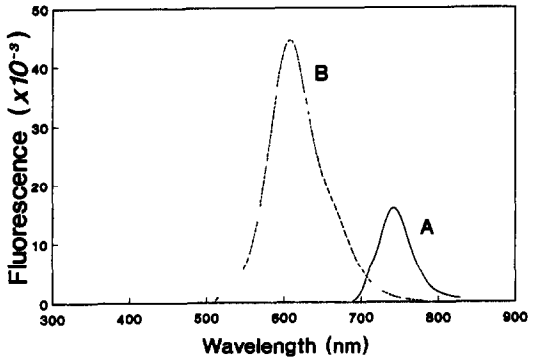

Fig. 6 Fluorescence for the pH sensitive dye 1 in isopropanol under acidic (A), pH 2 (——) and basic (B), pH 6 ( ) conditions

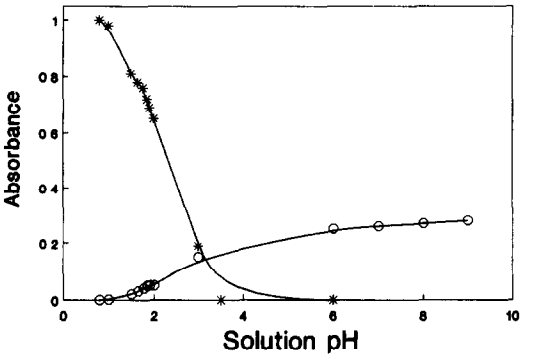

Fig 7 The pH dependence of the visible and NIR absorption peaks for dye 1 in methanol

dye showed a weak emission at $\lambda_{EX} = 495$ nm ($\lambda_{EX} = 425$ nm) while in the presence of acid a weak emission at $\lambda_{EM} = 660$ nm ($\lambda_{EM} = 545$ nm) could be observed. The solvent hydrophobicity dependence of fluorescence spectra was also studied using different methanol–water mixtures. The fluorescence intensity was the highest at high methanol concentrations indicating higher fluorescence quantum yield in alcohols (up to 100-fold). No significant change in the fluorescence intensity was observed up to 10% water concentration. The fluorescence intensity decreased at higher water concentrations; the fluorescence quantum yield was very low above water concentrations higher than 70% in methanol (v/v).

The fluorescence emission maximum of dye 1 in isopropanol was at 741 nm ($\lambda_{EX} = 709$ nm) under acidic conditions (Fig. 6A), while under basic conditions fluorescence maximum was at 606 nm (Fig. 6B). The dye fluorescence was also studied in dimethyl sulfoxide, acetonitrile and dichloromethane, and the results are shown in Table 2. These data indicate that the fluorescence spectra of this NIR dye are strongly dependent on the hydrophobicity of the solvent.

pK_a

The pK_a value for the dye was measured in 50%/50% water–methanol mixture with an automated titrator using NaOH dissolved in 50%/50% water–methanol mixture. The titration curves were analyzed with first and second order derivatives and only one pK_a was observed for the solution at 6.91. This value indicates that protonation is not the only factor that brings about changes in the absorption and fluorescence spectra of the dye with changing pH. When Figs 5 and 7 are compared to the pK_a value of the dye we can see that there is very little effect due to excited state deprotonation. Solvent effect may be the dominating factor as evidenced by spectral dependence on hydrophobicity. One possible explanation is the effect of pH on the dye aggregation.

Dye 1 as pH probe in organic solvents

The data presented here indicate that the dye is suitable as a pH probe in organic solvent medium. The advantages of this dye over other pH probes are a significant change in color and a relatively long absorption wavelength of the principal absorption band. Both the visible or the NIR bands can be used for determining the

pH of the environment around the dye molecule. Figure 7 can be used as a calibration curve for determining pH using the NIR absorption peak. Figure 7 (circles) indicates that this peak is not present in the dye spectra in basic solutions. In basic solutions, however, the visible absorption appears and the intensity of the peak increases with increasing basicity of the solution and levels off at pH 6–7. The appearance of this shorter wavelength absorption peak corresponds to a decrease in the NIR absorption peak (Fig. 2A), clearly indicating the removal of the positive charge from the dye molecule. The dye base ketone which forms during this process has significantly lower absorption wavelength and blue shifted absorption maximum. The hypsochromic shift in absorption maximum is a result of two effects, less extensive conjugation and lack of positive charge in the chromophore. The combination of these two effects results in a significant spectral shift, which may be very advantageous when observing pH change. This large spectral shift and the pH range of spectral change indicate that additional processes have an influence on the dye spectral behavior. Further studies are under way to fully characterize this process.

Dye 1 as hydrophobicity probe

The NIR dye **1** also exhibits spectral changes as the hydrophobicity of the solvent is changed. The utility of this application was demonstrated for the determination of water content in alcohols. Most likely the observed change in the absorption spectra with changing water concentration is a result of dimer formation. The dimerization property of carbocyanine dyes has been documented in the literature.[19] As the water concentration increases, the carbocyanines tend to form dimers or higher aggregates because of the strong dispersion forces associated with the high polarizability of the polymethine chain. However, in most cases, the dimer or higher aggregate band is not too well resolved from the monomer band, hindering the application. The utility of our NIR dye as a hydrophobicity probe is illustrated in Fig. 8. It shows a typical calibration curve obtained using the NIR pH sensitive probe as a hydrophobicity probe using a methanol–water mixture as the model solvent. It is important to point out, however, that the researcher must make sure that the two effects, pH and hydrophobicity, do not interfere.

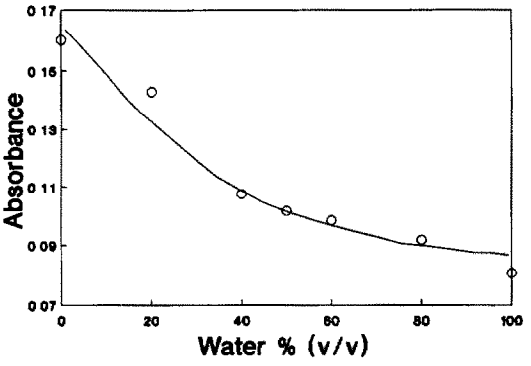

Fig 8 Typical calibration curve for determining water concentration in methanol by using dye **1** as a probe.

CONCLUSIONS

In summary, the NIR absorbing carbocyanine dye discussed in this paper can be valuable in determining analytical properties. The data presented illustrate the utility of this dye for determining pH and solvent hydrophobicity. The well separated absorption peaks of the protonated and non-protonated forms of the dye further enhance the analytical utility of this probe molecule. The dye is an especially useful probe organic solvents, e.g alcohols for the determination of pH. We are currently synthesizing and investigating similar NIR dyes for other probe and labeling applications. As a result of these studies the design of new, improved NIR absorbing probes may be available.

ELECTROCATALYSIS AND DETERMINATION OF HYDRAZINE COMPOUNDS IN LIQUID CHROMATOGRAPHY AT A MIXED-VALENT COBALT OXIDE/CYANOCOBALTATE FILM ELECTRODE

JIANXUN ZHOU and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, P R China

(*Received* 30 *July* 1992 *Revised* 5 *November* 1992 *Accepted* 8 *November* 1992)

Summary—A glassy carbon electrode coated with an electrodeposited film of mixed-valent cobalt oxide/cyanocobaltate (Co–O/CN–Co) enabled hydrazine compounds to be catalytically oxidized at the greatly reduced overpotential and in a wide operational pH range (pH 2.0–7 0) Electrocatalytic activity at the Co–O/CN–Co modified electrode was evaluated with respect to solution pH, film thickness, supporting electrolyte ions, potential scan rate, operating potential, concentration dependence and other variables The Co–O/CN–Co film electrode was completely compatible with a conventional reversed-phase liquid chromatographic (RP-LC) system. Practical RP-LC amperometric detection (RP-LCEC) of hydrazines was performed. A dynamic linear response range over three orders of magnitude and a detection limit at the pmol level were readily obtained The Co–O/CN–CO film electrode exhibited excellent electrocatalytic stability in the flowing streams

Liquid chromatography (LC) with amperometric and voltammetric detection (EC) represents a powerful tool for sensing and monitoring easily oxidizable species with high sensitivity and excellent selectivity. Unfortunately, hydrazine compounds which are of industrial and environmental significance exhibit such a large overpotential toward electrooxidation at ordinary carbon surfaces that they are not ideally suited for the quantitation with conventional LCEC approaches. Previous efforts toward enhancing the amperometric detection of hydrazines include the application of a preanodized glassy carbon electrode,[1] which enabled the hydrazines to be monitored at a modest positive potential (+0.50 V *vs.* Ag/AgCl). Chemically modified electrodes (CMEs) offer a promising approach for minimizing the overpotential effects, and various CMEs have been constructed and applied in LCEC of hydrazine sensing. These include cobalt phthalocyanine (CoPC) modified carbon paste electrodes,[2,3] a cobalt tetraphenylporphyrin modified electrode with heat treatment (HCME)[4] and an oxymanganese film modified electrode (MnCME).[5] In particular, intense research has been devoted recently to the preparation and characterization of mixed-valent inorganic catalytic centers,[6–20] of which the major advantages are the efficient electrocatalysis and inherent stability as needed for practical analysis; and various inorganic surface matrices based on mixed metal–hexacyano complexes, Prussian Blue (PB) and its analogues, have been successfully constructed and applied in electrocatalysis and determination of organic and inorganic species with LC amperometric detection. A Prussian Blue (PB) [iron (III) hexacyanoferrate (II)] film[6] and a mixed-valent ruthenium cyanide film[7] modified electrode have recently been prepared and used in flow injection amperometric detection of hydrazines. A PB filmed electrode has also recently been prepared and used in flow catalytically amperometric detection of sulfhydryl compounds (cysteine, *N*-acetylcysteine and glutathione),[8] upon which the catalytic reduction of dioxygen,[9] hydrogen peroxide,[9] CO,[10,11] hexacyanoferrate (III), iron (III) and $IrCl_6^{2-}$,[12] and the catalytic oxidation of ascorbic acid[13] have been previously reported. Nickel (II) hexacyanoferrate film modified electrodes have been devised and used in catalytic oxidation of reduced nicotinamide adenine dinucleotide (NADH) and the catalytic reduction of iron (III) in both batch and flow systems.[14–16]

*Author for correspondence.

Mixed-valent ruthenium cyanide film electrodes have been made and applied in the electrocatalysis and determination of As (III),[17] thiocyanate,[18] insulin,[19] cysteine and glutathione.[20]

In practical LCEC, the compatibility between the LC separation system and the EC detection unit is of great importance; and the media pH is the most crucial factor. Several of the above CMEs prepared, though successfully applied in flow-system detection of hydrazines, are limited to a relatively narrow operational pH range, or have not been broadly tested. Some of them[2,3,5] are limited to basic solution, and some others[4,6] to acidic media, making these CMEs of restricted use with conventional reversed-phase LC systems. The demonstration of a highly stable electrocatalytic surface with a broad operational pH range is therefore desirable for LCEC measurements of hydrazines.

The present work demonstrates that a glassy carbon electrode coated with an electrodeposited film of mixed-valent cobalt oxide/cyanocobaltate (Co–O/CN–Co), an analogue of Prussian Blue, enables the electrooxidation of hydrazines to proceed effectively at significantly low potential and in a wide pH range. The stable modified surface maintains long-term catalytic activity and is highly suitable for reversed-phase LCEC of the analytes. Features are characterized regarding several variables.

EXPERIMENTAL

Reagents and apparatus

Analytical reagent hydrazine sulfate (HZ) was from the Beijing Institute of Chemicals, and methylhydrazine (MHZ) and 1,2-dimethylhydrazine (DMHZ) were obtained from Merck. Stock solutions (0.1*M*) were prepared with doubly distilled water, and stored at 4°C in the dark. Standard working solutions in flow analysis were obtained by serial dilution of these stock solutions with the mobile phase used. $CoCl_2$ and $K_2Fe(CN)_6$ of analytical grade (Beijing Chem. Corp.), together with hydrazines, were used as received. All other reagents were of analytical grade; doubly distilled water was used for the preparation of all the solutions.

The chromatographic system consisted of a Model 510 pump, and a U6K injection valve. The analytical column was uBondapak C_{18} (5μm)250 × 4 mm i.d. (Waters Assoc., U.S.A.). The electrochemical detector was a BAS TL-5A thin-layer cell, with the potential monitored by a laboratory—made bipotentiostat.

Cyclic voltammetric experiments were performed with a laboratory-made potentiostat in a conventional three-electrode system cell, using a glassy carbon disk working electrode (with an area of 12 mm^2) in conjunction with a Ag/AgCl reference electrode and a platinum wire counter electrode.

Procedures

Prior to its modification, the glassy carbon (GC) electrode surface was polished with 0.05 μm α-alumina suspension, rinsed with water and ultrasonicated in an ethanol and a water bath, alternately, each for 2 min. The electrode was placed in a freshly prepared 2 m*M* $CoCl_2$/2 m*M* $K_3Fe(CN)_6$ solution in 0.5*M* KCl containing 10 m*M* HCl and subjected to potential sweep between −0.4 and 1.0 V at 50 mV/sec for 30 min (terminated at 0.0 V). The electrode was then removed from the solution and flushed with doubly distilled water; and a dark green film was clearly visible on the electrode surface. The modified electrode was scanned in 0.5*M* KCl (pH 4.0, adjusted with HCl) between −0.4 and 1.0 V at 50 mV/sec for several cycles until a steady-state current–voltage profile was observed.

RESULTS AND DISCUSSION

Electrocatalysis in a conventional cell

Figure 1A shows cyclic voltammograms of the Co–O/CN-Co film electrode in the solution of 0.5*M* KCl at pH 4.0. The Co–O/CN–Co film underwent a well-defined two-step oxidation at

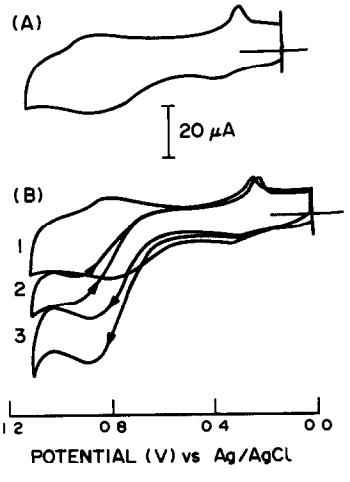

Fig 1 Cyclic voltammograms of Co–O/CN–Co film electrode in 0.5*M* KCl (pH 4 0) without [curve A and B(1)] and with the addition of 1 m*M* [curve B(2)] and 2 m*M* [curve V(3)] hydrazine Scan rate, 50 mV/sec

potentials of 0.34 and 0.85 V, respectively; and the oxidized film showed two-step reduction at potentials of 0.85 and 0.26 V.

So far, few studies have been reported concerning the formation of $Co^{2+}/Fe(CN)_6^{3-,4-}$ complexes, especially on a glassy carbon substrate which is commonly available in commercial electrochemical detectors. From previous literature,[21-25] there seems to be two possible mechanisms for the film formation of Co analogue to PB. Neff[21,22] and Itaya[23,24] suggested that PB and its analogues were formed mainly by the electrostatic interaction of the transition metal cations [Fe(II/III), Ru(III/IV), *etc.*] with the negatively charged $Fe(CN)_6^{3-,4-}$ to produce sparingly soluble mixed-valent metal deposits. Typical systems investigated include PB and Ruthenium Purple. Kulesza[25] has showed that a Ru analogue was converted to a mixed-valent Ru (III, IV) oxide crosslinked by cyanide during the modification procedure in 1:1(m*M*/m*M*) $RuCl_3$:$K_4Ru(CN)_6$, 0.5*M* KCl at pH 2. Surface measurements with X-ray photoelectron spectra (XPS) are helpful for the investigation of the mechanism concerning the film formation.

During the modification procedure, a gray–brown precipitate was readily formed in the $CoCl_2/K_3Fe(CN)_6$ mixture. A modified electrode was prepared, dispersed with the precipitate which had been treated with preliminary steps including filtering, rinsing with distilled water and air-drying, using the approach proposed by Dong and Kuwana[26] by rotating the GC surface under slight hand pressure over the slurry of the precipitate on a polishing paper. The voltammetric response of the resulting modified electrode was examined and was found to be virtually identical to that shown in Fig. 1A. It is plausible to hypothesize that Co analogue deposits formed on the electrode surface and in the solution are basically the same. Subsequently the solution-forming precipitate was applied to XPS measurements. XPS measurements were performed with a ESCALAB-MK II electron spectrometer (VG Scientific Limited, U.K.). A 20 mA at 14 KV $Al_{K\alpha}$ beam was used for excitation. XPS gave Co, O, C, N and K peaks, indicating that a CN group must be present in the coating. The absence of a Cl peak suggests that Cl^- did not play a significant role in the film formation, although it was present at a level of 0.5*M* in the solution for electrodeposition. Semi-quantitative analysis gave the approximate ratios of the atomic concentration: Co:O:CN as 1:7:10. These studies suggest that electrode coating was formed largely through the formation of mixed-valent Co oxo-bridges crosslinked by cyanide produced by the decomposition of $Fe(CN)_6^{3-}$, which is consolidated by the absence of an XPS Fe peak at Eb around 710–720 eV (not shown). The modified electrode surface can thus be best expressed as Co–O/CN–Co.

The anodic and cathodic peak currents increased linearly with potential scan rate up to 400 mV/sec, indicating essentially the surface behavior of the film electrode as in the case of PB and its analogues modified surfaces. The Co–O/CN–Co coating on the glassy carbon substrate was very stable in a wide pH range (2.0–7.0). For example, no obvious change was observed in the CVs at the modified electrode during at least a 1 hr period of continuous potential scanning between 0.0 and 1.0 V at 50 mV/sec in 0.5*M* KCl solution, corresponding to 90 cycles.

Figure 1B shows cyclic voltammograms of the Co–O/CN–Co film electrode in 0.5*M* KCl (pH 4.0) in the absence (curve 1) and in the presence of 1.0 m*M* (curve 2) and 2.0 m*M* (curve 3) hydrazine. Upon the addition of hydrazine, the anodic peak current of the second redox couple (at 0.85 V) increased, in proportion to the analyte concentration, and the corresponding cathodic wave disappeared. Such behavior is exactly what would be expected for an electrocatalytic CME oxidation.

The electrocatalytic capability of the Co–O/CN–Co film electrode toward MHZ and DMHZ was also determined and is shown in Fig. 2 (curves 2 and 3). An increased anodic and a decreased cathodic peak current were observed on CVs of the redox pair at 0.85 V with the addition of 2 m*M* MHZ (curve 2) and DMHZ (curve 3). The catalytic oxidation peak potential shifted negatively compared with that of the surface wave on the film electrode (from 0.85 to 0.80 and 0.65 for MHZ and DMHZ, respectively). The interaction of the analytes with the Co–O/CN–Co film may account for the peak potential variations. These analytes can not be effectively oxidized at the bare GC surface up to 1.2 V, as also illustrated in Fig 2 (dotted line).

Cyclic voltammetric experiments also provided other useful items of information preliminary to LCEC detection. First, there is no marked effect of media pH on either the peak potential (Fig. 3C, curve a) or the peak current (curve b) for catalytic oxidation of hydrazine at

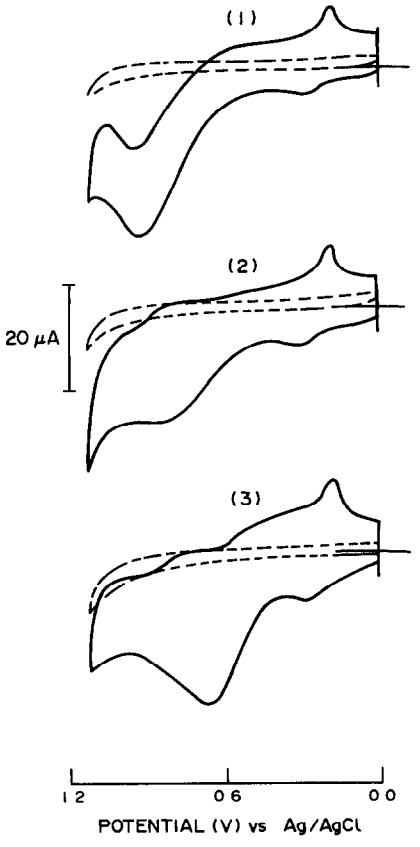

Fig 2 Cyclic voltammograms of 2 mM each of HZ (curve 1), MHZ (curve 2) and DMHZ (curve 3) at the Co–O/CN–Co film electrode (solid line) and the bare GC surface (dotted line) Scan rate, 50 mV/sec

the Co–O/CN–Co film electrode. This indicates that the electrocatalysis proceeds efficiently in a wider pH range (from acidic to neutral media) compared with previously reported catalytic surfaces,[2–7] and on the other hand, this pH effect can greatly favor the reproducibility of current measurements in LCEC detection, as the electrochemical detector is not sensitive to fluctuation of either the operating potential or the mobile phase pH during analysis. Second, the catalytic peak current as a function of the square root of the potential scan rate is linear over the range 5–360 mV/sec (Fig 3A), indicating a diffusion-controlled oxidation and a rapid reaction between the ferrocyanide species in the Co–O/CN–Co film and hydrazine.

Considering the fact that there exist channels in Prussian Blue and its analogues[14–25] favoring transport of K^+ during redox transitions, one could expect that K^+ concentration plays an important role in electrocatalysis of hydrazines at the Co–O/CN–Co film electrode. The cyclic voltammetric experimental results agree with this expectation. By the dilution of KCl electrolyte from 2.0 to 0.02M, the catalytic peak potential of 1 mM hydrazine at the Co–O/CN–Co film electrode surface shifted negatively (from 0.89 to 0.75 V); and then reduced sharply with lowering of the KCl concentration to less than 0.1M. Further, successive potential cycling produced deteriorated CV peaks at the Co–O/CN–Co film electrode in KCl electrolyte less than 0 1M (*eg.* 0.05M). These indicate that the long-term stability of the Co–O/CN–Co coating and efficient catalysis could only be practical when K^+ is present at a level higher than 0.1M in the supporting electrolyte and/or mobile phase.

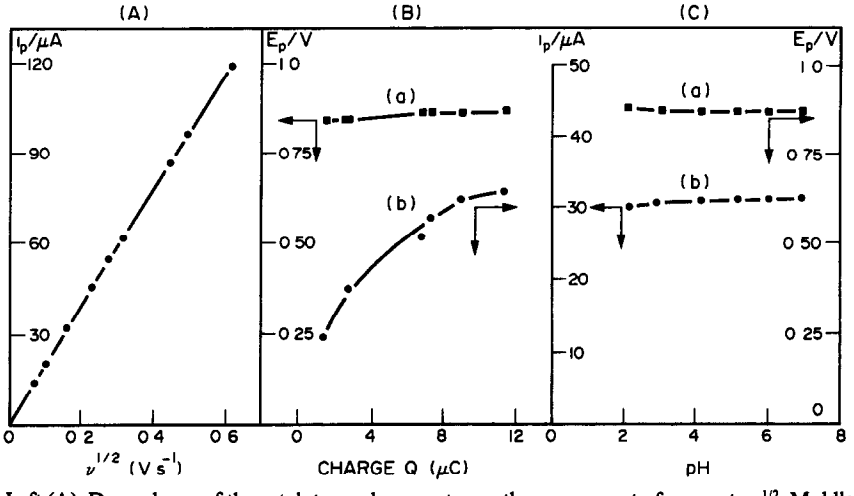

Fig 3 Left (A) Dependence of the catalytic peak current i_p on the square root of scan rate $v^{1/2}$ Middle (B) Film thickness effect on catalytic peak potential (curve a) and peak current (curve b) Right (C). The dependence of catalytic peak potential (curve a) and peak current (curve b) on pH from CVs of 1 mM hydrazine at the Co–O/CN–Co film electrode in 0 5M KCl, pH 4 0 (A and B) at scan rate of 50 mV/sec (B and C)

Cyclic voltammetric experiments also demonstrated that using either 0.5*M* KCl, 0.5*M* KH_2PO_4, 0.5*M* KNO_3, or 0.5*M* $KClO_4$ changed neither the peak potential (within 15 mV) nor the peak current (within 8%) for the catalytic oxidation of hydrazine by the Co–O/CN–Co film electrode. The effect of film thickness of the catalyst on the electrocatalytic response toward hydrazine was studied by cyclic voltammetry, with results as shown in Fig. 3B. The film thickness was estimated by charge consumed within the potential scan over the second anodic wave (at 0.85 V) (*ca.* 0.6–1.0 V) by calculating the peak area of the current–voltage profile at the Co–O/CN–Co film electrode in 0.5*M* KCl electrolyte. The catalytic peak potential (curve a) was virtually unchanged with film thickness, whereas the peak current (curve b) increased significantly with increased thickening of the film, the extent of which became less marked after 8.6 μC, that is 7.8×10^{-9} mol/cm^2; the corresponding time period required for film coating was *ca.* 25 min. Prolonging the modification time further contributed slightly to the electrocatalytic activity. Therefore, the modification time is selected as 30 min for the reproducible preparation of the Co–O/CN–Co film electrode. This is of analytical advantage in the reproducibility of both the current measurements and the electrode preparations. Five consecutive preparations beginning with bare glassy carbon substrate yielded charges of 8.3, 8.7, 8.5, 8.2 and 8.6 μC. The Co–O/CN–Co film was much thinner than the reported Prussian Blue deposits on glassy carbon. Since these inorganic film species have fairly high resistivities,[21] a modification procedure that produced a very thin film was important for applications to electrocatalysis and flow detection.

Chromatographic detection

The operating potential was optimized by hydrodynamic voltammograms (HDVs) of the analytes on the Co–O/CN–Co film electrode, as shown in Fig. 4A. Hydrazine and methylhydrazine (MHZ) exhibited peak-shaped HDVs at the modified surface, as seen for other electrocatalytic surfaces,[2-7] reaching their maximal levels at around 0.8 V. DMHZ, however, presented S-shaped HDV behavior up to 1.0 V. The sensitivity of current measurements follows the order HZ > MHZ > DMHZ. The amine groups might be responsible for these differences. No useful currents were obtained for the analytes on a bare GC surface up to 1.0 V under the same

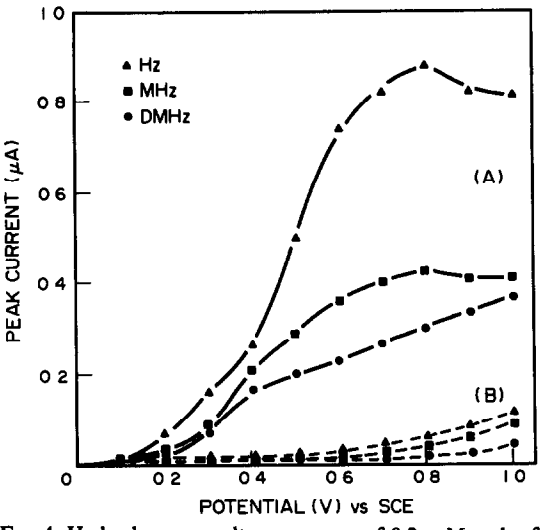

Fig. 4. Hydrodynamic voltammograms of 0.2 m*M* each of HZ, MHZ and DMHZ at the Co–O/CN–Co film electrode (curve A) and the bare GC surface (curve B) Column, μBondapak C_{18} (5 μm)250 × 4 mm i.d , mobile phase, pH 7.0, 0 1*M* KH_2PO_4 at flow rate of 1 0 ml min Injection volume, 10 μl

solution conditions (curve B). Based on the compromise among high sensitivity, selectivity and low background current, 0.80 V was selected for LC amperometric detection.

By virtue of the wide operational pH range available on the Co–O/CN–Co film electrode

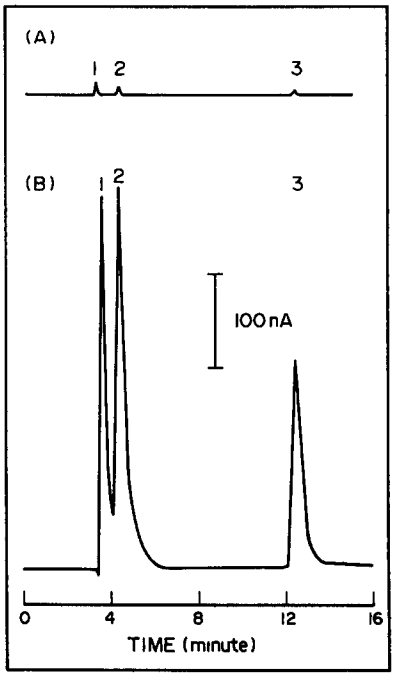

Fig. 5. Chromatograms of 0.2 m*M* HZ (1), 0 4 m*M* MHZ (2) and 0.26 m*M* DMHZ (3) at the Co–O/CN–Co film electrode (curve B) and the bare GC surface (curve A). Potential applied at 0 80 V *vs.* SCE Flow conditions as in Fig. 4

for electrocatalytic oxidation of hydrazines, practical RP-LCEC has been performed with a conventional ODS column, using pH 7.0, 0.1M KH_2PO_4 as mobile phase. Using higher concentration KH_2PO_4 was mobile phase is of a disadvantage for the maintenance of proper operating pressure and column efficiency, though contributing a little to the current response sensitivity. Well-defined and resolved chromatographic peaks were obtained as shown in Fig. 5, with the operating potential monitored at 0.80 V. Ten replicate injections of stock solutions containing 0.02 mM HZ, 0.04 mM MHZ and 0.026 mM DMHZ were carried out to determine the precision. The coefficient of variation of the peak heights was 1.7% for HZ, 2.5% for MHZ and 3.2% for DMHZ.

Under such conditions, LCEC of hydrazines at the Co–O/CN-Co film electrode gave dynamic linear response ranges of 3×10^{-7} to $7.5 \times 10^{-4}M$ for HZ, 6×10^{-7} to $9 \times 10^{-4}M$ for MHZ and 8×10^{-7} to $8 \times 10^{-4}M$ for DMHZ, with correlation coefficient greater than 0.99. The corresponding detection limit (based on three times the S/N ratio) was 1.5×10^{-4} mM, 3×10^{-4} mM and 5×10^{-4} mM for HZ, MHZ and DMHZ; that is 1.5, 3 and 5 pmol, respectively (10 μl loop).

The Co–O/CN–Co film coated electrode exhibited excellent stability for the continuous use in flowing streams. After 2 days service in the chromatographic system, during which working solutions containing 0.4 mM each of HZ, MHZ and DMHZ were injected at intervals, at least 80% of the initial current response level was obtained for hydrazines in LCEC with the Co–O/CN–Co film electrode; and the concentration dependence on the peak current was still linear up to two orders of magnitude. These features suggest that such a Co–O/CN–Co coating electrode is promising as an effective indicator for routine LCEC analysis of hydrazines.

CONCLUSIONS

A new inorganic catalytic electrode has been successfully constructed by electrodeposition on the glassy carbon surface of a Co–O/CN–Co film. The Co–O/CN–Co film electrode provides stable and efficient catalysis toward hydrazine compounds in a wide operational pH range, making it perfectly compatible with conventional reversed-phase liquid chromatographic systems. When used in LCEC, wide dynamic linear response range over three orders of magnitude and low detection limit at the pmol level are readily obtained. The Co–O/CN–Co coating shows acceptable long-term stability for continuous catalytic service in flow-through analytical systems. Moreover, the Co–O/CN–Co coated glassy carbon electrode offers the possibility of extending voltammetric techniques to hydrazine compounds otherwise poorly suited to electroanalysis at conventional carbon substrates.

BOOK REVIEWS

TrAC—Trends in Analytical Chemistry: Reference Edition, Volume 10, 1991. Elsevier, Amsterdam, 1992 Pages 372 Dfl. 545 00. ISBN 0-444-89503-5

This book is a compilation of the 10 issues of TrAC for the year 1991 and like all the 'Trends in' Reference Editions, is arranged in order of issue publication. Only the book reviews and news items are excluded The book finishes with a cumulative author and subject index for volumes 6–10

Each issue is divided into a number of subsections (meeting reports, monitor, computer corner, feature, observer, trends) that are not always distinguishable from one another. Attempts have not been made to divide articles up into general areas of analytical chemistry although one issue (Nov/Dec) is entirely devoted to environmental concerns

TrAC covers all areas of analytical chemistry and fills an important niche between specialized journals and text books The articles are intended for a wide readership and are accessible to the non-specialist whilst providing comprehensive references for those who need to look further TrAC is also a quick enjoyable way of keeping abreast with recent developments that are peripheral to your reading list or research interests

Elsevier have not wasted any time in publishing this reference edition. Coupled with a well balanced choice of articles from authors at the 'cutting edge' of their fields makes this a very useful update It is an invaluable source of teaching material and of new ideas for research

The price is apparently rather prohibitive, but hides the fact that for only a little more (Dfl 800 this year) your library can take all issues of TrAC and receive the reference edition when it is published. For the individual subscriber TrAC is very good value at Dfl 181 so there are few readers who would consider it necessary to purchase this reference edition

This book is available from the Amsterdam address or in the USA/Canada from Elsevier Science Publishing Company Inc , P.O Box 882, Madison Square Station, New York NY10159, U S A

Fig. P, Version 6: BIOSOFT, Cambridge, 1991. £280, US$499

This scientific graphics software package for IBM PC/PS2 and compatibles is a major upgrade from the previous version, and is now a very powerful tool. Almost any type of graph that a scientist might want can be produced. The user has full control over the nature of the axes, the positioning of the tick marks, the choice and positioning of the labels, etc Graphs may be annotated with text, boxes, circles, ellipses and arrows as desired, and a suitable size and font can be chosen for each piece of text Multiple figures can be produced on the same page Figures can be produced in colour if desired Output drivers are included for many printers and HPGL plotters, including HP Paintjet and Laserjet III Curve-fitting and statistical tests are also included The output quality is extremely good, even with a nine-pin dot-matrix printer, but especially with a laser printer or a Matrix slide camera

The manual has 420 pages, of which 20 give a quick overview, 56 give tutorial instruction, 280 comprise sample figures with brief instructions for their production but no data, and 68 the reference section I found the tutorial less helpful than I had expected instead of detailed step-by-step instructions, it starts by giving a summary of the items to be entered, then goes off into explanations of all the possibilities, then returns to entry instructions Thus, a lot of reference information is presented in the tutorial section The reference section, too, did not have the usual format Indeed, it seemed to consist mainly of "tutorial" sections on the advanced topics not covered earlier in the manual As a result, the best way to learn to make full use of the program seems to be to work through the instructions for the sample figures However, this would have been easier if the data values for the samples had been included either in the handbook or on the disc

Fairly comprehensive instructions were given on screen, with context-sensitive help, and I actually found it easier to learn to use the program from this than from the manual

In conclusion, I believe this is an excellent package for computer-literate scientists who wish to produce their own diagrams in a form suitable for publication It is less well suited for use by students or technicians, who are likely to be baffled by its complexities

Patterson's German-English Dictionary for Chemists—4th Ed.: J C. Cox and G E Condoyannis (Eds.). Wiley, Chichester, 1992. Pages liii + 890 £52.00 ISBN 0-471-66991-1

There cannot be many of the present older generation of English-speaking chemists who have not at one time or another had recourse to *Patterson* in its 3rd edition dating from 1950 While the German chemists of the turn of the century indulged

in a heavy literary style to describe their achievements in science, those of our generation have turned to a simpler style to aid international understanding But their efforts have been thwarted by those of others intent on developing an endless stream of new words, not to be found in our old *Pattersons* As it happens, the difficulties of going *into* German are confounded by the number of technical words which are *not* translated from the English but are used as such

Having struggled through German stock inventories and been able to translate them only with the help of illustrated English catalogues, I am very appreciative of the approach of the present two editors of *Patterson*, who have, over the years, been compiling their own glossaries out of their own experience in technical translating. Technical dictionaries abound good ones are rare

So, how does the 4th edition of *Patterson* score? Very well indeed Many older trivial names are still included—Blausäure, Hirschhornsalz—along with culinary delights—Müsli, Steinpilz—older and newer spellings—Cadmium/Kadmium (but not Ton/Thon)—care with foreign names—Mékerbrenner—and so on. Then the eternal problem of the German compound words is dealt with extensively, verbs with many different prefixes, nouns with extensions—Mehrwegbehalter, Dauerbiegefestigkeit—idiomatic phrases—letzten Ende,—sei dem wie es sei—more difficult parts of verbs—ging(gehen)—and so on In short, this is an excellent revision which will give pleasure to the user because he will always find more than he seeks, not just a question answered but a lesson learned This new dictionary deserves a place, not merely on the bookshelf, but on the workdesk of every chemist who reads German scientific literature

I L MARR

Trace and Ultratrace Analysis by HPLC: S AHUJA, Wiley–Interscience, New York, 1992 Pages xi + 419 £59.00 ISBN 0-471-51419-5

The title suggests that this book attempts to focus on the utility of high-performance liquid chromatography (HPLC) for the analysis of small quantities of compounds. In reality, however, the author has done more than this in producing a comprehensive all-embracing text on HPLC, containing nine substantial well-referenced chapters

After having outlined the scope of the book in the first chapter, illustrated by selected examples demonstrating the applicability of the technique for the analysis of macro-molecules and small molecules, the following chapter describes the fundamental concepts of chromatography, relating them to instrument and column performance There follows two chapters devoted to instrumentation comprising solvent delivery systems, microcolumn HPLC and a full description of all the available detectors suitable for trace analysis Chapter 5 describes in detail the various possible approaches for sample preparation varying from solvent extraction to solid-phase extraction systems

Obviously the core of any analysis is the selection of the appropriate stationary and mobile phases These topics are comprehensively dealt with in chapters 6 and 7 which in parts are repetitive. There is a full description of reversed-phase systems including ion-pair chromatography This is followed by a chapter on optimization which brings together a lot of the topics dealt with earlier Throughout the book there are examples of applications to illustrate the chapter topics but there is also a concluding chapter dealing solely with applications from the areas of pharmaceuticals, food and the environment. Whilst the applications are cross-referenced in the index they are not always readily accessible

This book, which contains some factual and typographical errors, is not a beginners' text, assuming as it does in parts that the reader has a biological and chromatographic background. However, the author has included in appropriate chapters useful descriptions of some of the newer developments and understanding of analyte separation mechanisms The synoptic nature of the book tends to make it somewhat prosaic in parts

G G. SKELLERN

Gas–Liquid–Solid Chromatography: V G BEREZKIN, Dekker, New York, 1991 Pages viii + 231 $99 75 (U S and Canada), $114.50 (elsewhere) ISBN 0-8247-8425-1

The fundamental approach of this treatise is that separation in "gas–liquid" chromatography not only involves the two bulk phases, the gaseous mobile phase and the non-volatile liquid stationary phase, but is influenced by the interfaces between the gas and the liquid, and between the liquid and solid support Hence, the stationary phase is regarded as a binary system in gas–liquid–solid chromatography with gas–liquid chromatography an important, but limited case of gas–liquid–solid chromatography

Berezkin's book discusses up-to-date concepts in gas–liquid–solid chromatography. Theoretical principles, calculation procedures and experimental methods developed to estimate the effects of adsorption phenomena on retention are described in the nine chapters of the book

Chapter 1 outlines the evolution of gas–liquid–solid chromatography. In Chapters 2–4, factors effecting the retention of analysed compounds are considered including a discussion of the influence of adsorption on relative retention times and the effect of the solid support on the efficiency of separation. In Chapter 5, the effects of the stationary liquid phase to solid absorbant phase ratio on the characteristics of chromatographic resolution are considered for packed and capillary columns. Irreversible or quasi-irreversible absorption of solutes on the solid support is discussed in chapter 6, along with the effects of chemical transformation at the solid support surface The next two chapters consider the contributions that gas–liquid–solid chromatography has made to physicochemical measurements Chapter 7 considers equilibrium parameters of the absorption (partition) interaction between solutes and the liquid phase, whereas Chapter 8 is devoted to the

in a heavy literary style to describe their achievements in science, those of our generation have turned to a simpler style to aid international understanding But their efforts have been thwarted by those of others intent on developing an endless stream of new words, not to be found in our old *Pattersons* As it happens, the difficulties of going *into* German are confounded by the number of technical words which are *not* translated from the English but are used as such

Then the eternal problem of the German compound words is dealt with extensively, verbs with many different prefixes, nouns with extensions—Mehrwegbehalter, Dauerbiegefestigkeit—idiomatic phrases—letzten Ende,—sei dem wie es sei—more difficult parts of verbs—ging(gehen)—and so on In short, this is an excellent revision which will give pleasure to the user because he will always find more than he seeks, not just a question answered but a lesson learned This new dictionary deserves a place, not merely on the bookshelf, but on the workdesk of every chemist who reads German scientific literature

I L MARR

Trace and Ultratrace Analysis by HPLC: S AHUJA, Wiley–Interscience, New York, 1992 Pages xi + 419 £59.00 ISBN 0-471-51419-5

The title suggests that this book attempts to focus on the utility of high-performance liquid chromatography (HPLC) for the analysis of small quantities of compounds. In reality, however, the author has done more than this in producing a comprehensive all-embracing text on HPLC, containing nine substantial well-referenced chapters

After having outlined the scope of the book in the first chapter, illustrated by selected examples demonstrating the applicability of the technique for the analysis of macro-molecules and small molecules, the following chapter describes the fundamental concepts of chromatography, relating them to instrument and column performance There follows two chapters devoted to instrumentation comprising solvent delivery systems, microcolumn HPLC and a full description of all the available detectors suitable for trace analysis Chapter 5 describes in detail the various possible approaches for sample preparation varying from solvent extraction to solid-phase extraction systems

Obviously the core of any analysis is the selection of the appropriate stationary and mobile phases These topics are comprehensively dealt with in chapters 6 and 7 which in parts are repetitive. There is a full description of reversed-phase systems including ion-pair chromatography This is followed by a chapter on optimization which brings together a lot of the topics dealt with earlier Throughout the book there are examples of applications to illustrate the chapter topics but there is also a concluding chapter dealing solely with applications from the areas of pharmaceuticals, food and the environment. Whilst the applications are cross-referenced in the index they are not always readily accessible

This book, which contains some factual and typographical errors, is not a beginners' text, assuming as it does in parts that the reader has a biological and chromatographic background. However, the author has included in appropriate chapters useful descriptions of some of the newer developments and understanding of analyte separation mechanisms The synoptic nature of the book tends to make it somewhat prosaic in parts

G G. SKELLERN

Gas–Liquid–Solid Chromatography: V G BEREZKIN, Dekker, New York, 1991 Pages viii + 231 $99 75 (U S and Canada), $114.50 (elsewhere) ISBN 0-8247-8425-1

The fundamental approach of this treatise is that separation in "gas–liquid" chromatography not only involves the two bulk phases, the gaseous mobile phase and the non-volatile liquid stationary phase, but is influenced by the interfaces between the gas and the liquid, and between the liquid and solid support Hence, the stationary phase is regarded as a binary system in gas–liquid–solid chromatography with gas–liquid chromatography an important, but limited case of gas–liquid–solid chromatography

Berezkin's book discusses up-to-date concepts in gas–liquid–solid chromatography. Theoretical principles, calculation procedures and experimental methods developed to estimate the effects of adsorption phenomena on retention are described in the nine chapters of the book

Chapter 1 outlines the evolution of gas–liquid–solid chromatography. In Chapters 2–4, factors effecting the retention of analysed compounds are considered including a discussion of the influence of adsorption on relative retention times and the effect of the solid support on the efficiency of separation. In Chapter 5, the effects of the stationary liquid phase to solid absorbant phase ratio on the characteristics of chromatographic resolution are considered for packed and capillary columns. Irreversible or quasi-irreversible absorption of solutes on the solid support is discussed in chapter 6, along with the effects of chemical transformation at the solid support surface The next two chapters consider the contributions that gas–liquid–solid chromatography has made to physicochemical measurements Chapter 7 considers equilibrium parameters of the absorption (partition) interaction between solutes and the liquid phase, whereas Chapter 8 is devoted to the

in a heavy literary style to describe their achievements in science, those of our generation have turned to a simpler style to aid international understanding But their efforts have been thwarted by those of others intent on developing an endless stream of new words, not to be found in our old *Pattersons* As it happens, the difficulties of going *into* German are confounded by the number of technical words which are *not* translated from the English but are used as such

Having struggled through German stock inventories and been able to translate them only with the help of illustrated English catalogues, I am very appreciative of the approach of the present two editors of *Patterson*, who have, over the years, been compiling their own glossaries out of their own experience in technical translating. Technical dictionaries abound good ones are rare

So, how does the 4th edition of *Patterson* score? Very well indeed Many older trivial names are still included—Blausäure, Hirschhornsalz—along with culinary delights—Müsli, Steinpilz—older and newer spellings—Cadmium/Kadmium (but not Ton/Thon)—care with foreign names—Mékerbrenner—and so on. Then the eternal problem of the German compound words is dealt with extensively, verbs with many different prefixes, nouns with extensions—Mehrwegbehalter, Dauerbiegefestigkeit—idiomatic phrases—letzten Ende,—sei dem wie es sei—more difficult parts of verbs—ging(gehen)—and so on In short, this is an excellent revision which will give pleasure to the user because he will always find more than he seeks, not just a question answered but a lesson learned This new dictionary deserves a place, not merely on the bookshelf, but on the workdesk of every chemist who reads German scientific literature

G G. SKELLERN

Gas–Liquid–Solid Chromatography: V G BEREZKIN, Dekker, New York, 1991 Pages viii + 231 $99 75 (U S and Canada), $114.50 (elsewhere) ISBN 0-8247-8425-1

The fundamental approach of this treatise is that separation in "gas–liquid" chromatography not only involves the two bulk phases, the gaseous mobile phase and the non-volatile liquid stationary phase, but is influenced by the interfaces between the gas and the liquid, and between the liquid and solid support Hence, the stationary phase is regarded as a binary system in gas–liquid–solid chromatography with gas–liquid chromatography an important, but limited case of gas–liquid–solid chromatography

Berezkin's book discusses up-to-date concepts in gas–liquid–solid chromatography. Theoretical principles, calculation procedures and experimental methods developed to estimate the effects of adsorption phenomena on retention are described in the nine chapters of the book

Chapter 1 outlines the evolution of gas–liquid–solid chromatography. In Chapters 2–4, factors effecting the retention of analysed compounds are considered including a discussion of the influence of adsorption on relative retention times and the effect of the solid support on the efficiency of separation. In Chapter 5, the effects of the stationary liquid phase to solid absorbant phase ratio on the characteristics of chromatographic resolution are considered for packed and capillary columns. Irreversible or quasi-irreversible absorption of solutes on the solid support is discussed in chapter 6, along with the effects of chemical transformation at the solid support surface The next two chapters consider the contributions that gas–liquid–solid chromatography has made to physicochemical measurements Chapter 7 considers equilibrium parameters of the absorption (partition) interaction between solutes and the liquid phase, whereas Chapter 8 is devoted to the

determination of physicochemical parameters for adsorption of solutes at the interfaces between the gas and liquid stationary phase and between the liquid phase and the solid support. the final chapter considers practical aspects of the effect of the solid support on the conditioning and ageing of columns.

Throughout the book, theoretical models and practical experiments are used in equal measure to guide the reader through a fairly detailed consideration of adsorption phenomena Emphasis is placed on understanding the basis of the technique rather than on specific applications in particular areas of analysis Numerous equations are presented, but often the reader has to look back several pages to be reminded of the definition of symbols A comprehensive table of definitions would have been a helpful addition to the text. All the chapters contain useful illustrations and tables of relevant data. Some of the figures have been reproduced directly from initial publications and are not of a high quality One would have thought that it would have been possible to redraw some of the graphs without too much difficulty. Each chapter has its own list of references, covering the literature up to the mid 1980s, although some of the papers in east European journals may not be easily accessible

The importance of adsorption phenomena in gas–liquid chromatography has been recognised for many years, so the topics considered in this book are not entirely new The author claims that this is the first time that an attempt has been made to consider consistently gas–liquid chromatography and gas–liquid–solid chromatography Whether or not this is true does not really matter The main point is that a text has been produced which considers, in some detail, theoretical and practical aspects of gas–liquid–solid chromatography and so it should be helpful to scientists interested in the fundamental basis of chromatographic separations

D LITTLEJOHN

Potentiometric Water Analysis, Second Edition: D MIDGLEY and K. TORRANCE, Wiley, Chichester, 1991 Pages xiv + 586 £65.00. ISBN 0-471-92983-2

This is a welcome revision of Midgley and Torrance's authoritative text first published in 1978 The format of the first edition has been maintained, but the content has been updated to include recent developments in electrode technology and potentiometric methods of importance in water analysis This is very much a practical textbook where the authors have tried to provide enough information to enable the analyst to use commercially available ion-selective electrodes without having to undertake extensive method development

Part I provides a theoretical and practical background to potentiometry and Part II contains almost 400 pages of analytical methods for water analysis Separate chapters in Part I cover electrochemical principles, potentiometric instrumentation and methodology The theory of electrochemistry is covered in sufficient detail to allow the analyst to understand the practical importance of the principles and relationships which affect activity, electrode potentials, liquid junction potentials, etc The fundamental basis of different types of ion-selective electrodes (ISE) are described, but without a detailed explanation of the mechanisms of electrode response Similarly, the chapter concerned with instrumentation describes what can be achieved with modern potentiometric equipment without labouring the technicalities In contrast, the authors have taken the trouble to point out the importance of establishing the analytical viability of a method and many readers will find the chapter on the statistical evaluation of data extremely helpful Many papers published on potentiometric analysis fail to give details of accuracy and precision and omit a discussion of errors The authors have tried to compensate for those deficiencies by providing a realistic indication of the performance of various types of electrodes when applied in water analysis

The value of the book to many readers will be the extensive notes on over 35 separate ISE applications given in Part II Not only are the apparatus, reagents and procedures described in adequate detail, but sources of error and electrode performance are discussed, comments on the lifetime of electrodes, typical response times and comparisons with other methods, where appropriate.

The ability of potentiometry to provide low-cost measurements in field and laboratory applications, as well as in on-line monitoring, has made the technique very important in water analysis Midgley and Torrance have provided an up-to-date review of methods and procedures which is clearly written and easy to read Each chapter is accompanied by a list of references covering developments up to 1990

Although the text does not contain all that many figures, it has numerous tables of useful information on electrochemical data, electrode comparisons and analytical methods. There is also a list of manufacturers of potentiometric equipment Anyone interested in potentiometry or water analysis should obtain a copy of this book

D LITTLEJOHN

Spectrochemical Analysis by Atomic Absorption and Emission: L. LAJUNEN Royal Society of Chemistry, Cambridge 1992 £18.50 (softback) Pages xii + 242 ISBN 0-851-86873-8

This book is very timely, coming on the market, as it does, when the modern analytical atomic spectroscopies such as ICP–MS are becoming firmly established necessitating their inclusion with more than a passing reference in our training courses Substantial chapters deal with Theory of atomic spectroscopy, Atomic absorption, Plasma atomic emission, ICP–MS, Atomic fluorescence, Sample preparation, while some smaller chapters cover the Histological background and Comparisons Flame emission is dismissed in two sides, so the book cannot be described as long-winded!

The author's practical experience comes over on many occasions through his comments on the practical consequences and the relevance of this or that aspect of theory and so on The author has included numerous diagrams, some his own,

determination of physicochemical parameters for adsorption of solutes at the interfaces between the gas and liquid stationary phase and between the liquid phase and the solid support. the final chapter considers practical aspects of the effect of the solid support on the conditioning and ageing of columns.

Throughout the book, theoretical models and practical experiments are used in equal measure to guide the reader through a fairly detailed consideration of adsorption phenomena Emphasis is placed on understanding the basis of the technique rather than on specific applications in particular areas of analysis Numerous equations are presented, but often the reader has to look back several pages to be reminded of the definition of symbols A comprehensive table of definitions would have been a helpful addition to the text. Spectrochemical Analysis by Atomic Absorption and Emission: L. LAJUNEN Royal Society of Chemistry, Cambridge 1992 £18.50 (softback) Pages xii + 242 ISBN 0-851-86873-8

This book is very timely, coming on the market, as it does, when the modern analytical atomic spectroscopies such as ICP–MS are becoming firmly established necessitating their inclusion with more than a passing reference in our training courses Substantial chapters deal with Theory of atomic spectroscopy, Atomic absorption, Plasma atomic emission, ICP–MS, Atomic fluorescence, Sample preparation, while some smaller chapters cover the Histological background and Comparisons Flame emission is dismissed in two sides, so the book cannot be described as long-winded!

The author's practical experience comes over on many occasions through his comments on the practical consequences and the relevance of this or that aspect of theory and so on The author has included numerous diagrams, some his own,

many taken from the publications of the major manufacturers Comparisons of performance and statements on interferences and other problems are illustrated by tables or figures, well referenced Nebulisers and sample introduction, Electrothermal atomization, Background correction, Hydride generation, Cold-vapour technique, Optics of spectrometers, all receive thorough treatment in this book.

It is suggested that this book is for undergraduates and lecturers would that we have sufficient time in undergraduate courses to deal so thoroughly with this topic and others in analytical chemistry. However, for advanced Diploma and Masters courses this could become a welcome course text, at a size and price appropriate to the market There are a few minor errors in text and in figures—even in fact, as when the temperature of the nitrous oxide flame is said to be only a little *lower* than that of the air–acetylene flame—but these do not detract from the considerable value of this book. The balance of the discussion is good, the illustrative detail is good, and the presentation is clear

I L. MARR

Biosensor Principles and Applications: L J BLUM and P R COULET (Eds), Dekker, New York, 1991 Pages x + 357 £125.00 (US and Canada), $143 75 (elsewhere) ISBN 0-8247-8546-0

This is the 15th volume in the series on Bioprocess Technology by W. C McGregor

For those who are already involved in the multi-disciplined biosensor field or about to embark into this field this book will serve as a comprehensive, up-to-date, reference source.

Every major type of biosensor is included The main emphasis is on the enzyme based types and fiberoptic biosensors But many others such as immunosensors, microbial biosensors, *in vivo* biosensors are all given separate chapters The presentation and language used to explain how a particular biosensor works is not too technical yet is sufficient to enable the reader to understand how it works, the characteristics of its performance and its limitations Considering the large number of contributors involved from different countries, a high standard of presentation is maintained throughout the 14 chapters As expected there are one or two isolated instances of variation, e g., Fig 3 on p 73 and the equation on p 250 are difficult to read—possibly because of size reduction problems

All authors uniformly make the reader aware that despite the advances in biosensor technology over the last 20 years, this field of endeavour is still in its infancy and has yet unfulfilled potential Those wishing to obtain a foretaste of achievable future developments in industrial, environmental and health monitoring need go no further than to read the final chapter In so doing there is no doubt that the rest of the text will be read and the book recognised as a valuable general reference source for biosensors

R R MOODY

Standardization Within Analytical Chemistry: P KIVALO, Akadémiai Kiadó, Budapest, 1989 Pages 155 + appendices US $36

As a scientific discipline, analytical chemistry is a branch of metrology As Lord Kelvin pointed out, " when you can measure what you are speaking about and express it in numbers, you know something about it " The expression of analytical information in numbers unfortunately cannot always be referred uniquely to the basic physical constants For this reason it is often necessary to specify in detail how the measurement is to be performed Uniform procedures are essential if the highest reliability and repeatability are to be attained The requisite definitions, procedures, and calculations are collectively embodied in the standardization for each particular measurement

This book discusses in detail the several aspects of standardization and the steps in their development Standard methods or techniques are based on sound scientific principles Nevertheless, standardized or test methods for specific purposes or commercial products must often take into account the individual characteristics of the material to be analysed in order to ensure quality control and fitness for the intended purpose. In these instances, "pure" analytical chemistry becomes "applied" analytical chemistry in the development of protocols and certified reference materials. This process, the domain of numerous national and international standardizing bodies, is traced with logic and clarity in the seven chapters of the book.

Following an introduction, the history of analytical chemistry and the development of metrology are reviewed briefly In Chapters 3 and 4, the reader is introduced to early international standardization efforts, especially through ISO and IEC (of which Lord Kelvin was the first president), and the International Union of Pure and Applied Chemistry (IUPAC) Chapter 5 contains 53 pages and is the longest in the book, it is devoted to such matters as terminology, sampling and quality assurance, collaborative studies, and standard reference materials The latter subject may merit more attention than it receives in the few pages allotted to it. Reference standards are currently available in a variety of forms, and they may be certified for composition or for many different properties critical to special analytical problems The short final chapters discuss legal aspects and future trends in standardization

Especially commendable is the inclusion, among the appendices, of the 49-page ISO Guide 2—1986, "General terms and their definitions concerning standardization and related activities". Terms relating to all aspects of standardization are defined in English, French, and Russian, while the equivalent terms in German, Spanish, Italian, Dutch and Swedish are listed

This book is recommended to all who are concerned with the development, nature, and application of analytical standards.

R G BATES

Chromatography, 5th Edition—fundamentals and applications of chromatography and related differential migration methods: E HEFTMANN (editor), Elsevier, Amsterdam, 1992 Part A· fundamentals and techniques. Pages xxxvi + 552 Dfl 350 00 Part B· applications. Pages xxxii + 630. Dfl 370 00 Parts A and B set price Dfl 650.00

The fifth edition comprising Part A, on fundamentals and techniques, and Part B, on applications, is a completely revised edition of an important text on chromatography with contributions from 38 authors. Chapters on countercurrent chromatography, supercritical fluid chromatography, affinity chromatography and field flow fractionation have been added to Part A In Part B, chapters on proteins on peptides, nucleic acids and their constituents and pharmaceuticals have been strengthened

Chapter 1 is an excellent introduction, providing an overview of the theory of chromatography with emphasis on a simplified treatment of the more practical chromatographic concepts The theory of chromatography has evolved to such an extent that no single volume, let alone a single chapter, could address this topic satisfactorily but to compensate for this fact, a number of valuable general references are listed amongst the 142 references for this chapter

Chapter 2 deals with countercurrent chromatography (CCC) The principles of the two basic systems of CCC, *i e* , the hydrostatic and hydrodynamic systems, are described together with the design and capability of 10 selected CCC instruments and a table of recent applications

Planar chromatography (PC) is the subject of the next chapter in which there are sections on classification of techniques, principal factors affecting separations, instrumentation, preparative PC and special PC techniques such as TLC/FID, a technique of growing importance in which separations take place on rods of adsorbent which, after development, are passed at constant speed through a flame ionization detector

Chapter 4, a very practical one on column liquid chromatography (CLC), is concerned mainly with the most widely used type of CLC—namely HPLC There are sections on solvent delivery systems, sample handling, columns and connectors, detectors, *etc.*, and a section on some new forms of liquid chromatography.

A comprehensive chapter on ion-exchange chromatography covers the synthesis and properties of ion-exchange resins, ion chromatography and variations of the ion-exchange technique such as ion-exclusion, ion-pair and ligand-exchange chromatography

Size exclusion chromatography (also variously known in the earlier literature as gel filtration, gel permeation chromatography, *etc.*) is dealt with in Chapter 6 in which there is a good balance of theoretical and practical aspects The next chapter on affinity chromatography is, not surprisingly, almost exclusively concerned with biospecific iterations and there is only a mention of the expansion of the method to include other types of interaction ,

Supercritical fluid chromatography (SFC), the subject of Chapter 8, was first applied in 1963 but, due to the rapid development of the instrumentally less challenging technique of HPLC, SFC has not progressed at the pace one might have expected However, many of the early problems associated with instrumentation and columns have been overcome and so the popularity of SFC is growing and it appears to have a bright future Since operating temperatures are typically much lower in SFC than in GC, it is suitable for thermolabile solutes such as explosives and for samples that are not sufficiently volatile for GC Furthermore, because on decompression, supercritical fluids turn into gases, typical GC detectors such as the FID may be used This is a very useful chapter which covers principles, columns, instrumentation and detectors

Gas chromatography, undoubtedly the principal method of analysis of volatile, thermally stable organic compounds present in mixtures, is the subject of the next chapter in which all the important aspects, from column type, carrier gas selection, instrumentation, detectors *etc* , are covered, although the chapter concentrates mainly on recent developments and trends There is a nice section on stationary phase selection including a consideration of chiral stationary phases and liquid crystal stationary phases

The penultimate chapter of Part A concerns field flow fractionation (FFF). The classification and treatment of the various techniques is well done but with a multitude of terms such as flow FFF (FFFF) and sedimentation/floatation focusing FFF (SFFFFF!) one is thankful for the comprehensive list of abbreviations provided at the beginning of the volume

The treatment of electrophoresis including immunoelectrophoresis, which forms the final chapter of Part A, is comprehensive, although in view of the growing importance of capillary zone electrophoresis, perhaps a little more space could have been devoted to that particular technique

In Part B there are chapters on the applications of the various techniques dealt with in Part A, to the separation and analysis of an assortment of compounds including inorganic species, amino acids and peptides, proteins, lipids, carbohydrates, nucleic acids, porphyrins, phenolic compounds, drugs, fossil fuels, synthetic polymers, pesticides and environmentally important samples

A useful feature of the work is a list of names and addresses of manufacturers and suppliers of chromatography and electrophoresis materials and equipment There are approximately 200 clear, good quality figures and 100 tables throughout this volume All chapters are well referenced—for example, three chapters have chosen 500 and 600 references and only two chapters have less than 100—the average being about 250.

Taken together, Parts A and B provide an incomparable source of reference for any worker engaged in the use of chromatographic methods

The flavour of this book is accurately indicated in the first line of the preface where the author states that "there is a real need for a book on emulsion polymers that speaks directly to the users The need is not so much for erudition, but

for simple explanation of operating mechanisms involved in the physics and chemistry of polymers and colloids as they apply to emulsion polymer manufacture and use".

There are four sections in this book which are sub-divided into essentially stand-alone chapters The first section contains a discussion of formulation for various industries, a very basic introduction to colloid science, an even more basic introduction to polymer chemistry and concludes with a useful discussion of emulsion polymerization procedures on the laboratory and pilot-plant scales. The second section is titled "The Monomers" It is sub-divided into the vinyl monomers, styrenes, acrylates and methacrylates, diene monomers, waterborne condensation polymers and by-products in the latex Each section is well referenced from both the patent and the scientific literatures The next section deals with analysis and testing which includes discussions of viscometry, surface tension measurements, particle size analysis, mechanical stability, electrophoretic mobility, residual monomer measurement and molecular weight determination. The final section contains a discussion of colloidal stabilizers, rheology modifiers, curatives, heat and UV stabilizers, biocides and of fillers, pigments and reinforcing agents

The book, which is well indexed, will be primarily of use to those readers who work in industry Although it is not aimed at the academic researcher, some parts would serve as useful introductions to specific topics such as particle size analysis Given its rather high price, it is likely to find itself predominantly on library shelves

HyperChem—Release 2 for Windows: 1992: AUTODESK Ltd , Cross Lanes, Guildford, Surrey, U K £500 00 (Educational users), £2000 00 (Other users)

HyperChem is a suite of programs for the generation and examination of molecular images on a personal computer It consists of two discs, three manuals and a hardware lock (dongle) which are all delivered in a large box If you lose the dongle the whole package must be purchased again so take great care that it stays firmly attached to the back of the computer. A free demonstration disc is also available The basic PC requirements are 4MB of memory, a 386 (or 486) with a maths co-processor, 20MB of hard disc space and preferably a colour monitor (VGA) HyperChem operates under Microsoft's Windows (version 3, at least) so a mouse is also required.

The manuals are, on the whole, very extensive and very helpful and the program suite loads easily into the PC On starting Windows a HyperChem icon consisting of a green liquid in a beaker appears, double clicking on this icon starts the show I tried HyperChem with a Cyrix 486 processor (an Intel chip is the standard processor) and Windows version 3 1—no problems were encountered

The "Getting Started" manual contains several tutorials for new users of the system and I was able to follow all of these with ease Details on how to drive HyperChem from Excel and Visual Basic are also given The "Computational Chemistry" manual is a good basic introduction to both molecular mechanics and quantum mechanics Compared to some other molecular graphic systems, I found it very easy to create images of molecules on the screen and one of my research students was manipulating 3D images within minutes of using the program suite Molecules are first drawn in 2D and then by a mere click of the mouse—hey presto—a 3D structure appears with hydrogens added automatically This is very impressive but care should be taken to realize that molecules will have been given standard geometrical values and, *e g* , staggered hydrogen arrangements if appropriate. Chirality also needs to be checked HyperChem then allows more realistic geometries to be generated by energy minimization. Measuring features of the molecular images was very simple—bond lengths, non-bonded distances, valency and torsion angles were all included in the available options.

HyperChem is especially helpful for those wishing to examine proteins and amino-acids as a library of such fragments is included Brookhaven protein database files can also be used and some of these files are included in the package

I was particularly interested in the molecular mechanics capabilities of HyperChem and the MM+, AMBER, BIO+ and OPLSA force fields are provided. Semi-empirical methods (Extended Huckel, CNDO, INDO, MINDO/3, MNDO and AM1) are also available I was pleased to see that the user may change or add parameters to the MM+ (based on Allinger's MM2) force field The appropriate files are available as text files and can hence be edited All atom types are available in MM+ and up-to-date references of parameters are given in the manuals and the programs When the potential energy of a molecular representation is minimized it must be remembered that we are dealing with just a sophisticated model of the system (generated by mathematical manipulations not actual experimental data) and that some "molecules" will be more accurately modelled than others When accurate structures of small molecules are already known from X-ray crystallographic studies the user should be able to import these (*e g.*, from the CSSR database) into HyperChem. In this respect the manuals do not explain how to use atom coordinates based on fractions of unit cell edges, but, as Brookhaven file can be read, this should presumably be a possibility. The user should also be warned that molecular mechanics studies involving, for example, heavy atom molecules are less accurate than those involving hydrocarbons as the latter are associated with better characterized parameters

The graphics are impressive and a student is in danger of believing that reality is being displayed but molecular chemistry in 3D is not the only way to view the subject

Molecular mechanics normally gives an insight into molecular conformations in a hypothetical isolated state at absolute zero However, with HyperChem molecular dynamics simulations can be performed in the presence of a box of water molecules

Investigations involving electrons requires the use of the semi-empirical options and plots of electron density and molecular orbitals can be obtained All of the semi-empirical calculations are best performed on small molecular systems as the computer time required can run into hours In this respect a powerful PC is recommended as such calculations are normally performed on more powerful machines—such as Cray supercomputers!

(*Received* 14 *December* 1992. *Accepted* 28 *January* 1993)

Summary—Potentiometric responses of a novel class of pH sensitive ionophores, namely several phenoxazine derivatives, were tested in different modified PVC matrices. The ionophores were compounded into liquid membranes as usual or were covalently coupled to the polymeric matrix. The general analytical performance of the membranes and other membrane characteristics (*i.e.*, resistance and response time, as measures of membrane decomposition or structural changes) were followed in time. The transient responses of membranes with mobile ionophores in high molecular weight (HMW) and carboxylated PVC (PVC–COOH) were compared to those with immobilized ionophores. The response time of membranes with immobilized ionophores was found to be between those with mobile ionophores in HMW (fast response) and PVC–COOH (sluggish response). Accordingly, the rate of response was correlated primarily to the –COOH content of the membranes.

To utilize the advantages of the existing semiconductor and microelectronics technologies and their potential for development of ion-selective microelectrode arrays for biological applications, attempts have been made to apply chemically sensitive membranes directly on to the surface of microelectronic devices.[1–4] Unfortunately, reducing the size of the sensor and changing the classical membrane electrode construction (internal reference electrode/internal filling solution/ion-selective membrane) to a planar sensor arrangement without a large liquid internal contact, brought several problems to light concerning the potential stability, reproducibility, response time and life time of these sensors, due to the stringent requirements in this field. Besides these, factors such as membrane biocompatibility and low membrane resistance became decisive in membrane optimization.

To reach the goal of microelectronically fabricated electrodes we were guided by existing information. Potentiometric sensors are useful when rapid direct signal transformation is needed, as in continuous monitoring and flow-through analysis.[5,6] The precision, reliability, short and long term stability, as well as the short response time of membrane-based sensors, make them attractive for biological applications.[6–13] Ionophore-based alkaline and alkaline earth ion-selective PVC membranes already proved their outstanding properties in different fields of potentiometric analysis.[10–17] Thus, we focus on two topics achieving (I) long sensor life time and (II) rapid response times.

(I) The sensor life time of planar microelectrodes is determined primarily by the dissolution of the membrane ingredients into the sample solution and by the adhesion of the membrane to the wafer (problems of encapsulation). In the recent past, ion-selective ionophore loaded PVC membranes have been extensively used for preparation of ion and molecule selective optical sensors.[18–23] Loss of membrane con-

stituents in these "bulk optodes" is even more important to be avoided, since, in contrast to the potentiometric sensors, the optical signal is directly dependent on the concentration of the components in the membrane.

Possibilities for elimination, or the slowing down of the process of leaching of membrane ingredients are: (1) use of ionophore and/or plasticizer free membranes;[24-30] (2) attachment of the ionophores to the matrix by covalent coupling;[31,32] (3) increasing the distribution coefficient of the components by introducing adequate structural elements (*e.g.*, large alkyl chains) or selecting membrane matrices of more advantageous partition properties;[33,34] (4) replacement of the low molecular weight mobile ionic additives (such as sodium tetraphenyl borate) with more lipophilic derivatives {*e.g.*, potassium tetrakis *p*-chlorophenyl borate or-sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]-borate};[35,36] and (5) use of PVC compatible polymers as fixed site additives[37-39] instead of the lipophilic salts.[31]

(II) Recently, PVC membrane based calcium selective bulk optodes with immobilized phenoxazine derivatives as chromoionophores were described.[31] An important enhancement in sensor life time could be achieved by immobilizing the chromoionophore. However, the response time of these bulk optical sensors with immobilized ionophores was increased as well. Since phenoxazine derivatives have proven to be excellent ionophores in potentiometric pH sensors[40] it was of interest to study the effect of ionophore immobilization on the response of potentiometric electrodes, known as surface sensors. PVC matrix pH sensors with extended life time may be serious competitors to pH sensitive glass electrodes in some special fields of applications[24-26,40-44] such as cardiology.

This paper describes the responses of large numbers of H^+ selective electrodes tested as possible candidates to prepare planar ion-selective microelectrodes for cardiovascular applications. The membranes were fabricated from different modified and compounded PVC membranes since our aim was to select an optimal membrane composition for acute and chronic applications in cardiology. Accordingly, we compared the responses of the different matrices, studied changes of the membrane properties during a long period of time, and noted alterations of the dynamic responses as a function of membrane matrix modifications. Aminated and carboxylated PVC (PVC–NH_2 and PVC–COOH, respectively) were selected for these studies primarily as a consequence of their excellent adhesion properties[45-47] (crucial in the preparation of planar electrodes) while hydroxylated PVC (PVC–OH) seemed to be attractive since it has been reported as having no interference from serum proteins.[48]

Theoretical and experimental evidence for membrane component loss, solvent uptake and response time degradation

The conclusions from extensive theory and experiments[49-55] on bathed ion exchange membranes include the following.

(1) Interfacial potential differences (pds) depend thermodynamically on external bathing ion activity when the ion is previously incorporated in the membrane at constant activity. For example, aminated PVCs containing added TPB^- at exactly the same concentration as amine sites, should provide an ideal system: $RNH_3^+TPB^-$ (and ion pairs in equilibrium) that should maintain constant proton activity in the membrane.
(2) Any extraneous processes including (a) exchange of TPB^- for any other bathing solution anions; (b) water uptake to dilute the interior proton activity; (c) loss of plasticizer to concentrate the site density and thereby change the proton activity, will perturb the interfacial pds.
(3) Factors in (2) shift each interfacial pd, and if the system does not respond exactly "symmetrically", there will be a shift in the asymmetry potential, *e.g.*, a shift in E°.
(4) Uptake of water or loss of plasticizer causes formation of surface layers of different composition compared with the bulk composition. The interfacial pds are then complicated by diffusion pds between the outer membrane surface and the interface between the perturbed layer and the original, homogeneous bulk. Thus, time dependent responses to activity steps in solution are predicted. As surface layers become thicker, time responses are longer.

These conclusions follow from studies of response mechanisms of ion-selective electrodes using different transient techniques.[27,56-59] The results for several ion-selective electrodes demonstrated high resistance surface film formation[27,56,58] from plasticizers and impurities in plasticizers and/or membrane matrix materials

such as PVC. In the case of glass electrodes, high resistance surface layers are formed by hydrolysis of the glass to form silica gel, and, if dried, partly silica layers.[60] Morf has shown that when the surface region has a different selectivity coefficient for each species, compared with the membrane bulk, there is a voltage off-set.[61] On the basis of his model, long term changes of electrode response to primary ion activity steps and interfering cation activity changes could be explained.

In polymers with positively or negatively charged groups,[45,46] uptake of water is expected by unbalance of osmotic pressure. This uptake may be accompanied by the formation of hydrophilic (colloidal) water droplets,[62–64] by membrane hydrolysis or by the formation of ion–dipole clusters.[65,66] The probability of formation of such "inhomogenities" (hydrophilic or hydrophobic domains) is considerably larger in modified PVC matrices with high concentrations of sites compared to high molecular weight PVCs of low ion exchange capacity. The process may start at the membrane surface as a consequence of aqueous solution contact, and is thought to be prolonged in time as water penetrates into the bulk of the membrane. Along with these structural changes, alterations of the selectivity coefficients and increases in the total membrane resistance and in the response time are expected.[26]

For the quantitative evaluation of the potential–time transients, the following two equations were used:[59,67]

$$E(t) = E_2 + S \log\left(1 - \left(1 - \frac{a_{i,1}}{a_{i,2}}\right) e^{-t/\tau_1}\right) \quad (1)$$

and

$$E(t) = E_2 + S \log\left(1 - \left(1 - \frac{a_{i,1}}{a_{i,2}}\right) \frac{1}{\sqrt{t/\tau_2 + 1}}\right), \quad (2)$$

where $E(t)$ is a time dependent potential at time t following a sudden change of the sample solution activity; E_2 is the final steady-state potential; $a_{i,1}$ and $a_{i,2}$ are the solution activities before and after the activity change in the sample, respectively; τ_1 and τ_2 are time constants and S is the experimentally determined slope of the EMF–log a_i calibration curve.

Equation (1) was suggested as an approximate description of the potential–time transients when diffusion/equilibration processes within the aqueous boundary layer are assumed to be rate determining. Equation (2) applies when transport processes within the membrane are thought to be decisive in determining the rate of response.[59,67] The time constant of equation (2) depends on the diffusion coefficients in the membrane and in the aqueous boundary layer, on the thickness of the boundary layer and on the partition parameter K. The partition parameter K was found to depend on the equilibrium constant (K_{ex}) of the dominant extraction reaction [equation (3)] and on the concentration of free ligand within the membrane.[67]

$$M^{z+}(aq) + zX^-(aq) + kR^-(m) + rL(m) \leftrightarrows ML_l^{z+}(m) + kR^-(m) + zX^-(aq) + (r - l)L(m). \quad (3)$$

Accordingly, the polarity of a membrane has a direct influence on τ_2.[67] Higher polarity (PVC membranes containing –COOH, –OH, $-NH_2$ or $-SO_3H$ functional groups) result in slower responses.[58,68] Furthermore, the formation of surface layers with different properties from the bulk (hydrophilic or hydrophobic regimes) as a consequence of aqueous solution contact, is more likely in high site density modified PVCs compared to more conventional HMW PVCs. The increase in response time values for modified PVC as a function of solution contact (hydration) is consistent with the expectations.[9]

EXPERIMENTAL

Chemicals

For all experiments, deionized water doubly distilled in Pyrex glass and chemicals of puriss or pa grade were used.

Buffer solutions

For the determination of the pH sensitivity and potentiometric selectivites of the electrodes, the following buffer solutions were used:[40] (I) citrate–borate buffer with 60mM Li^+ ion background; (II) a TRIS buffer with 140.0mM Na^+ ion background; (III) a TRIS buffer with 200.0mM K^+ ion background, (IV) a Britton–Robinson buffer with or without 140mM NaCl (see Table 10.47 in Ref. 69). The pH of the solutions was adjusted by means of a hydrogen ion-selective glass electrode (Orion model 91–57) by the addition of hydrochloric acid or sodium hydroxide to the stock buffer solutions.

Membranes

The solvent polymeric membranes were prepared according to Ref. 70. Their most common

Table 1. Characterization of ETH 3531 and ETH 3534 by gel permeation chromatography. The relative amount of each component was calculated from the respective peak area (SD; $n = 3$)

Form of Nile Blue	ETH 3531	ETH 3534
Immobilized	95.3 ± 1.0%	86.6 ± 1.2%
Mobile	4.0 ± 1.0%	12.9 ± 1.3%
Other derivatives	0.7 ± 0.2%	0.5 ± 0.2%

composition was 1 wt % ionophore, 64–66 wt % plasticizer and 33 wt % PVC and 70 mole % (compared to the ionophore) potassium tetrakis (*p*-chlorophenyl) borate (KT*p*ClPB) as lipophilic salt additive. However, in some cases membranes without ionophore (mainly aminated PVC membranes) were also cast.

All ionophores and plasticizers were products of Fluka AG (Buchs, Switzerland) or synthesized in our laboratories: tridodecylamine (TDDA) (Fluka 95292); ETH5294 (Fluka 27086); ETH 2439 (Fluka 27087); 2-nitrophenyl octylether (o-NPOE) (Fluka 73741); Bis(2-ethylhexyl) sebacate (DOS) (Fluka 84818); ETH 5350 was synthesized as described in Ref. 31. As polymeric membrane materials, several commercially available products were tested: poly(vinyl chloride) (PVC, high molecular weight, HMW), Fluka 81392, carboxylated PVC (PVC–COOH, with 1.8% COOH groups), Aldrich, 18955 and hydroxylated PVC (PVC–OH), a copolymer of 91% vinyl chloride, 3% vinyl acetate and 6% vinyl alcohol, Fluka 27827. The latter could not be used alone for membrane casting (as a consequence of the bad mechanical properties of the membrane), but only as a 1:1 mixture with HMW. The 1,4-diamino butane and piperazine modified PVC samples were prepared in our laboratories with the reaction scheme suggested by Ma and Meyerhoff.[25] The H^+ sensitive ETH 3531 and ETH 3534 membrane matrices were synthesized as described in Ref. 31.

Synthesis and analysis of ETH 3531 and ETH 3534

The synthesis of Nile Blue directly bound to carboxylated PVC (ETH 3534) and to carboxylated PVC through a spacer (ETH 3531) is described in detail by Rosatzin *et al.*[31] The efficiencies of the conversions were followed by elemental analysis and absorption measurements[31] and the products were characterized by gel permeation chromatography (Table 1). The equipment used for gel permeation chromatography was a LiChroGraph® HPLC System (Merck, Darmstadt, Germany) including a gradient pump L-6200 and a D-6000 HPLC Manager Chromatography Data Station Software. A Kontron Uvikon LCD 725 (Kontron, Zürich, Switzerland) served as a detector. The column (600 × 7.5 mm I.D.) was a PLgel 5μ 100Å (Polymer Laboratories Ltd, Shropshire, U.K.) and THF with 1% (v/v) 0.02*M* $NaOCH_3$ in methanol was used as solvent at a flow rate of 2.0 ml/min.

EMF measurements

Cell voltages were measured at room temperature with an Orion Expandable Ion Analyzer (Model EA 920). As a reference electrode an Orion model 90-02 Ag/AgCl double junction reference electrode was used throughout. The readings were made when the potential changes were less than 0.2 mV/min.

Determination of the internal resistance of the cells

The internal resistances of the cells were determined by the voltage divider method using known shunts.[71,72] The potential drop at $t = 0$ (ΔE_Ω) was used to evaluate the ohmic resistance (R_Ω).

Response time measurements

To determine the dynamic response of different electrodes a switched wall jet arrangement was used.[59,73] The standard deviation of $t_{90\%}$ data as well as the rise times of the measuring electronics are given elsewhere.[58] All response time measurements were carried out in the presence of a background electrolyte of constant ionic strength in order to minimize the effect of streaming and diffusion potentials in the streaming sample solution.

RESULTS AND DISCUSSIONS

Response ranges and slopes

In the course of this work a large number of modified PVCs were compared on the basis of their potentiometric behavior. The chemical constitutions of the ionophores used in this work are summarized in Fig. 1 while the membrane compositions and some of the relevant parameters of the H^+ sensitive membrane electrodes are given in Table 2. Comparing the analytical parameters (selectivity coefficients, stability and reproducibility) of mobile ionophores (ETH 5294, ETH 5350) loaded into membranes cast from different PVCs (HMW, PVC–COOH, PVC–NH_2, PVC–OH), no significant differences were found, and the data were the same as published earlier for HMW membranes.[40] The linear response range can be extended to lower pH values using PVC–COOH as the matrix and DOS as the plasticizer. The properties of ionophore free H^+ selective

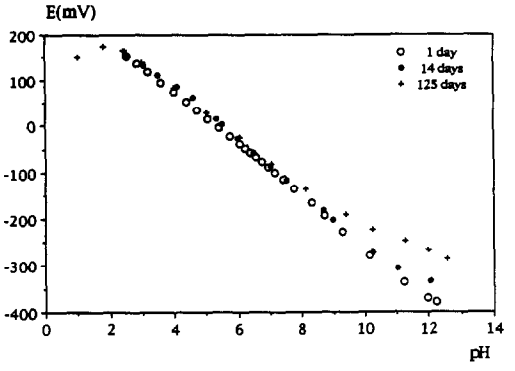

Fig. 3. EMF response of the ETH 5294 ionophore based pH electrode (3a) in the PVC–COOH matrix.

membranes (PVC–NH_2) are dependent on the chemical structure of the amine (basicity) as well as on several parameters related to the synthesis (*e.g.* N content and glass transition temperature of the aminated product *etc.*).[26] The analytical performance of the ionophore free membranes could be improved by the addition of mobile ionophore (Fig. 2). This improvement becomes more visible with elapsed time. The parameters of ETH 5350 compounded PVC–NH_2 membranes remain approximately constant, in contrast to the ionophore-free membranes where a slight decrease of the slope and a shift in detection limit to lower pH values were observed.[26] Similar loss of sensitivity was experienced with ETH 5294 compounded PVC–COOH electrodes in alkaline solutions after about 2 weeks (Fig. 3).

Time dependent membrane resistances

Information on the structural changes of the different membrane matrices as a function of aqueous solution contact is crucial in design of sensors for chronic applications. Accordingly, parallel to the analytical tests, membrane resistances were followed as a function of time by the voltage divider method (Table 3).[71,72] The electrodes were kept in a pH = 7.00 Tris buffer solution between the tests. The resistances of ETH 5294 based membranes increased significantly with time except with PVC–OH as the matrix. The largest increase in the bulk membrane resistance (R_Ω) was observed with PVC–NH_2 thereafter with PVC–COOH, HMW and PVC–OH membranes. These data correlate nicely with preliminary dissolution data carried out on modified PVC membranes containing the basic form of Nile Blue A as the ionophore. The amount of ionophore dissolved from different PVC membranes was the smallest for PVC–OH and the largest when PVC–NH_2 and PVC–COOH were used as matrices.[74]

The changes of membrane resistances with time (Table 3) substantially correspond with alterations of other membrane parameters as well. These changes are manifest in: (1) a shift of the lower limit of detection to higher hydrogen ion activities (Fig. 3); (2) changes of selectivity coefficients to larger values; (3) shift of the offset voltage of the cell ($E°$);[47] (4) slower time responses to step activity changes.[9,26]

No resistance increase was observed with TDDA compounded membranes during a 2 month period of time. In agreement with this result, the basic analytical parameters of these membranes were found to be constant.[47] Accordingly, we assume that the long term deterioration of ETH 5294 based sensor responses is mainly due to the loss of ionophore following its decomposition within the membrane. Naturally, the rate of decomposition is heavily influenced by several parameters like: (i) the pH of the sample solution, (ii) the energy and intensity of

illumination of the membrane, (iii) the pH of the matrix, *etc.* The pH of the matrix is quite acidic in the case of PVC–COOH or basic in PVC–NH_2. In addition to this the partition coefficient of the ionophore between the aqueous solution and PVC membrane may be different for the different modified PVCs.

Dynamic responses

Upon selecting ETH 5294 as a proton carrier for thin layer optical membranes[18] or planar micro pH electrode construction[47] the loss of membrane components from certain matrices seemed to be decisive in determining the corresponding sensor properties. To avoid problems connected with gradual changes in the membrane matrix composition, Nile Blue (the active ingredient) was bound directly or through a spacer to the carboxylated PVC matrix (Fig. 1; ETH 3531 and ETH 3534).[31] The efficiency of the conversion related to the available carboxyl groups was about 21% (ETH 3531) or 23% (ETH 3534) calculated from the elemental analysis.[31] The result of the gel permeation chromatography analysis showed that only a minor amount of the original ionophore (Nile Blue) was not covalently immobilized to the polymer (Table 1). All other reaction products of Nile Blue-like lipophylized derivatives were found to exist in concentrations smaller than 1%. The steady state and dynamic properties of membranes containing mobile ETH 5294 in HMW and PVC–COOH were then compared to the relevant characteristics of ETH 3531 and ETH 3534-based membranes. In this part of the work DOS was used as plasticizer. As a consequence, a considerable interference was experienced at relatively high pH values (Table 4).

The response times of membrane system 2a and 2b (mobile ETH 5294 or ETH 5350 in HMW (Table 2)) were found to be short and practically independent of the concentration of the sample solution. The same ionophores in carboxylated PVC (membranes 4a and 4b)

showed a considerably slower response (Fig. 4 and Tables 4 and 5). Some increase in response time was expected on the basis of earlier literature findings.[9,58,68] However, in the activity range of pH = 8.4→7.4 the rate of response was 10–15 times slower for PVC–COOH membranes compared to HMW membranes. In the high pH ranges the effect of cation interference may make an important contribution to the rate of response (see the decreased slope values in the case of PVC–COOH membranes), but PVC–COOH based membranes had about a 3 times slower response in the pH range pH = 6.0→5.0 as well, where no interference is expected. In addition to this, equation (2) gave a much better fit (smaller RMSD data) to the transients recorded with PVC–COOH based membranes compared to equation (1) (Table 5) suggesting diffusional phenomena in the membrane phase.

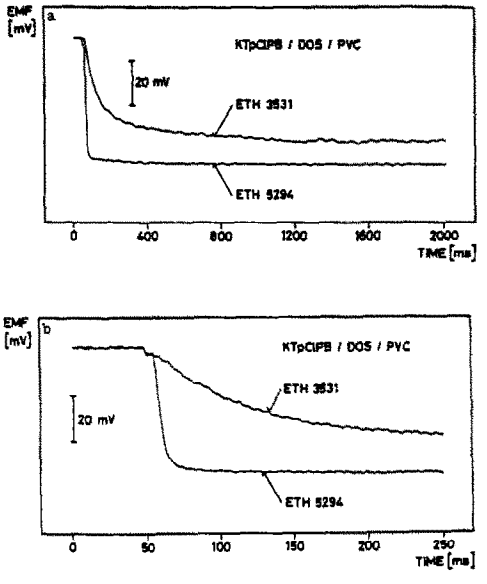

Fig. 5. Effect of ionophore immobilization on the dynamic response curves of pH sensitive liquid membranes in two different time domains (5a: 0–2000 ms; 5b: 0–250 ms). The membranes used for the response time studies contained the same amount of ionophore (mobile or immobilized) and the same PVC/plasticizer ratio.

The $t_{90\%}$ data (and in general the dynamic behavior) of membranes with covalently coupled active sites (ETH 3531 and ETH 3534) were found to be larger than those evaluated with mobile ETH 5294 in HMW (Figs 5a and b) but smaller compared to values determined with ETH 5294 in PVC–COOH. A comparison of the response time data summarized in Table 4 (for an activity step, pH = 8.4→7.4) suggests that the increase of response time is in close correlation with the free –COOH concentration of the membranes. The PVC–COOH concentration of membrane 4 (Table 2) is 33.5 wt % (the –COOH concentration ~134m*M*) while of membranes 13 and 14 (Table 2) 22.5 wt % (~95m*M*) or 12.6 wt % (~31m*M*), respectively. It is remarkable that the selectivity coefficients also vary in parallel with the –COOH content of the membranes (see the slopes in Table 4 in the range of pH = 7.4 and 8.4). The membrane with the highest –COOH content shows the most serious cation interference and so on. It is known that the rate of response of ion-selective electrodes becomes slower in the presence of considerable interference.[75] In addition the character of the response time curves proved to be more exponential with decreasing –COOH content [better fit to equation (1)—smaller RMSD values—compared to equation (2); see Table 6]. The increasing exponential character suggests that surface processes become more dominant with decreasing –COOH content. Consequently, the most dominant influence on the rate of response of H^+ selective membranes with covalently coupled ionophores cannot be attributed to the chemical structure or constitution of the ionophore–matrix coupling,

Table 6. Characteristic data of the response time curves ($t_{90\%}$ values) as well as of fitted theoretical equations (time constants τ_1, τ_2 and RMSDs), of membranes with mobile- and immobilized H^+-ionophores

but to the –COOH content of the membranes. It is primarily interesting in comparison to the transient response of bulk optodes with the same immobilized ionophores where the increased response times were attributed to changes in the membrane bulk transport properties.[31]

CONCLUSIONS

H^+-selective PVC membranes, fabricated from various modified PVCs, exhibit different short (response time) and long time (life time) behavior. The long time behavior of membranes with mobile ionophores is determined by the leaching out of membrane ingredients and is reflected in changes of the analytical performances (slopes and selectivities), electrical properties (bulk resistance and polarization) and dynamic response ($t_{90\%}$ response and response function) of the electrodes. These changes are related to the properties of the membrane matrix which is determined by the chemical character and the concentration of the various functional groups (–OH, –COOH, $-NH_2$) in modified PVCs. The immobilization of the ionophore extends the sensor life time. However, the concentration of the remaining functional groups (–COOH groups not converted in the immobilization reaction) proved to be decisive in the dynamic response behavior of membranes with covalently attached ionophores. The response times of membranes with immobilized ionophores decrease with decreasing –COOH content and approach the response time of membranes with mobile ionophores. By decreasing the –COOH content of the membranes to a minimal amount it should be possible to construct a pH sensitive microelectrode with an immobilized ionophore, having fast response and extended life time.

INVESTIGATION OF THE COMPOSITION OF COMPLEXES AND THE STOICHIOMETRY OF NON-COMPLEX REACTIONS BY FLOW INJECTION METHOD

JINGFU LIU and HUICHANG MA*
Research Center for Eco-Environmental Sciences, Academia Sinica, P.O. Box 2871, Beijing 100085, China

(*Received* 2 *December* 1992. *Revised* 7 *November* 1992. *Accepted* 8 *December* 1992)

Summary—Combining the Asmus straight-line method with the flow injection (FI) technique, a new FI–straight-line method is established to investigate the formulas of the blue, the purple and the red complexes formed by iron(III) and Tiron in different pH solutions. Using the proposed FI–straight-line method, the stoichiometries of cyanide and barbituric acid for producing the intermediate and the final product of the chromogenic reaction of cyanide with pyridine–barbituric acid reagent are also studied.

Various spectrophotometric methods have been established to investigate the empirical formulas of colored complexes in solution. Among them the Asmus straight-line[1] method has the advantages of being more suitable for determining the composition of weak complexes and applicable for complex systems where ligands are not pure and precise ligand concentration is not known.

The straight-line method is conventionally performed by a manual procedure which does not allow investigation of the composition of unstable products of intermediate of some complicated reactions. It has been adapted to a flow technique by Martinez *et al.*[2] The method is based on the merging of two solutions (metal and reagent), keeping the flow rate of one of them constant and increasing the other stepwise.

The flow injection (FI) technique has many advantages. One of them is that it allows fast reactions to be investigated. In the present study, the straight-line method was combined with the flow injection technique to measure complex formulas, determine the stoichiometry of non-complex reactions and to investigate the mechanism of complicated reactions.

PRINCIPLE

The straight-line method was initially established by Asmus to determine the composition of mononuclear complexes. Later, it was expanded to measure the composition of polynuclear complexes by Klausen *et al.*[3] The principle of the method can be expressed as follows.

For the reaction of the form

$$m\mathrm{M} + n\mathrm{L} = \mathrm{M}m\mathrm{L}n (m, n \geqslant 1). \quad (1)$$

Constant volume of a standard solution of M (concentration C_{M}^0) and varying volumes (V_{L}) of a standard solution of L (concentration C_{L}^0) are added into a series of volumetric flasks of volume V, the pH is adjusted and an inert salt solution is added. Then the mixtures are diluted to volume and the absorbance (A) is measured at a suitable wavelength. Assuming

$$[\mathrm{M}m\mathrm{L}n] \ll C_{\mathrm{L}} \quad (2)$$

$$\epsilon_{\mathrm{M}} = \epsilon_{\mathrm{L}} = 0 \quad (3)$$

where the brackets refer to the equilibrium concentration. C to the analytical or total concentration and ϵ to molar absorptivity. Expressing $1/(C_{\mathrm{L}})^n$ graphically as a function of $1/A$ for different sets of n, a straight line will be expected for the correct value of n. Similarly, if a constant concentration of L and different amounts of M are applied, a straight line would be obtained for the correct value of m by plotting $1/(C_{\mathrm{M}})^m$ against $1/A$ for different sets of m. If the complex formed during the determination of n is the same as that formed during the determination of m, the complex can be represented by $\mathrm{M}m\mathrm{L}n$.

When the straight-line method was adapted for a flow injection system, the flow system can be designed as following: A carrier stream composed of a buffer and an unreacting electrolyte is propelled to the system to control the pH and the ionic strength of the system. Component M

*To whom correspondence should be addressed.

is introduced into the system at a constant concentration. A series of L are injected into the system as samples. The sample zone merges with reagent M to form the colour species and the peak absorbance (A), corresponding to C_L^{max} (the analytical concentration of L at peak maximum), is detected.

In FIA, a chemical reaction is usually non-equilibrated. Namely,

$$C_{MmLn}^{max} \leqslant [MmLn]^{max} \quad (4)$$

in which C_{MmLn}^{max} represents the peak maximum concentration of the produced $MmLn$ when the peak absorbance (A) is detected. $[MmLn]^{max}$ is the equilibrium concentration of $MmLn$ at the peak maximum.

When

$$[MmLn]^{max} \ll C_L^{max}. \quad (5)$$

From equations (4) and (5), we have

$$C_{MmLn}^{max} \ll C_L^{max}. \quad (6)$$

Assuming

$$\epsilon_M = \epsilon_L = 0$$

a straight line will be obtained for the correct value of n if $1/(C_L^{max})^n$ is graphically expressed as a function of $1/A$ for different sets of n.

If the volume and the concentration of the injected L are S_v and C_L^0, respectively, then according to FIA theory,[4]

$$C_L^{max} = C_L^0/D_L^m = C_L^0/(2\pi^{3/2}R^2D_f^{1/2}T^{1/2}/S_v), \quad (7)$$

where D_L^{max} is the dispersion coefficient of L at peak maximum, D_f is the axial dispersion coefficient, R is the tube radius and T is the residence time. They are all constants for a certain manifold. Therefore,

$$C_L^{max} = KC_L^0Sv \quad (8)$$

in which K is a constant. If Sv is kept constant, then

$$C_L^{max} = K_1C_L^0 \quad (9)$$

$$1/(C_L^{max})^n = K_1'/(C_L^0)^n, \quad (10)$$

where K_1 and K_1' are constants.

It is well known that C_L^{max} will, for $D_L^{max} \geqslant 2$, increase linearly with increase of Sv. If C_L^0 remains unchanged and D_L^{max} is controlled in the region of $D_L^{max} \geqslant 2$, then from equation (8) we have

$$C_L^{max} = K_2Sv \quad (11)$$

$$1(C_L^{max})^n = K_2'/(Sv)^n. \quad (12)$$

According to equations (10) and (12), it is seen that a straight line will be obtained at the correct set of n by plotting $1/(C_M^0)^n$ against $1/A$ or by plotting $1/(Sv)^n$ against $1/A$. Similarly, if various concentrations or volumes of M are injected and a constant concentration of L is pumped into the flow system, the value of m can be obtained by plotting $1/(C_L^0)^m$ against $1/A$ or by plotting $1/(Sv)^m$ against $1/A$.

If $\epsilon_M \neq \epsilon_L \neq 0$, the absorbance of the excess ligand should be corrected. This can be done easily by the stopped-flow FIA technique if the reaction rate is not very fast. Unfortunately, the reaction of iron(III) and Tiron is too fast to use the stopped-flow FIA method. In the present study, absorbance was corrected simply by adjusting the baseline to $A = 0$.

EXPERIMENTAL

Reagents

Unless otherwise stated, analytical reagents from Beijing Chemical Factory were used throughout.

Iron(III) solution: A 0.1000M iron(III) stock solution was prepared by dissolving 0.5590 g of iron powder in 15 ml of 6M HCl, adding 3 g of $KClO_3$, and diluting to 100 ml with water. Working solutions were made by diluting this stock solution with 0.1M hydrochloric acid.

1,2-Dihydroxybenzen-3,5-disulfonate (trade name Tiron, chemical pure, Shanghai Chemical Reagent Factory) solution: A $5.0000 \times 10^{-2}M$ Tiron stock solution was prepared by dissolving 1.661 g of Tiron in 100 ml of water. Working solutions were made by diluting this stock solution with water.

Pyridine solution: Add 12 ml of concentrated hydrochloric acid in 60 ml of pyridine, dilute to 250 ml with water.

Pyridine–barbituric acid reagent: Place 8.205 g of barbituric acid in a 250 ml standard flask and add just enough water to wash the flask wall and wet the barbituric acid. Add 60 ml of pyridine and mix. Then 12 ml of concentrated hydrochloric acid is added and mixed. Dilute to volume with water and mix when the mixture has cooled to room temperature. This stock contains 0.20M barbituric acid. Working solutions were prepared by diluting this stock with the above prepared pyridine solution.

Chloramine-T solution: Dissolve 0.5 g of chloramine-T in 100 ml of water.

Standard cyanide solution: Standard cyanide solutions were prepared from a stock solution of potassium cyanide (1000 μg CN^-/ml, pH 11) with 1 g/l sodium hydroxide solution.

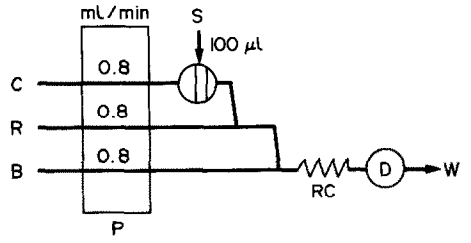

Fig. 1. Manifold used for determining formulas of complexes formed by iron(III) and Tiron in different pH solutions. C, water carrier; S, samples of Tiron or iron(III); R, iron(III) or Tiron solution; B, buffer solutions of pH 4.0, 5.9 or 9.0; RC, reaction coil (120 cm long, 0.7 mm i.d.); D, spectrophotometer, wavelength set at 620 nm, 560 nm or 480 nm; P, peristaltic pump; W, waste.

Buffer solution of pH 4.0: Dissolve 7.94 g of anhydrous sodium acetate in 100 ml of water, add 47 ml of acetic acid and dilute to 500 ml with water.

Buffer solution of pH 5.9: Dissolve 78 g of sodium dihydrogen phosphate in 1000 ml of water, and adjust to pH 5.9 with concentrated sodium hydroxide solution.

Buffer solution of pH 9.0: Dissolve 35 g of ammonium chloride in 100 ml of water, add 24 ml of ammonia solution (contains about 28% (w/v) ammonia, and dilute to 500 ml with water.

A FIA-91 flow injection analyzer (Shanghai No. 3 Analytical Instrument Factory) was used. This is an integrated instrument which consists of two 4-channel peristaltic pumps, a 16-port value, a grating spectrophotometric detector, a Laser PP40 4 color X–Y printer plotter and a microcomputer system. Program control and data processing are conducted automatically by the microcomputer system.

RESULTS AND DISCUSSION

Determination of composition of Fe(III)–Tiron complex

Ferric ions produce three different colored complexes with Tiron, depending on the pH of the solution. According to Harrey *et al.*,[5] the colors of the three complexes are blue (pH < 5.6), purple (pH 5.7–6.9) and red (pH > 7.0), and their metal–ligand molar ratios are 1:1, 1:2 and 1:3, respectively. The present study is to investigate the composition of the three complexes by the proposed FI–straight-line method.

The manifold depicted in Fig. 1 was designed to measure the formulas, represented by $Fe_m(Tir)_n$, of the three complexes. In the first series of experiments, the blue complex formed at pH 4.0 was investigated. To determine the value of n, a series of different concentrations of Tiron ($C^0_{Tir} = 0.8–2.0 \times 10^{-3} M$) were injected into water carrier, while a constant concentration of iron(III) ion ($C^0_{Fe} = 1 \times 10^{-3} M$) and a buffer of pH 4.0 were propelled into the flow system. Absorbance was detected at 620 nm, the peak absorbance wavelength of the blue complex, and the results are shown in Fig. 2(A), which was obtained by plotting $1/(C^0_{Tir})^n$ against $1/A$ for different sets of n. The value of m was determined similarly, the only difference being that the Tiron solution is introduced at a constant concentration ($C^0_{Tir} = 6 \times 10^{-3} M$) and various concentrations of ferric ion ($C^0_{Fe} = 0.6–1.8 \times 10^{-3} M$) were injected into the system. The curves obtained for the determination of m are shown in Fig. 2(B). Figure 2 indicates that a straight line occurs for $n = 1$ or $m = 1$. As

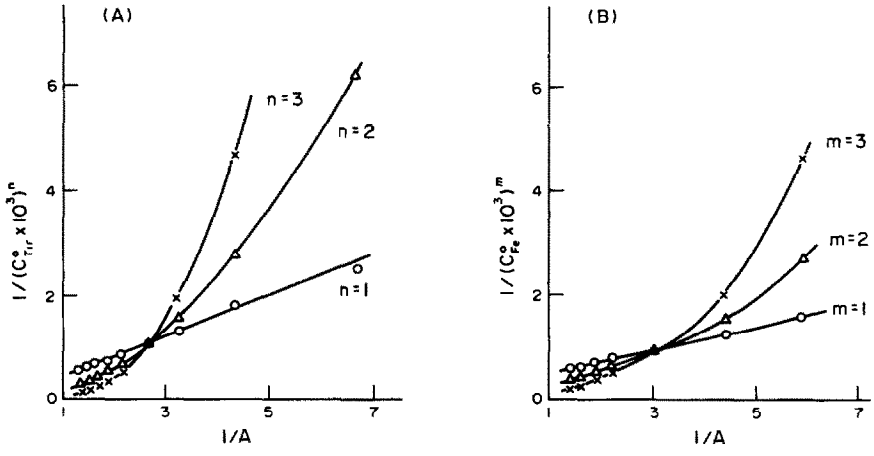

Fig. 2. The use of the FI–straight-line method for determining the formula of the blue complex formed by iron(III) and Tiron in a buffer solution of pH 4.0: (A) determination of n, $C^0_{Tir} = 0.8–2.0 \times 10^{-3} M$, $C^0_{Fe} = 1.0 \times 10^{-3} M$; (B) determination of m, $C^0_{Tir} = 6.0 \times 10^{-3} M$, $C^0_{Fe} = 0.6–1.8 \times 10^{-3} M$.

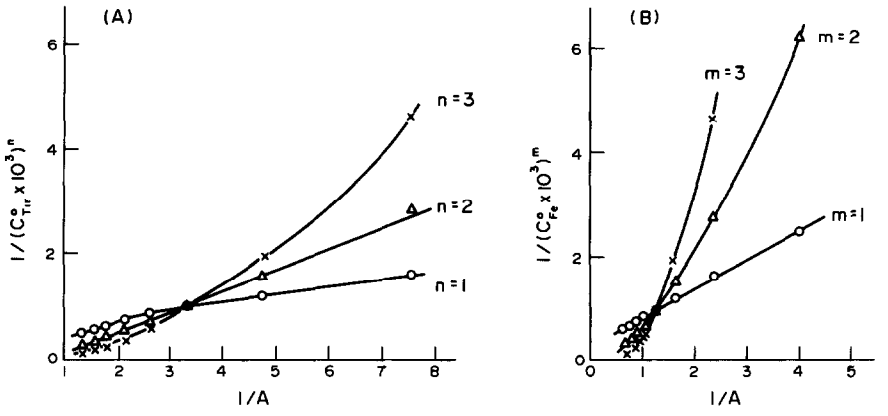

Fig. 3. The use of the FI–straight-line method for determining the formula of the purple complex formed by iron(III) and Tiron in a buffer solution of pH 5.9: (A) determination of n, $C^0_{Tir} = 0.6$–$2.0 \times 10^{-3}M$, $C^0_{Fe} = 1.0 \times 10^{-3}M$; (B) determination of m, $C^0_{Tir} = 6.0 \times 10^{-3}M$, $C^0_{Fe} = 0.4$–$1.8 \times 10^{-3}M$.

only one kind of complex is produced by iron(III) and Tiron in a buffer solution of pH 4.0,[5] the formula of the blue complex is Fe(Tir).

The compositions of the purple and the red complexes are measured similarly. For investigating the purple complex, a buffer of pH 5.9 was adopted and the absorbance was detected at 560 nm. Results are shown in Fig. 3. For producing the red complex, a buffer of pH 9.0 was adopted. Absorbance was detected at 480 nm and the resulting curves are shown in Fig. 4. From Figs 3 and 4 it is seen that the compositions of the purple and the red complexes are $Fe(Tir)_2$ and $Fe(Tir)_3$, respectively.

The formulas of the blue, the purple and the red complex obtained above agree well with the metal–ligand molar ratios obtained by Harrey *et al.*[5] This fact indicates that the FI–straight-line method is suitable for determining the composition of complex.

Reaction mechanism of cyanide with pyridine–barbituric acid

Cyanide is usually determined by the pyridine–barbituric acid method based on the Koning synthesis. Determination is conventionally conducted by detecting the final product of the reaction at 580 nm. In our previous study,[8] an intermediate of the reaction with a peak absorbance at 494 nm was found and was applied to determine cyanide successfully by FIA. In the present study, we measured the molar ratios of cyanide to barbituric acid for producing the intermediate and the final product, in order to propose a more detailed mechanism of the reaction.

This above-mentioned reaction is a complicated reaction, in which cyanide first reacts with chloramine-T or bromine water to produce cyanogen chloride or bromide. The produced cyanogen chloride or bromide quantitatively oxidizes pyridine to glutaconicaldehyde which condenses with barbituric acid to form a colored polymethine dye. The overall stoichiometry of cyanide and barbituric acid is 1:2.[7] Unfortunately, the stoichiometry of cyanide and barbituric acid for producing the intermediate is not clear. Obviously, a more detailed reaction

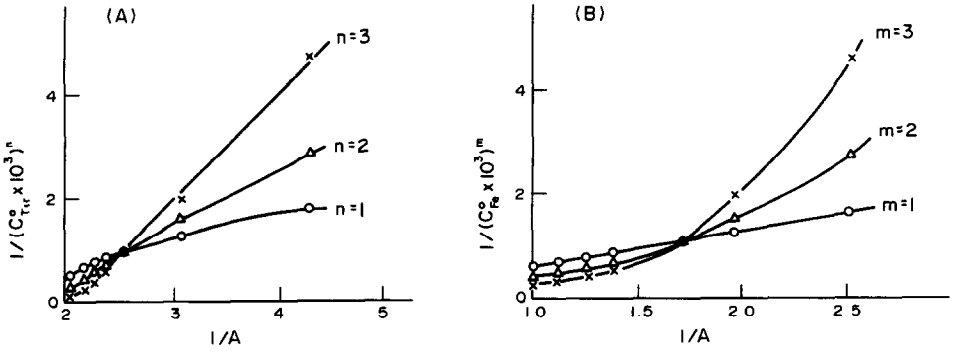

Fig. 4. The use of the FI–straight-line method for determining the formula of the red complex formed by iron(III) and Tiron in a buffer solution of pH 9.0: (A) determination of n, $C^0_{Tir} = 0.6$–$1.8 \times 10^{-3}M$, $C^0_{Fe} = 1.0 \times 10^{-3}M$; (B) determination of m, $C^0_{Tir} = 6.0 \times 10^{-3}M$, $C^0_{Fe} = 0.6$–$1.8 \times 10^{-3}M$.

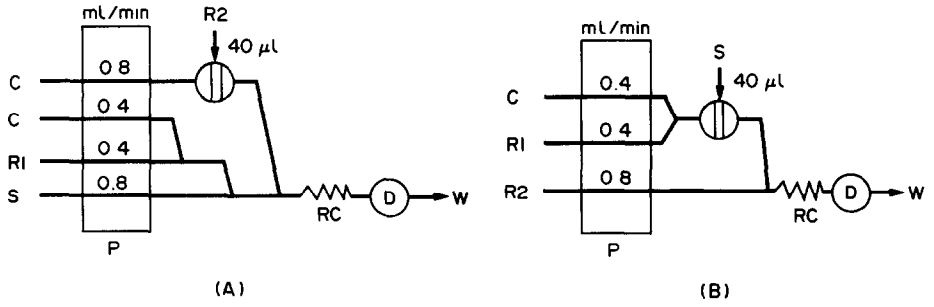

Fig. 5. Manifold used for investigating the stoichiometry of cyanide and barbituric acid during the formation of the intermediate and the final product: (A) determination of n; (B) determination of m; C, sodium dihydrogen phosphate buffer solution (pH 5.9): R1, chloramine-T solution; R2, pyridine–barbituric acid reagent; S, cyanide; RC, reaction coil (30 cm long, 0.7 mm i.d. or 270 cm long, 0.7 mm i.d.); D, spectrophotometer, wavelength set at 494 nm or 580 nm; P, peristaltic pump, W, waste.

mechanism could be acquired if the stoichiometry is determined. The stoichiometry of cyanide and barbituric acid could be measured by the FI–straight-line method if the concentration of chloramine-T and pyridine were constant and in sufficient excess. Assuming that cyanide and barbituric acid have a stoichiometry of $m:n$, then the value of m and n can be determined respectively by the proposed FI–straight-line method.

The manifolds shown in Fig. 5 were adopted. When the intermediate was investigated, the reaction coil was 30 cm long and absorbance was detected at 494 nm. However, the coil length and the detected wavelength were changed to 270 cm and 580 nm, respectively, when the final product was investigated. Figure 5(A) shows the manifold employed to determine the value of n for producing the intermediate and the final product, in which various concentrations of pyridine–barbituric acid reagent (C^0_{Barb} = 0.08–0.2M) were injected into the system while cyanide was propelled into the system at a constant concentration ($C^0_{CN^-} = 7.6 \times 10^{-5}M$). Results are shown in Fig. 6, which indicates that the values of n were 1 and 2, respectively, for producing the intermediate and the final product.

From Fig. 6(B) it can be concluded that the reaction molar ratio of cyanide to barbituric acid for producing the final product is 1:2, which agrees with results reported in literature.[5] This fact demonstrates that the FI–straight-line method can be applied to determine the stoichiometry of non-complex reactions.

Although the stoichiometries of cyanide and barbituric acid for producing the intermediate and the final product have been obtained, the reaction mechanism is not clear because the molecular number of cyanide for forming one molecule of the intermediate or the final product is still uncertain. A manifold shown in Fig. 5B was designed to determine the consumed molecular number of cyanide the value of m. In this manifold cyanide was injected at various concentrations ($C^0_{CN^-} = 0.2$–$1.4 \times 10^{-4}M$) while

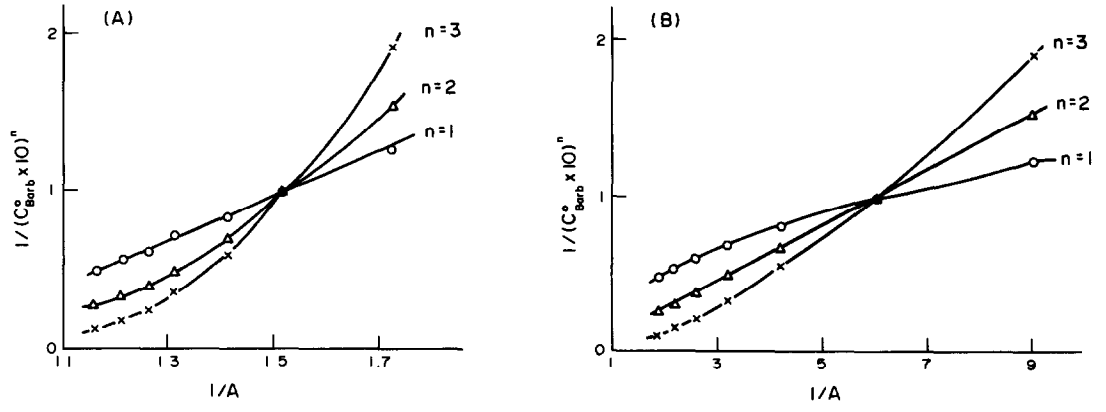

Fig. 6. Determination of the reaction molar ratios of cyanide to barbituric acid for producing the intermediate and the final product by the FI–straight-line method: (A) for investigation of the intermediate; (B) for investigation of the final product. $C^0_{Barb} = 0.08$–$0.2M$; $C^0_{CN^-} = 7.6 \times 10^{-5}M$.

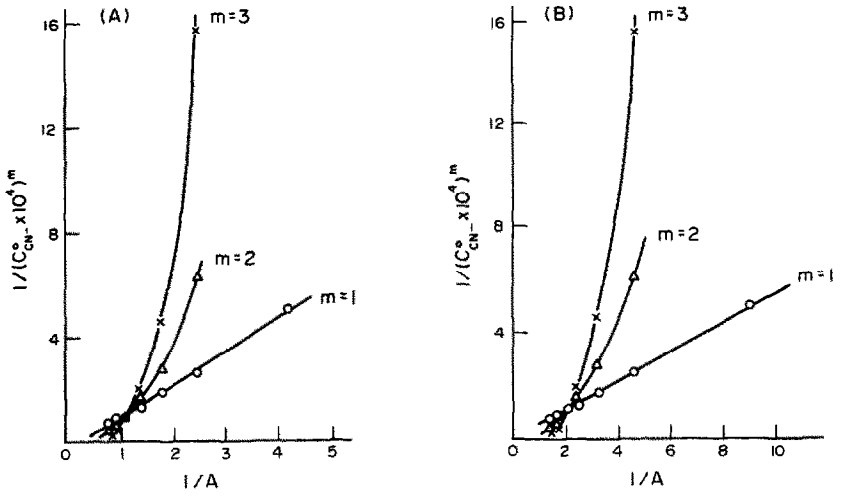

Fig. 7. Determination of the consumed molecular number of cyanide for producing one molecule of the intermediate and the final product by the FI–straight-line method: (A) for investigation of the intermediate; (B) for investigation of the final product. $C^0_{Barb} = 0.1M$; $C^0_{CN^-} = 0.2$–$1.4 \times 10^{-4}M$.

barbituric acid was introduced at a constant concentration ($C^0_{Barb} = 0.1M$). The results are shown in Fig. 7 which indicates that for both the intermediate and the final product a straight line was obtained by setting $m = 1$, *i.e.* only one molecule of cyanide was consumed for producing one molecule of the intermediate or the final product. As barbituric acid was always in large excess during the measurement of n and m, the intermediate and the final product formed during the determination of n must be the same as that formed during the determination of m. Therefore, we conclude that for producing one molecule of the intermediate and the final product, the consumed cyanide is one molecule while the consumed barbituric acid is one and two molecules respectively.

CONCLUSIONS

A new FI–straight-line method was established by combining the Asmus straight-line method with the flow injection technique. The proposed method is suitable for investigating compositions of stable and unstable complexes, especially unstable complexes which cannot be investigated by conventional methods. The method can also be applied to determine stoichiometries of some non-complexing reactions. Since it can be used to measure stoichiometry of reactants when an unstable intermediate is formed, the proposed method has great significance in investigating mechanisms of some complicated reactions.

THE DETERMINATION OF MOLYBDENUM IN A SEA WATER CANDIDATE REFERENCE MATERIAL BY INDUCTIVELY COUPLED PLASMA-MASS SPECTROMETRY

F. VANHAECKE,[1] J. GOOSSENS,[1] R. DAMS[1] and C. VANDECASTEELE[2]

[1]Laboratory of Analytical Chemistry, Ghent University, Institute for Nuclear Sciences, Proeftuinstraat 86, B-9000 Ghent, Belgium, [2]Department of Chemical Engineering, Katholieke Universiteit Leuven, de Croylaan 46, B-3001 Heverlee, Belgium

(*Received* 26 *November* 1992. *Revised* 12 *January* 1993. *Accepted* 12 *January* 1993)

Summary—In the framework of a certification campaign organized by BCR (Bureau Communautaire de Référence, Commission of the European Communities, Brussels) molybdenum was determined in a sea water candidate reference material (BCR CRM 403) using inductively coupled plasma-mass spectrometry. The determination was hampered by both non-spectral (signal suppression) and spectral interferences. Ten-fold dilution of the sea water and the use of a carefully selected internal standard allowed accurate correction for the signal suppression. Spectral interferences on Mo nuclides could mainly be attributed to BrO^+ and $BrOH^+$ ions. At the level of spectral overlap encountered, these interferences could be corrected for with sufficient accuracy by matrix matching of the blank for Br or by application of a mathematical correction method involving resolvation of a pair of simultaneous equations. Results obtained after application of anion exchange to separate Br from Mo confirmed the results obtained using the correction methods, proving the validity of the latter. A good agreement is established by comparison of the ICP-MS result with those obtained by other techniques in other laboratories.

Inductively coupled plasma-mass spectrometry (ICP-MS) is a powerful and versatile technique that has proven its utility in the analysis of water samples of different origin.[1–23] Due to its complex matrix and high salt content (salinity: *ca.* 35 g/kg), the accurate determination of (ultra-)trace elements in sea water is a difficult and challenging task for the analyst. High levels of dissolved solids not only cause orifice clogging of, and solid deposition on, the sampling cone,[24] but are also on the origin of severe matrix effects. In addition, the complexity of the sea water matrix leads to many spectral interferences.

For interference-free elements present at relatively high concentrations, dilution of the sea water can be sufficient to allow accurate determination.[18] In most cases however, the literature reports on the necessity of a separation (and preconcentration) step prior to ICP-MS analysis. This separation/preconcentration step can, *e.g.*, involve solvent extraction,[19] electrodeposition,[12] cation exchange[1,5,7,14] and anion exchange.[13] These procedures are often time-consuming and are not without risk for Mo due to the complex chemistry of this element.[5,25] In the present paper it is shown that ten-fold dilution and careful application of correction methods for both spectral and non-spectral interferences were sufficient to allow accurate determination of Mo in the sea water candidate reference material (BCR CRM 403).

EXPERIMENTAL

Instrumentation

The instrument used is a VG PlasmaQuad ICP-mass spectrometer (VG Elemental, Winsford, UK) equipped with a Fassel torch, a Gilson Minipuls-2 peristaltic pump, a Meinhard type Tr-30-A3 concentric glass nebuliser and a double pass Scott-type spray chamber with surrounding liquid jacket, the temperature of which is controlled with a recirculating refrigeration–heating system. Sampling cones (1.0 mm orifice) and skimmer cones (0.75 mm orifice) are made of nickel. Operation conditions are summarized in Table 1. The settings of the electrostatic lenses were optimized in order to obtain maximum signal intensity for $^{115}In^+$.

Reagents and solutions

For the quantitation of Mo in the sea water CRM, the sample pretreatment was limited to a

Table 1. PlasmaQuad operation conditions

ten-fold dilution using 0.14*M* HNO_3 and the addition of an appropriate internal standard (10 μg/l In in blank, sample and standard solutions); 0.14*M* HNO_3 solutions (with 10 μg/l In as an internal standard) were used as blanks for the standard solutions in all cases and for the sample solutions when using the mathematical correction method. For correction for the spectral interferences by matrix matching of the blank, simulated blank solutions for the sample were prepared by adding an equal amount of Br ($NaBrO_3$, analytical reagent grade, UCB) as determined in the ten-fold diluted CRM (*ca.* 6.75 mg/l) to the original blanks. As the ICP-MS response is known to be linear over a very wide range, standard solutions of only one concentration level, prepared at least in triplicate, were used for calibration. Since it is our experience that Mo causes severe memory effects,[26] the concentration of the standard solutions was kept limited to *ca.* 10 μg/l. These standard solutions were obtained by successive dilution of 1 g/l solutions prepared from Mo foil (Goodfellow Metals, 99.9% purity) or MoO_3 (UCB, 99% purity). In order to improve the stability, stock solutions (10 mg/l), from which standard solutions were prepared, contained 1% HF. By comparing results for "fresh" and "old" standard solutions, 10 μg/l Mo solutions were proven to be stable for over one month.

Anion exchange for the removal of Cl- and S-containing anions is described in detail in a previous publication.[27] In order to separate Br from Mo, this procedure was slightly modified with respect to the eluent concentration and elution rate. Fifteen millilitres of the sea water was mixed with 100 μl 0.2*M* $SnCl_2$ (analytical reagent grade, RPL) solution and 1.5 ml 1.4*M* HNO_3. After 1 min stirring the solution was brought on top of the anion exchange resin column (Dowex-1, converted to nitrate form). $SnCl_2$ is used as a reductant in order to convert possible present Mo(VI), retained as $Mo_xO_y^{z-}$ on the anion exchanger,[25] to lower oxidation states in order to ensure complete elution[27,28] and to reduce possibly present BrO_3^- to Br^-, which is likely to be retained more strongly by the resin.[29] After this pretreatment, Br^- is retained on the column (>99.5%), whereas Mo is eluted at 3 ml/min with 100 ml of 0.07*M* HNO_3 and collected in the effluent. Finally, Rh was added as an internal standard and the effluent was diluted to volume (150 ml) using 0.14*M* HNO_3.

Measurements

Measurements were done using the mass scanning mode of data acquisition (mass range: 90–120 u, number of channels: 512 or 1024, dwell time per channel: 320 μs, number of sweeps: 400). The total measuring time depended on the number of channels and was *ca.* 1 or 2 min. Every blank, sample or standard solution was measured three times. Solutions were measured in a sequence that avoided memory effects as much as possible. Where necessary, the sample introduction system was rinsed for 2 min with 0.14*M* HNO_3.

RESULTS AND DISCUSSION

Correction for non-spectral and spectral interferences

As a result of the high level of dissolved solids (salinity *ca.* 35 g/kg) it is necessary to dilute the sea water matrix in order to avoid orifice or nebuliser clogging and matrix effects too severe to allow accurate determination. A ten-fold dilution brought the signal suppression to acceptable levels, whereas the concentration of Mo in the diluted samples was still high enough (*ca.* 1 μg/l) to allow quantitation.

An earlier study of matrix effects in ICP-MS[30] showed that, in all cases studied, the magnitude of the signal suppression or enhancement depends in a regular way on the mass number. Hence, accurate correction for non-spectral interferences is only possible using an internal standard with mass number close to that of the

analyte element(s). This study also pointed out that the use of an internal standard with mass number closely matching that of the analyte also improves the precision. For both accuracy and precision, the ionization potential of the internal standard was established not to be of major importance. Hence, In was chosen as the internal standard for this determination. Only for the quantitation of Mo in sample solutions obtained after anion exchange, Rh was used instead of In as the internal standard due to the presence of Sn (isobaric overlap with $^{115}In^+$).

The quantitation of Mo in the sea water CRM was not only hampered by non-spectral, but also by spectral interferences. Mo has 7 isotopes: ^{92}Mo (14.8%), ^{94}Mo (9.1%), ^{95}Mo (15.9%), ^{96}Mo (16.7%), ^{97}Mo (9.5%), ^{98}Mo (24.4%) and ^{100}Mo (9.6%). The nuclides ^{92}Mo, ^{94}Mo and ^{96}Mo can suffer from an isobaric interference arising from the corresponding Zr nuclides, while an isobaric interference on ^{96}Mo, ^{98}Mo and ^{100}Mo from the corresponding Ru nuclides is also possible. Spectral interferences from BrO^+ and $BrOH^+$ ions were experimentally observed. Since Br has two isotopes, ^{79}Br (50.7%) and ^{81}Br (49.3%), the signals of ^{95}Mo, ^{96}Mo, ^{97}Mo and ^{98}Mo are affected to the largest extent. Polyatomic ions, such as *e.g.* $ArKO^+$ and KKO^+ (mainly affecting the signal of $^{95}Mo^+$ and $^{94}Mo^+$, respectively), were also observed[31] and finally $^{100}Mo^+$ is coincident with $^{84}SrO^+$. Careful study of the relevant part of the mass spectrum for the diluted sea water indicated that an additional interference at (m/q) = 97 was present. As a result, the latter nuclide was not used for quantitation. Comparison of the spectrum with and without the use of anion exchange prior to the measurement pointed out that the polyatomic ion on the origin of this interference contains an element present in anionic form in the sea water. Therefore it is strongly suspected that the interference on $^{97}Mo^+$ is due to $NaKCl^+$.

For the first correction method it was assumed that ^{98}Mo, the most abundant Mo nuclide only suffers from a spectral interference from $^{81}Br^{16}OH^+$ and $^{81}Br^{17}O^+$. The Br concentration of the diluted sea water was determined experimentally to be *ca.* 6.75 mg/l. Simulated blank solutions with an equal Br concentration were used for correction. Although the authors were aware of the possible influence of the matrix on the level of MO^+ an MOH^+ formation,[32] a systematic study of the influence of the sea water matrix on the levels of BrO^+ and $BrOH^+$ species was not carried out due to the relatively low level of spectral overlap (*ca.* 5%), while the results obtained were also checked by comparison with those obtained using the mathematical correction method.

For the mathematical correction method, it was assumed that the interferences on the signals of $^{95}Mo^+$ and $^{98}Mo^+$ were mainly to be attributed to $^{79}Br^{16}O^+$ and $^{81}Br^{16}OH^+$, respectively. Indeed, measurements of Br standard solutions showed that the signals at (m/q) = 96 and 98 necessarily have to be mainly attributed to $^{79}Br^{16}OH^+$ and $^{81}Br^{16}OH^+$, respectively, since the signal intensities observed were substantially higher than expected on the basis of the signal intensities for the corresponding $Br^{16}O^+$ ions and the relative abundances of ^{16}O and ^{17}O. The ratio ($^{81}BrOH^+/^{79}BrO^+$) was expected to be sufficiently constant and was determined experimentally by measuring Br standard solutions of various concentrations. Hence, the following pair of simultaneous equations could be resolved:

$$\begin{cases} {}^{95}S_{samp}(\text{total}) = {}^{95}S_{samp}(Mo^+) + {}^{95}S_{samp}(BrO^+) \\ {}^{98}S_{samp}(\text{total}) = {}^{98}S_{samp}(Mo^+) + {}^{98}S_{samp}(BrOH^+), \end{cases}$$

where S_{samp} is the net signal at the (m/q) value and of the origin specified, normalized to the signal of the internal standard ($^{115}In^+$). In a first approximation, the contribution of $^{81}BrOH^+$ to the total signal at (m/q) = 98 was neglected, allowing to predict the value for $^{95}S_{samp}(Mo^+)$ on the basis of $^{98}S_{samp}$(total) and the abundances of both Mo isotopes involved. Hence, the contribution of $^{79}BrO^+$ to the total signal at (m/q) = 95 could be estimated:

$$\begin{aligned} {}^{95}S_{samp}(BrO^+) &= {}^{95}S_{samp}(\text{total}) - {}^{95}S_{samp}(Mo^+) \\ &= {}^{95}S_{samp}(\text{total}) - \left[{}^{98}S_{samp}(\text{total}) \times \frac{\Theta^{95}Mo}{\Theta^{98}Mo} \right], \end{aligned}$$

where Θ is the isotopic abundance of the nuclide specified.

The ratio [$^{81}BrOH^+/^{79}BrO^+$] was determined experimentally to be *ca.* 0.025. The relatively limited importance of $BrOH^+$ justifies the approximation used. Application of this ratio allowed an estimation of the contribution of $^{81}BrOH^+$ to the total signal at (m/q) = 98:

$$\begin{aligned} {}^{98}S_{samp}(BrOH^+) = {}^{95}S_{samp}(BrO^+) \\ \times [{}^{81}BrOH^+/{}^{79}BrO^+]_{stand}, \end{aligned}$$

Table 2. ICP-MS results obtained after subtraction of a simulated blank solution, mathematical correction and anion exchange prior to the analysis

Applied method	Mean result (S.D.) (*nmole/kg*)
Subtraction of simulated blank	104.2 (4.3)
Mathematical correction	112.1 (5.3)
Anion exchange	110.5 (5.3)

so that this interference could be corrected for. Although this correction method offers the possibility for iteration, no attempt was made to improve the accuracy of the correction in this way, due to the relatively limited importance of the spectral interference. Finally, the possible presence of Ru was checked, since this would lead to an additional (isobaric) interference on $^{98}Mo^+$. Careful survey of the spectrum, taking into account the contribution of $NaKCl^+$ and SrO^+ signals, did not reveal any significant level of Ru. Of course, for routine determinations, this correction method can easily be automated by computer programming.

Quantitation

The quantitation of Mo in the sea water CRM was carried out during a certification campaign. Two bottles of the CRM were supplied by BCR. Analyses were carried out on 10 samples on different days. For each individual determination one of the two correction methods cited was used. Both methods lead to comparable corrections (*ca.* 5%). Results obtained after the use of anion exchange prior to the analysis confirmed the results obtained using the correction methods, proving the validity of the latter. Results are presented in Table 2. No significant difference (t-test, 95% confidence level) between the results obtained using the different methods could be established. Also the precision was seen to be comparable (F-test, 95% confidence level) for each of the methods applied.

As a mean result a Mo concentration of 109.4 nmole/kg with a standard deviation of 5.7 nmole/kg was obtained. This result can be compared with those obtained by other techniques/laboratories taking part in the certification campaign (Table 3). Since only two other laboratories were able to give results, the possibilities for comparison are rather limited. However, since these results were obtained using independent and totally different techniques, 103 ± 20 nmole/kg was certified as Mo concentration in CRM 403.[33]

CONCLUSION

In every case a trace or ultra-trace element has to be accurately determined in a complex, realistic sample using low resolution ICP-MS, the utmost attention must be paid to both matrix effects and possible spectral interferences. Ten-fold dilution of the sea water matrix and careful application of correction methods for both spectral and non-spectral interferences were shown sufficient to allow accurate determination of Mo in BCR CRM 403. In cases where the extent to which the Mo^+ signals are affected by BrO^+ and $BrOH^+$ is larger, the possibility for accurate quantitation is maintained by the use of an anion exchange resin column prior to the analysis. Mathematical correction on the other hand is less time consuming and reduces the possibility of sample contamination as a result of the limited amount of sample preparation and can hence be preferred at relatively low levels of spectral overlap or for routine analysis.

SPECTROPHOTOMETRIC DETERMINATION OF H_2O_2 WITH 1-ANILINONAPHTHALENE-8-SULFONIC ACID AND 4-AMINOANTIPYRINE WITH HEMATIN AS CATALYST

HYUNG-KEUN CHUNG, PURNENDU K. DASGUPTA* and JOHN N. MARX
Department of Chemistry, Texas Technical University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 16 *November* 1992. *Received* 9 *December* 1992. *Accepted* 9 *December* 1992)

Summary—A spectrophotometric flow injection method for the determination of H_2O_2 in aqueous solution is presented. The technique is based on the oxidative condensation reaction between 1-anilinonaphthalene-8-sulfonic acid (ANSA) and 4-aminoantipyrine (AAP) in the presence of H_2O_2. Hematin is a good peroxidatic catalyst for this reaction; its effectiveness is significantly enhanced in an ammoniacal medium. If the yellow product formed in the alkaline medium is acidified, a blue chromophore (λ_{max} 592 nm) is formed; a surfactant is necessary to keep the blue compound in solution. Chemical and instrumental parameters for FIA were evaluated and optimized. A detection limit of 0.3μM was achieved with a linear dynamic range extending to 50μM. The typical relative standard deviation is 1.5% or better. The structure of the reaction product has been identified.

Many determination procedures for H_2O_2 are based on enzymatic reactions and colorimetry. In the presence of peroxidase, various organic species are oxidized by H_2O_2 to form colored products. Such reaction substrates include *o*-dianisidine,[1] *o*-tolidine,[2] 2,6-dichlorophenol,[3] *etc.* Although these methods are adequately sensitive, the absorption maxima of the reaction products occur at relatively low wavelengths (< 500 nm) where the potential for interference from indigenous species present in real samples is much higher.[4,5]

Methods based on the oxidation of 4-methoxy-1-naphthol[6] or oxidative coupling between phenol and *N,N*-dimethyl-*p*-phenylenediamine[7] result in products that absorb at longer wavelengths (620 and 650 nm, respectively). However, for both these methods, we have found that the rate of the blank reaction is relatively fast. These methods can be successfully used to assay the activity of a catalyst. For the analytical determination of H_2O_2, poor reproducibility and sensitivity result. Methods based on a two-component substrate, notably those involving the oxidative condensation reaction of a hydrogen donor with AAP, have been developed. These methods combine good selectivity and reproducibility. Usually a mixture of AAP and phenol[8] or phenolic derivatives[9] is oxidized by H_2O_2 in the presence of peroxidase to produce quinonoid dyes. These methods are otherwise attractive but the product absorption maxima range from 500 to 520 nm. If phenol is replaced in this reaction with aniline derivatives, the resulting products exhibit more intense absorption and absorption maxima at longer wavelengths. Tamaoku *et al.*[10] synthesized various water-soluble aniline derivatives such as *N*-ethyl-*N*-sulfopropylaniline, *N*-ethyl-*N*-sulfopropyl-*m*-toluidine, and *N*-ethyl-*N*-sulfopropyl-*m*-anisidine. These were recommended as good substitutes for phenolic derivatives. Relative sensitivities obtained with the above anilines were about 2–3 times greater than that with phenol and the absorption maxima ranged from 540 to 561 nm. Generally equilibrium-based procedures involving incubation at a certain temperature (e.g. 37°C) have been reported. The condensation reaction between AAP and *N*-ethyl-*N*-sulfopropylaniline in the presence of peroxidase has been adopted to develop a FIA method for the determination of H_2O_2 in rainwater with a limit of detection (LOD) of 0.14μM and a linear dynamic range up to 40μM.[11]

Saito *et al.*[12,13] suggested the use of manganese–tetrakis (sulphophenyl) porphine immobilized on anion exchange resins as a substitute for immobilized peroxidase. They applied this solid catalyst for the determination of H_2O_2 using the condensation reaction of AAP with phenol and of AAP with *N,N*-diethylaniline. Recently,

*To whom correspondence should be addressed.

hematin has been shown to be a stable, inexpensive and highly effective catalyst in ammoniacal media for the determination of H_2O_2. However, only fluorometric procedures have thus far been reported.[14] In the present work, various phenol and aniline derivatives that are oxidized by H_2O_2 in conjunction with AAP were investigated. The aim was to devise a reaction that results in products absorbing at wavelengths longer than 550 nm, to form the basis of an improved colorimetric FIA method. Further modification was considered by replacing horseradish peroxidase by hematin as catalyst. Among tested reagents, the hematin catalyzed reaction of 1-anilinonaphthalene-8-sulfonic acid (ANSA), AAP and H_2O_2 showed the most promising results. A colorimetric flow injection procedure based on this principle is described.

EXPERIMENTAL

Apparatus

A Hewlett–Packard 8451A diode array spectrophotometer was used for batch experiments. A block diagram of the FIA system used in most studies is shown in Fig. 1. The FIA manifold consists of a multichannel peristaltic pump, a sample injection valve, a first stage reaction coil and an acidification reaction coil, and an absorbance detector. The sample injection valve (six-port rotary valve, type 5020P, Rheodyne Inc.) was operated by a microprocessor controlled timer (DVSP-4, Valco, Houston, TX) and the sample loop (200 μl) was filled by aspiration. Except as specified, absorbance measurements were made with a Spectroflow 757 absorbance detector (Kratos/Schoeffel, Applied Biosystems, Ramsey, NJ). In some experiments, a home built flow-through absorbance detector (6 mm length, 11 ul volume, glass windows) was used. This detector consists of a high intensity 605 nm GaAs light emitting diode as a light source (Stanley HAA5566X, Component Technology Corp., Richardson, TX), a reference and a detector silicon photodiodes (type S2007, Electronic Goldmine, Phoenix, AZ) (see Fig. 9 in Dasgupta *et al.*[16]) and a log-ratio amplifier. Gas chromatography–mass spectrometry (GC–MS) of the hydrolytic decomposition product of the blue analytical product was conducted on a Hewlett–Packard 5988A instrument.

Reagents

All chemicals were reagent grade. Solutions of AAP (2m*M*), ANSA or other chromogenic reagents (15m*M*), and Hematin (100μ*M* in 0.1*M* NH_4OH) were prepared and stored at ~4°C when not in use. The reagent carrier stream was prepared by dilution of these stock solutions in 0.2*M* NH_3/NH_4Cl buffer solution. Stock solutions of 1*M* HCl and 20m*M* surfactant (lauryl sulfate (LS) or Triton X-100 (TX100)) were used to prepare more dilute working solutions. Hydrogen peroxide (3%, Mallinckrodt) stock solutions were standardized by titration with secondary standard $KMnO_4$ solution and lower concentrations of H_2O_2 were prepared by dilution of this stock solution immediately before measurement. All water used in the preparation of solutions and carrier streams was distilled and then deionized by a Nanopure system.

Procedure

In initial batch experiments, 2 ml of a reagent mixture (AAP and one of the chromogenic reagents shown in Table 1), 2 ml of hematin in NH_3/NH_4Cl buffer solution, and 2 ml of a H_2O_2 standard were transferred to a test tube. The formation of a colored reaction product and its apparent rate of formation were visually screened. Reactions that appeared promising

for flow injection adaptation were further studied by spectrometry. For the AAP–ANSA reaction system, the initial product in basic medium (stable at least for a day) was acidified by the addition of 2 ml of HCl to produce a blue product. Absorption spectra for the final product were taken immediately. In flow injection studies of the AAP–ANSA reaction system, two-step optimization procedures were employed. Preliminary experiments were performed in a basic media. A reagent solution, including hematin, was prepared in NH_3/NH_4Cl buffer solution. Standard solutions of H_2O_2 were injected in a water carrier to which the reagent was merged. The resulting reaction product was monitored at a wavelength of 458 nm. The latter optimization study included the acidification step in which an acid solution was introduced to react with the initial reaction product. The final product was monitored at 592 nm. Samples were injected minimally in triplicate and thus all reported data represent means from at least three runs.

RESULTS AND DISCUSSION

Initial studies

Oxidative condensation reactions between AAP and a number of potentially useful chromogenic reagents were examined. We deliberately limited this study to commercially available reagents. The reagent mixture, including hematin as a catalyst, was dissolved in a 0.1*M* NH_3/NH_4Cl (pH 10) buffer solution. To initiate the reaction, an aliquot of 1m*M* H_2O_2 was added. Many phenol and aniline derivatives undergo the desired hematin catalyzed oxidative coupling reaction with AAP in basic medium. In addition to the reagents shown in Table 1, mono and dinitrophenols were studied. They do not react. *N,N*-dialkylanilines ($R = CH_3$, C_2H_5) were also found to be inapplicable due to limited solubility. As may be expected, water soluble naphthalene derivatives with hydroxyl or amino groups acting as auxochromes result in products that exhibit absorption maxima at longer wavelengths and also display greater absorption intensity. In particular, 2-naphthol, chromotropic acid and 6,7-dihydroxynaphthalene-2-sulfonic acid react relatively fast, forming products with $\lambda_{max} > 560$ nm. However, alkaline solutions of phenolic reagents are particularly susceptible to alkaline degradation and the products also tend to be unstable.

When aniline derivatives are used with AAP, the resulting products display absorption maxima at longer wavelengths and absorb more intensely than phenolic derivatives. Most such compounds (e.g. *N,N*-dimethylaniline), however, are too poorly soluble in alkaline solutions. *N,N*-dialkyl-1,4-phenylendiamines ($R = CH_3$, C_2H_5) are sufficiently soluble and produce a relatively stable product. Nevertheless, the absorption maxima for these products are below 550 nm.

The AAP–ANSA reaction system

ANSA was chosen for study because of the functional groups and its stability in solution. Among all the tested reagents, ANSA was unusual in that the reaction product behaved as an acid–base indicator. The product initially formed in ammoniacal solution was yellow (λ_{max}, 458 nm). It readily forms an intense blue color in acidic medium (λ_{max}, 575 nm). Such a large bathochromic shift in absorption in a base to acid transition is relatively rare. Although the yellow product formed in basic solution was stable over at least day-long periods, the blue material displayed limited aqueous solubility

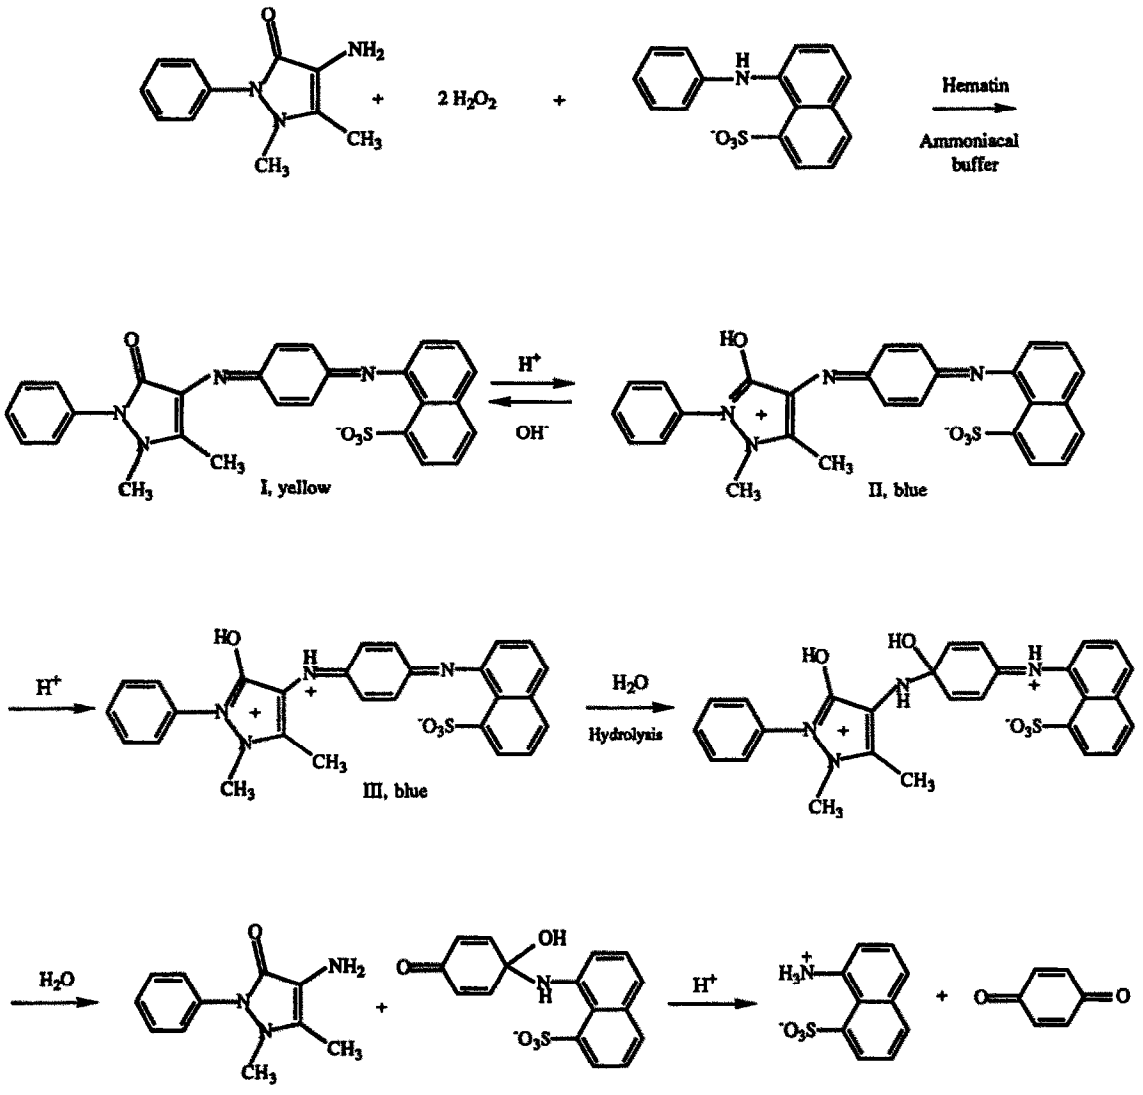

Fig. 2. The AAP–ANSA reaction scheme. The yellow product I initially formed is protonated to form the blue product II which undergoes acid hydrolysis as shown.

and was also hydrolyzed in an acid solution. The reaction itself did not proceed in acidic solutions. In analogy with previous studies involving AAP and chromogenic substrates,[12,13] we believe the structure of the yellow product to be I (Fig. 2) and that of the blue product to be II. Hydrolysis in acid medium of the blue product is believed to proceed according to the pathway shown in Fig. 2, resulting in 1-aminonaphthalene-8-sulfonic acid, benzoquinone and AAP. Benzoquinone was unambiguously identified in the acid hydrolyzate by GC–MS in comparison with an authentic sample (identical chromatographic retention time, parent mass and fragmentation pattern). The blue dye was synthesized in a milligram scale by scaling up the analytical procedure. The solid sample was acid hydrolyzed and the solution then made alkaline (pH 11). A chloroform extract of this sample was analyzed by GC–MS. AAP was unambiguously identified in this extract. 1-Aminonaphthalene-8-sulfonic acid cannot be analyzed by GC and such a procedure was not attempted. However, there remains little doubt that both the product structural identification and the hydrolytic pathways are as shown in Fig. 2.

The reaction itself does not proceed in acidic medium. Whereas the product formed in basic solution is soluble and stable, the protonated blue product has limited solubility probably because of its zwitterionic structure. Addition of surfactants increase solubility. In a medium containing micellar concentrations of LS, the

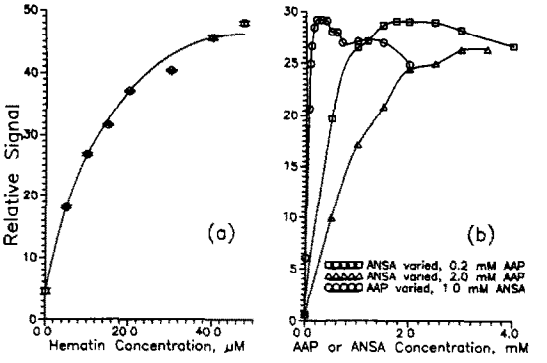

Fig. 4. Effect of reagent composition on system performance, 100μM H_2O_2 injected. (a) Variation of hematin concentration, 0.2mM AAP, 1.5mM ANSA, standard deviation of data are shown as error bars; (b) variation of AAP concentration, 1.0mM ANSA, 10μM hematin; variation of ANSA concentration, 10μM hematin, 0.2 and 2mM AAP; standard deviation of results are less than the dimensions of the points plotted.

absorption maximum of the blue product undergoes a bathochromic shift to 592 nm. Since the reagents show no appreciable absorption above 590 nm and the molar absorptivity in acidic surfactant containing solutions is more than four times that in basic solution, it was of interest to pursue the development of a new automated colorimetric method based on this principle.

Effect of NH_3/NH_4Cl buffer composition on hematin peroxidatic activity

Peroxidatic activity of horseradish peroxidase[17] or hematin[14] has been observed to be stimulated by NH_3, possibly due to the ligation of the nitrogen base to the metalloenzyme. The effect of NH_3 and NH_4Cl concentration on the peroxidatic activity of hematin was studied in the pH range of 8.5–10.5 with the flow injection system. Figure 3 shows that for a given pH (or ratio of NH_3 to NH_4Cl), the absorbance due to the product initially increases steeply as the buffer concentration increases and eventually becomes less dependent of the buffer concentration. At higher buffer concentrations ($<ca.$ 0.2M), it is clear that hematin peroxidatic activity depends mainly on NH_3 concentration. For further studies, a 0.2M NH_3/0.2M NH_4Cl buffer was chosen because buffering capacity is adequate at this composition, the dependence of the reaction rate on variation of the buffer components is minimal and relatively dilute acid can be used for later acidification.

Effect of hematin concentration

The effect of hematin concentration on product formation was studied with 100μM H_2O_2 as sample in the range of 0–45μM hematin. Figure 4(a) shows that the measured absorbance increases with increasing hematin concentration. However, the observed absorbance increases less than a factor of two as the hematin concentration is increased from 10 to 40μM while increased hematin concentrations were found to accelerate the decomposition of ANSA. A 10 μM hematin concentration was therefore used for further studies. With $<10\mu M$ hematin, the reagent mixture is stable for at least one day at room temperature (*ca.* 22°C). It should also be noted that hematin itself is colored and the baseline absorbance increases linearly with increasing hematin concentration.

Effect of substrate concentration

The effect of AAP concentration on product formation was studied with 100μM H_2O_2 in the range of 0–2 mM AAP. Figure 4(b) shows that the measured absorbance increases markedly up to an AAP concentration of about 0.15mM and then becomes relatively independent of the AAP concentration. Above 0.5mM AAP, the absorbance actually begins to decrease slightly.

The effect of ANSA concentration was studied in the range of 0–3.5mM with 0.2 and 2mM AAP (Fig. 4b). When AAP concentration is 0.2mM, the maximum absorbance was obtained at >1.5mM ANSA. With 2mM AAP, the maximum observed absorbance is ~20% less than that with 0.2mM AAP and is attained with >3mM ANSA. Hence 0.2mM AAP and 1.5mM ANSA were selected.

Acidification studies

If the effluent stream from the first stage is acidified without further measures, the blue product precipitates or is strongly adsorbed onto the flow injection system components including the optical window; this causes serious increase in baseline absorbance and noise levels. Addition of a surfactant into the acidifying carrier stream prevents such adsorption and has the additional benefit of shifting the absorption maximum to a longer wavelength with an attendant increase in molar absorptivity. To test the effect of pH on the formation of the final blue product, HCl or citric acid solutions in 10m*M* TX100 were used as the acidifying carrier stream. The absorbance at 592 nm as a function of pH is shown in Fig. 5. Maximum absorbance was attained at pH <3. A concentration of 0.25*M* HCl was chosen; at the flow rates used this was sufficient to attain a final pH of 2.5. In protonating the yellow product (I, Fig. 2), based on the basicity of the available sites, the carbonyl oxygen should be protonated first. The ring to which it is connected thence becomes a 6π-electron cationic system with considerable aromatic character. This results in a large bathochromic shift and enhanced absorptivity. With increasing acidity, one of the quinononoid *N* atoms will be protonated. This is expected to result in only a relatively minor increase in absorptivity over the monoprotonated form. Protonation here would also eventually result in hydrolytic cleavage of the bond, as indicated in Fig. 2. If the blue color is due solely to a monoprotonated form, the system may be modeled as:

$$\text{signal} = Q[\epsilon_{HA}[H^+]/(K_1 + [H^+]) + \epsilon_A K_1/(K_1 + [H^+])]. \quad (1)$$

Where Q is a proportionality constant, ϵ_{HA} and ϵ_A are the absorptivities of the protonated and non-protonated forms, respectively, at 592 nm and K_1 is the acid dissociation constant of the protonated form. If the blue color is due to both a mono- and a diprotonated form, the system may be modeled as:

$$\text{signal} = Q(\epsilon_{H2A}[H^+]^2 + \epsilon_{HA}[H^+]K_1 + \epsilon_A K_1 K_2/R \quad (2)$$

where

$$R = [H^+]^2 + K_1[H^+] + K_1K_2 \quad (3)$$

and ϵ_{H2A} is the absorptivity of the diprotonated form, K_1 and K_2 being the first and second acid dissociation constants of this form, respectively. Figure 5 shows the best fits of the experimental results to equations (1) and (2), respectively. It is clear that the diprotic acid model results in a much better fit. This model results in the best fit values of 3.6 and 5.5 for pK_1 and pK_2 a ratio of 1.53 for $\epsilon_{H2A}/\epsilon_{HA}$ and a negligible value for ϵ_A.

The effect of surfactants was studied with cetyltrimethylammonium chloride (CTAC), TX100 and LS solutions (cationic, non-ionic and anionic surfactant, respectively). The use of CTAC resulted in immediate precipitation of the blue product, probably due to ion pair formation with the sulfonate end of the molecule. The use of the other surfactants inhibited precipitation/wall adsorption. These effects take place only at surfactant concentrations sufficient to form micelles. Presumably the blue product partitions to the micelle. The significant increase of the molar absorptivity and the bathochromic shift indicates that the blue product either undergoes further aggregation within the micelle or participates in charge-transfer interactions with the surfactant molecules or both. As shown in Fig. 6, maximum absorbance is reached at >10m*M* TX100 and at >5m*M* LS. Since the use of LS gives about 20% higher signal than TX100 and prevents adsorption problems more effectively, the use of LS was adopted.

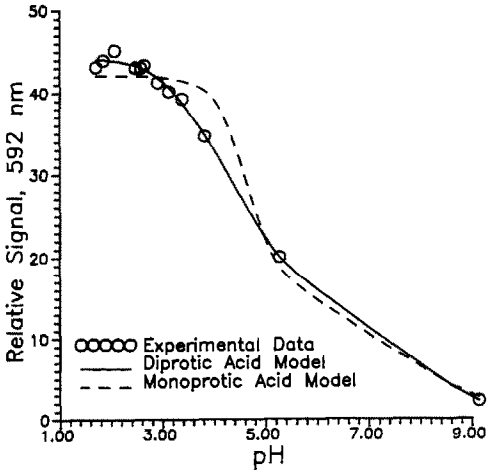

Fig. 5. The absorbance of the final blue product as a function of pH. The standard deviation of individual points is less than the dimension of the symbols plotted.

System performance

With experimental conditions optimized as described above, typical system output is shown in Fig. 7. The peak height response is linear in

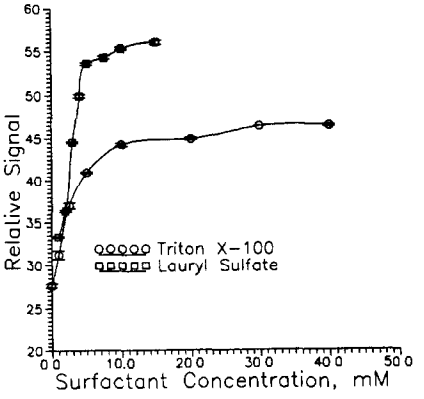

Fig. 6. Effect of surfactant concentration (added to 0.25*M* HCl solution), 10μM hematin, 0.2m*M* AAP, 1.5m*M* ANSA, 100μM H_2O_2.

the 1–50μM range; the best fit equation is given by:

$$\text{signal (AU)} = 6.1(\pm 0.061) \times 10^{-4}\ \text{C, } (\mu M) - 6.5(\pm 5.8) \times 10^{-6}. \quad (4)$$

Response becomes nonlinear at higher concentration, the signal for 100μM H_2O_2 is 13% below that predicted by the above equation. This is possibly due to saturation of the catalyst binding sites. Based on three times the noise level of the baseline divided by the calibration slope, the LOD is 0.30μM. The typical RSD for the entire 1–100μM range studied was $<1.5\%$.

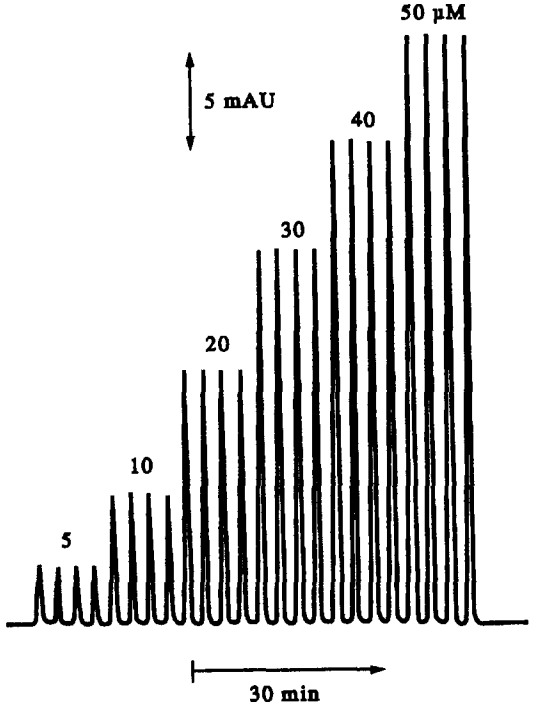

Fig. 7. Typical system output, conditions as in Fig. 1, 200 μl samples of 5–50μM H_2O_2.

Table 2. Effect of foreign species*

Substance	Added (μM)	Absorbance (mAU)	% Error
PO_4^{3-}	100	8.30	0
NO_2^-	10	17.7	110
HCO_3^-	100	8.28	0.24
HSO_3^-	100	8.34	0.48
Mn^{2+}	100	8.28	0.24
Ca^{2+}	100	8.08	2.65
Fe^{3+}	100	14.4	73.5
	50	11.1	33.3
OCl^-	100	8.22	0.96

*Total measured absorbance after addition of 10μM H_2O_2; in all cases, relative standard deviations were $\leq 0.8\%$.

When the LED-based detector was employed, the absorbance signal decreases by *ca.* 45% compared to the commercial detector (Spectroflow 757) because of the shorter pathlength of the LED-based detector cell. The RSD at 10μM H_2O_2 for this detector was 1.3%.

To test the effect of foreign species in the system, an excess amount (100μM in most cases) of such potential interferents were added to the H_2O_2 standard before determination by this procedure. The results presented in Table 2 show that only Fe^{3+} and especially NO_2^- seriously interfere with the determination. Both species react with ANSA itself to form blue products in acidic medium. However, no reaction due to NO_2^- ion occurs in basic medium. If acidification is omitted and the condensation product in basic medium is monitored at 458 nm, NO_2^- is no longer an interferent, at the expense of losing sensitivity. The use of sulfamic acid as masking agent for NO_2^- was tested. Addition of sulfamic acid into the reagent does not prevent blue color formation due to NO_2^-. However, addition of sulfamic acid to the sample prior to determination completely eliminates interference from NO_2^-. Except if ambient air samples containing HONO are scrubbed into an aqueous medium, H_2O_2 and NO_2^- are not expected to co-occur in the same sample. These measures are therefore not expected to be necessary for most real samples. Similarly, interference of Fe^{3+} may be prevented by addition of F^- but such measures are not expected to be necessary for real samples.

ISOLATION AND IDENTIFICATION OF IMPURITIES IN L-696,229 DRUG SUBSTANCE

S. V. PRABHU, J. M. BALLARD, R. A REAMER and D. K. ELLISON
Merck Research Laboratories, P.O. Box 2000, Rahway, NJ 07065–0900, U.S.A.

(*Received* 13 *November* 1992)

Summary—Two low level impurities in 3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-6-methyl-2(1H)-pyridinone drug substance (L-696,229) have been isolated by a combination of preparative HPLC, solid-phase extraction and liquid–liquid extraction. They were identified as 3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-6-(2-phenylethyl)-2(1H)-pyridinone (I) and 6,6′-(2-phenyl-1,3-propanediyl)bis[3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-2(1H)-pyridinone] (II) by mass spectrometry and by their ^{13}C and ^{1}H-NMR spectra.

INTRODUCTION

3-[2-(2-Benzoxazolyl)ethyl]-5-ethyl-6-methyl-2(1H)-pyridinone (L-696,229) belongs to a class of compound which exhibits potent *in vitro* inhibition of human immunodeficiency virus type 1 reverse transcriptase.[1,2] L-696,229, which is presently undergoing safety and pharmacokinetic evaluation in humans,[2] contains an ethylene linkage between a benzoxazole group and a substituted pyridone (Fig. 1).

In the development of new drugs, one analytical challenge is to quickly develop rugged methods for quality evaluation. The determination of the purity of a drug candidate is important in order to establish the acceptability of batches for safety assessment and clinical trials. Ideally the total amount of impurity, as well as the quantity of each individual impurity, should be monitored in the bulk drug. A serious attempt should be made to identify each individual impurity present at 0.1% area (or greater) of the main peak in the LC/UV impurity profile.

Several different methods have been used for the HPLC analysis of L-696,229. A column-switching system, in which multiple HPLC columns are interconnected by a switching valve, has been used as an alternative to gradient elution to eliminate interferences from late-eluting species.[3] We have developed a simple, 0.1% aqueous phosphoric acid/acetonitrile gradient system to routinely monitor the purity and stability of L-696,229. Two late-eluting impurities were detected in some batches of L-696,229 using this method. Identification of both of these impurities was attempted because they exceeded the 0.1% level in some samples.

This paper describes the isolation and concentration of these impurities using sequential preparative HPLC, solid-phase extraction and liquid–liquid extraction. The identification of these impurities as 3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-6-(2-phenylethyl)-2(1H)-pyridinone and 6,6′-(2-phenyl-1,3-propanediyl)bis[3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-2(1H)-pyridinone] was achieved by mass spectrometry and by comparison of their NMR spectra to those of precursors.

EXPERIMENTAL

Apparatus

The preparative HPLC system consisted of a Rabbit™ solvent delivery system with a Dynamax-60A, C-8 column (250 × 21.4 mm; Rainin Instr., Woburn, MA), a Model 201 fraction collector (Gilson Medical Electronics, Middleton, WI), a Spectroflow Model 757 UV detector (Kratos Analytical, Ramsey, NJ) and a Model TYP7025 stripchart recorder (Linseis Inc., Princeton Junct., NJ). The analytical HPLC system consisted of a Model SP8700XR liquid chromatography pump with a built-in column heater (Spectra-Physics Analytical, Fremont, CA), a Model 759A UV detector (Applied Biosystems, Foster City, CA) and a Zorbax RX-C8 column (250 × 4.6 mm; Mac-Mod Analytical, Chadds Ford, PA). Data were collected with an Access* Chrom Vax-based chromatography data system (PE Nelson, Cupertino, CA). Solid-phase extractions were performed using Model SPE-21 vacuum manifolds (J. T. Baker Inc., Phillipsburg, NJ) with Bond Elut C-8

II

Fig. 1. Structure of L-696,229 and impurities I and II.

cartridges (6 ml) and adapters (Varian Sample Prepn. Prods., Harbor City, CA).

Chromatographic conditions

The mobile phase for preparative HPLC was acetonitrile/water (40:60 v/v) at a flow rate of 20 ml/min. The column was at ambient temperature and 5 ml injections were made; the UV detector was set at 234 nm. For analytical HPLC, 10 μl injections were made into the column held at 40°C and the mobile phase was acetonitrile/water (50:50 v/v) at a flow rate of 1.0 ml/min.

Isolation of impurities

Preparative HPLC. A sample of L-696,229 (2.2 g), enriched in impurities at the 1–2% level, was dissolved in 100 ml of acetonitrile/water (80:20 v/v). Aliquots (5 ml) of the solution were injected repetitively into the preparative HPLC system and appropriate fractions were combined to isolate each impurity. The final volume collected was approximately 600 ml for each impurity.

Solid-phase extraction. The acetonitrile/water ratio of the two cuts collected by preparative HPLC was adjusted to 20:80 v/v by the addition of water to give a final volume of about 1500 ml for each impurity. Three solid-phase extraction cartridges, connected in series using adapters, were conditioned with acetonitrile (15 ml) followed by water (15 ml) prior to use. Each impurity was concentrated separately on the cartridges by passing about 500 ml of the dilute impurity solution through the cartridges. Very little breakthrough of the impurity was detected when the eluate was monitored by analytical HPLC. The retained impurity was eluted with 10 ml of acetonitrile/water (95:5 v/v). This procedure was repeated with 2 × 500 ml portions of the dilute solutions and the combined washings totalled about 30 ml for each impurity.

Liquid–liquid extraction. The 30 ml solution of each impurity was concentrated to about 10 ml under nitrogen. Water (5 ml) and dichloromethane (15 ml) were added, the mixture was shaken for 2 min and then centrifuged for 2 min. The organic layer was removed and the extraction was repeated with a second 15 ml aliquot of dichloromethane. The combined organic layers were concentrated to dryness under a stream of nitrogen at room temperature to obtain impurity I (10 mg) and impurity II (14 mg).

Each impurity was analysed by thermospray ionization LC/MS and by electron ionization (EI) using a direct insertion probe. LC/MS was performed by injection of the sample into a Zorbax RX-C8 column (250 × 4.6 mm) with aqueous 0.1*M* ammonium acetate/acetonitrile (50:50 v/v) at a flow rate of 1.0 ml/min as the mobile phase. The LC column was coupled to a Finnigan MAT TSQ 70B mass spectrometer *via* a TSP2 thermospray interface held at 119°C; the ion source block was at 300°C. Positive ion mass spectra were acquired repetitively over the range 200–700 μ. Electron ionization (EI) mass spectra were recorded at 70 eV over the range 40–700 μ on a Finnigan 4500 mass spectrometer, using a fast-heating direct exposure probe, at a source temperature of 150°C.

NMR spectra were run in $CDCl_3$ on a Bruker AM-400 spectrometer. Proton spectra were observed at 400.13 MHz and were referenced to residual $CHCl_3$ at 7.27 ppm. Carbon-13 spectra (100.61 MHz) were referenced to $CDCl_3$ at 77.0 ppm. Impurity I: ^{1}H NMR ($CDCl_3$) δ 12.69 (br, H_1), 7.69 (m, $H_{4'}$), 7.45 (m, $H_{7'}$), 7.30 (overlapping m, $H_{5'}$, $H_{6'}$, $H_{2'',6''}$), 7.20 (m, $H_{3'',5''}$), 7.18 (s, H_4), 7.10 (m, $H_{4''}$), 3.33 (t, J = 7.6, 2′-CH_2), 3.16 (t, J = 7.6, 3-CH_2), 2.96 (m, 6-CH_2), 2.85 (m, 1″-CH_2), 2.30 (q, J = 7.5, CH_2CH_3), 1.00 (t, J = 7.5, CH_2CH_3).

^{13}C NMR ($CDCl_3$) δ 166.8 ($C_{2'}$), 164.2 (C_2), 150.8 ($C_{7'a}$), 142.5, 141.4, 140.8 ($C_{1''}$, C_6, $C_{3'a}$), 141.6 (C_4), 128.5, 128.4 ($C_{2'',6''}$, $C_{3'',5''}$), 127.7 (C_3), 126.2 ($C_{4''}$), 124.4, 124.0 ($C_{5'}$, $C_{6'}$), 119.5

($C_{4'}$), 118.7 (C_5), 110.3 ($C_{7'}$), 36.0, 32.7, 28.1, 27.5 ($4 \times CH_2$), 27.5 (CH_2CH_3), 15.4 (CH_2CH_3).

Impurity II: ^1H NMR ($CDCl_3$) δ 12.17 (br, H_1), 7.60 (m, $H_{4'}$), 7.35 (m, $H_{7'}$), 7.23 (m, $H_{5'}$, $H_{6'}$), 7.19 (m, $H_{2'',6''}$), 7.13 (t, J = 7.2, $H_{3'',5''}$), 7.07 (m, $H_{4''}$), 7.03 (s, H_4), 3.60 (m, 1''-CH), 3.26 (m, 2'-CH_2), 3.05 (overlapping m, 3-CH_2, 6-CH_2), 2.00 (m, CH_2CH_3), 0.67 (t, J = 7.5, CH_2 CH_3). ^{13}C NMR ($CDCl_3$)δ 166.7 ($C_{2'}$), 163.7 (C_2), 150.7 ($C_{7'a}$), 141.3 ($C_{3'a}$), 141.0 (C_4), 140.6 (br, C_6), 128.5, 127.7 ($C_{2'',6''}$, $C_{3'',5''}$), 128.1 (br, C_3), 127.0 ($C_{4''}$), 124.3, 123.9 ($C_{5'}$, $C_{6'}$), 119.4 ($C_{4'}$), 119.3 (br, C_5), 110.2 ($C_{7'}$), 46.3 (br, CH), 37.4 (br, CH_2), 27.9, 27.5 (CH_2CH_2), 22.6 (CH_2CH_3), 14.8 (CH_2CH_3). Several signals are broad (as noted) and $C_{1''}$ is not observed.

RESULTS AND DISCUSSION

Since related by-products due to the reaction between a benzyloxy precursor and benzaldehyde contamination of benzyl alcohol had been identified at an earlier stage of the synthesis,[4] a sample of L-696,229 enriched in the final product impurities at about 1–2% each was prepared to facilitate the isolation work. Although preparative HPLC is a well established technique for the isolation of pure compounds from mixtures, it suffers from the disadvantage that the desired compound is often obtained in a rather large volume of the mobile phase. Concentration of this solution, usually on a rotary evaporator, can be time-consuming and is potentially harmful to thermally labile materials. Solid-phase extraction cartridges provide a convenient, alternative method for stripping the solvents from the HPLC fractions;[5,6] the material retained on the cartridge may then be eluted with a minimum volume of a suitable mobile phase, with subsequent procedures (*e.g.*, concentration, chromatography, extraction) being easier to perform.

An isocratic reverse phase separation with acetonitrile/water (50:50 v/v) was found to be ideal for the resolution and stability of the two impurities [Fig. 2*A*] and a similar mobile phase (40:60 v/v) was used for the preparative LC work. Isolation of the two impurities from L-696,229 was achieved using a series of preparative HPLC injections and collection of appropriate fractions. The amounts of impurity I and II present in the starting material and in the individual pools throughout the isolation process were monitored by analytical reverse phase

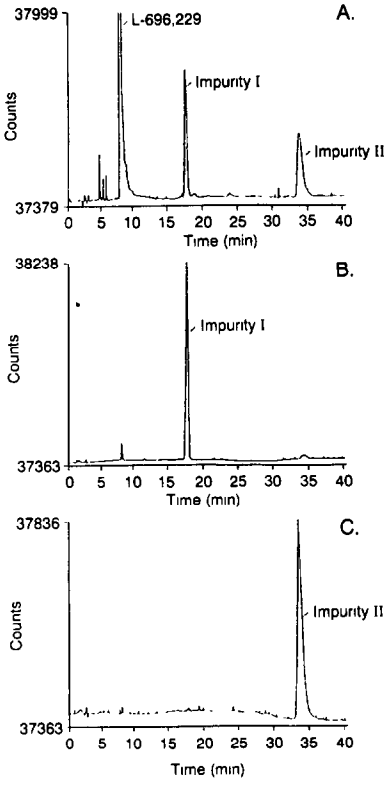

Fig. 2. Typical chromatograms of impurity-enriched sample and isolated impurities on analytical HPLC. *A*. Enriched L-696,229 sample. *B*. Chromatogram of isolated impurity I. *C*. Chromatogram of isolated impurity II. Chromatographic conditions: see Experimental.

HPLC. The initial preparative HPLC served as a rapid means of isolating the impurities from the bulk drug. Concentration of these impurities was then achieved by a combination of solid-phase extraction and liquid–liquid extraction. The isolated impurities I and II were better than 98% pure, as judged by HPLC area percentage and their retention times matched those of the low level impurities in typical batches of L-696,229 [see Figs 2*B* and 2*C*, respectively, for chromatograms].

Impurity I

The thermospray mass spectrum of impurity I contained the base peak at m/z 373 corresponding to $[M + H]^+$ of a compound with a molecular weight 90 u (C_7H_6) greater than L-696,229. A very low intensity peak at m/z 423 of unknown origin was also observed. The EI spectrum (Fig. 3) showed strong peaks at m/z 372 ($M^{+\cdot}$) and 91 ($C_7H_7^+$), the latter being characteristic of a benzyl group. The presence of a benzyl group was further indicated by the intense peak at m/z 281 $(M\text{-}C_7H_7)^+$ and the location of the benzyl group on the pyridone

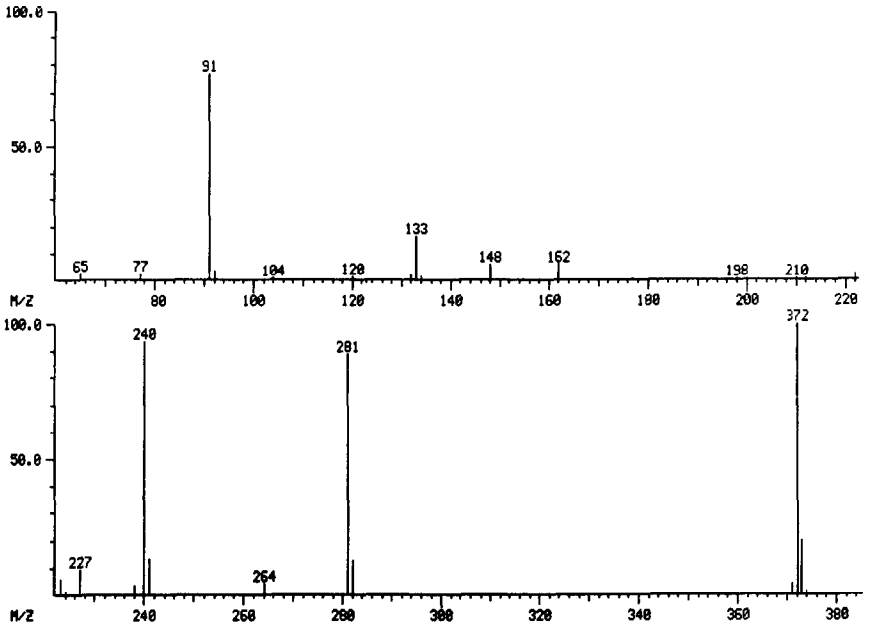

Fig. 3. EI mass spectrum of impurity I.

portion of the molecule was shown by the ion at m/z 240, which was 90 μ higher than the corresponding fragment ion (m/z 150; base peak) in the EI spectrum of L-696,229. The ions at m/z 240 and 133 can be ascribed to cleavage of the central CH_2-CH_2 bond between the benzoxazole and pyridone rings. The high field region of the proton NMR spectrum [see Fig. 4(*C*) and Experimental] of impurity I was similar to that of L-696,229 except for the absence of the 6-methyl group and the addition of a 1,2-substituted ethylene group. This was supported by the ^{13}C-NMR spectra [Figs 4(*A*,*B*); ^{1}H decoupled ^{13}C and APT[7] experiments] where five methylene groups and one methyl group were observed. The aromatic region of the ^{1}H and ^{13}C-NMR spectra supported the presence of an additional monosubstituted phenyl group. Taken together the data support the structure given in Fig. 1 for impurity I.

Impurity II

As an impurity I above, a methyl group is also missing from the proton NMR spectrum [see Fig. 5(*B*) and Experimental] of impurity II. Integrated intensities in the proton spectrum and ^{13}C-NMR experiments indicated the presence of an aliphatic methine. The aromatic region of the ^{13}C-NMR spectrum also showed a monosubstituted phenyl group. Unlike impurity I, the ratio of the monosubstituted phenyl to the pyridone/benzoxazole groups is 1:2. The ^{13}C-NMR spectrum of impurity II [see Fig. 5(*A*) and Experimental] has some unexplained broadening (not observed in the simpler analogue with a protected pyridone) but is consistent with the structure shown. Impurity II gave a thermospray mass spectrum which contained only the peak due to the $[M + H]^+$ ion at m/z 653. The molecular weight (652 μ) and the required even number of nitrogen atoms derived from the

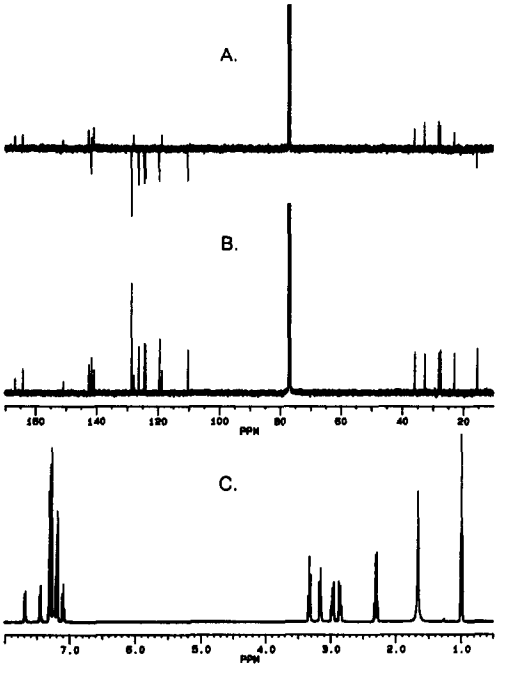

Fig. 4. *A*. ^{1}H decoupled ^{13}C, *B*. ^{13}C APT, and *C*. ^{1}H NMR spectra of impurity I.

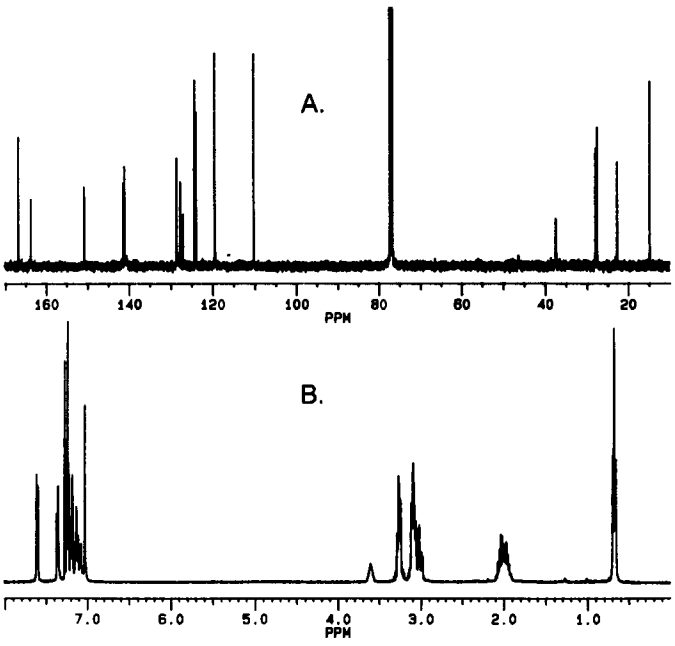

Fig. 5. *A*. ^{13}C,and *B*. ^{1}H NMR spectra of impurity II.

$[M + H]^+$ value are both consistent with the structure deduced from the NMR data. The EI spectrum (Fig. 6) showed a very weak molecular ion at m/z 652 together with peaks at m/z 371 and 282 due to cleavage of the bond between the benzylic carbon and the pyridone methylene group; as above, the ion at m/z 133 is ascribed to cleavage of the CH_2—CH_2 bond linking a benzoxazole group to the remainder of the molecule.

It should be noted that the structural characterization of related precursors[4] greatly

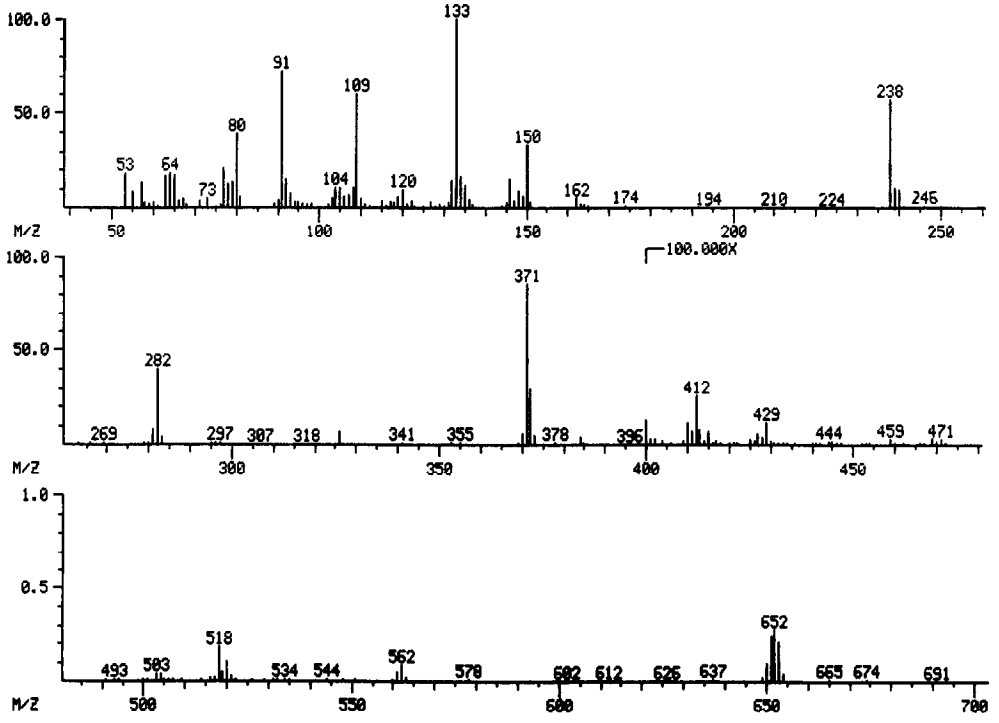

Fig. 6. EI mass spectrum of impurity II.

facilitated the identification of both of the isolated impurities.

CONCLUSION

The combination of sequential preparative HPLC, solid-phase extraction and liquid–liquid extraction has proved to be an effective and rapid strategy for the isolation of low level impurities from L-696,229 bulk drug substance. The isolated impurities were at least 98% pure. The structural characterization of these impurities was performed by NMR and MS.

Acknowledgements—Drs I. Houpis and J. Lynch are thanked for helpful discussions regarding the chemistry of formation of these impurities and for preparation of the impurity-enriched sample of L-696,229.

FLOW-INJECTION DETERMINATION OF L-TYROSINE IN SERUM WITH IMMOBILIZED TYROSINASE

NOBUTOSHI KIBA, HIROSHI SUZUKI and MOTOHISA FURUSAWA

Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

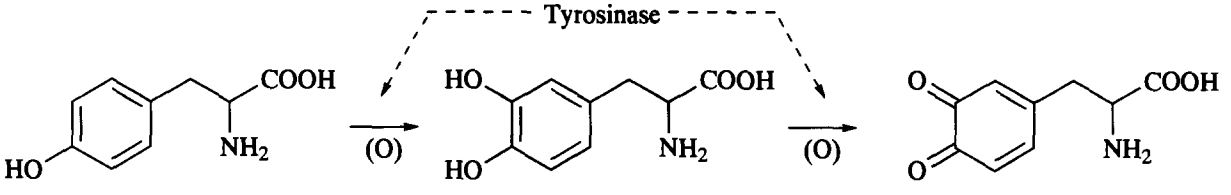
(*Received* 2 *November* 1992. *Revised* 21 *December* 1992. *Accepted* 22 *December* 1992)

Summary—A flow-injection method for the determination of the serum L-tyrosine is described. The method involves the conversion of tyrosine into dopaquinone by reaction of tyrosinase, followed by derivation of the dopaquinone with fluorogenic agent 1,2-diphenylethylenediamine. Serum was deproteinized with tungstic acid. Sample solution was injected into a reactor (50 × 4 mm i.d.) packed with glass beads on which tyrosinase was immobilized. The fluorescence was detected at 480 nm (excitation at 350 nm). The calibration graph was linear for 5×10^{-7}–2×10^{-4} *M* L-tyrosine; the detection limit was 2×10^{-7}*M*.

The concentration of tyrosine in serum is a useful indicator of disorders of metabolism (*e.g.*, phenylketonuria[1] and tyrosinosis[2]), and of disturbances in an organism (*e.g.*, hepatitis[3] and thyroid diseases[4]). The determination of tyrosine has been based on liquid chromatographic (LC) techniques.[5] However, the methods designed to quantify all serum amino acids are unnecessarily lengthy. A rapid and selective method is needed in order to provide the correct diagnosis.

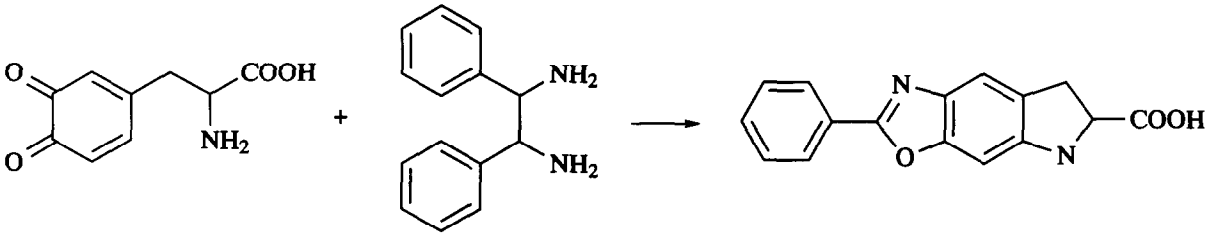
Compounds with 1,2-dioxo moieties readily form fluorescent derivatives with 1,2-diaryle thylenediamines.[6] 1,2-Diphenylethylenediamine (DPE) has been used in a post-column reaction system in high performance liquid chromatography for the determination of catechol compounds,[7] in which a coulometric technique was used for the oxidation of the compounds to the corresponding *o*-quinones.

Tyrosinase (EC 1.14.18.1) catalyses the hydroxylation of L-tyrosine to L-dopa and the dehydrogenation of the L-dopa to L-dopaquinone[8] according to the reactions:



L-Tyrosine L-Dopa Dopaquinone

A highly fluorescent derivative was obtained by a condensation reaction to dopaquinone with DPE under mild conditions in a pre-column derivation procedure[9] according to the reaction[10]:



Dopaquinone DPE Ex = 350 nm
Em = 480 nm

This paper describes a flow-injection method for the determination of L-tyrosine with immobilized tyrosinase reactor followed by fluorescence detection after the addition of DPE. The method was used for the determination of L-tyrosine in serum.

EXPERIMENTAL

Materials and reagents

Tyrosinase (2400 U/mg, from mushroom) and L-tyrosine were purchased from Sigma Chemical (St Louis). Aminopropyl-CPG (pore size 59 nm, particle size 200–400 mesh) was from CPG Inc. (Fairfield). DPE was synthesized using the method of Irving and Parkins.[11] All other reagents used were of analytical-reagent grade. DPE solution was prepared by dissolving 0.32 g of DPE in 15 ml of 0.6*M* hydrochloric acid and diluting to 50 ml with ethanol. The preparation of the immobilized tryosinase reactor was described in detail in the previous paper.[12] The immobilized enzyme was packed into a stainless steel column (50 × 4 mm i.d.).

Apparatus and procedure

A flow diagram of the FIA system is shown in Fig. 1. A 0.2*M* phosphate buffer (pH 7.2) was pumped by a double plunger pump (Kyowa Seimitsu, KHU-W-52) at a flow rate of 0.4 ml/min. The DPE solution was pumped by a LC pump (Hitachi, L-6000) at a flow rate of 0.3 ml/min. The immobilized tyrosinase reactor, reaction coil (PTFE, 1000 × 0.5 mm i.d.) and cooling coil (stainless-steel, 100 × 0.5 mm i.d.) were thermostatted at 15, 105 and 15°C, respectively. Sample solution (30 μl) was injected into the carrier stream by a loop injector (Sanuki, SVI-5U7). The separation column (40 × 4 mm i.d.) was packed with Capcell 120 C_{18} (5 μm) (Shiseido, Tokyo). The fluorescence was measured at 480 nm (excitation 350 nm) with a spectrofluorimeter (Jasco, FP-200) connected to a chart recorder (TOA, FBR 251A).

Serum (10 μl) was deproteinized by adding 5% (w/v) sodium tungstate solution (10 μl) and 0.15*M* sulphuric acid (30 μl). The mixture was filtered through an Airpress-30 filter [a filter with an ultrafiltration membrane (nominal molecular weight cut-off 30,000)] (Tosoh, Tokyo) and a 30 μl of the filtrate was injected into the carrier stream.

RESULTS AND DISCUSSION

Reactor performance

The properties of immobilized tyrosinase were evaluated, with the dopaquinone produced in the reaction being monitored at 475 nm with a spectrophotometer (Jasco, Uvidec-100-VI). The influence of pH on the enzymatic reaction was studied over the pH range 6.0–8.0. A standard solution of L-tyrosine (0.5 m*M*) was injected into the carrier stream (water) and mixed with 0.2*M* phosphate buffer at various pH values prior to elution through the enzyme reactor. The total flow-rate through the enzyme reactor was 0.4 ml/min. Other conditions were identical to those shown in Fig. 1. The optimum pH for the enzymatic reaction was about 7.2. The reactor was placed in a water bath and the temperature was varied between 10 and 30°C. The reactor exhibited the highest activity at 15°C. The reactor was used by repeated injections of tyrosine solution (0.5 m*M*) at a sample speed of 15/h. The activity decreased gradually and remained at 80% of the initial value after 800 injections. The decrease in the activity of tyrosinase occurs during the course of reaction and is known as reaction inactivation.[13]

Condensation reaction

The reaction conditions were examined with respect to the temperature, the concentration of

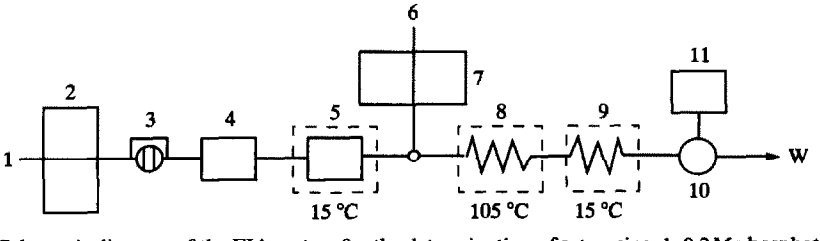


Fig. 1. Schematic diagram of the FIA system for the determination of L-tyrosine. 1: 0.2*M* phosphate buffer (pH 7.2); 2: pump (0.4 ml/min); 3: injector with 30 μl loop; 4: separation column (40 × 4 mm); 5: immobilized tyrosinase reactor (50 × 4 mm); 6: 30 m*M* DPE solution; 7: pump (0.3 ml/min); 8: reaction coil (1000 × 0.5 mm); 9: cooling coil (100 × 0.5 mm); 10: spectrofluorimeter (Ex = 350 nm, Em = 480 nm); 11: recorder, W: waste.

DPE, the kind of aqueous solvent systems, and the length of reaction coil. DPE solution was prepared by neutralizing with hydrochloric acid and diluting with organic solvent. Therefore, the reaction medium for the condensation reaction was adjusted to pH 7.2 by mixing the DPE solution with the carrier stream [0.2*M* phosphate buffer (pH 7.2)] which emerged from the reactor.

The effect of temperature on the reaction was examined over the range 80–110°C. The response increased linearly with an increase in temperature, but about 106°C bubbles generated in the reaction coil interfered with the measurement of the fluorophore. The effect of DPE concentration at a tyrosine concentration of 200 μM was examined from 10 to 50 m*M*. The response increased in the range 10–30 n*M* and became constant above 30 m*M*, where the DPE concentration in the reaction coil is about 13 m*M*. The response was dependent on the composition of the aqueous ethanol solution. The ethanol content in the DPE solution was changed from 40 to 90% (v/v) at a total flow rate of 0.7 ml/min. As shown Fig. 2, the maximum response was found at about 70% ethanol solution; at the maximum response, ethanol content in the reaction coil is about 30%. Various aqueous solvent systems were examined for their effect on the condensation reaction. The results are shown in Table 1. In ethanol, the response was higher than in other solvent systems. The changes in peak height as a function of the length of the reaction coil (0.5 mm i.d.) at a flow rate of 0.7 ml/min (0.4 ml/min carrier stream + 0.3 ml/min DPE solution) are shown in Fig. 3. The maximum response was obtained with a reaction coil of about 10 m. With increasing length of the reaction coil, the peak height decreased, but the peak area increased. The longer the reaction time, the nearer the conversion efficiency approaches 100%. The conversion efficiency was measured by using the fluorophore which was isolated by the method of Nohta *et al.*[10] Under the conditions shown in Fig. 1, the conversion efficiency of L-tyrosine (100 μM) to the fluorophore was 15%; in this case, it was assumed that L-tyrosine was converted to L-dopa in a 100% yeild. The sampling speed was 15/h.

Table 1. Effect of aqueous organic solvent on the condensation reaction

Solvent	Relative peak height
ethanol:water (7:3, V:V)	100
ethanol:DMSO:water (3.5:3.5:3)	66
ethanol:LDMF:water (3.5:3.5:3)	73
1,4-dioxane:water (7:3)	6
ethylene glycol:water (7:3)	3

DMSO:dimethyl sulfoxide.
DMF: *N*,*N*-dimethylformamide.

Specificity and interference

The responses to L-tyrosine and related compounds are shown in Table 2. This system exhibits low specificity for the compounds. As the concentrations of the compounds in serum are normally far lower than that of L-tyrosine, this system is not subject to interference from the compounds. Other L-amino acids normally found in proteins did not give any response.

In the presence of equimolar concentration of cysteine or ascorbic acid the peak height of tyrosine was depressed by about 50%. The interferences from the compounds (up to 1 m*M* each) were avoided by using on-line a separation column of ODS. Retention times of cysteine or ascorbate and tyrosine were 2.0 and 3.8 min, respectively.

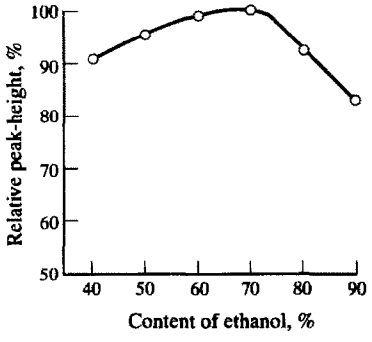

Fig. 2. Effect of ethanol content on the condensation reaction.

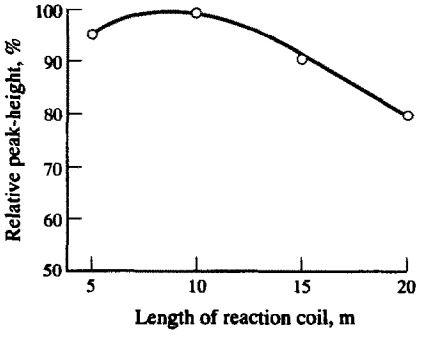

Fig. 3. Effect of length of reaction coil on the condensation reaction.

Table 2. Relative peak height for L-tyrosine and related compounds

Compound	Relative peak height
L-tyrosine	100
D-tyrosine	14
L-dopa	100
Dopamine	14
Epinephrine	13
norepinephrine	14
Tyr-Ala	45
Tyr-Glu	79
Tyr-Gly	36
Tyr-Leu	5
Tyr-Gly-Gly	79

Tyr-Ala: L-tyrosyl-L-alanine, Tyr-Glu: L-tyrosyl-L-glutamic acid, Tyr-Gly: L-tyrosylglycine, Tyr-Leu: L-tyrosyl-L-leucine, Tyr-Gly-Gly: L-tyrosylglycylglycine.

Calibration

Under the working conditions, the peak heights were plotted against the concentrations of L-tyrosine. A linear calibration graph was obtained for the range 1–200 μM. The least-square calibration equation was $y = 5.05x - 0.02$ with a linear correlation coefficient of $r = 0.997$ (9 data points), with the fluorescence intensity of 200 μM, tyrosine being taken as 1000 divisions, where y is peak height and x is tyrosine concentration. The detection limit (signal-to-noise ratio = 3) was 0.2 μM tyrosine (1 ng in a 30 μl injection).

Precision and reproducibility

Pooled human sera were repeatedly analysed during 10 days. The system was used for the analyses of 80 samples in a day and the immobilized tyrosinase reactor was stored in a refrigerator when not in use. In order to correct the variation of the conversion efficiency, standards were measured at 80-sample intervals. The immobilized tyrosinase reactor was renewed every 400 determinations. This system gave satisfactorily precise and reproducible results for serum containing 64 μM (11.60 mg/l) tyrosine, the within-day relative standard deviation (r.s.d.) was 0.97% and day-to-day r.s.d. was 1.8%.

Recovery

A sample of pooled human sera of known tyrosine concentration was supplemented with tyrosine to give final concentration of 70–985 μM. The recoveries were in the range 98–105%.

Comparison

Serum tyrosinase results ($n = 25$, range 61–210 μM) obtained using this system compared well with results obtained using amino acid analyser (Kyowa Seimitsu, K-201). The calculated linear regression and correlation coefficients were $y = 1.05x + 0.09$ and $r = 0.9798$, respectively.

CONCLUSION

An amino acid analyser for the determination of tyrosine is time-consuming. A flow-injection method, based on the fluorimetric detection of the dihydroxyindol produced in tyrosinase reaction, has been reported.[12] In the method, the use of a concentrated solution of potassium hydroxide (5M) caused poor reproducibility and poor dependability. The proposed method is three times more reproducible than the previous flow-injection method[12] and can easily be used for routine assay of tyrosine. The sensitivity and specificity of this method are sufficient to monitor concentrations of tyrosine in serum. The method has good recovery and within-run r.s.d. and between-run r.s.d.

THERMODYNAMICS OF COMPLEXATION OF MAGNESIUM AND CALCIUM IONS WITH DICHLOROMETHYLENEDIPHOSPHONATE

L. KAILA, L. H. J. LAJUNEN, E. N. RIZKALLA* and J. ELORANTA
Department of Chemistry, University of Oulu, SF 90570, Oulu, Finland

(*Received* 29 *October* 1992. *Revised* 12 *January* 1993. *Accepted* 12 *January* 1993)

Summary—Thermodynamic parameters for the complexation of Ca^{2+} and Mg^{2+} ions by dichloromethylenediphosphonate (clodronate) ligand were obtained by potentiometric and calorimetric techniques. The measurements were conducted at an ionic strength of 0.10*M* [$(CH_3)_4NCl$]) and at 25°C. The potentiometric data were consistent with a model involving the presence of ML^{2-} MHL^- and M_2L species (L = tetranegative clodronate anion). The enthalpies of formation of the ML^{2-} and MHL^- complexes were obtained from calorimetric data. Attempts to determine the enthalpies of formation of the M_2L species were unsuccessful due to the limited solubilities of these species.

Organophosphonates are quite interesting both from fundamental and applied points of view.[1] Their role in water decalcification[2] and stabilization of peroxide solutions[3,4] has long been recognized. *In vitro* studies[5–8] indicated that *gem* diphosphonates have high biological activities particularly in inhibiting bone lysis and in the treatment of malignant hypercalcemia. The operative mechanism seems to involve calcium ion complexation by the ligand anion.

This paper summarizes the results obtained for the complexation of magnesium and calcium ions by the therapeutically active dichloromethylenediphosphonate (Cl_2MDP) anion. The investigation was conducted as a series of potentiometric and calorimetric titrations, and ^{31}P-NMR measurements in aqueous tetramethylammonium chloride media. Earlier measurements of the complexation of Li^+ Na^+ K^+, Rb^+ and Cs^+ by a homologous series of alkalidiene diphosphonates were interpreted as to reflect dominance of the electrostatic interactions to the bonding. This was apparent from the linear dependence of log β_{101} for the reaction;

$$M^+ + H_nL^{n-4} \Leftrightarrow MH_nL^{n-3};$$

$$\beta_{101} = [MH_nL]/[M][H_nL]$$

on the cation radius (r_M).[9,10] Moreover, plots of log β_{101} for the individual cations across the *gem* diphosphonate series against the polar substituent constant, σ^*[11] for the alkyl groups attached to the bridging methylene group were also linear. The slope of the latter correlations, ρ^* was found to decrease with increasing the cation radius. Since, ρ^* reflects the susceptibility of a given series of interactions to the degree of transmission of the inductive effects from the attached substituents, it was suggested[10] that such trend is associated with a drop in the strength of the metal–ligand interactions. By contrast, this rationale did not hold for the binding of calcium and magnesium ions by the same ligands.[12] The explanation offered was based on the short range repulsive forces predicted upon grouping the two phosphonate groups around the metal ion.

EXPERIMENTAL

Reagents and solutions

All reagents were of AR grade. Metal solutions were prepared from the corresponding chloride salts and the exact molarities were determined by complexometric titrations in the presence of the appropriate indicator.[13] Tetramethylammonium chloride was used as such without further purification. The disodium salt of dichloromethylenediphosphonate, $Na_2H_2Cl_2MDP \cdot 4H_2O$ was kindly donated by Leiras Ltd, Finland. The concentration of the stock ligand solutions were determined by pH titrations.

*Present address: Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt.

Measurements

The potentiometric titrations were carried out using a Radiometer PHM64 pH meter fitted with calomel and glass (Orion Research 91-01) electrodes. The glass electrode was calibrated by standard acid–base titration to read directly—log $[H^+]$ and to self correct for the liquid–junction potential at high acidity.[14] In each run, 30 ml aliquot of the metal–ligand mixture was titrated with standard $(CH_3)_4NOH$ (0.01*M*). All solutions were adjusted to 0.10*M* ionic strength by the addition of $(CH_3)_4NCl$ and maintained at 25°C with constant-temperature water circulated through a sealed jacketed cell. All measurements were obtained in a nitrogen atmosphere.

Calorimetric measurements were obtained using a semiadiabatic home-built Peltier-cooled titration calorimeter interfaced to a computer.[15] The calorimeter was calibrated electrically after four incremental additions and the change in temperature was sensed with a 20 KΩ thermistor. In a typical run, 50 ml of the ligand solution or the metal–ligand mixture, adjusted to the proper buffer region and an ionic strength of 0.10*M* $[(CH_3)_4NCl]$ and thermostatted to 25.0°C was titrated by a total of 4–5 aliquots of 0.10*M* HCl. The heats of dilution of the ligand and its metal complexes were determined in separate runs.

^{31}P-NMR spectra were obtained using a Jeol GX-400 FT NMR spectrometer. The shifts were recorded relative to an external standard of H_3PO_4.

RESULTS AND DISCUSSION

^{31}P-NMR spectrum of the clodronate anion displayed a simple doublet with a baricenter chemical shift depends not only on the medium pH but also on the total sodium content. Figure 1 shows a plot of the observed shift as a function of the amount of sodium ion in solution. In all measurements, the ionic strength of the medium was adjusted to 1.00*M* by adding the appropriate amount of $(CH_3)_4NCl$. The pH of the measured solutions was adjusted to *ca.* 14 where the ligand is fully deprotonated and slight perturbations of the medium pH would not reflect on the measured shift. As indicated in Fig. 1, increasing the amount of sodium caused a downfield shift which levelled off at approximately $[Na^+] = 1.0M$. The deshielding effect is attributed to sodium ion complexation by the ligand anion. Fonong *et al.*[16] reported

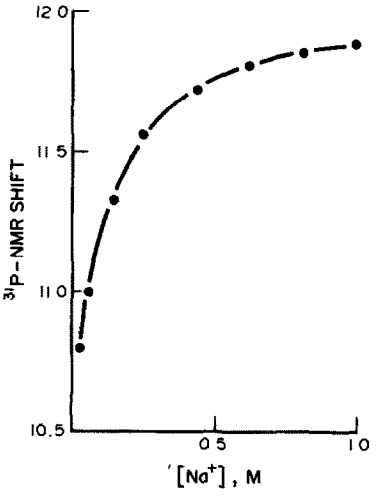

Fig. 1. Plot of the ^{31}P-NMR shift of the free Cl_2MDP^{4-} as a function of sodium ion concentration. $[Cl_2MDP^{4-}] = 24.2$ mM, pH ≃ 14.

a value of 1.28 for the formation of NaL^{3-} ($L = Cl_2MDP^{4-}$) in 0.10*M* NH_4Cl. Formation of $NaHL^{2-}$ species was also detected with other *gem* diphosphonate systems.[10,12] To avoid ambiguity, the present measurements were obtained in tetramethylammonium chloride.

The titration curve of the free ligand shows the presence of two distinct inflections corresponding to the liberation of two and three protons, respectively. Table 1 lists the p*K* values together with those obtained for other related ligands. The calculated constants are in excellent agreement with those reported in Refs 16 and 17 under similar experimental conditions. The entropies of protonation are larger than those reported for *gem*-dicarboxylates[18] presumably reflecting a larger degree of solvation of the free anion associated with the higher charge on these class of ligands.

The stability constants of the various metal complexes were refined by rigorous least squares using a modified version of the computer program SCOGS-2 written in this laboratory.[19,20] The program minimizes the sum of the square residuals between the observed and calculated hydrogen ion concentrations for a particular set of fitted stability constants. The program allows for the presence of different possible protonated and polynuclear species. In the present system, best fit was obtained when MHL and M_2L species were considered in addition to the normal ML complex.

The enthalpies of complexation were computed by fitting the observed heat changes, after correction for dilution effects, to the number of

moles of ML^{2-} and MHL^- complexes formed. The latter were calculated using the non-linear SIMPLEX program DELTA-H. In all cases, the concentration ranges were chosen as to minimize the formation of M_2L species. Attempts to determine the enthalpies of formation of these dinuclear species in separate runs were unsuccessful due to their limited solubilities. A sample set of the results obtained is shown in Table 2 and a summary of all the results is listed in Table 3. The errors given in Table 3 are based on the agreement between repetitive runs.

Experimental conditions: Cup contents: [Ca^{2+}] = 4.8017 mM; [ligand] = 9.5694 mM; [H^+] = 3.8338 mM; volume = 52.25 ml; Titrant = 0.10M HCl.

Computed constants: $\Delta H_{101} = 5.1$ kJ mole^{-1} and $\Delta H_{111} = 2.0$ kJ mole^{-1}.

In Fig. 2, the values of log β_{101} of some calcium and magnesium diphosphonate complexes are plotted as a function of the total ligand basicity, Σ pK_a. The values for EDP (ethane-1,1-diphosphonate) and PDP (propane-2,2-diphosphonate) were reported at 0.5M [$(CH_3)_4NCl$] ionic strength[1] and have been normalized to the 0.10M ionic strength. The linearity observed in both cases emphasizes the dominance of ionic interactions in these systems. The value of Ca^{2+}–PDP complexation is greater than that predicted from the pK_a value. Replacement of the two protons in MDP by the bulky methyl groups in PDP is expected to strain the P–C–P angle and leads, probably to a stronger interaction with the metal ions. The same phenomenon has been observed with the carboxylate analogues.[18] No explanation is offered, however, for the destabilization below the "norm" in the case of Ca–F_2MDP and Ca–MP complexation (MP = methylphosphonic acid). The only difference is that, these measurements[16] were obtained in NH_4Cl rather than $(CH_3)_4NCl$ medium. Stability constants for the

complexation by HCl_2MP^{3-} were found to fit these relationships, if the assumption is made that both phosphonate groups are bound to the metal ion and that the proton is bound to one of the remote free oxygens.

The entropy data can roughly be compared to those obtained for complexation by adenosine-5′-mono (AMP), di- (ADP) and triphosphate (ATP).[23] For both Mg^{2+} and Ca^{2+} ions, the ΔS value for MADP complexation was twice as much as that observed for MAMP complexation. This was taken as an evidence for the formation of a single M–O–P bond in the case of MAMP and two of such bonds in MADP. The average ΔS for the formation of an M–O–P bond was determined to be 60 and 51 J.K^{-1}.mole^{-1} for Mg^{2+} and Ca^{2+} ions, respectively. By analogy, the entropy changes for $MgCl_2MDP^{2-}$ and $CaCl_2MDP^{2-}$ supports chelation in both cases.

COMPLEXOMETRIC DETERMINATION OF MAGNESIUM OXIDE IN FLYASH BLENDED CEMENT

KA-KEUNG CHOI and SHIU-FAI LUK
Laboratory, China Cement Company, Tap Shek Kok, Tuen Mun, NT, Hong Kong

(*Received* 27 *October* 1992. *Revised* 11 *January* 1993. *Accepted* 12 *January* 1993)

Summary—A complexometric titration method is proposed to determine magnesium oxide in flyash blended cement. A 0.50 g of sample was heated with hydrochloric acid for 10 min. The solution was diluted to 500 ml, and 50 ml was pipetted and heated to boiling with 2.5 ml of 5% ammonium oxalate solution. The solution was then made alkaline by ammonium hydroxide. The suspension was cooled and filtered. The filtrate was titrated by standard 0.002*M* EDTA solution. The concentration of MgO in sample was calculated. The flyash content of the sample was determined by British Standard method and the recovery factor (f) was calculated by the equation of $f = 100/(99 - 0.315 \times \%FA)$. Concentration of MgO in sample was corrected by multiplying the recovery factor with concentration initially found by EDTA titration. The precision of the method is better with more time saving than the official methods.

Flyash blended cement is formed by grinding clinker with controlled proportions of flyash and gypsum. For simplicity it can be considered as made up of two components, namely, flyash (FA) and ordinary Portland cement (OPC). According to British Standard,[1] the magnesium oxide must not be greater than 4% because too much magnesium oxide may cause long-term expansion of concrete which may result in the cracking of a hardened concrete slab. There must be a method to determine the amount of magnesium oxide in a sample.

The BS method[1] requires hydrofluoric acid and perchloric acid to leach out the magnesium from the sample and uses atomic absorption spectrometry to determine its concentration. This method takes time to dissolve all the insoluble silica and requires special fume hoods for ventilation. The ASTM[2] method involves sodium carbonate fusion and is time consuming. Hence both official methods are not suitable for those laboratories that have many samples to be analysed.

Problems faced in the determination of magnesium oxide in blended cement include the quantitative extraction of magnesium and the interference from excessive amounts of calcium ions. Few methods[1,2] are reported to determine magnesium oxide in blended cement. Methods found to determine the magnesium in the presence of calcium include complexometric titration,[3–8] visible spectrophotometry,[9] polarography,[10,11] amperometric titration,[12] atomic absorption spectrophotometry,[1] X-ray fluorescence spectrometry[13,14] and inductively coupled plasma atomic emission spectrometry.[16] In cement or blended cement, the ratio of calcium oxide to magnesium oxide is usually more than 30:1. Complexometric titration is not possible to determine magnesium oxide directly without involving tedious sample preparation.[5] Yet it has been applied to cement where magnesium oxide was found by first determining the sum of CaO and MgO and then the CaO alone at higher pH. This approach is expected not to have satisfactory precision and accuracy because if 30 ml of titrant is for CaO alone, the amount for CaO and MgO is expected to be around 31 ml. Hence errors in these two separated titrations may cause MgO found to have a relative error greater than 10% which is outside of tolerance levels.

Instrumental methods have a greater tolerance to calcium concentration and they are more suitable to the analysis of blended cement because they are more time saving and have greater accuracy. Because of the expensive investment for such instrumentation, there is a need for a simple titration method to determine the magnesium oxide in blended cement. It is important especially to those cement plants in developing countries where there are difficulties in purchasing instruments, *e.g.* X-ray fluorescence spectrometer and atomic absorption spectrophotometer.

In this paper, a titration method is described with purification steps mentioned in ASTM[2] being simplified and the fusion procedure replaced by a leaching procedure with a recovery factor which depends on the percentage flyash in the sample. The method is simple, much quicker than both official methods, and has comparable accuracy.

EXPERIMENTAL

Analytical reagent grade chemicals and distilled water were used throughout the procedure.

Reagents

32% Hydrochloric acid
0.1% Methyl red indicator solution
12% Ammonium hydroxide solution, 1 vol. of distilled water mixed with 1 vol. of 25% ammonium hydroxide solution
5% Ammonium oxalate solution
50% Triethanolamine solution
1% Erichrome black T indicator solution, 0.2 g erichrome black T in 5 ml absolute ethanol and 15 ml of triethanolamine
0.002*M* Standard ethylenediamine tetraacetic acid solution
0.01*M* Standard ethylenediamine tetraacetic acid solution
Murexide indicator, 0.5 g murexide ground with 100 g sodium chloride.

Procedure

A 0.500 g of sample was accurately weighed into a 250-ml beaker and 50 ml of boiling distilled water was added. Then 10 ml of concentrated hydrochloric acid was added. The mixture was stirred by a glass rod and covered by a watch glass. The solution was kept boiling for 10 min to digest the sample. The solution was then diluted to 500 ml using a volumetric flask.

Fifty ml of sample was pipetted into a 250-ml beaker and 2.5 ml of 5% ammonium oxalate solution was pipetted into the beaker. Two drops of 0.1% methyl red indicator was added. The solution was heated to boiling. The solution was neutralized by 12% ammonium hydroxide and was made alkaline with 3–4 drops of ammonium hydroxide. The solution was boiled further for 10–15 sec.

The solution was cooled and filtered. The filtrate was collected and the residue was washed for several times with distilled water. To the filtrate, 10 ml of 50% triethanolamine and 20 ml of 12% ammonium hydroxide were added. The solution was then titrated by 0.002*M* standard EDTA solution using erichrome black T as indicator. The concentration of magnesium oxide was calculated as

$$\% \text{ MgO in sample} = f \times 40 \times 100 \times M \times V/(50 \times 2 \times m)$$

$$= f \times 40 \times M \times V/m$$

$$= f \times 80 \times M \times V \text{ for m} = 0.500 \text{ g}$$

m = sample mass
f = recovery factor
$= 100/(99 - (0.315 \times \%$ FA in sample))
M = molarity of standard EDTA solution
V = volume of titrant.

If the % FA is not known, to calculate the recovery factor, the % FA in sample was determined according to the BS method.[1] Twenty-five ml of the sample solution was pipetted out and filtered. The filtrate was collected. Ten ml of 50% triethanolamine solution was added and adjusted to a pH of 12. The CaO in sample was then titrated by 0.01*M* standard EDTA solution using murexide as indicator. The % FA was calculated by the following equation.

$$A \times \% \text{ FA} + B \times (100 - \% \text{ FA}) = \% \text{ CaO in sample}$$

A = % CaO in FA, can be taken as 2.0 if data not available[1]

B = % CaO in OPC, can be taken as 64.5 if data not available[1].

RESULTS AND DISCUSSION

In this method, the analyte is leached out by hydrochloric acid. The interferents which can complex with EDTA include iron, aluminium and calcium. The aluminium and iron are removed by adjusting the pH to around 10 and precipitating in the form of hydroxides. The main interferent, calcium, is removed by precipitation as calcium oxalate. As from Table 1, for 50 ml of sample solution, 2.0–4.0 ml of 5% oxalate solution gave a recovery of magnesium oxide from 103 to 92%. 2.5 ml of 5% oxalate solution was recommended to give recovery of magnesium oxide to be around 100%. Beyond 2.5 ml addition, the recovery decreases gradually which can be accounted as precipitation of magnesium as the oxalate. Any variation in the

Table 1. Effect of oxalate solution addition

Volume of 5% oxalate solution added (*ml*)	MgO found (%)	Recovery (%)
0.0	47.70	
1.0	22.27	2062.0
1.5	5.90	546.3
2.0	1.10	102.0
2.5	1.07	99.0
3.0	1.06	98.1
4.0	1.00	92.6
5.0	0.97	89.8
10.0	0.80	74.1

volume of oxalate added (*e.g.* 2.5 ± 0.5 ml) does not affect the recovery significantly.

Flyash blended cement is considered as composed of FA and OPC. The % MgO to be leached from FA and OPC by proposed method were studied. It was found that $99 \pm 2\%$ and $67.5 \pm 15.0\%$ of MgO could be extracted out from OPC and FA, respectively. A recovery factor is required to correct the incomplete extraction of magnesium oxide from the flyash component and this factor should be related to flyash content of sample. It is calculated as

$$f = \frac{100}{[\text{fractional recovery of OPC} \times (100 - \%\text{FA})] + [\text{fractional recovery of FA} \times \%\text{FA}]}$$
$$= 100/[99 - (0.315 \times \%\ \text{FA})].$$

Since the standard deviation in the % recovery of FA was great, its affect to accuracy may be significant. With theoretical approach, the recovery factor f for different recoveries from FA are calculated and are shown in Table 2. From British Standard,[1] the % FA in blended cement ranges from 15 to 35% and in Table 2, with the FA content at the upper limit, the relative error arised from the recovery of FA is about 6%. This is in the acceptable range and few cement samples have the FA content close to this value. Samples were prepared by using various standards of OPC and FA (from various regional sources). The known magnesium oxide concentrations were calculated based on the claimed values of standards. They were analysed by the proposed method. The results are listed in Table 3. The recoveries seem to be constantly low and it is attributed to low recovery of MgO from the flyash standards. The average recovery of MgO for FA as mentioned in preceding paragraph was the average of FA from different sources including USA, Australia, China and Indonesia. Most of flyash standards used in Table 3 were the standards from NIST and recoveries of these standards were at the lower side of the average. Hence the factor f was underestimated giving rise to negative deviation however, the errors observed were still within the tolerance level.

Table 2. Effect of variation in recovery factor at different recoveries from flyash

	15% FA		35% FA	
Recovery from FA* (%)	Calc. recovery factor	Relative error (%)	Calc. recovery factor	Relative error (%)
82.5	1.036	−2.4	1.073	−5.6
67.5	1.061	0.0	1.137	0.0
52.5	1.087	2.5	1.209	6.0

*% recovery from FA is calculated as $x \pm 6$ that is 67.5 ± 15.0.

Table 3. Accuracy analysis

Flyash content	MgO concentration (%) Known	Found	Relative error (%)
4.28	1.46	1.41	−3.4
5.46	3.77	3.52	−6.6
7.88	1.74	1.72	−1.1
9.65	2.22	2.13	−4.1
10.25	1.26	1.20	−4.8
10.50	2.24	2.15	−4.0
11.00	1.09	1.03	−5.5
13.10	0.68	0.69	1.5
13.18	1.06	1.06	0.0
13.38	3.55	3.41	−3.9
14.24	2.78	2.78	0.0
14.46	1.25	1.15	−8.0
15.76	1.21	1.15	−4.9
17.40	1.48	1.51	2.0
17.80	1.59	1.49	−6.2
18.81	1.19	1.19	0.0
19.23	2.04	1.90	−6.9
22.87	1.70	1.73	1.8
23.74	2.32	2.14	−7.7
28.78	3.59	3.46	−3.6
32.40	1.10	1.03	−6.4
35.64	2.92	2.88	−1.4
36.30	2.70	2.66	−1.5

In real sample analysis, the results were checked by either X-ray fluorescence spectrometry or BS method.[1] With the match pair technique, the calculated t-values are less than the theoretical values. It can be concluded that there is little difference between the proposed method with either the XRF or BS method. In the precision analysis, with triplicate determinations, the standard deviation of the method is less than the BS method.

Table 4. Sample analysis

	Theoretical		2.228	2.131

The method has several advantages over the BS method. It can be completed within an hour while the BS method usually takes more than 2 hr to complete the digestion. Second, it does not involve the use of hydrofluoric acid, perchloric acid, platinum crucibles or the expensive instrumentation. Therefore this method is suitable to be carried out by less experienced technicians. According to ASTM,[15] the difference between the extreme values in three results should be less than 0.15 and in the present work, the maximum difference is about 0.03. This satisfies the ASTM requirement and shows that this method has good reproducibility.

CONCLUSION

A simple and rapid method has been developed to determine the magnesium oxide in flyash blended cement. As compared with the official methods, it does not require tedious sample preparation procedures, hazardous chemicals, or sophisticated instrumentation, *e.g.* atomic absorption spectrophotometer is needed. The reagents used are common and inexpensive. Although this method sometimes requires an additional titration to find out the % flyash content, it does not increase the work load of the technician, because in usual practice, the determination of % FA in the sample must be included in routine blended cement analysis. This method is suitable for those laboratories with a lot of routine samples to be analysed.

FLUORIMETRIC DETERMINATION OF NITRITE

NIANQIN JIE, JINGHE YANG and FANQIN MENG
Department of Chemistry, Shandong University, Jinan, People's Republic of China

(*Received* 19 *October* 1992. *Revised* 11 *January* 1993. *Accepted* 13 *January* 1993)

Summary—A sensitive and rapid fluorimetric method for the determination of nitrite is described. The method is based on the reaction of nitrite with tryptophan to form a highly fluorescent compound in alkaline medium. The method has been applied in the determination of nitrite in water and food samples.

Determination of trace amounts of nitrite is of importance, particularly in the fields of environmental and food chemistry. Many spectrophotometric methods for the determination of nitrite have been reported.[1–5] Electrometric methods are also available,[6–7] as well as HPLC of the free ion.[8–9] However, some of these methods require close control of conditions, and some, which are too complex and time-consuming, are unsuitable for routine application.

Fluorimetric methods have also been reported for the determination of nitrite.[10–14] This paper describes a fluorimetric procedure, based on the reaction between nitrite and tryptophan. This method is very simple, rapid and suitable for the determination of nitrite in water and food samples.

EXPERIMENTAL

Apparatus and reagents

An RF-540 spectrofluorometer (Shimadzu, Kyoto, Japan) was used.

All reagents used were of analytical grade and all water used was demineralized and doubly distilled.

L-Tryptophan stock solution: 0.2 mg/ml.

Standard solution of sodium nitrite. A 100 μg/ml nitrite stock solution was made by dissolving 0.150 g of sodium nitrite, previously dried for 2 h at 100°C, in distilled water, and diluting accurately to 1000 ml. Diluted solution should be prepared fresh daily.

Hydrochloric acid: 0.24*M*. Sodium hydroxide solution: 0.75*M*.

Procedure

A 0.8 ml of *L*-tryptophan solution (0.2 μg/ml), 0.8 ml of hydrochloric acid solution (0.24*M*) and 1 ml of working nitrite solution (0.16 μg/ml) were added sequentially to a 25-ml volumetric flask. The contents of the flask were mixed, then the flask was placed in a boiling-water bath for 15 min. Add 2.5 ml of sodium hydroxide solution (0.75*M*) into the reaction mixture. Dilute to mark with water and measure the fluorescence intensity at an excitation wavelength of 320 nm and an emission wavelength of 385 nm.

RESULTS AND DISCUSSION

Fluorescence spectra

The excitation and emission spectra of the system investigated is shown in Fig. 1. The fluorescent species has excitation and emission maxima at 320 and 380 nm, respectively.

Effect of L-*tryptophan concentration*

The effect of *L*-tryptophan concentration on the fluorescence intensity of the system was studied. When the concentration of *L*-tryptophan was between 5.6 and 8.0 μg/ml, the fluorescence intensity reached a maximum and remained constant. An *L*-tryptophan concentration of 6.4 μg/ml was selected. Effect of hydrochloric acid concentration in the reaction.

Experiments indicated that the maximum and constant intensity was obtained for HCl concentration in the range 0.005–0.010*M*. The fluorescence intensity decreased for values outside this range. An HCl concentration of 0.008*M* was chosen.

Effect of sodium hydroxide solution in the final system

The optimum sodium hydroxide solution concentration is 0.075*M*. The tolerance range is 0.06–0.09*M*. In addition, it was shown that the

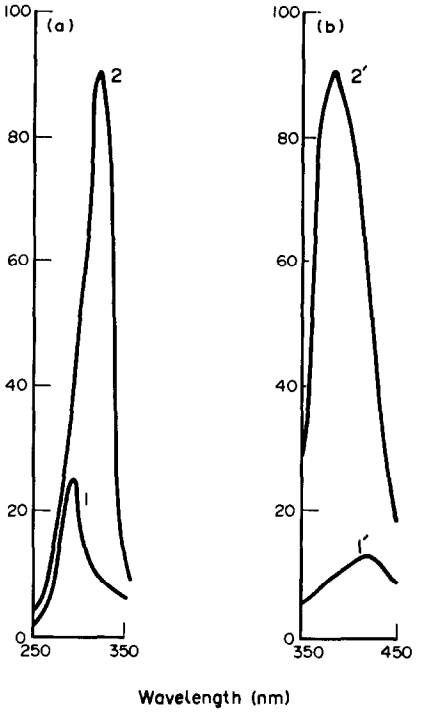

Fig. 1. Fluorescence spectra: (a) excitation, 320 nm; (b) emission, 385 nm. 1 and 1', tryptophan–NaOH system (reagent blank); 2 and 2', tryptophan–NO_2^--NaOH system; conditions: (tryptophan) = 6.4 μg/ml; (NO_2^-) = 0.16 μg/ml. There is tryptophan in the reagent blank. The tryptophan is a fluorescing substance, therefore in the absence of nitrite (reagent blank) an appreciable fluorescence signal was observed.

fluorescence intensity of the system reached a maximum after heating at 100°C for 15 min, and remained stable for 80 min.

Calibration graph

The calibration graph for the determination of nitrite was constructed under the optimum conditions. Good linearity obtained over the range 0.01–0.20 μg/ml. The detection limit is 0.001 μg/ml with the signal to noise ratio (S/N) value of 3.

Table 1. Tolerance of the method towards interference ions (amount of nitrite taken, 2 μg)

Ion	Ratio of ion to NO_2^- (μg/μg)		Ion	Ratio of ion to NO_2^- (μg/μg)
Al(III), Zn(II)	750		Fe(III)	1 15*
Ni(II)	500		NO_3^-	400
Mg(II)	400		PO_4^-	300
NH_4^+	200		F^-	200
Ba(II)	40		I^-	10
Ca(II)	30	60*	BrO_3^-	2
Cu(II)	2	10*		

*In the presence of 0.3 mg EDTA.

Table 2. Results for the determination of nitrite in water

Sample	NO_2^- found (μg)	NO_2^- added (μg)	Recovery (%)	Content (μg/ml)
Tap water	0.50	0		
(1 ml)	0.50	0		0.020
	1.50	1.0	100	
	1.50	1.0	100	
Water of a	1.55	0		0.062
lake (1 ml)	1.57	0		0.063
	2.55	1.0	100	
	2.62	1.0	105	

Interference of other ions

The interference of various cations and anions normally found in association with nitrite was studied. The amount of the diverse ion which brings about 5% variation in fluorescence was taken as its tolerance limit. Table 1 shows that only Fe(III), Cu(II) and BrO_3^- caused a severe interference, but Fe(III) and Cu(II) can be masked by adding EDTA. The presence of Fe(III) and BrO_3^- increased the fluorescence intensity owing to their oxidizing nature. Because Cu(II) exhibits a complexing ability, Cu(II) and tryptophan probably form a compound which is of stronger fluorescence. Hence in the presence of Cu(II), the fluorescence intensity of the system is increased.

Determination of nitrite in water and food samples

Transfer 1.0 ml of tap water into a 25-ml volumetric flask, then add 0.3 mg EDTA. Complete the determination by the procedure described above. The results obtained are given in Table 2.

The proposed method was also used to determine nitrite in sausage and milk samples. A 10-ml portion of spiked milk or 2.5 g sausage sample was placed into 200-ml standard flask and freed from proteins and fat according to a standard method,[15] then 1 ml of filtrate obtained was used for the fluorimetric determination of nitrite. The results are summarized in Table 3. The recoveries of nitrite were found to be 95.0–100%.

Table 3. Determination of nitrite in food samples

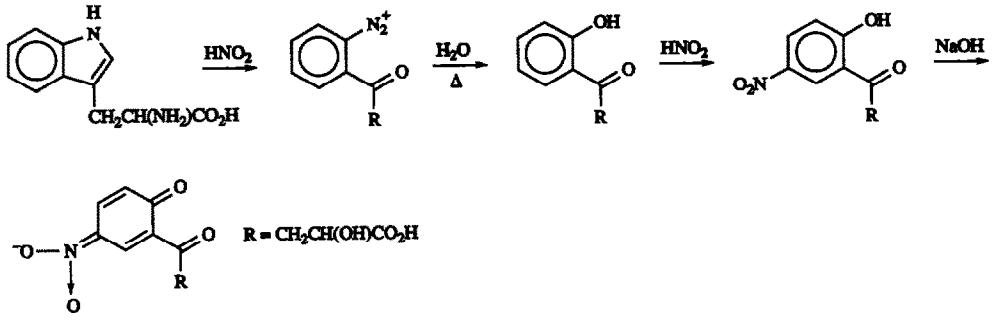
Sample	Found (μg/g)*	Standard deviation (μg/g)	Reference value†
Sausage 1	42.7	0.42	41.9
Sausage 2	33.5	0.23	33.4
Whole milk	15.9	0.30	15.6

*National Standard of China for nitrite in food sample: ≤0.03 g/kg.

†Obtained by the method reported by Shoji Motomizo *et al.*[10]

Mechanism of the reaction

The possible reaction between *L*-tryptophan and nitrite is:[16]



Based on the reaction, the conjugative effect in the reaction product is stronger than that in tryptophan, therefore the reaction product is of greater fluorescence intensity than tryptophan.

SIMPLIFIED DATA PROCESSING FOR THE SIMULTANEOUS DETERMINATION OF CATALYSTS BY CATALYTIC KINETICS

ZHONG-LIANG ZHU, ZHI-CHENG GU* and XIAN-DE WANG
Department of Chemistry, Tongji University, Shanghai, 200092, People's Republic of China

(*Received* 16 *October* 1992)

Summary—An approximate equation for data processing is proposed for the simultaneous determination of catalysts by catalytic kinetics. On applying the equation to the reaction between two reactants catalyzed by two catalysts, the calculation is simplified to that of only one reactant, simplifying the experiment and data processing. The equation was used to treat the simultaneous determination of ruthenium and osmium with Ce(IV)–As(III) as the indicator reaction, with the results in good agreement with those using the exact equation.

Because of their interference with each other, it is usually difficult to catalytically determine trace elements simultaneously when they catalyze a common indicator reaction. For example, while I^-, Ru and Os can be determined by their catalytic effect on the reaction between Ce(IV) and As(III) as the indicator reaction,[1,2,7] a prior separation is necessary if the others coexist when one is to be determined. Rodriguez described a method for the determination of Os and I^-, using Ag^+ or Hg(II) to mask the iodide.[3] Pardue proposed a method to determine Ru and Os based on their differences in their kinetic behaviour on the same indicator reaction.[4] It is necessary to carry out two kinetic runs to determine two elements in Rodriguez and Pardue's work. Gu has demonstrated the possibility for the simultaneous determination of catalysts with a single kinetic run, based on kinetic differences of catalysts on the indicator reaction.[5] As the kinetic behavior of the reactions between Ce(IV) and As(III) catalyzed by Ru and Os are quite different,[4,6] it is possible to determine the two elements simultaneously through a single kinetic run. In this paper Ru and Os are determined satisfactorily and an approximate equation is given, in which the experiment and the data processing for the reaction between two reactants catalyzed by two elements can be simplified as those for one reactant.

THEORY

In general, an indicator reaction between A and B in the determination of several catalysts $C_1, C_2, \ldots, C_n$ by catalytic kinetics may be written stoichiometrically as:

$$aA + bB \xrightarrow{C_1, C_2, \ldots, C_n} xX + yY$$

and the reaction rate equation for the ith catalyst is:

$$v_i = -\mathrm{d}[A]/\mathrm{d}t = (-a/b)\,\mathrm{d}[B]/\mathrm{d}t = k_i[A]^{p_i}[B]^{q_i}[C_i] (i = 1, 2, \ldots, n), \quad (1)$$

where p_i and q_i are the reaction orders of A and B, respectively. According to the stoichiometric relationships, the concentration of B can be expressed as

$$[B] = [B]_0 - (b/a)([A]_0 - [A]), \quad (2)$$

where $[A]_0$ and $[B]_0$ are the initial concentrations of A and B. Substituting equation (2) into equation (1), we have:

$$v_i = k_i[C_i][A]^{p_i}\{[B]_0 - (b/a)([A]_0 - [A])\}^{q_i}. \quad (3)$$

In a system with n catalysts which catalyze a common indicator reaction, when the behaviors of the catalysts are independent, the reaction rate may be written as follows,

$$v' = v'_0 + \Sigma k_i[A]^{p_i}[B]^{q_i}[C_i] = v'_0 + \Sigma k_i[A]^{p_i}\{[B]_0 - (b/a)([A]_0 - [A])\}^{q_i}[C_i]. \quad (4)$$

If $[A]_0$, $[B]_0$, p_i and q_i are known and p_i and q_i are different, $[C_i]$ can be calculated by multiple linear regression of v_i on $[A]^{p_i}[B]^{q_i}$. In the following, only two catalysts are considered, i.e. $n = 2$. Equation (4) may be simplified as:

$$v = v' - v'_0 = k_1[A]^{p_1}[B]^{q_1}[C_1] + k_2[A]^{p_2}[B]^{q_2}[C_2], \quad (4')$$

where p_1, p_2, q_1 and q_2 and the initial concentration of each reactant must be available. This would require a great number of experiments. For the sake of simplification, an approximate equation is proposed:

$$[B]^{q_i} = \{[B]_0 - (b/a)([A]_0 - [A])\}^{q_i} = T[A]^{p''_i}, \quad (5)$$

where T is a constant, called the model conversion coefficient. And equation (1) becomes:

$$v_i = k'_i[A]^{p'_i}[C_i] \quad (i = 1, 2), \quad (6)$$

where $k'_i = k_iT$, $p'_i = p_i + p''_i$ and p''_i is called "the reduced fractional reaction order". Taking the logarithm, equation (6) becomes:

$$\ln v_i = p'_i \ln[A] + \ln k'_i[C_i], \quad (7)$$

p'_i and k'_i can be obtained from the plot of the $\ln v_i$ *vs.* $\ln[A]$ by calibration with standard solutions of C_i. For a two-component mixture

$$v = \Sigma k'_i[A]^{p'_i}[C_i] = \Sigma f_i[A]^{p'_i} \quad (8)$$

f_1 and f_2 can be obtained by two linear regressions of v *vs.* $[A]^{p'_1}$ and $[A]^{p'_2}$ and $[C_i]$ can be solved from f_i and k'_i.

Unlike equation (4), when equation (8) is used, only two kinetic runs are needed to obtain p'_1 and p'_2. Furthermore, the exact initial concentrations of reactants need not necessarily be known, provided the amounts of them added in each experiment remain constant. In practice, Ru and Os are determined as the catalysts to the reaction between Ce(IV) and As(II).

EXPERIMENTAL

Apparatus

F7230 spectrophotometer equipped with a thermostat; IBM microcomputer.

Reagent

As(III) *solution.* Prepare a 0.20*M* As(III)–2*M* H_2SO_4 solution by dissolving 4.95 g As_2O_3 in 20 ml 1*M* NaOH and adding 2*M* H_2SO_4 to 250 ml. The solution was diluted to $1.8 \times 10^{-3}M$ with 2*M* H_2SO_4 (solution B).

Ce(IV) *solution.* Prepare a 0.039*M* Ce(IV)–2*M* H_2SO_4 solution by dissolving $(NH_4)_4Ce(SO_4)_4 \cdot 2H_2O$ in 2*M* H_2SO_4.

Stock standard Ru *solution.* Prepare a $5.00 \times 10^{-4}M$ solution by dissolving $RuO_2 \cdot H_2O$ in H_2SO_4. Dilute this stock solution as required before use.

Stock standard Os *solution.* Prepare a $5.00 \times 10^{-4}M$ solution by dissolving OsO_4 in water. Dilute this stock solution as required before use.

All the chemicals used were of analytical reagent grade. Redistilled water was used.

Procedures

A 5.0 ml portion of Ce(IV) solution was mixed with sample solution containing Ru and Os and diluted to 25 ml with water (solution A). Both solutions A and B were mixed with a proportion of 1:2 in a cell as quickly as possible. The absorbance change with time was measured at 418 nm against water. The absorbance at intervals of 10 sec was recorded automatically.

Data processing

The reaction rate v was calculated by the Savitzky–Golay method[8] from the A *vs.* t plot. Based on Beer's law, the absorbance A was used in equation (6) instead of [Ce(IV)]. Similar to the Savitzky–Golay convolution, the following equation was used.

$$v_j = -dA/dt = -\left(\sum_{i=-m}^{m} q_iA_{i+j}\right) \Big/ (\Delta t.N),$$

where Δt is the interval of sampling time, N is the normalization factor, q_i is the convolution coefficient and $2m + 1$ is points used for smoothing. When the reaction rate was obtained from square polynomials of first order,

$$N = 2\sum_{i=1}^{m} i^2$$

and

$$q_i = i \quad (i = -m, -m+1, \ldots, 0, 1, \ldots, m).$$

Experimentally, a smooth plot of v *vs.* t could be obtained by $m \geqslant 5$, and $m = 5$ was specified.

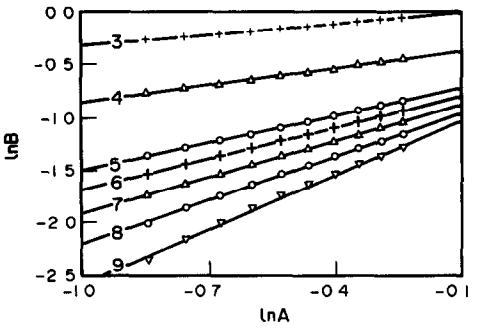

Fig. 1. The ln A–ln B relations. Simulated curves for different values of B_0 as given in Table 1.

RESULTS AND DISCUSSION

Confirmation of the approximate equation

From the logarithm of equation (5):

$$\ln[B] = p_i'' \ln[A]/q_i + \ln T/q_i.$$

Equation (5) can be tested when the ln[B] *vs.* ln[A] plot is linear. As an example, in the reaction between Ce(IV) and As(III) catalyzed by Ru and Os, $a = 2$, $b = 1$, and letting $q_i = 1$, equation (2) can be written as:

$$[B] = [B]_0 - 1/2([A]_0 - [A]).$$

The ln[B] *vs.* ln[A] plot computed by simulation is shown in Fig. 1. It is linear over a wide range of concentration; the values of p_i'' and T were obtained from the slope and the intercept. The data, as well as the correlation coefficients, are listed in Table 1. The correlation coefficients approach 1 in quite a wide range of reactant ratios. It means that equation (5) can be used extensively. Two special cases should be noted.

(a) When $[A]_0$ and $[B]_0$ are in stoichiometric ratio, equation (5) becomes exact. Hence $p_i'' = q_i$, $T = (b/a)^{q_i}$.

(b) When $[B]_0 \gg [A]_0$, while p_i'' approaches 0 and T approaches $[B]_0^{q_i}$ the reaction becomes a "pseudo p_i-order reaction".

Reaction conditions

The reaction between Ce(IV) and As(III) catalyzed by Ru and Os did not change much in the range of 1.0–2.0M H_2SO_4. Hence 1.7M H_2SO_4 was specified in the procedure.

The effects of As(III) on the reaction rate is shown in Fig. 2 and the effect of Ce(IV) is shown in Fig. 3. In agreement with Refs 4 and 6, it was found that the osmium catalyzed reaction was dependent upon the As(III) concentration, but almost independent of the Ce(IV) concentration; on the other hand the ruthenium catalyzed reaction was dependent upon the [Ce(IV)] but almost independent of the [As(III)]. q_{Ru}, q_{Os}, p_{Ru} and p_{Os} were obtained by regressing ln v on ln[As(III)] and ln v on ln[Ce(IV)]; the values of which were 0.09, 1.08, 1.91 and −0.10, respectively. The great differences between both q_{Ru} and q_{Os} and p_{Ru} and p_{Os} made it possible to determine Ru and Os simultaneously. Reactants at $1.23 \times 10^{-3}M$

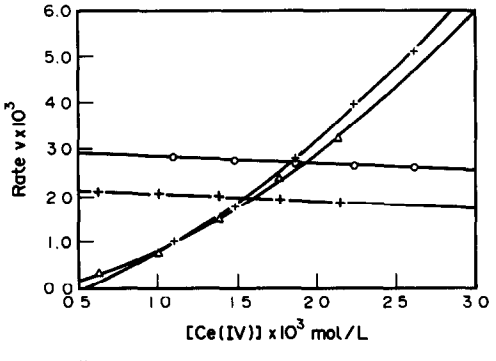

Fig. 3. Effect of [Ce(IV)] on reaction rate. + [Ru] = 8.0×10^{-8}, [As(III)] = $8.4 \times 10^{-4}M$; △ [Ru] = 8.0×10^{-8}, [As(III)] = $6.0 \times 10^{-4}M$; ○ [Os] = 6.7×10^{-8}, [As(III)] = $8.4 \times 10^{-4}M$; + [Os] = 6.7×10^{-8}, [As(III)] = $6.0 \times 10^{-4}M$.

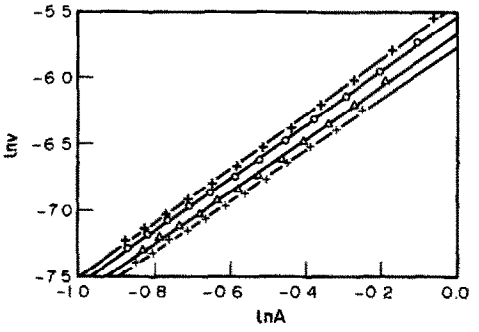

Fig. 4. p'_{Ru} dependence on initial concentration ratio of [Ce(IV)]/[As(III)] ([Ru] = $8.0 \times 10^{-8}M$).

p'_{Ru}	Initial ratio
+ 1.91	1.6:1
△ 1.98	1.9:1
○ 2.01	2.2:1
+ 2.06	2.5:1

As(III) and $2.59 \times 10^{-3}M$ Ce(IV) were specified in the procedure.

The plots of $\ln v$ *vs.* $\ln A$ of Ru and Os catalyzed reactions are shown in Fig. 4 and Fig. 5, respectively. The slopes of the plots refer to the apparent reaction order, i.e. p'_{Ru} and p'_{Os}. With an increase in the initial ratio of reactants, p'_{Ru} remained almost unchanged while p'_{Os} increased quite obviously.

The effect of temperature on reaction rate is shown in Fig. 6. The influence of temperature on the Ru catalyzed reaction was more serious than for the Os catalyzed one. A temperature of 28.0°C was specified in the procedure.

Reaction rate curves

The A *vs.* t plot and the v *vs.* t plot are shown in Figs 7 and 8, respectively. The patterns of the

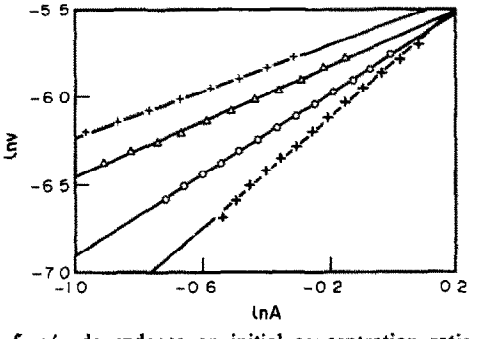

Fig. 5. p'_{Os} dependence on initial concentration ratio of [Ce(IV)]/[As(III)] ([Os] = $6.7 \times 10^{-8}M$).

+ 0.66	1.6:1
△ 0.78	1.9:1
○ 1.14	2.2:1
+ 1.55	2.5:1

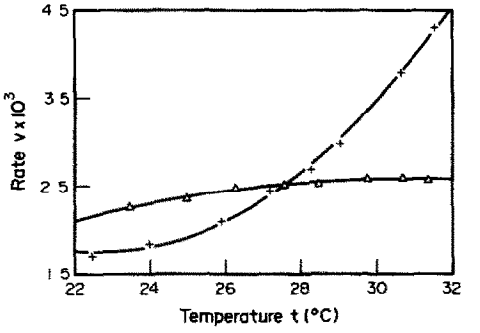

Fig. 6. Effect of temperature on reaction rate [Ce(IV)] = 1.8×10^{-3}, [As(III)] = $8.1 \times 10^{-4}M$. + [Ru] = $8.0 \times 10^{-8}M$; △ [Os] = $6.7 \times 10^{-8}M$.

curves for Ru and Os were different. This supports that the mechanism of the indicator reaction catalyzed by Ru and Os at the above conditions are different.

As shown in Fig. 9, linearity was observed in the experimental range for the reaction rate to be a function of the concentration of Ru and Os.

The reaction order p'_i *and rate constant* k'_i

The values of p'_i were obtained with Ru and Os, respectively, under the conditions mentioned above. The results are shown in Table 2.

In order to reduce the possibility of the interaction of Ru and Os, the reaction rate constants k'_i were determined with a mixture of Ru and Os with known concentrations. The results obtained are also listed in Table 2.

Determination of Ru *and* Os *mixtures*

A set of Ru(IV) and Os(VIII) mixtures were determined. The results calculated by

both equation (8) ($found_1$) and equation (4) ($found_2$) are listed in Table 3. The results calculated by approximate equation and the exact equation were coincident. This demonstrates that the approximate equation is accurate.

The method proposed in this paper has an advantage in that the result is independent of the initial time of reaction. Good results can be obtained, provided that A *vs.* t is recorded in the same range of reactant concentrations. In this paper the data of absorbance changing with time was recorded in the range of 0.70–0.40.

DETERMINATION OF ACTIVITY COEFFICIENTS OF TERMOLECULAR COMPLEX FORMATION

W. REGENSTEIN
Fachbereich Physik, Universität Potsdam, Am Neuen Palais 10, Potsdam D-O-1571, Germany

(*Received* 8 *October* 1992. *Revised* 7 *January* 1993. *Accepted* 12 *January* 1993)

Summary—The activity coefficients of CT-complexes exhibiting termolecular complex formation due to donor excess are determined. Since the solutions can be regarded as binary systems with respect to their activities the cases of non-volatile and volatile solutes in volatile solvents are considered here.

So far there is little information given in the literature[1–3] regarding the influence of the activity coefficients on termolecular complex formation of CT (Charge Transfer) complexes in case of high initial concentrations.

Whereas Childs *et al.*[2,4] combine spectroscopic with solubility measurements we apply spectroscopic and vapour pressure measurements to determining the equilibrium constants and activity coefficients, respectively.

DETERMINATION OF EQUILIBRIUM CONSTANTS

The formation of CT-complexes is controlled by the general scheme of reactions

$$qD + pA \overset{K}{\rightleftharpoons} D_qA_p. \tag{1}$$

Neglecting the activity coefficients and with the help of the law of mass action the equilibrium constant amounts to

$$K = c_i(c_D^q c_A^p)^{-1} \tag{2}$$

with c_i = complex concentration of stoichiometry q, p,
c_D, c_A = donor and acceptor concentration, respectively, at the state of equilibrium, and the initial concentrations

$$c_D^0 = c_D + qc_i \quad \text{and} \quad c_A^0 = c_A + pc_i.$$

In addition to 1:1-(termolecular) complexes there are also 2:1-complexes occurring under high donor concentrations. As Carter[5] has shown the coupled equilibriums now become

$$D + A \overset{K_1}{\rightleftharpoons} DA \tag{3}$$

and

$$D + DA \overset{K_2}{\rightleftharpoons} D_2A \tag{4}$$

with equilibrium constants

$$K_1 = c_1(c_D^0 - c_1 - 2c_2)^{-1}(c_A^0 - c_1 - c_2)^{-1}, \tag{5}$$

$$K_2 = c_2(c_D^0 - c_1 - 2c_2)^{-1}(c_1)^{-1}, \tag{6}$$

and the complex concentrations, respectively,

$$c_1 = R + (R^2 - 4K_1^2(c_A^0 c_D^0 - 2c_A^0 c_2 - c_D^0 c_2 + 2c_2^2))^{1/2}(2K_1)^{-1}, \tag{7}$$

where R is nondimensional,

$$c_2 = K_2(c_D^0 c_1 - c_1^2)(2K_2 c_1 + 1)^{-1} \tag{8}$$

$$R = K_1 c_A^0 + K_1 c_D^0 - 3K_1 c_2 + 1. \tag{9}$$

Provided the additivity of the extinctions E_i, and using the optical densities $E' = E/d$, where d denotes the layer thickness of the cuvette, the optical density is

$$E' = \epsilon_D c_D + \epsilon_A c_A + \epsilon_1 c_1 + \epsilon_2 c_2. \tag{10}$$

Application of data processing enables utilising complete information based on the total spectrum of specified points for computing the equilibrium constants. For that purpose Beer's law is written in matrix formulation

$$A = CE. \tag{11}$$

Let for instance the acceptor, the DA, and the D_2A complex be absorbing over the investigated spectral region, without loss of generality, and the spectra of m mixtures with l wave-

length are to be evaluated, then equation (12) is obtained

$$\begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1l} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ a_{m1} & a_{m2} & \cdots & a_{ml} \end{pmatrix} = \begin{pmatrix} c_{1A} & c_{11} & c_{12} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ c_{mA} & c_{m1} & c_{m2} \end{pmatrix} \begin{pmatrix} \epsilon_{A1} \cdots \epsilon_{Al} \\ \epsilon_{11} \cdots \epsilon_{1l} \\ \epsilon_{21} \cdots \epsilon_{2l} \end{pmatrix}. \quad (12)$$

The matrix of concentration includes the unknown equilibrium constants as non-linear parameters. There are several methods for the evaluation of the matrix equation given in literature.[6,7]

The equilbrium constants found with equation (12) are correct on the condition that the solutions are ideal. Yet, because of the acceptor's low solubility donor excess has frequently been applied. The relatively high donor concentrations do not permit looking upon the solutions as ideal any more. Instead of concentrations in equation (12) activities

$$a_i = \gamma_i c_i \quad (13)$$

have to be inserted. Then, and with low concentrations the activity coefficients tend to 1 whereas otherwise they may become greater or smaller than 1. Thus, for 1:1 and 1:2 complex formation the thermodynamical equilibrium constants arise as

$$K_1^{th} = c_1\gamma_1(c_D c_A \gamma_D \gamma_A)^{-1} = K_1\Gamma_1, \quad (14)$$

$$K_2^{th} = c_2\gamma_2(c_D c_1 \gamma_D \gamma_1)^{-1} = K_2\Gamma_2. \quad (15)$$

The Γ_i allow for the influence of the activity coefficients and permit a correction of the traditionally determined equilibrium constants. Besides, the activity coefficients can be derived through methods that are independent of the determination of equilibrium constants.

From the methods represented[8] vapour pressure decreasing proved appropriate for the investigations. The activity of the solvent can be found from the vapour pressure decrease according to Raoult's first law

$$a_s = p/p_{0s} \quad (16)$$

by vapour pressure measurements at different concentrations of the solvent. This method is bound to binary liquid solutions with no detectable vapour pressure developed by the solute, and provided that the magnitude of vapour pressure of the pure solvent at temperature is known. By means of the Gibbs–Duhem equation and the thus determined activity coefficients as well as taking into account the influence of the mol fractions of the solute x_i and the solvent x_s it is now possible to compute the activity coefficient of the solute by numerical integration of the equation

$$\lg a_i = -\int_{x_i'}^{x_i} x_s/x_i \, \mathrm{dlg}\, a_s + \lg a_i \quad (17)$$

through plotting x_s/x_i *vs.* $-\lg a_s$. The symbol a_i stands for the activity of the lowest measured mol fraction x_i. If the integral is referred to as A the equation turns by some transforming to

$$\lg(\gamma_i/\gamma_i') = A - \lg x_i + \lg x_i'. \quad (18)$$

Supposed that $\gamma_i = 1$ when $x_i' = 0$, the γ_i can be determined. For that purpose the quotient in equation (18) has to be plotted for a constant x_i and a variable x_i'. The quotient and hence the unknown activity coefficient[9] are found by extrapolation.

It seems to be more intricate to determine the activity coefficients γ_i of binary systems with two volatile components the vapour pressure of which is composed of the partial pressures of the components and the vapour phase being a non-ideal mixture. A detailed account of how to find the partial pressure by methods of non-statistical thermodynamics can be looked up in the monograph of Hildebrand and Scott.[10] Extensive data collections have been compiled and computed in Kraetsch's thesis.[11]

RESULTS

The measurements were carried out by using a vapour pressure osmometer of Knauer. The problem that emerges in evaluating CT-complexes consists in that there are not only two- but four- up to six-component-systems occurring depending on whether 2:1-complexes are formed and solvent mixtures are used. It could be shown, however, that the vapour pressure decreases of the solutions become negligibly small in case of the considered CT-complexes and within the frame of limited solubilities of the complex components. Merely the naphthalene–methylcyclohexane system makes an exception (see Table 1).

Table 1. Vapour pressures and activity coefficients of naphthalene in methylcyclohexane computed according to equations (16) and (18) at T = 298 K and $p_{0_2} = 6{,}27$ kPa

$x_1 = x_D$	c_D(M)	p(kPa)	γ_s	γ_D
0.006	0.05	6.248	1.00	2.15
0.013	0.1	6.228	1.00	3.24
0.026	0.2	6.186	1.01	4.61
0.039	0.3	6.142	1.02	5.37
0.052	0.4	6.091	1.02	6.0
0.065	0.5	6.043	1.03	6.66

The benzene–tetrachloromethane system clearly exemplifies that the slight differences in vapour pressures are not only caused by the limited solubility (see Table 2). Despite unlimited solubility the activity coefficients turn out to be approximately 1 over the total concentration range. Measurable differences in vapour pressure arise mainly from the donor. The influence of the other components (acceptor, complexes) remain negligible.

Thus the equlibrium constant of the 1 : 1-complex formation is obtained in accordance with Martire *et al.*[3] and Lane[2] by the activity coefficient of the donor

$$K_1^{th} = K_1/\gamma_D. \tag{19}$$

The measured vapour pressures of the benzene–TCNE (tetracyanoethylene) complex in tetrachloromethane and the activity coefficients computed from them were put together in Table 2.

Applying a regression program the vapour pressure of the binary benzene–tetrachloromethane system is described herein by the equation proposed in Barker's theory[12]

$$p \approx x_1 p_1^0 \exp\{(1-x_1)^2(A + Bx_1 + Cx_1^2)\} + (1-x_1)p_2^0 \exp\{x_1^2[(A - B/2) + (B - 2C/3)x_1 + Cx_1^2]\} \tag{20}$$

Table 2. Vapour pressures and activity coefficients of benzene in tetrachloromethane computed according to equations (21) and (22) at $T = 298$ K

$x_1 = x_D$	c_D(M)	p(kPa)	γ_2	$\gamma_1 = \gamma_D$
0.1	1.1	12.210	1.0	1.1
0.2	2.25	12.103	1.0	1.1
0.3	3.5	11.890	1.0	1.09
0.4	4.9	11.743	1.0	1.07
0.5	6.5	11.623	1.01	1.06
0.6	8.1	11.477	1.03	1.04
0.7	10.0	11.290	1.06	1.03
0.8	12.3	11.170	1.1	1.01
0.9	14.7	10.517	1.16	1.0

for known vapour pressures of the pure components p_1^0 and p_2^0 and with adaptation of the unknown coefficients A, B, C. From that the activity coefficients are found as

$$\ln \gamma_1 \approx (1 - x_1^2)(A + Bx_1 + Cx_1^2 + \cdots), \tag{21}$$

$$\ln \gamma_2 \approx x_1^2[(A - B/2) + (B - 2C/3)x_1 + (C - 3D/4)x_1^2 + \cdots]. \tag{22}$$

The vapour pressures of benzene $p_1^0 = 10.25$ kPa and tetrachloromethane $p_2^0 = 12{,}37$ kPa at $T = 298$ K for adaptation have been drawn from literature. The coefficients were calculated by non-linear compensation to $A = 0.213$, $B = -0.324$, $C = -0.049$ and $D = 0$. For calculation at least six datapoints are necessary. When the second number past point is not changing the computation was interrupted.

The vapour pressure measurements of the system naphthalene in methylcyclohexane with the non-volatile complex component compiled in Table 1 were determined by means of Raoult's law given in equation (16) and the Gibbs–Duhem equation (17).

CONCLUSIONS

The determination of activity coefficients of multiple-component systems such as, *e.g.* CT-complexes present today, is still a difficult and not yet satisfactorily solved problem. We could confirm by our system with aid of vapour pressure measurements, that the donor in access gets the most activity.

Using the benzene–TCNE in methylcyclohexane we could show that by unlimited solubility from donor-benzene the activity is not essential. The calculation of activity coefficients for the system with two volatile components was done by Barker's equation (20).

The experimental data show significant deviations from the UNIQUAC (Universal–Quasichemical),[13] UNIFAC (Universal group Activity Coefficients)[14] and NRTL (non random two-liquid)[15] equations which were derived on the basis of the grid model.

COLORIMETRIC DETERMINATION OF ISONIAZID AND ITS PHARMACEUTICAL FORMULATIONS

NADIA M. A. MAHFOUZ[1] and KAMLA M. EMARA[2]

[1]Department of Pharmaceutical Medicinal Chemistry, [2]Analytical Pharmaceutical Chemistry, Faculty of Pharmacy, University of Assiut, Assiut, Egypt

(*Received* 22 *September* 1992. *Revised* 30 *December* 1992. *Accepted* 12 *January* 1993)

Summary—Two colorimetric methods for the estimation of isoniazid are developed. The first method depends on coupling of isoniazid with diazotized 1-amino anthraquinone zinc chloride salt (fast red AL salt) to form a red colour (λ_{max} 510 nm). The second one is based on the formation of a green complex (λ_{max} 655 nm) between the acid hydrazide and 2,6-dimethoxy-1,4-benzoquinone (DMBQ). All measurements of the two procedures were carried out in the presence of sodium hydroxide at room temperature (20 ± 3°C). The two methods are applied for the determination of isoniazid in presence of congenial drugs, vitamins and additives normally encountered with it in pharmaceutical dosage forms. The reliability of these methods was established by parallel determination with the reported and official methods.

Isoniazid (INH), the antitubercular drug, has been determined by titrimetric[1–3] ultraviolet spectrophotometric,[4] Colorimetric,[5–8] fluorimetric,[9] polarographic,[10] paper or thin layer chromatographic,[11,12] and HPLC[13] methods. The compendial methods for the assay of isoniazid, in authentic and dosage forms, involve HPLC,[14] nitritimetric[14] and bromimetric titrations.[15]

In the present work, two spectrophotometric methods for the assay of isoniazid with fast red AL salt and DMBQ were described. The methods are sensitive, rapid and adopted for the assay of isoniazid in pure form and its pharmaceutical formulations.

EXPERIMENTAL

Apparatus

Uvidec-320 spectrophotometer (JASCO, Tokyo, Japan).

Infrared spectrophotometer (Perkin–Elmer 298) using potassium bromide disc.

^{1}H-NMR Spectra Varian EM 360A (60 MHz). The ^{1}H-NMR chemical shifts were measured against TMS = 0.0 ppm and compared with TMS = $CDCl_3$—7.289 ppm.

Melting points were determined on "Buchi-Gerat" in capillary tubes and were uncorrected.

Thin layer chromatography (TLC) was carried out using fluorescent silica get plates polygram -G UV_{254} (Macherey and Nagel, Duren). The spots were detected with UV at 254 nm.

Reagents and materials

Fast red AL salt solution, (Aldrich Chemical Co., Inc., USA). A 0.2% (w/v) aqueous solution was used, freshly prepared and protected from sunlight.

Sodium hydroxide, 0.4% (w/v) and 10% (w/v) aqueous solutions were used.

Isoniazid (Analar grade) (BDH, Poole, Dorset, UK).

2,6-Dimethoxy-1,4-benzoquinone reagent, A 0.1% w/v ethanolic solution was used. It was synthesized according to Hamblock[16] and Baker[17] procedures. Its purity and structure were confirmed by TLC ($CHCl_3$/MeOH 9:1), mp (254–255°C),[17] IR and ^{1}H-NMR spectra. IR (Fig. 1) revealed the presence of characteristic stretching bands, *viz.*, C—H (3070 and 2940/cm), C=O (1690 and 1640/cm), C=C conjugated (1590/cm), C—O—C (1260 and 1105/cm), in addition to one out of plane bending band at 880/cm corresponding to tetrasubstituted benzene. ^{1}H-NMR (Fig. 2) showed the presence of six protons at δ 3.86 ppm (singlet), corresponding to the methoxy functions and two aromatic protons at δ 5.85 ppm (singlet). The upfield shift of the latter protons was attributed to the shielding anisotropic effect of the ortho-carbonyl function.

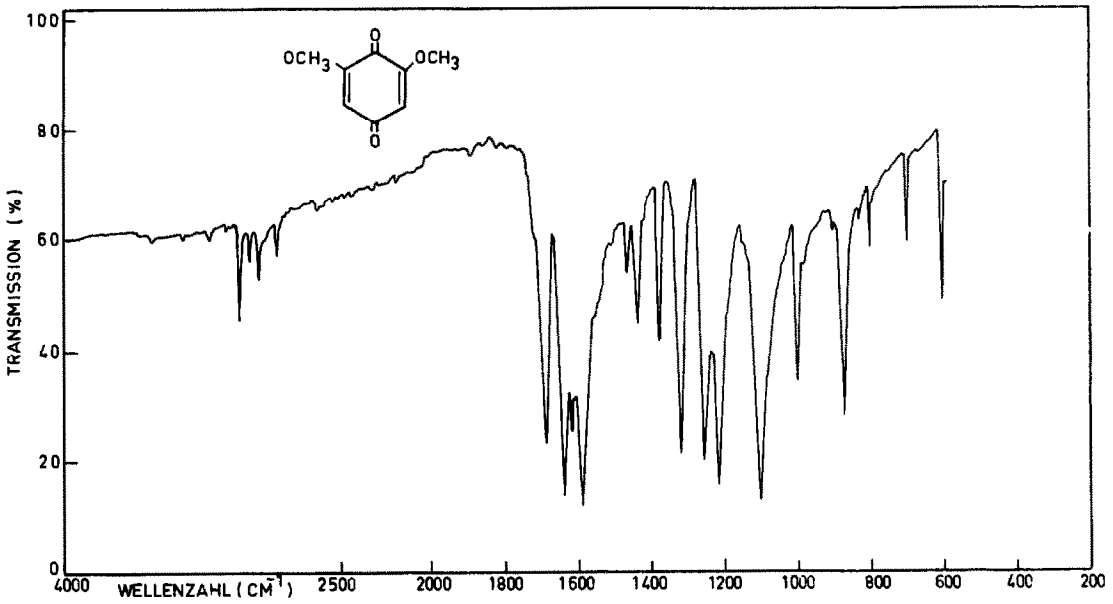

Fig. 1. IR spectrum of DMBQ (KBr disc).

All solvents and reagents were of analytical grade (Merck).

Pharmaceutical preparations

The following isoniazid commercial formulations were used:

(1)—Isocid tablets (CID, Egypt) contain 50 mg of isoniazid per tablet.

(2)—Isocid forte tablets (CID, Egypt) contain 200 mg of isoniazid per tablet.

(3)—Inhibex tablets (Misr, Egypt) contain 50 mg of isoniazid, 5 mg of nicotinamide and 5 mg of vitamin B_6 per tablet.

Method

Preparation of sample solutions. Isoniazid powder: Weigh 50 mg isoniazid and dissolve it in water and complete to 50 ml. Dilute this solution stepwise with water to obtain drug concentration 0.1 mg per ml. Use 1-ml aliquot of this solution for the procedure (fast red AL salt–isoniazid complex). For DMBQ–isoniazid

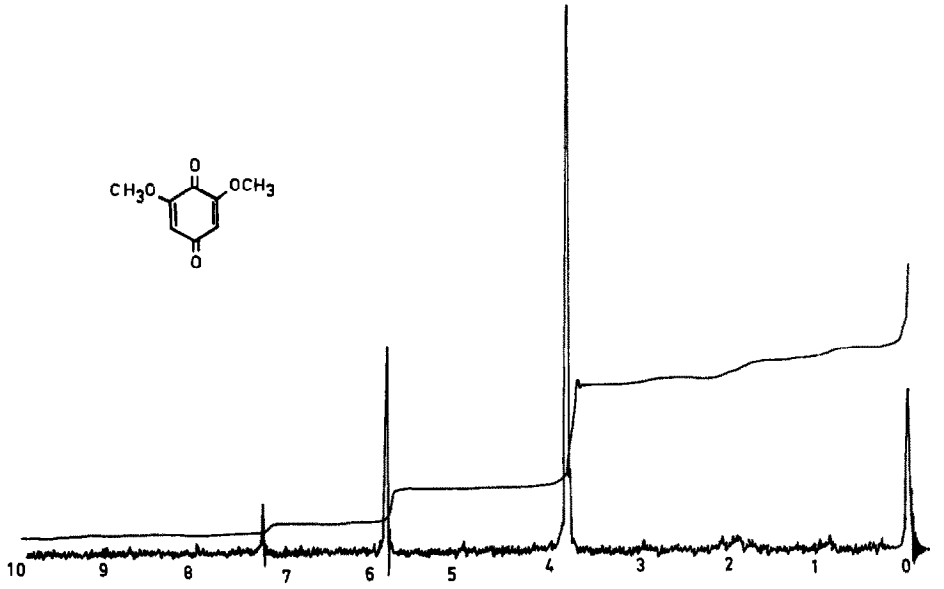

Fig. 2. ^{1}H-NMR spectrum of DMBQ.

complex; ethanolic solution of isoniazid was prepared similarly and diluted with the same solvent to obtain drug concentration 0.05 mg per ml. Use 1-ml aliquot of this solution for the procedure.

Tablets. Mix the contents of 20 tablets thoroughly. Weigh an amount equivalent to 50 mg of isoniazid into 50 ml calibrated flask, extract with 30 ml water (3 × 10 ml), filter and complete to 50 ml with water. Dilute this solution with water to contain 0.1 mg/ml of the drug. Use 1 ml of this solution for the procedure (for fast red AL salt–isoniazid complex). Similarly, for DMBQ–isoniazid complex, ethanolic solution of isoniazid tablets was diluted to obtain drug concentration 0.05 mg/ml and use 1 ml of this solution for the procedure.

Procedure

For fast red AL salt–isoniazid complex. To a 10 ml calibrated flask, add 1 ml of the sample solution, 2 ml of fast red AL salt solution, mix and stand for 10 min. Add 1.0 ml of sodium hydroxide solution (10% w/v). Make up to the mark with ethanol, mix and measure the absorbance at 510 nm against a reagent blank prepared similarly.

For DMBQ–isoniazid complex

Into 10 ml volumetric flask, transfer 1 ml of the sample solution, 1.5 ml of 2,6-dimethoxy-1,4-benzoquinone and 0.1 ml of sodium hydroxide solution (0.4% w/v). Mix the contents and leave for 10 min at room temperature (20 ± 3°C). Dilute the mixture to volume with ethanol and measure the absorbance at 655 nm against a reagent blank treated similarly.

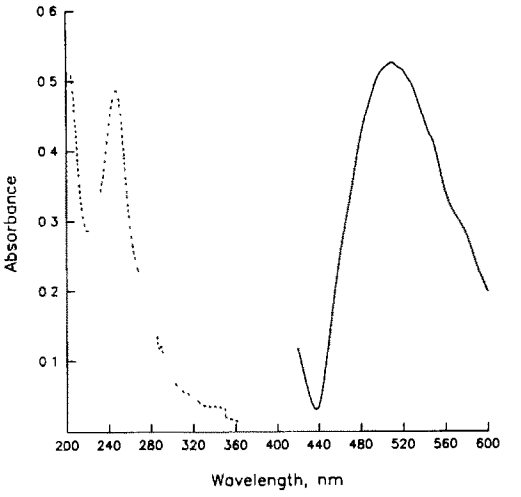

Fig. 3. Absorption spectra of fast red AL salt–isoniazid complex (——) and fast red AL salt (–·–·–), final drug concentration; 8.4 μg/ml.

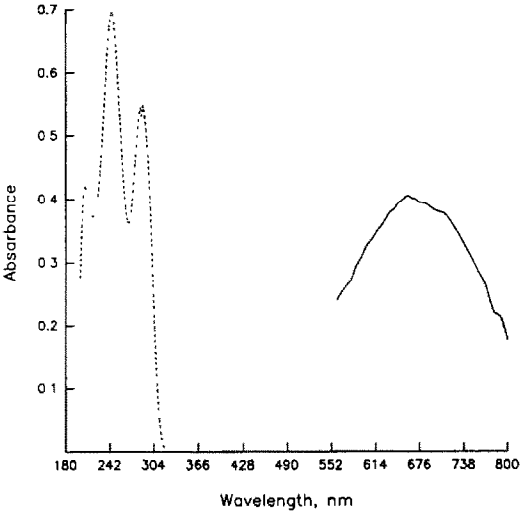

Fig. 4. Absorption spectra of DMBQ–isoniazid complex (——) and DMBQ (–·–·–), final drug concentration; 7 μg/ml.

RESULTS AND DISCUSSION

Absorption spectra

Isoniazid reacts with fast red AL salt in presence of sodium hydroxide in an aqueous ethanolic medium to form a red colour (λ_{max} 510 nm).

A green complex is formed when isoniazid is allowed to react with 2,6-dimethoxy-1,4-benzoquinone in presence of sodium hydroxide in an aqueous ethanolic solution. The absorption spectra of the two complexes are shown in Figs 3 and 4. Their spectral characteristics are summarized in Table 1.

Optimum conditions

To achieve maximum colour development, the reaction mixture of isoniazid and fast red AL salt must allowed to stand for 10 min before

Table 1. Spectral characteristics of the fast red AL salt–INH and DMBQ–INH complexes

addition of sodium hydroxide solution. The formed red colour was stable for 20 min at room temperature (20 ± 3°C) (Fig. 5). For complete formation of DMBQ–isoniazid complex, it is necessary to stand for 10 min, in presence of sodium hydroxide, before dilution. The maximum absorbance readings remain constant for ~20 min (Fig. 5).

It is clear from the data reported in Table 2 that isoniazid needs 2 ml of 0.2% fast red AL salt or 1.5 ml of 0.1% 2,6-dimethoxy-1,4-benzoquinone for the reactions to complete.

Different alkalies were tested for both methods, sodium hydroxide is the best one and 1 ml of 10% sodium hydroxide and 0.1 ml of 0.4% sodium hydroxide are recommended for the formation of fast red AL salt—isoniazid and DMBQ–isoniazid complexes, respectively (Table 3).

Methanol, ethanol, isopropanol, acetone, dimethyl formamide and dioxane were tested as diluting solvents in the two methods. The results revealed that ethanol was the best solvent (Table 4).

Interference

No interference was observed from the presence of other drugs, vitamins, commonly encountered excipients and additives when isoniazid was determined by the two methods (Table 5).

Quantification

Beer's law holds good over the ranges 2–15 and 1–10 μg/ml by fast red AL salt–INH and

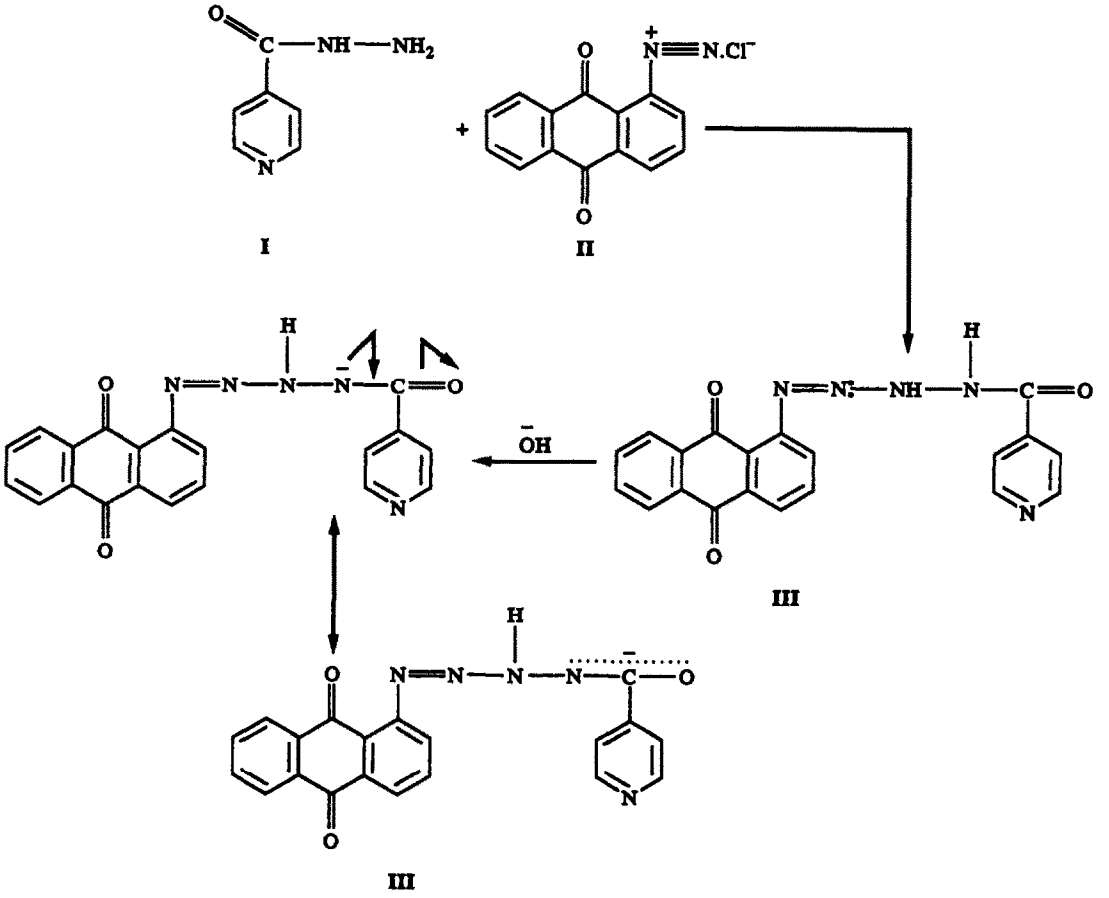
Applications

The proposed procedures were used to determine isoniazid in authentic and pharmaceutical



Scheme 1.

preparations. The results obtained are comparable to those given by the reported and official methods, Tables 6 and 7. Student *t*- and *F*-test show no significant differences between the proposed, and official methods. In addition, the suggested methods have the advantages of rapidity and simplicity.

Reaction involved

Fast red AL salt (I), in presence of sodium hydroxide, reacts with isoniazid (II) (molar ratio 1:1) to form a red colour with maximum absorption at 510 nm in aqueous ethanolic medium. The mechanism of the reaction may be interpreted as shown in Scheme 1.

A characteristic green coloured product (λ_{max} = 655 nm) is formed when isoniazid is allowed to react with DMBQ in presence of sodium hydroxide in aqueous medium. Under the experimental conditions, the suggestion that acid hydrazides form hydrazones with the carbonyl function of the reagent is excluded due to the failure of some aromatic amines, *e.g.* *p*-aminophenol, sulfonamide, dapsone, hydroxylamine and semicarbazide to give green colour with DMBQ. This negative response reveals that under a mild reaction condition no azomethine derivatives are formed.

However, quinones are easily reduced to hydroquinone derivatives by different reducing agents, *e.g.* hydrazine.[18,19] It was reported[18] that reduction of *p*-benzoquinone in alkaline medium give a deep green compound which formed from equimolar amount of *p*-benzoquinone and hydroquinone (charge-transfer or donor–acceptor complex).[18] In addition, it was reported[19] that aryl hydrazines are easily oxidized by benzoquinone (Q) to give aryldiimide and hydroquinone (QH_2)[19]

$$Ph\text{-}NHNH_2 + Q \rightarrow Ph\text{-}N = NH + QH_2$$

Moreover, isoniazid as hydrazine derivative can be attacked by oxidizing agents especially in presence of alkali solution.[18] Consequently the mechanism of formation of the green coloured product when isoniazid I reacts with DMBQ II may proceed through reduction of II into hydroquinone derivative III and formation of quinone: hydroquinone charge transfer or donor–acceptor complex IV (Scheme 2).

A preliminary chemical test to confirm the formation of hydroquinone derivative as a by-product was carried out by addition of few drops of ferric chloride T.S., disappearance of the green colour took place. This indicates the decomposition of the complex with oxidation of the hydroquinone derivative into 2,6-dimethoxy-1,4-benzoquinone with formation of a yellow colour.

In addition, the continuous molar variation for the reaction between isoniazid and DMBQ reveals that the interaction between these two compounds occurs at a ratio of 1:2. This provides further evidence for the suggested mechanism shown in Scheme 2. All attempts to separate the green coloured product IV failed.

PERFORMANCE OF AN ION TRAP MASS SPECTROMETER MODIFIED TO ACCEPT A DIRECT INSERTION MEMBRANE PROBE IN ANALYSIS OF LOW LEVEL POLLUTANTS IN WATER

SCOTT J. BAUER and R. GRAHAM COOKS
Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 17 *September* 1992. *Revised* 20 *November* 1992. *Accepted* 20 *November* 1992)

Summary—Modifications to a Finnigan ITS40 ion trap mass spectrometer are described which allow its use with a direct insertion probe. Details are given of the fabrication of a membrane probe for such an instrument. The membrane probe, which includes facilities for heating the fluid, employs a tubular membrane which is located just outside the electrode structure of the ion trap. Direct analysis of organic compounds in aqueous solution is demonstrated using a silicone membrane, with compounds such as benzene, chlorobenzene and dichloroethene being studied below the 1 ppb level. The effects of operating parameters including probe temperature, ion trap temperature, solution flow rate, mass spectrometer scan speed, and instrument tune procedures are explored in detail. Optimum performance characteristics are identified and trace level detection of eight organic compounds in the parts per trillion range is demonstrated. In seven of the eight cases studied, detection limits are below the EPA practical limit of quantitation levels. It is shown that the most sensitive mode of operation is when steady state passage of the analyte across the membrane is achieved, however, the time required for this is long in the case of some samples, and a dynamic flow injection analysis procedure is then favored. Use of the modified inlet system for solid sample introduction via a standard solids probe is also demonstrated.

The objective of this work was to develop an inexpensive mass spectrometer for use in screening organic compounds of environmental interest in drinking or ground water by membrane introduction mass spectrometry (MIMS).[1] It is well known that over 95% of the water samples that are tested in a typical environmental laboratory contain no detectable organic contaminants of environmental interest. However, verification of this requires the long and costly process of extracting 1–2 l. of water three times with either methylene chloride or diethyl ether, dehydration of the extract over sodium sulfate, evaporation of the extract in a Kuderna Danish apparatus down to 1 ml, solvent exchange to an appropriate GC medium such as hexane, and injection of the sample into a gas chromatograph for a 20–60 min temperature programmed run, depending on the analytes of interest.[2] The many steps involved in this process are costly in both material and manpower and are themselves potentially damaging to the environment through the loss and disposal of organic solvents. Clearly, a system that could effectively screen water samples for the presence of organic compounds by MIMS would be valuable since it would require that the traditional analysis be conducted only on the small fraction of the samples that were found to contain compounds of interest during the screening.

The direct analysis of organic pollutants in water by MIMS has been the subject of intense activity. Westover and co-workers detected and quantified organic analytes directly from aqueous solution using a silicone membrane probe coupled to their mass spectrometer in 1974.[3] Since then, many variations of the membrane inlet system have been applied to the task of analyzing a broad range of aqueous organic analytes at low detection limits.[4–10] Among the more successful methods, is the flow-through method in which a capillary or other membrane is placed within or in close proximity to the ion source of the mass spectrometer, and the aqueous solution is passed across this membrane.[9] In this type of procedure, transportation of the solution is conveniently done using a peristaltic pump and flow injection methods of sample handling extend to quantitation using external standard solutions.[9] In earlier experiments in this laboratory, a simple flow-though MIMS system was used with an ion trap and it gave encouraging results, even though the analyte was not heated and the probe was located some distance from

the ion trap electrodes.[8] In this as in most other MIMS work, silicone polymers were used since they allow passage of a large number of relatively non-polar organics into the spectrometer while excluding all but a trace of the water. The limitations of the silicone polymers to hydrophobic compounds of low molecular weight have led to the recent development of new MIMS techniques that allow the analysis of some polar organic compounds using microporous membranes.[11]

A Finnigan ITS40 ion trap GC/MS was chosen for this work because of its wide use, light weight, rugged construction and low cost. The ITS40 was modified to allow sample introduction via a standard 1/2 in. diameter direct insertion probe. A tubular membrane probe was constructed to allow organic analytes to be examined directly from aqueous solution. The inlet system was constructed in such a way that the gas chromatographic capability of the instrument was not compromised. Early experiments had demonstrated the need to place the membrane as close to the spectrometer source as possible, in order to minimize analyte loss through condensation or dilution in transfer lines, and to minimize memory effects and instability caused by contamination in the transfer lines.[12] When the probe is installed in the new inlet system, the membrane is positioned 1/2 in. from the ion trap providing greatly improved performance over earlier designs.

These modifications to the ITS40 allow it to be used in a number of applications that were previously the domain of much more expensive dedicated mass spectrometers. Such uses include analysis of industrial process and waste streams though flow injection analysis,[13] on-line monitoring of chemical reactions,[14,15] analysis of water samples for environmentally significant contaminants[8,16] and solid sample introduction by a direct insertion solids probe. The multiple capabilities of the modified instrument, coupled with its light weight and compact size, may also make it a viable choice for on-site environmental or industrial analysis.

EXPERIMENTAL

Ion trap modification

The ion trap was removed from the Finnigan ITS40 GC/MS and a 3/4 in. hole was bored through the instrument outer case. A KF-16 quick flange nipple was welded in place in the 3/4 in. hole. Viewed from the top of the instrument, the flange was located 72.8° counter clockwise from the GC inlet and located in such a way that the center was aligned vertically (along the z-axis) with the GC inlet line. This alignment was critical as the new entrance into the trap was designed to match the manufacturer's GC entry vertical dimensions and the rotation was necessary to avoid interference from the ion trap tie bolts. A flat stainless steel disk was welded into the end of the quick flange and a 5/32 in. hole drilled in it to accept and align a Teflon transfer line. A 5/32 in. hole was then drilled into the ion trap to provide an entrance for the Teflon transfer line between the ring electrode and the bottom endcap electrode. This hole was drilled in two parts to match the factory GC inlet location and required that 2/3 of the hold diameter be drilled through the stainless steel exit end cap and 1/3 of the hole diameter be located in the lower Teflon spacer ring. A Teflon transfer line was then fabricated to provide a direct analyte passage into the internal volume of the ion trap. The inner bore of the transfer line was threaded to facilitate its insertion and removal during maintenance. The existing manifold heating unit was also modified to accommodate the new inlet port. A 1 in. wide slot was cut into the bottom of the manifold that would allow the heating unit to be installed in its normal position with the new inlet in place. A Norcal bellows valve was installed with a 3/4 in. quick flange on one end and a 1/2 in. Cajon fitting on the other. This mated to the KF-16 flange on the ion trap manifold and also sealed the probe when inserted in the mass spectrometer. A 1/4 in. stainless steel line was welded in place just behind the Cajon fitting for inlet rough pumping controlled through a Nupro level valve. This completed the modification of the ion trap. The design is relatively simple but requires accurate machining to accomplish proper alignment of all the parts when assembled. Helium buffer gas is introduced into the trap through the GC transfer line and there is no need to disconnect the GC capillary when operating in the membrane introduction mode. This makes changing from GC operation to direct insertion probe operation a simple matter of inserting or removing the probe. Detailed blueprints and a description of the modifications are available.[17]

Membrane probe

The membrane probe was constructed according to the plan in Fig. 1. It is designed exclusively for capillary membranes but it accommodates a variety of lengths as might be dictated by future

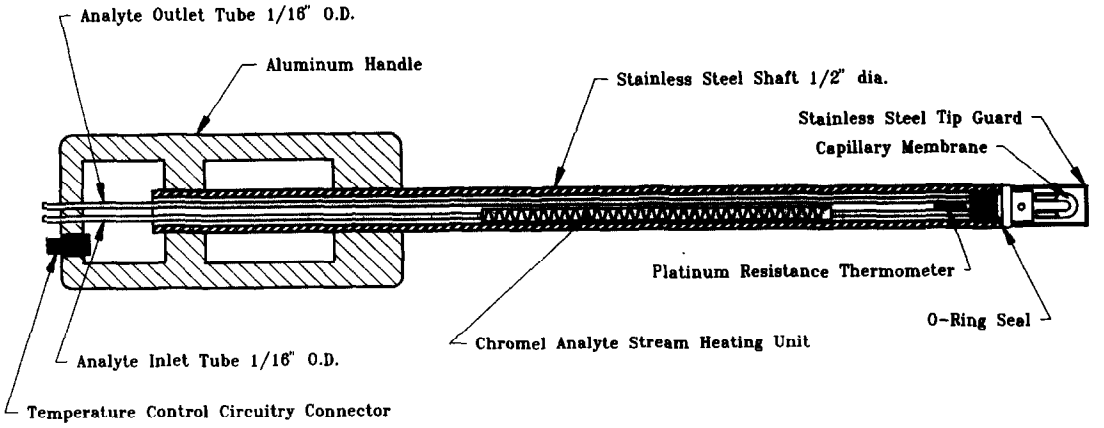

Fig. 1. Design of the tubular membrane probe.

experiments. The probe was constructed from an old Finnigan TSQ ion volume insertion tool. The inner parts were removed from the insertion tool and the end cut off. A probe tip was manufactured according to the plan in Fig. 1. The outer diameter of the probe tip matches the diameter of the probe tube to ease insertion through the inlet system Cajon fitting. Fluid transfer to the membrane is through two stainless steel 1/16 in. tubes welded into the back of the probe tip. Two 18 gauge needles were then welded into the end of the probe tip to accept the membrane tubing. A removable stainless steel guard was constructed to protect the membrane from damage when the probe is inserted into the instrument. A nichrome heating element and a platinum temperature sensor were installed on the inlet feed line to control the temperature of the inlet analyte stream. Electrical insulation between the heating element and the stainless steel inlet line was accomplished with Teflon shrink wrap applied to the tube surface. Heat insulation between the heating element and the internal wiring consisted of a layer of ceramic tape applied over the heating element which was covered in turn by a ceramic tube. All the internal wiring was routed to the probe handle end cap into a quick disconnect plug that matches the standard Finnigan solids probe heating controller. This control system was found to give fast heating and to result in stable temperatures over long periods of time. Passage of ana lyte through the membrane is strongly temperature dependent and small temperature fluctuations can cause baseline oscillations that may be unacceptable when doing trace analysis work.

Note that the design of the probe is such that it can be used in the modified ITS40 or also in any other spectrometer that will accept a 1/2 in. diameter probe. The probe length and electrical connections were also designed to provide maximum interchangeability.

With the probe installed in the ion trap as in Fig. 2, water is pumped through the probe by a

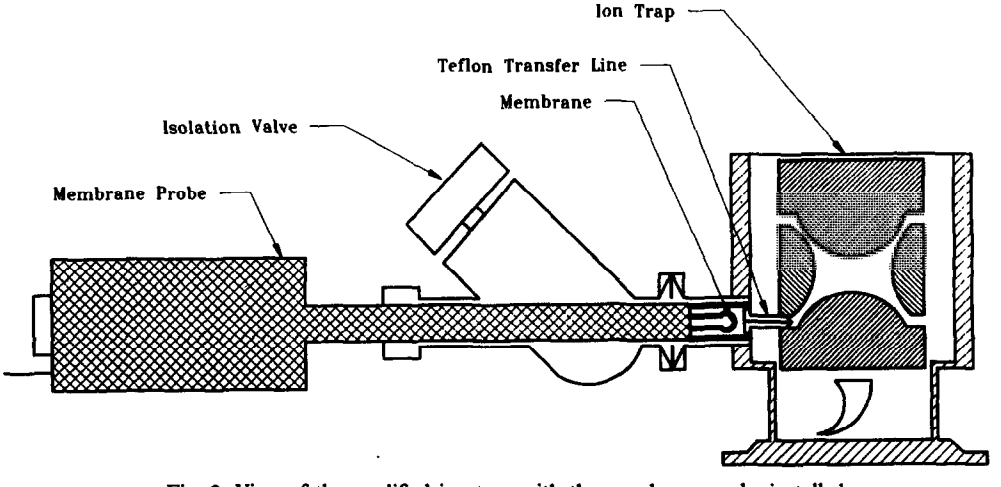

Fig. 2. View of the modified ion trap with the membrane probe installed.

peristaltic pump. Analyte solutions are injected into the mass spectrometer by simply switching the inlet line to the analyte solution. Note that the pump is located on the downstream side of the membrane probe and pulls water through the probe rather than pumping it through on the feed side. This was done as it was found that some compounds are adsorbed from solution by the tubing of the peristaltic pump itself. It was noted early in our experiments that more consistent results were obtained if the analyte stream did not pass through the pump on its way to the probe.[18]

Methods

Preliminary studies with the new membrane probe interface used a Dow Corning (Midland, MI) Medical Grade Silastic tubular membrane of 0.025 in. ID × 0.047 in. OD. The membrane was installed on the probe with approximately 1/2 in. exposed length. Instrument performance checks were made with aqueous solutions of three different organic compounds with different physical properties in order to assure that any results obtained were not compound specific. The analytes selected were benzene (860 pptr), THF (516 ppb), and *trans*-dichloroethene (8.8 ppb). Instrument parameters were varied to identify the optimum operating conditions, that is those where sensitivity was maximized and noise was minimized. The main factors explored systematically were:

1. Probe temperature.
2. Ion trap temperature.
3. Flow rate.
4. Scan rate.
5. Instrument tune parameters.

Trace analysis of several compounds was at- tempted using the optimized parameters identified in the performance studies. For the trace analysis work the following conditions were used: probe temperature 30°C, trap temperature 50°C, and solution flow rate 2 ml/min. The mass spectrometer was operated so as to scan a single diagnostic ion at 1 sec/scan, and helium buffer gas was introduced into the ion trap at a rate optimized during the tuning procedure. Most experiments were conducted by recording 600 scans, where the baseline was first recorded for 150 scans, the analyte solution was then injected for 250 scans to obtain a stable maximum signal, and the system was allowed to return to baseline conditions over the next 200 scans. We used single ion scans only to conserve disk space due to the large number of scans recorded per experiment. The large number of scans were required to cover the time period necessary for the analyte to reach its equilibrium flow rate through the membrane where the maximum response is obtained. Full spectra were obtained in later experiments to compare instrument performance. All analyte solutions were made up using reagent grade chemicals. Solutions were prepared in de-ionized water by weight and diluted to part per billion or part per trillion levels by serial dilutions. Duplicate tests were performed on separate days using freshly prepared solutions to verify the results. Tests of the probe interface were also done using a Finnigan solids probe operated at room temperature. Solid samples of acridine, phenanthridine, and 7,8-benzoquinoline were examined.

RESULTS AND DISCUSSION

Membrane probe performance

Initial tests were performed to identify optimum operating conditions for the analysis of aqueous solutions of organic analytes using the membrane probe. It was found that several operating parameters for the ion trap were quite different from those appropriate for membrane introduction into quadrupole instruments.[9] The main factors that affected performance in the analysis of aqueous organic analytes at low levels using the ITS40 are outlined below.

Probe temperature. The signal-to-noise ratio was found to be strongly dependent on the temperature of the analyte stream passing through the membrane probe. Temperature effects had been demonstrated previously on a triple quadrupole mass spectrometer,[5,8,18] where it was found that the analyte signal is enhanced at higher temperatures. Bier *et al.* demonstrated that as the temperature of the probe was raised more analyte passed through the membrane and signal was enhanced right up to a temperature of 100°C.[19] Surprisingly, in the case of the ion trap mass spectrometer, the temperature dependence is inverted. As the temperature was raised the signal-to-noise ratio decreased. Figure 3 shows how the signal-to-noise ratio depends on probe temperature over the range from 30 to 70°C. The experiment was done by monitoring the molecular ions of benzene, tetrahydrofuran (THF), and *trans*-dichloroethene (DCE) near the detection limits. All three compounds displayed substantial gains in S/N ratio at lower temperatures. As an illustration of the

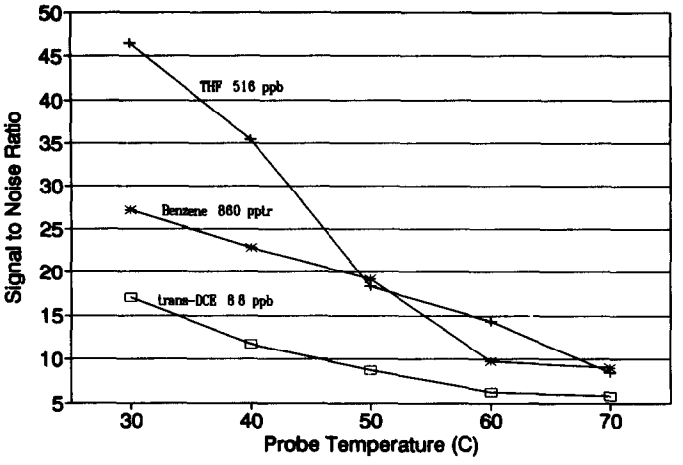

Fig. 3. Graph showing the signal-to-noise (S/N) for low level aqueous solutions as a function of probe temperature.

the raw data, Fig. 4 shows the ion current profiles recorded when monitoring m/z 78 from benzene at five temperatures. The inverse temperature dependence found for the ion trap spectrometer is due to the way the spectrometer handles ions compared to the quadrupole spectrometers. In the case of the quadrupole spectrometer, the ions pass immediately through the spectrometer and are pumped away as they are formed. A higher probe temperature increases the flow of analyte across the membrane and signal is enhanced. The increased flow of water that accompanies the analyte across the membrane is pumped away and does not interfere with the detection process. In the ion trap however, the ions are trapped as they are formed and a significant amount of the water that passes through the membrane with the analyte is also ionized and trapped. In this case the excess water at higher temperatures significantly interferes with detection of analyte ions as the instrument automatic gain control function decreases the ionization time to maintain a constant ion population. The high water ion concentration would otherwise result in space charging conditions with loss in sensitivity and resolution. Not only the rate of water passage but the rate of analyte diffusion through the membrane depends strongly on the probe temperature. Figure 5 displays this effect by plotting the time required to achieve maximum signal *vs.* probe temperature. Benzene and *trans*-dichloro- ethene diffusion rates are affected minimally as the time to maximum signal only differs by approximately 100 seconds between 30 and 70°C. THF on the other hand is affected dramatically. The time to reach maximum signal for THF at 30°C was 625 sec compared to 165 sec at 70°C. The result of this was the need for an extraordinarily long analysis time for the THF solution at 30°C, the temperature one would prefer to use in order to minimize contributions from water. Figure 6 shows the ion current profile for the response of the molecular ion of THF at temperatures between 30 and 70°C. All the ion current profiles in Fig. 6 are on the same time scale and the analysis of THF at 30°C requires nearly 30 min compared to less than 10 min at 70°C. Analysis-can be done by establishing a stable baseline, injecting the analyte until the maximum signal

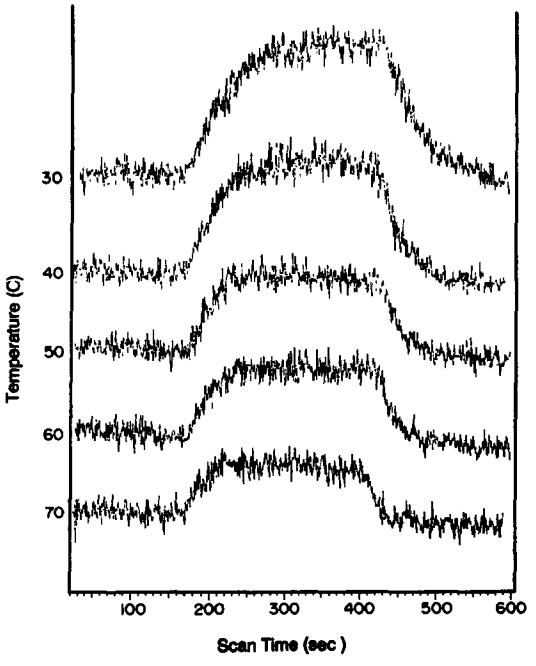

Fig. 4. Ion current profiles for m/z 78 for a 860 ppt benzene solution at probe temperatures of 30–70°C.

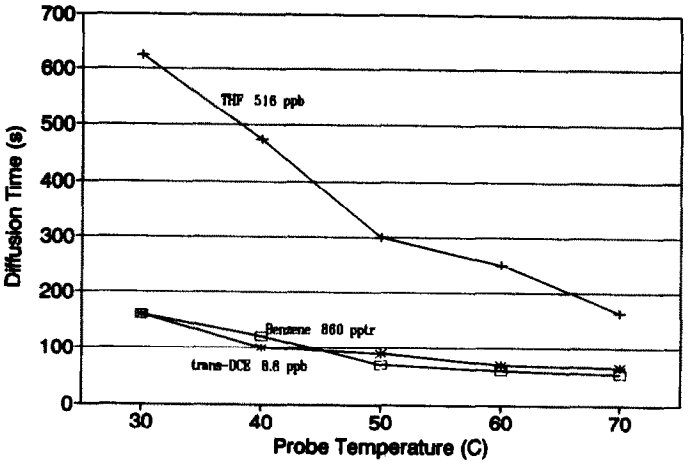

Fig. 5. Dependence of the analyte diffusion rate through the membrane on the probe temperature.

is reached and then examining the return to baseline conditions after the analyte solution is replaced by water. The minimum detection limits are estalished in this way. Using flow injection, analytes can also be quantitated without reaching the maximum response but concentrations must then be higher to obtain a measurable baseline deflection that can be compared to a standard. Clearly the type of compound analyzed must be considered when selecting the probe temperature and a balance must be struck between the desire to reach the lowest detection limits and the need for rapid quantitative analysis.

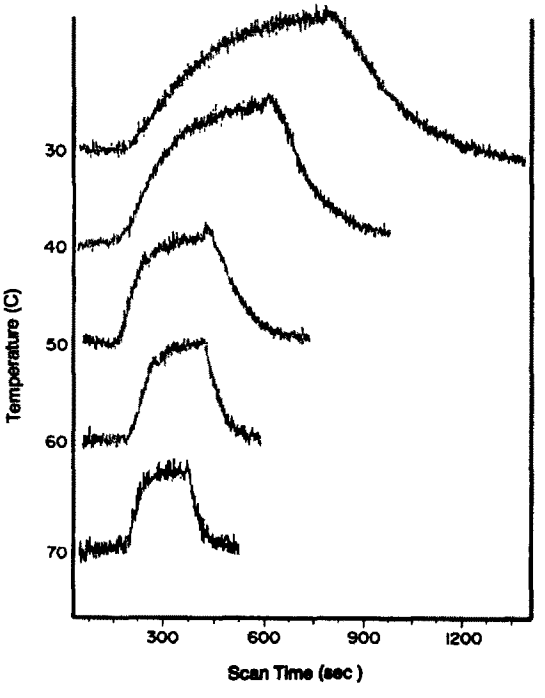

Fig. 6. Ion current profiles for m/z 82 for 516 ppb THF solution showing the time required to reach maximum signal at temperatures ranging from 30 to 70°C.

Ion trap temperature. In addition to the effects of probe temperature, the signal-to-noise depends on the ion trap temperature. Again the best signal-to-noise ratio was obtained at lower temperatures. Figure 7 plots the measured signal to noise ratios *vs.* ion trap temperature for the three test solutions 516 ppb THF, 860 pptr benzene, and 8.8 ppb *trans*-dichloroethene. All three compounds showed an increase in signal-to-noise ratio at lower temperatures. The S/N gains associated with changes in the temperature of the ion trap are not as dramatic as those associated with probe temperature but are significant and probably arise from the same cause. For the trace analysis studies reported in this paper, we chose a trap temperature of 50°C. This seemed to be a good low temperature where we could take advantage of the S/N enhancement without totally sacrificing the advantage of higher temperatures in desorbing contaminants that collect on the inner surfaces during routing use.

Analyte flow rate. The flow rate of the analyte solution through the membrane probe has an impact on the ability to detect analytes at very low concentrations. High flow rates deliver a higher number of analyte molecules to the inner surface of the membrane per unit time and signal is enhanced. Figure 8 shows how the S/N ratio changes with flow rate for a 500 pptr solution of chlorobenzene. The ratio is maximized at 3 ml/min. The flow rate enhancement undoubtedly depends on the nature of the analyte molecule and therefore will differ somewhat for different classes of molecules. We chose a standard flow rate of 2 ml/min for the trace analysis work as

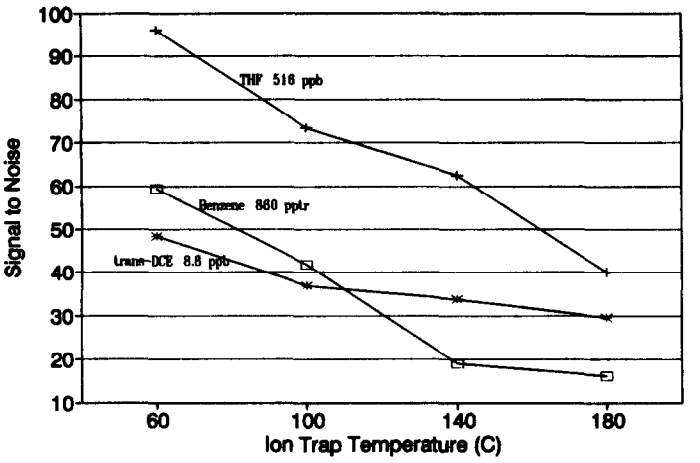

Fig. 7. The effect of ion trap temperature on the S/N ratio for the molecular ions of benzene, dichloroethene (DCE), and tetrahydrofuran (THF) at low levels in water.

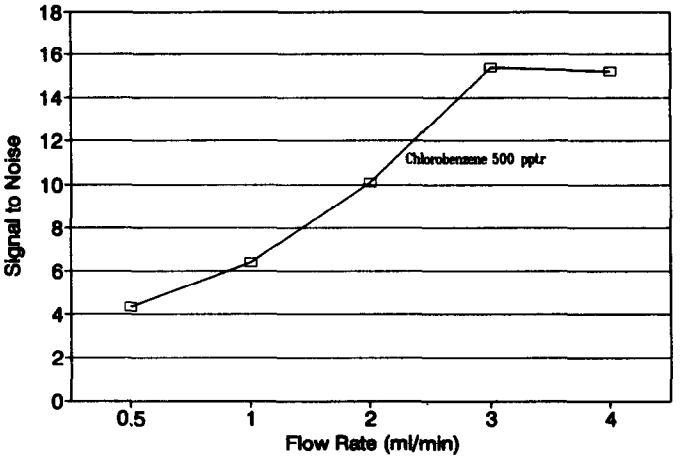

Fig. 8. The effect of analyte flow rate on S/N ratio for chlorobenzene (500 pptr in water).

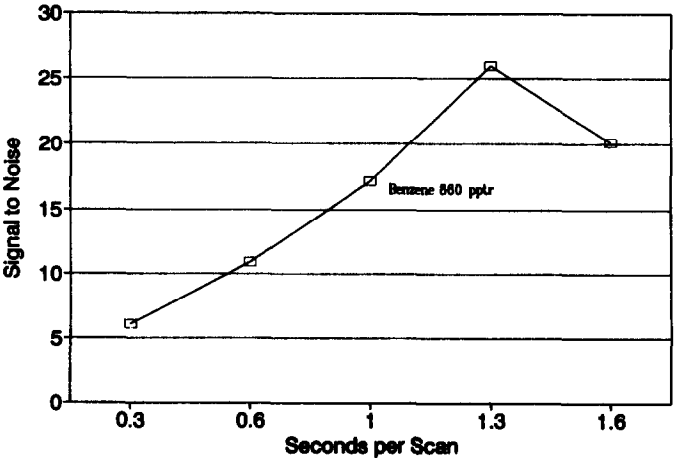

Fig. 9. The effect of scan speed on the S/N ratio for the molecular ion of benzene (860 pptr in water).

this seemed to provide good results for a wide range of organic analytes.

Scan speed. It was found that a mass spectrum scan rate such that a single ion scan at a rate of 1.3 sec per scan produced the most stable baseline. Figure 9 displays the effects of scan speed *vs.* signal-to-noise ratio for single ion monitoring of m/z 78 from a 860 pptr aqueous benzene sample.

Instrument tune factors. It was found that the instrument auto-tune set up conditions were not suitable for MIMS work and manual tuning had to be performed to optimize the results. Some of the manual tune factors changed slightly from day to day as would be expected under normal running conditions to achieve suitable peak shapes and mass assignments, but others were constant from day to day. Among these were segment RF settings which had to be set to 250 for all four segments with automatic gain control (AGC) in operation so that masses below 40 amu were continually swept from the trap. This eliminated much but not all of the very large ion load imposed on the trap by the presence of water which passes through the membrane continually. Other tune criteria, such as AGC prescan factors, AGC target values, and multiplier voltage, were set daily according to the needs of the experiment being run. These factors were optimized to provide maximum signal strength without inducing space charge effects in the trap. It was found that the best conditions were obtained in the shortest period of time if the instrument was tuned to FC-43 with the helium buffer gas on and the probe inserted in the instrument with deionized water running through it at the desired temperature.

Trace analysis of organic compounds in aqueous solution

Using the optimum conditions identified in the performance studies, we analyzed five organic analytes in aqueous solution in the parts per trillion range. Table 1 lists the analytes and their associated detection limits. The detection limits are based on a signal-to-noise ratio of three at maximum signal for the ion current obtained for the diagnostic ion of the analyte. The table also shows the practical quantitation limits (PQL) according to the EPA ground water monitoring list.[20] PQLs are the lowest concentrations of analytes in ground waters that can be reliably determined within specified limits of precision and accuracy by standard methods under routine laboratory operating conditions. Using these values as a guide, seven of the eight compounds tested were detected below the PQL. While the PQL provides a low limit goal that one may

Table 1. Detection limits for aqueous solutions obtained using the modified ITS40 MIMS system

Analyte	Detection limit (ppb)	EPA PQL (ppb)
Benzene	0.21	2
Trichlorofluoromethane	0.60	10
Chlorobenzene	0.16	2
trans-Dichloroetheane	0.81	1
Chloroform	0.58	0.5

Hexachloroethane	0.28	0.5
Carbon tetrachloride	0.60	1

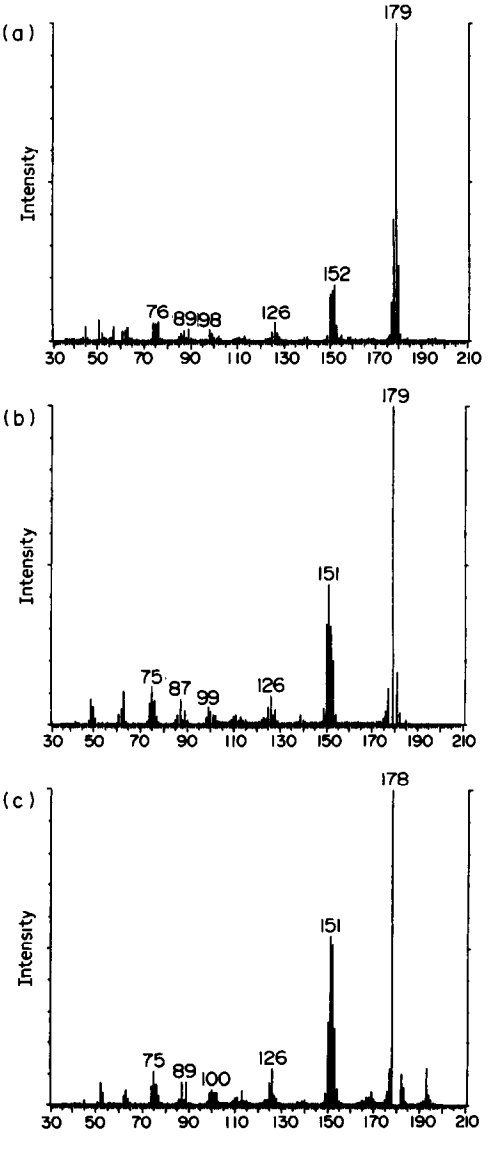

Fig. 10. Mass spectra obtained in the solids probe experiments using (a) phenanthridine, (b) 7,8-benzoquinoline and (c) acridine.

want to equal or exceed in experimental studies with new analytical methods, a more realistic question is whether or not a new method is applicable to routine daily analysis. The focus of routine work in a water quality laboratory is in assurance that the water sample being tested is free of contaminants above the maximum contamination level (MCL). The MCL in many cases is a regulatory limit that is often orders of magnitude greater than the PQL. Clearly this MIMS instrument has the ability to act as a very effective screening system for environmental or industrial applications.

Solids probe experiments

The modified inlet system was tested for its applicability to the analysis of solid samples using a standard solids probe. The experiment examined the fragmentation pathways of three isomeric compounds phenanthridine, acridine, and 7,8-benzoquinoline. The probe was operated at room temperature which provided a rate of sample vaporization which was large enough to necessitate lowering of the AGC target value to 1000 in order to avoid resolution losses due to trap overload. The system was therefore surprisingly sensitive in solid sample analysis. Figure 10 displays the mass spectra for the three compounds. The results of this experiment indicate that this inlet system may be used very effectively as a solid sample analysis system. The solids probe could be heated if necessary using the same temperature control system we use for the membrane probe as the heating and control circuits in the membrane probe were designed to match those of the standard Finnigan solids probe.

CONCLUSION

The experiments done here indicate that a simple quadrupole ion trap, after a few relatively simple modifications, can be used very effectively as a membrane introduction mass spectrometer. The instrument is also useful for analysis of solid samples and the modifications do not affect the original utility as a gas chromatograph/mass spectrometer. Remarkably good performance, including detection limits below 1 ppb, is achieved in the analysis of trace organic pollutants in water. The performance tests indicate that the operating conditions must be selected carefully to optimize analysis time and detection limits according to the type of compounds tested.

An instrument such as this could be used for rapid low-level screening of water samples by membrane introduction mass spectrometry. The size and weight of the instrument make *in situ* analysis a distinct possibility. One limitation in the dissemination of techniques based on MIMS is the need for new EPA standard methods which use this technology. The advent of new membrane materials that are more selective toward specific classes of compounds should improve performance further. Tests are underway in this laboratory to identify other useful membrane materials and to expand the list of compounds that can be analyzed at detection limits comparable with those achieved by existing purge and trap and other EPA methods.

STUDY ON CATALYTIC FLUORIMETRIC DETERMINATION OF TRACE MANGANESE

GUIEN ZHANG, DING XI CHENG and SULING FENG
Department of Chemistry, Henan Normal University, Henan XiXiang 453002, People's Republic of China

(*Received* 14 *September* 1992. *Accepted* 14 *November* 1992)

Summary—A new kinetic fluorimetric method has been proposed for the determination of trace manganese. The method is based on the catalytic oxidation of rhodamine 6G with potassium periodate in the presence of nitrilo triacetic acid as activator, in near neutral media. The detection limit for manganese is 0.018 ng/ml. The linear range of the determination is 0.04–1.00 ng/ml. The proposed method suffers from few interferences in the presence of more than 30 foreign ions. The method has been used to determine trace manganese in hair, urine, fish and water samples. The results are satisfactory.

INTRODUCTION

There have been reports on the determination of manganese by catalytic fluorimetric photometry [1–7], mainly based on the catalytic fluorimetric reaction with alkaline, hydrogen peroxide or dissolved oxygen as oxidants, but the sensitivity has been unsatisfactory. Some reports on catalytic fluorimetry with potassium periodate as oxidizing agent in acid medium, list higher sensitivity, but interference is more serious. So far there has been no report on the determination of manganese by catalytic fluorometry using rhodamine 6G in a neutral medium.

In our experiments, we use nitrilo triacetic acid as activator in near neutral medium, and manganese catalyzes potassium periodate oxidation of rhodamine 6G to produce fluorescence. On the basis of this, a detailed study of appropriate conditions for the indicated reaction was conducted, and the best reagent doses were determined according to the controlled and weighed centroile simplex method. We measured fluorescence at a fixed time and found a new way to determine manganese content with high sensitivity and high selectivity, the detection limit being 1.8×10^{-2} ng/ml and the linear range 0.04–1.00 ng/ml. Generally, common ions did not interfere with the determination. Satisfactory results have been achieved in the determination of the manganese content in biological specimens, human hair and urine, fish and water samples.

EXPERIMENTAL

Reagents and instruments

Standard manganese solution: dissolve 0.3904 g manganese sulfate monohydrate in water and dilute to 100 ml. The solution contains 1.006 mg/ml manganese and should be properly diluted as required before use.

Potassium dihydrogen phosphate-sodium hydroxide buffer solution, pH 6.8. Dissolve 1.36 g potassium dihydrogen-phosphate in 150 ml water, then use 0.2*M* sodium hydroxide solution to adjust the pH to 6.8 and dilute with water to 200 ml.

Nitrilo triacetic acid (NTA) solution: $5.0 \times 10^{-3}M$;
Rhodamine 6G solution: $1.0 \times 10^{-4}M$;
Potassium periodate solution: $5.0 \times 10^{-4}M$;
Mixed solution of three acids: (HNO_3:H_2SO_4:$HClO_4$ = 10:1:4);
RF-540 fluorophotometer;
Model 930 fluorophotometer;
Model 501 super constant temperature meter;
PH S-2 acidimeter.

All the reagents for the experiment were analytical reagent grade or guaranteed, and redistilled water was used to prepare solutions.

Procedure

Add 2.70 ml of pH 6.8 buffer solution, 2.35 ml of $5.0 \times 10^{-3}M$ nitrilo triacetic acid and

0.32 ml of $1.0 \times 10^{-4}M$ rhodamine 6G to a 25 ml measuring flask, add water up to 20 ml, and shake well. Then add 2.85 ml of $5.0 \times 10^{-4}M$ potassium periodate and the proper amount of standard manganese solution into the flask, dilute up to the mark before shaking, and heat in a thermostatted water bath (70 ± 0.2°C) for 10 min. Then cool the solution to room temperature with flowing water for 3 min, and determine its fluorescence value F with a fluorimeter, with an excitation wavelength of 348.4 nm and an emission wavelength of 548.3 nm.

RESULTS AND DISCUSSION

Rhodamine 6G is a triphenylmenthane dye and emits very strong yellow–green fluorescent light. When oxidized by such strong oxidizers as potassium periodate, its molecular structure is destroyed and the fluorescence disappears, but the reaction is very slow due to the difficulty of direct electron acceptance and the effect of steric hindrance. When trace manganese exists in the system, the reaction speeds up, illustrating that manganese catalyzes the reaction of potassium periodate with Rhodamine 6G. When activator nitrilo triacetic acid exists, the reaction accelerates very quickly, as shown in Fig. 1. On the basis of this, we have further studied the experimental conditions for the determination of trace manganese.

[Mn(II)] = 10.06 ng/ml
1–1′: Rh 6G aqueous solution;
2–2′: KH_2PO_4–NaOH, Rh 6G;
3–3′: KH_2PO_4–NaOH, NTA, Rh 6G;
4–4′: KH_2PO_4–NaOH, NTA, KIO_4, Mn(II);
5–5′: KH_2PO_4–NaOH, Rh 6G, KIO_4;
6–6′: KH_2PO_4–NaOH, Rh 6G, KIO_4, MN(II);
7–7′: KH_2PO_4–NaOH, NTA, Rh 6G, KIO_4;
8–8′: KH_2PO_4–NaOH, NTA, Rh 6G, KIO_4 Mn(II).

Choice of the best experimental conditions (with manganese concentration being 0.40 ng/ml under all conditions)

Influence of the property and acidity of the buffer solution. Having compared the five buffer solutions of tartaric acid–sodium tartrate, acetic acid–sodium acetate, potassium hydrogen phthalate–hydrochloric acid, potassium hydrogen phthalate–sodium hydroxide, potassium dihydrogen phosphate–sodium hydroxide, we have found that among the buffer medium of tartaric acid–sodium tartrate, manganese can hardly catalyze the reaction of potassium periodate oxidization of rhodamine 6G, probably because the complexation of tartrate with manganese makes manganese lose its catalytic activity. Among the buffer medium of acetic acid–sodium acetate, the reagent blank fades quickly, *i.e.*, the background value of the uncatalyzed reaction is very high, which makes it hard to accurately determined the result of the experiment and is not fit for practical analysis. Potassium hydrogen phthalate–hydrochloric acid, potassium hydrogen phthalate–sodium hydroxide and potassium dihydrogen phosphate–sodium hydroxide have about the same property. The background values of their uncatalyzed reactions are very low and the

Table 1. Simplex shifting process

Point number	Retention point	Simplex shifting mode	Simplex number	KH_2PO_4–NaHO *ml*	NTA *ml*	Rh6G *ml*	KIO_4 *ml*	ΔIF
1				3.10	3.10	0.38	3.10	15
2				1.90	3.10	0.38	3.10	11
3				2.50	1.90	0.38	3.10	16
4				2.50	2.50	0.22	3.10	15
5			1	2.50	2.50	0.30	1.90	17
6	5, 3, 4, 1, 2	reflection	2	3.35	1.90	0.26	2.60	12
6′	5, 3, 4, 1, 2	contraction	2′	3.00	2.20	0.29	2.72	17
7	5, 6′, 4, 3, 1	reflection	3	2.10	1.40	0.22	2.55	14
7′	5, 6′, 3, 4, 1	contraction	3′	2.84	2.68	0.34	2.96	16
8	5, 6′, 3, 7′, 4	reflection	4	2.94	2.16	0.42	4.0	12
8′	5, 6′, 3, 7′, 4	reflection	4′	2.61	2.42	0.27	2.42	18
9	8′, 5, 6′, 3, 7′		5	2.69	2.34	0.32	2.86	20

measurement sensitivity is high. With these solutions, a series of buffer solutions of different acidity with pH = 2.0–8.0, respectively, were prepared, and with their reagent blanks as references, experimental responses at different pH values were measured, and the results are shown in Fig. 2. From Fig. 2 it can be seen that when the heating time is fixed at 10 min, there are three plateaus appearing with increasing pH value on the ΔIF acidity curve, and the third plateau has the highest test sensitivity, with the relative pH value being 6.6–7.0 in the potassium dihydrogen phosphate–sodium hydroxide system. So potassium dihydrogen phosphate–sodium hydroxide buffer solution with pH = 6.8 is the best choice.

Choice of activator. The study of the influence of the 8 complexing agents—nitrilo triacetic acid, triethylenetetramine, triethanolamine, tetraethylenepentamine, EDTA, 8-hydroxyquiroline, thiourea, and phenanthroline upon the catalytic system shows that only nitrilo triacetic acid and phenanthroline can serve as activators and nitrilo triacetic acid does better and brings about better results. It is our best choice for activating agent.

Choice of the best dose of different reagents by controlled and weighted centroid simplex method. On the basis of conditional experiment 1 and 2, we experimented with the proper dose of buffer solutions, nitrilo triacetic acid, rhodamine 6G and potassium periodate, and determined the scope of their dose before choosing the best dose by controlled and weighted centroid simplex method. Simplex shifting was conducted 12 times, as shown in Table 1.

When simplex shifting reached 8′, it would meet the expected requirement, the relative deviation of the experiment response value of the five retention points was $R = 4.6\% < 5\%$, and the process stopped, with 9 being centroid of the five retention points.

Influence of reaction temperature. The system is very sensitive to the temperature change. Low temperature results in very slow catalyzed and uncatalyzed reactions. With the temperature increasing, the catalyzed reaction speeds up and ΔIF value increases with the rise of temperature from 45°C to 70°C. When the temperature is higher than 70°C, the uncatalyzed reaction speeds up as well, and is even faster than catalyzed reaction. ΔIF value drops more than at 70°C and analytical sensitivity decreases. For the results see Fig. 3. So the reaction temperature was fixed at 70°C and a model 501 super constant temperature meter was used to control temperature.

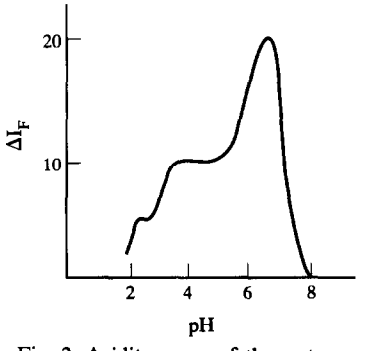

Fig. 2. Acidity curve of the system.

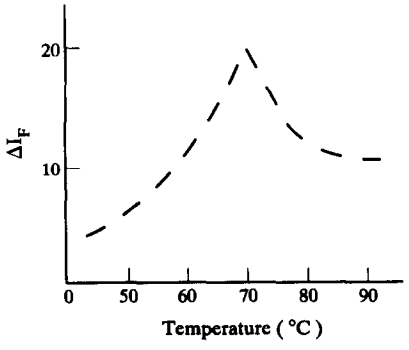

Fig. 3. Influence of temperature upon fluorescence intensity.

Influence of reaction time. After the study of influence of reaction time upon fluorescence intensity (with relevant reagent blank as reference), as shown in Fig. 4, it can be seen that between 2 and 12 min ΔIF–t is of linear relation and 10 min is taken as the reaction time.

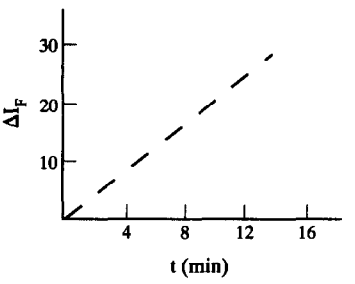

Fig. 4. ΔIF-Reaction time curve of the system.

Relation between manganese and IF

According to the described experiment method, we determined the value of fluorescence intensity IF (with manganese concentration being 0.04–1.20 ng/ml) and found the calibration graph, as shown in Fig. 5. It can be seen that within the scope of 0.04–1.0 ng/ml, IF value and manganese concentration suggest a linear relation, with the linear regression equation being $IF = 100.03 - 49.07x$ and correlation coefficient $r = 0.9999$.

Coexistence ions' interference

Under the chosen experiment condition, an interference experiment was conducted on more than 30 common ions. When the permitted relative deviation from the IF value is $\pm 5\%$, the interference is as listed in Table 2.

Sensitivity and accuracy of the method

Eleven parallel experiments were made on the following test solutions. The results are as follows:

IF value of reagent blank test: 99.6, 99.3, 100.0, 99.3, 100.4, 99.8, 100.3, 100.5, 100.0, 100.4, 99.7, standard deviation SD = 0.29, detection limit: 0.018 ng/ml.

Measured IF value of 0.40 ng/ml manganese: 80.6, 80.3, 80.2, 79.5, 80.6, 80.5, 81.0, 80.2, 80.8, 80.1, 79.9, standard deviation: 0.43, of coefficient of variation 2.2%.

Measured IF value of 0.80 ng/ml manganese: 62.3, 60.9, 61.0, 60.6, 61.2, 60.8, 60.0, 60.3, 60.1, 60.2, 61.4, standard deviation: 0.67, coefficient of variation: 1.7%.

Sample analysis

Determination of trace manganese in human hair. Get some hair cut from hind-brain scalp, have it soaked in 3% "White Cat" Brand detergent for 30 minutes, well stirred, washed clean in deionized water, baked dry under infrared lamp, and cut it into 0.5–1 cm segments with stainless steel blade. Take 0.3 g of this sample, put it into a 50 ml dry beaker before adding 5.0 ml mixed acid (HNO_3:$HClO_4$ = 3:5), cover it with a surface dish, put the beaker in a vent cabinet and keep it there overnight, then have it resolved for 40 minutes at a low temperature the next day. Remove the surface dish and heat it until almost dry at a low temperature (to get rid of the excess mixed acid), shift it into a 50 ml measuring flask, have it water-diluted to the mark (at this time the solution becomes transparent). At the same time a blank test is conducted. Take 0.50–1.00 ml aliquots of this sample solution into a 25 ml measuring flask and have the solution adjusted into neutral solution with 0.02M sodium hydroxide solution, determine the IF value using the experiment method. Ascertain the Mn(II) content from the calibration graph accordingly. After subtracting the reagent blank, convert it into manganese content in the sample and do recovery test for the results (see Tables 3 and 4).

Determination of trace manganese in human urine. Get 25.00 ml morning urine, have it digested, shifted into a 25 ml measuring flask, and water-diluted to the mark. Then get 2.5 ml and put it into another 25 ml measuring flask, have it adjusted to the neutral with 0.2M sodium hydroxide solution, determine the fluorescence intensity IF value using the experiment method, at the same time conduct a blank test, deduct the blank value, work out manganese content in the urine sample and do addition recovery test. The result is shown in Tables 5 and 6.

Determination of manganese content in skinned fish. Get 50 g skinned fish baked for

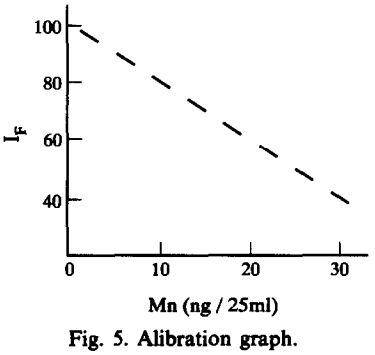

Fig. 5. Alibration graph.

let it stay overnight—for cold nitrification, then raise the temperature for high temperature nitrification. When solid granules are digested, take the flask out for cooling, then add 10 ml triple acid mixed nitrified solution for 2 hours at a low temperature digestion until a lot of white smog appears. This is followed by high temperature heating until digested liquid becomes colorless, transparent wet-salted state. After that, get it cooled, dissolved with hot distilled water and filtered into a 50 ml measuring flask, washed three times with hot distilled water until the filtrate is about 50 ml. Then have it diluted up to the mark with distilled water and well shaken for future use. For measurement, dilute the solution 10-fold (blank test is conducted at the same time).

Take 1.00 ml of the sample solution and empty it into a 25 ml measuring flask, adjust it to the neutral with 0.2*M* sodium hydroxide solution and determine its fluorescence intensity IF value using the experiment method. The result is shown in Table 7. Perform the standard addition-recovery test, for the result, see Table 8.

Determination of trace manganese in running water. Get 1.00 ml sample running water (two parallel portions), put it into a 25 ml measuring flask, determine the fluorescence intensity IF value using the experiment method and conduct addition-recovery experiment. The results are shown in Tables 9 and 10.

Study on kinetic character of the system

Determination of the reaction order. When choosing the best condition for the experiment, we drew Fig. 4 indicating the reaction system, from which it can be seen that when $t = 2$–12 min, ΔIF-t is of linear relation, and within this period the catalytic system can be regarded as pseudo-zero order reaction.

Determination of apparent activation energy of the catalyzed reaction. The determination of apparent activation energy of catalyzed reaction is mainly based on Arrhenius' equation:

$$K_{cat} = K_0 \exp(-E_{cat}/RT).$$

Here, K_{cat}, E_{cat} and K_0 stand for apparent rate constant, apparent activation energy and apparent frequency factor (determiner), respectively. Only when quantity is in direct proportion to the apparent rate constant (or reaction rate) can the above equation be used to determine apparent activation energy of the reaction.

The catalyzed reaction is pseudo-zero order reaction. The quantity in direct proportion to reaction rate is $\Delta IF(\Delta IF = IF_0 - IF_{cat})$. Therefore, there should be a straight line if $\ln \Delta IF$ is used to draw a graph for $1/T$ and from the slope $(-E_{cat}/R)$ of the straight line. The experiment rate and measured results are shown in Table 11.

Table 11. Determination of apparent activation energy

$T(K)$	$\frac{1}{T}(\times 10^3)$	ΔIF	$\ln \Delta$IF
318.15	3.14	4.0	1.39
323.15	3.09	5.4	1.69
328.15	3.05	8.0	2.08
333.15	3.00	10.6	2.36
338.15	2.96	14.6	2.68
343.15	2.91	19.9	2.99

By the data in Table 11, we can get the linear regression equation:

$$-\ln \Delta IF = 7063.6 \times \frac{1}{T} - 23.57,$$

regression coefficient $r = 0.9981$.

Hence, the apparent activation energy of this indicated reaction system:

$$E_{cat} = 7063.6 \times 8.314 \text{ J} \cdot \text{mol}^{-1}$$
$$= 58.73 \text{ KJ} \cdot \text{mol}^{-1}.$$

Summary—The solvent extraction of copper(II) with trimethylacetic acid using benzene and 1-octanol as solvents was performed at 25°C and 0.1 mole . dm^{-3} ionic strength in the aqueous phase. In contrast to the extraction of copper(II) with a saturated straight-chain carboxylic acid in benzene, the dimeric copper(II) trimethylacetate was observed to dissociate into the monomer, even at a moderately high concentration of copper(II) in the benzene phase. In the system using 1-octanol as a solvent, both the monomeric and dimeric copper(II) species are suggested to be solvated by some 1-octanol molecules. It has been found that the dimerization and adduct formation of copper(II) species in benzene may more effectively enhance the extractability of copper(II) than the solvation by 1-octanol molecules.

In a series of investigations[1–7] on the extraction of copper(II) with various carboxylic acids, the extraction of copper(II) with aromatic carboxylic acids has been found to proceed through a stoichiometry different from that with aliphatic carboxylic acids, by which copper(II) is well known to be extracted into nonsolvating solvents as a dimeric species, $Cu_2A_4(HA)_2$. The presence of a conjugated system in aromatic carboxylic acids can be anticipated to give some negative influence on the formation of the dimeric copper(II) carboxylate, and to result in a lowering of the extractability of copper(II).[4] Further, the extraction of copper(II) with various monosubstituted benzoic acids has been proven to be appreciably influenced by the position and properties of the substituents.[5–7] Also in an aliphatic carboxylic acid, the conjugated system in the carboxylic acid has been reported to inhibit the formation of the dimeric copper(II) carboxylate in the extraction of copper(II) with 2,4-hexadienoic acid.[8] On the other hand, in the extraction systems using an aliphatic carboxylic acid, the difference in carbon-chain length has been revealed not to affect the formation of dimeric copper(II) carboxylate in benzene.[9] Moreover, it has been proven that the formation of dimeric copper(II) carboxylate in benzene is not prevented by the bromine at the α-position in the pentanoic acid.[10] But, in the solvent extraction systems with cyclohexanecarboxylic acid, the adjacent cyclohexane ring to carboxyl group was found to inhibit the formation of the dimeric copper(II) carboxylate, even in benzene.[11] This can be due to the steric hindrance of the cyclohexane group on the formation of the dimeric copper(II) cyclohexane carboxylate. In contrast to nonsolvating solvents such as benzene, the dimeric copper(II) carboxylates were observed to dissociate at a moderately high concentration of copper(II) carboxylate into the monomers in solvating solvents such as alcohols[12] and ketones.[13] This can be attributed to the more extensive solvation of the monomeric copper(II) carboxylate than the dimeric one in these solvating solvents. According to these results, the following three factors can be anticipated to inhibit the dimerization of the monomeric copper(II) carboxylate: (1) the presence of the conjugated system in a carboxylic acid, (2) the solvation of copper(II) carboxylate, and (3) the steric effects of a bulky substituent at the α-position in a carboxylic acid.

In the present paper we report on the extraction of copper(II) with trimethylacetic acid (pivalic acid) by using benzene or 1-octanol as the solvent in view of the steric hindrance and solvent effect on the dimerization of copper(II) pivalate. In the extraction of copper(II) carboxylate, the formation of the dimeric copper(II) species has been found to be more effective than the solvation of the copper(II) species for the enhancement of the extractability of copper(II).

EXPERIMENTAL

Reagents

Commercial pivalic acid (purity: over 99%) was dissolved in purified benzene and 1-octanol, respectively. Benzene, 1-octanol, and sodium perchlorate were purified by the same methods as employed previously.[8] All other reagents were of reagent grade and used without further purification.

Procedures

Partition was carried out at 5×10^{-5} mole . dm^{-3} initial concentration of copper(II) in the aqueous phase and 0.5–2.0 mole . dm^{-3} pivalic acid in the organic phase for both the systems using benzene and 1-octanol as solvents. Shaking for about 1 hr was performed in a bath thermostatted at 25.0 ± 0.2°C, and was found to be sufficient for complete equilibration. Ionic strength in the aqueous phase was adjusted to 0.1 mole . dm^{-3} by sodium perchlorate. Both the concentrations of copper(II) and hydrogen ions in the aqueous phase after complete equilibration were determined by the same methods as presented previously.[4] The dissociation constant of pivalic acid was potentiometrically determined to be $K_a = [H^+][A^-]/[HA] = 10^{-4.83}$ in the aqueous 0.1 mole . dm^{-3} perchlorate solution at 25°C. In the evaluation of the partition constant of pivalic acid between the aqueous phase and benzene, the concentration of pivalic acid in the aqueous phase was determined by potentiometric titration. While, for that between the aqueous phase and 1-octanol, it was determined by measuring the absorbance at 208 nm, the absorption maximum of the acid.

Apparatus

The apparatus for mechanical shaking in a thermostat, centrifugation, pH measurement, and spectrophotometric determination were the same as employed previously.[4]

RESULTS AND DISCUSSION

Partition of pivalic acid

In the extraction of metal ions with a carboxylic acid, it is important to have information about the partition behavior of the carboxylic acid. The partition ratio of a carboxylic acid between the organic and aqueous phases can be expressed as follows:

$$D = \frac{C_{HA,o}}{C_{HA,w}} = \frac{K_{D,HA} + 2K_{2,HA}K_{D,HA}^2[HA]}{1 + \dfrac{K_a}{[H^+]}}, \quad (1)$$

where K_a, $K_{2,HA}$, $K_{D,HA}$, and [HA] denote the dissociation constant in the aqueous phase, the dimerization constant in the organic phase, the partition constant between the organic and aqueous phases of the carboxylic acid, and the concentration of the monomeric acid in the aqueous phase, respectively. The partition of pivalic acid was carried out between benzene and 0.01 mole . dm^{-3} perchloric acid containing 0.09 mole . dm^{-3} sodium perchlorate which was added to keep the ionic strength in the aqueous phase 0.1 mole . dm^{-3}, and between 1-octanol and 0.1 mole . dm^{-3} perchloric acid, respectively. Under these aqueous conditions, the dissociation of the acid in the aqueous phase can be neglected. In the former case the concentration of pivalic acid in the aqueous phase after the equilibrium was determined titrimetrically with the standard sodium hydroxide. Then, the concentration of perchloric acid coexisted with pivalic acid in the aqueous phase is fixed at 0.01 mole . dm^{-3} in order to make it as low as possible. In this case the partition constant, $K_{D,HA}$ and the dimerization constant, $K_{2,HA}$ in the organic phase were determined by the least-squares method from the linear plots of D against [HA]. The values are summarized in Table 1 together with the other constants. The partition ratio of pivalic acid was constant and independent of the concentration of pivalic acid. And it has been found that the dimerization of pivalic acid in 1-octanol does not occur to any appreciable extent. The distribution ratio of pivalic acid is equal to the partition constant. The value is listed in Table 1.

Extraction of copper(II) with pivalic acid

If a *j*-merized copper(II) pivalate of the composition $Cu_jA_{2j}(HA)_a$ is extracted, the extraction equilibrium using benzene as a solvent can be written as follows:

Table 1. Partition and dimerization constants of pivalic acid and extraction constants of copper(II) pivalates (at 25°C)

Solvent	$\log K_{D,HA}$	$\log K_{2,HA}$	$\log K_{ex(10)}$	$\log K_{ex(11)}$	$\log K_{ex(20)}$	$\log K_{ex(21)}$	$\log K_{ex(22)}$
Benzene	0.02	2.16	−8.39	−7.93			−11.81
1-Octanol	1.42		−8.57	−9.35	−14.13	−14.65	

$$jCu^{2+} + \frac{(2j+a)}{2}(HA)_{2,o} \rightleftharpoons [Cu_jA_{2j}(HA)_a]_o + 2jH^+$$

with

$$K_{ex(ja)} = \frac{[Cu_jA_{2j}(HA)_a]_o[H^+]^{2j}}{[Cu^{2+}]^j[(HA)_2]_o^{(2j+a)/2}}, \quad (2)$$

where $(HA)_{2,o}$ denotes the dimeric pivalic acid in the organic phase, and the subscript "o" refers to the organic phase. Pivalic acid acts primarily as a dimer in benzene through hydrogen bonding.

On the other hand, the extraction equilibrium for 1-octanol can be expressed as follows:

$$iCu^{2+} + (2i + a')(HA)_o \rightleftharpoons [Cu_iA_{2i}(HA)_{a'}]_o + 2iH^+$$

with

$$K_{ex(ia')} = \frac{[Cu_iA_{2i}(HA)_{a'}]_o[H^+]^{2i}}{[Cu^{2+}]^i[HA]_o^{(2i+a')}}, \quad (3)$$

where $(HA)_o$ denotes the monomeric pivalic acid in 1-octanol. The formation of the dimeric pivalic acid in 1-octanol does not occur to any appreciable extent because of solvation of monomeric pivalic acid by 1-octanol molecules.

The concentration of copper(II) in the organic phase is expressed by the following equations, corresponding to equations (2) and (3), respectively.

Using benzene as a solvent,

$$C_{Cu,o} = \sum_j \sum_a jK_{ex(ja)}[Cu^{2+}]^j[(HA)_2]_o^{(2j+a)/2}[H^+]^{-2j}, \quad (4)$$

and using 1-octanol,

$$C_{Cu,o} = \sum_i \sum_{a'} iK_{ex(ia')}[Cu^{2+}]^i[HA]_o^{(2i+a')}[H^+]^{-2i}. \quad (5)$$

Determination of the degree of polymerization of copper(II) pivalates

According to the same plot as employed previously,[2] it was suggested that the monomeric and dimeric copper(II) pivalates are responsible for the extraction of copper(II) with pivalic acid both in benzene and 1-octanol. Then, the following expressions can be derived from equations (4) and (5): for benzene,

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] = \log K_{ex(1a)} + \frac{(2+a)}{2}\log[(HA)_2]_o + \log\left(1 + \frac{2K_{ex(2b)}}{K_{ex(1a)}}[(HA)_2]_o^{(2+b-a)/2} \times [Cu^{2+}][H^+]^{-2}\right) \quad (6)$$

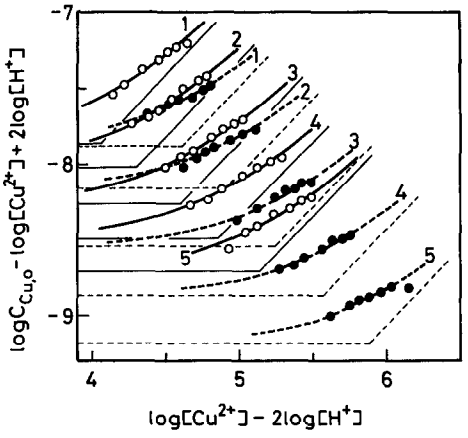

Fig. 1. Determination of the degree of polymerization of copper(II) pivalates. C_{HA}; (1) 2.0, (2) 1.5, (3) 1.0, (4) 0.7, and (5) 0.5 mole . dm^{-3}. Open and closed symbols refer to benzene and 1-octanol, respectively. Solid and dotted curves are the normalized ones, $\log(1+X)$ *vs.* $\log X$. Solid and dotted lines are the straight ones which are the asymptotes of the respective normalized curves.

and for 1-octanol,

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] = \log K_{ex(1a')} + (2+a')\log[HA]_o + \log\left(1 + \frac{2K_{ex(2b')}}{K_{ex(1a')}}[HA]_o^{(2+b'-a')} \times [Cu^{2+}][H^+]^{-2}\right), \quad (7)$$

respectively.

As described in the previous work,[2] by fitting the plots of $(\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+])$ against $(\log[Cu^{2+}] - 2\log[H^+])$ at constant $[(HA)_2]_o$ for benzene, and $[HA]_o$ for 1-octanol with the normalized curve, $\log(1+X)$ *vs.* $\log X$, it can be confirmed that both the monomeric and dimeric copper(II) species are extracted into both benzene and 1-octanol. The results are shown in Fig. 1. The plots fit well in the normalized curve in the range of the total concentration of pivalic acid from 2.0 to 0.5 mole . dm^{-3} under the extraction systems using either benzene or 1-octanol as a solvent. Therefore, the monomeric and dimeric copper(II) pivalates have been found to be responsible for both the extraction systems.

Determination of the number of pivalic acid molecules involved in the extracted species

In the region where the monomer prevails, the following relations for benzene and 1-octanol can be derived according to the similar manner described in the previous paper:[2]

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] = \log \sum_a K_{ex(1a)}[(HA)_2]_o^{(2+a)/2}, \quad (8)$$

for benzene, and

$$\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+] = \log \sum_{a'} K_{ex(1a')}[HA]_o^{(2+a')}, \quad (9)$$

for 1-octanol, respectively.

On the other hand, in the region where the main copper(II) species exist as the dimer, the following expressions can be obtained:

$$\log C_{Cu,o} - 2(\log[Cu^{2+}] - 2\log[H^+]) = \log 2 \sum_b K_{ex(2b)}[(HA)_2]_o^{(4+b)/2}, \quad (10)$$

for benzene, and

$$\log C_{Cu,o} - 2(\log[Cu^{2+}] - 2\log[H^+]) = \log 2 \sum_{b'} K_{ex(2b')}[HA]_o^{(4+b')}, \quad (11)$$

for 1-octanol. On the basis of equations (8)–(11), the number of pivalic acid molecules involved in the respective monomeric and dimeric copper(II) species can be estimated from the slope of the plots of $(\log C_{Cu,o} - \log[Cu^{2+}] + 2\log[H^+])$ *vs.* $\log[(HA)_2]_o$ for benzene and *vs.* $\log[HA]_o$ for 1-octanol, and $\log C_{Cu,o} - 2(\log[Cu^{2+}] - 2\log[H^+])$ *vs.* $\log[(HA)_2]_o$ for benzene, and *vs.* $\log[HA]_o$ for 1-octanol, respectively. The results for benzene are shown in Fig. 2. The plots for the dimer fell on the straight line with a slope of 3.0. It has been found that the dimeric species is $Cu_2A_4(HA)_2$. For the monomer the slope of the plots should be 1.0 or 1.5 or 2.0 in the presence of only one type of the monomeric species, since the value of a in equation (8) must be an integer. It is shown in Fig. 2 that the slope of the plots lies between 1.0 and 1.5. This suggests that at least two kinds of the monomeric species are extracted into the benzene phase and one of them is certainly CuA_2. While the results for the extraction using 1-octanol as a solvent are shown in Fig. 3. The plots for both the monomeric and dimeric species fall on the straight lines with slopes of 2.0 and 4.0, respectively, at lower concentration of pivalic acid in the organic phase, but deviate just a little upward from the respective straight lines with increasing $[HA]_o$. Then it has been found that two kinds of both the monomeric and dimeric copper(II) species are at least responsible for the extraction using 1-octanol as a solvent, and one of them is CuA_2 for the monomer, and Cu_2A_4 for the dimer, respectively.

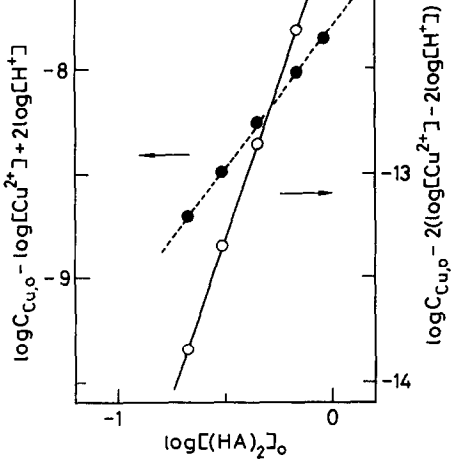

Fig. 2. Determination of the number of pivalic acid molecules involved in the monomeric and dimeric copper(II) species in benzene. Solid and dotted lines are the straight lines with slopes of 3.0 and 1 ~ 1.5, respectively. Open and closed symbols refer to the dimeric and monomeric copper(II) species, respectively.

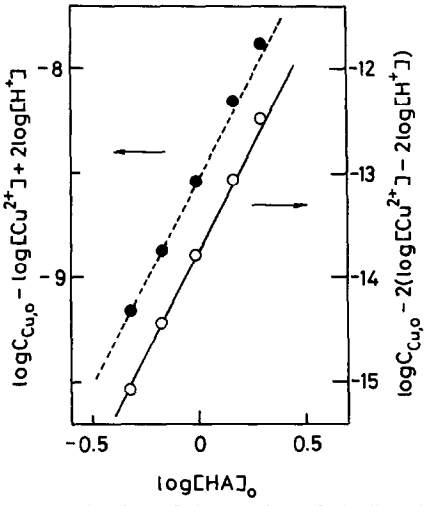

Fig. 3. Determination of the number of pivalic acid molecules involved in the monomeric and dimeric copper(II) species in 1-octanol. Solid and dotted lines are the straight ones with slopes of 4.0 and 2.0, respectively. Open and closed symbols refer to the dimeric and monomeric extracted species, respectively.

The monomeric copper(II) species other than CuA_2, which was recognized from Figs 2 and 3, can be expected to be CuA_2HA and/or $CuA_2(HA)_2$ for both the extraction systems using benzene and 1-octanol as solvents. Similarly for 1-octanol the dimeric ones other than Cu_2A_4, which was suggested from Fig. 3, can be anticipated to be Cu_2A_4HA and/or $Cu_2A_4(HA)_2$. Then,

in the region where the monomer prevails, the total concentration of copper(II) in the organic phase can be presumed as follows:

$$C_{Cu,o} = [CuA_2]_o + [CuA_2HA]_o + [CuA_2(HA)_2]_o. \quad (12)$$

In the region where the dimer prevails, the following expression can be obtained:

$$C_{Cu,o} = 2([Cu_2A_4]_o + [Cu_2A_4HA]_o + [Cu_2A_4(HA)_2]_o). \quad (13)$$

By use of the individual extraction constants these can be rewritten as follows: for benzene,

$$\frac{C_{Cu,o}}{[Cu^{2+}][H^+]^{-2}[(HA)_2]_o} = K_{ex(10)} + K_{ex(11)}[(HA)_2]_o^{1/2} + K_{ex(12)}[(HA)_2]_o, \quad (14)$$

and for 1-octanol,

$$\frac{C_{Cu,o}}{[Cu^{2+}][H^+]^{-2}[HA]_o^2} = K_{ex(10)} + K_{ex(11)}[HA]_o + K_{ex(12)}[HA]_o^2, \quad (15)$$

and

$$\frac{C_{Cu,o}}{2[Cu^{2+}]^2[H^+]^{-4}[HA]_o^4} = K_{ex(20)} + K_{ex(21)}[HA]_o + K_{ex(22)}[HA]_o^2, \quad (16)$$

respectively. From the plots of the values of the left hand side of each equation against $[(HA)_2]_o^{1/2}$ for equation (14), and $[HA]_o$ for equations (15) and (16), the other copper(II) species can be estimated. As shown in Figs 4 and 5, the plots gave a linear relationship in all cases. The plots on the basis of equations (14) and (15) are in good agreement with the straight line calculated by the least-squares method. Although the plots on the basis of equation (16) deviate from the line, a linear relationship between the values of the left hand side of equation (16) and $[HA]_o$ is found. The fluctuation of the plots of the dimeric copper(II) species in Fig. 5 can be due to the amplification of the experimental error on the value of the vertical axis for the plots based on equation (16) compared to that based on equation (15). This amplification of the error results from the fact that each concentration term in the denominator of the left hand side of equation (16) becomes the square of that in equation (15). The resulting information suggests that the third term on the right hand side of equations (14)–(16) can be neglected, that is, $CuA_2(HA)_2$ both in benzene and 1-octanol, and $Cu_2A_4(HA)_2$ in 1-octanol do not exist to any appreciable extent under the present extraction conditions. In addition, the extraction constants for the respective extracted species can be determined from the slope and intercept of the corresponding straight line. The resulting constants are summarized in Table 1. The composition of the dimeric copper(II) species in benzene is consistent with the dimer which has been presented in the extraction of copper(II) with pivalic acid using toluene as a solvent by Haffenden and Lawson.[14] They speculated that the monomeric copper(II) species was also extracted together with the dimeric one. But neither the composition of the monomer nor the extraction constant of the dimeric species were estimated in their work.

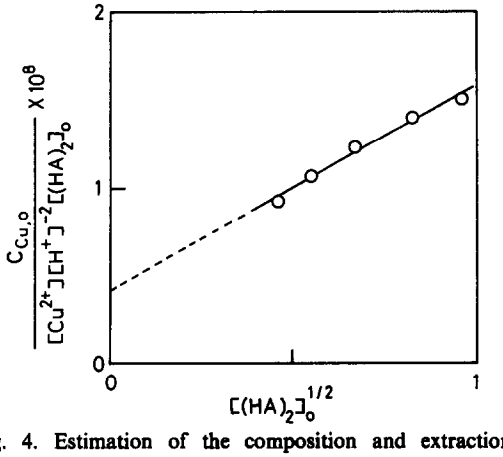

Fig. 4. Estimation of the composition and extraction constants of the monomeric copper(II) species in benzene. The straight line was drawn by the least-squares method.

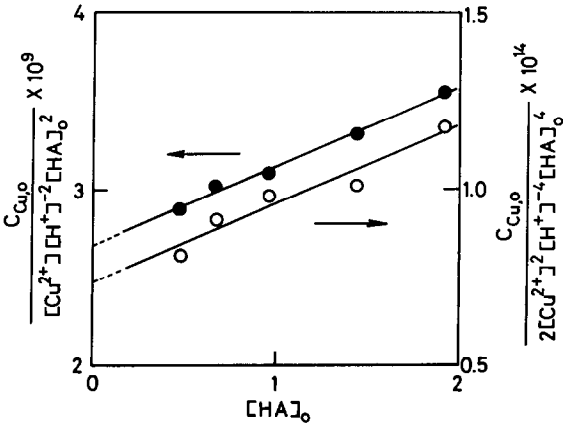

Fig. 5. Estimation of the composition and extraction constants of the monomeric and dimeric copper(II) extracted species for 1-octanol. Straight lines were drawn by the least-squares method. Open and closed symbols refer to the dimeric and monomeric species, respectively.

Consequently, the extraction equilibria for the present extraction systems can be expressed as follows: for benzene,

$$Cu^{2+} + (HA)_{2,o} \overset{K_{ex(10)}}{\rightleftharpoons} (CuA_2)_o + 2H^+$$

$$Cu^{2+} + \tfrac{3}{2}(HA)_{2,o} \overset{K_{ex(11)}}{\rightleftharpoons} (CuA_2HA)_o + 2H^+$$

$$2Cu^{2+} + 3(HA)_{2,o} \overset{K_{ex(22)}}{\rightleftharpoons} [Cu_2A_4(HA)_2]_o + 4H^+,$$

and for 1-octanol,

$$Cu^{2+} + 2(HA)_o \overset{K_{ex(10)}}{\rightleftharpoons} (CuA_2)_o + 2H^+$$

$$Cu^{2+} + 3(HA)_o \overset{K_{ex(11)}}{\rightleftharpoons} (CuA_2HA)_o + 2H^+$$

$$2Cu^{2+} + 4(HA)_o \overset{K_{ex(20)}}{\rightleftharpoons} (Cu_2A_4)_o + 4H^+$$

$$2Cu^{2+} + 5(HA)_o \overset{K_{ex(21)}}{\rightleftharpoons} (Cu_2A_4HA)_o + 4H^+,$$

respectively.

Then the adduct formation and dimerization of copper(II) pivalates in both the benzene and 1-octanol phases can be formulated as follows: for benzene,

$$(CuA_2)_o + \tfrac{1}{2}(HA)_{2,o} \overset{K_{ad,\,ml}}{\rightleftharpoons} (CuA_2HA)_o$$

$$2(CuA_2HA)_o \overset{K_{dim-2}}{\rightleftharpoons} [Cu_2A_4(HA)_2]_o,$$

and for 1-octanol,

$$(CuA_2)_o + (HA)_o \overset{K_{ad,\,ml}}{\rightleftharpoons} (CuA_2HA)_o$$

$$2(CuA_2)_o \overset{K_{dim-1}}{\rightleftharpoons} (Cu_2A_4)_o$$

$$(Cu_2A_4) + (HA)_o \overset{K_{ad,\,dl}}{\rightleftharpoons} (Cu_2A_4HA)_o$$

with the following adduct formation and dimerization constants calculated from the respective extraction constants: $\log K_{ad,\,ml} = 0.46$ and $\log K_{dim-2} = 4.05$ for benzene, and $\log K_{ad,\,ml} = -0.78$, $\log K_{dim-1} = 3.01$, and $\log K_{ad,\,dl} = -0.52$ for 1-octanol, respectively.

The relationship between the distribution ratio of copper(II) and the hydrogen ion concentration in the aqueous phase, which was drawn on the basis of the present results, is shown in Fig. 6. As can be seen from Fig. 6, benzene is more useful as a solvent than 1-octanol for the present extraction systems. That is to say, the dimerization and adduct formation of copper(II) species in benzene may contribute more effectively to the enhancement of the extractability of copper(II) than the solvation of copper(II) species by 1-octanol molecules.

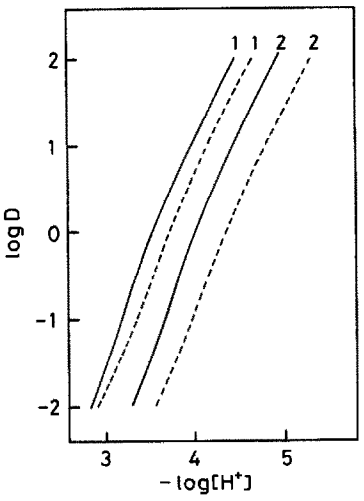

Fig. 6. Relationship between the distribution ratio of copper(II) and the hydrogen ion concentration. Solid and dotted curves, which were drawn on the basis of the results obtained from the present work, refer to benzene and 1-octanol, respectively. Symbols: (1) $C_{HA} = 2.0$, and (2) $C_{HA} = 0.5$ mole . dm^{-3}, respectively.

Distribution diagrams of copper(II) species

The distribution diagram of copper(II) pivalates in the organic phase in the presence of an excess of pivalic acid can be calculated from the results obtained by the present work. It is depicted in Figs 7 and 8. Both the dimerization and adduct formation of copper(II) pivalates are shown to proceed more easily in benzene than in 1-octanol in Figs 7 and 8. At the total copper(II) concentration in the organic phase as high as 10^{-3} mole . dm^{-3}, the dissociation of the dimeric copper(II) pivalate has been found to occur even in benzene. This has never been observed in aliphatic carboxylic acid–benzene systems except for the cyclohexanecarboxylic acid–benzene system.[11]

Solvent effects

The resulting constants suggest that both the adduct formation and dimerization reactions of copper(II) pivalates proceed more easily in benzene than 1-octanol. This can be attributed to stabilization of the monomeric copper(II)

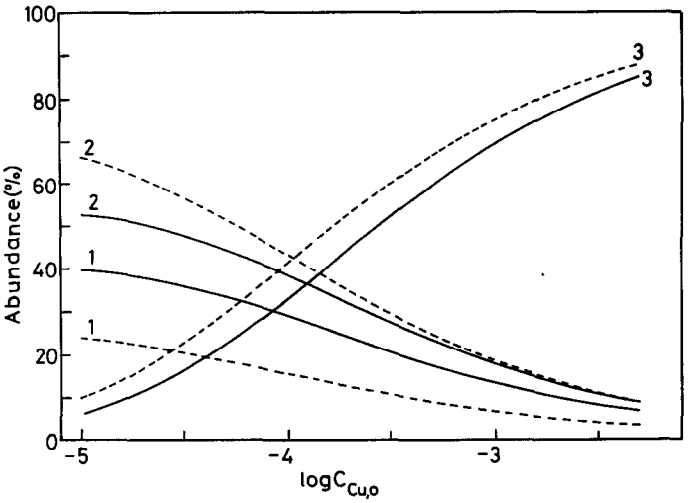

Fig. 7. Distribution diagrams of copper(II) pivalates in benzene. Solid and dotted curves refer to $C_{HA} = 0.5$ and 2.0 mole . dm^{-3}, respectively. Symbols: (1) CuA_2, (2) CuA_2HA, and (3) $Cu_2A_4(HA)_2$, respectively.

species by the solvation with some 1-octanol molecules in 1-octanol phase. The more favorable solvation of the monomeric copper(II) pivalate by 1-octanol molecules can be ascribed in part to the hydrogen bonding ability of 1-octanol as well as in the previous work[13] on the solvent effects on the dimerization of copper(II) decanoate, in which the monomeric copper(II) decanoate was found to be more extensively solvated in alcohol solvents than in ketone ones. On the other hand, in benzene the monomeric species, CuA_2 and CuA_2HA, which do not satisfy the coordination number of copper(II) ion only by pivalic acid, can be expected to be hydrated by two and one water molecules, respectively. This is supported by the fact that in benzene the extraction constant of CuA_2, in which two water molecules are supposed to be involved, is smaller than that of CuA_2HA, in which one water molecule can be involved. Contrary to the case of benzene, in the 1-octanol system, one or two 1-octanol molecules can be anticipated to attach to the coordination-unsaturated sites of copper(II) ion, in order to satisfy the coordination number of copper(II) ion, that is, CuA_2 and Cu_2A_4 can be involved with two 1-octanol molecules, and CuA_2HA and Cu_2A_4HA can be involved with one 1-octanol molecule. The species CuA_2 and Cu_2A_4 solvated by two 1-octanol molecules become more lipophilic than CuA_2HA and Cu_2A_4HA, in which one 1-octanol molecule can be involved, and

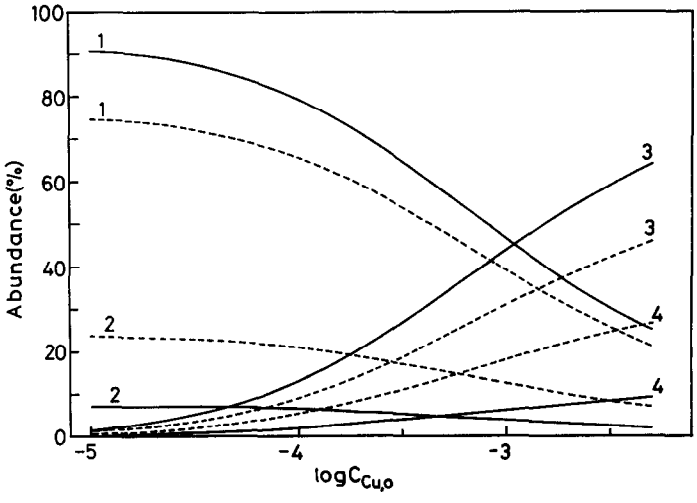

Fig. 8. Distribution diagrams of copper(II) pivalates in 1-octanol. Solid and dotted curves are same as in Fig. 7. Symbols: (1) CuA_2, (2) CuA_2HA, (3) Cu_2A_4, and (4) Cu_2A_4HA, respectively.

the extraction constants of the former species become greater than those of the latter ones as shown in Table 1.

The adduct formation reaction of copper(II) pivalates with pivalic acid molecules can be regarded as the ligand replacement of coordinated water or 1-octanol by pivalic acid. It proceeds more easily in benzene than in 1-octanol, because in the latter the exchange of coordinated 1-octanol with pivalic acid can be inhibited by bulk 1-octanol molecules. The expected results for the respective adduct formation constants have been obtained as described above.

In addition, it can be usually expected that the lower the dielectric constant, the more extensive is the dimerization of copper(II) carboxylate. In the previous paper[1] on the extraction of copper(II) with decanoic acid in various non-solvating solvents ranging in dielectric constant from 1.9 (*n*-hexane) to 10.4 (1,2-dichloroethane), copper(II) was found to be extracted only as the dimeric species $[Cu_2A_4(HA)_2]$ irrespective of the dielectric constant of the solvent used as a solvent. While, in the other paper,[2] we reported that the dissociation of the dimeric copper(II) decanoate to the monomer was observed in the extraction system using 1-octanol whose dielectric constant is similar in magnitude to 1,2-dichloroethane. According to these results, in the present extraction systems the solvation effect of 1-octanol on the dimerization of copper(II) pivalate is much larger than the effect resulted from the difference in the dielectric constant between 1-octanol and benzene.

Steric effect

Steric factors can be also expected to influence the adduct formation and dimerization of copper(II) pivalates in the present extraction systems. In contrast to the extraction with decanoic,[1] α-bromopentanoic,[10] and α-lipoic[3] acids, in which the dissociation of the dimeric copper(II) carboxylates was not observed in benzene in the range of the total concentration of copper(II) in the organic phase from 10^{-4} to 10^{-3} mole . dm^{-3}, the dissociation of the dimeric copper(II) pivalate in the benzene phase has been observed in the similar range as described above. This suggests that the formation of the dimeric copper(II) pivalate can be sterically inhibited by three methyl substituents which are just adjacent to the carboxylic group. Judging from the fact that not only in 1-octanol, but also in benzene, the monomeric copper(II) pivalate, $CuA_2(HA)_2$, could not be recognized to any appreciable extent, three methyl groups can be anticipated to make difficult sterically the arrangement of two pivalic acid molecules around CuA_2 species.

CONCLUSIONS

Consequently, steric hindrance by three methyl substituents at the α-position for the carboxylic group and solvation by 1-octanol and water molecules have been found to influence the adduct formation and dimerization of copper(II) pivalates. And both reactions play an important part on the extraction of copper(II) carboxylates, and can result in an effect similar to the synegistic one. Such steric and solvent effects can be also expected to influence the extractability of a metal ion which is extracted as a polymeric metal carboxylate. Previously, in the extraction of Al(III), Ga(III) and In(III) with decanoic acid, these metal ions have been found to increase the degree of polymerization of metal decanoates in the order, Al > Ga > In, both in benzene and 1-octanol phases.[15] The differences in the degree of polymerization of the extracted species, which will result also in the present extraction systems, can be anticipated to lead to the differences in the extractability of such metal ions as aluminum, gallium and indium.

Then, the present extraction systems can be expected to be also useful for the extraction of other metal ions which can be extracted as polymeric carboxylates with various degrees of polymerization.

Acknowledgement—The authors wish to thank Professor Hiroko Wada of Nagoya Institute of Technology for her valuable discussions.

(*Received* 6 *August* 1992. *Revised* 7 *December* 1992. *Accepted* 7 *December* 1992)

Summary—A microdetermination method at sub-μg/l. level for aluminium by solid-phase spectrophotometry has been developed. Chrome azurol S was used as chromogenic reagent to form a blue complex which was easily and strongly sorbed and concentrated on a dextran-type anion-exchange resin. The resin-phase absorbances at 615 and 800 nm were measured directly. Aluminium can be determined in the 0.6–4.0 μg/l. range with a RSD of 2.1%. The method is applied to the determination of aluminium in micaschist, natural and tap water samples.

The potential toxicity of aluminium in man is universally recognized. A series of clinical disorders, including dialysis dementia, has been associated with its accumulation in several tissues (brain and bone principally) in renal-failure patients undergoing regular hemodialysis.[1] It has been suggested[2] that aluminium increases the permeability of the blood–brain barrier which may lead to dementia or other neuronal disorders. Aluminium is present at approximately 1.4 ppm or 100 mg Al/70 kg man and it is ingested with food; the approximate daily dietary intake is 36.4 mg[2] varying with degree of dietary exposure. Aluminium ions in our diet are completely non-bioavailable from the small intestine because the aquated charged ions are not able to penetrate the lipid protein membranes of the duodenal mucosa and thus pass on into the bloodstream.[3] On the other hand, it can be assumed that at least part of human dietary aluminium intake is in the form of chelates with natural food components such as citric, lactic and oxalic acids.[4] In these chemical forms, Slanina *et al.*[4] showed (working with rats) that aluminium is bioavailable. In moderate amounts, aluminium does not exert prejudicial effects in man. It is used in the treatment of tap waters. On the other hand, it has been shown that aluminium is toxic to fish[5]. Hence a great deal of attention to the determination of this element has been paid recently.

Numerous binary complexes of Al(III) with (a) azo reagents, (b) xantene reagents and (c) triphenylmetane reagents [eriochrome cyanine R, pyrocatechol violet and chrome azurol S (CAS)] have been used for spectrophotometric determination of aluminium. They exhibit moderate sensitivity[6] but it can be increased by addition of a cationic surfactant such as cetyltrimethylammonium bromide, cetyltrimethylammonium chloride, cetylpyridinium chloride, cetylpiridinium bromide, tetraphenylphosphonium chloride and zephiramine.[7] However the spectrophotometric determination of aluminium at sub-μg/l. level requires a step of preconcentration. Nevertheless, solid phase spectrophotometry (SPS) enables determining analyte concentrations at this level without requiring an expensive instrumentation combining the measurements of solid-surface absorbance with using a solid support to preconcentrate selectively the analyte and measuring the absorbance directly in the solid phase with the aid of a chromogenic reagent.[8,9,10] Detection limits as low as 0.09 μg/l. have been reported.[11]

The aim of this paper has been to develop a sensitive and selective method for the spectrophotometric determination of aluminium

*Author for correspondence.

with CAS by selective enrichment of the metal as Al(III)–CAS species on a dextrane type resin and measuring of the absorbance in resin phase, *e.g.* by using SPS.

The proposed method has been satisfactorily applied to the determination of aluminium in natural and tap water samples, and other matrices, such as micaschist and enables determining of this element at sub-μg/l. level.

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade and the water was doubly distilled.

Ion exchanger, Sephadex QAE A-25 (Aldrich), anion-exchange resin was used in the chloride form in original dry state as obtained from the supplier and without pretreatment.

Aluminium (III) standard solution 1.000 g/l., prepared by dissolving 17.5820 g of aluminium potassium sulfate dodecahydrate $AlK(SO_4)_2 \cdot 12H_2O$ (Merck) in doubly distilled water containing 5 ml of concentrate. H_2SO_4 and diluting the solution with doubly distilled water to 1000 ml. Aluminium (III) working solutions were made *in situ* by dilution with doubly distilled water.

Buffer solution of pH 4.60, was made by dissolving 35.05 g of hexamethylenetetramine (HMTA) and 45 ml of HCl 4*M* in 1000 ml of doubly distilled water and adjusting the pH with a few drops of HCl 4*M* or NaOH 4*M*. This solution was stored under refrigeration.

Chromazurol S solution of various concentrations, prepared by dissolving the necessary amount of the dye in doubly distilled water. This solution was stored under refrigeration. In this conditions the solution is stable for at least one month.

Apparatus

A GBC 911 microcomputer-controlled UV-VIS spectrophotometer with glass cells (1-mm optical path length) was employed for all spectral measurements. The spectrophotometer was controlled by a Bravo AST/80286 microcomputer connected by means of a serial port. A Comx PL80 plotter was used for graphical representations. The pH measurements were made with a Crison Model 2002 pH-meter fitted with a glass-saturated calomel electrode assembly and a temperature probe. An Agitaser 2000 rotating agitator was also used and a centrifuge Selecta model S-240.

Absorbance measurements

The absorbance of the complex species sorbed on the resin was measured in a 1 mm cell at 615 (corresponding to the absorption maximum of the coloured species) and 800 nm (in a region where only the resin absorbs light). The net absorbance (A_c) for the complex was calculated from:[8]

$$A_c = A_{615} - A_{800}, \quad (1)$$

where: $A_{615} = A_{s615} - A_{b615}$ and $A_{800} = A_{s800} - A_{b800}$ and A_{sXXX} and A_{bXXX} are the absorbances of the sample and the blank (cell packed with resin equilibrated with blank solution), respectively at the indicated wavelength. In fact, the observed absorbance, A, at a given wavelength is obtained by:[8]

$$A = A_c + A_{soln} + A_R + A_{RL},$$

where A_c represents the absorbance of the complex species sorbed on the resin, A_{soln} that of the interstitial solution between the resin beads (it can be neglected), A_R that of the resin background ($A_{R800} \simeq 1.000$) and A_{RL} that of the reagent in the solid phase. The packing of the resin in the cell beads affects the values of A_c, A_R and A_{RL}, but when the absorbance is measured at two different wavelengths, one corresponding to the absorption maximum of the coloured species (615 nm) and the other in a region where only the resin absorbs (800 nm), the absorbance difference, $A_{s615} - A_{s800}$, can be assumed to be constant under the similar packing conditions. On the other hand, if the absorbance of a blank resin is measured at the same two wavelengths, the absorbance difference, $A_{b615} - A_{b800}$, allows us to estimate the absorbance of the complex, A_c (that is related with the concentration of analite in the solution as it was shown by Yoshimura)[8] from the equation (1).

Procedures

(I) A 10 ml sample solution containing 20–200 μg/l. (0.74–7.4 μmole/l.) of aluminium was transferred into a 20-ml glass tube with stopper containing 4 ml of 1.5×10^{-4} *M* CAS solution and 1 ml of pH 4.60 HMTA buffer solution (total volume = 15 ml). After 10 min, 30 mg of Sephadex QAE A-25 resin were added. The mixture was shaken mechanically for 5 min after which the resin beads were collected by suction with the aid of a pipette and packed into a 1 mm cell together with a small volume of the aqueous solution. Then, the cell was centrifuged

for 1 min at 5000 rpm. A blank solution containing all reagents except aluminium was prepared and treated in the same way as described for the sample. The absorbances (A_{s615}, A_{s800}, A_{b615} and A_{b800}) were measured as described under "Absorbance measurements" 30 min after collection of resin. The calibration graph was constructed in the same way using aluminium solutions of known concentration.

(II) A 100 ml sample solution containing 2.0–26 μg/l. (0.074–0.96 μmole/l. of aluminium was transferred into a 1-l. polyethylene bottle containing 10 ml of 1.5×10^{-4} *M* CAS solution, 5 ml of pH 4.60 HMTA buffer solution and, after 10 min, 30 mg of Sephadex QAE A-25 resin were added. The mixture was shaken mechanically for 15 min after which the resin beads were collected by filtration and with the aid of a pipette, packed into a 1-mm cell as above procedure, and the absorbance measurement was carried out in the same way.

(III) A 500-ml sample solution containing 0.7–5.0 μg/l. (0.026–0.185 μmole/l.) of aluminium was transferred into a 1-l. polyethylene bottle containing 20 ml of 1.5×10^{-4} *M* CAS solution and 25 ml of pH 4.60 HMTA buffer solution. After 10 min, 30 mg of Sephadex QAE A-25 resin were added. The mixture was shaken mechanically for 110 min. The absorbance of the coloured species was measured as the above procedures.

(IV) A 1000 ml sample solution containing 0.6–4.0 μg/l. (0.022–0.148 μmole/l.) of aluminium was placed in a 2-l. container of polyethylene containing 5 ml of 6.3×10^{-4} *M* CAS solution and 50 ml of pH 4.60 HMTA buffer solution. After 10 min, 30 mg of Sephadex QAE A-25 resin were added. The mixture was shaken mechanically for 125 min and the absorbance measured as described.

Treatment of samples

Analysis of micaschists. A suitable weight of sample (generally 50–100 mg) was treated in a nickel crucible with 2 g NaOH in the usual way. The melt was leached with distilled water with warming and poured into 250 ml HCl 0.44*M* and then distilled water added up to 500 ml (this solution was stored in a polyethylene container carefully cleaned with nitric acid and the samples were stored at 4°C until analysis). For the later process this solution was diluted 1:100 with addition of 0.4 ml NaOH 0.4*M* per ml of initial solution.

Waters. Natural waters were filtered through a filter paper with a pore size of 0.45 μm (Millipore), preserved with concentrate HNO_3 (0.25 ml/l. of water) and stored in a polyethylene container. The samples were stored at 4°C until analysis. Analysis were performed with the least possible delay. The usual general precautions were taken to avoid contamination. The tap water was analysed without pretreatment.

Distribution measurements

CAS, buffer solution and 30 mg of Sephadex QAE A-25 resin were added to an aqueous solution containing 740 nmole of Al(III) and the solution (100 ml) was stirred for 60 min. The equilibrated solution was separated from the resin. Afterwards, the solution was treated in the same way with a further batch of resin (30 mg) and the aluminium left in that was determined as described under "Procedures". The distribution ratio *D* (μmole of aluminium sorbed per gram of resin/μmole of Al(III) per ml of solution) was calculated from the initial and equilibrium concentration in the solution. An average value of $D = 23{,}400$ and S.D. = 600 was obtained from five replicates experiments.

RESULTS AND DISCUSSION

Absorption spectra in resin phase

CAS reacts with Al(III) to originate a blue complex in solution in the pH range 3.5–7.5. Between pH = 2.5 and 8.0 this complex is sorbed on an anion-exchange resin showing the absorption maximum at 615 nm and reaching the absorbance the highest value at pH about 4.6 (Fig. 1a–e). The spectrum of this complex at above pH in aqueous solution shows (Fig. 1f) much lower absorbance than in resin phase: the increasing of sensitivity in resin-phase is self-evident.

Optimization of variables

pH dependence. The optimum pH in the solution phase for the formation of the blue species on the resin falls in the range 3–5. At pH values below 3 and above 5 the absorbance value at 615 nm decreases significantly. We chose pH 4.60 as optimum pH value for the following experiences. The pH can be satisfactorily adjusted by addition of a 0.25*M* HMTA/HCl buffer solution. Other buffers (acetic acid/acetate, formic acid/formiate) decreased the absorbance in respect to

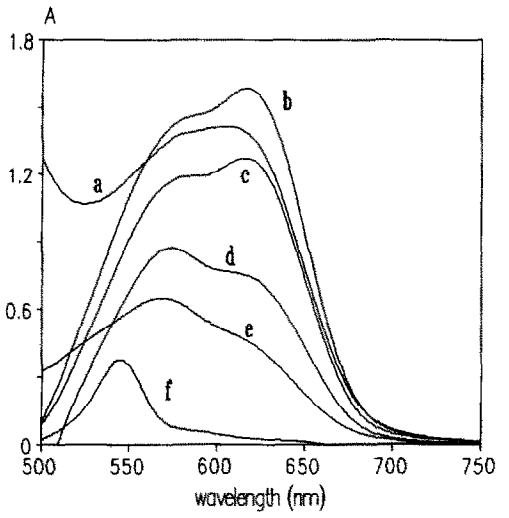

Fig. 1. Net absorption spectra of Al(III)–CAS species: (a)–(e) on the resin (resin as reference). [CAS] = 1.40×10^{-5} *M*, [Al(III)] = 1.48×10^{-6} *M*, 50 mg of resin, 1 mm optical path length, sample volume 100 ml, stirring time 15 min: (a) pH = 4.0; (b) pH = 4.5; (c) pH = 5.0; (d) pH = 5.5; (e) pH = 6.0; (f) in aqueous solution, [CAS] = 9.0×10^{-5} *M*, [AlIII)] = 9.0×10^{-6} *M*, 10 mm optical path length, pH = 5.0.

use HMTA/HCl buffer (80 and 26%, respectively for an aluminium concentration of 40 μg/l. using 50 mg of resin and a final volume of 100 ml).

Reagent concentration. Absorbance increases with an increasing CAS concentration, a plateau occurring from 1.2 to 2.5×10^{-5} (for 100 ml sample). It seems that the excess of free ligand competes with the complex for sorption on the resin phase and it originates these plateaux. The optimum molar [CAS/Al(III)] ratio necessary was 8, 13, 40 and 53 (for 15, 100, 500 and 1000 ml sample volumes, respectively). 4.0×10^{-5}, 1.5×10^{-5}, 6.0×10^{-6} and 3.15×10^{-6}*M* reagent concentration were chosen for 15, 100, 500 and 1000 ml sample volumes, respectively.

Other experimental conditions. The optimum stirring times are 5, 15, 110 and 125 min for 15, 100, 500 and 1000 ml sample volumes, respectively (Fig. 2). The fixed complex is stable for at least 7 hr after equilibration.

The order of addition of the reagents affects significantly the results obtained; the order used was: reagent, buffer, aluminium, resin. The use of a large amount of resin (m_r, g) reduces as usual[9–11] the absorbance values. Absorbance decreases according to the equation: ($r = 0.9987$) $A_c = -0.014 + 0.0224/m_r$ (Fig. 3). 30 mg is in the minimum amount of dry resin that gives the highest absorbance and greatest ease of handling.

Nature of the fixed complex

The composition of the fixed Al(III)-CAS complex on Sephadex was established at the

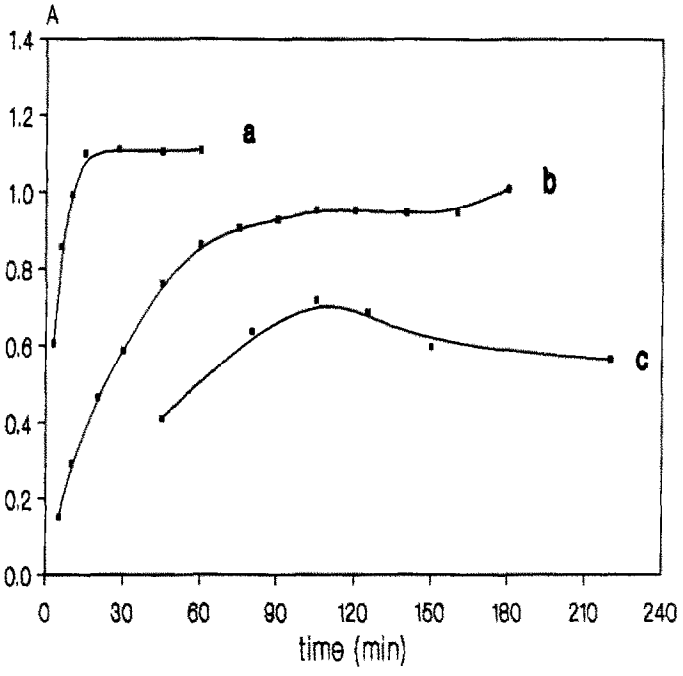

Fig. 2. Stirring time dependence on color development in resin-phase. 30 mg of resin, pH = 4.6, 0.074 μmole of Al(III). (a) 100 ml of sample, [CAS] = 1.5×10^{-5} *M*. (b) 500 ml of sample, [CAS] = 6×10^{-6} *M*. (c) 1000 ml of sample, [CAS] = 3.15×10^{-6} *M*.

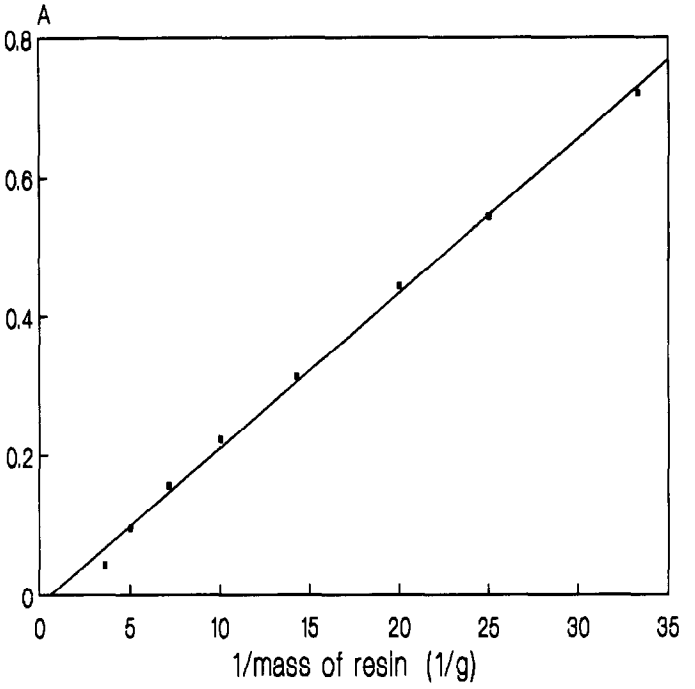

Fig. 3. Resin amount dependence. [CAS] = 1.5×10^{-5} M, [Al(III)] = 3.7×10^{-7}, pH = 4.60, 1 mm optical path length, sample volume 100 ml, stirring time 40 min.

working pH of 4.6 using the Job[12] and the equilibrium shift[13] methods. Job method showed a ratio CAS/Al(III) = 2. Moreover, the graph of log $(A/A_{max} - A)$ *vs.* log [CAS] (equilibrium shift method) gave a slope of 2.087 ($r = 0.9969$). Consequently, results indicated that a 2:1 [CAS:Al(III)] anionic complex is fixed on the anionic resin. These results agree with those found in aqueous solution.[14]

Analytical data

Calibration and precision. The calibration graphs are linear in the concentration ranges: 20–200 g, 2–26 g, 0.7–5.0 and 0.6–4.0 μg for 15, 100, 500 and 1000 ml samples, respectively. The analytical parameters are shown in Table 1.

The reproducibility was established using 15, 100, 500 and 1000 ml sample solutions with a Al(III) concentration of 107.0, 12.5, 4.0 and 2.0 μg/l., respectively. It was possible verifying that the reproducibility is improved when the cells packed with the resin are centrifuged, during 1 min at 5000 rpm, previously the spectrophotometric measurements. The relative standard deviation (RSD) was 4.4% without centrifugation for 100 ml sample and 10 determinations. With centrifugation the absorbance values increase about a 12% and the RSD decreases at 3.0%. For 15 ml sample volume it was studied the effect of adding the resin in a suspension (5 ml) of 3.00 g in 500 ml of distilled water. The RSD increases at 5.3%, but it offers the advantage of a quicker and easier measurement of the amount of resin because it was not necessary weigh it.

Sensitivity and detection limit. In Table 2 the sensitivity, expressed as apparent molar absorptivity, of the proposed procedures is compared with that of spectrophotometric procedures (including extractive procedures and formation

‡Ternary complexes.
§Solid-phase spectrophotometry.
‖Apparent molar absorptivity: absorbance value of the complex sorbed on the resin from a 1*M* aqueous solution of Al(III) and measured in a 10 mm optical path length cell.

of ternary complexes with surfactants) described in the literature. It is shown that SPS methodology using CAS gives a very noticeable increase in sensibility in relation to the solution and extractive methods.

The effect of volume on sensitivity. In SPS methodology the sensitivity can be enhanced by increasing the sample volume to be analysed. this effect may be calculated by measuring the absorbance of the resin equilibrated with different volumes of solutions containing the same concentrations of Al(III) and optimum established amounts of the other reagents. It is observed that a tendency of absorbance is to be independent of volume at higher volume values as usually in SPS[9–11] (Fig. 4).

The increase of sensitivity using a larger sample volume can be calculated, in practice, form the slope of the calibration graphs. The calculated values of the sensitivity ratio for the samples analysed here are: $S_{1000}/S_{500} = 1.42$, $S_{1000}/S_{100} = 4.79$ and $S_{1000}/S_{15} = 23.45$, where the subscripts represent the sample volume (ml).

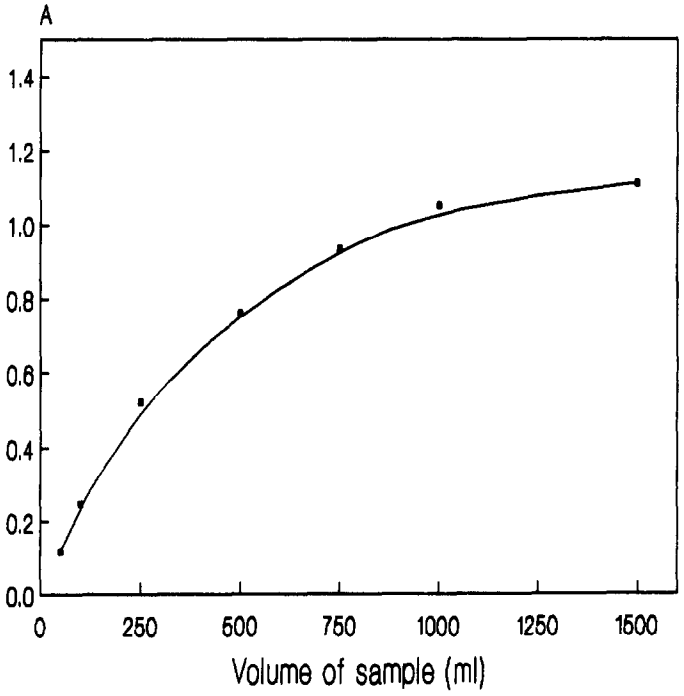

Fig. 4. Effect of volume on sensitivity. [CAS] = 3×10^{-5} *M*–2.5×10^{-6} *M*, [Al(III)] = 1.48×10^{-7} *M*, pH = 4.60, amount of resin = 0.030 g, stirring time = 15–150 min.

The standard deviation of the absorbance of the blank measured for 10 determinations (average values: 0.129, 0.373, 0.761, 0.869) were 0.004, 0.009, 0.012, 0.012 absorbance units for 15, 100, 500 and 1000 ml sample volumes, respectively. The IUPAC detection limit ($K = 3$)[15]and the quantification limit ($K = 10$)[16] were calculated for 15, 100, 500 and 1000 ml sample volumes (Table 1).

On the other hand, the interference level, can be reduced by diluting the samples, taking into account the sensitivity of the method proposed and the dependence of the sensitivity on the sample volume.

Effect of foreign ions

In Table 3 the effect of various potentials interferent species, commonly found in the water, on the determination of 12.5 μg/l. of Al(III) is listed. This effect was investigated by adding a known amount of the test ion to the aluminium solution. First a 20,000 μg/l. level of potentially interfering ions were tested and if the interference occurred, the concentration of interferent was reduced progressively until interference ceased. Higher concentrations were not tested. Tolerance level is defined as the foreign ion concentration that produces not more than ±5% spectrophotometric error in the recovery of Al(III).

The most severe interference is caused by iron. It causes positive error because the iron forms a complex with CAS and this complex absorbs at the wavelength used in the procedures. The use of 1,10-phenanthroline, after reduction with hydrogen in acidic medium, suppresses the iron interference up to 1500 μg/l. [for total Iron: Fe(II) + Fe(III)]. The cationic complex Fe(II)-1,10-phenantroline remained in solution and it was not sorbed on the resin. On the other hand, the high tolerance level for Cu(II) is probably due to the presence of HMTA as buffer. With respect to the interference from anions F^- and EDTA, it can be attributed to the complexation of aluminium. Moreover, in the case of the anions in general, the existence of competition for the anionic sites of the resin is probable.

Table 3. Effect of foreign ions on the determination of 12.5 μg/l. of aluminium

‡Standard calibration graph method. 15 ml sample. Composition of micaschist: 12.50% Al, 4.19% Fe(II), 1.36% Fe(III) and 0.65% Ti.

Analytical applications

The proposed method has been applied to the determination of aluminium content in natural waters (tap waters and raw waters) and a mineral (micaschist).

Natural waters. The method was applied to the determination of aluminium in water samples by standard addition calibration graph method (Table 4).

(a) *Tap water* from Jaén city and Ubeda city (Jaén province);

(b) *raw water* from the spring of Río Frío (Los Villares city, Jaén province).

The loss of sensitivity caused by the matrix effect could be evaluated from the ratio of slopes of the standard addition calibration graph and the standard calibration graph: the ratios were 0.476 (from Jaén), 0.565 (from Ubeda) and 0.555 (from Río Frío). It is seen that the matrix effect in these waters is noticeable. We attribute this strong matrix effect to the high content of, principally, Ca(II), Mg(II) and HCO_3^- in these waters, because they are very hard waters.

Mineral. The method was applied to the determination of aluminium in mineral samples (micaschist) by standard calibration graph method (Table 4).

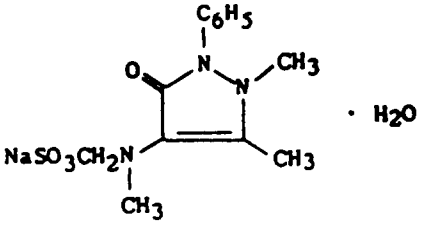
IMMOBILIZATION OF REAGENTS BY POLYMERIC MATERIALS. DETERMINATION OF METAMIZOL

L. LAHUERTA ZAMORA* and J. MARTINEZ CALATAYUD
Departamento de Química Analítica, Universidad de València, València, Spain

(*Received* 3 *August* 1992. *Revised* 4 *January* 1993. *Accepted* 19 *January* 1993)

Summary—A method for immobilization of inorganic reagents, based on the dispersion of the reagent into an unsaturated polyester solution is applied to immobilization of lead dioxide. The obtained solid is of application in a flow-injection manifold for indirect atomic absorption determination of metamizol in pharmaceutical formulations. The procedure gives a linear calibration graph up to 6 ppm of metamizol with a relative standard deviation of 1.6% (3.0 mg/l) and a sample throughput of 72 hr^{-1}.

Metamizol or dipyrone is a white or yellowish-white odourless crystalline powder, soluble in water and alcohol, slightly soluble in chloroform and practically insoluble in ether. It is the sodium sulphonate of amidopyrine (see formulae); it presents analgesic and antipyretic activities and has been implicated as a causative agent in immune haemalytic anaemia: severe hypothermia might result if it is administered concomitantly with chlorpromazine.[1] The official method (from some pharmacopoeias) for amidopyrine determination is titration against perchloric acid in acetic acid medium using methylrosaniline as an indicator.[2]



Scheme 1

FORMULAE

The use of insoluble or solid reagents as bed reactors is a consolidated trend in unsegmented continuous-flow methods mainly due to the advantages offered over homogeneous systems, namely simpler manifolds, saving reagents, increased sensitivity and quicker sample passage.[3–6] It is important to point out the number of applications offered by solid-bed reactors like sample or reagent pretreatment, sample-conversion reactions and integrated reaction–detection devices. The use of solid-bed reactors in FIA has been recently reviewed,[6] and also its application to pharmaceutical analysis.[7,8]

The present paper is concerned with the preparation of packed-bed reactors for use in unsegmented continuous-flow analysis. The proposed application is the oxidation of metamizol by means of lead dioxide in perchloric acid media; the drug oxidation yields Pb(II) in the dissolution which is measured by AAS at 217.0 nm. The procedure based on physical entrapment of solid reagents by polymeric resins,[9] is quite simple and fast and it is proposed for the control analysis of the metamizol in a pharmaceutical formulation.

EXPERIMENTAL

Reagents and apparatus

All solutions were prepared with distilled water. Aqueous solutions of metamizol (Guinama, pure), ascorbic acid (Probus, a.r.), thiamine (Acofarma, pure), pirodoxine chlorhydrate (Acofarma, pure), lidocaine chlorhydrate (Guinama, pure), dexamethasone (Guinama, pure), caffeine (Fluka, pure), paracetamol, (Acofarma, pure) and perchloric acid (Panreac, a.r.) were used. Other reagents used were of analytical grade. The packed-bed reactor was prepared with PbO_2 (U.C.B., a.r.) and a polyester resin solution Al-100 (from Reposa) containing low molecular polyester chains and a cobalt compound as activating agent for the reaction; and, methyl ethyl ketone (from Akco) as a catalyst.

*Departamento de Químèca, Colegio Universitario CEU, Moncada (València), Spain.

Flow-injection assembly

Figure 1 shows the continuous-flow manifolds; the sample injector was from Rheodyne, Model 5041; peristaltic pump Minipuls 2, from Gilson; the determination of lead was carried out by means of an AA from Varian, Model SpectrAA-10 at a wavelength of 217.0 nm; internal diameters of the PTFE tubing were of 0.8 and 1.5 mm for the manifold and the reacting column, respectively.

Procedures

Preliminary experiments were carried out by means of the flow assembly depicted in Fig. 1a, in order to test the reactivity in continuous flow of the PbO_2 reactor; 0.2*M* HCl aqueous solution was used for adjusting the acidity of the drug solution, an analyte stream containing 100 ppm

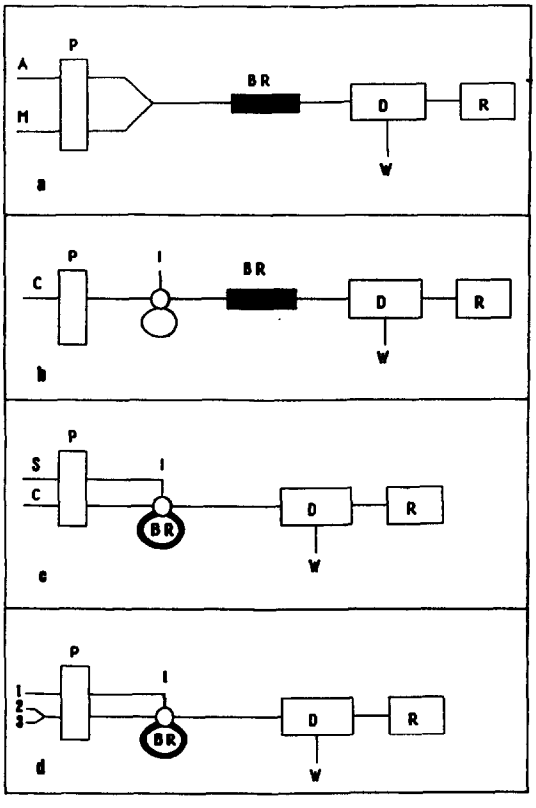


Fig. 1. Flow-injection manifolds. a: Manifold for testing the PbO_2 reactivity with metamizol in different media. b: First manifold proposed for the determination of metamizol. c: Manifold finally proposed for metamizol determination. d: Flow assembly for testing the life-span of the column. A, analyte solution; M, solution for adjusting the medium (acid); P, peristaltic pump; I, injection valve; BR, packed-bed reactor; S, sample; C, carrier; D, detector; and, R, recorder. Channels 2 and 3 (Fig. 1d only) for continuous flowing metamizol and acid, respectively; and 1, for alternative sample injections.

of metamizol, a reagent/polymeric weight ratio of 1/1, and the column was 0.8 i.d. and 15 cm long with 150–250 μm size particles. The procedure consisted of a continuous flow of analyte for 5 min (for column conditioning) and then 10 readings were recorded.

Having established the suitability of the packed-bed reactor, the influence of chemical parameters was sequentially studied: acidity, concentration of the selected acid medium, ionic strength and temperature. The flow manifold configuration was studied on the basis of the chemistry of the system according to the preliminary studies; then the characteristics of the bed reactor and the manifold parameters were established. Finally, the chemical parameters were re-optimized.

Preparation of the bed reactor. Here, 26.40 g of lead dioxide were added to 15.10 g of the polyester resin solution; the mixture was homogeneized by manual stirring and then 0.4 ml of ethyl methyl ketone was added and stirring was continued until the polymer became too rigid. The solid was dried (2–3 hr at room temperature) and then broken with a hammer and ground in a coffee grinder. The selected particles (by sifting) were washed, dried at 80°C, sifted again and stored. The packed-bed was prepared by introducing the particles with the aid of a mini-funnel and continuous stirring into a PTFE tube of 1.5 mm internal diameter.

Preparation of pharmaceutical formulations. The metamizol content was studied in injectables, capsules and solutions. The powder content of three capsules was put in contact with 50 ml of distilled water by magnetic stirring, the resulting mixture was filtered and diluted to 1 l; 1 ml of this solution was levelled to 200 ml. One injection unit was diluted to 1 l and, then, 1 ml of the resulting solution was levelled to 200 ml. The solution was also diluted in two steps: 1 ml to 1 l, and 1 ml to 250 ml.

RESULTS AND DISCUSSION

Preliminary experiments, whose aim was to test the reactivity of the PbO_2 entrapped by the solid polymer, were carried out by means of the manifold depicted in Fig. 1a. The acidified drug solution passing through the reacting column resulted in the oxidation and release of lead from the column; the readings were closely related to the concentration of the drug. Once the suitability of the bed reactor had been established, the flow assembly for the

pre-optimization of the chemical parameters was studied by injecting aqueous sample solutions into the carrier by means of the assembly depicted in Fig. 1b. Different acidic media were tested: hydrochloric, nitric, acetic, phosphoric and perchloric acids (sulphuric acid was excluded in order to avoid lead sulphate precipitation). The acid concentration in the carrier was 0.2*M*; the injected samples contained 50 mg/l of metamizol in 0.2*M* of the same acid as the carrier. Those experiments revealed that the greatest absorbance values were produced by perchloric and phosphoric media. Mean absorbances (5 replicates) were 1.014 HCl; 1.104 HNO_3; 1.122 H_3PO_4; 1.140 $HClO_4$ and 1.068 acetic acid.

Further experiments were carried out with different concentrations of perchloric and phosphoric acids. Both acidic media were studied in three different sets: (a) with a carrier stream of 0.5*M* and varying the acid concentration in the sample solution (50 mg/l of metamizol) over the 0.1–1.0*M* range; (b) aqueous metamizol solutions (50 mg/l) being injected into a carrier stream where acidity varied from 0.1 to 1.0*M*; and, (c) different acidic concentrations containing 50 mg/l of metamizol were injected into a pure distilled water stream. Results are depicted in Fig. 2. The obtained results lead us to select perchloric acid in the carrier and distilled water in the sample. Further work (0, 10^{-4}, 5×10^{-4}, 10^{-3}, 5×10^{-3}, 10^{-2}, 5×10^{-2}, 10^{-1}, 5×10^{-1} and 1*M* perchloric acid) revealed 10^{-1}–1*M* as the best acidic concentration range.

The configuration of the continuous-flow manifold could be important in influencing the degree of reactivity and the dispersion produced. The efficiency of a flow manifold in which the bed reactor is nesting in the sample loop (depicted in Fig. 1c) was tested and results compared with those obtained from the manifold in Fig. 1b. The sample solution was flowing through the sample loop for different time periods, from null to 5 min; best transient signals were obtained for short time intervals and all of them were higher and narrower than those obtained with the manifold in Fig. 1b. The manifold in Fig. 1c with a contact period of 30 sec was selected for further work and the previous results on the influence of acidity were re-optimized by preparing two sets of experiments in which: (a) 20 mg/l of the drug in distilled water were injected into a carrier stream containing different concentrations of perchloric acid, from 0.01 to 1.0*M*; and, (b) 20 mg/l of metamizol in different concentrations of perchloric acid were injected into a carrier 0.1*M* in perchloric acid. The final selected condition from the two sets of experiments was to inject the metamizol dissolved in pure water into a carrier formed by an aqueous solution of 0.1*M* in perchloric acid.

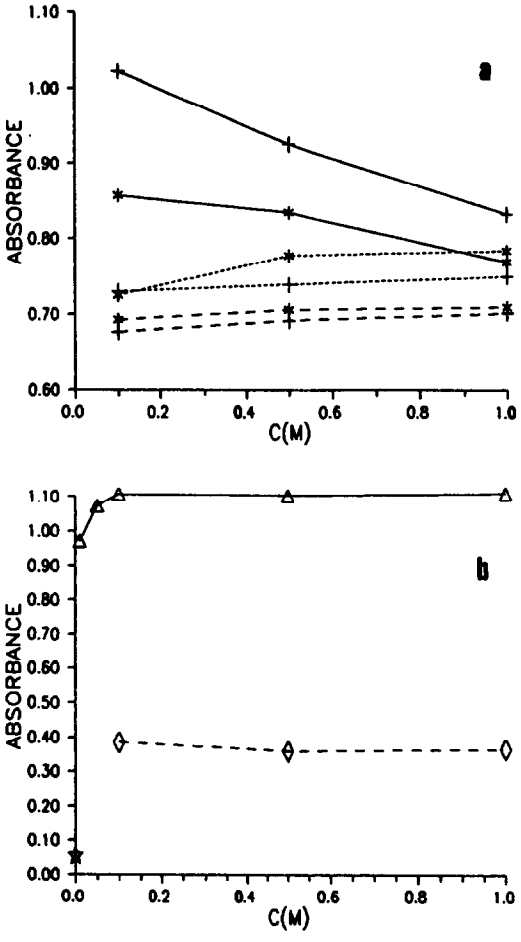

Fig. 2. Influence of acidity on the oxidation of metamizol. a: Influence of acidic media: †perchloric acid; *phosphoric acid solid line, sample in distilled water and perchloric acid solutions as carrier; discontinuous line, carrier stream 0.5*M* in perchloric acid and different acidic concentrations in sample; and, dotted line, different acidic concentrations in sample and distilled water as carrier. For details see text. b: Influence of perchloric concentration. ▲, drug in distilled water and perchloric as carrier; ◇, sample in acidic media and carrier 0.1*M* perchloric; and, ☆, distilled water for sample and carrier.

The influence of ionic strength was tested by preparing different concentrations of KCl in the sample solution; the tested range was 0–2.0*M* in KCl. No relevant influence was observed which lead to the selection of the pure distilled water as the sample and perchloric acid solution as the carrier.

The influence of temperature on the outputs was studied by introducing the carrier container into a water bath at different temperatures; from 20.0 to 78.0°C. Temperature proved not to be a critical parameter; transient signals were slightly increased with temperature. Because of that, room temperature was preferred for further work.

The bed reactor variables are also of relevant importance to the degree of reactivity and the dispersion produced onto the sample, which means a direct influence on the sensitivity and sample throughput. The tested parameters, in the reported order were, internal diameter of the column, size of the bed particles, column length and the weight ratio of entrapped lead dioxide in the resin (milligrams of lead dioxide/milligram of polymeric resin). The first parameter was tested over the range 0.5–1.5 mm at different flow-rates (see Table 1). An internal diameter of 1.5 mm and a flow-rate of 3.00 ml/min were the selected values for further work.

The size of the particles was also tested; selection of the particles was carried out by sifting; the studied range was from 90 to 120 μm up to 300–400 μm. Bearing in mind the peak height and the base width the selected sieve was the one which produced particles over the size 200–300 μm.

The column length was tested from 8.0 to 38.0 cm, with a flow-rate of 3.0 ml/min, particle size of 200–300 μm and 1.5 mm internal diameter, by injecting 20 ppm of that drug in pure water into a carrier containing 0.1M perchloric acid. Results are depicted in Fig. 3 and the selected length was 31 cm. The sample volume of the packed loop, studied by the usual calibration method, was 384.5 μl.

The influence of the weight ratio of immobilized lead dioxide in the resin was studied over the range 0.50–5.00 (g/g); the highest limit of lead dioxide which can be immobilized was limited by the physical consistency of the obtained solid. From the graph of absorbance *vs.* weight ratio, 1.75 was selected for further work.

Table 1. Influence of internal diameter of the column

Internal diameter (*mm*)	*Q*(*ml*/*min*)	Absorbance
0.5	1.1	0.216
0.8	1.1	0.181
	1.5	0.288
	2.3	0.573
1.5	1.1	0.612
	1.5	0.739
	2.3	0.945
	3.0	1.060
	5.5	1.143

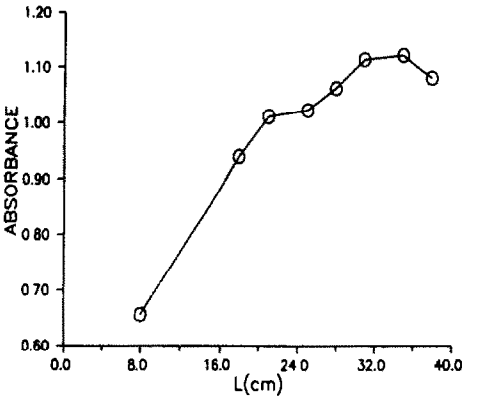

Fig. 3. Influence of column length.

The chemical parameters, concentration of perchloric acid (sample solution and carrier), were re-optimized on the basis of results obtained from the optimization of FIA parameters and by means of the univariate method. No changes are proposed from the above reported values.

After the optimization of chemical and FIA parameters and previous to the study of analytical application, a series of experiments were carried out with the aid of the assembly depicted in Fig. 1d in order to test the life-span of the column. The series of experiments was as follows: (a) the base-line was obtained by passing distilled water (channels 2 and 3), with mean absorbance −0.029; (b) an aqueous solution containing 40 ppm of metamizol was forced through channel 2 and distilled water through channel 3, mean absorbance 0.047; and, (c) as in (b) but the distilled water in channel 3 was replaced by a 0.1M $HClO_4$ stream, mean absorbance 0.615.

Provided the perchloric acid produced the higher degree reaction, (column consumption) the life-span of the column was checked by continuous flow of 40 mg/l of metamizol, channel 2, and 0.1M $HClO_4$, channel 3; after 30 min the column was washed with 0.1M $HClO_4$ and then a set of 10 injections of 5 ppm metamizol were carried out. The experiment was repeated; the average peak-height (in absorbance units) calculated for each set was: 0.735 (3.2%), 0.768 (2.4%), 0.780 (3.2%), 0.780 (3.8%) and 0.732 (4.2%). The readings during the continuous passing of metamizol solution were constant, at 0.645, during the whole experiment. The amount of metamizol forced through the

column by continuous passing was equivalent to 7813 injections of 3 ppm; although the readings remained constant, it was supposed that the life-span of the column did not merit further investigation.

ANALYTICAL APPLICATION

The study of the analytical application of the continuous flow procedures was carried out to establish the application range, reproducibility and sample passage.

The calibration graph was linear over the range 1.0–6.0 ppm of metamizol. The reproducibility of the columns behaviour was tested by preparing three different columns and obtaining the calibration graphs on different days. Table 2 depicts the linear equations and correlation coefficients calculated for the different days tested.

Forty-two different samples containing 3.0 ppm of metamizol were injected into the carrier stream in order to determine the relative standard deviation and sample passage; the results obtained were 1.64% (mean absorbance 0.463) and 72 samples/hr, respectively.

The tolerance of the method to foreign compounds which can be found in typical pharmaceutical samples containing metamizol was investigated by using solutions containing 5.0 mg/l of the drug and adding various concentrations of the interference up to 100 mg/l. The results obtained for various interfering compounds were as follows (concentration in milligrams per litre and relative error, as a percentage): thiamine 100, 1.8; pyridoxin 50, 1.5; lidocaine chlorhydrate 50, 0.6; dexamethasone 100, 1.2; paracetamol 5, 77; caffeine 100, 2.1; ascorbic acid 5, 2.7.

The metamizol content of Nolotil injectables, Nolotil Compositum capsules (from Europharma) and Syntaverin solution (from Igoda) was determined. At least five different preparations were analysed and results were compared with those supplied by the manufacturer. For Nolotil, with given content of 2000 mg/5 ml, the amount found was 2030 mg/5 ml (relative error 1.5%); for Syntaverin, with given content of 500 mg/ml, the amount found was 497.5 (relative error 0.5%) and for Nolotil Compositum, with given content of 300 mg/tablet, the obtained amount was 299.2 (relative error 0.3%).

Table 2. Stability of the column by preparing calibration graphs in different days for three different columns (A, B, C)

Column	Date	Linear equation	Correction coefficient
A	1-VI	$0.140 + 0.100\,X$	0.996

STUDY ON THE DETERMINATION OF METRONIDAZOLE IN HUMAN SERUM BY ADSORPTIVE STRIPPING VOLTAMMETRY

ZHENHUI WANG,* HONGXUN ZHOU and SHUPING ZHOU
Department of Chemistry, Henan Normal University, Xinxiang 453002, People's Republic of China

(*Received* 29 *July* 1992. *Revised* 9 *December* 1992. *Accepted* 14 *December* 1992)

Summary—In Britton–Robinson buffer, metronidazole is preconcentrated on a HMDE at 0.0 V (*vs.* Ag–AgCl). An adsorptive stripping peak is observed at −0.62 V. The response is linear from 1×10^{-8} to $1 \times 10^{-6} M$ with 1.5 min accumulation. The method has been successfully applied to the determination of metronidazole in human serum and formulations.

Metronidazole (MTZ)[1-(2-hydroxyethyl)-2-methyl-5-nitroimidazole] is an antimicrobial agent used for the treatment of trichomoniasis and amoebic dysentery. It can kill or inhibit the majority of anaerobic bacteria when its concentration is between 2 and 8 μg/ml in human serum.[1] Therefore, determination of trace levels of MTZ is very important in the prevention of *anaerobic* bacteria infection in clinics.

Various methods have been employed for the determination of MTZ, including spectrophotometry, high-performance liquid chromatography and polarography.[2–4] In this paper, a new method for the determination of trace amounts of MTZ by adsorptive stripping voltammetry has been established. The analyte was preconcentrated by adsorption on the surface of the electrode and the surface-active species was then determined by a voltammetric scan method. As the present study shows, submicromolar MTZ in human serum which has been pretreated can be measured by this method. The sensitivity of this method with 2 min preconcentration is over 50 times higher than that of the pioneer work.[4]

EXPERIMENTAL

Apparatus

A model 79-1 voltammeter (Jinan No.4 Radio Factory) with a Model JM-01 HMDE working electrode (Jiangsu Electroanalytical Instrument Factory), a Ag–AgCl (saturated KCl) reference electrode and a platinum wire auxiliary electrode were used for voltammetric assay. An Orion Research Model SA 720 pH Meter was used for pH determination.

Reagents

Stock solution (4 mg/ml) of MTZ, medical injection, standardized by the standard method.[5] More dilute solutions were prepared daily by dilution with deionized distilled water. The supporting electrolyte was a Britton–Robinson (B.R.) buffer (pH 4.6).[6] All the chemicals were of analytical-reagent grade.

General procedure for adsorptive stripping voltammetry (AdSV)

A 5.0 ml aliquot of B.R. buffer (pH 4.6) solution was placed in the polarographic cell, diluted to 10 ml with de-ionised distilled water, and deaerated by passage of high-purity nitrogen for 5 min. The HMDE was kept at the desired accumulation potential for a given time period, while the solution was stirred at 400 rpm. After a 15 sec rest period, a negative-going scan was initiated, the resulting voltammograms being recorded.

Serum treatment[7]

Pipette 1.00 ml of human serum into a 5-ml centrifugal tube, add 2.0 ml of 0.2 M $Ba(OH)_2$ and 1.0 ml of 5% $ZnSO_4$, mix thoroughly and stand for 2 min. Centrifuge at 2000 rpm in a high speed centrifuge, and then follow the procedure described above. All data were obtained at ambient temperature.

*Author for correspondence.

RESULTS AND DISCUSSION

The derivative technique is an improvement in linear-sweep voltammetry that has been developed for conventional voltammetric measurements. The sensitivity of using second-derivative stripping voltammetry is higher than that of conventional stripping methods.[8,9]

Figure 1 shows the second-derivative cathodic stripping voltammograms for MTZ at the $1 \times 10^{-7}M$ level after 1.5 min preconcentration at 0.0 V from a stirred solution (peak a). With a 4 min accumulation time, a detection limit of $2.5 \times 10^{-9}M$ was obtained. Direct measurement performed under the conditions as mentioned above, but without preconcentration, gave peak b. The stripping peak current b is too small to be useful. It is evident that MTZ can be determined by using AdSV at a mercury electrode.

The effect of pH on the peak potential at a concentration of $1 \times 10^{-7}M$ MTZ was studied over the pH range of 2–8. The peak potential shifts linearly to more negative values with the increase in pH. The peak potential varies with pH according to the following equation: $E_p = -0.24 - -0.08$ pH. Buffer solutions must be used to keep the pH value constant. The peak current was increased at high pH, but the reproducibility was unsatisfactory. The peak form and reproducibility of MTZ were best when pH 4.6 B.R. buffer was used as supporting electrolyte.

The stripping peak current of the MTZ is affected by the preconcentration potential E_a. Experiments showed that the peak current reaches a maximum value at $E_a = 0.0$ V which indicates that this potential is advantageous for the adsorption of the MTZ on the mercury electrode.

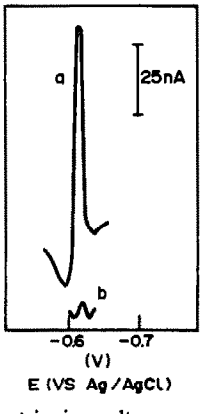

Fig. 1. Adsorptive stripping voltammograms for $1 \times 10^{-7}M$ MTZ in B.R. buffer (pH 4.6). HMDE, scan-rate 100 mV/sec. (a) Preconcentration for 90 sec; (b) without preconcentration.

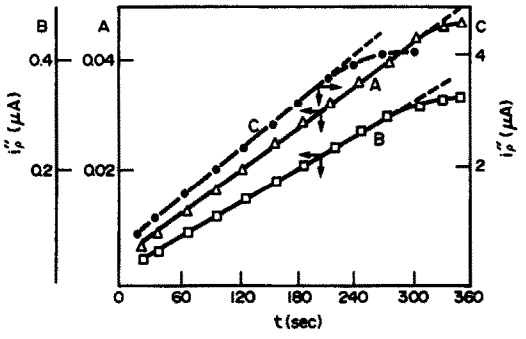

Fig. 2. Effect of preconcentration time on the stripping peak current. (A) [MTZ] = $1 \times 10^{-8}M$; (B) [MTZ] = $1 \times 10^{-7}M$; (C) [MTZ] = $1 \times 10^{-6}M$.

Figure 2 shows the dependence of the adsorptive stripping peak current on the accumulation time at three concentration levels of MTZ. The stripping peak current increased with increasing accumulation time, the corresponding dependence has the nature of an isotherm. At the lower concentration $1 \times 10^{-8}M$, a linear dependence of peak height with accumulation time is observed with a slope of $0.15nA$/sec. The slope is $1.1nA$/sec for $1 \times 10^{-7}M$. But at higher concentration ($1 \times 10^{-6}M$), a linear relation holds up to 200 sec (slope $12.7nA$/sec).

The linear region of the graph depends on the analyte concentration. Thus the choice of optimum accumulation time depends on the range of concentration studied.

The peak current increases linearly with the area of HMDE between 0.02 and 0.04 cm^2, and the latter value was chosen as the optimum.

The presence of other surface-active compounds which might affect the response with competitive adsorption on the mercury surface was investigated, particularly those which might be present in biological samples. The effects of some cations, Cl^- and albumin were examined with a $6 \times 10^{-7}M$ of MTZ solution. The addition of 4 ppm of albumin gives rise to a MTZ peak depression of 35%. It has been proven by our experiments that determination of MTZ has no interference after the human serum is pretreated as mentioned previously. The addition of up to 500 ppm of Na^+, K^+; 430 ppm of Ca^{2+}, Mg^{2+}; 450 ppm of Cl^- and 125 ppm of Cu^{2+}, Pb^{2+}, Cd^{2+} have no interference on the determination of MTZ.

Table 1. Recovery and precision

	MTZ found* (ng/ml)	C.V. (%)	Amount of MTZ added (ng/ml)	Amount of MTZ recovered (ng/ml)	Recovery (%)
Sample					
Human serum	32	4.7	25	55	92
Formulation	120	1.8	70	187	96

*Each value represents the mean of seven analyses.

The preparation of calibration graph in human serum

The serum sample pretreatment step is required owing to high protein content in human serum. The loss of MTZ is unavoidable in the process of serum treatment. For instance, a linear current–concentration relationship in which the slope is $2.9nA$ per $10^{-8}M$ is observed for aqueous standards, the slope is $1.8nA$ per $10^{-8}M$ for serum. Therefore it is necessary to prepare the calibration graph in human serum, and the procedure is as follows.

A 1.00 ml aliquat of human serum not containing MTZ was placed into a 5-ml centrifuge tube. Adding known amounts of MTZ it, and the treatment procedure for serum followed the method given above. The calibration graph passed through the origin and was linear from 1×10^{-8} to $1.6 \times 10^{-7}M$ (a slope of $1.8nA$ per $10^{-8}M$) for 120 sec preconcentration and from 1.8×10^{-7} to $1.6 \times 10^{-6}M$ for 60 sec preconcentration (slope is $2.7nA$ per $10^{-7}M$). The correlation coefficients were 0.9981 and 0.9993, respectively.

Application to determination of MTZ in human serum and in formulation

This determination is feasible for trace amounts of MTZ in human serum with short preconcentration time. The coefficients of variation for the determination of MTZ in human serum and in formulations are 4.7 and 1.8%, respectively, for seven replicate determinations as shown in Table 1.

The recoveries of known amounts of MTZ added to human serum and formulation samples are also given in Table 1. The detection limits have been estimated as 1.7 ng/ml in human serum and 0.63 ng/ml in formulation for 120 sec preconcentration. The results of practical clinical determination are shown in Table 2. This method is suitable for the determination of trace amounts of MTZ in human serum.

The electrochemical behavior of the reductive peak of MTZ was also investigated. The cyclic voltammogram was recorded at HMDE, a reductive peak is observed at −0.62 V, but the oxidative peak is not found on the anodic branch. This result shows that the electrode reaction is irreversible. According to controlled potential coulometry,[10] the number of involved electrons was found to be 4. The total reaction is described as following:

$$[R—NO_2] + 4e + 4H^+ = RNHOH + H_2O$$

This stoichiometry is consistent with the reaction process, in which the nitro group of MTZ is reduced to hydroxylamine in a four-electron process.

Table 2. The concentrations of MTZ in serum following intravenous drips of 0.5 g (drip volume 500 ml)

Time after drip (hr)	MTZ concentration (male serum) (μg/ml)	C.V. %
0	0.00	
1	12.78, 12.29, 11.88, 12.43	3.0
3	16.97, 17.38, 17.63, 17.78, 16.58	2.8
8	8.12, 7.67, 7.74, 8.05, 8.35	3.5

THE DESIGN OF AN ON-LINE FLOW INJECTION SYSTEM WITH A GRAVITATIONAL PHASE SEPARATOR FOR FLAME ATOMIC ABSORPTION SPECTROMETRY AND ITS ANALYTICAL PERFORMANCE

SOULIN LIN and HWIPING HWANG

Department of Applied Chemistry, China University of Geosciences, Wuhan 430074, People's Republic of China

(*Received* 1 *July* 1992. *Revised* 4 *December* 1992. *Accepted* 28 *December* 1992)

Summary—A liquid–liquid flow extraction system associated with a specifically designed phase separator has been developed. A common trisectional confluence connector was used for segmentation. The system was connected on-line with a flame atomic absorption spectrometer. The performance of the system was studied with respect to determining copper and gold. The detection limits were 1 μg/l. for copper and 1.8 μ/l. for gold, and the precision was 1.8 and 2.5%, respectively, with medium signal enhancement factor 70 for gold, and 78 for copper. Analytical results of real sample analysis were in good agreement with certified values.

Liquid–liquid on-line extraction and preconcentration of trace amounts of heavy metals by flame atomic absorption spectrometry has been found to be very effective and efficient.[1–4] Generic solvent extraction systems with typical segmentors and phase separators were described elsewhere.[5–8] The phase separator is the most critical component of these systems. It seems that the most commonly used phase separators are those constructed using a PTFE membrane sandwiched between two pieces of Perspex. However, these devices are not robust and their use might be restricted, owing to the relatively short life of the membranes. Authors sometimes use a minipore PTFE nylon backed membrane to overcome this difficulty. Backstrom *et al.*[9] described a modified separator using a fluoropore filter supported by a Teflon-coated screen. They used a 1.5 m length of 0.5 mm inner diameter tube as a pressure restrictor to increase the pressure drop across the membrane, which resulted in less loss of organic phase. Sahlestrom and Karlberg[10] developed an unsegmented extraction technique without separation of the two immiscible phases following extraction. Using this technique, they achieved efficiencies typically between 8 and 18% which were far less than routine solvent extraction efficiencies of 60–96%.

The aim of this work is to develop a semi-automated continuous extraction system which is robust and has long-term stability. In this system, the aqueous sample phase and organic solvent were merely segmented by a usual confluence connector. Good regularity of segments was obtained provided that pulse dampers were used to smooth the pulsed streams of the aqueous sample phase and the organic solvent caused by the peristaltic pumps. Copper and gold were used to test the effectiveness and efficiency of the proposed extraction system. Hioki *et al.*[11] reported the liquid–liquid extraction procedure of copper and zinc in 1988. They determined copper and zinc in high purity bismuth by extracting them together as their thiocyanate complexes into methyl isobutyl ketone and followed by atomic absorption spectrometry. In the present work, copper was extracted as its thiocyanate complex into methyl isobutyl ketone (MIBK) and quantified by flame atomic absorption spectrometry. As for gold, the most common method was chosen, which was based on the extraction of the trichloro-complex into MIBK and the gold content was then determined by flame atomic absorption spectrometry. Results obtained in this work demonstrated that the newly designed extraction system and manifold were suitable for routine sample handling and preconcentration of trace metals. This device has made it possible to mechanize the flow system and automate the operation. From the beginning with the aqueous sample to ending with flame atomic absorption measurement, only two manual steps of feeding

the sample and exchanging it with water were needed. A throughput of 28 samples per hour can be achieved with a sample consumption of less than 10 ml per determination.

EXPERIMENTAL

All reagents used were at least of analytical reagent grade. Deionized and distilled water was used throughout. The extraction reagent, NH_4SCN, was made to 15% aqueous solution (w/v) and purified by extraction with MIBK. The extraction was repeated several times until the organic extract was colorless. The purified solution was then diluted successively for use.

The copper standard solution (1000 mg/l. in 2% nitric acid) was prepared from metallic copper. All the standard solutions were prepared by serial dilutions and the standards with concentrations below 0.1 mg/l. were prepared fresh daily.

The gold standard solution (1000 mg/l. in 1% aqua regia) was prepared from metallic gold. All the standard solutions were prepared by serial dilution with 10% hydrochloric acid.

Nitric acid, hydrochloric acid, hydrofluoric acid and ascorbic acid were used in this work.

Equipment and apparatus

A WFX-1A atomic absorption spectrometer (Beijing Second Optical Instrument Factory, China) was used under the operating conditions listed in Table 1.

Table 1. Operating conditions for flame measurements

Wavelength (*nm*)	Au	242.8
	Cu	324.7
Lamp current (*mA*)		4
Slit width (*μm*)		200
Air flow-rate (*l./min*)		6.7
Acetylene flow-rate (*l./min*)		0.67
Optimum burner height (*mm*)		7
Solvent uptake rate (*ml./min*)		10

An IFIS-A intelligent flow-injection sampler (Xian Spring Institute, China) was used for sample handling and preconcentration throughout.

Manifold

The extraction manifold using an eight-channel valve and 1.06 mm inner diameter by 3-m long PTFE tubing as the extraction coil is shown in Fig. 1. The pulses in the sample flow and solvent flow were reduced with the pulse dampeners PD1 and PD2. A trisectional confluence connector with a 1.0 mm inner diameter was used as a segmentor. The flow rates used were 12.6 ml/min for the sample and 0.42 ml/min for MIBK. To facilitate the attainment of the desired flow-rate ratios, the two phases were propelled by separate peristaltic pumps. The sample and MIBK passed the extraction coil, proceeded to segment and finally entered the phase separator. The MIBK was automatically separated from the aqueous phase owing to the difference in specific gravities of the two phases. The solvent extract was then propelled

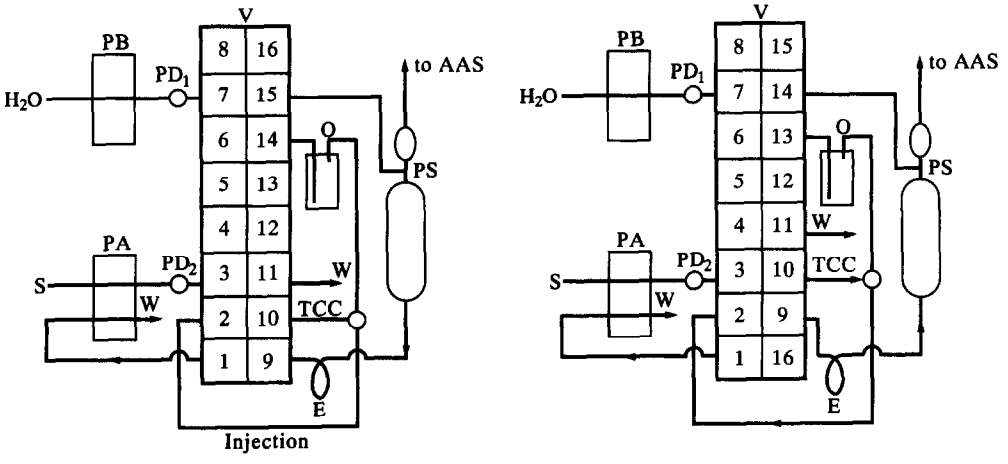

Fig. 1. Extraction manifold: (a) position for injection and washing; (b) position for sample loading. PA—pump A with one silicone rubber pump tube (1.35 mm i.d.) for sampling and a larger one for waste, PB—pump B with one silicone rubber pump tube (1.0 mm i.d.), O—displacement bottle for MIBK, PD1—pulse dampener for MIBK, PD2—pulse dampener for the sample, TCC—trisectional confluence connector, E—extraction coil, 3 m × 1.06 mm i.d. PTFE tubing. V—eight-channel valve, PS—gravitational phase separator, W—wastes.

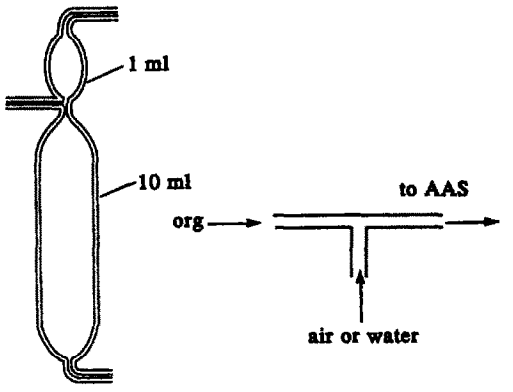

Fig. 2. Construction of the phase separator. (a) Phase separator, (b) compensator.

into the nebulizer of the spectrometer for atomic absorption measurement.

Phase separator

The construction of the phase separator is shown in Fig. 2. The capacity of the bulk of the device was 10 ml with a narrow neck for the separation of MIBK from the aqueous phase. A T-shaped capillary tube was inserted between the phase separator and the spectrometer in order to compensate the difference between the total flow-rate of the manifold and the uptake rate of the spectrometer. Both air and water can be used for compensation.

The capacity of the phase separator was calculated according to the following equation:

$$V_{PS} = Q_w/Q_{org} \times V_{org},$$

where V_{PS} is the capacity of the phase separator, Q_w/Q_{org} is the flow-rate ratio of the aqueous sample phase to the organic solvent, the V_{org} is the volume of organic extract that can give a signal greater than 90% of the equilibrium absorbance. Since an organic extract volume of 200 μl (see Fig. 6) was big enough to meet this requirement and the optimum value of Q_w/Q_{org} for the proposed extraction system was about 30 (see Fig. 5), the capacity of PS must be greater than or equal to 6 ml. In order to provide suitable capacity for extractions which have larger value of Q_w/Q_{org}, V_{PS} was made up to 10 ml. Larger capacity is not suggested, for the larger the capacity is, the longer exhausting time of V_{PS} will be.

The manifold program and time cycle of determinations are shown in Tables 2 and 3.

Segmentor

Several segmentor types of varying efficiency have been described in the literature.[9,12-14] In this work, a usual Teflon trisection confluence connector with 1.0 mm bore size was used as the segmentor instead of a specially designed one, with the three capillaries positioned horizontally. But for segmentation studies, a Perspex connector of the same size was used so that it is possible to follow the segment formation process visually. In these studies, the aqueous phase used was an acidic solution of methyl orange which has a strong red color to permit visual observation of the segments in the PTFE tubing. The organic phase was benzene which does not attack the Perspex connector.

Table 2. Manifold program

Step		1	2	3	4	5	6	7	8

Flow rate corresponding to the pump speed is as follows:

Speed of pump A	90	80	70	60	50	40
Flow rate (*ml/min*)	17.5	15.5	13.5	11.5	9.5	7.5
Speed of pump B	12	8	4			
Flow rate (*ml/min*)	1.23	0.82	0.42			

Unit of pump speed—rotations per minute.

Table 3. Time cycle of determinations

Time (*sec*)	Function
0–24	Waste in PS is drawn off by PA
25–31	PA stops, PB starts to rinse PS
32–50	PB stops, PA starts again to empty PS
51–52	PA stops. Manually place the sample in position.
53	PA starts, V turns to load position. The sample is allowed to fill up TCC
54–98	PB starts. The two immiscible phases enter TCC at different flow-rates. Segments form in the extraction coil, and then enter PS. The solvent extract is separated from the sample owing to gravitational differences
99–105	PA and PB stop simultaneously. Manually change the sample with water
106–114	PA starts to propel all the segments into PS until the organic extract goes up into the upper bulb of PS
115–117	PA stops, waiting for clear separation. V turns to injection position, waiting for measurement
117–127	PB starts to propel the organic extract to AAS

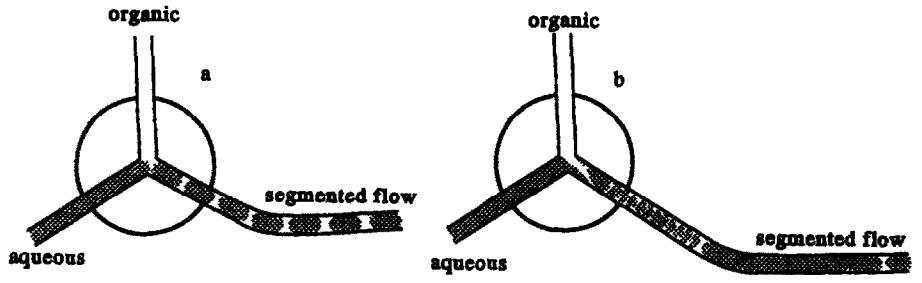

Fig. 3. Process of segment formation (a) at low Q_w/Q_{org} and low total flow rate (< 1 ml/min), (b) at high Q_w/Q_{org} and high total flow rate (10 ml/min). The concentration of Cu is 40 ng/ml.

Pulse dampeners

PD A was an air dampener which had a cylindrical cavity of 200 μl filled with air to smooth the sample flow by the air compressibility. The dampener was initialized 30 sec after starting the pump by introducing air for 4 sec into the sample flow, thus filling the cavity with air at the working pressure.[16] PD B was a glass column 10 cm long and 3 mm inner diameter filled with glass bits.

RESULTS AND DISCUSSION

Segmentation studies

Segments obtained with the trisectional confluence connector had a regular distribution when pulse dampeners for the two phases were incorporated. With the phase flow ratio near to unity, the lengths of the organic and aqueous phase segments were approximately equal. At low phase flow ratio and low total flow rate, droplets or plugs of the organic solvent formed immediately at the confluence point in the continuous flow of the aqueous sample phase, see Fig. 3(a). The segment size mainly depended on the flow rate difference of the two immiscible phases. Segment lengths were short under these flow conditions, e.g. 3 mm for MIBK and 15 mm for the aqueous sample phase. On the other hand, the segmentation mechanism was quite different when the phase flow rate was high. In this circumstance, the process leading to segment formation was attributed to the "ripple process",[15] in which the segment size was determined both by the flow rate difference and the interfacial tension between the two immiscible phases. Firstly, MIBK was drawn into a thin film by the aqueous sample phase. When the tangential force at the interface, which arose from the flow rate difference of the two phases, equalled the interfacial tension, the thin film was broken into very small droplets which wetted the wall of the PTFE tubing, resulting in coalescence so that bigger droplets of MIBK were finally formed at a distance of about 40 mm from the confluence point, see Fig. 3(b). Segmentation remained regular in the extraction coil as long as the inner wall of the tubing was clean and smooth. The segment length of the aqueous phase increased with increasing Q_w/Q_{org}, and in contrast, that of MIBK decreased somewhat when the flow ratio was increased.

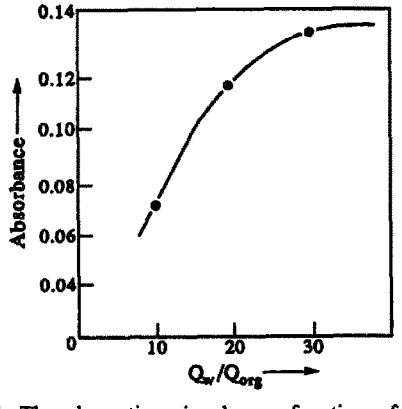

Fig. 4. The absorption signal as a function of Q_w/Q_{org}, varying Q_w at fixed Q_{org}. Length of extraction coil—3 m, Q_{org}—0.42 ml/min, concentration of Cu—40 ng/ml.

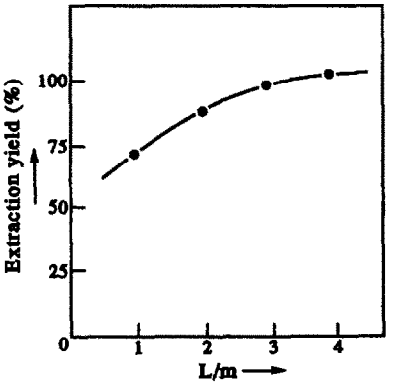

Fig. 5. The extraction yield as a function of extraction coil length.

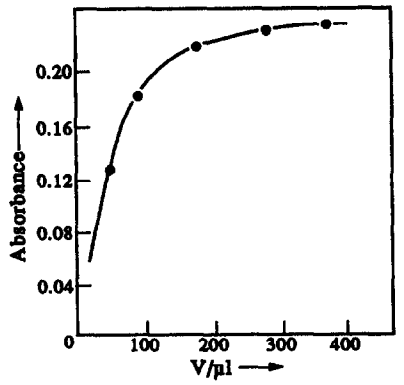

Fig. 6. The absorption signal as a function of the injected volume of the sample.

In the case without a pulse dampener, irregular segmentation may result from the pulse action. The segmentation pattern was complicated with many short segments and a long one sandwiched between them. However, it was found that repeatable patterns can be observed in the extraction coil, though the segment distribution was uneven.

Influence of phase flow ratio

The concentration factor value depends on the flow ratio of the aqueous phase to the organic phase and it would seem that the greater the ratio is the greater the concentration factor will be. However, this is not necessarily always true and there are practical limits to the ratio. Very high phase flow ratio, and thus total flow rate, may cause loss of extraction efficiency. It can be seen from Fig. 4 that the output signal of the spectrometer varies as a function of the phase flow ratio and the curve approaches a maximum plateau at a point corresponding to a flow ratio of 30.

Length of extraction coil

The extraction yields expressed as a percentage of the absorbance at equilibrium at phase flow ratio 30 is given in Fig. 5. It can be seen that the optimum value of tube length was 3 m, corresponding to an extraction time of 12.6 sec at the given pump rates.

Table 4. Extraction efficiencies for the extraction of gold from aqueous phase to MIBK

Coil length (*cm*)	200	200	200

Sample consumption (*ml*)			7
MIBK consumption (*ml*)			0.22

*Compared with nebulization of aqueous solution.

Injected volume of the organic extract

The effect of injected volume of the organic extract on the absorption peak height was examined. The results are plotted in Fig. 6. In the flow system used in this work for determining Cu and Au, an injected volume of 200 μl was used.

Concentration factor and signal enhancement

The concentration factor, CF, is defined as

$$CF = (Q_w/Q_{org}) \times E \times 100$$

where E is the extraction efficiency given as a percentage of the concentration of the analyte in the organic phase at equilibrium.

The extraction efficiencies for the extraction of gold with different Q_w/Q_{org} are shown in Table 4.

Using the present extraction system, about 70-fold enhancement in sensitivity compared to direct aspiration of aqueous standard was obtained for gold. From Table 4, we may conceive that 2.4-fold enhancement is due to the effect of the organic solvent.

The final manifold

The final manifold shown in Fig. 1 was considered suitable for extractions operating at phase flow ratios of 30 or less. Since much more sample was needed and much larger capacity of the phase separator was required when using higher flow ratios and these would inevitably increase the washing time of the phase separator, a very high phase flow ratio and total flow rate were therefore not preferred. Hysteresis of MIBK in the extraction coil was observed. It was found that MIBK cannot be completely driven out of the extraction coil by water if the resting time in step 5 for pump A in Table 2 was short. This problem was solved by increasing the resting time of pump A, for example 7 sec, allowing coalescence of MIBK which formed thin films on the inner wall of the PTFE tubing,

Table 6. Comparisons of the performance of different phase separators*

	Gravity separator	Membrane separator	Present separator
Construction	Simple	Complex	Simple
Capacity	200 *μl*	150 *μl*	10 *ml*

leading to the formation of drops and plugs. In order to protect the pump tubing from attack by MIBK, if any, a displacement bottle for MIBK was positioned between the outlet of the injection valve and the pump.

Analytical performance

The analytical performance achieved by the proposed flow extraction system, including detection limits, precision, sensitivity enhancement, sample throughout, sample consumption and MIBK consumption, are listed in Table 5. The sensitivity enhancement factor depends on complex formation, phase flow ratio and loading time, etc. The enhancement factor for a phase flow ratio 30 and a loading time of 30 sec, which is equivalent to a sample volume of 6.8 ml and a MIBK volume of 0.21 ml, is 78 for copper and 70 for gold. The detection limits were calculated on the basis of three times the standard deviation of 11 measurements.

Comparison of the performance of the designed phase separator and that of the existing phase separators are given in Table 6.

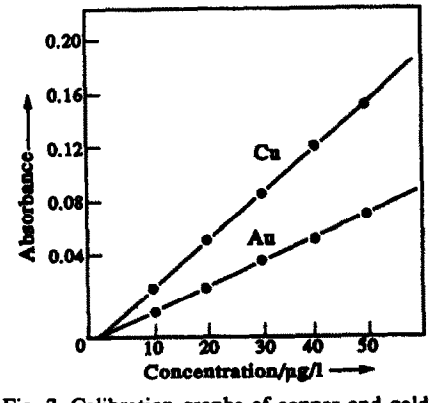

Fig. 7. Calibration graphs of copper and gold.

Real sample analyses

In order to evaluate the figures of merit of the manifold and the accuracy of the procedure, several national and local standard reference rock samples were analyzed. All measurements were performed with the same FI program and using aqueous standard solutions for calibration. As can be seen in Fig. 7, the calibration graphs were linear within the range of interest in this work. It should not be understood that the dynamic range of linearity is much wider. The results presented in Table 7 are in good agreement with the certified values and the precision is acceptable.

Sample preparation

Determination of gold. Weigh out 10 g of the rock sample into a 250 ml conical flask, wet the sample with water. Add 30 ml of hydrochloric acid and heat on a hot-plate for 30 min. Add 10 ml of nitric acid, heat to gently boiling and continue for 2 hr, and then evaporate to a minimum volume. The procedure is repeated one time for complete dissolution of gold and finally evaporate the solution to just dryness. Dissolve the residue with 20 ml of 10% hydrochloric acid, filter through a Bushner funnel

Table 7. Results for copper and gold in standard ore samples

Sample	Au Found	Au Certified value (*ng/g*)	Cu Found	Cu Certified value (*μg/g*)
CSD-1			21.1	21.7 ± 0.2
GSD-2			5.0	4.9 ± 0.2
GSD-3			175.5	177 ± 3
GSD-8				
23CRD-55	940	995 ± 16

23GRD-59	4200	4035 ± 23		

using gentle suction. The filtrate is collected in a 100 ml volumetric flask, made up to the mark with 10% hydrochloric acid. The resultant solution is allowed to stand for extraction.

Determination of copper. Weigh out accurately 0.1 g of the rock sample into a PTFE crucible, add 6 ml of hydrochloric acid and heat on a hot-plate for 20 min. Add 2 ml of nitric acid, 5 ml of hydrofluoric acid, followed by several drops of perchloroic acid. Heat gently for 2 hr, and finally evaporate to dryness. Dissolve the residue with 5 ml of hydrochloric acid, dilute with 20 ml of distilled water, filter with a suitable filter paper and collect the filtrate in a 50 ml volumetric flask. Make up to volume with distilled water. Pipette 5 ml of the resultant solution into another 50 ml volumetric flask, add 10 ml of 15% ammonium thiocyanate, 2 ml of 10% ascorbic acid and 1 ml of 5% sodium fluoride, dilute to the mark with distilled water. Shake the solution vigorously and allow to stand for extraction.

CONCLUSION

The results presented in this work demonstrate the applicability of the on-line liquid–liquid extraction system associated with the all-glass gravitational phase separator. This device has a long-term stability and is robust enough for routine analyses.

SPECTROPHOTOMETRIC DETERMINATION OF TRACE COPPER WITH A Cu-DIETHYLDITHIOCARBAMATE-β-CYCLODEXTRIN COLOUR SYSTEM*

SHIHE LI, SHENGQUAN LI† and ANJIA CHEN
Department of Basic Sciences, Shanxi Agricultural University, Taigu, People's Republic of China

(*Received* 23 *June* 1992. *Revised* 14 *December* 1992. *Accepted* 14 *December* 1992)

Summary—A simple, selective and accurate spectrophotometric method for determination of trace copper with diethyldithiocarbamate(DDTC) in the presence of β-cyclodextrin(β-CD) in ammonia media has been developed. The apparent molar absorptivity of Cu(II)-DDTC-β-CD inclusion complex is 1.3×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ at 436 nm, and Beer's law is obeyed for copper in the range 0–150 μg/25 ml. The detection limit is $4.38 \times 10^{-7} M (S/N = 3)$. The proposed method has been successfully applied to the determination of copper in aluminium alloys, soils, millet, wheat flour, herbs, vegetables and some traditional Chinese herbal medicines with satisfactory results.

Cyclodextrins are cyclic, non-reducing oligosaccharides containing six, seven or eight glucopyranose units. β-Cyclodextrin(β-CD), the most generally useful member of this group, contains seven glucopyranose units. Cyclodextrins are water-soluble since all of the free hydroxyl group are on the outer surface of the ring. The internal cavity of the doughnut-shaped CD molecule is slightly apolar.[1] The nature and cylindrical structure of cyclodextrin allows it to interact with small molecules having an appropriate size to form inclusion complexes. Qi *et al.*[2,3] have applied β-CD to colour systems for spectrophotometry. The CDs serve to solubilize or sensitize the analytical metal complex system due to the formation of the inclusion complexes.

The reagent diethyldithiocarbamate(DDTC) has been reported as a chromogenic agent for copper.[4–7] However in a great majority of these methods, an extractive procedure is required. Only in a few of these procedures can the determination be carried out directly in aqueous solution due to solubility problems. However upon addition of β-CD, an inclusion complex of Cu(II)-DDTC-β-CD forms in the presence of ammonia. That is, the $[Cu(DDTC)_2]$ complex binds to β-CD and is solubilized in water. The colour reaction of Cu(II) with DDTC can be conducted directly in water in the presence of β-CD. This paper reports on our spectrophotometric studies of Cu(II)-DDTC-CD-β-CD inclusion complex. The use of suitable masking agents ensures that the proposed method for determination of copper(II) is free from interferences from a large number of elements. Moreover, the recommended procedure has been successfully applied to the determination of copper in aluminium alloys, soils, millet, wheat flour, herbs, vegetables and some traditional Chinese herbal medicines with satisfactory results.

†Author for correspondence.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade. Demineralized water was used throughout.

Standard copper(II) solution, 0.1 mg/ml. Dissolve 0.0393 g of copper sulphate ($CuSO_4 \cdot 5H_2O$) in ca. 50 ml of water with 0.5 ml of 4*M* sulphuric acid and dilute to the final 100 ml volume with water. This stock solution is further diluted to 20 μg/ml Cu(II) as a working solution.

Sodium diethyldithiocarbamate(DDTC) aqueous solution, 0.011M.

β-CD aqueous solution, $8.8 \times 10^{-3}M$.

Ammonia solution, 7.5M (Ammonia : water = 1:1, v/v).

Ammonium citrate solution, 2M.

1,10-Phenanthroline aqueous solution, 0.01*M.*

Apparatus

Absorption spectra were measured with a Model DU-70 spectrophotometer (Beckman, USA) and the absorbance measurements were performed on a Model 721-100 spectrophotometer (Shanghai).

Procedures

General. To an aliquot containing no more than 150 μg of copper(II) in a 25-ml calibrated flask, add 2.0 ml of 7.5M ammonia solution, 5.0 ml of $8.8 \times 10^{-3}M$ β-CD solution, and 0.5 ml of 0.011M DDTC solution, dilute to the mark with water and shake thoroughly. Measure the absorbance in a 2-cm cell at 436 nm against a reagent blank (or water).

Determination of copper in aluminium alloys. Accurately weigh out 0.1000 g of control aluminium alloy specimen and transfer the specimen to a porcelain evaporating dish. Add 7 ml of 2.5M sodium hydroxide solution, heat, and add about 1 ml of 8.8M hydrogen peroxide after the specimen is decomposed, and continue heating until the bubbles cease. Cool and add 7.9M (1:1, v/v) nitric acid until all salts are dissolved. Transfer the solution to a suitable standard flask (determined by the amount of copper in specimen), add concentrated ammonia-water (about 15M) until the aluminium hydroxide precipitate appears, then add 7.9M nitric acid until the precipitate just dissolves, and dilute to the mark with water. Transfer two aliquots of the specimen solution containing no more than 150 μg of copper to two 25-ml calibrated flasks. Add the following solutions, in order, into both flasks: 5 ml of 2M ammonium citrate solution, 2 ml of 0.01M 1, 10-phenanthroline solution, 2 ml of 7.5M ammonia solution, and 5 ml of $8.8 \times 10^{-3}M$ β-CD solution. Add 0.5 ml of 0.011M DDTC solution to only one of the flasks. Dilute (both flasks) to the mark with water and shake thoroughly. Measure the absorbance of the sample at 436 nm against the solution without DDTC.

Determination of copper in soil. Transfer 1.000 g of the soil to a porcelain crucible and heat to 550°C in a muffle furnace to burn off the organic matter. Transfer the residue to a platinum crucible and dissolve by addition of minimum amount of hydrofluric acid (about 10 ml), heat cautiously, and finally evaporate the solution to dryness. After cooling add 10 drops of 1M sodium hydroxide, evaporate again to dryness, soak the residue with water and transfer the solution to a 50-ml volumetric flask. Next, adjust its pH to around 1 using 1M of sodium hydroxide, dilute to the mark with water, and filter the solution. Transfer two 10 ml portions of the filtrate to two 25-ml calibrated flasks. To both flasks, add ammonia solution (7.5M) until Fe(III) hydroxide precipitate forms completely, and add all 2 ml of 2M ammonium citrate solution (Note 1), 5 ml of $8.8 \times 10^{-3}M$ β-CD solution. Add 0.5 ml of 0.011M DDTC solution to only one of the flasks. Dilute (both flasks) to the mark with water and shake thoroughly. Measure the absorbance of the sample at 436 nm against the solution without DDTC (Note 2).

Notes

1. After adding ammonium citrate, precipitate of Fe(III) hydroxide can dissolve completely for samples that contain a relatively small amount of iron, while for samples that contain a relatively large amount of iron the partial precipitate of Fe(III) hydroxide may still exist in the solution, but with no influence on the determination of copper.

2. The differences between samples may give the following cases. If the diluted solution is clear the determination of copper can be immediately performed. If the solution is slightly turbid, leave it at room temperature for about 10 min, the solution may clear due to solubilization of β-CD. If the solution remains turbid, filtration of the solution is required prior to determination of copper.

Determination of copper in corn and plant samples. Weigh 1.0000 g of sample preliminarily treated (dried, crushed, ground and sifted) and transfer it to a Kjeldahl flask. Moisten the sample using a small amount of water, add 8 ml of concentrated sulphuric acid and leave to set at room temperature for about 12 hr. Boil for 5–10 min, cool, and add several drops of hydrogen peroxide, then continue to boil for about 5 min and follow the same process until the solution appears clear. Boil to remove residual hydrogen peroxide, cool, transfer the solution to a 50-ml volumetric flask. Wash the Kjeldahl flask with concentrated ammonia-water (about 15M) and transfer the washed solution to the 50-ml volumetric flask, adjust the solution so that it is basic with ammonia (add 1–2 ml each time and cool the flask in running tap water), dilute to the mark with water, mix, and then filter the solution. Transfer two 12.5 ml aliquots of filtrate into 25-ml volumetric flasks, add 2 ml

of 2M ammonium citrate, 2 ml of 0.01M 1, 10-phenanthroline, and 5 ml of $8.8 \times 10^{-3}M$ β-CD solution to each flask. Next, add 0.5 ml of 0.011M DDTC solution to the single flask. Dilute (both flasks) to the mark with water and shake thoroughly. Measure the absorbance at 436 nm against the blank solution which contains no DDTC.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the Cu(II)-DDTC-β-CD inclusion complex and its reagent blank are shown in Fig. 1. The maximum absorption of the inclusion complex is at 436 nm, a wavelength at which the reagent blank does not appreciably absorb. There is essentially no difference between the reagent blank absorbance and that of water.

Effect of acidity

The inclusion complex of Cu(II)-DDTC-β-CD is only formed under basic conditions. The effect of acidity on the absorbance of the complex was studied using 7.5M ammonia. The results obtained are shown in Fig. 2. The recommended amount of 7.5M ammonia is 2.0 ml in the procedures (*i.e.*, the concentration of ammonia is 0.6M).

Effect of β-CD concentration

The effect of β-CD concentration on the absorbance of inclusion complex was examined. The results are shown in Fig. 3. The recommended amount is 5.0 ml of $8.8 \times 10^{-3}M$ β-CD solution in the procedures (*i.e.*, the final concentration of β-CD is $1.76 \times 10^{-3}M$).

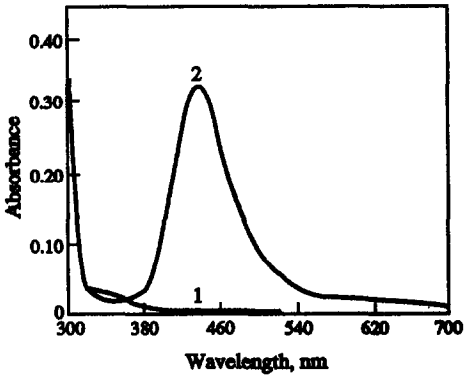

Fig. 1. Absorption spectra. Conditions: the final concentrations of the following reagents and cells are identical for 1 and 2. Ammonia, 0.6M; β-CD, $1.76 \times 10^{-3}M$; DDTC, $2.2 \times 10^{-4}M$; 1-cm cell. 1. DDTC against demineralized water. 2. Inclusion complex against reagent blank, the final concentration of copper(II) is 1.6 μg/ml.

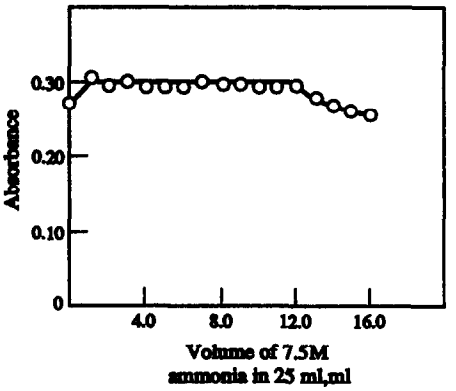

Fig. 2. Variation of the absorbance of the Cu(II)-DDTC-β-CD complex at 436 nm *vs.* the concentration of the ammonia present. Conditions: 1.6 μg Cu(II)/ml; β-CD, $1.76 \times 10^{-3}M$; DDTC, $2.2 \times 10^{-4}M$; 1-cm cell.

Effect of amount of DDTC

The effect of the amount of 0.011M DDTC solution on the absorbance of the inclusion complex was studied. The results obtained indicate that the absorbance is not appreciably affected by changes in the amount of 0.011M DDTC solution used in the procedure between 0.25–10.0 ml (*i.e.*, the final concentration of DDTC solution are between $1.1 \times 10^{-4}M$ and $4.4 \times 10^{-3}M$). The recommended amount of DDTC selected for the subsequent procedures was 0.5 ml (that is, the final concentration is $2.2 \times 10^{-4}M$).

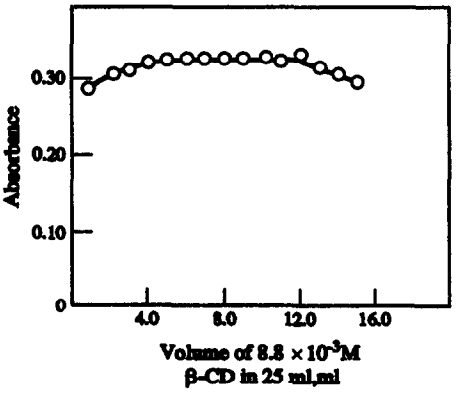

Fig. 3. Variation of the absorbance of the Cu(II)-DDTC-β-CD complex at 436 nm *vs.* the concentration of the β-CD present. Conditions: except ammonia and β-CD, as for Fig. 2. 0.6M ammonia for Fig. 3.

Table 1. Spectrophotometric behaviour of the Cu(II)-DDTC complex in different media

Medium	C	V (*ml*)	λ_{max} (*nm*)	ϵ ($\times 10^4$)	t (*min*)	S.T.
β-CD	1	5	436	1.30	in a tw.	72

β-CD + PVA-124	1,1	5,1	436	1.30	in a tw.	72
β-CD + arabic gum	1,0.5	5,5	436	1.32	5	72

C: Concentration of surfactant, %(w/v); V: Volume of surfactant added; ϵ: Apparent molar absorptivity; t: Time required for colour development; S.T.: Stable time of the complex, hour; in a tw.: in a twinking. The concentrations of DDTC and ammonia are identical with the procedure (general).

Effects of surfactants on the procedure

Spectrophotometric behaviour of the Cu-DDTC complex in the presence of surface-active substances was also studied. The surface-active substances included: arabic gum, polyvinyl alcohol-124 (PVA-124), emulsifier OP-[C_8H_{17}-⬡-$O(CH_2CH_2O)_{9\text{-}10}H$], AEO-9[$C_{12}H_{25}O$-$(CH_2$-$CH_2O)_9H$], Tween-80, cetyltrimethylammonium bromide (CTMAB) and Peregal $O[C_{18}H_{37}O(CH_2CH_2O)_{20}H]$. The test results (shown in Table 1) indicate that the tested surfactants all solubilize the complex and stabilize the colour system to some degree. However, β-CD is the best one, so β-CD was chosen in the procedure.

Effect of temperature

The influence of the temperature on the colour system of Cu(II)-DDTC-β-CD was studied by holding the solution at different temperatures between 20°C and 100°C. The absorbance is not appreciably altered by changes in the temperature between 20°C and 100°C (Fig. 4).

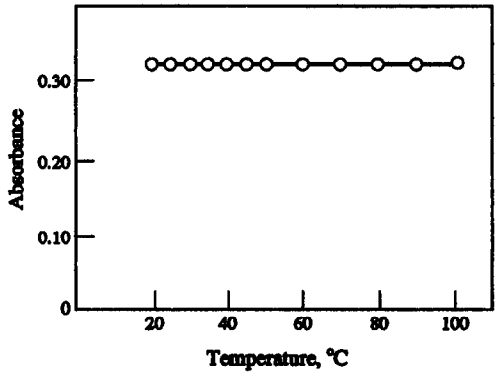

Fig. 4. Effect of temperature. Conditions: 436 nm; 1-cm cell; other conditions as for Fig. 1.

Characteristics of the system

Linear regression of the calibration data (the absorbance at 436 nm *vs.* the concentration of Cu(II), μg/25 ml) yields the equation $A = 0.005 + 0.008c$. The correlation coefficient is 0.9999. Beer's law is obeyed over the range 0–150 μg Cu(II) per 25 ml under the optimum conditions at 436 nm with a molar absorptivity of 1.30×10^4 l · mole^{-1} · cm^{-1}. The standard deviation of separation determination is 1.0×10^{-3} ($n = 10$) and relative standard deviation is 0.3%. The detection limit is $4.38 \times 10^{-7}M$ Cu ($S/N = 3$).

Selectivity

The selectivity was investigated by measurement of 20 μg of Cu(II) (in 25 ml) in the presence of a series of other ions. The results are tabulated in Table 2. The stated levels of the species in Table 2 did not cause an error exceeding 5%.

Masking of interfering ions

Some interfering ions may be masked by using proper masking agents. The tested results are as follows. 5 ml of 2M ammonium citrate can mask 100 mg of Al^{3+}, 7.5 mg of Mg^{2+}, 4 mg of Ti^{4+}, 0.75 mg of Mn^{2+}, 0.4 mg of Cr^{3+}, respectively. After precipitation of iron, 5 ml of 1, 10-phenanthroline (0.01M) can mask 0.3 mg of Ni^{2+}. Iron may be precipitated by adding ammonia-water in a 25-ml volumetric flask and the determination of Cu(II) can be performed directly, without the need for any additional separation steps.

As stated above, the proper masking agent may be added by aiming at different interfering ions according to the actual composition of a sample. For this reason, the selectivity of the proposed method is greatly improved and the

practicality is increased. Particularly, the copper amounts in complex samples may be determined by using the proposed method. Moreover, the tolerance limits of NO_3^-, ClO_4^-, SO_4^{2-} are especially high, which is advantageous with respect to the digestion of samples.

Accuracy and validity

In order to check the accuracy and validity of the proposed method, control aluminium alloy specimens, Chinese herbal medicines and various agricultural samples were analysed using the recommended procedure. The results are shown in Tables 3 and 4.

CONCLUSION

In Marczenko's opinion,[4] the popular spectral methods for copper are mainly the dithizone method, dithiocarbamate methods (*i.e.*, DDTC methods), cuproine methods and cuprizone method. All of these methods, except the cuprizone method, require an extractive procedure, employing organic solvents which are harmful to health and environment, such as carbon tetrachloride, chloroform and isopentanol. Though the proposed system (CU(II)-DDTC-β-CD) uses the old chromogenic agent (DDTC) for copper, it has many advantages over previous DDTC-systems[4-7] and other currently employed spectral methods for copper[4] owing to the presence of β-CD. First, the determination of copper with the proposed colour system can be directly conducted in aqueous solution without the need for any separations. Second, the characteristics of the system have been improved so that the colour development is almost instantaneous and the stability of the inclusion complex is particularly high. In addition, the useful concentration range (0–150 μg/25 ml) for Beer's law is widened. Third, the results obtained in this work show that the proposed method is applicable to a variety of copper containing samples and that the method is simple, selective and accurate.

THE HYDROLYSIS OF LEAD(II). A POTENTIOMETRIC AND ENTHALPIMETRIC STUDY

J. J. CRUYWAGEN* and R. F. VAN DE WATER
Department of Chemistry, University of Stellenbosch, Republic of South Africa

(*Received* 15 *June* 1992. *Revised* 2 *September* 1992. *Accepted* 20 *October* 1992)

Summary—The hydrolysis of lead(II) has been investigated by potentiometric titrations (ionic medium 1.0*M* $NaClO_4$ and 1.0*M* KNO_3) and enthalpimetric titrations (ionic medium 1.0*M* $NaClO_4$) at 25°. The reaction model that gave the best fit to the data for 1.0*M* $NaClO_4$ comprised the following five ions: $Pb(OH)^+$, $Pb_3(OH)_4^{2+}$, $Pb_3(OH)_5^+$, $Pb_4(OH)_4^{4+}$ and $Pb_6(OH)_8^{4+}$. The formation constants, and enthalpy changes (kJ/mol) for these species, defined according to equation (1), have the values $\log \beta_{11} = -7.8$, $\Delta H^0_{11} = 24$; $\log \beta_{34} = -22.69$, $\Delta H^0_{34} = 112$; $\log \beta_{35} = -30.8$, $\Delta H^0_{35} = 146$; $\log \beta_{44} = -19.58$, $\Delta H^0_{44} = 86$; $\log \beta_{68} = -42.43$, $\Delta H^0_{68} = 215$. Equilibrium constants determined in nitrate medium show good agreement with those pertaining to perchlorate medium if complexation of lead(II) with nitrate is taken into account.

The hydrolysis of lead(II) results in the formation of mono- and polynuclear hydroxo ions; the reaction equilibria can be represented by the general equation

$$p\,Pb^{2+} + q\,H_2O \rightleftharpoons [Pb_p(OH)_q]^{(2p-q)+} + q\,H^+ \quad (1)$$

Complete characterization of these equilibria has been hampered by experimental limitations. For example, to prevent precipitation either the concentration of lead has to be kept rather low or the pH range must be restricted to very narrow limits. Also, carbon dioxide and traces of sodium carbonate must be excluded from test solutions to avoid slow premature precipitation of lead as basic lead carbonate. However, careful experimentation and thorough data analysis have led to agreement among authors about the existence of the following ions: $Pb(OH)^+$, $Pb_3(OH)_4^{2+}$, $Pb_4(OH)_4^{4+}$, and $Pb_6(OH)_8^{4+}$.[1-7] Other species that have been postulated are: $Pb_2(OH)^{3+}$ as a minor component,[3] and more recently $Pb_3(OH)_3^{3+}$, and $Pb_3(OH)_5^+$; the latter ion was proposed as an addition to the model of four species mentioned above,[6] but the $Pb_3(OH)_3^{3+}$ ion was included in the model in the place of the $Pb(OH)^+$ ion.[7] Although medium ions could play a role in stabilizing a particular ion it is evident that the system still needs some clarification. A correct model together with reliable equilibrium constants for the species concerned are prerequisites not only for studies of lead complexation in aqueous solution, but also for the interpretation of calorimetric data. In fact, the calorimetric data collected in two previous investigations have not been interpreted in terms of the same model and appreciable differences occur in the values reported for the thermodynamic quantities of some species,[3,7] notably for the $Pb_3(OH)_4^{2+}$ ion.

In this paper we report the results of a potentiometric investigation of lead(II) in two different ionic media and at an ionic strength not previously studied, namely 1.0*M* $(Na)ClO_4$ and 1.0*M* $(K)NO_3$. Calorimetric data for the hydrolysis reactions were obtained for 1.0*M* $NaClO_4$ and used to calculate the enthalpy and entropy changes for the formation of the various species.

EXPERIMENTAL

Reagents and solutions

All reagents were of analytical grade and solutions were prepared with water obtained from a Millipore Milli-Q system. Carbonate-free sodium hydroxide, prepared from an aged saturated solution,[8] was standardized by titration against potassium hydrogen phthalate. Perchloric acid and nitric acid were standardized against recrystallized borax and the results checked by titration against standard sodium hydroxide. Sodium perchlorate, potassium nitrate, and lead nitrate were purified as follows: a saturated solution was allowed to stand for at least a week and then filtered through a porisity three sintered glass filter. From this solution,

*Author for correspondence.

relatively large crystals were grown by slow evaporation at ~25° in a dust-free environment. These crystals were filtered off, washed with pure water, and used to prepare a stock solution which was standardized by evaporating known volumes to dryness and heating to constant weight at 140°. Lead perchlorate was prepared by treating PbO with standardized perchloric acid.[2] The solid PbO was introduced to a cold acid solution stirred by a stream of purified nitrogen and left to stand overnight. This solution was then filtered through a porosity four sintered glass filter and standardized gravimetrically as lead iodate.[9]

Potentiometric titrations

The hydrolysis was investigated in ionic media, 1.0*M* $(Na)ClO_4$ and 1.0*M* $(K)NO_3$, by titrating an acidified lead solution with sodium hydroxide. The free hydrogen concentration, h was determined by measuring the potential to ±0.1 mV with a Radiometer PHM84 research pH-meter. For the measurements in perchlorate medium a Ross combination electrode (Orion Research) with a 3.0*M* $NaClO_4$ (instead of 3.0*M* KCl) internal salt bridge solution was used. A Radiometer glass electrode (G202C) and calomel reference electrode connected to a Wilhelm type salt bridge with renewable liquid junctions was used for the measurements in nitrate medium;[10] the composition of the salt bridge was: 1.0*M* KNO_3/3.0*M* NaCl/1.0*M* KCl.

The reaction vessel consisted of a double-walled glass vessel and the temperature was kept at 25.0 ± 0.1° by circulating water from a thermostatted bath. Purified nitrogen was passed through the medium solution and then bubbled slowly through the titration solution. The titrant, usually sodium hydroxide solution, was delivered with a Metrohm 665 Dosimat and sufficient time (at least 5 min) was allowed to ensure that equilibrium had been attained. The electrode systems were calibrated by titration of acid with sodium hydroxide in either 1.0*M* $(Na)ClO_4$ or 1.0*M* $(K)NO_3$. The data were treated with the program SUPERQUAD[11] to calculate values for E^0 and s in the Nernst equation

$$E = E^0 + s \log h \qquad (2)$$

The calculations were done on the assumption that a small amount of protolytic impurity was present in the medium salt.[12] For perchlorate medium the value for s obtained was 58.58 compared with the theoretical 59.16 at 25° and the concentration of the impurity (alkaline) was $7 \times 10^{-5}M$. For nitrate medium the impurity was found to be $1.1 \times 10^{-4}M$ and $s = 59.40$. These values were used in calculations of the free hydrogen ion concentration and also when E^0 was determined by titrating excess acid which had been added to the lead(II) solutions. For brevity, $-\log h$ is denoted by pH_c.

The initial concentrations of the lead(II) perchlorate solutions titrated with sodium hydroxide were as follows: 1.0, 1.5, 2.5, 5.0 and 1.0m*M*. The titrations were carried out in duplicate or triplicate, but with different initial acid concentrations in some cases. For the measurements in potassium nitrate medium the titrations were started with the following lead concentrations: 1.0, 2.0, 2.5, 5.0, 7.5, 10.0, 20.0 and 50.0m*M*. Because of the very low solubility of basic lead nitrate species, precipitation begins at lower pH_c values in nitrate medium and fewer data points could therefore be collected at a particular lead concentration.

Enthalpimetric titrations

An isothermal titration calorimeter, Tronac model 550, described elsewhere,[13] was used for the enthalpy measurements. Solutions containing lead perchlorate and some perchloric acid (20.0 cm^3) were titrated with sodium hydroxide from a precision microburette (2.5 cm^3) and the data collected as described previously.[14] The initial concentrations of lead(II) were 5.0, 7.5, 10.0, 25.0 and 50.0m*M* and all solutions were made 1.0*M* with respect to perchlorate. The titrations were carried out in duplicate. The sodium hydroxide was titrated as slowly as possible, typically at speeds varying from 1.25 to 2.50 μl per second, commensurate with the concentrations of the reagents and amount of heat evolved. Blank titrations were carried out which showed that the heat involved in the mixing and dilution of the reagents in 1*M* $(Na)ClO_4$ was negligible.

RESULTS AND DISCUSSION

Potentiometric investigation

Sodium perchlorate medium. The titration data were treated with the computer program SUPERQUAD.[11] Of the various reaction models considered, and taking into account all species previously proposed, the following model resulted in the best fit between calculated and experimental points:

$Pb(OH)^+$, $Pb_3(OH)_4^{2+}$, $Pb_3(OH)_5^+$, $Pb_4(OH)_4^{4+}$, and $Pb_6(OH)_8^{4+}$.

†Complex formation of Pb^{2+} with NO_3^- taken into account in the calculations.

The value of $s = 0.747$ (sample standard deviation[11]) based on estimated errors of 0.01 cm^3 in the volume and 0.2 mV in the potential implies a very good fit. The formation constants defined by equation (1) are given in Table 1 and the distribution of the various species, as a function of pH_c, is shown in Fig. 1. Also listed in Table 1 are literature values for constants pertaining to different ionic media. It is seen that the present model agrees with that obtained by Sylva and Brown,[6] but differs from the model reported by Ishiguro and Ohtaki[7] which included a $Pb_3(OH)_3^{3+}$ species but excluded both the $Pb(OH)^+$ and $Pb_3(OH)_5^+$ species. When the $Pb_3(OH)_3^{3+}$ ion was included in our model it was rejected by the program. SUPERQUAD automatically rejects species with ill-defined formation constants, *i.e.*, when the standard deviation of the constant is more than 33% of its value, or if its value is negative.[11] Apart from the inclusion of the minor species, $Pb_2(OH)^{3+}$, which occurs only at very high lead concentration (*cf.* next section) the model reported by Carell and Olin[3] differs from the present model only in respect of the $Pb_3(OH)_5^+$ ion. Omission of the $Pb_3(OH)_5^+$ ion from our model resulted in a significantly poorer fit, the value $s = 1.21$ was obtained. The absence in earlier models of the latter ion, first reported by Sylva and Brown,[6] can be ascribed to a lack of data in a small domain defined by relatively low concentration and high pH_c (*cf.* Fig. 1).[6]

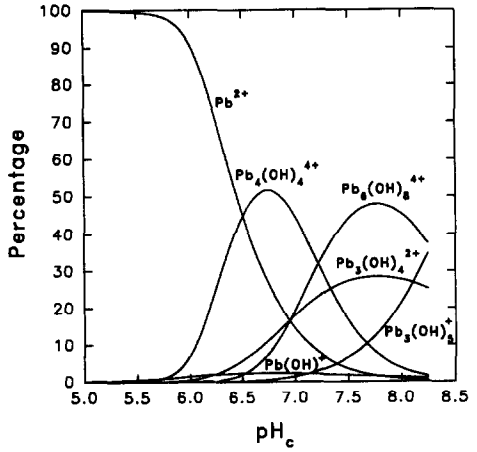

Fig. 1. Distribution of the lead(II) species, expressed as a percentage of the total lead concentration (0.01*M*).

Potassium nitrate medium. For a given lead concentration precipitation begins at much lower pH_c in this medium. Only the titrations at the lowest lead(II) concentrations could proceed to $pH_c \sim 7.5$. Under these conditions the percentage concentration of the $Pb_3(OH)_5^+$ ion is so small that its characterization becomes problematical. At 0.0025*M* Pb^{2+}, for example, the maximum concentration $Pb_3(OH)_5^+$ attained in 1*M* KNO_3 at pH_c 7.2 is only 3.5% of the total lead compared to the 18.2% at pH_c 7.7 in 1.0*M* $NaClO_4$ (*cf.* Fig. 1). Treatment of the data with the program SUPERQUAD resulted in a model comprising the species: $Pb(OH)^+$, $Pb_2(OH)^{3+}$, $Pb_3(OH)_4^{2+}$, $Pb_4(OH)_4^{4+}$, and $Pb_6(OH)_8^{4+}$. Apart from the expected absence of the $Pb_3(OH)_5^+$ ion, the only difference compared to the model obtained for perchlorate medium is the addition of the $Pb_2(OH)^{3+}$ ion. When the values for the stability constants for the two media are compared it is seen that the constants pertaining to the nitrate medium have greater (negative) values. A similar effect is noticeable in the constants reported by Hugel[4,5] for ionic media 2.0*M* $NaClO_4$ and 2.0*M* $NaNO_3$ respectively.

Part of these differences can be explained in terms of lead(II) nitrate complex formation. Introducing the complex ions $PbNO_3^+$ in the treatment of our data resulted in the rejection of the $Pb_2(OH)^{3+}$ species and supplied values for the hydrolysis constants which are very similar to those calculated for perchlorate medium (Table 1). The literature value[15] for the formation constant of $PbNO_3^+$, $\log K_1 = 0.33$, was

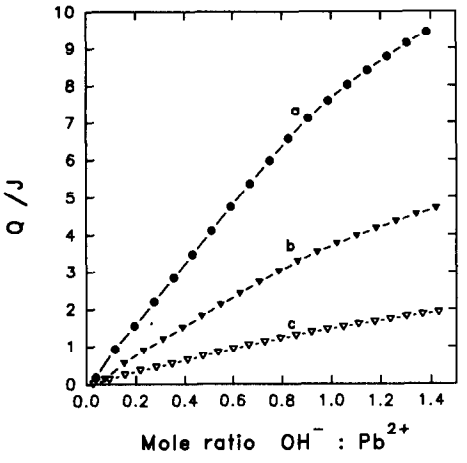

Fig. 2. Measured heat, Q, as a function of the molar ratio of hydroxide to lead(II) for titrations of (a) 0.05, (b) 0.025 and (c) 0.01*M* lead(II) solutions.For the 0.01*M* lead(II) solution $pH_c = 7.1$ at mole ratio 1.0.

treated as a fixed constant. When log K_1 was refined together with the other constants, the value 0.32 ± 0.01 was obtained in good agreement with the literature value.

The $Pb_2(OH)^{3+}$ ion is such a minor species (max. 1% at $pH_c = 6$) that its rejection by the program seems appropriate when NO_3^- complexation (which in effect reduces the free Pb^{2+} considerably at $pH_c < 6.5$) is taken into account. Although Olin and co-workers[3,16] found this species in perchlorate medium also, its maximum concentration under the most favourable conditions, *i.e.*, at lead concentration 1.45*M* and $pH_c = 4.5$, was only 2.1%. For solutions at moderate concentrations and $pH_c > 5.0$, the $Pb_2(OH)^{3+}$ ion can therefore be neglected for most practical purposes.

The reaction model and the values for the formation constants of the species can now be regarded as established with sufficient certainty to be used as basis for a calorimetric investigation, the results of which are described in the following section.

Enthalpimetric titrations

The results of representative titrations of lead (II) with sodium hydroxide are shown in Fig. 2. The total heat measured, Q, is plotted against the molar ratio of base added to lead(II). Depending on the lead concentration, a mole ratio of hydroxide:lead(II) of only about 1.4 could be effected before precipitation started.The measured heat actually represents the enthalpy changes for the following reactions:

$$p\mathrm{Pb}^{2+} + q\mathrm{OH}^- \rightleftharpoons [\mathrm{Pb}_p(\mathrm{OH})_q]^{(2p-q)+} \quad (3)$$

and is given by equation (4)

$$Q = n_w \Delta H^0_w + n_{pq}(\Delta H^0_{pq})' \quad (4)$$

where n_{pq} is the number of moles formed and $(\Delta H^0_{pq})'$ is the molar enthalpy change for the formation of a given species $[p,q]$ at 25°*C* in 1.0*M* $NaClO_4$ medium; n_w is the number of moles of free acid neutralized and ΔH^0_w is the enthalpy change for the formation of water. The contribution of the first term of equation (4) to the total heat measured was quite small because the lead solutions contained very little excess acid, typically $pH_c \sim 4.0$. The literature value[17] 56.1 kJ/mol for ΔH^0_w, pertaining to 1.0*M* $NaClO_4$, was used in the calculations and also to convert $(\Delta H^0_{pq})'$ values to the enthalpy changes for the hydrolysis reactions represented by equation (1). Values for n_{pq} at each titration point were derived from the concentrations of the species by simultaneous solution of the two mass balance equations (5) and (6).

$$B = b + \Sigma p\beta_{pq} b^p h^{-q} \quad (5)$$

$$C_A = h - K_w/h - \Sigma q\beta_{pq} b^p h^{-q} + C_B \quad (6)$$

where B, C_A and C_B are the total analytical concentrations of lead(II), acid and base, respectively; b is the equilibrium Pb^{2+} concentration and log $K_w = -13.71$. The set of linear equations thus obtained from corresponding Q and n_{pq} values were solved for the $(\Delta H^0_{pq})'$ parameters following a least squares procedure. The results are summarized in Table 2. All

Table 2. Values of the equilibrium constants and other thermodynamic quantities (kJ/mol) for the formation of lead(II) hydroxo species in 1.0*M* $(Na)ClO_4$ medium (298 K) according to equation (1). $(\Delta H^0)'$ refers to the reaction: $p\mathrm{Pb}^{2+} + q\mathrm{OH}^- \rightleftharpoons [\mathrm{Pb}_p(\mathrm{OH})_q]^{(2p-q)-}$ and $\Delta H^0 = (\Delta H^0)' - q\Delta H^0_w$ where $\Delta H^0_w = -56.1$ kJ/mol

species were present in relatively high percentage concentrations (maximum at least 35%) except the $Pb(OH)^+$ ion which attained a maximum concentration of only 4% at the lowest lead concentration (5.00m*M*) titrated. The value obtained for ΔH^0_{11} (24 kJ/mol) is therefore rather uncertain but seems quite reasonable when compared to $\Delta H_{pq}/q$ (~26 kJ/mol) for the polynuclear ions; it has been estimated[3] that ΔH^0_{11} should lie between the limits 20 and 40 kJ/mol. The ΔH^0 values determined for the polynuclear ions $Pb_3(OH)_4^{2+}$, $Pb_4(OH)_4^{2+}$, and $Pb_6(OH)_8^{4+}$ (Table 3) agree very well with those reported by Carell and Olin,[3] while the enthalpy change for the $Pb_3(OH)_5^+$ ion fits well into the pattern set by the other species. The value $\Delta H^0_{34} = 62$ kJ/mol reported by Ishiguro and Ohtaki[7] for the $Pb_3(OH)_4^{2+}$ ion differs greatly from our value (112 kJ/mol) and that of Carell and Olin[3] (111 kJ/mol) and should therefore be questioned. Although the hexanuclear complex is usually formulated as $Pb_6(OH)_8^{4+}$ in potentiometric studies, X-ray diffraction investigations have provided strong evidence[18] for a structure in solution similar to that obtained in the solid state, namely $Pb_6O(OH)_6^{4+}$, which consists of three face-sharing tetrahedra.[19]

CONCLUSION

The results of this investigation confirm the existence of the hydroxo complexes $Pb(OH)^+$, $Pb_3(OH)_4^{3+}$, $Pb_3(OH)_5^+$, $Pb_4(OH)_4^{4+}$ and $Pb_6(OH)_8^{4+}$ in the pH range 5.5–8.5 Hydrolysis constants and other thermodynamic parameters have been determined for these complexes; the enthalpy and entropy changes for $Pb(OH)^+$ and $Pb_3(OH)_5^+$, determined for the first time, are consistent with those of the other species. In view of the very good agreement between the values of thermodynamic quantities determined in this investigation and some values previously reported, the system can now be regarded as fairly well characterized. A comparison of the results for perchlorate and nitrate media shows that the reaction model and equilibrium constants are affected if complexation of lead(II) by nitrate is neglected. Also, due to lower solubility of basic lead nitrate species the range of either pH_c or concentration available for measurements is more limited in nitrate than in perchlorate medium.

PRESERVATION OF SOLID MERCURIC DITHIZONATE SAMPLES WITH POLYVINYL CHLORIDE FOR DETERMINATION OF MERCURY(II) IN ENVIRONMENTAL WATERS BY PHOTOCHROMISM-INDUCED PHOTOACOUSTIC SPECTROMETRY

EDWARD P. C. LAI,* BARBARA WONG and VICTORIA A. VANDERNOOT

Centre for Analytical and Environmental Chemistry, Ottawa-Carleton Chemistry Institute, Department of Chemistry, Carleton University, Ottawa, Ontario, Canada K1S 5B6

(*Received* 24 *April* 1992. *Revised* 11 *September* 1992. *Accepted* 11 *September* 1992)

Summary—A novel sample preparation technique has been developed to preserve solid mercuric dithizonate [$Hg(HDz)_2$] in a matrix of polyvinyl chloride (PVC) for analysis by photochromism-induced photoacoustic spectrometry (PCPAS). This technique, which begins with the extraction of Hg^{2+} from water with dithizone, allows for the determination of Hg^{2+} in environmental samples. Inclusion of $Hg(HDz)_2$ within the polymer matrix enhances the PCPAS signal amplitude over that from the bare $Hg(HDz)_2$ film by almost sixfold. The standard calibration graph of PCPAS signal amplitude as a function of Hg^{2+} concentration is linear in the concentration range of 5–100 μg/ml. A lower detection limit can be achieved by using a laser of higher power tuned to a wavelength closer to the maximum absorptivity of the excited $Hg(HDz)_2$ complex. A study, conducted to monitor the change in PCPAS signal amplitude obtained for the same sample over an extended storage period of 19 days, demonstrates that the PVC protects the integrity of the solid $Hg(HDz)_2$ sample. Hence, it is potentially feasible to collect environmental samples from a remote area for analysis at a later date.

Despite the toxic nature of mercury known since ancient times, the element and its compounds had been used and discarded with little thought to the consequences to human health and to the environment. The seriousness of the problem was first realized in the 1950s among small fishing villages along the shores of Japan's Minamata Bay.[1] The illness, which came to be known as Minamata disease, was caused by methylmercury poisoning as a result of eating contaminated fish. In humans, the initial symptoms include numbness of the lips and limbs. As the sickness progresses, permanent damage is done to the central nervous system, and the victim experiences visual constriction, loss of motor coordination, and, in the final stages prior to death, loss of memory, speech, hearing and taste. The source of the contamination was eventually found at a chemical plant near Minamata Bay. Along with an estimated 220 tons of elemental mercury released into the bay with the plant's waste effluent between 1949 and 1953, traces of methylmercury, produced unintentionally in a side reaction, were discharged. Swedish studies conducted in the 1960s revealed that the inorganic mercuric ion could be methylated by microorganisms in the sediments of waterways.[2] Methylmercury can bioaccumulate in fish as it is at least 1000 times more soluble in lipids than in water and concentrates in muscle tissues, the brain and the central nervous system.[3] Mercury levels as high as 24 ppm were found in the fish in Minamata Bay, which are well above the modern federal guideline of 0.5 ppm of mercury in fish.[4]

The use of mercury in industry and agriculture has decreased dramatically in the developed world since the early 1970s due to legislation regulating the discharge of mercury.[1] Despite efforts to remove the mercury from polluted waterways, mercury contamination of waterways still remains a problem today. Given the recent political changes on the international scene that have brought a new awareness of the environment, one sees the need for sampling at more and increasingly remote sites.[5] Analytical

*Author for correspondence.

methods for environmental specimens often require that samples be transported to sophisticated facilities prior to chemical analysis. As a result, considerable time may elapse between the collection of the samples and the initiation of the analytical procedure, thus potentially compromising the data generated by the analysis. Since many of the analytical methodologies require significant economic expenditures (and potential future clean-up processes even more so), ensuring maximum data reliability is blatantly crucial. Studies which defined the time frame in which samples can be expected to remain stable and recommended storage conditions that maximize this pre-analysis holding time have been reported previously.[6]

Analytical samples are in a chemically dynamic state at the time of collection. At the moment the sample is removed, it is exposed to conditions significantly different from the source conditions and the chemical processes may deviate from those that occur *in situ*. For example, photochemical reactions may take place and the temperature-dependent kinetics of reactions will be altered when the sample is exposed to ambient light and atmospheric temperature. In addition, the dissolved gases will change, air oxygen may initiate oxidation of some chemical species, and the pH of the sample will most likely change.[7] The dynamic process does not end after the sample has been carefully transferred into some vessel for subsequent delivery to an analytical laboratory. The analyte can be lost from samples because of volatilization, absorption, or reaction with container materials.[7] Sample containers may irreversibly adsorb analytes from the sample and act as a negative interference, leading to erroneously low measured values.[7] In fact, the loss of sample integrity is governed by several factors, including photodegradation, chemical action, volatilization, and biological action. Sample containers also represent a major source of sample contamination in environmental measurements; they may introduce extraneous compounds into the sample. Moody and Lindstrom[8] examined 12 different plastic materials including conventional and linear polyethylene, polycarbonate, and several types of Teflon. They found significant levels of leachable trace elements in all of the materials examined. In order to control contamination associated with a particular determination, potential sources of contamination must first be identified for the method employed. Contamination may be introduced either in the field during sample collection, handling, storage, or in transport to the analytical laboratory. Additional contamination may arise during sample preparation or in the analytical process itself.[9]

Significant effort has recently been placed on the development of procedures for the precise fortification and stabilization of collected samples. Preservation techniques are used to minimize changes in samples between collection and analysis; they preserve the integrity of the sample after collection. Physical changes such as volatilization, adsorption, diffusion and precipitation, and chemical changes such as photochemical and microbial degradation are minimized by expeditious, proper preservation of the sample.[7] Aqueous samples collected for soluble metals analysis are typically filtered in the field immediately after collection, and nitric acid is added until the pH is lower than 2. The combination of a low pH and an excess of nitrate ions ensures that the metal ions stay in solution. Since metals can adsorb irreversibly onto glass surfaces, samples are usually collected in plastic or plastic-lined containers to avoid contact with glass. Sample exposure to the ambient environment should also be minimized to avoid airborne contaminants.[9] The choice of storage conditions is dictated by practicality. Aqueous liquid samples probably should not be frozen; the preparation of an extract is expected to substantially increase the holding time.[6]

A new range of applications of polymers in analytical chemistry has recently been developed. Styrene-divinylbenzene copolymer resin (XAD-4) has been used in a sorbent cartridge to extract semivolatile explosive compounds from aqueous environmental samples in order to increase the preanalytical holding time.[6] After extraction of trace metals with diethyl-dithiocarbamate, polystyrene foam has been used for quantitative collection of these metal complexes for neutron activation analysis.[10] Various forms of polymeric substrate have been used for indicator immobilization in the fabrication of fiber-optic chemical sensors.[11–14] Disposable plastic film sheaths have been used over fiber-optic Raman probes to eliminate probe contamination.[15] In surface acoustic wave (SAW) sensors, the piezoelectric crystal has been coated with a polymer that captures the chemical of interest from the gas phase.[16,17] Ion-selective membrane electrodes have been developed based on the incorporation of interactive compounds in polymer membranes.[18,19] A platinized

reticulated vitreous carbon or platinum electrode has been used in the construction of a sensor for the determination of glucose in human serum; this used immobilized glucose oxidase and electropolymerized 1,2-diaminobenzene. The 1,2-diaminobenzene polymer coating drastically reduced the effects of electrochemically active interferents and virtually eliminated electrode fouling by proteins in blood serum. The polymer film also increased the thermal stability of the immobilized glucose oxidase.[20,21] A diffusion-plasticization based electrochemical gas chromatography detector has recently been developed.[22] Most unfortunately, Colombian drug dealers are using a mixture of cocaine and polystyrene plastic in products that can be shipped into the United States of America undetected. Traffickers mix a portion of about 20% cocaine with polystyrene plastic and mold it with heat and chemicals. The unprecedented technology makes it possible to transform the cocaine into a form (*e.g.*, black electrical bushings) undetectable by drug-sniffing dogs or routine visual or chemical tests. The cocaine can be removed later by heating the composition, dissolving the plastic bonds.[23]

In the present study, a sample preparation technique which allows the preservation of a large number of small water samples collected from a remote area was developed. Extraction of Hg^{2+} with dithizone (H_2Dz) was first performed quantitatively. Solid $Hg(HDz)_2$ samples were prepared by placing a given volume of the extract on a glass disk to dry in air. The solid $Hg(HDz)_2$ film, which was susceptible to physical disfiguration and loss, was preserved in a layer of polyvinyl chloride (PVC) until PCPAS measurements could be carried out at a later date.

EXPERIMENTAL

Preparation of solutions

The extraction solution of 0.3–0.4% (w/v) dithizone in CCl_4 was prepared according to Irving's method[24] and stored under 0.5*M* H_2SO_4 in the dark to prevent photodecomposition. The aqueous Hg^{2+} standard solutions were made from the chloride salt. A 0.025-g/ml solution of PVC in tetrahydrofuran (THF) was prepared and molecular sieves were added to keep the solution dry.

Extraction of Hg^{2+} from water (preconcentration)

The extraction was carried out by shaking 50 μl of aqueous Hg^{2+} solution, 30 μl of 1*M* H_2SO_4 and 80 μl of the extraction solution (dithizone in CCl_4) in a small screw-cap vial. After 5 min had passed, 50 μl of the organic extract was placed in another vial and washed with 100 μl of 1:1000 (v/v) aqueous ammonia to remove the excess dithizone.

Sample preparation

Method 1. This method of sample preparation is based on the procedure for making solid films of $Hg(HDz)_2$ described by Chen *et al.*[25] A drop of PVC solution from a pasteur pipette was placed in the center of a small glass disk (18-mm diameter), and the THF solvent was allowed to evaporate. A certain volume of organic extract (*e.g.*, 5 μl) was delivered, drop by drop, from a syringe onto the central area of the PVC, allowing the CCl_4 solvent to evaporate before the next drop was added. The resultant solid film of $Hg(HDz)_2$ was then covered by a drop of PVC solution dispensed from a pasteur pipette.

Method 2. This procedure was similar to method 1 except that the bottom layer of PVC was not used. The top layer of polymer was added by dispensing 1 μl of PVC solution from a micro-pipette.

Method 3. A 25-μl aliquot of the organic extract was placed in a small glass cup. After the CCl_4 solvent had evaporated, the solid $Hg(HDz)_2$ was redissolved by adding 20 μl of the PVC solution. Using a micro-pipette, 1 μl of the resultant solution was placed on the centre of a glass disk. The samples used for the study of PCPAS signal amplitude as a function of Hg^{2+} concentration were prepared in this manner.

Photoacoustic spectroscopy (PAS)

A sample disk was placed in the photoacoustic cell shown in Fig. 1. This special cell was designed so that photochromism could be induced in the sample by a white light source while PAS measurement was being performed. It was then attached to the microphone and placed in the photochromism-induced photoacoustic spectroscopy (PCPAS) set-up as shown in Fig. 2. The mirror was adjusted so that the He–Ne laser beam (spot size = 2 mm in radius), modulated at 200 Hz, passed directly through the sample. Several minutes after the data-collection had begun, a steady PAS signal baseline was observed. At this point, photochromism was induced by using the light from a standard 35-mm slide projector (80 mW). The light was guided by an optical fiber bundle (6-mm diameter) and passed through the sample with the aid

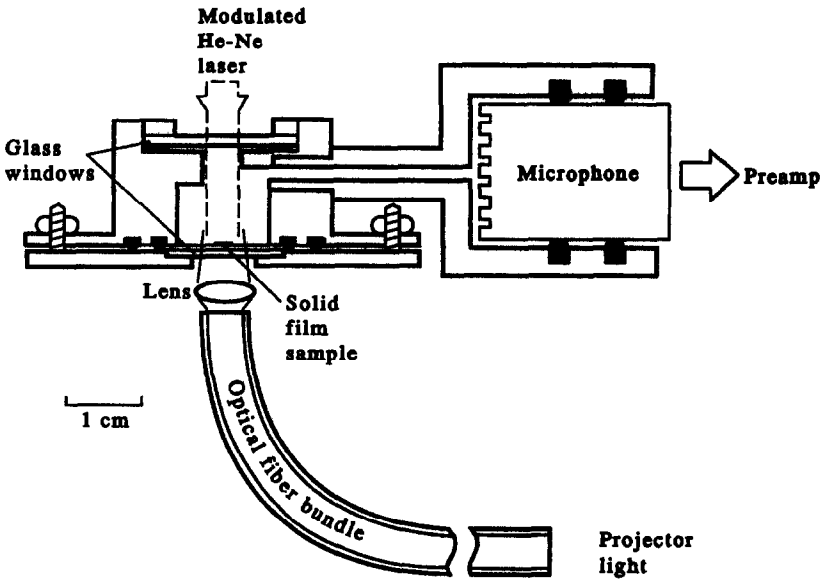

Fig. 1. Sample cell for photochromism-induced photoacoustic spectroscopy of $Hg(HDz)_2$.

of a focusing lens. The projector was left on until the PAS signal stabilized at its new maximum value for the excited state of $Hg(HDz)_2$.

Reproducibility of sample preparation method 3

The precision of the PCPAS measurement was determined by taking triplicate measurements of the same sample. Two sets of measurements were taken in order to find the precision at a high concentration (100 μg/ml) and at a low concentration (12.5 μg/ml). The precision of the solid sample preparation was found by measurement of the PCPAS signals of three samples prepared from a single extraction of a 50-μg/ml Hg^{2+} solution. The precision of the extraction was studied by performing PCPAS on three samples prepared from three different extractions of Hg^{2+} solutions of the same concentration (50 μg/ml).

PCPAS of a $Hg(HDz)_2$ film with and without a PVC cover

A sample was prepared from a 50-μg/ml Hg^{2+} solution as described above in method 2. The volume of organic extract applied to the glass disk was 1.0 μl. PCPAS runs were carried out before and after a top layer of PVC was applied to see how the PVC layer affected the analytical signal.

Changes in the PCPAS signal over time

A sample was prepared from a 100-μg/ml Hg^{2+} solution using method 3. PCPAS measurements of this sample were taken over the course of 19 days in order to study how the sample changed with time.

PCPAS with a laser of higher power

A sample was prepared from a 25-μg/ml Hg^{2+} solution using method 3. In order to study the effect of using a laser of higher power, two PCPAS runs were performed. The first run was carried out using the experimental set-up shown in Fig. 2. The second one was conducted using an Ar^+-pumped dye laser (75 mW, $\lambda = 610$ nm) in place of the He–Ne laser (18 mW, $\lambda = 632.8$ nm). A defocusing lens was used to enlarge the spot size of the dye laser beam so that it was comparable to that of the He–Ne laser beam.

RESULTS AND DISCUSSION

Photochromism

Photochromism literally means a coloration by light. Today the accepted definition of

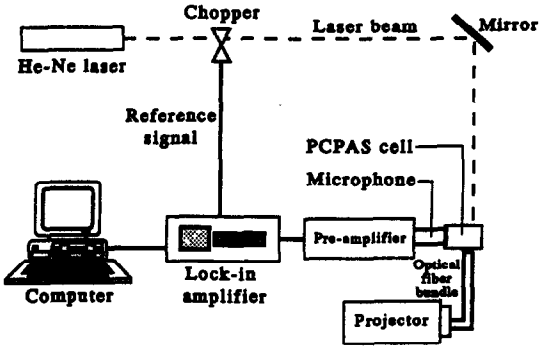

Fig. 2. Experimental set-up for PCPAS measurements.

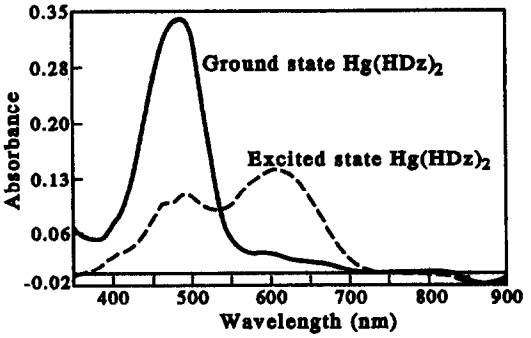

Fig. 3. Visible absorption spectrum of ground and excited state mercuric dithizonate in solution, as measured by a Perkin-Elmer Lambda 4B spectrophotometer. The limited level of projector light irradiation did not produce excited-state $Hg(HDz)_2$ to 100%; some ground-state $Hg(HDz)_2$ remained in the sample.

photochromism is a reversible change of a single chemical species between two states that have distinguishably different absorption spectra. Such a change is induced at least in one direction by the action of electromagnetic radiation.[26] In the mid-1960s, Meriwether *et al.* conducted studies on the photochromic properties of metal dithizonates.[27] Nine of 24 primary dithizonates exhibited photochromism in solution, but only mercuric dithizonate, $Hg(HDz)_2$, was found to be photochromic in the solid state. This complex changes its color from orange to blue upon exposure to bright light, corresponding to a shift of the absorption maximum from 485 to 605 nm (Fig. 3). The structural change that the complex undergoes when going from the normal to the excited state is shown in Fig. 4.[24]

Photoacoustic spectroscopy

In photoacoustic spectroscopy, the sample to be studied is typically placed in a closed cell or chamber. Samples in the gaseous phase usually fill the entire chamber. In the case of liquids or solids, however, only a portion of the cell is occupied by the sample, and the remainder of the cell contains a non-absorbing gas such as air. In addition, the chamber contains a sensitive microphone capable of the detection of minute pressure changes. The sample is illuminated with modulated monochromatic light. If any of the incident photons are absorbed by the sample, the electronic energy levels within the sample are excited. Upon subsequent de-excitation of these energy levels, all or part of the absorbed photon energy is converted to heat energy through non-radiative deexcitation processes. Since the incident radiation is modulated, the internal heating of the sample is also modulated. For solid samples, the periodic heat flow from the sample to the surrounding gas will result in a change of gas pressure within the cell which can be detected by a sensitive microphone. The PAS signal amplitude, S (in mV), can be represented by

$$S = K\,P\,\epsilon(\lambda)\,N \qquad (1)$$

where K is an experimental constant, P is the power of the monochromatic light source (in mW), $\epsilon(\lambda)$ is the optical absorptivity at wavelength λ (in $mole^{-1}\,cm^{-1}$) and N is the amount of solid sample present (in mmoles).[28]

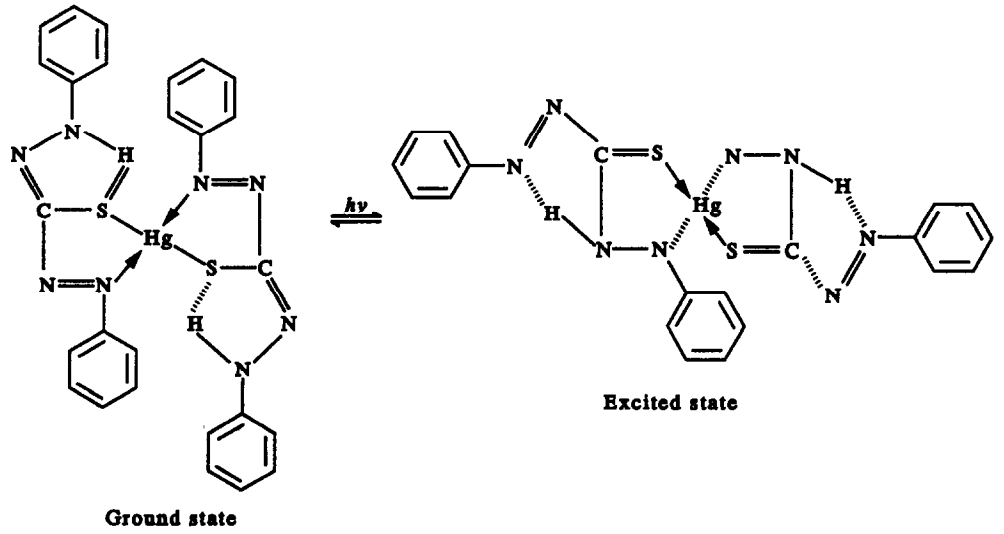

Fig. 4. Structures of normal and excited $Hg(HDz)_2$.

Photochromism-induced photoacoustic spectrometry

By combining the two aforementioned phenomena, Chen *et al.* have developed an analytical technique that allows the determination of Hg^{2+} as its dithizonate in the solid state. A standard calibration curve was obtained in the quantity range from 1.5 to 450 picomoles.[25] A similar experimental arrangement is used in this work (Fig. 2), except that the gas microphone showed signs of performance deterioration in sensitivity due to aging. The modulated light from the He–Ne laser (output wavelength = 632.8 nm) will be absorbed strongly by the excited-state $Hg(HDz)_2$, while the ground-state complex has a negligible absorptivity at this wavelength. Since the He–Ne laser cannot induce photochromism, the PAS signal produced by the ground state will be approximately zero. Upon irradiation by projector light, the excited-state complex is formed and will generate a PAS signal as shown in Fig. 5. The resulting PCPAS signal will be proportional to the change in optical absorptivity, $\Delta\epsilon(\lambda)$, between the ground- and excited-state $Hg(HDz)_2$ and to the amount of solid $Hg(HDz)_2$, thus mercury(II), present. This relationship is only valid when all the $Hg(HDz)_2$ in the sample has undergone photochromism.[25]

Sample preparation

A major problem with sample preparation method 1 was that the dispensed volume of PVC in THF was too large. Thus, the resultant samples were too big to be covered entirely by the laser beam (spot size = 2 mm radius). Precision in measurements of the same sample was poor because the area being sampled might not be the same each time. Also, because the drops dispensed from the pasteur pipette were not always of the same volume, the $Hg(HDz)_2$ was spread over a different area each time. Different volumes of PVC solution thus caused variation in the amounts of the mercury complex in the illuminated polymer matrix even when the original sample solutions contained the same concentration of Hg^{2+}.

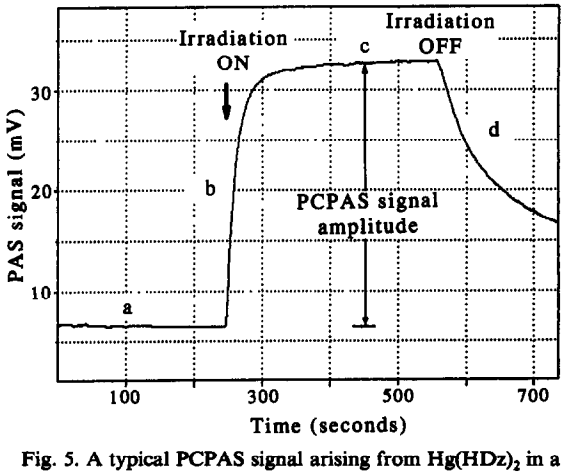

Fig. 5. A typical PCPAS signal arising from $Hg(HDz)_2$ in a PVC matrix. Projector light irradiation started at 245 sec and stopped at 555 sec: (a) ground state without irradiation; (b) forward photochromic reaction; (c) excited state under irradiation; (d) relaxation from excited state to ground state.

Method 2 eliminated the problems discussed above, but difficulty was experienced in trying to cover the entire solid sample film with only one μl of PVC solution. A volume of 2 μl was tried, but the resulting samples became larger than desired. In practice, a defocusing lens could not be used to enlarge the spot size of the laser beam beyond the dimensions of the PAS cell windows.

Another difficulty encountered with the first two methods was that, while dispensing 5 μl of $Hg(HDz)_2$ solution from the syringe, the CCl_4 would sometimes evaporate before the drops could be placed on the glass disk.

Method 3 was designed to achieve reproducible results. The samples were all approximately 2 mm in diameter so that they were easily covered by the laser beam. Using this method of sample preparation, a linear relationship was found between PCPAS signal amplitude and Hg^{2+} concentration in the range 12.5–100 μg/ml. This concentration range is high relative to that which would be useful for certain environmental analyses. The main problem with the present method 3 is the transference of a relatively large volume of the extract to the glass cup and the removal of only a small fraction for analysis. It may be improved by use of a larger fraction of the extract to form the sample. Also, adjustment of the volumes or concentrations of the solutions used in the Hg^{2+} extraction process may help to lower the concentrations that can be determined.

Reproducibility of sample preparation method 3

The variability in the analysis was a combination of the variability associated with the sample preparation technique and the variability of the analytical methodology. The variability of sample preparation method 3 was determined by the repeated preparation and analysis of solid $Hg(HDz)_2$ samples from a given Hg^{2+} solution. Measurements in this study were

carried out in triplicate and the precision of each step was calculated by use of the following equation:

$$P = (S_{extreme} - S_{average})/S_{average} \quad (2)$$

where $(S_{extreme} - S_{average})$ was the greatest deviation from the average and $S_{average}$ was the average of the three PCPAS signal amplitudes. The following precisions were found:

P_1 = precision of the PCPAS measurement (3)

P_2 = [(precision of solid sample preparation technique)$^2 + P_1^2$]$^{\frac{1}{2}}$ (4)

P_3 = [(precision of extraction)$^2 + P_2^2$]$^{\frac{1}{2}}$. (5)

The experimental values of P_1, P_2, and P_3 are listed in Table 1 for easy comparison. These statistical results show that a greatest source of error in sample preparation method 3 lay in the solid sample preparation technique, particularly at high concentrations of Hg^{2+}. Although the micro-pipette was designed to deliver exact volumes of aqueous solutions, the viscous $Hg(HDz)_2$ in PVC solutions could not be delivered as accurately. The precision of the solid sample preparation technique may improve if the PVC solution is delivered from a syringe to the glass disk, as the syringe (calibration = ± 0.05 μl) would transfer a given volume of sample solution more accurately than the micro-pipette (calibration = ± 0.1 μl).

PCPAS of a $Hg(HDz)_2$ film with and without a PVC cover

A solid $Hg(HDz)_2$ sample was prepared from a 50-μg/ml Hg^{2+} solution according to method 2. Before a PVC cover was added, the sample produced a PCPAS signal of 4 mV in amplitude. The same sample, after application of a PVC cover, gave a 23-mV signal amplitude. A possible explanation for this increase in PCPAS signal amplitude is that the bare solid sample scattered incident laser and projector lights, thus decreasing the power of the lights that reached its inside. When the PVC solution was added, the solid complex was redissolved in the THF solvent. Upon evaporation of the solvent, the dispersed film sample became transparent. This allowed the laser and projector lights to reach the $Hg(HDz)_2$ molecules more uniformly than it could in the bare solid sample. The increase in the PCPAS signal amplitude could also be due to a more efficient transfer of heat energy from the dispersed complex to the air in the PAS cell when the PVC cover layer was present. This is, in accordance with the PAS theory, governed by the thermal diffusivity of the material which is typically 10^{-3} cm^2 sec^{-1} for polymers.[29] In comparison, no literature value is available for $Hg(HDz)_2$ and must now be measured in our laboratory using either the conventional calorimetric methodology or the method of Adams and Kirkbright for thin solid films.[30] Another explanation for the increase in PCPAS signal amplitude may be that the polymer matrix was acting as a "solvent" so that excitation of the complex could occur more efficiently. Inclusion of mercury(II) dithizonate within the polymer matrix, whether by entrapment or cross-linking, had a stabilizing effect on the complex. The polymer matrix, like immobilization, increased the rigidity of the complex making it harder to unwind and relax. Similar spectrophotometric determination of tetraphenylporphinecobalt(II) by its catalysis of the photochromic isomerism of norbornadiene immobilized on porous glass beads has recently been reported.[31] Regardless of the nature of the exact mechanism, the addition of a PVC cover did enhance the PCPAS signal amplitude. This lowered the detection limit of 3 pg/ml for the determination of Hg^{2+} in aqueous samples using PCPAS, as reported previously by Chen *et al.*[25] to about 0.5 pg/ml.

Stability study over time

A sample was prepared by extraction of a 100-μg/ml Hg^{2+} solution, and its PCPAS signal was measured over a period of 19 days. A linear signal decrease was observed, at a rate of 1.6%

Table 1. Precisions of PCPAS measurement, solid sample preparation technique and extraction

Concentration of Hg^{2+} solution	Precision of PCPAS measurements*			Precision of solid sample preparation technique	Precision of extraction
(μg/ml)	P_1	P_2	P_3	$[P_2^2 - P_1^2]^{1/2}$	$[P_3^2 - P_2^2]^{1/2}$
100	1.1%	5.5%	7.1%	5.4%	4.4%
12.5	5.2%	7.5%	10.1%	5.4%	4.4%

*See text for definitions of P_1, P_2, and P_3.

per day from the initial amplitude. This loss is possibly ascribed to slow photodissociation of $Hg(HDz)_2$ during projector light irradiation in the PCPAS measurements. Nevertheless, the above results have demonstrated the sample preservation properties of the PVC matrix. The polymer provides the Hg complex with efficient protection from physical disfiguration and loss of sample over an extended period of storage time. It is not difficult to imagine how sample integrity can easily be lost by physical processes, such as scraping and flaking, in the absence of a PVC coating. Any delay in sample analysis would only require a proportional normalization of the PCPAS signal. Extrapolation of the maximum preanalysis holding time allowed for a particular analysis may be statistically possible from the reproducible data. The American Society for Testing and Materials (ASTM) defines the holding time as "the period of time during which a sample can be stored after collection and preservation without significantly affecting the accuracy of analysis".[32] In this case, a month may elapse before the PCPAS signal from a PVC-covered $Hg(HDz)_2$ sample is reduced to one-half of its initial value. The above PCPAS measurement could not be validated for a longer term than 19 days after damage to the gas microphone was accidentally incurred.

PCPAS with a laser of higher power

Vibrations from the surroundings (*i.e.*, ambient noise) caused amplitude fluctuations in the PAS signal. Interference in the PCPAS signal determination by ambient noise, which degraded the analytical detection limit, were overcome by using a high-power, low-noise laser. In one experiment the sample prepared from a 25-μg/ml Hg^{2+} solution gave a PCPAS signal amplitude of 20 mV and a signal-to-noise ratio of 10:1 when the He–Ne laser ($\lambda = 632.8$ nm) was used. Using the Ar^+-pumped dye laser operating at 610 nm, a 94-mV signal amplitude and a signal-to-noise ratio of 47:1 was obtained for the same sample. The enhancement of the PCPAS signal is believed to be the result of two factors: the increase in output power of the dye laser and the use of a wavelength of light which was closer to the maximum absorptivity of the excited-state complex at 605 nm. The output power from the dye laser was measured to be 75 mW which was four times that of the He–Ne laser. Since 94 mV $\gg 4 \times 20$ mV, the $\Delta\lambda$ advantage is clearly evident. No photobleaching of mercury(II) dithizonate and no PAS signal saturation were noticed at this laser power level. Ideally, the dye laser should have been tuned to a wavelength identical with that of the He–Ne laser in order to study the effect of the power of the laser used. Unfortunately, a significant power increase could not be achieved at 632.8 nm for the Rhodamine 6G dye employed.

CONCLUSION

Proper preservation of analytical samples requires planning of critically timed activities performed in both the field by the sampling crew and in the laboratory by the analysis staff. From the results presented in this report, polyvinyl chloride can be used to preserve the integrity of solid $Hg(HDz)_2$ samples prepared by extraction of Hg^{2+} from water with dithizone. The PVC cover provides the $Hg(HDz)_2$ with protection from physical damage (*e.g.*, scraping and flaking) to facilitate easy transport and storage. This allows a longer time period between sampling and analysis. As the polymer also immobilizes the solid complex and may increase its photostability, the maintenance of calibration standards in the laboratory will be easy. In general, equipment used for sample analysis is a common source of sample contamination. Use of PCPAS of solid film samples deposited on disposable glass disks eliminates problems of carry-over and memory effects from consecutive analyses of high- and low-level samples which are common to many types of instrumental methods (viz., carry-over from high-level samples contaminates subsequent low-level samples).

By comparing solid $Hg(HDz)_2$ samples with and without PVC covers, it has been verified that the presence of the polymer matrix enhances the PCPAS signal amplitude obtained. In addition, a greater PCPAS signal amplitude can be obtained with the use of a laser of higher power and an optimum wavelength of the excitation light. Hence, a higher signal-to-noise ratio (and thus a lower detection limit) can be achieved. In view of the promise shown by the preliminary data, the method merits further study and sensitivity enhancement will be pursued in our laboratory.

Finally, the ease of use of this novel sample preservation technique for potential field applications should not be understated. The analysis of standard reference materials, as well as the exchange of samples with laboratories that are skilled in mercury analyses, are underway to

allow further validation of the method. Note that the PCPAS equipment, which measures no more than 70 cm × 85 cm × 25 cm on an optical breadboard, has good potential for use in a mobile laboratory.

DETERMINATION OF B, Si, Cr, Mo, Th AND Hf IN UF_6 BY END-ON VIEWED ICP-AES

PAN FUXING, TONG DEZHI, REN MING and MA HEYING
P.O. Box 151-21, Lanzhou, Gansu, People's Republic of China

(*Received* 12 *February* 1992. *Revised* 13 *October* 1992. *Accepted* 8 *December* 1992)

Summary—A spectrographic analysis method is described for the determination of B, Si, Cr, Mo, Th and Hf in UF_6 Uranium is separated from UO_2F_2 using a TBP [tributyl phosphate] extraction-elution resin column technique. The six impurity elements, including B and Si, in the fluorine-containing extraction-elution solution are determined by end-on viewed ICP-AES. The method is simple, rapid and suitable for routine analysis.

INTRODUCTION

The ASTM C996-83 (standard specification for UF_6 enriched to less than 5% U-235) requires the determination of impurity elements B, Si, Cr, Mo and Th. However, B and Si in UF_6 are difficult to determine spectrographically among the five elements because they would be lost in large amounts during the conversion of the sample into U_3O_8 if the carrier distillation method is used. Also, Si would be lost completely, and B by large fractions during the driving off of HF by nitric acid if a chemical-spectral analysis method or ordinary ICP-AES is used.

For these reasons, for decades, both the DOE ORO-671-2 method and its replacement ASTM C761-91 method stipulate that UF_6 be hydrolyzed in freshly prepared ammonia water to form NH_4UF_5, NH_4BF_4 and $(NH_4)_2SiF_6$,[1] and that the hydrolyzate be evaporated to dryness below 100°C, charged into a boiler electrode and excited with a dc arc for spectrographic analysis.

However, the development of the modern analytical technique has provided the possibility of determination of B and Si in UF_6 using chemical separation at room temperature.

Our method is as follows: after UF_6 is hydrolyzed in high purity water to form UO_2F_2, an aliquot of it is treated with concentrated nitric acid, and passed through a TBP [tributyl phosphate] extraction-elution resin column for separation. Uranium is absorbed on the column and the impurities remain in the elution solution. Then end-on viewed ICP-AES is used to determine the six impurity elements (B, Si, Cr, Mo, Th and Hf) simultaneously. As both the sample treatment and the separation are performed at room temperature, the loss of volatile fluorides of B and Si does not occur.

The experimental results show that a recovery of 86–114% and a precision (RSD) of less than ±16% are obtained because of the simple operation and the stability of the selected ICP operating conditions and sample inlet system. Analysis of production samples agrees with the analytical results of other methods used for comparison analysis.

Preparation of the TBP [tributyl phosphate] extraction-elution resin chromatographic column

A 75–120 mesh TBP extraction-elution resin is put into a glass beaker, rinsed with water, and immersed for over 24 hours after removing the floating material. Then the resin is gently flowed into the column (Fig. 2), stirring the resin frequently with a glass rod so that it can be packed uniformly and no bubbles occur. After packing, the column is eluted with 5% sodium carbonate solution, the volume of which is four times that of the resin, to remove residual butyl and dibutyl, and washed with water to neutrality. To remove the impurities, the column is eluted repeatedly with 1*M* HCl, H_2O and 3*M*

HNO_3 to an acceptable blank value for routine use.

Preparation and pipetting of standard series solutions

Prepare original solutions with oxides or salts of B, Si, Cr, Mo, Th and Hf, take a portion from each according to the requirements for the analysis of a 300 mg sample, dilute to a standard series (N1-N5) of solutions with certified high purity water, and store in 100 ml plastic containers. Pipet, respectively, 1 ml from each of the standard series solutions, add 1.5 ml of concentrated HNO_3, 3.2 ml high-purity water and 0.3 ml HF to each of them, and mix in PTFE cups (each to a total volume of 6 ml and a total acidity of $4M$ HNO_3–$1.1M$ HF) for future use.

Sample treatment and separation procedure

Hydrolyze UF_6 in high-purity water, and maintain its concentration at 150–300 mg/ml. Pipet a volume of hydrolyzate containing 300 mg of UF_6 into a PTFE cup with a plastic pipet, add first an appropriate amount of high-purity water to give a sample volume of 2 ml and then 1 ml of concentrated HNO_3, and mix thoroughly. Pipet the sample into the column which has been acidified with $4M$ HNO_3, and elute with $4M$ HNO_3 with a flow rate of 0.3 ml/min for separation. Discard the first 4 ml, and collect the last 6 ml effluent solution which contains all the impurities. Uranium absorbed on the column is desorbed with water. Keep one blank of reagent during separation.

Take spectrograms of the effluent solutions and the standard series solutions simultaneously.

RESULTS AND DISCUSSION

Interference by fluorine

Since the elutant solution received during separation is an acidic mixture of HNO_3 and HF, the effect of fluorine content on the determination results must be taken into account. Theoretically, 100 mg of UF_6 contains 32.4 mg of fluorine. Our measurement result is 33 ± 2 mg. The fluorine content in 0.1 ml of commercial hydrofluoric acid is 38 mg which is roughly of the same order.

Based on the above consideration and calculation, we studied the addition of 0.1–0.4 ml of hydrofluoric acid (*i.e.*, 38, 76, 114 and 152 mg of fluorine) and the results are listed in Table 3. The increase in the density of the spectral lines due to the gradual addition of the fluorine

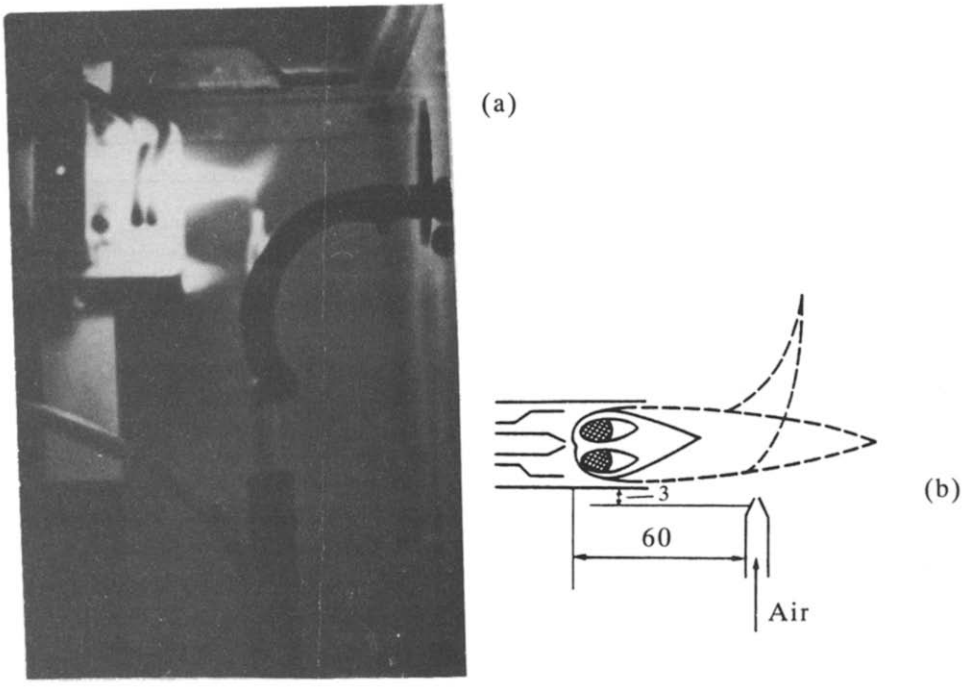

Fig. 1. End-on viewed ICP with a lens protecting unit: (a) photograph; (b) schematic drawing.

content made the corresponding quantitative content of each element tend to increase gradually, notably B. In the range of 114–152 mg of fluorine, the change in determination results of six elements tended toward stabilization. In addition, greater B content may be due to the formation of strongly volatile fluoride in B which increased the flow rate of B into the central channel of ICP; this is also one of the reasons for the lower determination limit of B.

Based on this result, and guided in the principle that the standard solution should correspond with the acidity of the sample solution as closely as possible, for sampling of 300 mg UF_6, we added 0.3 ml of hydrofluoric acid to standard series solution.

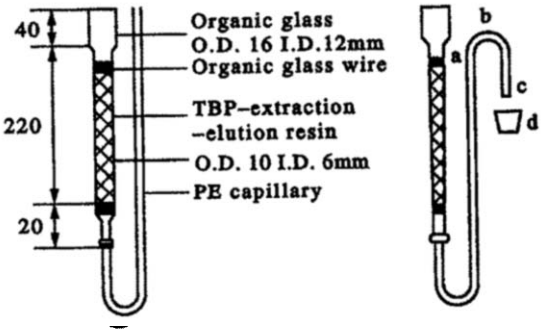

Fig. 2. A TBP-extraction-elution resin chromatographic column.

Spectral interference by CA and Fe

Since our analytical object is high-purity UF_6 with impurity elements at the parts per million level and end-on viewed ICP is used, we studied only Ca which is likely to be a contaminant that may give rise to ionization interference, and Fe which has complicated spectral lines. Since the two elements have similar effects on the determination result, only results of Ca are listed in Table 4.

For samples of 300 mg, Ca with as high as 340 μg/gU (also Fe with 192 μg/gU) has no effect on the results of the six elements. Neither interference of spectral lines nor interference of ionization are apparent.

Interference by U

Since this was our first attempt to separate uranium from HNO_3–HF medium using a chromatographic method, doubt may arise as to whether trace uranium would be lost and thus affect the spectrographic determination. In our practice, within the useful life of a chromatographic column, no noticeable uranium loss occurred, and the separation was complete. But when a column approaches the end of its life, the loss of a small amount of uranium is possible. For this reason and also because uranium is a matrix element with multiple spectral lines, it was necessary to study its interference.

Table 3. Effect of F content in the solution on the determination results (μg/gU)

Fluorine	B	Si	Cr	Mo	Th	Hf
0	0.94	180.0	9.8	10.8	11.5	4.4
38	2.6	220.0*	13.0	13.0	11.5	4.9

152	5.0	200	15.5	17.0	13.0	5.7

*Possible contamination.

Under the selected ICP conditions we performed an experiment on the interference with 14–110 μg uranium and the result is shown in Fig. 3.

Below 110 μg and within the range of error of the spectrographic method, BI 249.773 nm, SiI 251.611 nm, Cr II 267.716 nm, Th II 401.913 nm and Hf II 264.141 nm experienced only small influences. Only for a larger amount of uranium did the density of Mo II 281. 615 nm tend to decrease. As the residual uranium is generally below 15 μg, no serious interference with the spectrum would occur.

Accuracy and precision

The accuracy and precision of this method were assessed by analyzing a series of laboratory prepared synthetic samples, check samples and several real UF_6 samples following "sample treatment and separation procedures", under the experimental conditions defined in Table 1.

Two synthetic samples were prepared by adding standard solutions to a UO_2F_2 solution. The impurity contents in one sample were at the lower analytical limits of this method, and those in the other sample were at the level of product quality standard. Each of the two synthetic samples was analyzed five times. The mean determination value, average percentage recovery, and relative standard deviation (RSD) after separating with TBP chromatography are listed in Table 5.

To our knowledge, at present there are no certified standard samples for the impurity elements in UF_6. Thus, check samples were used instead. The check samples we used were prepared in the same manner as the reference

Table 4. The effect of Ca content on the determination results (μg/gU)

Ca content	B	Si	Cr	Mo	Th	Hf

solution. The impurity contents in check samples were unknown. Only after the analysis of check samples had been performed, were the impurity contents made known by the checking personnel. Each of the check samples was analyzed five times. The quantitative results obtained and the standard deviation are listed in Table 6.

To demonstrate the effectiveness of this method, several UF_6 samples were analyzed. These samples were taken from an enriched UF_6 product for nuclear reactors. Each of these samples was divided into several aliquots which were subsequently determined by the present method, a chemical method, and TEHP [tri(2-

ethyl-hexyl) phosphate] separation—ICP-AES method[2]. The results obtained are listed in Table 7. The results of this method agree with those obtained by other methods.

The data in Tables 5–7 show that TBP chromatographic separation—end-on viewed ICP-AES, is an effective method for the determination of B, Si, Cr, Mo, Th and Hf in UF_6. Its determination limits can satisfy the requirements of UF_6 quality appraisal. The time required for sample preparation and analysis is one working day. This method is simpler and more rapid than the test method for B and Si in UF_6, provided by ASTM C761-91 standard procedure.

(*Received* 15 *July* 1991. *Revised* 10 *December* 1992. *Accepted* 10 *December* 1992)

Summary—An experimental comparison between the relative performances of the Powell and simplex methods for the optimization of a Flow Injection Analysis (FIA) system for the determination of nitrite in water is reported. An evaluation of the advantages of using a weighted linear combination of two variables (related to sensitivity and sample throughput rate) as the response function in the guidance of the optimization procedures towards different practical requirements is also included.

Both methods proved to be effective for the optimization, none having shown definite advantages over the other. The use of a weighted response function in these optimization methods proved to be useful for assessing the versatility of FIA systems.

The need to optimize the parameters which define FIA systems to improve their response characteristics (usually sensitivity and/or sample throughput rate) is nowadays commonly accepted. For this purpose, due to the complex and strong interdependence which exists between the various parameters (flow rates, lengths and internal diameters of tubes, injection volumes, reagent composition, *etc.*) and performance variables (peak height, residence time, linear working range, *etc.*), methods able to promote their simultaneous optimization in a systematic way are required.

The lack of mathematical models to describe the behaviour of all but the simplest FIA systems prevents the utilization of methods that use derivatives. Among the direct optimization methods, the simplex method,[1–3] devised by Spendley *et al.*,[1] and significantly improved by Nelder and Mead,[2] has been the most commonly used in FIA applications. Its application to analytical chemistry has had a large impetus after the work of Morgan and Deming,[3] and it was first applied in the optimization of FIA systems by Betteridge *et al.*[4] The choice of an adequate response function is a critical step for the optimization procedure,[5–8] and several different kinds of response function have been used for the optimization of FIA systems.[5–16] The automated optimization of FIA systems using simplex procedures has also been reported.[8–10] The utilization of the Powell[17] method has also been proposed for the optimization of FIA systems,[18] and a comparison between the two methods was recently described for a particular FIA system.[19]

This paper reports an evaluation of the relative efficiency of the simplex and Powell methods to promote the optimization of another FIA system and a study of the performance of a particular kind of response function (a weighted linear combination of variables) in the guidance of the optimization procedures towards different compromise requirements between the variables chosen (in this case sensitivity and sample throughput rate).

The response function (*RF*) is a linear combination of two variables,the peak height (*H*), which is to be maximized as it is taken as a measure of sensitivity, and the residence time (*T*), which is to be minimized since it is inversely related to the sample throughput rate. Expressed in terms of the normalized variables (R_H, R_T), *RF* is

$$RF = C_H \cdot R_H + C_T(1\text{-}R_T).$$

*Author for correspondence.

The normalization of variables[3,4] is accomplished through the use of the expression

$$R = (R_{exp} - R_{min})/(R_{max} - R_{min}),$$

where R_{exp} stands for the experimental value of the variable measured and R_{min} and R_{max} for the values of the corresponding minimum and maximum values, found by means of preliminary tests.

Response functions based on independent additive terms can result in unexpected and unwelcome results when one of the terms dominates. In the present case, problems could arise if the residence time coefficient was very large, leading to very fast systems, with small and narrow peaks, thus having low sensitivity and poor repeatability, or if the peak height coefficient was too large, leading to unpractically large systems, with very long residence times and broad peaks. Two possible ways to avoid this problem are the definition of boundaries for the variation of the parameters (to prevent the occurrence of unpractical system) and the use of suitable normalization conditions of the variables (to assure that there is no indirect weighting of them, *i.e.*, when equal coefficients are assigned to both variables, their relative contributions to the response function should be similar).

For this study, the system for the determination of nitrite proposed by Nakashima *et al.*,[20] whose optimization by the simplex method was previously reported,[15] was chosen. The degree of complexity of this system is intermediate and typical of a large number of FIA systems. It involves four hydrodynamic parameters of the manifold (two coil lengths and two flow rates).

Five different sets of the weighting coefficients (C_H, C_T) were used as before[15] to cover systematically their allowed range ($0 \leqslant C_i \leqslant 1$), thus permitting an evaluation of the guidance features of the type of response function used and providing a broader base for the comparison of the simplex and Powell procedures than before.[19]

EXPERIMENTAL

Equipment and reagents

Figure 1 shows the manifold used in the optimization experiments which was fully described in a previous work.[15] Reagents were prepared and stocked as described in the work by Nakashima *et al.*[20]

Algorithms

The program algorithm used for the simplex optimizations has been described in detail before[14] and is based on the modified simplex method of Nelder and Mead,[2] but with some modifications to include boundary conditions, to take into account Aberg's suggestion[21] that the value of *RF* for an expansion should be compared with its reflected point instead of with the best of the simplex values, and to combine the use of massive contraction with the application of "rule 3" from Spendley's original method[1] (this rule states that, if the value of *RF* obtained for the point resulting from the reflection of the worst vertex of the simplex is smaller than the value of *RF* for the worst vertex of the simplex, then the advance in the optimization is achieved through reflection of the next-to-worst vertex).

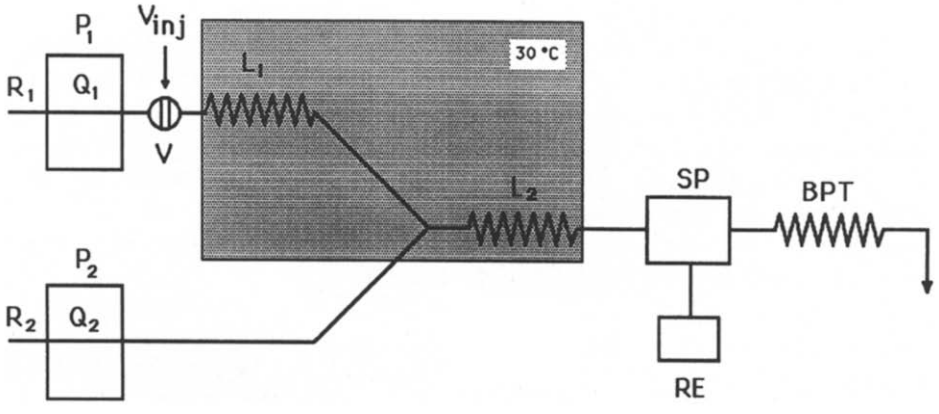

Fig. 1. Flow injection manifold for the optimization experiments: $R_1 = 0.04\%$ (w/v) *p*-aminoacetophenone, pH 1.5; $R_2 = 0.11\%$ (w/v) *m*-phenylenediamine, pH 2.4; P_1 P_2 = peristaltic pumps; V_{inj} = injection valve; SP = spectrophotometer; RE = recorder; BPT = back-pressure tube. The tubing used was made of Teflon with 0.8 mm internal diameter. The tee piece used was made of Perspex and with 120° angles. Parameters allowed to vary: Q_1, Q_2 = flow rates; L_1, L_2 = reaction tube lengths.

The program algorithms used in the Powell optimizations were also previously described in detail,[18] and are based on the original algorithms of Powell.[17]

Both programs were implemented on an Apple IIe microcomputer.

Convergence criteria

The convergence criterion used in the simplex algorithm stated that the sample standard deviation between the values of the response function should be less than a preset value, fixed by the user at the beginning of the optimization procedure. In this study this value was set at 0.5.

In the Powell method a double convergence criterion was used. First, both the coordinate values and the target function increments in two consecutive iterations must be below a present value, in this case 0.5. Second, in each unidirectional search, the interpolated point on the assumed parabolic shape is also checked against the mentioned preset value. This double criterion requires a complete iteration cycle to achieve convergence, which provokes the occurrence of some final points with very similar coordinate values.

Procedure

L_1 and L_2 (see Fig. 1) were allowed to vary from 60 to 400 cm, with 5 cm intervals, and Q_1 and Q_2 were allowed to vary continuously in the range 0.7–4.5 ml/min.

The normalization conditions for peak height (0–0.1 absorbance units) and residence time (0–5 min) and the intial vertices of the simplex were determined in preliminary experiments, using a few systems with extreme values of the variables to be optimized. The coordinates of the initial point used in the Powell method were calculated as the mean value of its corresponding values in the five initial vertices of the simplex (see Table 1).

The values of peak height and residence time were evaluated as averages of the responses to triplicate injections of 500 μl of a 100 ppb(N) nitrite solution.

To study the influence of the relative weights (C_H/C_T) on the optimization results, the optimization experiment was repeated five times, both for the simplex[15] and Powell methods, with different values for the coefficients (C_H/C_T: 0.9/0.1; 0.7/0.3; 0.5/0.5; 0.3/0.7; 0.1/0.9). In each optimization method the same initial values of the parameters (L_1, L_2, Q_1 and Q_2) were used in all experiments.

Table 1. Starting points used for the optimization experiments

	L_1 (cm)	L_2 (cm)	Q_1 (ml/min)	Q_2 (ml/min)
Simplex	300	400	0.94	0.72
	200	400	1.41	0.72
	200	300	1.18	0.72
	300	300	0.94	1.10
	300	200	1.41	0.91
Powell	325	260	1.04	0.96

RESULTS AND DISCUSSION

The five optimization procedures with different combinations of weighting coefficients (C_H/C_T) were carried out in the usual way: the experimental set-up required by the optimization algorithm was assembled, the experimental responses (peak height and residence time) were measured, and all values were interactively introduced into the computer program, in order to calculate the next experimental conditions. Whenever the optimization algorithm proposed points which were too close to their points previously evaluated (*i.e.* when the differences between the values of each of the parameters in the proposed and evaluated points were smaller than 5 cm for tube lengths and 0.02 ml/min for flow-rates), these were not assembled and evaluated. Instead, the characteristics of the previously evaluated point (parameters and variables) were introduced again in the computer program. This decreases the amount of experimental work and is possible in the present case because the system is stable and presents no significant drift.

Figure 2 shows how the response function varies with the number of experiments, both in the simplex and Powell methods, for the five different sets of weighting coefficients used. It should be noticed that, since there are four variables to be optimized, the simplex has five vertices, and so the experimental points before the sixth do not reflect the simplex method's ability to climb the surface but merely the chosen ordering of the points of the initial simplex. This figure, along with the data in Table 2 for the number of experimental points, shows that the Powell method is usually faster in reaching the maximum. This was quickly attained, a few more experiments were made to verify that there was no further improvement in the response function, and in practice the optimization was terminated before meeting the convergence criterion. On the other hand, the convergence criterion was always met on the simplex optimizations. This implied in some

cases a considerable number of complementary experiments, after the maximum response function was attained (see Table 2).

It should be noted that, conceptually, the speed of optimization is associated with the ability of the optimization method to evolve to the maximum after the beginning of the procedure, which is different for the two methods. In fact, the Powell optimization procedure always starts immediately after the first point while for the simplex the begining of the optimization depends on the number of variables considered (in the present case it is after the fifth point). Nevertheless, what is of primordial importance to the analytical chemist is the time spent on and the amount of work required for the optimization. The significance given in this paper to speed of optimization is thus associated with the number of experimental points used, which still has to be discussed in terms of the amount of work required to attain and use each of the experiment points in the optimization procedures used since, as pointed out by Greenfield *et al.*,[23] this increases with the number of variables which change their values in successive experiments.

*In this case, the same value of response function was obtained for two different experimental points with identical coordinates except L_2. The presented values are the mean values and mean deviations for the two systems.

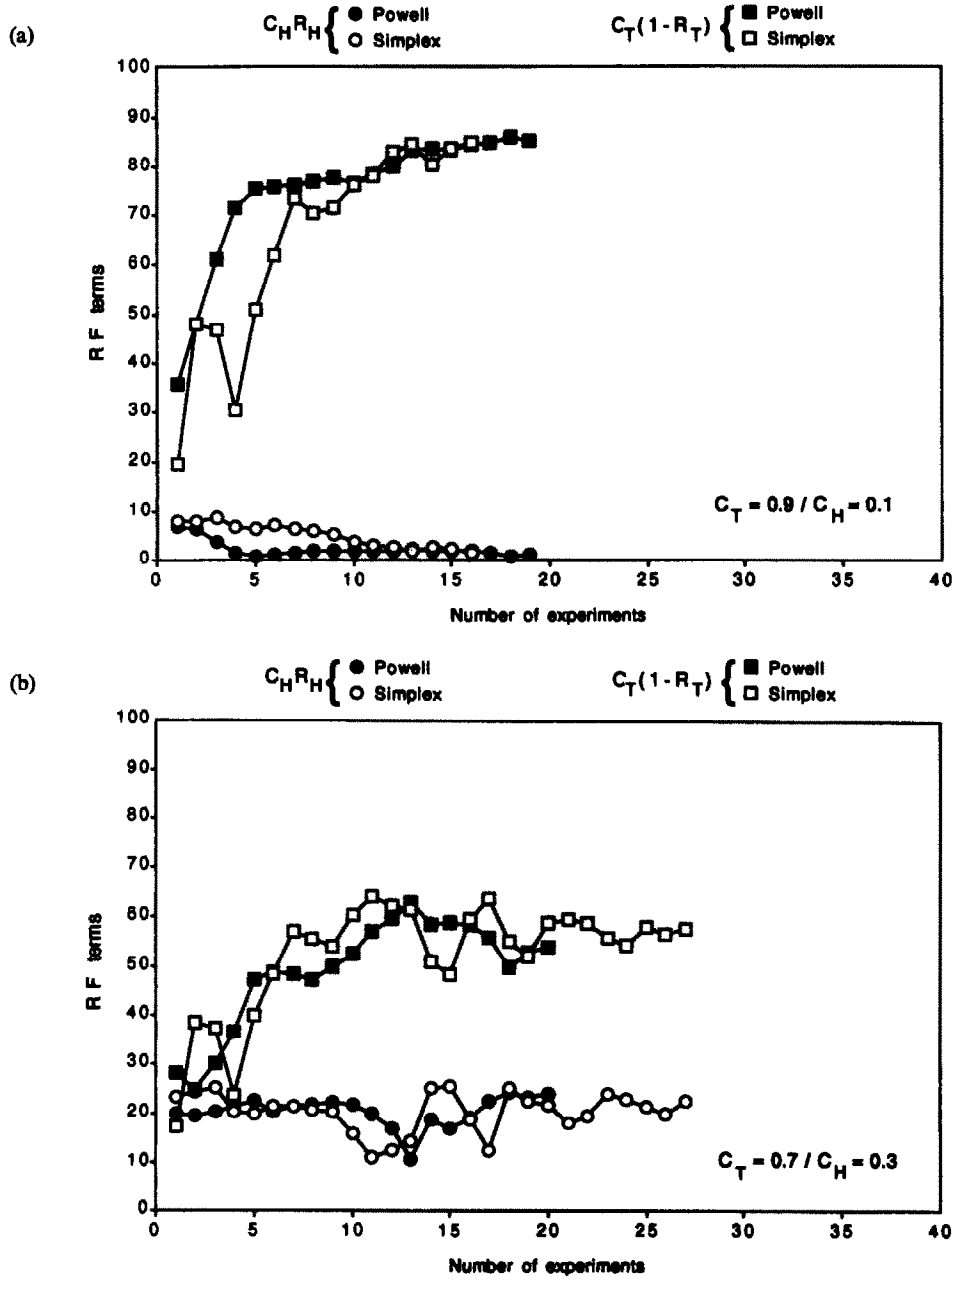
†The results presented are the mean and its corresponding confidence interval for the five vertices of the final simplex.

‡The number in brackets indicates the point with the highest value of response function. In both cases the experimental point proposed by the algorithm which were equal or too close (see text) to points previously evaluated were not included.

to 0.5 [Fig. 3(c)] the importance of both factors is equally stressed.

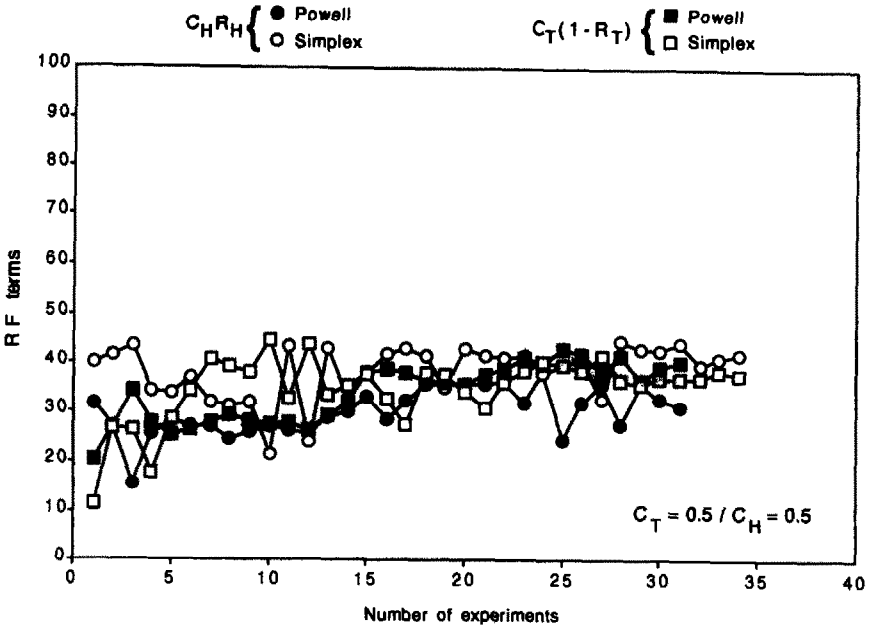
Figure 4 shows the variation of values of experimental parameters with experiment number, both for the simplex and Powell methods. The weighting coefficients were set at $C_H = 0.5/C_T = 0.5$ to emphasize equal sensitivity and speed requirements. The experimental responses (H and T) present a very similar variation profile in both methods. On the other hand, the variations of the parameters (L_1, L_2, Q_1 and Q_2) show different profiles, mainly because the unidirectional searches made at the beginning of the Powell method keep three parameters fixed while the fourth varies, but in the simplex method all the parameters change simultaneously.

The effectiveness of the parabolic interpolation in the unidirectional searches of the Powell method can be easily observed from Figs 4(a)–(d), which show that after starting its unidirectional search, each parameter quickly reaches a region close to its optimized value.

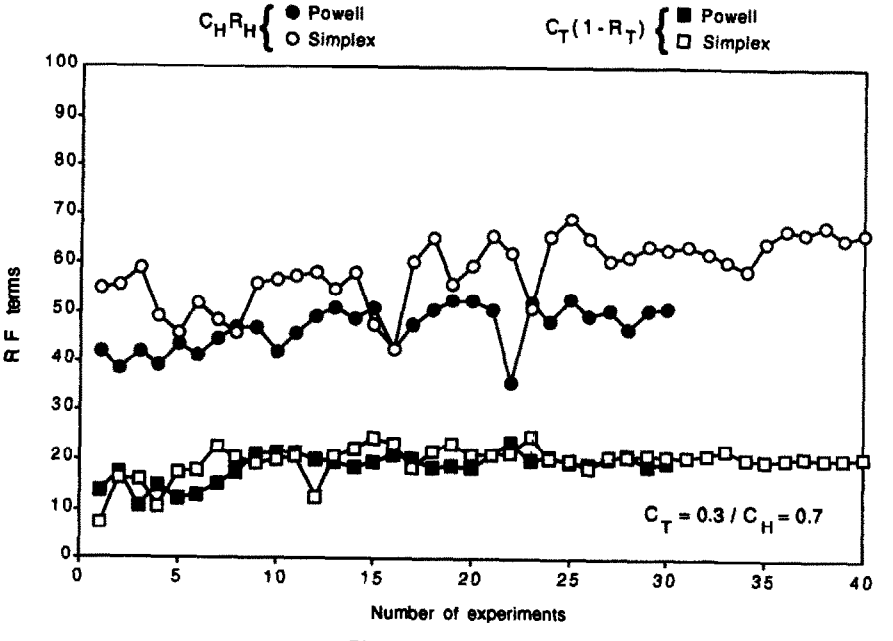


Figs 3(a) and (b).

(c)



(d)



Figs 3(c) and (d).

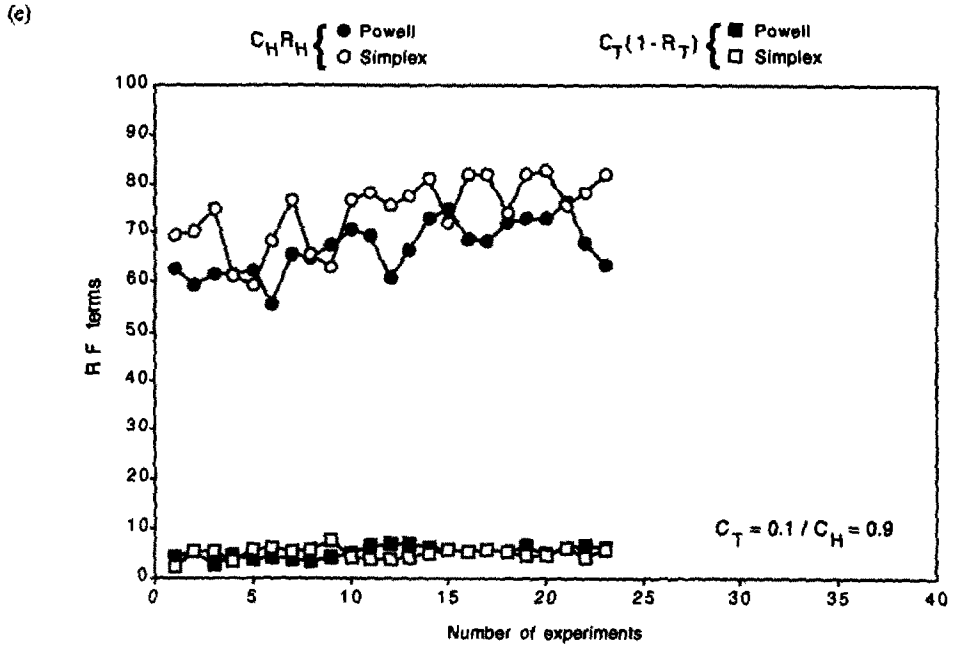


Fig. 3. Variation of the contribution of both terms of RF ($C_H \cdot R_H$ and $C_T(1-R_T)$ with experiment number, for the five different sets of weighting coefficients, in simplex (○, □) and Powell (●, ■) methods. C_H/C_T: A. 0.1/0.9; B. 0.3/0.7; C. 0.5/0.5; D. 0.7/0.3; E. 0.9/0.1.

The final results obtained by both methods are summarized in Table 2. Each of the simplex results presented are the average and the corresponding confidence interval (calculated by the t-function at the 5% significance level)[23] for the set of their respective values in the five vertices of the final simplex. On the other hand, the Powell results are the values corresponding to the point with the highest value of the response function. This is a consequence of the different natures of the convergence criteria used in two methods.

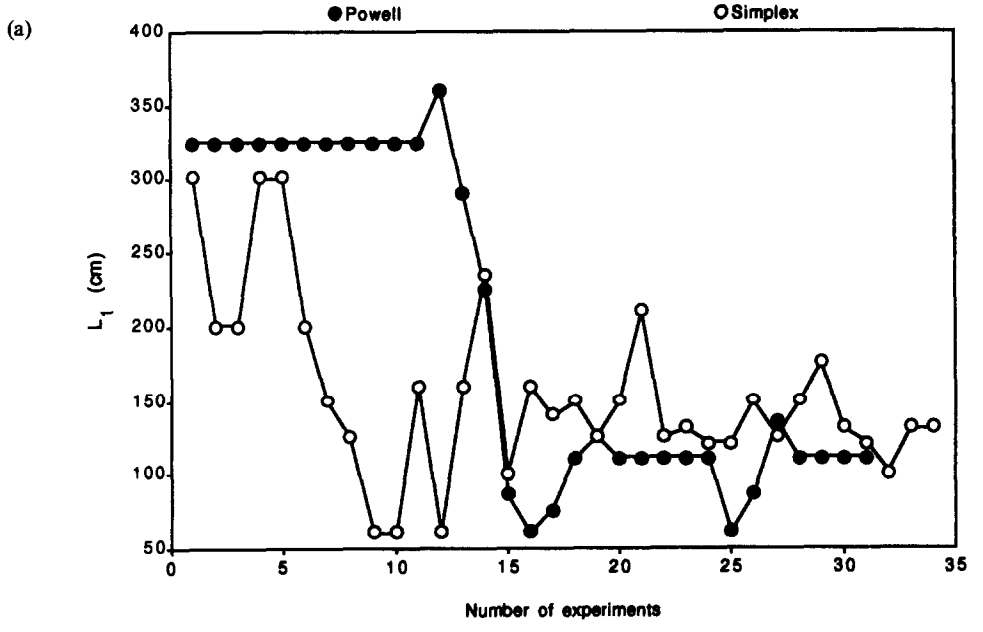
As Table 2 shows, the values of H generally increase with the sensitivity coefficient, C_H, and the sample throughput rate generally increases (*i.e.* the value of T decreases) in the opposite direction, as would be expected from the structure of RF.

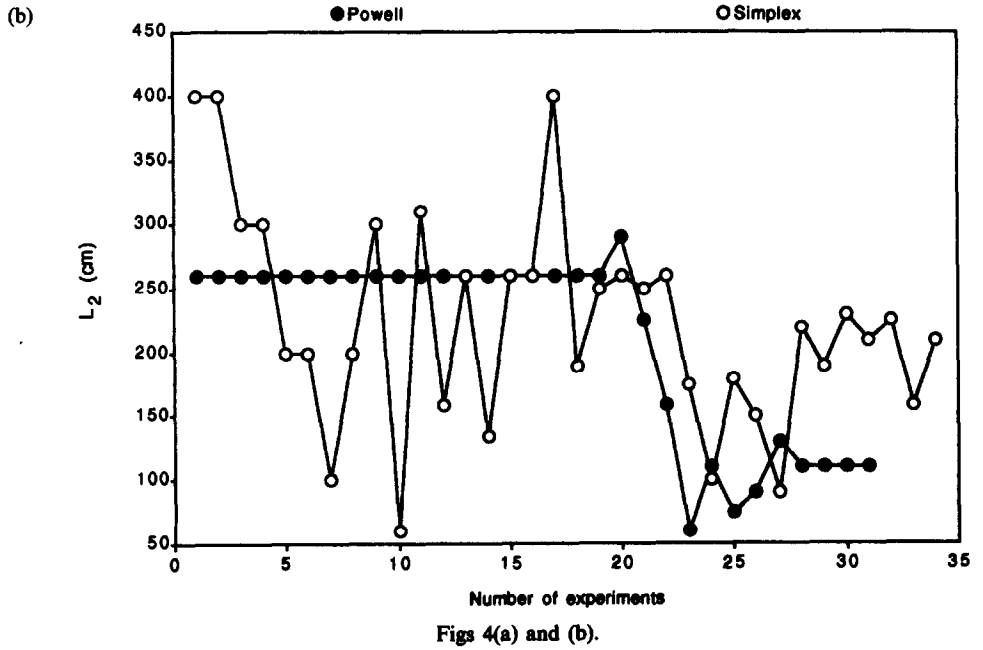
For both methods, the marked importance conferred to the sample throughput rate in the optimization experiments with the first set of weighting coefficients, $C_H = 0.1/C_T = 0.9$, leads to very fast systems, whose sensitivity is however very low. It is therefore not surprising that the largest increase in sensitivity and decrease in sample throughput rate between successive sets of weighting coefficients are observed, in both optimization methods, on passing to the following set of coefficients, $C_H = 0.3/C_T = 0.7$. However, some unexpected features are found in the results of the remaining experiments for the two methods. The simplex results proceed its expected trend (increasing the values of peak height and residence time) until the experiment with coefficients $C_H = 0.7/C_T = 0.3$, but on passing to the last, $C_H = 0.1/C_T = 0.9$, the importance of sensitivity cannot be further stressed and no improvement in the resulting systems is obtained, probably due to the fact that the reaction had already almost reached completion and dispersion effects now dominate. A similar situation occurs for the Powell method between the second ($C_H = 0.3/C_T = 0.7$) and third ($C_H = 0.5/C_T = 0.5$) sets of coefficients, from which result systems with very close characteristics. The Powell method was not very successful in optimizing the sensitivity in the central area ($C_H = 0.3/C_T = 0.7$ to $C_H = 0.7/C_T = 0.3$), where the difference in the optimization results are mainly due to the influence of the other term of RF, the sample throughput rate, but a significant increase in sensitivity was obtained in the optimization with the last set of coefficients ($C_H = 0.9/C_T = 0.1$).

The complex interdependence between the parameters and variables of a FIA system leads to the occurrence of points that have the same value of RF (since this is determined by the values of the variables), although they correspond to different sets of parameters (these

points fall on an *RF* surface contour in a *RF vs.* parameters plot). After a surface contour close to the maximum is reached, further iterations provide only small improvements in the value of *RF*, and therefore, to limit the number of experiments, the convergence criteria cannot be too strict. Thus, although the maximum might be unique, it is seldom reached exactly. Therefore, depending on the way the optimization algorithm approaches the maximum, the final value reported as the maximum value of *RF* may correspond to different sets of parameters in the two optimization methods.

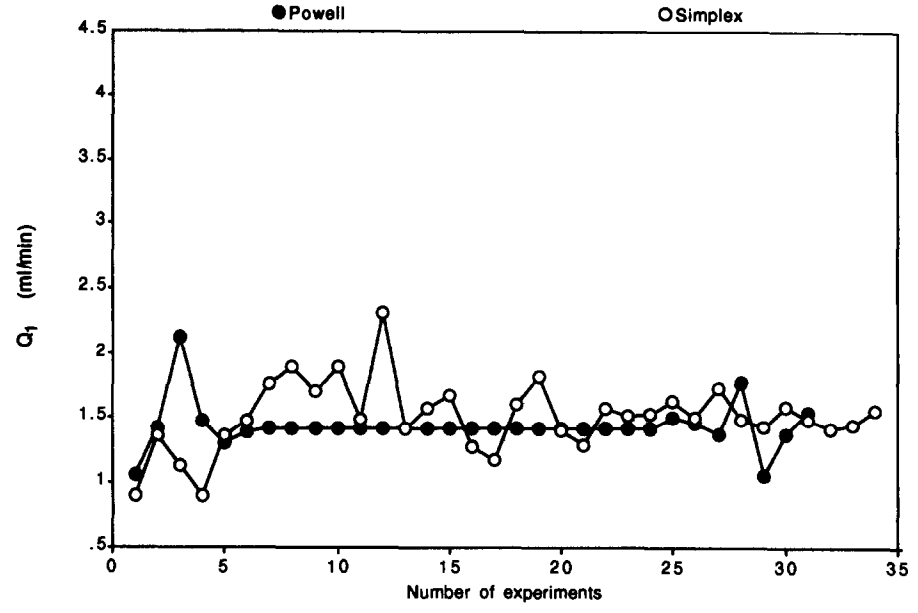
For instance, in the experiment with coefficients $C_H = 0.1/C_T = 0.9$, where the importance of analysis time is stressed over sensitivity, a large difference is observed between the values of Q_2 obtained by the two methods. This may be due to an unfavorable simplex orientation with respect to a ridge, while the results from Powell are set on a boundary condition. A few more experimental points confirmed that the simplex would increase Q_2 while maintaining all the



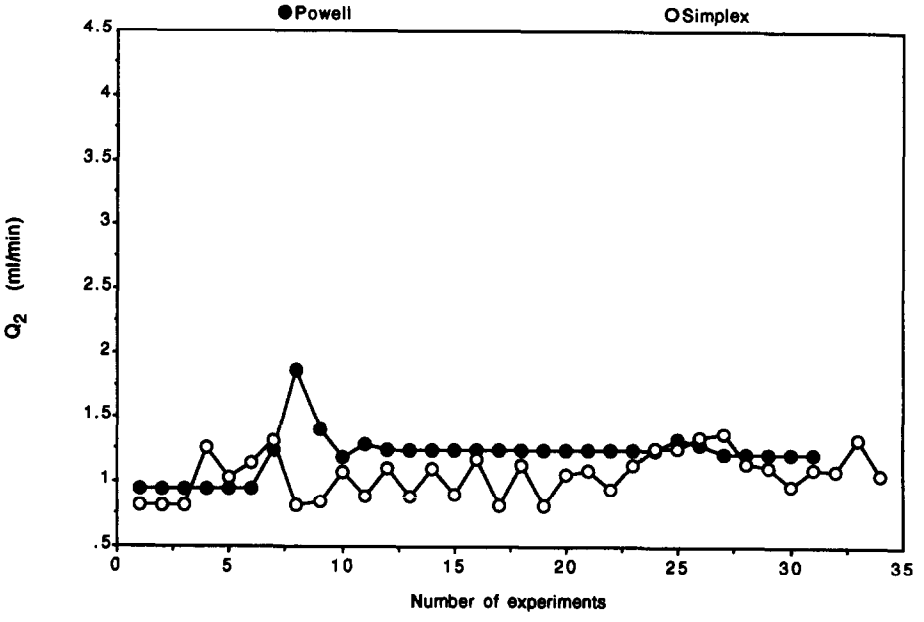


Figs 4(a) and (b).

(c)



(d)



Figs 4(c) and (d).

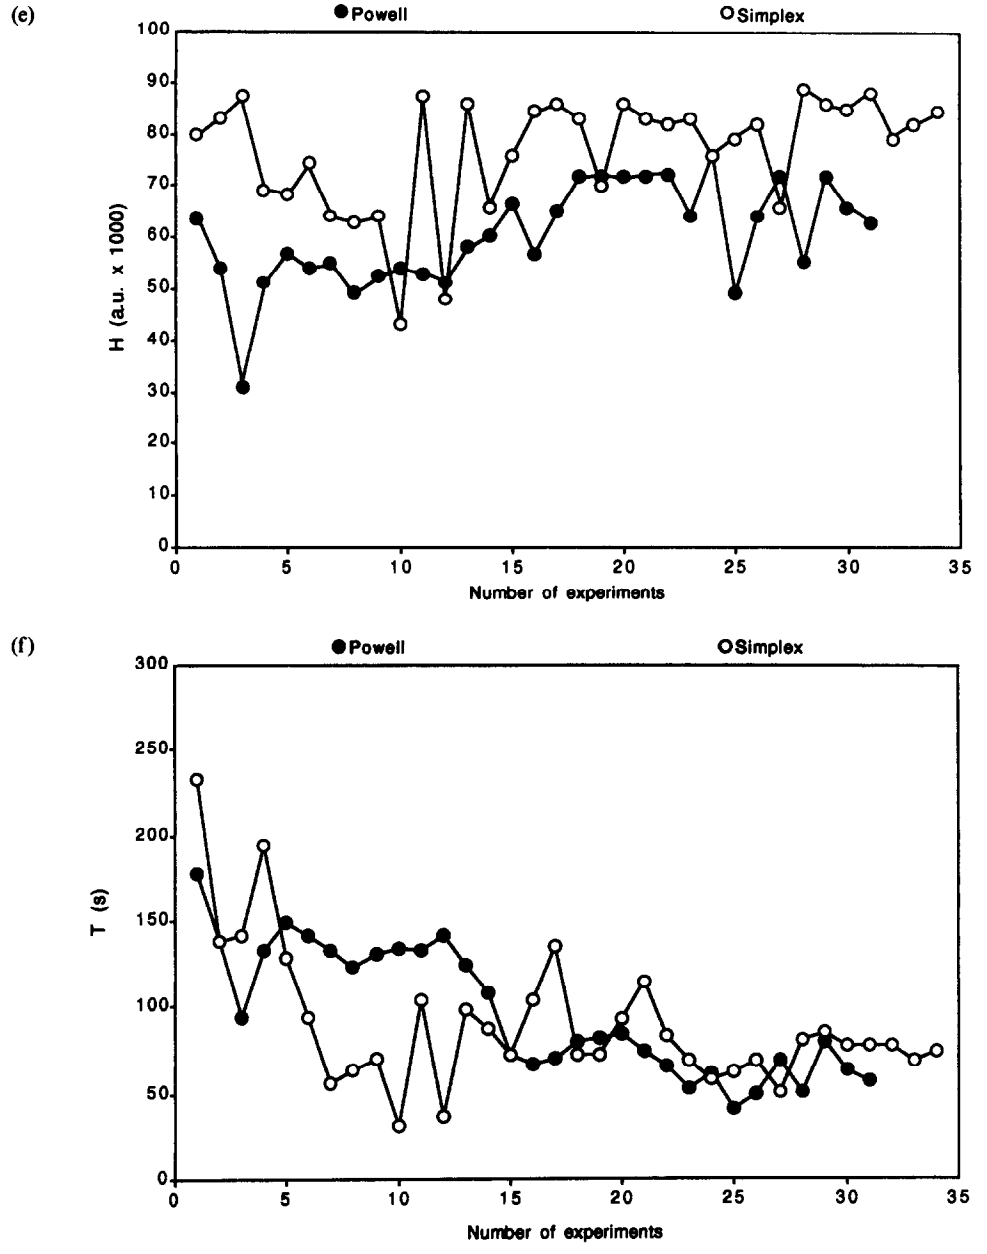


Fig. 4. Variation of parameters and variables with the number of experiments in the optimization experiment with weighting coefficients $C_H = C_T = 0.5$ for simplex (○) and Powell (●) methods. A. L_1; B. L_2; C. Q_1; D. Q_2; E. R_H; F. R_T.

other parameters, which would make closer the final results of both optimization procedures.

In the experiment where sensitivity was given more importance ($C_H = 0.9/C_T = 0.1$), the parameters obtained by both methods were very similar. Some differences were found in the other experiments, which can be explained by the way the variables depend on the parameters.

In the case with $C_H = 0.5/C_T = 0.5$, the only difference found was in the value of the tube length L_2. This is a result of the kind of response function used. Indeed, in the region around the maximum, the alteration of the value of one of the parameters generally provokes variations in the same direction of both variables considered (*i.e.*, if one flow rate is decreased usually both the peak height and the response time increase). Since we intend to maximize the former and minimize the latter, the net consequence in the response function may be very small or even null, and systems with different values of the parameters may have similar values of response

function. The situation for $C_H = 0.7/C_T = 0.3$ is similar, but as there is a certain difference in the values of the response function obtained by the two methods, the comparison may have less relevance.

For the function with $C_H = 0.3/C_T = 0.7$, large differences were found in Q_1 and L_2 (as well as smaller differences in Q_2 and L_1). This results from the fact that variations in the same direction of flow rate and tube length in one channel may produce similar values of peak height and response time. For example, if both tube length and flow rate are increased, the effect in response time will usually be very small, because the distance covered is larger but the speed is also higher, and the same is true for peak height, since the dispersion is higher but so is the extension of the reaction (unless it had already almost reached completion, in which case dispersion effects would dominate).

CONCLUSIONS

The use of a weighted response function in the Powell optimization of FIA systems provides a useful procedure for the characterization of their performances and for stressing the relative importance of sensitivity and sample throughput rate. This fully confirms the conclusion of a previous work with the simplex optimization procedure,[15] showing the usefulness of that type of response function in assessing the versatility of FIA procedures in different practical situations. To guide the optimization procedure to the desired balance requirements between sensitivity and sample throughput rate, it is only necessary to assign adequate values to the wei ghting coefficients and to have determined previously the normalization values of the variables.

The comparison between the simplex and Powell methods demonstrates that both can be useful for the optimization of FIA systems, neither having revealed definite advantages over the other.

In its early stages, at least during the first iteration cycle, the Powell method evolves through univariate searches. These are easier to accomplish experimentally than searches where various parameters have to be changed, thus allowing for savings of time in experimental work. This is particularly important in FIA when tube lengths are to be optimized, since their changes require a complete reset of the system and stabilization of baseline and therefore the savings in time are substantial if the number of alterations of tube length decreases. However, the Powell method requires a deeper knowledge of the system, necessary in order to choose the right order of optimization of the parameters, which is essential to avoid any disorientation of the search path, especially in the early stages of the process.

Although the Powell method was usually faster in searching the maximum, the simplex method provided more consistent results for the optimization, being much more robust. Additionally, the simplex method yields the uncertainty figures of the different parameters upon statistical treatment for the final polyhedron, which provide an indication of the final point precision. In the Powell method, due to the different convergence criterion used, this information cannot be obtained, although as several close points are collected at the final stage of the process, further confidence is also achieved. A more effective convergence criterion would make the Powell method more efficient.

SHORT COMMUNICATION

SPECTROPHOTOMETRIC DETERMINATION OF Fe(III) IN ALKALINE SOLUTIONS WITHOUT NEUTRALIZATION

LUMINITA VLADESCU and RENATE LERCH-GURGUTA
Department of Analytical Chemistry, Faculty of Chemistry, University of Bucharest, 13, Bv. Carol I, 70346-Bucharest, Romania

(*Received* 25 *July* 1991. *Revised* 15 *December* 1992. *Accepted* 12 *January* 1993)

Summary—Spectrometric study on the complexation of Fe(III) with an organic reagent obtained by coupling 3-methyl-1-phenyl-5-pyrazolone with diazotized 3-hydroxy-4-amino-benzene sulphonic acid was carried out in alkaline solutions.

A 1:2 Fe(III):reagent water soluble complex is formed. The optimum pH is 9.0–11.8. The maximum absorbance of the complex lies at $\lambda = 560$ nm, where the absorbance of the reagent is low. The molar absorptivity is 9000 $l.mole^{-1}.cm^{-1}$ at pH = 11.6. The value of the stability constant determined at $20 \pm 1°C$, pH = 11.6 and $\lambda = 560$ nm is $4 \times 10^5 M$. The Beer–Lambert law is followed for iron concentration in the 0.2–5.0 μg/ml range.

The spectrophotometric method was tested on synthetic solutions and thus applied for determination of traces of Fe(III) in several samples of alkaline hydroxides and carbonates without the neutralization of the solutions.

In a study of the effects of Fe(III) in technical processes and for quality establishment of analytical grade reagent, a simple method for the determination of microgram amount of Fe(III) in commercial 50% solutions and solid NaOH p.a., or other alkaline products p.a., was required. Usually, the amounts of Fe(III) encountered vary between 0.5 and 10 ppm. Other metal ions, such as calcium, magnesium, barium, aluminium, nickel, mercury, manganese and copper may be present in metal/iron ratios varying from 1/2 to 5/1.

All the methods commonly utilized requires that the sample must be first neutralized.[1-9]

In this paper a spectrophotometric investigation of the complexation of Fe(III) with an organic reagent obtained[10] by coupling 3-methyl-1-phenyl-5-pyrazolone with diazotized 3-amine-4-hydroxy-benzenesulphonic acid was carried out. The reagent formula (R) is given in Fig. 1.

The date obtained were used in developing a spectrophotometric method of determining Fe(III) directly in alkaline hydroxides and carbonates without the neutralization of solutions.

EXPERIMENTAL

Reagents and equipment

All chemicals used were analytical reagent grade.

Aqueous solutions of known titre of $10^{-3}M$ and $2 \times 10^{-3}M$ of Fe^{3+} ions were obtained from concentrated stock solution Merck for atomic absorption spectrometry.

$10^{-3}M$ and 2×10^{-3} aqueous solutions of reagent R were prepared starting from the reagent synthesized and characterized by elementary analysis, NMR, IR and UV–VIS technics and by chromatographic methods; on this basis the physical properties, the structure and the purity of the reagent were established.[10]

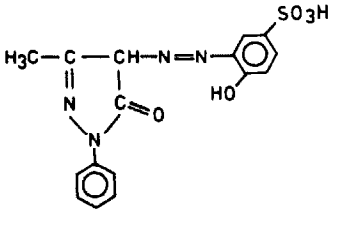

Fig. 1. Formula of reagent R.

1*M* NaOH aqueous solutions were prepared from solid NaOH (Merck), or from alkaline products for analysis and the titre of each solution was determined titrimetrically by 0.1*M* HCl standard solution (Merck); in this way samples with known concentration of NaOH were obtained.

pH buffer NH_3–NH_4Cl and KHphtalate–NaOH solutions.[11]

Absorbance measurements were carried out on a SPECORD UV–VIS Karl Zeiss–Jena spectrometer. The pH of the solutions was measured with a MV-84 (VEB, Pracitrönic Dresden) pH-meter.

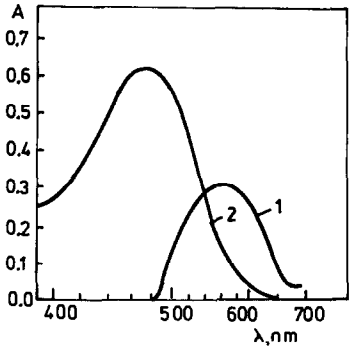

Fig. 2. Absorption spectra of: (1) complex against reagent blank (pH = 11.6); and (2) reagent in buffer solution against buffer solution (pH = 11.6).

PROCEDURE

The solutions to be studied were prepared in 25 ml calibrated flasks where exactly measured volumes of Fe(III) and reagent *R* solutions were introduced; 5 ml of a pH buffer solution, or a calculated volume of 1*M* NaOH solution of known concentration were added to obtain a determined pH. The flasks were filled up to the mark with distilled water. Absorbance of each solution was measured against a corresponding Fe(III) free reagent blank, similarly prepared.

RESULTS AND DISCUSSION

The influence of wavelength, of amount of reagent, of Fe(III) concentration and of pH on the absorbance of Fe(III)-reagent solutions was studied in order to establish the optimal working conditions for the spectrophotometric determination of Fe(III) directly in alkaline hydroxide and carbonate samples without the neutralization of solutions.

The pyrazolonic derivative forms a red complex instantaneously with Fe(III) at room temperature. The absorption spectra of the complex and of the reagent solutions at pH = 11.6 are shown in Fig. 2. The maximum absorbance of the complex is located at $\lambda = 560$ nm, i.e. where the reagent absorbs very little.

The effect of the pH on the absorbance of the solution of the complex at $\lambda = 560$ nm shows that the optimal pH range is 9.0–11.8.

Job's method and the spectrophotometric titration methods were employed for establishing the composition of the complex. The results indicate the formation of a 1:2 complex between Fe(III) and reagent. A 3–4-fold molar excess of the reagent over Fe(III) is required in order to obtain maximum constant absorbance.

The Beer–Lambert law is followed for Fe(III) concentration in the 0.2–5.0 μg/ml range.

The molar absorptivity coefficient is 9000 $l.mole^{-1}.cm^{-1}$ at pH = 11.6. The mean value of the apparent stability constant of the complex calculated from the absorbance data by the mole ratio method at $20 \pm 1°$ and pH = 11.6 was $4 \times 10^5 M$.

The study of the interferences shows that the ions of alkaline, alkaline-earth metals and of Hg(II), Zn(II), Cu(II), Ni(II), Co(II), Al(III), Ti(IV) in a 5-fold molar excess do not interfere in determination of Fe(III).

The method was tested on synthetic solutions containing known amounts of Fe(III) in the presence of 5-times higher amounts of the above-mentioned ions and a volume of 1*M* NaOH standard solution Merck, corresponding at a pH 9.0–11.8 in the total volume of the solution to be analyzed. The results obtained show a good agreement between Fe(III) amount taken in the sample and those determined. Relative standard deviation was $0.5 \pm 0.05\%$.

The method was applied for determining the Fe(III) content in several samples of alkaline hydroxides and carbonates without the neutralization of the solution. The stock sample solution was prepared in a 100 ml calibrated flask and its HO^- concentration was determined titrimetrically with a standard 0.1*M* HCl solution Merck. The solution to be analyzed was prepared and added to a 25 ml calibrated flask containing 5 ml solution $10^{-3}M$ reagent and exactly measured solution of the stock sample solution (calculated to provide a final pH 9.0–11.8). The flasks were filled up to the mark with distilled water. Absorbance of each solution was measured against a corresponding

Table 1. Results of the Fe(III) content determination in alkaline hydroxides and carbonates without the neutralization of solution

Compound analyzed	Fe(III) content %: Spectrophotometric determination with KSCN[7]	with Feron[8]	with *R*	Determination by atomic absorption spectrometry

Fe(III) free reagent blank similarly prepared utilizing a standard 1 *M* NaOH solution Merck. The results in Table 1 show a good agreement between the data obtained by this method and those offered by other methods commonly utilized for the quantitative determination of Fe(III).

CONCLUSIONS

Fe(III) may be determined spectrophotometrically in alkaline hydroxide and carbonate samples without the neutralization of solutions by means of the organic reagent obtained by coupling 3-methyl-1-phenyl-5-pyrazolone with diazotized 3-amine-4-hydroxy-benzenesulphonic acid. This reagent forms with Fe(III) a 1:2 complex with the maximum absorbance at $\lambda = 560$ nm for pH 9.0–11.8.

DEVELOPMENT OF A POLYPYRROLE-BASED AMPEROMETRIC DETECTOR FOR THE DETERMINATION OF CERTAIN ANIONS IN WATER SAMPLES

PEIG WARD and MALCOLM R. SMYTH*
School of Chemical Sciences, Dublin City University, Dublin 9, Ireland

(*Received* 27 *October* 1992. *Revised* 23 *December* 1992. *Accepted* 4 *January* 1993)

Summary—The development of a polypyrrole-based modified electrode for use in the detection of anions in flow-injection analysis and ion chromatography is described. Chloride, nitrate, nitrite, perchlorate, bromide, carbonate, sulphate and phosphate were detected by using flow-injection analysis combined with the polypyrrole-based CME electrochemical detector. All of the anions were detected conveniently and reproducibly over a linear concentration range 1–100 μg/ml. A detection limit of 0.1 μg/ml was obtained for chloride and a limit of 1.0 μg/ml for all of the other anions. Chloride, nitrate, sulphate and phosphate, following separation using ion chromatography, were detected simultaneously by using a conductivity detector and the polypyrrole-based CME electrochemical detector in series. Both methods of detection yielded similar results with comparable sensitivity, linearity and limits of detection. This method was then applied to the analysis of fresh water samples. The electrode was stable over a 2-week period of operation with no evidence of chemical or mechanical deterioration.

Polypyrrole and other conducting polymers have proved very popular in the development of chemically modified electrodes (CMEs) as analytical sensors in recent years. The main advantages of these CMEs lie in improvements in sensitivity and selectivity, as well as the ability to detect electroinactive species.

The ability to deliberately control and manipulate the surface properties can lead to a variety of attractive effects. Such tailoring of the surface can meet the needs of many analytical problems. The incorporation of CMEs into flowing streams or coupled to chromatographic systems has made electrochemical detection a powerful tool for the determination of a wide variety of species.

Many applications of polymer modified electrodes with amperometric detection exist in the recent literature. For example, Ikariyama and Heineman[1] described a flow-injection analysis (FIA) method in which a polypyrrole modified electrode was used as a detector for electroinactive anions based on the repetitive doping–undoping of the polypyrrole layer. They investigated the electrode response for carbonate, phosphate and acetate and found it was linear over the concentration range from 10 μM to 1 mM for each anion. Wallace and co-workers[2–4] have developed polypyrrole and poly(pyrrole-*N*-carbodithionate)-based electrodes incorporating various counterions, for the determination of a variety of cations.

Ye and Baldwin[5] have developed a similar method to that of Ikariyama and Heineman,[1] but used polyaniline as the conducting polymer matrix. They applied the method to a wider range of anions and also looked at the selectivity of the electrode by varying the background electrolyte composition and concentration. Wang and Liu[6] then reported on the use of a polyaniline modified electrode for the detection of anions such as perchlorate, nitrate, sulphate, oxalate and iodate in FIA and ion chromatography (IC). Sung and Huang[7] have also applied a polyaniline–Nafion composite electrode to the determination of alkali and alkaline earth metal ions using FIA and IC. This method involved holding the CME at a potential at which the polymer is reduced, and as the sample plug containing cations arrive at the composite electrode, a transient current signal is obtained which is proportional to the cation concentration.

*Author for correspondence.

This paper reports on the preparation of a polypyrrole CME using a platinum wire (0.5 mm o.d.) as the substrate incorporated into a microelectrochemical flow cell.[8] The aim was to apply this CME as an amperometric electrochemical detector for the detection of a series of electroinactive anions using both FIA and IC. The analysis of river water samples taken from different locations using both IC with conductivity detection and IC using the CME as an amperometric detector was then compared.

EXPERIMENTAL

Reagents

All chemicals used were of Analar grade purity. All standard solutions were prepared using distilled water which was further purified by passing it through a Milli-Q water purification system. Pyrrole was purchased from Riedel-de Haen (Seelze, Germany) and was freshly distilled and stored under nitrogen at 0°C. Platinum wire (0.5 mm o.d.) and silver wire (0.1 mm o.d.) were purchased from Goodfellow Metals (Cambridge, UK). Silver loaded epoxy resin (RS 567-604) was purchased from Radionics (Dublin, Eire). The AG4A guard and AS4A separator ion chromatography columns were purchased from Dionex (Surrey, UK). Polyethylene tubing was purchased from Gallenkamp (Loughborough, UK), and low pressure fittings and peristaltic tubing were purchased from Omnifit (Cambridge, UK).

Instrumentation

The electrochemical system consisted of an EG & G Model 264A potentiostat, a Lloyd PL3 X–Y recorder and a Phillips PM 8251 X-t recorder. The FIA system consisted of a Gilson Minipuls 3 peristaltic pump and a 7125 Rheodyne injection value. The Ion Chromatography system was a Dionex Ion Chromatograph Model 4500 IC system, consisting of a gradient pump (GPM), a conductivity detector (CDM II), an eluant degas module (EDM), a micro membrane suppressor (MMS), a 50 μl fixed loop 6-port pneumatic injection valve and an ACI AI 450 software package (version 2.1). The Dionex columns used were a AG4A guard and a AS4A separator column. The chromatographic conditions used were 1.8 mM Na_2CO_3/1.7 mM $NaHCO_3$ as eluant at a flow rate of 2 ml/min, and the suppressor regenerant used was 12.5 mM H_2SO_4 at a flow rate of 5 ml/min.

Preparation of polypyrrole-based chemically modified electrode

Platinum wire was cleaned by placing a piece of 0.5 mm o.d. platinum wire in chromosulphuric acid for 5 min. It was then removed, and washed thoroughly with deionised water. The wire was then placed in a solution of aqua regia for 5 min, removed, and washed with deionised water. The wire was then polished using alumina powder (0.03 μm) and left to soak in deionised water overnight.

The platinum wire, washed following the above procedure, was then used to construct the working electrode as described in a method previously reported.[9]

Preparation of Ag/AgCl *reference electrode.* Silver chloride was coated onto a silver wire (20 mm length, 0.1 mm o.d.), by connecting the wire to the anode of a 1.5 V battery and connecting a platinum wire to the cathode of the battery. Both wires were then immersed in a solution of 1 mole/dm^3 hydrochloric acid for 2 min. The coated wire was then inserted into a polyethylene tube (30 mm length, 2 mm o.d., 1 mm i.d.). A porous ceramic rod (2 mm length, 1 mm o.d.) was fitted into one end of the tube and was heated sealed into the tube using an electric soldering iron. The tube was filled with an internal reference solution containing 1 mole/dm^3 potassium chloride. Finally, this end of the tube was sealed using an epoxy glue. The electrical connection was made by soldering a copper wire (0.5 mm o.d.) onto the uncoated tip of the Ag/AgCl wire. The auxillary electrode used was a piece of stainless steel tubing (20 mm length, 2 mm o.d., 1 mm i.d.)

The working electrode, reference electrode and auxillary electrode were mounted together in a T-tube (30 mm length, 20 mm height, 2 mm i.d.), the connections being made using silicone tubing (5 mm o.d., 1.5 mm i.d.). The flow cell configuration was as shown in Fig. 1. The cell arrangement is such that the electrolyte first passes the working electrode, then the reference, and finally passes the auxillary electrode to waste.

Modification of the working electrode. The flow cell was connected to a peristaltic pump via a low pressure fitting (Omnifit). The platinum wire and auxillary electrodes were taken through a further cleaning step by pumping a 0.1 mole/dm^3 sulphuric acid solution through the cell at a flow rate of 0.8 ml/min for 1 hr while cycling the potential between -1000 and

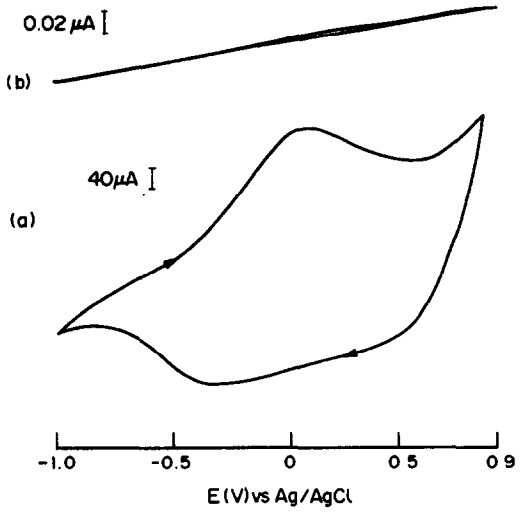

Fig. 2. Cyclic voltammograms of polypyrrole-based CME in (a) 1 mole/dm^3 NaCl and (b) 0.1 mole/dm^3 glycine, scan rate of 50 mV/sec.

+1400 mV at a scan rate of 50 mV/sec. The potential was then held at +400 mV until a steady decay current was obtained. The system was then flushed with deionised water for 10 min.

The electrode was modified by injecting a deoxygenated solution of 0.5 mole/dm^3 pyrrole in 1.0 mole/dm^3 sodium chloride as the electrolyte, into the flow cell using a 2 ml syringe. Electropolymerisation was carried out by slow potential cycling from −1000 mV to +900 mV at a scan rate of 20 mV/sec, for three complete cycles. The polymer film was deposited onto the platinum wire as a purple coloured film.

During the electropolymerisation step, faster scan rates of 100 and 50 mV/sec were investigated, but films produced using these conditions were thin and patchy and not as stable or reproducible as those prepared using the slower scan rate of 20 mV/sec.

RESULTS AND DISCUSSION

Characterisation of polypyrrole-based CMEs

The freshly prepared polypyrrole-based CME was placed in the flow system and using deoxygenated 0.1 mole/dm^3 NaCl as the electrolyte, its cyclic voltammetric behaviour was investigated. The potential was cycled from −1000 to +900 mV at a scan rate of 50 mV/sec. The cyclic voltammogram produced for the electrode shows the classic redox transitions from the neutral to conducting state at potentials similar to those observed by other workers.[4,6]

The cyclic voltammogram (Fig. 2a) shows the anodic current peak at approximately +50 mV (*vs.* Ag/AgCl) which corresponds to the switching of the polymer from its neutral to charged state as well as the counterion incorporation (doping) into the polymer. The reduction response corresponding to the switching of the polymer from its conducting state to its non-conducting state, as well as the non-faradaic current associated with the counterion-exchange (undoping), can be seen at approximately −400 mV (*vs.* Ag/AgCl). On continuous cycling, no noted changes were observed.

A cyclic voltammogram (Fig. 2b) was also recorded in 0.1 *M* glycine as electrolyte. This time no redox waves were observed for the polypyrrole-based CME over a potential range −1000 to +900 mV. The background current observed in this medium was only a fraction of what it was in the sodium chloride electrolyte. This results because of the low conductivity of the glycine zwitterion.

Flow-injection analysis

As described in the previous section, the polypyrrole-based CME did not show any response when cycled in glycine. This was therefore a suitable electrolyte to be used as a mobile phase for flow-injection analysis. A solution of 0.1 mole/dm^3 glycine was deoxygenated using nitrogen and used as mobile phase. The flow rate of mobile phase was set at 0.4 ml/min.

The response of the polypyrrole-based CME was then evaluated using the Cl^- anion. The applied potential was varied to obtain a maximum response. Then, using this potential, the reproducibility of the electrode was investigated. Parameters such as selectivity, linearity, sensitivity and limit of detection (LOD) were then determined. All standard solutions were prepared in 0.1 mole/dm^3 glycine solution and were deoxygenated using nitrogen before

injection. Potentials quoted throughout this section are quoted versus the Ag/AgCl reference electrode.

Effect of applied potential. The applied potential was varied from +200 to +900 mV in 50 mV increments and injections of 20 μl of a 40 μg/ml Cl^- standard solution were made at each potential. The hydrodynamic voltammogram produced showed the response for the Cl^- anion commenced at a low positive potential of +200 mV and increased with increasing applied potential reaching a maximum response at +800 mV.

Reproducibility. To investigate the reproducibility of the response, the applied potential was constantly maintained at +900 mV and a series of 10 injections of 20 μl of a 100 μg/ml Cl^- standard were made, and the anodic peak current recorded each time. The response of the CME was reduced slightly following each injection. This was probably due to the doping of the polymer with the Cl^- anion each time the anion plug passed the electrode surface. An average current response ($n = 10$) of 1.39 μA with a RSD of 1.33% was obtained.

The solution to this doping effect would be to undope the polymer by stepping the applied potential down to a more negative potential, where the polymer is reduced and the dopant anion is released from the polymer, as previously employed by Ikariyama and Heineman.[1] Another solution would be to employ the method reported by Ye and Baldwin,[5] which involved setting the applied potential to a less positive potential where the anion did not fully dope the polymer, but was capable of entering and leaving the polymer as the sample anion plug passed over the electrode surface. The latter method was then investigated where a series of applied potentials were selected and constantly maintained at the working electrode, and the above series of injections repeated at each selected potential. A potential of +500 mV was chosen as the optimum potential as at this potential the response did not vary, an average current response ($n = 10$) of 504 *nA* with an RSD of 0.75% was obtained, and this potential was therefore selected for future studies.

Selectivity. The electrode response to different anions was determined by injecting 20 μl of 100 μg/ml of each of the following anions: chloride, nitrate, nitrite, perchlorate, bromide, carbonate, sulphate and phosphate. The applied potential was constantly maintained at +500 mV and 0.1 mole/dm^3 glycine was used as mobile phase at a flow rate of 0.4 ml/min. The CME showed a response to all of the anions injected, as shown in Fig. 3. The CME exhibits best selectivity for the chloride anion, as this was the counterion used during the electropolymerisation step. Selectivity also seems to depend on anion size, since the response for the smaller anions is much better than that for the bulkier anions. All of the anions investigated produced well defined sharp anodic current peaks, and if a separation step was incorporated into the flow system, the polypyrrole-based CME could be used as an amperometric detector to detect a mixture of the above anions.

Linearity and limit of detection. The linear response of the electrode for all of the anions used in the previous section was investigated over the concentration range $1 \rightarrow 100$ μg/ml. This was done by injecting 20 μl of each standard in the above concentration range for each individual anion and obtaining the response. The mobile phase used was 0.1 mole/dm^3 glycine

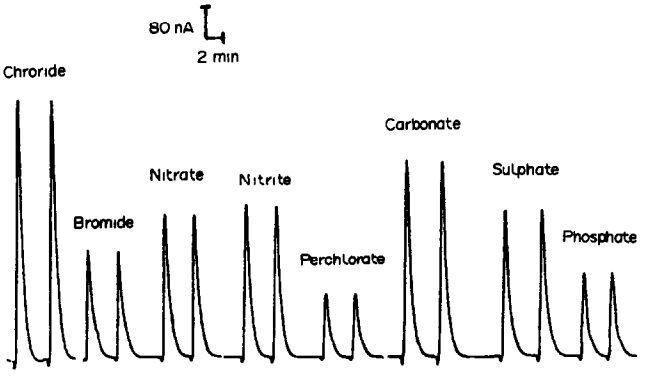

Fig. 3. Selectivity of polypyrrole-based CME for various anions using a 20 μl injection of 100 μg/ml Cl^-, Br^-, NO_3^-, NO_2^-, ClO_4^-, CO_3^{2-}, SO_4^{2-} and PO_4^{3-} standard mixture, a 0.1 mole/dm^3 glycine mobile phase and an $E_{app} = +0.5$ V (*vs.* Ag/AgCl).

at a flow rate of 0.4 ml/min, and a applied potential of +500 mV.

The response produced was linear in this concentration range for all of the anions investigated. The sensitivities for each anion varied, as the CME was found to be more selective for some of the anions. Calibration curves were then constructed by plotting anodic current response (*nA*) versus concentration (μg/ml), and from the graphs obtained the linear correlation coefficients were all better than 0.998 in the concentration range 1–100 μg/ml.

A limit of detection (LOD) of 1 μg/ml was obtained using a S/N ratio of 3/1 or greater for all of the anions investigated, except for the chloride ion. The LOD for the chloride ion was 0.1 μg/ml using a S/N ratio of 3/1.

Effect of flow rate on electrode response. The effect of flow rate on the electrode response was investigated by increasing the mobile phase flow rate in the range 0.2 ml → 2.0 ml/min, while injecting 20 μl of 100 μg/ml Cl^- standard. The response was higher at the lower flow rates, and decreased slightly with increased flow. The peak shape was closer to ideal at faster flow rates, with no major loss in peak height. As the flow rates associated with ion chromatography are in the order of 2–3 ml/min, this result was very promising for the incorporation of the CME as an amperometric detector in an IC system.

Stability. The polypyrrole-based CME was extremely durable. The same CME surface could be used for cyclic voltammetry and flow injection studies for a period of 2 weeks, with no evidence of chemical or mechanical deterioration.

Ion chromatography

In the following section, the polypyrrole-based CME was investigated as an amperometric detector to detect a series of anions, separated using ion chromatography. The results obtained using the CME detector were compared to the results obtained using a conductivity detector. The electrochemical flow cell containing the polypyrrole-based CME was linked in series with the outlet from the conductivity cell on the ion chromatograph system. Using the conditions mentioned under experimental and with an applied potential of +500 mV (*vs.* Ag/AgCl) constantly maintained, the background current obtained for the suppressed eluant carbonic acid, was similar to that previously obtained using glycine as mobile phase in FIA. A stable baseline at similar sensitivities as those used in FIA was also achieved. The CV behavior of the polypyrrole-based CME in this weakly conducting electrolyte was similar to that obtained using glycine as an electrolyte. The response to an injection of 50 μl of a 100 μg/ml standard solution mixture of chloride, nitrate, sulphate and phosphate for both conductivity and amperometric detection is shown in Figs 4 (a) and (b).

Reproducibility. The reproducibility of the both detection methods was tested by repetitive injections ($n = 10$) of a 10 μg/ml standard mixture of chloride, nitrate, sulphate and phosphate. The applied potential of the CME was held constantly at +500 mV throughout.

For the CME, the reproducibility of peak currents for each anion was satisfactory and the RSD varied between 0.53 and 2.14%. Again the CME in this system shows better selectivity for

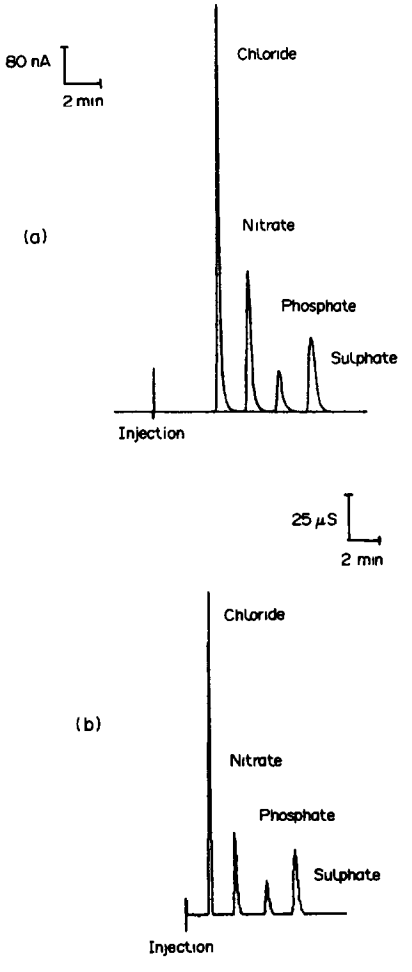

Fig. 4. Signals obtained using (a) a polypyrrole-based CME amperometric detector, $E_{app} = +0.5$ V (*vs.* Ag/AgCl), (b) conductivity detector, for a 50 μl injection of 50 μg ml^{-1} Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} standard mixture with a carbonic acid mobile phase.

the smaller anions, and especially for the chloride ion. The reproducibility using conductivity detection is also very good for all the anions with an RSD varying between 0.7 and 1.38%, except for the Cl^- ion. In this case an RSD of 8.76% was obtained, because the chloride had eluted close to an impurity peak, which could not be eliminated, even using the highest quality salts of both NaCl and KCl. The presence of this impurity obviously affects quantitation of the peak using peak height. Its presence also had a slight effect on reproducibility using the CME as the RSD calculated was higher than that obtained previously in FIA. An RSD of 1.57% was obtained when peak area was used as the quantitation method for the conductivity response. Overall both methods of detection gave comparable results.

Linearity and limit of detection. The linear relationship between the concentration of the solution of anions injected and the corresponding peak currents/conductivity was then examined. The concentration range used was from 1 to 100 μg/ml for each anion. A 50 μl injection of each standard containing chloride, nitrate, phosphate and sulphate at the same concentration level was made, the conditions used being the same as those reported previously.

The linear correlation coefficients obtained using CME as a detector were greater than 0.998 for chloride, nitrate and phosphate and 0.993 for sulphate. Using conductivity detection, correlation coefficients of greater than 0.999 were obtained for nitrate, phosphate and sulphate. A correlation coefficient of 0.952 was obtained for chloride using peak height, whereas a correlation coefficient of 0.999 was obtained when calibration was done using peak area.

The limit of detection for all of the anions investigated using this method was very similar to those limits obtained in the FIA experiment. Again, the LOD for the chloride was 0.1 μg/ml, using a S/N ratio of 3/1. The linearity in this lower range was determined by constructing a calibration curve in the range 0.1–10 μg/ml Cl^-. A 50 μl injection of each standard was injected and the peak current and conductivity obtained. The correlation coefficients obtained using both methods of detection were better than 0.999 in this concentration range.

Application to water analysis

In this section, the polypyrrole-based CME was used as an amperometric detector to detect anions present in fresh water samples, following separation using ion chromatography. The samples were collected from different locations around the country, which had various agricultural and industrial activities nearby. For this reason, quite varied results would be expected. The results obtained using the CME as a detector were compared to those obtained using conductivity detection.

A calibration curve in the range 0.1–50 μg/ml of each of the following anions namely, chloride, nitrate, phosphate and sulphate was constructed. Using the CME as the detector, the linear correlation coefficients were all better than 0.999 except for the chloride anion which had a correlation coefficient of 0.997. Using conductivity detection, linear correlation coefficients obtained using peak area as the calibration method were all better than 0.998.

Each water sample was injected in duplicate and the resulting peak current/conductivity was averaged and the final results reported as the concentration of each anion present in mg/dm^3. Phosphate was not present in any of the water samples analysed. The final results obtained are reported in Table 1.

As can be seen from the final results reported in Table 1, the results obtained using both methods of detection were comparable, and the levels of sensitivity of both methods are similar. Thus in conclusion, the results show that the polypyrrole-based CME is a very promising electrochemical method of detection in ion chromatography.

CONCLUSIONS

A polypyrrole-based CME was incorporated into a flow cell and used as an amperometric

Table 1. Results obtained for various water samples

	Anion concentration determined (mg/dm^3)

Conductivity	22.6	5.5	19.2

detector to detect a series of electroinactive anions following their separation using FIA and ion chromatography. The polypyrrole-based CME has been shown to respond to as low as 0.1 μg/ml anion concentration with good reproducibility. The approach is based on the reversible doping–undoping of electroinactive anions within the polymer matrix. At the doping potential, the electroinactive anion causes electron flow from the polymer to the platinum base electrode. This electron flow depends on anion concentration.

At higher anion concentrations it is necessary to undope the electrode. This can be carried out by briefly exposing the CME to a reducing potential (of the order of -300 mV) between successive anion exposures. Holding the electrode potential at a potential lower than its doping potential (of the order of $+500$ mV) has the effect of allowing the anion to enter and leave the polymer matrix, thus improving reproducibility, without having to undope the electrode between each successive anion exposure.

The selectivity of the polypyrrole-based CME was also shown to depend on the size of the dopant anion, with a much greater selectivity for the smaller less bulkier anions. The CME shows best selectivity for the chloride anion, as this was the counterion employed during the electropolymerisation process and this probably has the effect of allowing the chloride ion to dope the polymer matrix more efficiently because of pore size similarity.

The polypyrrole-based CME has similar sensitivity and limits of detection to conductivity detection, was very stable and gave a fast response. The stability of the CME over a 2 week period of operation was observed and the response did not vary during this time period. The CME had a linear range over three orders of magnitude for all of the ions investigated. This range is extended to four orders or magnitude for the chloride ion.

The polypyrrole-based CME flow cell is simple to construct and easy to change without great expense. If the CME stops functioning owing to degradation of the polymer film due to overoxidation or any other reasons, the polymer-coated platinum wire can be removed from the polyethylene tube and the polymer film stripped off by sonication in aqua regia solution.

The low cost, ease of construction of the flow cell and its small size, make this system very suitable as an amperometric detector for use in an ion chromatographic system. In comparison to conductivity detection, both methods produced similar results, proving that the polypyrrole CME could be used as an alternative method of detection.

In the use of conducting polymers electrodes as analytical sensors, careful attention must be paid to the substrate preparation and coating procedures if reproducibility is to be assured.

In studies of the practical application of both conductivity and amperometric detection using the polypyrrole-based CME, the results obtained for the analysis of water samples following separation by ion chromatography were found to be comparable. This proves that the polypyrrole-based CME had a practical application and could be successfully applied to the analysis of real samples.

(*Received* 1 *July* 1992. *Revised* 21 *October* 1992. *Accepted* 21 *October* 1992)

Summary—Fluorescein, Texas Red, Cascade Blue, 7-amino-4-methylcoumarin-3-acetic acid, and Lucifer Yellow were evaluated as fluorescent labels for homogeneous fluorophore-linked binding assays. Conjugates of avidin with these fluorophores exhibited an enhancement in fluorescence emission in the presence of biotin or biotin derivatives. This property was used in the development of assays for biotin. The biotin-induced fluorescence enhancement of each labeled avidin were compared. Fluorescein led to the most sensitive calibration (dose–response) curve for biotin with a detection limit of $8 \times 10^{-10} M$.

Homogeneous fluorophore-linked assays have gained increasing interest in chemical analysis.[1] Usually in these assays, a fluorescent label is chemically bound to a ligand (analyte) or a ligand-specific binding protein. By monitoring the fluorescence signal, the extent of the binding between the ligand and the binding protein may be determined.[2,3] During the past several years, many different types of homogeneous fluorophore-linked assays have been reported.[4] In one of these approaches, a fluorescent label is attached to a ligand-specific binding protein, and a property of the fluorescence signal (*e.g.*, emission intensity) is altered when a free ligand binds to the labeled protein. This modification of the signal is proportional to the concentration of free ligand present in the sample.[5]

Recently, we proposed the use of homogeneous competitive binding assays for improving the on-line detection of biomolecules separated by HPLC.[6,7] This was accomplished by using a postcolumn reaction detection system that is based on the natural affinity between analytes and the corresponding biological binders (*e.g.*, antibodies, binding proteins, receptors, *etc.*). Because of our interest in designing chromatographic postcolumn reaction detection systems based on homogeneous non-competitive fluorophore-linked assays, a study was undertaken to identify factors that control the detection capabilities of such assays. It should be noted that heterogeneous fluorophore-linked assays typically have better detection limits than homogeneous techniques, however, their use in the development of postcolumn reaction detection systems is not an easy task.

An assay for biotin has been reported that is based on the biotin-induced fluorescence enhancement of fluorescein-labeled avidin.[5] However, there is limited understanding of the variables that control the performance of this assay, including the effect of the nature of the fluorescent label, and of possible interferences by biotin derivatives. Because the proper selection of the fluorophore affects the detection limit and sensitivity of the assay, the applicability of different fluorescent probes in the development of homogeneous fluorophore-linked assays for biotin was evaluated. The fluorescent labels employed in this study were fluorescein, Texas Red, 7-amino-4-methylcoumarin-3-acetic acid (AMCA), Cascade Blue, and Lucifer Yellow. Conjugates of avidin with

these compounds were used that had a comparable number of fluorescent labels attached to each protein molecule (f/p molar ratio), and the corresponding biotin-induced fluorescence enhancements were compared. Each conjugated avidin was also used in the development of assays for biotin.

EXPERIMENTAL

Reagents

Biotin, biocytin, biotin methyl ester, 2-iminobiotin, fluorescein isothiocyanate (FITC) isomer I (on celite), gelatin, and an avidin-FITC conjugate ($f/p = 3.9$) were purchased from Sigma (St. Louis, MO, U.S.A.). Biotin hydrazide was purchased from Pierce (Rockford, IL, U.S.A.). The conjugates avidin-AMCA ($f/p = 6$), avidin-Cascade Blue ($f/p = 6.5$) and avidin-Lucifer Yellow ($f/p = 4$) were obtained from Molecular Probes (Eugene, OR, U.S.A.). Avidin-Texas Red ($f/p = 3$) was from Vector (Burlingame, CA, U.S.A.). Avidin (egg white, lyophilized) was purchased from Calbiochem (San Diego, CA, U.S.A.). Sephadex G-25 (bead size medium) was obtained from Pharmacia LKB Biotechnology (Piscataway, NJ, U.S.A.). All solutions were prepared by using deionized, distilled water obtained with a Milli-Q Water Purification System (Millipore, Bedford, MA, U.S.A.). The various buffers used in this study were: 0.0500*M* sodium phosphate, pH 8.00 and 0.100*M* sodium bicarbonate, pH 9.10. The sodium phosphate buffer, pH 8.00 was used to prepare a 0.10% (w/v) gelatin solution. Stock solutions (0.10 g/l.) of biotin and biotin derivatives, as well as further dilutions of the stock solutions were prepared with the 0.10% (w/v) gelatin solution. In addition, all the avidin-fluorophore solutions including the stock solutions (0.10 g/l.) were prepared with the 0.10% (w/v) gelatin solution to prevent non-specific binding.

The free fluorophores used to test the validity of the model depicted in Fig. 1 were fluorescein (Matheson Coleman & Bell, Norwood, OH, U.S.A.), 7-amino-4-methylcoumarin (Aldrich Milwaukee, WI, U.S.A.), 1-pyrenebutyric acid (Aldrich), sulforhodamine 101 hydrate (Texas Red) (Aldrich), and *N*-(2-aminoethyl)-4-amino-3,6-disulfo-1,8-naphthal-imide, dipotassium salt (a Lucifer Yellow derivative) (Molecular Probes).

Apparatus

Fluorescence measurements were performed with a Perkin-Elmer (Norwalk, CT, U.S.A.) Model LS 50 luminescence spectrometer that was interfaced with an Epson (equity III+) personal computer (Epson America, Torrance, CA, U.S.A.). Both excitation and emission slits were set at 5 nm. A Perkin-Elmer (Lambda 6) UV/Vis spectrophotometer was employed for all absorbance measurements.

Preparation of avidin–FITC conjugates

Aliquots (500 μl) of a solution of avidin (0.50 g/l.) in sodium bicarbonate buffer were stirred for 4 hr with chosen amounts of a suspension of FITC on celite in buffer.[8] The celite was removed by centrifugation and the avidin-fluorophore conjugate was isolated using

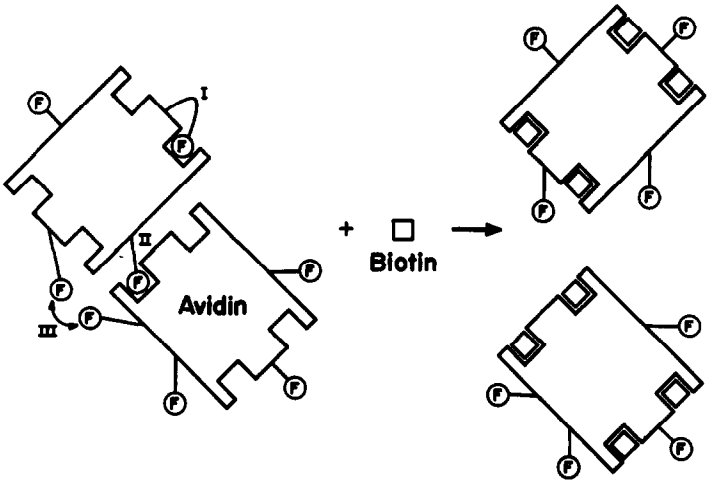

Fig. 1. Model for possible interactions between fluorescent labels and avidin in the presence and absence of biotin.

chromatography on Sephadex G-25 (0.050*M* ammonium bicarbonate as eluent).[9] The conjugate was freeze-dried and stored at −20° in amber vials.

The number of FITC molecules attached to avidin (*f*/*p* ratio) was estimated by measuring the absorbance at 494 nm and by using a molar absorptivity of $7.2 \times 10^4 M^{-1}$ cm^{-1}.[10] The avidin concentration was obtained from the absorbance at 280 nm after correction for the contribution by FITC to the absorbance signal at this wavelength. Molar absorptivities at 280 nm of $2.0 \times 10^4 M^{-1}$ cm^{-1} and $1.5 \times 10^5 M^{-1}$ cm^{-1} were used for FITC and avidin, respectively. This method of estimation of the degree of conjugation was tested on the avidin–FITC conjugate purchased from Sigma. The value obtained was within 5% of the value claimed by the manufacturer. The degree of conjugation for the other avidin–fluorophore conjugates used in this study was provided by the respective manufacturers.

Fluorescence lifetime measurements

All fluorescence lifetime measurements were performed on a frequency-domain cross-correlation fluorometer (ISS, Champaign, IL, U.S.A.). A 300-W Xenon lamp was used as the light source. The excitation monochromator was set at 495 nm. A non-fluorescent glycogen solution was used as a reference sample. A 500-nm lower wavelength cut-off filter (model KV-500, Corning Glass-Works, Corning, NY, U.S.A.) was used to remove the scattering light from the fluorescent signal of the samples and no filter was used for the reference sample. Both the phase delay and modulation ratio were measured at different modulation frequencies ranging from 1 to 200 MHz.

Dose–response curves for biotin

Varying amounts of biotin (or biotin derivative) were dispensed into test tubes to a total volume of 500 μl. A volume of 1.60 ml of the avidin–fluorophore solution was added to each tube. After 15 min incubation, the fluorescence signal was measured. Fifteen minutes was sufficient to reach equilibrium with all concentrations of conjugate and biotin used in this study. Dose–response curves were constructed by plotting the percent enhancement of the fluorescence signal observed versus the concentration of biotin (or biotin derivative) in the assay test tube.

RESULTS AND DISCUSSION

In homogeneous fluorophore-linked assays, the spectral characteristics of the fluorescent label are monitored as a function of the reaction between the ligand and the ligand-specific binding protein. The proper selection of the fluorescent label is critical to the detection limits and sensitivity of these assays. The ideal fluorophore should have high fluorescence intensity, should not interfere with the reaction between the ligand and the binding protein, and the fluorescence signal should be distinguishable from the background.[2,3,11]

In this study, several fluorescent compounds (fluorescein, Texas Red, Cascade Blue, 7-amino-4-methylcoumarin-3-acetic acid and Lucifer Yellow) were evaluated as potential labels for the development of homogeneous fluorophore-linked assays that are based on the use of binding proteins tagged with fluorescent molecules. The avidin–biotin couple was used as a model system in these studies. The only available information on this system is the observation by Al-Hakiem *et al.* that the fluorescence of fluorescein-labeled avidin is enhanced by approximately two-fold upon binding to biotin, a fact that was exploited to develop a fluorometric assay for biotin.[5] In the present study, it was found that conjugates of avidin with fluorophores other than fluorescein also showed fluorescence enhancement upon binding to biotin. The biotin-induced fluorescence enhancement of each labeled avidin is shown in Fig. 2.

Two groups of avidin-fluorophore conjugates were used that had comparable fluorophore/protein molar ratios within each group (Table 1). Because of the noncommercial availability of an avidin–FITC conjugate with an *f*/*p* molar ratio close to 6, several avidin–FITC conjugates were prepared using different initial molar ratios of FITC and avidin. Table 2 summarizes the avidin–FITC conjugates prepared and the *f*/*p* molar ratios obtained. It should be noted that similarity in the *f*/*p* ratio does not necessarily ensure the same degree of self-quenching for each avidin–fluorophore conjugate. Indeed, there is some evidence in the literature that AMCA (an umbelliferone derivative) and Cascade Blue are not as susceptible to concentration-dependent quenching as fluorescein.[12,13] Compared to the other fluorophores, the emission intensity of fluorescein-labeled avidin was enhanced by biotin to the greatest extent (Fig. 2). It should be noted that there is

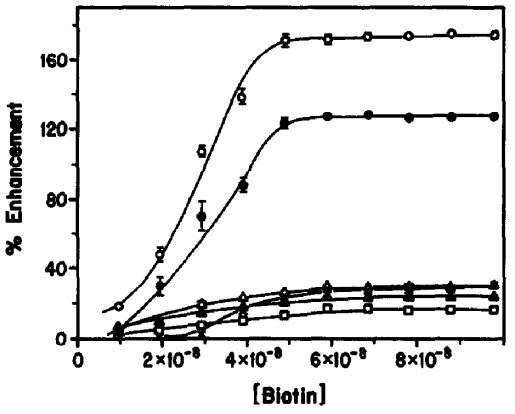

Fig. 2. Dose–response curves that relate the concentration of biotin to the percent enhancement of the fluorescence signal of (○) avidin–FITC-2 ($f/p = 5.9$), (●) avidin–FITC ($f/p = 3.9$), (△) avidin–Cascade Blue ($f/p = 6.5$), (x) avidin–Texas Red ($f/p = 3.0$), (▲) avidin–Lucifer Yellow ($f/p = 4.0$), and (□) avidin–AMCA ($f/p = 6.0$). The concentration of each avidin–fluorophore conjugate in the assay cup was 0.8 mg/l. Error bars indicate ± one standard deviation ($n = 3$). Some error bars are obstructed by the symbol for the point.

no change in the binding capacity of avidin due to fluorescent labeling. Specifically, as it is shown in Fig. 2, the labeled avidin is still capable of binding four biotins per protein molecule (at the break point for all curves the molar ratio biotin/labeled-avidin is *ca.* 4:1).

In order to better understand the variables that control the enhancement of the fluorescence signal, several factors (*i.e.*, local polarity, pH, and the vicinity of quenching groups) that may effect the microenvironment of the fluorophores were considered.[2,12,14,15] Since there is some conformational change in the structure of avidin upon binding to biotin,[16] it is possible that the magnitude of these factors may change in the presence of biotin, thus affecting the intensity of the fluorescence signal. It should be noted that the contribution of each factor to the enhancement of the fluorescence intensity may vary among the various fluorophores employed in this study.

Table 1. Characterization of avidin labeled with different fluorescent moieties

Fluorescent label	f/p	λ_{ex}, nm*	λ_{em}, nm*
AMCA	6.0	390	450
Cascade Blue	6.5	378	418
Fluorescein†	5.9	495	518
Fluorescein	3.9	495	518
Lucifer Yellow	4.0	430	504
Texas Red	3.0	596	614

*λ_{ex} and λ_{em} for the fluorophore while attached to avidin.

Table 2. Characterization of the avidin–FITC conjugates

Conjugate	Initial FITC:avidin molar ratio	f/p
Avidin–FITC-1	300:1	3.2
Avidin–FITC-2	600:1	5.9
Avidin–FITC-3	900:1	7.3
Avidin–FITC-4	1800:1	10.9

Spectral changes were used to probe the microenvironment of the fluorophore-avidin conjugates in the absence and presence of biotin. Some of the fluorophores employed in this study can be used as environment-sensitive probes. In particular, it has been reported that the emission maxima of fluorescein[10] and Lucifer Yellow [17] are sensitive to solvent changes, whereas the emission of AMCA exhibits very weak solvent dependence.[18] The emission spectra of the various avidin–fluorophore conjugates in the presence and absence of biotin show that none of the labeled avidins exhibited a shift in its emission maximum that was greater than 1 nm in the presence of biotin. Therefore it may be concluded that there is no significant change in the solvent environment at the sites of immobilized fluorophores on avidin upon binding with biotin.

The high degree of fluorescence enhancement observed when FITC was used as the label can be explained by considering microenvironmental pH changes. The fluorescence spectrum of fluorescein is dependent on pH (the fluorescence intensity is enhanced in more alkaline environments),[19] while for the rest of the fluorophores employed in this study the fluorescence intensity is either pH-independent (Cascade Blue[20] and Lucifer Yellow[21]) or less sensitive to pH changes compared to fluorescein (Texas Red[20] and AMCA[22]). Indeed, of the fluorophores used only avidin–FITC gave a large enhancement in fluorescence in the presence of biotin. These considerations are consistent with a recent report, in which changes in the fluorescence intensity of fluorescein-labeled protein A upon binding to an IgG antibody were attributed to pH changes.[23] Finally, it was found that an excess of biotin does not affect the fluorescence intensity of free fluorescein in solution.

The vicinity of side-chain groups of certain amino acids may also affect the intensity of the

fluorescence signal of the fluorophores attached to avidin. The effectiveness of such a quenching process may vary upon biotin binding, considering that the binding may alter the distance between the interacting groups. This form of dynamic quenching can be verified through fluorescence lifetime measurements. Fluorescence intensity decay measurements of mixtures composed of different ratios of avidin–FITC and biotin were performed at modulation frequencies ranging from 1 to 200 MHz. From the frequency-domain data, it is apparent that the avidin–FITC conjugate ($f/p = 3.9$) has multiple fluorescence lifetimes. By simply fitting the results using a single exponential decay function an effective lifetime of 1.7 nsec was obtained, which is significantly shorter than the lifetime of free fluorescein (3.4 nsec). In contrast, at high biotin concentrations, a single lifetime of 3.3 nsec was measured. At intermediate biotin concentrations effective lifetimes between 1.7 and 3.3 nsec were observed. The lifetime experiments were repeated three times and the standard deviation for each data point was less than 0.1 nsec. These lifetime data suggest that the enhanced fluorescence in the presence of biotin may be due to a different extent of dynamic quenching of the fluorescence signal. However, they do not preclude the existence of additional static quenching that is related to microenvironmental pH changes in the vicinity of the fluorophore.

An alternate explanation for the enhanced fluorescence intensity may be based on the affinity of avidin for certain chromophoric and fluorescent dyes.[24-26] If the fluorophores used in this study behave in a similar manner, then as shown in Fig. 1, avidin may bind fluorophores that are attached to the same (I) or neighboring (II) avidin molecules in the assay mixture. Moreover, type II interactions may also create additional concentration-dependent quenching of the fluorescence intensity (III). The effectiveness of events labeled I–III, in Fig. 1, may vary upon biotin binding, considering that biotin may displace the fluorescent labels from the avidin binding sites. Control experiments were performed to test this hypothesis with unlabeled avidin and free fluorescein. These experiments indicated that the fluorescence intensity of a solution containing avidin and free fluorescein is enhanced on addition of biotin, indicating a possible biotin-induced displacement of the fluorophore from avidin. However, this only happened at high avidin concentrations, which indicates a low binding constant between avidin and fluorescein. Indeed, when this experiment was repeated using a concentration of avidin at the same level as that used for the labeled avidin experiments, no enhancement was observed. Consequently, the mechanism shown in Fig. 1 does not contribute significantly to the observed enhancement in fluorescence emission.

Biocytin, biotin methyl ester, and biotin hydrazide were tested as possible chemical interferents in the assay for biotin. The avidin-fluorophore used was the avidin–FITC-2 conjugate ($f/p = 5.9$). It was revealed (Fig. 3), that the dose–response curves obtained for the several biotin derivatives had worse detection limits in comparison to the dose–response curve obtained for biotin. It should be noted that when 2-iminobiotin was tested as an interferent, the dose–response curve was shifted toward higher concentrations of analyte (in comparison to the other biotin derivatives), and it was out of the concentration range shown in Fig. 3. These observations can be explained by considering the magnitude of the association constants between avidin and the various biotin derivatives. Specifically, the association constant of the avidin–biotin complex has been reported to be in the order of $1 \times 10^{15} M^{-1}$.[27] To the best of our knowledge, the association constants for the rest of the biotin derivatives mentioned above are not known. However, there is some evidence in the literature that the association constant of biocytin with avidin is lower than that of biotin.[7,28] Therefore, it appears that the detection limits of the assays are controlled by the association constants between the labeled avidin and the biotin derivatives, as is expected from

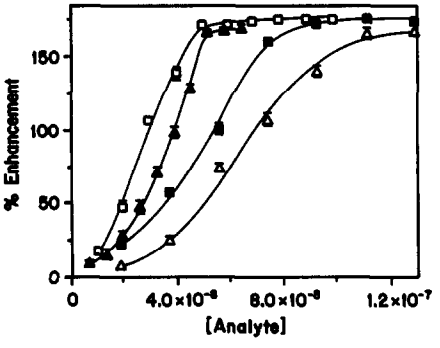

Fig. 3.Dose–response curves that relate the percent enhancement of the fluorescence signal of the avidin–FITC-2 conjugate ($f/p = 5.9$) (0.8 mg/l.) to the concentration of (□) biotin, (▲) biocytin, (□) biotin methyl ester, and (△) biotin hydrazide. Error bars indicate ± one standard deviation ($n = 3$). Some error bars are obstructed by the symbol for the point.

Table 3. Effect of the fluorescent label on the detection limit of the biotin assay

Fluorescent label	f/p	Intensity* arbitrary units	Conjugate concentration,† g/l.	Detection limit, M‡
AMCA	6.0	6.4 ± 0.2	8.0×10^{-4}	2×10^{-8}
Cascade Blue	6.5	216.0 ± 0.4	8.0×10^{-5}	2×10^{-9}
Fluorescein	5.9	59.4 ± 0.5	2.7×10^{-5}	8×10^{-10}
Fluorescein	3.9	35.8 ± 0.5	8.0×10^{-5}	2×10^{-9}
Lucifer Yellow	4.0	12.3 ± 0.5	8.0×10^{-4}	2×10^{-8}
Texas Red	3.0	13.3 ± 0.3	8.0×10^{-4}	3×10^{-8}

*Intensity of the fluorescence signal (in arbitrary units) ±standard deviation ($n = 3$) that corresponds to an avidin–fluorophore concentration of 8.0×10^{-4} g/l. (no biotin present).
†The lowest concentration of avidin–fluorophore (in the assay cup) which gave dose–response curves with a pooled standard deviation for the fluorescence intensity of less than 10%.
‡Detection limit (based on two times the standard deviation of the blank) for the biotin assay using the concentration of avidin–fluorophore in the previous column.

protein binding theory; the higher the association constant between a biotin derivative and avidin, the better the assay detection limits. Furthermore, by keeping the biotin/avidin–FITC-2 concentration ratio constant at a value of 8.4 and varying the amount of avidin–FITC-2 in the assay cup from 8.0×10^{-4} to 2.7×10^{-5} g/l., it was observed that at lower concentrations of avidin–FITC-2 the percent enhancement was lower. The difference in enhancement indicates that at lower avidin–FITC-2 concentrations, a lower percentage of avidin–FITC-2 was complexed with biotin. These data also suggest that binding constants determine the extent of complex formation in the assay, which provides additional evidence in support of the data shown in Fig. 3.

Further, a study was performed to identify the avidin–fluorophore conjugate that gives the best detection limits for assays for biotin. The data given in Table 3 refer to the most diluted solution of the labeled avidin that gave dose–response curves that had a pooled standard deviation for the fluorescence intensity of less than 10%. Note that, although Cascade Blue gives the higher fluorescence intensity, fluorescein allows for the development of assays with better detection limits because it provides a higher percent enhancement. In addition, it was found that the avidin–fluorescein conjugate with the higher f/p ratio (equal to 5.9) gave higher sensitivity for the biotin assay because it provided both high fluorescence intensity and percent enhancement. No further improvement in the detection limits was observed with avidin–FITC conjugates that had higher f/p ratios since, compared to avidin–FITC-2, the conjugates with f/p ratios of 7.3 and 10.9 demonstrated a lower percent enhancement in fluorescence intensity in the presence of biotin.

Development of homogeneous non-competitive fluorophore-linked assays for other analytes is possible as long as the corresponding fluorophore-labeled biological binders undergo spectral changes as a function of the concentration of the analytes. For example, Betts *et al.* developed immunosensors for haptens that were based on the fluorescence enhancement of dansylated Fab antibody fragments upon hapten binding.[29]

CONCLUSIONS

It has been demonstrated that in order to optimize homogeneous fluorophore-linked assays for biotin several factors that may affect the sensitivity and detection limits have to be considered. These factors include the type of fluorescent label used and the association constant of the ligand with the binding protein. These factors should also be important in designing optimization strategies for homogeneous fluorophore-linked binding assays for other analytes.

(*Received* 23 *December* 1992. *Accepted* 3 *February* 1993)

Summary—A series of 22 chelating reagents were tested for plumbane generation. Besides nitroso R salt, the reagents Bromo Pyrogallol Red, Pyrocatechol Violet, Alizarine Red-S, 5-Br-PADAP and PAN-S could significantly enhance the lead signal. The PAN-S system has been optimized. The characteristic concentration (5 ml sample) is 1.3 ng/ml, and the RSD at the 50 ng/ml level is 3.9%. Lead spiked into tap water and natural water was determined by HG–AAS in the presence of PAN-S. Recoveries of spiked lead were between 90 and 105%. Study of the mechanism suggests that the lead hydride might be directly generated from the chelated Pb(II) instead of the metastable Pb(IV).

Trace amounts of lead, like other hydride forming elements, can be determined by atomic absorption spectrometry in combination with a hydride generation technique (HG–AAS).[1] However, plumbane generation is quite peculiar. In 1974, Thompson and Thomerson first reported that lead(II) could be directly reduced to plumbane in hydrochloric acid, but the sensitivity of AAS determination was very low.[2] Later, Fleming and Ide found that, in the medium of tartaric acid–potassium dichromate, the efficiency of plumbane generation was greatly increased.[3] Since then, various systems with strong oxidizing reagents, such as hydrogen peroxide[4–7] and ammonium peroxodisulphate,[6–8] have been developed for plumbane generation. Recently, a system of lactic acid–potassium dichromate[9] and a system of oxalic acid–ammonium cerium(IV) salt[10] have been developed by a Spanish group and a Chinese group, respectively, and the latter was claimed to be the most sensitive system for HG–AAS determination of lead. It should be noted that, in the latter case, the characteristic concentration of lead was 0.04 ng/ml. The authors did not mention the sample volume; hence the characteristic mass is unknown. Nevertheless, the authors tested various systems, and concluded that the Ce(IV) system is the most sensitive. Vijan *et al.* attributed the increase in the generation efficiency to the conversion of Pb(II) into metastable Pb(IV) before it was reduced to plumbane.[4] Based on the proposed mechanism, Brindle and coworkers improved the generation efficiency of germane with ammonium peroxodisulphate.[11]

Plumbane has also been generated in a non-aqueous medium after solvent extraction of lead(II) with the chelating reagents pyrrolidine-1-carbodithioate or sodium diethyldithiocarbamate.[12] Moreover, Zhang *et al.* reported that lead(II) could be easily reduced to plumbane in aqueous medium in the presence of a chelating reagent, nitroso R salt,[13] and the developed HG–AAS method was successfully applied to the determination of lead in various environmental samples. From the well recognized phenomenon that nitroso R salt reacts with cobalt(II) and forms a cobalt(III) chelate upon air oxidation, the authors assumed that the lead(II) might be similarly oxidized to lead(IV) whilst chelating with nitroso R salt.

To further investigate the influence of chelating reagents on the plumbane generation, 22 chelating reagents with different molecular structures were studied. It was found that some chelating reagents, in addition to nitroso R salt, enhanced the sensitivity of lead determination by the HG–AAS technique. 1-(2-Pyridylazo)-2-naphthol-6-sulphonic acid, (PAN-S), is among

*Author to whom correspondence should be addressed.

the most effective. Thus a method of HG–AAS determination of lead in the presence of PAN-S has been developed, and the mechanism investigated. This paper presents the main results of the investigation.

EXPERIMENTAL

Reagents

Lead(II) standard solution (1.000 mg/ml) was prepared with spectroscopically pure lead oxide (Shanghai, China). Working standard solutions were made daily through appropriate dilutions.

PAN-S solution (1.5%) was prepared by dissolving 1.5 g laboratory made PAN-S in 0.1*M* NaOH solution. The solution was neutralized to pH 3–6 with 0.5*M* HNO_3 before it was diluted to 100 ml. The water soluble PAN-S was made from commercial 1-(2-pyridylazo)-2-naphthol (Shanghai, China) through simple sulphonation of the water insoluble dye with fuming sulphuric acid as described elsewhere.[14]

Sodium tetrahydroborate (III) solution (3%) was prepared from powder (Merck) by dissolution in 0.1*M* sodium hydroxide. The solution was filtered through filter paper before use.

All other reagents used were analytical grade or better. Deionized and distilled water was used throughout the work.

Equipment

An AAS-meter of model WFX-1D (Beijing, China) equipped with a lead hollow cathode lamp (Shanghai, China) and a chart-recorder (Shanghai, China) was used for absorption measurement.

A batch-wise hydride generator, as shown in Fig. 1, was adapted from a 125 ml pear shaped separatory funnel. A "T"-shaped electrically heated quartz cell 10 mm i.d. × 160 mm length was used throughout the experiments. The experimental conditions for AAS measurement and hydride generation are summarized in Table 1.

Procedure

Five millilitres of the test solution, that was made 0.2*M* in HNO_3 or HCl was transferred into the generator. Then 1 ml of 1.5% PAN-S solution was added to make the final reagent concentration 0.25%, and the sample introduction port was closed with a rubber stopper. After the recorder pen moved back to the baseline, 2 ml of 3% sodium tetrahydroborate(III) solution was injected with a syringe. The peak trace was recorded and the peak height measured for calibration.

RESULTS AND DISCUSSION

The influence of various chelating reagents on the plumbane generation

In the preliminary study, 22 kinds of chelating reagent were tested. No attempt was made to optimize the conditions individually for each reagent, yet the comparison serves the purpose of providing a rough guide to the choice of reagent. The results are listed in Table 2. Besides nitroso R salt, the reagents Bromo Pyrogallol

Table 1. Experimental conditions

AAS Measurement		Plumbane generation	
Wavelength	217.0 nm	Sample	5 ml
Band pass	1 nm	Sample acidity	0.2*M* (HNO_3)
Lamp current	5 mA	Volume of PAN-S solution	1 ml (1.5%)
Background correction	No	Volume of $NaBH_4$ solution	2 ml (3%)
Cell temperature	950°	The flow rate of carrier gas	0.8 l/min (N_2)

Red, Pyrocatechol Violet, Alizarine Red-S, 2-(5-bromo-2-pyridylazo)-5-diethylamino-phenol (5-Br-PADAP) and PAN-S significantly enhanced the lead signal. In these systems, lead hydride was generated immediately after the injection of $NaBH_4$, and the reduction was completed in around 30 sec. 8-Hydroxyquinoline-5-sulphonic acid, 4-(2-pyridylazo)-resorcinol (PAR), 2-(o-arsenophenylazo)-1,8-dihydroxynaphthalene-3, 6-disulphonic acid (Arsenazo-I), Acid Chrome Blue K, Tiron and 2-nitroso-1-naphthol have little enhancement effect on the lead signal. The remaining tested reagents were found to be ineffective in the improvement of the plumbane generation efficiency. It appeared that effective reagents belonged mainly to o-nitroso-naphthol, o-hydroxy-phenol and o-hydroxy pyridylazo compounds, and that the compounds containing the chelating functional group of iminodiacetic acid do not enhance the lead signal. Also, it seems that the chelating functional group is not the unique factor affecting the generation effiency. The chelating functional group of 2-nitroso-1-naphthol is similar to that of nitroso R salt, but the former had only a small effect on plumbane generation in comparison with the latter. This might be ascribed to its poor solubility in water. Moreover, surface tension and viscosity of test solution containing organic reagent might also affect the lead signal. Both PAR and PAN-S are water soluble o-hydroxyl pyridylazo compounds. However, the influence of the former on plumbane generation was much less than that of the latter. It is observed that, when sodium tetrahydroborate(III) solution was injected to the acidic test solution containing PAR, a large quantity of fine bubbles (foam) were formed, which were stable over a period of time. In the PAN-S system, the bubbles were relative few and bigger, and they burst quickly. Thus the poor sensitivity of the PAR system could be related to formation of foam which retarded the elimination of plumbane from solution. A similar phenomenon has been reported by Madrid *et al.* in their study on plumbane generation in slurry medium.[15]

The design of the reaction vessel is critical. If a small cylindrical vessel (60 ml) was used as the generator, the bubbles formed on the addition of $NaBH_4$ to the test solution caused some problems even for the PAN-S system. First, the bubbles would rise upwards to reach the gas outlet of the generator. Secondly, when a big bubble burst, a considerable volume of plumbane was released from the bubble, resulting in a small pulse of the signal. Therefore, a 125 ml separatory funnel was used, as shown in Fig. 1. The internal geometry of the generator prevented the risk of any bubbles from being swept into the tube leading to the quartz cell. The generator vessel also acted as a buffer tank to reduce the signal noise. Its use also resulted in some sacrifice of sensitivity in the AAS determination. It would be possible to further improve both sensitivity and precision if an effective and lead-free antifoaming reagent could be found.

Optimization of a PAN-S system

As can be seen from Table 2, although PAN-S is a little inferior to nitroso R salt in the behaviour of enhancing lead signal, it seems to provide a wider acid range in which the generation efficiency is high. Therefore PAN-S was chosen for the further studies.

The enhancement effect of PAN-S on plumbane generation is clearly shown in Fig. 2. Without PAN-S, almost no lead signal could be detected from a 50 ng/ml Pb(II) solution. However, the lead signal increased almost linearly with the increase of PAN-S concentration up to 0.20% (final concentration); where it reached a plateau. Figure 3 shows the influence of the acid concentration. In the concentration range of 0.1–0.3*M*, the lead reached its maximum signal. No significant difference was found between nitric acid and hydrochloric acids. For the PAN-S system, the optimum acid range is wider than other oxidant systems[3,4] and is also wider than the requirements of the nitroso R salt system.[13] Figure 4 shows the influence of sodium tetrahydroborate(III) concentration and of the injection volume of the reductant solution. It is clear that 2 ml of 3% $NaBH_4$ generates the largest signal. Compared with oxidizing reagent systems,[6–10] the PAN-S system consumes less reductant, since the reagent itself does not decompose the reductant. The temperature of the quartz cell, and the flow rate of nitrogen carrier gas have no significant influence over the ranges 800–1000°C and 0.5–1.0 l/min, respectively. Under the optimum conditions shown in Table 1, the characteristic concentration (0.0044 absorbance) was 1.3 ng/ml, and the relative standard deviation for a solution containing 50 ng/ml was 3.9%.

Interference of foreign ions

When studying interference, amounts of foreign ions, in 0.2*M* HNO_3, were added directly to the generator containing 5 ml of 50 ng/ml lead(II) followed by the addition of 1 ml of PAN-S solution. The signals obtained in this way were compared with those where no interfering ion has been added. As shown in Table 3, among the tested foreign ions, Cu(II), Se(IV), Bi(III), Sn(II) and Sb(II) caused severe interference; while interference free levels of Fe(II), Fe(III), Mn(II), Cr(VI) and Hg(II) were relatively higher.

When no foreign ion was introduced to the test solution, the orange–red coloured test solution became light orange after the injection of $NaBH_4$. In the presence of such foreign ions as Fe(II), Fe(III), Mn(II) and Cd(II), the test solution turned from its original colour (orange–red) to dark red (the colour of the corresponding chelate) upon the injection of $NaBH_4$. Thus, the interference probably resulted from the competition for PAN-S between lead(II) and these foreign ions.

Recovery of lead spiked into water samples

Although the low level of the lead concentration in the water samples is beyond the quantitative determination limit of the technique, the recoveries of the spiked lead are satisfactory, as shown in Table 4.

Mechanistic studies

Initially, different emission lines were used to verify that the absorption signal was produced by lead atoms instead of any possible molecular species. When absorption was measured at both lead 217.0 nm and lead 283.3 nm, a sharp signal was recorded; the signal obtained at 217.0 nm was greater than that at 283.3 nm. However, no signal could be detected when zinc, which absorbs at 213.9 nm, close to the lead line at 217.0 nm, was used. Therefore, the absorbing species was atomic lead.

Since PAN-S exerts a great influence on the lead signal, it was felt worthwhile investigating the interaction of PAN-S and lead(II). Spectrophotometric studies reveal that lead(II) can react with PAN-S to form a red chelate whose maximum absorption wavelength is 548 nm at pH 8.6. As shown in Fig. 5, the chelate begins to form at around pH 4, and the best pH range of the colour reaction is between 7 and 9. The pH range does not coincide with the initial acidity of the test solution used for plumbane generation. However, tests showed that the pH of the test solution rose quickly during injection of sodium tetrahydroborate(III) solution. After half of the reductant had been injected, the pH value of the reacting solution went up to around 3, and it was between 5 and 6 at the end of the injection. At this point, the gas was violently released. Usually 15 sec after the injection, the pH value reached 8.0–8.2. With the relatively slow response rate of the glass electrode being considered, the real pH value of the reacting solution might be a little higher than the measured one. Thus, the injection of alkaline $NaBH_4$ solution created a condition under which the PAN-S could react with lead(II).

At this point, we cannot yet exclude the possibility that the lead atomic absorption

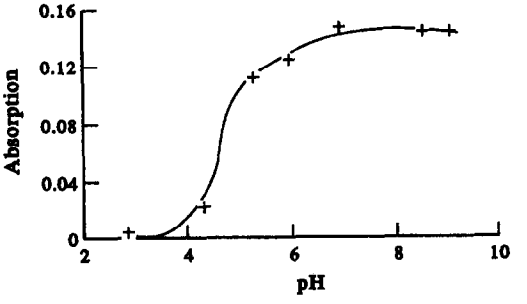

Fig. 5. Effect of acidity on the formation of lead–PAN-S chelate. Test solution was buffered with H_3BO_3–NaOH; absorption was measured at 545 nm against a reagent blank.

might result from the decomposition of the lead-PAN-S chelate that, if it were volatile, was stripped out of the solution by the hydrogen, formed *in situ*, and transported to quartz cell by the carrier gas. To check this, $NaHCO_3$, which has been used to strip $Pb(Et)_4$ from solution,[16] was used to replace $NaBH_4$. When 5 ml of 0.2*M* $NaHCO_3$ solution was injected into the acidic test solution, CO_2 was violently released at the first stage of the injection. At the end of the injection, the pH of the reacted solution reached between 4 and 4.5, while the release of CO_2 diminished. In this way, no lead signal was detected from a 250 ng/ml Pb(II) solution. It appeared that the violent release of the CO_2 formed *in situ*, occurred a little earlier, and, at the first stage of the injection of $NaHCO_3$ solution, the PAN-S-lead(II) chelate might not be formed due to the low pH value of the reacting solution. Therefore, an attempt was made to inject 2 ml of 1*M* HNO_3 solution into 5 ml of 0.5*M* $NaHCO_3$ solution containing both PAN-S and lead(II). In this way, CO_2 was generated violently through the whole course of the injection, while the pH of the test solution decreased from 8.25 to 5.99. Under these conditions, the lead–PAN-S chelate formed before the injection of NHO_3 solution, and it had not totally dissociated by the end of the injection. Once again, no lead signal was observed from a 250 ng/ml solution of lead(II). Therefore, the $NaBH_4$ is essential to the production of lead signal, and the volatile lead species is the reduction product formed by $NaBH_4$, that is, plumbane.

It is well known that the generation efficiency of plumbane is poor if no oxidizing reagent is involved. With respect to the PAN-S system, no other oxidizing reagent was introduced except the dissolved oxygen. Aznarez[12] has reported that plumbane could be generated readily from a solution of chloroform and glacial acetic acid. Zhang *et al.*[17] however, found that a chelating reagent was required to generate plumbane from solutions of chloroform and glacial acetic acid. Thus the chelating agent appears to play a crucial role in the generation of plumbane. If the formation of Pb(IV) is essential to the increase of generation efficiency of plumbane, the air or dissolved oxygen might play the role of an oxidizing reagent which, although it cannot oxidize free Pb(II), may oxidize the chelated lead(II) to lead(IV). If the hypothesis is correct, to purge both the test solution and the reagent solution with nitrogen before they were mixed together in the generator (where the air has been flushed out by carrier gas) will isolate the lead(II) from oxygen and should, in turn, decrease the lead signal. On the other hand, to purge the solution with pure oxygen should further increase the yields of the hydride. However, bubbling the solutions with either nitrogen or oxygen for 10 min produced no change in the lead signal. Thus, the enhancement effect can only be attributed to PAN-S itself. Since o-hydroxyl pyridylazo compounds are not oxidizing reagents, the effect of PAN-S cannot be accounted for in the formation of Pb(IV). Thus it is assumed that the plumbane is generated directly from the PAN-S chelated lead(II). The higher generation efficiency of lead hydride in the PAN-S system is probably chelated lead(II) being kinetically more easily reduced by $NaBH_4$ than free lead(II).

CONCLUSION

This study has shown that some chelating reagents enhance the lead signal obtained by HG–AAS, and that PAN-S is among the most effective. Mechanism studies revealed that in the presence of PAN-S the lead hydride might be generated directly from the chelated lead(II) ions instead of the metastable lead(IV). Though the analytical characteristics of the system are not totally superior to those of the systems with strong oxidizing reagents, it opens a new field for people to search for more effective systems for plumbane generation.

(*Received* 14 *December* 1992. *Accepted* 27 *January* 1993)

Summary—The performance and analytical characteristics of a glassy carbon glutaraldehyde immobilized glucose oxidase electrode have been established with regard to the direct detection of hydrogen peroxide produced from the reaction of glucose with oxygen. Measurements were performed at +1.1 V *vs.* SCE, and selectivity was obtained by casting the surface with a cellulose acetate membrane. Results compared favorably with the classical platinum-enzyme probe. The mechanism of ascorbic acid interference in hydrogen peroxide detection is reported. Mediated detection was also investigated for oxidase enzymes (glucose oxidase and xanthine oxidase) immobilized on the bare glassy carbon electrode. The probes were characterized using a specific enzyme mediator in solution (phenazine methosulfate or dichlorophenol-indophenol) plus hexacyanoferrate(III) as an electrochemical mediator. The electrode was poised at +0.36 V *vs.* SCE for the detection of hexacyanoferrate(II). The advantages of this dual mediator configuration include high stability and sensitivity of the electrochemical signal and the ability to use less positive potentials for increased selectivity. Application to other enzymes, such as hydrogenases, using such a binary redox configuration is suggested.

Determination of glucose by direct amperometric measurement of hydrogen peroxide has been reported using immobilized enzyme chemically modified graphite electrodes,[1] adsorbed enzyme on non-porous carbon rod electrodes,[2] covalently attached enzyme on rotating glassy carbon surfaces to produce an extremely thin (*i.e.*, monolayer) with low enzyme activity[3] or by incorporating the enzyme into carbon paste electrodes.[4,5,6] However, in these carbonaceous electrodes, various reducing substances present in biological samples, for instance ascorbic acid or uric acid, may significantly interfere in the oxidation of hydrogen peroxide.

The most frequently used hydrogen peroxide sensor is the platinum electrode[7,8,9] and most commercial glucose analyses are based on the platinum electrode. Recently unmodified glassy carbon, poised at +1.3 V *vs.* SCE, was used to directly monitor the production of hydrogen peroxide produced by choline oxidation in the presence of soluble choline oxidase.[10]

In this work we report a stationary glassy carbon glucose sensor used in two configurations. In the first, the electrode is coated with a cellulose acetate membrane (to protect against electro-oxidation of ascorbic or uric acid), plus glutaraldehyde crosslinked glucose oxidase (to generate hydrogen peroxide), with the electrode poised at +1.1 V *vs.* SCE. In the second, the glutaraldehyde crosslinked enzyme (glucose oxidase or xanthine oxidase) is coated directly on the electrode without cellulose acetate, and an electron mediator (*e.g.*, phenazine methosulfate or dichlorophenolindophenol) in solution is reduced by the enzyme and then reacts with ferricyanide(III) to produce ferrocyanide(II) which is detected at the glassy carbon electrode. The iron(III)-mediator reaction avoids oxygen interference, provides enhanced sensitivity, and allows detection at +0.36 V where interference from other electroactive materials is diminished.

EXPERIMENTAL

Apparatus

Voltammograms were recorded with a BAS CV 27 voltammograph connected to a Hewlett-Packard 7090A X–Y recorder and a three electrode system: a glassy carbon disk (diameter 3 mm) working electrode, a platinum wire counter electrode and a saturated calomel (SCE) reference electrode. Amperometric measurements

were made with a Brucker E-100 potentiostat reference electrode. Amperometric measurements were made with a Brucker E-100 potentiostat polarograph connected to a Servagor X–Y recorder. The 50 ml electrochemical cell used to test the enzyme electrodes was operated in a three electrode configuration. The working electrode was a glassy carbon disk or a platinum disk (3 mm diameter). All experiments were conducted at room temperature and the potentials are referred to the SCE. The pH of the solution was measured with a Tacussel Mini 80 pH meter.

Reagents

All reagents were of analytical grade and supplied by Sigma or Merck. The solutions were prepared with demineralized water. Glucose oxidase, type X-S, activity 150,000 U/g and xanthine oxidase, X3751, from bovine milk, activity 150–300 U/g, were from Sigma. Standard stock solutions of glucose (1*M*) were prepared at least 1 day before use to allow equilibration by dissolution in 0.1*M* phosphate buffer (pH 7.0) and were stored at 4°C for no longer than 1 week. Standard stock solutions of xanthine (10 m*M*) were prepared by dissolution in 0.05*M* NaOH and stored at 4°C for no longer than 1 week. Enzymes were crosslinked on the surface of an Immunodyne membrane (Pall Industrie, Saint-Germain-en-Laye, France) for physical support (BIA002HC5, pore diameter 0.2 μm).

Electrode preparation

To 1 mg of enzyme dissolved in 20 μl 0.02*M* phosphate buffer (pH 7.0), was added 5 μl of 2.5% aqueous glutaraldehyde solution. After 30 sec mixing, the mixture was deposited on a Pall Immunodyne membrane. The crosslinking process proceeded at room temperature for 2 hr. Then the Biodyne membrane was rinsed thoroughly with demineralized water and fixed on the electrode body either with or without a cellulose acetate membrane.

RESULTS AND DISCUSSION

The linear sweep voltammetric behavior of 1 m*M* H_2O_2 at the glassy carbon electrode in solution of varying pH was investigated in the pH range 3.0–10.0 (acetate, phosphate and borax buffers, all 0.1*M*), Fig. 1. Clearly defined diffusion current plateaus were observed in the pH range 4.0–10.0. As expected the plateau range becomes more anodic at lower pH values.[1,7]

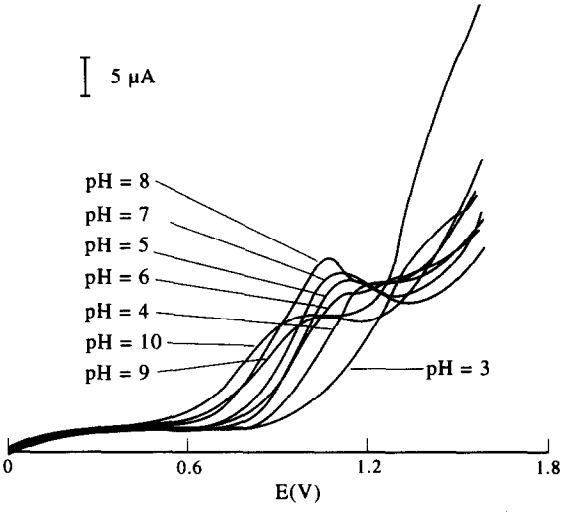

Fig. 1. Linear sweep voltammogram behavior of H_2O_2 at the glassy carbon electrode. $H_2O_2 = 1$ m*M*. Scan rate: 20 mV/sec.

Enzyme immobilized on bare electrode

Figure 2 shows the linear sweep voltammetric behavior of product H_2O_2 at the glassy carbon coated with immobilized glucose oxidase (non-mediated). In these experiments, the electrode was dipped into the solutions of varying pH containing 5 m*M* glucose and a potential of 0.0 V was applied. The current decayed and reached a stable value rapidly (about 1 min) and then the scan was applied. At pH 4.0, the current plateau disappears; this may be attributed to its anodic shift into the region of solvent breakdown and/or low activity of GOX at this pH. At pH 9.0, the enzyme activity decreases, thus a small response was obtained. The glassy carbon enzyme

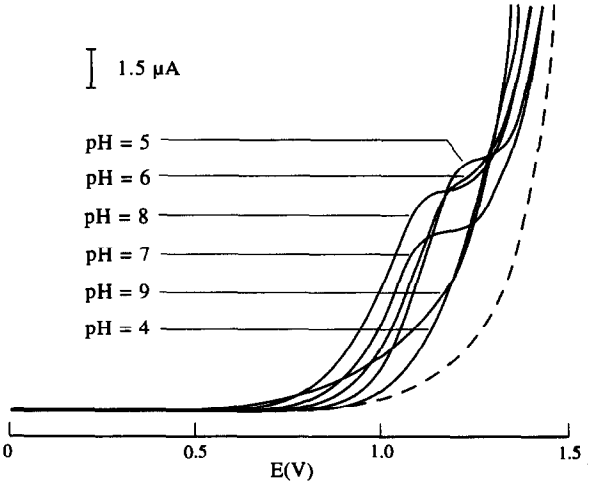

Fig. 2. Linear sweep voltammogram behavior of product H_2O_2 at the glassy carbon enzyme coated electrode. Glucose = 5 m*M*, scan rate: 20 mV/sec (--- background, pH 7.0).

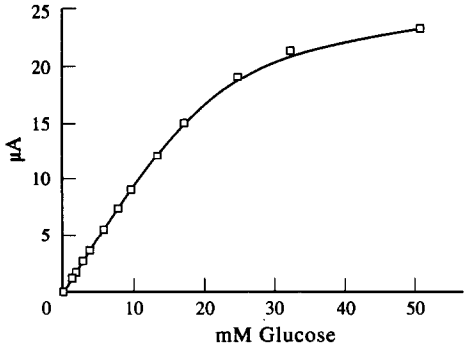

Fig. 3. Calibration curve for glucose coated enzyme electrode. Steady-state current measured at +1.1 V *vs.* SCE, pH 7.0.

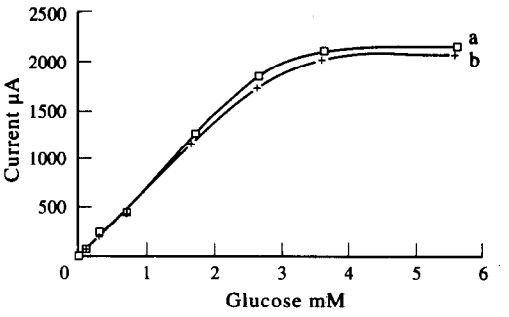

Fig. 5. Calibration curve for glucose (curve a) and after addition of freshly prepared 0.5 m*M* A.A. (curve b). Pt electrode covered with GOX immobilized on Biodyne membrane. Steady-state current measured at +0.65 V *vs.* SCE, pH 7.0.

electrode employed in this study can be used in the pH range 5.0–8.0. It was found that the best signal-to-background and signal-to-noise ratios were obtained around +1.1 V at pH 7.0.

Electrode response as a function of glucose concentration exhibits a Michaelian behavior (Fig. 3). The apparent Michaelis constant (K'_m) calculated from a Lineweaver–Burk plot was 26 m*M*. This value is an order of magnitude greater than some reports for platinum,[7] carbon rod,[2] graphite[1] and powdered graphite carbon[11] electrodes, comparable to a previous report for a monolayer of glucose oxidase covalently attached to glassy carbon[3] and less than the report for glucose oxidase incorporated in a carbon paste electrode.[6] Since the value of the apparent K'_m (26 m*M*) using glassy carbon was higher than the value for GOX in solution ($K_m = 0.2$ m*M*),[12] diffusion resistance of glucose through the enzyme membrane was suspected. Figure 4 shows the Eadie–Hofstee plot of data from Fig. 3. As can be seen, the presence of external diffusional limitations manifests itself by deviation from the straight line, the curve becoming concave towards the origin of the axes.[13] Such shape of deviation was reported with a transaminase bound collagen membrane.[14]

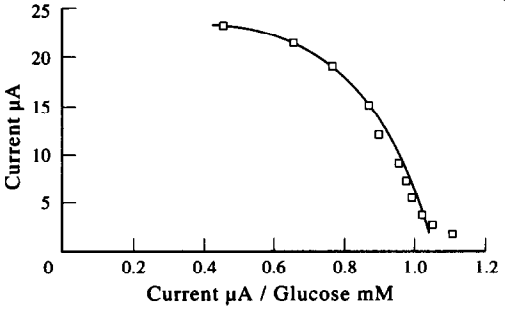

Fig. 4. Eadie–Hofstee plot of data from Fig. 3.

When the Biodyne membrane is assembled with a Pt electrode poised at +0.65 V (Fig. 5 curve a) the apparent K'_m was about 2 m*M*, which is less than the value obtained with a glassy carbon electrode poised at 1.1 V. This is explained by a slight evolution of oxygen at the glassy carbon sensor surface, thus increasing the linear measurement range for glucose.

The response was linear from $5 \times 10^{-7}M$ up to $1.7 \times 10^{-2}M$ (slope 0.9 μA/m*M*, intercept 0.009 μA and linear correlation coefficient 0.999). The anodic oxidation of peroxide and slight evolution of oxygen for water electrolysis at +1.1 V *vs.* SCE results in an increased oxygen concentration at the sensor surface, thus increasing the linear measurement range from glucose. This is reflected by an increased value of the apparent K'_m, as mentioned above. The selected +1.1 V for monitoring reflects a compromise between background current and dynamic range.

Study of interferences: enzyme immobilized on cellulose acetate coated electrode

Electroactive species, *e.g.*, ascorbic acid (A.A.) and uric acid, may oxidize directly on the electrode surface[15] or react with H_2O_2 produced in the enzymatic reaction as reported recently.[16] It is essential to eliminate these effects in the development of a reliable oxidase based sensor. It is known that A.A. is very unstable and breaks down rapidly, and can react easily with dissolved O_2 or with H_2O_2 produced in the enzymatic reaction, as reported in a spectrochemical assay for glucose[17] or an electrochemical assay with GOX immobilized in poly(*o*-phenylendiamine) films.[16] In the latter system, Malitesta *et al.*[18] have also reported a reduction in the current of the H_2O_2 product by A.A., but only at high

glucose concentrations, and attributed this to depletion of dioxygen by A.A.

In order to understand this we performed experiments on hydrogen peroxide with a classical Pt electrode covered with an enzymatic Biodyne membrane and poised at +0.65V, which is less than the potential of water oxidation and thus there was no increase of O_2 at sensor surface. Figure 5, curve a, shows a typical calibration curve for glucose. Curve b shows the calibration curve after addition of freshly prepared 0.5 m*M* A.A. It appears clearly that the sensor response was unaffected by the presence of A.A., except at high glucose concentrations above 1 m*M*. Similar results were obtained with GOX immobilized in poly(*o*-phenylendiamine) films.[18] The decrease in current is ascribed to oxygen depletion, whose effect is particularly pronounced at high substrate concentrations when the reaction rate becomes limited by cosubstrate availability as in concurrence with the GOX ping-pong mechanism.[19] Our results are in agreement with the report of Malitesta *et al.*[18] and in contrast to the recent report[16] which proposed that reduction of the glucose signal is due to the reaction of A.A. with H_2O_2. Normally in the latter hypothesis, we should have a decrease in the glucose signal only at low glucose concentrations, and the glucose concentration calculated should be less than the true glucose concentration by an amount almost exactly equal to the A.A. concentration, as reported in the spectrochemical assay with GOX in solution.[17]

In order to eliminate interference from electroactive chemicals which are directly oxidized on the electrode surface, a cellulose acetate membrane (kindly provided by Prof. M. Mascini, and prepared as previously reported[9]) was first fixed on the glassy carbon surface. Then a Biodyne membrane with immobilized enzyme was layered on top of this and the two membranes were held with an o-ring. Addition of the cellulose acetate membrane resulted in a decrease in the glucose signal about 3-fold, but highly increased the selectivity.[20] A 100 μM solution of A.A. gave no response at all. The signal response of 0.5 m*M* glucose in buffer obtained was exactly equal to the signal of 0.5 m*M* glucose in buffer containing 10 μM A.A., in agreement with the results of Fig. 5, curves a and b (see above for explanation). These concentrations of A.A. and glucose correspond to physiological levels in blood (diluted 10-fold in buffer). The glucose response was

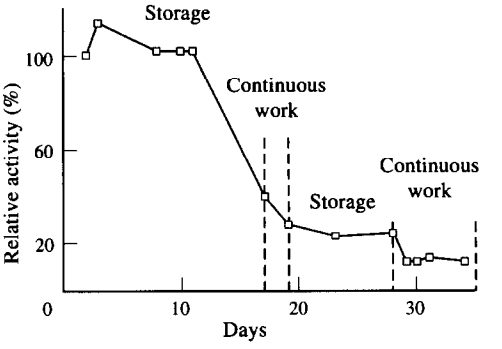

Fig. 6. Long term stability of cellulose acetate coated electrode. Continuous work refers to continuous exposure of the electrode to 1 m*M* of glucose at a permanently poised potential of +1.1 V at pH 7.0. Relative activities were measured at the points indicated.

linear from $1 \times 10^{-6} M$ to $1 \times 10^{-3} M$ glucose (slope 0.34 μA/m*M*, intercept 0.003 μA, linear correlation coefficient 0.999), reaching steady state within 100–120 sec. This measurement range is in approximate agreement with that listed for commercial platinum hydrogen peroxide sensors (Yellow Springs Instrument Co. and Tacussel Electronique).

The stability of the electrode is presented in Fig. 6. There is no significant decrease in activity for 11 days, and from 19 to 28 days the activity of the enzyme remains stable at about 23% of the initial activity. It is important to note that the electrode was stored in phosphate buffer at pH 7.0 and ambient temperature (*ca.* 25°), except under the continuous work conditions when the electrode was permanently poised at +1.1 V *vs.* SCE in 1 m*M* glucose.

Contrary to previous results with a monolayer of covalently linked enzyme[3] there is no large decrease in enzyme activity under working conditions. The apparent continuous decrease during the initial continuous work region is probably just an extension of the original decay, although a relative decrease in enzyme activity under working conditions may be due to inactivation of GOX by H_2O_2.[21] The previous work demonstrated large decreases over a working period of 6 hr.[3] The high ionic strength of the buffer (0.1*M*) and the acetate cellulose membrane interposed between the glassy carbon surface and the enzyme membrane may protect the enzyme from a change in the local pH.

Electron mediated electrode

Table 1 shows that ferricyanide is the best electrochemical mediator in terms of stability. However, in the literature we find that methyl viologen (MV^+) is the best mediator for

Table 1. Electrochemical properties of some mediators

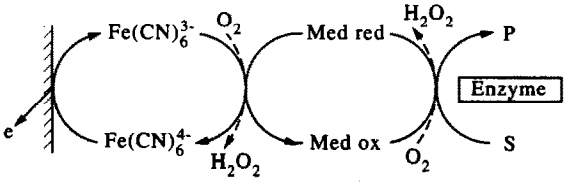
Name	E_0'* (*Volts vs. NHE*)	Oxidizability of reduced form	Other properties	Ref.
Methyl viologen	−0.45	Rapidly oxidized by oxygen	Rapid signal decline attributed to the high instability of reduced form	[22,31]
Phenazine methosulfate	+0.08	Readily oxidized by oxygen	Rapid signal decline attributed to the high instability of reduced form	[23,25,31]
Methylene blue	+0.01	Oxidized by oxygen fairly rapidly at pH 7, only slowly at pH 5	The redox potential is highly dependent on pH	[31]
2,6-Dichlorophenol indophenol	+0.21	Oxidized by oxygen	Risks of surface fouling at high positive potentials	[31,35]
Potassium ferricyanide	+0.36	Quite stable. Only slowly oxidized by oxygen	Stable and large current on glassy carbon. No surface fouling	[23,31]

*E_0' = redox potential at pH 7 at 25°.

hydrogenase enzymes,[22] and phenazine methosulfate (PMS^+) the most effective for NADH,[23] while the list compiled by Dixon[24] shows that the molecules listed in Table 1 are effective mediators for flavoproteins and in general ferricyanide does not react with these enzymes in the presence of O_2.

Kulys and Cenas listed different mediators for GOX.[25] In their report some experiments were carried out anaerobically (undoubtedly because of low stability of the reduced form of the mediator in the presence of dissolved O_2) or in a buffer with 6.6% ethanol (because of low solubility in water of the mediator). Turner and coworkers[26,27] and Thomas and coworkers[28] have reported the use of ferrocene based mediators for electrochemical detection and Bartlett and Whitaker[29] discuss dehydrogenase mediators and TTF·TCNQ mediator for a glucose oxidase electrode.

Owing to these considerations, we chose an effective enzyme mediator at low concentration (0.1 m*M*) in conjunction with ferricyanide at high concentration (10 m*M*) which has a stable reduced form and gives a high oxidation signal on glassy carbon at a relatively low potential, +0.36 V *vs.* SCE (Scheme 1). Recently PMS^+ in conjunction with ferricyanide has been used for regeneration of NAD^+ for glutamate dehydrogenase.[23] Two enzymes were tested, glucose oxidase (GOX) and xanthine oxidase (XOD).



Scheme 1. Reaction sequence for biosensor based on an electron mediator in the presence of ferricyanide for oxidase immobilized glassy carbon electrode.

Neither reacts with ferricyanide in the presence of glucose or xanthine, respectively, at concentrations lower than 1.5 m*M*, due to the competition with O_2 for the cofactor.

PMS^+ is an effective mediator for GOX,[24] but due to the instability of its reduced form, in the presence of oxygen, a steady-state current is not observed[23] even when PMS^+ is adsorbed on graphite electrode surface and thus the reduced form of PMS^+ is in the vicinity of graphite sensor.[30] If we use PMS^+ in conjunction with ferricyanide we obtain a response in the range of 0.1–1.5 m*M* glucose, as presented in Fig. 7. There is no electrochemical response towards the hydrogen peroxide product at the glassy carbon electrode at +0.36 V (according to Fig. 1). The reaction of XOD with 2,6 dichlorophenolindophenol (DCPIP) in conjunction with ferricyanide exhibits a xanthine calibration curve as shown in Fig. 8. The electrochemical response corresponds to oxidation of ferrocyanide and the uric acid product of the enzymatic reaction at +0.36 V *vs.* SCE.

The local oxygen concentration at the surface of the electrode decreases as the substrate (glucose or xanthine) increases, and hence a

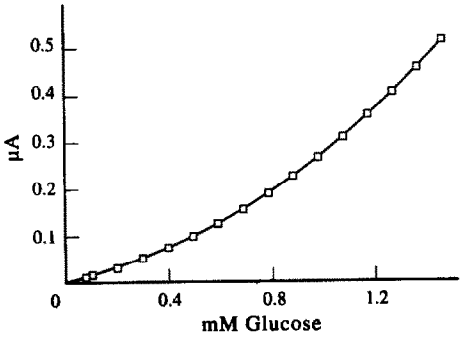


Fig. 7. Calibration curve for electron mediated glucose enzyme electrode in presence of PMS^+ (0.1 m*M*) and ferricyanide (10 m*M*), pH 7.0, +0.36 V *vs.* SCE.

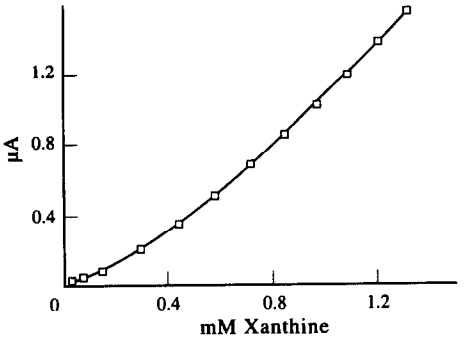

Fig. 8. Calibration curve for electron mediated xanthine enzyme electrode in presence of DCPIP (0.1 m*M*) and ferricyanide (10 m*M*), pH 7.0, +0.36 V *vs.* SCE.

larger fraction of the reduced mediator reacts with ferricyanide owing to the competition of O_2 and the mediator for the enzyme cofactor. The current observed for added standard substrate therefore increases as the total concentration of substrate in solution increases, giving rise to the non-linear calibration graph (Figs 7 and 8).

Compared to the non-mediated cellulose acetate covered glassy carbon electrode, the selectivity of the mediated electrode is lessened, but one aim of this work is to show that this binary redox configuration is easy to prepare and can be generalized for enzymes other than those dependent on O_2. For example, MV^+ is an effective mediator for hydrogenase enzymes[22] but its reduced form, which is readily oxidized,[31] should be successfully coupled with ferricyanide. We should point out that hexacyanoferrate (III) has been successfully used for L-lactate determination in blood plasma[32,33] by measurement of the hexacyanoferrate (II) produced in the reaction (directly at a platinum electrode at +0.35 V *vs.* SCE). The only slight interference was uric acid, and in most cases, this interference was insignificant (maximum 7% at the highest possible uric acid concentration). A bioenzyme electrode for L-carnitine was recently base on hexacyanoferrate (II) detection[34] and an analyzer based on this approach is now commercially available (Microzym-L from SGJ, France).

DETERMINATION OF L-MALATE IN WINE BY FLOW-INJECTION WITH CO-IMMOBILIZED MALATE DEHYDROGENASE/OXALOACETATE DECARBOXYLASE

NOBUTOSHI KIBA, MIE OGUCHI and MOTOHISA FURUSAWA
Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

(*Received* 14 *December* 1992. *Revised* 29 *January* 1993. *Accepted* 3 *February* 1993)

Summary—A method for determination of L-malate in wine is described. Malate dehydrogenase and oxaloacetate decarboxylase were immobilized on poly (vinyl alcohol) beads and incorporated in a flow-injection system with fluorescence detection. Sample solution (50 μl) was injected into the carrier stream [4*mM* NAD^+ in glycine buffer (pH 10.0)]. The fluorescence based on the NADH formed could be directly related to the amount of malate. The calibration graph was linear over the range 0.4–300μM. The detection limit was 0.2μM. Sampling throughout was 25 samples/hr.

L-Malate affects the taste and flavour of wines. The malate concentration decreases continually during storage due to decomposition by micro-organisms (malo-lactic fermentation). The best time for shipping is decided primarily on the basis of the malate concentration.

Malate in wines has been determined by ion chromatography[1,2] and high-performance liquid chromatography.[3] For the specific determination of malate, batch enzymatic methods have been developed using malate dehydrogenase (EC 1.1.1.37, MDH) and aspartate aminotransferase (EC 2.6.1.1., AAT)[4] (F-kit, No. 139068, Boehringer Mannheim GmbH), and MDH, citrate synthase (EC 4.1.3.7) and phosphate acetyltransferase (EC 2.3.1.8).[5] These methods are unsuitable for the rapid assay of a large number of samples.

MDH reversibly catalyzes the following reaction;

$$\text{malate} + NAD^+ = \text{oxaloacetate} + NADH + H^+$$

The equilibrium strongly favours the formation of malate. Displacement of the equilibrium of the reaction in favour of NADH formation was assisted by increasing the NAD^+ concentration, raising the pH and/or adding a trapping enzyme.[4,5] MDH and AAT were co-immobilized onto controlled-pore glass (CPG) and used in a flow-injection system for the determination of L-malate in wines at pH 9.5.[6] However, CPG is not suitable as the support for the enzymes since CPG is unstable in alkaline solution.[7]

Oxaloacetate decarboxylase (EC 4.1.1.3, OXD) catalyzes the decarboxylation of oxaloacetate to pyrvate and carbon dioxide according to the reaction;

$$\text{oxaloacetate} \rightarrow \text{pyrvate} + CO_2.$$

In this paper, a flow-injection fluorimetric method for the determination of L-malate with co-immobilized MDH/OXD reactor is reported. Here, OXD was used as a trapping enzyme and poly(vinyl alcohol) beads which are relatively stable in alkaline solution were used as support. The enzymes were covalently immobilized with glutaraldehyde on the beads and a fluorimetric procedure was used to monitor the appearance of NADH. The flow-injection method was applied to the determination of free L-malate in wines.

EXPERIMENTAL

Materials

MDH (L-Malate: NAD^+ oxidoreductase, from Thermus sp., type III, 120 U/mg) and OXD (Oxaloacetate carboxy-lyase, from Pseudomonas sp., 350 U/mg) were obtained from Amano Pharmaceutical Co. (Nagoya) and Asahi Chemical Industry (Tokyo), respectively. NAD^+ (free acid, 96%) was from Kohjin (Tokyo). Poly(vinyl alcohol) beads (GS-520, 13 μm diameter) were from Asahi Chemical Industry. A purity of L-(−)-malic acid, obtained from Sigma Chemical Co. (St Louis), was

checked by the enzymatic method.[8] All other chemicals were of analytical-reagent grade.

Glycine buffer (pH 10.0) consisting of 0.1*M* glycine–0.1*M* NaCl–0.1*M* NaOH was prepared. The method for the amination of the beads was similar to that described previously.[9] The aminated beads were packed into a stainless-steel column (5 cm × 4 mm i.d.) by the slurry-packing method. Glutaraldehyde (4%) in 0.1*M* sodium hydrogencarbonate solution was pumped through the column for 2 hr at 0.3 ml/min and the column was washed with deaerated water for 30 min at 0.5 ml/min. Enzymes solution [MDH 3 mg (360 U) and OXD 9 mg (3150 U) in 10 ml of 0.05*M* phosphate buffer (pH 7.0)] was circulated through the column at 0.3 ml/min for 6 hr at 20°. MDH activity in the solution was measured with L-malate as substrate at pH 9.0 at 30°. Also OXD activity was measured with oxaloacetate as substrate and lactate dehydrogenase (EC 1.1.1.28) at pH 8.0 at 30°. MDH and OXD were immobilized on the beads with 69 and 32% yields, respectively.

Apparatus and procedure

The glycine buffer (pH 10.0) containing 0.1*M* $MgCl_2$ and 8*mM* NAD^+ solution were each pumped by a double-plunger pump (KHU-W-52, Kyowa Seimitsu, Japan) at a flow-rate of 0.25 ml/min and mixed before an injector (TVM-6M2, Sanuki, Japan) with a 50 μl loop. The combined solution entered the reactor which was maintained at 30° with a thermostated water bath. Enzymatic reactions took place in the reactor and the NADH produced was monitored at 465 and 340 nm with a spectrofluorimeter (FP-210, Jasco, Japan).

RESULTS AND DISCUSSION

Properties of co-immobilized MDH/OXD reactor

The effect of pH on the activity of the co-immobilized enzymes reactor was studied in the pH range 9.0–11.0 using glycine buffer. The optimum pH was found to be about 10.0. The effect of temperature on the activity of the reactor was studied over the range 20–40°. The reactor exhibited maximum activity at 30°. Compared with the immobilized MDH[10] (optimum pH and temperature are 11.5 and 45°, respectively), the maximum pH and temperature for the co-immobilized enzymes are 1.5 pH units more acidic and 15° lower, respectively.

The optimum NAD^+ concentration in the reactor was investigated in the range 1–10*mM* at the 300μ*M* L-malate level. The peak height increased with increasing concentration. Above 8*mM*, the peak height was constant. A concentration of 8*mM* NAD^+ was chosen; at this concentration, the NAD^+ concentration in the reactor is 4*mM*.

Immobilized OXD was activated by Mg^{2+} in a similar manner as the free OXD.[11] The effect of the $MgCl_2$ concentration on the peak height was investigated in the range of 0.01–0.2*M*. The peak height become constant at 0.03*M*. A solution of 0.1*M* $MgCl_2$ was used; at this concentration, the Mg^{2+} concentration in the reactor is 0.05*M*.

The peak height decreased linearly as the flow-rate of carrier stream increased from 0.3 to 0.8 ml/min. The peak height was strongly influenced by the flow-rate and the peak height at 0.3 ml/min was about 3.4 times that at 0.8 ml/min. A total flow-rate of 0.6 ml/min was selected, as a compromise between sensitivity and sample throughput: at this flow-rate, the sample throughput was 25 hr^{-1}.

Under the conditions described in Apparatus and Procedure, the conversion efficiency of the reactor was 44%. Under the same conditions, the relative activities for L-malate and D-malate were 100 and 9, respectively. Other carboxylic acids such as tartaric acid, citric acid, lactic acid, succinic acid and acetic acid did not interfere at the 2*mM* level. The presence of up to equimolar amounts of pyruvic acid, sulphite or ascorbic acid did not interfere with the measurement of L-malate. In the presence of equimolar oxaloacetate, the peak height decreased to 75% of the standards. However, since the concentrations of the compounds in wines are normally far lower than that of L-malate, this method is not subject to interferences from the compounds.

The operational stability of the reactor was evaluated over 3 weeks. The reactor was used for the analysis of 100 samples (20μ*M* L-malate) during 4 hr/day and stored at 4° in 0.1*M* phosphate buffer (pH 7.0) when not in use. The activity decreased gradually to 80% of the initial value after 3 weeks.

Calibration

The calibration graph of peak height against malate concentration was linear over the range 0.4–300μ*M* with a correlation coefficient of 0.997 ($n = 11$) under the same conditions as described in Apparatus and Procedure. Above a

concentration of 300μM, the graph became curved. The relative standard deviation for 11 replicate injections of 20μM L-malate was 0.95%. The limit of detection (signal-to-noise ratio = 3) was 0.2μM (1.3 ng in a 50 μl injection).

Application

This method was applied to the determination of free L-malate content in wines. White wine (10 μl) was diluted 1000-fold with water because the concentration of free L-malate in white wines is normally in the range from 14mM (2 g/l) to 45mM (6 g/l).[12] Red wines were decolorized by nylon beads (A-1030, 100–150 mesh, Unitika, Osaka) and diluted 500-fold with water because the concentration is in the range from 3mM (0.4 g/l) to 45mM (6 g/l).[12] Diluted sample (50 μl) was injected into the carrier stream.

Red wines with low and high L-malate concentrations were repeatedly analysed during 4 weeks with the reactor. The reactor was used for analyses of 60 samples in a day and standards were measured at 30-sample intervals, in order to correct the variation of the conversion efficiency. The reactor was renewed every 2 weeks. The method gave satisfactorily precise and reproducible results; for wine containing 3.6mM L-malate, the within-day coefficient of variation (CV) was 1.3% and day-to-day CV 1.8%. For wine containing 38mM L-malate, the respective CV values were 0.95 and 1.6%.

A sample of red wine of known L-malate concentration was supplemented with L-malate to give final concentrations of 4.0–41.7mM. The recoveries were in the range 97–102%.

The results (n = 36, 20 red wines, from 3.8 to 42.1mM) were compared with those obtained by F-kit (Boehringer Mannheim) with soluble MDH and AAT. The calculated linear regression and correlation coefficient were $y = 0.979x + 0.03$ and $r = 0.992$, respectively.

CONCLUSION

The flow-injection system with co-immobilized MDH/OXD reactor is useful for the sensitive and reliable measurement of L-malate and can easily be used routinely for the analysis of wines. The method is about twice as sensitive as that with co-immobilized MDH/AAT reactor,[6] conversion efficiencies for MDH/OXD reactor and MDH/AAT reactor are 44 and 25%, respectively. The co-immobilized MDH/OXD reactor is stable enough to permit the measurement of more than 1400 samples.

(*Received* 25 *November* 1992. *Revised* 16 *February* 1993. *Accepted* 18 *February* 1993)

Summary—A new method is described for the determination of Ni based on the cathodic adsorptive stripping of Ni(II) complexed with hydroxynaphthol blue (HNB) at a static mercury drop electrode. Optimal conditions were found to be: accumulation potential −0.50 V (*vs.* Ag/AgCl); final potential −1.10 V; accumulation time 50 sec; scan rate 200 mV/sec; linear scan mode; filter 0.1 sec; supporting electrolyte acetic acid/acetate (0.25*M*, pH = 6.0) and concentration of HNB $3.3 \times 10^{-5}M$. The response of the system was found to be linear in a range of Ni concentrations from 25 ppb to the detection limit. The detection limit was found to be 1.7 nM (0.10 ppb) with 2 mins of accumulation time. The effect of various potential interferences (including a variety of cations, anions and organic surfactants) were also studied. With the exception of Co, at less than equimolar concentrations no significant interferences were observed. Al was found to interfere at high concentrations with respect to Ni, but Al concentrations up to 1000 ppb may be masked by sodium citrate or sodium fluoride. The utility of the method is demonstrated by the recovery of Ni in a doped sample of commercial mineral water.

Nickel, which is a potentially toxic and carcinogenic metal, has been previously quantitatively determined by adsorptive voltammetric techniques utilizing complexing agents such as dimethylglyoxime,[1] 2-2′-bipyridine[2] and cyclohexane-1,2-dione dioxime.[3] Each technique has its particular sensitivity and is subject to various interferences and limitations. In our laboratory we have been investigating various pre-adsorptive voltammetric techniques utilizing a variety of organic complexing agents for trace and ultratrace metal determinations which both maximize sensitivity and selectivity.[4–7] We report here the trace determination of Ni by cathodic stripping voltammetry using the complexing agent hydroxynaphthol blue (HNB). We have found this technique to be both sensitive (detection limit of 0.10 ppb with a 2-min accumulation time), relatively unaffected by a variety of commonly interfering substances and is performed in an acidic medium (pH ≅ 4.8–6.0). The effect of a number of experimental parameters is presented. The utility of the method is demonstrated by the recovery of nickel in a doped mineral water sample.

EXPERIMENTAL

Apparatus and reagents

The voltammograms were obtained with a PAR 264-A voltammetric analyser interfaced with a PAR 303 static mercury drop electrode which have been described elsewhere.[6,7] A large-sized static mercury drop electrode (SMDE) with a surface area of 0.032 cm^2 was used. A Ag/AgCl (saturated KCl) reference electrode and platinum wire auxiliary electrode were used. All potentials reported are with respect to the Ag/AgCl electrode. Water purified in a Milli-Q water purification system (millipore) was used for all dilutions and sample preparations. All chemicals were of analytical reagent grade. A 2000-ppm stock solution

*Author for correspondence.

(Merck, titrisol) was used to prepare Ni solutions. A $3.3 \times 10^{-3}M$ stock solution of HNB was prepared in water. A stock solution of $1M$ acetate was prepared as supporting electrolyte followed by addition of acetic acid to achieve pH = 6.0. The mineral water subsequently analyzed was obtained commercially.

Procedure

Ten milliliters of a supporting electrolyte solution (7.5 ml of water + 2.5 ml of the stock acetate buffer) containing 100 μl of the $3.3 \times 10^{-3}M$ HNB stock solution were pipetted into the cell and purged with nitrogen for 8 min. The preconcentration potential (−0.5 V *vs.* Ag/AgCl) was applied to a fresh mercury drop while the solution was stirred. Following the accumulation (typically 50 sec) the stirring was stopped and allowed to equilibrate for 30 sec. The voltammogram was recorded by a linear scan of negative-going voltage (scan rate = 200 mV/sec) terminated at −1.10 V. After the background stripping voltammogram has been obtained, aliquots of the nickel standard solution are introduced into the cell while maintaining a stream of nitrogen over the surface. All data were obtained at (23 ± 1)°.

RESULTS AND DISCUSSION

Parameters affecting the adsorptive stripping behaviour

Figure 1 shows the resulting cyclic voltammograms by varying the scan rates from 20 mV/sec up to 500 mV/sec. The ligand peak is seen to become broader with increasing scan rate until at higher scan rates begins to overlap with the complex's peak. A scan rate of 200 mV/sec was found to yield a reasonable sensitivity while retaining resolution. In contrast to some similar systems we have studied, [8] the Ni–HNB complex did not display an adsorptive–accumulative effect with repetitive cyclic voltammetry.

Figure 2(A) shows the effect of pH on the linear scan stripping peak current of the Ni–HNB complex. The current is seen to increase from pH = 4.40 until levelling off at pH = 5.2. It is worth noting that a pH of 6.0 was generally used for subsequent quantitative determinations, as it was later observed that this pH minimized potential interferences by other ions.

The effect of the accumulation potential on the stripping peak's current was evaluated over the range −0.70–0.00 V [Fig. 3(A)]. The largest peak current is obtained using a potential near −0.5 V. A similar dependence of current with accumulation potential was previously observed for the V–TAC system.[9]

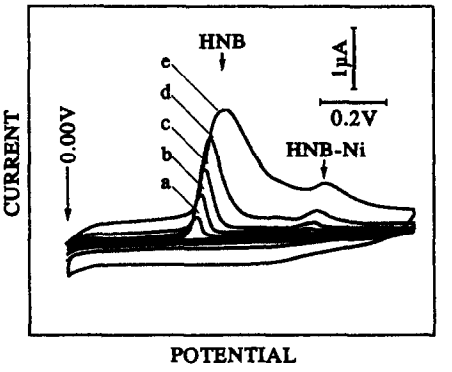

Fig. 1. Effect of scan rate on the cyclic voltammogram of the Ni–HNB system. Experimental conditions: acetic acid/acetate supporting electrolyte, $0.25M$, pH = 6.0; unstirred solution; [HNB] = $3.3 \times 10^{-5}M$; 20 ppb Ni; large size drop; equilibrium time 30 sec and filter 0.1 sec. Curve a = 20; b = 50; c = 100; d = 200; e = 500 mV/sec.

Other experimental variables affecting the adsorptive stripping response were evaluated and optimized. The effect of scan rate on peak potentials and current is shown in Fig. 4(A) and (B), respectively. A similar result was obtained

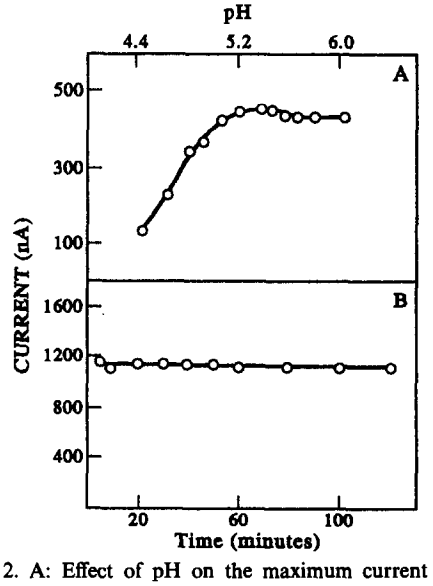

Fig. 2. A: Effect of pH on the maximum current of the stripping peak. Experimental conditions: acetic acid/acetate supporting electrolyte, $0.05M$; large size drop; filter 0.1 sec (linear scan mode); 25 ppb Ni; [HNB] = $3.3 \times 10^{-5}M$; stirred solution; t_{acc} = 30 sec at −0.41 V; t_{equil} = 30 sec; E_{final} = −1.30 V and scan rate 100 mV/sec. B: Repetitive measurements of a single sample of Ni–HNB. Experimental conditions as for A with acetic acid/acetate supporting electrolyte, $0.25M$, pH = 6.0; 20 ppb Ni; t_{acc} = 50 sec at −0.50 V; E_{final} = −1.10 V and scan rate 200 mV/sec.

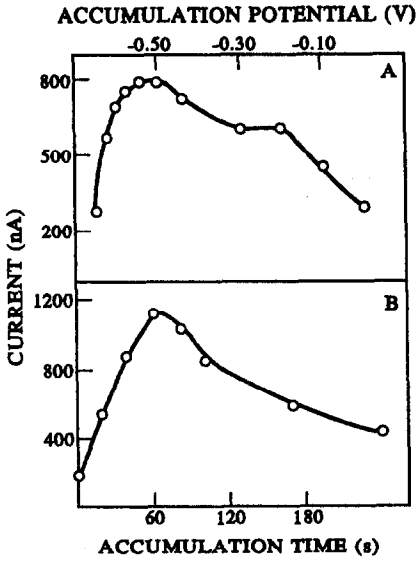

Fig. 3. The effect of accumulation potential (A) and time (B) on the current of the stripping peak for Ni–HNB. Experimental conditions as for Fig. 2(B) with an accumulation time of 30 sec.

by cyclic voltammetry as discussed above. The potential ranges from −0.71 to −0.81 V within the range of scan rates from 10 mV/sec to 500 mV/sec. A plot of current with respect to the scan rate is linear (correlation coefficient of 0.9926 for a scan rate range of 10–200 mV/sec) as expected for the reduction of an adsorbed specie.[10]

The effect of accumulation time is shown in Fig. 3(B) (20 ppb Ni). As can be seen, the current increases linearly until a maximum is obtained at 50 sec of accumulation with a subsequent drop in the peak's current. This is in contrast to the saturation behaviour more commonly observed.[11] Hence to maximize sensitivity, a 50-sec accumulation time was generally used for subsequent quantitative determinations.

The complex was observed to exhibit a high degree of stability. Repeated measurements of a sample over a period of 120 min showed no changes in the stripping peak current [Fig. 2(B)].

A comparison between a linear and differential pulse scan show an eight-fold increase in current for the linear scan mode under the conditions of this study (Fig. 5) and, as the linear scan mode is also faster, it was used for subsequent determinations. It is important to note that the factor of differing scan rates for the two modes plays an important role in this effect, as in order to maintain a similar peak resolution for the differential mode a reduced scan rate was used, which in turn yields a lower observed current.

Quantitative utility

Figure 6 shows the voltammograms obtained by varying the Ni concentration from 0 to 25

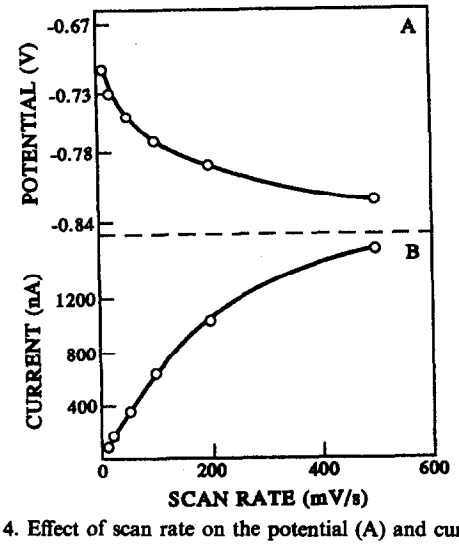

Fig. 4. Effect of scan rate on the potential (A) and current (B) of the Ni–HNB stripping peak. Experimental conditions as for Fig. 2(B).

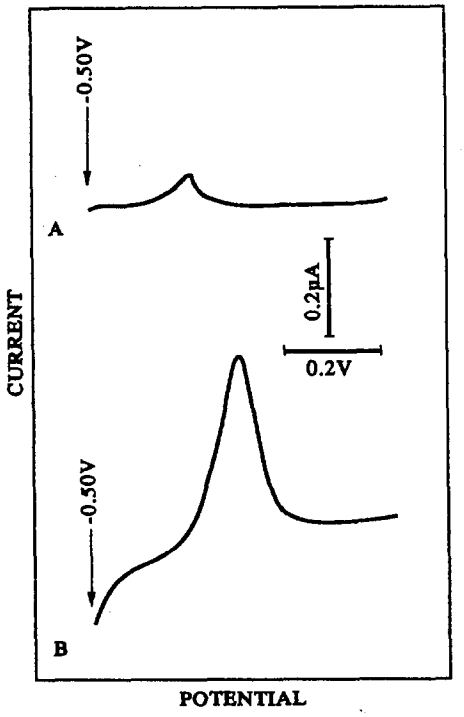

Fig. 5. Comparison between differential pulse (A) and linear scan (B) modes. For differential pulse scan pulse amplitude = 50 mV and scan rate = 10 mV/sec. For linear scan experimental conditions as for Fig. 2(B). Both modes were with a solution of 5 ppb Ni and an accumulation time of 60 sec.

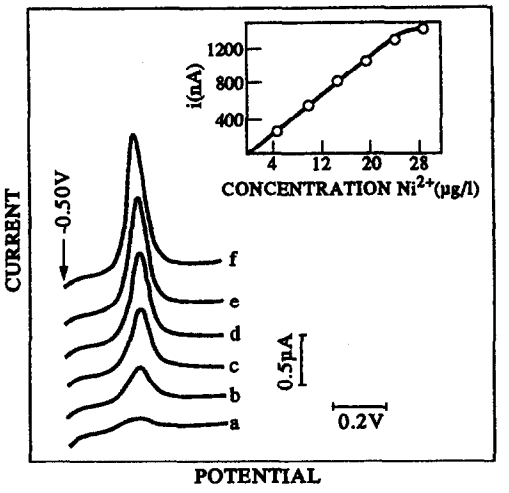

Fig. 6. Voltammograms and resulting calibration curve (inset) obtained by the variation of Ni concentration from 0 (a) to 29.56 ppb (b–f). Experimental conditions as for Fig. 2(B).

ppb (electrolyte acetic acid/acetate, pH = 6.0, accumulation time 50 sec, accumulation potential −0.5 V, final potential −1.10 V, scan rate 200 mV/sec, large drop size, equilibrium time 30 sec). The resulting calibration curve, shown as the inset, is seen to be linear up to 25 ppb (correlation coefficient = 0.999 up to 25 ppb Ni). The detection limit was estimated to be 0.10 ppb (1.7nM) after an accumulation time of 2 mins of $4.3 \times 10^{-8}M$ Ni (S/N = 2). The detection limit was also calculated with an accumulation time of 50 sec (the accumulation time more commonly used in this study) to be 0.14 ppb (2.4nM) using $8.5 \times 10^{-8}M$ Ni.

The major sources of interferences are likely to be coexisting ions and organic surfactants. These species could result in either new reduction peaks or the overlap with the Ni–HNB peak thus obscuring the measurement. The effect of various ions that could yield interferences was studied. The determination of 5 ppb Ni was not affected by the addition of up to 5000 ppb of Ca^{2+}, Ba^{2+}, Mg^{2+}, Sr^{2+}, Cu^{2+}, Zn^{2+}, Mn^{2+}, Th^{4+}, Bi^{9+}, Mo^{6+}, oxalate, carbonate, sulphate, $B_4O_7^{2-}$. tartrate, thiocyanate, chlorate or 4,5-dihydroxy-1,3-benzenedisulphonic acid (tiron). The determination of 5 ppb Ni was not affected by the addition of up to 500 ppb of Ti^{4+}, Al^{3+}, UO_2^{2+}, Br^-, CDTA or cyanide. The interference of Ti^{4+}, is due to a stripping peak near that for the Ni–HNB complex ($E_{Ni} = -0.78$ V, $E_{Ti} = -0.62$ V) which was not masked by fluoride, tiron or oxalate.[12] Figure 7(A) shows the effect of 1 ppm Ti on the stripping voltammogram of 5 ppb Ni–HNB.

The interference by aluminum (due to overlapping peaks) was successfully masked by fluoride or citrate (20 ppm, which were separately observed to not interfere at these concentrations). The determination of 5 ppb Ni was not affected by the addition of up to 50 ppb of Pb^{2+}, Fe^{3+}, V^{5+}, EDTA, triton x-100. The interference by lead is due to the presence of a stripping peak near that for the Ni–HNB complex ($E_{Ni} = -0.78$ V, $E_{Pb} = -0.59$ V). Figure 7(B) shows the effect of 1 ppm Pb on the stripping voltammogram of 5 ppb of the Ni–HNB complex. The determination of 5 ppb Ni was not affected by the presence of up to 5 ppb of Cd^{2+}, at a concentration of 50 ppb Cd^{2+} an increase of 20% of the Ni–HNB peak is observed. The presence of Co(II) was found to interfere at 5 ppb as it displays a strong stripping peak at nearly the same potential as the Ni–HNB complex. An interference by Co(II) was also observed for the determination by adsorptive stripping of the Ni complex of 2,2′-bipyridine (bpy).[2] In that system the presence of Co caused the Ni–bpy complex peak to diminish, whereas in this case (for 1:1 Co/Ni) an augmentation of the stripping peak by 10% was observed.

The method was applied to a sample of commercial mineral water. As it was found that the mineral water contained undetectable quantities of Ni, the sample was "doped" with aliquots of Ni(II) of known concentration. The current of the doped sample was then measured and compared to a previously prepared calibration curve to determine the ability to quantitatively determine the Ni concentration in the sample. For a sample with an added nickel concentration of 0.75 ppb, the analyzed concentration was 0.77 ± 0.19 ppb for three determinations of the sample. For a second sample with

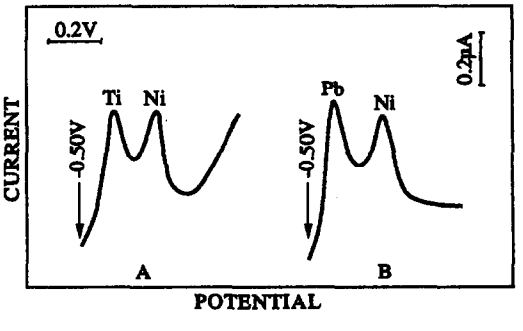

Fig. 7. Effect of the presence of Ti (A) and Pb (B) on the stripping voltammogram of the Ni–HNB complex. Experimental conditions: 5 ppb Ni; 1 ppm Ti (A); 1 ppm Pb (B) and other conditions as in Fig. 2(B).

an added nickel concentration of 10.5 ppb the analyzed concentration was 10.5 ± 0.1 ppb for seven determinations.

CONCLUSIONS

The cathodic stripping of the Ni–HNB complex is seen to be an effective method for the determination of Ni at ppb levels. The possible interference by a very large number of substances was studied and generally the technique was found to be unaffected by a wide variety of materials. In the case of interference by Co, it is worth noting that in natural waters the concentration of Ni is generally much higher than that of Co.[2] For samples with relatively high Co:Ni ratios, the methods of Braun *et al.*[1] or Donat *et al.*[3] are useful as the stripping potentials of the peaks of the Co and Ni complexes are well resolved. However, the technique presented here offers an advantage in those cases where lower pH and shorter accumulation times may be desirable. In addition, the ability to perform successive determinations of other metals which form complexes with HNB (*e.g.*, Pb and Ti), that have stripping peaks well resolved from the Ni–HNB complex, add to the versatility of the technique.

Summary—An automated procedure has been developed for the determination of formetanate and its metabolite *m*-aminophenol (MAP) in water samples.

MAP can be selectively determined in the presence of formetanate by direct on-line reaction with *p*-aminophenol and spectrophotometric measurement of the absorbance at 576 nm in the presence of KIO_4, as oxidizing agent. The method has a limit of detection of $5 \times 10^{-7}M$, it provides a recovery percentage from 95 to 104% and permits one to carry out 120 measurements/hr.

The spectrophotometric determination of formetanate must be carried out after a previous hydrolysis to MAP. To determine formetanate in the presence of MAP, two steps are necessary. Firstly, the MAP content is selectively determined as has been mentioned above. After that, the sample is treated with $0.05M$ NaOH at 90°C, to hydrolyze the formetanate to MAP, and then the sum of both is determined spectrophotometrically. The difference between the results obtained in each step gives the formetanate concentration.

The developed procedure for the determination of formetanate provides a sensitivity of 1070 absorbance units mol^{-1} l and a limit of detection of $1.9 \times 10^{-7}M$, which corresponds to 50 μg/l of formetanate hydrochloride.

The method has been applied to the analysis of natural water samples fortified with formetanate and MAP, and formetanate has also been quantitatively recovered in irrigation waters at a concentration level of $1.9 \times 10^{-6}M$ which corresponds to 500 μg/l.

On the other hand, working in the stopped-flow mode, for a reaction time of 100 sec, the sensitivity of the formetanate determination can be increased to 4642 absorbance units mol^{-1} l but the limit of detection remains of the order of 44 μg/l.

Formetanate, [*m*-[[(dimethyl amino) methylene] amino] phenyl] methyl carbamate, is a pesticide which has two active functional groups, dimethyl formamidine and methyl carbamoyl, with potential biological activity.[1-3] Therefore, formetanate is used as an effective acaricide product against the motile stages of fruit tree red spider mites, and glasshouse red spider mite. It is also used as an insecticide and it is effective against several plant bugs, beet fly and thirps. Formetanate has a low stability and because of this, it is formulated as the hydrochloride that is more stable, and highly soluble in water (more than 50%); other formulations, such as "dicarzol 200" and "carzol SP", are prepared from hydrochloride, or as a combined formulation with chlordimeform.[4] The lethal dose LD_{50} of formetanate in mice is 4.5 mg/20 kg.[5]

Few data have been reported about the analysis of formetanate and its residues. However, high performance liquid chromatography (HPLC) has been used in this field.[6-10] Gas chromatography was also employed to determine the pesticide residues by using α-Bromo-2,3,4,5,6-pentafluoro toluene or bromine as derivatization agents.[11-12] However these procedures have a low sensitivity and also, previous preconcentration steps must be employed.

An alkalimetric titration method has been proposed for the indirect determination of formetanate from the presence of hydrochloride, after the identification of the pesticide by thin layer chromatography (TLC)[12] but, this procedure has a poor selectivity.

A spectrophotometric method has been developed to determine formetanate residues. The active principle is separated by TLC, hydrolysed to *m*-aminophenol and this latter coupled with

*Corresponding author.

N-(1-naphthyl)ethylene diamine to form a blue azo dye which absorbs at a wavelength of 555 nm.[12]

m-aminophenol (MAP) is the final major metabolite of formetanate. This compound is soluble in 40 parts cold water and freely soluble in hot water. MAP has a biological effect on the growth of bacteria. However, this product must be handled carefully because it could cause damage to kidneys, eyes and skin, and so, the recommended maximum permissible concentration of MAP in the air is 1 mg/m^3.[13–20]

Many studies and analytical methods have been reported on determining of MAP by HPLC,[21–28] TLC,[29–32] gas chromatography,[33,34] spectrofluorometry[35–38] and spectrophotometry,[39–46] and these methods could also be applied to the determination of formetanate, after a previous hydrolysis to yield MAP. However, we have not found any reference in the literature to the selective determination of formetanate and MAP in the same sample.

Flow injection analysis (FI)[47,48] provides a useful way to automate the analytical determinations and can be very interesting to carry out the control of pesticide residues in environmental water samples, but no data have been reported as yet, on using FI for the determination of formetanate or MAP. However, in a previous work[49] we have found that propoxur, another carbamate pesticide, can be determined by flow injection spectrophotometry at 600 nm after its alkaline hydrolysis and reaction with *p*-aminophenol (PAP), and this reaction could be applied to the direct determination of MAP and to the determination of formetanate after its hydrolysis. So the aim of the present work is to develop an automated spectrophotometric method to determine formetanate and its metabolite MAP.

We have carried out a series of studies on the reaction between MAP and PAP in order to obtain a selective procedure, which can be directly applied in water analysis, and also we have studied the reactivity of formetanate against the PAP, both directly and after alkaline hydrolysis.

EXPERIMENTAL

Apparatus

A Hewlett Packard 8452A diode array spectrophotometer, equipped with HP-89530A MS DOS UV/V software with a response time of 0.1 sec, was used to carry out spectrophotometric determinations. A flow cell of 50 μl internal volume and 1 cm pathlength was used for measurements.

A four channel flow injection manifold [Fig. 1(A)] was employed to carry out the FI–spectrophotometric determination of MAP. A Gilson 2 minipulse peristaltic pump was used to transport the carrier solutions and a Reodhyne 50 valve, with a loop of 100 μl was employed for the injection of samples.

A and B channels were connected by a Y-shaped merging zone, in order to provide a good mixing between PAP and metaperiodate. A similar connection was made between channels C and D and a further connection was made to join the A/B channel and the C/D channel before the measurement zone.

Flexible peristaltic pump tubing of 1.52 mm internal diameter, which provides a carrier flow rate from 2 to 4 ml/min, in each channel, was used.

A 45 cm long coil (LR_1) permits one to obtain the quinoneimine of PAP from the oxidation of PAP by potassium metaperiodate (see the reaction scheme below). The LR_2, 45 cm long coil, provides an adequate alkaline medium for the reaction of samples with PAP. The LR_3 reaction coil, with a length of 800 cm, permits one to obtain a good reaction yield between MAP and the reactive quinoneimine in order to produce the blue dye, which is measured at 576 nm.

All the tubing employed to construct the reaction coils were made of Teflon with an internal diameter of 0.8 mm.

Alternatively to the above described manifold, a three channel assembly [see Fig. 1(B)] was employed in order to avoid an excessive dilution of samples.

On the other hand, some additional experiments were carried out in the stopped-flow mode, using a continuous aspiration of the samples by channel C, as can be seen in Fig. 1(C).

Reagents

All reagents were of analytical grade. Formetanate hydrochloride was supplied by Riedel-de Häen (Germany), *p*-aminophenol (PAP) was supplied by Fluka (Switzerland), *m*-aminophenol (MAP) was supplied by Aldrich (Germany), sodium hydroxide and potassium metaperiodate were supplied by Probus (Spain).

The stock standard solutions were prepared in demineralized distilled water as follows. To

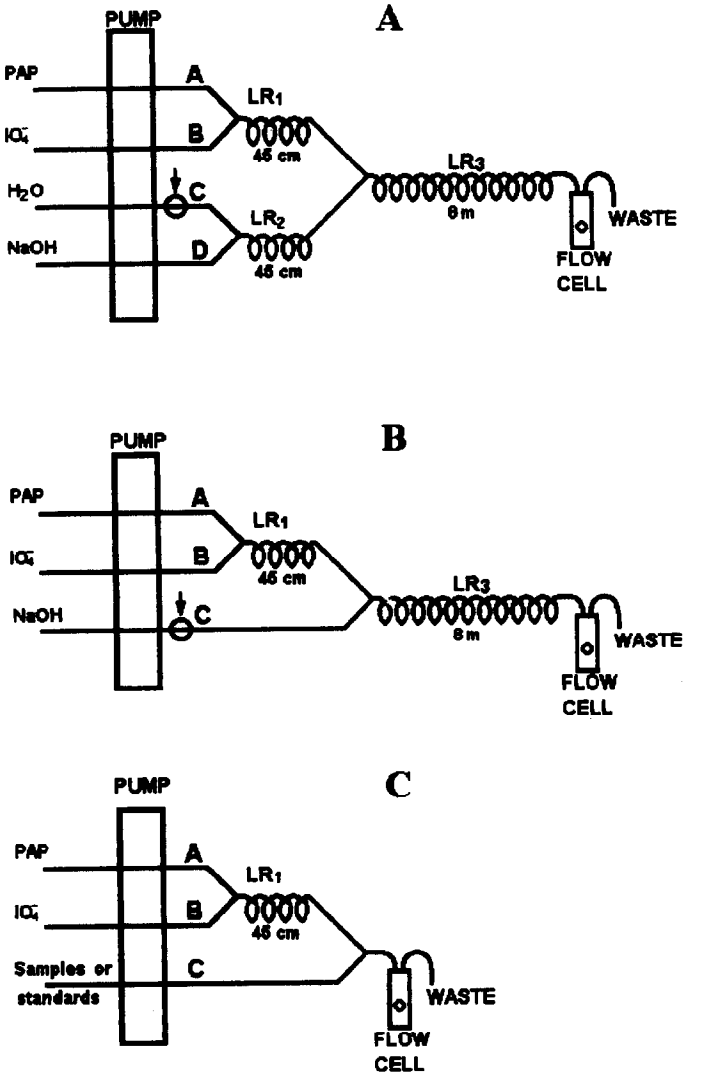

Fig. 1. Manifolds employed for the determination of *m*-aminophenol and formetanate. The length of the reaction coils has been established from experimental studies.

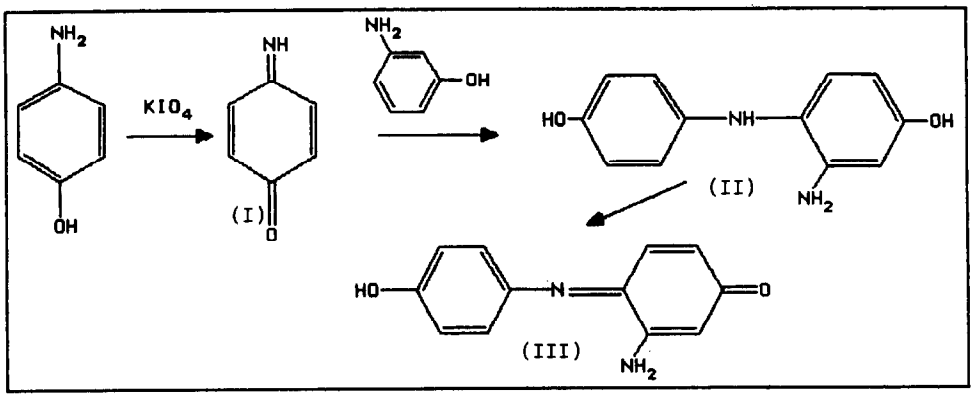
obtain a $3.88 \times 10^{-4}M$ formetanate solution, 10.0 mg of formetanate hydrochloride was dissolved in 100 ml of distilled water; then 50 ml of this solution was diluted to 100 ml with distilled water in order to obtain a $1.94 \times 10^{-4}M$ concentration. In all experiments the standard solution of formetanate was prepared and used the same day, in order to avoid any hydrolysis occurring. A $1.05 \times 10^{-3}M$ PAP solution was prepared by dissolving 0.0287 g in 250 ml of boiled and cooled distilled water (in order to avoid its oxidation by the dissolved oxygen); this solution is stable for more than 8 hr. Standard solution $9.16 \times 10^{-4}M$ MAP was prepared by dissolving 25.0 mg in 250 ml of distilled water. This latter solution is more stable than the PAP solution and does not need special conditions to be prepared.

RESULTS AND DISCUSSION

As previously reported,[50] PAP in alkaline medium and in the presence of a suitable oxidizing agent produces a reactive benzoquinoneimine (I), which can be coupled with MAP through the electrophilic attack on the C_4 of MAP, to give the corresponding diamine (II). (II) undergoes a rapid oxidation to a blue compound (III), as is shown in the following schematic diagram (see over).

Figure 2(A), shows the UV absorption spectra of MAP in distilled water, and in an alkaline medium. As can be seen, the formation of *m*-aminophenolate provides a bathochromic shift of the absorption maximum to 292 nm and it has a hyperchromic effect.



Scheme 1

It can be seen from Fig. 2(B) that the reaction between MAP and PAP provides a very high enhancement of the sensitivity and selectivity of the UV/V determinations of MAP. The reaction product has a maximum of the absorption spectrum at 576 nm.

We have applied the reaction with PAP, from an analytical point of view, to determine MAP in water; therefore, the effects of NaOH, potassium metaperiodate (employed as oxidizing agent), PAP concentrations as well as the reaction time, were studied and monitored by using a diode array spectrophotometer.

Several experiments carried out in batch (results not shown) indicate that $0.02M$ NaOH, $0.004M$ KIO_4 and $2.6 \times 10^{-4}M$ PAP, are the best conditions under which to carry out the reaction between MAP and PAP at room temperature, and so these concentrations were employed in the FI mode.

The variation of the absorbance at 576 nm as a function of time, for a mixture of MAP and PAP, at room temperature and using the oxygen of the air as an oxidizing agent shows that the colour of the reaction product develops gradually during the first 10 min and remains stable for more than 10 min. When potassium metaperiodate ($0.004M$) is used as the oxidizing agent, the reaction rate between MAP and PAP increases rapidly and a reaction time of the order of 120 sec is sufficient to obtain stable absorbance measurements. On the other hand, a typical calibration equation $A = 0.035 + 17{,}100\ C\ (M)$ with a regression coefficient $R = 0.998$ was obtained for MAP concentrations.

An increase in the concentrations of NaOH, KIO_4 and PAP as well as the use of a temperature higher than 90°C, provide an increase in the reaction rate between MAP and PAP. However, the stability of the reaction product is reduced in these conditions and the excess of PAP is decomposed by KIO_4 and NaOH providing an increase in the background. So,

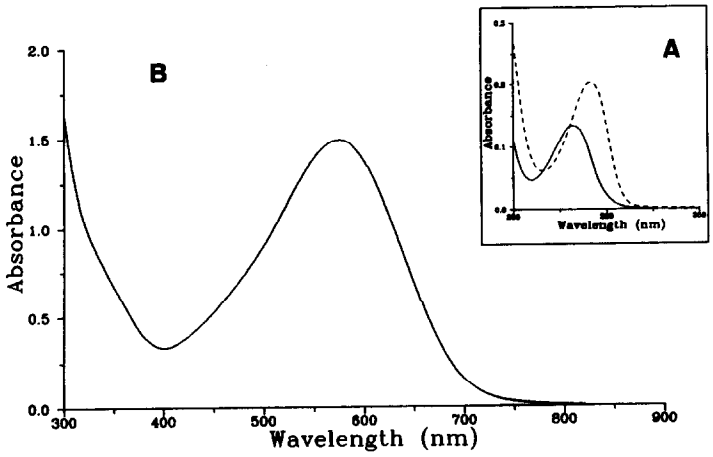


Fig. 2. (A) UV spectra of $7.3 \times 10^{-5}M$ of *m*-aminophenol in distilled water (——) and in $0.2M$ NaOH (– – –). (B) UV/V spectrum of $7.3 \times 10^{-5}M$ of MAP after reaction with $2.6 \times 10^{-4}M$ of PAP in the presence of $0.004M$ of KIO_4. The measurements were taken 2 min after mixing.

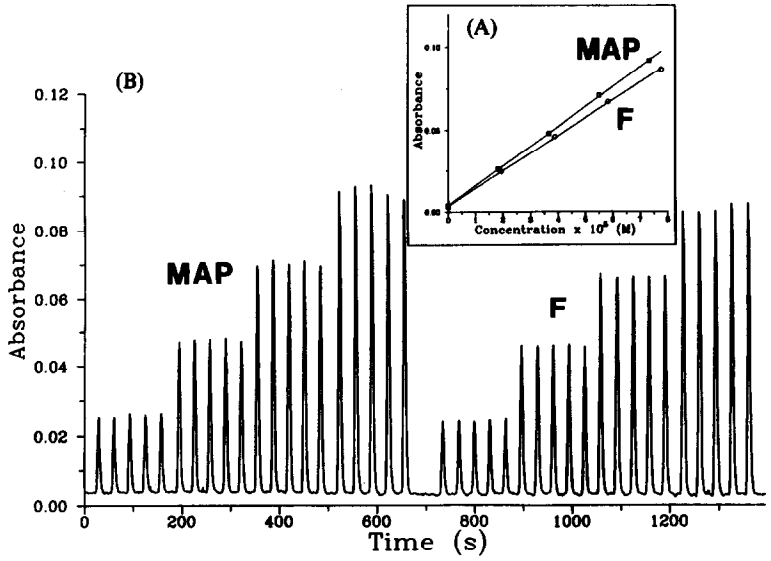

Fig. 3. (A) Calibration graph obtained for the determination of MAP and formetanate (F). (B) FI recording for these calibration graphs.

the use of concentrations higher than those recommended or the use of high temperatures must be avoided.

FI SPECTROPHOTOMETRIC DETERMINATION OF MAP

In order to develop a FI spectrophotometric procedure for the analysis of MAP with PAP, the concentrations of NaOH, KIO_4 and PAP, previously established in batch, were employed. For the above mentioned concentrations of reagents the effect of flow rates of the carrier streams (from 2 to 4 ml/min in each one) and lengths of the reaction coils (LR_1, from 10 cm to 1 m, LR_3 from 1 to 10 m), were studied in a univariate mode. LR_2 was fixed of 45 cm. The obtained results indicate that $LR_1 = 45$ cm, $LR_3 = 8$ m and a flow rate of 2.3 ml/min per channel were the best conditions under which to carry out the reaction between MAP and PAP, providing high absorbance values with low background levels.

A series of standard solutions of MAP were injected in the manifold and the absorbance at 576 nm was monitored as a function of time.

Figure 3 shows the FI-recording profiles and a calibration graph of MAP (from 0 to $7.33 \times 10^{-5}M$) in distilled water, which provides a linear-relationship over the investigated range with the following regression features:

$$A = 0.003 + 1440\ C\ (C \text{ in } M)$$

The regression coefficient, R, for this line was 0.9999. As compared with the regression line found in batch after 120 sec, it can be seen that the FI procedure involves a strong reduction in the analytical sensitivity; however, the FI measurements are carried out in a short period of time and this avoids the PAP decomposition and so, a better intercept value was obtained. The limit of detection in these conditions was $5 \times 10^{-7}M$ of MAP, which is appropriate for the analysis of water samples. The standard deviation of five replicate measurements of a concentration $3.66 \times 10^{-5}M$ of MAP was 1.8%. Using the three channel manifold the sensitivity increases up to 1920 absorbance units mol^{-1} l and the limit of detection reduced to $4 \times 10^{-7}M$. The developed procedure permits one to carry out more than 120 injections/hr, which is an additional advantage of the FI methodology.

DIRECT DETERMINATION OF *m*-AMINOPHENOL IN WATER

To show the applicability of the developed method for the analysis of MAP, three types of natural water, from different sources (tap, irrigation and well water), have been fortified with different concentrations of MAP. The spiked samples were analysed by using the recommended FI procedure. The obtained results, summarized in Table 1, show that the reaction between PAP and MAP is not affected by the sample matrices, and relative errors lower than 8% were found in all cases for MAP concentrations of the order of $10^{-5}M$. On the other hand the relative standard deviation

Table 1. FI spectrophotometric analysis of MAP in spiked water samples

Water	*m*-aminophenol added, *M*	*m*-aminophenol found, *M*	E_r, %

	1.10×10^{-4}	$(1.13 \pm 0.03) \times 10^{-4}$	+2.7

Results found are the average of three independent analyses of each sample ± the standard deviation.
E_r (%): relative error in percentage.

obtained for three independent analyses of the same sample was lower than 1%.

HYDROLYSIS OF FORMETANATE

Formetanate does not react with PAP; it must be previously hydrolysed to MAP in order to carry out its spectrophotometric determination by the above mentioned reaction. The alkaline hydrolysis of formetanate, and similar compounds, to phenols has been reported.[12,51–54] All the previous works indicate that the hydrolysis of formetanate is very slow even at 60°C. The effects of sodium hydroxide (from 0.02 to 0.3*M*) and time on the hydrolysis of formetanate were studied at 90°C, for a concentration $7.77 \times 10^{-5}M$ of formetanate, and the absorbance measurements were carried out in batch. The obtained results show that a NaOH concentration of 0.02*M* provides the quantitative hydrolysis of formetanate in 130 min, and 0.1*M* NaOH permits the total hydrolysis in 40 min. A 0.05*M* NaOH concentration provides a 95% hydrolysis yield in 1 hr and this was selected for the formetanate hydrolysis in order to avoid the use of high concentrations of sodium hydroxide, which affects the reaction between PAP and MAP.

On the other hand, it has been noticed that, a heating time for formetanate higher than 1 hr causes a slight degradation of the resulted MAP and so, another absorption maximum could have appeared at 325 nm. The same thing takes place with standard MAP in distilled water heated for long periods of time. However, in the recommended conditions these problems are avoided.

The slow hydrolysis process of formetanate avoids the possibility of carrying out this process on-line and so, for the FI spectrophotometric determinaton of formetanate, the following procedure must be followed. Take the sample, add NaOH to obtain a 0.05*M* NaOH concentration, and allow to stand in a thermostatic water bath at 90°C for 1 hr, then cool at room temperature and after that, take 100 μl of the hydrolyzed sample and inject it in the FI-manifold indicated in Fig. 1. Standard aqueous solutions of formetanate are treated with a NaOH solution in the same conditions as samples.

FI SPECTROPHOTOMETRIC ANALYSIS OF FORMETANATE

The alkaline hydrolysis of formetanate and the injection of the obtained MAP in the FI-manifold provides good analytical signals at 576 nm, which corresponds to the blue form of the reaction product between PAP and MAP.

Figure 3 shows the calibration graph obtained from the injection of standard solutions of formetanate (from 0 to $7.77 \times 10^{-5}M$), previously heated at 90°C for 1 hr and cooled at room temperature. The regression characteristic features of this analytical curve are:

$$A = 0.003 + 1070\ C\ (C \text{ in } M)$$

with a regression coefficient of 0.9998 which provides a detection limit of $1.9 \times 10^{-7}M$ formetanate (which corresponds to 0.05 mg/l). The relative standard deviation of five replicate measurements of a solution with a concentration of $3.9 \times 10^{-5}M$ formetanate was 0.5%.

On comparing this curve with that obtained for MAP in the same work session (see Fig. 3), it can be concluded that the 10% reduction of the analytical sensitivity found for formetanate analysis is due to the non-quantitative hydrolysis of the pesticide in the recommended conditions; so, it is necessary to calibrate the system

with formetanate standard solution treated in the same way as samples.

On the other hand, low levels of formetanate have been determined by the above mentioned procedure in irrigation waters, treated with this pesticide. Results found agree with those previously obtained and, for example, a concentration of $1.7 \pm 0.2 \times 10^{-6}M$ (0.44 ± 0.05 mg/l) of formetanate was found in a sample containing $1.9 \times 10^{-6}M$ (which corresponds to 0.5 mg/l) and $5.3 \pm 0.2 \times 10^{-6}M$ (1.37 ± 0.05 mg/l) was found in another irrigation water containing $5.8 \times 10^{-6}M$ which corresponds to 1.5 mg/l. Note that for these low levels of formetanate concentrations the relative standard deviation of three analyses was 11% and 3.6%, respectively, one order of magnitude higher than those found for the determination of a concentration $10^{-5}M$.

STOPPED-FLOW DETERMINATION OF FORMETANATE

In order to increase the sensitivity of the spectrophotometric determination of both MAP and formetanate, some experiences were carried out in the stopped-flow mode. For this purpose the manifold indicated in Fig. 1(C) was employed.

The use of a three channel manifold reduces the sample dispersion and the stopped-flow avoids the use of a long reaction coil.

Previous experiments, carried out with a 20 mg/l of formetanate previously hydrolyzed, showed that 100 sec is the minimum time required to obtain a maximum sensitivity for the determination of MAP and PAP in the stopped-flow mode and using the KIO_4, NaOH and PAP concentrations previously recommended.

In the above mentioned conditions, a typical calibration line for the determination of formetanate after hydrolysis to MAP corresponds to:

$$A = 0.008 + 4640\ C\ (C \text{ in } M)$$

with a regression coefficient of 0.9998. So, the sensitivity is increased four times, as compared with results found in the flow injection mode. However, the use of high reaction times also increases the degradation of PAP and so, an increase of the blank measurements was found. So, the limit of detection was only 44 μg/l which is comparable to that found in the FI mode.

The standard deviation of three independent measurements of a sample containing $5.8 \times 10^{-5}M$ formetanate was 1.5% and, in summary, it must be accepted that the use of the stopped-flow approach does not improve the limit of detection and reduces the sample throughput.

ANALYSIS OF MIXTURES OF FORMETANATE AND MAP

The fact that formetanate does not react directly with PAP offers the possibility to determine sequentially both formetanate residue and MAP, in the same sample. The procedure involves two steps: a direct determination of MAP in the presence of non-hydrolyzed formetanate, and the determination of the sum of MAP and formetanate after hydrolysis with NaOH and subsequent reaction with PAP.

To obtain an indication about the suitability of the developed procedure to determine MAP in partially hydrolyzed samples, a series of synthetic mixtures of formetanate and MAP were prepared in distilled water. The obtained results for MAP are indicated in Table 2, and it can be seen that a recovery percentage from 101 to 105% was found. The slight increase in the obtained results is due to partial hydrolysis of formetanate by the NaOH solution used in the FI-manifold.

Further evidence was also found about the applicability of the proposed method by analysing a series of synthetic mixtures of formetanate (freshly prepared) and MAP which were prepared in a matrix of irrigation water.

Table 2. FI spectrophotometric determination of MAP in mixtures of formetanate and *m*-aminophenol in distilled water

Formetanate added ($\times 10^{-5}$)	*m*-aminophenol added ($\times 10^{-5}$)	*m*-aminophenol found ($\times 10^{-5}$)	Recovery (%)
1.94	1.83	(1.86 ± 0.04)	101.3
3.89	3.67	(3.73 ± 0.08)	101.8
5.83	5.50	(5.63 ± 0.06)	102.4
7.77	1.83	(1.93 ± 0.02)	105.4

Values found correspond to the average of three independent analyses of each sample $\pm$ the standard deviation.

Table 3. FI spectrophotometric analysis of irrigation water fortified with synthetic mixtures of formetanate and *m*-aminophenol

Formetanate added ($\times 10^{-5}$)	*m*-aminophenol added ($\times 10^{-5}$)	*m*-aminophenol found ($\times 10^{-5}$)	Recovery (%)	Total MAP found	Recovery (%)
1.94	1.83	(1.80 ± 0.06)	98	$(3.85 \pm 0.04) \times 10^{-5}$	103
3.89	3.67	(3.48 ± 0.02)	96	$(8.25 \pm 0.04) \times 10^{-5}$	113
5.83	5.50	(5.22 ± 0.03)	95	$(1.28 \pm 0.07) \times 10^{-4}$	113
7.77	1.83	(1.92 ± 0.02)	104	$(1.044 \pm 0.005) \times 10^{-4}$	108

Total MAP found corresponds to the sum of MAP and formetanate measured after the hydrolysis of the latter.

MAP was directly analysed and after that, samples were hydrolyzed and then analysed using a standard calibration graph of formetanate treated in the same way as the samples. Table 3, indicates that recovery percentages from 95 to 104% were obtained in the analysis of MAP in the presence of formetanate. The recovery percentage of the sum of MAP and formetanate varies from 103 to 113% and so, it can be concluded that the developed methodology permits one to quantitatively recover MAP and the sum of MAP and formetanate in the same sample.

SELECTIVITY OF THE DEVELOPED PROCEDURE

The benzoquinoneimine form of PAP reacts with phenols by an electrophilic attack to produce the corresponding dihydroxyamine. Thus, the determination of MAP by the developed procedure can be affected by any phenolic compound with a free para position; and, on the other hand, after the previous hydrolysis step, any compound which could be hydrolyzed by NaOH to form a para position free phenol, could interfere with the determination of formetanate.

However, the selectivity of the FI spectrophotometric determination of MAP and formetanate with PAP can be due to the differences observed between the maximum wavelength at which the PAP derivatives of different compounds absorb and on the different reaction rates and conditions found for each compound, as for example, the spectrophotometric determination of propoxur by reaction with PAP requires the use of $0.33M$ NaOH, $9 \times 10^{-3}M$ PAP and $0.02M$ KIO_4 as compared with formetanate which requires lower concentrations of each one of these reagents. On the other hand the reaction product of PAP with the hydrolysis product of propoxur absorbs at 600 nm instead of the 576 nm wavelength employed for MAP.

From these comments it can be concluded that the developed procedure is especially interesting for the evaluation of pesticide residues in water samples when crops were treated with formetanate and that, in the analysis of ground water a careful standardization must be carried out.

CONCLUSIONS

The studies carried out show that the reaction of MAP with PAP, in the presence of KIO_4, provides a sensitive and selective way for the determination of MAP in water samples. MAP can be directly analysed in the presence of formetanate and the sum of both MAP and formetanate can be established after the alkaline hydrolysis of formetanate.

The developed method permits one to follow up the degradation of formetanate in environmental waters. Also, it can be successfully used to determine concentrations of the order of $1.8 \times 10^{-6}M$ of *m*-aminophenol or formetanate in real water samples, which correspond to 0.2 and 0.5 mg/l, respectively, with a high sample throughput. The method is very economical and does not need any clean up step, which is an important advantage compared with the previously developed methods for formetanate or MAP determination.

Also, this is the only proposed methodology for the determination of MAP and formetanate in the same sample. The only draw-back of the method is the relatively high limit of detection found, but, the sensitivity of the procedure could be improved by using a preconcentration step based on sorbent or solvent extraction procedures, in order to obtain a better limit of detection.

TRACE MEASUREMENT OF DIPYRIDAMOLE BY ADSORPTIVE STRIPPING VOLTAMMETRY

XIANGQUN ZENG, SHUCHANG LIN and NAIFEI HU*
Department of Chemistry, Beijing Normal University, Beijing 100875, P. R. China

(*Received* 19 *November* 1992. *Revised* 8 *February* 1993. *Accepted* 18 *February* 1993)

Summary—A sensitive adsorptive stripping voltammetric method for trace measurement of dipyridamole in alkaline solution is described. The method is based on the adsorptive accumulation of the drug at the hanging mercury drop electrode, followed by linear sweep voltammetric determination. The response is evaluated with respect to percentage of ethanol, preconcentration time and potential, and concentration of NaOH. The detection limit of $1.0 \times 10^{-9}M$ is obtained under optimized conditions with a 5-min preconcentration. Applicability to injection, tablets and urine analysis is illustrated.

Dipyridamole (DPRM) is known for its effective treatment of heart diseases. Its structure is shown in Fig. 1. The drug can be easily absorbed by the human body and enter into blood. Its effect in the body lasts long and the concentration in urine and blood is low. Highly sensitive methods are thus essential for the determination of dipyridamole. Various chromatographic,[1,2] and spectroscopic[3,4] procedures have been employed for this purpose. However, electrochemistry has not been widely used for measurements of dipyridamole. The drug produces a single 4-electron polarographic reduction wave in alkaline solution.[5] This polarographic method yielded detection limits in the micromolar level that were sufficient only for tablet assay.

The present work reports a sensitive voltammetric procedure for trace measurement of dipyridamole, based on its adsorptive accumulation at a hanging mercury drop electrode. Adsorptive stripping voltammetry has been used for trace measurements of numerous compounds of pharmaceutical significance.[6] As illustrated in this paper, this method yielded detection limits at the subnanomolar levels for measuring dipyridamole. The characteristics of the resulting adsorptive stripping scheme are elucidated and the electrode reaction mechanism is discussed.

EXPERIMENTAL

Apparatus

A model 370 electrochemistry system (EG&G Princeton Applied Research) was used for cyclic voltammetry. The working electrode was a model 303 static mercury drop electrode (SDME). A medium sized drop (surface area 0.0171 cm^2) was employed. The counter electrode was a platinum wire and the reference electrode was a saturated Ag/AgCl electrode.

Chemicals

Dipyridamole was from Beijing Yimin Pharmaceutical Factory. A stock standard solution of dipyridamole in ethanol ($1.00 \times 10^{-2}M$) was prepared and stored in the dark; working standard solutions ($1.00 \times 10^{-4}M$, $1.00 \times 10^{-5}M$ and $1.00 \times 10^{-6}M$) were prepared by dilution with water. All other chemicals were of analytical reagent grade. Triply distilled water was used throughout.

Procedure

A 10-ml volume of $0.05M$ sodium hydroxide containing a specific amount of sample solution and 10%(v/v) ethanol was added to the cell and purged with purified nitrogen to remove oxygen for 4 min. The preconcentration potential (−1.2 V) was applied to a new mercury drop for a selected time while the solution was stirred at 400 rpm. The stirring was then stopped, and after 15 sec the voltamperogram was recorded by applying a linear sweep scan. The scan was terminated at −1.6 V.

RESULTS AND DISCUSSION

Adsorptive properties

Figure 2 is a repetitive cyclic voltamperogram for $5 \times 10^{-7}M$ dipyridamole, recorded after

*Author for correspondence.

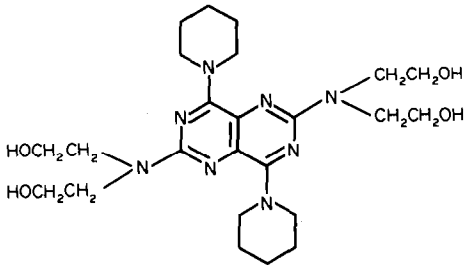

Fig. 1. Structure of dipyridamole.

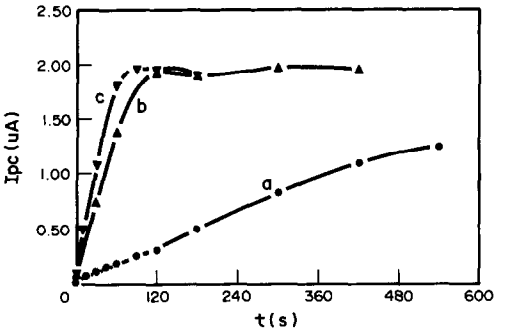

Fig. 3. Effect of preconcentration time on the cathodic voltammetric peak current for $1 \times 10^{-7}M$ (a), $6 \times 10^{-7}M$ (b) and $1 \times 10^{-6}M$ (c) dipyridamole. Other conditions as for Fig. 2.

preconcentration at -1.2 V for 30 sec. A large and well-defined cathodic peak is observed at the first scan (designated as 1) at -1.42 V. Subsequent scans exhibit a dramatic decrease of the peak to a stable value representing the response of solution species. This is an obvious indication that dipyridamole has adsorptive characteristics at a Hg electrode. No peaks are observed in the anodic branch, illustrating that the reduction of dipyridamole at the Hg electrode is irreversible.

Figure 3 shows plots of cathodic peak current (i_{pc}) of linear sweep voltammetry *vs.* preconcentration time (t) for different concentrations of dipyridamole. At first, i_{pc} increased linearly with t at all three levels, indicating that before adsorptive equilibrium is reached, the longer the preconcentration time, the more dipyridamole was adsorbed, and the larger the peak current. However, after a specific period of accumulation time, the peak current at different concentration levels invariably tended to level off, showing that the adsorptive equilibrium of dipyridamole on the Hg electrode surface was achieved.

The adsorption of dipyridamole can be used as an effective preconcentration step before the voltammetric measurement. In this way, highly sensitive adsorptive stripping measurements of the drug can be achieved.

Selection of experimental conditions

Various supporting electrolytes, such as HCl, HOAc–NaAc, NH_3–NH_4Cl, KH_2PO_4–K_2HPO_4, NaOH and Britton-Robinson buffer solution were tested by adsorptive stripping voltammetry, and NaOH was found to be the best because of the well-defined voltamperogram and reasonably high sensitivity.

The amount of ethanol added to the dipyridamole solution strongly affects the adsorptive stripping response (Fig. 4). For example, increasing the percentage of ethanol (v/v) from 0 to 10 resulted in a sharp increase in the peak,

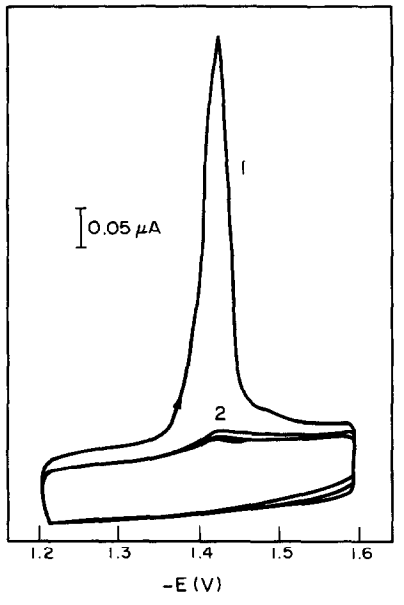

Fig. 2. Repetitive cyclic voltamperograms for $5 \times 10^{-7}M$ dipyridamole after 30 sec accumulation at -1.2 V. Scan rate, 100 mV/sec. Electrolyte, 0.05M NaOH, 10%(v/v) ethanol.

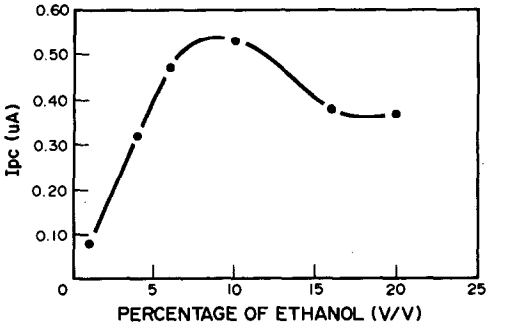

Fig. 4. Effect of the amount of ethanol added to dipyridamole system on the cathodic response. Dipyridamole concentration, $3 \times 10^{-7}M$. Preconcentration time, 60 sec. Other conditions as for Fig. 2.

but a rapid decrease in the response was observed when the percentage of ethanol was larger than 10. The dependence of i_{pc} on the preconcentration potentials was also examined. The results showed that between -0.8 and -1.2 V, i_{pc} kept almost constant at a high level, but above -0.75 V or below -1.25 V it decreased. The concentration of NaOH effects the peak current of dipyridamole, too. The experiments revealed that a concentration of NaOH larger than 0.05M (pH 12.7) offered the best responses.

The adsorptive stripping voltammetric response of dipyridamole was further characterized concerning concentration dependence, detection limit and reproducibility. Under the optimized condition of 10%(v/v) ethanol, 0.05M NaOH and preconcentration potential of -1.2 V, the peak current had a linear relationship with c_{DPRM} over the range from 5.0×10^{-9} to $1.0 \times 10^{-6}M$ when the accumulation time was 60 sec (correlation coefficient 0.9989). The detection limit could reach $1.0 \times 10^{-9}M$ when the preconcentration time was set to 5 min (S/N = 3). The precision was estimated by 12 successive measurements of $5 \times 10^{-7}M$ dipyridamole under the same conditions as above but with accumulation of 15 sec. The average peak current was 0.342 μA, range 0.325–0.370 μA, and relative standard deviation 1.7%.

System weakly adsorbed reactant

Figure 5 indicates the effect of scan rate on i_{pc} at different preconcentration times. When $t = 0$, i_{pc} had a linear relationship with $v^{1/2}$ illustrating the reduction of dipyridamole was diffusion-controlled [curve (a)]. When $t = 10$ sec, the i_{pc} *vs.* $v^{1/2}$ curve showed an upward slope, indicating that the system began to show some adsorptive characteristics [curve (b)]. When

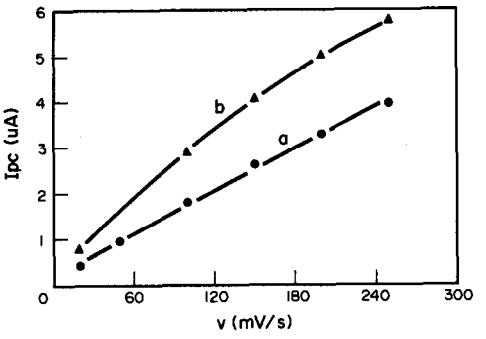

Fig. 6. Influence of scan rate on the cathodic peak current. Dipyridamole concentration, $1 \times 10^{-6}M$ (a) and $2 \times 10^{-5}M$ (b). Preconcentration time, 60 sec. Other conditions as for Fig. 2.

$t = 60$ sec, the upward turning of i_{pc}–$v^{1/2}$ curve was more pronounced [curve (c)] and i_{pc}–v curve became a straight line [Fig. 6, (a)], suggesting the electrode process now was adsorption-controlled.

The effect of c_{DPRM} on i_{pc} at two different accumulation times is shown in Fig. 7. When $t = 0$, the relative peak current expressed as the ratio of i_{pc}/c_{DPRM} was small and kept nearly constant with increasing the concentration of dipyridamole [curve (a)]. This indicates that the reduction of dipyridamole at Hg electrode is almost totally diffusion-controlled. However, when $t = 60$ sec, the values of i_{pc}/c_{DPRM} were much greater than those of curve (a) at lower c_{DPRM} because of the adsorption of dipyridamole on the Hg surface. At higher c_{DPRM}, the adsorption of dipyridamole reached saturation and its contribution to peak current did not increase any more. The ratio then declined very rapidly with increasing concentration of dipyridamole, and eventually tended toward the constant value of curve (a) [curve (b)]. Even with 60 sec of accumulation, the i_{pc} *vs.* v relationship at

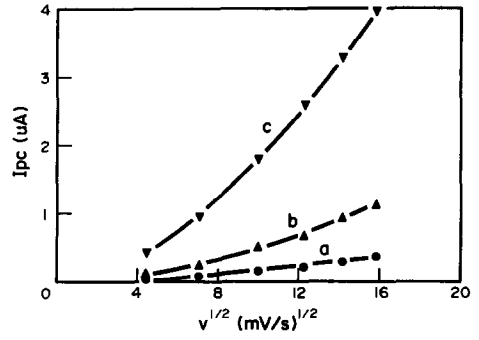

Fig. 5. Influence of square root of scan rate on the cathodic peak current. Preconcentration period, 0 sec (a), 10 sec (b) and 60 sec (c). Dipyridamole concentration, $1 \times 10^{-6}M$. Other conditions as for Fig. 2.

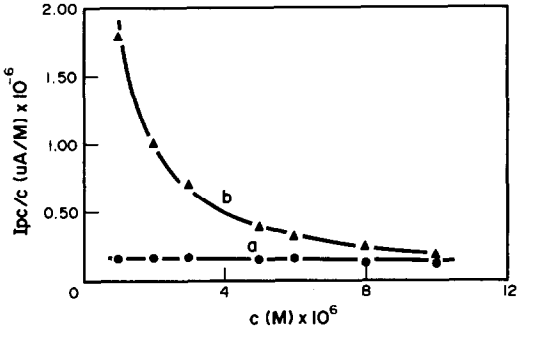

Fig. 7. Effect of concentration of dipyridamole on relative peak current as the ratio of cathodic peak current to dipyridamole concentration. Preconcentration period, 0 sec (a) and 60 sec (b). Other conditions as for Fig. 2.

higher concentration of dipyridamole was not a straight line but a downward bending curve [Fig. 6 (b)]. All of these suggest the gradual transformation of the system from adsorption-controlled to diffusion-controlled when the concentration of dipyridamole grows.

In summary, the reduction of dipyridamole at Hg electrode is contributed to by the reduction of both surface species adsorbed on the electrode surface and solution species diffusing to the electrode surface. However, because the adsorption of dipyridamole is not strong enough, both of the adsorbed and solution species are reduced at the same potential. The cathodic peak current is thus made up of two parts: adsorption current and diffusion current. The preconcentration time, scan rate and concentrations of dipyridamole have different effects on them. Generally, in the condition of smaller c_{DPRM}, faster v and longer t, the system manifests itself mainly with adsorptive properties, but in the condition of larger c_{DPRM}, slower v and shorter t, the system essentially exhibits diffusion properties. This is characteristic of the system when the reactant is weakly adsorbed.[7]

Measurement of the number of electrons transferred

Electrolysis experiments at the potential of -1.6 V with large area of Hg cathode showed that the number of electrons transferred per dipyridamole molecule, n, was 4. This result is in good agreement with that of Boneva.[5] The mechanism of reduction of dipyridamole is not very clear now and the study in our lab is still under way. There are two pyrimidine rings in a dipyridamole molecule. Preliminary UV-visible spectroscopic experiments of dipyridamole system before and after electrolysis indicated that the functional group undergoing reduction was probably the two imines in one of the two pyrimidine rings. Each of the two imines in the same pyrimidine ring may gain 2 electrons and become an amine. The dipyridamole could then retain another pyrimidine ring of conjugate system after electrolysis.

Measurement of the amount of dipyridamole adsorbed

As mentioned above, under the condition of low c_{DPRM}, long t and fast v, the reduction of dipyridamole can be considered to be totally controlled by adsorption of dipyridamole. In this case, the cathodic peak current almost decays to its baseline with little diffusion tail (ref. Fig. 2). Integration of this peak gives a charge Q_a, which represents the reduced charge of surface species of dipyridamole adsorbed at Hg electrode. According to the equation

$$\Gamma = Q_a/(nFA)$$

the surface coverage Γ (mol/cm^2) can then be calculated, where A is the area of electrode (0.0171 cm^2), n is the number of electrons transferred (4) and F is the Faraday constant.

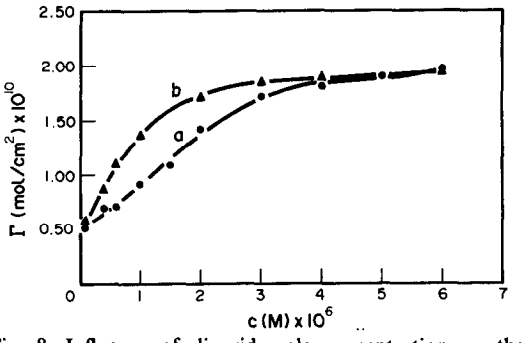

Fig. 8. Influence of dipyridamole concentration on the amount of dipyridamole adsorbed on Hg electrode surface. Preconcentration time, 30 sec (a) and 90 sec (b).

Figure 8 illustrates the relationship between Γ and c_{DPRM} at two different accumulation times. When the concentration of dipyridamole was small, the surface coverage increased linearly with c_{DPRM}. However, at higher concentration of dipyridamole, the curves tended to level off. Γ at two different levels tended to reach the same constant value, which represented full surface coverage of 1.94×10^{-10} mol/cm^2. Each dipyridamole molecule adsorbed thus occupied an area of 0.85 nm^2 if the adsorption of dipyridamole was monolayer adsorption.

Analysis of samples

Measurements of dipyridamole in injection samples were performed by the adsorptive stripping voltammetry. No sample preparation was used other than dilution with the supporting electrolyte. The determination was performed by the standard addition method and the results of a few analyses are given in Table 1.

Table 1. Analytical results of dipyridamole in injection samples

Sample	n	Mean value, mg/injection	S	Recovery of added DPRM,%
1	6	9.54	0.34	88
2	6	9.79	0.34	92

This method was also used to determine dipyridamole in tablets. Before analysis, a sample solution of dipyridamole tablet was prepared by grinding, dissolving and filtering. The excipients in the tablet (starch, talc, *etc.*) did not interfere in the voltamperogram. The results of determination were satisfied. For example, 5 repeated measurements of a tablet showed that the average amount of dipyridamole was 24.6 ± 2.3 mg per tablet with RSD 9.4% and the recovery was 105%.

Determinations of dipyridamole in urine of several patients who took the drug through injection or tablets were also made by the method. Some extraction procedures were required before analysis because of interference by other substances in urine. The results showed that within 24 hr after the patients took the drug, the concentrations of dipyridamole in their urine were in the order of 10^{-5}–$10^{-4}M$.

All of these experiments illustrate the feasibility of measuring dipyridamole in the samples of injection, tablets and urine.

DETERMINATION OF DIBENZO[b,f]-1,4-OXAZEPINE BY DIAZOTIZATION CLEAVAGE OF AZOMETHINE BOND

EMIL HALÁMEK and ZBYNĚK KOBLIHA
Department of Chemistry, Faculty of Arms, Military University, 682 03 Vyškov, Czech Republic

VILIAM FÖLDEŠI
Army Factory VOZ 072, 972 43 Zemianské Kostolany, Slovak Republic

(*Received* 16 *November* 1992. *Revised* 4 *February* 1993. *Accepted* 4 *February* 1993)

Summary—A spectrophotometric determination of dibenzo[b,f]-1,4-oxazepine (CR) has been elaborated, which is based on a diazotation cleavage of azomethine bond followed by a coupling reaction. Twelve coupling agents have been used in the experiments and the following three agents have been recommended for the determination: *N*-(1-naphthyl)ethylenediamine dihydrochloride ($L_Q = 85$ mg/ml), 7-hydroxy-4-methyl coumarin ($L_Q = 105$ mg/ml) and 1-naphthol ($L_Q = 110$ mg/ml). 2-[2-(hydroxy-1-naphthylazo) phenoxy]benzaldehyde has been identified by ^1H and ^{13}C NMR and elementary analysis as the product which results from the diazotization reaction followed by coupling of the CR substance with 2-naphthol. The azo-dye prepared by the described reactions shows azo-hydrazo tautomerism.

Apart from bromobenzyl cyanide (BBC), chloroaceto phenone (CN) and *o*-chlorobenzylidene malononitrile (CS), the dibenzo[b,f]-1,4-oxazepine (CR) is, for the time being, the latest representative of a large group of irritants used in war conflicts and for police purposes.

The tricyclic heterocompounds, among which the CR substance belongs, are used in medicine as antidepressants.

A number of physical methods of determination of the CR substance[1] have been used, apart from the extraction spectrophotometry of ion associates of the proteinized base with some anion active dyes.[2]

Dibenzo[b,f]-1,4-oxazepine is a relatively stable chemical substance. So far, only oxidation[3,4] and chlorination[5] reactions of CR substance have been described.

The purpose of our effort has been to develop a spectrophotometric determination of CR substance based on diazotation cleavage of the azomethine bond and consequent coupling with selected coupling agents, and to identify the product of reaction with 2-naphthol.

EXPERIMENTAL

Chemicals and instruments

Dibenzo[b,f]-1,4-oxazepine (99.5% m/m) was synthesized[6] in the Army Factory VOZ 072, Zemianské Kostolany, Slovak Republic. Its purity was checked by means of extraction spectrophotometry using azodye Orange II ($\lambda_{max} = 480$ nm, $CHCl_3$).[7] The coupling agents *N*-(1-naphthyl)ethylenediamine dihydrochloride (1, *i.e.*, Bratton–Marshall agent), 1-naphthyl amine (2), 8-anilino-1-naphthalene sulphonic acid (3), phloroglucinol dihydrate (4), 1-naphthol (5), resorcinol (6), 7-hydroxy-4-methyl coumarin (7), 4-amino-5-hydroxy-2,7-naphthalene disulphonic acid monosodium salt (8), 3-methyl-1-phenyl-2-pyrazoline-5-one (9), 4,5-dihydroxynaphthalene-2,7-disulphonic acid disodium salt (10) (chromotropic acid disodium salt), 2-naphthol (11) and 4-amino-2,6-dihydroxy pyrimidine (12) (6-amino uracil) were supplied by Merck. The other chemicals were supplied by Lachema, Brno and were of analytical purity.

^1H and ^{13}C NMR spectra were measured by the instrument Bruker AM 400. Elemental analyses were carried out by the Elemental Analyser Model 1102, Carlo Erba. Spectrophotometric determinations were carried out by the spectrophotometer Spekol 11, Zeiss, Jena.

Procedures

(A) Into 5 ml calibrated test tubes were pipetted 10–100 μl of 0.5*mM* solution of the

CR substance in 2*M* HCl, 0.1 ml of mixture (1:1 vol) of dimethyl formamide (DMF) and 2*M* HCl and 0.1 ml of 10*mM* aqueous solution of $NaNO_2$. The test tubes were shaken for 5 min and then 0.1 ml of 0.5*M* aqueous solution of amido sulphuric acid was added. The test tubes were shaken for 3 min. Then 0.1 ml of the coupling agent ($c = 0.1M$) in 2.8*M* NaOH was added. The reaction mixture was allowed to stand for 5 min and then 0.1*M* NaOH was added to make up the final volume of 2 ml. The absorbance was measured at λ_{max} in 1 cm cuvette.

(B) Into 5 ml calibrated test tubes were pipetted 10–100 μl of 0.5*mM* solution of the CR substance in 2*M* HCl, 0.1 ml of mixture (1:1 vol) of dimethyl formamide (DMF) and 2*M* HCl and 0.1 ml of 10*mM* aqueous solution of $NaNO_2$. The test tubes were shaken for 5 min and then 0.1 ml of 0.1*M* aqueous solution of amido sulphuric acid was added. After shaking for 3 min 0.1 ml of the coupling agent was added ($c = 0.1M$) in a mixture of DMF and 2*M* HCl in the ratio 1:1. After 5 min standing the reaction mixture was made up to 2 ml with a mixture of DMF and 2*M* HCl. Absorbance was measured at λ_{max}.

(C) Into 5 ml calibrated test tubes were pipetted 10–100 μl of 0.5*mM* solution of the CR substance in 2*M* HCl and 0.1 ml of 74*mM* aqueous solution of $NaNO_2$. After 5 min shaking, 0.1 ml of 0.5*M* aqueous solution of amido sulphuric acid was added. After 3 min shaking 0.1 ml of aqueous solution of the coupling agent was added ($c = 0.1M$). After an additional 5 min, the reaction mixture was made up to 2 ml with 1*M* HCl and absorbance was measured at λ_{max}.

Preparation and identification of 2-[2-(2-*hydroxy*-1-*naphthylazo*)*phenoxy*]*benzaldehyde*

In a mixture of 16 ml DMF, 8 ml concentrated sulphuric acid and 10 ml water, 0.9761 g of CR substance were dissolved. After cooling to $T = 8°C$, 0.422 g $NaNO_2$ in 10 ml of water were added. The reaction mixture was stirred until all the color disappeared ($t = 30$ min), then 3 ml of aqueous solution of 0.15 g of amido sulphuric acid were added and the mixture was stirred for 10 min. The prepared diazonium compound was gradually poured with vigorous stirring into a solution of 0.721 g of 2-naphthol dissolved in 22.5 ml of 2.8*M* NaOH. The temperature of the reaction mixture did not exceed 10°C. After stirring for 40 min the reaction mixture was filtered. The filtration cake was washed with water and recrystallized from 15 ml of acetic acid. The crystallized product was sucked off and washed by a small amount of ethanol. Melting point of 2-[2-(2-hydroxy-1-naphthylazo) phenoxy]benzaldehyde 152–153°C. Elemental analysis for $C_{23}H_{16}N_2O_3$ ($M_r = 368.4$) was:

calculated: 75% C, 4.4% H, 7.6% N;

found: 74.5% C, 4.4% H, 7.6% N.

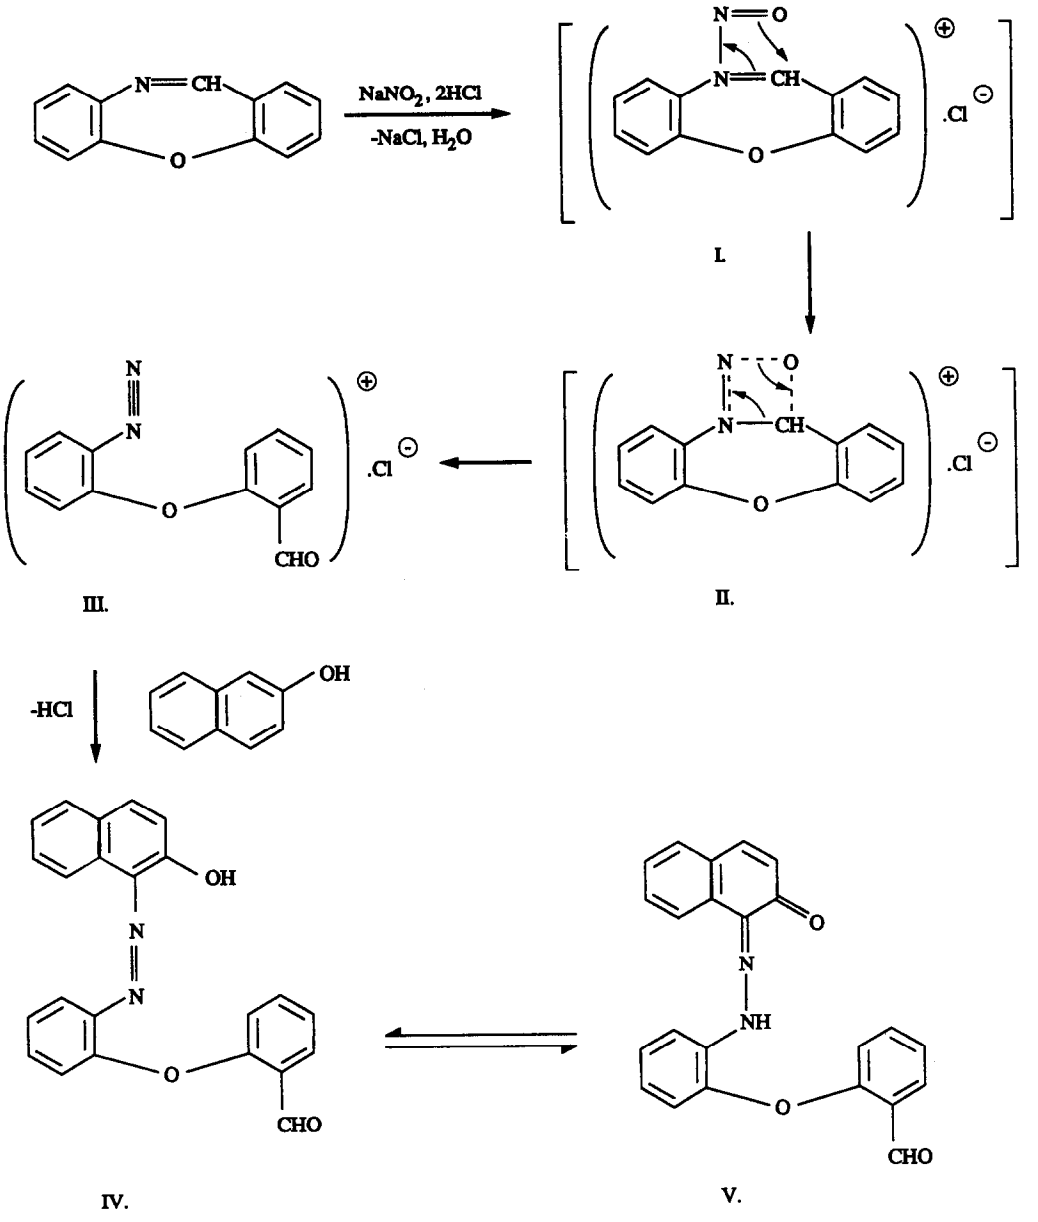
RESULTS AND DISCUSSION

Reaction of the CR compound with $NaNO_2$ in acidic environment probably results in *N*-nitrosonium chloride (see I of the outline), a consequence of the addition of the actual diazotization agent—dinitrogen trioxide—on a free electron pair of the nitrogen atom. Intramolecular effect of the oxygen atom of a nitroso group on a strongly electrophilic carbon atom (originally in the azomethine bond) gives rise to a transient quadruple cycle [see II in the outline]. The rearrangement of two electron pairs results in the final product of diazotization, 2-(2-formylphenoxy) benzendiazonium chloride [see III in the outline]. Coupling with 2-naphthol is implemented by a well-known mechanism which results in 2-[2-(2-hydroxy-1-naphthylazo)phenoxy]benzal dehyde [see IV in the outline]. This product exists mainly in the hydrazone formation [see V].

Outline



The prepared azo dye shows typical properties of an azo dye, *i.e.*, it is insoluble in alkaline agents. This insolubility comes from the azo-hydrazo tautomerism and from creating stable intramolecular hydrogen bonds.

Absorption maxima (λ_{max}), linear regression parameters, detection limits L_D and determination limits L_Q for spectrophotometric determination of the CR substance are shown in Table 1. All the determinations obey the Lambert–Beer law in the measured concentration range of 2.5–25 μM of the CR substance, as was found from the values of the correlation coefficient r, which is equal to 0.995 in the least favourable case. The prepared solutions of azo dyes are stable. For the spectrophotometric determination of low concentrations of the CR substance in 1 ml sample, first of all *N*-(1-naphthyl)-ethylenediamine dihydrochloride (1), and then 1-naphthol (5) and 7-hydroxy-4-methyl coumarin (7), may be recommended. Our developed method exceeds the extractive spectrophotometry of the ionic pairs[2] in sensitivity and especially in selectivity. Thus, the determination of the CR substance is possible not only in the group of irritants but also in the group of topical warfare chemical agents.

A PHOTOMETRIC DETECTOR BASED ON A BLUE LIGHT-EMITTING DIODE

PETER C. HAUSER* and DAVID W. L. CHIANG
The University of Auckland, Department of Chemistry, Private Bag 92019, Auckland, New Zealand

(*Received* 10 *November* 1992. *Revised* 26 *January* 1993. *Accepted* 26 *January* 1993)

Summary—The suitability of blue light-emitting diodes as radiation sources in molecular absorption spectroscopy was evaluated. Electronic as well as spectral considerations are discussed. A transducer based on a blue light-emitting diode and a photodiode is described which yields direct absorbance readings by passing the photocurrent to an integrated circuit logarithmic converter. The performance of this device was tested for commonly used spectrophotometric procedures for Cr, Mn, Zn, Fe and Cl and compared with conventional molecular absorption spectroscopy. Also investigated was the application of the transducer as a detector in flow-injection analysis.

The radiation from light-emitting diodes (LEDs) has limited spectral bandwidths of about 20–70 nm. This imparts a degree of spectral selectivity and often allows the substitution of the commonly used combination of broadband sources and monochromators with these inexpensive devices. Photometric transducers for molecular absorption spectroscopy based on LEDs and photodiodes or phototransistors have been reported repeatedly.[1–14] These have either been dip type probes or more frequently flow-through cells for flow-injection analysis (FIA). The latter application has been reviewed by Trojanowicz *et al.*[15] Devices based on green (565 nm),[1,2,3,5,6,9,11,14] yellow (595 nm),[11,13,14] orange (605–620 nm),[4] red (630–660 nm)[1,3,5,8,11,12,14] and near-infrared (820 nm)[7,10] LEDs have been reported. Blue LEDs however, are not as readily available as those of other colours, because the gallium arsenide or phosphide semiconductor technology normally used in LED manufacture cannot be extended to the production of light of shorter wavelengths. The authors are not aware of any reports on the use of blue LEDs in photometry although they have been employed in passive and active fluorescence based chemical sensors.[16–18] On the other hand, the absorption bands for several commonly employed spectrophotometric procedures lie in the wavelength region of peak emission of blue LEDs. Blue LEDs from two different sources were evaluated for their application in spectrophotometry using a cell with a 1 cm pathlength and a log converter to yield measurements that correspond to absorbance.

*Author for correspondence.

EXPERIMENTAL

Electronic components

Blue LEDs were obtained from Siemens (LB 5410-HO) and Radiospares (RS 589-569). The LEDs of other colours were from Radiospares (Green: RS 585-927; Yellow: 585-933; Orange: RS 578-200 and Red: RS 585-911). The photodiode was from Siemens (SFH 250V), the phototransistors from Siemens (SFH 350-V) and Motorola (MFOD72), the low input bias current operational amplifier (OPA121) and the log converter (LOG 100) from Burr-Brown. The 1 mm plastic optical fibre was purchased from Radiospares.

Intensity measurements

The intensity and stability measurements of the LEDs were carried out by conducting the light from the LEDs through a short length of optical cable to the photodiode which was connected in the photoamperic mode to the operational amplifier. The output voltage from the amplifier in the current follower configuration was passed to a 16 bit analogue-to-digital converter card (NB-MIO-16XH-42 from National Instruments) which was located in a Macintosh IIci computer and controlled by a program written in Lab VIEW (Version 2.1, National Instruments).

Emission spectra of LEDs

These were obtained by positioning the LEDs in the cuvette holder of a Hitachi F-2000 spectrofluorimeter. The spectra were redrawn from the scaled numerical output of the instrument.

Absorbance measurements and spectra

Absorbances were measured with a Shimadzu UV-160A spectrophotometer using 1 cm cuvettes. For the FIA-determinations a Cecil CE 373 spectrophotometer fitted with a Hellma flow-through cuvette with a 1 cm pathlength was used. The blue LED from Radiospares was used for all photometric measurements with the transducer reported here.

Estimated absorbance values

The measured emission intensities for the LED (for 5 nm intervals from 400 to 600 nm) were corrected for the sensitivity of the detector by multiplying with the sensitivity factor for the respective wavelength. The sensitivity factors were taken as 0.327 at 400 nm and to be linearly increasing to 1 at 600 nm. These data were obtained from a plot in Ref. [19]. The resulting values were scaled to a peak intensity of unity. The measured absorbance values for the respective dyes (again at intervals of 5 nm from 400 to 600 nm) were normalized to a peak absorbance of 1. These values were then numerically transformed into transmittance. A numerical estimate of the light intensities measured by the detector was obtained by multiplying the values under both curves, since

$$T = I/I_0 \text{ and } I = T \cdot I_0$$

where T is the measured transmittance, I_0 the original intensity (emission intensities for the LED) and I the intensity after passage through the cell. Adding the results for all wavelength intervals gave an estimate for the total intensity over the wavelength range from 400 to 600 nm. By comparing the total for the individual dyes with the total initial intensity (sum of the values for the normalized LED emission spectrum) an estimate for the integrated overall transmittance was obtained. This value was then transformed back into absorbance according to Lambert–Beer's law.

Solutions

All reagents were of analytical reagent grade. The standard solutions for the chromium calibration curves were prepared by appropriate dilution of a stock solution of potassium dichromate. The reagent for the formaldoxime method was prepared by diluting 7.9 g formaldehyde and 7 g hydroxylamine hydrochloride to 100 ml with water.[20] Then 10 ml of this solution was mixed with an appropriate amount of a stock solution of $1 \times 10^{-5}M$ $MnSO_4$ and 15 ml of $1M$ NaOH, and diluted to 100 ml. The reagent solution for the zinc determination consisted of 100 mg 4-(2-pyridylazo)resorcinol in 100 ml of water. Then, 5 ml of this reagent was mixed with an appropriate amount of $1 \times 10^{-4}M$ $ZnSO_4$ solution and 10 ml of $1 \times 10^{-2}M$ $Na_2B_4O_7$ and made up to 100 ml. The reagent stream for the iron determination in FIA by the phenanthroline method consisted of 1.2 g/l 1,2-phenanthroline, 50 g/l ammonium acetate and 140 ml/l of glacial acetic acid. Standard solutions were made up with an appropriate amount of a stock of $FeNH_4(SO_4)_2$ and 10 ml of a 2% solution of hydroxylamine hydrochloride, and diluted to 100 ml. The reagent stream for the chloride determination consisted of 0.626 g of $Hg(SCN)_2$, 30.3 g of $Fe(NO_3)_3 \cdot 9H_2O$, 4.72 g of concentrated nitric acid and 150 ml of methanol, and was made up to 1 l with water.[21] Standard solutions were made up by appropriate dilution of a stock of a 1000 ppm NaCl solution.

RESULTS AND DISCUSSION

Electronic considerations

Light intensity. The luminous intensities of the two blue LEDs (13 mcd[22] and 2.5 mcd[23]) are very low compared to that of LEDs of other colours which may have intensities 2–3 orders of magnitude higher. Semiconductor detectors based on silicon are most sensitive in the near-infrared and are not very efficient at the lower end of the visible range. The photocurrents obtained by the photodiode irradiated with the blue LEDs were therefore found to be as low as about 50 nA. Phototransistors with their built-in amplification result in significantly higher currents, but the response of two types of phototransistors tested was found not to be linear with light intensity over the relevant range. A photodiode was therefore used. However, the current obtained was too low for direct input to the logarithmic converter (see below) and was therefore amplified by an operational amplifier in the current follower configuration. The input bias current of the operational amplifier used is specified as less than 5 pA[24] and therefore is not a source of error.

Stability. The stability in intensity of the blue LED from Radiospares was tested while operating it with its recommended current of 25 mA. The photocurrent on the detector was acquired in regular intervals over a period of 1 hr. It was found that the intensity was decreasing by 0.06% over this initial period. This corresponds to the same relative error in transmittance measurements and was deemed to be tolerable.

Logarithmic conversion. To obtain an output that corresponds to absorbance, the photocurrent was transformed by a log converter contained in a single integrated circuit package. According to Lambert–Beer's law this leads to calibration curves linear with concentration. Direct analog log or antilog converters are generally useful building blocks for analytical instruments and the use of an antilog converter for example has been reported for the linearization of the response from ion-selective electrodes.[25] The approach has not previously been reported for LED-based photometry, commonly the voltage obtained from a current follower amplifier has been measured directly (this value corresponds to transmittance and in principle yields non-linear calibration curves) or the log conversion has been carried out numerically after the measurements. The complete circuitry is shown in Fig. 1. A provision for an offset adjustment is featured by the log converter which allows the instrument to be zeroed on blank solutions. The output is a potential, with a voltage of zero corresponding to absorbance zero and 1 V being equivalent to an absorbance of 1.

Spectral considerations

The emission spectra of two available blue emitting LEDs (both based on SiN)[23,26] and of typical LEDs for the other colours are shown in Fig. 2. The figure shows the visible range of the spectrum from 400 to 700 nm. As evident, conventional LEDs from green to red cover about half of the range. They show a relatively narrow bandwidth of 20–40 nm (full width at half height) compared to the bandwidths of 65–70 nm for the two blue LEDs. This imparts a higher spectral selectivity for the more conventional colours. A good spectral match should be possible for many absorbing species in the 100 nm span from 565–660 nm because of the availability of the four colours with peak separations of about 15–35 nm. Other LEDs with different peak wavelengths for this region are available. For the lower half of the visible range (from 400 to 565 nm) such a choice is not possible. As can be seen, the emission bands for the two blue LEDs are very similar with peak wavelengths at 460 and 470 nm. However, the fact that the bands from the two blue LEDs encompass a wide region at lower wavelengths may be considered an advantage in the absence of emitters of different wavelengths in that range since a spectral match will always be obtained.

Construction of the cell

A cross-sectional diagram of the cell is shown in Fig. 3. Black perspex was used in order to eliminate the interference from ambient light and internal reflections. The optical path is 1 mm in diameter and the pathlength

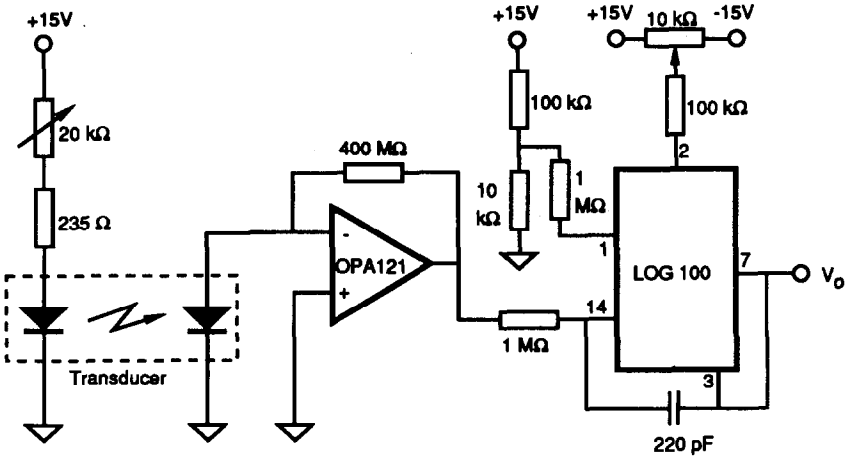

Fig. 1. Electronic circuitry of the transducer.

1 cm, deliberately chosen to match conventional cuvettes. The cell volume is 8 μl. The solution is passed in and out of the cell through tubing attached with the common 1/4 × 28-type fittings. Light is passed through by the use of 1 mm plastic optical cable. This allowed the location of the opto-electronic components removed from the wet-chemical part. The cell was mounted on a metal housing which contained the electronic circuitry including the emitter and detector. This effectively shielded the detector against electromagnetic noise pick-up. The diameter of the optical cable is ideal for combination with opto-electronic components and specially designed emitters and detectors are available. The photodiode that was used is housed in a package which allows easy screw-on connection to the cable. The plastic bodies of the LEDs used in this project were cut off close to the emitting semiconductor surface and polished so that efficient light coupling into the plastic fibre could be achieved. A specially designed Perspex adaptor was used to facilitate this connection.

Equilibrium measurements

The transducer was tested for its use in five common spectrophotometric procedures. The absorption bands for the coloured species detected in these methods all show their highest sensitivity in the emission region of the blue LEDs. The suitability of the LED based transducer was tested with sets of calibration standards. Absorbances at the wavelength of maximum sensitivity were also measured with a conventional spectrophotometer using a cuvette with a 1 cm optical pathlength. Since the transducer has the same pathlength a direct comparison of the two results is possible.

The LED based device was found to be successful for the determination of chromium by oxidation to dichromate with periodate.[20] The two response curves are given in Fig. 4. The response curve for the transducer shows a loss

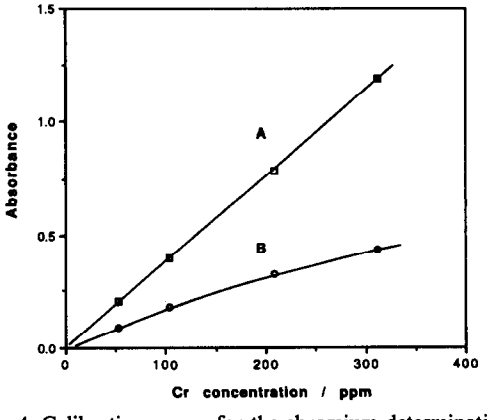

Fig. 4. Calibration curves for the chromium determination by the dichromate method: (A) spectrophotometer (445 nm), (B) LED-based transducer.

of sensitivity and a deviation from Lambert–Beer's law in the form of a curvature. These aspects will be discussed below. Manganese could be determined successfully by the formaldoxime method,[20] as is illustrated by Fig. 5. Here the differences between the two detectors are not very pronounced. Also successful was the determination of zinc by complexation with 4-(2-pyridylazo)resorcinol (PAR) as reagent. Again a somewhat reduced sensitivity was found as illustrated in Fig. 6. This reagent shows a significant background absorption which however did not cause any problems. The detector was zeroed on a blank solution.

The precision of the transducer measurements was found to be excellent, the standard deviation of the absorbance measurements in no case exceeded a value of 0.003 ($n = 5$), which is comparable to the results obtained with the spectrophotometer. The resulting precision in concentration was 1, 0.3 and 0.8% (relative standard deviation, $n = 5$) for the Cr, Mn and Zn methods, respectively. These values were obtained at the high end of the calibration curves and illustrate that the loss of sensitivity observed with the LED-device is not significant in terms of the signal-to-noise ratio. The detection limits (concentration corresponding to a signal three times its standard deviation) were determined as 6, 0.2 and 0.02 ppm for the three analytes, respectively.

The transducer was also tested for its application to the determination of Fe(II) by complexation with 1,10-phenanthroline[20] and of chloride by the thiocyanate method.[27] The results were comparable with the ones obtained for the procedures above and are not shown here because these methods were also adapted

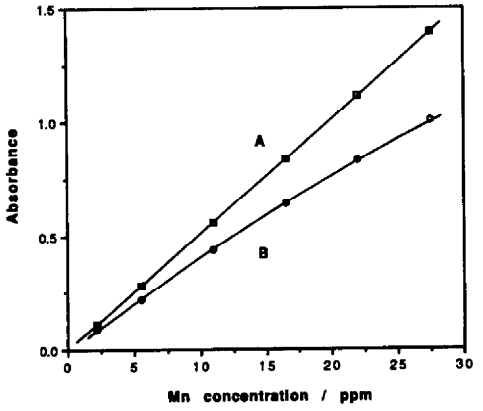

Fig. 5. Calibration curves for the manganese determination by the formaldoxime method: (A) spectrophotometer (451 nm), (B) LED-based transducer.

to flow-injection analysis using the detector cell, the results of which are reported below.

FIA measurements

The low internal volume of the transducer makes it well suited as a detector for flow-injection analysis and this aspect was therefore investigated. Measurements were again carried out using both a conventional spectrophotometer and the LED-transducer. A flow through cuvette with a pathlength of 1 cm was used with the spectrophotometer and the manifolds were identical, so that a direct comparison between the two detectors is again possible.

For the determination of Fe(II) by the phenanthroline method in FIA, an aqueous carrier stream at 2 ml/min into which 100 μl sample was injected was used. The reagent solution (2 ml/min) was merged in downstream from the injection valve and the combined streams passed through a 120 cm long mixing coil of 0.5 mm diameter before detection. The results for the Fe(II) determination using the phenanthroline method in the FIA-mode are given in Fig. 7. The detector performs well for this method. The precision in concentration obtained at the high end of the calibration curve for the transducer was 1.3% (r.s.d., $n = 5$). The detection limit was 0.4 ppm. The detector cell showed some tendency to trap gas bubbles from the carrier stream, which was not a problem when the solutions were degassed before use.

It was also found to be possible to successfully carry out chloride determinations by FIA using the thiocyanate method,[21] as the calibration graphs of Fig. 8 illustrate. The precision in concentration obtained at the high end of the calibration curve for the transducer was found

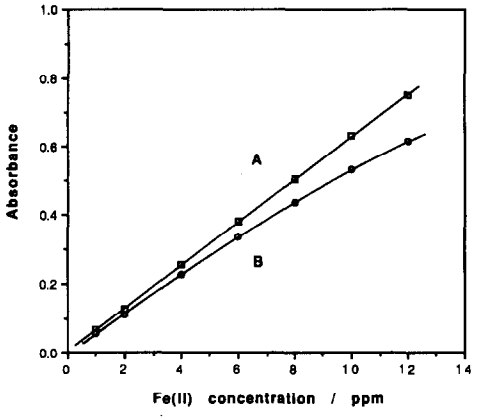

Fig. 7. Calibration curves for the Fe(II) determination by the phenanthroline method in FIA: (A) spectrophotometer (510 nm), (B) LED-based transducer.

to be 0.6% (r.s.d., $n = 5$) and the detection limit as 0.2 ppm. The chloride content of four atmospheric aerosol samples was determined. These had been analysed by ion-chromatography and the agreement between the two methods were found to be good. The following data were obtained: sample (1) LED: 98 ppm; IC: 96 ppm, (2) LED: 90; IC: 82 ppm, (3) LED: 48; IC: 49 ppm, (4) LED: 36; IC: 34 ppm. The correlation coefficient for these data is 0.994.

Sensitivity and shape of calibration curves

The LED-based transducer was always found to show a loss in sensitivity as compared to the conventional spectrophotometer. This behaviour is expected since the light source is not strictly monochromatic and therefore the measured signal contains contributions from wavelengths with lower absorptivities. It was found that it was not possible to estimate the loss of sensitivity from the closeness of the absorbance peak to the emission maximum of the LED. Such a comparison would, for example, predict a high sensitivity for the Cr-determination and a low sensitivity for the Fe-determination when in fact the opposite was observed. The entire spectra have to be considered. The transmittance spectra for the measured species for the Mn-, Cr-, Fe- and Cl-determinations are therefore given in Fig. 9 (the spectrum of the Zn–PAR complex was not included since the blank PAR solution shows a significant absorbance, a fact which complicates the following discussion). These spectra were normalized for an absorbance value of one at the wavelength of peak-sensitivity. Also included in the plot is the emission spectrum for the blue LED. This spectrum has been corrected for the spectral sensitivity of a silicon photodiode as used in this work. Such detectors show their peak at about 900 nm with an almost linear loss of sensitivity from 600 to 400 nm,[19] the wavelength range where emission from the blue LED occurs. The comparison of the emission spectrum of the blue LED and the four transmittance spectra allows a visual estimation of the light intensity observed by the detector after passage through the cell. The larger the area shared by both the LED-spectrum and the respective dye spectrum, the lower the remaining light intensity, and the higher the detected absorbance. Note that all four hypothetical solutions would give identical absorbances of 1 if measured at a monochromatic wavelength at peak sensitivity.

A quantitative estimate of the light intensities measured by the detector was obtained by

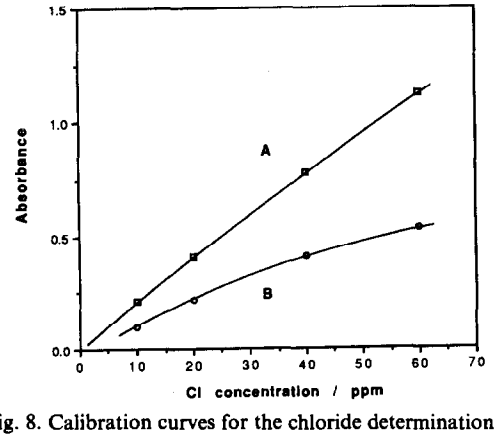

Fig. 8. Calibration curves for the chloride determination by the thiocyanate method in FIA: (A) spectrophotometer (480 nm), (B) LED-based transducer.

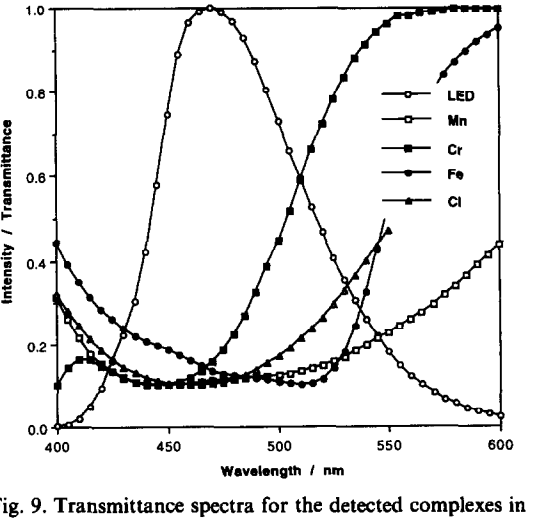

Fig. 9. Transmittance spectra for the detected complexes in comparison with the corrected emission spectrum for the blue LED employed.

multiplying the values under both curves and numerically integrating the result (see the Experimental section for details). This procedure led to estimated absorbance values for the LED-transducer (for an absorbance of 1 at the wavelength of maximum sensitivity) of 0.88, 0.44, 0.74 and 0.70 for the Mn-, Cr-, Fe- and Cl-methods, respectively. The respective experimental data are 0.76, 0.38, 0.73 (estimated) and 0.50. The observed sensitivities can therefore be corroborated reasonably well with the extent of the spectral match between the emission spectrum of the LED and the respective absorbance spectrum.

The calibration curves for the transducer all show a more or less pronounced deviation from the Lambert–Beer law in the form of a curvature. Such a deviation is expected when not strictly monochromatic light sources are employed and the absorptivity and/or the intensity of the incident light varies over the detected wavelength range.[28] As can be seen from Fig. 9 both of these factors are not constant in the case of the LED-transducer. That this indeed causes a non-linearity of the response curve can be demonstrated with the help of Lambert–Beer's law by assuming that the light intensity is measured for two wavelengths simultaneously.[28] The above described modelling procedure for different peak absorbance values can also be applied for a more detailed simulation of a calibration curve for the transducer. As is illustrated by the predicted calibration curve for the chromium method given in Fig. 10, the observed non-linearities can be accounted for by spectroscopic principles.

The loss of sensitivity compared to conventional spectrophotometry is expected to be more significant for the blue LED than for other LEDs, because its wider emission band reduces the probability of a good spectral match. However, there is very little quantitative data available on this aspect for different LEDs, with the exception of the data presented by Trojanowicz *et al.*[15] For peak wavelengths of the absorbing species ranging from 540 to 660 nm, sensitivities of 85–99% of the conventional methods were reported. No information on how these data were obtained was given. Also included were results obtained for the iron determination by the phenanthroline method and for the chloride determination by the thiocyanate method using a green LED at 565 nm. Sensitivities of 21 and 9% of the conventional methods were reported for the two procedures, respectively. This compares to values of 61 and 55% obtained in this work by comparing the measured absorbances in the centre of the calibration curves. Using a blue LED certainly leads to an improvement for these two methods, and the use of the green LED would not be possible or yield very low sensitivities for the other coloured species discussed above.

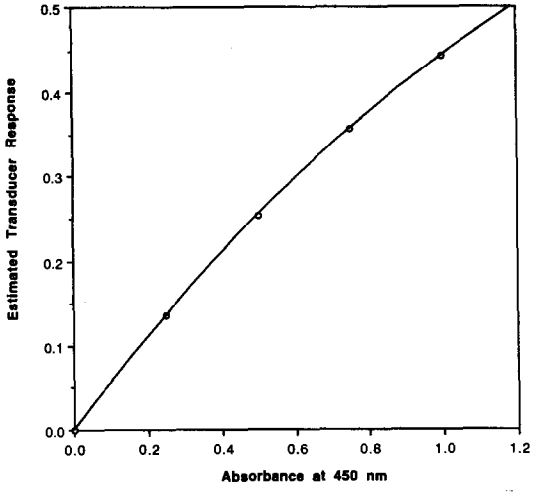

Fig. 10. Correlation of estimated absorbance readings for the chromium determination with the transducer with absorbances for monochromatic determination at 450 nm.

CONCLUSIONS

It was found that the transducer based on a blue LED can be used successfully for quantitative determinations in equilibrium applications as well as flow-injection analysis. The sensitivity is always reduced when compared to the results obtained with conventional instrumentation and perhaps also in comparison to systems employing LEDs of other colours. The calibration graphs tend to show a deviation from Lambert–Beer's law in the form of a downward curvature towards the high end of the calibration curves. This effect is more pronounced for cases of low sensitivity compared to the spectrophotometric measurements and is expected for absorbance measurements with broad-band light sources. The precision of the absorbance measurements however, was found to approach that of conventional double-beam instruments. Therefore the precision in concentration can be expected to be in the order of 1%, even in cases where the sensitivity is strongly degraded. This means that the relatively low sensitivities encountered in some instances with the blue LED do not adversely affect practical applications of this system.

Acknowledgements—The authors thank Dean Clark from Siemens Wellington for providing samples of opto-electronic components, David Wiley for the analysed aerosol samples and Glenn Boyes for preparing solutions. The work was mainly funded by University of Auckland grant number A18/XXXXX/61890/F3391087 and a special Vice Chancellor's grant.

RAPID ASSAY FOR PROCAINE PENICILLIN G IN PHARMACEUTICAL DOSAGES BY SPECTROFLUORIMETRY

J. A. MURILLO PULGARIN and A. ALAÑON MOLINA

Department of Analytical Chemistry and Food Technology, University of Castilla-La Mancha, 13071 Ciudad Real, Spain

(*Received* 5 *November* 1992. *Revised* 2 *February* 1993. *Accepted* 2 *February* 1993)

Summary—A method for the spectrofluorimetric determination of procaine penicillin G is proposed ($\lambda_{ex} = 294$ nm, $\lambda_{em} = 348$ nm) for concentrations between 0.10 and 1.0 ppm. The method was performed in ethanol/water medium (60% V/V), at apparent pH 9.9 provided by adding ammonium/ammonia buffer solution with pH = 10.0.

The effect of other penicillins on the determination of procaine penicillin G was examined over a wide range of concentrations, interferences were not observed in the range of studied concentrations.

The method was successfully applied to assay all Spanish commercialized injections containing procaine penicillin G, penicillin G and/or benzathine penicillin G.

Fifty years after its introduction, penicillin G remains a very useful antibiotic; it is found to be a safe and effective agent. Serious toxic events are rare and dosage flexibility proves to be broad. It is the antibiotic of choice for most infections caused by gram-negative cocci and majority grampositive bacteria.[1]

Penicillin G is available as the sodium or potassium salt in aqueous solutions for intramuscular injection. It is spread all over the organism and is eliminated through urine fundamentally. It reaches the maximum of plasmatic concentration in 15 or 30 min; it has a small half-life. Therefore, the use of the long-acting penicillins like benzathine penicillin G and procaine penicillin G is necessary.

Procaine penicillin G is a result of the combination of 1 mole of penicillin G and 1 mole of procaine. It forms a tissue deposit, from which the drug is slowly absorbed within 12 or 24 h.

The penicillins are not fluorescent compounds because the association of β-lactam and thiazolidine rings does not exhibit native fluorescence.

The penicillins are fluorescent only when the bound group to carboxylate in position 3 (procaine penicillin G) or the group in position 6 (methicillin or nafcillin) are appropriate.

Only one direct fluorimetric assay for penicillins[2] is described but a previous extraction is necessary. The others are based on derivatization reactions.

Jusko *et al.*[3] developed the first fluorimetric determination of penicillins based on the formation of a strongly fluorescent yellow product during acid hydrolysis at elevated temperatures of ampicillin and other α-aminopenicillins.[4–6]

Other described methods involve basic hydrolysis[7] in the presence of 2-methoxyethanol, or acid hydrolysis in the presence of Hg (II).[8–10]

Baker and Havlicek[11] use the fluorescamine derivative of penicillins and Mori *et al.*[12] developed a method of penicillins determination based on quenching reaction.

Procaine penicillin G is one of the few penicillins that shows fluorescence by itself, no existing method of fluorimetric determination is described in the literature.

The purpose of this study is to report the development of a direct and simple fluorimetric method for the estimation of procaine penicillin G in pharmaceutical dosages in the absence and presence of penicillin G and benzathine penicillin G.

REAGENTS AND MATERIALS

Reagents

Stock solution of procaine penicillin G, 250 ppm: prepared by dissolving the standard procaine salt of penicillin G in Milli-Q water.

Stock solution of benzathine penicillin G, 250 ppm: prepared by dissolving the standard benzathine salt of penicillin G in 96% ethanol.

Stock solution of penicillin G, 250 ppm: prepared by dissolving the standard potassium salt of penicillin G in Milli-Q water.

The standard procaine, benzathine and potassium salt of penicillin G were obtained from the Sigma Chemical Products.

Injectable dosage of Farmaproína, Cepacilina 3:2:1, Cepacilina 6:2:1, Cepacilina 6:3:3 (Lab. Cepa), Aquacilina 600, Aquacilina D-A 600, Zoocilina 1000000, Benzetacil 3:2:1, Benzetacil 6:2:1, Benzetacil 6:3:3 (Lab. Antibioticos S.A.), Ortopén 400000 and Ortopén 1000000 (Lab. Fides S.A.) with different nominal contents, were randomly purchased from local pharmacies.

Buffer solution 0.15*M*: buffer solution of pH 10.0 was prepared by mixing adequate amounts of ammonium chloride with sodium hydroxide.

Stock solutions of procaine and potassium salt of penicillin G were stored, protected from light and maintained below 5°C and a stock solution of benzathine penicillin G was stored in the dark and maintained at room temperature. Under these conditions, the solutions of procaine penicillin G and penicillin G were stable for 7 days and the solution of benzathine penicillin G was stable for 3 days.

The working samples of procaine penicillin G were stable at least for 4 hr at room temperature.

Apparatus

All fluorimetric measurements were performed on a Perkin-Elmer LS-50 equipped with a Xenon lamp, connected to an Ataio S 3000 ST 386 computer fitted with the Perkin-Elmer FL Data Manager software (design for handling fluorescence data on a personal computer) and Epson FX-850 printer.

Thermostatic equipment and a Crison, mod. 2001, pH-meter with a glass-saturated calomel combination electrode and centrifuge Selecta mod. Mixtaxel were also used.

CALIBRATION GRAPH, SAMPLE PREPARATION AND PROCEDURE

Calibration graph

A suitable aliquot containing 2.5–25 μg of procaine penicillin G was transferred into a 25 ml volumetric flask, 5.0 ml of buffer solution pH = 10.0 added and enough ethanol to ensure a final ethanol content of 60% V/V to every volumetric flask. This was diluted to the mark with water. The fluorescence intensity was measured at 348 nm, with excitation at 294 nm. Since dissolution prepared in a similar way without procaine penicillin G exhibits negligible fluorescence, a reagent blank is not necessary.

Procedure for injections

To determine procaine penicillin G in the presence of penicillin G, the sample solution was prepared by dissolving the content of the vial in Milli-Q water and diluting to adequate volume with Milli-Q water.

To determine procaine penicillin G in the presence of benzathine penicillin G, which is insoluble in water, a representative amount of aqueous obtained suspension was centrifuged to 2500*g* for 15 min. Five millilitres of clear solution was taken and this was diluted to the mark with Milli-Q water.

In both cases, the assay was completed as described for calibration graph. The percentage recovery of antibiotic is computed from regression equations for pure drugs.

RESULTS AND DISCUSSION

Spectral characteristics

The best characterization of the penicillin fluorescence is achieved by obtaining the tridimensional spectrum with suitable computer program.[13] This spectrum can be obtained and presented as the isometric projection, where the emission spectra at stepped increments of excitation wavelength are recorded and plotted (Fig. 1). A reversed projection of the data can sometime indicate emission peaks hidden by the foreground. Alternatively, the tridimensional

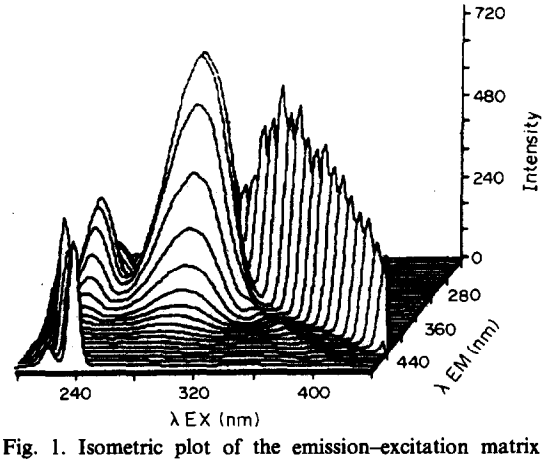

Fig. 1. Isometric plot of the emission–excitation matrix (forward projection) of procaine penicillin G (0.70 ppm). Ethanol–water content 60–40% (V/V), pH = 10.0.

spectra can be effectively transformed to a plot in two dimensions of excitation and emission wavelength by linking points of equal intensity to form contours, as shown in Fig. 2 where Rayleigh scatter has been removed. This contour presentation has generally been found to be more useful than the isometric projection for indicating the presence of hidden emission peaks.

As can be seen, the procaine penicillin G presents three fluorescence maxima, two of them localized at different excitation wavelength (223 and 294 nm) and at the same emission wavelength, 348 nm and the other localized at 220 nm and 295 nm as excitation and emission wavelengths, respectively. The wavelengths chosen were 294 and 348 nm for excitation and emission, respectively, where the higher intensity was obtained.

Factors affecting fluorescence intensity

The effect of changes in solvent composition was investigated using ethanol, methanol, chloroform and aqueous solutions at pH 2.0, 5.0 and 10.0. The highest and the smallest fluorescence intensities were obtained when ethanol and an aqueous solution at pH = 2.0 were used as solvents, respectively. A bathochromic effect was observed in the fluorescent emissions when the solvent polarity increased. Although the intensity of fluorescence in ethanol is higher than in water, we have chosen ethanol–water as the working medium because the aqueous stock solution is more stable than ethanolic stock solution.

The effect of ethanol content in the medium was investigated by preparing samples of penicillin varying only ethanol percentage between 0 and 96% V/V. The results are shown in Fig. 3(a), although the relative intensity of fluorescence increases with the ethanol content in the medium, we have selected a 60% V/V ethanol–water mixture because it provides the maximum intensity with regard to aqueous fraction [Fig. 3(b)].

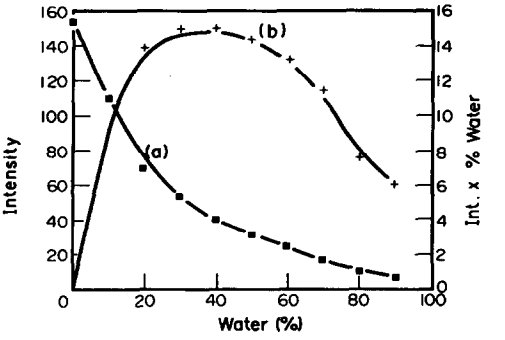

Fig. 3. Influence of the ethanol content. (a). Representation of fluorescence intensity with regard to aqueous fraction. (b). [Procaine penicillin G] = 1.0 ppm, pH = 10.0.

The influence of pH on the fluorescence spectrum was studied in an ethanol–water medium (60–40%) changing the pH by adding $HClO_4$ or NaOH. In Fig. 4 it can be observed that the fluorescence intensity is constant up to apparent pH value 7.0. It vastly increases for pH values between 7.0 and 9.0, the maximum fluorescence intensity is obtained for apparent pH value higher than 9.0. A pH = 9.9 was selected as the optimum apparent pH, which is proportioned by adding ammonium–ammonia buffer solution with pH = 10.0, whose concentration does not affect the fluorescence.

The dependence of the fluorescence intensity on temperature is critical, decreasing the fluorescence emission by 1.1%/°C when the temperature increases from 3 to 70°C. This effect can be explained by the higher internal conversion as temperature increases, facilitating non-radiative

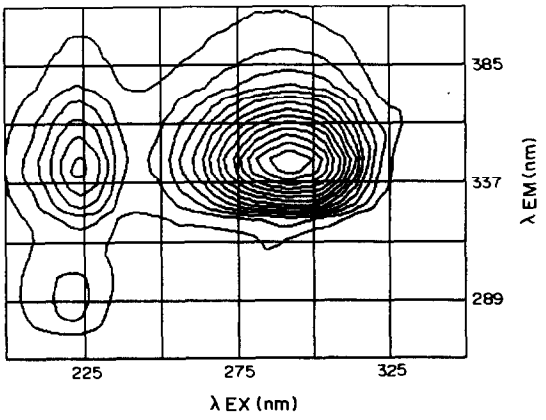

Fig. 2. Contour plot of procaine penicillin G fluorescence (0.70 ppm). Ethanol–water content of 60–40% (V/V), pH = 10.0.

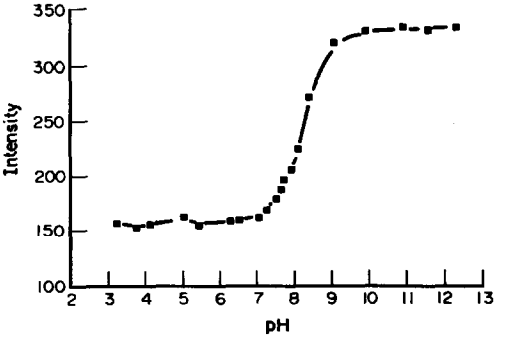

Fig. 4. Influence of the pH. [Procaine penicillin G] = 1.0 ppm. Ethanol–water content 60–40% (V/V), pH = 10.0.

deactivation of the excited singlet state. Thus, it is recommendable to use a thermostat, choosing a measurement of temperature of 20°C, independent of the room temperature.

The influence of the penicillin concentration on the fluorescence intensity was studied. The results show that there is a linear relationship between fluorescence intensity and procaine penicillin G concentration in the range of 0.10–1.0 ppm.

Spectrofluorimetric determination of procaine penicillin G

Under the operating conditions outlined above, we propose a method to determine procaine penicillin G by the direct measurement of fluorescence intensity at 348 nm, with excitation at 294 nm in the range of 0.10–1.0 ppm.

The proposed method was evaluated by a statistical analysis of experimental data by fitting the least squares line according to "$y = a + bx$". The results are presented in Table 1.

To verify if the intercept on the y axis is negligible, its significance was studied by applying the Student's "t" test at 95%[14] of confidence level and nine degrees of freedom. If the intercept on the y axis for the line calculated by the least squares technique is negligible, it is necessary to perform it again according to function "$y = b'x$" and therefore the new value of the slope of graph calibration (b') may be calculated. As can be seen in Table 1, the intercept on the y axis, is negligible, since experimental "t" is smaller than theoretical "t" and therefore the new slope is calculated.

The high value for the correlation coefficient of the regression equation and a negligible value for the intercept on the y axis demonstrate the satisfactory linear relationship between fluorescence intensity and procaine penicillin G concentration.

For a series of 10 standard samples containing 0.48 ppm of procaine penicillin G a relative error of 0.99% and standard deviation of 6.7×10^{-3} ppm were obtained (95% confidence level).

The detection limit is 9.4×10^{-3} ppm when defined as the analyte concentration leading to a luminescence intensity that is three times a blank standard deviation and determination limit is 0.024 ppm when defined as the analyte concentration leading to a luminescence intensity that is 10 times the blank standard deviation.[15,16]

Table 1. Statisticals parameters

Intercept on the y axis	3.30
Standard dev. of intercept	1.89
Slope	484.97
Standard dev. of slope	4.56
Correlation coeffic.	0.9998
Theoretical "t" value	2.262
Experimental "t" value	2.019
New slope	489.67

Interference study

It is easy to find penicillin G, procaine penicillin G and benzathine penicillin G mixtures for combining prompt action with prolonged effects.

For this, the effect of penicillin G and benzathine penicillin G was studied on the determination of 0.70 ppm of procaine penicillin G until a 100:1 ratio of interferent penicillin to procaine penicillin G. No appreciable variation of fluorescence intensity was observed in the value expected when the procaine penicillin G is in its own (all the obtained values are found in the "$\bar{x} \pm ts$' interval, where "x" is the mean of 10 determinations of procaine penicillin G in the absence and presence of penicillin G and benzathine penicillin G, "s" is standard deviation of these determinations and "t" is Student's "t" for nine degrees of freedom and at 95% confidence level).

Applications

The recommended procedure has been applied satisfactorily to the determination of procaine penicillin G in the presence of penicillin G and benzathine penicillin G in all the Spanish commercialized pharmaceutical products that contain these antibiotics in different proportions. Table 2 shows the assay results expressed as a percentage of the nominal contents (%R) resulting from the average of three determinations of three different vials. The recoveries agree well enough with the nominal content and the precision is quite satisfactory.

CONCLUSIONS

A new method for the fluorimetric determination of procaine penicillin G is described. The fluorescence is monitored at 348 nm (wavelength of excitation 294 nm) and the range of application of the method is between 0.10 and 1.0 ppm. Values of 9.4×10^{-3} and 0.024 of the detection and determination limits, respectively are obtained.

Table 2. Results obtained in the determination of procaine penicillin G in commercial pharmaceutical preparations

P.P.G = Procaine penicillin G.
P.G = Penicillin G.
B.P.B = Benzathine penicillin G.

The method has been satisfactorily applied to the determination of procaine penicillin G in the presence of other salts of penicillin G.

The proposed method has been compared with spectrophotometric, chromatographic and spectrofluorimetric methods obtaining the following conclusions.

The spectrophotometric methods used to determine penicillins are based on derivatization reactions. The three typical assay are: iodometric,[17] the mercury imidazole[18] and the ferric hydroxamate[19] methods. All of them have a smaller sensitivity than the proposed method. Pillai *et al.*[19] proposed a direct spectrophotometric method to determine procaine penicillin G, obtaining a linear range, a sensitivity and a limit of detection smaller than the proposed method.

Generally the chromatographic methods to determine penicillins include precolumn derivatization or derivatization prior to detection.[20–21] Although the sensitivity is similar, the methods are slower than the proposed method. Procaine penicillin G was determined in pharmaceutical preparation by chromatography[22] without any derivatization with a relative deviation of 2% higher than the value obtained with the method described in this paper (1.4%).

The indirect spectrofluorimetric methods are tedious and high sensitivity is rarely obtained with them.[3–12]

A COMPLETE DISSOLUTION PROCEDURE FOR Sn–Pb SOLDERS USING NITRIC AND HYDROCHLORIC ACIDS WITH SIMULTANEOUS DETERMINATION OF MAJOR AND TRACE ELEMENTS BY ICP/OES

D. A. WYNN

Johnson Controls, Inc., Advanced Battery Research, 5757 N. Green Bay Avenue, Milwaukee, WI 53209, U.S.A.

(*Received* 27 *October* 1992. *Revised* 29 *January* 1993. *Accepted* 3 *February* 1993)

Summary—A complete and fast dissolution procedure for tin and lead based solders is described. Trace and major elemental concentrations are determined by inductively coupled argon plasma emission (ICP) spectroscopy. One gram solder samples in the concentration range of 40–63 wt % tin are completely dissolved using nitric and hydrochloric acids. ICP analyses of certified reference materials prepared by this dissolution method are reported and compared to reference values. Based on comparison, the sample preparation method discussed is successful for quantitative analysis of trace and major elements in tin–lead solders.

The purpose of this work is to dissolve solder samples quickly for normal inductively coupled argon plasma emission spectroscopy (ICP) analysis procedures without using any special equipment. Tin and lead based solders are very difficult to dissolve because of metal oxide formation during dissolution. Dissolution is usually accomplished after hours of using nitric and fluoroboric acids. Microwave-oven dissolution procedures have been used to reduce the dissolution time to 4 min for 1 g sample. There is one undesirable problem with fluoroboric acid. It corrodes glass or quartz parts commonly found in analytical instruments and instrument components of special chemically resistant materials must be used.

Other methods for dissolution of solders can be found in the literature. A hydrofluoric acid (HF) and nitric acid mixture[1] is used, but this mixture is also corrosive to glass. A complete dissolution procedure using *aqua regia* is described for 0.1 g of a 50% Sn, 47% Pb and 3% Bi solder.[2] Three other HCl/HNO_3 methods are found in the literature[3,4,5] for determinations of one or two elements, but problems are noted with solution stability. The disadvantages of these procedures are that large dilution volumes must be used to avoid precipitation of the sample, the large dilution factor adversely affects the detectability for most trace elements of interest, the procedures are time consuming, and they have not been validated for multi-element analysis.

Several extraction techniques[6,7,8,9] are reported in the literature with subsequent element determinations by atomic absorption. Extraction techniques are very time consuming which is a major disadvantage.

A novel method for the dissolution of lead and tin based solders has been developed. The procedure requires concentrated nitric (70%) and hydrochloric (37%) acids for complete dissolution of a 1 g solder sample within 15 min. This new method allows multi-element analysis by ICP with no special changes to the ICP instrument (*i.e.*, HF or HBF_4 resistant nebulization systems are not required). Another advantage of ICP analysis is that trace non-metals (< 10 ppm) such as sulfur and phosphorus can be measured. These elements are of interest because of the effect on the quality of wave soldering.[10]

Tin is determined gravimetrically and compared to the ICP results for precision analysis. Reference solder materials are analysed for trace- and major-element concentration comparisons. There is good agreement between the ICP results and reference material values for all elements. This demonstrates that the new dissolution method is complete and is an acceptable alternative method.

EXPERIMENTAL

Apparatus

The ICP instrumentation used was described previously.[11] Modifications of the instrument were made through replacement of the 27 MHz generator with a 40.68 MHz generator (RF Plasma Products) and the Digital computer system with an IBM PS/2 Model 30. Under normal operating conditions, the mini-monochromator was set at 766.490 nm for K and the Hilger–Engis monochromator was set for 588.995 nm for Na. The Hilger–Engis monochromator was also used for element wavelengths which are not available on the polychromator. Off-peak background correction was not available with the two monochromators. Detection limits[11] for this ICP system for water and lead matrixes have been previously reported.

Reagents

House distilled water was purified to 18 MΩ by a MILLI-Q water purification system (Millipore Corp., Bedford, MA). All further references to water implies the use of 18 MΩ water. Reagent grade ("Baker Analyzed"®) nitric acid and purified (Ultrex®) hydrochloric acid were used for sample preparation (J. T. Baker Chemical Co., Phillipsburg, NJ). The nitric acid was further purified by distillation before use.

Dissolution preliminaries

Solder dissolution and dilution of sample solutions were performed in an acid fume hood. Dissolutions were done on Lindberg hot plates (model 53202, Watertown, WI). The surface temperature of the hot plate was measured using a surface thermometer (PTC® model 314F, Pacific Transducer Corp., Los Angeles, CA). All reported temperatures were the measured surface temperature of the hot plate during dissolution. The hot plates were always preheated to the desired temperature before use.

Glassware was soaked in 10% (v/v) hydrochloric acid, followed by 10% (v/v) nitric acid, and finally rinsed with water before use. All solder samples were dissolved in 300 ml tall form beakers (PYREX®, Corning, NY) and the solutions were brought to volume with water in class-A volumetric glassware. During dissolution samples were covered with watch glasses.

The disks of solder alloys used in this study were sampled by using a hard steel saw (nickel chrome alloy steel, model D-23, Disston, Danville, VA). No measurable contamination has been seen from this saw type when used on similar solder alloys. There was a designated saw for each solder alloy group. The saw was not specially cleaned between samples when used only for the designated solder alloy group. Historically this approach has proven satisfactory for sampling lead and its alloys. In this study, cross contamination was not observed between NIST certified and in-house reference materials using this saw.

At least three radial saw cuts towards the center of the sample were made and the chips collected to obtain a representative sample for analysis. Ten to 20 g (dependent on thickness of sample disk) were collected for the analysis. The chips were approximately 0.5 mm in diameter. All sawing chips were then mixed and the appropriate amount was weighed for dissolution.

Solder dissolution

Solder samples were dissolved by adding 1 ml of water and 20 ml of concentrated nitric acid to 1.000 ± 0.001 g of saw chips in a 300 ml tall form beaker. The sample was heated at 150°C for 5 min. Then 5 ml of concentrated hydrochloric acid was added slowly to the hot sample solution and heated for 5 min. Then 30 ml of water was added to the hot sample solution and heating continued for 5–20 min at 150°C until the sample was dissolved. During this time, more water (1 ml at a time) must be added if a white precipitate ($PbCl_2$) forms. The sample solution was cooled and diluted to 100 ml with water. Sample solutions show no visible sign of precipitation after more than 1 month.

Calibration standards

All standard stock solutions were acidic aqueous solutions. The calibration standard solutions were matrix-matched to the sample using the same reagents and acids used in sample dissolution. The appropriate amounts of purified tin (granular, 20 mesh, J. T. Baker Chemical Co., Phillipsburg, NJ) and lead (Doe Run Co., Herculaneum, MO), for the Sn–Pb portion of the calibration standard, were added to 300 ml tall form beakers to matrix-match the samples. The Sn–Pb calibration samples are then treated like samples. Once dissolved, aliquots of multi-element (Inorganic Ventures, Inc., Brick, NJ), single element 10,000 mg/l, and single element 1000 mg/l standard stock

solutions were then added to the Sn–Pb solutions to make complete calibration standards. A sample blank solution containing only 40% Pb and 60% Sn was prepared with the standards to subtract any trace element contamination in the starting materials and reagents.

Major alloy elements (Sn,Pb) contained in the standard stock solutions were compared to appropriate National Institute of Standards and Technology (NIST) standard reference materials (SRM) (Gaithersburg, MD). The SRMs were 10,000 mg/l stock solutions of each analyte.

RESULTS AND DISCUSSION

Preparation procedures

Hydrated tin oxides and/or tin nitrates were formed when nitric acid was added to solder chips. A white–yellow precipitate was suspended in solution. Tin chloride was formed when concentrated hydrochloric acid was added, but dissolution was still not complete until water was added because of the saturated condition of the solution. Some small white particles may still remain after water was added, but continued heating and stirring dissolved them. National Institute of Standards and Technology (NIST) (Gaithersburg, MD) Standard Reference Material (SRM) 127b (40% Sn, 60% Pb) in powder form, NIST SRM 1129 (63% Sn, 37% Pb) in disk form, Alpha (Newark, NJ) reference material TL-62X, lot 101 (60% Sn, 40% Pb) in disk form, and a 50–50 solder sample in disk form were dissolved successfully using the described dissolution method. Other certified solders (*i.e.*, 50–50 type) were not available. The method described should work for all tin–lead solders in the concentration range between the two NIST reference materials.

Matrix-matched calibration solutions were prepared from stock standard solutions containing all elements except Pb and Sn. The aliquots of the stock standard solutions containing all other elements were added to Pb–Sn solutions containing 4000–6300 mg/l Sn and 6000–3700 mg/l Pb. The Pb–Sn solutions were made from granular (20 mesh) purified tin metal and pure lead metal dissolved in the same manner as the samples. In this way, the calibration standard solution acid matrix was the same as that of the sample solution. Adding concentrated hydrochloric and nitric acids directly to purchased Sn and Pb stock standard solutions resulted in problems with precipitation.

Purified tin metal powder (>100 mesh, smaller particles), was first tried for the calibration standards, but resulted in incomplete dissolution. It was not clear why this happened. The incomplete dissolution may be due to the presence of tin oxides in the tin powder because of the higher surface area. Additional tin metal powders (>100 mesh) packaged under argon would need to be investigated to obtain the highest purity tin (oxide free) if >100 mesh powders were used for calibration standard preparation.

Instrumental results

A comparison of tin concentrations (reported in Table 1) as determined by two analytical methods, was done for four reference solder samples. All ICP results were in agreement within the standard deviation of the gravimetric technique. Uncertainty values for the Alpha reference materials and NIST 127b were not available. An estimated uncertainty value was given for the NIST 1129 SRM and agreed with the ICP value within the standard deviation. The gravimetric results were obtained to identify standard deviation values that could be obtained under routine analysis conditions. The standard deviation for Alpha TLS-36X is higher compared to the other standard deviations, in both the ICP and gravimetric methods.

A comparison of ICP results and the certified values of impurities in Alpha TL-62X and NBS 127b was carried out (Table 2). All major-,

‖Average and standard deviation for triplicate analyses.

minor- and trace-element concentrations were determined simultaneously by ICP in this laboratory. The ICP results were shown to be in reasonable agreement with SRM 1129 results when compared to the estimated uncertainty for SRM 1129. No statistical data were reported for the other reference materials, but ICP results are generally within 10% of the reported values. As previously discussed for lead alloys,[11] slight sample inhomogeneity of the Alpha certified reference materials may be the cause of the larger differences (>10%) between the ICP and the Alpha certified results. Several elements (*i.e.*, Ag, Fe, As, Bi and Zn) fall into the category of differences >10%. The Alpha reference materials were solder disks originally prepared for arc/spark emission instruments. Such disks may be subject to segregation effects if not properly prepared. There did not seem to be any segregation problems with the NIST 1129 SRM disk. No definite conclusions can be made about the larger differences between results without Alpha reference precision data.

The segregation effects observed in lead alloys are based on disk cooling speed. Slower disk cooling times cause less soluble elements to generally form a gradient distribution in the disk. The concentration of the additive elements gradually increases towards the top of the disk. The bottom (surface in contact with the mold) is the surface used for spark emission. There is then a gradual increase in measured concentration as the disk is resurfaced before each spark analysis. A disk with segregration problems in time will become more and more inaccurate. Severe segregation can have more dramatic results. Taking a cross-section of the disk, as done for the ICP determinations, gives an average of the entire disk and different results will be obtained if the sample disk has segregation problems.

Silver analysis was not a problem with the materials analysed. The higher silver sample (Alpha TLS-36X) was cloudy after dissolution and was shaken just before analysis. The precipitation of silver chloride may be more of a problem if the silver concentration increases above 3% by weight.

CONCLUSIONS

Quantitative information for important solder elements can be obtained by using a single dissolution method which eliminates the need for fluoroboric and hydrofluoric acids to dissolve solders in the concentration ranges of 40–63% tin and 63–40% lead. This procedure allows complete dissolution of the solder with nitric and hydrochloric acids with no adverse effects on the elemental determinations by ICP. The detectable limits for all routinely analysed elements are below maximum specification limits.[10] This procedure should be applicable to the majority of solder materials based on the results of the two NIST certified SRMs and the complete dissolution of the two NIST SRMs and the 50–50 solder alloy.

ICP components resistant to fluoroboric and hydrofluoric acid corrosion are thus not required. Simultaneous multi-element determinations of trace impurity and major alloy elements are performed by ICP under normal acidic solution conditions.

Another advantage of ICP determination is that sulfur and phosphorus can be measured. These impurities are of interest because of the undesirable effects of high concentrations (>10 ppm S and >100 ppm P) of these elements on the quality of wave soldering.[10]

More work could be done in the area of improving the precision of the Sn and Pb determinations by using different wavelengths and/or modifying the sample size taken for analysis. Measurement of minor and trace elements by ICP is an ideal situation because of analysis time savings which are realized by simultaneous multi-element analysis.

KINETIC STUDY OF *N*-BROMOSUCCINIMIDE REACTIONS AND KINETIC DETERMINATION OF PYRIDOXINE USING A BROMIDE-SELECTIVE ELECTRODE

STERGIOS A. HALVATZIS, MEROPI M. TIMOTHEOU-POTAMIA* and CONSTANTINOS E. EFSTATHIOU
Laboratory of Analytical Chemistry, University of Athens, Panepistimiopolis, 157 71, Athens, Greece

(*Received* 8 *October* 1992. *Revised* 21 *January* 1993. *Accepted* 26 *January* 1993)

Summary—The bromide released by the alkaline hydrolysis of *N*-bromosuccinimide and its reactions with bromide, pyridoxine and thiamine have been studied potentiometrically using a solid-state bromide-selective electrode to monitor the consumed or produced bromide ion. Potential–time indications are obtained using a microcomputer-controlled potentiometric system. The overall rate constants and the activation energies have been calculated. A kinetic–potentiometric procedure for the determination of pyridoxine in the presence of thiamine in pharmaceutical preparations, based on its reaction with *N*-bromosuccinimide, is presented.

N-Bromosuccinimide (NBS) is probably the most important organic compound used as a source of the strong oxidant Br^+ ("positive bromine"), finding a variety of applications in both chemical synthesis and analysis. NBS is commonly used to bring about specific types of reactions *e.g.*, substitution, bromine addition, oxidation, *etc.* A great number of compounds have been determined using NBS with certain advantages over hypobromites which are usually prepared *in situ* since they disproportionate easily to bromate and bromide ions.[1,2]

Pyridoxine has been determined by many techniques such as spectrophotometry,[3] voltammetry[4] and potentiometric titrimetry with NBS.[5] Thiamine can be determined by spectrofluorimetric measurement of its oxidation product (thiochrome)[6] and by colorimetric[7] and chemiluminometric[8] techniques. Recently, NBS has been proposed for the kinetic–potentiometric determination of these vitamins.[9]

In this paper the bromide-selective electrode is used for the kinetic study of the reactions of NBS with pyridoxine and thiamine by monitoring the produced bromide, over a wide pH range. Since NBS consumes bromide ions generating bromine in acidic solutions and it is also hydrolyzed in alkaline solution generating hypobromite ion which is decomposed yielding bromide ions (the whole sequence hereafter is simply called "alkaline hydrolysis"), it was deemed necessary to study the kinetics of these reactions too. Based on the obtained kinetic data, a kinetic–potentiometric method has been developed for the determination of pyridoxine in the presence of thiamine. The method has been used for the assay of pyridoxine in pharmaceutical preparations containing thiamine.

EXPERIMENTAL

Apparatus

The system for potentiometric rate measurements consisted of a solid-state bromide electrode (Orion Model 94-35-00) in conjunction with a double-junction Ag–AgCl reference electrode (Orion Model 90-02-00), whose outer compartment was filled with a 10% (w/v) KNO_3 solution, and a digital voltmeter (Heath EU-805) interfaced to a microcomputer (Amstrad CPC 6128). The general interface technique and the main features of the control program (KINMOD) have been described elsewhere.[10]

All measurements were carried out in a thermostatted (±0.1°C) double-wall glass cell under constant magnetic stirring. The bromide-selective electrode was stored in 0.0010*M* KBr solution when not in use. pH measurements were carried out with a Metrohm Model E-350B pH-meter equipped with a low alkaline error combination glass electrode.

*To whom correspondence should be addressed.

Reagents

All reagents were of analytical grade and demineralized distilled water was used throughout.

N-Bromosuccinimide solution (0.0200*M*) was prepared by dissolving 0.178 g of NBS (Serva) in water and diluting with water to 50.0 ml. This solution was prepared daily and it was kept in an amber-coloured bottle.

Working standard bromide solutions were prepared by dilution of a 0.100*M* KBr stock solution.

Pyridoxine (Sigma) and thiamine (Serva) hydrochlorides stock solutions (0.0200*M*) were prepared daily by dissolving the appropriate amount of each compound in water and diluting to volume.

The following buffer solutions were used: acetate buffers (pH 3.0–5.0) 0.050*M* in total acetate, phosphate buffers (pH 2.0–4.0 and 5.0–11.0) 0.18 and 0.050*M* in total phosphate, respectively, and bromide containing phosphate buffers (pH 5.0–12.0) $5.0 \times 10^{-6}M$ in KBr and 0.050*M* in total phosphate.

PROCEDURES

General measurement procedure for kinetic studies

The following solutions are transferred into the reaction cell prior to the injection of NBS solution. For the study of the hydrolysis of NBS, 10.00 ml of the mixed bromide–phosphate buffer (pH 10.0–12.0) solution. For the study of the NBS–Br^- reaction, 5.00 ml of the phosphate buffer (pH 2.0–4.0), a 0.200–5.00 ml volume of $1.0 \times 10^{-4}M$ KBr and water to make a total volume of 10.00 ml. For the study of the reactions of NBS with pyridoxine and thiamine, 10.00 ml of the bromide containing buffer (pH 5.0–9.0) and 25–250 μl of the vitamin solution (0.00200*M*).

After transferring the above solutions into the reaction cell the stirrer is started and when the potential has stabilized (after 15–30 sec as shown by the electrometer readings), the reaction is initiated by rapid injection of the appropriate volume of the NBS solution. Potential indications are automatically collected by the microcomputer at constant time intervals. The reaction is followed for about 30–60 sec, its course is shown on the monitor of the microcomputer and the data (potential *vs.* time, *E–t* curve) are stored in magnetic disks for further processing. The cell is then evacuated and washed twice with the same buffer solution, before proceeding to the next measurement.

The data are recalled and the initial slope $(\Delta E/\Delta t)_0$ is measured (in millivolts per second) by interactive selection of the initial linear part, the correlation coefficient (r) of this part being a measure of the linearity (typically: $|r| \geq 0.995$).

The slope (S) of the electrode response, corresponding to the experimental prelogarithmic factor of the Nernst equation (theoretical value: $-RT/F$) and required for the calculation of reaction rate constants, is determined under the same conditions (temperature, pH and ionic medium) by successive additions of small volumes of 0.100*M* KBr stock solution in 10.00 ml of bromide-free buffer solution. An auxiliary computer program is used for the acquisition of potential indications and fast evaluation of S.

Sample preparation

Tablets. At least 20 tablets of the pharmaceutical preparation were weighed and finely powdered. A sample equivalent to approximately 200 mg of analyte was weighed accurately, transferred into a 1 l volumetric flask and diluted to volume with water. The powder was sonicated for 10 min to accelerate the dissolution. Working solutions were prepared from this sample solution by appropriate dilution so that the final analyte concentration was within the linear range of the calibration graph.

Injections. An accurately measured volume of the mixture of five ampules was transferred into a 250 ml volumetric flask and diluted to volume with water. The solution was diluted further so that the final analyte concentrations lay within the linear range of the calibration graph.

Measurement procedure for kinetic determination of pyridoxine

The general procedure, followed for the kinetic study of the reaction of NBS with the vitamins was used: 10.00 ml of bromide containing phosphate buffer of pH 5.0 was transferred into the cell and the reaction starts by adding 100 μl of sample containing pyridoxine in the concentration range 5×10^{-4}–$5 \times 10^{-3}M$. The

analytical signal, $(\Delta E/\Delta t)_0$, is measured as described above. Calibration graphs of $(\Delta E/\Delta t)_0$ *vs.* concentration of the examined reactant are constructed using standard solutions of the latter.

RESULTS AND DISCUSSION

Study of the electrode static and dynamic characteristics

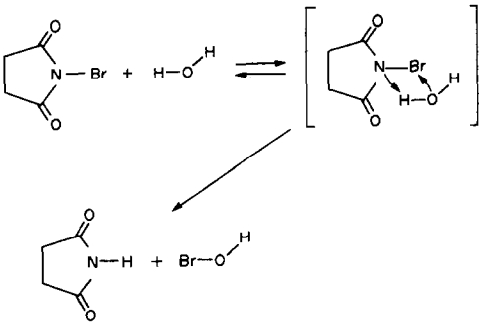
In order to evaluate the operational characteristics of the bromide-electrode at the pH used, calibration graphs were obtained over the concentration range 5.0×10^{-7}–$1.0 \times 10^{-4}M$ at pH range 3.0–11.0 and temperature range 10–35°C. The lower linear concentration limit was $5.0 \times 10^{-6}M$ or less over the temperature and pH range studied.

The dynamic response time of the bromide ion-selective electrode was studied by rapid injections of a bromide solution to cause an increase $\Delta[Br^-]$ of an initial bromide concentration $[Br^-]_0$ and measuring the time required for the stabilization of the potential within 1% of the final potential change. The dynamic response times for the following changes ($[Br^-]_0 + \Delta[Br^-]$, M): $0 + 9.9 \times 10^{-7}$, $9.9 \times 10^{-7} + 4.9 \times 10^{-6}$, and $5.9 \times 10^{-6} + 4.90 \times 10^{-5}$ were found in the range 5.2–17.4, 2.7–9.0 and 0.5–3.6 sec, respectively, over the pH range 3.0–11.0 and temperature range 15–35°C.

From this study, it was concluded that the bromide-selective electrode can be used for the kinetic study, provided that a bromide background concentration not less than $5.0 \times 10^{-6}M$ is present before the initiation of the reaction, when bromide is a reaction product (hydrolysis of NBS and reactions of NBS with vitamins). Similarly, when bromide is consumed (reaction of NBS with Br^-), measurements must be obtained before its concentration becomes lower than $5 \times 10^{-6}M$. A time interval not less than the actual dynamic response time must be allowed before the acquisition of E–t indications for the calculation of $(\Delta E/\Delta t)_0$ to minimize errors due to hysteresis of the electrode response.

Kinetic study of NBS hydrolysis

NBS is relatively unstable in alkaline solutions[1] though no kinetic data of its hydrolysis reaction have appeared in the literature. The hydrolysis can be depicted by the following scheme.



(I)

Hypobromous acid is a rather unstable weak acid ($K_a = 5 \times 10^{-9}$) and its decomposition is influenced by many factors (concentration, pH, temperature, presence of other salts, catalysts, activators, promoters and light).[11] The main competing decomposition reactions are

$$2HBrO \rightarrow 2H^+ + 2Br^- + O_2 \qquad (2)$$

$$3HBrO \rightarrow 3H^+ + 2Br^- + BrO_3^- . \qquad (3)$$

Since, each bromide ion may be the decomposition product of 1–1.5 molecules of NBS, the produced bromide is not expected to correspond stoichiometrically to NBS, nevertheless its production rate is indicative of the overall loss of total Br(+1) activity and indirectly of NBS, as well. Considering that the concentrations of NBS and hydroxide ions influence the overall reaction rate, the bromide formation rate can be generally described by the equation

$$d[Br^-]/dt = k_h[NBS]^x[OH^-]^y \qquad (4)$$

where k_h is the experimental rate constant of the hydrolysis.

By differentiation of the Nernst equation for the bromide-electrode with respect to time, we have

$$dE/dt = S(1/[Br^-])\ (d[Br^-]/dt) \qquad (5)$$

where S is the *experimental value of the* slope of the E *vs.* $\ln[Br^-]$ calibration graph (theoretical value: $-RT/F$).

Combining equations (4) and (5), at the beginning of the reaction where the initial slope $(\Delta E/\Delta t)_0$ is measured and $[Br^-]$ remains practically equal to the initially added (background) bromide concentration $[Br^-]_0$ we have

$$(\Delta E/\Delta t)_0 = (S/[Br^-]_0)\ k_h\ [NBS]_0^x[OH^-]_0^y. \qquad (6)$$

Rate measurements with $[NBS]_0$ in the range 1×10^{-5}–$4 \times 10^{-5}M$, over the pH range 10.0–12.0, and temperature range 10–25°C revealed reaction orders for NBS and OH^- equal to

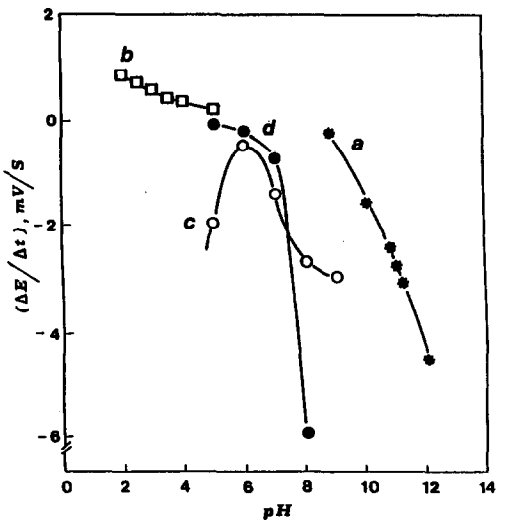


Fig. 1. Effect of pH on the reaction of NBS with reactants: (a) water (alkaline hydrolysis), (b) bromide, (c) pyridoxine and (d) thiamine, at 20°C. [NBS] = $2.0 \times 10^{-4}M$, [Reactant] = $2.0 \times 10^{-5}M$.

1.04 ± 0.08 (range: 0.96–1.18) and 0.23 ± 0.03 (range: 0.20–0.25), respectively.

The effect of pH on the initial rate of the NBS hydrolysis reaction is shown in Fig. 1 [curve (a)].

At pH 10.5 and temperatures of 10, 15, 20 and 25°C, the experimental k_h values were found to be equal to 0.018, 0.026, 0.034 and $0.042M^{-0.23}$/s, respectively and the calculated activation energy was 9.4 ± 0.7 kcal mol.

All data concerning the rate of Br^- production are incorporated in the equation

$$d[Br^-]/dt = 3.6 \times 10^5[NBS][OH^-]^{0.23}\exp[-4753]/(273.15+\theta)] \quad (7)$$

which is valid over the aforementioned ranges of pH, temperature (θ) and NBS concentration.

According to the above results, all kinetic studies of reactions of NBS with other compounds based on monitoring of the produced bromide ions, must take into consideration the parallel hydrolysis of NBS which is particularly pronounced at pH $\geq$ 10.0. This hydrolysis must be considered as a plausible source of blank in kinetic measurement, since part of the intermediately formed hypobromite may escape the primary reaction (in the present case with vitamins) and be decomposed according to reaction (2) and/or (3).

Kinetic study of the NBS–bromide reaction

In acidic solutions NBS reacts with Br^- according to the overall reaction

$$NBS + H^+ + Br^- \rightarrow NHS + Br_2. \quad (8)$$

Considering that the rate of bromide consumption is affected by NBS, bromide and

5.0	0.98 ± 0.03 ($n = 4$)*	1.06 ± 0.04 ($n = 6$)	176 ± 3.7 ($n = 6$)	1.05 ± 0.08 ($n = 4$)	0.99 ± 0.03 ($n = 5$)	0.47 ± 0.00 ($n = 5$)
6.0	1.12 ± 0.10 ($n = 4$)	1.01 ± 0.03 ($n = 6$)	28.4 ± 0.3 ($n = 6$)	1.08 ± 0.07 ($n = 4$)	1.09 ± 0.09 ($n = 4$)	8.3 ± 0.3 ($n = 4$)
7.0	0.98 ± 0.02 ($n = 5$)	1.06 ± 0.06 ($n = 6$)	102 ± 2.6 ($n = 6$)	0.96 ± 0.18 ($n = 3$)	1.05 ± 0.05 ($n = 5$)	33.4 ± 0.8 ($n = 5$)
8.0	0.97 ± 0.06 ($n = 4$)	1.05 ± 0.09 ($n = 4$)	133 ± 3.2 ($n = 4$)	1.06 ± 0.10 ($n = 5$)	1.13 ± 0.08 ($n = 5$)	749 ± 45 ($n = 5$)
8.0	1.02 ± 0.05 ($n = 5$)	1.09 ± 0.11 ($n = 4$)	324 ± 16 ($n = 4$)	1.08 ± 0.10 ($n = 4$)	1.04 ± 0.04 ($n = 5$)	941 ± 24 ($n = 5$)

*n = number of standard solutions, each measured three times.

hydrogen ion concentrations, this rate is described by the overall equation

$$-(\mathrm{d}[Br^-]/\mathrm{d}t) = k_{exp}[Br^-]^x[NBS]^y\ [H^+]^z \quad (9)$$

where k_{exp} is the experimental rate constant of the overall reaction.

Combining equations (5) and (9) at the beginning of the reaction, we have

$$(\Delta E/\Delta t)_0 = Sk_{exp}\ [Br^-]_0^{x-1}[NBS]_0^y[H^+]_0^z. \quad (10)$$

Rate measurements with $[NBS]_0$ and $[Br^-]_0$ in the range 2.5×10^{-5}–$5.0 \times 10^{-5} M$ and 5.0×10^{-6}–$5.0 \times 10^{-5} M$, respectively, over the pH range 2.0–3.5 and the temperature range 10–30°C, revealed reaction orders for NBS, Br^- and H^+ equal to 0.98 ± 0.04 (range: 0.93–1.07), 1.20 ± 0.04 (range: 1.11–1.25) and 0.28 ± 0.06 (range: 0.19–0.32), respectively. Therefore equation (10) can be written

$$(\Delta E/\Delta t)_0 = Sk_{obs,H}[Br^-]_0^{x-1}\ [NBS]_0 \quad (11)$$

and $k_{obs,H}$ expresses the pH dependent overall observed second-order rate constant.

$k_{obs,H}$ values at pH 2.0, 2.5 and 3.0, over the temperature range 15–35°C were calculated in the ranges 1.3×10^3–3.2×10^3, 1.0×10^3–2.4×10^3 and 0.9×10^3–$1.7 \times 10^3/M$ s, respectively. The respective calculated activation energies were 8.1 ± 0.4, 8.4 ± 0.4 and 5.6 ± 0.3 kcal/mol.

Typical E–t curves of the NBS–Br^- reaction, used for the calculation of the reaction order with respect to NBS at pH 2.5 at 25°C are shown in Fig. 2. The effect of pH on the initial rate of the NBS–bromide reaction is included in Fig. 1 [curve (b)].

According to the above results, all kinetic studies of reactions of NBS (in excess) with other compounds based on monitoring of the produced bromide ions, must also take into consideration the parallel consumption of bromide which is particularly pronounced at pH ≤ 4.0.

Kinetic study of NBS reactions with pyrodoxine or thiamine

Recently, potentiometric monitoring of the bromide production rate during the reaction of pyridoxine or thiamine with NBS has been exploited for developing a kinetic–potentiometric procedure for the determination of these vitamins in pharmaceutical preparations. However, no detailed kinetic data were obtained.[9]

Considering that the rate of bromide production is affected by NBS and vitamin (Vit) concentrations, and combining the relevant

7.0	$y = 0.17 + 1.90 \times 10^4 x$	0.997	5
8.0	$y = 0.18 + 16.3 \times 10^4 x$	0.997	5
9.0	$y = 0.31 + 56.6 \times 10^4 x$	0.999	5

*$y = (\Delta E/\Delta t)_0$ (mV/s) and $x = C$ (M).
†n = number of samples, each measured three times.

kinetic expression with the Nernst equation we finally obtain the following equation

$$(\Delta E/\Delta t)_0 = (S/[Br^-]_0)\, k_{obs}[NBS]_0^x[Vit]_0^y \quad (12)$$

where k_{obs} is the overall experimental rate constant which is expected to be pH-dependent.

Plots of $(\Delta E/\Delta t)_0$ *vs.* $[Vit]_0$ (for both vitamins) are linear denoting a practically first-order reaction with respect to vitamins ($y \approx 1$), but a positive intercept (blank) is consistently observed probably due to a catalysis of the NBS-hydrolysis reaction by coexisting species or unknown side reactions also producing bromide. Therefore all initial rates $(\Delta E/\Delta t)_0$ used for the subsequent calculations were previously corrected for this blank.

From experiments with various concentrations of vitamin and a constant concentration of NBS, the reaction order with respect to vitamin and k_{obs} can be obtained. From similar experiments, in which NBS concentration is varied with constant vitamin concentration, the reaction order with respect to NBS can also be obtained. The results of this kinetic study at 20°C and at pH range 5.0–9.0 are summarized in Table 1.

The k_{obs} values obtained as described above at pH 5.0 and 9.0 for the NBS–pyridoxine reaction and at pH 6.0 and 9.0 for the NBS–thiamine reaction, at various temperatures (10–40°C) and the calculated activation energies are given in Table 2.

The effect of pH on the NBS–pyridoxine and NBS–thiamine reactions are included and shown comparatively in Fig. 1 [curves (c) and (d), respectively].

Determination of pyridoxine in the presence of thiamine

Equation (12) shows that the initial slope of the reaction curve is linearly related to the

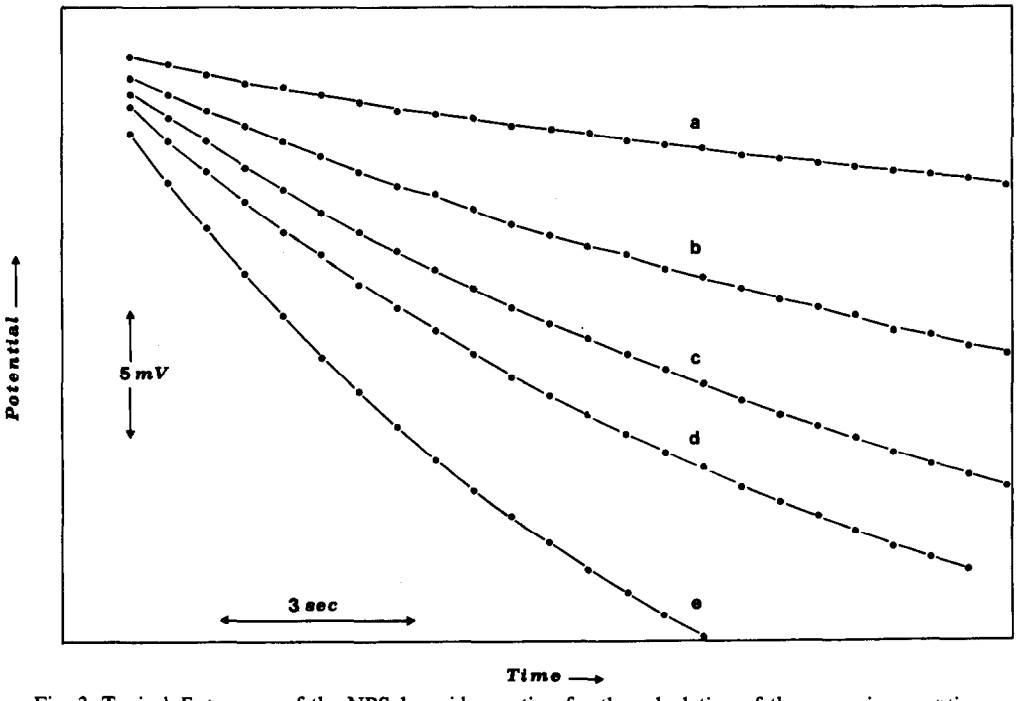

Fig. 3. Typical E–t curves of the NBS–bromide reaction for the calculation of the regression equation for the determination of pyridoxine at 20°C and pH 5.0. $[Pyridoxine]_0$: (a) 5.0×10^{-6}, (b) 1.0×10^{-5}, (c) 1.5×10^{-5}, (d) 2.0×10^{-5} and (e) $3.0 \times 10^{-5} M$ ($[NBS]_0 = 2.0 \times 10^{-4} M$).

Table 4. Determination of pyridoxine in commercial formulations containing thiamine with the proposed method and an official method[12]

Formulation	Pyridoxine content (*mg*/ampule or tablet)			
	Stated composition	Official method	Proposed method ($\pm s$)*	Relative difference (%)
Neurobion (tablet)	200 mg pyridoxine 100 mg thiamine 200 μg cyanocobalamin	192	174 ± 3	−9.4

*Each sample measured three times.

vitamin concentration as the reaction is first-order with respect to vitamin (Table 1). The working curves obtained with concentrations of vitamins in the range of 5.0×10^{-6}–$5.0 \times 10^{-5}M$ at various pH values are described by the regression equations shown in Table 3. Maximum reaction initial rates for both reactions are observed at pH 9.0, where thiamine reacts faster than pyridoxine. However, at pH 5.0 the reaction rate of NBS with pyridoxine is about two orders higher than that with thiamine. Therefore the kinetic determination of pyridoxine in the presence of thiamine is feasible when both vitamins are present within the same order of concentration. Typical E–t curves of the NBS–pyridoxine reaction are shown in Fig. 3. Using these curves the regression equation for the determination of pyridoxine at pH 5.0 is obtained.

The method developed was used in the assay of pyridoxine in pharmaceutical preparations containing both vitamins. The mole ratios of thiamine and pyridoxine in all pharmaceutical preparations examined were within the range of 0.2–5.0. Results obtained from determinations of pyridoxine in pharmaceuticals with the proposed method for the determination of pyridoxine are compared very well with those obtained by the US Pharmacopoeia procedure[12] and they are shown in Table 4.

Simultaneous determination of both vitamins by applying differential kinetic analysis[13] and obtaining measurements at *e.g.*, pH 5.0 and 9.0, gave satisfactory results with synthetic mixtures of vitamins, but positive analytical errors were consistently observed with thiamine in real samples.

CONCLUSIONS

N-Bromosuccinimide reactions can be indirectly studied by potentiometric monitoring of the produced bromide with a bromide-selective electrode. This method may be applied for studying reactions of NBS with a number of inorganic and organic compounds (*e.g.*, ammonia, aminoacids, hydrazides). The parallel hydrolysis of NBS, which is particularly fast in the alkaline pH range (pH ≥ 10.0), and the reaction of NBS (when present in excess) with the produced bromide, particularly in acidic pH range (pH ≤ 4.0), must be taken into consideration. The kinetic data presented in this study, concerning these possible parallel reactions of NBS, may prove useful in this case.

It must be stressed that fast NBS reactions *e.g.*, with ascorbic acid, cannot be monitored reliably due to the inherent inability of potentiometric sensors to follow fast reactions.

INVESTIGATIONS ON ADSORPTION POTENTIOMETRY—PART VIII. DETERMINATION OF ULTRATRACE COPPER IN FOOD BY DERIVATIVE ADSORPTION CHRONOPOTENTIOMETRY

LI XIAO and WENRUI JIN*
Department of Chemistry, Shandong University, Jinan 250100, Shandong, P.R. China

(*Received* 14 *September* 1992. *Revised* 5 *February* 1993. *Accepted* 18 *February* 1993)

Summary—An electroanalytical method, based on derivative chronopotentiometry of the copper complex with 4-[(4-diethylamino-2-hydroxyphenyl) azo]-5-hydroxy-naphthalene-2,7-disulphonic acid (Beryllon III) accumulated on the surface of a hanging mercury drop electrode, for determining trace copper in food has been developed. The dependence of the peak height of reduction of the copper complex on the preconcentration time and preconcentration potential are discussed. Optimum experimental conditions include 0.01 *M* HOAc, 0.01*M* NaOAc, 1.0×10^{-6} Beryllon III and a preconcentration potential of 0.10 V (*vs.* SCE). Under these conditions the detection limit and the linear range are $4 \times 10^{-11}M$ and 6×10^{-11}–$4 \times 10^{-7}M$, respectively. The method was applied to samples of digested rice.

Of the methods for determination of trace copper by electrochemical analysis, anodic stripping voltammetry is usually used. Since its anodic peak is near the peak of oxidation of the mercury, determining copper is not any more sensitive than other heavy metals, such as zinc, cadmium and lead. Another disadvantage of anodic stripping voltammetry for the determination of copper is interference of metal ions, in particular, Zn(II), due to formation of intermetallic compounds in amalgams. Adsorption voltammetry is well suited to the determination of trace copper ion through its complexes with CNS^-,[1] catechol,[2,3] 8-hydroxyquinoline[4] and thiorea.[5] Usually, the limit of detection of these methods is 10^{-8}–$10^{-9}M$. Of these methods, the adsorption voltammetry of the Cu(II)–catechol system is the most sensitive and the limit of detection is as low as $6 \times 10^{-11}M$. However, the disadvantage of using catechol to determine copper lies in its instability against oxidation by dissolved oxygen.[3] The stock solution needs to be prepared freshly every day.

More recently an ultra-trace electroanalytical method for the determination of inorganic ions, *e.g.*, cobalt,[6] nickel,[8] iron,[7] bismuth[8] and beryllium,[9] called derivative adsorption chronopotentiometry has been proposed. This method is similar to chronopotentiometry stripping analysis, and its theory has been reported.[10] In this method, instead of electrolytic accumulation, inorganic complexes can be accumulated by adsorption like adsorption voltammetry, and the derivative of time with respect to potential is then recorded. The peak height $(dt/dE)_p$ of the curve, adsorption chronopotentiogram, can be written as the following equation[10]

$$(dt/dE)_p = Kt_a c/i_o \quad (1)$$

where K is a constant, t_a is the preconcentration time, i_o is a constant reducing current and c is the concentration of adsorbed complex in the solution which is proportional to the concentration of metal ion.

In this paper the derivative adsorption chronopotentiometry of copper in the presence of 4-[(4-diethylamine-2-hydroxyphenyl)azo]-5-hydroxy-naphthalene-2,7-disulphonic acid (Beryllon III) at a hanging mercury drop electrode (HMDE) was developed. The limit of detection of the method is as low as $4 \times 10^{-11}M$. Except for the lower limit of detection, another advantage of the method is that the ligand (Beryllon III) is stable in the stock solution which can be stored for at least one month at room temperature.

EXPERIMENTAL

Apparatus

A Model DPSA-3 stripping analyser (Shandong Seventh Electronic Factory, China) for derivative adsorption chronopotentiometry coupled with a Model LZ_3-200 X-Y recorder (Shanghai Dahua Instrument Factory, China) was used in connection with a cell, using potentiostatic control of the electrode potential by means of a three electrode system consisting of a Model SH-84 HMDE (Department of Chemistry, Shandong University, China) as the working electrode, a platinum plate as the counter electrode and a saturated calomel electrode (SCE) as the reference electrode, connected to the analyte via a salt bridge filled with $0.01M$ HOAc + $0.01M$ NaOAc. In the preconcentration step, the solution was stirred with a PTFE-covered stirring bar, rotated by a Model MCP-IT magnetic stirrer (Shandong Seventh Electronic Factory, China).

Reagents and solutions

A $1 \times 10^{-2}M$ stock solution of Cu(II) was prepared by dissolving an appropriate amount of metal copper in 1:1 HNO_3. The solution was then evaporated in a sand-bath until white smoke appeared. The solution was transferred to a 1 l standard flask. The standard solution was obtained by diluting the stock solution with water. A $5 \times 10^{-4}M$ stock standard solution of Beryllon III was prepared by dissolving an appropriate amount of Beryllon III in water. Other reagents were of analytical-reagent grade and all solutions were prepared with triply distilled water.

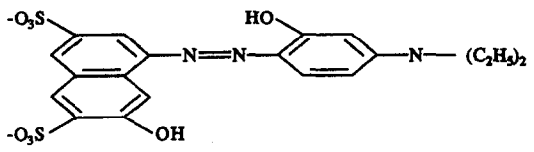
Procedure

The supporting electrolyte consisted of $0.01M$ HOAc + $0.01M$ NaOAc. The solution was deaerated for 15 min with pure nitrogen. The measurements were carried out after a preconcentration step in which the solution was usually stirred for 60 sec at a preconcentration potential, E_a, of 0.10 V (*vs.* SCE). After a rest period of 30 sec, the potentiostatic circuitry was disconnected and a constant reducing current, i_o, of 1 μA or 0.1 μA was passed through the HMDE and the counter electrode. The plot of dt/dE *vs.* E was stored in the stripping analyser and plotted subsequently. All potentials were measured against the SCE.

RESULTS AND DISCUSSIONS

Derivative adsorption chronopotentiogram of the Cu(II) complex with Beryllon III adsorbed on the HMDE

The structure of Beryllon III, L, is



In HOAc + NaOAc solution, it can form a complex with Cu(II), CuL, which is reduced at a mercury electrode[11] according to the following scheme,

$$Cu(II)L + Hg \rightleftharpoons Cu(II)L(ads)(Hg) \quad (1)$$

$$Cu(II)L(ads)(Hg) + 2e^- \rightarrow Cu(O)(Hg) + L(ads) \quad (2)$$

Figure 1 reproduces the derivative chronopotentiogram of Cu(II) (curve 1) and the derivative adsorption chronopotentiograms of Beryllon III (curve 2) and its complex with Cu(II) (curve 3). Cu(II) produces a diffusion-controlled peak at about -0.04 V in the supporting electrolyte. In $1.0 \times 10^{-6}M$ Beryllon III and the supporting electrolyte, one peak appears in the potential range from 0 to -1.0 V, the potential of the peak is -0.26 V. When $5.0 \times 10^{-8}M$ Cu(II) is added into the solution, a new peak appears at a position between the peak of reduction of Cu(II) and that of Beryllon III with the peak potential of -0.13 V and the peak height of reduction of Beryllon III decreases. It is the result of reduction of the Cu(II) complex with Beryllon III adsorbed on the electrode. The relationship between the peak height and the preconcentration time, t_a, is shown in Fig. 2. The peak height increases with increasing t_a, when $t_a > 240$ sec, the straight line begins to deflect, this means that the Cu(II) complex can be adsorbed on the surface of the electrode. The adsorptivity of the complex on the surface of the HMDE is dependent on the preconcentration potential, E_a. The relationship between the peak height, $(dt/dE)_p$, and E_a is shown in Fig. 3. The adsorption is stronger in the potential range 0.15–0 V.

Optimum experimental conditions

Figure 4 shows the dependence of the peak height of reduction, of the Cu(II) complex adsorbed on the electrode, on the concentration of

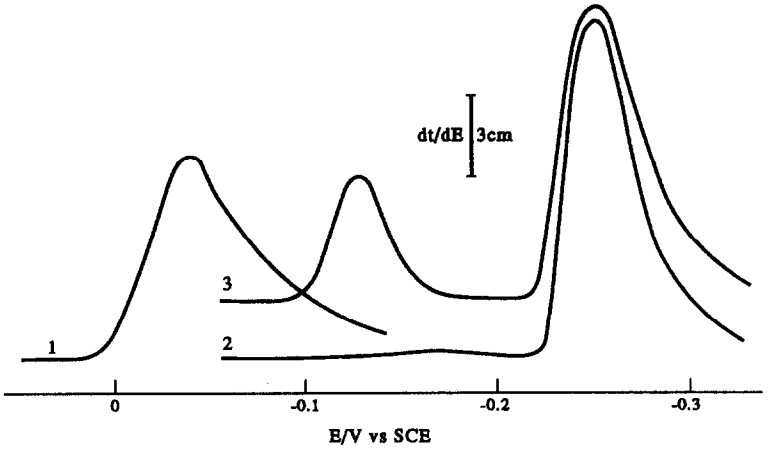


Fig. 1. Derivative chronopotentiogram of Cu(II) and derivative adsorption chronopotentiograms of Beryllon III and its complex with Cu(II). (1) $2.5 \times 10^{-5}M$ Cu(II); (2) $1.0 \times 10^{-6}M$ Beryllon III; (3) (2) + $5.0 \times 10^{-3}M$ Cu(II). $0.01M$ HOAc + $0.01M$ NaOAc. Sensitivity of the analyser is 60; sensitivity of the recorder is 50 mV/cm; $E_a = 0.10$ V; $i_o = 1$ μA; (1), (2) $t_a = 60$ sec, (3) $t_a = 360$ sec.

NaOAc (curve 1) and HOAc (curve 2). NaOAc ($0.01M$) and HOAc ($0.01M$) were chosen in our experiments as supporting electrolytes.

It was found that the optimum concentration of Beryllon III is different for different concentrations of Cu(II), if the concentration of Beryllon III is too high, the peak height of the complex decreases because of the adsorption competition of Beryllon III; if the concentration of Beryllon III is too low, the peak height of the complex decreases too, because not all the Cu(II) can form the complex with Beryllon III. The optimum concentrations of Beryllon III are $2 \times 10^{-8}M$ for $1\text{–}10 \times 10^{-10}M$ Cu(II), $4 \times 10^{-7}M$ for $1\text{–}10 \times 10^{-9}M$ Cu(II) and $1 \times 10^{-6}M$ for $10^{-8}\text{–}4 \times 10^{-7}M$ Cu(II).

Linear range, detection limit and reproducibility

The peak height $(dt/dE)_p$ of the derivative adsorption chronopotentiogram is dependent on the reducing current, i_o. The smaller i_o is, the higher the peak height,[10] so we used $i_o = 0.1$ μA to obtain the linear range and detection limit. The linear range of derivative adsorption chronopotentiometry is $6 \times 10^{-11}\text{–}7 \times 10^{-10}M$ Cu(II) for $2.0 \times 10^{-8}M$ Beryllon III, $1 \times 10^{-9}\text{–}1.8 \times 10^{-8}M$ Cu(II) for $4.0 \times 10^{-7}M$ Beryllon III; $9 \times 10^{-9}\text{–}4 \times 10^{-7}M$ Cu(II) for $1.0 \times 10^{-6}M$ Beryllon III. The detection limit of the method is $4 \times 10^{-11}M$ with a preconcentration time of 200 sec. Figure 5 shows the adsorption chronopotentiograms of the Cu(II) complex with Beryllon III at lower concentrations. For comparing, the derivative anodic stripping chronopotentiogram of Cu(II) at $t_a = 120$ sec and the derivative adsorption chronopotentiogram of Cu(II) complex with Beryllon at $t_a = 60$ sec at the same concentration are plotted in Fig. 6. It is obvious that the present method is more sensitive. The precision, calculated from 10 successive measurements of $5 \times 10^{-8}M$ Cu(II) is 2.6%.

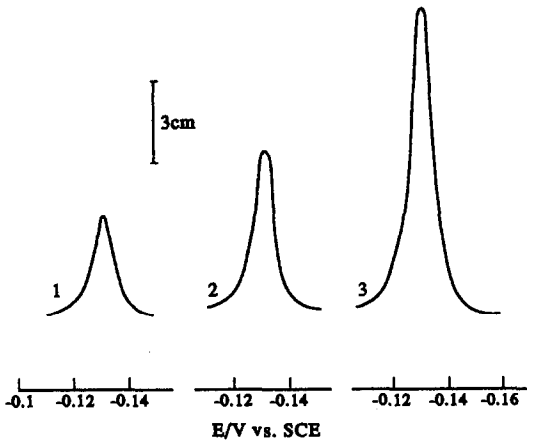

Fig. 5. Derivative adsorption chronopotentiograms of Cu(II) complex with Beryllon III, (1) 6×10^{-11}; (2) 1×10^{-10}; (3) $2 \times 10^{-10}M$ Cu(II). $2 \times 10^{-8}M$ Beryllon III, $E_a = 0.10$ V, $t_a = 200$ sec, $i_o = 0.1$ μA, 0.01M HOAc + 0.01M NaOAc. Sensitivity of the analyser is 5.

Analytical application

The interference of Zn(II) with Cu(II) is a difficult problem in anodic stripping voltammetry due to their intermetallic bonding in amalgam. In the derivative adsorption chronopotentiometry mentioned above, a 200-fold excess of Zn(II) does not interfere with the peak of reduction of the Cu(II) complex with Beryllon III adsorbed on the surface of the HMDE, because the accumulation occurs on the surface of the electrode, not on the inside of the electrode for derivative adsorption chronopotentiometry.

Experimental results show that a 100-fold excess of Ni(II), Bi(III), Co(II) and Mn(II), a 200-fold excess of Zn(II), Cd(II), Sb(II), Pb(II), As(V), Mg(II) and Fe(III) and large amounts of Ca(II), Ba(II), Al(III), Na(I), K(I), SO_4^{2-}, PO_4^{3-}, Cl^- and NO_3^- do not interfere with the determination of Cu(II). For usual biological samples, Cu(II) can be determined directly after digestion.

Samples of rice were digested with an electric oven prior to adsorption chronopotentiometric determination. The procedure is as follows: *ca.* 0.1 g samples of rice were weighed to an accuracy of 0.1 mg in individual 10-ml quartz

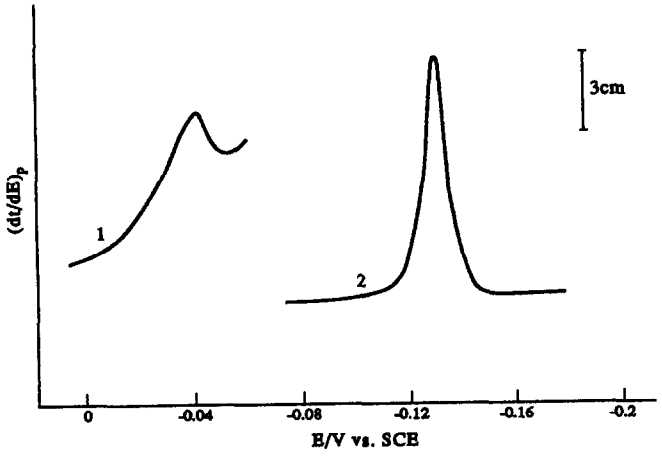

Fig. 6. Comparison between (1) derivative anodic stripping chronopotentiogram of Cu(II) and (2) derivative adsorption chronopotentiogram of Cu(II) complex with Beryllon III. 0.01M HOAc + 0.01M NaOAc, $i_o = 0.1$ μA, sensitivity of the analyser is 30. (1) $1.86 \times 10^{-8}M$ Cu(II), $E_a = -0.60$ V, $t_a = 120$ sec; (2) $1.86 \times 10^{-8}M$ Cu(II) + $1.0 \times 10^{-6}M$ Beryllon III, $E_a = 0.10$ V, $t_a = 60$ sec.

Table 1. Results of the determination of copper in samples of rice

Sample	Content determined by DACP ($\mu g/g$)	Content determined by DASCP ($\mu g/g$)
Rice A	7.28 7.45 7.33	7.37 7.44 7.53
Rice B	7.80 7.88 7.93	7.90 7.87 7.98

crucibles. They were placed on a big clean culture dish to avoid contamination from the electric oven during digestion. Nitric acid (500 μl) was added to each, and then the crucibles were covered overnight. The quartz crucibles on the culture dish were heated slowly for about 5 hr with an electric oven until the yellow smoke disappeared. Then 1 ml of perchloric acid was added to each and the sample solution was digested further until the sample solution was colourless. The solution was cooled, the cover of the crucible was washed with triply distilled water and the sample solution was then evaporated to dryness. The remaining substance should be white. After cooling it to room temperature, water was added and the remaining substance was dissolved. Then the solution was transferred into a 50-ml standard flask and diluted to the mark with water. A 5-ml sample solution was transferred to a 25-ml standard flask containing appropriate amounts of HOAc, NaOAc and Beryllon III. Then the solution was diluted to the mark, which contained 0.01M HOAc, 0.01M NaOAc, $1 \times 10^{-6}M$ Beryllon III and Cu(II).

After the solution was transferred to a cell, the derivative adsorption chronopotentiogram of Cu(II)–Beryllon III was recorded by the method above.

Typical results obtained by derivative adsorption chronopotentiometry with two successive standard additions for samples of rice are summarized in Table 1. The results from the determination of Cu(II) by derivative adsorption chronopotentiometry (DACP) are in agreement with the data obtained by derivative anodic stripping chronopotentiometry (DASCP). The recovery of added copper was 102–106%.

(*Received* 18 *August* 1992. *Revised* 15 *February* 1993. *Accepted* 15 *February* 1993)

Summary—A new method for the determination of trace amounts of manganese(II) in aqueous solutions by its affect on some types of the chaotic regimes in the Belousov–Zhabotinskii reaction has been proposed. The method is based on the high sensitivity of some types of chaotic regimes of the BZ reaction to small perturbations of initial conditions (*e.g.*, low concentrations of some metal ions). The experimentally obtained detection limit for manganese is 3 pg/ml.

The kinetic methods of analysis are of interest for the determination of trace amounts of different substances and are widely used for quantitative determination of low concentrations of different compounds in solution, among them metal ions.[1–5] The basis of kinetic methods utilizes the ability of a substance to be analysed in order to change the kinetic parameters of a chemical reaction. The choice of such a reaction suitable for the determination of a given compound is determined primarily by picking a regime of chemical process. It was found that chemical reactions can possess different dynamic regimes, for example, monotonic, regular oscillations, quasi-periodicity, chaos *etc.*[6–8] Among them, only monotonic regimes are widely used in kinetic methods for chemical analysis.

The first paper concerning the use of regular chemical oscillations for the determination of trace amounts of ruthenium(III) ions was published in 1978.[9] After this several studies on the possibility of analytical applications of chemical oscillations have been performed.[3,10–12] However, there is no information at the moment on analytical applications of chemical chaos (irregular, unpredictable chemical dynamics) except for some general theoretical discussions.[13–14] A comprehensive discussion on chaotic chemical reactions and proposed models has been published.[6,15–18] The chaotic dynamics are built up by the expanding and folding processes of chaotic orbits, *i.e.*, the path of the chemical system in its phase space with the coordinates represented by chemical species concentrations, and may be described in terms of the local expansion rates of nearby orbits.[18–20] A useful quantity for the description of their structures has recently turned out to be given by the largest Lyapunov characteristic exponent.[18–22] The distinguishing feature of chaotic process is its high sensitivity to initial experimental conditions.[15–22] For example, for the Belousov–Zhabotinskii (BZ) reaction such sensitivity is observed experimentally near the bifurcation point or when the reaction proceeds into chaotic regimes.[17,23–24]

EXPERIMENTAL

Reagents

All reagents were of analytical grade and doubly distilled water was used for dilutions. Aqueous ferroin solution was prepared by the use of the standard method.[25]

Apparatus

Studies were carried out with a 100 ml reactor. The reactor was placed in a constant temperature bath with $T = 21 \pm 0.05$°C, stirring rate was 2000 rpm for a volume of 40 ml in all experiments. The state of the system was followed by measuring the potential of a platinum electrode using a silver–silver chloride electrode

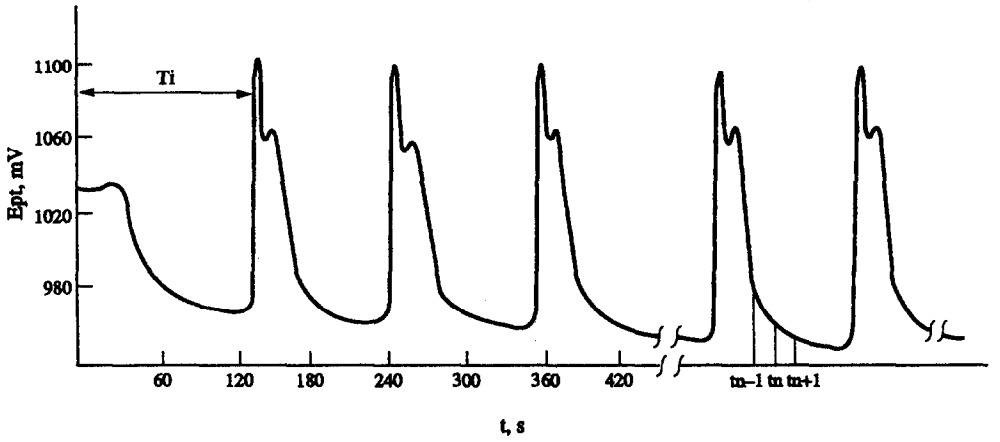

Fig. 1. The Pt-electrode potential–time dependence of the BZ reaction with the following initial concentrations ($T = 294$ K): $[KBrO_3]_0 = 0.115M$: $[H_2SO_4]_0 = 0.32$M; [malonic acid]$_0 = 0.68M$; [ferroin]$_0 = 1.7 \times 10^{-3}M$.

as reference. The potential was recorded as a function of time on Radelkis x–t recorder.

Analyses of the time series obtained were carried out on a IBM PC/AT compatible computer. All programs were written in-house based on the Borland Turbo Pascal system version 3.01A. The reconstruction of phase portraits was adapted from the Packard and Crutchfield algorithm in three-dimensional space, with a time delay of 3 sec from the obtained Pt electrode time series.[26–28] The largest Lyapunov characteristic exponent for each time series was calculated in reconstructed three-dimensional phase space by using the Wolf algorithm with accuracy of approximately 7%.[29]

Procedures

Determination of manganese(II) concentration in aqueous solution was carried out using 0.1 ml of aqueous solution of manganese(II) sulphate added to 39.9 ml of the BZ reaction mixture 30 sec after its preparation. The Pt electrode potential was recorded to the end of the chaotic regime. The mixing solutions were chosen so that in the final solution the reagents were in the following concentrations: $[KBrO_3]_0 = 0.115M$; $[H_2SO_4]_0 = 0.32M$; $[MA]_0 = 0.68M$ (malonic acid); $C_{Fe} = 1.7 \times 10M$ (ferroin). The Lyapunov exponent (λ_L) and time interval from the starting point to the first maximum of potential–time dependent (T_i, see Fig. 1) were calculated from the obtained time series.

The calibration was obtained from the plot $\lambda_L T_i$–Log C_{Mn} of different concentrations of manganese(II).

The determination of manganese(II) trace concentrations can be carried out by using the above method and the obtained calibration.

The concentrations of $KBrO_3$, H_2SO_4 and malonic acid were kept fixed throughout the series of measurements.

The typical view of the Pt electrode potential oscillations is presented in Fig. 1. The Pt electrode potential oscillations have a relaxed character, *i.e.*, they consist of very fast jumps in potential followed by a slower decrease. However, in spite of the regular and pseudoregular oscillations, its amplitudes and "periods" (*i.e.*, the times between maxima) were not constant. These oscillations are not periodic but chaotic.[16] Certainly, the behaviour of the chaotic chemical system is not reproducible, but, in contrast to

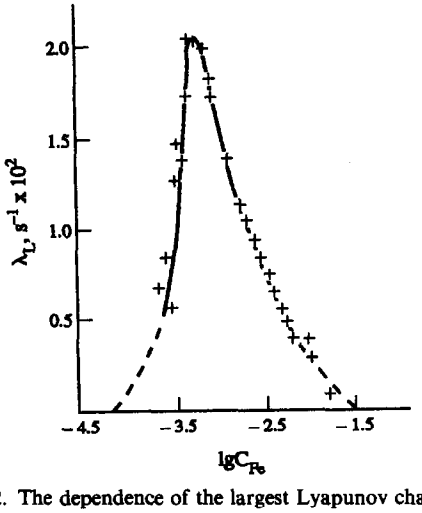

Fig. 2. The dependence of the largest Lyapunov characteristic exponent with respect to the initial ferroin concentration for the BZ reaction (other experimental conditions are as in Fig 1).

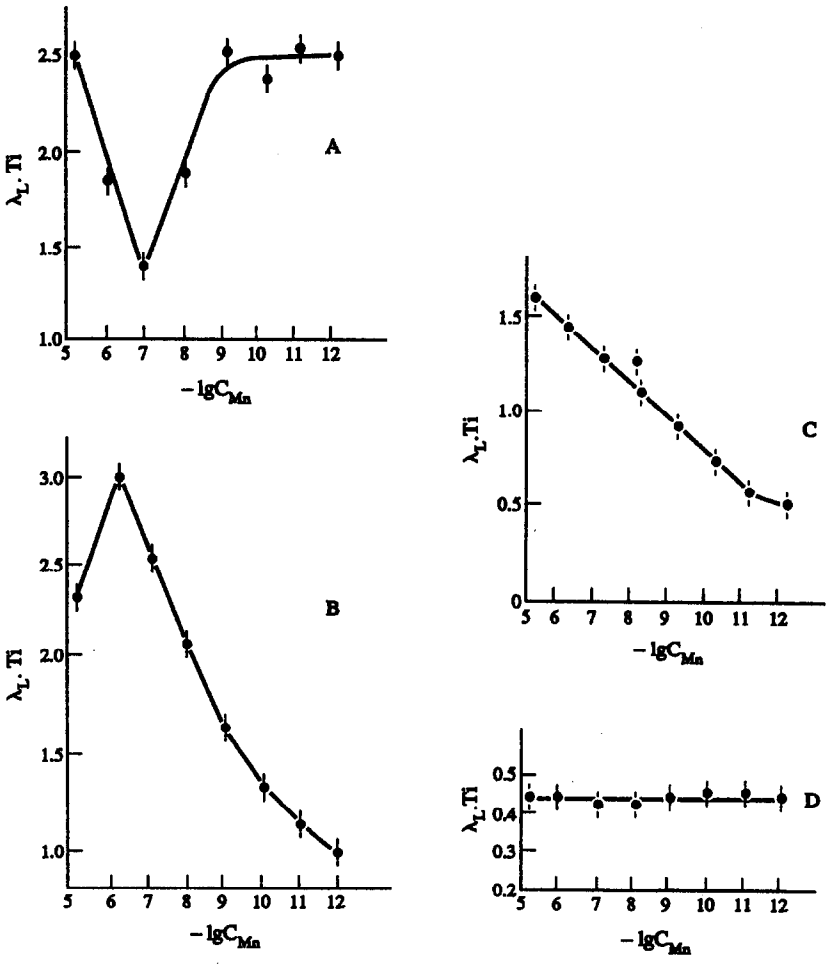

Fig. 3. The dependence of values of $\lambda_L T_i$ with respect to changes in initial time concentration of manganese(II) for BZ chaotic reaction with the following initial ferroin concentrations (other experimental conditions are analogous to Fig. 1): A—[ferroin]$_0 = 8.7 \times 10^{-4} M$; B—[ferroin]$_0 = 1.25 \times 10^{-3} M$; C—[ferroin]$_0 = 1.7 \times 10^{-3} M$; D—[ferroin]$_0 = 5 \times 10^{-3} M$.

the Pt-electrode potential time dependence, the statistical characteristics (for example, the probability density, and fractal dimension) of chaotic motion are reproducible.

RESULTS AND DISCUSSION

The possibility of an analytical application of chemical chaos may be based on the definition of the largest Lyapunov characteristic exponent which can be represented by the following expression:[15-22,29-31]

$$\lambda_L = \lim_{t \to \infty} 1/t \ \mathrm{Log} \ |\delta X(t)/\delta X(0)| \qquad (1)$$

where $\delta X(0)$ is almost any initial perturbation of the starting point $X(0)$ in the phase space of the chemical system, and $\delta X(t)$ describes its evolution in time. In general, the complex chaotic chemical reaction is characterized by a great number of chemical species. So we have no practical possibility for constructing a chaotic attractor from experimental data by using the values of concentrations of all chemical species, but we may construct this attractor from the values of a single variable (in our case, the Pt-electrode potential) at different times, $E(t)$, $E(t + \Delta t)$, $E(t + 2\Delta t)$, ..., *i.e.*, from the experimentally obtained time series.[26-28] For the deter-

mination of the largest Lyapunov characteristic exponent the following expression was used[29]

$$\lambda_L = 1/(t_M - t_0) \sum_{i=1}^{M} \mathrm{Log}(L'(t_i)/L(t_{i-1})) \quad (2)$$

where $L(t)$ is a distance (in the Euclidian sense) between two nearest points in constructed phase space and $L'(t)$ is its evolution after the time interval Δt. Three-dimensional phase space is required for the determination of λ_L for the BZ reaction.[15-18] Notice that the largest Lyapunov characteristic exponent is positive only for chaotic regimes.[18]

Let us consider the case of small perturbation of the initial conditions of a chemical system by the addition of a trace amount of a given compound (with concentration C in the system). In this case the chemical system is perturbed by the variation in the initial conditions, *i.e.*, in (1) we can make the substitution of C for $\delta X(0)$ and obtain the following expression

$$\lambda_L \sim \frac{1}{T} \mathrm{Log} \frac{\bar{X}}{C}$$

where T is a suitable chosen characteristic time of the chemical system, and $\bar{X}$ is an average value of $\delta X(t)$, which depends on the value of T. This relation gives the following expression for the correlation between C and

$$\mathrm{Log}\, C \sim \gamma - \lambda_L T \quad (3)$$

where the constant γ is dependent on $\bar{X}$.

The possibility of the analytical application of chemical chaos on the basis of the expression (3) was verified by the investigation of the influence of trace amounts of manganese(II) on the transient chaotic dynamics in a BZ reaction (L^1S^1 regime). It was estimated that the existence of the linear $\lambda_L T - \mathrm{Log}\, C_{Mn}$ plot occurs only if the characteristic time interval (T) is the time interval from the starting point to the first maximum of the time-dependent potential (T_i, see Fig. 1).

It is necessary to know the largest Lyapunov characteristic exponent for such an investigation. Figure 2 shows the plot of λ_L *vs.* the log of the concentration of the catalyst (ferroin) in the BZ reaction. The typical feature of this dependence lies in the large changes of λ_L values caused by the small changes in ferroin concentrations. This is a result of the high sensitivity of quantitative parameters of the chaotic process to small variations in the experimental conditions. It follows from Fig. 2 that it is possible to vary the value of λ_L (*i.e.*, the sensitivity of the chemical system) through the variation of the ferroin initial concentration in the BZ reaction.

The plots of $\lambda_L T_i$ values *vs.* the log of the manganese(II) concentrations are shown in Fig. 3. It follows from the data presented in Figs 2 and 3 (A) that the dependence observed is not linear in the case of large values of λ_L. So the relationship (3) is not valid and linear calibration can not be obtained in the range of the maximal sensitivity of chaotic process.

Figures 3(B) and 3(C) show the possibility of obtaining the linear calibration. It follows from

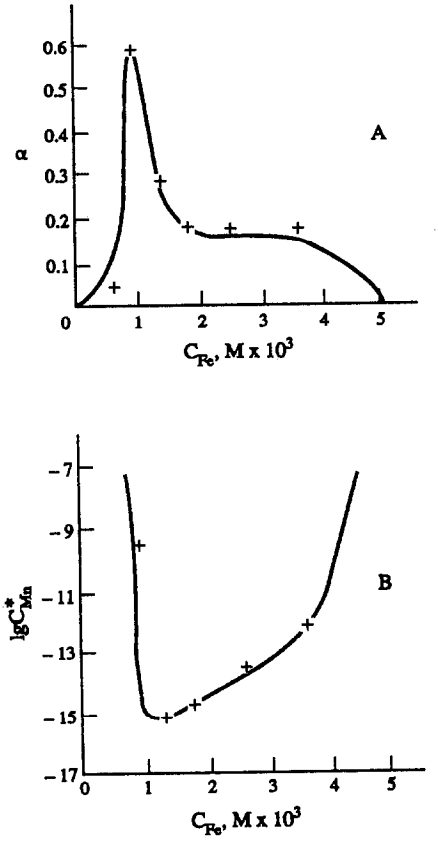

Fig. 4. The dependence of a sensitivity (A) and theoretically attainable detection limit (B) with respect to initial ferroin concentration for BZ reaction (experimental conditions are as in Fig. 1).

Fig. 2 that the expression (3) is valid in the case of intermediate values of λ_L. The chaotic system loses its sensitivity when the largest Lyapunov characteristic exponent decreases to zero. This is illustrated by the data represented in Fig. 3(D). Hence the analytical application of chemical chaos is possible only in the case of intermediate sensitivity. This holds for investigated chaotic reaction at $C_{Fe} = (1-2) \times 10^{-3} M$.

It follows from Fig. 2 that the optimal conditions for the linear $\lambda_L T_i - \text{Log } C_{Mn}$ plot can exist also in the case where $C_{Fe} \sim 3.2 \times 10^{-4} M$. However, linear correlation was not found in this region. Maybe it is due to the short time when the chaotic process exists for such ferroin concentrations.

It follows from data presented in Fig. 3 that the $\lambda_L T_i - \text{Log } C_{Mn}$ is linear in a narrow region of the initial ferroin concentration. This creates the possibility of an analytical application of the method developed for the determination of trace amounts of manganese(II). The results of such a determination are shown in Table 1.

The question about the reproducibility of data obtained, appears to be due to high sensitivity of chaotic regimes and their irreproducibility. It follows from our experiments that small accidental variations of the experimental conditions may cause great variations of the values of λ_L and T_i, but its product is practically constant (Table 2).

The results obtained allow the discussion of the principal possibility of the chemical chaos analytical application on the basis of expression (3). In general, the existence of the chaotic strange attractor (SA) for a chemical system is a condition of the existence of regions with $\lambda_L > 0$ in the phase space. The variations of the initial conditions in a given chemical system [in our case, by the addition of trace amounts of manganese(II)] give rise to the displacement of the starting point in phase space. Hence the possibility of the existence of the linear $\lambda_L T_i$–Log C plot is determined by the relative positions of the starting point, regions where $\lambda_L > 0$, and SA in the phase space of an oscillating chemical system. In general, such a possibility cannot be predicted because the regions $\lambda_L > 0$ and SA are not continuous and are characterized by a fractal structure. So the trajectories of evolution of the system flow alternatively diverging and converging.[18–22]

Let us consider the sensitivity and the detection limit of the manganese determination by proposed method. It follows from data represented in Fig. 3 that linear portions of the $\lambda_L T_i$–Log C_{Mn} plots can be described by the following expression

$$\lambda_L T_i = \alpha \text{ Log}(C_{Mn}/C^*_{Mn}). \quad (4)$$

The calculation of the parameters α and C^*_{Mn} was performed by using the extrapolation of the linear portions of the $\lambda_L T_i$–Log C_{Mn} plots in Fig. 3.

The parameters α and C^*_{Mn} characterize the sensitivity and theoretical attainable detection limit, respectively. This is, of course, a tentative estimation of the values for $C_{Fe} < 10^{-3} M$ because in this case only initial portions of plots were chosen. The influence of the starting ferroin concentration (bifurcation parameter that determines the value of λ_L) on the sensitivity and the detection limit is illustrated by Fig. 4. These plots show that the sensitivity and the value of Log C^*_{Mn} vary qualitatively in a similar manner according to the bifurcation parameter. The maximum sensitivity and the minimum detection limit are reached in the case of $C_{Fe} = 1.25 \times 10^{-3} M$. Notice that it follows from the general run of the curve represented in Fig. 4(B) that the value of the theoretical attainable detection limit is approximately $10^{-15} M$.

CONCLUSIONS

On the basis of results obtained we may formulate some conditions for the realization of the analytical application of chemical chaos.

(1) A substance to be determined must be involved in the chemical reactions with the components of the chaotic chemical system and must cause a change in the rates of their accumulation or degradation.

(2) The addition to chaotic chemical system of a substance to be determined must not lead to any bifurcations of the regimes observed.

(3) The optimal conditions for the existence of a suitable linear calibration are determined by the existence of a lower limit of λ_L, beyond which the system loses its sensitivity, and by the existence of a higher limit of λ_L above which the behaviour of the system is irreproducible.

(4) The parameters (in our case, characteristic time of the evolution of system and largest Lyapunov characteristic exponents) may be irreproducible but some combinations of them (for example, their product) must be reproducible.

Hence, in this work we developed a method for the determination of trace amounts of manganese(II) that is rather complicated and cumbersome. However, the principal significance of such an approach is the illustration of the possibility

of analytical applications of some types of chemical chaos. Such an application enables the determination of trace amounts of manganese(II) due to the high sensitivity of chaotic regimes to initial conditions. We found experimentally that the detection limit is approximately 3 pg/ml for the determination of manganese(II). There does not appear to be a lower limit for this method. We emphasize that the detection limit, obtained by using the traditional kinetic methods, is approximately 100 pg/ml.

In addition, the approach developed in this work can be used for the determination of trace amounts, not only of manganese, but of other metal ions as well. Such a possibility remains to be verified.

Summary—Novel polysiloxanes, with 4-(dialkylamino)pyridine substituents, are characterized by pyrolysis tandem mass spectrometry. These polymers form abundant cyclic oligomeric ions under both desorption electron ionization (DEI) and desorption chemical ionization (DCI) conditions. Product MS/MS spectra of the cyclic ions reveal characteristic fragmentations under low energy collision activated dissociation. Protonated cyclic oligomers higher than the pentamer are mainly due to the proton bound dimers of lower oligomeric units. The cyclic oligomers are shown to have proton affinities greater than 1000 kJ/mole. It is proposed that thermal depolymerization occurs through an intramolecular siloxane bond rearrangement, which is in agreement with a previously proposed "loop mechanism". Markovian statistical calculations are applied to the DCI mass spectral data in order to determine the sequence distribution of siloxane copolymers. Application of this method show that the monomers in the copolymers examined are non-randomly distributed.

Mass spectrometry is widely used for direct analysis of polymers.[1–9] Increasingly, the combination of tandem mass spectrometry (MS/MS)[10,11] and desorption ionization techniques[12] has been used in the characterization of polymers, including biopolymers present in mixtures.[13–20] Some of these MS/MS studies involve chemical degradation[16–18] but most utilize thermolysis in conjunction with ionization in the mass spectrometer. The advantages of pyrolysis/tandem mass spectrometry include speed, sample economy and simplicity.

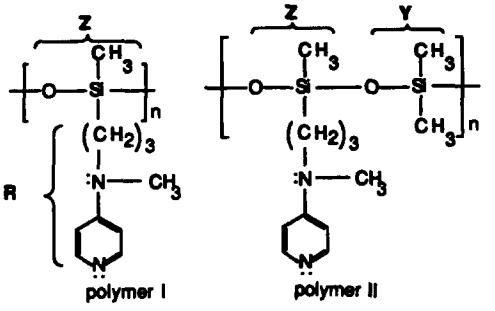
The importance of determining monomer distributions in copolymers, together with recent successes achieved in characterizing alkylisocyanates[13] by a combination of pyrolysis tandem mass spectrometry and DCI, encourage further application of this method to other types of copolymers. An important question is whether a copolymer has a random or a non-random arrangement of monomers. The data from such experiments were compared with statistical (Bernoullian) calculations in a previous pyrolysis DCI study on alkylisocyanate copolymers.[13] The monomer distribution in random co-polymers has also been calculated by a simple method due to Price[21] and compared with chemical degradation and FAB–MS data to describe the sequence distribution of co-polyesters[22] and poly(β-hydroxybutyrate-*co*-β-hydroxyvalerate).[23] In both cases the polymers gave results which were consistent with a random distribution of monomers.

Polysiloxanes are well recognized for their useful physical and chemical characteristics, *viz.*, good chain flexibility, low-temperature elasticity, low viscosity, permeability, hydrophobicity, low entropies of dilution, thermal stability and stability towards thermal oxidation. Owing to these useful properties, polysiloxanes are of commercial importance as synthetic polymers.[24–30] Some of their common uses are as membranes, electrical insulators, high performance-elastomers, synthetic lubricants, coolants, plastics, brake fluids, sealants, surfactants, water repellents, adhesives, dielectric fluids, artificial organs and contact lenses.

This study includes structural and sequence analysis of a new class of polysiloxanes functionalized with 4-(dialkylamino)pyridines.

*Author for correspondence.

4-(Dialkylamino)pyridines are well known as highly active nucleophilic catalysts for a variety of reactions, *viz.*, alkylation, acylation, phosphorylation, silylation, esterification, polymerization and redox reactions.[31,32] The polymers used in this study retain the desirable properties of polysiloxanes as well as the catalytic properties of 4-(dialkylamino)pyridines. Their structures are shown below.



Unit	m/z
Y	74
Z	208
R	149

Polymer-I is a homopolymer containing methyl 3-[*N*-methyl-*N*-(4-pyridinyl)amino] propylsiloxane monomer (Z) units and was synthesized by hydrolytic polycondensation of 4-[*N*-(3-diethoxymethylsilyl)propyl]-*N*-methylamino]pyridine with a strongly basic catalyst.[31,32] Polymer II is a copolymer containing dimethyl siloxane (Y) and Z monomer units and was synthesized by polymerization of octamethylcyclotetrapolysiloxane (tetramer) and 4-[*N*-(3-diethoxymethylsilyl)propyl]-*N*-methylamino]pyridine in a molar ratio of 1:4, respectively. The sequence distribution of these copolymers prepared by such polymerization methods can be predicted based on the concentration and the functionality of the different pre-polymeric units. For example, ring opening copolymerization of octamethylcyclotetrasiloxane (1 mole) with 4-[*N*-(3-diethoxymethylsilyl)propyl]-*N*-methylaminopyridine (1 mole) should yield a copolymer with a block of four Y units along with randomly distributed Z single units along the polymer chain. However, redistribution reactions occurring under equilibrium conditions might change the expected sequence.

It is well known that siloxane polymers equilibrate under the influence of a catalyst or heat to produce a thermodynamically controlled distribution of ring and chain molecules.[33,34] Furthermore, these polymers, upon heating in a vacuum, depolymerize to smaller cyclic molecules of varying sizes. Ballistreri and coworkers[35] have studied the thermal decomposition mechanism of polydimethylsiloxane (PDMS) using pyrolysis mass spectrometry. Although no intact cyclic ions were observed in the mass spectrum, they interpreted the fragment ions as originating from the cyclic neutral molecules. The very rapid heating employed in the DCI technique is known to yield higher mass molecular ions in other classes of compounds without causing significant fragmentation.[36] The redistribution of monomer units during mass analysis is also highly improbable under these non-equilibrium conditions. Therefore, DCI mass spectral data, with the help of statistical methods, are expected to provide information on the sequence distribution of copolymers. The polymers investigated are potentially useful as artificial enzymes,[37] and their catalytic properties depend on the polymer micro-environment at the reactive sites which, in turn, depend on their structural arrangements.[31,32,37] Thus, structure elucidation and sequence distributions of these macromolecules have direct significance.

The specific objectives of this study are to (i) characterize polymers I and II using DEI, DCI and MS/MS, (ii) study the ion chemistry of these novel siloxanes, and (iii) develop a general mass spectrometric method for sequence distribution of siloxane copolymers.

EXPERIMENTAL

Experiments were performed using the Finnigan TSQ 700 mass spectrometer. All samples were dissolved in methanol or methylene chloride, transferred to the loop of rhenium wire filament of the direct insertion probe, and dried before introduction into the ion source. The amount of sample on the probe tip was approximately 0.5 μg. Samples were pyrolyzed by heating the probe from 30 to 800° at a rate of 170°C/sec. At this heating rate, desorption of the sample starts when the temperature of the filament is approximately 200° and continues until the temperature is 700°. The filament was held at 800° for 5 sec and then at 1200° for another 5 sec at the end of each ramp. These times had no effect on the spectra because the sample completely desorbs before it reaches

800°. However, over the temperature range 30–800°, the heating rate should be sufficiently high (100°C/sec and above) to minimize thermally induced decompositions. At lower rates, the DCI ion abundances of lower protonated oligomers increase at the expense of higher oligomers, indicating that thermal decompositions of higher oligomers occur. The scan speed of the quadrupole was typically 1000 amu/sec. This allows the data system to average 3–4 scans covering a range of 1000 amu during sample desorption. The signal-to-noise ratio can be improved by narrowing the mass range and keeping the scan speed constant. Temperatures of the ion source and the manifold were 150 and 70°C, respectively. Electron energy was 20 eV during DEI and 70 eV during DCI. The filament emission current was 0.2 mA. Isobutane was used as the reagent gas for chemical ionization at a pressure of 0.5 torr. Argon was used as collision gas for MS/MS experiments at a pressure of 2.0×10^{-3} torr measured using an ion gauge connected to the collision cell. Polydimethylsiloxane (PDMS; average molecular weight distribution, 11400) was obtained from Hüls America, Inc. Bristol, PN.

RESULTS AND DISCUSSION

The 20 eV DEI mass spectra of polymer I and II are shown in Fig. 1. Note that in all the figures only the $^{12}C^{1}H$ isotopic peaks are indicated. Ions corresponding to the intact cyclic oligomers, the trimer (m/z 624) and tetramer (m/z 832), occur in both spectra. The base peak in Fig. 1(a) is due to the ion, m/z 121, which is assigned the structure $CH_2 = N^+(CH_3)C_5H_4N$. The other major peaks, m/z 503 and 711, are fragments originating from the cyclic oligomeric ions, m/z 624 and 832, respectively, by loss of a neutral radical $CH_2(CH_3)NC_5H_4N$ (mass 121). For example, the molecular ion of the tetramer,

m/z 832, fragments to yield the ion, m/z 711, losing the neutral radical. The copolymer [Fig. 1(b)] shows fragment ions resulting from both the mixed-oligomers and homo-oligomers. For example, m/z 369, 443, 577 and 651 are formed as a result of losing the neutral amino radical (mass 121) from the corresponding mixed-oligomer units, 2Z + Y (m/z 490), 2Z + 2Y (m/z 564), 3Z + Y (m/z 698) and 3Z + 2Y (m/z 772), respectively. These observations were confirmed by recording the product ion MS/MS spectra of individual cyclic oligomeric ions mass selected from polymer II. Figure 2 shows a typical MS/MS product spectrum, that of m/z 564, which corresponds to the cyclic mixed-tetrameric ion (2Z + 2Y). EI fragmentation mechanisms of cyclic polysiloxanes with various substituents have been studied in detail.[38–40] The loss of the whole substituent as a neutral radical forming an even electron cyclic ion is the major fragmentation path for cyclic siloxanes under EI conditions. Furthermore, when the silicon substituents have different chain lengths, the loss of the larger alkyl group is favored. This is in agreement with many other observations on competitive radical losses.[41] When a substituent containing a π bond (*e.g.*, a phenyl group) is present, extra stabilization occurs as a result of the bonding between the *d* orbitals of silicon and the π bond and the other silicon substituent is lost preferentially. In contrast to the behavior of these simple systems, for polymers I and II major fragmentation is the C–C bond cleavage with the loss of $CH_2(CH_3)NC_5H_4N$ group. Loss of the whole substituent (mass 149) is a minor path. For example, co-tetramer, 2Z + 2Y (Fig. 2), shows an abundant ion, m/z 443 (2Z + 2Y − 121), while showing low abundance signals for the ions, m/z 549, m/z 415 and 429 resulting from the loss of CH_3, $CH_2CH_2CH_2(CH_3)NC_5H_4N$ and $CH_2CH_2(CH_3)NC_5H_4N$, respectively.

The DCI mass spectrum of homopolymer I (Fig. 3) is dominated by abundant oligomeric

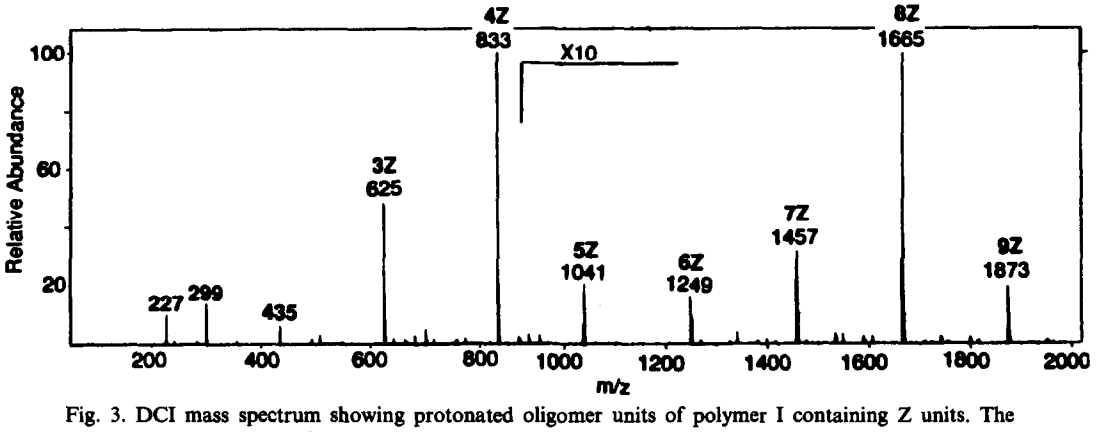

Fig. 3. DCI mass spectrum showing protonated oligomer units of polymer I containing Z units. The nomenclature *n*Z refers to the protonated cyclic oligomer containing *n* number of Z units.

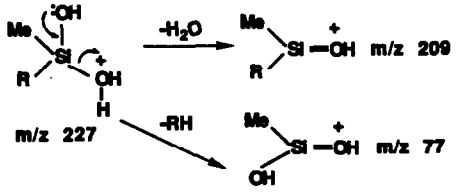
ions assigned as the protonated cyclic oligomers. The most abundant ions are the protonated trimer (m/z 625) and the protonated tetramer (m/z 833), assigned as 6-membered and 8-membered cyclic structures, respectively. The protonated cyclic dimer (m/z 417) is not observed, as expected, because of the instability of the 4-membered ring. However, the corresponding protonated open chain disiloxanodiol (m/z 435) and the silanodiol monomer (m/z 227) are seen. Their structures and the associated fragmentation paths are confirmed by product ion MS/MS spectra. For example, protonated silanodiol monomer undergoes fragmentation upon CAD to yield m/z 77(100%), 109(97%), and 209(17%).



The DCI mass spectrum of polymer II (Fig. 4) is similar to that of polymer I, except that protonated mixed-oligomers are present as well as the protonated homo-oligomers. The DCI mass spectrum of polydimethylsiloxane (PDMS) also shows analogous behavior, giving abundant protonated cyclic oligomers. These simple DCI mass spectra, consisting mainly of protonated cyclic oligomers, are noteworthy because earlier reports[42,43] of the mass spectral behavior of PDMS under conventional CI and EI conditions showed only fragment ions arising from the cyclic oligomers, but not the cyclic oligomeric ions themselves. The ions present in the EI and CI mass spectra of PDMS are remarkably similar and only the relative ion abundances are different in the two experiments. Since the CI spectrum of PDMS gives abundant high mass ions, it is used as a mass reference for calibrating mass spectrometers in the higher mass range.[44,45] The protonated cyclic ions formed under DCI conditions are very stable and they require a relatively high collision energy (100 eV) to cause fragmentation upon collision with Ar (2.0 mtorr). These observations suggest that DCI imparts very little internal energy to the neutral cyclic oligomers and they make DCI/MS/MS a very promising technique for the sequence distribution and structural characterization of these polymers. A characteristic feature of the protonated cyclic oligomers of polymers I and II is the sequential loss of the neutral radical (mass 121) upon CAD. This is illustrated in the MS/MS product spectrum of the protonated trimer, m/z 625, (Fig. 5) which shows fragment ions m/z 504 and 383 which are formed by the loss of one and two radicals, respectively. This is noteworthy because it violates the odd–even electron rule of fragmentation, which states that the dissociation of even-electron-ion to yield a radical ion and a neutral radical is energetically unfavorable. The more favored path of decomposition of an even-electron-ion is to yield an even-electron-ion and a closed shell neutral molecule. The corresponding protonated trimer with all methyl substituents (m/z 223) does not lose a radical neutral under the same conditions. The major fragmentation path in this latter ion upon CAD is the sequential loss

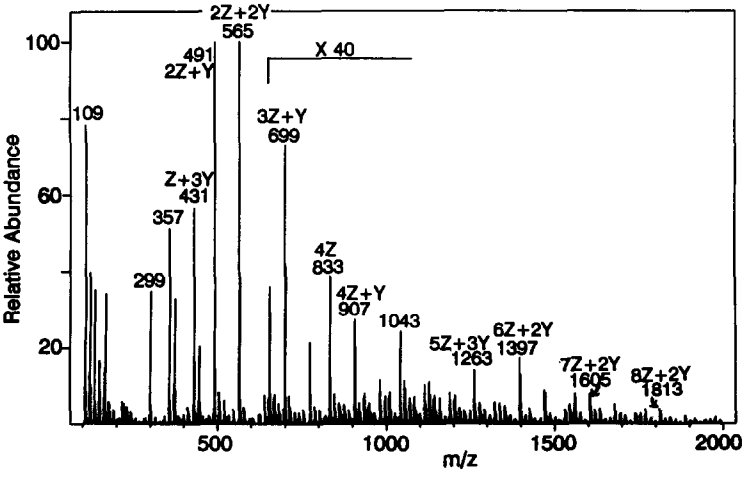


Fig. 4. DCI mass spectrum showing protonated co-oligomer units of polymer II containing Z and Y units.

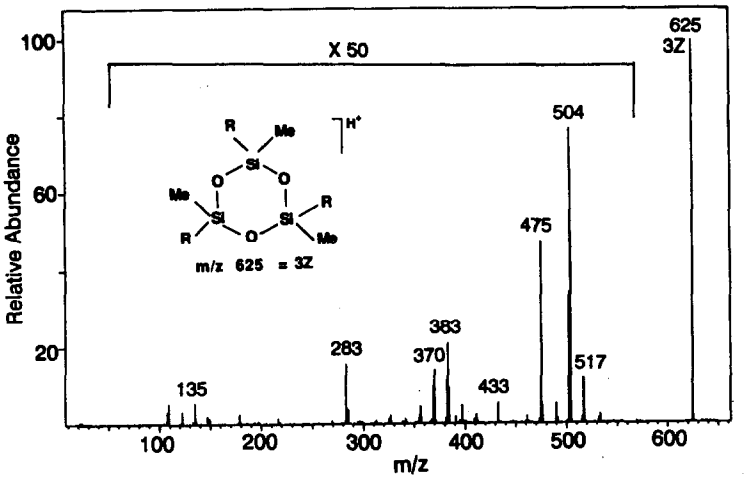

Fig. 5. MS/MS product spectrum of the protonated trimer (3 Z units) from polymer I, collision energy 50 eV.

of neutral methane molecules to yield even-electron ions, m/z 207 and m/z 191. Elimination of the closed shell neutral molecule, $[CH_3,CH_2CH_2(CH_3)NC_5H_4N]$, from the protonated trimer (Fig. 5), to form an even-electron ion, m/z 475, is also observed.

Proton bound dimers

The protonated oligomers higher than the pentamer show strikingly different behavior when compared to the lower members of the series. Figure 6 shows the MS/MS product spectrum of the protonated heptamer, m/z 1457, derived from polymer I. Unlike the oligomers up to the pentamer, this ion undergoes CAD readily, yielding the protonated tetramer at very low collision energy (8 eV). Also note that no other product ions are generated, even though some, including the trimer, are very stable. The EI mass spectra of higher cyclic polydimethylsiloxanes are known to produce lower ring structures through a ring contraction mechanism.[39] However, the corresponding protonated heptamer generated from PDMS (m/z 519) does not produce significant fragmentation under the same CAD conditions (Ar pressure 2.0 mtorr, collision energy 8 eV). These observations lead us to believe that these protonated ions of higher oligomers are mainly comprised of the proton bound dimers of the lower ones. Proton bound dimers have weak interactions through hydrogen bonds, and they undergo CAD fairly easily at low collision energies, giving the corresponding protonated monomers. The fragmentation of proton bound dimers has been used[46] to estimate relative gas phase basicities of the constituent monomers. The product ion abundances are very sensitive to the proton

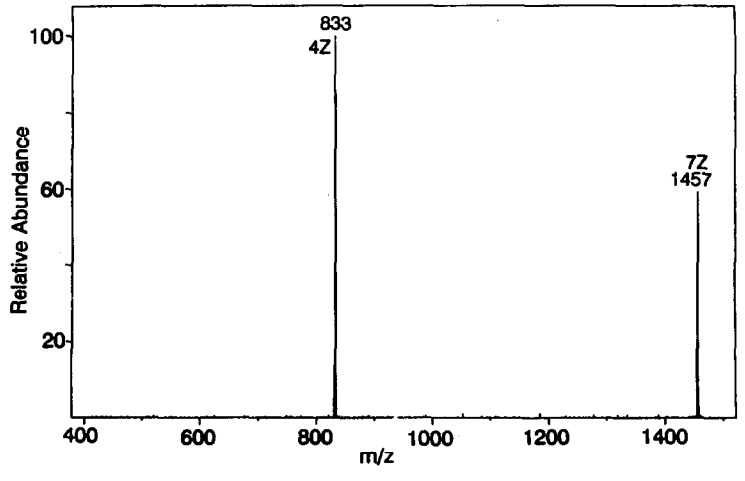

Fig. 6. MS/MS product spectrum of the protonated heptamer (7 Z units) from polymer I, collision energy 8 eV.

affinity difference between the different monomers comprising the proton bound dimer, and under typical conditions, only one protonated monomer is formed when the PA difference is greater than 2 kJ/mole.[47] This explains the formation of the protonated tetramer, and not the protonated trimer, from the heptamer upon CAD, since the tetramer has four *N*-methylalkylpyridyl units compared to three in the trimer. Other higher protonated oligomers showed similar behavior, producing only a single product ion upon CAD. For example, CAD of the hexamer (6Z), the octamer (8Z) and the nonamer (9Z) yielded the trimer (3Z), the tetramer (4Z) and the pentamer (5Z), respectively.

Product ion MS/MS spectra recorded at 8 eV collision energy for the copolymer, polymer II, are summarized in Table 1. Note that polymer II shows abundant protonated mixed-oligomer units in the product spectra. As seen from the results, the product distributions are consistent with the expectation that they are governed by the proton affinity difference between the individual oligomer units; the most abundant product ion, formed from a particular dimer, in a particular product spectrum is the one expected to have the highest proton affinity. Because several combinations of oligomer units can form a particular dimer, the product distribution does not directly reflect the proton affinity of individual oligomers. For example, the ion, *m/z* 1055 (4Z + 3Y), yields four product ions, with different relative abundances (see Table 1). Although the proton affinity of 3Z + Y is expected to be higher than that of 2Z + Y, the former has the lower relative abundance of the two. However, the parent ion population of 4Z + 3Y is not expected to contain proton bound dimers formed between 2Z + Y and 3Z + Y. Therefore, one has to consider the proton affinity difference between certain pairs in order to apply the proton affinity rule. In this example, 2Z + 2Y *vs.* 2Z + Y, 3Z + Y *vs.* Z + 2Y, 3Z *vs.* Z + 3Y and 4Z *vs.* 3Y are the combinations which are expected to form the parent dimer, 4Z + 3Y. The product 3Z is formed upon CAD of 4Z + 3Y whereas the corresponding partner, Z + 3Y, is not formed, indicating that the proton affinity of the former is the higher of the two. Another important parameter, which affects the relative abundances of the product ions originating from a particular parent ion (protonated dimer), is the concentration of the individual oligomer units which make up the parent ion population. Although 4Z has the highest proton affinity of all the oligomer units which make up the parent dimer, 4Z + 3Y, the probability of combining 4Z and 3Y units is very low because of the low abundance of those units in the polymer chain. Note that the abundance of 4Z and 3Y units are much lower than the mixed-oligomer units, 2Z + 2Y and 2Z + Y, in the DCI mass spectrum of polymer II (Fig. 4). Therefore, 4Z is not seen in the product MS/MS spectrum of the ion 4Z + 3Y.

In an attempt to evaluate the proton affinity of the cyclic oligomers using the kinetic method,[46,47] polymer II was pyrolyzed in the presence of standard compounds with known proton affinities. Although the exact proton affinities of these cyclic oligomers were not determined, the results show that these oligomers have very high proton affinities, above 1000 kJ/mole. For example, the proton bound dimer formed between the mixed-trimer, Z + 2Y, and 4-dimethylaminopyridine (PA = 990 kJ/mole[48]) yields, upon CAD, only the protonated trimer (Fig. 7). With another standard with higher PA, tetramethylethylenediamine (PA = 1003 kJ/mole[47]), it again yields only the trimer (spectrum not shown), suggesting that the PA of the trimer is even higher than 1003 kJ/mole. These results further

Table 1. Product MS/MS spectral data for protonated mixed-oligomers, collision energy 8 eV

Parent ion		Product ions				
m/z	Composition	Composition (normalized abundances)				
787	2Z + 5Y	Z + 3Y (100)	Z + 2Y (44)			
847	3Z + 3Y	2Z + Y (100)	Z + 2Y (13)			
921	3Z + 4Y	2Z + Y (100)	2Z + 2Y (46)	Z + 2Y (6)		
995	3Z + 5Y	2Z + 2Y (100)	2Z + Y (65)	2Z + 3Y (17)		
1055	4Z + 3Y	2Z + 2Y (100)	2Z + Y (36)	3Z + Y (7)	3Z (6)	
1129	4Z + 4Y	2Z + 2Y (100)	2Z + Y (50)	2Z + 3Y (30)		
1163	5Z + 3Y	3Z + Y (100)	2Z + 2Y (10)	3Z + 2Y (7)	2Z + Y (2)	
1189	5Z + 2Y	3Z + Y (100)	3Z (50)	2Z + 2Y (13)	2Z + Y (5)

1277	4Z + 6Y	2Z + 3Y (100)	2Z + 4Y (78)	2Z + 2Y (51)		
1337	5Z + 4Y	3Z + Y (100)	2Z + 3Y (81)	3Z + 2Y (73)	2Z + 2Y (16)	

confirm that the higher ionic-oligomers are mainly comprised of proton bound dimers of lower oligomers.

Mechanism of thermal depolymerization

Two major mechanisms have been proposed for the thermal depolymerization of polysiloxanes.[33] One is based upon siloxane bond rearrangement which is thought to occur via an intramolecular, four-center cyclic transition state (loop mechanism).[49] Zeldin *et al.* suggested[50] that depolymerization through the loop mechanism involves the random cleavage of siloxane bonds followed by a rapid and complete unzipping of the kinetically active fragments. The other mechanism involves intermolecular siloxane bond interchange reactions occurring via a cyclic transition state (bond scission mechanism).[51] It is important to elucidate the mechanism of depolymerization operating under the present experimental conditions of rapid heating (DCI) and non-equilibrium processes because the bond scission mechanism allows redistribution of monomers to occur during the heating process in the mass spectrometer, whereas the loop mechanism does not. Therefore, sequence distribution of the copolymer becomes impossible if the bond scission mechanism is operative. To test which mechanism best represents the thermal depolymerization of polysiloxanes under DCI conditions, a physical mixture of the two homopolymers, polymer I and PDMS was deposited on to the rhenium filament and heated under the same DCI conditions. The mass spectrum of the physical mixture revealed no new ions besides those originating from individual homopolymers. In other words, there were no protonated co-oligomers present. These observations eliminate the bond scission mechanism for explaining depolymerization in our experiments. Therefore, we can confidently use the mass spectral data of polymer II to obtain monomer sequence distribution as discussed below.

Sequence distribution of copolymers

The first-order Markovian statistics have been used in ^{13}C-NMR to determine the sequence distribution of copolymers.[52] In previous studies,[13] we have implemented a Bernoullian model (zero-order Markovian) to determine the sequence distribution of synthetic polymers using pyrolysis DCI mass spectral data. However, the Bernoullian model is insufficient to discriminate between block, alternating random ordering of monomers. For a Markovian distribution of a two component copolymer (components A and B), six parameters are needed to calculate the intensities of MS peaks of the different oligomers. They are S_a, S_b, P_{aa}, P_{ab}, P_{bb} and P_{ba} (P_{ij} in general) where, S_a (or S_b) is the probability that an oligomer starts with A (or B), P_{ij} is the probability of finding the component j after the component i. If these parameters are known, the normalized peak intensity, $I_{a,b}^{\text{calc}}$, of any oligomer can be calculated. For example, $I_{a,b}^{\text{calc}}$ of a sequence $AABBA$ is equal to $S_aP_{aa}P_{ab}P_{bb}P_{ba}$. We have the following four independent equations to solve for the six parameters:

$$S_a + S_b = 1 \quad (1)$$

$$P_{aa} + P_{ab} = 1 \quad (2)$$

$$P_{bb} + P_{ba} = 1 \quad (3)$$

$$S_aP_{aa} + S_bP_{ba} = S_a \quad (4)$$

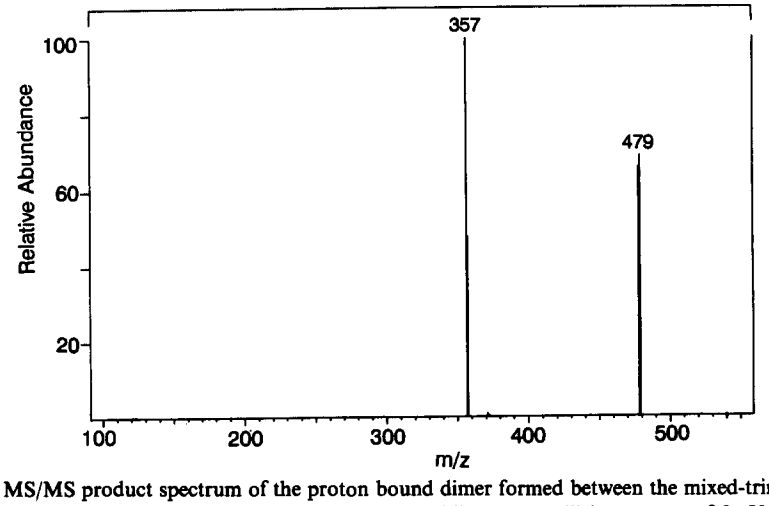

Fig. 7. MS/MS product spectrum of the proton bound dimer formed between the mixed-trimer (Z + 2Y) from polymer II and 4-dimethylaminopyridine, at a collision energy of 8 eV.

Because there are two independent variables, if we have more than two sets of experimental data, this system of equations is sufficiently over-determined to test for first-order Markovian behavior. The Bernoullian distribution is a special case of Markovian distribution, where, $S_a = P_{ba} = P_{aa} = M(A)$ and $S_b = P_{ab} = P_{bb} = M(B)$. $M(A)$ and $M(B)$ are mole fractions of monomers A and B used during polymerization.

A computer program has been written to search for those independent variables from which the peak intensities are calculated. By comparing $I_{a,b}^{calc}$ with the experimental intensity, $I_{a,b}^{exp}$ from the DCI mass spectrum, the program adjusts these variables to minimize the agreement factor χ^2 in order to determine the best fit with the experimental data. The Nedler and Mead[53] algorithm is used for χ^2 minimization.

Agreement Factor

$$X^2 = \frac{\sum_i \left(I_{y,z}^{exp} - I_{y,z}^{calc}\right)^2}{\sum_i \left(I_{y,z}^{exp}\right)^2}$$

The information obtained from the calculated parameters is important to understand the properties of the polymer. Two-component copolymers, when P_{aa} is equal to P_{ba}, represent a random distribution. When $P_{aa} = 0$, $P_{bb} = 0$ and $P_{ab} = P_{ba}$, the system has an alternating distribution. The number-average lengths of like monomers, n, *viz.* the degree of "blockness", can also be calculated as $n_a = 1/P_{ab}$ and $n_b = 1/P_{ba}$.

DCI data of the siloxane copolymer with Z and Y units (*i.e.*, $A = Z$; $a = z$; $B = Y$; $b = y$) were treated in this way. The calculated intensities based on zero-order Markovian (Bernoullian) and first-order Markovian statistics along with the experimental intensities are shown in Table 2. Both trimer and tetramer data correspond to non-random distributions. The agreement factors, χ^2, for a random distribution were 0.16 and 0.21, for the trimer and tetramer, respectively. The best-fit calculation showed that the trimer had $S_z = 0.39$, $P_{zz} = 0.12$, $P_{yy} = 0.44$ with χ^2 of 0.001 and the tetramer had $S_z = 0.40$, $P_{zz} = 0.12$ and $P_{yy} = 0.42$ with χ^2 of 0.001. The results, obtained from data for open-chain oligomers, are also in agreement with the results obtained from the protonated cyclic oligomers. For example, open-chain dimer (Table 2) data show $S_z = 0.43$, $P_{zz} = 0.17$, $P_{yy} = 0.39$ at χ^2 of 0.0001. These parameters suggest that the larger monomer unit Z, prefers to react with the smaller monomer unit Y, therefore, the probability P_{zz} is small and P_{zy} is large (0.91). On the other hand, P_{yy} and P_{yz} are both close to 0.5, suggesting that Y does not have a preference during polymerization and

thus reacts with Y or Z randomly. This preferential reaction of a Z unit with a Y unit may be perhaps due to the steric interference from the large Z unit during the equilibration process occurring in the solution. The blockness of like monomers, n_z and n_y, are approximately 1 and 2, showing that the dimethylsiloxyl units (Y) have a tendency to aggregate in blocks of two units.

CONCLUSIONS

This study clearly demonstrates the strengths of DCI/MS/MS in characterization and sequence distribution of siloxane polymers. The polymers used in this work yield abundant protonated cyclic oligomers upon thermolysis. These neutral cyclic oligomers undergo two processes under DCI conditions. The primary process is simple protonation, as indicated by the lower series of protonated oligomers (dimers, trimers, tetramers and pentamers) in the DCI mass spectra. These oligomers, up to the pentamer, directly represent the original polymers. Markovian statistical calculations applied to DCI mass spectral abundances of protonated oligomers up to the tetramer reveal that the monomer distribution in the copolymer II is non-random. The second process yields the proton-bound dimers comprised of the protonated oligomers and the neutral oligomers, which are held together by weak hydrogen bonds. The formation and dissociation of these higher oligomers, which represent a low percentage compared to the overall ion abundance, are governed by several factors including proton affinities.

CONTINUOUS-FLOW CHEMILUMINOMETRIC DETERMINATION OF AMMONIUM ION IN FERTILIZERS

STERGIOS A. HALVATZIS and MEROPI M. TIMOTHEOU-POTAMIA*
Laboratory of Analytical Chemistry, University of Athens, Panepistimiopolis, 157 71 Athens, Greece

(*Received* 3 *August* 1992. *Revised* 8 *January* 1993. *Accepted* 25 *January* 1993)

Summary—A simple continuous-flow chemiluminometric method for the determination of 0.0540–5.40 μg/ml of ammonium ion is described. The method is based on the chemiluminescence generated during the oxidation of ammonium ion by *N*-bromosuccinimide in alkaline medium. The emission intensity is greatly enhanced if dichlorofluorescein is also present in the reaction solution. The analysis is automated, requires no sample pre-treatment and solutions can be analysed at a rate of 106 solutions/hr with a relative error of about 2.5%. The method was applied satisfactorily to the determination of ammonium ion in solid and liquid fertilizers.

A wide variety of methods and techniques are available for the determination of ammonium ion. Spectrofluorimetry,[1,2] molecular emission cavity analysis,[3] gas phase molecular absorption spectrometry,[4] capillary isotachophoresis,[5] ion-selective electrodes,[6] conductometry,[7,8] and thermometric titrimetry[9] are only some examples of the techniques available for the determination of ammonia and ammonium ions. Flow injection systems with gas diffusion or ion exchange modules and spectrophotometric detection are described in the literature.[10–12] The spectrophotometric determination of ammonia can be carried out either by the Nessler[12] or the Berthelot reaction,[13] or by using pH indicators.[11] However, special precautions must be taken when these methods are applied to coloured or turbid sample solutions.

Few chemiluminometric methods have been established for the determination of ammonia. Ammonia reacts with hypochlorite to form monochloramine in alkaline solution. Thus, the intensity of chemiluminescence (CL) generated during the reaction of luminol with hypochlorite decreases.[14] Ammonia has also been determined by oxidative pyrolysis and subsequent measurement of the CL intensity of excited NO_2.[15] However, a direct CL method for the determination of ammonia or ammonium ion has not been traced in the literature.

This work involves the development and optimization of a method for the analysis of ammonium ion in fertilizers, based on a new CL reaction between *N*-bromosuccinimide (NBS) and ammonium ion in alkaline medium. During the development of the method, it was found that a number of fluorescent compounds enhance the CL emission intensity if present in the reaction medium. The effect of these compounds on the emission intensity is investigated. Reduction of interferences by cations on the emission intensity is also reported in this paper.

EXPERIMENTAL

Apparatus

A schematic diagram of the continuous-flow CL analyser is shown in Fig. 1. It consisted of two basic units, the detector housing and the flow-through system.

The detector housing included a coiled glass flow cell situated in front of the photomultiplier tube (PMT). The cell consisted of 3.5 turns of glass tubing (i.d. 2 mm) and its total height was 22 mm. The coil volume was 300 μl. The distance of the coil from the PMT was 2 mm for greatest sensitivity. The coil was backed by a mirror for maximum light collection by the PMT. High voltage (−720 V) was supplied to the PMT (EMI 9783R, S-5 response) by two Heath Universal Power Supplies (0–500 V) connected in series. The output of the PMT was connected to an operational amplifier (RCA CA 3140) which served as a current-to-voltage converter (I–V). Damping was provided

*To whom correspondence should be addressed.

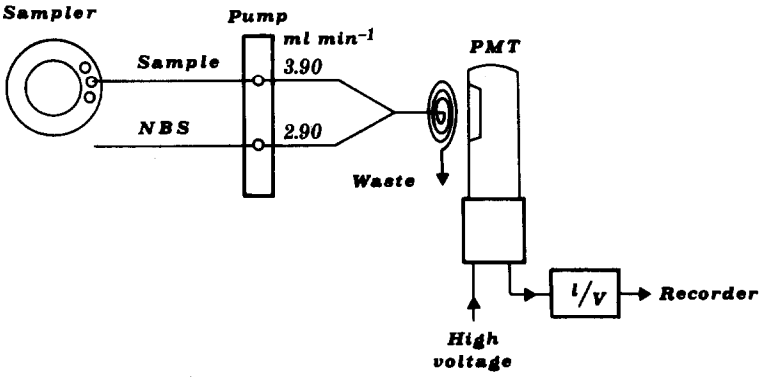

Fig. 1. Schematic diagram of the continuous-flow CL analyser (not to scale).

by inserting an RC circuit between the output of the I–V converter and the recorder. The output of the CL analyser was recorded with a Knauer (Model 73341) recorder.

The solutions of reactants were supplied by a Technicon Proportioning Pump III and were mixed at a Y-junction, 20 mm before entering the flow cell. The final solution was carried into the flow cell by a Tygon tube with an i.d. of 2 mm. Samples were supplied to the manifold by a Technicon Sampler II with a 40-sample capacity.

Reagents

All solutions were prepared from analytical-reagent grade materials with de-ionized, distilled water.

N-Bromosuccinimide stock solution (0.0500*M*) was prepared daily by dissolving 2.225 g of NBS (Serva) in water, transferring the solution into a volumetric flask and diluting to 250 ml with water.

Dichlorofluorescein stock solution (0.0010*M*) was prepared daily by dissolving 0.200 g of dichlorofluorescein (Fluka) in 0.10*M* sodium hydroxide solution, transferring the solution into a volumetric flask and diluting to 500 ml with the same alkaline solution.

Ammonium chloride stock solution (0.100*M*) (1800 μg/ml of ammonium ion) was prepared by dissolving 2.675 g of ammonium chloride (Merck) in water, transferring the solution into a calibrated flask and diluting to 500 ml with water.

More dilute solutions were prepared daily by the minimum number of dilution steps possible.

All other common laboratory chemicals were of the best grade available and were used without further purification.

PROCEDURES

Measurement procedure

The instrument was set at the optimized conditions shown in Fig. 1, but the sampling needle was kept in the "wash" position until the baseline on the recorder had been established. The sampler was adjusted to allow analyte or standard solution and washing water to enter the manifold at equal time intervals and at a rate of 106 solutions/hr. The sampler was then activated and the analysis proceeded automatically. A calibration graph was constructed by plotting the emission intensity [I(mV)] vs. concentration of ammonium ion [C(μg/ml)] in standard solutions and the ammonium content of the sample solution was determined. A standard solution after every 12 sample solutions was included.

Sample preparation

Ten millilitres of 1.0*M* sodium hydroxide solution and 10.00 ml of 0.0010*M* dichlorofluorescein solution were transferred into a 100 ml volumetric flask with the appropriate volume of stock ammonium ion solution and were diluted to volume with water.

For the preparation of fertilizer stock solutions, an amount about 10 g of fertilizer was weighed accurately, transferred into a 1 l volumetric flask and diluted to volume with water. The mixture was sonicated for 10 min to aid dissolution and then filtered. An appropriate volume of the filtrate was diluted further with water so that the concentration of ammonium ion in the final solution was within the working range (0.0540–5.40 μg/ml). The final solution should also contain 0.10*M* sodium hydroxide and $1.0 \times 10^{-4}M$ dichlorofluorescein.

RESULTS AND DISCUSSION

Chemiluminescent reactions that occur by the action of oxidants containing positively charged bromine atoms are restricted to hypobromite[16] and 1,3-dibromo-5,5-dimethyl-hydantoin.[17] *N*-Bromosuccinimide belongs to the same group of compounds, it is more stable than hypobromite and has been used extensively as a brominating and oxidizing agent.[18] Recently, the CL intensity generated during the oxidation of isoniazid by NBS has been found to increase when ammonia is present.[19] This observation was attributed to the CL oxidation of ammonia to nitrogen by NBS. The reaction which occurs is:[20]

$$NH_4^+ + OH^- \rightarrow NH_3 + H_2O$$

$$3NBS + 2NH_3 + 3OH^- \rightarrow 3NHS + N_2 + 3Br^- + 3H_2O$$

NHS: succinimide.

The reaction probably belongs to the group of CL redox reactions which generate nitrogen.[21] Nitrogen is probably produced in an excited state,[22] and has the ability to chemi-excite coexisting fluorophores, like dichlorofluorescein.

A series of experiments were conducted to establish the optimum analytical conditions for the CL oxidation of ammonium ions by NBS.

Effect of flow-rate

Figure 2 shows the effect of flow-rate of NBS on the emission intensity from 18.0 and 54.0 μg/ml of ammonium ion. At flow-rates of oxidant ⩾2.90 ml/min, the emission intensity is independent of NBS flow-rate. This was expected since the concentration of NBS is at least four times higher than the stoichiometric and the reaction is therefore, pseudofirst-order with respect to ammonium ions.

The chosen values for reagent and sample flow-rates were 2.90 and 3.90 ml/min, respectively. The manifold configuration and the optimized flow-rates allow the constituents of the final solution to react for about 0.6 sec before entering into the cell. The sampling and wash times of the sampler were chosen to give sharp and smooth peaks. Under these experimental conditions, the response

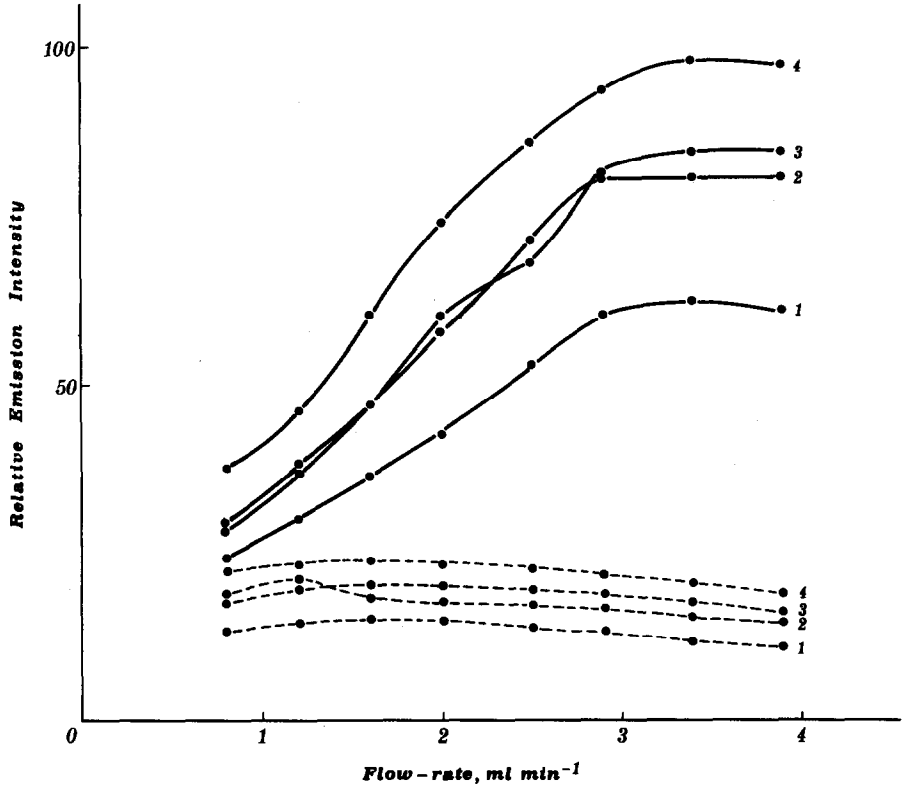

Fig. 2. Effect of the flow-rate of 0.150*M* NBS in 0.50*M* sodium hydroxide on the CL intensity, from 18.0 (broken line) and 54.0 (solid line) μg/ml of ammonium ion supplied to the manifold at (1) 2.50, (2) 2.90, (3) 3.40 and (4) 3.90 ml/min.

was equivalent to 95% of that from the steady state.

Effect of NBS and alkali concentrations

The oxidation of ammonium ions by NBS is accompanied by radiation only when the reaction is carried out in alkaline medium. The effect of NBS concentration on 18.0 and 54.0 μg/ml of ammonium ions at various sodium hydroxide concentrations (range 0.010–2.0 M) is shown in Fig. 3. Concentrations of 0.0150M for NBS and 0.30M for sodium hydroxide were determined to be optimal. A decrease in light intensity at higher concentrations of NBS was observed probably due to kinetic reasons. The rate increases and the reaction proceeds to completion before entrance of the solution into the measuring cell. The same reason explains the decrease of the signal at concentrations of sodium hydroxide > 0.5M.

Effect of surfactants and fluorescent compounds

The efficiency of some CL reactions increases by using surfactants.[23] Their action alters favourably chemical pathways and reaction rates[24] and, therefore, the sensitivity of the analytical measurement is greatly improved. However, typical surfactants did not show such an effect on the CL reaction examined. Each surfactant tested, when present in concentrations higher than the critical micellar concentration (CMC), caused severe reduction in response due to suppression of the CL reaction and quenching of the emission. The effect of 3-cyclohexylamino-propanesulphonic acid (CAPS), a well known CL sensitizer,[25] on the emission intensity, was also investigated. Concentrations of CAPS $\geq 1.0 \times 10^{-4}M$ reduce severely the emission intensity from ammonium ion.

Fluorescent compounds, such as rhodamine B,[26] fluorescein[27] and riboflavin,[28] have been used as sensitizers in CL procedures. Their action is mainly due to energy transfer.[29] In this work, fluorescent compounds which belong to the triphenylmethane dyes containing an "oxo bridge" were examined. The oxidation of these dyes was accompanied by light emission.[30] The chemiluminescence is due to the emission from singlet oxygen and intermolecular energy transfer.[31] However, a mixed solution of ammonium ion and a fluorescent compound generates emission with intensity higher than the sum of the intensities from each component of the mixture. This observation is due to energy transfer from the excited states of nitrogen (produced by the

*Not detectable.

reaction of ammonium ion with NBS) to the emitting species produced by the reaction of fluorescent compound with NBS which caused an increase in the CL efficiency. Table 1 shows that the most enhanced emission was obtained when $1.0 \times 10^{-4}M$ dichlorofluorescein was present in the analyte solution. As the addition of dichlorofluorescein allows the determination of very low concentrations of ammonium ions, the effect of sodium hydroxide on the emission intensity was re-investigated (Fig. 4). When dichlorofluorescein was also added to the ammonium ion solution the optimum was $0.10M$ sodium hydroxide, while the optimum values of NBS concentration and flow rates of reagents remain unaffected.

Analytical parameters

A typical recording for a series of ammonium ion standards obtained by the proposed method is shown in Fig. 5. The calibration graph [I(mV) vs. concentration, C (μg/ml)] was linear in the range 0.0540–0.540 μg/ml of ammonium ion

$$I = (11.9 \pm 0.38) + (75.4 \pm 1.3)C;$$

$$r = 0.9992, \quad (n = 7)$$

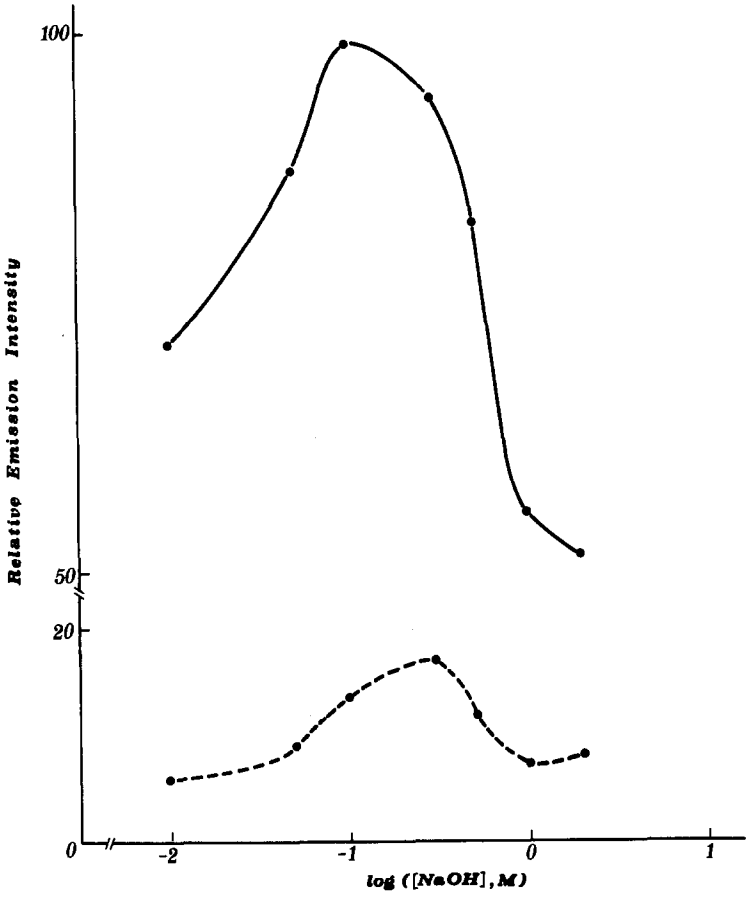

Fig. 4. Effect of concentration of sodium hydroxide on the CL intensity from 0.180 (broken line) and 0.900 (solid line) μg/ml of ammonium ion ([Dichlorofluorescein] = $1.0 \times 10^{-4}M$ and [NBS] = $0.0150M$).

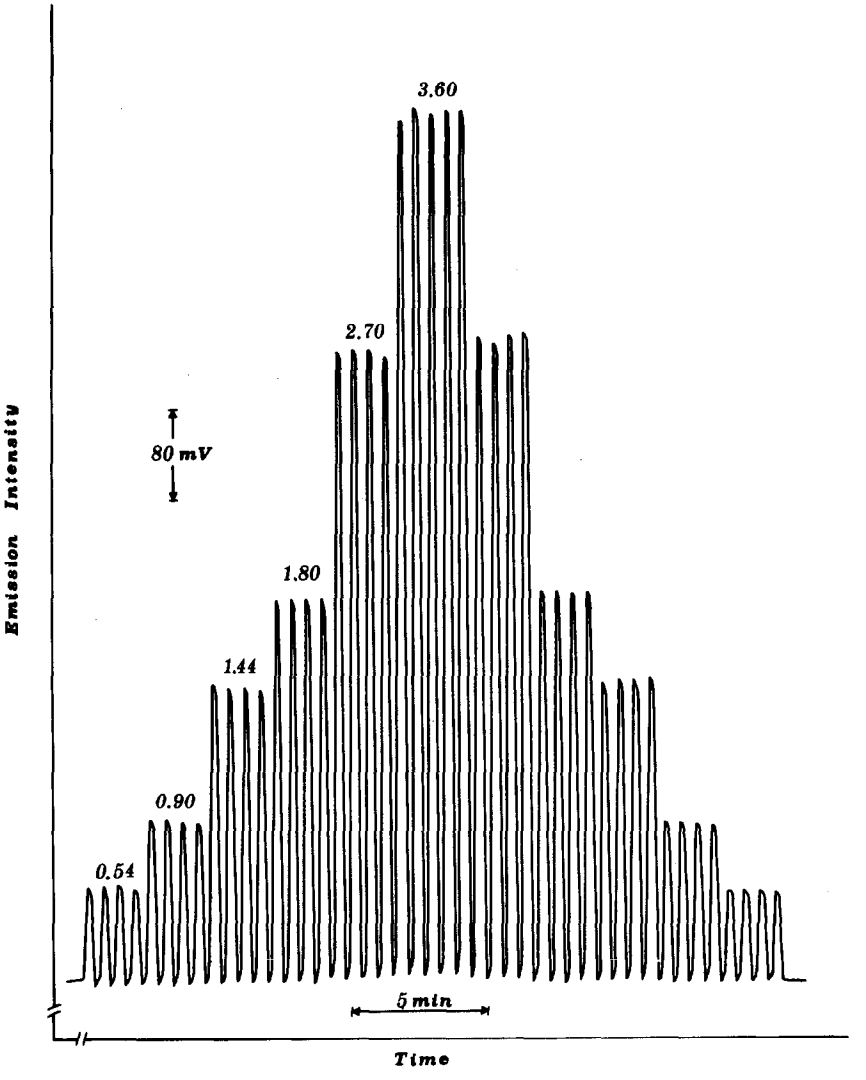

Fig. 5. Typical recording output for the NBS–ammonium ion reaction under the recommended conditions (the numbers above each set of peaks are micrograms per millilitre of ammonium ion).

and in the range 0.540–5.40 μg/ml of ammonium ion

$$I = (-49.6 \pm 11) + (225 \pm 3.7)C;$$

$$r = 0.999, \quad (n = 11).$$

The change of slope of the calibration graph was attributed to the increase of energy transfer yield from the lower to the higher ammonium ion concentration range.

The detection limit (blank + three times its standard deviation[32]) was 0.032 μg/ml of ammonium ion. Repeatability was measured with standard solutions. The relative standard deviations for 10 measurements were 1.6 and 0.4% for 0.540 and 3.60 μg/ml, respectively. Aqueous solutions of ammonium ion (0.0900–5.40 μg/ml) were analysed as samples of unknown concentration with a mean relative error of 1.3% (range 0–3.5%).

Interference studies

Interferences from anions were investigated by recovering 1.80 μg/ml of ammonium ions in the presence of 180.0, 18.0 and 1.80 μg/ml of anion. The results are shown in Table 2. No CL emission was observed from pure solutions of the anions except sulphide, which therefore interferes severely. No effect was observed from nitrate and phosphate which are major constituents of solid fertilizers. Hexacyanoferrate(II), arsenite, nitrite and sulphide interfere since they react with NBS and reduce its concentration.

Interferences from cations were investigated by the same procedure followed for anions.

Table 2. Analytical recovery of 1.80 μg/ml of ammonium ion from solutions which contain various anions

Anion	Concentration ratio (anion:ammonium ion)	Recovery (%) ($n = 3$)

S^{2-}	100	34.2
	10	76.7
	1	100.3

However, most cations form insoluble compounds in alkaline medium. Formation of precipitates can be avoided by using complexing agents. Common complexing agents were found to decrease the emission intensity from ammonium ions due to quenching effect (Table 3). The least severe reduction in response is caused by citrate which was used at 0.010*M*. This concentration is in adequate excess for complexing the cations tested. The equation of the calibration graph, using citrate in standard solutions, obtained in the range 0.540–5.40 μg/ml of ammonium ion was:

$$I = (-102 \pm 12) + (227 \pm 4.0)C;$$

$$r = 0.999, \quad (n = 9).$$

Table 3. Effect of some common complexing agents on the CL emission from 1.80 μg/ml of ammonium ion (emission intensity from pure ammonium ion = 100)

	0.1000	50.7

*Ethyleneglycol-bis(2-aminoethylether)-*N,N,N′,N′*-tetraacetic acid.

†1,2-Diaminocyclohexane-*N,N,N′,N′*-tetraacetic acid.

‡Ethylenediamino-*N,N,N′,N′*-tetraacetic acid.

When citrate was present in the analyte solution, the detection limit was 0.450 μg/ml of ammonium ion and the relative standard deviations for 10 measurements were 1.8 and 0.5% for 0.600 and 4.50 μg/ml, respectively.

The results of the recovery studies for cations are shown in Table 4. Manganese(II) was the most severe interferant of all the cations examined. Cobalt(II) and chromium(III) increase the intensity, probably due to a catalytic effect.[33,34] The unusual effect of copper(II) is probably due to the absorption of radiation by the coloured solution and the catalytic effect of cation on the CL reaction.

Since many fertilizers contain urea, the effect of this compound on the emission intensity was also investigated. The recovery results of 1.80 μg/ml of ammonium ions from solutions with 18.0, 1.80 and 0.180 μg/ml of urea were 153.1, 110.4 and 100.3% ($n = 3$), respectively. The increase in the CL intensity is attributed to

ammonia produced by hydrolysis of urea in alkaline medium. The method can only be applied to samples that also contain urea at concentrations lower than that of ammonium ion.

Accuracy

The accuracy of the proposed continuous-flow CL method was examined by performing recovery experiments on solutions prepared from commercial solid and liquid fertilizers. Table 5 summarizes the results of these studies. 0.010*M* sodium citrate was added to all solutions used in the analysis of samples which contained cations, in order to avoid formation of precipitates. Average recoveries were 100.6% (97.0–106.1%) and 110.9% (104.6–119.7%) for solid and liquid samples, respectively. High recoveries of ammonium ion from liquid samples might be related to the effect of cations, such as copper(II). The proposed method was also evaluated by analysing commercial samples and the results are compared with the values determined by the standard method.[35] A satisfactory agreement between the results was obtained (Table 6), with a mean relative difference of 1.3 and 4.2% for solid and liquid samples, respectively.

CONCLUSIONS

The proposed automated method is the first direct chemiluminometric method developed for ammonium ions. Dilution is the only sample pre-treatment required and the detection limit, sensitivity and selectivity compare very well with existing analytical methods for ammonium ion. The results are repeatable and show that the method can be applied to the determination of ammonium ion in fertilizers. Urea is the only severe interferent when present at concentration ratios $\geqslant 1$. The method has no interferences

CHEMICALLY MODIFIED ELECTRODE BASED ON POLY[TETRA(4-AMINOPHENYL)PORPHYRIN] AS A pH SENSOR

RUO YUAN, YA-QIN CHAI, GUO-LI SHEN and RU-QIN YU*
Department of Chemistry and Chemical Engineering, Hunan University, Changsha, 410082, People's Republic of China

(*Received* 29 *July* 1992. *Revised* 19 *October* 1992. *Accepted* 26 *October* 1992)

Summary—A chemically modified platinum electrode with coated poly[tetra(4-aminophenyl)porphyrin] has been used as a potentiometric pH sensor. It gives a linear response over the pH range 1.5–13.7 with a slope of 55 mV/pH (at 20°). The sensor has fair resistance to erosion of hydrofluoric acid and to interference of a coexisting redox couple. The sensor can be used for pH determination and end-point indication for potentiometric titration of hydrofluoric acid with sodium hydroxide. The a.c. impedance of the polymer membrane has also been studied.

Although the glass membrane pH sensor is the most widely used device for determination of pH, there are limitations to its use due to its high resistance, fragility, erosion by hydrofluoric acid, "sodium error" and "acid error". There has been a considerable interest in designing non-glass sensors for pH measurements. One direction for non-glass pH electrodes using neutral ionophores.[1–4] These electrodes have relatively low impedance and are easier to miniaturize than glass pH sensors. For the purpose of miniaturization, an even more convenient version of the non-glass pH sensor has been the coated-wire type chemically modified electrode (CME). Several papers reported the use of chemically modified electrodes as potentiometric sensors, especially as pH sensors.[5–9] Recently, a pH-sensor based on electrochemical polymerization of amino derivatives on platinum wires was investigated in this laboratory.[10] However, these chemically modified pH sensors reported so far showed rather poor potentiometric response characteristics in solutions of pH below 3 or above 11. Searching for new monomers to prepare polymer film coated electrodes with potentiometric response characteristics similar to those of a glass electrode is of considerable interest. In the present paper, tetra(4-aminophenyl)porphyrin (TAPP) was used as the monomer for a CME pH sensor preparation. Poly(cobalt(II)tetrakis(2-aminophenyl)porphyrin) film was reported as a potentiometric anion sensor.[11] A poly[tetra-(2-aminophenyl)porphyrin] film can easily be formed on a platinum surface by electropolymerization.[12] We use the 4-amino derivative to prepare a similar polymer film and CME. The resulting polymer film coated electrode has fair pH response characteristics and can be used for the potentiometric determination of pH and end-point indication of acid–base titrations.

*Author for correspondence.

EXPERIMENTAL

Apparatus and reagents

Electropolymerization was carried out with an EG & G Princeton Applied Research Potentiostat galvanostat (Model 270) in conjunction with an X-Y recorder (Houston Instrument, Model 200). A conventional three-electrode cell was used with a platinum wire as the working electrode, and a saturated calomel electrode (SCE) and a platinum electrode as reference and counter electrodes, respectively. Potentiometric and pH measurements were made with a Microprocessor Ionalyzer (Orion Research, Model 901) or PHS-3 pH meter (Shanghai Rex Instrument Factory). The a.c. impedance was recorded with a Potentiostat galvanostat (PAR 368). IR spectra were recorded with a Nicolet FT-IR spectrometer (Model 740).

Samples of TAPP were purchased from Dahua Chem. Co. (Sichuan) as well as being synthesized according to Collman *et al.*,[13] and the product was identified by elemental analysis. Tetrabutylammonium perchlorate (TBAP) was

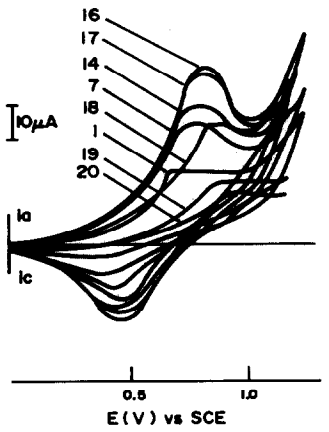

Fig. 1. Cyclic voltammetric scans at Pt electrode: 5m*M* TAPP in CH_3CN (0.1*M* in TBAP) at 100 mV/sec. The scan number is indicated above the voltammograms.

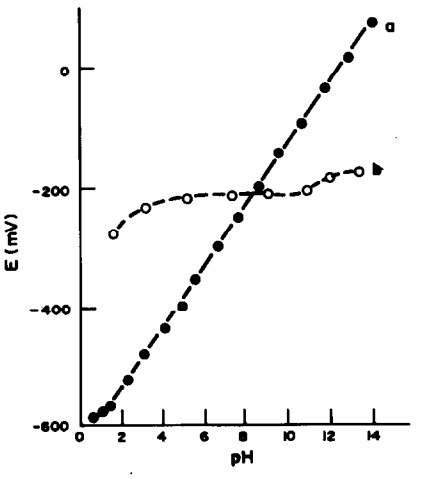

Fig. 2. pH response of PTAPP coated Pt electrode(a) and solvent polymeric membrane containing TAPP coated Pt electrode(b) as pH sensors.

prepared by the reaction of tetrabutylammonium bromide with sodium perchlorate. Redistilled demineralized water and analytical grade reagents were used throughout all experiments.

Electropolymerization

The solution used to prepare the electropolymerized film was 10.0 ml of 5.0m*M* TAPP in acetonitrile (0.10*M* in TBAP). The electrolytic solution was deoxygenated by bubbling nitrogen through the solution for approximately 10 min and then allowing the N_2 to flow over the solution during the experiment. TAPP was polymerized onto the platinum electrodes from the electrolytic solution by cycling the working electrode potential repetitively between 0 and 1.2 V (*vs.* SCE) at a scan rate of 100 mV/sec for 20 complete cycles (Fig. 1). The newly formed brown poly[tetra(4-aminophenyl)-porphyrin] (PTAPP)-coated electrodes were thoroughly washed with acetone and water.

RESULTS AND DISCUSSION

pH response of the PTAPP-coated electrode

The PTAPP-coated electrode performance was examined in a 69.0m*M* solution in Na^+, 11.4m*M* in BO_3^{3-}, 10.0m*M* in PO_4^{3-} and 6.7m*M* in citrate. The PTAPP electrode and a glass electrode together with the SCE reference were dipped into the solution and 2*M* orthophosphoric acid (or 4*M* sodium hydroxide) was added dropwise with simultaneous recording of the emf of the PTAPP-SCE pair and the solution pH given by the glass electrode. As shown in Fig. 2(a), the response was linear from pH 1.5 to 13.7 with a slope of 55 mV/pH (at 20°, correlation coefficient 0.998). The response time was less than min. The electrode has a lifetime of at least 3 weeks. The d.c. resistance of the electrode was 310 ± 0.3 kΩ which was much lower than that of a glass membrane pH electrode. The standard deviation of the electrode potential readings over a period of 2 hr in a *tris*-buffered solution of pH 7.3 was

Table 1. pH measurements on serum samples

Serum sample	pH measured by PTAPP coated electrode	pH measured by glass electrode
A	7.40	7.43
B	7.36	7.38
C	7.37	7.41
D	7.72	7.79
E	7.75	7.82
F	7.74	7.82
G	7.78	7.85

A, B, C: fresh serum samples; D, E, F, G: samples exposed to the air for 2 days.

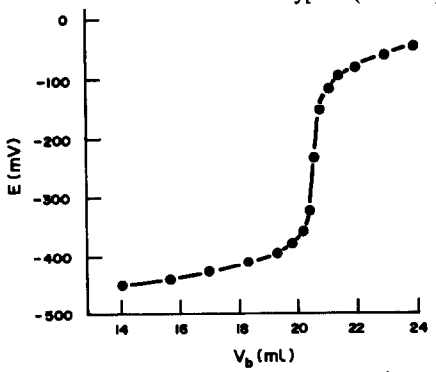

Fig. 3. E–V curve for titration of HF with NaOH (V_b: volume of base added).

0.7 mV ($n = 24$) and potential readings for the electrode dipped alternatively into stirred solutions of pH 7.0 and 7.6 showed a standard deviation of 0.6 mV over 2 hr ($n = 12$). The potentiometric selectivity coefficient with respect to some clinically important ions such as Na^+, K^+, Li^+, Ca^{2+} were determined by the fixed interference method, the values obtained for log $K^{pot}_{H^+,M^{n+}}$ for different M^{n+} were: -13.6 for Na^+; -13.5 for K^+; < -12.0 for Li^+; < -11.4 for Ca^{2+}. The interferent concentration was kept at the level of 1M.

Preliminary applications

Clinical chemistry. The PTAPP coated electrode has fair response characteristics in the pH range 6.5–8.5 which is of interest for biological studies. Seven serum samples were chosen for pH measurements using the PTAPP electrode as the pH sensor. A glass-membrane pH electrode was also used for comparison (Table 1). The PTAPP electrode gave acceptable results, though these results tended to be slightly lower than the glass electrode readings and the reason was not uncovered.

End-point indication in titrations of hydrofluoric acid with sodium hydroxide. There is no erosion effect for the PTAPP coated electrode as a pH sensor in hydrofluoric acid. The electrode can be used for end-point indication in titrations of hydrofluoric acid with sodium hydroxide. Figure 3 shows an E–V curve for this type of titration using a sample of 20 ml of 0.0514M HF titrated with 0.0504M NaOH. The HF concentration found was 0.0517 with a standard derivation of 0.0003 ($n = 3$).

Mechanism of PTAPP-coated electrode toward hydrogen ion

Figure 1 shows a typical cyclic voltamperogram for the oxidation of TAPP. As the number of cycles increased, the anodic peak shifted toward more positive potentials and the cathodic peak shifted in the reverse direction. This was probably due to the iR drop of the growing PTAPP film. The anodic peak current for the oxidation of TAPP increased with increasing numbers of cycles, n, until reaching 16, and then decreased. It was thought that the amount of TAPP monomer diffusing from bulk solution to Pt working electrode increased initially with each successive potential scan, the electrochemical oxidation of TAPP then produced the insulating PTAPP film which was adhesively coated on the platinum electrode surface. The insulating PTAPP film blocked the access of the TAPP monomer to the Pt working electrode surface. The initial electrochemical oxidation of TAPP produced a cation radical, followed by chemical reactions such as hydrolysis or polymerization to form an amine-linked polymer or at least some amine linkages. The same phenomenon was observed in the case of the electrochemical oxidation of amino derivatives.[5,8,14–15] The PTAPP film was chemically inactive and it showed no electronic conductivity in dry conditions. However, when a PTAPP film was immersed in a supporting solution, swelling of the polymer films occurred. Electrolyte ions could penetrate selectively into the swollen polymer films. The hydrogen ions seemed preferable to other ions to penetrate through the swollen polymer films. Similar results were observed with polyphenol, polyaniline and poly(1,2-diaminobenze)films.[6]

Figure 4 shows the effect of the redox couple Ce^{4+}/Ce^{3+} on the electrode potential. It is well known that the emf of a bare platinum electrode is affected by the presence of oxidation–reduction agents. To show whether the coated

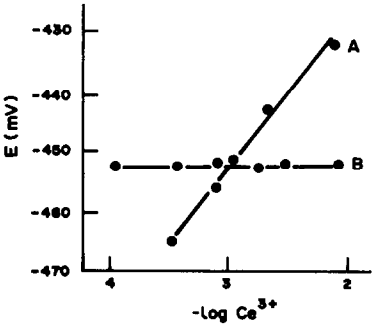

Fig. 4. Effect of concentration ratio, Ce^{4+}/Ce^{3+} on electrode potential measured *vs.* SCE: (A) uncoated Pt electrode; (B) PTAPP coated electrode.

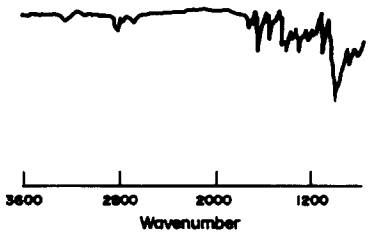

Fig. 5. The IR spectrum of PTAPP film.

platinum electrode has the same effect, different amounts of Ce^{3+} were added into a pH 5.2 buffer which was 0.01*M* in Ce^{4+}, and the bare platinum electrode and PTAPP coated electrode showed potential change as measured against the SCE reference as shown in Fig 4. It can be seen that the effect of the redox couple on the potential of the bare platinum electrode was eliminated by coating PTAPP on the electrode surface. The slope of the bare electrode response toward the cerium redox couple was about 1/3 of that expected from the Nernst equation. The result obtained was similar to that of poly(4,4′-diaminobiphenyl)polymer film.[9] This seemed to be related to the hydrolysis of Ce^{4+} and Ce^{3+} ions in the pH 5.2 aqueous solution. The quinone/hydroquinone redox couple in a concentration of 0.02*M* also did not affect the potential of PTAPP coated electrode (not shown in Fig. 4). This indicated that Ce^{4+} ions, Ce^{3+} ions, quinone and hydroquinone cannot penetrate into the PTAPP film.

White *et al.*[12] reported the preparation of polymer film of tetra(2-aminophenyl)porphyrin using electropolymerization. Their experiments showed the electrochemical and spectral similarities of the monomer to the electropolymerized porphyrin film. From this fact the authors claimed that the monomer porphyrin π-system had remained intact upon electropolymerization. We tried to examine the IR spectra and a.c. impedence of PTAPP obtained from the 2-amino derivative as the monomer to obtain some information about the mechanism of the pH response of the PTAPP-coated electrode. The IR spectrum (Fig. 5) showed one wide peak at 3330 cm^{-1}, which presumably represented a combination peak of both symmetric and unsymmetric stretching vibrations of the N—H bond due to the TAPP π-system. Other IR absorption peaks observed seemed to originate from the stretching vibration of the ArC=N double bond, the skeletal vibration of the benzene ring and the characteristic peaks for 1,4-substituted benzenes. Figure 2(b) shows the pH response of a solvent polymeric membrane electrode with TAPP monomer as the ionophore toward hydrogen ion. The solvent polymeric membrane electrodes was prepared as follows: an uncoated Pt electrode was soaked repeatedly in the mixture containing 10 mg of TAPP, 4 mg of potassium tetrakis(*m*-chlorophenyl)borate, 200 mg of poly(vinyl chloride), 80 mg of *o*-nitrophenyl ether, and 10 ml of tetrahydrofuran and dried after each dipping. The Pt electrode coated with a solvent polymeric membrane containing TAPP did not have normal potentiometric response towards hydrogen ion. This indicated that the monomeric TAPP probably entrapped in the film during the electropolymerization made no contribution to the hydrogen ion response. The rate of diffusion of hydrogen ion within the film varied with the kind of the polymer films.[6] The hydrogen ion response functional group of the PTAPP film was probably the nitrogen atoms in PTAPP which could pump hydrogen ion into the polymer film. The pH response of a hydrogen ion sensor based on neutral ionophores depended on the acidity constant (p*K*) and the net surplus charge in the vicinity of nitrogen atom of incorporated ionophores.[2,4] The basicity of the nitrogen atom in the porphyrin ring was different from that of nitrogen atoms in the phenyl ring. It seems that different nitrogen atoms of the PTAPP were responsible for the different pH range functions of the PTAPP-coated electrode. The equilibrium could be described by the following equation:

$$\text{PTAPP(m)} + \text{H}^+\text{ (aq)} + \text{X}^-\text{ (aq)} \rightleftharpoons \text{PTAPP}\cdot\text{H}^+\text{ (m)} + \text{X}^-\text{ (m)}$$

This explanation is in accordance with the a.c. impedance of the PTAPP film. The PTAPP-coated electrode conditioned in phosphoric acid–*tris* buffer solutions of different pH for 4 hr displayed well-resolved bulk

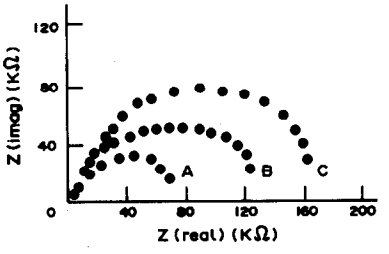

Fig. 6. Impedance plots of PTAPP-coated electrodes bathed in (A) pH 3.0, (B) pH 5.0 and (C) pH 9.0 H_3PO_4-*tris* buffered solutions for 4 hr (frequency: 10^5–10^{-3} Hz, 26°).

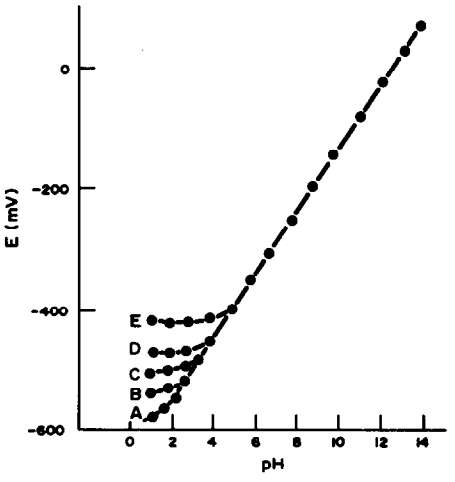

Fig. 7. Influence of the anion contained in solutions ((A) 0.1*M* NO_3^-; (B) 0.1*M* Cl^-; (C) 0.1*M* Br^-; (D) 0.1*M* SCN^-; (E) 0.1*M* I^-).

impedance semicircles. The bulk resistances increased with increasing pH values (Fig. 6). It is proposed that the energy of transfer of the hydrogen ion across the polymer membrane increased with increasing pH values. The effect of anions on the pH response can be seen from the left ends of the response curves shown in Fig. 7. The following sequence of anion interference was observed: $I^- > SCN^- > Br^- > Cl^- > NO_3^-$. The iodide was actually an interfering ion. As Karagozler *et al.*[16] reported, an electrode based on a poly(3-methylthiophene) films doped with iodine by electrochemical oxidation of iodide showed Nernstian response towards iodide at pH 2–10. The PTAPP coated electrode dipped in aqueous solution of pH below 5.5 displayed a Nernstian response toward iodide. The linear response ranges toward iodide increased with decreasing pH values of the solution. Work is in progress to study the response mechanism of the PTAPP film toward iodide.

SOLVENT EXTRACTION OF URANIUM(VI) INTO TOLUENE BY DICYCLOHEXANO-18-CROWN-6 FROM MIXED AQUEOUS-ORGANIC SOLUTIONS

J. P. SHUKLA, ANIL KUMAR* and R. K. SINGH*
Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-400085, India

(*Received* 22 *July* 1992. *Revised* 18 *November* 1992. *Accepted* 23 *November* 1992)

Summary—Extraction behaviour of uranium(VI) from mixed organo-aqueous solutions containing water-miscible protic aliphatic alcohols and several aprotic solvents was investigated by using dicyclohexano-18-crown-6(DC18C6) as an extractant. The organic phase was a binary solution of DC18C6 and toluene while the polar phase was a three component solution of uranyl nitrate, polar additive and aqueous nitric acid. Methanol, ethanol, isobutanol, dioxane, acetone, propylene carbonate and acetonitrile were used as the organic components of the mixed (polar) phase. Propylene carbonate, acetone, acetonitrile and dioxane increased the extractability of U(VI), whereas alcoholic additives showed only an antagonistic effect. The relative increase in extraction was found to be more at lower nitric acid concentrations. Possible reasons for such behaviour are briefly discussed. Recovery of U(VI) from loaded organic phase was easily accomplished using dilute perchloric acid and sulphuric acid. A sample method was standardized for the separation of plutonium(IV) from uranium(VI) based on its reductive stripping.

Liquid–liquid extraction has been commercially exploited, particularly for the separation and purification of both rare earths and actinides such as thorium, uranium and plutonium. The separation of the metals is difficult, however, if their chemical properties are similar. To this end, several techniques have been suggested to improve the separation factors between such metals, such as: (i) introducing an auxiliary extractant with the main extractant, generally called a "synergic" extraction;[1] (ii) adding a complexing agent such as EDTA, acetylacetone, *etc.*, to an aqueous phase,[2,3] and (iii) incorporating a polar water-miscible organic additive such as acetone, dioxane, dimethyl sulfoxide, acetonitrile, *etc.*, to an aqueous phase.[4,5] Among these, solvent extraction of metals from mixed aqueous–organic solutions has especially drawn attention recently owing to several practical advantages and ease of manipulations. To date, most of the effort in this field has been restricted to extractions with amines and tributyl phosphate,[6,7] whereas use of mixed solvents with macrocyclic crown compounds has not been significant so far. Macrocycles are novel cyclic liposoluble organic molecules which contain hetero atoms, *e.g.* O, N, S and P, capable of forming electron-rich interior cavities and possess the ability to complex ions or molecules via ion–dipole or dipole–dipole stereo-selective interactions. Among several 18-crown-6 derivatives, dicyclohexano-18-crown-6 (DC18C6) has already been shown to have potential for uranium(VI) and plutonium(IV) extraction[8] from aqueous nitric acid media.

As part of comprehensive studies on the extraction of actinides with polydentate macrocycles, we have recently reported on the extraction behaviour of plutonium(IV) from several hydro-organic solutions using DC18C6 as the extractant.[9] This paper now reports data on the extraction characteristics of uranium(VI) under similar conditions for which no data are available for the extraction from acidic nitrate solutions in the presence of protic as well as aprotic common organic solvents.

EXPERIMENTAL

All the chemicals used were "analytical reagent".

Reagents

Aliphatic alcohols (methanol, ethanol and isobutanol), dioxane, propylene carbonate (PC), acetone and acetonitrile (AN) used were all G.R. grade. The organic and the aqueous phase were saturated with each other prior to their use in order to prevent any volume change during

*Power reactor fuel reprocessing plant, BARC.

extraction. DC18C6, obtained from Aldrich, USA, was of high purity grade.

Tracer

U-233 used was purified by tributyl phosphate (TBP) extraction and checked for its radiochemical purity. U-233 radiotracer (10^{-6}–$10^{-4}M$) was used throughout this study and assayed radiometrically by alpha scintillation counting.

Distribution ratio (D_U) measurements

Equal volumes (1 ml) of U-233 tracer containing an organic additive in the desired nitric acid molarity and DC18C6 dissolved in toluene, were pipetted into a 15-ml glass-stoppered equilibration tube and stirred mechanically for about 40 min at room temperature (23–25°C). Preliminary experiments had shown that equilibrium was established in about 25 min. After settling for half an hour, and centrifuging if necessary, suitable aliquots from both the phases were withdrawn for radioassay. The distribution ratio (D_U) of uranium, defined as: D_U = total concentration of uranium in the organic phase/total concentration of uranium in the aqueous phase, was thus calculated.

From a knowledge of D_U, the volume of the aqueous phase (V_w) and the volume of the organic phase (V_o), the percentage extraction (%E) was then evaluated:

$$\%E = 100\ D_U/[D_U + (V_w/V_o)].$$

All the measurements were done at least in duplicate and the agreement in D_U values obtained was within ±2% with good material balance (>95%).

In evaluating the effect of various organic additives such as alcohols, acetone, acetonitrile, dioxane and propylene carbonate on D_U, the procedure adopted was essentially the same except that the aqueous phase contained the appropriate proportion of an organic additive. The relative permittivity of the mixed aquo-organic media, D, was calculated from the equation (10).

$$D = (V/100)D_1 + (100 - V/100)D_2,$$

where D_1 and V are the relative permittivity and percentage organic additive present, respectively, and D_2 is the dilectric constant of pure water.

For studying the back extraction, suitable aliquots from the loaded organic phase were withdrawn into an equilibration tube and subsequently back extracted for about 10 min with similar volumes of the strippant.

Absorption spectra

Uranium(VI) was extracted from 7M HNO_3 containing 20% AN and 0.2M DC18C6/toluene and the spectra of the organic extracts thus separated were recorded on a Shimadzu, model UV-160, UV-visible spectrophotometer.

RESULTS AND DISCUSSION

Liquid–liquid extraction of U(VI) into toluene by DC18C6 from mixed aquo-organic solutions is strongly influenced by the addition of certain organic additives to the aqueous acidic phase. Distribution ratios attained were quite high and quantitative extraction was even possible at the lower nitric acid concentrations admixed with suitable non-aqueous solvents. Values of D_U were virtually independent of the initial metal concentration employed (10^{-6}–$10^{-4}M$), indicating the absence of polynuclear species in the extraction systems. Detailed study on mutual solubility of the various components and on the swelling of the organic phase was not attempted. Generally, however, it is known that at concentrations of alcohols of about 30% or less in the polar phase, the change in the volume of phases is of the same order as in the case of pure aqueous mineral acid solutions. Higher proportions of organic additives than 30% were therefore not employed to avoid such complications. Also, the presence of a high concentration of the alcohols in the polar phase results in a decrease in the specific gravity of the latter, resulting in the reversal of the extraction phases. Owing to its reversal, separation of the phases becomes difficult. Sometimes only one phase is formed when the percentage of organic additive is increased beyond a certain limit.

Dependence of D_U on nitric acid concentration

To assess the dependence of the extraction capacity on the polar phase acidity, the extraction behaviour of uranium(VI) from increasing nitric acid molarity into toluene by DC18C6 was systematically examined. Representative data for only acetonitrile and propylene carbonate are shown in Fig. 1. The upper two curves show that the values of D_U were considerably enhanced by addition of these organic solvents. Maximum extractability is slightly shifted towards lower acidity in the presence of such additives, though the general pattern of acid

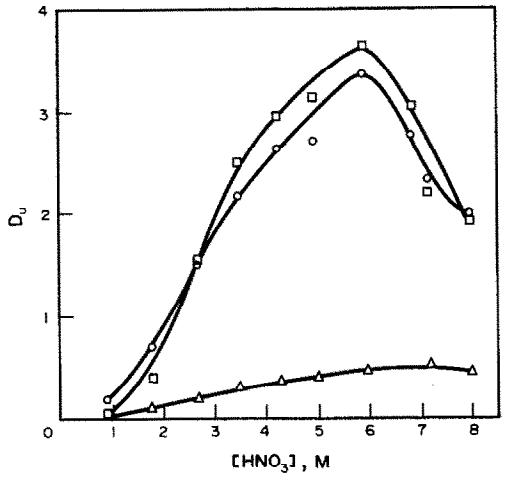

Fig. 1. Effect of nitric acid concentration on the extraction of U(VI) with 0.2*M* DC18C6/toluene from pure nitric acid solution (—△—); solution containing 20% (v/v) propylene carbonate (—○—); solution containing 20% (v/v) acetonitrile (—□—).

dependence is essentially similar to that with no additive. Maximum extraction of uranium took place at around 6–7*M* HNO_3 and the same trend was followed in the presence of 20% AN or PC in the polar phase with significant increase in D_U values. Similarly maximum enhancement in Pu(IV) extraction by this macrocycle took place at acidity around 5–6*M* HNO_3 in the presence of 20% PC.[9] After the maximum, values of D_U decreased with further increase in polar phase acidity. The initial growth in the extraction was probably caused by the salting out effect of the nitric acid in the presence of the water-miscible organic solvents, the further increase in the content of which decreased the concentration of free extractant as a result of coextraction of nitric acid which is attributed to the competitive formation of CE.*m* HNO_3 ($m = 1,2$) complex in the organic phase[11] and incomplete dissociation of HNO_3 in the polar phase. It is evident that at the same acidity, extraction was generally higher in the presence of acetonitrile than propylene carbonate in the polar phase (Table 1). At higher acid concentrations (>5*M*), extraction of U(VI) was relatively less influenced by introducing organic component in the polar phase, whereas comparatively higher D_U values were obtained by adding organic solvents at lower acid concentrations (<3–4*M* HNO_3). This phenomenon has been previously observed for extraction from mixed media.[12]

*Extraction without organic additive.

Dependence of D_U *on DC18C6 concentration*

The concentration of the crown ether, DC18C6, in the organic phase strongly influenced the extraction of uranium from polar media. To examine this, extraction of uranium with 0.05–0.5*M* DC18C6 from aqueous–organic media (HNO_3 + AN) with varying acetonitrile concentration was investigated. From the results summarized in Table 2, it is quite evident that metal extractability was markedly enhanced by increasing the concentrations of both DC18C6 and acetonitrile up to 30 vol. (%). The height of synergic maximum followed the trend: 0.5 > 0.2 > 0.1 > 0.05*M* DC18C6. Thus the synergic effect was more pronounced at higher crown ether concentrations. Extraction of U(VI) exceeding 90% could be readily achieved in a single equal-volume contact by 0.5*M* DC18C6 from 4*M* HNO_3 solutions containing 30% (v/v) acetonitrile (Table 2). A similar behaviour was also noted with propylene carbonate as the organic component.

In order to study the extraction mechanism, the dependence of D_U on crown ether

Table 2. Effect of DC18C6 concentration on uranium(VI) extraction into toluene from aqueous-acetonitrile polar phase*

Acetonitrile (%)	Distribution ratio (D_U) DC18C6† (*M*) 0.05	0.1	0.2	0.5
0	—	0.17	0.31	—
10	0.17	0.93	1.69	3.29
20	0.29	1.19	2.78	5.28
30	0.52	1.46	3.15	7.12
40	0.39	1.21	2.26	4.78

*Initial concentration of acidity in the polar phase was 4*M* HNO_3.
†Dissolved in toluene.

concentration was examined at $HNO_3 = 4M$. The extraction of U(VI) is represented by,

$$UO^{2+}_{2(a)} + 2\ NO^{-}_{3(a)} + nCE_{(o)} \rightleftharpoons UO_2(NO_3)_2 \cdot nCE_{(o)}, \quad (1)$$

where subscripts a and o refer to the species present in aqueous and organic phases, respectively, for which the equilibrium constant, K_{ex}, is

$$K_{ex} = \frac{[UO_2(NO_3)_2 \cdot nCE]_{(o)}}{[UO_2^{2+}]_{(a)}[NO_3^-]^2_{(a)}[CE]^n_{(o)}}. \quad (2)$$

Introducing the distribution ratio,

$$D_U = [UO_2(NO_3)_2 \cdot nCE]_{(o)}/[UO_2^{2+}]_{(a)},$$

one obtains

$$\log D_U = \log K_{ex} + 2 \log[NO_3^-]_{(a)} + n \log [CE]_{(o)}. \quad (3)$$

Since U(VI) is at the tracer level and the partition of free DC18C6(CE) in the aqueous phase is negligible, particularly with toluene, the equilibrium concentration, $[CE]_o$, is equal to $[CE]_{initial}$. The plot of log D_U *vs.* log $[CE]_o$ in the organic phase is depicted in Fig. 2. The line drawn through the experimental points yielded a slope, n of 1.1 which indicated that the extracted species in the macrocycle–diluent phase is predominantly of the type $UO_2(NO_3)_2$.CE. Contrary to this, PU^{4+} forms an 1:2 ion pair complex of the type, $Pu(NO_3)_4$.2CE, as studied recently under similar conditions.[9] With acetonitrile the slope is nearly +1, showing that this additive, and presumably also most of the others, does not change the type of the extracted species. Values of log K_{ex} with DC18C6/toluene for $4M$ HNO_3 + 20% AN, $4M$ HNO_3 + 20% PC and pure $4M$ HNO_3 are 0.66, 0.63 and −0.20, respectively, which reflects the relatively high extractability of U(VI) from mixed media (Table 1). Visible absorption spectra of the U(VI) complex extracted with DC18C6 from $7M$ HNO_3 aqueous solution and that from $7M$ HNO_3 admixed with 20% AN were essentially alike which indicated the similarity of the species involved in the extraction process.

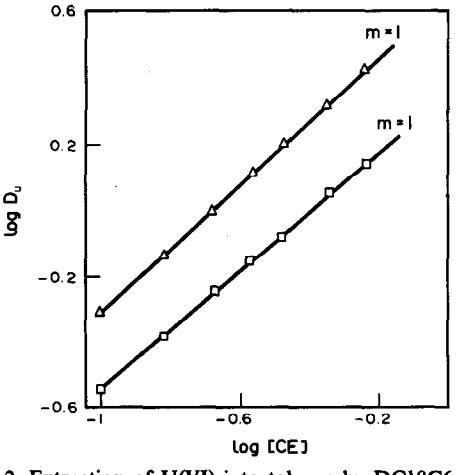

Fig. 2. Extraction of U(VI) into toluene by DC18C6 as a function of extractant concentration from pure $4M$ HNO_3 solutions (—□—); solutions containing $4M$ HNO_3 + 20% (v/v) acetonitrile (—△—).

Dependence of D_U *on the concentration of organic additives*

Preliminary experiments indicated that the organic additives generally exerted a pronounced effect on uranium extraction. Table 3 presents data on its extraction into toluene by $0.2M$ DC18C6 from $4M$ HNO_3 containing varying amounts of methanol, ethanol, isobutanol, acetone, dioxane, propylene carbonate and acetonitrile. It is evident that the values of D_U are significantly enhanced by introduction of some of these polar organic additives to the aqueous phase, except alcohols. When protic solvents such as methanol, ethanol and higher alcohols like isobutanol were used as additives, a remarkable depression in the metal extraction was observed as compared with the extraction using aprotic components, *e.g.* acetone, acetonitrile, dioxane and propylene carbonate. Such an inhibitory effect is presumably caused by the interaction of alcoholic solvents with DC18C6/toluene in the organic phase and to the decrease in the partition coefficient of the macrocycle caused by the swelling of the organic phase. In general, the addition of both types of such organic substances brings about a considerable decrease of relative permittivity (D) of the

Table 3. Effect of organic additives on the extraction of U(VI) into toluene by DC18C6 from aqueous nitric acid media (organic phase: $0.2M$ DC18C6/toluene; aqueous phase: $4M$ HNO_3 + organic additive; volume ratio (O/A): 1)

Organic additive	Distribution ratio* (D_U) (%) 10	20	30	40
Dioxane	0.92	1.36	1.86	1.25
Acetone	1.75	2.01	2.75	1.60

*Mean value of D_U obtained from pure $4M$ HNO_3 medium is 0.31.

aqueous phase. Maximum enhancement in extraction was accomplished in the presence of both acetonitrile as well as propylene carbonate. Thus their additions to the aqueous phase may prove helpful in uranium recovery. To illustrate the advantage obtained by using these additives, the D_U values and the advantage factor (AF), defined as,

$$AF = D_U \text{ in mixed medium}/D_U \text{ in pure aqueous medium}$$

for 20 vol. (%) PC and AN are presented in Table 1. These results indicate that for most of the nitric acid concentrations ranging from 0.9 to 8*M* HNO_3, high D_U values (AF: 4–9) could be easily realized for uranium extraction. At the same additive percentage, the values of distribution ratio follow the sequence: methanol < isobutanol < ethanol < dioxane < acetone < propylene carbonate < acetonitrile (Fig. 3). Extraction of uranium had maxima at about 30% (v/v) additive concentration and then it steadily decreased with further proportions. Such behaviour has also been observed earlier[9] while studying Pu^{4+} as well as Am^{3+} extractions.[13] It merits mention that these substances did not pass into the nonpolar phase (the volume of the latter phase remained nearly constant after reaching equilibrium except when it contained about 30 vol. % or more of higher alcohols) and hence their effects can be explained by interaction in the aqueous phase only. Such organic liquids, being less polar than water, favour the formation of the neutral adduct, $UO_2(NO_3)_2.CE$, which ultimately brings about a substantial increase in extraction. At low additive concentrations, the dehydration effect[14] due to their presence facilitates interaction with the NO_3^- anion to form the extractable nitrate complex, and should lead to an increase in the metal extraction.

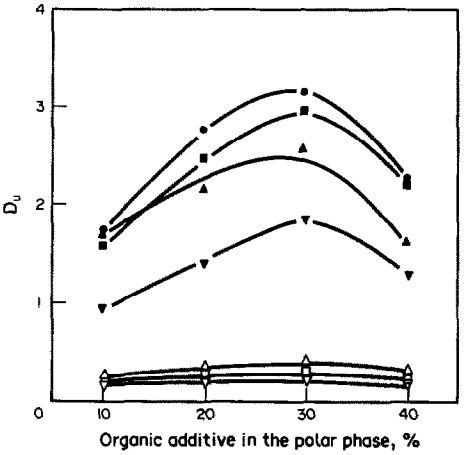

Fig. 3. Effect of organic additives on the extraction of U(VI) into toluene by 0.2*M* DC18C6 as a function of initial concentration of the organic solvents in the polar phase; initial acidity of polar phase: 4*M* HNO_3. Methanol (—▽—); isobutanol (—□—); ethanol (—△—); dioxane (—▼—); acetone (—▲—); propylene carbonate (—■—); acetonitrile (—●—).

Back extraction of uranium

Several aqueous solutions were evaluated as strippants for uranium from loaded toluene solutions of DC18C6 extracted from a polar phase containing 4*M* HNO_3 + 20% AN. From Table 4, it is evident that the strippants like $HClO_4$ as well as H_2SO_4 could strip uranium from DC18C6/toluene solutions almost quantitatively (>95%) in a single step. Sodium carbonate and oxalic acid were also tested for back extraction, and could only recover around 87 and 40%, respectively.

Separations of plutonium from uranium when extracted together

Since both U(VI) and Pu(IV) at mg/ml levels could be efficiently extracted (>95%) with 0.2*M* DC18C6/toluene from a polar phase containing 4*M* HNO_3 + 20% (v/v) CH_3CN, reductive stripping with 0.2*M* ascorbic acid or 0.2*M* $NH_2OH.HCl$ was attempted to separate them when present together. Both these strippants could recover plutonium around 95% in a single equal volume contact, while back extraction of uranium was negligibly small (<1%). Uranium

H_2SO_4 (2.0*M*)	0.10	91
$HClO_4$ (1.0*M*)	Negligible	>99

*U(VI) was extracted from a polar phase containing 4*M* HNO_3 + 20% (v/v) AN.

†Aqueous solutions of strippants were made by directly weighing or measuring the volumes approximately; concentrations (*M*) are given in brackets.

‡Dissolved in 0.5*M* HNO_3.

was subsequently back extracted (>98%) with 1*M* $HClO_4$ from loaded organic extracts. Applicability of this method was successfully tested in the analysis of several low/medium level fuel reprocessing waste solutions containing large amounts of uranium (mg/ml) and trace concentrations (μg/ml) of plutonium. Recovery of uranium from triplicate experiments exceeded $98 \pm 1\%$ under the standardized conditions.

CONCLUSIONS

Extraction of uranyl ions with DC18C6 from the mixed aqueous–organic solution has been examined in order to evaluate the synergistic effect of several common polar water-miscible organic solvents. Its extraction is strongly affected by the addition of some of these components. Acetonitrile and propylene carbonate prove to be most efficient for this purpose. Slope analyses and spectral studies of the uranyl complex extracted from pure nitric solutions and those admixed with organic additives have shown the similarity of the species involved in both the systems. Separation of Pu(IV) and U(VI) is easily accomplished using reductive strippants.

(*Received* 22 *May* 1992. *Revised* 29 *December* 1992. *Accepted* 5 *January* 1993)

Summary—The reaction of nickel (II) with Br–PADAP, in the presence of tergitol NPX surfactant, forms a complex with absorption peaks at 520 and 560 nm. The iron(II)–Br–PADAP system at the same conditions forms a chelate with absorption peaks at 560 and 748 nm. This allows the simultaneous spectrophotometric determination of nickel and iron by measuring the absorbance at 560 and 748 nm. The proposed method, at pH 4.0–5.7, shows a molar absorptivity of 1.22×10^5 l · mole^{-1} · cm^{-1} for nickel at 560 nm and 8.20×10^4 l · mole^{-1} · cm^{-1} at 560 nm and 3.35×10^4 l · mole^{-1} · cm^{-1} at 748 nm for iron(II). Beer's law is obeyed up to 0.40 μ/ml of nickel(II) and up to 0.65 μg/ml of iron(II). Thiosulphate as masking agent allows the simultaneous determination of iron and nickel in the presence of high concentrations of copper. The ethylene glycol 2-(2-amino-ethyl) tetracetic acid provides the elimination of many other interferences. The method has been applied successfully to the simultaneous determination of nickel and iron in reference samples.

The reagent 2-(5-bromo–2-pyridylazo)-5-diethylaminophenol (Br–PADAP) has been frequently used as a spectrophotometric reagent, because of its sensitivity for metallic cations. As it has low solubility in water, the reagent cannot be used in aqueous media. Proposed methods include extractions using organic solvents in the presence of surfactants or in aqueous-ethanol systems. The main applications of Br–PADAP as a colorimetric reagent are for the determination of uranium(VI),[1] palladium,[2] thorium,[3] cadmium[4] and nickel.[5,6] The first study of the reaction of Br–PADAP with nickel(II) was made by Fu-Sheng and co-workers.[5] In it, nickel(II) reacts with Br–PADAP in aqueous-ethanol media, forming a complex with a composition of 1:2, cation:reagent, which has two absorption maxima at 520 and 560 nm.

The use of Br–PADAP as reagent for spectrophotometric determination iron was described several times. It reacts with iron(II) and iron(III). Its reaction with iron(II) forms a stable complex that has been applied for the analysis of iron in several materials.[7–11]

The iron(III)–Br–PADAP system was used for iron determination in irrigation water.[12] Wang and Song[13] used Br–PADAP for simultaneous determination of iron(III) and iron(II). Bursik *et al.*[14] proposed a simultaneous method for determination of iron(III) and copper(II).

Table 1 shows the characteristics of systems used during the proposed methods for the determination of nickel and iron with Br–PADAP. The reaction of nickel with Br–PADAP in the presence of tergitol NPX surfactant provides the formation of a complex with absorption peaks at 530 and 560 nm, while the reaction of iron(II)–Br–PADAP under the same conditions, forms a complex with absorption peaks at 560 and 748 nm. Considering these facts, a method has been proposed for the simultaneous determination of nickel and iron, by measuring the absorbances at 560 and 748 nm, based on the additive property of the absorbance.

EXPERIMENTAL

Apparatus

Spectrophotometric measurements were made a VARIAN DMS-100 spectrophotometer with matched 1.00-cm quartz cells. A FISHER-600 pH meter was used to measure the pH values of the solutions.

Reagents

All reagents were of analytical reagent grade unless otherwise stated.

Br–PADAP (MERCK) solution. 0.10 g in 100 ml of ethanol.

†DMF: Dimethylformamide; OP emulsifier: polyoxyethylene glycol octylphenyl ether; ϵ: molar absorptivity ($l \cdot mole^{-1} \cdot cm^{-1}$).

Standard nickel(II) solution (100 μg/ml). Prepared by dissolving pure nickel in diluted hydrochloric acid and dissolution up to 1 l. demineralized water.

Standard iron(II) solution (100 μg/ml). Prepared by dissolving iron(II) ammonium sulphate in sulphuric acid (0.50%).

Working solutions of nickel(II) and iron(II). Prepared by dilution of the standard solution in demineralized water.

Buffer solution. Prepared by mixing 2.0*M* sodium acetate and 2.0*M* acetic acid in appropriate ratios.

EGTA solution (0.40 mg/ml $\simeq 1.05 \times 10^{-3}M$/l). Prepared by dissolving ethylene glycol 2-(2-amino-ethyl) tetracetic acid (Merck) in water.

Tergitol NPX (J. T. Baker Chem. Co.) solution. 10.0 g in demineralized water (100 ml).

Thiosulphate solution (10.0%). Prepared by dissolving sodium thiosulphate in water.

Reducing solution (5.0%). Prepared by dissolving hydroxylammonium chloride in water.

General procedure

Transfer a portion of solution containing 5.00 μg of nickel and/or 10.0 μg of iron, into a 25 ml volumetric flask, add 2.0 ml of a 5% solution of hydroxylammonium chloride, 2.0 ml of tergitol NPX (10%), 2.0 ml of EGTA (0.40 mg/ml), 5.0 ml of acetate buffer (pH 4.5) and 1.0 ml of a 0.10% ethanolic solution of Br–PADAP. Dilute to the mark with water, mix, and after 50 min, measure the absorbances at 560 and 748 nm *vs.* an approximately prepared blank.

RESULTS AND DISCUSSION

Characteristics of the complexes

The reaction of Br–PADAP with iron(II) in presence of Tergitol NPX forms a coloured complex with absorption peaks at 560 and 748 nm. The absorbance of the complex reaches a maximum after 2 min of mixing the reagents and it is stable for at least 6 hr. Br–PADAP reacts with nickel(II) in presence of Tergitol NPX forming a red complex with absorption peaks at 520 and 560 nm. The colour developed within 40 min and is then stable for at least 6 hr. Therefore, measurement of the absorbances by the proposed method must be made after 50 min.

Effect of Tergitol NPX surfactant on the system N:(II)–Br–PADAP and iron(II)–Br–PADAP

The reagent and its complex have a low solubility in water, but the use of Tergitol NPX solves this inconvenience. The solubilization of 1000 μg of reagent is obtained with 50 mg of Tergitol NPX per 25 ml. Thus, 200 mg was selected as optimal. The study of the effect of the amount of Tergitol NPX on the iron(II)–Br–PADAP system revealed that it does not affect the absorbance signal of the iron(II)–Br–PADAP system when the Tergitol NPX is in the concentration range of 2.00–12.00 mg/ml. However, it was observed that, with the increase

Fe(II): 0.40 μg/ml; Ni(II): 0.20 μg/ml.

of the amount of Tergitol NPX, the absorbance signal of the nickel(II)–Br–PADAP system is reduced (Table 2).

Effect of the pH

The effect of the pH on the nickel(II)–Br–PADAP system was studied and the results demonstrated that the absorbance signal is maximum and constant in a pH range of 4.0–6.0 (Table 3). The same study for the iron(II)–Br–PADAP revealed that the optimum range is 4.0–5.7. Then, the pH range indicated for the method is 4.0–5.7. The general procedure was developed with an acetate buffer at pH 4.50, because in this pH the effect of the EGTA on the nickel(II) reaction was lower and the buffer-index of the acetate buffer was higher.

Effect of the EGTA

EDTA has been used as masking agent during iron[7,10] determination with Br–PADAP, but it cannot be used in nickel determination because its complex formation constant is too high. However, the EGTA can be used because its complex formation constant is lower.

$$\log \beta_{\text{NI(II)-EDTA}} = 18.6 \quad \log \beta_{\text{NI(II)-EGTA}} = 12.0.$$

The study of the masking agent EGTA on the iron(II)–Br–PADAP system revealed that it does not affect the absorbance signal of the system when the masking agent EGTA is in the concentration range of $0.0–1.6810^{-4}M$. However, it was observed that, with the increase of the concentration of EGTA, the absorbance signal of the nickel(II)–Br–PADAP is reduced (Table 4).

Effect of the amount of acetate buffer solution

The effect of the buffer concentration on the nickel(II)–Br–PADAP and iron(II)–Br–PADAP systems was studied and the results demonstrated that it does not affect the absorbance signal of the system when the buffer is in the concentration range of $0.04–0.20M$ in acetate.

Interference

The selectivity of the Br–PADAP during the simultaneous determination of iron and nickel was investigated by determining of 5 μg iron(II) and 5 μg of nickel(II) in the presence of various amounts of other ions. The interference limit of an ion was attributed as the proportion in which a change of ±2% in absorbances of the chelates were observed. The results are shown in Table 5.

Calibration curve

Ni(II)–Br–PADAP system. The calibration curve for the determination of nickel(II) was determined using the optimum experimental conditions. The straight line calibration curve indicated that Beer's Law is obeyed up to 0.40 μg/ml.

The equation found for the calibration curve was:

$$A = 2.075 \cdot \text{Conc} \cdot \text{Ni(II)} + 0.003, \quad r = 0.9998 \quad (\mu\text{g/ml}).$$

Table 4. Effect of EGTA on the system

Concentration (*M*)	Ni(II)–5-Br–PADAP	Fe(II)–5-Br–PADAP
	Absorbance at 560 nm	
0.0	0.430	0.605
4.20×10^{-5}	0.420	0.606
8.41×10^{-5}	0.409	0.607
1.26×10^{-4}	0.396	0.600
1.68×10^{-4}	0.376	0.601

Fe(II): 0.40 μg/ml; Ni(II): 0.20 μg/ml.

Table 5. Simultaneous determination of iron and nickel in the presence of various ions

PO_4^{-3}	Na_3PO_4	Y	Y	N

N = Does not interfere; Y = interferes.
Fe(II): 0.20 μg/ml; Ni(II): 0.20 μg/ml.

The apparent molar absorptivity (at 560 nm) calculated from the slope of the regression line is 1.22×10^5 l · mole^{-1} · cm^{-1}.

Fe(II)–Br–PADAP system. Beer's Law is obeyed up to 0.65 μg/ml; molar absorptivities were determined as being 8.20×10^4 and 3.35×10^4 l · mole^{-1} · cm^{-1} at 560 and 748 nm, respectively.

The equations found for the calibration curves were:

$A = 1.474 \cdot \text{Conc} \cdot \text{Fe(II)} - 0.002$, $r = 0.9997$ (at 560 nm) μg/ml:

$A = 0.606 \cdot \text{Conc} \cdot \text{Fe(II)} + 0.001$, $r = 1.0000$ (at 748 nm) μg/ml.

Thiosulphate as masking agent for copper (II)

The effect of the masking agent thiosulphate on the iron(II)–Br–PADAP and nickel(II)–Br–PADAP systems was studied. The results showed that thiosulphate does not affect the absorbance signal of the systems when it is in the concentration range of 0.016–0.065*M*.

Addition of 400 mg of sodium thiosulphate is enough to mask 2500 μg of copper(II) when 4 μg of iron(II) and 4 μg of nickel(II) are simultaneously determined.

Simultaneous determination of nickel and iron in copper-base alloys

The present work has as an objective for the simultaneous determination of nickel and iron in copper-base alloys. These elements are normally present in copper-base alloy. The copper(II) is a serious interferent, but the reaction in the presence of thiosulphate solves this inconvenience.

The proposed procedure (in the Experimental section) was applied for the simultaneous determination of iron and nickel in copper-base alloys standards of compositions given in Table 7. The results are shown in Table 6.

CONCLUSIONS

Br–PADAP has high sensitivity for the simultaneous determination of iron and nickel. The use of EGTA as masking agent decrease the signal absorbance of the nickel(II)–Br–PADAP,

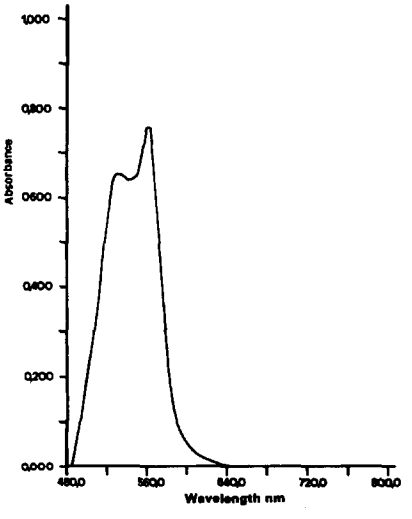

Fig. 1. Absorption spectra system nickel(II)–Br–PADAP.

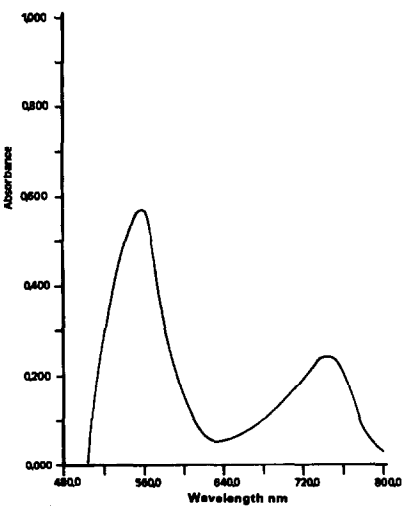

Fig. 2. Absorption spectra system iron(II)–Br–PADAP.

but this effect is constant and the calibration curve has a good correlation coefficient.

Cobalt(II) is the main interferent in the simultaneous determination of iron and nickel, however it is not a usual constituent of copper-base alloys.

The application of the proposed method indicated that it has very good accuracy and precision. Synthetic samples analysed showed that this method under the proposed conditions can deal with samples with iron/nickel ratio in the range of 10:1–1:10. As a result, the proposed method is perfectly useful for routine analysis due to its simplicity and possibility of determining simultaneously iron and nickel in aqueous solutions.

DETERMINATION OF GALLIUM BY SQUARE-WAVE VOLTAMMETRY ANODIC STRIPPING, BASED ON THE ELECTROCATALYTIC ACTION OF 2,2′-BIPYRIDINE IN DIMETHYLSULPHOXIDE: COMPARISON WITH AN AQUEOUS NaSCN/$NaClO_4$ ELECTROLYTE

GASTON EAST* and PABLO COFRE†

Facultad de Química, Pontificia Universidad Católica de Chile, Vicuña Mackenna 4860, Santiago, Chile

(*Received* 23 *March* 1992. *Revised* 1 *February* 1993. *Accepted* 10 *February* 1993)

Summary—Deposition potential, deposition time, square-wave frequency, 2,2′-bipyridine concentration, and gallium concentration have been studied in detail, for the determination of trace concentration levels of the metal by square-wave voltammetry anodic stripping analysis, in dimethylsulphoxide. Optimum conditions have been found for gallium(III) determination and results compared to those obtained in $0.5M$ NaSCN + $4.2M$ $NaClO_4$ aqueous electrolyte by obtaining calibration graphs for the range $1 \times 10^{-8}M$–$1 \times 10^{-5}M$ gallium. Accuracy (±3%) and precision (4–6% SD) of this method were assessed with both $4 \times 10^{-8}M$ and $4 \times 10^{-7}M$ gallium solutions used as synthetic samples. The efficiency of solvent extraction of gallium with di-isopropyl ether was found to be 99.98% at a $4 \times 10^{-7}M$ gallium concentration. The proposed method was applied to the determination of the gallium content in rock mineral samples (using the above mentioned solvent extraction procedure), and results compared to those obtained with the NaSCN–$NaClO_4$ based electrolyte. No statistically significant difference was observed. Analytical procedures followed are given in detail.

The need for sensitive and reliable methods for the determination of trace concentrations of gallium has been recognized in different fields. The special affinity of sarcomatous tissues for this element has led to studies of its tissue retention and cytotoxicity and motivated previous analytical works.[1,2]

From an environmental point of view, the increasing importance and use of compounds such as gallium arsenide in the semiconductor industry, has posed the question of its toxicity and potential hazard when suspended in the industrial atmosphere.[3] As a doping element, it has to be determined in microscopic weighed samples in minute amounts.[4] On the other hand, surveys in the mining industry require the determination of trace concentrations of gallium in samples of different mineral compositions.

Our attention in the past has been focused on the use of anodic stripping combined with square-wave voltammetry in a $0.5M$ NaSCN + $4.2M$ $NaClO_4$ electrolyte.[5] This electrolyte has proven to be effective in transforming an inherently irreversible electrochemical reduction of gallium(III)[6] into a reversible process,[7,8] a condition which is required for electroanalytical methods. However, the high concentration of electrolyte required is a disadvantage, because of the metal impurities introduced by the reagents, and this has led us to initiate studies in the search for alternative systems.

In previous work[9] we explored the possibility of changing from aqueous to non-aqueous media (acetonitrile and dimethylsulphoxide) and the use of 2,2′-bipyridine (DIPY) as electrocatalyst[10] to transform the irreversible reduction of aquo-gallium(III) to a more facile process. We succeeded in obtaining a catalytic wave in dimethylsulphoxide (DMSO), corresponding to the reduction of gallium(III) to gallium metal which deposits in the mercury drop electrode, with catalyst concentrations between 10^{-3} and $10^{-2}M$, only.

In this work we extend our study to the application of this electrocatalytic reduction to the determination of trace concentrations of gallium, by means of anodic stripping combined with square-wave voltammetry. A comparison

with the previous NaSCN–$NaClO_4$ aqueous electrolyte is carried out. Our results show how well this new system works, with some sacrifice in sensitivity.

EXPERIMENTAL

Instrumentation

The anodic stripping experiments were run with an EG & G Princeton Applied Research polarographic analyzer model 384B in its square-wave voltammetry mode. This was connected to the PAR 303A static mercury drop electrode (HMDE), which contains a silver–silver chloride reference electrode. The filling solution was substituted with an aqueous tetramethyl ammonium chloride (TMACl) solution. Its concentration was adjusted so that the electrode potential was coincident with that of a saturated calomel electrode (SCE).

Curves were plotted on a Houston Instrument model DMP-40 plotter. A cell design with a side tube at the bottom for collection of mercury drops[11] was modified to contain 5 ml of solution. Solutions were degassed with high purity argon presaturated with DMSO and stirred with a 305 EG & G magnetic stirrer in its slow speed setting (nominally 400 rpm).

Gallium(III) stock solution volumes were measured with Gilson Pipetman micropipettes.

A 600 W SAMSUNG microwave oven model RE-610TC, provided with an acrylic plastic box and fume exhaust tube, was used for rock mineral sample digestion.

The samples plus digesting acids were placed into Parr microwave acid digestion bombs model 4781 (23 ml capacity).

Test tubes used in solvent extraction were shaken with an HEIDOLPH vortex shaker model REAX 2000.

Reagents

Supporting electrolytes were made with sodium thiocyanate (Fluka purum p.a.) and sodium perchlorate, obtained by neutralization of sodium carbonate (Merck p.a.) with 70% perchloric acid (Baker analysed) in aqueous media. Tetraethylammonium perchlorate (TEAP), made by neutralization of 20% (w/w) aqueous tetraethylammonium hydroxide (Aldrich) with 70% perchloric acid (Baker analysed) and recrystallization from absolute ethanol (Merck p.a.), was used in non-aqueous media. Solvents used were dimethylsulphoxide (DMSO) with 0.03% water (Merck p.a.), or >99% purity from Aldrich and distilled water, obtained from a high performance automatic self-flushing still.[12]

Gallium(III) perchlorate [$Ga(ClO_4)_3 \cdot 6H_2O$] was prepared by dissolving 6N grade gallium metal (Strem Chemicals) in 70% perchloric acid (Merck, Suprapur) following a known procedure.[13] The electrocatalyst used was 2,2′-bipyridine (DIPY) from Aldrich (dissolved in the corresponding solvent). Antimony(III) chloride (Merck p.a.) was used to prevent the formation of a Ga–Zn intermetallic compound which raises the detection limit.[5]

Gallium primary standard solutions were made by dissolution of Strem Chemicals 99.999% pure gallium(III) oxide in the smallest amount of Merck Suprapur concentrated hydrochloric acid.

Solvent extraction of gallium(III) was made with di-isopropyl ether (Merck p.a.). Digestion of rock mineral samples was made with a mixture of 30% hydrochloric acid, 65% nitric acid and 40% hydrofluoric acid (all Merck Suprapur).

The rock mineral samples were provided by Laboratorio de Química Analítica y Electroquímica, PUC. Composition was mainly feldspar with gallium content between 5 and 30 ppm.

Procedures

Voltammetric measurements. The required amount of dry TEAP was weighed directly in the cell and dissolved by the addition of 5 ml of DMSO. The required gallium(III), antimony(III), perchloric acid and DIPY concentrations were obtained by spiking the solution in the cell with the appropriate stock solutions. Solutions were degassed for 300 sec and then preconcentration of gallium on a small size (0.13 mm^3) mercury drop was conducted at the specified deposition potential (E_d) and deposition time (t_d) with constant speed stirring (~400 rpm). This was followed by a 15 sec rest period before stripping. The gallium stripping was performed by square-wave voltammetry with 120 Hz frequency, 2 mV step height and 20 mV amplitude. Peak stripping currents ($I_{p,a}$) were automatically measured by a tangent fit programme, together with the measurement of peak potentials (E_p), which are referred to the SCE.

Experiments in aqueous 0.5*M* NaSCN + 4.2*M* $NaClO_4$ or 4.2*M* $NaClO_4$ were carried out after adjustment to pH 2.0.

Synthetic gallium samples. The synthetic gallium samples were prepared as follows: a $2 \times 10^{-2}M$ stock solution was made by dissolving the required amount of 99.999% Ga_2O_3 in 3 ml of 30% HCl in a digestion bomb, which was heated for 5 min at 300 W in the microwave oven. It was cooled to room temperature and the excess HCl evaporated on a hot plate. The resulting solution was transferred to a 25 ml volumetric flask and made up to volume with DMSO. Then fresh $1 \times 10^{-4}M$ and $2 \times 10^{-5}M$ gallium solutions in DMSO were made daily from the $2 \times 10^{-2}M$ stock solution. The synthetic sample concentrations were obtained by spiking the cell with 20 μl of the $1 \times 10^{-4}M$ solution to provide a $4 \times 10^{-7}M$ sample or with 10 μl of the $2 \times 10^{-5}M$ solution to provide a $4 \times 10^{-8}M$ sample.

The gallium determination was made as follows: 115 mg of TEAP was weighed directly in the cell. Then 5 μl of a $10^{-2}M$ Sb(III) stock solution were added plus 100 μl of a $0.15M$ DIPY stock solution in DMSO, and 5 ml of DMSO which was transferred, through a PTFE tube by pressurizing the solvent bottle with argon, into a measuring cylinder and then into the cell. The resulting solution was then spiked with the corresponding gallium stock solution to obtain the desired concentration. After degassing, preconcentration in the mercury drop was performed at $E_d = -1.3$ V, $t_d = 180$ or 300 sec. This was followed by the rest period and stripping step.

Solvent extraction experiments. The gallium solvent extraction experiments were performed as follows: 5 ml of a $10^{-4}M$ gallium solution were prepared daily from a $2 \times 10^{-2}M$ stock solution (aqueous and non-aqueous $10^{-4}M$ gallium solutions were prepared and when an aqueous solution was made, 50 μl $7M$ HCl was first added to the 5 ml volumetric flask to prevent hydrolysis). To a 15 ml stoppered test tube, 40 μl of the $10^{-4}M$ gallium solution were transferred, followed by 4 ml of $7M$ HCl and 4 ml of di-isopropyl ether. The tube was shaken for 5 min with the vortex shaker and allowed to stand until phase separation ($\sim$5 min). After decantation, 2 ml of the organic phase were transferred to a 20 ml beaker and the organic solvent was evaporated to dryness with an air blower. This was followed by the addition of 115 mg of TEAP, 5 ml DMSO, 100 μl of $0.15M$ DIPY and 5 μl of $10^{-2}M$ Sb(III) solution. This solution was transferred, after mixing, to the polarographic cell.

The gallium content was determined by means of a standard addition method (one or three additions) by spiking the solution with a $10^{-4}M$ gallium solution in DMSO. The experimental parameters for deposition and stripping were the same as before.

Rock mineral samples. The determination of gallium in rock mineral samples was performed as follows: the sample was ground and sieved to a particle size below 350 μm and dried at 100°C overnight. Then ca. 0.2000 g of the sample were weighed out in the PTFE vessel (which is part of the digestion bomb), 1 ml of HNO_3, 3 ml of HCl and 2 ml of HF were added, and after assembling the digestion bomb, it was heated in the microwave oven for 3 min at 600 W. It was cooled to room temperature, disassembled and after collecting all the droplets from the vessel lid with water, the solution was evaporated to dryness on a hot plate. Then 1 ml of HCl was added and the solution was evaporated to dryness again. This step was repeated once more. The solid residue was dissolved with 1 ml HCl and transferred into a ground glass stoppered test tube. The vessel was washed twice with 1 ml HCl portions and once with 1 ml H_2O and transferred into the test tube. This results in a $7M$ HCl solution. Then 0.2–0.4 ml of Hg were added to reduce the iron(III) to iron(II) and the air in the test tube was displaced with argon before replacing the stopper. The test tube was shaken for 3 min. and after solution decolouration, 4 ml of di-isopropyl ether was added and the tube was shaken again for another 5 min. Phase separation was allowed and after decantation 2 ml of the organic phase were taken and transferred into a 20 ml beaker. The solvent was evaporated with an air blower. Then, 115 mg TEAP, 5 ml DMSO and 5 μl of $0.15M$ DIPY solution were added and after dissolution transferred into the polarographic cell. The gallium determination was made by a standard addition method (spiking with 50–100 μl of a fresh $4 \times 10^{-4}M$ solution in DMSO). The experimental parameters for deposition and stripping were the same as before except that a shorter deposition time ($t_d = 30$ sec) was required.

RESULTS AND DISCUSSION

Effect of deposition potential

The effect of deposition potential (E_d) on the gallium stripping peak current was studied to compare the catalytic action of SCN^- in

water [Fig. 1(a)] with that of DIPY in DMSO [Fig. 1(b)].

In the absence of SCN^- [Fig. 1(a)], a peak-shaped curve (●), which suddenly drops to zero at −1.75 V, is obtained. This shape is consistent with an irreversible reduction of gallium(III) that approaches a diffusion controlled current at −1.7 V, but which gradually overlaps with the proton and solvent reduction at more negative potentials. The reduction and consumption of protons at the electrode–solution interface raises the local pH so that the gallium(III) diffusing towards the electrode precipitates before it can be reduced.

In the presence of SCN^- [Fig. 1(a)], gallium deposition is obtained at more positive potentials and higher stripping currents are observed (×). A current plateau appears around −1.0 V and two maxima at −1.25 and −1.55 V are found before the current drops to zero at −1.85 V.

The electrocatalytic effect of SCN^- which makes the gallium(III) reduction a more reversible process, explains the lower deposition potentials required and also the higher stripping currents observed. The existence of the current plateau around −1.0 V, with a height equal to that of the current peak at −1.25 V, suggests that two different processes involving two different species, that are reduced to gallium metal at different electrode potentials, are present.

This was confirmed by cyclic voltammetry (cyclic voltammogram not shown) in which two cathodic peaks appeared at −0.9 and −1.2 V. The current drop at −1.4 V is the result of proton reduction, with the consequent precipitation and loss of gallium(III) at the electrode–solution interface. The following current increase, that reaches a maximum at −1.55 V, is due to the overlapping of the irreversible reduction of gallium(III), as described by Fig. 1(a) curve (●), which adds to the reduction of gallium(III) catalyzed by $SCN,^-$ and counteracts the previous process. At deposition potentials more negative than −1.55 V, the current drop observed is the result of the solvent reduction which produces a gallium(III) loss due to the pH increase at the electrode–solution interface[14] as for Fig. 1(a) curve (●).

When DMSO is substituted for water [Fig. 1(b)], the reduction of gallium(III) in the absence of DIPY (○) takes place at less negative potentials, but the stripping currents found are lower and decrease at potentials more negative than −2.0 V. The fact that deposition of gallium is obtained at a lower E_d indicates that more labile (easily desolvated) species are present in this solvent, probably due to a much lower water activity. On the other hand, the more bulky solvated species, assumed to have smaller diffusion coefficients as compared to the aquo gallium(III) ions, produce lower deposition currents. The current drop observed at sufficiently negative potentials can be ascribed to changes in the local pH and gallium(III) loss at the electrode–solution interface, because of the reduction of protons. The gallium(III) loss is observed in this solvent at more negative

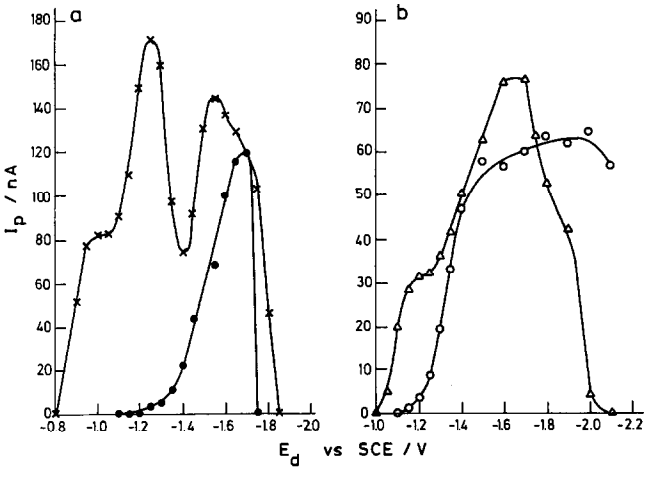

Fig. 1. Effect of deposition potential (E_d) (deposition time t_d = 180 sec) on the gallium stripping current ($I_{p,a}$) for a $10^{-7}M$ gallium(III) perchlorate plus $2 \times 10^{-5}M$ antimony(III) solution in: (a) 4.2M $NaClO_4$ (●) and 0.5M NaSCN + 4.2M $NaClO_4$ (×), both of pH = 2.0. (b) 0.1M TEAP (DMSO) in the presence (△) and in the absence (○) of $2 \times 10^{-3}M$ DIPY, both containing $10^{-3}M$ $HClO_4$.

deposition potentials than in aqueous media due to the lower water activity.

In the presence of DIPY (△), a catalyzed reduction of gallium(III) is observed at less negative deposition potentials and higher stripping currents are obtained. A slight shoulder appears around −1.2 V and a current maximum at −1.65 V. For potentials more negative than −1.7 V the current drops and reaches zero at −2.1 V. The shoulder at −1.2 V is a consequence of the existence of different catalytic waves at different electrode potentials as described in our previous report.[9] The current drop at the negative end in the presence of DIPY is observed at more positive potentials as a result of the catalytic action of this compound on the proton reduction. Now, only one maximum at −1.65 V is observed due to a greater degree of overlapping between the catalyzed (△) and non-catalyzed (○) reduction of gallium(III).

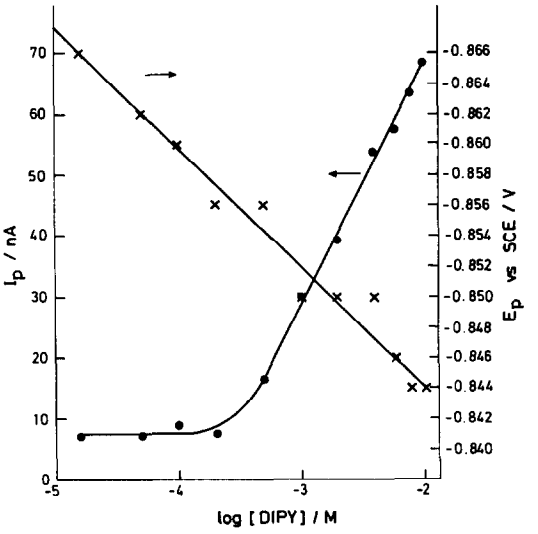

Fig. 3. Effect of DIPY concentration on the gallium stripping current ($I_{p,a}$) for $10^{-7}M$ gallium perchlorate plus $2 \times 10^{-5}M$ Sb(III) and $0.1M$ TEAP (DMSO). Deposition potential $E_d = -1.25$ V; deposition time $t_d = 180$ sec.

Effect of square-wave frequency

A linear dependence of gallium stripping peak current with the square root of the frequency (f) (Fig. 2) is observed in the NaSCN (●) as well as in the DIPY (○) based electrolytes (currents for frequencies below those shown were not detected). While a straight line which goes through the origin is obtained in the first case, as one would expect for a diffusion controlled process, in the second case the straight line gives a negative intercept. If we consider that the only common process to both systems is the diffusion of the deposited gallium in the mercury drop towards the electrode surface during the stripping step, to give a soluble species after charge transfer, the difference observed has to be due to a difference in the following steps. The smaller slope obtained with the DIPY based electrolyte can be interpreted as a consequence of a lower diffusion coefficient of the more bulky gallium–DIPY as compared to the gallium–SCN^- species in solution during the deposition step, so that a smaller amount of gallium metal is deposited for the same deposition time.

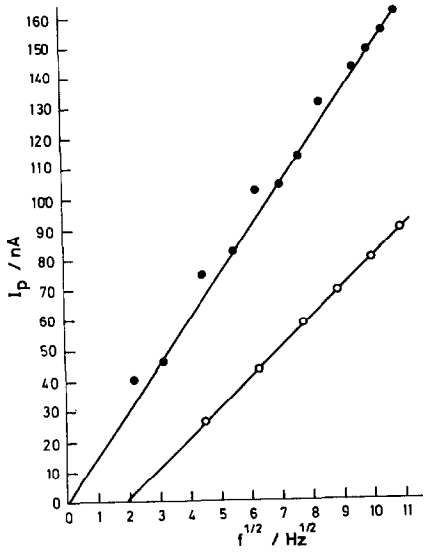

Fig. 2. Effect of square-wave frequency (f) on the gallium stripping peak current ($I_{p,a}$) after a deposition time $t_d = 180$ sec, for a solution containing $[Ga^{III}] = 1 \times 10^{-7}M$ + $[Sb^{III}] = 2 \times 10^{-5}M$ in: $0.5M$ NaSCN + $4.2M$ $NaClO_4$ (pH = 2.0; $E_d = -1.05$ V) (●) and $0.1M$ TEAP + $2 \times 10^{-3}M$ DIPY in DMSO ($E_d = -1.25$ V) (○).

Effect of DIPY concentration

The effect of DIPY concentration on the gallium stripping current, Fig. 3 (●), was explored within the range 1.5×10^{-5}–$1.0 \times 10^{-2}M$. No gallium stripping current increase is observed when DIPY concentrations up to $2.8 \times 10^{-4}M$ are used. For concentrations over this point a linear increase of stripping current with log[DIPY] is observed. This is an indication that there is a DIPY consumption by coordination to the different metal ions present in the electrolyte, which precludes its catalytic action on the gallium discharge. Only when excess DIPY is added, to complex first all these metal ions, the catalytic action of the ligand appears. Figure 3 also depicts the effect of DIPY concentration on

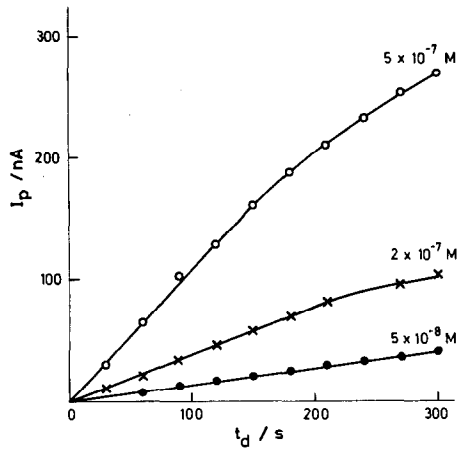

Fig. 4. Effect of deposition time (t_d), on the gallium stripping current ($I_{p,a}$) for $5 \times 10^{-8}M$ (●), $2 \times 10^{-7}M$ (×) and $5 \times 10^{-7}M$ (○) gallium perchlorate, plus $2 \times 10^{-5}M$ Sb(III), $3 \times 10^{-3}M$ DIPY and $0.1M$ TEAP in DMSO. Deposition potential $E_d = -1.25$ V.

the stripping peak potential (×). There is a linear positive shift of peak potential with log[DIPY]. This potential shift is in the opposite direction to that predicted by a Nernstian effect. Therefore, the linear dependence of the stripping current with log[DIPY] cannot be attributed to the effect of DIPY on the equilibrium potential, but rather to an adsorption of DIPY on the electrode surface, which follows a logarithmic Temkin isotherm.[15] The electrocatalytic action of DIPY on the gallium(III) discharge prevails over a possible Nernstian effect.

Effect of deposition time

The effect of deposition time (t_d) on the gallium stripping current was explored for three different gallium concentrations in the range 5×10^{-8}–$5 \times 10^{-7}M$. Results in Fig. 4 show a linear dependence for the lowest concentration as one would expect for an ideal system. However, negative deviations to linearity are soon seen for higher concentrations. This is a consequence of gallium loss due to diffusion towards the mercury thread in the capillary. The longer the deposition time, the greater the loss. An equilibrium could eventually be attained, between the amount of gallium being deposited into the mercury drop and the amount of gallium loss per unit time. At this point, the stripping current becomes independent of deposition time. Also, the greater the gallium concentration the shorter the deposition time required to observe this deviation.

A similar deviation was previously observed for zinc and gallium in an aqueous $NaSCN/NaClO_4$ electrolyte, and a detailed study was carried out.[5] This problem, also known as backdiffusion, is a disadvantage of the Kemula-type HMDE. We have found with our PAR 303A electrode, that this phenomenon can seriously affect sensitivity, detection limit and reproducibility unless a preconditioning to obtain electrode stabilization is performed before the set of measurements. This means that several deposition-stripping cycles have to be run or alternatively, a long deposition time run has to be carried out previously, to get a stable electrode; this creates an amount of residual gallium along the mercury thread, which minimizes the concentration gradient between the mercury drop and the mercury thread, and thus, hinders the gallium backdiffusion.

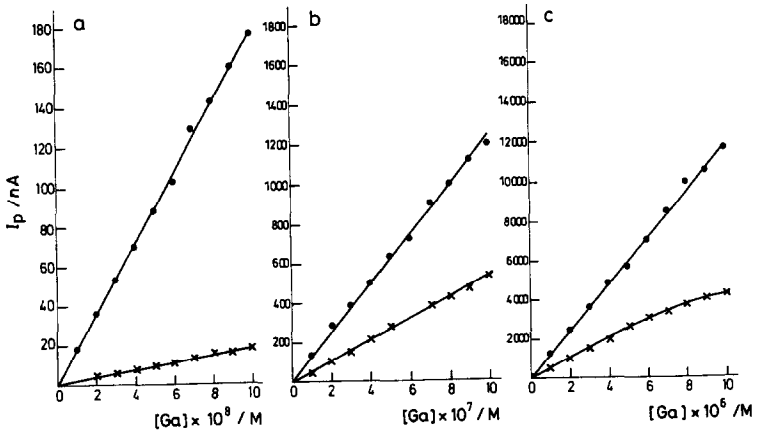

Fig. 5. Effect of gallium concentration on the gallium stripping currents in an aqueous $0.5M$ $NaSCN + 4.2M$ $NaClO_4$, pH 2.0 ($E_d = -1.15$ V; $[Sb^{III}] = 1 \times 10^{-5}M$) (●) and in $3 \times 10^{-3}M$ DIPY + $0.1M$ TEAP, DMSO ($E_d = -1.30$ V; $[Sb^{III}] = 2 \times 10^{-5}M$) (×). $E_d = 180$ sec.

Calibration graphs

Figure 5 shows calibration plots obtained in aqueous $NaSCN + NaClO_4$ (●) and non-aqueous DIPY + TEAP (×) electrolytes. Linear relationships between peak current and gallium concentration are found in both cases for all the ranges under survey, except for a slight negative deviation observed in DMSO for concentrations over $6 \times 10^{-6}M$. Blank substraction was applied when necessary but no peak current normalization using the zinc stripping peak current was required for the 10^{-8}–$10^{-7}M$ range as used previously,[5] since good linear correlations were always obtained. As a rule, higher slopes are observed in aqueous solutions than in DMSO, *e.g.*, the slope in DMSO is about one half of the slope in water for the 10^{-7}–$10^{-5}M$ range [Fig. 5(a)]. This loss in sensitivity when DIPY is substituted for NaSCN as electrocatalyst, is counterbalanced by the much lower concentrations of DIPY, one hundredth of the NaSCN, and TEAP, one fortieth of the $NaClO_4$, required. This is a clear advantage when trace levels of gallium are determined since much smaller amounts of metal contaminants are introduced by the reagents.

The DIPY concentration required is not very stringent provided that an excess is used. In fact, in the 10^{-8}–$10^{-7}M$ gallium range we could use lower values (1.5×10^{-3} and $3 \times 10^{-4}M$ DIPY) with no significant loss in sensitivity while preserving the linear dependence of the peak currents with gallium concentration.

The lower electrocatalyst concentration required was interpreted as a consequence of a greater DIPY adsorption compared to SCN^- However, the loss in sensitivity can be attributed to lower diffusion coefficients of the Ga–DIPY species in DMSO, to a higher solvent viscosity and also to a slower charge transfer rate, which would result in smaller amounts of gallium deposited and lower stripping currents.

The use of a shorter deposition time, 180 sec instead of the 360 sec employed in the previous work,[5] decreases the method sensitivity but, linearity of $I_{p,a}$ *vs.* [Ga] is preserved up to higher concentrations.

Some benefit could be gained in both electrolytes, if a more negative deposition potential was used, as one can infer from Fig. 1. For instance, sensitivity was doubled when a calibration plot for the 10^{-8}–$10^{-7}M$ range was obtained in DMSO with $E_d = -1.8$ V. The disadvantage of applying such a negative deposition potential is the likely codeposition with gallium of other interfering metals at the mercury drop electrode.

The order of addition of DIPY and gallium (III) into the cell proved to be important. When DIPY was added prior to gallium(III), a drastic sensitivity drop was observed and no stripping peak was obtained for gallium(III) concentration below $4 \times 10^{-8}M$. We have no clear explanation to this fact, but it deserves further study.

We also observed that upon mixing of the reagents in the cell, the peak currents are rather low at the start, but if several consecutive runs are performed with the same solution, an increase of the peak height is observed from one scan to the next. This behaviour could be ascribed to a slow rate of formation of the Ga–DIPY species [from Ga(III) and adsorbed DIPY] responsible for the Ga deposition at the mercury drop and also to the backdiffusion of Ga into the mercury thread as described in the previous work.[5]

Determinations in synthetic samples

The accuracy and precision of the method were assessed by analysing synthetic samples of gallium(III) solutions in DMSO at two different concentration levels. Single and multiple standard addition methods were employed. The 384B built-in standard addition programme was found to give erroneous results and was thus abandoned. Table 1 shows the results obtained, after rejection of all those values with a relative error $\pm > 10\%$. The relative mean error in all cases is exceptionally low for both concentration levels. However, the multiple standard

addition method is biased to lower results. It was found that the plot of stripping current *vs.* standard concentration always showed a slight positive deviation from linearity, so that the extrapolated intercept value on the concentration axis was lower than expected. This curvature is again a consequence of gallium backdiffusion towards the mercury thread, which gradually decreases after each standard addition, so that the first few measurements of stripping current are in fact lower than they should be. Therefore a single standard addition method should be preferred with the Kemula-type HMDE.

The precision obtained at both concentration levels is between 4 and 6% SD which is very good for trace analysis.

Solvent extraction of gallium(III)

The determination of gallium in DMSO imposes the need of transferring the metal in a quantitative way from an aqueous medium, after a mineral sample digestion, to the organic solvent. Solvent extraction of gallium(III) as a gallium–chloride complex species with di-isopropyl ether[1] has been used down to only 9.04 ppm ($\sim 1.3 \times 10^{-4} M$). It is therefore necessary to evaluate the percentage of extraction at lower concentration levels. For this purpose, a $4 \times 10^{-7} M$ aqueous gallium solution in $7 M$ HCl was used, following the procedure previously described.

Table 2 shows the results obtained. The precision of 11 determinations is of the same order of that reported on Table 1 and the average percent of extraction (99.98%) is quite satisfactory at this low concentration level.

Determinations in a rock mineral sample

The gallium content of a rock mineral sample was determined with this new method and results were compared to those obtained with the NaSCN–$NaClO_4$ method.[9]

The solvent extraction with di-isopropyl ether was used after iron(III) reduction with mercury metal, as described previously.

Results in Table 3 show that the DIPY–DMSO method gives a mean value which is 1.8% lower than the mean value obtained with the NaSCN–$NaClO_4$ method. This difference is not significant at this concentration level. However, the precision of both methods, when applied to a solid sample, is lower than that reported in Table 1. This is a consequence of a greater number of operations involved in the sample handling. If an F-test with a 95% confidence level[16] is applied to both sets of data, one can conclude that there is no statistically significant difference between both methods (calculated $F = 2.42 < 4.95$ tabulated value for 95% confidence level).

CONCLUSIONS

Gallium(III) concentrations down to $2 \times 10^{-8} M$ can be determined with the DIPY–DMSO method, Fig. 5(a), as opposed to 1×10^{-8} M previously reported with the NaSCN–$NaClO_4$ method.[9] The new method requires a somewhat more negative deposition potential ($E_d = -1.3$ V) as compared to the thiocyanate based method ($E_d = -1.05$ V). Stripping current *vs.* square root of frequency is linear in the range studied (Fig. 2) with both

DIPY and SCN^- electrocatalysts, which is an indication that diffusion of gallium metal in the mercury drop is the rate determining step during stripping in both cases.

The electrocatalyst required is [DIPY] at only $1.5 \times 10^{-3}M$, as opposed to [NaSCN] at $0.5M$, and the supporting electrolyte concentration $[TEAP] = 0.1M$ is also much lower than $[NaClO_4] = 4.2M$ required previously. The use of Sb(III) to suppress the formation of a Ga–Zn intermetallic compound is still recommended, as traces of zinc can also be found in high purity organic solvents and/or reagents.

Separation of gallium(III) from its mineral matrix can be successfully achieved by solvent extraction with di-isopropyl ether from a $4 \times 10^{-7}M$ (or stronger) gallium aqueous solution in $7M$ HCl.

An accuracy of $\pm 3\%$ was obtained with a precision between 4 and 6% SD at $4 \times 10^{-8}M$ and $4 \times 10^{-7}M$ gallium concentrations (Table 1).

Comparison with the NaSCN based method proved that equally good results can be obtained with the DIPY–DMSO method (Table 3), when applied to rock mineral samples, but with the great advantage of introducing much less impurities from reagents since the supporting electrolyte and electrocatalyst concentrations are much lower.

(*Received* 26 *December* 1991. *Revised* 22 *April* 1992. *Accepted* 22 *April* 1992)

Summary—A rapid, indirect gas-diffusion flow injection analysis (FIA) method with amperometric detection has been developed for the selective and sensitive determination of tetrahydroborate (BH_4^-). The injected analyte reduces arsenic(III) to arsine. The arsine formed diffuses through the PTFE (polytetrafluoroethylene) membrane and is quantified amperometrically at a platinum working electrode. The precision of the technique was better than a relative standard deviation of 2.1% at 60 μM levels and better than 0.5% at 0.1 mM, with a throughput of 60 samples/hr. The detection limit of the method was found to be 1 μM (1.5 ng BH_4^-) with a linear range up to 1 mM. The dynamic range extends over five orders of magnitude in BH_4^- concentration. The effects of working potential, concentration of As(III) and HCl in the reagent stream, type and flow rate of the acceptor solution, temperature and interferents on the FIA signals were studied.

Tetrahydroborate (borohydride) salts have been extensively utilized in inorganic and organic syntheses.[1,2] As was pointed out recently,[3] for carrying out these syntheses and in studies of the methods for the synthesis of borohydride, rapid, selective and accurate analytical methods to control its concentration in solution are needed.

To the best of our knowledge, there are no FIA methods reported for tetrahydroborate analysis, even though FIA methods are well suited for studying and/or continuously monitoring processes of importance to the chemical and metallurgical industries.[4–7]

On the other hand, there are only a few FIA publications[8–13] that combine separation based on membrane diffusion with amperometric detection, which is surprising considering that the selectivity of the diffusion process and inherent sensitivity of the amperometric detection makes this combination a powerful analytical tool. Extensive discussions of the merits of gas-diffusion FIA methods may be found elsewhere.[14–16]

The present paper describes a novel approach to the use of gas-diffusion in combination with amperometric detection for the indirect determination of BH_4^-. In the FIA manifold developed, the injected analyte reduces on-line arsenic(III) to arsine. The arsine formed diffuses from the donor stream through the hydrophobic PTFE membrane into the acidic acceptor solution. The latter carries arsine to the flow-through amperometric detector, where it is oxidized at a platinum working electrode. The anodic current measured is proportional to the concentration of BH_4^- in the sample or standard injected.

It is interesting to note that, to the best of our knowledge, this is the first time FIA amperometry is utilized in an analytical procedure based on the hydride generation principle. This opens up the possibility of utilizing similar FIA schemes for determining the elements which form volatile hydrides, as well as mercury.

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade. The aqueous reagent and standard solutions

*Author for correspondence.

were stored in glass containers. Demineralized water was used throughout. A stock solution of 0.01*M* BH_4^- was made from sodium borohydride (Fisher Scientific, Fair Lawn, NJ, U.S.A.) and checked using the published procedure.[17] Standard BH_4^- solutions, which were stabilized with 1% (w/v) sodium hydroxide, were prepared by diluting aliquots of the stock solution to the appropriate volume. The As^{3+} solutions were made by dissolving reagent-grade sodium arsenite (Carlo Erba, Milan, Italy) in reagent-grade hydrochloric acid and diluting to the appropriate volume.

Apparatus

The FIA manifold is illustrated in Fig. 1. Two peristaltic pumps were used. One was a Model Mini S-840 (Ismatec, Zurich, Switzerland) and the other was a Model MS-4-REGLO 100 (Ismatec). The injection valve was a Model 5020 (Rheodyne, Cotati, CA, U.S.A.) equipped with a 100-μl sample loop. The gas-diffusion unit, which was obtained from Shenyang Film-Projector Reflector Factory (Shenyang, China), is similar in construction to the Tecator (Högänas, Sweden) Chemifold V gas diffusion cell. The PTFE membrane used was supplied with the unit. All connections were made with 0.5 mm i.d. tubing.

A thin layer flow-through amperometric cell was part of a LC-17A package (BAS, West Lafayette, IN, U.S.A.) and was equipped with a Model MF-1012 dual platinum working electrode (BAS) and a Model MW-2021 Ag/AgCl reference electrode (BAS). A 0.13 mm thick MF-1047 PTFE gasket (BAS) was used to separate the working electrode from the cell body. The working electrode was polished daily with CF-1050 polishing alumina (BAS). The potential was applied to the flow-through amperometric cell and currents were measured with a Model MA 5450 polarograph (Iskra, Kranj, Yugoslavia); the resulting FIA signals were recorded on a Servograph Model 61 strip-chart recorder (Radiometer, Copenhagen, Denmark) equipped with a REA 110 unit. The measurements were made with both donor and acceptor streams flowing continuously and concurrently. Temperature regulation was achieved with a constant temperature bath, type VEB MLW (Prüfgeräte, Medingen, Germany).

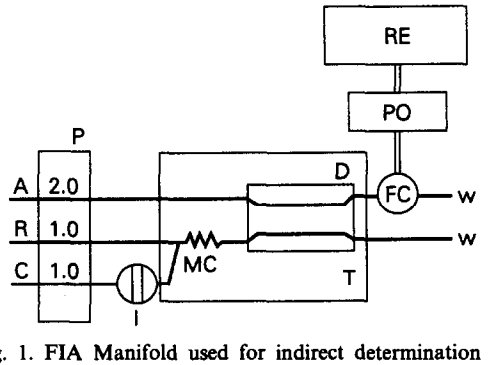

Fig. 1. FIA Manifold used for indirect determination of BH_4^-: C, carrier; R, reagent (25 m*M* As^{3+} in 1.0*M* HCl); A, acceptor solution (0.01*M* H_2SO_4); P, peristaltic pump; I, injection valve; MC, mixing coil (30 cm × 0.5 mm i.d.); D, diffusion cell; T, constant temperature bath; FC, amperometric flow-through cell; PO, potentiostat; RE, recorder; W, waste. Flow rates are given in ml/min.

RESULTS AND DISCUSSION

The indirect gas-diffusion flow injection amperometric determination of BH_4^- was performed with the manifold illustrated in Fig. 1. The alkaline (1% w/v sodium hydroxide) BH_4^- standard or sample, after injection (I), is washed by the water carrier (C) to a mixing point with a reagent (R) (0.025*M* As^{3+} in 1*M* hydrochloric acid). The mixing coil (MC), positioned downstream ensures thorough reduction of As^{3+} to arsine by the injected analyte, according to the following reaction:

$$H_3AsO_3 + NaBH_4 + HCl \Rightarrow AsH_3 + B(OH)_3 + NaCl + H_2.$$

The arsine formed on-line in the FIA manifold diffuses from the donor stream through the hydrophobic PTFE membrane into the acidic (0.01*M* sulphuric acid) acceptor solution. The latter carries arsine to the flow-through amperometric detector (FC), where it is oxidized at a platinum working electrode. The anodic current measured is proportional to the BH_4^- concentration in the injected standard or sample.

The main reason for choosing hydride generation of arsine *vs.* some other volatile hydride was based on the fact that the number of publications dealing with hydride generation of arsine is larger than for any other volatile hydride, which facilitates comparisons with the present work.

The effects of several parameters on the performance of the FIA system were studied. The effect of the applied potential at the working Pt electrode, shown in Fig. 2, was investigated in the range 0.4–1.0 V *vs.* the Ag/AgCl reference electrode. Taking into account the signal-to-noise ratio achieved, the

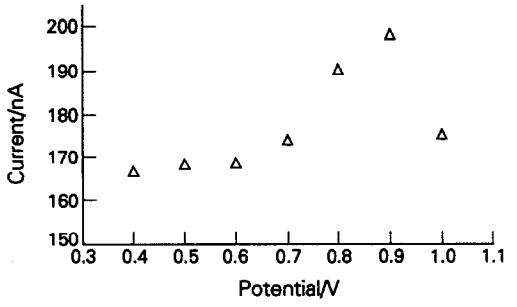

Fig. 2. Hydrodynamic voltamperogram for a 100 μl injection of a 1.00 mM sodium borohydride standard.

optimum potential was found to be 0.8 V. A possible reason for the current decrease at potentials greater than 0.9 V is the enhanced anodic formation of thin oxide films at the Pt-working electrode.[18] Of the three acceptor solutions tested (0.01M sodium hydroxide, potassium nitrate and sulphuric acid), the best results were obtained with the latter. For example, when sulphuric acid was used as the acceptor stream, the peak current for a 1.00 mM BH_4^- standard was over eight times greater than with sodium hydroxide as the acceptor solution. Even though no tendency to form "onium" (MH_4^+) ions for arsenic has been established, it is plausible that sulphuric acid in the acceptor solution might show a slight trapping effect (small AsH_3 and relatively large hydronium ion concentrations). Also the highest FIA signals were achieved with the shortest mixing coil utilized. Hence, for most of the subsequent experiments, a potential of 0.80 V *vs.* Ag/AgCl reference electrode, a 0.01M sulphuric acid acceptor solution and a 30 cm × 0.5 mm i.d. mixing coil were used.

The effect of arsenic(III) concentration in the reagent stream, illustrated in Fig. 3, was studied by injecting the same BH_4^- standard, while varying the concentration of As^{3+} in the reagent from 2.5 mM to 0.15M. In this series of experiments the concentration of hydrochloric acid in the reagent solution was kept constant at a 1.0M level. It should be pointed out that no statistically significant change in the blank signal was observed as As(III) concentration in the donor stream increased. As a compromise between reagent consumption and sensitivity, the concentration of As^{3+} used for most of the subsequent experiments was 25 mM. The concentration of hydrochloric acid in the reagent solution chosen was 1.0M since an increase in its concentration causes a slow but steady decrease in sensitivity. At this point in time we do not have a definitive explanation for the observed phenomenon. A possible reason for the decrease observed could be that the concurrent reaction of BH_4^- with H_3O^+ to form hydrogen is more pronounced at higher hydrochloric acid levels. It was suggested in the review process that formation of volatile $AsCl_3$ and its effects on the membrane pores due to possible hydrolysis at the interface might play a role. However, in a recent study of utilizing polymer-bound tetrahydroborate for arsine generation in a FIA system, Tesfalidet and Irgum[19] found similar hydrochloric acid concentration effects on the sensitivity of the system, even though they employed a "classical" gas–liquid separator for hydride generation atomic spectroscopy and not a microporous membrane. This observation coupled with what we have seen probably rules out the notion that, under our particular experimental conditions, hydrolysis reactions at the membrane surface play an important role.

The effect of acceptor flow rate was investigated by injecting a 1.00 mM sodium borohydride standard, while varying the flow rate in the range 0.5–2.5 ml/min (Fig. 4). As may be seen, the highest peak current was obtained when the acceptor flow rate was 2.0 ml/

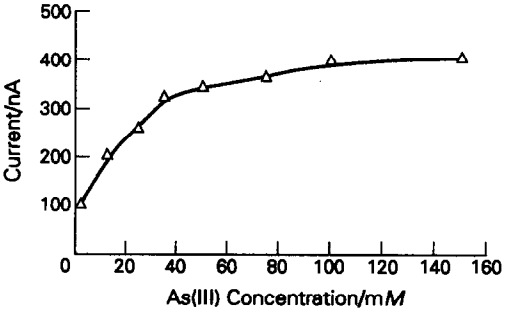

Fig. 3. Variation of the peak current as a function of As^{3+} concentration in the reagent stream.

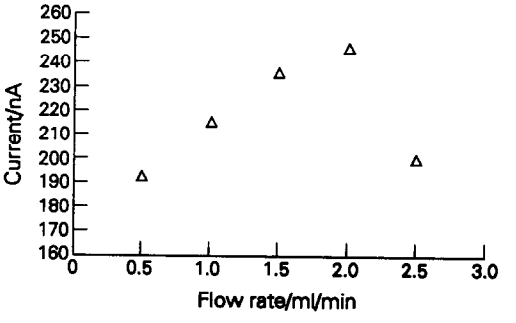

Fig. 4. Variation of the peak current as a function of the acceptor flow rate.

min. Bearing in mind that the total donor stream flow rate was also 2.0 ml/min, this finding is in agreement with the previously reported observation[16] that the optimum FIA signals were obtained when the donor and acceptor flow rates were equal.

Temperature effects were studied by injecting the same sodium borohydride standard, while varying the temperature in the interval 20–50°. No increase in the sensitivity with increase in temperature was observed. This is contrary to previously described indirect gas-diffusion amperometric FIA methods.[11,13] A plausible explanation for the observed phenomenon could be based on the much lower solubility of the diffusing species; arsine in comparison to chlorine[11] or bromine.[13] Also, it is obvious that the reduction of As(III) to arsine is fast on the FIA time scale (longer mixing coils decreased the peak currents), which was not the case with the permanganate oxidation of chloride[11] and bromide.[13]

Linearity studies were conducted by injecting in triplicate a total of 12 BH_4^- standards between 8.00 μM and 1.00 mM stabilized with 1% (w/v) sodium hydroxide. The linear calibration equation for a typical calibration run was: $i = (-5.38 \pm 1.42) + (196.0 \pm 7.3) \times C$ (i is the peak current expressed in nA and C is the millimolar concentration of BH_4^-) with a correlation coefficient of 0.9986 (all the statistics were calculated for a 95% confidence level). The relative standard deviations were found to be 2.01% ($n = 5$) at 60 μM levels and only 0.45% ($n = 5$) at 0.10 mM. The detection limit, calculated according to the recommended procedure,[20] was 1 μM which corresponds to only 1.5 ng BH_4^- (the sample loop volume was 100 μl). Figure 5 illustrates the dynamic range for the method obtained at two different As(III) concentrations in the reagent stream. As may be seen, the dynamic range (defined as that range of concentrations of the test substance, over which a change in concentration produces a change in detector signal)[21] extends over five orders of magnitude in BH_4^- concentration.

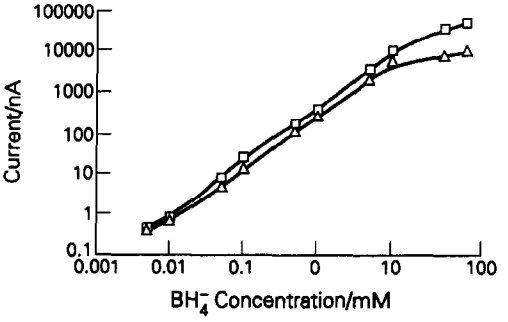

Fig. 5. Logarithmic calibration graphs illustrating the dynamic range of the method developed; As(III) concentration in the reagent stream: 25 mM (△△△) and 100 mM (□□□).

Table 1. Solutions tested for their possible interference*

Compound	Conc./M	Compound	Conc./M

Na_2S	1×10^{-5}	L-cysteine	0.1

*All samples contained 1% (w/v) NaOH. The response of the amperometric detector to 100 μl injections of the solutions tested could not be distinguished from the base line. The maximum concentrations tested were 0.1M.

†Na_2EDTA = Disodium ethylenediaminetetraacetate.

Table 1 summarizes the study of possible interferents. It has been established previously that the PTFE membranes used in the FIA gas-diffusion studies are effective barriers for ionic species.[22,23] Hence, in order for a particular species to interfere in the determination of BH_4^- with the manifold described, it has to satisfy two conditions. It has to form a gas or a molecular species with a high vapor pressure when acidified (the donor stream of the FIA manifold contains hydrochloric acid) and the gas or molecular species formed has to be electroactive (oxidizable) at the potential applied to the platinum working electrode. As can be seen from Table 1, the only serious interferents found were the sulphite and sulphide ions.

This work demonstrates that it is possible to use gas-diffusion FIA amperometry for the development of novel analytical procedures based on a hydride generation principle.

SPECTROPHOTOMETRIC DETERMINATION OF CLOTRIMAZOLE IN BULK DRUG AND DOSAGE FORMS

OSAMA H. ABDELMAGEED and PAKINAZ Y. KHASHABA
University of Assiut, Department of Analytical Pharmaceutical Chemistry, Faculty of Pharmacy, Assiut, Egypt

(*Received* 22 *December* 1992. *Received* 10 *February* 1993. *Accepted* 11 *February* 1993)

Summary—A simple, specific, rapid and sensitive spectrophotometric method has been developed for the assay of clotrimazole, in bulk drug and its pharmaceutical preparations. This method is based on the ion-pair complex reaction of clotrimazole and methyl orange in aqueous methanol, and in the presence of citric acid. The chromogen, being extractable with chloroform, could be measured quantitatively at 422 nm. All variables were studied to optimize the reaction conditions. Regression analysis of Beer's plot showed good correlation in a general concentration range of 2–14 μg/ml. The proposed method has been successfully applied for the analysis of the bulk drug and its dosage forms such as powder, vaginal tablets, topical solution and creams. No interference was observed from betamethasone dipropionate (Lotriderm cream) or dexamethasone acetate and azidamphenicol (Baycuten cream) or other common pharmaceutical adjuvants. In addition, this method was also found to be specific for the analysis of clotrimazole in the presence of its hydrolytic products as well as imidazole, as a possible impurity.

Clotrimazole, 1-[(2-chlorophenyl) diphenyl methyl]-1H-imidazole (pKa: 4.7), is a broad spectrum antifungal agent[1] which is available in different pharmaceutical formulations such as creams, topical solutions, vaginal tablets and pessaries. Several methods have been reported for the quantitative determination of clotrimazole in pure form or in its dosage forms, including titrimetry,[2–5] TLC,[6] GC,[7] HPLC,[8,9] derivative spectrophotometry[10,11] and colorimetry.[12–14] The reported methods required high concentration of the drug,[2–5,12] or sophisticated equipment and were time consuming.[6–9] In addition, UV spectrophotometric analysis of clotrimazole has been limited due to its low absorptivity and absence of characteristic bands.[15] Some of the colorimetric methods required heating for a long time with the reagent under investigation and sensitivity is low.[13,14] Therefore the aim of this work is to develop an accurate, simple, sensitive, inexpensive and specific colorimetric method for the estimation of clotrimazole either in pure form and single dosage forms, or in the presence of other drugs such as betamethasone dipropionate (Lotriderm cream) and azidamphenicol, dexamethasone acetate (Baycuten cream). This method depends on the formation of an ion-pair complex between clotrimazole, in methanol, and 0.1% W/V methyl orange (M.O.) (in 40% aqueous methanol), in the presence of 0.1*M* citric acid solution. The formed complex was found to be extractable with chloroform as a yellow colored product which could be measured quantitatively at $\lambda_{max} = 422$ nm. In addition, the specificity of our proposed method for the estimation of clotrimazole in the presence of imidazole, as a possible impurity, and its hydrolytic products was also studied.

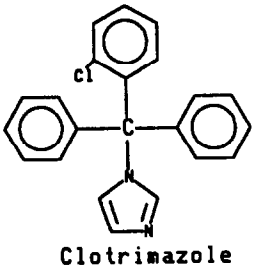
EXPERIMENTAL

Apparatus

Perkin-Elmer model Lambda 3B UV–Vis spectrophotometer and chart recorder model 561 were used.

Chemicals and reagents

All chemicals and reagents were of analytical grade. Clotrimazole (the Arab Drug Co., Cairo, Egypt), betamethasone dipropionate (Memphis



Clotrimazole

Scheme 1

Chemical Co., Egypt), dexamethasone acetate and azidamphenicol (Alex. Co., Egypt), imidazole (Merck product) were used as working standards. The methyl orange solution was 0.1% W/V (M.O.) in 40% aqueous methanol. The citric acid solution was 0.1*M* solution in distilled water, and the sulphuric acid solution was 1*M* solution in distilled water. The ammonia solution was 2*M* solution in distilled water, with the sodium hydroxide solution being 20% W/V solution, in distilled water.

Dosage forms used in this investigation were: Canesten powder, Canesten vaginal tablets, Canesten topical solution and Canesten cream (Alex. Co., Egypt, and Bayer, GFR) labeled to contain clotrimazole as 10 mg/g, 100 mg/tablet, 10 mg/ml and 10 mg/g, respectively. Lotriderm cream (Medical Union Pharm. Co., Egypt and Schering Co., U.S.A.) was labeled as containing 10 mg clotrimazole and 0.6 mg betamethasone dipropionate per each gram of cream. Baycuten cream (Alex. Co., Egypt, and Bayer, GFR) was labeled to contain 10 mg clotrimazole, 10 mg azidamphenicol and 0.443 mg dexamethasone acetate per each gram of cream.

Preparation of standards

Twenty five milligrams of clotrimazole, accurately weighed, were transferred into a 10 ml volumetric flask, dissolved in methanol and completed to volume with the same solvent. From this solution, a series of dilutions were prepared in methanol so as to obtain a range of 50–350 μg clotrimazole/ml.

Preparation of samples

Canesten powder. A portion of the powder equivalent to 25 mg clotrimazole was accurately weighed and transferred into a 100 ml volumetric flask. It was then shaken with about 50 ml of methanol and completed to volume with the same solvent. The resulting solution was filtered and the first portion of the filtrate rejected.

Vaginal tablets. Twenty tablets were weighed and finely powdered, and then completed as indicated above.

Topical solution. Into a 100 ml volumetric flask an aliquot of the solution equivalent to 25 mg of clotrimazole was accurately pipetted. This was then diluted to the mark with methanol.

Creams. An accurately weighed portion of cream, equivalent to 25 mg of clotrimazole, was placed in a 20 ml beaker. Then 12 ml of a mixture of 1*M* sulphuric acid and methanol (1:4) was added and melted in a water bath at ~50°C for 5 min, then sonicated for another 5 min. The mixture was transferred quantitatively to a 100 ml separating funnel, then shaken with three, 10 ml quantities of carbon tetrachloride, discarding the organic layers. This was made alkaline with 2*M* ammonia, then a further 2.5 ml was added. Extraction with three, 10 ml quantities of chloroform was carried out. Combination of the chloroform extracts into 100 ml volumetric flask was carried out and the samples were evaporated to dryness. The residue was dissolved in 100 ml methanol.

Preparation of hydrolyzed sample of clotrimazole

Twenty five milligrams of clotrimazole powder was accurately weighed into a 10 ml volumetric flask. Then 1 ml of 1*M* HCl was added, and the solution heated in a water bath at 90°C for about 2 hr and cooled to room temperature (25°C). This was neutralized with 20% sodium hydroxide solution, filtered if necessary, then diluted to volume with methanol.

General procedure for the assay method

One millilitre of the standard or sample solution of clotrimazole was pipetted into a 100 ml separating funnel containing 3 ml 0.1*M* citric acid solution. Then 2 ml of 0.1% W/V M.O. in 40% aqueous methanol was added. This was mixed well and three 8 ml quantities of chloroform extracted. The extracts were collected in a 25 ml volumetric flask and diluted to volume with chloroform. Approximately 0.1 g anhydrous sodium sulphate was added, shaken for about 1 min, filtered and the first portion of the filtrate rejected. The absorbance of the resulting solution at 422 nm against a similarly treated reagent blank was measured.

Assay of clotrimazole in the presence of its hydrolytic products

A certain volume from a standard solution of clotrimazole was pipetted into an accurately measured volume of the hydrolyzed sample and mixed. Methanol was used to dilute the solution so as to obtain final dilutions of 125 μg/ml of pure clotrimazole plus a hydrolyzed sample equivalent to 75, 150 and 225 μg/ml of clotrimazole. The method described under general procedure was then followed.

Stoichiometric relationship

According to Job's method[16] of continuous variation, an equimolar solution of clotrimazole and M.O. ($14.5 \times 10^{-5}M$) were prepared. A

series of extraction experiments were carried out using 10 ml portions of the solutions in different complementary proportions (from 0 + 10 to 10 + 0 inclusive) using 3 ml of buffer in all cases.

RESULTS AND DISCUSSION

Ion-pair extraction spectrophotometry has received considerable attention for quantitative estimation of many pharmaceutical compounds.[17–19] Clotrimazole was previously determined through colorimetric methods based on measuring the yellow color of the complex formed, using buffered bromothymol blue (pH 3.4), at 410 nm.

In this study M.O., being an anionic dye, forms with clotrimazole, in acidic pH, a yellow colored ion-pair complex which is soluble in chloroform and can be measured at λ_{max} 422 nm (Fig. 1). Applying Job's method of continuous variation the reaction stoichiometry of this associated ion-pair proved to be 1:1. A number of immiscible organic solvents were tested so as to provide an applicable extraction procedure. Table 1 shows that the yellow colored product is extractable only with methylene chloride and chloroform. Although methylene chloride was found to be slightly better, owing to its high volatility chloroform was used throughout this work.

The optimum conditions for the quantitative estimation of the associated ion-pair formed were established by a number of preliminary experiments. The effect of pH was studied by extracting the colored complex formed in the presence of Teorell and Stenhagen buffer[20] of different acidic pH values. Accordingly, Table 2 shows that a pH below 3 is recommended, and best results were found at pH 2.3. This result is more or less comparable with that obtained using 0.1*M* citric acid. Stability of color in both cases was studied. Figure 2 shows that the colored product in the case of citric acid is more stable for about 3 hr even when kept overnight. Therefore, 0.1*M* citric acid was selected. The optimum volume of citric acid was found to be 3 ml as indicated in Fig. 3. The significant decrease in absorbance at little or excess volume of citric acid may be explained on the basis of the change of the overall pH and incorrect ratio between methanol and water which may lead to the incomplete extraction of the complex by chloroform.

Table 1. Effect of different solvent on the extraction efficiency of the ion-pair complex

Solvent	Color of organic layer	Absorbance*
Benzene	No color	—
Toluene	No color	—
Cyclohexane	No color	—
Carbon tetrachloride	No color	—
Chloroform	Yellow color	0.430
Methylene chloride	Yellow color	0.464

*Final concentration of clotrimazole is 6 μg/ml.

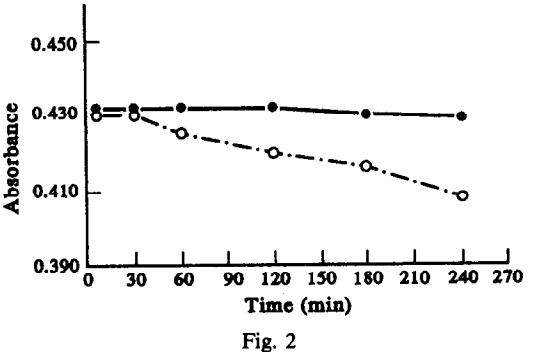

Fig. 2

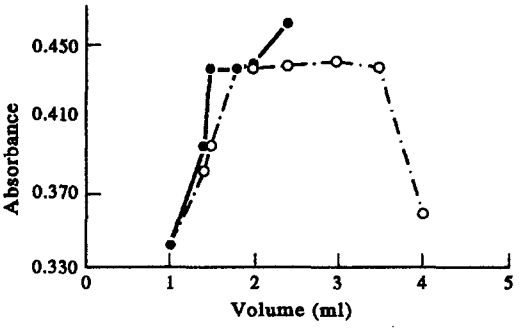

Fig. 3

The optimum volume of the dye used was also studied. Figure 3 revealed an increase in the absorbance readings with the increase of volume of M.O. used up to 3.0 ml. However, a significant increase in the absorbance value of the blank was observed at volumes larger than 2.2 ml. Therefore, 2 ml of 0.1% W/V M.O. was found to be quite enough.

Quantification

A linear correlation was found between absorbance and concentration of clotrimazole in the range 2–14 μg/ml (where the Y intercept = 0.019 ± 0.013, slope = 0.066 ± 0.002, and $r = 0.999 \pm 0.0002$; $n = 3$). Regression analysis of Beer's plot gave the following linear regression equation:

$$A_{422} = 0.019 + 0.066\ C,$$

where A_{422} is the absorbance at 422 nm and C is the concentration in micrograms per milliliter. The calculated molar absorptivity ϵ is 2.37×10^4 l moles^{-1} cm^{-1}.

The detection limit of the studied drug was calculated according to a reported method[21] and was found to be 0.05.

Precision of the proposed method was excellent as indicated from the relative standard deviation (0.37%) calculated from eight replicate analyses of 10 μg/ml of pure clotrimazole.

The proposed method was applied for the determination of clotrimazole in bulk drug as well as in various pharmaceutical formulations. Tables 3 and 4 show that average recoveries range from 97.7–99.4% indicating efficiency, accuracy and reproducibility of the method.

†Average of three determinations.

Absence of interferences from frequently encountered common excipients and additives was proved by the resulting high percentage recoveries of the add method (99.0–99.9%; Table 4).

Formation of the associated ion-pair complex with the anionic dye needs a basic drug; therefore any possible interference from other common active ingredients combined with the studied drug such as betamethasone dipropionate (in Lotriderm cream) and azidamphenicol and dexamethasone acetate (in Baycuten cream), during analysis by the proposed method, is not expected at all due to lack of any basic center in these drugs. This was proved by the analysis of clotrimazole in two laboratory synthetic mixtures, constituting these common drugs, where no interference is observed (Table 5). The same fact was also confirmed, first from the high recoveries obtained after analysis of clotrimazole in Lotriderm and Baycuten creams (Table 4) and second from the spectra of these drugs when each one was analysed by the proposed method (Fig. 4).

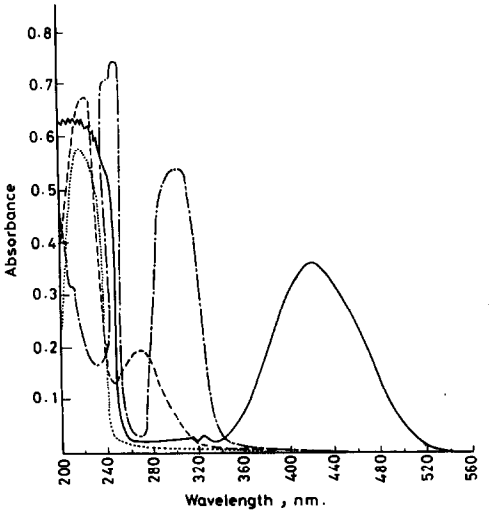

Fig. 4

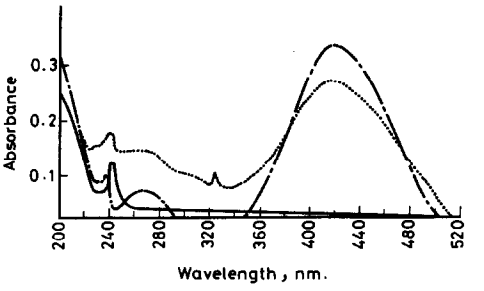

Fig. 5

Results of analysis show good agreement with those obtained by the official methods[2,4] (Tables 3 and 4). No significant differences were found between calculated and theoretical values of the t and F tests (95% confidence) which indicates high accuracy and precision. Furthermore, the proposed method appears superior to current official methods owing to its simplicity, sensitivity and selectivity.

In addition, it is possible that imidazole, which is well known as a weak base and is used in the synthesis of clotrimazole as described,[22] is present as a common impurity in clotrimazole bulk drug. Therefore attention was focused to investigate if there is any interference from imidazole upon the analysis of clotrimazole by the proposed method. This was done by analysis of authentic imidazole samples (containing initial concentrations of 50–2500 μg imidazole/ml methanol) by the proposed method. As shown in Fig. 5 no chromogen could be detected at 422 nm in a concentration range of 5–30 μg/ml (final dilution). However at concentrations ⩾40 μg/ml, a yellow chromogen was being formed at λ_{max} 422 nm, but no accuracy, precision or even reproducibility was observed. This finding seems obvious owing to the fact that imidazole—unlike clotrimazole—is freely soluble in water as well as in chloroform.[23] Accordingly the complex of imidazole: M.O—being formed—might be soluble in an aqueous as well

as in an organic layer. At concentrations $\leqslant 30$ μg/ml the absence of chromogen at 422 nm is probably due to low sensitivity, under the established experimental conditions. In the case of a concentrated sample ($\geqslant 40$ μg/ml), the complex started to partitionate between the aqueous and organic layer where a volume of chloroform more than 25 ml was found to be needed for full extraction. Consequently no correlation was found between absorbance and concentration as shown in Fig. 5. By comparison with the specified concentration of clotrimazole (2–14 μg/ml) imidazole should never interfere with its analysis by the proposed method as long as sample concentration is kept within the specified limit. This was further confirmed by analysis of synthetic mixtures containing fixed amount of clotrimazole with increasing concentration of imidazole. Results of these analyses (Table 6) revealed that no interference from imidazole as proved by reproducible recoveries in all cases.

Analysis of clotrimazole in the presence of its acid hydrolytic products

It is well known that stability of clotrimazole in solution is pH dependent. Only in acid medium is it hydrolyzed to O-chlorophenyl-diphenyl methanol and imidazole.[24] Hydrolysis has been carried out using different concentrations of hydrochloric acid (0.1, 0.5, 1, 2, 5 and 10*M* HCl). This study revealed that 0.1*M* HCl is not enough for complete hydrolysis, as proved by the UV spectrum of the resulting hydrolytic sample which indicates the presence of clotrimazole, as well as the formation of a yellow chromogen under the condition of the assay method. However, concentrations $\geqslant 0.5M$ HCl were found to be good enough for hydrolysis. Therefore 1*M* HCl was used throughout this study. Neutralization was carried out, before dilution with methanol, using 20% sodium hydroxide to pH 7. High percentage recovery (99.0 ± 0.22%, Table 7) of an added known concentration of the studied drug to the hydrolytic sample indicates the absence of interferences. Accordingly, the proposed method is considered not only specific for analysis of clotrimazole in the presence of its hydrolytic products but also may be applied as a stability indicating assay, under acidic condition, and detailed studies will be described in the next paper.

(*Received* 3 *February* 1992. *Revised* 11 *May* 1992. *Accepted* 11 *May* 1992)

Summary—The effect of four concentrations of Ba (as nitrate) on emission intensities of La(II) 337.7, Mg(I) 285.2, Mg(II) 279.1, Cd(I) 228.8, Cd(II) 226.5, Zn(I) 213.8 and Zn(II) 206.2 nm as a function of power and height above the load coil is studied. The detection limits of atomic and ionic lines of La, Mg, Zn and Cd with/without addition of Ba are reported. Low Ba concentration (0.001M) decreases the detection limit of the element of low ionization energy (La) while high Ba concentration (0.3M) decreases detection limits of the elements of high ionization energies (Cd and Zn) and increases the detection limit of the element of medium ionization energy (Mg).

Effect of an excess of easily ionizable elements (EIE) on atomic and ionic emission intensity in ICP–AES is a problem numerous investigators have already been faced with. This effect has been considered, in a number of papers, as a serious obstacle to quantitative spectrochemical analyses. Solution of the problem lies in determination of suitable operation conditions under which these interferences can be reduced or even eliminated. Since the operating conditions are always connected to a particular ICP instrument and a specific type of sample, it is difficult to draw a general conclusion on the changes in the excitation mechanism caused by the presence of an excess of EIEs.

In the first detailed study of the effect, Larson *et al.*[1] have investigated the effect of different Na concentrations on atomic and ionic emission intensity from Ca, Cr and Cd at various heights above the load coil (ALC). They have found that an increase in Na concentration from 100 to 1000 μg/ml depresses the intensity of Ca(II), Cr(II), Cd(II) and Cd(I), and enhances the intensity of Ca(I), while the intensity of Cr(I) is depressed at a height of 15 mm but increased at heights from 20 to 25 mm. Due to depression of all ionic lines, the authors suggested an ionization suppression mechanism, including also some other factors, since the behaviour of some atomic lines was in conflict with the interpretation given. However, axially and radially-resolved measurements of excitation temperatures, electron number densities, *etc.* revealed that several excitation mechanisms must be considered and that the predominance depends on the location in the ICP.[2–13]

The aim of this paper was to investigate the influence of Ba addition on the detection limits of elements of different ionization energies.

EXPERIMENTAL

Details of instrumentation and operating conditions are given in Table 1.

Low in the plasma, in the Initial Radiation Zone, excitation of both atoms and ions is

	1.1	0.93	1.05	1.34	1.25

usually enhanced. This effect is generally greater on ion than on neutral atom.[14] However, analytical measurements are generally made in the plasma region termed the Normal Analytical Zone,[9] within which EIEs usually depress the atomic and ionic excitation.[15] In this paper, ALCs in both zones were selected. Choice of elements (from easily to hardly ionizable) was made on the basis of the ionization energies of their atoms.

All reagents were of analytical grade. Solutions were prepared in doubly distilled water. Concentration of Mg was 0.5 mg/l., Cd and Zn 1.0 mg/l., and La 2.0 mg/l.

RESULTS AND DISCUSSION

Detection limits are calculated using the relation[16]

$$C_L = \frac{3 \cdot (RSD)_B C}{I_n/I_B}$$

where:

- I_n is the net line intensity for an analyte concentration,
- I_B is the background intensity,
- $(RSD)_B$ is the relative standard deviation of the background
- C is the analyte concentration.

According to the relation, low detection limits are obtained with as high as possible signal-to-background ratio (I_n/I_B) and as low as possible relative standard deviation of the background $(RSD)_B$.

Optimization of the central gas flow rate was carried out by determining the minimum relative standard deviation of the background $(RSD)_B$. The reason for such an approach was to establish a plasma discharge, as stable as possible, at introduction of samples in the plasma. $(RSD)_B$ was determined for Zn(II) 206.19, Cd(I) 228.80, Mg(II) 279.55, and La(II) 333.75 at an observation height of 15 mm, RF powers of 1.0 and 1.75 kW, and central gas flow rates of 0.9, 1.0 and 1.1 l./min. The results (an average value of 10 measurements) are given in Table 2.

As $(RSD)_B$ is minimum for the central gas flow rate of 1.0 l./min, both RF powers, and for all four wavelengths, this central gas flow rate was selected as optimum.

To achieve a maximum signal-to-background ratio, optimization of ALC (8–20 mm) for four RF powers (1.0, 1.2, 1.5, and 1.75 kW) has been performed. Results are summarized in Table 3.

Table 3. Influence of RF power on signal-to-background ratio for optimum ALC

	RF power							
	1.0 kW		1.2 kW		1.5 kW		1.75 kW

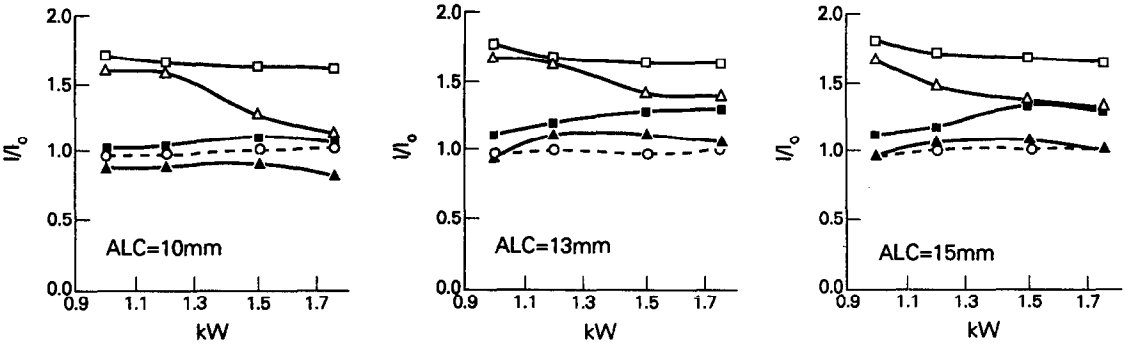

Fig. 1. Effect of different concentrations of Ba on La(II) 337.7 nm line as a function of RF power and ALC. I/I_0 is the ratio of the relative intensities with/without Ba added; □ 0.001M; △ 0.01M; ■ 0.1M; and ▲ 0.3M Ba. —— is the ratio of the background intensity with 0.3M Ba/without Ba added.

The effect of barium (as nitrate) of four different concentrations (0.001, 0.01, 0.1 and 0.3M) on the atomic and ionic emission intensity from the selected elements was investigated. Spectral line intensities were measured at the following powers: 1.0, 1.2, 1.5 and 1.75 kW. Investigations were carried out at ALCs of 8, 10 and 13 mm line intensities were measured at the following powers: 1.0, 1.2, 1.5 and 1.75 kW. Investigations were carried out at ALCs of 8, 10 and 13 mm for Zn and Cd, 10 and 13 mm for Mg, and 10, 13 and 15 mm for La. Selection of ALC was based on the values from Table 3 and the fact that the EIE effect is more pronounced in lower regions of the plasma. Measurements of the background intensity at wavelengths for all investigated lines in the presence of 0.3M Ba were performed. A slight change in the background intensity, regardless of the applied power, was found compared to the sample without Ba (Figs 1 and 2).

The ion emission intensity of La(II) is presented in Fig. 1, where I/I_0 is the ratio of

0.1	0.85	1.02	1.13	1.19
0.3	0.75	0.82	1.03	1.08
		Z = 13 mm		
0.001	1.22	1.51	1.68	1.79
0.01	0.89	1.12	1.45	1.65
0.1	0.80	0.95	1.05	1.08
0.3	0.50	0.80	0.95	0.95

the relative intensities with/without Ba added. When the sample contains 0.001M Ba, the La(II) intensity in the plasma is the highest at all RF powers. As can be seen this ratio is insensitive to changes in RF power. When the sample contains 0.01 and 0.1M Ba the position of the La(II) emission intensity maximum depends on the height above the load coil. For 0.3M Ba concentration, the intensity is close to that of the sample without Ba added. Effects of different Ba concentrations on the increase of the relative intensity of atomic and ionic lines of Mg are negligible. On the contrary, a certain depression trend (up to 50%) is noticeable at higher Ba concentrations.

Effect of different Ba concentrations on the relative intensities of atomic and ionic lines of Cd is presented in Fig. 2. Similar curves were obtained for Zn(I) and Zn(II).

Changes in Cd(I) and Zn(I) atomic line intensities lead to a conclusion that there is a similarity in their behaviour. Irrespective of applied RF power or observation height, the lower concentrations of Ba gave no measurable effect. An increase in Ba concentration causes an increase in the intensity. Thus, for 0.3M Ba this increase is by a factor of between 2 and 3. The emission intensity in both cases is higher at lower observation heights. Similar behaviour was observed for Cd(II) and Zn(II) ionic lines except that the enhancement factor is somewhat lower, about 1.5.

Behaviour of the relative intensities of the investigated lines proved a complexity of the processes is taking place in the excitation mechanism with addition of Ba.

The fact that an increase in the Ba concentration results in an increase in the relative intensity of atomic and ionic lines of Zn and Cd, the effect being higher for atomic lines, suggests a simultaneous action of collisional excitation and ionization depression processes. Justification of such a suggestion is confirmed by the effect of Ba concentration on the relative intensity ratio of ionic to atomic lines of Cd (Table 4).

Results in Table 4 illustrate not only the presence of shifts in ionization equilibrium, but a participation of this process in different zones of the plasma as well. This is obvious from the data showing that:

(a) an increase in Ba concentration decreases the I_{CdII}/I_{CdI} ratio at all powers and observation heights;

(b) the I_{CdII}/I_{CdI} ratio, at a given Ba concentration and constant RF power, decreases with increasing height above the load coil.

Table 5. Detection limits of investigated elements with and without Ba at different ALC and optimum RF powers

Elements	ALC, *mm*	Detection limits, *ng/ml* Without Ba	0.001M Ba	0.3M Ba
		1.0 kW	1.0 kW	1.0 kW
La(II)	10	11.4	6.3	11.6
	13	9.6	5.4	10.1
	15	10.1	5.9	11.5
	Ref. 17	6.5	—	—
		1.0 kW	1.0 kW	1.0 kW
Mg(I)	10	7.9	8.3	9.1
	13	8.1	8.3	11.4
	Ref. 17	1.1	—	—
		1.0 kW	1.0 kW	1.0 kW
Mg(II)	10	2.0	2.1	3.2
	13	2.5	2.6	4.6
	Ref. 17	0.1	—	—
		1.0 kW	1.0 kW	1.2 kW
Cd(I)	8	15.1	15.2	5.1
	10	14.1	14.1	5.8
	13	13.3	13.7	6.1
	Ref. 17	1.8	—	—
		1.0 kW	1.0 kW	1.5 kW
Cd(II)	8	12.7	11.6	8.0
	10	12.1	14.1	7.8
	13	13.3	14.4	9.6
	Ref. 17	2.5	—	—
		1.0 kW	1.0 kW	1.5 kW
Zn(I)	8	9.9	9.7	6.4
	10	9.7	10.1	5.7
	13	11.2	11.7	8.5
	Ref. 17	1.2	—	—
		1.2 kW	1.5 kW	1.75 kW
Zn(II)	8	14.3	15.1	12.2
	10	14.6	14.9	12.3
	13	15.9	14.8	13.3
	Ref. 17	4.0	—	—

In general, according to the above comments, an increase in height lowers the collisional excitation effect making the influence of shift in ionization equilibrium more pronounced.

Table 5 lists the calculated detection limits for the La ionic line, Mg, Zn and Cd atomic and ionic lines with (0.001M and 0.3M) and without Ba at different ALC and optimum RF powers.

As can be seen from Table 5, small Ba concentration (0.001M) decreases detection limit of the element of low ionization energy (La), while high Ba concentration (0.3M) decreases detection limits of the elements of high ionization energies (Cd and Zn), and increases detection limit of the element of medium ionization energy (Mg).

Summary—Amperometric enzyme electrode probes have been constructed for the specific determination of *L*-lysine and used in batch and flow analysis. The enzyme lysine oxidase was immobilized on a preactivated polymer support which was placed on a platinum electrode. Additional blocking membranes conferred high stability, reproducibility and avoided electrochemical and enzyme interferences. Parameters including pH, temperature, storage and operational times were optimized. Lysine was determined in the range 10^{-6}–$2.10^{-3}M$ with a detection limit of $5 \times 10^{-7}M$. The Michaelis constant was $2 \times 10^{-3}M$. This value was approximately two order of magnitudes higher than that reported in literature for the free enzyme. The response time of the probe was about 2 min in batch and flow analysis and 30 sec in flow injection analysis (FIA). The resulting probes were stable for more than three months with more than 300 analyses performed. The determination of lysine was carried out by both flow-through analysis and FIA. Analysis in feeds was carried out by acid hydrolysis to liberate lysine; then the solution was analyzed by the bioprobe and HPLC procedures. Results by the two methods correlated well.

The increasing demand in many countries for regulatory rules on the nutritional values for proteins has led scientists to develop new, rapid and specific methods for the determination of essential aminoacids in food and feeds. In this context, *L*-lysine, an essential amino acid is an important indicator of the nutritional quality of food.[1,2]

Several analytical methods for quantitative determination of lysine have been proposed, including reverse-phase liquid chromatography with precolumn derivatization,[3] liquid chromatography with fluorescence detection via precolumn dansylation,[4] aminoacid analysis[5] and paper electrophoresis.[6] These methods often do not satisfy the requirement for fast, accurate and specific analysis. Moreover they require expensive instrumentation and reagents. Electroanalytical methods based on the use of a CO_2 electrode and the enzyme lysine decarboxylase,[7] or using a platinum electrode coupled to *L*-lysine dehydrogenase have been reported.[8]

The first electrode, however, suffers from interference by atmospheric CO_2 and has a high detection limit ($10^{-4}M$). The second requires the cofactor NAD^+ and the mediator ferricyanide ion in solution. This makes the analysis more complicated with the potential problem of collateral reactions when the probe is used in a real matrix.

Recently a flow-through analyzer was described for lysine analysis using a Clark-type oxygen electrode and *L*-lysine-2-monooxygenase immobilized on silica gel.[9]

Romette *et al.*[10] used a Clark O_2 electrode coupled with *L*-lysine oxidase Li *et al.* used an optical sensor for determining lysine.[11]

Our system is based on an amperometric H_2O_2 electrode assembled with the enzyme, *L*-lysine oxidase, immobilized on a polymer support placed in intimate contact with the platinum electrode.

The reaction is as follows:

$$L\text{-lysine} + O_2 + H_2O \rightarrow \alpha\text{-keto-}\mathcal{E}\text{-aminocaproate} + NH_3 + H_2O_2$$

*Author for correspondence.

The production of H_2O_2 is detected by the platinum electrode held at 650 mV applied potential *vs.* a silver/silver chloride cathode. The output current is correlated to the concentration of lysine in the sample. The use of blocking membranes eliminated all electrochemical and enzymatic interferences. The detection limit ($5 \times 10^{-7} M$) was two orders of magnitude lower than the O_2 probe used in previous work.[10]

EXPERIMENTAL

Reagents and materials

L-lysine α-oxidase from *Trichoderma viride* (EC 1.4.3.14) lyophilized powder, 45 U/mg, was obtained from Yamasa Shoyu Co. Tokyo, Japan.

L-lysine monohydrochloride (*puriss. p.a.*) was from Fluka (Germany). Other amino acids tested were from Sigma Chemical Co. (St Louis, MO). All other reagents of pure grade were from Farmitalia C. Erba (Milan, Italy).

Five samples of feed (dietetic preparations for laboratory animals) were a gift from ENEA, two samples of feed for rabbits were obtained from a local grocery store.

The Immobilon-AV affinity membrane, 0.65-μ pore size, 125 μm thick was from Millipore (Bedford, MA).

Cellulose acetate membrane, with an approximate molecular weight cut-off of 100, was prepared in our laboratory. The procedure is reported in the literature.[12]

Polycarbonate membrane (0.03-μm pore size) 6 μm thick was from Nucleopore, Pleasanton, CA.

Apparatus

For batch analysis the probe used was a hydrogen peroxide sensor from Universal Sensors Inc. Metaire, LA.

For FIA and flow through analysis we used a wall-jet cell model 656 electrochemical detector from Metrohm, Herisau, Switzerland. This cell was assembled with a platinum working electrode (1.6 mm diameter) (Model MF 2013) from BAS, Lafayette, IN.

Steady state and transient currents were measured with an Amperometric Biosensor Detector ABD from Universal Sensor, Metaire, LA and recorded with an AMEL model 868 recorder, Milan, Italy.

The peristaltic pump was a Minipuls 3 from Gilson, France. For the FIA technique a HPLC Rheodyne valve model 7125 with a closed loop of 20 μl was used.

Electrochemical biosensor and biocell assembling

The biosensor probe consists of a platinum electrode polarized at +650 mV *vs.* a built in silver/silver chloride reference electrode. This probe was assembled by placing on an inverted electrode jacket in the given order the following membranes: cellulose acetate which protects the platinum electrode from electrochemical interferences, [13] the enzyme membrane and a polycarbonate membrane which protects the enzyme from proteins or bacteria. These membranes were then secured with an O-ring. The electrode jacket was filled with a solution of potassium chloride 0.1*M*, then the electrode was inserted into the jacket and screwed down until the tip of the platinum was firmly in contact with the membranes.

The wall jet cell was assembled covering the working electrode with the same membranes. Then the electrode was firmly secured into the cell which was connected to the flow system.

Procedures

Lysine oxidase was immobilized on the Immobilon membrane according to the following procedure: for a single membrane of 1 cm diameter, 200 μg of dry enzyme were placed on the Immobilon membrane, 20 μl of 0.1*M* phosphate buffer pH 7.0 were added, the resulting mixture was homogeneously spread-out on the membrane with a glass stick. The membrane was air-dried for about 1 hr and then kept immersed in the same buffer until ready to use. When the bovine serum albumine (BSA)/glutaraldehyde immobilization on Immobilon was performed we used the procedure described by Villarta *et al.*[14]

Batch procedure

The lysine probe was immersed in 10 ml of stirred phosphate buffer solution (PBS) and then allowed to equilibrate. Aliquots of standard *L*-lysine solutions were then injected into the buffer and the current change recorded.

Flow through procedure

The assembled probe was inserted in the electrochemical wall-jet cell. The buffer was passed through the flow system and a current baseline recorded.

Then lysine standard solutions prepared in the same buffer were introduced into the cell and the current change recorded.

FIA

A closed 20-μl loop of a HPLC valve previously connected in series to the flow system was filled with the analyzing solution, then after the initial steady-state current was recorded, the solution was injected into the flow stream and a transient current variation recorded.

Feeds

When feeds were analyzed, samples were first ground to pass through 0.75-mm diameter openings and then mixed thoroughly by tumbling. Then 300-mg samples were weighed and transferred into test tubes. Then 10 ml of 6*N* HCl was added and heated at 120 ± 5° for 24 hr. The hydrolyzate was filtered and adjusted with dry NaOH and 1*M* NaOH to pH values between 6 and 7.5. The solution was then centrifuged, and appropriately diluted with buffer in order to have a response which fits within the calibration curve.

Analysis of lysine by HPLC was carried out using a C 18 reversed phase column and a solvent mixture consisting of acetonitrile and 100 m*M* sodium acetate pH 7.2 pumped at 0.8 ml/min.

RESULTS AND DISCUSSION

The lysine probe was first used in batch analysis. To select the best immobilization procedure and the optimum response, we assembled our probe using different protective membranes and different immobilization procedures. In previous work[14] it has been demonstrated that an enzyme immobilized on an Immobilon pre-activated membrane has higher specific activity if the immobilization is carried out by adding BSA and glutaraldehyde on the Immobilon membrane.

The same approach has been used in this work. Figure 1 shows calibration curves obtained using the enzyme lysine oxidase immobilized on Immobilon in the presence and absence of BSA and glutaraldehyde, and using polycarbonate membranes of different porosity.

The best response was attained using the BSA/glutaraldehyde procedure on Immobilon and a 0.8-μm polycarbonate membrane. This result was expected because the polycarbonate membrane has the highest porosity and the

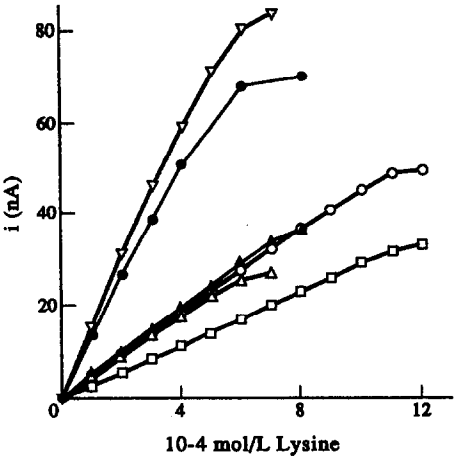

Fig. 1. Lysine calibration curves using two different immobilization procedures and protective polycarbonate membranes with different porosity. ▽ BSA/glutaraldehyde on Immobilon and 0.8-μm polycarbonate; ● Immobilon only and 0.8-μm polycarbonate; ○ BSA/glutaraldehyde on Immobilon and 0.03-μm polycarbonate; ▲ BSA/glutaraldehyde on Immobilon and 0.05-μm polycarbonate; △ Immobilon only and 0.05-μm polycarbonate; □ Immobilon only and 0.03-μm polycarbonate. Buffer phosphate 0.1*M* pH 7.0 $T = 25°$.

immobilization procedure was optimized to have a higher amount of enzyme. However the linearity reached for this immobilization was up to $5 \times 10^{-4}M$ lysine. Using a 0.03-μm polycarbonate membrane the sensitivity of the probe decreased because of slower diffusion of the substrate through the membrane pores but better linearity was attained. This phenomenon, already observed for other substrates in previous work,[15] allowed us to detect lysine up to $10^{-3}M$.

The enzyme immobilized on Immobilon without BSA/glutaraldehyde gave the same linearity but less sensitivity.

Since our goal was to use this sensor for the analysis of lysine in feeds, we selected the probe assembled with the enzyme immobilized on Immobilon with BSA/glutaraldehyde procedure and with the 0.03-μm polycarbonate. The last membrane was used to protect the enzyme from possible interferences in the hydrolized matrix, and to obtain an extended linear range of the probe to allow the analysis of a wider range of concentrations. Calibration curves for Fig. 1 were obtained in pH 7.0 phosphate buffer. This pH was previously selected by studying the probe response *vs.* pH with lysine injections of $10^{-4}M$ in a solution containing an appropriate buffer.

Figure 2 shows the current response of our probe used in different buffers for different pHs.

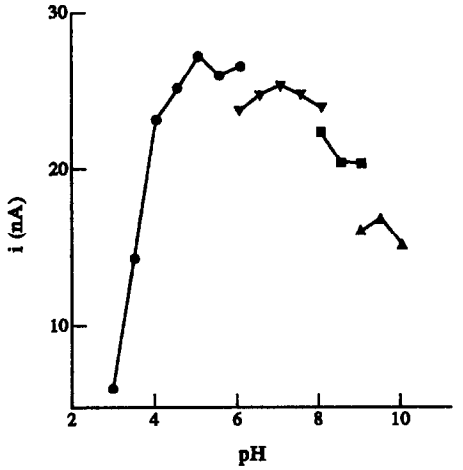

Fig. 2. Effect of pH on lysine oxidase activity. The enzyme activity was measured in the following buffers: ● citrate; ▼ phosphate; ■ tris; ▲ borax, $T = 25°$.

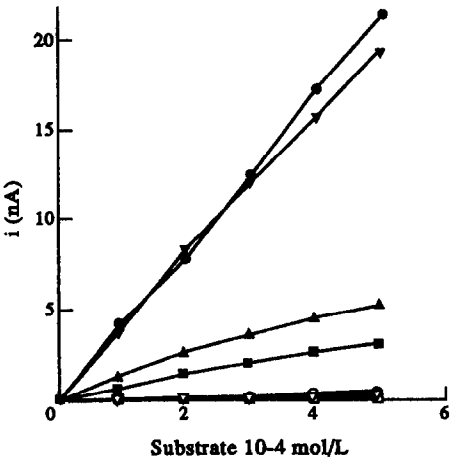

Fig. 4. Relative lysine oxidase activity toward some substrates pH 7.0 phosphate buffer $T = 25°$. ● lysine; ▼ lysine after the analysis of other aminoacids. ▲ ornithine; ■ arginine; ○ tyrosine; □ phenylalanine; ▽ histidine.

The best response was obtained between 5 and 7.5 which enabled use of our probe over a large pH range and in different buffers. For our study, phosphate buffer pH 7.0.

Temperature studies were carried out in the range 15–40°. By increasing the temperature, an increase in the probe response was observed. This effect is due to two factors; the increase in enzyme activity and the increased rate of diffusion substrates through the membrane pores. However, for temperatures up to 30° the current noise also increased, resulting in a lower current/noise signal output.

The best compromise was reached at 25° and this temperature was selected for further experiments.

A calibration curve for lysine after these parameters had been optimized is shown in Fig. 3. The detection limit was $5 \times 10^{-7}M$ with a linearity up to $10^{-3}M$. The apparent Michaelis Constant (Km) was 2×10^{-3} which is almost 2 orders of magnitude higher than that reported in the literature for the free enzyme (0.04 mM).[16]

The reproducibility of our probe was tested by running several calibration curves.

Five consecutive calibration curves gave a maximum variation of 5% over the lysine concentration range 10^{-5}–$10^{-3}M$.

The catalysis of this immobilized enzyme to oxidize various L-aminoacids as L-lysine derivatives and amines was investigated. Figure 4 shows calibration curves of lysine, and other aminoacids which gave a detectable response. The major interferent was ornithine followed by

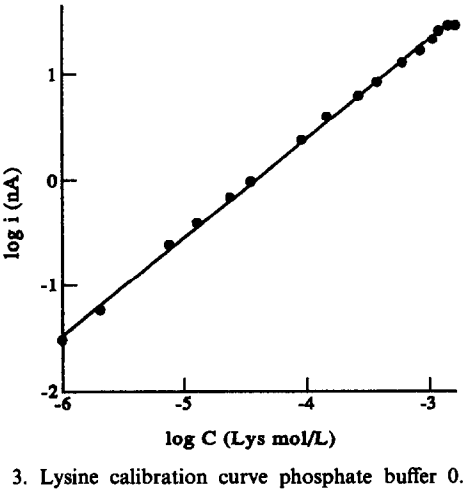

Fig. 3. Lysine calibration curve phosphate buffer 0.1M; $T = 25°$; immobilization: BSA/GLU on Immobilon.

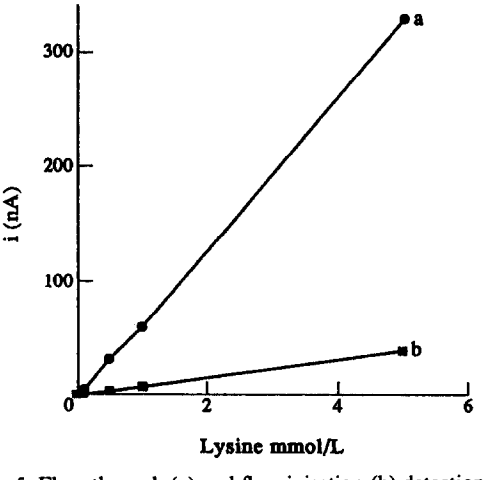

Fig. 5. Flow-through (a) and flow injection (b) detection of lysine. Sample carrier phosphate buffer 0.1M pH 7.0 $T = 25°$.

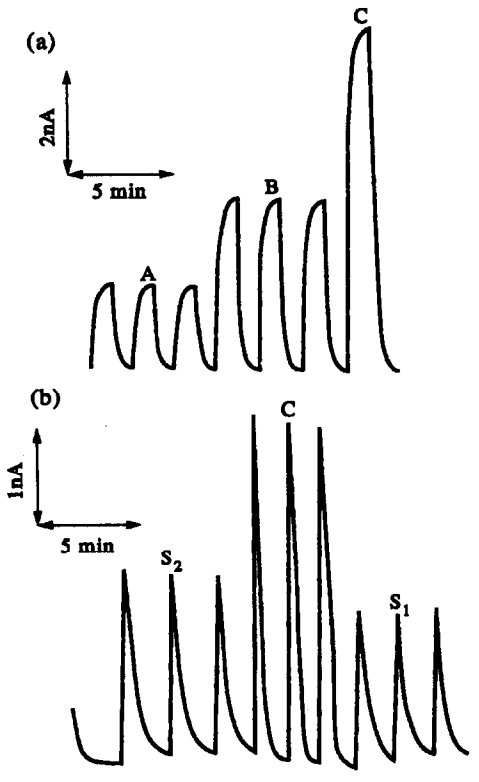

Fig. 6. Reproducibility and response time of the bioprobe in flow through analysis and FIA a = flow through: lysine concentration in standard solution. A = $5 \times 10^{-5}M$; B = $10^{-4}M$; C = $2 \times 10^{-4}M$; b = FIA; S_1 and S_2 foodstuff samples. C = lysine standard $5 \times 10^{-4}M$.

arginine. The effects of tyrosine, phenylalanine and histidine were negligible. Other aminoacids did not give any appreciable response. A calibration curve for lysine was run after measurements of all interferences were studied. Complete signal recovery was attained.

The lifetime of our sensor was investigated by studying the decrease of the enzyme activity with time.

The probe lost 70% of its original activity in 10 days, then it remained constant for more than 90 days. This decrease in enzyme activity did not pose any particular problem to probe performance. In fact analyses of lysine could be performed in the range 10^{-5}–$10^{-3}M$ with a detection limit of $5 \times 10^{-6}M$. These concentrations largely cover the range for feed analyses.

The operational time of our probe was more than 300 analyses of lysine. The response time was 2 min with 90% response in less than 1 min.

In order to make this method suitable for continuous flow analysis we used a wall-jet electrochemical cell with a lysine probe, assembled as previously described, inserted into the cell. Calibration curves of lysine were optimized by varying the flow rate to select the best linear range and the lower and upper detection limits of the analysis. The best results were attained at a flow rate of 0.2 ml/min, compromise between the probe sensitivity and stability and the time of analysis.

Analysis of lysine by FIA was carried out at the same flow rate used for continuous flow analysis. In this case an injection valve with a closed loop of a 20-μl sample was placed between the peristaltic pump and the electrochemical cell. Results are reported in Fig. 5. As is shown in this figure, the flow analysis is much more sensitive than FIA but despite this, the response time of FIA is less than 30 sec and the reproducibility is higher. However the sensitivity of the two methods was good enough to carry out analysis of lysine in foodstuff.

Figure 6 shows the reproducibility of the sensor both in flow analysis and FIA.

Feed analysis

Table 1 reports the determination of lysine in some products used to feed animals. The analysis was carried out by continuous flow and by FIA. Both flow-through and FIA methods correlated well with the HPLC procedure with a relative error varying between 1 and 12%. Only one sample gave an error of 17% in flow/HPLC correlation and 13% in FIA/HPLC correlation but gave only 3% when both the amperometric

Table 1. Lysine concentration (% w/w) in foodstuff determined with the biosensor method (continuous flow and FIA) and by HPLC

Sample	Flow	FIA	HPLC	Relative error (E%)		
				Flow/HPLC	FIA/HPLC	Flow/FIA
1	0.171	0.164	0.167	2.4	1.8	4.1
2	0.198	0.189	0.191	3.7	1.0	4.6
3	0.128	0.115	0.127	0.8	9.4	10.2
4	0.089	0.086	0.076	17.2	13.2	3.4
5	0.123	0.112	0.110	11.8	1.8	8.9
6	0.074	0.071	0.066	12.1	7.6	4.1
7	0.061	0.055	0.058	5.2	5.2	9.8

procedures were compared. Values obtained with the three methods were the mean of three determinations. Each sample was determined within 2 min, in flow, and 30 sec in FIA.

During the analysis of feeds the required washing time was longer than that measured during calibration with the buffer solution. This is probably due to the effect of some compounds present in the matrix which adhere to the polycarbonate membrane and require a longer washing time. Using the buffer solution as a washing solution between foodstuff samples, the time required to recover the initial current background was 3 min for flow through analysis and 2 min for FIA.

This allows a sampling rate of 12 samples/hr in flow through analysis and 20 samples/hr in FIA.
