THEORY OF INTRALABORATORY VALIDATION OF ACCURACY OF AN ANALYTICAL TECHNIQUE BY STANDARD REFERENCE MATERIALS

I. KUSELMAN

National Physical Laboratory of Israel, Danziger A Building, Hebrew University, Jerusalem 91904, Israel

(*Received* 9 *January* 1992. *Revised* 6 *May* 1992. *Accepted* 6 *May* 1992)

Summary—The theory is presented for intralaboratory accuracy validation of a sample analysis technique, employing standard reference materials. The validation criteria and the corresponding probabilities of erroneous conclusions concerning accuracy are given.

The most problematic part of metrological certification of a sample analysis technique is its accuracy validation, *i.e.*, evaluation of accuracy of the analysis results received by this technique.* Interlaboratory experiment is a common method for accuracy validation,[1–11] requiring, however, significant organization efforts, expenses and time.[12] In the absence of standard reference materials (SRM's) adequate for the object being analysed this expenditure might be unavoidable. On the other hand, the use of SRM's allows validation of the accuracy by means of an intralaboratory experiment, employing the SRM values as the result of convolution of data of previous interlaboratory experiments, carried out in the course of certification of the reference material. An intralaboratory experiment consists of the SRM analysis according to a technique being certified, carried out K times in a single laboratory. Accuracy of the analysis results is characterized by the bias[13] of their mathematical expectation C_r from the true value of the determined mass fraction of the element δ_{tr}, *i.e.*, by the magnitude $C_r - \delta_{tr}$. Thus, it is possible to calculate, using the K results of the analysis, the sample average $\bar{C}_r$, which, at the normal distribution of the analysis results, constitutes a sample estimate of C_r and allows us to obtain the respective estimate of the bias magnitude $\bar{C}_r - \delta_{tr}$. The sample estimate S_r of the standard deviation σ_r of the analysis results from their mathematical expectation C_r allows the construction of the confidence interval for $C_r - \delta_{tr}$. This, in turn, permits us to infer whether the accuracy has been satisfactory or not, provided the requirements on $C_r - \delta_{tr}$ have been specified in terms of σ_r fractions. This method has been introduced in ferrous metallurgy.[14,15]

In these and later works the certified values C_{cert} have been used for the true component contents' in SRM's, *i.e.*, δ_{tr} and C_{cert} have been taken as identical ones. At the same time, it is known that the greater the uncertainty in the determination of the true value of the component mass fraction in a SRM, the greater the standard deviation σ_{cert} of C_{cert}.[12] Nearly the same is true about the uncertainty of the analysis results, as far as the magnitude σ_r is concerned. Thus there is also uncertainty in the accuracy validation of the analytical technique using SRM's.[1,2]

The present paper considers the relation of the interlaboratory experiment data on the reference material (RM) certification to the intralaboratory experiment results used for validation of the technique accuracy under conditions of the above-mentioned uncertainty, when distributions only are known and the certified value in the SRM is not being accepted as a true one. The criteria for intralaboratory validation of a technique accuracy has been formulated and the confidence indexes of such validation have been calculated.

The relation between RM certification data and results of experiment for validation of the technique accuracy

Since the technique which is being studied could not be used in RM certification, the data of RM certification and results of experiment for validation of the technique accuracy are to

*The techniques considered here do not include sampling.

be considered as independent random events. Due to this independence, the correspondence of these data to the experimental results can be characterized by the total area P under their density function curves. The value P allows the determination of the degree of proximity of the results, obtained by the studied technique, to the results, obtained by the techniques used in RM certification. Taking into account that the accuracy of the techniques, used in the RM certification, has been proved previously, the correspondence will imply the acceptability of the studied technique as satisfying the accuracy requirements. The above-mentioned problem is similar to several known problems of mathematical statistics, such as determination of the degree of connection between the observed and expected frequencies. Unfortunately, the common tools employed in this context—the so-called connection coefficients[16] are quite cumbersome and their physical meaning is less elucid compared to the magnitude P introduced below.

Let, for the sake of simplicity, both distributions be normal with parameters C_{cert}, σ_{cert} and C_r, σ_r as shown in Fig. 1(a). The area to be determined (probability) P has been shaded. To calculate the latter, let us find first the mass fraction of element C_1 and C_2, corresponding to the density function curves crossings. As both density functions are equal at these values

$$f_{cert} = \frac{1}{\sqrt{2\pi}\sigma_{cert}} e^{-\frac{(C-C_{cert})^2}{2\sigma_{cert}^2}} = \frac{1}{\sqrt{2\pi}\sigma_r} e^{-\frac{(C-C_r)^2}{2\sigma_r^2}} = f_r, \quad (1)$$

which yields the quadratic equation

$$(\sigma_{cert}^2 - \sigma_r^2)C^2 - 2(\sigma_{cert}^2 C_r - \sigma_r^2 C_{cert})C + \left(\sigma_{cert}^2 C_r^2 - \sigma_r^2 C_{cert}^2 - 2\sigma_{cert}^2\sigma_r^2 \ln\frac{\sigma_{cert}}{\sigma_r}\right) = 0, \quad (2)$$

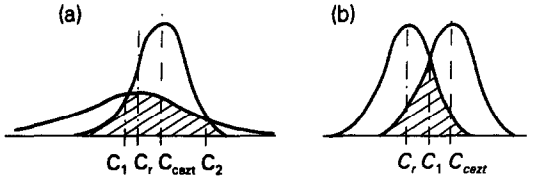

Fig. 1. Density functions of the RM certification data and experiment results for the validation of the technique accuracy: (a) at different σ_r and σ_{cert}; (b) at $\sigma_r = \sigma_{cert}$.

whose roots are the required values C_1 and C_2:

$$C_{1,2} = \frac{(\sigma_{cert}^2 C_r - \sigma_r^2 C_{cert}) \pm \sigma_{cert}\sigma_r\sqrt{\rho}}{\sigma_{cert}^2 - \sigma_r^2}, \quad (3)$$

where

$$\rho = (C_{cert} - C_r)^2 + 2(\sigma_r^2 - \sigma_{cert}^2)\ln\frac{\sigma_r}{\sigma_{cert}}. \quad (4)$$

Then the probability is

$$P = \int_{-\infty}^{C_1} f_{cert}\,dc + \int_{C1}^{C2} f_r\,dC + \int_{C_2}^{\infty} f_{cert}\,dc = \phi\left(\frac{C_1 - C_{cert}}{\sigma_{cert}}\right) + \phi\left(\frac{C_2 - C_r}{\sigma_r}\right) - \phi\left(\frac{C_1 - C_r}{\sigma_r}\right) - \phi\left(\frac{C_2 - C_{cert}}{\sigma_{cert}}\right) + 1; \quad (5)$$

where ϕ stands for normalized normal distribution.

Substituting C_1 and C_2 given by equation (3) into equation (5) we obtain, after some transformations

$$P = \phi\left[\frac{\sigma_{cert}(C_{cert} - C_r) - \sigma_r\sqrt{\rho}}{\sigma_r^2 - \sigma_{cert}^2}\right] + \phi\left[\frac{\sigma_r(C_{cert} - C_r) + \sigma_{cert}\sqrt{\rho}}{\sigma_r^2 - \sigma_{cert}^2}\right] - \phi\left[\frac{\sigma_r(C_{cert} - C_r) - \sigma_{cert}\sqrt{\rho}}{\sigma_r^2 - \sigma_{cert}^2}\right) - \phi\left[\frac{\sigma_{cert}(C_{cert} - C_r) + \sigma_r\sqrt{\rho}}{\sigma_r^2 - \sigma_{cert}^2}\right] + 1. \quad (6)$$

If $\sigma_{cert} = \sigma_r = \sigma$, there is only one point of intersection of the curves of the density function [Fig. 1(b)], the second point being shifted to infinity. In this connection, for $\sigma_{cert} = \sigma_r = \sigma$, it follows from (2) that $C_1 = (C_{cert} + C_r)/2$, and also:

$$P = 2\left[1 - \phi\left(\frac{|C_{cert} - C_r|}{2\sigma}\right)\right]. \quad (7)$$

In particular, since $\phi(0) = 0.5$, for $C_{cert} = C_r$, $P = 1$. This is the only case when we can definitely say that the accuracy of the studied technique is satisfactory: the distributions coincide. At any other choice of distribution parameters, $P < 1$. For example, if $C_r = 3.20$, $\sigma_r = 0.04$, $C_{cert} = 3.25$, $\sigma_{cert} = 0.03$, the value $P = 0.46$. For more complicated distributions, the problem under consideration may be solved numerically, if the analytical methods are not available.

At the first sight, the received relationships seem to contradict to the "common sense" of accuracy validation, according to which the smaller the certification error of the SRM employed the better.[12] On the other hand, it has been concluded here that for the situation to be optimal, the certification errors and the SRM analysis errors according to the technique which is being studied, should be equal. The meaning of this becomes clear if one takes into account both uncertainty components in the validation of technique accuracy, *i.e.*, if instead of identifying the true element content in SRM with C_{cert}, one remembers that each of the certification data may be equal to the true one, but with a different probability. In the same manner, $\bar{C}_r$ is not the only value received in the experiment, the others must also be taken into account, although their probability is lower than that of $\bar{C}_r$.

In particular, for $C_{cert} = C_r$ and $\sigma_r > \sigma_{cert}$, it is impossible to conclude definitely about the accuracy of the technique, as opposed to the case when all distribution parameters are equal.

Thus, in formulating "yes–no" type sample criteria for accuracy validation of a technique the correctness of the neglection of the SRM certification error as well as the correctness of the null hypothesis concerning the bias insignificance have to be established in each case. For example, let us consider the null hypothesis

$$H_0: |C_r - C_{cert}| \leqslant 0.3\sqrt{\sigma_r^2 + \sigma_{cert}^2}, \qquad (8)$$

meaning that the systematic errors in the results of measurement performed are insignificant* as compared with the total of random errors of the analytical technique and the RM certification. Let us denote $\sigma_{cert}/\sigma_r = \gamma$. Equations (6) and (7) show that such a null hypothesis at $\gamma = 0.4$ corresponds to $P \geqslant 0.56$, at $\gamma = 0.7 - P \geqslant 0.77$, and at $\gamma = 1.0$ to $P \geqslant 0.83$.

In comparison, a similar hypothesis

$$H_0: |C_r - C_{cert}| \leqslant 0.3(\sigma_r + \sigma_{cert}) \qquad (9)$$

at $\gamma = 0.4$ corresponds to $P \geqslant 0.54$, at $\gamma = 0.7$ to $P \geqslant 0.63$, and at $\gamma = 1.0$ to $P \geqslant 0.76$, *etc.* Apparently, the hypothesis (8) is preferable as implying higher probability P for the same γ value. The increase of the numerical coefficient in the right hand side of equations (8) and (9) yields a decrease of probability P, whereas for $|C_r - C_{cert}| > 2(\sigma_r + \sigma_{cert})$ the distributions "diverge" that is $P \to 0$. In this case it is unbelievable that technique under consideration would be accurate. Almost the same is done for $|C_r - C_{cert}| > 2\sqrt{\sigma_r^2 + \sigma_{cert}^2}$, which suggests that the tradiational two sigma criterion, based on the hypothesis

$$H_0: |C_r - C_{cert}| \leqslant U_{1-\alpha/2}\sqrt{\sigma_r^2 + \sigma_{cert}^2}, \qquad (10)$$

at $\alpha = 0.05$ is unacceptable (here U—quantile of normal distribution). The same applies to the t-criterion using quantile of Student's distribution instead $U_{1-\alpha/2}$ in equation (10) when population standard deviations σ_r and σ_{cert} are unknown, but their sample values S_r and S_{cert} are known.

It is necessary to keep in mind that the probability P as such is not an indicator of accuracy. For example, $P \to 0$ also if $\sigma_{cert} \to 0$ ($\gamma \to 0$) which only means that, unlike the reproduced values, the certified one is practically non-random. In this relation, the experimental results for the accuracy validation of a technique do not match the RM certification data. In such a case (for $\gamma < 0.3$), it is possible to neglect the uncertainty of the true element content in SRM. We should also take into consideration that the information about the distributions of both certified and experimental values are limited by small sample sizes of experimental data. Therefore, the discussed magnitude P can adequately characterize the technique only as long as the hypothesis concerning the certified and experimental value distributions fit the reality.[17]

The practical importance of the above presentation lies in the fact that the P calculation may guide a search for a suitable null hypothesis for the construction of a sample criterion directed at the accuracy evaluation of a technique, through the results of an experiment of relatively small size.

Confidence of accuracy validation

Naturally, when it is necessary to validate the accuracy of an analytical technique through the results of an experiment limited by time and expense, the confidence of this validation is being questioned.

The confidence is characterized by the probabilities of not rejecting the hypothesis about technique's accuracy when it is true, and rejecting it when it is untrue.[18] It is known that these probabilities depend on how the hypotheses have been formulated as well as the criterion for their examination.

*The ratio 1/3 (~0.3) used in equation (8) is commonly accepted in metrology as a condition for insignificance.[12,15]

Let the null hypothesis H_0 consist of the assumption that the systematic errors of the technique are negligible compared to the sum of random errors of the SRM analysis results (experiment results) and the RM certification errors. It corresponds to the formula (8), where standard deviation σ_{cert} approximately equal to half the semiwidth of confidence interval for C_{cert}, given in the SRM certificate.

Alternative hypothesis H_1 assumes that systematic errors are significant, *e.g.*,

$$H_{11}: |C_r - C_{cert}| = 0.8\sqrt{\sigma_r^2 + \sigma_{cert}^2}, \quad (11)$$

$$H_{12}: |C_r - C_{cert}| = 0.9\sqrt{\sigma_r^2 + \sigma_{cert}^2} \quad (12)$$

etc.

With the results of K analysis of SRM at our disposal, it is possible to view the accuracy of a technique as satisfactory, if

$$|\bar{C}_r - C_{cert}| + t_{1-\alpha/2} S_r/\sqrt{K} \leqslant 0.3\sqrt{\sigma_r^2 + \sigma_{cert}^2}, \quad (13)$$

where the left hand side of this expression represents the upper bound of the confidence interval for $|C_r - C_{cert}|$; $1-\alpha/2$ is the probability that the bias $|C_r - C_{cert}|$ does not exceed the upper bound of its confidence interval; S_r, sample value of standard deviation of the SRM analysis results (sample estimate of σ_r for the number of degrees of freedom $K-1$, calculated from the same K results of analysis as the sample average $\bar{C}_r$). Substituting the ratio $\sigma_{cert}/\sigma_r = \gamma$ into expression (13), we obtain, after some simple transformations:

$$\frac{|\bar{C}_r - C_{cert}|}{S_r} \leqslant 0.3\frac{\sigma_r}{S_r}\sqrt{1+\gamma^2} - \frac{t_{1-\alpha/2}}{\sqrt{K}}. \quad (14)$$

Let us introduce in equation (14) instead of S_r/σ_r the magnitude $\sqrt{\chi^2_{\alpha/2}/(K-1)}$, where χ^2-quantile of chi-square distribution for the number of degrees of freedom $K-1$. Then we obtain the following accuracy criterion

$$\frac{|\bar{C}_r - C_{cert}|}{S_r} \leqslant 0.3\sqrt{\frac{(K-1)(1+\gamma^2)}{\chi^2_{\alpha/2}}} - \frac{t_{1-\alpha/2}}{\sqrt{K}}. \quad (15)$$

Table 1 gives the numerical values for the right hand side of the criterion at $\alpha = 0.05$. These tabulated values are the bias norms of the average analysis result from the value indicated in SRM (in S_r units).

For example, in silicon determination in samples of SRM No. 1721-79 (USSR) of tinless bronzes by the extractive photometric method according to the standard:[19] $C_{cert} = 0.100$, $\sigma_{cert} = 0.005$, $\gamma = 1.0$. If $\bar{C}_r$ will be derived from $K = 30$ analysis results, then the accuracy may be viewed as satisfactory, when $|\bar{C}_r - 0.100|/S_r \leqslant 0.20$, *i.e.*, $|\bar{C}_r - 0.100| \leqslant 0.20 S_r$.

Table 1. Bias norms of average analysis result from the value indicated in SRM (in S_r units) by null hypothesis (8)

	K			
γ	20	30	40	50
0.4	0.01	0.06	0.10	0.12
0.7	0.07	0.12	0.16	0.17
1.0	0.15	0.20	0.23	0.24

Table 1 shows that for small size experiments the requirements on $\bar{C}_r$ are more strict since for the small size experiment $\bar{C}_r$ may deviate further from the population C_r as compared to the large size experiment.

The criterion obtained does not allow rejection of hypothesis H_0 with probability $1-\alpha/2$, when it is true. The probability to reject H_0, when it is untrue, *i.e.*, when the alternative hypotheses H_1 are correct (criterion power)[20] is:

$$P_a = \phi\left(\frac{t_{\alpha/2} + \lambda}{\sqrt{1 + \frac{t^2_{1-\alpha/2}}{2(K-1)}}}\right), \quad (16)$$

$$\lambda = \frac{|C_r - C_{cert}| - 0.3\sigma_r\sqrt{1+\gamma^2}}{\sigma_r/\sqrt{K}} \quad (17)$$

The magnitude λ is being calculated by substituting into equation (17) instead of the expression $|C_r - C_{cert}|$ its value, corresponding to an alternative hypothesis. For example, for the hypothesis (11) this is $0.8\sqrt{\sigma_r^2 + \sigma_{cert}^2}$. Thus for H_{11} given by (11) and (17) we have $\lambda = 0.5\sqrt{(1+\gamma^2)K}$ and at H_{12} $\lambda = 0.6\sqrt{(1+\gamma^2)K}$. Figure 2 shows the results of P_a calculation for $\alpha = 0.05$.

In the accuracy validation procedure the probabilities of errors of the first and second type relate in a simple manner to the calculated confidence characteristics: the probability of an error of the first type (to reject the H_0 hypothesis when it is correct) equals $\alpha/2$; the probability of an error of the second type β (not to reject the H_0 when it is not correct) equals $1 - P_a$ (see Fig. 2).

When $\gamma \leqslant 0.3$ and it is possible to neglect the RM certification error, as compared with the random errors of analysis, a special case follows from the criterion (15).[21] In this case the null hypothesis consists of the statement that the

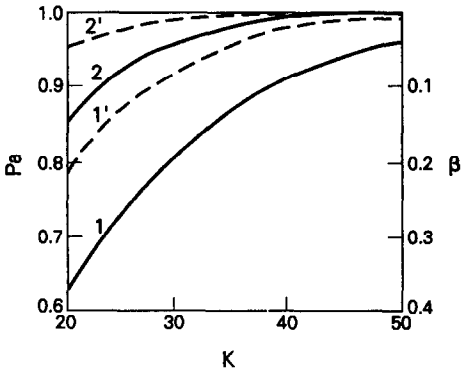

Fig. 2. Operational characteristics of criterion (15), *i.e.*, power P_a and probability of the error of second type β versus experiment size (K) with probability of the error of first type $\alpha/2 = 0.025$. Solid curves correspond to alternative hypothesis H_{11}, dotted lines $-H_{12}$: 1 and 1'—at $\gamma = 0.4$; 2 and 2'—at $\gamma = 1.0$.

accuracy of the analytical technique is satisfactory when the systematic errors of the analysis results are insignificant as compared to the random errors.

At the first sight, it seems that the requirements obtained for the accuracy of the analytical techniques are excessively strict in comparison to those used, for example, in verification of routine measuring instruments by standard ones.[22] However, the relation between the analytical technique and the SRM is basically different from that between the routine and standard measuring instruments, since the technique considered may be used further for certification of another (new) RM.

So far as different null hypotheses lead to different criteria and, accordingly, to different confidences of accuracy validation of the analytical technique, the experiment for accuracy validation can be executed only after a detailed discussion of the programme for the technique certification. Such a discussion should exclude incorrect problem formulations[11] and specify the limitations on applicability of the technique concerned. The characteristics of the used SRM's should be taken into account, in particular, in connection with possible composition variations in the samples analysed, compared with the SRM composition.

Accuracy criterion for techniques of routine analysis

Let us consider a technique which is not meant for the RM certification or similar purposes, but is only meant for the routine analysis of samples whose composition is compatible with the available SRM composition. Then by analogy with the routine measuring instruments according to Ref. 22, we shall consider the accuracy of the analysis results as satisfactory when their systematic errors exceed the standard deviation σ_{cert} by a magnitude which is insignificant in comparison with random errors of the analysis. In this case the null hypothesis has the following form:

$$H_0: |C_r - C_{cert}| \leqslant \sqrt{(0.3\sigma_r)^2 + \sigma_{cert}^2} \quad (18)$$

In the course of a SRM analysis according to such a technique, the probability P to consider the obtained results of the analysis as belonging to the population of SRM is: $P \geqslant 0.53$ for $\gamma \geqslant 0.4$ (Fig. 1 shows it as a shaded area). Respectively, the right hand side of equation (18) reaches in this case the value of $1.25\sigma_{cert}$.

In comparison, the authors of Ref. 22 recommend the errors of the routine measuring instruments, erroneously accepted as fit ones, to exceed the allowed values no more than 1.35 times, and the probability to accept an actually defective instrument as fit to be no more than 0.5.

Alternative hypotheses H_1 assume that systematic errors of the analytical technique exceed significantly the RM certification errors, *i.e.*,

$$H_{11}: |C_r - C_{cert}| = 2.0\sqrt{(0.3\sigma_r)^2 + \sigma_{cert}^2}, \quad (19)$$

$$H_{12}: |C_r - C_{cert}| = 2.1\sqrt{(0.3\sigma_r)^2 + \sigma_{cert}^2} \quad (20)$$

etc.

Considering, as in the previous case, the upper bound of the confidence intervals for $|C_r - C_{cert}|$ on the basis of a sample from K results of the SRM analysis, we get

$$|\bar{C}_r - C_{cert}| + t_{1-\alpha/2} S_r/\sqrt{K} \leqslant \sqrt{(0.3\sigma_r)^2 + \sigma_{cert}^2}. \quad (21)$$

From here, after some transformations we obtain the criterion

$$\frac{|\bar{C}_r - C_{cert}|}{S_r} \leqslant \sqrt{\frac{(K-1)(0.09+\gamma^2)}{\chi^2_{\alpha/2}}} - \frac{t_{1-\alpha/2}}{\sqrt{K}}. \quad (22)$$

Table 2 gives the numerical values of the right hand side of this criterion at $\alpha = 0.05$. They are significantly "softer" than those given in Table 1. In particular for the given example of silicon in tinless bronzes, it is necessary that $|\bar{C}_r - 0.100| \leqslant 1.03 S_r$.

Table 2. Bias norms of average analysis result from the value indicated in SRM (in S_r units) by null hypothesis (18)

	K			
γ	20	30	40	50
0.4	0.26	0.30	0.32	0.34
0.7	0.64	0.65	0.66	0.67
1.0	1.06	1.03	1.02	1.02

According to the formula (22), the criterion like the previous one, allows us with probability $1-\alpha/2$ not to reject the hypothesis H_0 [equation (18)], when it is correct. The criterion power can be calculated according to formula (16), where

$$\lambda = \frac{|C_r - C_{cert}| - \sigma_r\sqrt{0.09+\gamma^2}}{\sigma_r/\sqrt{K}}. \quad (23)$$

According to formulae (19) and (20), respectively, for H_{11} $\lambda = \sqrt{(0.09+\gamma^2)K}$ and for H_{12} $\lambda = 1.1\sqrt{(0.09+\gamma^2)K}$. Figure 3 shows the results of P_a and β calculated at $\alpha = 0.05$ for the considered hypothesis. It is clear, that with increasing γ the criterion power (22) increases faster than the criterion power (15), and at $\gamma = 1.0$ they both approach unity. This is so because when γ increases, criterion (22) reveals greater values of systematic errors [the right hand side of expression (18) increases more rapidly than the right hand side of (8) when γ is increased]. Thus, accuracy validation of analytical techniques for routine control of a sample composition may be performed under less stringent requirements than those applied for RM's certification and other arbitration purposes.

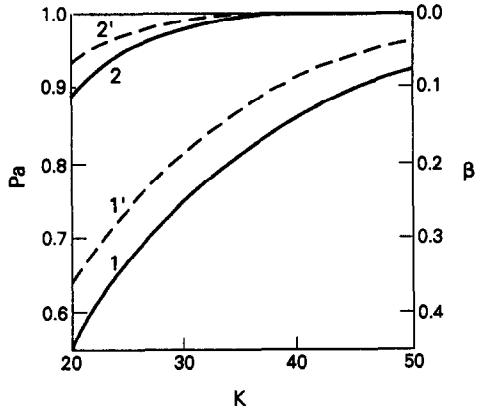

Fig. 3. Operational characteristics of criterion (22), *i.e.*, power P_a and probability of the error of second type β versus experiment size (K) with probability of the error of first type $\alpha/2 = 0.025$. Solid curves correspond to alternative hypothesis H_{11}, dotted lines $-H_{12}$: 1 and 1'—at $\gamma = 0.4$; 2 and 2'—at $\gamma = 0.7$.

When $\sigma_{cert} \ll \sigma_r$, criteria (15) and (22) reduce to a simpler one introduced previously.[21]

CONCLUSIONS

It has been shown that intralaboratory accuracy validation of an analytical technique by SRM's may be carried out by means of testing a statistical hypotheses about the relation between the systematic and random errors of analytical results under conditions of uncertainty due to errors of SRM's used.

In order to compare the systematic errors of a certificated technique with the random errors of another ("standard") technique, as it is practised in ferrous[23] and non-ferrous[18,21,24,25] metallurgy, it is sufficient to introduce the value σ_r for this "standard" technique into hypotheses (8) and (18).

In cases when distribution of the analysis results differs from the normal one, and it is impossible to determine and remove the causes for this difference, similar criteria can be formulated by the nonparametric statistics methods.[25,26]

The considerations presented have been used successfully for metrological certification of numerous analytical techniques, applied in secondary non-ferrous metallurgy.[27,28]

(*Received* 25 *November* 1991. *Revised* 7 *May* 1992. *Accepted* 6 *May* 1992)

Summary—A procedure for the determination of traces of rare earth elements by inductively coupled plasma–optical emission spectrometry (ICP–OES) and X-ray fluorescence spectrometry (XRF) is presented. The samples are decomposed either by fusion with lithium tetraborate or by acid attack in a microwave oven. Separation of the rare earth elements from accompanying elements is achieved by anion exchange. For the determination by ICP–OES the samples are injected in hydrochloric acid solution, for the determination by XRF the rare earth element traces are co-precipitated with rhodizonate and tannin and measured as a thin film on a membrane filter. All preconcentration steps have been optimized and tested using radiotracers. Furthermore the rare earth element contents of some international standard reference rocks have been determined; the results are compared to the certified values and other values given in the literature. The procedure is applied to a series of petrographically identical metabasites with different degrees of metamorphism to show the mobility of those ions under metamorphic conditions.

In spite of their similar chemical behaviour the rare earth elements may be fractionated during mineralogical and petrological processes. This fractionation arises from different types and volumes of coordination polyhedra that can be formed and is also due to the fact that some of the elements, especially cerium and europium, occur in oxidation states other than +III, the main oxidation state of the group. The type and degree of fractionation can therefore be an indicator of the genesis of a rock and give hints for processes like partial melting, fractional crystallization or mixing of magmas as far as igneous rocks are concerned.[1]

For many years most of the rare earth element determinations in geological samples have been carried out by neutron activation analysis.[2,3] This method offers low detection limits and can sometimes be applied without sample preparation but the need for a suitable reactor and long cooling times prior to the determination are disadvantageous. Some other techniques usually applied to the determination of rare earth element traces are inductively coupled plasma optical emission spectrometry (ICP–OES),[4–6] stable isotope dilution–mass spectrometry[7] and to a minor extent X-ray fluorescence spectrometry (XRF).[8,9] For each of these techniques at least a group separation of the rare earth elements from accompanying elements is required.

The aim of this work was to develop a procedure that allows the determination of rare earth element traces by XRF and ICP–OES. Important characteristics of the new preconcentration procedure are high reliability, corrections for too low recoveries are not necessary, and reproducibility. The elution volumes for preconcentration by anion exchange are smaller than those of comparable cation exchange procedures.[10]

EXPERIMENTAL

Reagents and reference materials

For decomposition by fusion Spectromelt A 10 (lithium tetraborate, Merck) is used. Decomposition by microwave heating is done

using HF (40%), HNO_3 (68%) and HCl (33%); in the separation procedure HCl, HNO_3, acetic acid (100%) and propanol-2 are used. The ion exchange steps are carried out on strongly basic anion exchange resin Dowex 1 × 8, 100–200 mesh. For the mixed solvent anion exchange the resin is in the nitrate form, for the separation of iron it is used in the chloride form. The pH for the co-precipitation is adjusted by addition of sodium hydroxide. Sodium rhodizonate and tannin are dissolved in water to give solutions of 2.5 and 2.0 mg/ml, respectively. The precipitate is collected on Millipore membrane filters HVLP 01300. All reagents except tannin and rhodizonate are of analytical grade. Stock solutions of the rare earth elements are prepared from the oxides (99.99%, Johnson Matthey). The procedure has been optimized using the following radiotracers: ^{139}Ce, ^{152}Eu, ^{153}Gd, ^{169}Yb and ^{59}Fe.

The procedure has been tested by analyzing samples of the following standard reference rocks: NIM-G granite, NIM-S syenite, NIM-L lujavrite, NIM-N norite (National Institute of Metallurgy, South Africa), USGS AGV-1 andesite (US Geological Survey).

Apparatus

Decomposition by fusion is done in platinum crucibles in a muffle furnace. For the decomposition assisted by microwave heating a microwave system with pressure resistant vessels and an optical pressure control (Anton Paar, Graz) is used. The beaker and the pressure containment are schematically shown in Fig. 1.

The filtrations are carried out in a previously described vessel[12] that permits the simultaneous filtration of five solutions under nitrogen pressure. For the anion exchange procedure a peristaltic pump Ismatec ip-12 is used.

A γ-spectrometer (E & G Ortec) has been used to determine the count rates for the radiotracer experiments.

X-ray spectrometry. For nearly all measurements a wavelength dispersive spectrometer Philips PW 1410 with a gold tube operated at 60 kV and 40 mA and a flow counter is used. This system is equipped with an automation unit (Dapple Inc., Sunnyvale) to drive the goniometer, set the discriminator and acquire the data. Further measurements are done using a wavelength dispersive spectrometer Philips PW 1140 with tandem operation of flow counter and scintillation counter and a tungsten tube. At an earlier stage some measurements with an energy dispersive spectrometer Philips EDAX Exam VI with zirconium secondary target and a Si(Li)-detector have been done.

For the determination by ICP–OES a sequential spectrometer Perkin Elmer Plasma II (range 170–440 nm) with a cross flow nebulizer is used.

Sample preparation

A schematic overview of the procedure is given in Fig. 2. Each step of this sample preparation scheme has been optimized using

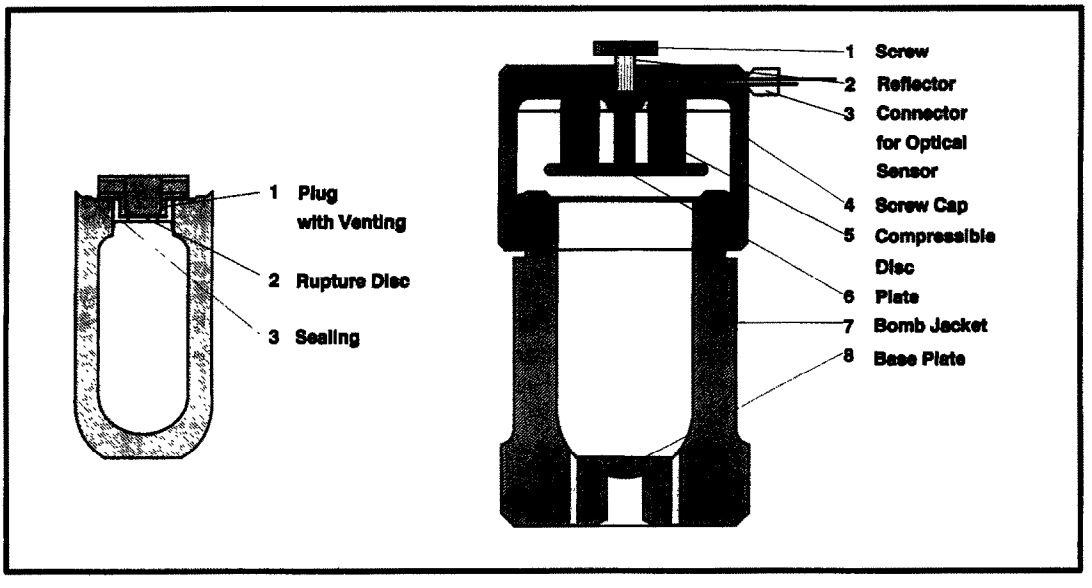

Fig. 1. Pressure resistant beaker and pressure containment.

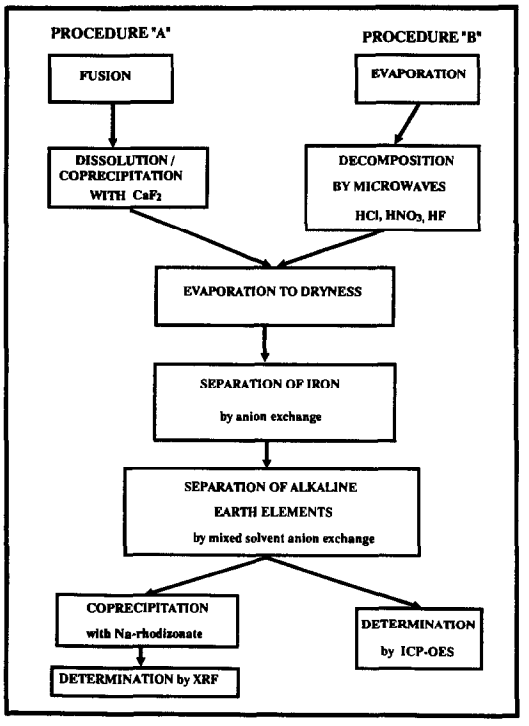

Fig. 2. Analytical procedure.

radiotracers for some of the rare earth elements, those results will be given below.

Decomposition

During our work we tested two decomposition procedures; samples were decomposed by fusion or by microwave heating in a pressure resistant vessel.

For the decomposition by fusion the samples are mixed with the five-fold mass of lithium tetraborate in platinum crucibles, which are put into a muffle furnace and kept at a temperature of 1000° for one hour. The melt is dissolved in HF and HNO_3. To volatilize silicium and part of the boron in the form of their fluorides around 30 ml of HF—added in five portions—and 10 ml of HNO_3 are used. Under these conditions the alkaline earth elements form fluoride precipitates, the rare earth elements are coprecipitated and a first separation can be achieved by centrifugation. Elements that tend to form fluoride complexes like zirconium and titanium can be separated at that stage.

For decomposition by microwave heating the samples (approximately 0.25 g) are weighed into the beaker and taken to dryness with 2 ml of HF once to avoid deposits of silica near the plug during the decomposition. Then HNO_3 (1.5 ml), HCl (0.5 ml) and HF (0.5 ml) are added, the beaker is closed, put into the pressure containment and put into the oven. The samples are decomposed at a pressure of approximately 30 bar for 10 min (setting #8 of 10 in the microwave oven). After cooling down the samples are transferred to teflon beakers and treated according to the preconcentration scheme.

If the samples are decomposed by fusion with lithium tetraborate prior to preconcentration, the procedure is referred to as procedure A in the following text, if the samples are decomposed by microwave heating, then they are referred to as procedure B.

Preconcentration

The volumes given in the following sections corresponds to procedure B and samples of 0.25 g.

To remove fluoride the samples are taken to dryness with hydrochloric acid (3 ml) and nitric acid (3 ml) several times and the residue is taken up in 10 ml of 5*M* hydrochloric acid. From this solution iron is removed in the form of its chloride complexes on anion exchange columns (10 mm in diameter, height: 6 mm; washings: 20 ml of 5*M* hydrochloric acid. The solution containing the rare earth elements is taken to dryness, the residue is taken up in approximately 4 ml of 5.8*M* nitric acid.

The removal of alkaline earth elements and other accompanying elements is achieved by mixed solvent anion exchange[11] from acetic acid/nitric acid (90 + 10, v/v) media. The rare earth ions are retained on anion exchange columns while the alkaline earth ions pass through. The columns are washed with 40 ml of 5.8*M* nitric acid propanol-2 (10 + 90 v/v) to remove residual alkaline earth elements, then the rare earth elements are eluted with 15 ml of 5*M* hydrochloric acid.

After heating for the removal of alcohol and cooling down again the solution is transferred to a standard flask.

To produce a sample well suited for X-ray fluorescence measurements the rare earth elements are finally coprecipitated with rhodizonate and tannin at pH 13 (pH adjusted by addition of sodium hydroxide). The precipitate is collected on membrane filters which are mounted on Spectrocups for the measurement.

Determination by X-ray fluorescence spectrometry

$L\alpha_1$-lines are measured for all the rare earth elements with the exception of praseodymium

Experimental conditions: Power 1200 W, plasma flow 15 l./min, neublizer flow 1 l./min, photomultiplier voltage 600 V, sampling time 50 msec.
The blank solution contains some Li-tetraborate.

($L\beta_1$). For iron, manganese and nickel, where some blank values occurred, the Kα-lines are measured. A calibration set consisting of 20 different compositions in the expected concentration range was prepared from stock solutions according to an experimental design by precipitation with rhodizonate. Overlap coefficients were derived from those samples, furthermore absorption corrections in the Delta-I mode were applied to samples with high concentrations of La, Ce and Nd. The detection limits (3 s) are listed in Table 1.

Determination by ICP–OES

First, single element standard solutions have been used to detect line interferences. The different concentration ranges of the rare earth elements in rock samples have been taken into account. The lines chosen for the determination and the corresponding limits of detection (3 s) are listed in Table 2. The values were estimated from data for a blank solution from pure lithium tetraborate treated according to procedure A. The values for 5*M* hydrochloric acid are given there, too. For gadolinium the spectral line has to be changed to 358.496 nm when the samples are prepared according to scheme B, because titanium and zirconium are not removed and lead to a line interference of Ti at 335.047 nm.

RESULTS AND DISCUSSION

As the rare earth elements can often be enriched in minerals that are hardly attacked by acids at normal pressure (*e.g.*, zircon) the complete decomposition of the samples is most important. We used two procedures, fusion with tetraborate of acid attack at 30 bars in a microwave oven. Both methods have been successfully applied to zircon bearing granitic standard reference materials but there are still some differences that must be taken into account: there is no limitation of the sample mass if the sample is fused with lithium tetraborate but a large amount of "salt" is imported to the sample. Therefore solution volumes and time consumption in the following preconcentration steps are higher compared to the samples decomposed by microwave heating. On the other hand the decomposition by microwave heating is limited to sample masses of up to 0.3–0.4 g leading to detection problems if the rare earth element content of the samples is low. To reduce the problem due to the high salt content after decomposition by fusion coprecipitation with calcium fluoride has been introduced to the procedure. This coprecipitation is incomplete up to calcium concentrations of 0.7%, the recoveries for higher calcium contents (that means 1% Ca in the test samples) have been determined in tracer experiments and are listed in Table 3, column 1.

The group separation of the rare earth elements is achieved by mixed solvent anion exchange. Although the recoveries for propanol-2 (recovery: 96.8% for 90% organic phase in a batch experiment) are higher, acetic

acid (recovery 87.6% under similar conditions) was chosen for the preconcentration procedure because the residues of the former preconcentration steps are more readily dissolved in this solution. In the washings propanol-2 was used as organic phase. Table 3, column 3 shows the recoveries for some of the rare earth elements for this preconcentration step.

Iron could not be removed quantitatively by mixed solvent anion exchange, therefore a second ion exchange step has been introduced. Figure 3 shows the elution profile for Eu (fractions 1–20, 5*M* hydrochloric acid) and Fe (fractions 21–27, 0.6*M* nitric acid), the recoveries for the rare earth elements are given in Table 3, column 4.

It is advantageous to present samples in the solid form if small concentrations are to be determined by XRF. In addition, the geometry has to be kept constant. Therefore a coprecipitation of the rare earth element traces with an organic complexing agent was taken into consideration. Best results were achieved with sodium rhodizonate and tannin at pH 13; the recoveries that have been determined from tracer experiments are given in Table 3, column 5. For samples containing more than approximately 100 μg rare earth elements in total an absorption correction was applied.

Finally, procedure A has been tested with rock samples spiked with radiotracers to estimate an overall recovery which is given in Table 4. The variances given there are much smaller than the sum of the variances of the single preconcentration steps. One reason is that the measured standard deviation always includes the counting statistics, in addition the activities used for spiking the rock samples have been higher than those used for the other experiments. To test the decomposition and preconcentration procedure as well as the model used for calculating the rare earth element concentrations from X-ray intensities the rare earth element contents of some international standard reference rocks have been determined. Some of the results are listed in Tables 5–8. In general the agreement between certified and measured concentrations appears to be satisfactory although there are some difficulties to take into account the influence of manganese on dysprosium when calculating the concentrations from X-ray intensities (*e.g.*, for NIM-G, Table 5).

Application

The analytical procedure presented within the previous sections is applied to rock samples from the complex of the Saualpe in Carinthia (Austria). The metabasites of this crystalline massif show different degrees of metamorphism (from weakly metamorphic spilites to amphibole-eclogite).[14,15] Those rocks are well suited for studies of the mobility of ions under metamorphic conditions. Some results presented in the literature indicate conservative metamorphosis but other results point to a progressive "homogenization". The determination of the rare earth element concentrations is supposed to give valuable further information.

Our first results indicate that there is no single "rare earth element pattern" characterizing all the samples we analyzed but there are some groups of samples with similar rare earth element contents. Figure 4 shows the rare earth element pattern for two different samples to give an example; as usual in geochemistry they are presented as chondrite normalized plots, but we abstain at this place from any geochemical interpretation.

By way of concluding it can be stated that both methodological variants described in

this work are feasible. Although the X-ray fluorescence procedure has proved reliable, the additional precipitation step and the higher detection limit at least on the currently used X-ray spectrometer have made this variant somewhat less desirable compared to ICP–OES measurements.

SPECTROFLUORIMETRIC DETERMINATION OF ZINC IN FOODS WITH 8-(*p*-TOLUENESULPHONAMIDO)QUINOLINE IN MICELLAR MEDIUM

M. FALCON, J. GUITERAS, A. IZQUIERDO and M. D. PRAT
Departament de Química Analítica, Universitat de Barcelona, Avda. Diagonal 647, Barcelona 08028, Spain

(*Received* 10 *February* 1992. *Revised* 11 *May* 1992. *Accepted* 11 *May* 1992)

Summary—A new method for the spectrofluorimetric determination of zinc with 8-(*p*-toluenesulphonamido)quinoline in a Brij-35 micellar medium has been developed. This method allows the determination of 8–550 ng/ml Zn(II) and is relatively free from interferences. It has been applied to food samples with satisfactory results.

The use of 8-(*p*-toluenesulphonamido)quinoline [Fig. 1(a)] as a reagent for the spectrofluorimetric determination of Zn(II) and Cd(II) was first described in 1959 by Bozhevol'nov *et al.*[1] in a paper stating that 0.1 μg of Zn(II) could be detected in 5 ml of solution at pH 8.0–8.3, and that this sensitivity could be increased to 0.01 μg/ml after extraction of the complex into $CHCl_3$. Later papers confirmed these data and also indicated that Al(III) had little interference.[2,3] In 1962, Shcherbov and Kolmogorova[4] used this reagent to determine zinc in iron ores, with an absolute error of 15–25%. The use of 8-(*p*-toluenesulphonamido)quinoline as a spectrofluorimetric reagent was also reported by Bozhevol'nov and co-workers,[5–7] which gave a 2:1 stoichiometry for the TSQ:Zn complex [Fig. 1(b)].

The use of surfactant agents can increase the stability and solubility of many organic compounds and metal complexes in water and, when these are fluorescent, a marked increase in fluorescence intensity can frequently be observed. For this reason the use of surfactant agents can improve many existing spectrofluorimetric methods by increasing their sensitivity and/or eliminating the need for extraction procedures or the use of mixed hydroorganic solvents.[8–12]

In this paper, the influence of several surfactant agents (anionic, cationic and non-ionic) on the fluorescence of the complex of Zn(II) with 8-(*p*-toluenesulphonamido)quinoline has been studied and a new method for the spectrofluorimetric determination of zinc is proposed. This method has the advantage of a better detection limit than flame AAS and has been successfully used for the determination of zinc in natural samples.

EXPERIMENTAL

Apparatus

Perkin–Elmer MPF-66 fluorescence spectrophotometer with 150 W Xenon lamp and 10-mm silica cells. Excitation and emission slits were both set at either 2 nm or 4 nm, depending on the concentration of Zn(II). All spectra and intensities were corrected against Rodamine B.

Perkin Elmer 1100B atomic absorption spectrometer.

Radiometer pHM64 pHMeter with Orion 8102 SC combination electrode. It was standardized against aqueous buffer solutions at pH 4.008 and pH 6.863 at 25°C (DIN 19266).

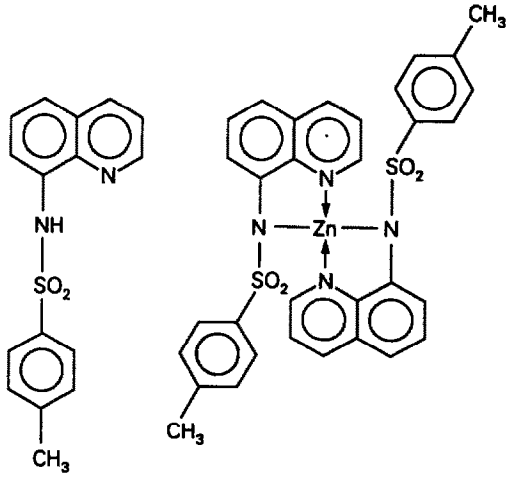

Fig. 1. Structures of (a) TSQ (b) TSQ–Zn complex.

All glassware was previously soaked in 10% nitric acid for 24 hours and rinsed with doubly distilled water (Culligan Ultrapure).

Reagents

8-(*p*-toluenesulphonamido)quinoline (TSQ) was synthesized following the method of Billman and Chernin,[13] by reaction of 8-aminoquinoline with *p*-toluenesulphonylchloride in pyridine. The product was recrystallized from ethanol as white needles. The melting point (153–154°) was in good agreement with literature values. Elementary analysis also agreed with theoretical values. (Calculated for $C_{16}H_{14}N_2O_2S$: C:64.41%; H:4.73%; N:9.39%; S:10.75%. Found: C:64.45%; H:4.68%; N:9.41%; S:10.80%.).

TSQ stock solution ($8.5 \times 10^{-3}M$) in ethanol was used.

Buffer solutions were prepared with R.A.-grade succinic acid–NaOH, Na_2HPO_4–KH_2PO_4, tris(hydroxymethyl)amminomethane–HCl and glycine. After the optimum pH range was selected, all further work was carried out in a $0.4M$ tris–HCl buffer.

Zinc stock solution, approximately 1 g/l., was prepared by dissolving about 4 g of $Zn(NO_3)_2.4H_2O$ (Merck, p.a.) in 1 l. of water and was standardized against EDTA.

Surfactant solutions. Stock solutions of the following surfactant agents were prepared: sodium dodecylsulphate (SDS) (Merck, $0.61M$, 75 cmc), polyoxyethylenedodecylether (Brij-35) (Scharlau, $1.8 \times 10^{-2}M$, 200 cmc), and hexadecyltrimethylammonium bromide (HTAB) (Merck, $9.2 \times 10^{-2}M$, 100 cmc).

Organic solvents (ethanol, dimethylketone and dioxane) were Merck p.a. and were used without further purification.

Doubly distilled water (Culligan Ultrapure GS) of 18.3 MΩ/cm resistivity was used in all cases.

General procedure

Into 25-ml standard flasks add 2 ml of buffer solution, the required volume of zinc solution, 2.5 ml of surfactant solution, 0.5 ml of $8 \times 10^{-3}M$ TSQ in ethanol and dilute to volume with distilled water.

RESULTS AND DISCUSSION

Effect of surfactants

In Fig. 2 the emission spectra of the Zn–TSQ complex in the presence of different surfactant agents (SDS, Brij-35 and HTAB) are represented. For comparison purposes, the spectra of the same complex in ethanol–water, dimethylketone–water and dioxane–water mixtures are also represented. Fluorescence intensities are higher in solutions containing non-ionic (Brij-35) or anionic (SDS) surfactants than in those containing cationic surfactants (HTAB) or the mixed hydroorganic solutions. Wavelengths for the excitation and emission maxima are similar in all tested media.

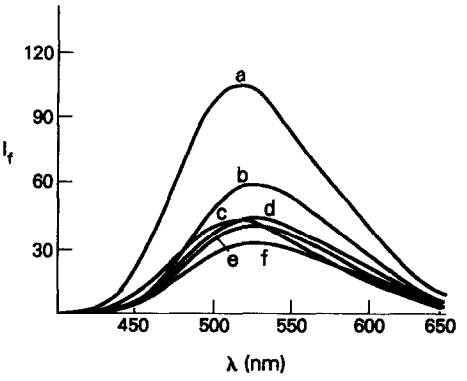

Fig. 2. Emission spectra of the Zn–TSQ complex in (a) 20 × cmc Brij-35 (b) 20 × cmc Sodium dodecylsulphate (c) 20 × cmc HTAB (d) 30% (v/v) ethanol/water (e) 30% (v/v) dimethylketone/water (f) 30% (v/v) dioxane/water.

The highest emission intensities are obtained in the presence of non-ionic surfactants, and for this reason all further research has been carried out in a Brij-35 micellar medium.

Effect of pH

In Fig. 3 the fluorescence intensity of the Zn–TSQ complex *vs.* pH in a Brij-35 micellar medium is plotted. Intensity does not depend on pH in the range 7.0–8.7.

Effect of surfactant concentration

For solutions containing less than 100 ng/ml Zn(II), the intensity is independent of surfactant

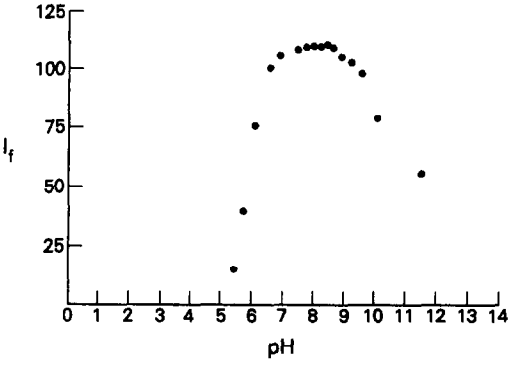

Fig. 3. Effect of pH on the fluorescence intensity of the Zn–TSQ complex in a Brij-35 micellar medium.

concentration when this is higher than $9.0 \times 10^{-5}M$ (about the critical micellar concentration). However, surfactant concentration should be higher than this value if zinc concentration is relatively high, to prevent precipitation of the Zn–TSQ complex, which has a low solubility in water. In further experiments Brij-35 concentration has been $1.8 \times 10^{-3}M$ (20-fold cmc).

Effect of reagent concentration

Fluorescence intensity increases with increasing TSQ concentration until the TSQ/Zn molar ratio reaches a value of 20. Higher TSQ concentrations have no significant influence.

Effect of ethanol concentration

The influence of ethanol on the fluorescence intensity of the Zn–TSQ complex has been investigated because TSQ is used in ethanolic solution. Fluorescence intensity decreases slightly when ethanol concentration is increased from 0.4% v/v (minimum possible concentration, corresponding to 0.1 ml of ethanolic TSQ solution) to 12%. In further experiments, ethanol concentration has been 2% v/v.

Stability of the complex

Fluorescence intensity reaches a maximum in a few seconds and remains constant for over two hours.

Order of mixing

The order in which reagent, surfactant, metal ion and buffer solutions are mixed has no influence on fluorescence intensity. However, in some cases a precipitate may appear. It dissolves readily when the surfactant is added, but in order to avoid this the recommended order of mixing is as follows: buffer, zinc, surfactant and reagent solutions.

Optimum working conditions

The conditions for the determination of zinc with TSQ in Brij-35 micellar medium are as follows:

excitation wavelength: 367.2 nm
emission wavelength: 515.4 nm
pH: 7.0–8.7
[TSQ] > $2.3 \times 10^{-5}M$
[Brij-35] > $1.8 \times 10^{-3}M$ (20 cmc).

Analytical characteristics

Calibration graphs are linear in the range 8–200 ng/ml Zn (excitation and emission slits set at 4 nm, [TSQ] = $3.8 \times 10^{-5}M$, $r = 0.9999$) and 70–550 ng/ml Zn (excitation and emission slits set at 2 nm, [TSQ] = $2.1 \times 10^{-4}M$, $r = 0.9991$). These two ranges have been selected because a low TSQ concentration has the advantage of a lower reagent background blank, but it is necessary to increase reagent concentration at greater zinc concentrations in order to keep the required TSQ/Zn molar ratio.

The detection limit, calculated from $3s$ (where s is the standard deviation of the blank) ($n = 15$) is 3 ng/ml Zn. Quantification limit, calculated from $10s$ ($n = 15$) is 8.0 ng/ml Zn. The precision of the method has been determined at two different zinc concentrations. Relative standard deviations are 2.4% for 25 ng/ml Zn and 1.9% for 150 ng/ml Zn.

Interferences

The effect of several ions on the fluorescence intensity of the Zn–TSQ complex has been investigated. An ion is considered to be an interference if its presence produces greater than a 5% change in fluorescence intensity. The investigated ions and the maximum concentration at which they do not interfere are listed in Table 1. It should be mentioned that Al(III) and Fe(III) have little influence and can be tolerated in relatively high concentrations.

	Spectrofluorimetric method, μg/g	AAS, μg/g	Certified value, μg/g
Powdered milk (commercial brand)	43.4 ± 1.0*	42.9 ± 1.2*	—
Powdered milk (NBS SRM-1549)	47.3 ± 1.1*	—	46.2 ± 2.2
Tinned clams	10.9 ± 0.6*	11.0 ± 1.2*	—

*Mean of six independent determinations.

APPLICATION

The proposed method has been used for the determination of zinc in two different samples of powdered milk (one of them of a commercial brand, the other a NBS standard) and in commercial tinned clams. In the commercial samples, results have been confirmed by atomic absorption spectroscopy. In all cases the method of standard addition was employed.

Procedure

The required amount of sample (0.5 g of powdered milk or 2–3 g of drained, tritured clams) was mineralized in a Kjeldahl flask with a H_2SO_4–HNO_3 mixture. Most of the acid was then neutralized with sodium hydroxide, the solution was transferred to a 100-ml calibrated flask and diluted to volume with water.

For spectrofluorimetric determinations, 10-ml aliquots of this sample solution were added into five 25-ml calibrated flasks, which contained 2.5 ml of pH 8.2 tris–HCl buffer solution, 2.5 ml of 200 cmc Brij-35 solution, 0.5 ml of $4 \times 10^{-3}M$ TSQ solution, 2.5 ml of $0.5M$ sodium thiosulphate solution, 1.0 ml of $10^{-3}M$ $Na_2P_2O_7$ solution and different volumes of standard zinc solution, and diluted to volume. Fluorescence intensities were measured against blanks via the same procedure.

For AAS, 10-ml aliquots of the sample solution were added into five 25-ml calibrated flasks, which contained different volumes of standard zinc solution, and diluted to volume. Absorbances were measured against blanks run through the same procedure.

Results are shown in Table 2. In all cases there is a very good agreement between values obtained by the spectrofluorimetric method and either certified NBS values or those found by AAS, with the additional advantage that the spectrofluorimetric method has a detection limit of 3 ng/ml and a quantification limit of 8 ng/ml, which are much better than the limit for Zn by flame AAS.

SOLID INTERFACES AS ANALYTICAL PROBLEM SOLVERS IN FLOW INJECTION ANALYSIS

M. D. LUQUE DE CASTRO and M. T. TENA
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

(*Received* 14 *February* 1992. *Revised* 24 *April* 1992. *Accepted* 14 *May* 1992)

Summary—An overview of the advantages gained by using solid interfaces in flow injection analysis is presented. The enhancing effect on such basic analytical features as selectivity and sensitivity, diminished sample and reagent consumption, ease of automation of the preliminary steps of the analytical process and of implementation of multideterminations arising from the use of solid interfaces are discussed and illustrated by selected examples.

The new problems of social concern with which analytical chemistry is confronted call for solutions relying on complex, expensive technologies.[1] Flow injection analysis (FIA) is one exception to this general rule as it is based on straightforward systems characterized by their flexibility to accommodate the specific demands of each situation or problem.[2,3] The wide variety of FI methodologies developed in the last decade make FIA a firmly established analytical tool. However the high potential of this technique remains unknown to many analytical chemists who are therefore missing an advantageous alternative to other automatic and manual methods for a number of purposes.

The aim of this paper is to illustrate the potential of solid interfaces as parts of FI systems through selected examples. The different nature of these interfaces and the versatility of FIA offer a host of opportunities to improve such analytical features as sensitivity, selectivity and sample and reagent consumption.

Solid phases included or formed in FI manifolds can be of very different nature, which in turn determines their function, performance and advantages derived from their use.

Thus, the role of the solid phase can be played by the sample itself if it is inserted into the system in a solid state. Alternatively, the solid phase can be formed along the flow system as a result of a chemical reaction (*e.g.*, precipitation), or on a solid surface by an electrochemical reaction (stripping techniques). Also, the solid phase can be a reactant that interacts with the analyte, its reaction product or undesirable components of the sample, as is the case with absorbent or ion-exchange material, immobilized catalysts or solid reagents.

The material presented in this paper is organized according to the analytical parameter or aspect that is improved as a result of using a solid interface. Thus, solid interfaces have been classified according to whether they provide enhancement of sensitivity; increased selectivity; decreased sample and reagent consumption; or allow one to automate the preliminary steps of the analytical process; develop multidetermination methods; indirect determinations, and other methods.

Increasing sensitivity by using solid interfaces

The sensitivity of FI methods is usually lower than that of their manual and air-segmented counterparts as a result of measurements in an FI manifold being performed under non-steady state conditions and also owing to dispersion. The fact that the derivatizing reaction does not develop to completion results in decreased sensitivity to an extent dependent on the point of the kinetic curve at which measurements are performed. The dispersion of the sample plug, whether into the carrier stream or through mixing with streams of reagents, masking agents, *etc.*, detracts from the sensitivity. Nevertheless, the sensitivity of an FI method can be increased in two main ways[4] by using solid interfaces, namely: 1) by on-line preconcentration or *in situ* concentration, 2) by decreasing dilution using solid reagents. Micellar media and amplification reactions also provide increased sensitivity in this respect.

Preconcentration. The use of a preconcentration step is one of the more effective ways of increasing sensitivity. This operation can be performed in an FI system by: (a) coupling it on-line to a conventional separation unit such as a minicolumn packed with a suitable adsorbent or ion-exchange material, or a liquid–liquid extraction unit; (b) by implementing a precipitation reaction in the flowing injected plug and collecting the solid phase formed *in situ* by means of a suitable filter; and (c) by forming a solid phase in the detection cell or electrode surface, as in stripping techniques implemented in FI systems.[5]

(a) Minicolumns used for preconcentration involve a chemical reaction between the analyte and the solid column packing if the active material is an ion exchanger rather than an adsorbent.[6] The minicolumn can be placed [Fig. 1(A)] in the loop of the injection valve or between the injection and detections systems.

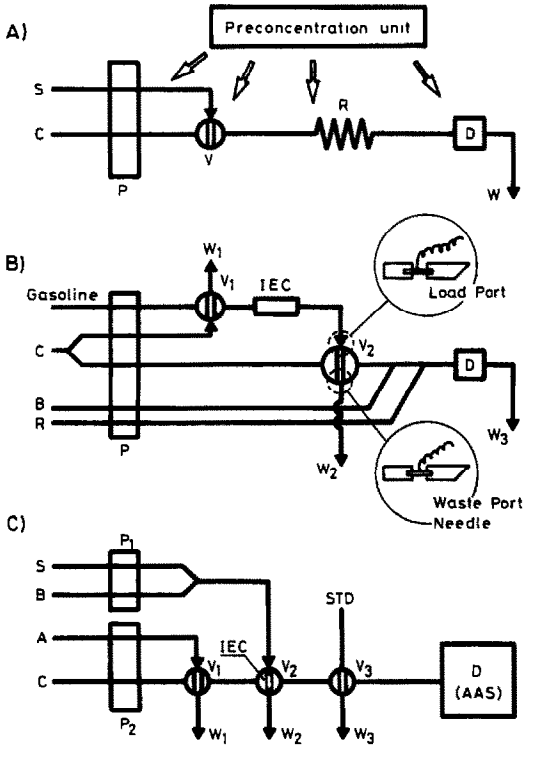

Fig. 1. A) Possible locations of separation units for preconcentration. B) Arrangement for the measurement of mercaptans in gasoline (the insets show the conductivity probes connected to V_2). C) Manifold for preconcentration/determination of lead with timed sample loading (V_2) and injection of reagent and standard solutions (V_1 and V_3, respectively) with saving purposes. S denotes sample, A eluent, C carrier, P pump, V valve, D detector, W waste, B buffer, R reagent, IEC ion-exchange column, STD standard and AAS atomic absorption spectrometer.

Occasionally, it is also inserted into the sample stream prior to the injection point. Also, placement of the solid material in the flow-cell of a non-destructive optical detector provides a peculiar *in situ* concentration mode involving integrated reaction and detection[7,8] or retention and detection.[9] The performance and efficiency of minicolumns used for preconcentration can be boosted in various ways. Thus, performance can be improved by loading the column in the opposite direction to elution, thus avoiding the shortcomings derived from the increased compactness of the packed material and from the appearance of parasitic signals due to the sample matrix, which can be sent directly to waste. Higher efficiency can be achieved by using conical rather than cylindrical columns, which must be arranged in the FI manifold in such a way that sample loading takes place from the narrower to the broader end. Also, the retained analytes must be eluted in the opposite direction in order to minimize dispersion in the column,[10] which can be accomplished by using time-based injection techniques.[11]

C_{18} bonded silica beads and, to a lesser extent, alumina and silica, are the most commonly used solid adsorptive materials for packing minicolumns. Sorbent extraction in flow injection system with AAS detection has been proposed by Růžička and Arndal for preconcentrating copper and lead by complexation with several chelating agents.[12] A typical example of preconcentration by using a conical column packed with C_{18} is the method reported by Fang *et al.*, in which lead is preconcentrated as a diethyldithiocarbamate chelate before determination by graphite furnace atomic absorption spectrometry which a 26-fold increase in peak area for 60-sec preconcentration compared with direct introduction of 50 μl of sample,[10] activated alumina has been used for adsorption of oxyanions[13] and Mo[14] prior to their determination by ICP/AES.

Solid exchange materials used as packings for preconcentration minicolumns can be commercially available ion-exchange resins or ion exchangers prepared in the laboratory from an adsorbent material (*e.g.*,C_{18}, silica gel, controlled-pore glass) that is activated and bonded to a chelating molecule. The concentration step usually precedes introduction of the sample into an atomic detector for individual or multideterminations by AES and ICP techniques. Such is the case with the determination of twenty elements by ICP/AES proposed by Wang and

Barnes,[15] who assessed the performance of two resins. Implementing the separation step prior to molecular spectroscopic detection is usually intended either for preconcentration or for interference removal (*e.g.*, in the photometric method for determination of sulphate after separation by a strong anion-exchange resin minicolumn located in the loop of the injection valve). By using adequate preconcentration times and a less sensitive method (displacement of the methylthymol blue/barium complex by the analyte) Karlsson *et al.* accomplished a determination range between 25 and 1000 ng/ml.[16] The decrease in the sampling frequency resulting from the preconcentration step can be overcome by using a system of two columns that function alternately for retention and elution. Wu and Qi achieved a sampling frequency of 30 hr and a detection limit of 3 ng/ml in the photometric determination of uranium in geological samples.[17] An unconventional method was developed by Lei *et al.* for the determination of mercaptans in gasolines based on preconcentration of the analytes on ion-exchangers and elution with an immiscible eluent[18] in the manifold shown in Fig. 1(B). The gasoline sample was circulated through an electropneumatically actuated rotary valve, V_1 (sample loop 60 μl), and a microcolumn packed with a strong anion-exchanger, and then through the load port of valve V_2 to waste. Valve V_2 is the same as V_1 but has a 15-μl loop volume. The loading loop and waste port of this valve accommodate a stainless-steel hypodermic needle inserted as shown in Fig. 1(B). The conductivity between these two metal probes is monitored; when the loop is filled with a conductive aqueous eluent rather than gasoline carrier, the electrical resistance drops and valve V_2 is automatically switched to its injection position.

8-Hydroxyquinoline has been the most frequently immobilized chelating agent used for preconcentration purposes. It is usually supported on silica and placed in the transport zone[19,20] or in the loop of the injection valve.[21] Occasionally, it has also been immobilized on controlled-pore glass[22] and on Fractogel.[23] Preconcentration of lead was assayed by using various FI manifolds and chelating agents for the determination of this element by FAAS. Detection limits down to 1.4 ng/ml Pb were obtained by using an FI manifold with three serially arranged injection valves such as that shown in Fig. 1(C), in which timed sample loading and matrix removal without the matrix reaching the nebulizer were achieved with a single valve. Reagent consumption and the calibration time were reduced by using two additional valves to introduce the eluting and standard solutions.[24] Inert columns such as SBSRs (single beads string reactors[2,3]) also exert a sensitivity enhancing effect by avoiding dilution.

(b) Such an old technique as precipitation has not been incorporated into flow systems other than FIA. *In situ* formation of a solid phase in a flow injection manifold and retention on an appropriate filter provides high preconcentration factors, in both direct and indirect methods for individual species or multideterminations.[25]

The filter used can be stainless-steel and located prior to an atomic absorption detector (*e.g.*, in the direct determination of lead, where a preconcentration factor of 700 was achieved by precipitating the metal with ammonia[26]), non-metallic (*e.g.*, a disposable cellulose acetate membrane—that was also used for the direct AAS determination of copper by precipitation as hydroxide, and of calcium as oxalate.[27]) A special filter (Tygon tubing 7 cm long, 2.8 mm bore, filled with 1.9-mm diameter Pyrex glass beads) was used for the indirect determination of chloride and carbonate ions by AAS after preconcentration by precipitation as silver and calcium salts, respectively.[28] A reagent injection manifold in which the dissolving and washing solutions were introduced through an injection valve was used. Detection limits of 3×10^{-7} and $5 \times 10^{-7} M$ were achieved for Cl^- and CO_3^{2-}, respectively, by using thiosulphate and hydrochloric acid as dissolution agents.

A procedure for co-precipitation of lead in the presence of high concentrations of iron and its subsequent determination by FAAS was reported by Fang *et al.*[29] Lead was co-precipitated quantitatively with an iron(II) complex and collected in a knotted reactor made of Microline tubing without using a filter. The precipitate was dissolved in isobutyl methyl ketone and introduced directly into the nebulizer-burner of an AA detector. A preconcentration factor of 20 was obtained for a co-precipitation time of 30 sec and a sampling frequency of 90 hr. The results obtained in the determination of lead in reference materials (blood and bovine liver) showed the procedure to be suitable for biological materials.

(c) Stripping techniques[30] are among the most frequently used enhancers of the key

analytical parameters, namely sensitivity and selectivity. Stripping techniques (whether voltammetric or potentiometric) and FIA have a synergistic effect,[5] particularly for preconcentrations; in fact, detection limits as low as a few pg/ml have been accomplished by using differential pulse voltammetry for the determination of lead in blood with no sample deoxygenation.[31,32] Also, potentiometric stripping has provided excellent determination methods for lead and cadmium in whole blood by using carbon fibre electrodes,[33] and in acid digest of biological samples without further treatment.[34] A special chemical stripping and potentiometric hybrid method was developed by Nakayama *et al.* for the determination of iodine species in seawater by using a continuous flow system in which the iodide was electrochemically oxidized to iodine and quantitatively concentrated onto a carbon wool electrode in a preconcentration cell. After interfering ions were removed, the iodine was eluted with a reductant and subsequently measured at a polished Ag_3SI electrode in the detection cell. Iodate was determined on reduction to iodide.[35] The new mode of performing stripping voltammetry proposed by Wang (batch injection stripping[36]) is a very promising alternative in this field.

Preconcentration as well as an efficient control of the accuracy were provided with a dual detection system based on potentiometric stripping and atomic absorption spectrometry.[37,38]

Increasing sensitivity by decreasing dilution. Flow injection system provides various means of introducing or bringing reagents and catalysts into contact with the sample in the manifold. Solid interfaces consisting of solid reactors, such as redox, enzymatic, passive and pressurized membrane releasers, decreasing dilution.

(a) The earliest solid reactors used in FIA were redox in nature (*e.g.*, those employed in the photometric determination of nitrate by its reduction to nitrite prior to its reaction with the classical Griess reagents). The dilution arising from the use of an additional reductant was thus avoided.[39] Configurations including internally coupled injection valves and a solid reactor in the loop of the injection valve allowed nitrogen speciation.[40] Also, organic species have been oxidized by using solid reactors, as in the determination of paracetamol with potassium hexacyanoferrate(III) previously immobilized on an anion-exchange column for the oxidation of the analyte prior to its photometric determination based on its reaction with an imine reagent.[41] Other reagents have been assayed, whether immobilized and packed in microcolumns or as derivatizing agents. Mottola developed interesting strategies to optimizing their performance.[42] The reagent itself can also be packed in the microcolumn as in peroxyoxalate solid reactors, thereby avoiding mixing problems and facilitating instrumental development.[43] The features of chemiluminescence monitoring make it preferable to immobilize the reagent in the flow-cell in order to accomplish integration of reaction and detection.

(b) Reagent-releaser membranes. Dasgupta *et al.* have used both passive membranes (ion-exchange membranes that release ammonia or sodium hydroxide) for conditioning the reaction medium, as well as pressurized membranes that are crossed by the derivatizing reagent or catalyst. Such is the case with the fluorometric determination of aqueous sulphite, sulphide and methanethiol after reaction with *N*-acridinylmaleimide (introduced through a pressurized membrane) in an ammonia medium (introduced through a passive membrane),[44] and that of peroxides based on the *p*-hydroxyphenyl acetate/peroxide/peroxidase system, in which a pressurized porous PTFE membrane reactor introduces the enzymes and the pH of the flow stream is altered by inserting NH_3 through a non-porous cation-exchange membrane reactor.[45]

(c) Enzymes immobilized on suitable supports have been widely used in on-line couplings to FI manifolds, both for determining substrates[46,47] and for facilitating monitoring in the determination of the activities of other enzymes.[48] Although the most commonly used support for immobilization of these catalysts is controlled-pore glass and to a lesser extent gels,[46] magnetic particles have also been used for this purpose.[49] Also catalysts have been entrapped in tubular microporous membranes.[50] The efficiency of the catalytic effect involved depends on the number of molecules of catalyst that were immobilized (or entrapped) and on the ability of the analyte to reach the active sites. Two,[51] three,[52] four[53] and up to five[54] enzyme reactors have been used in serial arrangements to develop FI methods.

In addition to the decreased dilution achieved by using immobilized catalysts other solid interfaces included in FI manifolds can be used for different purposes. One case in point is the determination of serum-galactose, which calls

for on-line dialysis, activator, ion-exchange and enzyme reactors.[52] Immobilization on the walls of a cell placed in an ordinary photometer or fluorimeter enables reaction-rate measurements with decreased dilution.[55] A further increase in sensitivity can be achieved by coupling an amplification reaction for determining very small amounts of substrates. Thus, a substrate recyling system was developed by Hansen *et al.*[56] by incorporating a small column reaction containing co-immobilized enzymes into the FI manifold in order to implement the degradation step and ensuing detection of a suitable reaction product to be individually optimized for assays of lactate or pyruvate in the micromolar range with an amplification factor of 40 for each of the substrates.

(d) Micellar media make special solid interfaces that are used in FIA to increase sensitivity in different ways. Among major roles of micellar media are increasing the solubility of reagents and acting as concentration sites in order to shift the derivatizing reaction equilibrium.[57–59] But micellar media can also increase selectivity by acting as ideal interfaces in reaction between water-soluble reagents and non-aqueous samples, thus allowing the development of liquid–liquid extraction processes without phase separation.[60,61] A novel chemiluminescence system was reported for the flow injection determination of phenylpyruvic acid (PPA) in which the presence of both ordered surfactant molecular assemblies and a metal ion catalyst was essential to the phosphorescence of benzaldehyde (emitter) produced by aerobic oxidation of PPA in alkaline solution. Dioctadecyldimethylammonium chloride bilayer aggregates and cobalt allowed PPA to be selectively determined down to $1 \times 10^{-7}M$. The bilayer aggregates were found to contribute favourably both to the production of key intermediates and to efficient phosphorescence emission.[62]

Increasing selectivity by using solid interfaces

Flow injection methods usually surpass their manual and segmented-flow counterparts in selectivity as a result of measurements being made under non-steady state conditions which avoids interferences from species reacting more slowly than the analyte.[63] In addition to the characteristic fixed-time kinetic measurements of FIA, selectivity can be enhanced by using solid interfaces for, 1) interference removal; 2) reaction-rate measurements based on immobilized enzymes; 3) and coupling of FI manifolds to powerful separation techniques such as HPLC.

Interference removal. One of the most typical ways of increasing selectivity is by interference removal, which can be accomplished in FI manifolds by coupling/forming solid interfaces such as ion-exchange or sorbent columns, membranes or precipitation processes.

(a) Separation on an ion-exchange or sorbent column involves retention of the analyte or the interferents. Thus, the interferences from cations in the chemiluminescence determination of bromide was overcome by using a strong cation-exchange column.[64] Also, ammonia, the only interferent with the determination of biuret in fertilizers, was removed by using a Dowex ion-exchange column located prior to or after the injection valve.[65] When a reagent injection manifold is used[66] or for the removal of reagents interferences when the normal FI mode is used, the matrix interference removal column must always be inserted into the main stream, as it must for the removal of reagents interferences when the normal FI mode is used.[52,67] Absorbents such as C_{18} bonded silica beads have been used for retention of the sample matrix in the determination of bitterness in virgin olive oils by using a solid minicolumn located in the loop of the injection valve in order to avoid passage of the matrix through the detector in the eluting/washing step.[68] On the other hand, the amperometric determination of copper in complex matrices such as serum with high albumin content was carried out by using a chelating column to retain heavy metals while allowing albumin to run to waste.[69]

Enhanced selectivity was accomplished together with interference removal by using masking agents such as triethanolamine, thiourea, fluoride and cyanide in the preconcentration of lead by using 8-hydroxyquinoline immobilized on silica,[70] and by on-line coupling of another separation technique such as hydride generation.[71]

(b) Membranes have been widely used in FI manifolds as they allow selective passage of a great variety of substances (gases and low molecular weight, ionic, polar and non-polar compounds, *etc.*) depending on their nature. The low yield of these separation processes is a result of equilibrium not being reached in the very short contact time between sample and membrane. This sensitivity loss has been overcome in different ways (Fig. 2), namely: by using ultrasounds on the separation unit[72]; by halting the

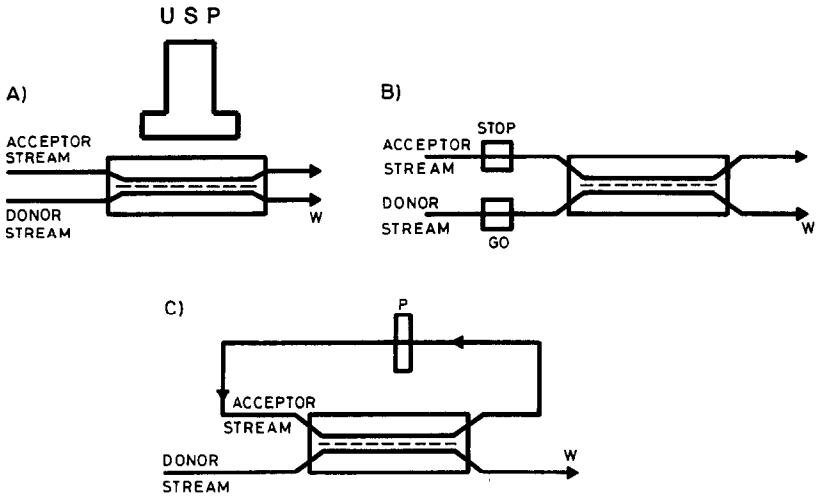

Fig. 2. Different ways of increasing sensitivity in membrane/separation processes. A) By use of an ultrasonic source acting on the separation unit. B) By halting the flow of the acceptor stream. C) By using a closed-loop system to recirculate the acceptor stream. USP denotes ultrasonic probe. The rest as in Fig. 1.

flow of the acceptor stream, whether by using valve,[73] or a time-based mode[74]; and by using a closed loop through which the acceptor stream is recirculated for the analyte to build up.[75]

Dialysis is a very useful means of avoiding interferences from proteins and other macromolecules occurring in biological samples, as was shown in the potentiometric determination of chloride in milk by using a selective electrode for this analyte. The interference from casein was thus overcome and a stable baseline was obtained.[76] The determination of this analyte in serum calls for both interference removal and dilution, which was accomplished by using a dialysis membrane whose yield was accommodated within the linear range of the determination method by employing an adequate ratio of acceptor to donor stream.[77] A dialysis step was also required to isolate low molecular-weight substances from samples obtained in a cellular permeation process in order to monitor the intracellular enzyme activity.[78] A particular method for extraction-preconcentration of phenol compounds from kerosene and naphtha was based on separation through a silicone membrane into a basic acceptor stream which contained 4-aminoantipyrine.[79] The sensitivity of the method was also manipulated by modifying the size of the extraction cell and the preconcentration time. Ionomer membranes enhance the selectivity of electrode-based biosensors, thereby improving the quality of FI measurements, as shown by Rosario *et al.*[80] in the determination of urea in blood serum and *L*-glutamine in hybridoma bioreactor media. A coil of cation-exchange tubing was used as a direct replacement for the injection loop of a conventional sample injector enabling Donnan dialysis to be performed under static conditions while allowing enriched samples to be injected into an FAA spectrometer.[81] On-line coupling of a dialyzer to another solid interface for separation or derivatization purposes results in improved features, as in the determination of galactose by use of up to three enzyme reactors and two separation minicolumns after the dialyzer in order to ensure a selective determination of this analyte in serum.[52]

Membranes allowing gas-diffusion to take place across them have also been widely used in FI manifolds for the determination of either species occurring as gases in the samples (e.g., O_3, ClO_2),[82–84] or others that can be converted into gases by an acid–base reaction[85–93] or by heating.[93,94] A method that is 1500 times more selective towards chlorine dioxide than it is towards chlorine on a mole basis, and with a detection limit of 5 ng/ml, was developed by combining gas-diffusion and chemiluminescence detection.[84] The method avoided the interference from iron and manganese compounds, as well as those of other oxychlorinated compounds such as chloride ion and chlorate ion. Species that are readily converted into gases (*e.g.*, cyanide and ammonium ions) have been determined in complex matrices by using an FI manifold including a gas-diffusion cell.[85–89] A method for the determination of cyanide based

on gas-permeation and reaction with a highly selective reagent has been recently proposed by Kubán.[95] It featured a detection limit of 3 ng/ml and most interferences, including those of SCN were eliminated by discrimination of mass transport through a non-porous silicone-rubber membrane. Urea has also been determined after enzymatic conversion into ammonia and diffusion of the generated gas as in the conductimetric determination involving a reactor packed with naturally immobilized urease in the donor stream and mixed bead ion-exchange minicolumn in the acceptor stream for final purification of demineralized water prior to the separation unit in order to facilitate monitoring of conductivity changes involved.[67]

Microporous membranes provide excellent results in the separation of hydrides generated prior to their introduction into an atomic detector, whether AAS[96] or ICP/AES.[95] Tubular designs are more efficient in this respect, and allow fast, quantitative release of the gas phase.[96,97] Also gas-diffusion separation and detection have been integrated. A porous gold layer, deposited on one side of a porous Teflon membrane, serves as an amperometric electrode which consumes volatile species transported from the flowing solution through the membrane. Thus, nitrite ion has been determined without interference from nonvolatile electroactive species by reaction to produce nitric oxide and iodine.[98]

Pervaporation, *i.e.*, integrated evaporation and gas-diffusion, can be used to enhance selectivity dramatically, as shown in the determination of ethanol and diacetyl in fermentation monitoring.[93] A simple modification of the membrane (*e.g.*, with silicone) allows the linear range for the determination of ethanol to be expanded to 0.0006–60% v/v.[94]

On-line coupling of an FI manifold to a continuous liquid–liquid extractor including a membrane separator has been used for the selective determination of both organic and inorganic species.[99,100] This solid interface offers major advantages over separators based on density differences (*i.e.*, smaller inner volume, possibility of using high flow-rates, no density differences between the aqueous and organic phase required, and a higher efficiency). One example of the enhanced selectivity inherent in liquid–liquid extraction is the method for the determination of lithium in biological fluids by using cryptand 211, which features a linear range for the analyte of 70 ng/ml to 2.1 μg/ml and tolerates up to 1000 μg/ml sodium ion.[101] A higher selectivity can be achieved by coupling the liquid–liquid extraction process to another separation technique such as chromatography. The discriminating effect of GC allows the separation/determination of phenol compounds prior to simultaneous on-line derivatization–extraction into n-hexane of the esters formed with acetic anhydride.[102]

Inert hydrophobic membranes[103,104] as well as thin layers of organic solvent immobilized on microporous inert supports (liquid supported membranes)[105,106] have been used for sample clean up and preconcentration in FI systems even coupled to a gas chromatograph as an alternative to liquid–liquid extraction. Amines in urine and phenols, chlorinated aromatic compounds and pesticides are examples of nonpolar compounds extracted by means of these devices, the advantages of which have been recently reviewed by Jönsson and Mathiasson.[107]

(c) Precipitation allows the selective determination of calcium at the μg/ml level in the presence of over 1000 μg/ml aluminium thereby avoiding its interference with the AAS determination of this alkaline earth by use of an air–acetylene flame.[28]

(d) Reaction-rate methods based on the use of immobilized enzymes combine the selectivity of the enzymatic processes with the advantages of reaction-rate monitoring, viz. avoidance of interferences from the matrix signal and from species that react faster or slower than the analyte. There are three main alternatives to performing these measurements which involve three different. FI approaches, namely: stopped-flow,[2,3] iterative change of the flow direction,[108] and open-closed configurations.[109]

Enzymes immobilized on the walls of a photometric or fluorometric flow-cell enable reaction-rate measurements by halting the flow as the sample plug reaches the flow-cell. Pairs of signal-time data can be acquired during the stop interval, and related to the concentration of the analyte. Iterative passage of the sample plug through an ordinary photometer or fluorimeter can be accomplished either by changing the flow direction[108] or by using an open-closed system.[109] In both cases, an enzyme reactor can be included in the FI manifold so the sample can be circulated through it between two consecutive passages through the detector, thereby providing additional development of the enzyme reaction.[110]

Both selectivity and sensitivity can be improved through biochemical reactions, whether by using immobilized catalysts (*e.g.*, enzymes, as described in section A) or reagents. Immunoassay makes a very powerful means of enhancing the selectivity of FI methods.[111] The FIA-ELISA coupling allows on-line monitoring of biological macromolecules. The operational principle is based on the competitive binding of an antibody and a native antigen in the sample to an enzyme-labelled antigen that is added in a preset amount. The antibodies are immobilized onto a solid support and placed in a small column inserted in the flow system. After one assay cycle, the system is rinsed and the column is re-used for the next assay. The total time for one assay cycle is 6–10 min.[112] Fluorometric on-line monitoring of monoclonal antibodies in the course of a hybridoma cell fermentation has also been accomplished by using immunoreactors containing membranes for magnetic particles as the solid phase for the bound antibodies.[113]

Multideterminations based on FI systems involving solid interfaces

The development of multiparameter methods is one of the current goals of FIA as they may make this technique competitive with other automatic alternatives, whether continuous or batch.[1] Multideterminations in FI/solid interface systems are made possible either by the presence of the solid interface itself, by the features of the detector (*e.g.*, MS, ICP), by alterations to the detection zone [integration of reaction(retention) and detection], or by more than one of the previous choices (stripping techniques, use of derivative synchronous fluorescence in integrated reaction-detection systems). Solid interfaces used for discrimination purposes in FIA include the following:

Precipitation. Precipitation of the analytes with further selective dissolution, as in the indirect sequential determination of chloride and iodide by AAS after precipitation with silver ion, retention of the precipitated salt on a filter and dissolution of chloride and iodide by sequential injection of ammonia and cyanide solutions.[114]

Membranes. Membranes accommodated in liquid–liquid extractors, dialysers and gas-diffusers have been used for multidetermination purposes. Membranes for separation of immiscible phases have been used in the simultaneous determination of diphenydramine and 8-chlorotheophylline in dramamine tablets.[115] A porous membrane was used to isolate the cyclohexane phase and a paper membrane was employed to separate the aqueous buffer phase after solvent extraction via a segmented flow. At pH 10, diphenydramine was quantitatively extracted into the cyclohexane phase while 8-chlorotheophylline remained in the buffer phase. Assays were performed at the rate of two per minute and with r.s.d. values of 1%. Speciation of calcium in milk (as total and free calcium) was accomplished by using a dialysis membrane which allows the photometric determination of free calcium in the acceptor stream and that of total calcium on an undialysed sample by AAS.[116] Inclusion of a further dialyser arranged in series with the previous one allows the potentiometric determination of chloride in milk in addition to calcium speciation. Three parallel detectors are required in this case.[117] Also, two serially arranged dialysers were used for the simultaneous determination of sodium and potassium by flame emission spectrometry and of chloride by spectrophotometry.[118]

The use of diffusion membranes for simultaneous determinations occasionally involves passing only one analyte through the membrane, as in the simultaneous determination of hydroxylamine and cyanide, where cyanide is amperometrically determined in the acceptor stream, while hydroxylamine remains in the donor stream and is oxidized by iodine, which is then determined photometrically.[119] However, sometimes both species are allowed to cross the porous membrane in order to be simultaneously determined in the acceptor stream by using two serial detectors, as in the determination of CO_2 and SO_2 with a potentiometric detector responsive to both analytes and a photometric detector for SO_2 alone (*p*-rosaniline-formaldehyde method).[120] If a single detector is used, discrimination between analytes can be achieved sequentially by changing the pH of the acceptor stream, as in the determination of cyanide and thiocyanate, which react with pyridine/barbituric acid at pH 6.0, whereas only cyanide reacts at pH 8.1.[121]

Microcolumns. Microcolumns packed with solid materials have been used to develop a number of multidetermination methods.

(a) Ion-exchange resins can selectively retain one analyte, thereby enabling discrimination, as in the resolution of V(V)–Ti(IV) mixtures by use of a modified injection valve to introduce two

samples sequentially into the reagent stream. One of the samples is passed through a cation exchanger minicolumn and the other through an empty column before reaching the detector. The former allows vanadium alone to be measured, and the latter vanadium plus titanium.[122]

(b) Redox columns, particularly those of cadmium and copperized cadmium have been employed for nitrogen speciation as nitrite and nitrate on the basis of the Griess reaction. The complexity of FI manifolds used for this purpose has increased with time. Thus, Anderson[123] reported a fairly simple design in which, after injection, the sample was split and driven through two parallel configurations, one of which included a redox column, and then through a photometric detector. A more recent reversed FI system uses a valve to switch the cadmium column in and out of line so that nitrate plus nitrite or nitrite alone can be determined.[124] A configuration with internally coupled valves and a reductant column located in the loop of the secondary valve provided plugs with two distinct reaction zones, one of which was passed through the redox column while the other was not.[33] A similar manifold using an MnO_2 solid reactor instead was used for the determination of hydrogen peroxide and organic peroxides.[125]

(c) Immobilized catalysts, usually enzymes, have also been employed to determine one or more of the analytes in multideterminations.

Thus, two types of configurations were used for the simultaneous determination of two species, of which one required an enzymatic reaction: one of the manifolds included two injection valves coupled in parallel [Fig. 3(A)] or in series [Fig. 3(B)] in such a way that only one of the injected plugs passed through the enzymatic reactor. This was the basis of the simultaneous fluorometric determination of urea and ammonium with the *o*-phthalaldehyde/2-mercaptoethanol system and a reactor containing immobilized urease.[126] The FI manifold to be

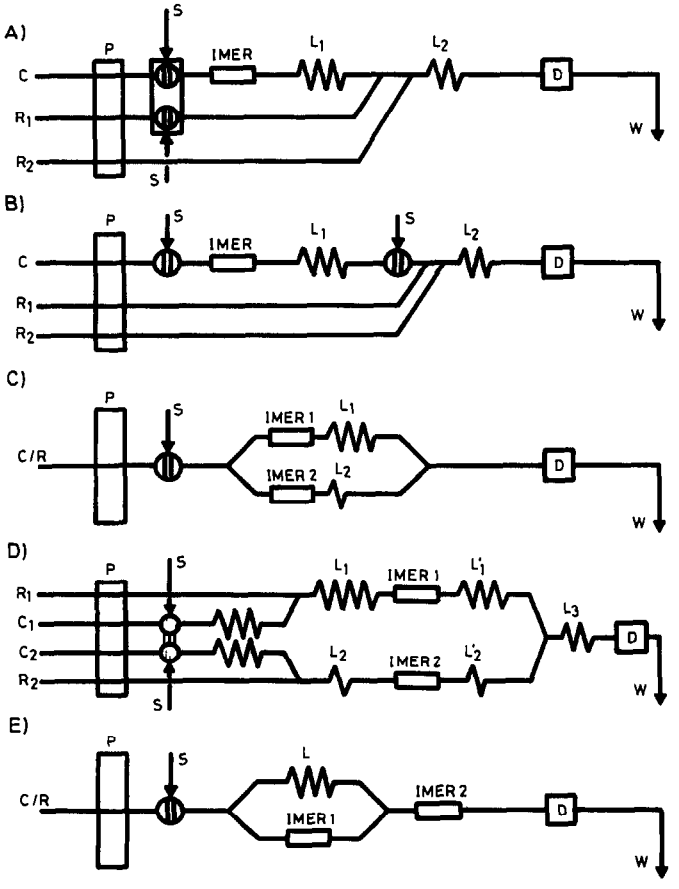

Fig. 3. Approaches to multideterminations based on immobilized reactors. A) and B) Only one of the determinations is based on enzyme reactions. C) and D) A different enzyme is required for each analyte. E) One analyte requires two enzymatic steps and the other only one, but common with the former. IMER denotes enzyme reactor, L an open reactor, the rest as in Fig. 1.

used when both analytes require an enzymatic derivatizing reaction is determined by whether or not one of the biocatalysts is common to both analytes. Thus, two solid interfaces were used for derivatization in the simultaneous determination of L(+) and L(−) lactic acid, which require different enzymes, so an FI manifold with splitting and confluence points [Fig. 3(C)] and two channels including an enzymatic reactor each was used.[127] By performing two-fold injections the splitting point can be dispensed with, as in the determination of ethanol and acetaldehyde in wines by using alcohol and aldehyde dehydrogenases and monitoring the formation of the reduced form of the coenzyme photometrically. Despite the rather different concentrations at which these analytes occur in wines, they required only a single dilution of the sample and appropriate choice of the injected volumes and length ratios of the $IMER_1$–$IMER_2$, and L_1–L_2 reactors [Fig. 3(D)].[128] On the other hand, the simultaneous determination of species which call for a common reagent and another specific to each, such as sucrose and glucose, can be developed in a manifold such as that shown in Fig. 3(E)].[129]

Multideterminations involving separations by using two solid interfaces have been effected with, as in the photometric method for the determination of sodium and potassium by separation on a silica column and liquid–liquid extraction into benzo-18-crown-6 and tetrabromophenylphthalein ethyl ester.[130]

Two different solid interfaces were used for separation–discrimination and derivatization, respectively, in the determination of bile acids in serum by use of an enzymatic derivatizing reaction after chromatographic separation. The overall manifold allows the determination of total or individual analytes depending on whether or not the sample is injected via the FIA or the HPLC valve. Thus, the FIA plug does not pass through the chromatographic column, but only through the enzymatic reactor, while the HPLC plug calls for individual determination.[131] When the HPLC instrument is coupled to an open-closed FI manifold[109] including the enzymatic reactor, reaction-rate measurements can be performed in addition to separation and enzymatic derivatization. Such is the case with the overall determination of the activity of creatine kinase and its different isoenzymes.[132]

Three solid interfaces were used in the sequential determination of NH_3, NO_2 and NO_3 in the manifold shown in Fig. 4. Ammonia was determined by merging the injected sample with an alkaline solution (NaOH/EDTA) and passing the resulting mixture through a diffusion cell. Released ammonia was collected by a flowing stream of deionized water that was subsequently passed through a conductance flow cell. The nitrate and nitrite concentrations were determined after reduction to ammonia in an alkaline medium by using a column filled with metal zinc. The ammonia thus produced was then measured as described above. Speciation was accomplished by adding sulphanilic acid to remove nitrite from the sample and determine the ammonia without using the column.[133]

Unconventional detectors. Some multideterminations rely both on intrinsic features of unconventional detectors and on the use of solid interfaces in the FI manifold which play a major role in the overall process. Such is the case with the on-line monitoring of acetic acid, acetoin and ethanol by membrane introduction tandem mass spectrometry proposed by Hayward *et al.*,[134] in which the analyte is directly inserted by a membrane probe that introduces aqueous solutions past a membrane place in the ion source of a mass spectometer,[134] or in an ion-exchanger coupled to an ICP/AES instrument for the preconcentration and simultaneous determination of metals.[15]

Modified flow-cells located in conventional or unconventional detectors. These arrangements have been used to integrate reaction (retention) and detection of analytes in mixtures. Any of the components of an analytical reaction

(analytes, reagents, catalysts and products) can be permanently or temporarily retained on a support that is used to pack the flow-cell.[7-9] The rate difference of the derivatizing reactions of two analytes retained on the C_{18} packing of the flow-cell of an ordinary spectrophotometer was the basis for a simultaneous determination of phosphate and silicate. A kinetic optosensing method was developed in which the rate difference in the reduction of the heteropoly complexes allowed the simultaneous determination of phosphate in the ng/ml range, and that of silicate at the μg/ml levels.[135] By placing a flow-cell packed with C_{18} support in a diode array spectrophotometer (DAS), the retained analytes can be simultaneously monitored at various wavelengths provided their absorption spectra are fairly different, as is the case with the simultaneous triple determination of aromatic amines based on differences in their spectral features.[136] The same type of cell and support, but placed in a spectrofluorimeter, were used for the determination of pyridoxal, pyridoxal-5-phosphate and pyridoxic acid based on derivative synchronous fluorometric measurements.[137]

Saving sample and reagent consumption by using solid interfaces in FIA: miniaturization

Miniaturization. Miniaturization is one of the main trends in today's analytical chemistry in response to social demands for assays involving increasingly smaller amounts of sample (particularly in the clinical field) and expensive reagents that must be used sparingly (especially in routine analyses). Flow injection analysis is in itself a miniaturized technique that can be further improved in this respect. Integrated microconduits[138] make the most promising approaches to miniaturization. Their performance can be boosted by incorporating ion-exchange minicolumns and enzyme reactors[139] in the transport system, or by integrating reaction(retention) and detection. Flow-through sensors for penicillin[140] and urea[141] microconduits have thus been developed. They consist of penicilinase or urease that is cross-linked with bovine albumin into a cellulose pad, and an acid–base indicator dye covalently bound to the surface of the cellulose, the sensor pad being placed at the endface of fibre optic bundles. Another, more sophisticated approach to the determination of urea involved a flow-cell combining gas-diffusion and optosensing; the separating barrier between the donor and accepting stream is a sandwich of a hydrophobic gas-permeable membrane and a hydrophylic membrane between which a gel of covalently immobilized urease is contained. The urea content in the sample is quantified by the colour change of an acid–base indicator contained in the acceptor stream.[142]

Another advantage of miniaturization is the possibility of performing *in vivo* monitoring. A rapid, specific measurement of the lactic acid content of extracellular fluid can be accomplished by direct combination of intracerebral dialysis and flow injection analysis with enzymatic fluorescence detection.[143]

Integration of reaction (retention) and detection. The integration of these two aspects is the central philosophy of one other of the most exciting trends in analytical chemistry: (bio)chemical sensors. Some (bio)chemical sensors were already commented on earlier (*e.g.*, in dealing with immobilization in the flow-cell in section A, and with analyte/product immobilization for simultaneous determinations in section C. There are other interesting examples in the FIA literature that testify to the suitability of these approaches. One such example is the immobilization of a reagent on a support packed in a flow-cell (luminol on CPG or silica for peroxide determinations[144]) and the attachment of antigens (IgG) to a membrane mounted in a flow-cell of 5-μl dead volume.[145] In this case, the analyte, in the form of mouse antibovine IgG, was injected into the flowing stream followed by a goat anti-mouse IgG horseradish peroxidase (HRP) conjugate. The HRP was used to catalyse the enhanced luminol reaction, which produced chemiluminescence that was detected directly within the immunoreactor. Other interesting biosensors for determination of ATP with bioluminescence detection,[146] that of ammonia with gas-diffusion/optosensing system,[147] and for enzyme activity monitoring[148] have been reported. Also, a solid-surface room-temperature optosensor was developed for the determination of aluminium in clinical chemistry.[149]

Automation of the preliminary steps of the analytical process by use of solid interfaces

One of the chief targets of automation is the preliminary steps of the analytical process, which involve a variety of tedious operations that are the source of major error in the overall process.[1] Several attempts have been made at developing FI methods in which solid samples are directly introduced into the manifold, thus

avoiding the dissolution step by leaching the solid sample with a suitable agent and the aid of auxiliary external energy such as ultrasounds, electrical current or heat.

Selective electrolytic dissolution. Selective electrolytic dissolution of some minor components in stainless-steels has been achieved by applying an adequate current intensity, whether for further simultaneous determination by ICP/AES[150] or for a single determination by using FAAS[151] or a conventional spectrophotometer after a derivatizing complex-formation reactions.[152]

Ultrasonic energy. This allows lixiviation of solid samples placed in a special cell through which the leaching solution is recirculated while the cell is subjected to ultrasonic cavitation. The photometric determination of boron in soils[153] and that of iron in plant material[154] testify to the high potential of this approach.

The determination of total organic halogen in solid substances was addressed by sample combustion/FI conductimetry with on-line preconcentration.[155] The sample was subjected to high-temperature combustion in an oxygen stream. Halogen-containing decomposition products were preconcentrated from the gas stream by absorption in a capillary denuder tube coated with an aqueous solution of hydrazine monohydrohalide salt, whereas carbon-sulphur- and nitrogen-containing combustion products were removed by the carrier gas. The hydrohalic acid formed in the liquid film was then eluted by a stream of the adsorbent circulated through an electrolytic conductivity microdetector.

Indirect determinations involving solid interfaces

On-line couplings of continuous separation techniques such as ion-exchange, liquid–liquid extraction and precipitation to atomic absorption spectrometric detection results in the above-described advantages, and also in the possibility of implementing indirect determinations and thus extend the scope of application of these detectors to organic and non-metal inorganic species. These determinations may involve dissolution of the retained precipitate,[156] or ion-exchange processes.

Precipitation. Chloride and oxalate were determined by continuous precipitation/filtration/dissolution in the ranges 3–100 μg/ml and 5–90 μg/ml, respectively.[157] The precipitate was formed by injecting the anion (analyte) into a carrier containing a cation (reagent) and was retained on a stainless-steel filter. In the determination of local anaesthetics (lidocaine, tetracaine and procaine) at the μg/ml level[158] and of sulphonamides in pharmaceutical preparations,[159] the precipitate was formed by injecting cobalt, copper or silver ion into a carrier containing the sample and was subsequently retained on a filter. The difference between the signals obtained by injecting the cation into a blank carrier and by using the sample as carrier was related to the concentration of the drug.

Ion-exchange processes. These also provide a means of performing indirect determinations. Thus, a Chelex-100 resin packed column was used to determine EDTA by FAAS. In a first step, a copper(II) solution was injected to regenerate the column. The excess copper ion not retained on the column was washed with an ammonia solution carrier. In the second step, an injected EDTA sample displaced an equivalent amount of copper(II) from the chelating column which was subsequently determined by FAAS.[160] Petersson *et al.* reported an FI method that combines precipitation and ion-exchange for the indirect determination of sulphide by FAS. Sulphide was precipitated by cadmium(II) and the precipitate was allowed to pass unhindered through the FI system for AAS detection, while excess cadmium was removed by the ion-exchange column and later eluted.[161] Also, the overall concentration of anionic surfactants was determined indirectly by AAS measurement of the copper(II) present in an organic layer after formation of a detergent/1,10-phenanthroline/copper(II) ion-pair and extraction into methyl isobutyl ketone.[162]

Other problems solved by using solid interfaces in FI systems

In addition to the above-described advantages, solid interfaces provide a valuable means of circumventing some shortcoming and improving the features of given methods. Thus, by *in situ* formation of unstable reagents in FI systems using solid redox reactors, derivatizing reaction can be improved by avoiding heat losses (thermochemical reactions) by allowing sequential development of multi-step derviatizing reactions, or enabling simultaneous measurements on matrix and sample, among others.

Generation of unstable reagents. Shortcomings involved in the use of unstable reagents in batch systems (*e.g.*, frequent standardization, storage difficulties, time consumption) are avoided by

in situ generation in the flow manifold as the time interval between production and use is quite short and reproducible.[163] Strong reductants such as chromium(II),[164–166] vanadium(II)[165–167] and molybdenum(III)[168] can be generated in-line from stable Cr(III), V(IV) and Mo(VI), respectively, by using a Jones reductor column.

Minimization of heat losses. A packed bed reactor was used instead of the ordinary narrow-bore in the thermochemical determination of iodine based on its catalytic effect on the reaction between Ce(IV) and As(III) in order to minimize heat losses. As a rule, thin tubes have a much larger surface area across which heat can leak than do packed beds of an equivalent volume.[169]

Simultaneous samples and matrix measurements. Two conductance cells and an enzyme reactor placed between them provide a simple means of performing simultaneous sample and matrix measurements. Figure 5(A) shows the FI manifold used for the determination of urea based on its urease-catalysed hydrolysis and conductimetric monitoring of the sample both before and after passage through the enzyme reactor.[170]

Sequential development of different steps. Figure 5(B) makes an excellent example of the different steps involved in the pre-treatment and derivatizing reaction for complex samples. This manifold, which was used for the determination of galactose in serum samples, allows sequential development of the following items: a dialysis process for removing macromolecules, passage of the dialysate through a Bond-Elut-NH_2Cu column for interference removal and through a catalase reactor for withdrawal of hydrogen peroxide (not only that from the sample, but also that yielded in reactions taking place in the Cu reactor). On passing through the galactosidase reactor, galactose produces hydrogen peroxide that is monitored through the colour formed in an oxidative coupling reaction in the peroxidase reactor. A column packed with arylamine-activated porous glass inserted in the reagent stream adsorbs the impurities.[52]

CONCLUSIONS

As shown above, solid interfaces endow flow injection analysis with an even higher potential that can be exploited for a wide variety of purposes only limited by the user's ingenuity.

Future developments in the use of solid interfaces in FIA will presumably be concerned with:

(a) The introduction of solid samples into FI manifolds in order to avoid or reduce the preliminary steps of the analytical process,

(b) the miniaturization of experimental setups so as to decrease sample and reagent consumption, and

(c) the development of new types of (bio)chemical sensors for on-line and in-line measurements in the industrial and clinical field.

These three general trends of today's analytical chemistry are particularly outstanding in flow injection analysis, for which the use of solid interfaces is an irreplaceable means of implementing approaches that open up new prospects for solving past, present and future problems.

DETERMINATION OF SULFUR SPECIES BY CATHODIC SQUARE WAVE STRIPPING VOLTAMMETRY; COMPOUNDS RELEVANT TO NATURAL SULFUR MINERALIZATION

R. VON WANDRUSZKA* and X. YUAN
Department of Chemistry, University of Idaho, Moscow, ID 83843, U.S.A.

M. J. MORRA
Division of Soil Science, University of Idaho, Moscow, ID 83843, U.S.A.

(*Received* 17 *March* 1992. *Revised* 7 *May* 1992. *Accepted* 13 *May* 1992)

Summary—The feasibility of rapid analysis of a number of environmentally important sulfur compounds by cathodic square wave stripping voltammetry at a mercury electrode has been investigated. For cysteine/cystine a relatively anodic peak was identified, which is ascribed to the stripping of a mercurous species. The dependence of the peak currents on pH was found to be different for cysteine and cystine. Methionine and thioproline gave similar stripping peaks to those for cysteine. It is proposed that they arise from species deposited by oxidative hydrolysis. A complex ion is proposed to cause the stripping peak of thiosulfate and tetrathionate, while polysulfides give both a HgS stripping peak and a non-adsorptive reduction peak. Limits of detection are in the 10^{-8}–$10^{-9}M$ range.

A number of analytical techniques have been used to investigate the mineralization processes of *L*-cysteine, $HSCH_2CH(NH_2)COOH$, [CySH], and *L*-cystine, $HOOC(NH_2)CHCH_2S$-$SCH_2CH_2CH(NH_2)COOH$, [CySSCy], in soils and other matrices.[1–8] A general shortcoming of the various determinations is the analytical speed, which is often too slow to resolve the rapid chemical changes that occur during the incubation of the compounds with soil, especially in the early stages. Square wave voltammetry provides a fairly comprehensive analysis in a matter of seconds, without sample pretreatment. Its high sensitivity and wide range of application for S-compounds allow the use of small sample sizes, minimizing the disturbance of the system.

Many of the major sulfur containing anions other than sulfate react with the mercury electrode according to the reactions in Table 1.[9,10] The anodic reactions of sulfide, sulfite, and thiosulfate have been much studied, and in general their $E_{1/2}$ values depend on the pH and the composition of the supporting electrolyte. Some compounds give double voltammetric waves, of which the first (least negative $E_{1/2}$) is usually the best defined. Recently, adsorptive stripping voltammetry has been developed to determine organic S-compounds at the mercury electrode.[10–16] Florence[10] explained the adsorption in terms of the formation of a mercury-thiol complex. Forsman[14] observed that in the presence of copper ion, the stripping current of cysteine and cystine is enhanced due to the adsorption of their Cu(I) complexes. In this investigation, a number of species relevant to natural mineralization has been determined. The present study focuses on the mechanism of the electrode reactions involved.

EXPERIMENTAL

Instrumentation and procedure

Voltammetric measurements were taken with a Sargent-Welch 7001 voltammetric analyzer. The working electrode was a Metrohm 335 hanging mercury drop electrode (HMDE), with an electrode surface of 1.4 mm^2. A platinum wire auxiliary electrode and a saturated calomel reference electrode were used to complete the cell, which was closed, deaerated, and blanketed with oxygen-free nitrogen. The assembly was connected to a Sargent-Welch Model-VES electrode stand. For mechanistic studies, 60-sec anodic accumulation times and stirred solutions

*Author for correspondence.

Table 1. Reactions of S-species at the mercury electrode

1.	$2\,S_2O_3^{2-} + Hg = Hg(S_2O_3)_2^{2-} + 2e^-$	$E_{1/2} = -0.12$ V
2.	$2\,SO_3^{2-} + Hg = Hg(SO_3)_2^{2-} + 2e^-$	$E_{1/2} = -0.60$ V
3.	$SH^- + Hg = HgS + H^+ + 2e^-$	$E_{1/2} = -0.68$ V
4.	$S_x^{2-} + Hg = HgS + (x-1)S + 2e$	$E_{1/2} = -0.68$ V
5.	$S_x^{2-} + 2(x-1)e^- + xH_2O = xOH^- + xSH$	$E_{1/2} = -0.68$ V

7.	$CySSCy + Hg = (CyS)_2Hg$	$E_{1/2} = -0.52$ V

were used, unless stated otherwise. Each determination was carried out on a fresh mercury drop. Square wave voltammograms were run at a frequency of 150 Hz, with 5-mV step size and 5-mV pulse amplitude. Cyclic voltammetry was conducted in the staircase mode, with a step width of 5 msec and a scan rate of 100 mV/sec.

Chemicals

The sulfur containing organic and inorganic compounds used in the experiments: *L*-cysteine, *L*-cystine, thioproline (4-thiazolidinecarboxylic acid), DL-methionine, *L*-cysteic acid (cysteine sulfonic acid), cysteamine, sodium sulfate, sodium thiosulfate, sodium sulfite, sodium sulfide, sodium tetrathionate, sodium dithionite, and sodium meta-disulfite were of reagent grade, supplied by Sigma, Baker, and Aldrich. The purity of organic reagents was checked by thin-layer chromatography, using silica gel plates and 1:1 ethanol:water eluent. All stock solutions were prepared in deaerated demineralized water, treated with a Millipore purification system to 18 MΩ cm resistivity. The buffer solutions used were $0.01M$ $NaB_2O_7 + 0.01M$ Na_2HPO_4 (pH 8.5), $0.1M$ $KH_2PO_4 + 0.017M$ NaOH (pH 6.2), and $0.01M$ NaOAc + $0.01M$ HOAc (pH 4.5). They were purged with oxygen-free nitrogen to remove dissolved oxygen, before being used for the determination of easily oxidized S-compounds.

RESULTS AND DISCUSSION

Cysteine and cystine

It is generally agreed that the anodic voltammetric behavior of cysteine is a result of the reaction:

$$Hg + 2CySH \rightarrow Hg(CyS)_2 + 2H^+ + 2e^- \quad [1]$$

It has been observed, however, that the reduction of mercury cysteinate sometimes results in two waves, separated by 0.1 V, usually at relatively high cysteine concentrations.[10,17-19] Miller[19] attributes the double wave to the presence of both $Hg_2^I(CyS)_2$ and $Hg^{II}(CyS)_2$ deposited on the surface, the more positive peak being due to the Hg(I) compound. Stankovich[17] explains the split as a result of "compacting" of the mercury cysteinate film, while Florence[10] ascribes it to a surface impurity. In the present study, cathodic square wave voltammetry (CSWV) was found to produce a narrow, well defined peak at −0.55 V (SCE) for low concentrations (nM level) of both cysteine and cystine. The wave is split somewhat unpredictably, with a separation of 0.05–0.1 V, but the peak areas are complimentary (Fig. 1). The split may be due to the formation of an adsorbed Cu(I)-cysteinate complex,[14,15] the Cu(I) arising from a copper impurity and producing the more positive peak. The possible influence of other

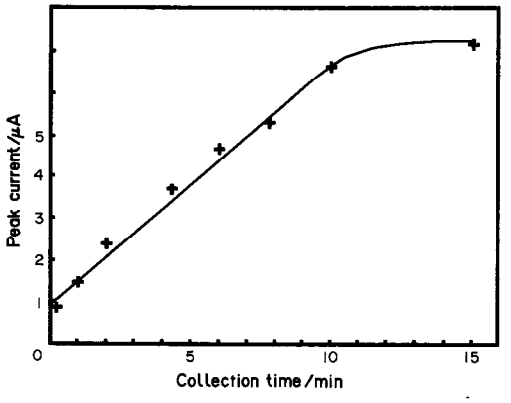

Fig. 3. Plot of combined cysteine stripping peak heights (−0.15 V and −0.55 V) *vs.* collection time; [CySH] = $1.0 \times 10^{-7}M$; pH = 8.5; deposition potential 0.0 V.

adventitious metal ions requires further investigation. The CSWV peak current at −0.55 V was found to be proportional to the cysteine concentration up to $5 \times 10^{-7}M$ with measurement possible down to $5 \times 10^{-9}M$ (Fig. 2) when a −0.2 V deposition potential was used. This is an improvement over results obtained with differential pulse cathodic stripping voltammetry.[10] When a 0.0 V deposition potential, or open circuit conditions are used, the calibration curve loses its linearity at concentrations greater than $5 \times 10^{-8}M$.

Besides the peak at −0.55 V, a broad wave around −0.15 V was found for both cysteine and cystine (Fig. 1). The peak height increases with concentration in the range 8×10^{-8} to $1 \times 10^{-6}M$, but this variation is not linear, since the peak heights at −0.15 V and at −0.55 V were found to be complementary. Their sum varies linearly with concentration, as well as with deposition time up to about 10 min (Fig. 3). The loss of linearity at longer times may be due to eventual surface saturation. The cyclic voltammogram (taken after 60 sec deposition at 0.0 V; Fig. 4) shows only an anodic peak, corresponding to the −0.55 V cathodic peak.

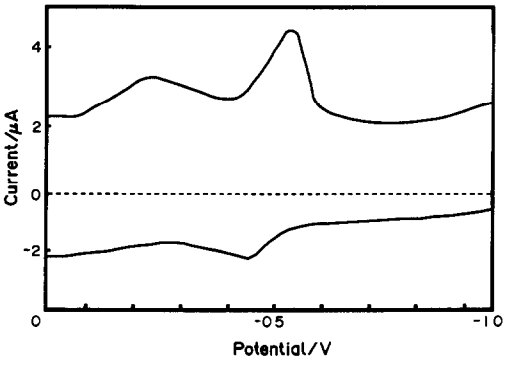

Fig. 4. Cyclic voltammogram of cysteine; [CySH] = $1.0 \times 10^{-5}M$.

In view of these observations it may be proposed that both $Hg_2^{I}(CyS)_2$ and $Hg^{II}(CyS)_2$ are formed, and that the former can be stripped over a fairly wide potential range around −0.15 V. Cysteine is therefore present in two adsorbed forms, resulting in the complementary nature of the two stripping peaks. Once stripped, the mercurous species does not reform at the electrode in the reverse (anodic) sweep of the cyclic voltammogram. This seeming irreversibility, indicated by the absence of the anodic peak at −0.15 V, may be due to a disproportionate reoxidation of the stripped species to the mercuric complex during the reverse sweep.

To provide further evidence for the origin of the peak at −0.15 V, cathodic scans were taken from a deposition potential of +0.20 V, at a relatively high cysteine concentration of $1.0 \times 10^{-6}M$. The only peak observed was the one at −0.55 V, corresponding to $Hg^{II}(CyS)_2$. This is consistent with the proposed process, since Hg_2^{2+}—and hence the mercurous complex —cannot exist at such an anodic potential.

The solubility product of $Hg_2^{I}(CyS)_2$ can be estimated from the peak potential, E_p, of the complex and the dissociation constant of the amino acid:[10]

$$E_p = E^\circ(Hg_2^{2+}/Hg) + 0.060(0.5 \log K_{sp} + \log K_a - \mathrm{pH} - \log[\mathrm{CySH}]) \quad (2)$$

With a buffer solution of pH 8.5, [CySH] = 1.0×10^{-7}, $E_p = -0.15$ V (SCE), $E^\circ(Hg_2^{2+}/Hg) = 0.556$ V, and $pK_a = 8.36$ (thiol group), pK_{sp} for $Hg_2^{I}(CyS)_2$ is 29.2. In view of the much smaller solubility of $Hg^{II}(CyS)_2$ ($pK_{sp} = 56.7$), the loss of linearity of the calibration curve can be explained. When the cysteine concentration is low ($< 5 \times 10^{-8}M$), only $Hg^{II}(CyS)_2$ is produced, because of the larger solubility of $Hg_2^{I}(CyS)_2$, which shifts its decomposition potential in an anodic direction [equation (2)], precluding the formation of the complex at a deposition potential of 0.0 V. At higher cysteine concentrations both species can be formed, and a deposition potential of −0.2 V (more cathodic than the first stripping peak) is necessary to avoid formation of $Hg_2^{I}(CyS)_2$. The occurrence of $Hg_2^{I}(CyS)_2$ is therefore limited to potentials that lie roughly between 0.2 V and −0.2 V. Cystine behaves similarly.

Equation (2) indicates that a lowering of the pH should cause an anodic shift of the cathodic

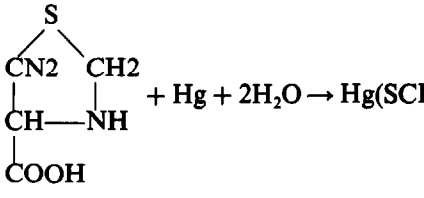
stripping peak for the cysteine–mercury complex. This is borne out by the data presented in Fig. 5. A lowering of the pH also causes a decrease in peak heights due to proton competition [a shift to the left in the amino acid dissociation, equation (1)]. At pH 8.5 the sensitivities of the peaks are nearly the same for cysteine and cystine. However, the sensitivity for cysteine is much greater than that for cystine at pH 6.2 and 4.5, *i.e.*, cystine is more strongly affected by pH change. At a total amino acid concentration of $5 \times 10^{-7}M$ and a pH of 6.2, the peak for cysteine reduces to about 80% of its size at pH 8.5, but the cystine peak reduces to about 20% under similar conditions. At pH 4.5 the peak corresponding to the cystine reaction disappears, while the one for cysteine remains (Fig. 5). The different effect of pH on cysteine and cystine could provide a way to distinguish the two compounds by CSWV.

The peak due to the mercurous cysteine complex, $Hg^{I}_2(CyS)_2$, also disappears at pH 4.5. This may be due to increased solubility of the complex at lower pH values, or to the anodic shift of E_p, that moves it beneath the large mercury oxidation wave at 0.2–0.3 V.

Other sulfur compounds

The cathodic square wave stripping peaks of a number of compounds important for sulfur cycling in soil are listed in Table 2. Thioproline and methionine give voltammograms that are similar to those of cysteine/cystine, with only slight shifts in the three peaks. In view of the fact that these compounds give strong stripping peaks that are proportional to the bulk concentration, and that thin layer chromatography shows the absence of detectable cysteine/cystine impurities, it must be concluded that the similarity of the stripping peaks of cysteine, cystine, methionine, and thioproline indicates that the anodically adsorbed species of these four compounds are alike. This calls for an adsorption mechanism involving the methylated sulfhydryl group. In order to lead to similar stripping behavior, this interaction probably also involves oxidative compound formation, as shown in cysteine in Table 1. It may be suggested that the following anodic accumulation reactions take place with methionine and thioproline, respectively:

$$2HOOC(NH_2)CHCH_2CH_2SCH_3 + Hg + 2H_2O \rightarrow (HOOC(NH_2)CHCH_2CH_2S)_2Hg + 2CH_3OH + 2H^+ + 2e^-$$



The stripping of these compounds produces the observed cathodic peaks. The stripping behavior of cysteamine, $HSCH_2CH_2NH_2$ is also similar to that of cysteine, which is expected in view of its chemical similarity.

Cathodic stripping voltammetry of inorganic sulfide has been extensively studied.[12,20–23] In the present work, a sharp stripping peak was

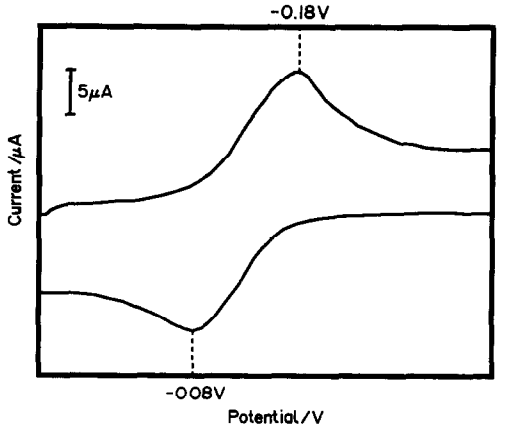


Fig. 6. Cyclic voltammogram of thiosulfate ($5.0 \times 10^{-5}M$).

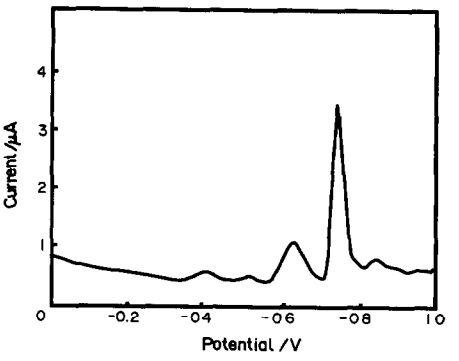

Fig. 7. CSWV of polysulfide ($1.0 \times 10^{-6}M$).

observed at −0.72 V by CSWV. An accumulation potential of 0.0 V was applied for 60 sec prior to stripping, and analytical results were similar to those obtained by other workers.[21]

The anodic electrode reaction of thiosulfate has been used for analytical purposes for many years.[9,24,25] Wienhold and Sohr[26] have described a catalytic hydrogen wave, useful for the determination of thiosulfate in the concentration range 5×10^{-8}–$5 \times 10^{-5}M$. No information is available in the literature on the determination of thiosulfate by cathodic scan voltammetry. In the present investigation, a reductive stripping peak was found at −0.18 V, which is linearly related to the thiosulfate concentration over the range 8×10^{-9} to $5 \times 10^{-7}M$. The peak height and potential are virtually unaffected by pH in the range 2.5–9.2 and by deposition time. The latter indicates that the electrode process is not an adsorptive one. The cyclic voltammogram shows both cathodic and anodic peaks (Fig. 6).

A mechanism for the production of the thiosulfate peak by CSWV may be proposed, which is the reverse of the anodic mechanism described by Renard *et al.*[25] These authors suggest that the anodic peak is due to the following reactions:

$$Hg \rightarrow Hg^{2+} + 2e^- \quad [3]$$

$$Hg^{2+} + 2\ S_2O_3^{2-} \rightarrow [Hg(S_2O_3)_2]^{2-} \quad [4]$$

The $E_{1/2}$ value for this process (Table 1) is −0.12 V, and it will therefore occur significantly in the early parts of the cathodic scan starting in 0.0 V. A surface equilibrium of the ionic species is quickly established, and extended accumulation does not substantially alter its concentration near the electrode, as it is subject to diffusion. During the cathodic scan, the reverse of reactions 3 and 4 takes place, leading to the observed current peak. The cathodic process has a limit of detection of $8 \times 10^{-9}M$, which is almost 4 orders of magnitude lower than the reported value for the anodic process. This may be partially due to the inherent response of the fast square wave scan, and partially to a relatively high surface concentration of $[Hg(S_2O_3)_2]^{2-}$, enhanced by some degree of electrostatically induced adsorption of the ion.

Polysulfides, synthesized as described by Rosen and Tegman,[27] gave cathodic square wave voltammograms that were very similar to those of sulfide, showing a large HgS stripping peak at −0.72 V (Fig. 7). In addition, some smaller peaks are shown, that probably arise from other adsorbed sulfide species. However, the peak at −0.62 V is independent of accumulation time and may be due to the reaction:

$$S_2^{2-} + 2e^- + 2H_2O \rightarrow 2SH^- + 2OH^- \quad [5]$$

Reaction (5) involves no anodically adsorbed species and depends on bulk concentrations only.

Tetrathionate gives cathodic scan peaks that are similar to those observed for thiosulfate, and probably arise through a similar mechanism. Sulfite gives no peaks in CSWV.

CONCLUSION

CSWV of environmentally important sulfur compounds is a sensitive and widely applicable analytical technique that provides the speed of analysis needed for natural samples that are subject to rapid chemical changes. A series of applications to the mineralization study in natural samples will be communicated in a subsequent publication. A number of the analytically useful current peaks observed require mechanistic interpretation, and anodic compound formation is proposed in most instances.

APPLYING THE PHENOL RED COLORIMETRIC METHOD FOR BROMIDE ANALYSIS TO REDUCING WATERS

DAVID R. JONES
CSIRO Division of Coal and Energy Technology, P.O. Box 136, North Ryde, N.S.W. 2113, Australia

(*Received* 26 *March* 1992. *Accepted* 12 *May* 1992)

Summary—Chemical species present in reducing waters have the potential to produce severe negative interferences by consuming the chloramine T (CT) which is used as the oxidising agent in the phenol red-based colorimetric method for trace bromide analysis. Mn^{2+} and Fe^{2+} were found not to interfere at concentrations up to 200μM. However, hydroxylamine (NH_2OH), which can be present in both ground- and surface-waters, exerts a strong negative interference. A method involving pre-treatment with permanganate and hydrogen peroxide has been developed for the destruction of NH_2OH prior to adding the colour reagents. The procedure is not only compatible with the chemistry of the colorimetric method, but is also robust and technically easy to implement.

The reaction of hypobromite with phenol red to produce bromophenol blue affords a very sensitive method for the determination of bromide in solution.[1] Previous work by the author has been directed towards optimizing this method for the analysis of bromide in aerobic surface waters.[2,3]

However, there are many cases in which naturally or anthropogenically produced waters of low redox potential may need to be analysed for bromide. The Chloramine T (CT) used in the colorimetric method for the oxidation of Br^- to reactive OBr^- can be consumed by competitive reactions with the reduced chemical species that are present under such circumstances. Significant depletion of CT by this route would result in a negative interference in the formation of bromophenol blue.

Iron and manganese oxides dissolve under mildly reducing conditions to produce Mn^{2+} and Fe^{2+}. The electrochemical half cell potentials for reactions involving these ions indicate they should be oxidized by CT.[4,5] Elevated levels of Mn^{2+} and Fe^{2+} are typically found in groundwaters and in surface water draining areas such as marshes where decay processes have lowered the redox potential. The reduced nitrogen compound hydroxylamine (NH_2OH) is an intermediate both in nitrification reactions and in the reduction of oxidized nitrogen to ammonia.[6,7] This compound is therefore likely to be found in mildly reducing waters. Concentrations up to 100μM have been measured in water draining marshlands in Ethiopia.[7] It has also been detected, at much lower concentrations, in coastal marine systems.[8] Anthropogenic sources of hydroxylamine include boiler water to which it is added as a corrosion inhibitor.

Previous work by the author has shown that hydroxylamine produces a severe negative interference in the bromide method since it reacts stoichiometrically with CT, with a rate constant that is comparable with the oxidation of bromide.[2] Although both Mn^{2+} and Fe^{2+} have the potential to interfere with the method, little work has been published on quantifying the extent of such interferences.[9,10]

There were two major objectives for the work reported in this paper. Firstly, to establish the extent to which hydroxylamine, Mn^{2+} and Fe^{2+} interfere with the colorimetric method for bromide analysis. Secondly, to develop a robust and technically practical method to overcome the identified interferences. The essential criterion for such a method was that it must be compatible with the chemistry of the CT–phenol red procedure.

EXPERIMENTAL

Reagents

All chemicals used were of analytical reagent grade or better. The Chloramine T (sodium *N*-chloro-4-toluenesulphonamide), CT, was recrystallised from hot water and freeze dried

prior to use.[11] Stock solutions of hydrogen peroxide were prepared by dilution of 100 volume hydrogen peroxide, and standardized by titration with potassium permanganate. The stock solutions of hydroxylammonium chloride (NH_3OHCl), potassium permanganate, hydrogen peroxide, CT, and sodium thiosulphate used for this work were stored in amber glass bottles at 4° between experiments to minimise degradation. Fresh working solutions of the $KMnO_4$, H_2O_2, and CT were prepared daily by dilution. The preparation of the reagent solutions (acetate buffer, phenol red, and CT) required for the colorimetric bromide method has been reported previously.[1,2]

All experiments were carried out in 20-ml capacity screw-cap polyethylene scintillation vials. These vials had been precleaned by sequential soaking with detergent and dilute nitric acid. They were rinsed three times with distilled, demineralized water and oven dried prior to use.

Effect of Fe^{2+}, Mn^{2+}, NH_2OH and H_2O_2 on colour development

A separate series of vials was prepared for each of the four test species. For each series 0.5 ml of acetate buffer (final pH on dilution = 4.6) and 0.5 ml of a $5 \times 10^{-3}M$ potassium bromide stock solution (to produce a final concentration of $25\mu M$ Br^- in a volume of 10 ml) was added to each vial. Increasing volumes of working solutions of Fe^{2+}, Mn^{2+}, NH_2OH, or H_2O_2, as appropriate, plus the required volume of distilled water to make up a 10-ml total volume, were then added to each successive vial in the series so that a range of concentrations from 0 to $200\mu M$ was spanned. The bromide colorimetric procedure was then applied to each of the test series, and the extent of bromophenol blue formation measured at 590 nm.[2]

Reaction of Fe^{2+} with CT

The rate of this reaction was studied by measuring the residual concentration of Fe^{2+}. The reaction was initiated by adding CT to a solution of iron(II) sulphate in pH 4.6 acetate buffer such that the initial concentrations of CT and Fe^{2+} were 40 and $100\mu M$, respectively. Aliquots of solution were withdrawn at 30-sec intervals, and quenched by the addition of $100\mu M$ NH_2OH. A solution of 2,2′-bipyridyl was added after 2 min to form the extremely stable and intensely red coloured Fe^{2+}-bipyridyl complex.[12] The colour produced was measured at 470 nm, and the concentration of Fe^{2+} determined by comparison with a standard curve.

The NH_2OH was added to destroy residual CT, whilst preserving the redox speciation of the iron. Although NH_2OH will reduce Fe^{3+} to Fe^{2+}, a preliminary control experiment showed that, under the conditions of this experiment, the rate of this process was sufficiently slow that it would not complicate interpretation of the results from the above experiment.

Screening of reagents to decompose hydroxylamine

To vials containing $25\mu M$ potassium bromide and $100\mu M$ NH_2OH buffered at pH 4.6 were added stoichiometric excesses of $NaClO_3$, $Fe_2(SO_4)_3$, $KMnO_4$, K_2CrO_4, or H_2O_2. After 20 min the bromide colorimetric reagents were added. The developed colour was measured at 590 nm after a further 20 min.

Stoichiometry of the MnO_4^-/NH_2OH reaction

The optimum MnO_4^- to NH_2OH ratio was found by measuring the extent of colour formation following the addition of the phenol red and CT reagents to solutions containing fixed concentrations of Br^- and NH_2OH that had been treated with different amounts of MnO_4^-. The MnO_4^- to NH_2OH ratios studied ranged from 0 to 0.67.

The required volume of potassium permanganate stock solution plus sufficient distilled water to make up 1 ml was rapidly mixed with 10 ml of a premixed solution containing $25\mu M$ Br^-, $110\mu M$ NH_2OH, and 0.5 ml of acetate buffer concentrate. The initial concentration of NH_2OH in the total volume of 11 ml was therefore $100\mu M$. The phenol red and CT reagents were added after 20 min since spectrophotometric kinetic experiments showed that the reaction between the MnO_4^- and NH_2OH was complete within 10 min in the temperature range 20–25°. A second experiment was carried out in order to measure the extent of MnO_2 production as a function of the amount of MnO_4^- added. In this case the procedure was terminated after 20 min when the absorbance of the solution was measured at 425 nm. This wavelength, although not corresponding to the maximum in absorbance for the colloidal suspension of MnO_2, was found to be the least susceptible to overlap from chromophores of the other reagents used in this investigation.

The first experiment detailed above was repeated with the addition of $250\mu M$ hydrogen

peroxide prior to the colorimetric reagents. The H_2O_2 was added to decompose the excess MnO_4^- that would otherwise negatively interfere with the subsequent colour development. Kinetic experiments showed that the reaction with hydrogen peroxide was complete in less than 5 min. A time of 10 min was therefore allowed for this step.

Reaction between Mn^{2+} and MnO_4^-

The reaction between these two species was monitored at both 425 and 542 nm. The former wavelength provides a measure of the production of MnO_2 (see above) whilst the latter corresponds to the absorbance maximum of MnO_4^-. Appropriate volumes of dilute solutions of $MnCl_2$ and $KMnO_4$ were rapidly mixed to obtain the required initial concentrations of reactants.

Measurement of NO_2^- production

The NO_2^- produced in the reaction between NH_2OH and MnO_4^- was measured by using a colorimetric diazotization procedure.[13] Trial experiments showed that the pH for the NO_2^- method must be below 2 to ensure full colour development. This necessitated preparing the sulphanilamide reagent in a 36% (v/v) solution (36 ml of concentrated acid in 100 ml total volume) of hydrochloric acid in order to overcome the buffering capacity of the acetate buffer solution in which the reaction between NH_2OH and MnO_4^- was carried out.

It was also found that the presence of MnO_2 (generated when the MnO_4^- to NH_2OH ratio exceeded 0.5) resulted in a severe negative interference. This was overcome by reducing the MnO_2 to Mn^{2+} with 130μM hydrogen peroxide prior to adding the nitrite reagents. A standard curve prepared in the presence of 130μM hydrogen peroxide was used to convert absorbance values to concentrations.

Evaluation of the method

All of the experiments described above were done in a reaction medium based on distilled water. However, in evaluating the robustness and precision of the coupled NH_2OH decomposition-bromide colorimetric procedure a synthetic medium of initial ionic composition likely to be more typical of a real sample was used. This contained 3mM NaCl, 1mM $NaHCO_3$, 1.5mM $MgCl_2$, and 0.3mM $MgSO_4$.

Four standard curves (0, 5, 10, 15, 20, 30μM Br^-) were prepared using 0, 20, 50 or 100μM NH_2OH. Each point on each of the standard curves was run in triplicate. The generic procedure used is detailed below:

(1) Prepare a vial containing the required volume of 500μM potassium bromide standard, the required volume of 2000μM NH_3OHCl standard, and sufficient synthetic ionic medium to make up a total of 10 ml.

(2) Add 0.5 ml of acetate buffer, and mix.

(3) Add 0.5 ml of a 2mM potassium permanganate solution, and mix. Then stand for 20 min.

(4) Add 0.5 ml of a 6mM hydrogen peroxide solution, and mix. React for 10 min.

(5) Add 0.5 ml of phenol red solution.

(6) Add 0.5 ml of CT and **immediately** mix well. React for 20 min.

(7) Add 0.1 ml of sodium thiosulphate reagent, and mix. Stand for at least 10 min before measuring the absorbance of the solution at 590 nm.

RESULTS AND DISCUSSION

An initial set of experiments was carried out to determine the ability of hydroxylamine, Mn^{2+} and Fe^{2+} to interfere with colour development. The colorimetric procedure developed by the author was applied to solutions containing 25μM Br^- and varying concentrations of the three test solutes (Table 1).[2] The hydroxylamine (NH_2OH) would be predominantly in its protonated hydroxylammonium form (NH_3OH^+, $pK_a = 5.98$) at the prevailing pH of 4.6.[14] The results in Table 1 show that NH_2OH is by far the most potent inhibitor of bromophenol blue formation. Fe^{2+} exhibits a slight interference at 200μM, whilst Mn^{2+} has no significant effect up to 200μM. This result was surprising since electrochemical potentials indicate that Fe^{2+} and Mn^{2+} should be readily oxidized by CT.[4] The reaction between Fe^{2+} and CT was therefore investigated in more detail to determine

Table 1. Effect of inhibitor concentration on colour development

Concentration of inhibitor, μM	Percent colour development at 590 nm		
	NH_2OH	Fe^{2+}	Mn^{2+}
0	100	100	100
20	61	100	—
40	0	101	101
80	0	101	—
100	0	100	103
200	—*	95	103

*This concentration of potential inhibitor was not used.

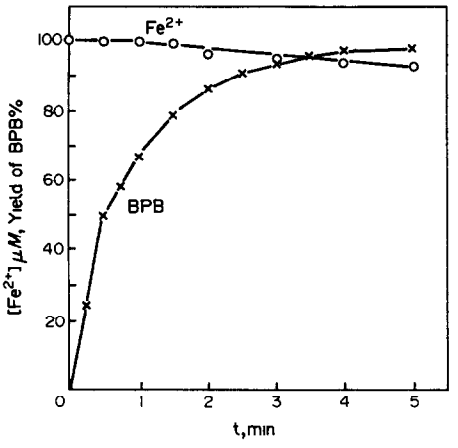

Fig. 1. Kinetics of oxidation of Fe^{2+} by CT (O——O) compared with kinetics of bromophenol blue (BPB) formation (×——×) in the bromide method. The generation of BPB is expressed as a percentage of the maximum absorbance at 590 nm attained by applying the colorimetric method to a 25μM Br^- standard solution.

why the above results differed from the outcome predicted by thermochemical considerations.

Reactivity of Fe^{2+}

The data from the experiment to measure the rate of reaction between Fe^{2+} and CT are plotted in Fig. 1. They show that the rate of this reaction is at least an order of magnitude slower than the series of reactions leading to the formation of bromophenol blue. In this case the extent of interference is limited by kinetic rather than thermodynamic constraints. It is probable that the reaction with Mn^{2+} is similarly rate limiting.

Removal of interference by hydroxylamine

The starting point for this investigation was the selection of reagents that could oxidize NH_2OH. There are several possible oxidation products of this compound that could be formed.[15] However, published work indicates that N_2, N_2O, NO_2^- and NO_3^- (nitrogen oxidation states of 0, +1, +3, and +5, respectively) are the most likely ones in this case.[16–18] The half cell reactions for each of these potential products are shown in equations (1) to (4). The half cell potentials were obtained directly from the literature or were derived from published thermodynamic data.[4,19] It should be noted that a number of sequential fundamental steps could be involved in the multiple electron transfer half cell reactions described by equations (1) to (4).

$$N_2 + 4H^+ + 2H_2O + 2e^- \rightarrow 2NH_3OH^+ \qquad E^0 = -1.87\ V \quad (1)$$

$$N_2O(aq) + 6H^+ + H_2O + 4e^- \rightarrow 2NH_3OH^+ \qquad E^0 = -0.03\ V \quad (2)$$

$$NO_2^- + 6H^+ + 4e^- \rightarrow NH_3OH^+ + H_2O \qquad E^0 = 0.66\ V \quad (3)$$

$$NO_3^- + 8H^+ + 6e^- \rightarrow NH_3OH^+ + 2H_2O \qquad E^0 = 0.72\ V \quad (4)$$

Based on purely thermodynamic considerations, there are a number of common inorganic oxidizing agents that could oxidize the hydroxylamine. Organic reagents were not considered to be suitable since they could potentially compete with phenol red as substrates for reaction with hypobromite in the subsequent production of bromophenol blue.[2,20]

Potential inorganic oxidizing agents were tested for their ability to decompose hydroxylamine to a non-interfering form. The species studied were MnO_4^-, Fe^{3+}, H_2O_2, $HCrO_4^-$ and ClO_3^-. Solutions containing stoichiometric ratios of hydroxylamine and the test reagents were prepared, and the interference by hydroxylamine measured after 20 min and 3 hr. The criterion for success was that the reaction should be complete within 20 min at pH 4.6 in the temperature range 20–25°. These boundary conditions were selected for both chemical compatibility (with the colorimetric method) and technical (an acceptable time) reasons. Of the reagents tested only permanganate passed this initial screening test.

Permanganate was then subjected to a much more rigorous evaluation. The optimum conditions for reaction needed to be determined, and its compatibility with the colorimetric method rigorously evaluated.

The mechanism of the NH_2OH-MnO_4^- reaction

There are a number of potential products [equations (1) to (4)] of the MnO_4^- oxidation of NH_2OH and each of these will have its own stoichiometric requirements. Since there are two possible half reactions involving the MnO_4^-, this makes a total of eight possible overall reactions that initially needed to be considered. These reactions, together with their respective NH_2OH: MnO_4^- ratios are listed in Table 2. Since the oxidation of NO_2^- to NO_3^- occurs readily only under strongly acidic conditions,[21]

Table 2. Potential reactions between NH_2OH and MnO_4^-*

	Reaction	NH_3OH^+/MnO_4^-
(A)	$4MnO_4^- + 10NH_3OH^+ + 2H^+ \rightarrow 4Mn^{2+} + 5N_2O + 2H_2O$	2.5
(B)	$4MnO_4^- + 5NH_3OH^+ + 2H^+ \rightarrow 4Mn^{2+} + 5NO_2^- + 11H_2O$	1.25
(C)	$MnO_4^- + 5NH_3OH^+ \rightarrow Mn^{2+} + 2.5N_2 + 9H_2O + 2H^+$	5
(D)	$6MnO_4^- + 5NH_3OH^+ + 8H^+ \rightarrow 6Mn^{2+} + 5NO_3^- + 14H_2O$	0.83
(E)	$4MnO_4^- + 6NH_3OH^+ \rightarrow 4MnO_2 + 3N_2O + 11H_2O + 2H^+$	1.5
(F)	$4MnO_4^- + 3NH_3OH^+ \rightarrow 4MnO_2 + 3NO_3^- + 5H_2O + 2H^+$	0.75
(G)	$MnO_4^- + 3NH_3OH^+ \rightarrow MnO_2 + 1.5N_2 + 5H_2O + 2H^+$	3
(H)	$2MnO_4^- + NH_3OH^+ \rightarrow 2MnO_2 + NO_3^- + 2H_2O$	0.5

*At pH 4.6 the NH_2OH will be in its protonated form.

it was considered that the overall reactions represented by equations D and H (which undoubtedly would involve NO_2^- as an intermediate) were not likely to be of relevance to this work. This was confirmed by measuring the rate of reaction between MnO_4^- and NO_2^- at pH 4.6. The half time was found to be of the order of several hours.

The effect of the MnO_4^- to NH_2OH ratio was determined by measuring the extent of colour development in a series of solutions containing fixed concentrations of NH_2OH and bromide, and increasing levels of MnO_4^- (Fig. 2). The initial rise in the percentage of colour (bromophenol blue) formed indicates that the interference from NH_2OH is being removed. However, a maximum of only 80% colour development is attained at $40\mu M$ MnO_4^-. Above $60\mu M$ MnO_4^- there is a steep decline in colour yield.

During the 20 min reaction period following the addition of the MnO_4^- to the reaction vials

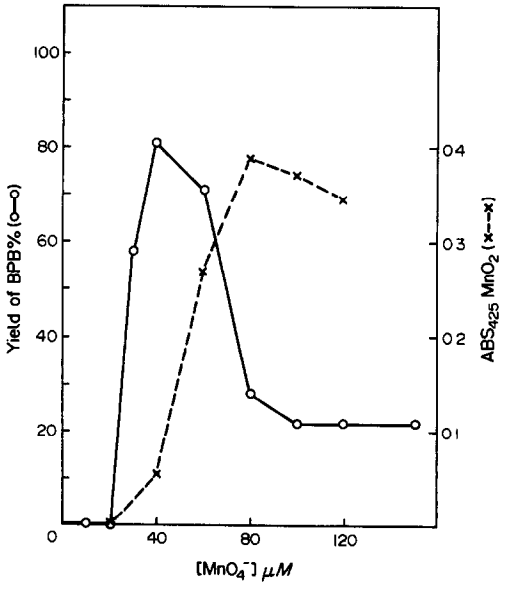

Fig. 2. Production of BPB (O——O) and MnO_2 (×---×) as a function of $[MnO_4^-]$; $[Br]_0 = 25\mu M$, $[NH_2OH]_0 = 100\mu M$, pH = 4.6.

(and prior to the addition of PR and CT) it was noted that a marked brown coloration (presumably due to colloidal manganese oxide, MnO_2) developed in the vials containing greater than $40\mu M$ added MnO_4^-. A surrogate measure of the amount of MnO_2 produced was provided by measuring the absorbance of the solutions at 425 nm after 20 min. These data have been plotted in Fig. 2 for comparison with the bromophenol blue colour development profile.

The above result suggested that manganese oxide, or a residual excess of MnO_4^- was inhibiting colour development. Two control experiments were carried out to test the effects of these species. In the first experiment, the colorimetric reagents were added to a bromide standard solution containing a pre-formed colloidal suspension of manganese oxide. This suspension was produced by stoichiometric reaction between Mn^{2+} and MnO_4^- according to equation (5).[21] Complete development of colour occurred in this case.

$$2MnO_4^- + 3Mn^{2+} + 2H_2O \rightarrow 5MnO_2 + 4H^+ \quad (5)$$

In contrast, the addition of MnO_4^- resulted in a substantial diminution of colour. More detailed testing showed that the MnO_4^- destroyed the bromophenol blue after it was formed (Fig. 3). [The solid line in Fig. 3(b) shows the effect of adding MnO_4^- after colour development was complete, whilst the broken line shows the effect of added MnO_4^- on a standard solution of bromophenol blue.]

The data in Fig. 2 provide a firm foundation for deciding which of the possible reactions listed in Table 2 make a significant contribution. Reactions D and H have already been eliminated from consideration for the reasons given above. Reactions C and G are inconsistent with the stoichiometry revealed in Fig. 2 (maximum BPB production occurs for a NH_2OH to MnO_4^- ratio close to 2.5). The reactions described by equations E and F are also unlikely, both for stoichiometric reasons and for the fact that no

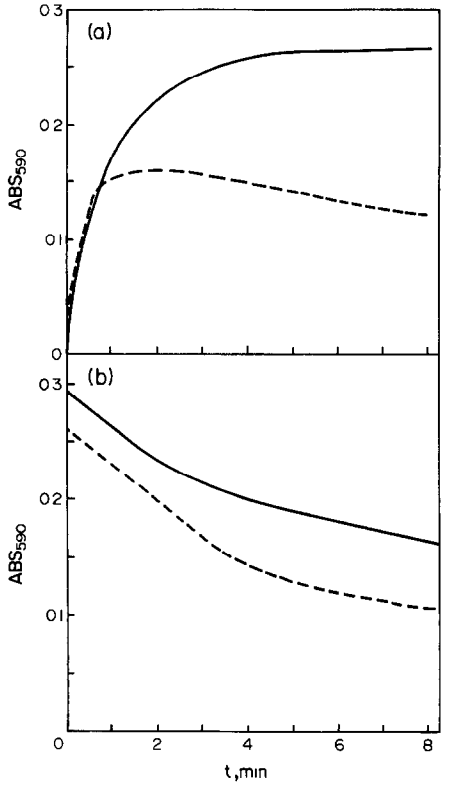

Fig. 3. (a) Kinetics of BPB formation in a 25μM Br^- standard solution in the presence (– – –) and absence (——) of 100μM MnO_4^- (b) Decay of BPB absorbance following the addition of 60μM MnO_4^- to a 25μM Br^- solution in which the colour had initially been fully developed (——); reduction of colour in a solution of reagent grade BPB dye after 60μM MnO_4^- was added (– – –).

MnO_2 is produced until the NH_2OH has been largely destroyed. As a result of this process of elimination, one is left with equations A and B. The results in Fig. 2 are consistent with the stoichiometry of equation A. However, only 80% of the expected colour development in the bromide method occurs at this equivalence point, where there should be no residual NH_2OH or excess MnO_4^- (inhibitors).

The possible products of the oxidation of the NH_2OH in this system are NO_2^- and N_2O (equations A and B, respectively). If the concentration of one of these species is measured directly, the yield of the other product can be obtained by difference. In this case the amount of NO_2^- produced was measured.[13] The results in Fig. 4 show that NO_2^- is a minor, albeit significant, product with a peak solution concentration of 14μM at 40μM MnO_4^-.

This is a very important finding since NO_2^- is the one oxidation product of NH_2OH that will rapidly react with, and consume CT.

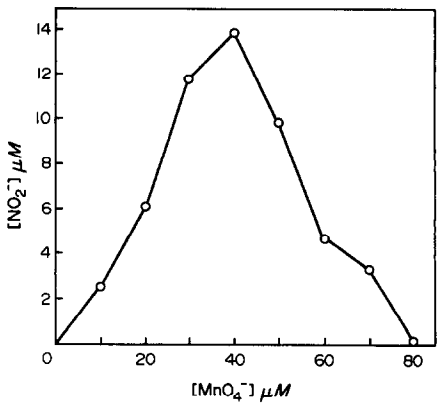

Fig. 4. Production of NO_2^- as a function of $[MnO_4^-]$; $[NH_2OH] = 100\mu M$.

The less than 100% colour yield of bromophenol blue at 40μM MnO_4^- is therefore explained by the production of a small amount of NO_2^-. This problem with residual NO_2^- can be overcome by increasing the concentration of MnO_4^- to 80μM. However, as seen in Fig. 2, the excess MnO_4^- causes serious problems.

The remaining unanswered question is the origin of the colloidal manganese oxide produced in appreciable amounts at MnO_4^- concentrations greater than 40μM. The distribution of the initial products of the reaction between MnO_4^- and NH_2OH can be calculated for each concentration of MnO_4^- by using the yield of NO_2^- (Fig. 4), coupled with the stoichiometries specified by equations A and B in Table 2. This method for calculating the initial distribution of products is a valid one since kinetic measurements show that the MnO_4^- is consumed before MnO_2 is produced (Fig. 5). For 60μM MnO_4^- the absorbance measured at 542 nm (the MnO_4^- chromophore) does not decay to zero owing to

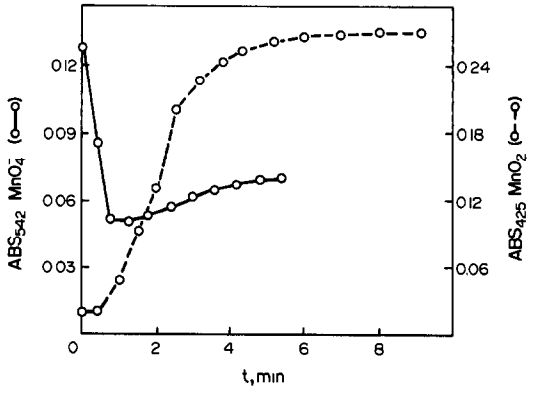

Fig. 5. Reaction between 100μM NH_2OH and 60μM MnO_4^-; decay of MnO_4^- (O——O) and production of MnO_2 (O– – –O).

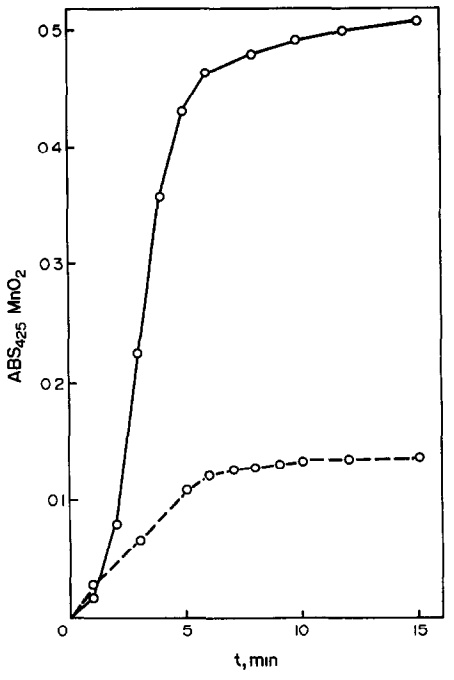

Fig. 6. Production of MnO_2 from the reaction between MnO_4^- and Mn^{2+}. The initial reactant concentrations corresponded to those calculated in Table 4 for the primary distribution of products arising from initial MnO_4^- concentrations of 50μM (O---O) and 80μM (O——O).

spectral overlap from the broad absorbance band of colloidal MnO_2 that develops after 1 min.

The initial calculated concentration balances for the reaction products are shown in Table 3. These results show there will be an excess of MnO_4^- for initial MnO_4^- concentrations greater than 40μM. It has already been mentioned above that Mn^{2+} and MnO_4^- can react at pH 4.6 to produce MnO_2 [equation (5)]. The results of kinetic experiments (Fig. 6) using Mn^{2+} and MnO_4^- concentrations corresponding to $[MnO_4^-]_0$ concentrations of 50 and 80μM in Table 3 showed that the profile of MnO_2 production in Fig. 2 could be accounted for by this reaction. This also explains why the yield of MnO_2 plateaus above $[MnO_4^-] = 80\mu M$. The concentration of Mn^{2+} reaches a constant value, and hence imposes an upper limit on the amount of MnO_2 that can be produced by its reaction with MnO_4^- [equation (5)].

Destruction of residual MnO_4^-

The above investigation showed that residual MnO_4^- must be decomposed before the bromide colorimetric reagents are added. Hydrogen peroxide was initially chosen for this purpose since not only do mildly acidic solutions of this reagent reduce MnO_4^- to Mn^{2+} [equation (6)] but it has also been shown that the Mn^{2+} product of this reaction would not adversely affect the bromide method.

$$2MnO_4^- + 5H_2O_2 + 6H^+ \rightarrow 2Mn^{2+} + 8H_2O + 5O_2 \quad (6)$$

The effect of hydrogen peroxide itself on the colorimetric method was evaluated by measuring the extent of colour production in solutions containing hydrogen peroxide. It was found that colour yield was not decreased by concentrations of hydrogen peroxide as high as 300μM. Trial experiments that involved the mixing of a slight stoichiometric excess of hydrogen peroxide with pH 4.6 solutions containing 80μM MnO_4^- or suspensions of manganese oxides (generated by reaction between 100μM solutions of MnO_4^- and NH_2OH) showed that reduction to Mn^{2+} was complete in less than 10 min (T = 20–25°).

The experiment shown in Fig. 2 was repeated with a hydrogen peroxide reduction step between the initial MnO_4^- treatment and the addition of the colorimetric reagents (Fig. 7). The results from Fig. 2 are included for comparison. The yield of bromophenol blue is seen to be 100% (relative to a bromide standard solution) for MnO_4^- concentrations greater than 70μM ($[NH_2OH]_0 = 100\mu M$).

Although a maximum of 100μM NH_2OH was used in the above optimization experiments, higher concentrations could be readily

accommodated by proportional scaling of the amounts of MnO_4^- and hydrogen peroxide.

Implementation and testing of the method

The robustness of the method was evaluated by producing a series of standard curves in the presence of 0, 20, 50, and 100μM NH_2OH. Each measurement was made in triplicate. It should be noted that, in contrast to the mechanistic investigations described above, a reaction medium containing Na^+, Mg^{2+}, Cl^-, and SO_4^{2-} ions was used to simulate the ionic composition likely to be found in real freshwater samples. The blank-corrected absorbances for the standard curves corresponding to each concentration of NH_2OH are listed in Table 4. The coefficient of variation between replicate absorbance values was always better than 3% for bromide concentrations spanning the range 5–30μM.

Table 4. Bromide standard curves as a function of $[NH_2OH]$*

Br^-, μM	Br^-, mg/l	NH_2OH, μM 0	20	50	100
0	0	0	0	0	0
5	0.4	0.029	0.028	0.030	0.027
10	0.8	0.070	0.070	0.071	0.070
15	1.2	0.118	0.118	—	—
20	1.6	0.169	0.168	0.171	0.169
30	2.4	0.277	0.284	0.287	0.281

*Absorbance measured at 590 nm. Standard deviation for triplicate determinations was less than 3% for $[Br^-] = 5$ to 30 μM.

The data in Table 4 show that the colorimetric method incorporating the NH_2OH decomposition step is capable of yielding excellent results. However, a potential problem could arise if the MnO_4^- is consumed in competing side reactions with other dissolved species, at a rate which is comparable with its reaction with NH_2OH. It has already been noted above that Fe^{2+} could be present at significant concentrations in water that contains NH_2OH. Whilst Fe^{2+} does not cause problems with the colorimetric method itself (see above), it does react quite rapidly with MnO_4^- at pH 4.6. The potential for Fe^{2+} to interfere with the decomposition of NH_2OH by MnO_4^- was evaluated by measuring the response of the integrated MnO_4^--colorimetric method to increasing concentrations of Fe^{2+}. The results showed that a maximum of 300μM Fe^{2+} could be tolerated in the presence of 100μM NH_2OH. Higher levels would require an additional amount of MnO_4^- to be added. For this reason it is recommended that the approximate concentration of Fe^{2+} be measured in samples collected from reducing environments.

Summary—Simple inexpensive high performance optical absorption detectors are possible using light emitting diodes (LEDs) as light sources. The designs presented in the literature are reviewed. Designs used by the investigators are described in detail with respect to construction, electronic design, performance and cost; these have not previously been described in the literature. Characteristics of commercially available LEDs are tabulated. At the simple end, a single beam, dc driven, transmittance output detector can be constructed within the body of a LED. At the high performance end, fully referenced, computer interfaced detectors are described that are pulsed at high speeds to attain measurement standard deviations in the range of 2–3 × 10^{-6} absorbance.

Light-emitting diodes (LEDs) are small, inexpensive, power-efficient light sources that are widely used as indicator lamps. These electroluminescent devices first became commercially available in the late 1960's. Today, it would be difficult to find an electronic instrument that does not sport an LED. Of special interest to the analytical chemist is that LEDs cover much of the visible and some near infrared (NIR) wavelengths of interest (470–1300 nm; 630–1550 nm for laser diodes) with acceptable monochromaticity for most applications. Further, without abuse, the expected lifetimes for LEDs are orders of magnitude greater than incandescent or discharge sources; mean time between failure for operation at 25° is typically 5 × 10^4 hr or approximately 6 yrs[1] of continuous service for typical LEDs; for some infrared LEDs, expected lifetimes are more than 10^6 hrs.[2] The short term spatial and intensity stability of a typical LED is respectively 30–200 and 50 times better than a He–Ne laser.[3] With a battery operated power source, the intensity noise is stated to be about 2 × 10^{-3}% of the total amplitude (throughout the present paper noise levels cited are the peak to peak values). If this were the only noise source in a complete detector, absolute noise levels of the order of 9 × 10^{-6} in absorbance and a detection limit (LOD) of 3 × 10^{-5} absorbance (based on a S/N = 3 criterion) would be possible; this can be favorably compared with noise specifications of present day state-of-the-art commercial flow-through absorption detectors (1 × 10^{-5} absorbance with a rise time of 1.0 sec).

LED based optical absorption detectors

LED-based photometers were first proposed by Barnes in 1970 (as stated by Flaschka *et al.*[4]) and the concept of an LED-phototransistor (PT) photometer with a 30-cm pathlength flow-through cell was realized in 1973.[4] Three years later, Anfält *et al.*[5] described a dual beam LED-based photometric titration probe for the measurement of total alkalinity in seawater. The LED was powered by a symmetrical square wave and both reference and principal detector photodiode (PD) outputs were processed by synchronized demodulators tuned to the LED chopping frequency, thus providing immunity against ambient light. However, such measures are largely unnecessary in flow-through photodetectors which are easily protected from ambient light by their design. The first practical LED-based flow-through photodetector of this type was described by Betteridge *et al.*[6] This was a single beam instrument utilizing an ∪-geometry and a path-length of 3 cm with a reported LOD (S/N = 2) corresponding to 6 × 10^{-4} absorbance for a 1-cm cells, from which a noise level of 9 × 10^{-4} absorbance can be calculated. The development of this detector was of particular help to the facile practice of flow injection analysis (FIA).[7] Several papers have

since appeared that utilize this basic detector design; particularly notable are the applications reported by Johnson *et al.*[8,9] who report on the seaworthiness of such instruments for continuous shipboard analysis of seawater, including submerged applications. For a nitrate/nitrite determination system,[8] noise levels of 8×10^{-4} absorbance were reported (2-cm cell). A variation of this cell design was reported by Trozanowicz *et al.*[10] to permit facile replacement of the LED and the photodetector. Since the original work,[6] a different design was reported by Betteridge *et al.*;[7,11–13] the LED and the PT were located on the radially opposite sides of a transparent tubular flow conduit (0.3–2.0 mm dia), thus facilitating construction. Sufficient data are not available to judge if any meaningful changes in S/N performance resulted over the previous design. Schmidt and Scott[14] reported the design and construction of a Z-geometry flow cell of 4-mm pathlength as an LED-based dedicated detector for metal ion chromatography utilizing postcolumn reaction with 4-(2-pyridylazo)resorcinol. A PD was used as the detecting transducer in this single beam design and the signal processing circuitry included a simple but effective second-order Butterworth filter (50% cut-off at 10 Hz) to reduce noise. From the reported data on the LOD of the various metals, their known molar absorptivities, injected and observed peak volumes, we estimate that the absorbance noise level of this detector was about 5×10^{-4}. This was a particularly small aperture microvolume detector (0.74 mm bore, 1.7 μl) and this performance in a post column reaction system, where mixing noise is always a factor, is noteworthy.

Since this time, several papers have reported the utilization of LED-based absorbance detectors but few details appear in regard to either design or performance characteristics. Imasaka *et al.*[15] appear to hold the record on the lowest noise performance, albeit this was based on static measurements. With an ultrabright 814 nm emitter operated from batteries and producing an optical output of 36 mW, it was reportedly possible to attain a noise level of 7.5×10^{-7} absorbance using a dual beam arrangement, conversion of the PD outputs using voltage→frequency converter and an integration time of 50 sec. More recently, Worsfold *et al.*[16–20] have championed the use of LED-based photometric detectors in field monitors for various water quality parameters and have also provided an overview of their use in flow injection analysis.[21] The detector design involves two individual LEDs and radial beam path flow cells; the two individual PD outputs were fed into a differential amplifier. The dual cell arrangement was used to compensate for turbidity in unfiltered river water samples and performed acceptably in that regard. However, it is not strictly a double beam arrangement as stated;[16] it was not intended for compensating source fluctuations. A computer-addressable single beam photometer with multiple LED sources and a **-geometry flow cell is reportedly commercially available;[22] no performance details have been given. Fluorometric applications of LEDs as excitation sources have also been described.[23,24]

In this laboratory, LED-based optical absorbance detectors have been used for several years now, with many different cell designs. We have used them with and without coupling to optical fibers, in referenced and unreferenced source configurations, with transmittance or absorbance as the primary output, in stand-alone or computer-controlled configuration, in dc and in pulsed mode. They have been configured as part of both laboratory and field-deployable instruments. The use of such detectors was mentioned in several publications[25–30] but no details were cited. A detailed consideration of their design, both in the form where the ultimate in performance is not necessary and also where the latter is desirable, is presented here.

Sources

Light emitting diodes and laser diodes. Several excellent volumes are available for more detailed information on LEDs and laser diodes (LDs).[31–35] Briefly, when charge carriers are injected across a forward-biased p–n junction, the current is largely due to hole-electron recombination in the transition region and in the neutral regions near the junction. In indirect band gap semiconductors like Si or Ge, the energy is released as heat. In a semiconductor permitting direct recombination, a considerable amount of the energy is released as light, the effect being known as injection electroluminescence. The wavelength of the light emitted is related to the band gap of the semiconductor. Some common semiconductor materials are listed below with the corresponding photon wavelengths in nm given in parenthesis: ZnS (345), SiC (434), ZnSe (460), AlP (507), CdS (513), GaP (550), AlAs (575) CdSe (718), GaAs (868), Si (1120), Ge

(1850), PbSe (4600) and InSb (6900). Virtually all can be configured into some type of photodetector where they respond to light of wavelength equal to or less than that corresponding to the bandgap. Only some semiconductors show practical injection electroluminescence. The energy distribution of the emitted photons corresponds approximately to a skewed normal distribution, the typical peak wavelength being somewhat higher than the wavelength corresponding to the cited band gap energy. However, the photon wavelength can be varied by making compound semiconductors. Thus, while GaAs emits in the NIR and GaP in the green, various amounts of As can be introduced into GaP. The resulting material is often written as $GaAs_{1-x}P_x$ (or simply GaAsP) and the resulting light can range from green to far red, depending on the degree of As content. From one production batch to another, the composition can vary sufficiently for the peak wavelength to change by 5–10 nm (typically the uncertainty is 1% of the stated wavelength in nm) for the same device designation; this should be borne in mind before a search is mounted to find an emitter that precisely matches some wavelength. Moreover, the exact peak wavelength depends on the junction temperature; at a fixed ambient temperature the junction temperature is a function of the drive current. Leidecker and Powers[36] report that for a common "660 nm" LED, the peak wavelength changed linearly from 663 nm to 671 nm as the case temperature was varied from 20 to 75°.

Commercially available LEDs. Most commercial LEDs are made from GaAs or GaP substrates. An epitaxial layer is grown thereon to form the light emitting p–n junction. Common red LEDs are based on an GaAsP epitaxial layer grown on GaAs. GaAsP epitaxi are grown on GaP to produce high efficiency yellow and red LEDs. GaP epitaxi are grown on GaP to produce green LEDs. More recently, Al is being doped into the epitaxial layer to produce a double heterojunction AlGaAs structure that produces a very intense red light at modest currents. Blue LEDs, with peak emission at 490 nm were originally introduced in late 1984 by Panasonic Industrial Co. and were based on GaN. These multijunction devices required a forward bias of 7.5 V. The present generation of blue LEDs are based on SiC and are more power-efficient but the optical output is still small compared to longer wavelength emitters. very recently high output GaN LEDs have been reintroduced, these emit in the green-blue (482 nm). Infrared LEDs in the 880–950 nm region are based on GaAs or AlGaAs and those in the 1200–1300 nm region are based on AlInGaAsP. Very high output orange LEDs based on the AlInGaP structure have been realized and are expected to be commercially available soon.[37]

Most LEDs are made starting with slicing the base crystals into thin wafers. The epitaxial layer is then grown. The wafers are next scribed and broken into individual LED chips, typically 0.25 mm square. The crystal base is the cathode and the epitaxi side is the anode. The chips are then attached to a lead frame. The cathode is usually shaped like a cup to reflect the emitted light forward and the chip is connected to it by conductive silver epoxy. The anode is then wire bonded (typically 25 μm in diameter gold wire, ending in a ball) to the top of the chip and the whole is packaged in epoxy. Tie-bars that hold cathode and anode leads together during the above operations are finally sheared, resulting in the familiar device of Fig. 1.

Performance characteristics of available LEDs. The use of a bright, narrowly focused source is preferred for all detector applications to obtain the best S/N. Table 1 lists several commercially available LEDs with their characteristics; based on our experience, they are particularly well suited for detector applications. With a few exceptions (such as a device that can provide an optical output of 100 mW and can handle peak currents up to 10 amperes) we have considered here only LEDs in the most common size (T 1–3/4, 5 mm). It should be noted that the values cited are typical values, considerable variations may be encountered for the optical power output of individual LEDs. For example, in a lot of 1000 LEDs supplied to us by a

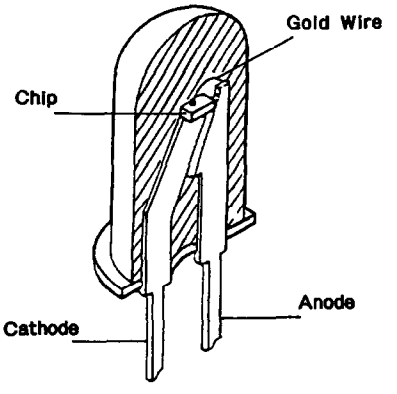

Fig. 1. Cutaway view of a typical T-1-3/4 epoxy bodied LED.

Table 1. Characteristics of some commercially available LEDs well suited for detector applications[a]

Device type	Peak wavelength, *nm*	Manufacturer	Device designation	Intensity/ Power (at rated current, *mA*)	Half-intensity wavelength bounds, *nm*	Maximum continuous current, *mA*	Maximum pulse current, *mA*[c]
SiC	470	L[d]	L200CWB5	20 mcd (20)	435–510	50	300

manufacturer, the brightest 10% averaged 4x greater luminous intensity than the dimmest 10%. We have recorded the emission spectra of some LEDs and have generally found them to correspond closely to manufacturer's data, within the 1% tolerance limit previously stated. With the exception of the GaN emitter, in no case were distinct doublets as reported by Worsfold *et al.*[17,21] observed. Cited peak wavelengths are somewhat dependent on the operating temperature as well as the total output. Some NIR LEDs are known to show a negative wavelength shift in the location of the peak maximum with increasing output power, the direction of shift is reversed at still higher powers.[2] Operating LEDs at excessive currents

(short of catastrophic failure) for prolonged periods can permanently reduce the luminous output *and* change the peak wavelength. One astute observation has been made: "... like traffic lights, all turn yellow before they go".[38]

Laser diodes. Laser diodes are 2–2.5 orders of magnitude more expensive than their LED counterparts. Nevertheless, on an absolute scale, this cost is modest for many applications. Based on several different layered structures (GaAs, AlGaAs, InGaAsP), LDs presently span a wavelength of 630–1550 nm with continuous power levels ranging from a few mW to several watts. Experimental ZnSe LDs, emitting in the blue–green, have been made.[39] Many LDs operate with a multimode pattern that involves emission over a large wavelength range (as much as 80–90 nm) with emission bands equally spaced, 1 to several nm apart. The intensity, spacing and the location of the principal emission band change with the temperature and the operating power; often, single mode emission results at higher powers. The half bandwidth of an LD emission band can range from 1–10 nm depending on the device. The use of LDs in analytical chemistry has been reviewed.[40] If used in a conventional mode to perform absorption measurements, they offer no significant advantage over LEDs. Still, it is possible to operate with LDs in the laser intracavity absorption spectroscopic mode where the sample is placed in an optical feedback path between the LD and a mirror; absorbance noise levels of 1×10^{-5} are reportedly routinely attained with very simple apparatus.[41,42] Practical applications, ruggedness, and immunity from mechanical perturbations are still to be unequivocally demonstrated and further discussion of the use of LDs is best deferred until such time.

Use of optical fibers in constructing a detector cell. Some of the cell designs reported here use optical fibers for light transmission. Relative to directly locating the LED and the photodetector(s) within the cell, such an arrangement unavoidably involves some light loss. However, the cell itself can be made very small and located in a region remote from any electronic components. Longer wavelength high optical output LEDs, used for optical communication purposes, are often available with attached fiber pigtails. But the fiber core diameter is rarely larger than 250 μm; this is generally too small for typical detector applications. Several manufacturers (*e.g.*, Sanyo Inc., Stanley Electric, Telefunken AG) also market specially molded LEDs with optical fiber connectors. In our experience, the best permanent fiber connection to a 5-mm LED is made by cutting off most of the dome material, getting down to within 0.5 mm of the chip using fine sand paper and finally polishing the surface by rubbing it on smooth paper. If a plastic optical fiber is used, its end can be polished in the same manner or by using a wet polishing stone. With both components held in place (the fiber being positioned to cover the chip), the two are glued together using UV-cure optical adhesive (Norland Optical Products, New Brunswick, NJ) and then epoxy is applied around the fiber to make the connection more secure. Fibers can be coupled to the sensing chip of a photodetector in the same manner. Figure 2 shows the relative amounts of light reaching a photodetector under different coupling conditions, at identical LED drive currents.

Detectors—photodiodes or phototransistors?

Both photodiodes and phototransistors can be used as detectors. The difference is that the latter typically provide 1.5–2 orders of magnitude greater current output albeit the response is slower.[43] This does not necessarily mean that the use of phototransistors results in better S/N. If the detector cell and the connecting cables are appropriately shielded, extraneous noise can be minimized. Even with blue LEDs, the photocurrent from a detector photodiode is in the several nA range and can be directly handled by present-day log-ratio amplifier chips (*vide infra*). Under such circumstances, we have observed that phototransistors are typically more noisy than photodiodes. But if a single beam arrangement is used with a low output source and if the photodetector in the cell is coupled to an external low-cost photocurrent→voltage converter, a phototransistor may be worthy of consideration. Phototransistors, and especially the even higher gain photodarlingtons, are generally not desirable for high speed pulsed detector applications because of their slower response speed. Excellent descriptions of the different strategies of monitoring photodiode outputs with operational amplifiers are available.[44,45]

Major suppliers of photodetectors include EG&G Optoelectronics, Hamamatsu Corp., United Detector Technologies, among others. For the detector applications at hand, very inexpensive small silicon photodiodes (active area 3×3 mm, polymer encapsulated) commonly available from surplus houses (*e.g.*, type S2007,

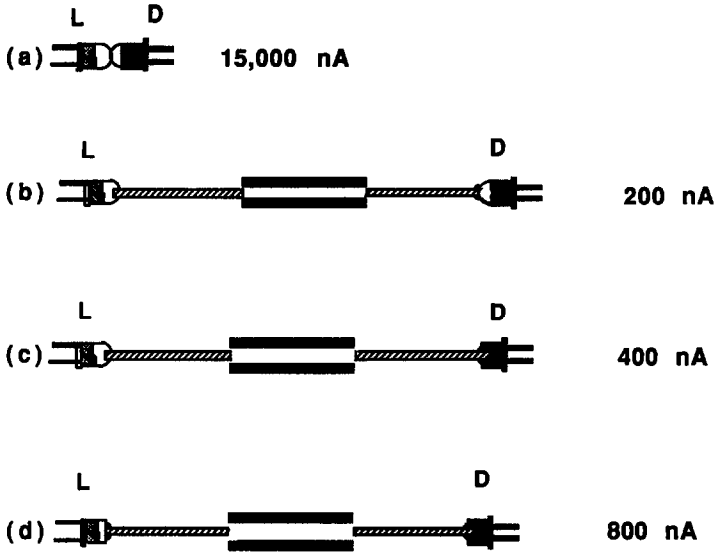

Fig. 2. Light throughput with different test configurations, 560 nm LED, 50 mA drive current. (a) LED (L) and lens end photodiode (D) coupled face to face; (b) 1.5 mm fiber optic coupled to drilled hole in L, intervening cell is air filled glass tube (1.6 mm i.d. × 10 mm), 1.5 mm fiber optic coupled to lens end of D; (c) as in *b* except fiber coupled directly to chip on D: and (d) as in *c* except fiber coupled to L after dome removal.

Electronic Goldmine, Phoenix, AZ) produce results that are indistinguishable from their more expensive counterparts. Because of a greater illuminated area, the total photocurrent obtained is larger than the small profile photodiodes. But the signal gain with increasing active area of the detector is also associated with increasing noise; a detector with an active area much larger than the transmitted beam cross section is undesirable. The relative response profiles of a few detector types, of importance to the present discussion are shown in Fig. 3 as a function of the wavelength of light. NIR detectors that do not respond to visible light are also commonly available. This makes it possible to have simple DC dual wavelength detectors using a bifurcated optical fiber (*e.g.*, from Dolan Jenner Industries, Woburn, MA). This is schematically shown in Fig. 4(a); independent electronics can serve each source-detector combination. As shown, each emitter can be individually referenced. Alternatively the simpler design of Fig. 4(b) can be used with any pair of LEDs. An appropriate electronic strategy is used to alternately turn on each LED (*ca.* 100 Hz) through a clock and a flip-flop circuit, take the log ratio of the reference and the signal detectors and provide individual outputs via appropriately enabled sample/hold (S/H) amplifiers (Fig. 5). To achieve good S/N in this type of design, it is vital to reduce external noise and the (log) amplifier circuitry is preferably located within the same metal housing as the flow cell itself. The cell body is used as the common ground. This approach is easily extended to a multiplicity of LEDs. If the capability to set each of the final outputs individually to zero is desired, a final offset stage not shown in Fig. 5 is, in general, necessary after each S/H amplifier.

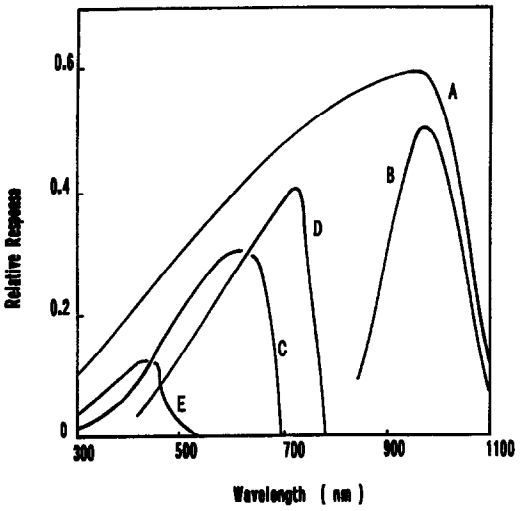

Fig. 3. Typical response profiles of solid state photodetectors as a function of wavelength. (A) Silicon, *e.g.*, type S2386; (B) silicon, with visible light cutoff, *e.g.*, type S2506; (C) GaAsP, standard, *e.g.*, type G1115; (D) GaAsP, extended red sensitivity, *e.g.*, type G1735; and (E) GaP, *e.g.*, type G1961; device numbers refer to products from the Hamamatsu Corp. The ordinate scale is approximately equal to photocurrent in amperes per watt of incident power.

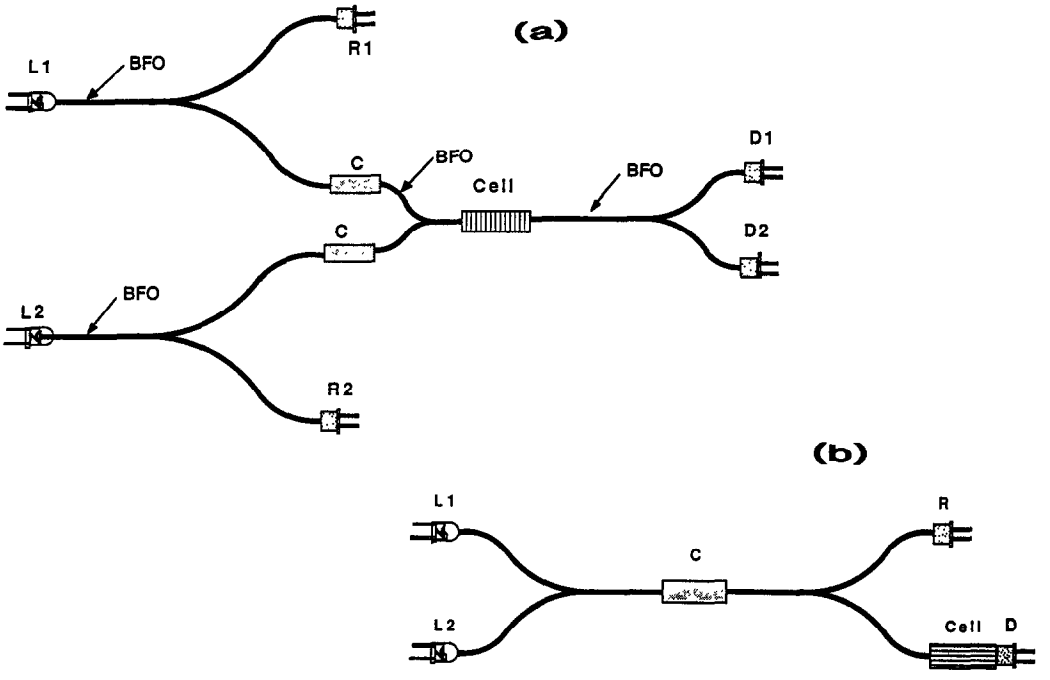

Fig. 4. (a) Dual wavelength photodetector using wavelength selective detectors. L1: visible LED; L2: infrared LED; BFO: bifurcated fiber optic; C: coupler; R1, R2: reference detectors responding to L1 and L2 respectively; D1, D2: signal detectors responding to L1 and L2, respectively. (b) Dual wavelength photodetector using single reference and signal detectors and the time-multiplexing circuitry in Fig. 5 to provide individual outputs.

The offset capability provided to the S/H amplifiers themselves is not adequate for this task.

In this connection, it is interesting that like any other p–n junction, LEDs respond to light, *i.e.*, they are photodiodes as well. This bidirectional transducer behavior (see Table 2) can be used to construct dual wavelength detectors of adjacent wavelengths, with an LED mounted on each side of the cell and functioning alternately as a source and a detector. However, such an approach should be regarded more as a curiosity than a practical method; LEDs are photodiodes, but pretty poor ones!

Cell design

Poppe[46] has provided an outline on the basic characterization and design of liquid phase flow-through detector systems and in a subsequent paper[47] has specially considered miniaturization of such detectors. Stone and Tyson[48] have shown that the design of flow cells can significantly affect the peak profile observed in FIA. Stewart[49,50] has specially considered the optics of flow cells used in liquid chromatography (LC). Optical acceptance of a flow cell is inversely related to the optical path length, by as much as the fourth power of the latter. Most typical present-day flow cells for conventional LC are designed with pathlengths of 4–8 mm. By appropriately imaging the source at the exit window and using a tapered cell construction, Stewart[49] showed that it is possible to reduce refractive index (RI) effects greatly. The RI effect was reduced to the limit where it was solely due to the change in reflectivity at the interface of two media with different RI. The original detector of Betteridge *et al.*[6] was sufficiently sensitive to changes in RI to function as an RI detector. The role of the flow cell in influencing the apparent effect from changing RI has recently received more attention.[51] The full importance of the flow cell is rarely appreciated, however. Figure 6(A) shows the detector response when 50% methanol is injected into a water carrier in a FIA system (shown in inset)

Table 2. Photocurrents (nA) with LEDS as detectors*

Emitter LED	Detector LED 555 nm	570 nm	605 nm	660 nm
555 nm	1.2	3.6	3.0	2.4
570 nm	2.5	9.0	22	52
605 nm	0.02	0.2	6.4	105
660 nm	0.01	0.02	0.27	200

*All are Stanley 5566x series LEDs (see Table 1), emitter drive current 50 mA, emitter and detector separated by 1 cm, intervening medium is air.

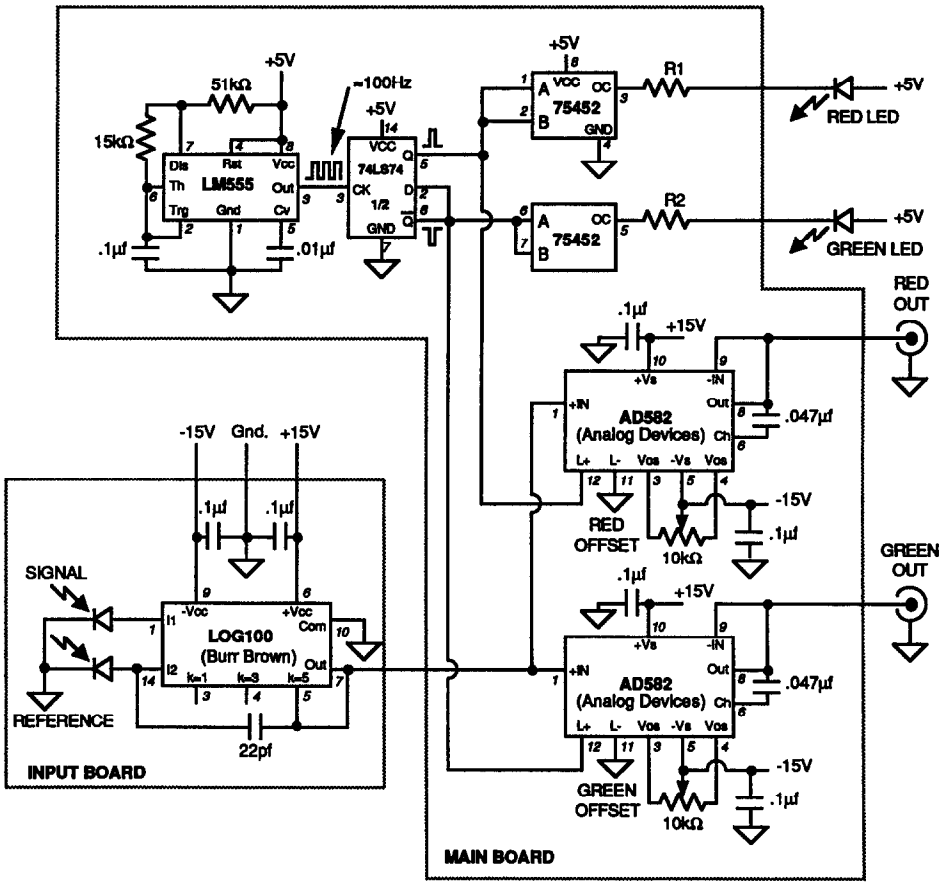

Fig. 5. Schematic for performing dual wavelength absorbance measurement with a time-shared reference and signal detector. R1 and R2 are chosen to obtain the desired value of the current pulse; 33 ohms provide a pulse of *ca.* 100 mA for most LEDs. The input board is integrated with the flow cell. This concept can be extended to use a greater number of LED sources.

using an 8-μl and a 40-μl volume black wall flow cell installed in a Perkin–Elmer 559 spectrophotometer. The reflectivity of the wall also entirely changes the qualitative behavior of the artifact signal. Figure 6(B) shows the appearance of the signal upon 50% methanol injection when a flow cell with integral LED-photodiode detectors (1.5 × 10 mm path) is used; in one case the exterior of the glass tube constituting the flow path has been painted black, in the other case it has been silvered to increase reflectivity. Note that in one case a peak appears before a dip and in the other case the peak follows the dip.

Radial path flow cells. The simplest flow-cell construction undoubtedly involves using the radial dimension of a tube as the optical path. The original design of Betteridge *et al.*[11–13] has already been cited; a filter photometric detector in which the detector body can slide along a glass tube was also described earlier.[52] Presently, this type of radial optical path detection strategy is obligatorily used in capillary electrophoresis and capillary LC where dispersion induced by connections to external detectors cannot be tolerated. For conventional bore LC, tubes of 1–1.5 mm bore are the largest that can be used as radial path detectors without causing major dispersion; this often causes a larger sacrifice in detection sensitivity (due to the small optical path length) than can be tolerated. The sensitivity requirements are often less stringent in FIA or similar analytical systems and this type of cell may be ideally suited for such applications. This is particularly true if the emitter used is of low optical output (*e.g.*, a blue LED) because the S/N in an absorbance detector based on such a source quickly becomes limited by the decreasing amount of light reaching the light detector with increasing path length. Strategies and considerations of designing small bore radial optical path detectors using optical fibers have been recently outlined.[53,54] The radial path design we favor for FIA applications is shown

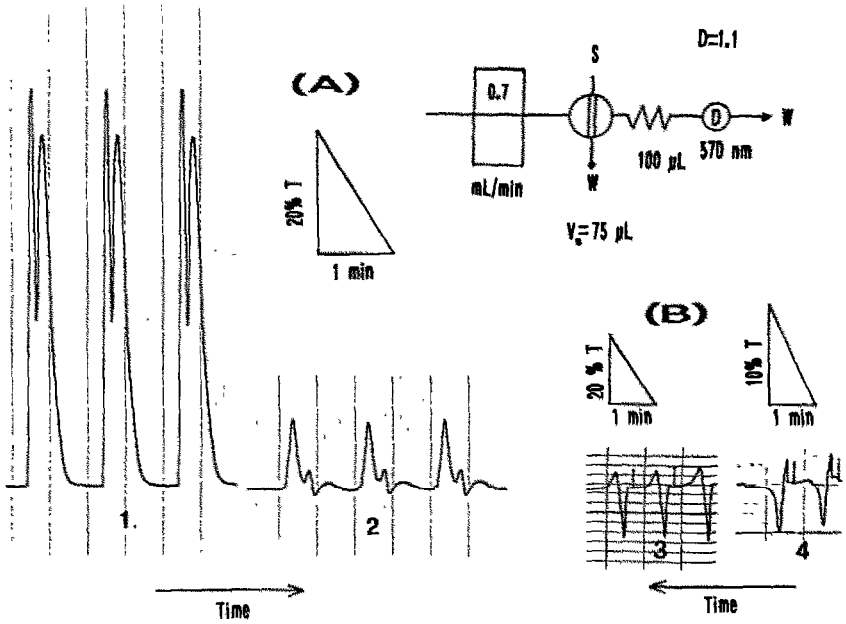

Fig. 6. Detector output upon injection of 50% methanol into a water carrier using the flow injection manifold depicted in the inset. (A) Detector: Perkin–Elmer 559A dual monochromator spectrophotometer equipped with black walled cells of volume (1) 8 μl and (2) 40 μl; (B) detector: LED based, 8 mm path length, 16.5 μl volume, (3) black walls and (4) reflective walls. In all cases light is incident on the window next to the fluid entrance point.

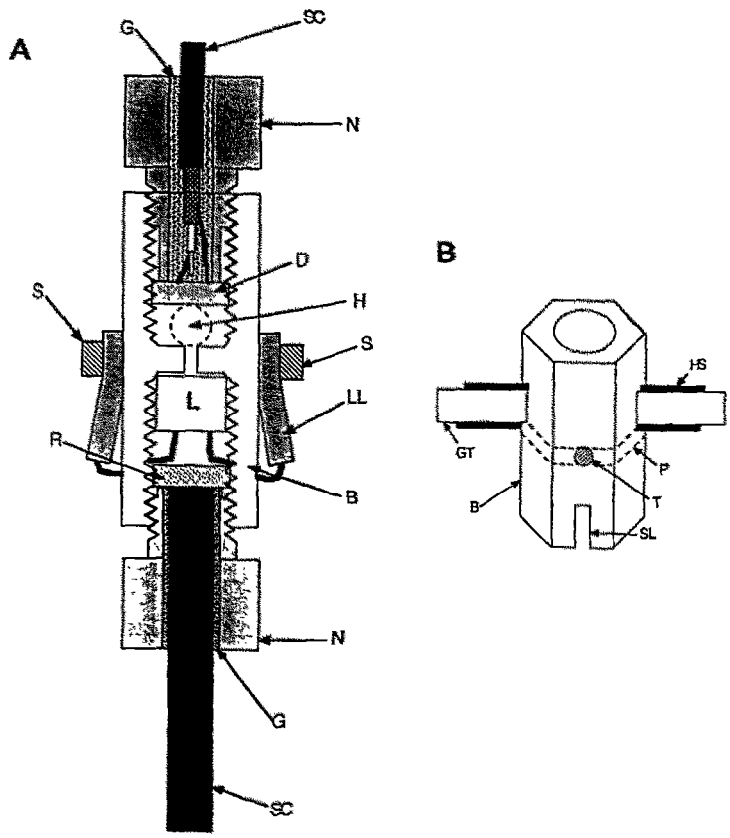

Fig. 7. Radial path detector. (A) Cross sectional view. N: male fitting; B: 1/4-28 threaded union with center partition; L: flat faced LED; LL: LED leads soldered to miniature lugs held in place by screws S; R,D: reference and signal photodiodes; SC: shielded cable to photodiode: G: opaque glue. (B) Front view of the union B. SL: slot cut on opposing sides to fold over LED leads; P: location of center partition; T: 0–80 threads for screw S; GT: glass tube; HS: opaque heat shrink tubing.

in Fig. 7. Opaque 1/4-28 threaded polymeric unions with a center partition containing a small connecting hole are inexpensively available (*e.g.*, from Dionex Corp., Sunnyvale, CA and Upchurch Scientific, Oak Harbor, WA). An appropriately centered hole is drilled through the wall of the fitting immediately adjacent to the partition, to snugly fit the glass tube used as the flow conduit. The LED (dome removed, flat faced) is then put on the other side of the partition with the leads extending through slits cut on the sides of the union, as shown. The LED termini and connecting leads are held firmly in place by 0–80 threaded miniature screws. The reference PD is immediately behind the LED and receives light reflected off the front plane. It is held in place by a threaded male fitting, with (shielded) leads exiting through the 1/8 in. bore of the fitting; the bore is then filled with opaque adhesive. If a single beam arrangement is used (no reference), the LED can be held in place directly by the male fitting with its leads exiting through the bore of the fitting; it is not necessary to make slits in the union. The hole in the partition may be drilled out to the extent desired to define the optical aperture (preferably $\leq$ tube radius). The glass tube and polymeric inlet/outlet tubes connected to it (inserted within it) are affixed in place with opaque heat-shrunk polyolefin tubing. The detector PD is cemented to the end of a threaded male plug, with a hole drilled in it for the connecting leads.

The optical path using the radial dimension of a tube actually involves a multiplicity of path lengths.[52–54] For the purist, this problem is solved and the response linearity over a large range is improved by replacing the circular tube with one of square (or rectangular) cross section. Such tubes are available (both in glass and silica) from many sources (*e.g.*, Wilmad Glass Co., Buena, NJ; Vitro Dynamics Inc., Rockaway, NJ). The great virtue of the straight flow path design with the optical probe traversing it at a right angle is that when it is deployed in a vertical configuration, stray bubbles are never trapped in the cell.[55]

Z-path flow cells. The biggest shortcoming of the radial path design is the limited optical path lengths that can be attained without excessive dispersion. The small bore Z-geometry flow cell is widely used in commercial detectors and represents a good combination of reasonable optical path length, low volume, low dispersion and fast washout profile (minimum unswept volume). Some commercial cells also utilize a bore that is tapered, rather than uniform, to minimize artifact signals from RI changes.[49] Making such a cell requires skilled machining; the design is also patent-protected. Figure 8(a) shows a design that is fabricated very simply. The choice of the material is largely governed by the intended application. If the application is compatible with acrylic polymers (used for many inexpensive polymeric optical fibers,

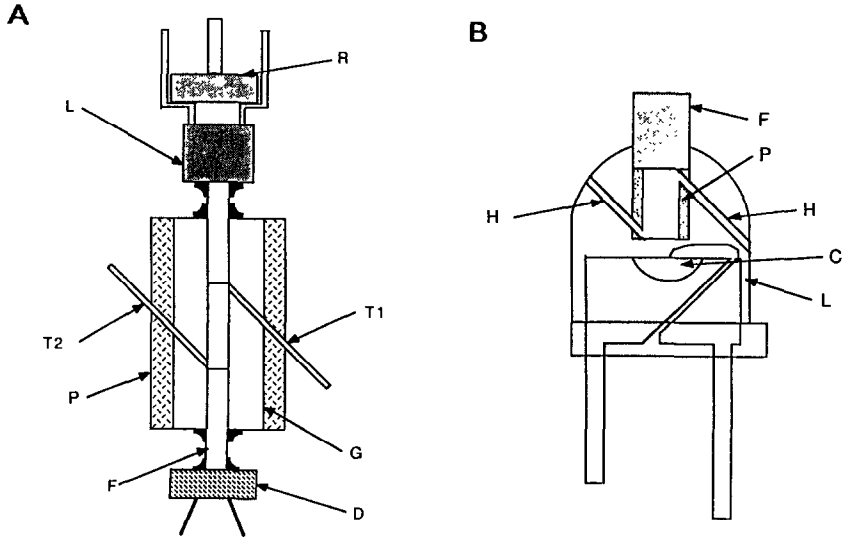

Fig. 8. Two simple flow cell designs. (A) Z-configuration flow cell with direct connection to fiber optic. L: LED; R: reference PD; F: fiber optic; G: flow conduit; T1, T2: flow in/out tubes; P: PVC pump tubing (used when conduit G is of glass); D: detector photodiode. (B) Flow cell built within the body of an LED. C: emitting chip; H: entrance/exit apertures; P: opaque PEEK sleeve; F: fiber optic leading to signal photodiode; a reference photodiode can be placed under the LED.

e.g., ESKA fibers from Edmund Scientific, Barrington, NJ), 1.0 or 1.5 mm dia. optical fibers (F) can be placed 6–10 mm apart at the termini of the main flow conduit (G), their spacing defining the optical path length. The conduit G itself is a 15–20 mm segment of a 6.3-mm diameter rod, drilled out to accommodate snugly the optical fibers. The conduit can be of any polymer that accepts an adhesive and is compatible with the application. Inlet/outlet holes are drilled at a $\sim 45°$ angle and inlet/outlet tubes (stainless steel hypodermic needle tubing, Small Parts Inc., Miami, FL or small o.d. PEEK tubing, Upchurch Scientific) are cemented in place with epoxy adhesive, without protrusion in the main flow conduit. The fiber optic ends, already connected to an LED (L) or PD (D) by a short length, are then inserted to the measured depth and cemented in place. If the application involves solvent media that are compatible with epoxy resin and any reactants or products formed do not absorb strongly thereon, many LEDs are available already terminated in a 2-mm diameter cylindrical protrusion ("chimney shaped") and can be directly used, with the corresponding end of the conduit G being drilled to accept the LED terminus. If a reference detector (R) is used, it is cemented on the bottom of the LED, using optical adhesive. For additional strength and protection from ambient light, the whole assembly can now be encased in an opaque material. Black silicone sealant is particularly useful for this purpose since it is removed easily if necessary.

For some applications, polymeric optical fibers are simply not suitable. Essentially the same design can be attained with a 1-mm i.d. glass tube as the flow conduit and 1-mm single strand silica optical fibers (available, *e.g.*, from Ensign–Bickford Optics Co., Avon, CT). To maintain good S/N with the limited optical aperture, the pathlength should not be greater than 6 mm. The difficult part about using a glass conduit is to provide the inlet/outlet apertures. Even for a skilled machinist using diamond-tipped bits, it is difficult to drill holes in small bore thin wall glass tubes. But it is possible to create a slanted cut into the wall of a glass tube with a thin motorized cutting wheel (as with a DREMEL Moto-Tool®, available in most hardware and hobby stores) without much difficulty. Once the apertures have been made, the glass tube is coated with a thin layer of epoxy adhesive. While the adhesive is still tacky, the coated tube is slipped inside a plasticized poly(vinyl chloride) tubing P (commonly used with peristaltic pumps, a great variety of such tubing, of varying i.d. are available from Elkay Products, Shrewsbury, MA). Connecting inlet/outlet tubing are then put in and cemented in place after first puncturing the protective tubing P at the appropriate locations with a hypodermic needle.

Flow cells within an LED. If the application is compatible with epoxy, very simple detectors are possible where the flow cell is built wholly within the body of the original LED, as shown in Fig. 8(b). With 5-mm LEDs, a maximum path length of 3 mm is possible, larger pathlengths are possible with a 13-mm (T-4) size LED. A hole of desired size, typically 1.5 mm, is drilled from the top of the LED to within 1 (preferably 0.5) mm of the chip C. Careful manual drilling under a low magnification microscope is recommended. The bottom of the hole is then made flat with an appropriate bottoming tool. Angled entrance and exit holes (H) of desired diameters are now drilled. However, the bottom surface is still rough and light transmission through this surface will be very poor if it is used in this state. Polishing compounds cannot be used since it is not possible to remove them from the surface. Rather, it is best to use some slow curing transparent epoxy and coat the drilled rough surface with it, using the bottom of a suitably sized drill bit for even distribution. When the adhesive cures, an even and transparent surface is left. An optical fiber F is then cemented in at the distal end and terminates in the detector PD. Again, if desired, a reference PD can be placed at the bottom of L. Beyond a compact design, this configuration results in some interesting properties. When the bottom of the flow path is very close to the chip, the flowing fluid actually helps to cool the chip; the light output is measurably higher when the chip is cooled (*vide infra*) by the flowing fluid. (Conceivably, this may be used as the basis of a flow transducer, albeit such use is likely to be complicated by variations in the ambient and the fluid temperature and heat capacity of the fluid.) The response of such a detector is not linear over a large range of absorbance; stray light is conducted to the detector fiber through the body of the LED. The linear range can be extended by drilling the initial flow path to accommodate a small segment of an opaque PEEK tube P (1.0 mm i.d./1.5 mm o.d.) as an optical isolation sleeve.

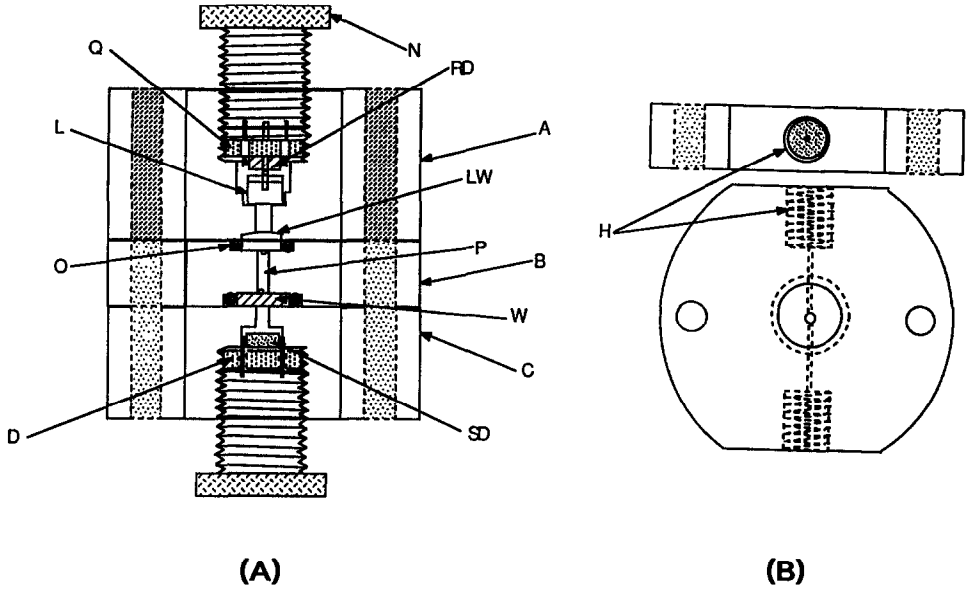

Fig. 9. Demountable cell shown in horizontal cross section in (A) and the top view and vertical cross section of the middle section B appears in (B). A, C: aluminum end-blocks; B: central polymer block housing the flow cell; N: knurled male nuts; Q: socket; RD, SD: reference and signal PD; L: LED; LW: lens window; W: flat window; P: flow-path; O: O-rings; D: opaque disc; H: threaded apertures for fluid inlet/outlet.

Demountable flow cells. The above designs call for little machining but sacrifice versatility. Two robust designs in which the various components of the cell are readily changed are shown in Figs. 9 and 10 respectively. The flow cell of Fig. 9 is shown in horizontal cross section in (A). It is composed of two aluminum parts (A and C) sandwiching a central part B made from an inert plastic. (Most of our cells were made from translucent Kel-F®. While this material is very inert and machines well, all exposed surfaces need to be covered up by an opaque tape to prevent intrusion of light. We have also used glass filled Ryton®; this is highly opaque and reasonably inert but requires carbide faced tools for machining. More recent experience shows that PEEK may be the best choice; opaque Kel-F is also available.) The three parts are held together by two 8–32 screws (not shown in the figure) placed at opposite corners; one endplate contains recessed holes and the other contains a threaded aperture with through holes in block B to complete the assembly. A top view of block B and a vertical cross-section is shown in (B). Threaded (1/4–28) Inlet/outlet apertures (H) are provided in B. These terminate in 0.5-mm bore passages that open on the optical windows LW and W. It is important to note that the termini of the entrance/exit passages break out partially into the surface facing the windows, if these termini are completely contained within the flow path, the cell will be more prone to occasional bubbles being trapped in the cell. The optical path P is 1.5 × 6 mm. A circular recess, 1.6 mm deep and 9 mm in diameter, is machined on each face of block B. These recesses hold the window W and lens L, each surrounded by a No. 009 O-ring O. The latter are thick enough to protrude slightly out of the recess and when the three blocks are assembled, a seal is formed by compression. If machining is not sufficiently precise to accomplish this, circular gaskets can be punched out of folded-over Teflon tape and used between the optical windows and the

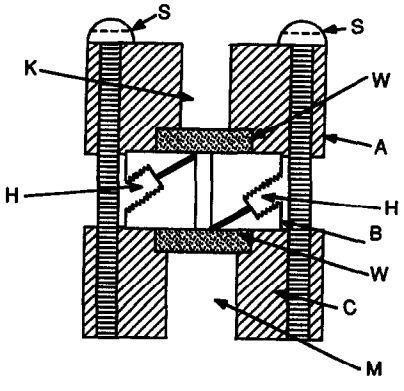

Fig. 10. Fiber optic based demountable cell. H: 1-72 threaded aperture communicating to the 1.0 × 6 mm illuminated flow path; S: Machine screws (4), holding blocks A, B and C together; K, M: aperture for optical fibers; W: flat optical windows.

aluminum faceplates. Window W is a 6.3-mm diameter 1.5-mm thick optically flat glass disc and LW is a 6-mm diameter, 9-mm focal length piano convex lens (center thickness 1.75 mm), both inexpensively available from Edmund Scientific. The use of the lens instead of a flat window (cost difference *ca.* $5) is not essential but results in at least 25% better light throughput through the cell. Blocks A and B are similar and both contain 1/2–20 threaded holes, terminating in 3 mm diameter apertures. Hollow knurled aluminum male fittings N are machined to fit into these threads. On the detector side, disc D, *ca.* 1.5 mm thick, machined from nonconductive opaque plastics like phenolic resins, sits atop of N and appropriate small holes are drilled in D to allow passage of the leads of the signal detector SD (3 × 3 mm silicon PD, Electronic Goldmine) that end in a shielded cable S and a BNC connector. On the source side, below N sits an 8-pin socket Q (ECG 407, only 4 pins are used) and reference detector RD (same as SD) straddles two opposite holes. The leads of the LED L (dome removed, face polished) are carefully bent and excess lengths cut off such that it will fit tightly over R and into the two unused holes in Q. At the bottom of Q (the pin end), unused pins are removed and the cathode ends of RD and L are combined into a single lead (constituting a common ground in a shielded cable; the center conductor carries the anode signal from RD, the whole terminating in a coaxial connector). The anode lead from L is connected to a current limiting resistor that will limit the current to *ca.* 80% of the maximum value continuously allowable for the LED when connected to the positive power supply of the signal processing electronics (typically +12 or +15 V) and thus terminates in a lead going to the power supply. Such a detector allows rapid change of the emitter and thus the wavelength.

Demountable flow cells with optical fibers. There are certain advantages if signal communications to the flow cell are solely by optical fibers, in particular regarding noise caused by the environment around the detector. The design in Fig. 9 is easily modified to accept optical fibers, especially jacketed fiber bundles terminating in polished, metal-colleted ends. Simpler and substantially smaller designs are possible, however. Figure 10 shows such a design, composed of three individual blocks, machined from PEEK. The central block B is 6.3 mm in diameter and 6 mm long, containing a 1-mm bore central flow path. Angled holes H terminating in 0.5-mm apertures provide liquid inlet/outlet paths and are provided with 1–72 threads and a flat seat. PEEK chromatography tubing, 1.5 mm in o.d. are threaded on the exterior with a 1–72 die and can then be screwed into holes H to form leakproof connections that will withstand considerable pressure.[56] The top block A contains a 0.135 inch diameter drilled aperture K to house snugly a 0.130 inch o.d. jacketed, 0.08 inch core plastic optical fiber, held in place by a set screw not shown in the drawing (perpendicular to the plane of the paper). The polished end of the fiber butts directly against the cell window W (same as that in Fig. 9) and the latter is housed within an appropriately sized recess machined into block A. The depth of the recess is marginally less than the thickness of W; the compression on the window itself provides the necessary sealing. The bottom block C is similar to A except that hole M is larger (*ca.* 0.190 inch) to accommodate one leg of a standard bifurcated fiber optic bundle (Dolan-Jenner type E624, terminal o.d. 0.187 inch) held in place with a set screw not shown in the drawing. The common arm goes to an LED. The fiber end and the LED are essentially of the same diameter, they are put face to face in an aluminum sleeve and held in place by set screws. The second bifurcated leg goes to the reference photodetector, typically placed directly on the detector electronics board and the fiber optic end put thereon with appropriate protection from adventitious light. The fiber from A also returns to the detector electronics board, to communicate with the signal photodetector on the electronics board. The three blocks are held together by four 2–56 × 3/4 inch screws between blocks A and C, two of the screws (S) are shown in Fig. 10.

Unreferenced vs. referenced detectors. Transmittance or absorbance output?

For most analytical applications, absorbance is the parameter directly related to the analyte concentration and is therefore of the most immediate interest. That the choice of a transmittance output is considered at all is because the output of the detector phototransducer is typically linearly related to the intensity of light falling on it, *i.e.*, it is linear with transmittance. The simplest designs (which includes virtually all of the LED-based detectors described in the literature thus far), contain an unreferenced LED source and the photodetector output signal is typically processed by some amplifying

and noise filtering circuitry and provided with a variable offset capability. The final output signal remains linearly related to the transmittance. It is possible to convert the transmittance signal into absorbance via the logarithmic transfer function of a device, *e.g.*, a transistor[43] or better, a dedicated logarithmic amplifier (*e.g.*, AD755N, Analog Devices, Norwood, MA). However, in our judgment, the additional effort is better spent by providing a reference detector to the LED source and a log ratio amplifier (LRA) integrated circuit (IC) that then directly provides an absorbance output (*vide infra*). At the very least, before log conversion circuitry is added to an unreferenced detector (which are really best suited for the less demanding applications), it should be recognized (especially in defense of the many previous designs that have utilized transmittance outputs) that at low absorbance levels (≤ 0.3), essentially a linear relationship exists between transmittance and absorbance. This is graphically illustrated in Fig. 11.

Of course, if the output of an (unreferenced) detector is acquired by a computer, all transformations can be made in the software. One caveat is necessary, if the effective resolution of the data acquisition process is not high enough, this may become the determining factor governing noise as well as the accuracy of any subsequent mathematical transformations.

The major shortcoming of an unreferenced detector is its temporal drift at high sensitivities. Although an LED is a substantially more stable source than any incandescent lamp, the luminescence efficiency does still depend on temperature. Consequently, even if constant current sources are used to drive it, ambient temperature fluctuations lead to changes in the junction temperature that translate to variations in light

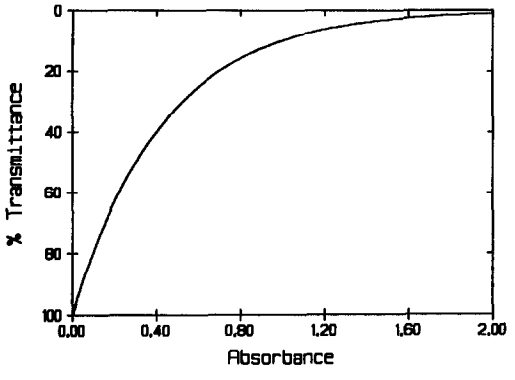

Fig. 11. The relationship between absorbance and Transmittance is linear at low absorbance values.

output. There is little or no difference in short-term noise between single-beam and referenced designs but a vast difference exists in long term drifts. The differences in initial stabilization time are also substantial. In our opinion, the additional energy and investment required to fabricate a referenced detector compared to an unreferenced detector is minor and it is difficult to justify continued fabrication of unreferenced detectors. When a referenced source design is used, it is most convenient to use a log-ratio amplifier IC as previously mentioned. Such a device can directly accept the signal and reference photocurrent inputs (from 1 nA to 1 mA) and provide an output linearly related to log i_s/i_r with user selectable gain per decade (*i.e.*, volts per absorbance unit), with very large offset capabilities to set the initial zero. These ICs are not inexpensive ($60–160) but their performance and convenience make it well worth the investment. These include for example, AD757N (Analog Devices) and its less expensive counterparts 4127KG, 4127JG, LOG100JP, etc. (Burr-Brown Corp.). For most LED-based detector applications, there is no significant performance difference among these devices. Few additional components are necessary with these devices; necessary circuits are very simple and are detailed in the literature from the manufacturer. Experimentally we find that a plot of log i_s *vs.* log i_r has a slope of 1.00 ± 0.01 (tested over 5 orders of magnitude for all of the above amplifiers, the manufacturers claim "less than 1% deviation of linearity over six orders of magnitude"). One additional note of caution is in order, our experience indicates that the last device, the least expensive among the choices above, is best used with an additional final buffer amplifier stage to avoid spurious noise caused by feedback.

Radiant output from LEDs. Effect of temperature and device type

The optical output of an LED is temperature dependent; the efficiency of injection electroluminescence increases with decreasing junction temperature. This is shown in Fig. 12 for a 560-nm LED (HPG5566X). The light output was measured by coupling a fiber optic to the LED and connecting a photo diode at the other end. Relative to the standard mold, removing most of the encapsulating epoxy from the standard LED ("modified LED") improves coupling to the fiber. When the device is surrounded with dry ice, the junction is cooled and the

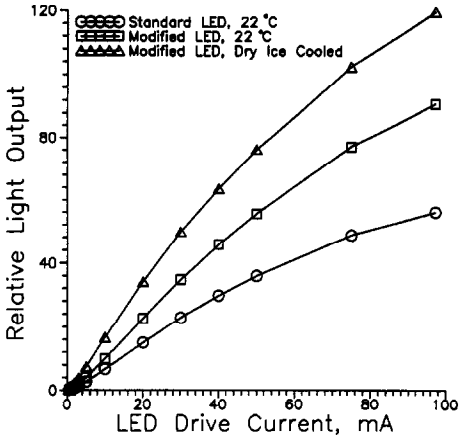

Fig. 12. Temperature dependence of LED light output. Modified LED connotes removal of most of the dome plastic material and coupling of the fiber optic to the polished, flat faced LED.

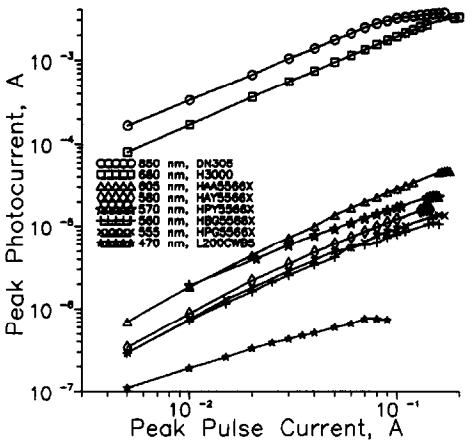

Fig. 13. Light output of various LEDs as a function of drive current, 100 μsec pulses, 1% duty cycle,.

optical output increases by 30–200%, depending on the drive current level. Based on these data, if we assume a nominal figure of 100% increase in light output for a temperature change of 100°, the temperature coefficient of the light output is *ca.* 0.7%/°C. An absorbance change of 10^{-3} is equal to a change in the light level of 0.23%; it should be obvious why referenced beam designs are vital to a practical detector that does not drift excessively.

The optical output is greatly dependent on the nature of the LEDs. In Table 1, a deliberate effort has been made to choose the brightest LEDs available in their class, because higher light levels reaching the detector typically translates into a better signal to noise ratio. The light output of several high brightness LEDs was measured using 50-μsec wide constant current pulses with a 1% duty cycle, supplied by the pulsed emitter photodetector electronics (*vide infra*), the light output measurement being made after the initial 10 μsec of the pulse (to avoid jitter) by a fast photodiode. The light output is presented in terms of detector photocurrent in Fig. 13. The sensitivity of the detector increases with increasing wavelength in the range studied, the sensitivity at 850 nm being about twice that at 470 nm. This difference is, however, insignificant relative to the orders of magnitude differences observed in photocurrent output. The longer wavelength LEDs can handle much greater currents before they saturate and it is remarkable that at high drive currents they elicit photocurrents exceeding 1 mA in a coupled photodiode. It is interesting that the LEDs shown in Fig. 13 clearly fall in three groups of output intensities that are characteristic of the substrates, with the AlGaAs pair at the top and SiC at the bottom and the GaP (or GaAsP/GaP) group in the middle.

Performance, DC excitation

Representative examples are given below for the performance of some of the flow cell designs/electronic arrangements. The flow cell of Fig. 8(a) operated with a typical midwavelength LED (HAA5566X @30 mA, 605 nm) in the single beam mode (transmittance output) with a constant current source and a high quality commercial current→voltage converter (Keithley model 427) exhibited a noise level of 7×10^{-5} absorbance (0.3 sec rise time, water flowing through the cell under gravity, no pulsations). This S/N performance was degraded by a factor of 2–3 with a low offset error FET-input operational amplifier based current→voltage converter. More importantly, the output drift rate of this configuration was high, often higher than 10^{-3} absorbance/hr. A plot of the logarithm of the output signal was linearly correlated with the concentration of indigotrisulfonate over two orders of magnitude, with a linear correlation coefficient of 0.9998 and an uncertainty of slope of 0.42%.

When the same LED was used as the light source in a referenced beam design in the cell of Fig. 10, output drift improved substantially, to $\leq 10^{-4}$ absorbance/hr and a noise level of 7×10^{-5} absorbance was observed. (LOG100JP log-ratio amplifier with an output buffer was used and only modest capacitive damping was utilized, permitting 10→90% and 90→10% respective rise and fall times of 420 and 190 msec.)

With a lower output LED, both the noise and the drift increased, *e.g.*, to 10^{-4} absorbance and 3×10^{-4} absorbance/hr respectively with a 470 nm (L200CWB5) source. However, this performance is respectable considering this is the lowest output emitter in Table 1. Linearity of response for the above detectors was tested with indigotrisulfonate and acidic dichromate solutions respectively for the two above detectors, in a FIA configuration with each analyte spanning a two orders of magnitude range in concentration. Typical chart outputs indicating attainable S/N are shown in Fig. 14. It is interesting to note that the nature of the noise changes considerably between the two detectors, this is caused by a loss of effective bandwidth of the LRA at low input currents as with the 470 nm source. In a duplicate series of tests, the respective linear coefficients of determination (r^2) for the peak height *vs.* injected concentration data were respectively 0.9998 and 1.0000 with y-intercepts statistically indistinguishable from zero. The uncertainty of the linear slope was 0.91 and 1.00% for the 605 nm detector data and 0.40 and 0.42% for the 470 nm detector calibration. This performance is better than many commercial detectors using a continuum source and a monochromator where stray light degrades linearity. Similar experiments conducted with the cell design of Fig. 9 and an AD757N LRA produced essentially the same results with regard to linearity. In this case, a rise time of 0.5 sec was used and a marginal improvement in the noise level of the 605 nm detector was observed, to 5×10^{-5} absorbance. It should be noted that this appears to be the performance limit of this basic design approach, it is not further improved with longer wavelength higher power emitters. It has also been our experience that the best results are not necessarily obtained by driving the emitters at their maximum rated current to obtain the maximum amount of light possible. No referencing scheme is perfect and excessive heat generated degrades the relative stability of the LED output and S/N performance actually deteriorates.

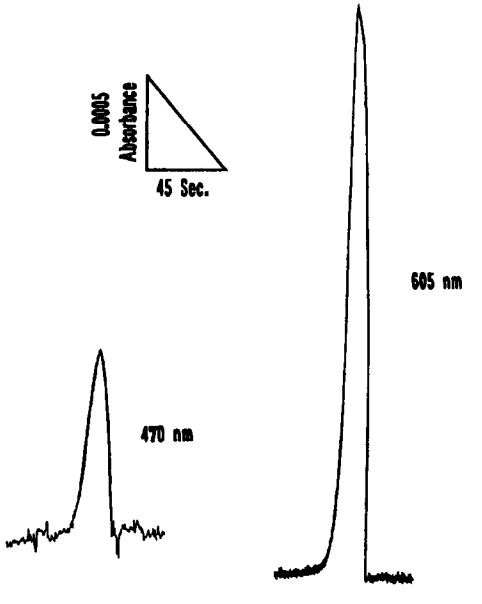

Fig. 14. Typical FIA chart output from detector of Figure 10 operated in the referenced beam absorbance output configuration.

It may therefore appear that the performance difference between low output and high output sources is not very great after all. This is true, but only if considerable trouble is taken to shield the detector and the electronics from external noise, *e.g.*, by using heavy gauge metallic enclosures, *etc.* The detectors with higher output sources are simply much more immune to extrinsic noise and the limiting level of performance, *e.g.*, that cited above, can be reached without extraordinary shielding needs. A consideration of the absolute current levels involved with the lowest output LED should be illustrative of the need for good shielding. Figure 13 indicates that the 470 nm LED L200CWB5, when driven at 50 mA, produces about 200 nA in a PD coupled head on to it. When installed in a flow cell, the reference PD on the back of the LED generates about 20 nA and the signal PD, separated from the source by several mm and a small aperture, generates a current only marginally greater than this. An absorbance change of 10^{-4} is equal to an induced noise current of < 5 pA under these conditions!

The results observed with the radial path flow cell (AD757N LRA) of Fig. 7 conforms to the criterion of $< 1\%$ deviation from linearity (with the 470 nm LED and acidic dichromate as test solution) over a 1.7 order of magnitude range of concentration. The exact design of this detector strictly involves a multiplicity of pathlengths because the optical aperture is not infinitesimally small compared to the tube diameter. The simplicity of the design makes it nevertheless an attractive candidate where detector induced dispersion is to be avoided. For the other designs, it should be noted that the intrinsic linearity of response (electronic linearity) is much greater, as previously mentioned, than the two orders of magnitude cited above. The half bandwidths

of LED sources are obviously not negligible (Table 1), the concentration-absorbance linearity observed in any given situation is more dependent on the degree of match between the emission band of the LED and the absorption band of the LED than any other factor. The broadly centered absorption band of the dye methylene blue at 666 nm matches closely the 660 nm emission band of an AlGaAs LED, with such a source the observed absorbance showed excellent linearity with the concentration of methylene blue over a 3.5-order of magnitude range of concentrations ($r^2 = 0.9997$, uncertainty of linear slope 0.6%, flow cell of Fig. 9, AD757N LRA).

Pulsed detector operation

Especially for low output LEDs it is possible to enhance performance by increasing the output in a transient fashion, *i.e.*, by pulsing it for brief periods at high current. A modest degree of sophistication is necessary to accomplish this; a suitable schematic is shown in Fig. 15. A programmable crystal oscillator (U7) provides the time base and synchronization for all operations. The width of the emitter pulse is governed by U9A while U11, its associated circuitry and a driver transistor hold the current pulse constant at some desired adjustable value. The signal and reference photodiode outputs are processed respectively by input amplifiers U1 and U3; these signals are sampled and held by U2 and U4, respectively. The sampling is delayed from the initiation of the emitter pulse to avoid problems associated with jitter and allow emitter stabilization; this delay is selected by U8A and the duration of the sample period is set by U8B. The outputs of U2 and U4 are processed by the log-ratio amplifier U5 and the final output is provided through the buffer and offset amplifier U6. This arrangement permits attainment of noise levels of $2\text{–}3 \times 10^{-5}$ absorbance with a rise time less than 0.3 sec for all the LEDs other than the 470 nm; for the latter, a noise level of 5×10^{-5} absorbance is attainable under the same conditions. The linearity performance is the same as that with the DC detectors described in the foregoing section.

Automated zeroing of detector output

For all detectors described above, the output is offset (or adjusted to zero) by a manually operated potentiometer. The schematic in Fig. 16 allows one to zero the output with 12-bit precision by a reset button (or by a logic signal from a remote source) and is particularly convenient when the determination system shows a systematic drift; auto-zeroing can be carried out every time the injection valve is switched. Approximate component cost is $100; essentially identical commercial units are offered for $1200 (*e.g.*, from Systec Inc., Minneapolis, MN). Of course, the use of such a device is not limited to the present detector applications.

Computer interfaced operation of pulsed detectors. Performance

The ultimate in flexibility and performance is achieved with computer-interfaced pulsed operation of the detector and acquisition and processing of the resulting data. The photodetector of Fig. 9 (560 nm LED, HPG5566X) was used with the arrangement in Fig. 17. The interface board and associated components were located inside a 0.1 inch thick wall Al box to provide improved shielding. The information content of FIA or liquid chromatography systems are in a very low frequency domain, typically well below 1 Hz. The operation of the LED at a modest frequency (< 100 Hz) and the use of a low-pass filter as shown in Fig. 17 results in a system with significant immunity to high frequency noise (an appreciable amount can be contributed by video monitors in their usual location atop the CPU unit housing the interface board).

In operation, during the LED-off period (typ. 20–70 msec), after an initial brief wait period of 3 msec, the dark current levels from both the signal and reference photodetectors are alternatively and repeatedly sampled. At a sampling rate of 33 kHz, *ca.* 280 individual A/D conversions are made for reference and signal currents each within 20 msec, including the wait period. The reference and signal current values are then individually summed. The digital integration procedure thus results in a large and necessary increase in the effective resolution of the 12-bit interface board used (DAS-16G1, Metrabyte Corp., Taunton, MA). The average values of the reference and signal dark currents are then stored. The LED is then turned on (for a period of typically 20–70 msec) using the digital to analog output function of the interface board as a square wave generator. Generally the LED is driven at the maximum current at which it is rated for continuous duty (typically 50 mA). Again following a brief wait period (3 msec) for any ringing to subside (typically ≤ 1 msec), the signal and reference detector currents are alternately and repeatedly sampled. Software

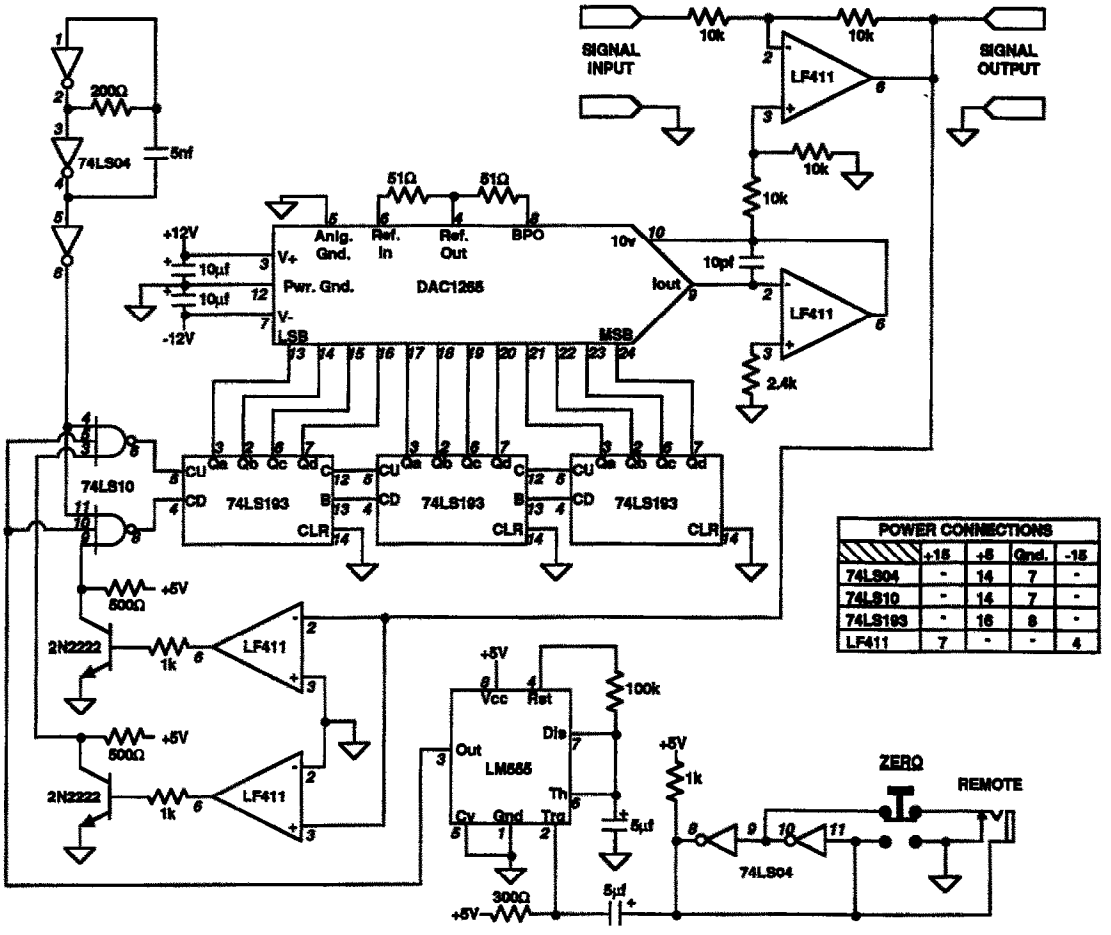

Fig. 16. Auto Zero Schematic.

(written in machine language) permit data acquisition rates up to 66.7 kHz on a 80386 processor based computer, close to the maximum sampling rate achievable by the A/D converter. The average dark current from the previous cycle is then subtracted from the corresponding average photocurrents from the LED-on period. The logarithm of the dark current corrected ratio value of the signal to the reference photodetector current is computed. The standard deviation (SD) of a number of such successive values (typically 30–50 are used) provides an index of the measurement stability (or precision). The peak to peak noise levels used in the rest of this paper are comparable to approximately twice this value. Figure 18 shows the improvement in measurement precision of measuring a blank solution (water) with increasing number of samples averaged (the effective integration period is indicated in the figure, a sampling rate of 22 kHz was used to generate these data). Little is gained beyond a sampling period of 500 msec but by this time the standard deviation of absorbance reaches $< 2 \times 10^{-6}$ absorbance; this is well beyond the performance capabilities of presently available commercial detectors. Note also that the slope of the best fit line in the log–log plot of Fig. 18 is -0.5, indicating correspondence to the theorem that the uncertainty of the measurement is reduced in direct proportion to the square root of the number of measurements, within the limits of the study. The measurement precision is also excellent with an absorbing solution in the cell, for 30 successive 66.7 msec measurements of a dye solution with a mean absorbance value of 0.430, the relative standard deviation was only 0.0026%. Note that the noise levels generated in FIA systems operated with peristaltic pumps are significantly greater than the intrinsic performance level of such a detector, the overall performance is limited by the flow/mixing noise in such systems.

Detector linearity was tested with a 605 nm LED and alkaline bromothymol blue as the test solution. Over a range of concentrations

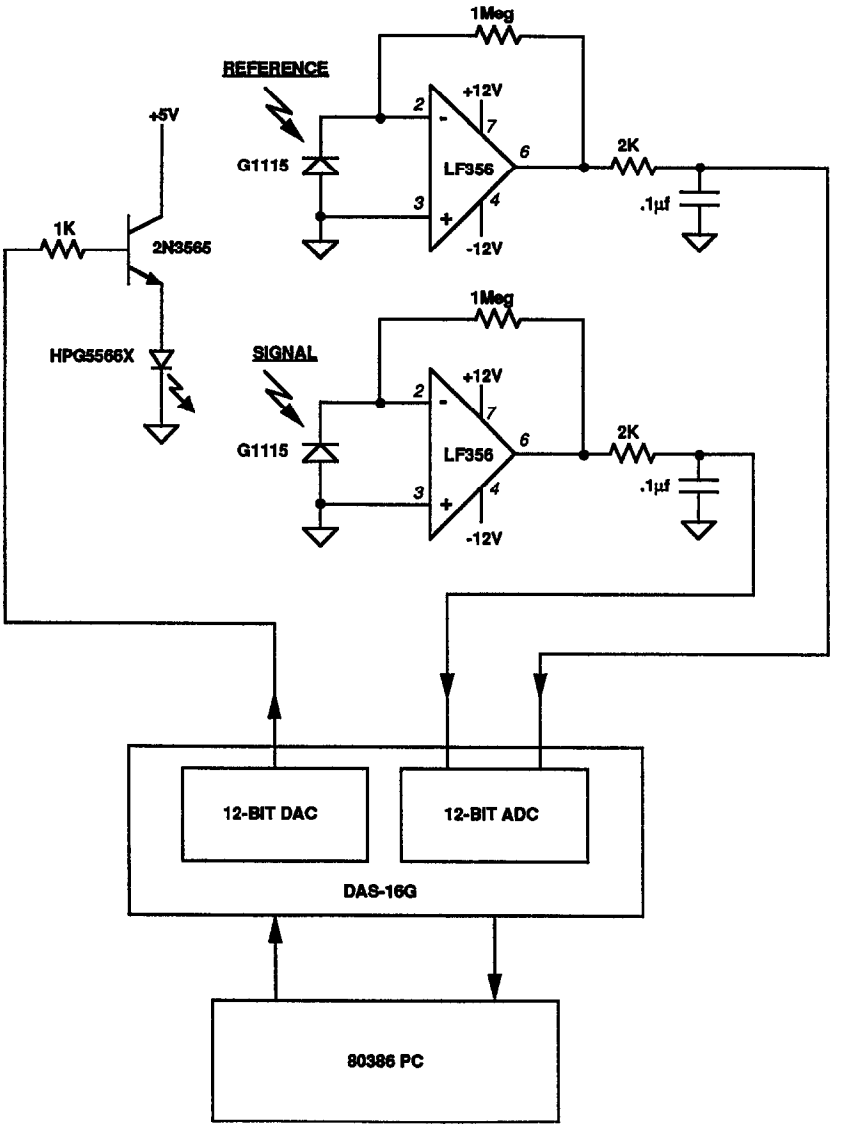

Fig. 17. Arrangement for computer interfaced pulsed detector.

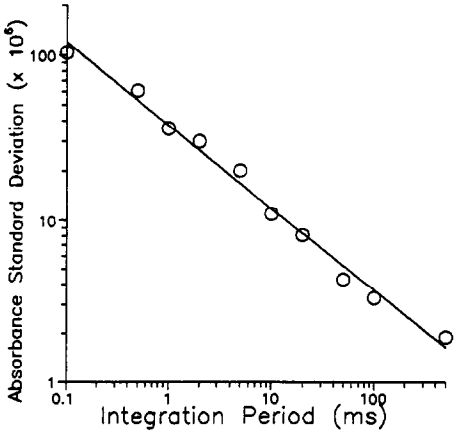

Fig. 18. Measurement precision as a function of the integration period for the computer-interfaced pulsed detector, sampling rate 22 kHz.

spanning two orders of magnitude, the absorbance–concentration relationship exhibited good linearity ($r^2 = 0.9997$, uncertainty of slope 0.78%).

CONCLUSIONS

LED-based optical detectors provide inexpensive high performance long life alternatives to continuum source detectors. For applications in which a reasonable match can be obtained between an LED wavelength and the analyte absorption, such detectors will generally outperform other available designs. If the chemical system can be so designed, a longer absorption wavelength is desirable because of the

availability of very high output sources. It is almost certain that the lower limit of the available LED wavelengths will continue to decrease for some time to come and thus broaden the scope of application of LED based optical detectors. Clearly, multiwavelength detectors containing a multiplicity of emitter LEDs can be made easily and may constitute a high light throughput alternative to continuum sources coupled to a diode array detector. Several sequentially turned on LEDs can be serially placed along a tube opposite correspondingly placed PDs, constituting a series of radial path detectors with unusual flexibility in making kinetic measurements. In essence, the low cost, small size and ease of fabrication of LED-based detectors hold unusual promise for those willing to experiment with them in unconventional ways.

Acknowledgement—This work spans several years of effort and has benefitted from the counsel of many people. In particular, we wish to acknowledge the help and interest of Steve Gluck, Dow Chemical Co.; Don Olson, Shell Development Co. and Doug Gjerde, Sarasep Inc.; Adrian Wade, University of British Columbia, is thanked for sharing his knowledge on the available literature on LED based detectors. This work was supported variously by grants from the Dow Chemical Co., Shell Development and by the Office of Basic Energy Sciences, U.S. Department of Energy through DE-FG05-84ER13281. However, this report has not been subject to review by any of the above agencies and no endorsement should be inferred.

(*Received* 26 *March* 1992. *Accepted* 4 *April* 1992)

Summary—A flow injection method is proposed for the determination of nanogram amounts of chromium(III) using a pyrogallol chemiluminescence system. It is based on its catalytic effect on the oxidation of pyrogallol with periodate at a neutral medium. The addition of 3-(*N*-morpholino)propanesulphonic acid to the reaction system increased the chemiluminescence signal for chromium(III). The present method allows the determination of 5–100 ng/ml of chromium(III). The relative standard deviation of 2.2% ($n = 10$) was obtained at 20 ng/ml of chromium(III) and the detection limit (signal-to-noise ratio = 2) was 1 ng/ml with the sampling frequency of 25/hr.

Kinetic methods of analysis using catalyzed reactions are powerful techniques for the determination of trace amounts of catalysts because they participate in the indicator reactions in a cyclic manner.[1,2] Further, the introduction of flow injection analysis makes kinetic–catalytic methods more attractive; the rapid and reproducible mixing of sample and reagents can be achieved.[3]

Some applications of chromium-catalyzed reactions including colour development and chemiluminescence (CL) for the determination of this element have been reported by several authors.[4–17] Table 1 shows the pertinent results of kinetic–catalytic methods for the determination of chromium at trace levels. Most of these methods required a separation step prior to analysis because co-existing ions interfered with the determination. The main problem in utilizing the catalyzed reactions for the assay of chromium lies in the selectivity.

The oxidation of pyrogallol (1,2,3-trioxybenzene) with molecular oxygen or hydrogen peroxide is accompanied by CL in aqueous alkali solutions;[18,19] the light emission was thought to be due to the excited singlet oxygen molecules. The reaction of pyrogallol with hydrogen peroxide has been applied to the assay of peroxidase activity[20,21] and cobalt(II).[22] Little attention have been paid to pyrogallol as a CL reagent and few papers have dealt with the CL oxidation of pyrogallol with other oxidants. The CL oxidation of gallic acid with hydrogen peroxide is thought to give similar results to the pyrogallol–hydrogen peroxide system and has been utilized for the determination of proteins,[23] formaldehyde,[19] silver(I) and cobalt(II).[24]

Recently, Evmiridis[25–27] has reported the CL flow injection determination of pyrogallol and periodate with a pyrogallol–periodate system. We found that chromium(III) enhanced the CL intensity resulting from the reaction of pyrogallol with periodate in a neutral pH region. Furthermore, the presence of 3-(*N*-morpholino)propanesulphonic acid (MOPS) in the reaction system markedly increased the CL signal for chromium(III). This paper describes the flow injection determination of nanogram levels of chromium(III) based on its catalytic effect on the CL oxidation of pyrogallol with periodiate in the presence of MOPS. As low as $10^{-8}M$ chromium(III) can be easily determined by measuring the intensity of the light produced. Total chromium can be determined by reducing chromium(VI) to chromium(III) with sulphite.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade and Millipore (Milli-Q) reagent grade demineralized water was used throughout.

A chromium(VI) stock solution (1.00 mg/ml) was prepared by dissolving 1.414 g of potassium dichromate (primary standard, Wako Junyaku Co.) in 500 ml of water. A chromium(III) stock solution (0.50 mg/ml) in 0.1*M* hydrochloric acid was prepared by mixing the chromium(VI) stock solution, 6*M* hydrochloric acid and ethanol. The excess of ethanol was removed by boiling.

Pyrogallol from Kanto Kagaku was used without further purification. A pyrogallol stock solution (0.1*M*) was prepared by dissolving 1.26 g of the compound in $10^{-3}M$ hydrochloric acid, diluting to 100 ml with the same acid and filtering through a 0.45-μm Millipore filter. The stock solution was stable for at least a week if it was stored in a refrigerator. Generally, 250 ml of working solutions ($1.0 \times 10^{-4}M$) were prepared daily from the stock solution. A periodate solution ($6.0 \times 10^{-3}M$) was prepared by dissolving 0.690 g of potassium periodate (Nakarai Kagaku Co.) and diluting to 500 ml with water. A MOPS (Dojin Kagaku Co.) buffer solution ($8.0 \times 10^{-2}M$) involving ammonia (0.3*M*) and EDTA ($6.0 \times 10^{-3}M$) was also prepared; the pH of the solution was adjusted to about 7.0 with 3 and/or 0.1*M* hydrochloric acid when $1.0 \times 10^{-3}M$ hydrochloric acid was used as a carrier solution.

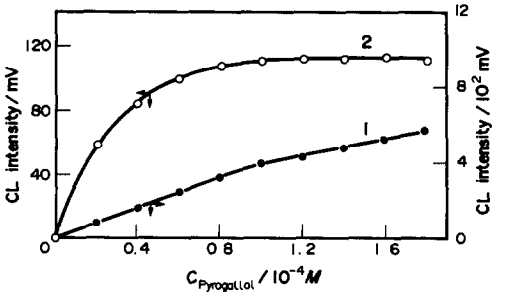

Fig. 5. Effect of pyrogallol concentration on the CL intensity. 1, baseline; 2, 20 ng/ml chromium(III). Other conditions as in Fig. 1.

Apparatus

The flow system is shown in Fig. 1. It consists of two double-plunger micropumps (Kurahashi Giken DLP-2000), a six-way injection valve (Sanuki Kogyo SVM-6M2) with variable sample volume, a circulating thermostated bath (Toyo LH-1000C), a CL detector (Soma Kogaku S-3400) equipped with a spiral type flow cell and a recorder (Rika Denki R-01). The flow cell was a 55-cm coil of Teflon tubing. All coils in the manifold are made from Teflon tubing (0.5 mm i.d.). Chemiluminescence spectra of the reaction system were obtained with a JASCO FP-777 spectrofluorometer installed with a Soma S-3400 CL flow cell over the wavelength range from 300 to 700 nm. A Toa Denpa Model HM-55 pH meter was also used.

Procedure

The carrier (R1, 1.0×10^{-3} or $0.1M$ hydrochloric acid), MOPS buffer (R2), pyrogallol (R3) and periodate (R4) solutions were propelled at a flow-rate of 0.7 ml/min. A 321-μl aliquot of sample solution was injected into the carrier stream, which was then mixed with the buffer solution. The mixed solution was sent to a heating coil (one metre) immersed in a water-bath at $30.0 \pm 0.1°$. Pyrogallol and periodate solutions heated at 30° were merged with the carrier stream in front of the flow cell. The emission light from the CL reaction was monitored with the detector without wavelength discrimination.

RESULTS AND DISCUSSION

Chemiluminescence spectra

The CL intensity from the reaction of pyrogallol with periodate was relatively weak compared with those produced by other CL reagents. Chromium(III) has a pronounced catalytic effect on this reaction at a neutral medium. Figure 2 shows the CL spectrum of the pyrogallol–periodate–chromium(III) system; an emission maximal peak exists at 507 nm. The rapid decrease in the CL emission light was observed; the CL emitting species with a high rate of formation had short lives.

Effect of reaction variables

The CL reaction of pyrogallol with periodate was studied as a fast assay method of chromium(III) with the flow injection technique. From the results of preliminary studies, the highly sensitive flow injection system shown in Fig. 1 was adopted and used in optimizing the variables such as flow-rate, the sampling loop,

temperature and reagent concentrations that influenced the chromium(III)-enhanced and background CL intensity.

The effect of flow-rates of the carrier and reagent streams on the heights of peak and baseline was examined in the range 0.2–1.0 ml/min. With the increase in flow-rate up to 0.5 ml/min, the peak height increased; an almost constant peak remained at higher flow-rates. While the height of baseline was almost constant. A flow-rate of 0.7 ml/min was selected for the procedure.

The effect of the temperature on the CL intensity was studied by keeping the heating coils (1 m) at 20–50°. A constant and maximal peak height was obtained at 30–40°; the height of baseline increased with increasing temperature. A temperature of 30° was selected for further studies. Sample volumes varying from 110 to 460 μl of 20 ng/ml chromium(III) solution were injected into the system. The peak height increased with increasing injected sample volume up to 310 μl; at larger volumes it slightly increased. A 321-μl sample volume was adopted.

Preliminary experiments revealed that the catalytic effect of chromium(III) on the CL reaction was observed at a neutral medium and the optimum pH region was slightly shifted with the buffer agent used. For example, the maximal peak height was obtained at pH 7.3 and 7.7 in the presence of *N*,*N*-bis(2-hydroxyethyl)-2-aminoethanesulphonic acid (BES) and 2,4,6-trimethylpyridine (TMP), respectively. Thus, the effect of pH and buffer concentrations including imidazole, BES, MOPS, TMP, *N*-tris(hydroxylmethyl)methyl-2-aminoethanesulphonic acid (TES), *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulphonic acid (HEPES) and triethanolamine was examined by adding a constant concentration of ammonia and various amounts of hydrochloric acid. Of these, the maximal peak height was obtained in the presence of MOPS at pH 6.9 as shown in Fig. 3. The height of baseline was maximal at pH around 7. Figure 4 shows the effect of MOPS concentration on the heights of peak and baseline; they increased with increasing concentration of MOPS. This phenomenon cannot be explained at present and requires further investigation. On the other hand, the higher concentrations of the other buffers decreased the CL signal for chromium(III). From these results, the CL reaction was carried out at pH 6.9 in the presence of MOPS ($8.0 \times 10^{-2}M$). In order to optimize the concentration of ammonia, its initial concentration was varied in the range 0.01–0.8M, while keeping the concentrations of all other

Table 3. Maximum tolerance limits for diverse ions in the determination of 20 ng/ml chromium(III)

Tolerance limit, ng/ml	Ion added
10,000...	Al(III), As(V), Ba(II), Ca(II), Cd(II), Cu(II), Hg(II), Mg(II), Ni(II), Pb(II), Se(IV), Sr(II), V(IV), V(V), Zn(II), BO_3^{3-}, Br^-, ClO_4^-, CO_3^{2-}, F^-, NO_3^-, PO_4^{3-}, SO_4^{2-}, Citrate, Oxalate, Tartrate
1,000...	As(III), Te(IV), NO_2^-, I^-
100...	Ag(I), Ce(III), Ce(IV), Fe(II), Fe(III), Mn(II), Mo(VI), Ti(IV), Sn(II), W(VI)
50...	Bi(III), Sn(IV)
25...	Co(II)

ingredients constant. An ammonia concentration of 0.3M was chosen as optimal because it was maximal and a constant peak height was observed in the range 0.2–0.4M ammonia.

Figures 5 and 6 show the effect of the pyrogallol and periodate concentrations, respectively. The peak height was constant at pyrogallol concentrations above $0.8 \times 10^{-4}M$; the baseline height increased gradually. Thus, a $1.0 \times 10^{-4}M$ pyrogallol solution was used. As the heights of peak and baseline increased with increasing concentration of periodate, $6.0 \times 10^{-3}M$ periodate was selected taking account of the baseline stability.

Calibration graph

Calibration graphs were prepared by using the flow system shown in Fig. 1. The dynamic range for the chromium(III) determination was from 5 to 100 ng/ml at a sampling rate of 25/hr. Figure 7 shows a typical calibration graph for chromium(III) in the concentration range 5–50 ng/ml. Though the graphs were slightly curved, the reproducibility of the method was satisfactory; the relative standard deviations for 10 replicate determinations of 10, 20 and 50 ng/ml chromium(III) were 3.1, 2.2 and 1.9%, respectively. The detection limit (signal-to-noise ratio = 2) was 1 ng/ml.

Chromium(VI) at concentrations below 50 ng/ml was not detected by the present procedure. The method was tested for several synthetic mixtures of chromium(III) and chromium(VI) in the absence and presence of sulphite ($1.0 \times 10^{-4}M$) which hardly affected the chromium(III)-catalyzed reaction. The analytical results are given in Table 2. As can be seen, total chromium concentration can be determined by reducing chromium(VI) with sulphite; the chromium(VI) content is obtained by subtracting the chromium(III) content from total concentration of chromium.

Interferences

From preliminary experiments, some metal ions such as aluminum(III), iron(III) and zinc(II) at 100 ng/ml levels gave a negative error in the absence of a masking agent because of formation of their hydrolyzed species at the neutral medium; it was necessary to add a masking agent to the reaction system. It was expected that EDTA acted as an activator for chromium(III)[8] and could effectively suppress the interferences of diverse ions. Therefore, the effect of EDTA concentration on the chromium(III)-catalyzed reaction was examined over the range 0–$1.0 \times 10^{-2}M$. The peak height slightly increased with increasing concentration of EDTA up to $1.0 \times 10^{-3}M$; at higher concentrations, it was almost constant. Thus, a $6.0 \times 10^{-3}M$ EDTA solution was used.

The selectivity was tested by analyzing standard solutions containing 20 ng/ml chromium(III) and various amounts of diverse ions in the presence of EDTA. The tolerance limit was estimated with a 5% relative error. The results are summarized in Table 3. Most diverse ions did not interfere, at least at concentrations of 100 ng/ml. Negative interferences were observed from bismuth(III) and tin(IV) at concentrations higher than 100 ng/ml. But 50 ng/ml concentrations of these ions did not interfere. Cobalt(II) showed positive interference with a maximum tolerable concentration of 25 ng/ml because of its catalytic action on the CL reaction.

CONCLUSION

The proposed method, based on the catalysis of the CL oxidation of pyrogallol with peroxide in the presence of MOPS, provides a simple and sensitive approach for the determination of chromium(III) at nanogram levels. The dynamic range of the method is 5–100 ng/ml chromium(III) with the sampling frequency of 25/hr. The reproducibility of the method is satisfactory with the relative standard deviation of 2.2% ($n = 10$) at 20 ng/ml chromium(III) and the detection limit (signal-to-noise ratio = 2) is 1 ng/ml. The total chromium content can be determined by reducing Cr(VI) with sulphite.

SEQUENTIAL INJECTION TECHNIQUE FOR AUTOMATION OF COMPLEX ANALYTICAL PROCEDURES: FLUOROMETRIC ASSAY OF FACTOR THIRTEEN

MIGUEL GUZMAN, CY POLLEMA, JAROMIR RŮŽIČKA and GARY D. CHRISTIAN
Department of Chemistry BG-10, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 11 *February* 1992. *Revised* 31 *March* 1992. *Accepted* 31 *March* 1992)

Summary—A non-segmented flow method is used to automate an analysis which involves five different reagents. The fluorometric assay for factor thirteen (FXIII) is performed by the sequential injection analysis (SIA) technique. Two reactions take place in a single line SIA system to produce the final fluorescing product. Because of its mechanical simplicity and versatility, the sequential injection (SI) technique is shown to be an attractive tool for automation of a complex analytical procedure. In addition to collecting quantitative and kinetic information, the SI system is illustratively used for optimization of the analysis and for obtaining validation information.

The sequential injection (SI) technique was developed to satisfy the demands for mechanically simple and robust, yet versatile, flow injection (FI) methodology.[1–4] The heart of a SI system is a selector valve which, in the simplest case, is used to connect a detector with the system and to introduce a wash solution, sample solution, and reagent(s) into a holding coil (Fig. 1). Sequential aspiration of solutions from specific ports of the selector valve leads to the formation of well-defined zones in the holding coil. Upon flow reversal, the entire contents of the holding coil are propelled towards a detector, and the zones penetrate each other due to combined axial and radial dispersion. The overlap of the reagent and sample zones triggers the formation of a reaction product. Propelling the product zone through an appropriate detector provides a signal similar to that obtained by conventional flow-injection analysis.[5]

The versatility of the SI manifold is a major advantage of the technique since each port of the selector valve allows a different operation to be performed. Although Fig. 1 illustrates a SI set-up for a simple one reagent analysis, the very same manifold (single pump, single valve) may be utilized for far more complex analytical procedures. This is achieved by assigning specific functions to free ports on a multiport valve and by designing an appropriate flow program. Thus, specific free ports are dedicated for introduction of different reagent solutions, while others allow introduction of a standard solution to the holding coil or connect a mixing chamber or a dilution coil to the SI system into which an aspirated sample may be introduced from the holding coil.[6] Computer control of the SI system is an essential prerequisite since an analytical procedure often requires a complex and highly reproducible flow pattern. Under the computer control, the flow rate and the direction of the flow can be varied at will and stopped flow often becomes an integral part of the analysis for monitoring slow reactions.

In contrast to conventional flow injection systems, the increasing complexity of the analysis will not sacrifice the mechanical simplicity of the SI manifold. In fact, most analyses performed in the SI mode can be applied to a single line, one pump, one valve configuration. Besides its versatility and mechanical simplicity, the SI technique offers additional advantages, namely the ability to change experimental parameters without physical restructuring of the manifold and the ability to control reaction time and the degree of zone dispersion.[2]

The significance of the two major disadvantages of the SI technique quoted in previous publications,[1–3] the lower sampling frequency and a requirement for a computer controlled system, will vary for different applications. For many applications, the positive aspects of the technique make, however, the SIA an attractive tool for development of automated analyses. To

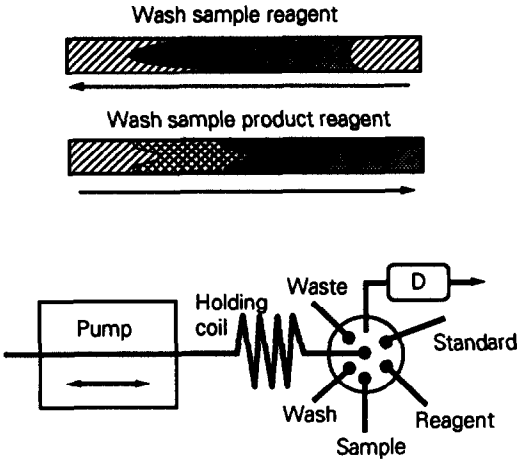

Fig. 1. Sequential injection analysis (SIA) system: zones are stacked sequentially in the holding coil. Substantial overlap of the zones occurs when the flow is reversed.

test this claim, SIA was used in this study for the development of an automated fluorometric assay of factor thirteen (FXIII), an analysis which involves a complex procedure and which, to date, has been performed exclusively in a manual model.

FXIII is an enzyme which plays an important role during the final stages of blood coagulation. A fluorometric assay[7] is used to determine its quality after it is produced by a fermentation process and after various stages of its purification. The fluorometric assay of FXIII is based on activation of the enzyme by thrombine followed by the active FXIII catalyzed condensation reaction between monodansyl cadaverine and *N,N*-dimethyl casein to form a fluorescing compound (Fig. 2). The amount of fluorescing product is directly related to the amount of the active FXIII formed during the activation period.

Two routinely performed assays include a single point measurement and a kinetic measurement of the FXIII activation.[7] In currently used methods, both measurements involve manual operations such as sample dilution, thermal equilibration of the reaction

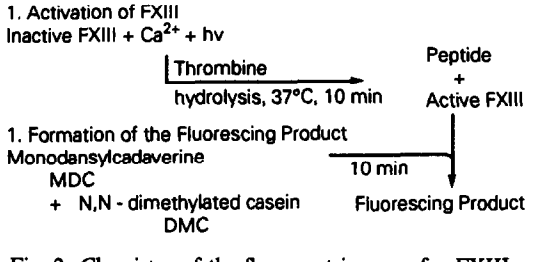

Fig. 2. Chemistry of the fluorometric assay for FXIII.

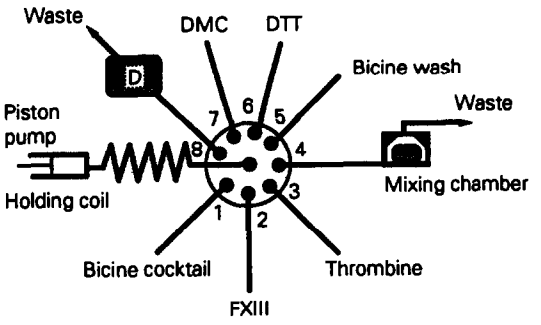

Fig. 3. System design for SIA of FXIII.

mixture, addition of reagents at specific times, monitoring of the reaction time and transportation of sample cuvets to the detection compartment. Each sample is run in duplicate to validate the results of the assay. The more concentrated samples require extensive dilution in order to bring the absorbance signal into the linear calibration range. As a result, some samples do not fall into the calibration range after the first dilution step and must be re-analysed.

Clearly, these manual operations and the inability to select the appropriate dilution factor for all samples on the first attempt make the analysis labor-intensive and time-consuming. This in turn prevents thorough investigation of the FXIII production. The automation of the assay by means of SI technology leads to significant improvement because the crucial operations are no longer performed manually, human bias is largely eliminated from the process, and the whole procedure is simpler.

The following studies describe the automation of the fluorometric assay by the SI technique. The experimental SI manifold and typical signal outputs resulting from the automated analysis of FXIII are shown and the ability of the SI system to provide a validation and diagnostic information is investigated.

EXPERIMENTAL

Chemicals

The concentration of standard FXIII solutions ranged from 0 to 50 μg/ml. The solutions employed included 0.05*M* bicine buffer at pH 10, 0.05*M* Tris buffer at pH 7.4, 0.4*M* calcium chloride in bicine buffer, 2% *N,N*-dimethyl casein (DMC), 100 NIHU/ml and 500 NIHU/ml thrombine, 0.2*M* dithriothreitol (DDT), and 4m*M* monodansyl cadaverine (MDC). In addition, a stock solution of bicine cocktail was prepared by mixing the bicine

buffer with MDC and calcium chloride in a 60:1:2.4 ratio.

Hardware

The SIA set-up consisted of an Alitea (S-2) piston pump (cam driven, sinusoidal flow) equipped with a 1-ml syringe, a Valco 8 port selector valve, an HP 1046A fluorescence spectrometer, an IBM personal computer, a water bath, a mixing chamber (0.75 ml internal volume), a stirring plate and PTFE (Teflon) tubing (0.5 mm internal diameter). Figure 3 shows the SI configuration. Ports 1 through 3 were used for introduction of bicine cocktail, FXIII, and thrombine solutions into the holding coil, respectively. Port 4 was connected to a mixing chamber by a 10-cm length of PTFE tubing of 0.5-mm internal diameter (20 μl volume). Ports 5 through 7 were used for injection of bicine wash, DTT (a component which quenches the FXIII activation), and DMC solutions into the holding coil, respectively. Port 8 was connected to the detector.

The pump, the valve and the detector were computer interfaced using a real time devices (RTD) board. A program written in Matlab software was used for controlling the pump and the valve, as well as for collecting, displaying and storing the signal output from the detector.

Procedure

The FXIII fluorescence assay requires injection of six different zones into the holding coil and then to the mixing chamber at specific stages of the analysis, using the SI configuration as depicted in Fig. 3. In the absence of a mixing chamber it would have been a difficult and impractical task to stack so many reaction zones in the holding coil and still ensure proper mixing with the sample. Obviously, a different approach is required. Connecting a mixing chamber to one of the ports is the most direct solution to the problem. The wash, sample and appropriate reagent solutions are sequentially aspirated in a specified order into the holding coil and then transferred into the mixing chamber at times selected suitable for the analysis. The contents of the mixing chamber are gently mixed, so that the reaction can take place. After the fluorescent product begins to form, a number of aliquots are withdrawn at selected times from the chamber and propelled through the detector thus providing both quantitative and kinetic information of the rate of fluorescing product formation, as well as allowing a wide dynamic range for analysis offered by measurements made at different reaction times of the fluorescing product formation.

The automated procedure consists of four stages: 1) sequential introduction of the bicine cocktail, FXIII sample and thrombine solutions into the mixing chamber which results in FXIII activation, 2) addition of DMC and DTT solutions into the mixing chamber which quenches FXIII activation and initiates formation of the fluorescing component, 3) a sampling cycle comprising aspiration of a sample aliquot from the mixing chamber and propelling the aliquot zone into the detector, and 4) washing out the system with bicine buffer. Although minor modifications accompanied the experimental procedure, this general outline was followed throughout the test period.

System preparation

First, all the solutions used in the assay were placed in a water bath and equilibrated to 37° and the syringe was filled with the wash solution. After 10 min, lines from ports 1, 2, 3, 5, 6 and 7 were filled with the appropriate solutions by selecting an appropriate port and aspirating 50 μl into the system for each solution. Since smaller volumes were required to fill the connecting lines, an excess of solutions was introduced into the holding coil. After all lines were filled, the excess solutions in the holding coil were propelled to waste. The mixing chamber and its connecting line remained empty at the beginning of each analysis. Next, the line connecting port 8 and the detector was flushed with bicine buffer and the spectrometer was set up for the measurement. The excitation wavelength was set to 350 nm and the emission wavelength was set to 500 nm. The lamp remained, however, off and was turned on only during the sampling stage to prevent excessive heating of the detector. A sinusoidal flow pattern provided an average flow rate of 21 μl/min over the working range of the pump and all volumes were approximated using this value.

Stage 1. Active FXIII was formed during the first stage of the analysis. After inputting two delay times (one for the hydrolysis activation of the FXIII and one for the development of the fluorescent product prior to the sampling stage cycle) and the number of sampling cycles into the computer, the analysis began by sequential aspiration of 210 μl of the bicine wash (port 5) and 210 μl of the bicine cocktail (port 1) into the holding coil. With flow reversal, 119 μl of the

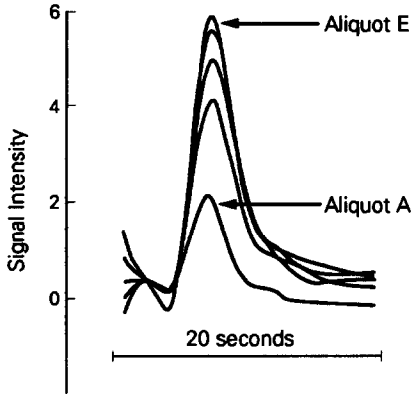

Fig. 4. Signals resulting from measurements of 50 μg/ml FXIII standard. Five aliquots were withdrawn from the mixing chamber in 67-sec sequences. Aliquot A provides the smallest signal because the fluorescence producing reaction time is shortest for this aliquot and the sample is, in addition, diluted by the dead volume of the line connecting the chamber and the valve.

holding coil content was expelled to the mixing chamber (port 4). The volumes are determined by the average flow rate and the time of aspiration. Bicine cocktail provided calcium ions used during the FXIII activation and MDC which was used later for the second reaction. Next, 42 μl of FXIII (port 2), and 10.5 μl of thrombine (port 3) were aspirated into the holding coil and 115 μl of the holding coil content was expelled to the chamber and mixed gently with the whole content. The hydrolysis of FXIII began and the length of the reaction was determined by delay time 1 which was selected prior the analysis.

Stage 2. At this stage the fluorescing product was formed in the mixing chamber. After the expiration of the delay time 1, 10.5 μl of DTT (port 6) and 42 μl of DMC (port 7) were sequentially aspirated into the holding coil and 115.5 μl of the holding coil content was injected into the mixing chamber and the valve was turned to port 8. At this stage, the mixing chamber was nearly filled to its capacity. The introduction of DTT quenched the activation process and the presence of DMC, MDT and active FXIII in the reaction mixture initiated the formation of the fluorescing product. The delay time 2 determined the time elapsed between introdution of DTT and DMC into the mixing chamber and first sample aliquot aspiration.

Stages 3 and 4. Following the delay time 2, the first sampling cycle was performed by sequential aspiration of 525 μl of the bicine wash (port 5) and a 63 μl aliquot from the mixing chamber (port 4) into the holding coil and expulsion of 588 μl of the holding coil content through the detector line (port 8) into waste. Signal collection was initiated at the time the liquid began to flow through the detector line. A signal in a form of a peak was obtained and the data were stored in the computer. The sampling cycle was then repeated with successive aspiration of equal aliquots from the mixing chamber, depending on the number of cycles selected prior to the analysis. Data for a total of three of five sample aliquots were collected and stored in presented experiments. Finally, all flow lines and the chamber were thoroughly flushed with the bicine wash and the system was prepared for injection of a new sample.

RESULTS AND DISCUSSION

Signal output profile

Figure 4 shows a typical signal output resulting from analysis of a 50-μg/ml FXIII standard sample. Five sampling cycles were selected for analysis of the sample, providing five peaks which, in Fig. 4, are shown overlapped to facilitate the graphical presentation. For each analysis, the first aliquot (aliquot A) provided the lowest peak and the last aliquot (aliquot E in this case) provided the highest peak, assuming the continuous formation of the fluorescing compound. Two features influence the changes in signal intensity: 1) for each consecutive aliquot the reaction time for formation of the fluorescent product increased by 67 sec, corresponding to a higher intensity signal and 2) aliquot A is diluted by the dead volume of the tube which connects the mixing chamber and the valve, which is reflected by proportionately lower signal for aliquot A. Using 150 sec for delay time 1, 194 sec for delay time 2 and five

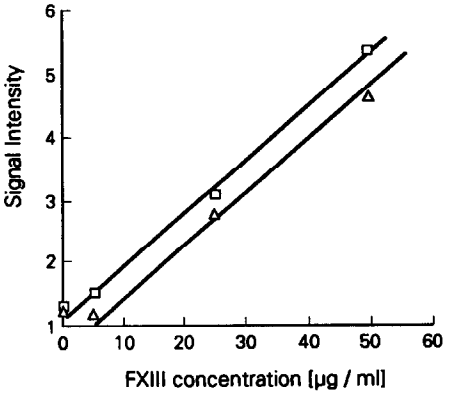

Fig. 5. Calibration curves constructed from measurement of four standards using two aliquots: △—aliquot B and □—aliquot C.

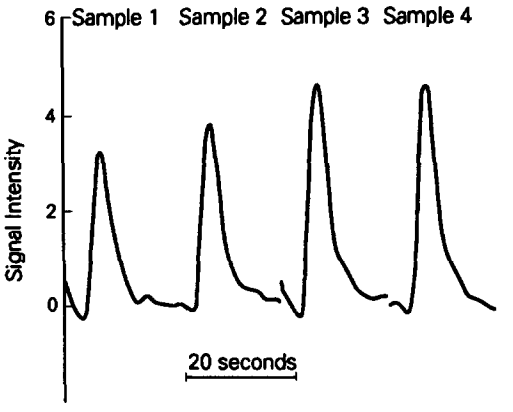

Fig. 6. The trend in the signal for aliquot C with successive doubling of the sample volume of a 50 μg/ml FXIII standard.

sampling cycles, the analysis of each sample took about 8 min.

Calibration curves

In the next experiment, four standards of FXIII in the concentration range from 0 to 50 μg/ml were measured in order to construct a calibration curve. Signal intensities of the peak heights resulting from monitoring aliquots B and C for each calibration sample are plotted against the concentration of the calibration samples (Fig. 5). A linear response was obtained with correlation coefficients of 0.98 and 0.99 for aliquots B and C, respectively. The importance of selecting the proper time for the measurement is illustrated by measuring the 5-μg/ml sample. For this sample, aliquot B does not provide a detectable signal but aliquot C, which was withdrawn 67 sec later, provides a readily detectable signal.

FXIII volume variation

The sample volume parameter was investigated. Only one stock solution, 50 μg/ml of FXIII, was used for generating data shown in Fig. 6. The concentration of inactive FXIII in the mixing chamber varied from sample to sample since the volume of FXIII sample was doubled for each consecutive injection of the analyte into the mixing chamber, starting with 21 μl and continuing with 42 μl, 84 μl and 168 μl while the total volume of reaction mixture in the mixing chamber was kept constant by decreasing the volume of bicine cocktail. The volumes of thrombine, DTT and DMC were kept constant throughout. Thus, the variables included concentration of FXIII, which was increasing, and concentrations of calcium ions and monodansyl cadaverin (MDC), which were decreasing. An increase of the signal can be observed for the first three samples, an expected trend since all the reagents are in excess and FXIII is the limiting reactant. The signal intensity is, however, increasing by only 15–20%, although the FXIII concentration was actually doubled. There are three primary reasons for this trend: 1) The blank (bicine buffer) provides a substantial background signal. The maximum signal intensities for the five aliquots of the blank are 0.68, 1.23, 1.35, 1.30 and 1.32 for corresponding sample aliquots A–E, respectively. 2) The decrease in MDC concentration affects the formation of the fluorescing compound. This is a known trend shown previously on manually performed assays, where measurements of the same FXIII sample using bicine cocktail solutions containing different MDC concentrations provided decreasing signal with decreasing MDC concentrations. 3) Similar experiments showed that decrease of calcium ion concentration also affects the kinetics of FXIII activation, but not as significantly as the MDC concentration if the molar concentration remains higher than the molar concentration of FXIII. The signal intensity for the fourth volume of analyte is actually slightly lower than for the previous volume, although the total FXIII concentration in the mixing chamber increased. Most likely, the MDC began to limit the reaction kinetics significantly.

Influence of delay times

The value of the delay time (1) selected for the SI procedure determines the success of the analysis. Too short a time results in too low a signal because the activation is not allowed to

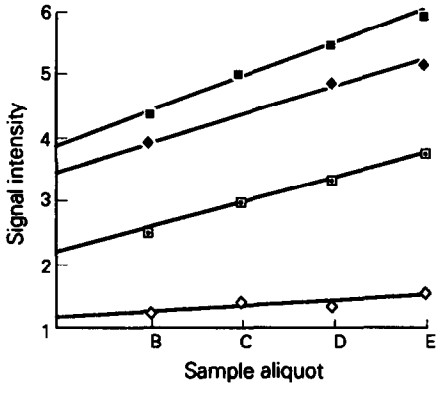

Fig. 7. Effect of variation in delay time (1): ◆—60 sec, blank, ⊡—60 sec, 50 μg/ml FXIII standard, ◆—300 sec, 50 μl/ml FXIII standard, and ■—450 sec, 50 μl/ml FXIII standard.

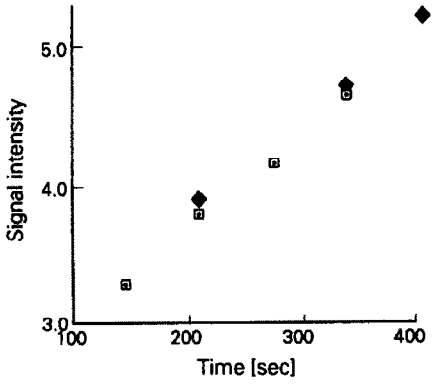

Fig. 8. Effect of variation in delay time (2): ⊡—60 sec, ◆—194 sec.

proceed to the desired degree, while too long a time will limit the sample throughput. Proper selection of the delay time (2) is easier since it determines the time for the aliquot sampling but does not influence the reaction process. In addition, the sampling occurs over a time period which is long enough for selection of an appropriate delay time (2) for all subsequent runs.

In one experiment, delay time (1) was varied from 60 to 450 sec while delay time (2) was kept at 194 sec for all samples. The results for aliquots B, C, D and E are presented in Fig. 7. For a given aliquot on the x-axis, the variation along the y-axis shows the effect of the increasing reaction time of protein activation. The lowest signal corresponds to the blank which was measured with delay time (1) set to 60 sec, while the other signals correspond to measurements of 50 μg/ml FXIII standard with varying delay (1) time. As important as an increase in absolute signal with increased delay time (1) is the relative signal intensity increase from aliquot to aliquot for each sample, because this parameter determines the sensitivity of the analysis. As Fig. 7 shows, the slope of the kinetic curve increases steadily over this time range, from a value of 0.38 for a 60-sec delay time to values of 0.45 and 0.52 for delay times of 300 and 450 sec, respectively. The delay time (1) was then set to 150 sec for subsequent experiments, a good compromise between the sensitivity factor and sampling frequency consideration.

The delay time (2) is less crucial since the second reaction is monitored over a certain time range and, therefore, the collected data provide more information about its kinetics. As a result, the appropriate sampling time can be easily selected. In one experiment, the same sample was injected twice, but with two different delay (2) times, 60 sec for the first injection and 194 sec for the second injection. Since all the other variables were kept constant and the first reaction was actually quenched by the addition of DTT solution, the signal intensity changes reflect the kinetics of the second reaction. In Fig. 8 the signal maximum for each aliquot from the two injections are plotted against the actual reaction time of the second reaction (time elapsed from the introduction of DMC and DTT into the chamber to the detection of an aliquot). As expected, the results suggest that the variation in delay time (2) has no effect on the activation process.

Temperature effect

Another important aspect of the assay is the temperature. In one experiment, all solutions were kept in the water bath at 37° for 9 hr. To investigate the effect of extended exposure to higher temperatures, the same sample was analyzed repeatedly during this period. The collected signals for a 50 μg/ml FXIII solution analyzed two hours apart provided comparable results and, therefore, indicated a reasonable stability of reagents and the sample over this time period. This was not the same, however, for extended periods. Figure 9 shows results for the sample containing 121 μg/ml FXIII which was analyzed at 1, 7, 8 and 9 hr after the reagents were immersed into the water bath. A definite steady decrease in the signal intensity is obvious. Thrombine, DMC and FXIII are likely to be most affected by the extended exposure to higher temperature. Thus, for process control applications it will be necessary to limit the time during which all the solutions are equilibrated. One possible solution is to thermostat the SI

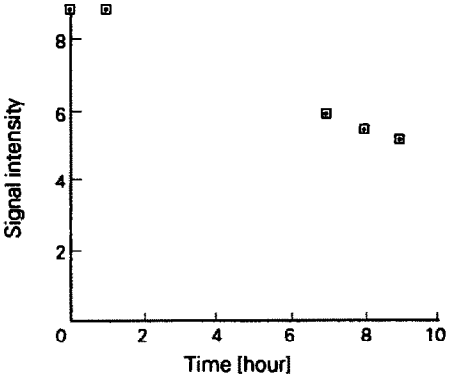

Fig. 9. Temperature effect on the analysis. Peak heights of aliquots E for a sample analyzed at 0, 1, 7, 8 and 9 hr after it was immersed together with all other solutions into a 37° water bath.

system and the bicine wash solution while the other solutions are kept at lower temperatures and perform thermal equilibration of them in the SI system. Considering small volumes of reagents and samples aspirated into the system and significant dilution in the bicine wash, it is likely that the resulting mixtures will require a short time for equilibration.

CONCLUSION

For the first time, a complex analytical assay was performed in the SIA mode. In the past, mentioned drawbacks of non-segmented flow systems often included the inability to perform an analysis involving a large number of reagents and extended reaction times. Furthermore, the mechanical complexity of the flow system was directly proportional to the increase in complexity of the analysis. Clearly, these objections are not valid for sequential injection methodology. In the presented example of FXIII assay, six different solution zones were introduced into the system at various times, two different reactions took place, appropriate dilutions were achieved and both quantitative and kinetic information was obtained. All this was performed with a single line, one pump, one valve system configuration.

When a SI method is being optimized, the parameters can be varied without physical restructuring of the system. The volumes of reagents and samples, the sequence of zones aspirated, the flow pattern and reaction times are varied interactively through the computer keyboard without a need to modify the system. Thus, once the SI system is properly assembled, an analyst can concentrate on the method development without involving hardware changes.

Collecting signal output for several sample aliquots from each sample provides both kinetic information (assuming the reaction takes place during the sampling period) and single point information (*i.e.*, the quantitative value for a particular reaction time). The concentration range of the analyte is extended since any of the aliquots can be used for calculating the quantitative values. Thus, for samples with high analyte concentration, an aliquot corresponding to shorter reaction time (aliquots A, B or C) can be used for quantitative prediction, while aliquots D and E are used for samples with very low analyte concentration. Of course, there is no objection to using all aliquots for the calculations if their signals fall within the calibration range.

As illustrated by the experiments, the SI system can be effectively used for method optimization, validation and diagnosis. Automation of an assay eliminates errors associated with manual manipulation, but one must exercise caution during the computer interfacing process to minimize other sources of errors. Precise timing and reproducibility of parameters such as flow rates, zone volumes and time delay will be crucial for successful analysis. For example, a sinusoidal flow piston pump (1) was used in these experiments to ensure pulse free flow and the flow was always stopped when the valve changed its position in order to avoid problems associated with back up pressure created if the flow continues during the valve rotation sequence. Clearly, for each hardware setup, it is important to identify the potential sources of errors and either eliminate or minimize them. Then the SI system can provide a powerful sample handling and sample pretreatment tool suitable for research, and clinical and process control applications.

FIA–FT–IR DETERMINATION OF IBUPROFEN IN PHARMACEUTICALS

SALVADOR GARRIGUES, MAXIMO GALLIGNANI and MIGUEL DE LA GUARDIA*
Department of Analytical Chemistry, University of València, 50 Dr Moliner St. 46100 Burjassot, València, Spain

(*Received* 25 *March* 1992. *Revised* 29 *April* 1992. *Accepted* 30 *April* 1992)

Summary—A method has been developed for the determination of Ibuprofen (2-[4-isobutylphenyl]-propionic acid) in pharmaceuticals by FT–IR, using the carbonyl band which this compound presents at 1710 cm^{-1} in carbon tetrachloride solutions. Samples are dissolved in carbon tetrachloride. In this solvent the excipients are not soluble and so the drug can be directly determined without any additional treatment. The use of a simple FIA manifold permits one to carry out this analysis with a low consumption of reagent and the FT–IR provides a continuous monitoring of the spectral base-line which permits an accurate determination of the maximum in the absorbance band. Also, the FIA system permits easy and fast sampling and cleaning of the measurement cell. The method has a dynamic range between 0.5 and 20 mg/ml with a sensitivity of 0.366 ± 0.004 au $\cdot$ $mg^{-1} \cdot ml \cdot mm^{-1}$ and a variation coefficient of 0.8% for 5 independent measurements of a real sample containing 200 mg of Ibuprofen per capsule. The developed procedure provides concentration values comparable with those found by UV spectrophotometry in the analysis of real samples but is free from matrix interferences.

Infrared spectrometry (IR) provides a useful way for the identification of drugs.[1–4] However, the traditional techniques employed to obtain the IR spectra, such as alkali halide disks, mulls and thin films, are not adequate for quantitative analysis, and because of this, ultraviolet spectrometry[5] is usually employed in the analysis of pharmaceuticals rather than IR.

The use of flow cells for handling appropriate solvents and with spacers opens the possibility of carrying out quantitative IR determinations of drugs in pharmaceuticals, especially for the development of automated procedures based on flow injection analysis (FIA).[6–9] There are few precedents in the use of FIA in infrared analysis[10–16] and until now only two papers have been applied to pharmaceutical analysis.[14,15]

Ibuprofen (2-[4-isobutylphenyl]-propionic acid) is a non-steroidal anti-inflammatory analgesic[1,2] commercialized under different propietary names, such as Amersol, Brufen, Ebufac, Fembil, Inabrin, Inflam, Librofem, Motrin, Nurofen, Poxofen, Proflex, Relcofen, Seclodin and Uniprofen. Ibuprofen is determined by chromatography,[17–22] spectrometry[2,23–25] and also titrimetric methods.[26] However, only one paper has been published concerning the determination of Ibuprofen by infrared spectrometry,[27] and this is a time consuming procedure.

In the present paper, a FIA-Fourier transform infrared procedure has been developed in order to determine Ibuprofen in capsules of ALTIOR™.

EXPERIMENTAL

Apparatus

A Perkin Elmer Fourier transform infrared spectrometer 1750 equipped with a temperature stabilized coated detector FR–DTGS was employed to carry out the absorbance measurements, with a resolution of 4 cm^{-1}.

The spectrometer is controlled by a 7700 data station and the absorbance continuously measured using a series of computer programs written in OBEY and BASIC, which permits us to obtain and store the FT–IR spectra as a function of time with a frequency of 17 sec, search the exact position of the absorbance maximum peak and correct the peak height absorbances from the base-line values, and record the FIA peaks. All these programs have been developed in our laboratory and can be supplied on request.

The scanning of a full interferogram is carried out in only two seconds and the software permits the storage on a micro floppy

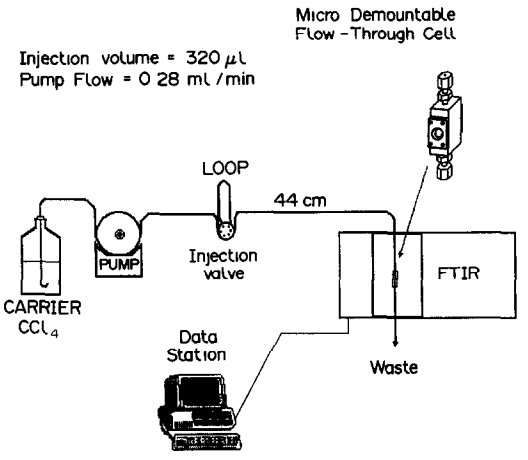

Fig. 1. Manifold.

disk in 15 sec. This process takes place during the FIA run and, after that, the corrected absorbance peak height values are established, the FIA recording obtained, and the calculations carried out.

The manifold employed (see Fig. 1) is a monochannel assembly with: a Gilson P-2 Minipulse peristaltic pump with solvent resistant Viton (Iso-versinic) 0.1 cm internal diameter pump tubes, a Rheodyne injection valve, type 50, with various fixed volume loops, PTFE connecting tubes with 0.8 mm internal diameter and a Spectra-Tech (Warrington, U.K.) microdemountable flow through cell.

Reagents

Ibuprofen (2-[4-isobutylphenyl]-propionic acid) standards were prepared from the crystalline compound (ESTEVE, Barcelona, Spain).

Analytical grade carbon tetrachloride (Panreac, Barcelona, Spain) was employed as carrier and also for the preparation of standards and samples.

IR spectroscopy grade potassium bromide (Merck, Darmstadt, Germany) was employed to obtain the FT–IR spectrum of Ibuprofen in pellet disks.

RESULTS AND DISCUSSION

FT–IR spectrum of Ibuprofen

The FT–IR spectrum of disks of Ibuprofen standards diluted in potassium bromide exhibits acid bands around 3000 cm^{-1} [see Fig. 2(A)], the transmittance band of the carbonyl group at 1710 cm^{-1}, and also the characteristic finger printing of the disubstituted aromatic hydrocarbons. Ibuprofen is very soluble in carbon tetrachloride and it has been confirmed that in the treatment of ALTIOR™ formulations with this solvent the drug is completely dissolved and the excipients remain undissolved. So, the transmittance IR spectra of standards and samples

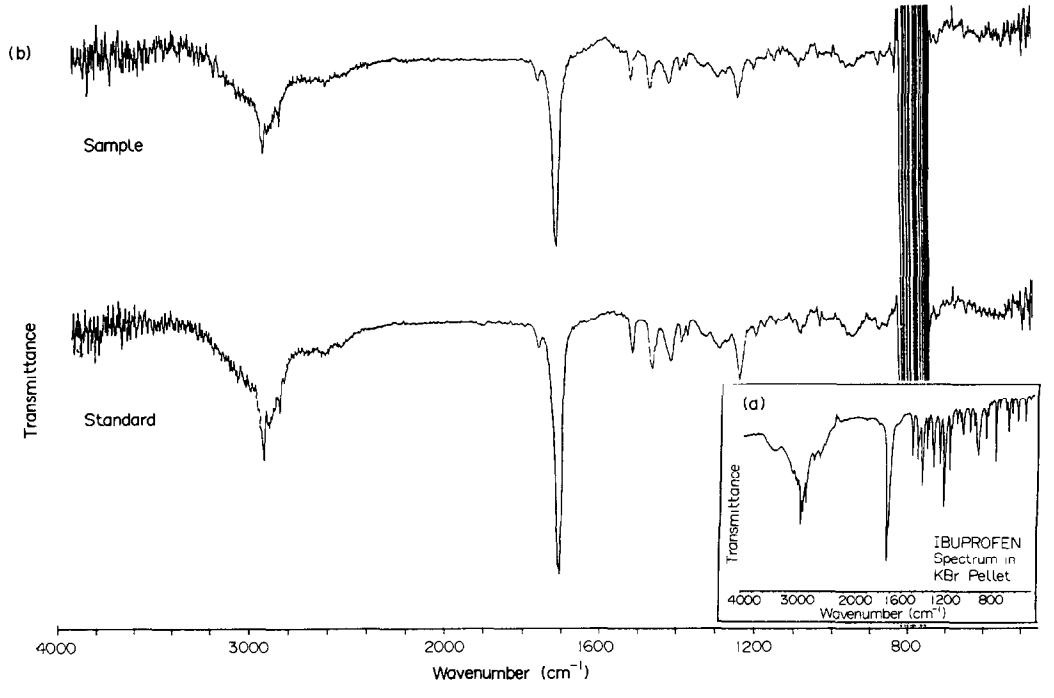

Fig. 2. FT–IR transmittance spectra of Ibuprofen in KBr disks (2A) and in CCl_4 solution (2B).

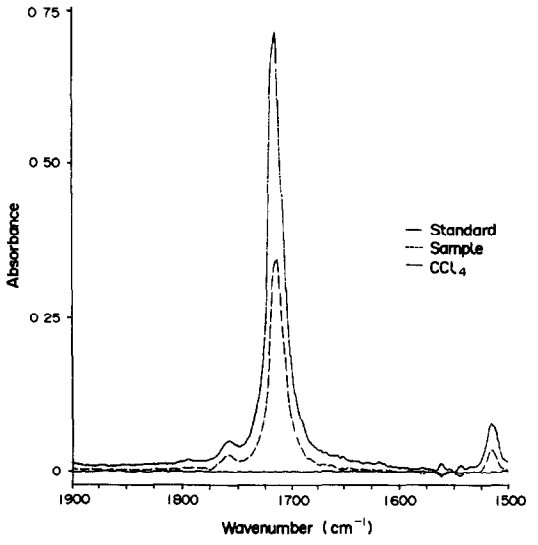

Fig. 3. FT–IR absorbance in the carbonyl region of blank solutions, sample and standard of Ibuprofen in CCl_4.

treated with carbon tetrachloride are identical and provide a way for the direct determination of Ibuprofen in pharmaceuticals [Fig. 2(B)].

In the present study the carbonyl band at 1710 cm^{-1} was selected for the quantitative determination of Ibuprofen because this band is very strong and appears in a transparent region of the CCl_4 (as can be seen in Fig. 3). The base-line of the absorbance spectrum was established between 1785 and 1650 cm^{-1}.

Effect of the FIA parameters on the absorbance of Ibuprofen

For a fixed concentration of 10 mg/ml Ibuprofen using a 0.1-mm cell (which provides a measurement volume of 1 μl) the effect of both the injection volume and the carrier flow were studied, in a univariate mode. Figure 4 indicates that an increase in the injected volume of sample provides an increase in the absorbance. However, this also increases the time required to carry out the analysis due to an increasing peak width. On the other hand (see Fig. 5), an increase in the carrier flow reduces drastically the absorbance readings and affects the precision of the measurements because, at the faster flow rates the sample does not remain in the cell at its maximum concentration for a long enough time to measure a full interferogram.

From these experiments a compromise value of 320 μl injection volume and 0.28 ml/min carrier flow were selected in order to obtain the highest sensitivity with good repeatability in the fastest experimental conditions.

Calibration of the system

Under the experimental conditions, previously selected, the absorbance of a series of 11 Ibuprofen standards dissolved in carbon tetrachloride was measured. A typical calibration equation of $A = -0.012 + 0.0358C$ (in mg/ml) was obtained with a regression coefficient R of 0.99959 [Fig. 6(B)].

Figure 6(A) shows the FIA recordings obtained by plotting the corrected absorbance peak height values found as a function of time, after the computer treatment of the monitored spectra.

Preparation of samples

As previously indicated, water soluble excipients are not solubilised in carbon tetrachloride and so Ibuprofen can be directly determined in pharmaceuticals, such as ALTIOR™, which does not contain other active ingredients. ALTIOR™ has a nominal content of 200 mg of

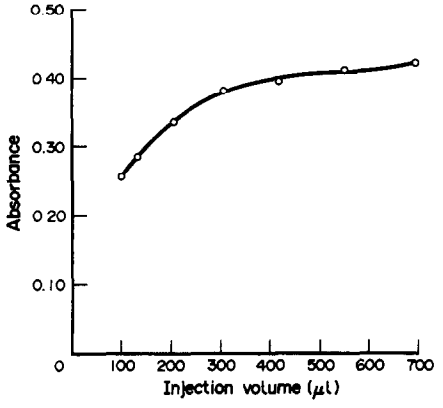

Fig. 4. Effect of the sample injection volume on the absorbance of Ibuprofen at 1710 cm^{-1}. Carrier flow: 0.28 ml/min.

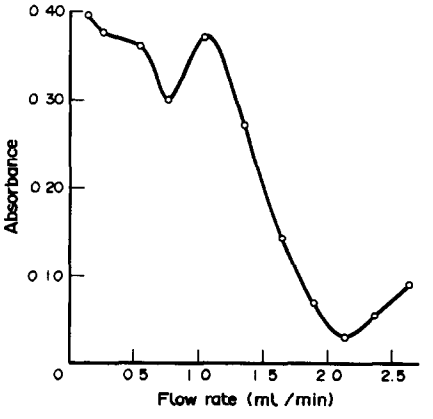

Fig. 5. Effect of the carrier flow on the absorbance of 320 μl of Ibuprofen. Concentration of Ibuprofen: 10 mg/ml.

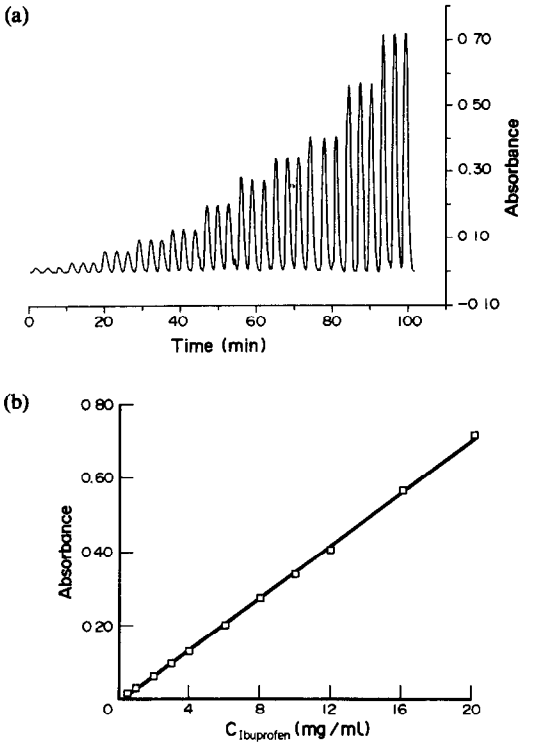

Fig. 6. FIA recording obtained from CCl_4 solutions of Ibuprofen (6A) for the FT–IR absorbance data of Ibuprofen solutions.

Ibuprofen per capsule and in order to obtain a good absorbance value, the following procedure is recommended.

Take five capsules of the pharmaceutical and grind to obtain a fine powder. Weigh accurately the amount of sample necessary to provide approximately 100 mg of Ibuprofen and extract with 10 ml of carbon tetrachloride. Filter to retain the excipient and inject 320 μl of the sample solution in the FIA manifold, using a carrier flow of 0.28 ml/min, and select the FT–IR spectrum between 1900 and 1500 cm^{-1}. Establish the spectral base-line from 1785 to 1650 cm^{-1} and record the absorbance, at the maximum of the carbonyl band, as a function of time. Interpolate the peak height of the FIA recording in the calibration graph, previously established from carbon tetrachloride solutions of pure Ibuprofen.

Analytical performance of the developed procedure

The sensitivity of the direct FIA–FT–IR analysis of Ibuprofen corresponds to a 0.366 ± 0.004 absorbance units $mg^{-1}.ml.mm^{-1}$ and this value could be increased using higher injection volumes or working in the stop flow mode. However these latter strategies diminish the sample frequency.

Using the recommended conditions, the limit of detection of the method (for a probability level of 95%) corresponds to a concentration of 0.08 mg/ml.

As compared with the method previously published for batch IR analysis of Ibuprofen in tablets,[27] the dynamic range obtained by us (from 0.5 to 20 mg/ml) is of the same order as that reported and the coefficients of variation, obtained for 5 independent measurements of a sample containing 10 mg of Ibuprofen per ml, is 0.8% in our case, five-fold lower than that reported by Husain *et al.*[27] The developed procedure could also be applied using a dispersive instrument working at a fixed wavenumber. However in this latter case the spectral base-line cannot be monitored and it produces a poorer linearity of the calibration lines and lower reproducibility.

The FIA–FT–IR method proposed has the inherent advantages of automated methods, such as speed, reproducibility and low consumption of reagents. Using the instrument described, it is possible to carry out 20 measurements per hour, which is a throughput 20-fold higher than that of the batch method of Husain *et al.*[27]

Compared with the UV reference method[2] the methodology developed provides matrix effect free measurements, because the excipient is not soluble in carbon tetrachloride and a higher dynamic range.

Analysis of real samples

Different lots of ALTIOR™ pharmaceutical, with a nominal content of 200 mg per capsule, have been analysed spectrophotometrically at 265 nm by a pharmaceutical laboratory and by the proposed FIA–FT–IR procedure. As can be seen in Table 1 results found are of the same order as those previously reported and compare well with the theoretical content.

The differences found with the UV analysis in terms of the t-test, could be due to the lack of information about the standard deviation of the spectrophotometric values, which avoids a more rigorous comparison. In this sense Table 1 shows that differences between values found by two different laboratories, using the same UV method, are higher than those between FT–IR and UV.

Table 1. Analysis of different lots of ALTIOR™ pharmaceutical

Sample	Ibuprofen found (mg/capsule)			
	FIA–FT–IR		UV Analysis	
	$\bar{X} \pm$ sec	t_{exp}	Lab 1 Reference	Lap 2
1	204 ± 3	1.10	207.3	196.2
2	209.0 ± 0.6	1.83	207.9	202.4
3	200.4 ± 1.5	0.47	201.1	213.6
4	206.7 ± 0.9	3.44	209.8	188.5
5	200.9 ± 0.7	9.57	194.2	204.1
6	201.0 ± 0.6	6.17	197.3	199.8
7	199.3 ± 0.9	4.89	203.7	215.7
8	202.8 ± 0.6	11.0	196.2	208.3
9	206.2 ± 0.3	15.33	201.6	190.8
10	195.6 ± 0.6	4.17	198.1	186.4

*Theoretical content: 200 mg per capsule.

t_{exp} values have been obtained from $(X - \bar{X})$/sec, X being the value obtained by the reference laboratory (Lab 1), $\bar{X}$ our average value for each sample and sec the standard deviation of three independent measurements. For a probability level of 0.95% and $n = 2$ and t_{theor} correspond to 4.303.

CONCLUSIONS

The FIA–FT–IR quantitative analysis of Ibuprofen in ALTIOR™ capsules can be carried out directly on carbon tetrachloride solutions of the pharmaceutical. In this solvent the excipient remains undissolved and so the only sample treatment is the dissolution of the drug and the filtration of the excipient. The injection of sample solutions in a carbon tetrachloride carrier stream provides very precise and accurate analysis of Ibuprofen with a good limit of detection and a sample throughput of 20/hr. The method requires low consumption of reagents and can be applied over a wide dynamic range. Results obtained in the analysis of real samples agree with those found by two independent laboratories using a UV reference method.

POTENTIOMETRIC AND SPECTROPHOTOMETRIC DETERMINATION OF CALCIUM IN THE WET END OF PAPER MACHINES BY FLOW INJECTION ANALYSIS

JOHAN NYMAN and ARI IVASKA*
Laboratory of Analytical Chemistry, Åbo Akademi University SF-20500 Turku-Åbo, Finland

(*Received* 19 *February* 1992. *Revised* 18 *May* 1992. *Accepted* 18 *May* 1992)

Summary—A spectrophotometric and a potentiometric FIA method were used to determine calcium in samples of back water from paper mills. The spectrophotometric method used the complexation reaction between calcium and *o*-cresolphthalein complexon. Optimum pH for the method was calculated theoretically. An ion-selective calcium electrode based on neutral carrier was used in the potentiometric method. The spectrophotometric method had a linear range between 10 and 250 ppm calcium and the potentiometric method between 10 and 300 ppm. Samples were acidified to pH 4 either before or after filtration. Total calcium was determined by a d.c. plasma emission method. Significant amounts of calcium were found to be bound both to the solid matter and to soluble complexes in the samples. The spectrophotometric method gave higher values than the potentiometric method but both of them gave lower values than the d.c. plasma emission method. Calcium concentrations in the range 30–250 ppm were found in the samples.

Paper machine back water contains a wide variety of dissolved and colloidally dispersed detrimental inorganic and organic substances. The concentration of these substances, including calcium, is dependent on the degree to which the wet end of the paper machine is closed.[1,2] Fillers containing calcium, such as calcium carbonate are the main source of calcium in the circulating water in paper machines. Also reuse of discarded paper, containing gypsum ($CaSO_4$) as coater, from other stages in the manufacturing process and returned for reprocessing is a considerable source of calcium.[3]

Free ionized calcium can react in the back water with anions of fatty acids resulting in insoluble and sticky soaps. These soaps, forming pitch deposits, have negative effects on both the quality of the paper and running of the paper machine.[4] Due to these effects monitoring of calcium levels in the back water of paper machines has begun to gain interest in the paper industry. Calcium concentrations up to 300 ppm are usually of interest.

Various color forming reagents, *e.g.*, Eriochrome Black T,[5] chlorophosphonazo III,[6] calmagite[7] and *o*-cresolphthalein complexon (CPC),[8] have been used in the spectrophotometric determination of calcium by flow injection analysis (FIA). Among these, CPC is the most frequently used and will be studied in more detail in this work.

There are several ways of performing potentiometric calcium determination by the FIA technique. Calcium can be determined indirectly by using a copper wire electrode where the excess of EDTA in the carrier solution is measured.[9] Ion-selective electrodes (ISE), based on neutral carriers, *e.g.*, the ETH 1001 ionophore, are often based in direct determination of calcium in FIA.[10] Similar measurements have also been done with ISFETs.[11]

EXPERIMENTAL

Instrumentation

The central unit in the spectrophotometric and the potentiometric FIA system was a FIAstar® 5010 Analyser (TECATOR), featuring two 4-channel peristaltic pumps and injection valve. Appropriate reaction coil combinations were achieved with Chemifolds.

A FIAstar® 5023 Spectrophotometer (TECATOR), connected to the 5010 Analyser, was used in the spectrophotometric measurements. Absorbances were measured at 570 nm. A Schneider 386 PC was used to control the FIA system and to do data acquisition and evaluation.

*Author for correspondence.

Potentiometric determination of calcium by FIA was done with a small volume (20-μl), flow-through cell equipped with a Ca-selective electrode based on a neutral carrier. Potentials were measured against a flow-through Ag/AgCl reference electrode. Both electrodes were obtained from KONE Instruments, Finland. The 5010 Analyser was used as the pumping, injection and mixing unit. Data was gathered with a Perkin-Elmer strip chart recorder and the FIA system was operated manually.

Total calcium in samples was determined with dc-plasma emission spectroscopy (DCP). The instrument used was a SpectraSpan III B plasma emission spectrophotometer.

Chemicals

Calcium carbonate ($CaCO_3$) supra pure (Merck), $NaNO_3$ *p.a.* (Merck), NaOH *p.a.* (Merck), sulphuric acid *p.a.* (Merck), *o*-cresolphthalein complexon *p.a.* (Fluka), 2-amino-2-methylpropan-1-ol for synthesis (Merck), 8-hydroxyquinoline *p.a.* (Analar) and nitrilotriacetic acid (NTA) *p.a.* (Fluka) were used as received. Millipore water was used through the whole work.

Standards and samples

Standard solutions in the range 10–300 ppm Ca^{2+} were used and prepared by successive dilution of a 500 ppm Ca^{2+} stock solution prepared as described in the literature.[8] Slurries of back water from Finnish paper mills were used as samples. They were filtered through a paper filter prior to the analysis. Standards and samples were injected in triplicates.

RESULTS AND DISCUSSION

Spectrophotometric determination

Back water contains a large number of different inorganic compounds that may interfere in the spectrophotometric determination of calcium. Magnesium is the most severely interfering species due to its strong complexation with CPC:

$$\begin{aligned} Ca + L &\rightarrow CaL; \quad K_{CaL} = 10^{7.8} \\ Ca + CaL &\rightarrow Ca_2L; \quad K_{Ca_2L} = 10^{5.0} \end{aligned} \qquad (1)$$

$$\begin{aligned} Mg + L &\rightarrow MgL; \quad K_{MgL} = 10^{8.9} \\ Mg + MgL &\rightarrow Mg_2L; \quad K_{Mg_2L} = 10^{5.2} \end{aligned} \qquad (2)$$

where L represents CPC. Notations in this paper will follow the principles introduced by Ringbom.[12] Values of the stability constants are taken from Ref. 13, p. 340.

Interference of magnesium can be diminished by masking it with 8-hydroxyquinoline, 8-HQ:

$$Mg + X \rightarrow MgX; \quad K_{MgX} = 10^{4.7} \qquad (3)$$

where X stands for 8-HQ. The value of the stability constant, K_{MgX}, is taken from Ref. 13, p. 408. The masking reaction (3) can be considered by calculating the side reaction coefficient $\alpha_{Mg(X)}$:

$$\alpha_{Mg(X)} = 1 + [X'] \, K_{MgX}/\alpha_{X(H)} \qquad (4)$$

where [X'] stands for the total concentration of 8-HQ not bound to magnesium. In our application it is approximately $0.02M$. The protonation reaction of 8-HQ can be considered by introducing the side reaction coefficient $\alpha_{X(H)}$. Values for $\alpha_{X(H)}$ can be found in Ref. 13, p. 424. Concentrations of calcium and magnesium at the color transition point with CPC are denoted by $[Ca]_{trans}$ and $[Mg]_{trans}$ and their values can also be found in Ref. 13, pp. 426, 428. Effect of the masking reaction (3) on $[Mg]_{trans}$ can be calculated in the following way (Ref. 13, p. 233)

$$pMg'_{trans} = pMg_{trans} - \log \alpha_{Mg(X)} \qquad (5)$$

Values of pCa_{trans}, pMg_{trans}, $\log \alpha_{Mg(X)}$ and pMg'_{trans} between pH 9 and 11 are given in Table 1. Values of $\log \alpha_{Mg(X)}$ and pMg'_{trans} are calculated by using equations (4) and (5), respectively. The last row, ΔpM_{trans}, is the difference between pCa_{trans} and pMg'_{trans} and is a measure of the interference of magnesium on determination of calcium. The difference should be as large as possible in order to have minimum interference of magnesium. As can be seen in Table 1, pH 10–10.5 gives the maximum separation between the color transition points of the two metals. On the other hand the value of pCa_{trans} should be as large as possible in order to give a clear colour transition for calcium. Therefore, pH 10.5 is recommended. This is also the value used earlier by other workers[8] for

Table 1. Effect of pH and magnesium on the color transition point of the Ca–CPC complex. Magnesium is masked with $10^{-1.8}M$ 8-hydroxyquinoline

pH	9	10	10.5	11
pCa_{trans}	3.4	4.5	5.1	6.2
pMg_{trans}	3.6	4.7	5.7	7.3
$\log \alpha_{X(H)}$	1.0	0.3	0	0
$\log \alpha_{Mg(X)}$	2.0	2.7	3.0	3.0
pMg'_{trans}	1.6	2.0	2.7	4.3
ΔpM_{trans}	1.8	2.5	2.4	1.9

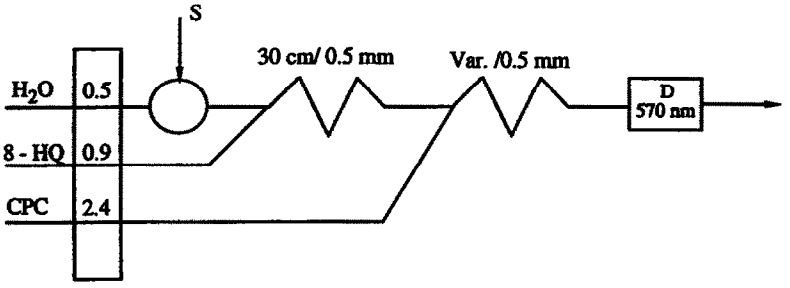

Fig. 1. The FIA manifold used in the spectrophotometric method with CPC. Flow rates are given in ml/min and the values for the coils are length/id.

the same determination. Their recommendation was obviously based on experimental results. The effect of soluble Ca-complexes, *e.g.*, sulphates, can be taken into consideration by introducing the side reaction coefficient log $\alpha_{Ca(SO_4)}$. This would slightly lower the pCa_{trans} values in Table 1, and give pCa'_{trans} when calculated according to equation (5). This effect, however, is only marginal at concentrations generally found in back waters and therefore is not considered here.

The FIA manifold used in the spectrophotometric determination is shown in Fig. 1 and is a modification of the one given in Ref. 8. Absorbance of the Ca–CPC complex was measured at 570 nm. Millipore water was used as the carrier solution. The masking solution for Mg^{2+} was 0.02*M* 8-hydroxyquinoline (8-HQ) buffered with 2-amino-2-methylpropan-1-ol to pH 10.5.

In order to find the optimum experimental parameters, the concentration of CPC was varied between 0.119 and 0.200m*M* while keeping the length of the second coil at 60 cm. When using a 0.119m*M* CPC solution, a linear calibration curve was found up to 100 ppm Ca^{2+}, whereafter the curve started to bend down. Concentrations of 0.15m*M* and higher gave a colour intensity which exceeded the working range of the spectrophotometer. By changing the length of the second coil to 30 cm and still keeping the reagent concentration of 0.15m*M* the dispersion was diminished to such a degree that the intensity of the color of the formed complex did not exceed the dynamic range of the spectrophotometer. When the reagent concentration was further increased to 0.20m*M* in this configuration the working range of the spectrophotometer was again exceeded. Based on these studies, a coil length of 30 cm and a CPC concentration of 0.15m*M* were used in this work. With these parameters the calibration curve was linear from 10 to 250 ppm Ca^{2+} ($r = 0.996$). The rsd was *ca.* 0.5% through the entire linear range.

Potentiometric determination by a calcium selective electrode

The manifold used in the potentiometric determination of calcium by FIA is shown in Fig. 2. A reagent stream of 0.28*M* $NaNO_3$ was used to give a constant ionic strength required for the potentiometric detection.

Interferences from the streaming potential were eliminated by grounding the inlet and outlet of the flow through electrode. The electrode showed linear response ($r = 0.997$) over the entire concentration range studied, 10–300 ppm Ca^{2+}. The slope of the line was 30 mV/pCa and the relative standard deviations were 0.6

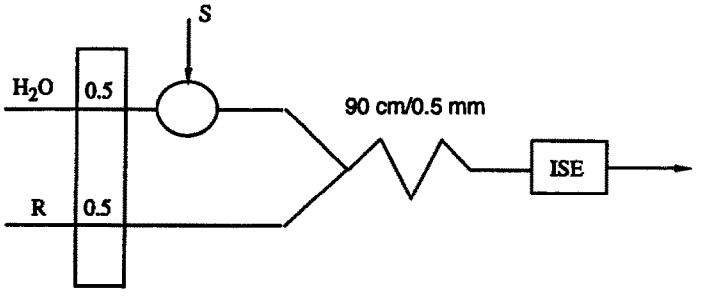

Fig. 2. The FIA manifold used in the potentiometric determination of calcium. Flow rates are given in ml/min and the values for the coils are length/id.

and 0.4% at the lower and the higher end of the curve, respectively.

Stability of the electrode response was tested by injecting 15 different back water samples in triplicate. During this process the slope of the calibration line decreased by 1 mV/pCa. This change in the slope was not irreversible and falls within variations of the slope when determined with standards on a daily basis.

Samples from paper mills

The spectrophotometric and the potentiometric methods were compared by determining calcium in two samples from paper mills. The results are given in Table 2. The spectrophotometric method had earlier been used in analysis of two samples from other mills. These results, #3 and #4, are also included in Table 2. All the samples were acidified to pH 4 by hydrochloric acid either (a) prior or (b) after filtering the solid matter. The purpose of acidification was to release the complex bound calcium. Acidification prior to filtering would release calcium bound both to solid matter and in soluble complexes. That procedure would therefore give the total calcium in the sample. Acidification after filtering effects only the soluble complexes. Calcium was also determined by a DCP method. Those results are included in Table 2 as well.

As can be seen in Table 2, higher calcium concentrations are found in the samples acidified prior to filtering indicating that significant amount of calcium is bound to the solid matter in the samples. The difference in the measuring principles of the DCP and ISE methods is that ISE gives the free, ionized amount of calcium, and DCP the total amount of calcium in the samples. The reason that higher calcium concentrations are found by the DCP method than by the ISE method, even after acidification of the samples, indicate that pH 4 is not acidic enough to break all calcium complexes in the samples, *e.g.*, sulfate complex or colloidal calcium oxalate. Due to the operating conditions of a paper machine pH values below 4 are not relevant in paper production and therefore were not used in this work.

Table 2. Calcium concentration in back water samples from paper mills determined by dc-plasma emission (DCP), potentiometric (ISE) and spectrophotometric methods. Samples were acidified to pH 4 with HCl (a) before and (b) after filtering

	Method					
	DCP		ISE		Spectroph.	
Sample no.	ppm	r.s.d., % $n = 3$	ppm	r.s.d., % $n = 3$	ppm	r.s.d., % $n = 3$
1(a)	102	1.2	69.1	0.2	77.5	0.6
2(a)	100	0.2	60.2	0.2	73.7	0.4
2(b)	65.5	1.5	30.2	0.3	43.5	0.1
3(a)					225	0.3
3(b)					170	0.3
4(a)					182	0.2
4(b)					78.2	0.4

Results in Table 2 show that the spectrophotometric method gives a higher calcium concentration than the ISE method. This discrepancy can be explained by considering how the principles of determination of these two methods differ. The ISE-method, as explained earlier, "senses" only the ionized calcium. The spectrophotometric method, however, uses a complexation reaction where calcium forms a stable complex with the reagent. Therefore calcium still bound to weaker complexes in the sample will be available to the spectrophotometric method.

CONCLUSIONS

With further development of the methods presented in this paper, *i.e.*, introducing a sampling and sample pretreatment system it would be possible to use the FIA methods in on-line applications for continuous analysis of back water. This would, in real time, give the concentrations of calcium in free form and also in weak, labile complexes to the process engineers running the paper machines and responsible of production and quality of the product.

As the results in this paper indicate, the ISE and the spectrophotometric methods give slightly different results due to the different principles of the two methods. By employing different sample pretreatment procedures in combination of different methods of determination it would also be possible to gain information of calcium speciation in the samples, if that is sought.

REVERSE FLOW INJECTION ANALYSIS OF COMPLEXING AGENTS AND ITS APPLICATION TO ESTIMATION OF COMPLEXING CAPACITY

NORIO TESHIMA, HIDEYUKI ITABASHI and TAKUJI KAWASHIMA*

Laboratory of Analytical Chemistry, Department of Chemistry, University of Tsukuba, Tsukuba 305, Japan

(*Received* 1 *May* 1992. *Accepted* 22 *May* 1992)

Summary—A redox reaction of copper(II) with iron(II) proceeds slowly in the presence of neocuproine, although the reaction would not take place in its absence. This reaction is accelerated by the presence of complexing agents such as EDTA, DTPA, CyDTA, EDTA-OH, NTA, citrate, pyrophosphate, producing a copper(I)-neocuproine complex ($\lambda_{max} = 454$ nm). A reverse flow injection analysis (r-FIA) method is presented for the determination of trace amounts of complexing agents by measuring the increase in absorbance at 454 nm. Complexing agents at the $10^{-6}M$ level can be determined at a rate of 120 samples/hr. By using this r-FIA system, a new procedure for the measurement of complexing capacity with metal ions such as Al(III), Cu(II), Zn(II), Cd(II) and Pb(II) has been developed. Complexing capacity for each metal ion can be measured at a rate of 120 samples/hr.

The effect of complexing agents such as aminopolycarboxylic acids and inorganic polyphosphates on environmental and biological cycles has been considered since these agents have been widely used in various industrial fields.[1] On the other hand, toxicity and bioavailability of trace metals in natural waters depend on the concentrations of various complexing agents because such metals form complexes with these complexing agents.[2–4] From this point of view, a concept of complexing capacity with metal ions was introduced for environmental assessment.[2,5] Several experimental procedures have been proposed for the measurement of complexing capacity of natural waters and have been reviewed by Florence[4] and Neubecker and Allen.[6] These methods can be classified into the following groups:[4,6] solubilization,[7] biological response,[2] ion-exchange,[8] voltammetric,[7,9] and ion selective electrode.[10,11] Recently, Akaiwa *et al.*[12] reported a method for the measurement of copper(II)-complexing capacity of natural waters by a back-extraction technique using bis(4,4,4-trifluoro-1-phenyl-1,3-butanedionato)copper(II). Taga *et al.*[13] also proposed a method for the complexing capacity of humic acids with copper by using a macroreticular weak-base anion exchanger, diethylaminoethyl Sephadex A-25 resin which can adsorb the metal-humic acids complex, but not the free metal ions. However, most of the methods are laborious and time consuming, and also no consistent relation can be found among the complexing capacity values obtained by these techniques.[7] Thus, reliable methods are still needed for measurements of complexing capacity in natural waters.

Recently, we showed that the redox reaction of copper(II) with iron(II) takes place in the presence of neocuproine.[14] In addition, this reaction was greatly accelerated by the presence of various complexing agents together with neocuproine, and a copper(I)–neocuproine complex ($\lambda_{max} = 454$ nm) was then produced. We have reported the flow injection analysis (FIA) of complexing agents such as EDTA, DTPA, CyDTA, EDTA–OH, NTA, citrate, pyrophosphate (diphosphate) by using this redox reaction.[15] The reverse flow injection analysis (r-FIA) method is known to be very valuable when a large volume of sample is available and reagent consumption should be minimized.[16] Thus, the present paper describes an indirect photometric determination of complexing agents by r-FIA based on the same reaction. By using this r-FIA system, a new procedure for the measurement of complexing capacity with metal ions such as Al(III),

*Author for correspondence.

Cu(II), Zn(II), Cd(II) and Pb(II) is also presented.

EXPERIMENTAL

Reagents

Stock solutions of iron(II) ($1.0 \times 10^{-2}M$), copper(II) ($1.0 \times 10^{-2}M$) and zinc(II) ($0.1M$) were the same as described previously.[14,15] An aluminum(III) solution ($0.1M$) was prepared by dissolving aluminum potassium sulfate dodecahydrate (potassium alum) in water. A cadmium(II) solution was prepared by diluting a stock standard solution for atomic absorption spectrophotometry with water. A lead(II) solution ($0.1M$) was prepared by dissolving lead(II) acetate trihydrate in water. Working solutions of metal ions were prepared by suitably diluting each stock solution with water and/or buffer solution. Neocuproine, ethylenediamine-*N,N,N',N'*-tetraacetic acid (EDTA), diethylenetriamine-*N,N,N',N'',N''*-pentaacetic acid (DTPA), *trans*-1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetic acid (CyDTA), *N*-hydroxyethylethylenediamine-*N,N',N'*-triacetic acid (EDTA-OH), nitrilotriacetic acid (NTA), citrate and pyrophosphate solutions were the same as described previously.[14,15] Triphosphate solution ($0.1M$) was also prepared by dissolving an appropriate amount of sodium triphosphate in water.

All reagents used were of analytical reagent grade. Water used to prepare the solutions was purified by a Milli-Q water purification system (Millipore).

Apparatus

A schematic r-FIA diagram for the determination of complexing agents and of complexing capacity is shown in Fig. 1. Four double-plunger micro pumps (Sanuki Kogyo, DM2M-1026) and a six-way injection valve (Sanuki Kogyo, SVM-6M2) with a loop were used to assemble the system. The flow lines were made from Teflon tubing (0.5 mm i.d.). The absorbance change was monitored at 454 nm with a Soma Kogaku S-3250 spectrophotometer with a 10-mm micro flow cell (8 μl) and recorded on a Hitachi Model 056 recorder. A Corning Model 12 pH/mV meter was also used to monitor the pH of waste solution.

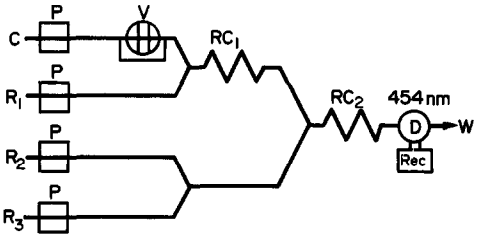

Fig. 1. Flow diagram of r-FIA for complexing agent and complexing capacity. Measurement of complexing agent; C, carrier solution ($0.05M$ acetate, pH 5.6); R_1, iron(II) ($1 \times 10^{-4}M$); R_2, R_3, sample solution (complexing agent); V, mixed solution of copper(II) ($1 \times 10^{-4}M$) and neocuproine ($5 \times 10^{-4}M$). Estimation of complexing capacity; C, carrier solution ($0.05M$ acetate, pH 5.6); R_1, sample solution (complexing agent); R_2, iron(II) ($1 \times 10^{-4}M$); R_3, mixed solution of copper(II) ($1 \times 10^{-4}M$) and neocuproine ($5 \times 10^{-4}M$); V, metal ion solution [Al(III), Cu(II), Zn(II), Cd(II) and Pb(II), $2 \times 10^{-5}M$]. The symbols P, RC, D, Rec and W are pump, reaction coil (0.5 mm i.d.), spectrophotometer (454 nm), recorder and waste, respectively.

Procedure for the measurement of complexing agent

In the flow system (Fig. 1), a buffer carrier solution (C), an iron(II) solution in reservoir R_1 and a complexing agent solution in reservoirs R_2 and R_3 were pumped at a flow rate of 2.3 ml/min. An aliquot (80 μl) of mixed solution of copper(II) and neocuproine was injected into the carrier stream. The reduction rate of copper(II) with iron(II) was accelerated by the presence of complexing agent and the copper(I)–neocuproine complex was produced in a reaction coil (0.7 m long) at room temperature. The absorbance of the complex produced was monitored continuously at 454 nm.

Procedure for the measurement of complexing capacity

In the flow system (Fig. 1), a buffer carrier solution (C), a complexing agent solution in reservoir R_1, an iron(II) solution in reservoir R_2 and a mixture of copper(II) and neocuproine in reservoir R_3 were pumped at a flow rate of 2.0 ml/min. An aliquot (200 μl) of metal ion such as Al(III), Cu(II), Zn(II), Cd(II) and Pb(II) was injected into the carrier stream. The metal ion reacts with the complexing agent to form a complex in a reaction coil RC_1 (0.5 m long): a decrease in absorbance at 454 nm was observed and monitored.

Table 1. Features of the calibration curves

Complexing agents	Intercept	Slope	Regression coefficient	r.s.d. (%) ($n = 10$)

Pyrophosphate	−0.0041	0.0076	0.999	1.7

RESULTS AND DISCUSSION

Effect of reaction variables for the measurement of complexing agent

The optimum conditions for r-FIA were studied by propelling $1 \times 10^{-5}M$ EDTA solution in reservoirs R_2 and R_3. All measurements were carried out at room temperature.

The absorbance at 454 nm increased rapidly with increasing pH up to 5.1, and remained constant in the pH range 5.1–6.1. A pH value of 5.6 was used for the procedure.

The effect of iron(II) concentration was examined over the range 2×10^{-5}–$1 \times 10^{-3}M$. The absorbance increased with increasing concentration up to $7 \times 10^{-5}M$, and remained constant in the concentration range 7×10^{-5}–$1 \times 10^{-4}M$. At concentrations more than $1 \times 10^{-4}M$ the absorbance decreased gradually. A $1 \times 10^{-4}M$ iron(II) concentration was chosen for the procedure.

The effect of copper(II) concentration was examined over the range 2×10^{-5}–$7.5 \times 10^{-4}M$. The reproducibility of the flow signals became poorer at copper(II) concentrations more than $1 \times 10^{-4}M$, although maximum absorbance was obtained around $2 \times 10^{-4}M$. Hence, a $1 \times 10^{-4}M$ copper(II) concentration was chosen.

Maximum and constant absorbance was obtained over the concentration range 5×10^{-4}–$1 \times 10^{-3}M$ neocuproine. A $5 \times 10^{-4}M$ neocuproine concentration was selected.

The effect of reaction coil length was examined by varying coil length (RC_2, 0.1–5 m). The absorbance increased with increasing coil length and the absorbance showed maximum at 0.7 m, decreasing gradually beyond this length due to an increase in the degree of dispersion. A coil length of 0.7 m was used for the procedure.

Calibration graphs

The linear calibration graphs were obtained over the range 2×10^{-6}–$1 \times 10^{-5}M$ EDTA, NTA, citrate and pyrophosphate. The sampling rate of 120/hr is attained for the proposed method. The reproducibility of the method is satisfactory with low r.s.v. %. The features of the calibration graphs for each complexing agent are summarized in Table 1.

Interferences

The effect of foreign ions on the determination of $1 \times 10^{-5}M$ EDTA was studied. The tolerance limits for foreign ions are summarized in Table 2; a 5% error was considered to be tolerable. As can be seen from Table 2, Li(I), Na(I), K(I), Cl^-, NO_3^-, SO_4^{2-} and CH_3COO^- ($0.02M$), BO_3^{3-} ($0.01M$), CO_3^{2-} ($5 \times 10^{-3}M$), Mg(II) and Sr(II) ($2 \times 10^{-3}M$), Ca(II) and F^- ($1 \times 10^{-3}M$) showed no influence. However, Al(III), Co(II), Ni(II), Cu(II) and Zn(II) ($1 \times 10^{-5}M$) caused serious negative interferences because these ions reacted with EDTA to form stable complexes. Similar masking effects for these metal ions were also observed for DTPA, CyDTA, EDTA-OH and NTA.

Effect of reaction variables for the measurement of complexing capacity

In the flow system as shown in Fig. 1, a $1 \times 10^{-5}M$ EDTA and/or pyrophosphate solution was pumped as a model ligand and a

$2 \times 10^{-5}M$ metal ion concentration such as Al(III), Cu(II), Zn(II), Cd(II) and Pb(II) was injected into the carrier stream. The accelerating effect of complexing agents on the reduction of copper(II) with iron(II) is retarded by adding such metal ions. A decrease in absorbance at 454 nm corresponded to the concentration of each ligand in the presence of metal ion. By this phenomenon, a measurement of complexing capacity in natural water is also possible. The concentration of each model ligand solution was measured as a function of each metal ion such as Al(III), Cu(II), Zn(II), Cd(II) and Pb(II). Complexing capacities measured by using Al(III), Cu(II), Zn(II), Cd(II) and Pb(II) solutions are abbreviated as AlCC, CuCC, ZnCC, CdCC and PbCC. The concentrations of iron(II) ($1 \times 10^{-4}M$), copper(II) ($1 \times 10^{-4}M$), neocuproine ($5 \times 10^{-4}M$) and the reaction pH 5.6 were selected for the measurement of complexing capacity based on the above results. The reaction coil (RC_2) length of 0.7 m was also used.

The effect of reaction coil length of RC_1 was examined over the range 0.1–2 m (Fig. 2). Zn, Cd and Pb exhibited curves similar to those

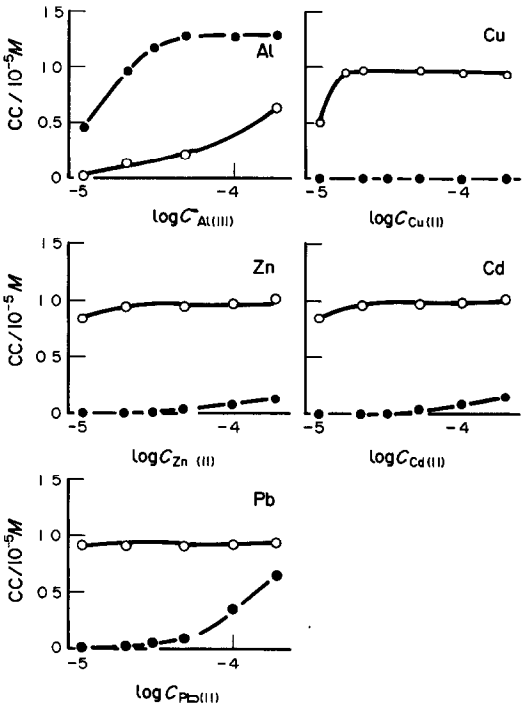

Fig. 3. Effect of metal ion concentration for the measurement of complexing capacity with each metal ion. Complexing agents ($1 \times 10^{-5}M$): (○), EDTA; (●), pyrophosphate. Other conditions as in Fig. 1.

for Cu. In the case of EDTA, maximum and constant values for CuCC, ZnCC, CdCC and PbCC were obtained at the reaction coil length greater than 0.3 m. The AlCC value increased gradually with increasing the reaction coil length and a lower CC value than the others was obtained. This is attributable to the fact that the rate of complex formation of Al(III) with EDTA is much slower than those of other metal ions.[17] In the case of pyrophosphate, the AlCC value increased with increasing reaction

coil length. A maximum and constant AlCC value was obtained at a reaction coil length greater than 0.3 m, while CuCC, ZnCC, CdCC and PbCC values were very low.

The effect of metal ion concentration was examined at a constant concentration ($1 \times 10^{-5}M$) of EDTA and/or pyrophosphate. The results are shown in Fig. 3. In the case of EDTA, maximum and constant CuCC, ZnCC, CdCC and PbCC values were obtained at concentrations higher than $2 \times 10^{-5}M$. The AlCC value increased gradually with increasing concentration of aluminum(III) and the value was lower than those obtained for other metal ions. In the case of pyrophosphate, the maximum and constant AlCC value was obtained at greater than $5 \times 10^{-5}M$. The CuCC, ZnCC, CdCC and PbCC values were not obtainable over the range 1×10^{-5}–$3 \times 10^{-5}M$.

The effects of EDTA and pyrophosphate concentrations were examined by injecting $2 \times 10^{-5}M$ of each metal ion solution. The results for EDTA are shown in Fig. 4. The CuCC, ZnCC, CdCC and PbCC values were the same and the values increased linearly with increasing concentration of EDTA, while the AlCC value was not obtained. In the case of pyrophosphate, the AlCC value increased linearly with increasing concentration of pyrophosphate, while the CuCC, ZnCC, CdCC and PbCC values could not be obtained. Similar situations as for pyrophosphate were observed for triphosphate. From these results, a characterization of complexing agents in natural waters should be possible. Complexing capacity corresponding to the pyrophosphate type ligands would be obtained by injecting Al(III) solution. On the other hand, the CC value obtained by injecting other metal ions corresponds to the concentration of aminopolycarboxylic type ligands. Complexing capacities for each metal ion in natural waters at the 10^{-7}–$10^{-6}M$ level were determined at a rate of 120 times/hr by the proposed method.

Application to water samples

The applicability of the proposed method was evaluated by measuring complexing capacities of both river and lake waters. After the samples were filtrated with a 0.45-μm membrane filter, the measurement of complexing capacity was performed by the proposed method. The results, given in Table 3, are compared with those obtained by the extraction method.[12] Complexing capacities of the samples collected at the Tsukuba area were in the $10^{-7}M$ range. The values obtained by the proposed method were in the same order as those obtained by the extraction method. The ZnCC, CdCC and PbCC values should correlate with CuCC values obtained by the extraction method, corresponding to aminopolycarboxylic type ligands, while the AlCC values represent pyrophosphate type ligands. Although the proposed method was not evaluated in full detail, it can be seen from the results in Table 3 that it is useful for estimating two types of complexing capacity in natural waters.

DIRECT FIA–AS DETERMINATION OF POTASSIUM AND MAGNESIUM IN CEMENT SAMPLES BY USE OF THE SLURRIES APPROACH

R. MARTINEZ-AVILA, V. CARBONELL, A. SALVADOR and M. DE LA GUARDIA*

Department of Analytical Chemistry, University of Valencia, 50 Dr Moliner St., 46100 Burjassot, Valencia, Spain

(*Received* 25 *March* 1992. *Revised* 5 *June* 1992. *Accepted* 8 *June* 1992)

Summary—A direct procedure has been developed for the flame atomic determination of potassium and magnesium in cement samples. A 50-mg sample is dispersed in 25 ml of 0.13*M* nitric acid; 100 μl of this slurry is injected in a double channel FIA manifold simultaneously with 100 μl of a 10% (w/v) lanthanum solution. This procedure allows the rapid extraction of potassium and magnesium by leaching of the sample; nitric acid is not necessary if only potassium must be determined and the sample can be diluted with only distilled water. Aqueous standards are used. The manifold employed includes a well-stirred mixing chamber, which provides an adequate on-line dilution of the sample, in order to obtain emission or absorbance measurements in the dynamic range of the elements to be determined. The results obtained in the analysis of real samples agree with those found by flame atomic spectrometry after a previous alkaline fusion with lithium carbonate, and exhibit better precision. The limit of detection of the procedure is 0.007% for K_2O and 0.01% for MgO and the precision of the entire procedure corresponds to a relative standard deviation of 1%.

The analysis of cements by atomic spectrometry requires the dissolution of samples after a previous wet ashing or fusion procedure.[1,2] This is usually the most time consuming step and may introduce contamination or interelemental interferences, the latter caused by the total dissolution of all the sample components.

An alternative to the dissolution of solid samples for their analysis by atomic spectrometry is the direct introduction of slurries. Slurries are fine dispersions of powdered solids in water or other solvents. Previous work has shown that the use of slurries can be a convenient way to introduce solids into flames,[3–5] plasmas[6,7] and electrothermal atomization systems.[8–12]

The direct determination of mineral elements in slurries requires the use of solid particles of small diameter:[13] moreover, in some cases, problems related to inefficient volatilization of the elements from the solid phase may produce low results. In these cases, it is more suitable to treat the slurries in order to dissolve the elements to be determined. When the elements under study can be extracted from the suspended solid by a fast and easy way, direct analysis of the slurry by atomic spectrometry can be carried out without matrix separation.[14,15] So, losses or interelemental interferences can be avoided. The slurry sample introduction method has been applied to the determination of Na in standard reference cements using glycerol as a stabilizer for the dispersion and nitric acid as extractant agent.[16]

Recent studies in our laboratory have shown that slurries can be injected in flow systems and so Cu, Mn and Pb were determined in sewage sludge samples.[17]

In the present paper, the direct introduction of cement slurries has been carried out in a flow system for the determination of potassium and magnesium in real cement samples, with on-line dilution of the samples.

EXPERIMENTAL

Apparatus

A Perkin–Elmer 5000 atomic spectrophotometer equipped with a magnesium hollow-cathode lamp was used for absorbance measurements. Potassium was determined by flame emission spectrometry using a Varian SpectrAA-10 atomic absorption spectrophotometer. An air-acetylene flame was used in

*Author for correspondence.

both cases. All measurements were carried out without background correction.

A flow injection procedure was used to carry out the analysis, using the manifold indicated in Fig. 1. A Gilson P-2 Minipuls peristaltic pump with two 2.79 mm internal diameter polyvinylchloride tubes was employed to transport the aqueous carrier streams. Samples and lanthanum solutions were introduced using a double simultaneous injector constructed with two Rheodyne injection valves type 50 with fixed loops. A three way Y-shaped connector Omnifit, with an internal diameter of 0.8 mm, provides the merging point. A mixing chamber is connected after the merging point and before the nebulizer in order to obtain adequate dilutions of the samples. This chamber has a volume of 1 ml and the escape of any air bubbles can be assured by a slight dome in the upper part. A Teflon covered magnetic stirring bar assures an appropriate mixing in the dilution chamber. All the connecting tubes used were made of Teflon and with 0.8-mm internal diameter (Omnifit).

The dispersion coefficient provided by the manifold was 22. It was preferred to carry out the on-line dilutions of the samples than to use less sensitive instrumental conditions because FIA provides fast and reproducible dilutions and moreover, the analysis of real samples under conditions different than those providing the best sensitivity can be affected by matrix interferences.

Instrumental and flow injection parameters used in the analysis are given in Table 1.

Table 1. Instrumental and FIA parameters used in the determination of K and Mg in cement samples

Parameter	K	Mg

Total flow rate/ml/min	8.4	
Mixing chamber volume/ml	1	

*The burner height being the distance below the focal point of the optical system.

FE: flame emission; AA: atomic absorption.

A Perkin–Elmer 5000 and a Varian SpectrAA-10 atomic spectrophometer were used for the measurement of absorbance of magnesium and emission of potassium respectively.

Reagents

A magnesium stock solution of 1000 ppm was prepared by dissolving 1 g of magnesium metal (Merk) in 50 ml of 5*M* hydrochloric acid and diluting to one litre with demineralized water.

Potassium stock solution of 1000 ppm was prepared from 1.9070 g of dry potassium chloride (Panreac) dissolved in one litre of demineralized water.

A 10% (w/v) lanthanum solution, prepared from lanthanum chloride ($LaCl_3 \cdot 7H_2O$) (Panreac), was used as a buffer solution to avoid anionic and ionization interferences.

Real cement samples were obtained from different Spanish and North African producers. Before the analysis, samples were ground in an agate ball mortar for half an hour in order to obtain a fine powder which was carefully homogenized.

All the reagents employed were analytical grade.

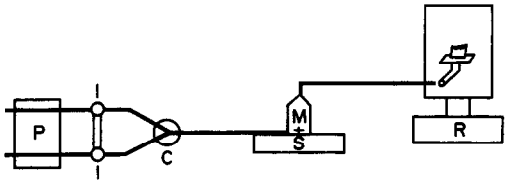

Fig. 1. FIA manifold employment in the analysis of potassium and magnesium in cement samples. P: peristaltic pump, I: injection valves, C: three-way connector, M: dilution chamber, S: magnetic stirrer and R: recorder.

Procedures

Recommended procedure

Preparation of slurries. The 50-mg sample was weighed into a standard flask and diluted up to 25 ml with 0.13*M* nitric acid. Homogenization of this dispersion can be achieved by introduction into an ultrasonic bath for 5 min. This procedure allows the rapid extraction of potassium and magnesium by leaching of the sample. If only potassium is to be determined, nitric acid is not necessary and distilled water is sufficient to extract it from the dispersed solids into the aqueous phase.

The size of 100% of the suspended particles determined by a laser diffraction system (Malvern Instruments, model 2600) was lower than 70 μm in all cases.

Flow injection analysis. Direct introduction of the dispersed sample is carried out without separation of the two phases, as follows:

One hundred microlitres of the slurry of the sample was injected in the double channel flow

injection system (Fig. 1) at the same time as one hundred microlitres of a 10% (w/v) lanthanum solution. Aqueous standards of K and Mg containing lanthanum and nitric acid were employed.

Reference method. Weigh 0.1 g of sample into a platinum crucible and add 1.5 g of lithium carbonate and 0.3 g of boric acid. Introduce the crucible into a muffle furnace, at 1100°; after 40 min, allow to cool to 700–800°. Transfer the molten contents of the crucible into a 250-ml porcelain evaporating basin. After cooling to room temperature, add 50 ml of hydrochloric acid (1 + 1 v/v) and stir until the solids are completely dissolved. Place the basin under an infrared lamp and evaporate to dryness at 130°. Add 5 ml of concentrated hydrochloric acid to re-suspend the silica and then dilute to 100 ml with hydrochloric acid (1 + 1 v/v). Filter using red-band (medium-textured) ashless Schuller filter-paper and dilute to 250 ml. Potassium and magnesium were determined by atomic spectrometric analysis of the filtered solution.

RESULTS AND DISCUSSION

Influence of the acidity of the medium

Preliminary experiments proved that atomic spectrometry determination of potassium in cement by direct injection of a discrete volume of a slurry containing 50 mg of sample dispersed in 25 ml of water in the FIA manifold provides results comparable to those found by analysis of samples using a previous alkaline fusion. However, the use of a 0.13*M* nitric acid medium for slurry preparation is necessary to obtain accurate results in the magnesium determinations as

Table 2. Effect of the concentration of nitric acid on the determination of Mg in cement samples

HNO_3 M	Sensitivity/au $mg^{-1}l$.	% MgO a	% MgO b

Note: Percentage of MgO is expressed by the mean concentration of three analyses of each sample ± the standard deviation of the entire procedure.

a The appropriate volume of concentrated nitric acid was added directly to the solid sample and after that diluted with distilled water.

b Nitric acid was added in the concentration indicated.

*Data found after alkaline fusion.

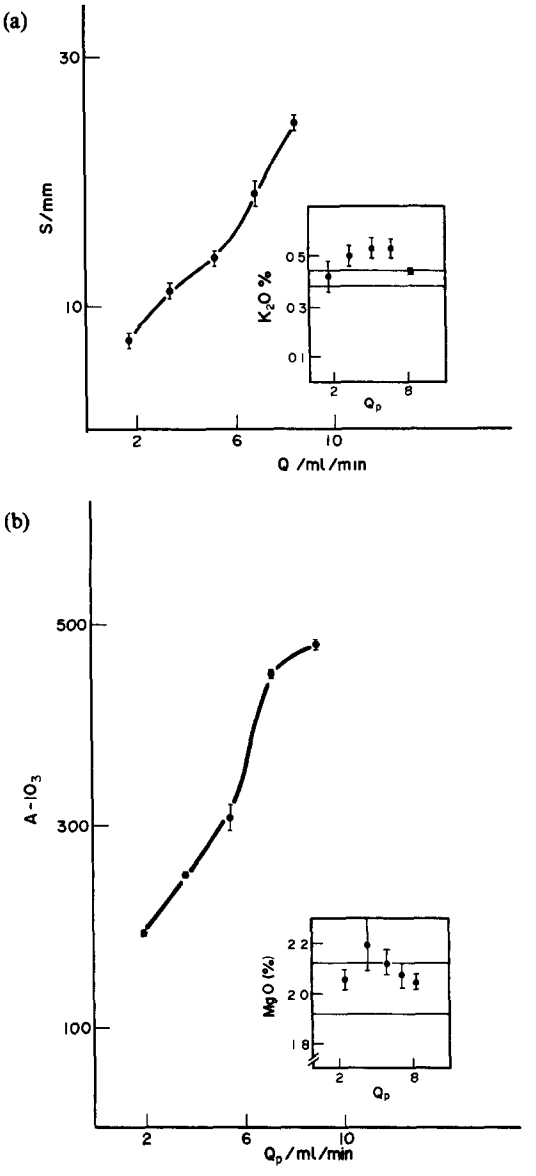

Fig. 2. Effect of the carrier flow on the sensitivity and accuracy of the determination of potassium (a) and magnesium (b) in cement. S: emission signal in mm; A: absorbance units. The horizontal lines in the insert correspond in both cases to the average value obtained for the analysis of these samples after an alkaline fusion ± the standard deviation.

can be seen in Table 2. The difference between the two analytes could be due to the high solubility in water of potassium salts that is sufficient to obtain complete extraction from the solid phase into the slurry, whereas an acid medium is required for the solubilization of magnesium. On the other hand, Table 2 shows that the analytical sensitivity for magnesium is not affected by the acid addition and that high concentrations of nitric acid are not required. The form of addition of nitric acid

(concentrated or diluted) is not important whereas the final concentration in the slurry is.

Effect of the FIA parameters

In order to study the influence of the FIA parameters on the analytical sensitivity and accuracy of the direct analysis of potassium and magnesium in cement, aqueous and acid slurries of 50 mg of a sample containing 0.4% (w/w) K_2O and 2.0% (w/w) MgO were prepared in a 25-ml volume. One hundred micolitres of slurry was injected in an aqueous carrier using different carrier flows, and the analytical measurements are shown in Fig. 2 (a and b).

The sensitivity of both determinations increases when the carrier flow rate increases. A carrier flow of 8.4 ml/min was selected for both cases because it provides an adequate sensitivity and also accurate values for both elements.

The inserts in Fig. 2 (a and b) represent the average values found for the direct analysis of the sample slurry at different values of the carrier flow. The average concentration values of samples, obtained after an alkaline

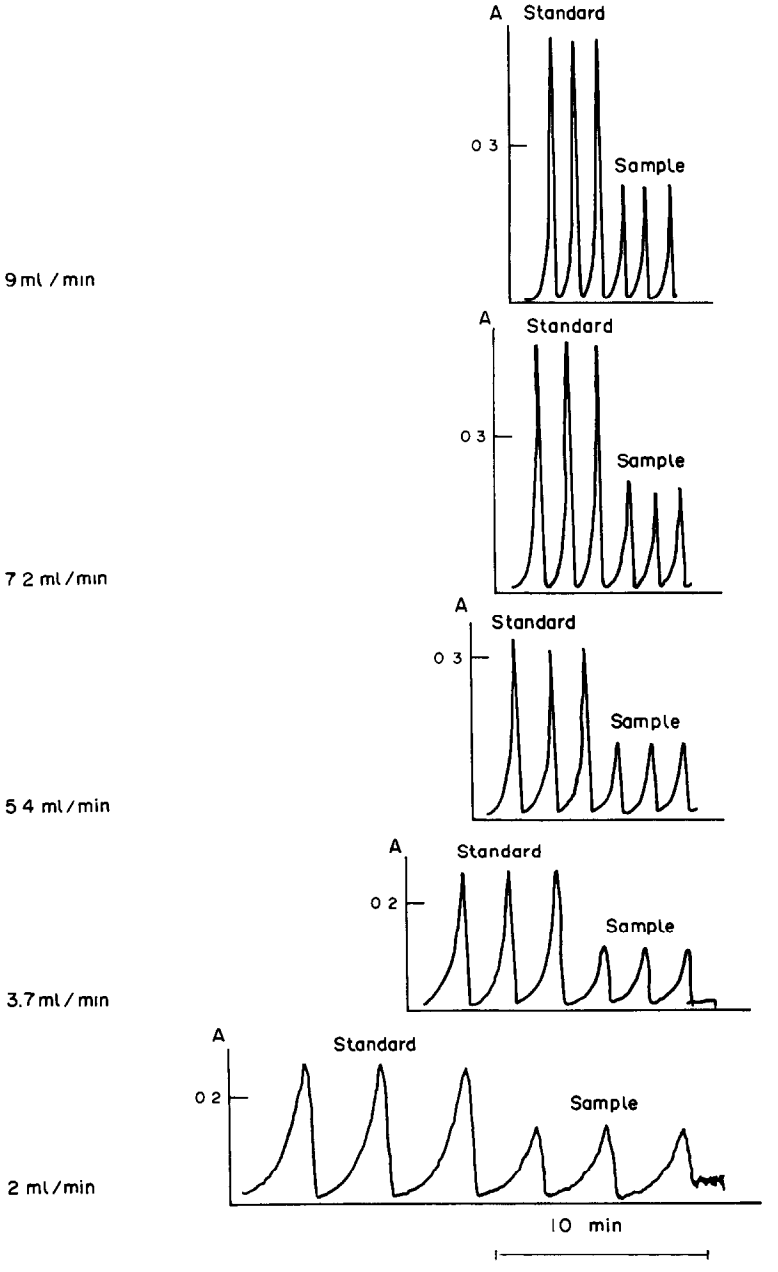

Fig. 3. FIA recording obtained for a standard of 10 μg/ml of magnesium and a sample containing 2.06% MgO as a function of the carrier flow.

fusion ± the standard deviation are represented by the horizontal lines. The comparison between these values provides an idea about the accuracy that could be obtained working at each carrier flow.

Flow injection recordings obtained from a magnesium standard of 10 μg/ml and a sample containing 2.06% MgO for different carrier flows, are shown in Fig. 3. The use

Note: Percentage of K_2O and MgO are expressed by the mean concentration of three analysis of each sample ± the standard deviation of the entire procedure.

of high carrier flows provides a higher sensitivity and sample throughput with fast return to baseline. Samples may be injected at the rate of 48/hour compared with 10 samples/hour provided by dilution and continuous aspirations.

Figure 4 shows the effect of the sample volume injected on the sensitivity and accuracy of the determinations of potassium and magnesium. A 100-μl loop was selected (using the selected carrier flow rate) in order to obtain the best accuracy, although it provides a poorer sensitivity. The analytical sensitivity of the atomic spectrometric analysis of these elements is very high, and the content of K and Mg in cement samples is of the order of 0.5 to 1% (w/w). So, the use of low injection volume at high carrier flow rate provides a compromise between sensitivity and dynamic range of the potassium and magnesium determination with a high sample frequency.

Analysis of real samples

A series of real samples of cement were analysed by both the recommended and a reference method and Table 3 shows the results obtained for % K_2O and MgO. Results are comparable for both methods, as can be seen from the mean concentration data, taking into account the standard deviation values. The precision of the measurements by the proposed method is higher than the fusion procedure for both potassium and magnesium determinations; this could be due to the fact that the proposed method using slurries is direct, whereas the classical method requires several experimental operations.

Figure 5 shows a flow injection recording obtained from the injection of magnesium standards (from 4.8 to 30 μg/ml) and four acidified samples of cement. As can be seen, more than 48 injections can be carried out per hour.

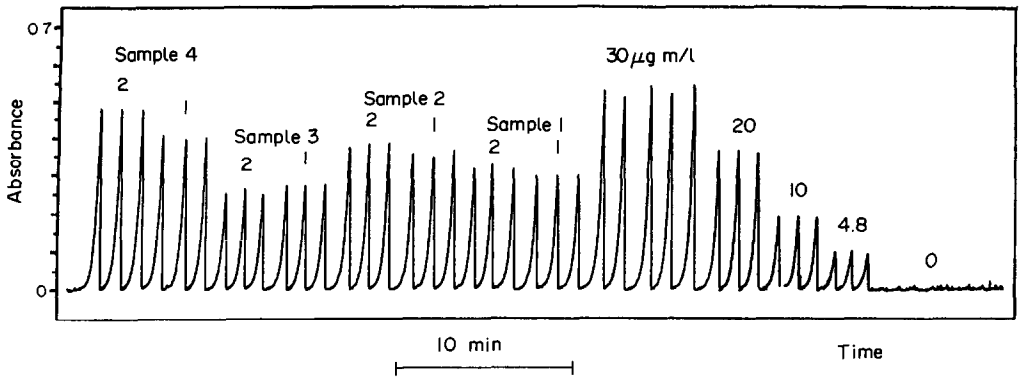

Fig. 5. FIA recording obtained for the injection of magnesium standards and acidified samples of cement.

Analytical performance of the developed procedure

Sensitivity is established from the slope of the calibration line. In the case of potassium, sensitivity has been determined for peak height values measured in cm, and is of the order of 0.20 $cm \cdot mg^{-1}$ l. The sensitivity for magnesium corresponds to 0.015 units of absorbance $\cdot mg^{-1}$ l. The regression coefficient of the calibration lines is 0.99995 for magnesium and 0.9994 for potassium, for a dynamic range up to 30 and 20 μg/ml respectively.

The limit of detection has been determined from ten measurements of the emission (potassium) or absorbance (magnesium) of a blank solution containing acid and lanthanum and it corresponds to the concentration of the element which provides an emission or absorbance value equal to twice the standard deviation of ten blank readings. A limit of detection of 0.15 mg/l. was obtained for potassium and 0.29 mg/l. for magnesium. These are concentrations of the elements in the slurry, corresponding to 0.007 K_2O and 0.01 MgO%, respectively, in the cement sample.

Precision has been derived from the relative standard deviation of ten analyses of a sample containing 0.54% of K_2O and 1.72% of MgO, respectively, and is of the order of 1% in both cases.

CONCLUSIONS

Using the recommended procedure, it is possible to take advantage of direct introduction of slurries in the flame flow injection analysis of solid samples, permitting an increase in the speed of the method, especially concerning the dilution of samples, and making possible the on-line addition of buffer solutions (as lanthanum) or other reagents, and decreasing the cost of the analysis.

DETERMINATION OF HYDROGEN PEROXIDE IN REACTOR MODERATOR SOLUTIONS BY FLOW INJECTION ANALYSIS

M. J. WHITAKER

Westinghouse Savannah River Company, Savannah River Site, Aiken, South Carolina 29808, U.S.A.

(*Received* 13 *January* 1992. *Revised* 2 *June* 1992. *Accepted* 4 *June* 1992)

Summary—A flow injection analysis (FIA) method for the determination of hydrogen peroxide in reactor moderator water has been developed and installed at the Savannah River Site (SRS) Water Quality Laboratory. The mode of detection is amperometric and the technique has an analytical range of 0.10–2.50 μg/ml with a sampling rate of 40 samples/hour. The calibration curve is linear with a correlation coefficient of 0.999 and the relative standard deviation is at the 0.50% level for both 0.10- and 2.50-μg/ml standards. When the FIA procedure is compared to the manual method previously used at the SRS Water Quality Laboratory for hydrogen peroxide analysis, it demonstrates a minimum twenty minute reduction in analysis time per sample and the total liquid waste generated per sample analyzed is reduced by 95%.

The moderator water used in the reactor at SRS is heavy water. For the reactor to function at an optimum, it is important that contaminants and radiolysis products be removed from the solution. Hydrogen peroxide is generated as an unwanted radiolysis product during normal reactor operations. Because of its corrosive nature it is imperative that the hydrogen peroxide be removed from the heavy water solution so that the delicate balance of this pristine system not be upset. Therefore, to ensure that the removal system is functioning properly, a variety of analyses are performed several times daily, of which, hydrogen peroxide is one.

This research project focused on the implementation of an automated analysis system for the determination of hydrogen peroxide in reactor moderator water. Flow injection analysis was selected as the technique of choice. Four major areas of development were investigated to improve the analysis of hydrogen peroxide over the existing methodology; (1) reduce the analysis time, (2) reduce the amount of radioactive waste, (3) reduce the analyst's length of contact and exposure time with the sample and, (4) develop a simple automated system and integrate it into the existing analyzer at the SRS Water Quality Laboratory.

The reduction in analysis time and total toxic liquid waste are extremely important issues in any analytical research or production laboratory. But, the importance of these particular issues takes on a much more significant role when the sample matrix is reactor moderator water and the sample is radioactive. For that reason, a great deal of effort was taken to reduce the analysis time and the amount of total radioactive liquid waste generated per sample analysis. The FIA method has reduced the analysis time per sample by a minimum of 20 min and the total radioactive sample waste by 95%. By accomplishing the first two objectives, 90% reduction of contact and exposure time of the analyst was also achieved.

To fulfill the final objective, the first step was to evaluate the various modes of detection that were available for hydrogen peroxide determination.[1–3] The criteria used in selecting a detector were that it must be simple and easy to operate, capable of measuring 0.10 μg/ml, small and compact, reliable, and reasonably priced. Reactor moderator water is extremely clean in terms of matrix interferences and hydrogen peroxide is the only electrochemically active species in the solution, thus it was determined that amperometric detection would be ideal for this particular application. The amperometric detector manufactured by Fiatron[4–6] for their modular FIA system was selected because it met all the criteria mentioned above.

The hydrogen peroxide procedure described in this paper is the second FIA method to be installed at the SRS Water Quality laboratory, the first of which was for the determination of

boron. To satisfy the objective of integrating the hydrogen peroxide system into the existing analyzer and to simplify the total system, the two FIA manifolds (boron and hydrogen peroxide) were integrated in such a way that switching from one method to the other would be a simple task and accomplished within a matter of a few minutes.

EXPERIMENTAL

Reagents and standards

All reagents and standards were of analytical-reagent grade quality and prepared in distilled, demineralized water from a Nanopure system (Barnstead/Thermolyne).

A 1% solution of sodium chloride in deionized water was used as the carrier and the electrolyte for the FI electrochemical (EC) detection system.

Stock and working standards were prepared from a 3% solution of hydrogen peroxide (Fisher Scientific CAS #7722-84-1) by adding the appropriate volume to each standard volumetric container and diluting to volume with demineralized water. Once stock standards were prepared, all solutions were refrigerated when not in use to reduce degradation. The working range of 0.10–2.50 μg/ml hydrogen peroxide were prepared daily to ensure accurate results.

Instrumentation

The flow injection analyzers used for this study were the Fiatron modular units. Each system includes a Fiatron SC-110 autosampler with a capacity of 120 samples, a FIA-Valve 2000 eight port sample injection valve equipped with a 58-μl sample loop, a FIA-Pump six channel peristaltic pump, and a master control module with a FIA-Zyme amperometric detection drawer. The FIA peaks were collected on a Cole-Parmer 100 millimeter strip chart recorder and a hard copy of the data results was printed on a Brother M-1109 dot matrix printer. A schematic diagram for the hydrogen peroxide FI manifold is shown in Fig. 1.

The master module unit of the Fiatron FI analyzer is the microprocessor controller where various timing parameters, sample and standard information, *etc.* are programmed and stored for each methodology. The unit is designed so it will accommodate several different detection techniques. Each technique is built into an individual detection drawer and only one detection device is functional at a time. The amperometric probe of the FIA–Zyme detector is a single constructed unit with a platinum working electrode and a silver/silver chloride reference electrode. It was determined when the probe was allowed to soak in 1% sodium chloride solution (carrier solution) overnight before use, it demonstrated better stability and reduced equilibration time at initial start-up.

This detection device is actually designed to analyze for various types of sugars. The sugar molecules react with a specific enzyme immobilized on the surface of a membrane to produce hydrogen peroxide as a reaction product, which is subsequently measured by the amperometric

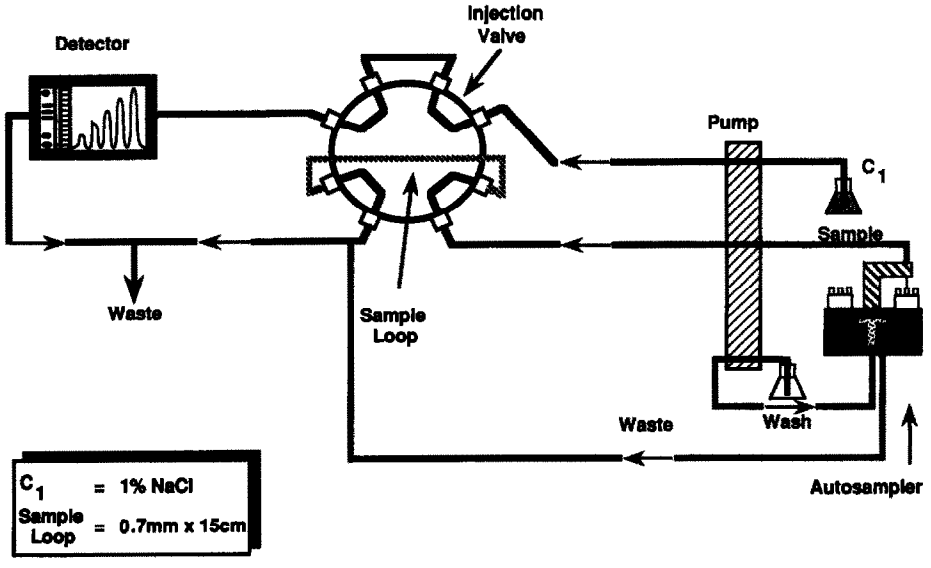

Fig. 1. Flow injection manifold for hydrogen peroxide.

Table 1. Experimental results of flow rate study using a 2.00-μg/ml hydrogen peroxide standard

Pump speed (%)	Flow rate (ml/min)	Analysis rate (min/sam)	Sample rate (sam/hr)	Response (Rel. Units)
14	0.70	3:36	17.00	109,000
18	0.90	3:05	19.00	107,700
22	1.10	2:30	24.00	100,900
24	1.20	2:15	27.00	96,400
26	1.30	1:59	30.00	95,200
28	1.40	1:51	32.00	85,700
30	1.50	1:44	35.00	85,000
32	1.60	1:40	36.00	82,200
34	1.70	1:35	38.00	81,200
36	1.80	1:30	40.00	78,600
38	1.90	1:21	44.00	75,500
40	2.00	1:16	47.00	73,600

probe. The potential of the probe is preset at the factory at 0.70 V. Hydrogen peroxide is a radiolysis by-product in reactor moderator water, therefore, it can be measured directly in the collected samples. Obviously, then, it was not necessary to utilize the immobilized enzyme membranes to generate hydrogen peroxide, so they were removed from the probe and only an o-ring remained to prevent leakage. Also, it was determined when using only a blank membrane (polycarbonate membrane without immobilized enzyme) sensitivity varied dramatically, probably due to variation in the thickness from one membrane to the next. Sensitivity and stability in the signal and the baseline improved considerably once the polycarbonate membrane material was removed.

RESULTS AND DISCUSSION

Flow rate study

A constant flow rate is a key parameter in the flow injection analysis technique and is determined by the size of the pump tubing used and the speed of the peristaltic pump. The pump tubing utilized for both the sample and carrier stream was Tygon tubing of 1.02 mm i.d., color coded as white/white.

The pump speed and size of pump tubing also affect the analysis rate, sample rate, and response factor of the sample or standard analyzed. Table 1 lists the data for a series of experiments in which the pump speed was increased from 14 to 40% of maximum velocity, giving the changes observed in flow rate, analysis rate, sample rate, and the response of a freshly prepared 2.00 μg/ml standard.

The flow rate ranged from 0.70 ml/min to 2.00 ml/min, with the corresponding responses ranging from 109,000 to 73,600 relative units. When the flow rate increases, the amperometric response decreases. A fixed sample loop of 0.7 mm × 15 cm dimensions was used to deliver a volume of 58 μl of standard into the FIA system for all flow rates studied in this series of experiments. The analysis time per sample includes loading of the sample loop, injection of sample, response, and return of signal to the baseline at a preset threshold, which decreases substantially with increased flow rate. The number of samples analyzed in one hour increases accordingly.

There are many reasons for automating sample analysis. One of the most obvious is reduction in man hours needed to accomplish the same job done manually. A much more important effect and impact when the samples are radioactive is reduction in exposure. To analyze one sample by the manual procedure at the SRS Water Quality Laboratory requires 20–30 min. Results of the time savings using the FIA method at different flow rates compared to an average 25 min for the manual method are illustrated in Fig. 2. The minimum time saved by the flow injection analysis technique at a flow rate of 0.70 ml/min is 21.40 min and the maximum time saved is 23.73 min when the flow rate is 2.00 ml/min. Of course, what is

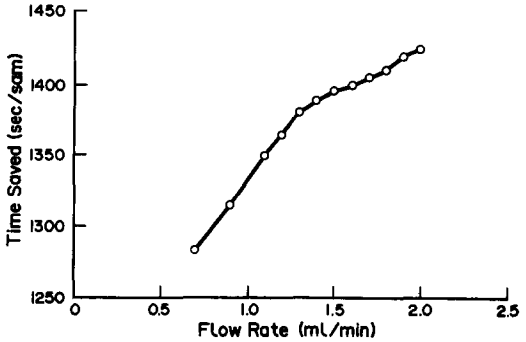

Fig. 2. Time savings per sample analyzed when using the FIA method at different flow rates, compared to an average 25 min analysis time for the manual method.

much more important here is that we have reduced the contact and exposure time of the analyst to the radioactive sample by more than 20 min, to 1–3 min per sample, a very significant improvement.

Sample volume study

The sample injection volume was varied by changing the length of the sample loops which were constructed from 1/16 inch Teflon tubing that had a 0.7 mm I.D., with the flow rate set at 1.80 ml/min. The results of analyzing various sample injection volumes of the upper limit standard of 2.50 μg/ml hydrogen peroxide are listed in Table 2. As expected, when the volume increases the response increases with each incremental enlargement in volume. It is important to realize that as the sample volume increases, so does the analysis rate (amount of time to analyze one sample), therefore a trade-off between sensitivity and analysis rate is created. The increased analysis rate is due to longer periods of time required to flush out the larger volumes of standard/sample introduced into the flow cell, plus the increase in response time with each volume enlargement. Because of the improved sensitivity achieved by removing the probe membrane, it was not necessary to use large volumes of standards/samples in this procedure. As a result, the 0.7 mm × 15 cm sample loop provided sufficient volume for analysis and was used for the remaining work.

pH Effects

The ideal operating pH range for reactor moderator water is 4.60–4.80. To determine the pH effects on the procedure described in this report a pH study was conducted. A 1.44 μg/ml hydrogen peroxide standard, prepared as described, has a measured pH of 4.45 and the carrier solution (1% sodium chloride) has a pH of 6.57. The pH of the 1.44 μg/ml standard was adjusted from 4.45 to 6.50 and analyzed after each adjustment to monitor the effects it might have on the FIA signal. The results of the pH experiments are listed in Table 3.

Table 2. Experimental results of sample volume study using a 2.50-μg/ml hydrogen peroxide standard

Sample loop (cm)	Sample volume (μl)	Response (Rel. Units)
15	58	201,000
20	77	213,400
25	96	261,600
30	115	286,200
35	135	312,900
40	154	347,600
45	173	406,500
50	192	418,900
55	212	432,300
60	231	452,400

Table 3. Experimental results of pH effects

pH	Response (Rel. Units)	Conc. (μg/ml)
4.45	202,900	1.44
5.00	204,300	1.45
5.90	206,500	1.46
6.50	209,800	1.48

It is noted that the difference in response from pH 4.45 to 6.50 is 6,900 relative units, in the order of 3%. It was therefore concluded, in the pH range studied, that pH has little effect on the amperometric detection of hydrogen peroxide when determined by this FIA methodology.

Calibration and reproducibility

The flow rate was set at 1.30 ml/min and the surface of the probe was freshly cleaned and prepared when calibration results were generated. The data are recorded in Table 4, demonstrating the linearity of the calibration curve which has a correlation coefficient of 0.999.

The precision of this procedure is excellent with relative standard deviations of 0.52% for 0.10 μg/ml and 0.34% for 2.50 μg/ml standards ($n = 5$).

Integration with the boron analyzer

A schematic diagram of the combined hydrogen peroxide and boron manifold is shown in Fig. 3. The combination manifold incorporates the two methods by adding four additional components to the hydrogen peroxide manifold to accommodate the boron method. These include a mixing coil, a 3-way valve to allow reagent to be added to the sample, a pump tube to deliver the reagent, and a colorometric detection drawer to replace the amperometric

Table 4. Calibration data with flow rate set at 1.30 ml/min

Conc. (μg/ml)	Response (Rel. Units)
0.10	19,200
0.25	40,450
0.50	72,600
1.00	138,900
1.50	212,400
2.00	271,100
2.50	325,100

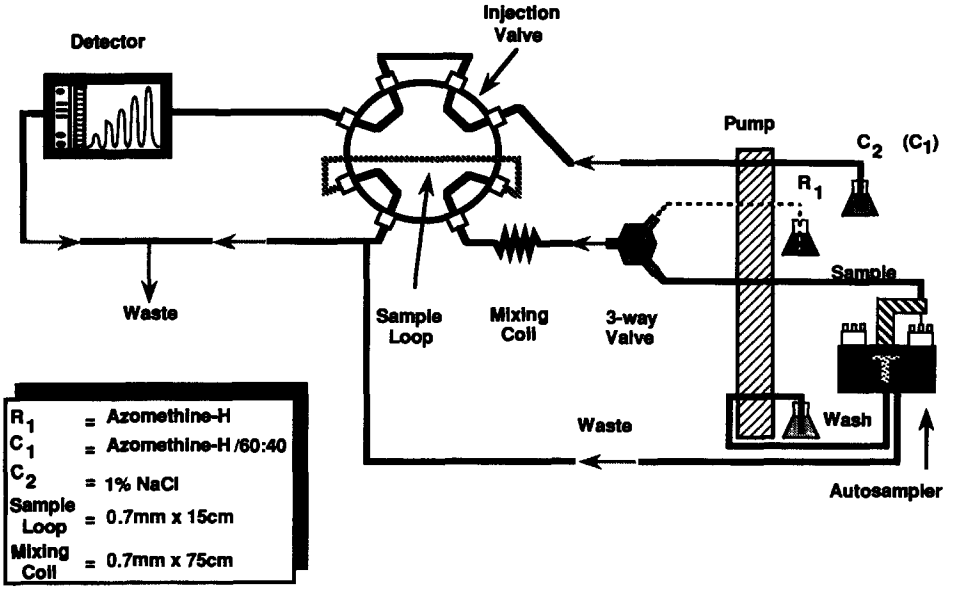

Fig. 3. Combined flow injection manifold for boron and hydrogen peroxide.

drawer. The illustration depicts the manifold as set for hydrogen peroxide analysis. This is indicated by the dashed line from R_1 to the 3-way valve, which represents there is no flow in the conduit, therefore no reagent is being delivered and the carrier solution is 1% NaCl (C_2). To change methods is a simple procedure, taking 2–3 min, requiring switching the detector drawers, adjusting the 3-way valve to the proper position, and using the appropriate carrier and reagent solutions.

CONCLUSION

The four major objectives established at the onset of this project were met and accomplished over and above expectations. Time required for analysis of an individual sample was reduced by 80%. The amount of liquid radioactive waste generated from the analysis of samples for hydrogen peroxide in reactor moderator water was reduced by 95%. The analyst's contact and exposure time with the radioactive samples was reduced by 90%. An automated system was developed, utilizing FIA technology, that was simplistic in design for ease of operation, and was integrated into the existing analyzer.

SPACE-AGE ANALYSIS: A GUIDE FOR AUTHORS AND REVIEWERS

The lead article in this issue by Professor R. A. Chalmers, retired Editor-in-Chief of *Talanta*, is taken from his invited lecture in the symposium on "The Status of Analytical Chemistry in the World" held at the 1992 Pittsburgh Conference. It reflects on his editorial experiences for over twenty years, and includes many words of wisdom that young and not so young researchers ought to take to heart. We, as his replacement editors—it takes two to do his job—asked him to publish it in *Talanta* because our readers should all benefit from and enjoy reading his comments. Our jobs as Editors-in-Chief and those of our referees would be made much easier if his guidelines for originality, usefulness and correctness were followed. Likewise, if referees would keep these guidelines in mind when evaluating manuscripts it would help assure the quality of publications we strive to maintain. Professor Chalmers addresses concerns about sources of error, use of statistics, basic chemical knowledge, and reference accuracy. We particularly direct readers to the section "Pluş a Change ...". All too few researchers fail to really justify why their work is important and ought to be published. It is easy to sweep dozens or hundreds of published methods under the rug with a broad claim that they are laborious, insensitive or non-selective, and then proceed to develop a presumably improved method where the real improvement is marginal or not made apparent. Often a work is presented with no attempt to even justify why it was done or what its advantages are, or only old or relatively inaccessible literature is cited.

We invite you to read Professor Chalmers' article. All should benefit from his words of wisdom.

SPACE-AGE ANALYSIS*

ROBERT A. CHALMERS
Department of Chemistry, University of Aberdeen, Old Aberdeen, Scotland

(*Received* 26 *June* 1992. *Accepted* 26 *June* 1992)

Summary—A survey is given of present-day analysis, from an editorial point of view, and suggests that though techniques have changed in order to meet the challenges of modern technological advances and materials, the fundamental character of analytical research and its publication has not.

The first task in any research project is to look at the history of the problem. If we do this in a survey of analytical chemistry as a whole, we find that in the past people sometimes knew what needed to be done, but did not have the equipment to do it, and sometimes had the equipment but did not see what to use it for. An example of the first is Faraday's testing of the pollution in the River Thames by dropping in pieces of white card and observing the depth at which they disappeared from view;[1] this was usually less than an inch, and the bottom of a card inserted vertically disappeared from sight before the top entered. The second is optoacoustics, examined by Alexander Graham Bell,[2] John Tyndall[3] and others, around 1880 (though Tyndall did indicate that the technique might be used for detecting methane in coalmines).

These two examples have one thing in common—technology—either as lack of it for use, or lack of technical problems to which to apply it. As the use of new materials and inventions increased, so did the problems and the technology and instrumentation needed to deal with them. Ideas that are often considered to be "modern" (which many regard as meaning post-World War II) appeared surprisingly early. An automatic carbon monoxide monitor had been reported by 1925,[4] and by 1928 no fewer than fourteen of them were in use for checking air quality in the Holland Tunnel in New York.[5] A quick look through the first twelve or so volumes of *Ind. Eng. Chem., Anal. Ed.* is very instructive and shows the shape of things to come. A thermal conductivity method for continuous recording of the carbon dioxide and oxygen levels in air was described in 1930,[6] for example, and so was an automatic photometric titrator.[7] A paper on what would now be called library searching or spectra matching appeared in 1938, with data for the X-ray diffraction patterns for 1000 substances.[8] A review by Ralph Müller in 1940 showed the very wide range of instrumentation even then available in the United States.[9]

THE INSTRUMENT REVOLUTION

It was evident that the main thrust in development of instrumentation arose in the USA, though there were notable contributions from Europe, such as polarography, which gave rise to an entire sub-discipline, electroanalytical chemistry, with its own specialist journals. All this is well described in the excellent A.C.S. publication "A History of Analytical Chemistry",[10] along with many other aspects of modern analytical chemistry. Some of these, such as Raman spectroscopy, were before their time and had to await the development of suitable instruments. FT–IR was another. Its principles were known to Michelson in 1891,[11] and he developed a mechanical harmonic analyser in 1898,[12] but the calculations were still extremely laborious, even with the aids developed later by Beevers and Lipson,[13] and the method really came into its own only with the arrival of the computer age, information theory and instrument science. An excellent account of this is given in a recent book.[14]

During the last two or three decades there has been an unprecedented display of ingenuity in devising instrumentation and computational

*This contribution is based on the opening lecture "Space-Age Analysis" in the Symposium on "The Status of Analytical Chemistry in the World" at the 1992 Pittsburg Conference, held in New Orleans, which in turn was partly based on earlier lectures.

methods for use in research and industrial analysis, catalysed by cross-fertilization of ideas between different disciplines. In particular, once a technique has been devised, a good deal of effort has gone into exploiting it to the full. Perhaps the prize examples are electrochemical stripping methods and flow-injection analysis, which are still being expanded in scope and versatility. These techniques also show well that the same idea may arise almost simultaneously in several different places.

As a result of the development of computers, microprocessors, robotics, chemometrics and so on, we now have the possibility of operating with very small quantities of material, with numerous data-points from a given experiment, and of exploring structure, structure–behaviour relationships, speciation, spatial distribution and so forth, to an extent never previously attainable.

"PLUS ÇA CHANGE ..."

All this is very exciting and full of promise, and it is all too easy to take the attitude "isn't science wonderful", without questioning its validity. As happens with almost all new techniques, however, we are carried along by the first flush of enthusiasm to believe that here at last we have the means to solve all problems, until further work begins to show up any shortcomings of the techniques and we find that the answers may be incomplete or even wrong.

If we survey the current literature, we quickly see that we have substantial dedicated groups of leading thinkers and innovators, working to extend the frontiers in their particular fields. Then we have a larger group of workers we might call "implementers", who apply these new techniques along with others to solving specific problems in industry or in research projects. Finally we have a possibly even larger group of those who, whether from choice or because of economic restrictions, continue to tread well-worn paths in analytical research, operating a kind of cottage industry to turn out methods that, though "new", are devoid of much originality and are hardly ever likely to be used. Take organic reagents for spectrophotometric determinations, for instance. Until about twenty years ago, research in this field involved finding fairly non-selective reagents and applying them to as much of the Periodic Table as possible, or finding reasonably selective (or even specific) reagents and then shunting various harmless substituents around the parent molecule to create "novel" reagents. The result was thousands of reagents, mainly for copper, cobalt, the palladium metals, iron and vanadium, that very seldom had any real advantages. The substituted hydroxamic acids developed as reagents for vanadium are a good example, and an entire book[15] has been devoted to reagents for copper. Then came the advent of micellar systems, so all these reagents were given a new lease of life as sources of "research" papers, and this was further extended by use of derivative spectrometry, solvent extraction and combinations of these and other ancillary techniques. Most of these authors were doubtless driven by the "publish or perish" syndrome, and perhaps did not realize that they could publish *and* perish.[16]

The resulting clutter in the literature could have been reduced if reviewers and editors had been far more critical in judging the value of such papers, as has been pointed out in various editorials.[17–19] After all, such reseach projects are quite suitable for *training* students in research methodology and to think analytically, but the results do not *have* to be published. Ph.D. examiners are usually asked whether the work *is* publishable, but not *where*, so may safely answer "yes". My plan for financing retirement would be to start a new journal called *Journal of Useless New Knowledge* (JUNK), with a page-charge and circulation only to authors (with one copy of the issue in which their paper appeared).

"A LITTLE LEARNING ..."

There is an unfortunate by-product of the computer/microprocessor age, however. Because the results are obtained automatically, the experimenter may come to believe they must automatically be correct, and take no thought about errors that may arise from the chemistry and methodology involved. Worse, the experimenter may run only a single experiment to obtain a large number of data points for interpretation, and forget that any mistake in setting up the experiment will invalidate the results.

The experimenter may be expected to be aware of the obvious sources of error, such as sample inhomogeneity, too small a sample, use of impure materials, failure to calibrate equipment or check commercial standards, non-linear instrumental response, noise, and so on, but

may well be unaware of some of the more subtle sources of error.

Adjustment of pH may seem a simple and trouble-free operation, but many factors can affect the relationship between the pH-meter reading and the effect of the hydrogen-ion concentration. As Kragten has pointed out,[20] if the adjustment is not done in the correct manner, and kinetically inert hydroxo-complexes are formed during it, the results obtained may not be as true as the operator thinks.

Some species used as buffering agents, or as auxiliary masking agents, may cause interference for totally unexpected reasons. Tartrate and citrate, for example, can form binuclear ligand-bridged kinetically inert complexes with two different metal ions, and if one of these is the ion of interest, it can be partially or even completely lost in the analysis.[21] If partial loss occurs, an analytical result will be obtained, but it will not be the correct one. On the other hand, as so often happens in analytical chemistry, what is a disadvantage in one situation can be turned into an advantage in another, and formation of such complexes can be used for masking purposes or even for determination of the bridging ligand. A further complication, however, is formation of mixed-ligand complexes of this type.[22] Another example is the effect of zirconium or hafnium on the hydrolysis of niobium and tantalum, where in certain pH-ranges the hydrolysis is inhibited by formation of soluble hydroxo-bridged polymeric mixed-metal species.[23]

Even established decomposition procedures may be suspect. It is well known that volatile compounds may be lost, or contamination occur, but there may be unsuspected problems. For example, prolonged heating of mixtures containing alkali-metal, aluminium, iron and sulphate ions can lead to insoluble jarosites—a fact well known to rock analysts, but probably not to analysts wet-ashing foodstuffs or other organic matter. Again, in many researches on determination of platinum metals, all the work is done with mixtures of solutions of pure salts in defined oxidation states, and no indication is given of how to get a real sample into solution with all the components in the desired oxidation states, and without formation of polymeric or kinetically inert species.

Interference tests are often too simplistic, being run with one species at a time, without regard to the compatibility of the oxidation states of different species, or the likelihood of appearance of these states. Interactive effects are hardly ever looked at, though they are known to occur in atomic-absorption spectrometry[24] and electrochemical stripping,[25] for example.

In equilibrium constant and speciation studies, some compounds used as background electrolytes may be significantly incompletely dissociated if used at too high a concentration, so ionic strength corrections may not be completely valid. Also, the anions of such electrolytes (notably nitrate) may form weak complexes with the metal ions of interest, and this can cause significant error if a high electrolyte concentration is used.[26]

A more subtle error may arise in computation of stability constants and speciation. The usual approach is to find the set of components which will give the lowest sum of the squares of the differences between the experimental and calculated data. Various combinations of components, with more added as the search progresses, are tested until the apparently best fit is obtained. Quite often a very similar fit is yielded by more than one set of components. It is then necessary to decide on chemical rather than statistical grounds which should be taken as "correct", and in such circumstances it would seem prudent to remember Occam's razor and employ it. Sometimes a major new species may be postulated on the basis of such calculations, but not independently verified or substantiated by repetition of the work or by other methods. It may, however, enter the literature compilations and be taken as gospel. Any subsequent work based on it will be in error if the species is in fact a bogus one. In this connection, utmost care in proof-reading papers on new species is of vital importance. In a recent case, the accidental omission of a subscript 2 from a chemical formula (one of eighteen listed in the source paper) led to a completely false set of results in a different work based on that erroneous formula.[27] The error was not easy to trace.

Editorial experience suggests that today's researchers may sometimes be unaware of the "hidden" sources of error such as those outlined above. This may be due to the fact that the increasing complexity of chemistry, together with the expectation that a chemist will be skilled in physics, statistics, computing science, electronics, economics, *etc.*, means that unless the student's course is lengthened, less will be taught about each topic. For graduate students this can be at least partly remedied by further instruction, but this is all too often restricted to

advanced material in the field of the research topic, and the student may remain only partly educated in other areas. This may seem a pessimistic outlook, but an editor sees not only the published papers, written by those whose work is scientifically sound, but also the papers which are rejected for some reason or other, and which raise such questions as "if this is how they do research, what do they teach their students?" Readers see only the papers that are accepted; reviewers will see some that are unacceptable, but only the editor will see the whole lot in both categories. Two examples of "question-raisers" may suffice as illustration. In one paper sodium was said to interfere when present at the 50-μg level, but in an application 1 ml of 1M sodium fluoride was added as a masking agent. In another it was stated that a chromium(VI) solution was used at pH 0–5.5, and that the chromium would be present in the tervalent state. This was supported by a reference to a well-known textbook, which actually said nothing of the sort—the passage referred to dealt with the equilibrium constants for the $Cr_2O_7^{2-}/HCrO_4^-/CrO_4^{2-}$ system. It is quite common to see references to use of buffers at pH-values where their capacity is practically zero, or of masking agents at pH-values where practically no free ligand would be present.

"STATISTICS MAY BE USED AS A DRUNK USES A LAMP-POST—MORE FOR SUPPORT THAN ENLIGHTENMENT"

Authors often quote more significant figures than can be justified by the experimentation or statistical needs, or produce a standard deviation on the basis of only two or three results. Sometimes the standard deviation is greater than the mean, but no comment is made on possible skewness of the distribution. Nowadays relative standard deviations of 2% are commonplace, and values of 10, 15 and even 20% seem acceptable to some authors, reviewers and editors. Papers on instrumental methods often compare the results with those of classical methods, usually claiming superiority. To anyone with long experience of the classical method used, such claims often seem untrue and to reflect only lack of classical experimental skill by the operator. Poor performers should practise and learn to do better! A typical case was a claim that a thermometric method (error $\pm$ 3%) was better than manual titration for iodometric determination of copper. Even a freshman can do better than that. An early robotics paper reported 0.6% relative standard deviation for titration of 1M hydrochloric acid.

Results are often compared by t and F tests and said to be equally as good, but it would sometimes be more correct to say "equally as bad". The precision of both the "new" and "standard method" results sometimes leaves much to be desired, and this can frequently be ascribed to the use of small samples and volumes, and an apparent lack of calibration of glassware.

Much is made of clinical tests as an aid to diagnosis of illness, but though these tests are undoubtedly useful when properly used, back-up by diagnostic skills is at least equally important, especially if the tests happen to have a high incidence of false positive or negative results. As some young physicians may never have seen clinical cases of certain illnesses and so be unable to recognize them, an inaccurate test result could have unfortunate consequences. This is perhaps even more the case with tests used in criminal investigation, where recent work on some old tests and development of new ones has shown that some prisoners have been convicted on the basis of highly questionable or at least equivocal evidence.

"ALTHOUGH THEY WROTE IT ALL BY ROTE, THEY DID NOT WRITE IT RIGHT ..."

The foregoing may be thought a rather jaundiced outlook, but editorial assessment of some 8000 papers has left the impression that a surprisingly large number of authors were apparently ignorant of some basic chemical facts or had not read the literature very carefully. It has also revealed that a great many authors fail to understand that language is a precise tool, and if misused can result in ambiguous or even erroneous information being conveyed. Some papers are so badly written that the reviewer is obliged to edit them before being able to assess them. Reading other journals in the course of checking manuscripts has shown that the standards of editing vary widely, and that some editors even manage to introduce errors themselves (to protect the guilty, no examples will be given). A frequent cause of annoyance in editing is error in references, and finding the correct version can take a great deal of time. Sometimes a reference may have nothing to do with the topic concerned (usually because the author has pulled out the wrong file card, or copied some-

one else's erroneous reference, having never tried to use it). In 23 manuscripts looked at early in 1991, there were 55 errors in authors' names, 3 in journal names, 2 in journal year, 5 in volume number, 3 in issue number (where this was necessary) and 5 in page number; 2 references were completely wrong and one was untraceable. There is no real excuse for such errors[28] (although even *Chemical Abstracts* can very occasionally be blamed). There are those who insist that editors do not need to check references and that the responsibility for correctness lies not just primarily, but absolutely, with the author. But how does the editor know references *are* correct, without checking them? It is, of course, always possible to blame the printer, but such errors can be corrected by means of a list of errata.

BACK TO THE FUTURE?

The thoughts above represent one person's view of the current scene in analytical chemistry. It would appear that the scene has changed only in range and technology since Lundell wrote his classic paper "The Chemical Analysis of Things as They Are" nearly sixty years ago,[29] but the chemistry sometimes seems only incidental in comparison with the instrumentation, and if the chemistry happens to be wrong ...

So what should we look for in the future? I would like to see an overhaul of teaching, with stronger emphasis on the chemical properties of elements and compounds, and preferably longer courses. Next I would like to see organization and co-ordination of research with a view to solving important and hitherto unresolved problems as a priority. This could not apply to all workers, of course, and I would like to see the cottage industry workers turning away from trivialities and achieving satisfaction by work such as obtaining more precise values for the equilibrium constants and other data that are basic to our understanding of chemistry and are needed for computerized speciation studies *etc.* Other useful pursuits for them might be in-depth studies of decomposition processes, explanation of anomalous results obtained in established methods, or critical comparison of alternative methods. Finally, a concerted effort by reviewers, publication committees and managing editors to raise the standard of published work by refusal to accept work that is fragmented, or offers no significant improvement over existing methods, or is based on inadequate experimentation. Aid with the last point might be achieved by publication of more guideline papers of the type pioneered by *Talanta* (Table 1). What is needed is better quality control.

Table 1. Research guideline papers

What I *expect* to see is much the same scene as now, with a vanguard of innovators and explorers, and the main body of troops consolidating the ground won. There are still problems to be solved and advances to be made, however, and the programmes at meetings such as the Pittsburgh Conference always generate great hopes for the future.

REVIEW

MICROBIAL CALORIMETRIC ANALYSIS (MCA) OF AQUEOUS ORGANIC COMPOUNDS

MARK L. FERREY and REX E. LOVRIEN
Biochemistry Department, University of Minnesota, 1479 Gortner Avenue, St Paul, MN 55108, U.S.A.

(*Received* 24 *February* 1992. *Accepted* 10 *June* 1992)

Summary—Adapted bacteria used in heat conduction calorimetry may be developed as 'analytical reagents' for compounds that can be metabolized by such bacteria. Adaption can be done by growing cells such as *E. coli* on the analyte of interest, for example a sugar. Samples to be analyzed are mixed with adapted cells which aerobically metabolize the sought-for analyte, producing heat. The method is called microbial calorimetric analysis, MCA. Average requirements are 2–200 nanomoles of analyte, "carbon", an excess of cells *ca.* 2–5 mg of cells, and 1–2 ml of air to maintain aerobicity. Heat production is usually completed in 300–600 sec at 25°. The combination of bacteria and heat conduction calorimetry is a sensor system having a sensitivity and selectivity dependent on bacterial adaption. The system is useful in analytical problems when analytes are in turbid suspension, are poor chromogens or not even prochromogenic. MCA takes advantage of the large aerobic heats usually generated by bacteria in active utilization of organic analytes. Typically from 20 to 70 kcal exothermic heat per mole of carbon atoms is generated, *e.g.*, (−)300 kcal/mole glucose. Heat conduction calorimeters, batch mixing instruments, measure 2–100 millicalorie heat with ±3% error in each run. Bacteria can be grown on many different kinds of compounds. Accordingly it is fairly easy to create diverse, specific 'analytical reagents' which function in MCA much as they function in their usual environment, in soils, *etc.* Intact, adapted bacteria have decided advantages over isolated enzymes as 'biosensors' for a number of practical reasons.

When bacterial cells are grown on carbon sources such as sugars or alcohols they adapt to metabolize the compounds on which they were grown. They become selective in their uptake of particular compounds, often quite narrowly selective. For example some bacteria metabolize ethanol but not methanol, yet others metabolize methanol but not ethanol.[1] Bacterial metabolism of organic carbon using oxygen, aerobic metabolism, tends to produce considerable heat. Bacterial aerobic metabolism of aqueous carbon commonly generates half or more of the heat generated by oxygen bomb calorimetric combustion of the dry compounds.[2] Such microbial metabolism (biological combustion) in a simple batch mixing calorimeter provides a means for analysis which is called microbial calorimetric analysis, MCA. Bacteria or yeast cells are the 'analytical reagents'. Dissolved oxygen is the main reactant in addition to the organic compounds in the aqueous sample. Figure 1 is an outline of the essentials of MCA.

Bacteria as reagents may seem odd as a basis for analysis. However bacterial cells together with heat conduction calorimetry have a few advantages that may be useful. For example MCA can accommodate turbid, even opaque samples such as a food slurry, not acceptable for direct spectrophotometric analysis. Bacteria can often continue to function under quite severe conditions that quickly denature isolated enzymes. This point is discussed more below.

Bacteria able to adapt and become selective are quite easily grown using the simplest equipment, shake-flasks. Several different kinds of bacteria effective in MCA may be stored in a frozen state to be used when wanted. Three of the most studied bacteria are *Pseudomonas*,[3] *Escherichia coli*[4] and *Salmonella*.[4] Hundreds of individual strains exist in each genus. Several Pseudomonads can metabolize and combust myriad carbon sources including petroleum and lignin fragment compounds. *E. coli* are enteric (intestinal) bacteria able to metabolize common sugars in foods and several fatty acid anions including acetate. It is not always necessary to use carefully identified bacteria as MCA reagents however. If one wants to analyze methanol in water a few milligrams of soil may be started with. The soil is added to a simple

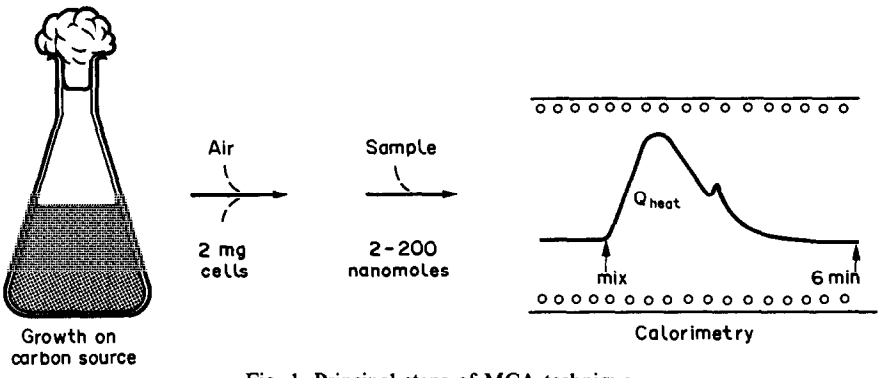

Fig. 1. Principal steps of MCA technique.

enrichment apparatus[5] through which air is bubbled. Small amounts of glucose are added to increase cell populations. Then glucose is withdrawn and methanol is added to *ca.* 0.2–0.6% methanol concentration. The surviving 'methylotrophs' although not identified, usually can combust a few dozen nanomoles of methanol, in 3–5 min. The resultant heats are proportional to the amount of methanol. Such an adaptive technique is not new; it is routine in several older analytical methods such as in measurement of biological oxygen demand, the B.O.D.[6] In order to take advantage of microbial biodegradative capacities, applying them to analysis, some points concerning bacteria may be reviewed.

Adapted bacteria develop quantities of enzymes, also porins and transport particles, to quickly absorb targeted compounds and metabolize them to get 'energy'. Adaption commonly raises concentrations of key enzymes 10X to 1000X[7] above concentrations seen under non-adapted conditions, 'constitutive enzymes'.[8] Bacterial adaption for MCA is simply use of processes occurring on a large scale in the environment and agriculture, biodegradation in soil, sewage, fermentation and silage making.

Of equal importance in MCA is the self-protection and self-maintenance which bacterial cells are able to do. Commonly it is suggested that biosensors can be devised using simply isolated enzymes in 'enzyme electrodes' to focus on reactions wanted to be transduced or biosensed such as an oxidation or a reduction. These biosensors frequently rely on an oxygen electrode for transduction to an electric signal.

Although such 'enzyme electrodes' are popular for research projects, they engender difficult practical problems. Many bacterial enzymes but especially those in redox (electron transfer) pathways are notably unstable when taken out of their protective cellular environment. Several prooxidative enzymes are destabilized on contacting dissolved oxygen.[9,10] These enzymes require intermediates, NADH, NADPH, *etc.* Therefore such biosensors have to be kept supplied with NADPH *etc.*, which may not be a trivial task. In contrast intact bacteria protect such enzymes, plus supply necessary flavin, NADPH intermediates. How bacteria do this, protect their enzymes, and also supply necessary intermediates, is not always well understood. *E. coli* bacteria for example, maintain about 2 m*M* reduced glutathione inside (intracellular GSH), to protect themselves against internal oxidative damage.[11] Many bacteria are endowed with rather remarkable survival capacities. But isolated or 'biosensor attached' enzymes usually are not so equipped.

When biosensors are constructed around oxygen electrodes the rough, fluctuating environments in real samples such as in fermenters knocks oxygen concentrations around so much that the baseline oxygen levels are hard to control. Oxygen electrodes can detect very small differences in oxygen concentrations, of the order of 5μM O_2/minute.[12] However in industrial environments the sensitivity of oxygen electrodes or enzyme-coupled oxygen electrodes are of little help when dissolved oxygen concentration fluctuations in baselines are larger than analyte concentrations. In contrast, MCA is 'carbon limited'. MCA is rather insensitive to oxygen concentration fluctuations so long as there is enough oxygen present to maintain aerobicity. Hence roughly fluctuating oxygen concentrations matter little, so long as there is enough to keep the system aerobic.

Bacterial response to 'carbon' is conventionally thought of as bacterial growth, which can be counted or otherwise measured. The MCA method is not based on cell growth, but avoids it. Not enough carbon as analyte is used to promote bacterial growth in the calorimeters. Bacterial doubling times—one

cycle of growth—usually require 20–60 min depending on the kind of cell and the temperature. Much more carbon has to be provided to obtain bacterial growth, than amounts of carbon needed to get an initial 'priming' pulse of heat in MCA's mode of operation, by a factor of about 10. When cells are adapted and in excess, their aerobic uptake and utilization of carbon is usually completed in a few minutes. No new cells are made nor wanted. The MCA method measures a burst of heat, proportional to the cells initial metabolism of the compound in question.

Summarizing so far, MCA or bacterial calorimetry uses *ca.* 0.5–1 ml of sample containing 10^{-6}–$10^{-4}M$ analyte. Measurement times after mixing cells and sample are 3–10 min. Oxygen concentrations usually need not be kept within narrow limits if there is enough oxygen available to keep the system aerobic through the analytical run. Namely 10–50% air saturation, equivalent to 10^{-3}–$10^{-4}M$ dissolved oxygen. Specificity is determined by the specificity with which cells can be adapted to absorb and metabolize the analyte. Microbial calorimetry takes advantage of microbial behaviour of a kind, that isolated enzymes coupled to sensors have considerable difficulty with. Namely enzyme protection, generation of needed intermediates, imperviousness to foreign compounds destructive to enzymes. Microbial calorimetry is quite like conventional wet chemistry analysis, in that the principal reagent or catalyst is discarded after each run. Bacteria in quantities needed for MCA are relatively inexpensive. About an hour's labour is sufficient to provide enough cells from sub-culture, for two to three days of use.

EXPERIMENTAL

Seebeck thermopile sensors and reaction vessels

The central parts for a batch mixing calorimeter are shown in Fig. 2. Thermoelectric devices which generate the Seebeck effect also exhibit the Peltier effect. Thermoelectrics used by us are sold primarily as Peltier pumps, *e.g.*, by the Melcor Company. They function with about 35% power efficiency, transducing heat to electric current and so are called Seebeck thermopiles when used in the Seebeck mode. Two Seebeck thermopiles are placed in good contact with the two faces of the mixing vessels and in contact with the aluminum metal heat sink as shown in Fig. 2. The heat sink which surrounds the assembly and contacts the outer faces of the

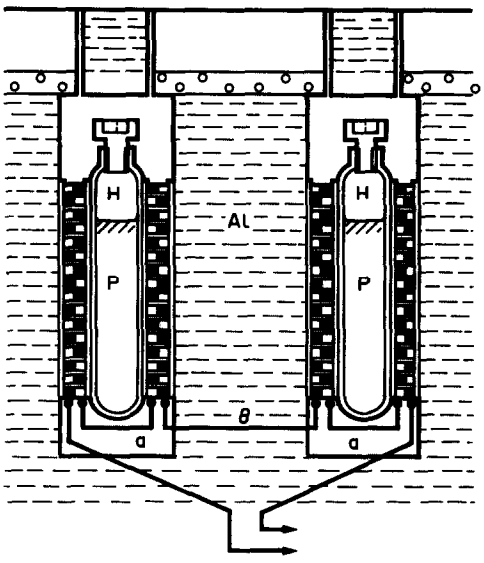

Fig. 2. Twin heat conduction batch mixing calorimeter using Seebeck thermoelectric sensors. Partition P divides the internal space in the lower part of both mixing vessels into two compartments, keeping reactants from mixing until the whole is inverted. Seebeck sensors are connected so a (=add) causes addition of voltages from the sensors within each pair. Connection o (=oppose) causes subtraction of the pairs of summed voltages from each other giving a net voltage (arrows) for transmittal to an external dc amplifier. Net voltage output is directly proportional to net power from the two vessels, reference and sample, with a figure of merit 7 μWatts net power (as heat) per μVolt net output signal. Al = aluminum heat sink, for promoting thermal equilibrium throughout before mixing and absorption of any heat from samples; H = headspace, air.

thermopiles weighs *ca.* 0.5 kg. Seebeck thermopiles are made mostly of metal, with thin ceramic face plates for electric insulation. Thus the path from the sample chamber is a good heat conduction path able to pass heat from the sample to the heat sink in a few seconds. About one third of such heat is transduced to electric power, a signal, by the Seebeck units. Thermopile resistances are *ca.* 1–2 ohms. Therefore signal source impedance is low, a distant advantage in low level dc amplification.

The mixing vessels are round in shape—short cylinders—about 35 mm in diameter and 4–6 mm thick, small versions of the 1927 design by Lipsett, Johnson and Maas.[13] A partition inside, about 20 mm long, keeps the reactants separated while the vessel is upright. Reactants (*e.g.*, microorganisms, and carbon analyte) are loaded in through a common port, using a syringe. After loading, each port is closed with a plastic screw. From 3 to 5 ml of air is left in the headspace of each mixing vessel. The system is left for 5–15 min to reach internal thermal equilibrium and disperse the thermal shock of

loading. Good thermal equilibrium—no heat being transmitted through any thermopile—appears as a flat baseline on the recorder or monitor. Net signal output is zero volts at that point. Then the assembly is inverted, mixing the reactants and also mixing in additional air from the headspaces.

The reference vessel is usually loaded with 2 ml of bacteria suspension on one side of the partition P indicated in Fig. 2, and 0.5–1 ml of solvent without carbon on the other side of the partition. The sample vessel is similarly loaded except the smaller aliquot contains the analyte, the compound or carbon source of interest. The method can thus be represented:

REFERENCE VESSEL	Microorganisms (2–5 mg, 2 ml) Excess cells	+	Buffer, no added carbon (1 ml)	Air ⇄ Mix	Heat of aerating bacteria, no added carbon	(1)
SAMPLE VESSEL	Microorganisms (2–5 mg, 2 ml) Excess cells	+	Buffer, include carbon, the analyte	Air ⇄ Mix	Heat of metabolism of carbon	(2)

The two Seebeck thermopiles belonging to the sample vessel are connected in series so their voltages add. Likewise, the two thermopiles interfacing the reference vessel are connected in series. However as Fig. 2 indicates, the common connection between the two pairs of thermopiles is chosen so these two sums oppose one another; subtract from each other. In effect the power from the reference is continuously subtracted from the sample's power, giving a net overall signal. The arrangement is similar to other 'differential' instruments such as spectrophotometers in which the signal from the reference subtracted from that of the principal sample. The net power, the difference signal between reactions (1) and (2) above is detected by the dc amplifier as a voltage. The amplifier is a 'single ended' amplifier that we construct, based on an Analogic Co. MP-221 chopper integrated circuit. It is fitted with gains from X100 to X3000 to cover various ranges of heat production. Amplifier outputs are displayed on a chart recorder or with a data logger-computer-monitor. The signal from the amplifier at any instant is proportional to net power from the sample and reference. Power is a rate of heat generation. Integrated over time, the area of the envelope under each curve (Fig. 3) is proportional to the overall heat of metabolic combustion of the analyte.

Seebeck calorimeters of this kind may be constructed with more than two mixing vessels, to make simultaneous measurements for two or more samples, referenced against a common control. Each mixing vessel requires its own pair of thermopiles and its own dc amplifier.

Precautions

The principal precaution in MCA, in solution–solution mixing calorimetry in general, pertains to H^+ transfer and H^+ titration heats. If solutions when first mixed have a pH mismatch, and considerable buffering capacity, hydrogen ions are shifted about. Considerable heat might be generated simply from mixing different buffers having different pHs. Most carboxylic and phosphate buffers have small ionization enthalpies, only one or two kcal/mole, or less. For example acetic acid ionization is (−)0.02 kcal/mole,[14] and $H_2PO_4^-$

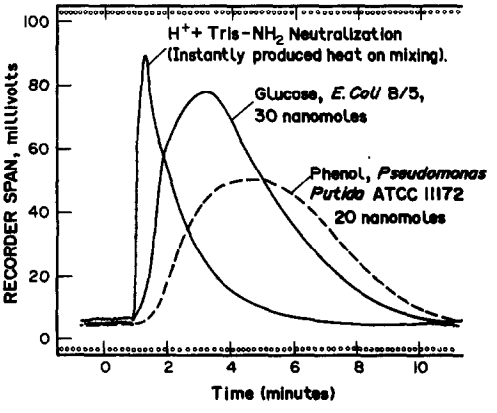

Fig. 3. Microbial calorimetry of metabolism by bacteria adapted to oxidize phenol, and glucose; calorimetric response to tris neutralization of H^+ in calibration of the instrument. The amplified voltages, the ordinate values are proportional to net power as heat generated by the sample at each instant. Integrated over time, the area under each envelope is proportional to the overall heat. Temperature = 25°, 1–2 ml reactant volumes.

ionization is (+)0.80 kcal/mole.[15] However amine buffers, tris, imidazole, and ammonium have large protonation and ionization enthalpies, from 5–15 kcal/mole magnitude. Elementary calculations based on volumes, buffer capacities, and ΔpH mismatches of from 0.2 to 2 pH units show that several dozen millicalories of heat can be generated from H^+ exchange. There are two means for dealing with this problem. (i) Use 0.15*M* sodium chloride or similar electrolyte as the solvent in which to suspend the bacteria after centrifuging them out of culture. The salt does not titrate so that if acids or H^+ sources are carried in by the sample upon mixing, they generate little if any neutralization heat. (ii) Heat generation of this kind is clearly seen because it is produced far more quickly (in a few seconds) than metabolism of any carbon compound. Figure 3 shows an example. H^+ titration heats can be subtracted out in effect, by deconvoluting them.

A second precaution pertains to sealing the reaction vessels. Port closers have to be gas tight. If they are not tight, water vapor may leak out. Water has a large, endothermic heat of vaporization, (+)540 cal/g H_2O. Even a few micrograms of water effusion causes severe drifting, and hence inability to reach a stable baseline. Heat conduction calorimeters respond to endothermic (cooling) heats with the same sensitivity as in exothermic heating, except with opposite signal polarity.

In some applications one may need to study anaerobic utilization of carbon *vs.* aerobic metabolism, particularly in fermentation analysis. Accordingly the vessels may be purged with nitrogen gas, so fairly rigorous anaerobicity can be maintained inside. Considerably less heat is usually produced in anaerobic utilization,[16] and more slowly than in aerobicity. Hence for MCA, aerobic conditions are used for three reasons: (i) convenience, only air is included, (ii) speed and (iii) sensitivity; heats of aerobic metabolism are large, often from 30–80 kcal/mole of carbon atom in various analytes studied so far.[17]

Dissolved oxygen for maintenance of aerobicity during MCA

Only limited amounts of analyte, *ca.* 2–200 nanomoles, are used in MCA. In case of glucose, probably nearly all bacteria for which careful measurements exist, produce close to (−)305 kcal/mole heat of glucose under MCA's conditions. That is, with an excess of cells and excess oxygen. About 15 millicalories of heat (exothermic) are expected from 50 nanomoles of glucose. Is there actually enough oxygen to maintain aerobicity?

If the sample and bacterial suspension were preequilibrated with air by simple exposure to air, usually they are 80–90% air saturated. Since air is 20% oxygen and its aqueous solubility is *ca.* 1.3×10^{-3} (25°), then 3 ml of solution has roughly 700–800 nanomoles of oxygen. Aerobic metabolism of hexoses usually requires *ca.* 3 moles O_2/mole hexose. Hence 150–200 nanomoles of O_2 are required for 50 nanomoles of a hexose such as glucose. Headspace oxygen is also available from the 3–4 ml of volume above the solutions in the mixing vessel. This provides several thousand additional nanomoles of O_2. Hence maintenance of aerobicity is ensured over nearly any reasonable range of carbon concentration, micromolar to submillimolar concentrations. As in more conventional analysis wherein reagents are kept in excess to drive consumption of the analyte, MCA likewise is suited to keep its two main reactants in excess; bacteria, and dissolved oxygen.

Rates of carbon utilization

Rates of carbon utilization and of heat production by bacteria are important because they govern the time needed for analysis. One might first expect that the many existing papers about carbon utilization should indicate the magnitudes of uptake rates in commonly studied cells such as *E. coli*, and thereby heat production rates. The two principal means for measuring carbon utilization rates have been developed over many years by observing microbial growth (the 'growth curve') and by oxygen uptake (Warburg manometry, later by the oxygen electrode). Several other means have been used; radioisotopes and trapping $^{14}CO_2$, and H^+ extrusion rates. The common ground under all these traditional means including heat production is metabolism. But large differences are seen in velocities so measured, from method to method when the same cells and carbon source are compared. Reasons for such differences cannot be reviewed here in detail, except for two points. (i) Microbial growth rates and their oxygen utilization rates depend on times necessary to entirely complete each microbial cell growth cycle for making new cells. Many bacteria have doubling times of 30–90 min even at optimum temperatures. (ii) In contrast,

velocities of *initial* carbon uptake and carbon metabolism by cells adapted to the targeted compound, are much larger than velocities or rates of growth. Priming metabolism heat generation mostly finishes in several seconds to a few minutes under conditions used for MCA. Namely, with excess cells, oxygen in excess, limited carbon.

Adapted bacteria take nutrient carbon compounds first into pathways variously called fueling reactions[18] and anaplerotic pathways. These are the Embden-Meyerhof-Parnas, the tricarboxylic acid, and the pentose phosphate cycles. It is in these early sectors of metabolism when carbon enters bacteria, that most of the heat and byproducts like CO_2 are produced. How exothermic they actually are depends on how well incoming compounds are fitted to the cell's pathways.[19] They make intermediates and cofactors, NADPH, carbon skeletons, several compounds necessary for the next tasks. Namely biosynthesis of cell material, provision of protecting compounds like GSH, etc. However this next tier of tasks is 10 to 100 times slower than priming metabolism, hardly exothermic, and not very heat productive. Priming metabolism heat production, being oxidative, is analogous to ordinary chemical reactions in one respect. Oxidative reactions in chemistry usually are much larger, roughly by a factor of 10, than heats of most other classes of reactions in water, molecular rearrangements, chelation, H^+ ionization, *etc.* Likewise, the kinds of aerobic metabolism and oxidation on which MCA hinges, are outstandingly exothermic. Commonly these metabolic molar heats are 50–70% as large as oxygen bomb combustion calorimetric heats taking compounds all the way to carbon dioxide and water. Thus heat production in the way MCA is carried out is generated with considerably larger magnitudes than those predicted by "indirect calorimetry" when it relies on cell growth, or on a mixture of cell growth and oxygen uptake.

A table of glucose uptake rates for aerobic *Escherichia coli* using data from our laboratory and a number of others was published in 1990.[20] Under MCA's conditions glucose is assimilated by *E. coli* at rates from about 2 to 20×10^{-19} mole glucose/bacterial cell/second. Using an average of 10×10^{-19} mole glucose/cell/second, 2 mg of cells (*ca.* 5×10^9 cells) might consume 20 nanomoles of glucose in about 5 sec. But this estimate is based on maintenance of the glucose concentration, whereas in fact it falls off rapidly under the normal conditions for using MCA; an excess of cells, carbon (glucose) is limited. Hence the rates seen after the initial burst of heat production fall off because the analyte depletes to concentrations below the K_m values for such cells which usually are approximately $0.1–1 \mu M$. Thus Fig. 3 represents average rate of heat production seen from many analytes, sugars, phenols, lower fatty acids and alcohols. In practice, when cells are adapted and in excess they usually oxidize limited amounts of carbon in 100–500 sec at 25°. All our work so far has been carried out at 25°, laboratory temperature. It is likely that 30–40° temperatures for assay would hasten microbial consumption of analytes, perhaps several fold. This aspect of MCA has not been investigated.

The figure of merit for Seebeck sensors of the kind we use (*e.g.*, Melcor C. P. 1.4-71-10 Peltier units) is close to a 7-μWatt power input/μVolt signal output. The sensor figure of merit enables estimation of the amplified signal one expects. For example, using 20 nanomoles of glucose, (−)300 kcal heat/mole, a 200-second combustion time to use all the sugar, an amplifier gain by a factor of 2000 and that there are 4.18 joules/calorie, an average amplified signal output of 36 mV is calculated.

RESULTS AND DISCUSSION

In order to compare microbial calorimetric analysis with a conventional analytic technique, Fig. 4 shows the behavior of phenol in MCA, and in Folin reagent spectrophotometry. *Pseudomonas putida* ATCC 11172 were adapted to

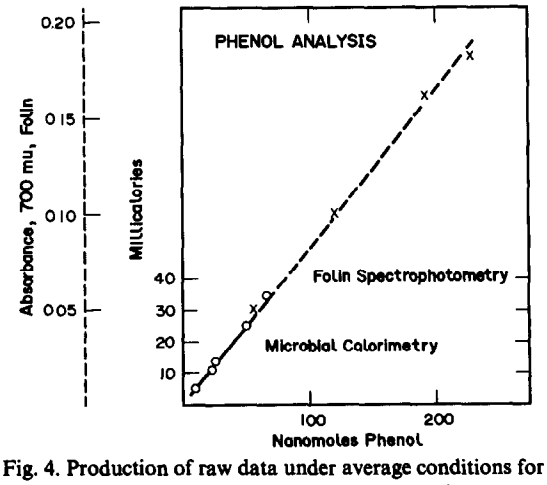

Fig. 4. Production of raw data under average conditions for the lower practical ranges for phenol analysis, in spectrophotometry (Folin–Ciocalteau reagent), and in microbial calorimetry using a bacteria adapted to phenol.

phenol by growing them on phenol, similar to growth on a series of lignin related fragments and cresols.[10] The vertical axes in Fig. 4 plot the minimal practical ranges of data production for both methods: zero–30 millicalories of heat in MCA, absorbance range 0.03–0.30 in spectrophotometric Folin analysis for a 1-cm pathlength and a 3-ml assay volume. Approximately 5–30 nanomoles of phenol suffices for MCA to span this heat production. A range of 30–100 nanomoles of phenol is required for such a spectrophotometric analysis. Thus in lower ranges of analytic capability for the two methods, MCA competes well with Folin spectrophotometry in the amount of phenol analyte required.

The slopes of such plots equal the parameters that characterize microbial calorimetry, and spectrophotometry. Namely the aerobic molar metabolic heat, $\Delta H_{a.m.} = (-)551 \pm 30$ kcal/mole, and the molar absorbance coefficient for Folin color, $\epsilon_{700} = 8460 M^{-1}cm^{-1}$ for phenol, respectively. Several cresol isomers and cogeners produce similar parameters in both methods, Folin spectrophotometry, and MCA technique using *P. putida*.[10]

Likewise several spectrophotometric analytic methods in which the analyte is a prochromogen, have value of $\epsilon_{\lambda max.} \sim 4000$ to $10{,}000 M^{-1}$ cm^{-1} when developed. Nelson–Somogyi analysis of reducing sugars[21] and ninhydrin analysis of amino acids are examples. Their four to seven carbon analytes give aerobic heat productions from a few hundred to several hundred kcal heat/mole of compound. Lower molecular weight analytes which are mostly not good prochromogens such as acetate, C_1–C_3 compounds like methanol, ethanol, glycerol, acetate, propanol yield from $(-)102$ to $(-)250$ kcal heat/mole in the MCA technique.[22] Therefore the relationship between conventional spectrophotometric analysis, where spectrophotometry can be used, and the MCA technique, illustrated in Fig 3, is expected to hold in many examples.

Microbial calorimetry is not expected to compete in sheer sensitivity with some modern techniques based on electrochemical detectors, or gas chromatography. However these techniques have requirements that make them labor intensive to use, despite the power of their instrumentation. For example it is possible to use gas chromatography of carbohydrates as a basis for analysis, but samples must be completely dry, derivatized, and extracted for G.C.'s purposes. A number of spectrophotometric and fluorimetric techniques are quite powerful in their way, but do not accept optically bad samples such as food or tissue slurries, very turbid solutions, nor analytes that are unreactive toward the reagent on which they rely to develop color. The MCA method is only of intermediate sensitivity. However MCA efficiently works with analytes in water that are poor chromogens or are not derivatizable to make color. Compounds that seriously interfere in other methods, foreign pigments and particles, are usually of little consequence in MCA, if a bacteria is available that can combust the sought-for analyte. If such a bacteria is not immediately at hand, usually one can be raised, adapted, by simply growing it on the sought for analyte. The MCA technique uses simple, inexpensive instrumentation. It allows the analyst to easily 'manufacture' as if it were, the necessary reagents by simply growing them via conventional microbiologic practice.

DETERMINATION OF VANADIUM: AN OPTIMIZATION OF THE GALLIC ACID PERSULPHATE METHOD

L. DARBHA and J. ARUNACHALAM
Analytical Chemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay 400 085, India

(*Received* 16 *September* 1991. *Revised* 19 *March* 1992. *Accepted* 22 *March* 1992)

Summary—An optimization procedure for the gallic acid–persulphate method for the ultratrace determination of vanadium is reported. The optimization step has improved the sensitivity by a factor of three. The linearity range of the calibration graph is also extended.

The catalytic-photometric method involving the catalytic effect of vanadium (V) on the oxidation of gallic acid by ammonium persulphate reported by Fishman and Skougstad,[1] is accepted as a standard method for the determination of vanadium in water samples.[2] Qiang weiguo[3] had suggested some improvements in the analytical parameters to give better reproducibility. We report an optimization procedure which gives an improved sensitivity for the determination of vanadium.

Optimization of experimental parameters can be done by non-parametric as well as parametric methods. One of the popular non-parametric methods of optimizing experimental conditions is the simplex approach.[4] In the simplex method, a regular geometric figure known as simplex having n + 1 vertices is chosen, where n is the number of variables. The experiment is performed at the values of the parameters representing the vertices, and the process is continued until the desired optimum (maximum) is reached.

In the parametric approach, a set of experiments is carried out, usually based on factorial designs, to obtain an analytical expression (a function) relating the response with the experimental parameters. Among the parametric approaches, the Response Surface Method, coupled with the Method of Steepest Ascent, developed by Box,[5,6] is the most popular. In this method the response function is approximated, in a certain region of the factor space, by a polynomial, usually a second degree, in the form,

$$R = \beta_0 + \sum_{i=1}^{n} \beta_i X_i + \sum_{i,j=1}^{n} \beta_{ij} X_j X_j + \sum_{i=1}^{n} \beta_{ii} X_i^2 \quad (1)$$

where, R is the response, β are the coefficients and X are the experimental factors (variables).

The computation of the slope of the function reveals the variables that influence the response the greatest. At various new levels of this variable, the equation is solved for the others and the experiment is repeated at new values to locate the optimum in steps.

Assuming that the functional dependence of the response with the factors does not vary with the approach to the optimum, the coefficients of the parameters in the analytical function, obtained using the first set of experiments, can be examined to reveal the existence of a maximum or minimum. In such cases, it will be possible to obtain the values of the parameters that correspond to the maximum or minimum response.

In the present investigation a 3×3 (3^2) factorial design was used, with the concentrations of gallic acid and persulphate as the two variables, to obtain an analytical expression relating the concentration of the reactants to absorbance.

EXPERIMENTAL

Reagents and apparatus

All the reagents were prepared as suggested by Qiang weiguo.[3] Demineralized water was used in all the experimental steps. Gallic acid was recrystallized from hot water after the removal of any oxidized products by adding activated charcoal. A Hitachi 330 Model spectrophotometer was used for obtaining the absorbance. All the measurements were carried with 10-mm cells.

All the glassware used in the experiments was kept for a week in 10% nitric acid, and rinsed several times with demineralized water before use. Class A glassware was used throughout.

Procedure

3^2 Factorial design and optimization. The complete 2 variable at 3-level design used in the experiment is given in Table 1. The base level is denoted as 1 ml of 1% gallic acid and 1 ml of 5% persulphate. The upper and lower levels were obtained using a difference of ± 0.5 ml from the base level.

An aliquot of 20 ng of vanadium was pipetted into nine 10-ml standard flasks. Ammonium persulphate solution was pipetted into each of these bottles as given in the design. Required volumes of gallic acid solution were pipetted as given in Table 1, leaving an interval of 2 min between addition to each flask and the volumes were made up to the mark. Corresponding blanks were also run as per the design without the addition of vanadium. Maintaining a constant duration of one hour for the reaction to proceed at each level, the absorbances were measured for all the solutions. The increased absorbance due to the catalytic effect of vanadium for each experimental solution was obtained by subtracting the absorbance recorded for the corresponding blank. The values are given in Table 1.

RESULTS AND DISCUSSION

Optimal conditions

A second order polynomial function [equation (2)],

$$-0.008X^2 - 0.052Y^2 - 0.007XY + 0.076X + 0.134Y - 0.077 = 0 \quad (2)$$

(where X is the volume of 1% gallic acid and Y is the volume of 5% persulphate), was derived using the procedure (relative to the base point 1,1) discussed in Beveridge and Schechter,[4] relating the absorbance to the amounts of gallic acid and persulphate. The fitted response values are also given in Table 1 which show a very good agreement with the experimentally obtained responses.

Table 1. Factorial design used in the experiment

Exp. No.	Volume of 1% Gallic acid in ml	Volume of 5% persulphate in ml	Absorbance	
			Experiment	Fitted
1	1.0	1.0	0.066	0.067
2	1.5	1.5	0.090	0.088
3	1.5	0.5	0.068	0.069
4	0.5	1.5	0.039	0.039
5	0.5	0.5	0.010	0.012
6	1.0	1.5	0.060	0.066
7	1.0	0.5	0.043	0.042
8	1.5	1.0	0.087	0.092
9	0.5	1.0	0.038	0.038

Table 2. 2 × 2 Factorial design around the maximum

Exp. No.	Volume of 1% Gallic acid in ml	Volume of 5% persulphate in ml	Absorbance
1	3.7	0.5	0.058
2	3.7	1.5	0.074
3	4.7	0.5	0.068
4	4.7	1.5	0.057
5	4.2	1.0	0.106

The Lagrange's criteria for the existence of a maximum, minimum and a saddle point of the function are as follows.

$$\text{If} \quad D_1 > 0 \text{ and } D_2 > 0$$

a minimum exists, and,

$$\text{If} \quad D_1 < 0 \text{ and } D_2 > 0$$

a maximum exists, where,

$$D_1 = |\chi_{x1,x2}| \quad \text{and} \quad D_2 = \begin{vmatrix} \chi_{x1,x1}\chi_{x1,x2} \\ \chi_{x2,x1}\chi_{x2,x2} \end{vmatrix}$$

where χ is the partial derivative of the function with respect to variables X_1 and X_2. By applying these criteria, it is seen that a maximum exists for this function. This maximum was found algebraically, using the partial derivatives with respect to the two variables, and corresponds to 4.2 ml of 1% gallic acid and 1 ml of 5% persulphate.

Since the region of experimentation is far removed from the suggested maximum position, *i.e.*, 4.2 ml of (1%) gallic acid and 1 ml of (5%) persulphate, confirmatory experiments were carried out using 2 levels–2 factor experimental design using the same step size of 0.5 ml, around this optimum. The results are given in Table 2, confirming the suggested optium is the maximum.

Degree of enhancement

A set of experiments was performed with the suggested optimum quantities of gallic acid and persulphate with different amounts of vanadium. For comparison, the experiments were also performed with the quantities of the reagents suggested by Qiang weiguo,[2] for the same quantities of vanadium. The absorbances obtained in the two cases are given in Fig. 1. It is seen that the optimization has improved the sensitivity by a factor of 3. The response is also linear up to 70 ng of vanadium. Qiang wieguo[2] has indicated linearity only up to 35 ng of V (in

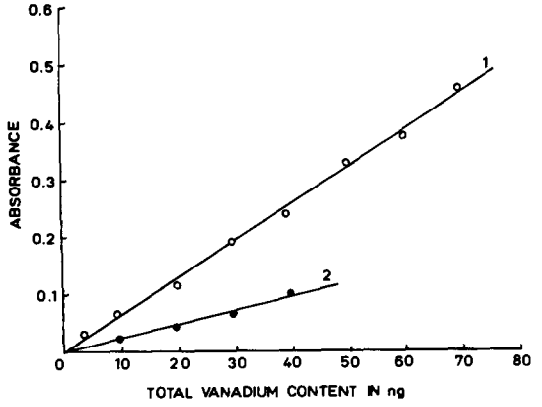

Fig. 1. Comparison of sensitivities of the present (optimized) method to the reported method. Curve 1. Absorbance obtained with the optimum values (4.2 ml of 1% gallic acid and 1 ml of 5% persulphate). Curve 2. Absorbance obtained with 1 ml of 1% gallic acid and 1 ml of 5% persulphate. Absorbances in both cases were measured with a 10-mm cell.

13 ml total solution) which might have been due to the use of 50-mm cells for the measurement of absorbance in his experiments.

The optimum volume of 4.2 ml of 1% gallic acid and 1 ml of 5% persulphate corresponds to equimolar concentrations of gallic acid and persulphate (0.022M for both gallic acid and ammonium persulphate, whereas the quantities of gallic acid suggested by other authors have been much lower (0.009M and 0.0045M in Ref. 1 and Ref. 2, respectively). Independent experiments carried out on different days showed that the absorbances are reproducible within $\pm 8\%$ at 2 ng/ml V.

OPTIMAL DESIGN OF DIFFUSIVE SAMPLERS

DWIGHT W. UNDERHILL
Department of Environmental Health Sciences, School of Public Health, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 16 *July* 1991. *Revised* 18 *May* 1992. *Accepted* 18 *May* 1992)

Summary—Some commercially available diffusive samplers use two layers of adsorbent placed in series. After sampling is completed, the time weighted average concentration of analyte is estimated from the weighted sum of the uptake of analyte on these two layers. It is known that such a division into layers can increase the permissible sampling time. Here the principles underlying this sampling procedure are analyzed through a fundamental application of the theory of diffusion. Using a trial and error procedure, the optimal division of adsorbent was calculated, and the increase in sampling time that such a division can give was confirmed theoretically. Also, should the uptake in the backup layer exceed a predetermined fraction of the total uptake, this will indicate misuse of the diffusive sampler.

Diffusive samplers are commonly used to determine the time weighted average concentrations of gases and vapors in both the workplace and the environment. Many such samplers contain two layers of adsorbent, and the concentration of analyte is determined from a weighted average of the uptakes on these two layers.[1-3] This paper develops a calculation for the optimal design of such diffusive samplers, and shows that an optimal use of the uptakes on these two layers can lead to a very significant increase in the useful sampling time for a diffusive sampler over what would be possible if only the total residue in the sampler were to be considered.

Mathematical analysis

Figure 1 gives a schematic diagram of the type of diffusive sampler considered here. In this sampler, the analyte diffuses into the sampler from the left, across the windscreen and air gap, to the adsorbent. The absorbent, which may be divided into two or more sections, serves as a sink for the analyte. The following are needed to describe the mass transfer in this diffusive sampler: 1) the sampler geometry, 2) the adsorption coefficient, 3) the diffusion coefficient of the analyte in air and in the sorbent, and 4) the ambient concentration of analyte as a function of time. These factors are accounted for in the following partial differential equations:
Transfer of analyte across the air gap:

$$\frac{1}{\alpha}\frac{\partial c}{\partial x_{(x=+0)}} = c_0 - c_{(x=-0)} \qquad (1)$$

Zero flux of analyte at the unexposed surface of adsorbate (an impervious backing)

$$\frac{\partial c}{\partial x_{(x=1)}} = 0 \qquad (2)$$

Diffusion within the adsorbent

$$\frac{\partial^2 c}{\partial x^2} = \alpha\frac{\partial c}{\partial \tau} \qquad (3)$$

where the above dimensionless factors are defined as follows:
Reduced Distance,

$$x = \frac{x}{W} \qquad (4)$$

Geometric Factor,:

$$\alpha = \frac{W}{\epsilon y L} \qquad (5)$$

Reduced Time, τ:

$$\tau = \frac{tD}{(1-\epsilon)LWK} \qquad (6)$$

Reduced Concentrations:

$$c = C/C_1 \qquad (7)$$

$$c_{(X=-0)} = C_{(x=-0)}/C_1 \qquad (8)$$

$$c_0 = C_0/C_1 \qquad (9)$$

The factors used in the above definitions are:

C = concentration of analyte in the interparticle void of sorbent pad, g/m^3
$C_{(X=-0)}$ = airborne concentration of analyte at the exposed surface of sorbent, g/m^3

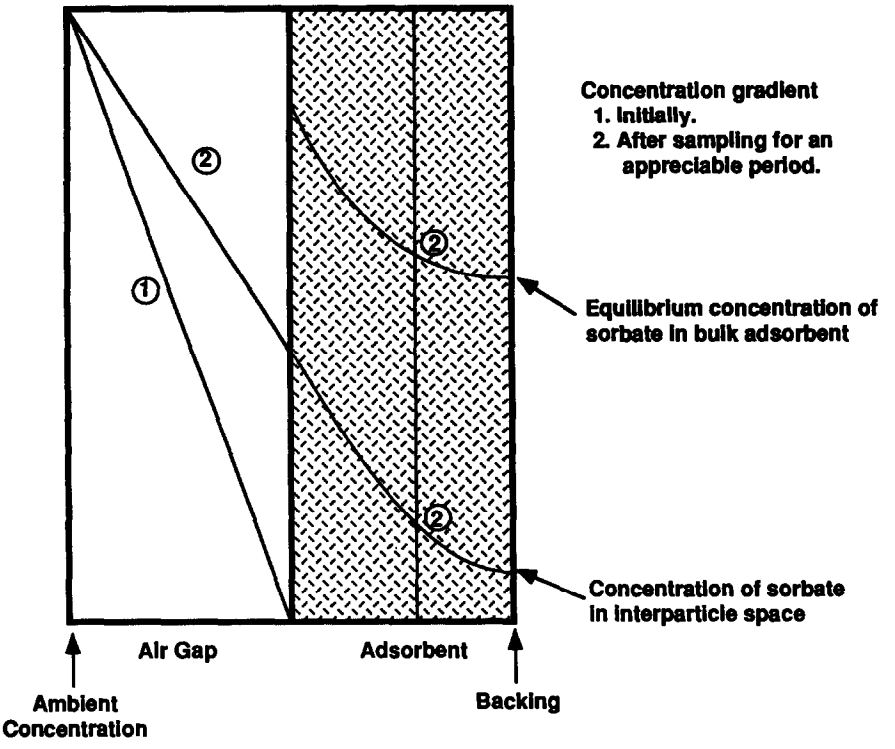

Fig. 1. Schematic diagram of a diffusive sampler.

C_0 = ambient concentration of analyte, g/m^3
C_1 = hypothetical unit concentration of analyte, 1 g/m^3
D = molecular diffusion coefficient for analyte in air, m^2/sec
K = partition coefficient for analyte-sorbent, defined as
$$= \frac{\text{(g analyte/m}^3\text{ compacted sorbent)}}{\text{(g analyte/m}^3\text{ ambient air)}}$$
L = width of air gap, m
t = sampling time, sec
W = thickness of the sorbent pad, m
X = distance into sorbent pad, m
y = tortuosity factor for interparticle diffusion, dimensionless
ϵ = fractional interparticle void volume, dimensionless

The reduced time is the actual sampling time divided by the time it would take the sampler to become saturated with analyte if exposed to a constant unit concentration of analyte (C_1), and the rate of uptake remained at the initial rate of input ($C_1 D/L$). The above equations can be solved to give analytical solutions that allow the relationship between exposure and uptake to be found in closed form.

The following two equations can be derived from Crank's[4] equation 4.50 by: 1) differentiation with respect to time to obtain the response from a pulse input; 2) integration with respect to bed depth to determine the amount of analyte in a layer of a given thickness. Because of the linearity of these equations, the order of these operations is immaterial. Then $m(\tau)$, the reduced uptake of analyte remaining in the sampler at a reduced time, τ, following a unit pulse input at $\tau = 0$, is

$$m(\tau) = \sum \frac{\alpha \exp(-\tau/\alpha)}{\vartheta_i^2(\vartheta_i^2 + \vartheta_i + \alpha)} \qquad (10)$$

The reduced uptake, $m_1(\tau)$, of the original analyte contained within the back-up section at a reduced time, τ, is:

$$m_2(\tau) = \sum \frac{\alpha \exp(-\tau/\alpha)\sin(\alpha x)}{\vartheta_i^2(\vartheta_i^2 + \vartheta_i + \alpha)\cos(\alpha)} \qquad (11)$$

where:

ϑ_i = the positive roots of $\vartheta_i \tan(\vartheta_i) = \alpha$

The reduced uptakes are defined as the actual uptake divided by the equilibrium uptake of analyte in the sampler exposed to a unit concentration of analyte (C_1). The quantity of analyte in the primary layer is the difference between the total residual uptake and the residue in the back-up layer.

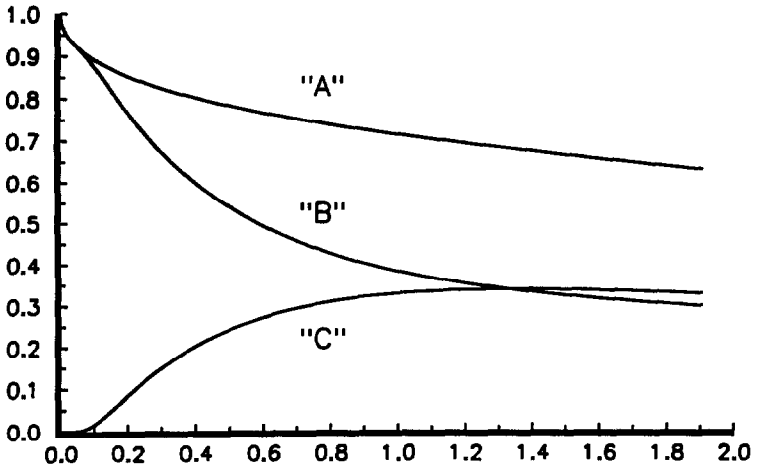

Fig. 2. Residue following a pulse input. A = Total residual analyte following a unit pulse input; B = Residue in primary layer; C = residue in secondary layer.

Also because of the linearity of the equations considered here, the solutions are additive. Thus equations (10) and (11) can be generalized to characterize the uptake from any possible exposure: any other input can be constructed as a series of pulses, so that the response to a pulse input can be generalized to include all other exposure scenarios.

RESULTS AND DISCUSSION

To demonstrate the applicability of this analysis to diffusive sampling, the residual analyte in a diffusive sampler was calculated assuming a geometric factor (α) of 0.7, a value that was chosen because it seems representative of commercially available diffusive samplers. In Fig. 2, lines "A", "B" and "C" show, respectively, the total amount of analyte, the analyte in the primary layer, and the analyte remaining in the back-up section of the sampler at a reduced time, τ, following a unit pulse input at a reduced time, $\tau = 0$. The treatment that follows, however, is independent of any particular value chosen for the geometric factor.

Here the "best" estimate of exposure is assumed to be the estimate that permits the sampler to sampler for the longest period of time within the error bounds cited for its accuracy. Figure 3 gives the results of using the residues shown in Fig. 2 to estimate within an absolute error of 5% the TWA exposure of the sampler. In this figure, the Y-axis gives the ratio of the estimated TWA to the true TWA. The X-axis gives (in units of the reduced time) the interval between the pulse input and time at which the

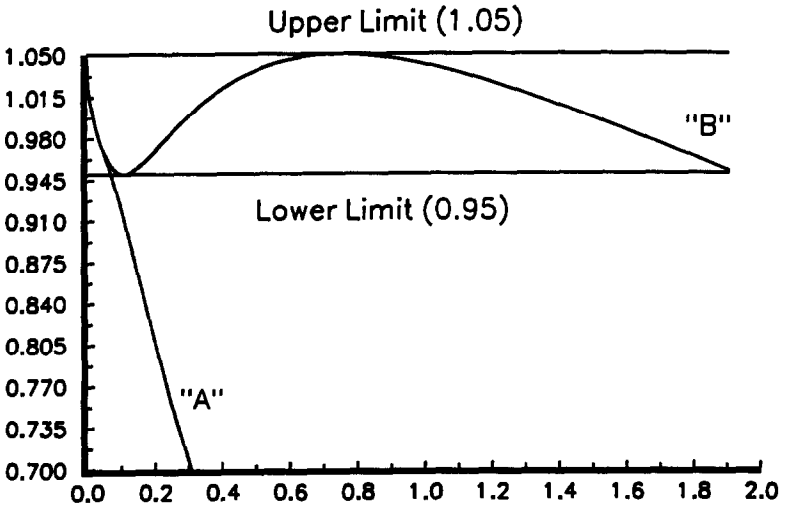

Fig. 3. Estimated uptake as a function of reduced time. A = calculated from total residue; B = calculated from the weighted sum of residues in the two layers of adsorbent.

residue in the sampler was determined. Line "A", which gives the "best" *i.e.*, longest satisfactory, estimate of the TWA exposure from the total residue in the sampler, is the total residue multiplied by a factor of 1.05. Thus a pulse input sampled just before the sampling period ended would be overestimated by 5%, and a pulse applied to a diffusive sampler given a unit pulse input at a reduced time of $\tau = 0.069$ before the sampling period ended, would be underestimated by a factor of 5%. Furthermore, any input sampled between these times would give an estimated TWA that lay between $\pm 5\%$ of the true TWA exposure of the diffusive sampler. Therefore for the criterion given above, the effective use time of the diffusive sampler, if only total uptake is considered, is for a reduced time of 0.069.

This effective use time can be extended considerably if adsorbent is divided into layers and a weighting factor applied to the uptake in each layer. In Fig. 3, line "B" shows the linear combination of primary and back-up layers giving the longest sampling time for which the estimated uptake remains within $\pm 5\%$ of the original input. The calculation giving the best division of the adsorbent bed into primary and back-up layers required sequential division of the adsorbent bed into hypothetical primary and back-up layers, and for each possible division, finding the maximum permissible sampling time. This process was continued until the optimal division and the weighting factors consistent with that division, were located. It was found for the sampler under consideration here (with a geometric factor of 0.7), that the longest sampling time consistent with a maximum absolute error of $\pm 5\%$, was obtained if the primary layer comprised 50.6 per cent of the total adsorbent, and further, if the residue on the primary layer was multiplied by a factor of 1.049 and added to the residue in the back-up layer multiplied by a weighting factor of 1.942. This gives a very significant extension of the permissible sampling time. The increase in the permissible sampling time, consistent with a maximum estimation error of $\pm 5\%$, is from a maximum value of the reduced time of $\tau = 0.069$ for the estimate from the total uptake, to a reduced time of $\tau = 1.91$, a factor of 28, for the estimate from the weighted sum of the uptakes on the primary and the backup layer.

These results are highly dependent on the value of the geometric factor, α. For example if the geometric factor has a value of 0.5 or less, then the adsorbent is so thin that equilibrium is rapidly established across the adsorbent as sampling progresses. With essentially the same concentration of analyte across the adsorbent, then very little is gained from dividing the adsorbent into primary and back-up layers and attempting to extract additional information from their linear combination. It was found that with a geometric factor of 0.2, the optimal division into primary and back-up layers was obtained if the primary layer contained 99.8% of the adsorbent. The increase in sampling time (still assuming a maximum absolute error of $\pm 5\%$) was only 19%.

Finally, the uptake on the back-up layer can serve as a warning of sampling error. After the sampling is concluded, there is an upper limit to the ratio of the residue in the back-up layer to the residue in the primary layer. For the first example considered here ($\alpha = 0.7$), if the ratio of the residue in the back-up layer exceeds 1.089 of the residue in the primary layer, this proves an error in either the design or the employment of the diffusive sampler.

CONCLUSION

A substantial increase in the effective use time of a diffusive sampler is possible through the selection of an appropriate sampler geometry, *i.e.*, the width of the air gap, the thickness of the adsorbent, and an optimal division of the adsorbent into primary and back-up layers. As shown here, the effect of these design parameters on the use time can be determined directly—and the use time of the sampler optimized—through equations derived from Fick's second law of diffusion.

ERROR BOUNDS IN DIFFUSIVE SAMPLING WITH REVERSIBLE ADSORPTION

DWIGHT W. UNDERHILL

Department of Environmental Health Sciences, School of Public Health, University of South Carolina, Columbia, SC 29208, U.S.A.

(*Received* 21 *November* 1991. *Revised* 20 *May* 1992. *Accepted* 20 *May* 1992)

Summary—Diffusive samplers are commonly used in the work place for compliance monitoring of gases and vapors. Because the workplace concentrations of analyte are not constant, the usual procedure of calibration of a diffusive monitor by exposure to a known constant concentration of analyte may lead to an unacceptable error. By considering the maximum possible error in the time weighted average (TWA) concentration, with no restrictions regarding the concentration as a function of time, a permissible sampling time is defined that is consistent with any possible concentration fluctuation.

Diffusive samplers are commonly used to determine the levels of toxic gases and vapors in the workplace. In the near future, most of what we think we know about worker exposure to noxious gases will probably be through the use of these devices. The National Institute of Occupational Safety and Health (NIOSH) is in the process of defining calibration procedures for diffusive samplers.[1] It is presumed that eventually the Occupational Safety and Health Administration (OSHA) will adopt these or similar procedures. It is important that the fundamental basis for the accuracy of diffusive sampling be established now so that future work with diffusive samplers will have an assured validity.

Many diffusive samplers currently used to monitor the time weighted average (TWA) exposure to gases and vapors in the work place have been calibrated using a constant concentration of contaminant.[2–4] Several theoretical analyses of the error in diffusive sampling also considered the uptake following exposure to a constant concentration of analyte.[5,6] Fluctuating concentrations of analyte have been considered in calculations of the effect of mass transport in the air gap in a diffusive sampler, but these analyses neglected the effect of a fluctuating concentration on the retention of analyte in the adsorbent, which is the area of primary concern in most diffusive samplers.[7,8]

Experience has shown that controlled constant exposures may reflect poorly the actual work place experience. In industry, there is the possibility of short duration, highly intense exposures that may occur, *inter alia*, during equipment failure. A calibration based on a constant exposure of contaminant may be significantly inaccurate when applied to the short duration, intense exposures that may occur anytime in a work shift.

This paper defines a procedure for determining the maximum effect of a fluctuating concentration of analyte on its measurement by a diffusive monitor. Using this procedure a "use time" for a diffusive sampler is defined such that the error in the TWA must be equal to or less than some predetermined value. The only general restriction on the calculations that follow is that the adsorption and diffusion coefficients are constant, thereby giving linear partial differential equations for mass transfer. This is not as severe a restriction as might first appear. Although at high concentrations, most adsorption isotherms are nonlinear, the adsorption of low airborne concentrations of many organic compounds, including chloroform, 1,1,1-trichloroethane, carbon tetrachloride, and benzene, on adsorbents such as Tenax can be described by linear adsorption isotherms. Under these conditions the adsorption is reversible, and, further, the mass transfer equations can be solved by standard methods.

Analytical solution to the transport equations

Figure 1 shows schematically the essential components of the diffusive sampler considered here. Ideally the rate of mass transport across

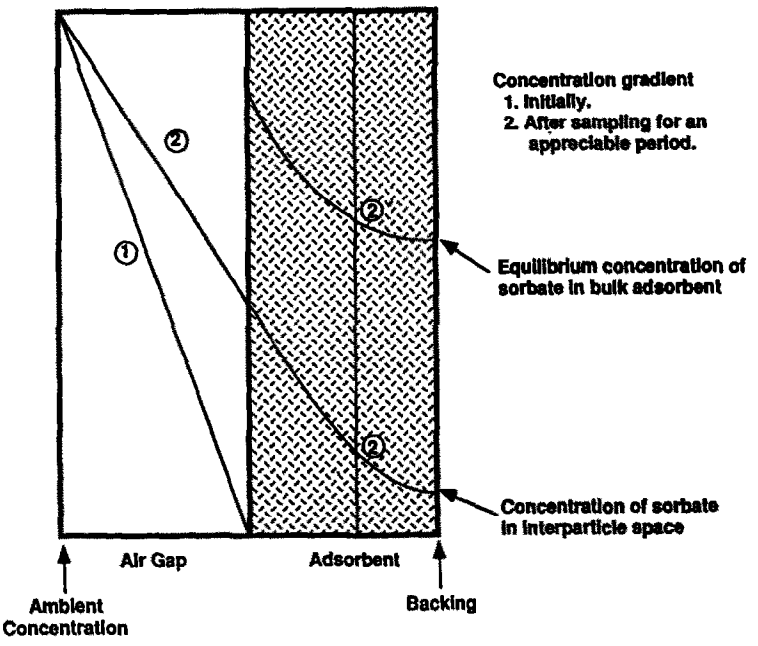

Fig. 1. Schematic diagram of a diffusive sampler. The analyte diffuses into the sampler from the left, across the windshield and the air gap, to the adsorbent. The adsorbent, which may be divided into two or more sections, serves as a sink for the analyte. The purpose of the windshield is to prevent any convective air currents from passing into the air gap and affecting the transport of analyte across the air gap.

the air gap is controlled by diffusion, and the overall uptake by the adsorbent is:

$$M = \frac{ADCt}{L} \tag{1}$$

where:

A = exposed surface of the diffusive sampler, cm^2
C = ambient concentration of analyte, g/cm^3
D = molecular diffusion coefficient for analyte in air, cm^2/sec
L = width of air gap between adsorbent bed and ambient atmosphere, cm
M = mass of samples analyte, g
t = sampling time, sec

Because physical adsorption is a reversible process, diffusive samplers that rely on physical adsorption are subject to loss of analyte by desorption and diffusion back to the atmosphere, and the overall uptake will be less than that given by equation (1).

The starting point for this analysis is to ask how long a diffusive sampler can remain open, adsorbing and desorbing analyte into the atmosphere until an unacceptable error occurs. This requires two steps, the first of which is to define what is meant by "an unacceptable error". The most common definition of exposure is the time weighted average exposure, defined as:

$$C_{twa} = \int_0^t C\,dt/t \tag{2}$$

where

C_{twa} = the time weighted average (TWA) ambient concentration of analyte, g/cm^3.

To show that this standard is met, a "successful" measurement must be within some predetermined value of the true TWA concentration.

Our objective is to determine the TWA within a predetermined error band for any fluctuating concentration of airborne analyte. Figure 2 shows the basic approach applied here. In this figure, the hypothetical concentration–time curve can be considered as a series of pulses, of equal duration but variable intensity. The residual analyte in the diffusion sampler can then be looked upon as the residue from each pulse. Because of the linearity of the diffusion equation, each pulse can be considered independently. The basic point is that as long as the error in estimating the magnitude of a pulse from its residue is within some predetermined value, then the TWA ambient

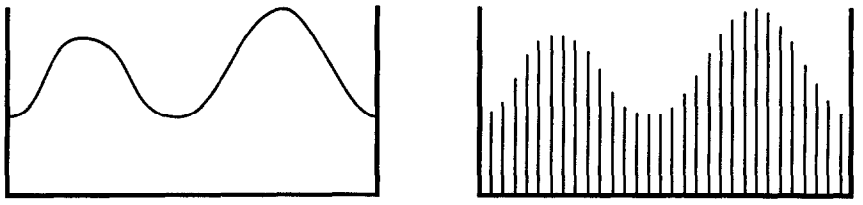

Fig. 2. Representation of a continuous input by a series of pulses. A = Continuous input; B = Pulse representation.

concentration of analyte can also be determined within this predetermined error.

The next step is to determine how long a diffusive sampler can be used to determine the TWA within a predetermined error band. The maximum high side error (overestimation) will occur for uptake at the end of the sampling period, and the maximum low side error (underestimation) will occur for the analyte sampled at the start of the sampling period. If the acceptable high side error in the estimate of the concentration is X%, and the corresponding acceptable low side error in the estimate in the concentration is Y%, then this standard can be met if the maximum percent loss of analyte during the sampling time is:

$$Z = 100\left\{1 - \frac{(100 - Y\%)}{(100 + X\%)}\right\} \tag{3}$$

To give specific examples, if it is desired to determine the TWA within an error band of ±5%, then sampling can continue until the residual analyte from a pulse is reduced by 9.53%, and for an error band of ±25%, the loss can be 40%.

Before determining the maximum time before an unacceptable loss of analyte by desorption can occur, it is necessary to estimate the rate at which the loss of analyte occurs. The required equations are well known, having been previously used to model surface diffusion from a sheet[9–11] before being applied to diffusive samplers.[4,5] Accordingly, the fraction of analyte remaining in the sampler following a pulse input is:

$$m(\tau) = \sum \frac{\alpha \exp(-\tau/\alpha)}{\vartheta_i^2(\vartheta_i^2 + \vartheta_i + \alpha)} \tag{4}$$

where:

ϑ_i = the positive roots of $\vartheta_i \tan(\vartheta_i) = \alpha$

and the two dimensionless parameters used in this calculation, α and τ, are defined as:

$$\alpha = \frac{W}{\epsilon\gamma L} \tag{5}$$

W = thickness of the sorbent bed, cm

γ = tortuosity factor for interparticle diffusion, dimensionless

ϵ = fractional interparticle void volume in the sorbent bed, dimensionless

$$\tau = \frac{tD}{(1-\epsilon)LWK} \tag{6}$$

K = equilibrium partition coefficient for analyte-sorbent, dimensionless, defined as

$$\frac{\text{(g analyte/m}^3\text{ compacted sorbent)}}{\text{(g analyte/m}^3\text{ ambient air)}}$$

Equations (3)–(6) permit the maximum use time, consistent with a predetermined error band, to be calculated. Figure 3 gives this same information graphically. There, the x-axis characterizes the geometry of the diffusive sampler (in terms of the geometric factor, α, and the y-axis gives the maximum sampling time, in terms of the reduced time, τ. Notice the very strong loss of sampling time as the error band is reduced from ±25 to ±5%, especially at high values of the geometric factor.

Application to laboratory validation of diffusive samplers

Laboratory validation of diffusive samplers, using the theory developed here, requires

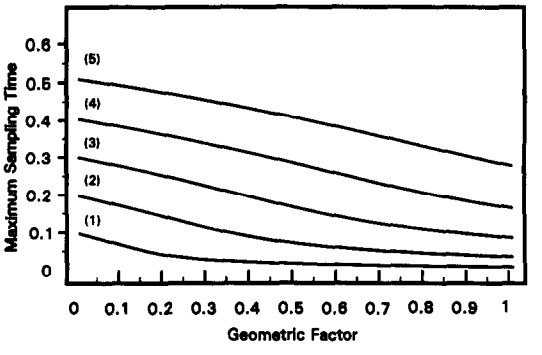

Fig. 3. Sampling time. Error bounds: (1) = ±5%; (2) = ±10%; (3) = ±15%; (4) = ±20%; (5) = ±25%.

measuring the retention of a pulse input by a diffusive sampler. One possible procedure is to expose a set of diffusive samplers to a high concentration of analyte for a short period of time, and then to analyze the retention in the samplers after various periods of time following this exposure. In a similar approach, the analyte lost from the sampler by desorption is collected and measured.[12] This latter procedure is better suited to determining small losses of analyte. In any case, the usual "validation" of diffusive samplers by exposure to a constant concentration of analyte does not seem appropriate if the criterion is that the estimated TWA be within a known error band following exposure to a variable concentration of analyte.

These results show what is ideally possible. Outside the laboratory, non-ideal effects from uneven packing, temperature fluctuations, co-adsorption of additional compounds (including water vapor), will reduce the performance calculated here. Because of the importance of diffusive sampling in monitoring worker exposures, it is important to determine how closely this idealized performance can be attained in the workplace.

(*Received* 2 *December* 1991. *Revised* 18 *May* 1992. *Accepted* 20 *May* 1992)

Summary—Supercritical fluid extraction (SFE) with CO_2, a clean and rapid alternative to conventional organic solvent extraction techniques, was investigated for the extraction of 2,4-D from soils using a variety of pre-extraction soil treatments to enhance extraction recoveries. Initial experiments with silylation, ion-pairing, methyl esterification, and ionic displacement are reported. Methyl esterification and ionic displacement during SFE proved to be the most promising approaches for quantitative extraction. Although the SFE procedures were not fully optimized, comparison between SFE and a standard Soxhlet extraction method demonstrated the potential for improving analytical measurement for highly polar pesticides in soil by modifying SFE–CO_2 extraction with derivatizing reagents and ionic solutions.

The herbicide 2,4-D (2,4-dichlorophenoxyacetic acid) is applied widely in the US and Canada, as well as in other countries, for the control of broadleaf weeds.[1–3] It is considered by the EPA to be a herbicide of heavy use which marginally leaches out of the root zone. It has been found in groundwater wells of at least two states in the US.[1]

Because of its polar nature, 2,4-D is difficult to extract from soils. One method used for the extraction of chlorinated hydrocarbons is Soxhlet extraction (EPA method 3540).[4] This method requires an 8–24-hr extraction with an acetone/hexane or methanol/toluene solution, followed by concentration in a Kuderna–Danish apparatus and a derivatization process before gas chromatographic analysis. This is a slow and organic solvent-consumptive method. An alternative method for chlorinated herbicides (EPA method 8150) involves acidifying the soil to pH 2 with HCl, shaking with acetone and then diethyl ether (each 3 times), placing the extract in a separating funnel, adding acidified sodium sulfate, readjusting the pH to 2, separating aqueous and organic layers, re-extracting the aqueous layer with diethyl ether, and evaporating the final extract in a Kuderna–Danish apparatus.[4] The final step, as in the Soxhlet method, is derivatization before gas chromatography.

A relatively new, solvent-efficient and rapid analytical extraction method is supercritical fluid extraction.[5] In this method, gases, such as CO_2 and N_2O, are heated and pressurized above their critical pressures and temperatures to produce supercritical extracting fluids. These fluids have densities intermediate to those of liquids and gases, with many solvating characteristics similar to liquids and diffusivities similar to gases.

To date, CO_2 is the supercritical extracting fluid of choice. It is non-toxic, relatively inexpensive and has conveniently low critical parameters. Unfortunately, while supercritical fluid CO_2 is a good solvent for nonpolar compounds,[5] it does not extract polar compounds well. Extraction recoveries of moderately polar pesticides such as diuron and linuron have been improved by modifying the CO_2 with a small amount of a polar additive such as methanol or ethanol.[6]

For highly polar compounds, modification of the extraction solvent with derivatizing reagents can be used to enhance extraction either by reaction with the solute or the matrix.[7] Hawthorne *et al.*, have investigated *in situ* chemical derivatization for the extraction of such polar analytes as fatty acids from whole cells, phenols from C_{18} sorbent disks, and 2,4-D from soils.[8] These promising results obtained

for the SFE extraction of 2,4-D from soil and sediment encourages further investigation. In this paper we report initial results on the development of sample derivatization and matrix modification methods for the SFE of 2,4-D from soil.

EXPERIMENTAL

Soil samples were spiked with 10 and 40 ppm of 2,4-D acid and extracted by SFE with CO_2 as the extracting fluid. Comparison of various sample treatments prior to extraction were made to determine relative extraction efficiencies of the various methods. These sample treatments included (1) silylation, (2) methyl esterification, (3) ion pairing and (4) ionic displacement. Finally, Soxhlet extraction was compared with SFE using an organic-rich soil containing 4.2% organic carbon.

Soils

One soil used for supercritical fluid extraction was from the 2C horizon of a Hoypus sandy loam collected in Island County, Washington. This soil had a pH of 6.6, electrolytic conductivity (EC) of 0.9 dS/m (saturation extract), and total organic carbon content of 0.3% as determined by wet combustion.[9]

The other soil was an organic-rich soil, the Ap horizon of the Coupeville soil also from Island County, Washington, which had a pH of 8.2, an EC of 0.05 dS/m, and an organic carbon content of 4.2% by weight.

All analyses were performed on air-dried soil.

Spiking procedure

Stocks of 2,4-D acid (purity 98.6%) and 2,4-D methyl ester (purity 97%) (Sigma Chemical Company, St Louis, Missouri) were prepared in acetone. Soils were spiked with 2,4-D acid in all cases, using acetone solutions of the herbicide and allowing the acetone to evaporate under an operating fume hood at laboratory conditions after application to the soil. Spike levels of 40 ppm 2,4-D on soil were achieved by applying 20 ml of a 5.6×10^{-2} g/l. solution of 2,4-D acid in acetone to 28 g of soil. The acetone-soil slurry was stirred and the acetone was allowed to evaporate. Spike levels of 10 ppm were achieved by applying 50 ml of a 1.2×10^{-2} g/l. solution of 2,4-D in acetone to 60 g of soil.

Supercritical fluid extractor

The supercritical fluid extractor is shown in Fig. 1. It was constructed by mounting 2 Valco HPLC/SFC valves (one 8-port and one 6-port) on a stainless steel block (17.5 cm × 7.5 cm ×

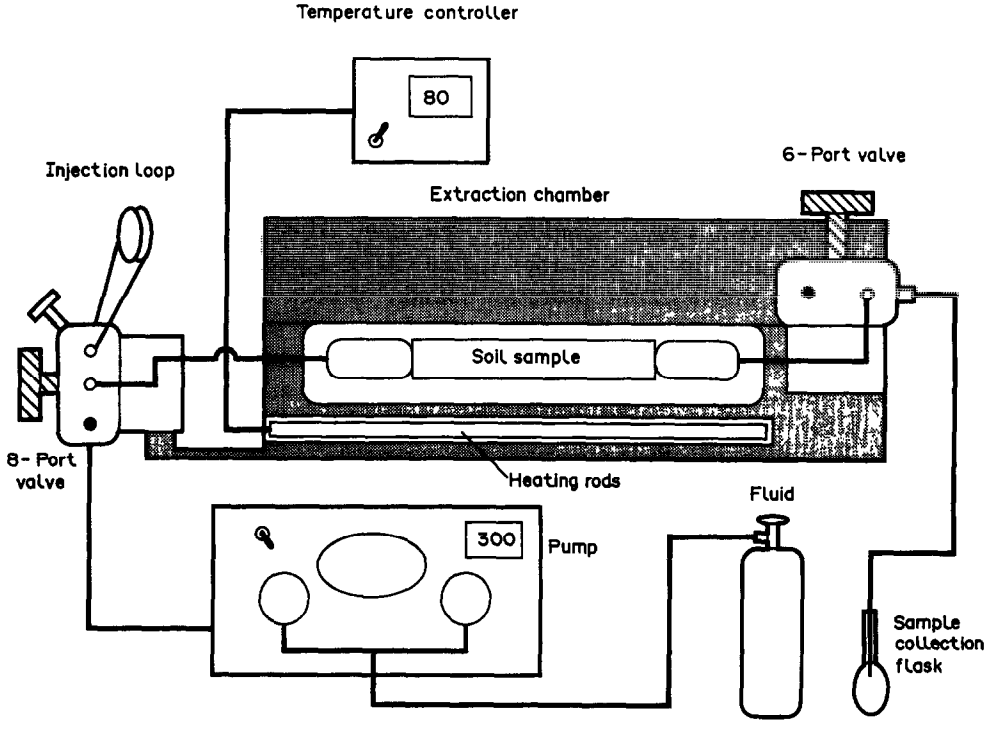

Fig. 1. Schematic of the supercritical fluid extractor.

2.5 cm). The stainless steel block, containing a trough (13.5 cm × 2.9 cm) to house the extraction cell, was heated with two 120 V Watlow heating rods (E4J30) controlled by an OMEGA CN 9000 temperature controller.

The 8-port valve was attached to an Altex Model 100A liquid chromatography pump, and precedes the extraction cell. The Altex pump could be set for specific pressures, though the pressure display showed some oscillation as the pistons alternated strokes. These pressure oscillations were typically from 5 atmospheres below the set pressure to 5 atmospheres above the set pressure. The flow rate of the pump was set at its maximum capability (9.99 ml/min). The 8-port valve was set up to allow injection of derivatizing reagents and solvents through an injection port and calibrated loop into the cell during extraction. The extractor was pressurized to roughly 85 atmospheres and heated to 80°. Injections of reagents were made with a glass syringe into the injection port of the 8-port valve while it was in the load position; the pressure was then raised to the desired level and the valve toggled to inject the solution. Meanwhile, the 6-port valve was in the closed position, stopping flow to the collection vessel.

Flow of CO_2 through a heated (80 to 90°) 60-μm fused-silica restrictor (roughly 0.5 m) was turned on or off with the 6-port valve. Static extractions (extractions in which the supercritical fluid is in contact with the matrix without fluid flow) were performed with the 6-port valve in a closed position. Dynamic extractions (extractions in which the supercritical fluid continuously flows through the matrix) were performed with the 6-port valve in an open position.

The extraction cell used was a Keystone Scientific 0.8-ml SFE cell made of stainless steel and sealed on each end with PEEK-rimmed, 2-μm stainless steel frits. PEEK unions were situated before and after the extraction cell to allow for easy removal and replacement of the extraction cell during sample loading and unloading. PEEK ferrules are replaceable and the wear problems of stainless steel are avoided.

For all methanol-based reagents added to the extractor, the SFE cell, 8-port valve, and tubing to the cell were rinsed with demineralized water and methanol as soon as possible after use; for the valve this involved making several injections of demineralized water followed by methanol. Hexane was used instead of methanol when Tri-Sil Concentrate was the additive. We believe that, with the possible exception of BF_3/methanol, this procedure has prevented degradation of the extractor.

Silylation

Silylations were performed using Tri-Sil Concentrate (Pierce, Rockford, IL, U.S.A.), which is a 2:1 mixture of hexamethyldisilazane (HMDS) and trimethylchlorosilane (TMCS). A volume of 200 μl was injected on to 1.2 g of soil, unless indicated otherwise. Samples treated with phosphate and hydrochloric acid, to be described, underwent SFE *in situ* silylation. Silylation extraction conditions were 380 atmospheres, 80°, in static mode for 15 min, followed by dynamic mode for 60 min at 340 atmospheres, unless stated otherwise. Extracts from silylation experiments were collected in 2 ml of hexane, and were injected directly into the GC after volume adjustments with hexane.

Extracts from extractions in which *in situ* silylation was not performed were derivatized in solution with 200 μl of Tri-Sil concentrate to 2 ml of solution, and a reaction time of at least 5 min at room temperature as recommended by the manufacturer. This procedure was followed for standards of 2,4-D acid to convert them to 2,4-D silyl esters.

Methyl esterification

Methyl esterification was performed using a BF_3 (14%)/methanol solution (Alltech Associates, Deerfield, IL, USA); this was used during extraction with SFE as well as for post-extraction derivatization as needed. Extraction conditions for methyl esterification were 300 atmospheres, 80°, for 10 min in the static mode, followed by dynamic extraction for 20 min at 300 atmospheres, 80°. Extracts were collected in 2 ml of methanol. Post-extraction treatment after *in situ* methyl esterification involved treatment of the extract with 1*M* aqueous sodium chloride solution and partitioning of the methyl ester into benzene before gas chromatographic analysis (1 extract:1 BF_3/methanol:1*M* sodium chloride:1 benzene, v:v:v:v). A standard, prepared from 2,4-D methyl ester powder, was dissolved in methanol and underwent the same treatment as the extract. The 2,4-D methyl ester powder was stored in a refrigerated (4°) desiccator; its low melting point (38°) precludes oven drying. Also, a standard prepared from 2,4-D acid powder was dissolved in methanol, underwent BF_3/methanol derivatization in solution for at least 5 min at roughly 60° in a sealed derivatization

vial, and then underwent the same treatment as the supercritical fluid extract (1 extract:1 BF_3/methanol:1*M* sodium chloride:1 benzene, v:v:v:v).

Ion pairing extraction

A 0.2*N* methanolic solution of m-trifluoromethylphenyl trimethylammonium hydroxide (TFTMFA) (Meth Prep 2, Alltech Associates, Deerfield, IL, USA) used for gas chromatographic on-column derivatization, was added during SFE. A volume of 300 μl of this solution was injected into the extraction cell and allowed to react with 1.1 g of soil under supercritical fluid conditions of 300 atmospheres, 80°, in static mode for 10 min, followed by dynamic mode for 20 min. The extracts were collected in 2 ml of methanol and were injected directly into the GC for analysis. Standards of 2,4-D methyl ester powder were prepared in methanol. Also, standards of 2,4-D acid powder were prepared in a 0.2*N* TFTMPA/methanol mixture (300 μl 0.2*N* TFTMPA to 2 ml of solution) and directly injected into the GC for analysis.

Methanol-modified extraction was identical to the TFTMPA extraction, except that 300 μl of methanol was injected onto the sample rather than TFTMPA. After the methanol-modified extraction, 300 μl of TFTMPA was added to the extract and the volume was adjusted to 2 ml.

Ionic displacement

Soil phosphate treatment involved addition of 0.2 ml of an aqueous solution of 1m*M* phosphate as phosphoric acid, adjusted to pH 4 with potassium hydroxide, to 1.2 g of soil. Addition of the phosphate solution was made to the soil in the SFE cell; the solution was allowed to evaporate for 7 hr under an operating fume hood, until the soil appeared dry by visual inspection. The coarse-grained nature of the soil allowed for relatively rapid drying. Extraction conditions were 380 atmospheres, 80°, 60 min in dynamic mode. The extract was treated in solution with Tri-Sil concentrate as was described in the silylation section. After 200 μl of Tri-Sil was added, the extraction conditions were 380 atmospheres, 80°, 15 min in static mode, followed by 45 min in dynamic mode at 340 atmospheres, 80°. Extracts were collected in 2 ml of hexane.

Soil hydrochloric acid treatment involved the addition of 0.2 ml of a 0.01*N* solution of hydrochloric acid in acetone to 1.2 g of soil to reduce the soil–acetone solution to a pH of roughly 2. The acetone was allowed to evaporate prior to silylation and extraction. Extraction conditions were 380 atmospheres, 80°, 15 min in static mode, followed by 40 min in dynamic mode, at 340 atmospheres, 80°. The hydrochloric acid-treated sample was treated *in situ* with 200 μl of Tri-Sil concentrate during extraction. The extract was collected in 2 ml of hexane, and injected directly into the GC for analysis after volume adjustments with hexane, as were extracts from silylation experiments.

Calcium chloride treatment involved adding $CaCl_2 \cdot 2H_2O$ dissolved in methanol (0.2*M*) to the extraction cell (300 μl to 1.1 g of soil) under supercritical fluid conditions. Extraction conditions were 300 atmospheres, 80°, 10 min in static mode, followed by 20 min in dynamic mode at 300 atmospheres, 80°. Extracts were collected in 2 ml of methanol. The extracts underwent BF_3/methanol derivatization in solution, and otherwise the same treatment (1*M* sodium chloride addition, partitioning into benzene) as that described for methyl esterification extracts. Likewise, the same 2,4-D methyl ester and 2,4-D acid standard preparation was performed as that of the methyl esterification experiment.

Some concern might be expressed regarding the use of chloride and its potentially corrosive effects on the high pressure stainless steel extractor and fittings. To date we have noticed no corrosive effects of methanolic calcium chloride treatment. The extractor, of course, was thoroughly cleaned after each use.

SFE collection efficiency

Lindane (γ-1,2,3,4,5,6 chlorocyclohexane) was used as a check on collection efficiency by placing 3 μl of a 1-ppm acetone solution onto the filter frit on the outlet end of the extraction cell, and allowing the acetone to evaporate before cell closure. Extraction conditions were 300 atmospheres, 80°, 10 min in static mode, followed by 20 min in dynamic mode under the same conditions. The lindane was collected in 2 ml of methanol. The recoveries obtained were 104, 94, 101 and 99% for four identical trials. Since lindane is more volatile (m.p. 112°) than 2,4-D (m.p. 138°), high collection efficiencies were assumed for 2,4-D.

Soxhlet extraction

Soxhlet extractions (EPA method 3540),[4] were performed using 6 g of soil placed in an acid-washed glass extraction thimble. The thimble was placed in the upper portion of an acid-

washed standard Soxhlet extractor with 300 ml of acetone/hexane (1:1) in the lower flask, heated in a heating mantle, and allowed to cycle for 24 hr. The extract was evaporated to 10 ml using an acid-washed 500-ml Kuderna–Danish apparatus and Snyder column, passed though 2 g of baked Na_2SO_4, which was further rinsed with 3 × 2-ml portions of acetone into the collection flask; the collected extract was quantitatively transferred using acetone to an acid-washed 40-ml Kuderna–Danish apparatus with a Snyder column, and further evaporated to a volume of approximately 0.5 ml. Soxhlet extracts, and standards of 2,4-D acid prepared in 0.5 ml of acetone/hexane (3:1) underwent BF_3/methanol derivatization (1 ml BF_3/methanol), 1*M* aqueous sodium chloride addition (1 ml), and partitioning into 5 ml of benzene. Standards of 2,4-D methyl ester were prepared in 0.5 ml of acetone/hexane (3:1), were mixed with 1 ml of methanol, 1 ml of 1*M* aqueous sodium chloride, and were partitioned into 5 ml of benzene.

This Soxhlet procedure gave recoveries of 98 and 96% of the 2,4-D acid added directly to the Soxhlet without a soil matrix.

Chromatography

Analyses were performed with a Tracor gas chromatograph equipped with an 18-meter DB-5 capillary column, a split-mode injection system, and an electron capture detector (ECD). Analyses for silyl esters of 2,4-D were performed using a column temperature set at 190°, injector at 250°, column flow of 0.8 ml/min, and an ECD temperature set at 325°. For methyl esters of 2,4-D, the column temperature used was 180°, while all other conditions are the same as for silyl esters.

RESULTS AND DISCUSSION

Silyl esterification

Silylation of 2,4-D under supercritical fluid conditions was successful when a known amount of 2,4-D was placed in the cell in the absence of soil. Figure 2B shows a chromatogram of 2,4-D silylated under SFE conditions, and Fig. 2C shows a chromatogram of a standard of 2,4-D derivatized under laboratory conditions. This extraction without matrix recovered 91% of the 2,4-D as 2,4-D silyl ester.

When 1.2 g of 2,4-D-spiked soil (40 ppm) were placed in the extraction cell with no derivatizing reagent added, no 2,4-D was extracted using supercritical CO_2 (Fig. 3B). Addition of 200 μl of Tri-Sil Concentrate (which fills the soil pores with solution) recovered approximately 18% of the 2,4-D (Fig. 3C) from the spiked soil. Second and third subsequent additions of Tri-Sil concentrate recovered approximately 7 and 6%, respectively, of the original 2,4-D in the sample (Fig. 3D and 3E).

The average recovery for 6 independent extractions was 31% with a standard deviation of 9% (Table 1). For soils containing more moisture than the 0.4% of this sample, the use of silylating reagents is likely to be even more of a problem since water may interfere with silylation. Another disadvantage of making 2,4-D silyl esters is that these esters are not commercially available, making standard preparation a source of uncertainty in the results. However, 2,4-D methyl esters are commercially available and can be used to test recoveries from supercritical fluid extractions.

Methyl esterification

The methyl ester of 2,4-D was formed in the extraction cell using BF_3/methanol in soil spiked at the 10 ppm level. BF_3-catalyzed/methanol derivatization is commonly used for esterifying

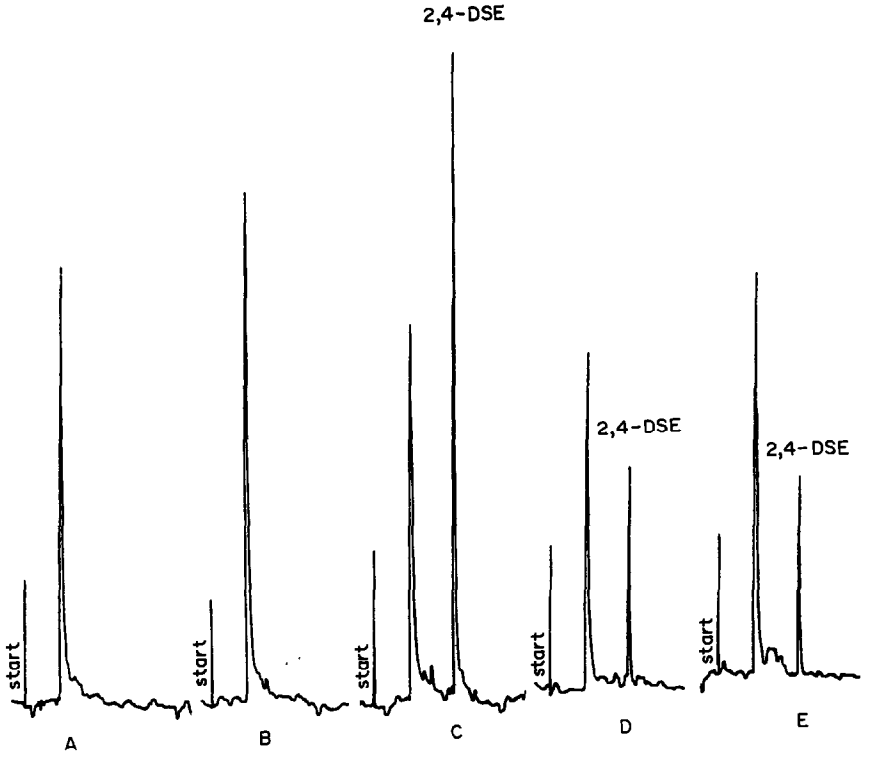

Fig. 3. Chromatograms of supercritical fluid extracts resulting from successive additions of Tri-Sil concentrate to 2,4-D-spiked soil in the extraction cell. A. Procedural blank prior to extraction B. B. Soil with no Tri-Sil added. C, D, E. First, second, and third increments (200 μl each) of Tri-Sil added to the soil, respectively.

2,4-D in solutions for gas chromatography,[11-16] and has been used by Hawthorne *et al.*, to recover 2,4-D from spiked and agricultural soil by supercritical fluid extraction.[8]

For solutions, BF_3/methanol is normally used at elevated temperatures (above the boiling point of methanol), and takes roughly 5 to 10 min. These conditions were met during SFE in the work of Hawthorne *et al.*,[8] and in ours; however, we found it necessary to destroy the BF_3 after extraction with an aqueous solution (such as 1*M* sodium chloride), and to partition the 2,4-D methyl ester into a non-polar solvent such as benzene for gas chromatography to prevent deterioration of the GC column. Initially when extracts and standards with BF_3/methanol were injected into our GC with a glass injector, 2,4-D methyl ester peaks were normal. However, use of the GC twenty-four hours later gave substantially broadened peaks. Peak widths at half maximum of 2,4-D methyl ester standards (not containing BF_3) were 2.3 times greater than before BF_3 injections. After the subsequent replacement of the glass injector and removal of roughly 0.3 m of the column, chromatographic efficiency was restored.

Another problem experienced with BF_3/methanol in the SFE was the development of holes at unions made of PEEK during the second extraction. This prevented multiple extractions and would make the routine use of BF_3 difficult and prompted us to abandon BF_3 as an *in situ* derivatizing reagent. During the first extraction, however, a recovery of 90% of the 2,4-D as its methyl ester was obtained (Table 1).

Table 1. SFE recoveries of 2,4-D from Hoypus sandy loam using various modifiers

CO_2 Modifier	No. trials	Recovery	Form of 2,4-D
No modifier added	5	0	Acid
Tri-Sil conc.	6	31 ± 9%	Silyl ester
0.2*M* $CaCl_2$/MeOH	2	86%, 87%	Acid
BF_3/MeOH	1	90%	Methyl ester
MeOH	2	6%, 6%	Acid
0.2*N* TFTMPA/MeOH	2	19%, 14%	Undetermined

Ion pairing

When an ion-pairing reagent, m-trifluoromethlphenyl trimethylammonium hydroxide (TFTMPA) was added to the soil sample during extraction, improved recoveries of 2,4-D were

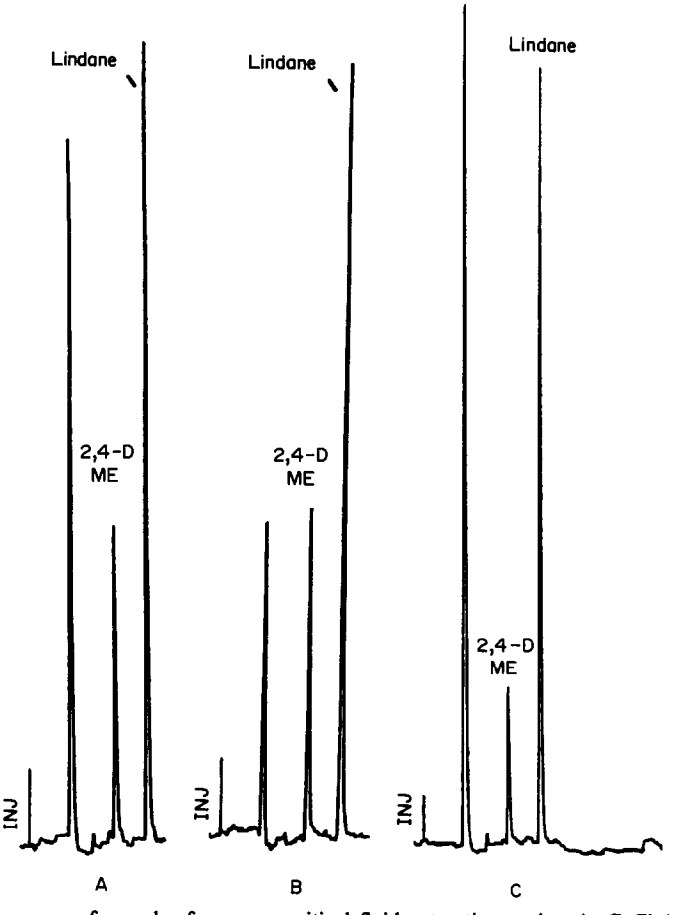

Fig. 4. Chromatograms of samples from supercritical fluid extractions using A. $CaCl_2$/methanol with post-extraction derivatization with BF_3/methanol, and B. BF_3/methanol derivatization during extraction (Hoypus zc). C. $CaCl_2$/methanol with post-extraction derivatization from the soil containing 4.2% organic carbon. Lindane was used as an internal standard.

obtained over those when the sample was extracted with methanol alone (Table 1). Apparently, TFTMPA extracts the 2,4-D acid by forming the trifluoromethylphenyl trimethylammonium salt, which dissolves into the supercritical fluid as an ion pair. Upon introduction into the hot gas chromatographic injector, the ion pair is thermally decomposed to form the methyl ester.[10,17] The use of TFTMPA or other quaternary ammonium additives provides an attractive alternative to BF_3/methanol treatment because the extracts require no post-extraction treatment. Unfortunately, the overall 2,4-D recoveries from SFE experiments in which TFTMPA was the additive were low compared to standards of 2,4-D methyl ester (14–19%).

Table 2. Comparison of standard Soxhlet extraction to $CaCl_2$-modified CO_2 SFE for the extraction of 2,4-D from organic-rich Coupeville Ap soil

Method	No. trials	Recovery	Form of 2,4-D
0.2*M* $CaCl_2$/MeOH on organic-rich soil	2	52%, 42%	Acid
Soxhlet on organic-rich soil	2	23%, 26%	Acid

Ionic displacement

In addition to ion pairing, TFTMPA may have been serving as an ion displacement reagent. Either the quaternary ammonium cation and/or its counterion may have displaced the acid or its conjugate base from active sites on the soil. To investigate this possibility in more detail, experiments with phosphate, hydrochloric acid and calcium chloride were made.

Because 2,4-D is a weak acid it may be dissociated and adsorbed by the soil as an anion. Thus, phosphate at a pH of 4 was chosen as an anion exchanging reagent. Under acidic conditions, phosphate is known to form inner-

sphere complexes with metal hydroxides by exchanging with anions in the soil to become irreversibly adsorbed.[18] The phosphate-treated soil was supercritically extracted with carbon dioxide. This extract was silylated after collection and analyzed for the 2,4-D silyl ester.

Unfortunately, the phosphate treatment produced an extraction of only about 19% of the adsorbed 2,4-D in the soil. However, remember that no 2,4-D can be extracted from this soil without some treatment, even though the acid form is soluble in supercritical carbon dioxide. After this extraction, 200 μl of the silylating reagent was added to the sample but only about 7% more of the original 2,4-D was recovered in this step for a total recovery of 26%. This was about the same as that observed for silylation alone. The addition of phosphate had little improvement on extraction efficiency from that of simple silylation.

The partial success of phosphate treatment indicated that perhaps some of the 2,4-D was adsorbed in the free acid form. Treatment with hydrochloric acid and silylation prior to extraction produced an enhanced recovery of 42%. We speculate that this was due to competitive displacement of hydrogen-bonded acid to hydroxy and/or anionic sites with protons to release the free acid which then formed the silyl ester.

Encouraged by these results, a strong cation displacing reagent, calcium chloride, was added to the soil during extraction. In this case the 2,4-D was extracted as the free acid and converted to the methyl ester for GC analysis after collection (Fig. 4). For two independent but identical experiments, extraction yields were 86 and 87%. Remember that when methanol without calcium chloride was used under the same conditions, only 6% yields of 2,4-D were obtained. The choice of calcium chloride was in part based on work by Cheng[19] in which a combination of methanol and calcium chloride was notably more efficient at extracting atrazine from soil than was methanol alone. This work was done using liquids only (not supercritical fluids).

Organic-rich soil

After these encouraging results, experiments with various soils were initiated. An example of these experiments is that of an organic-rich soil (4.2% organic carbon by weight). This soil was spiked with 2,4-D at the 10 ppm level. The results of duplicate experiments are shown in Table 1, including the results of comparative Soxhlet extractions. The recovery from this soil was 52 and 42% (Table 2). The Soxhlet extraction technique was notably less efficient, giving only 25 and 26% recovery of the 2,4-D. A lower Soxhlet recovery was also seen for the sandy soil, which gave a Soxhlet recovery of 47%.

Critique of methyl ester standard preparation

For experiments in which GC analyses involved methyl esters, the standard was prepared from 2,4-D methyl ester powder. For comparison, standards were also prepared from 2,4-D acid powder and then converted to the methyl ester as described in the experimental section. When 2,4-D acid standards derivatized with BF_3/methanol were used recoveries for the methanolic calcium chloride displacement experiment were 72 and 72%, rather than the 86 and 87% recoveries reported in Table 1 for the methyl ester powder standard. Similarly, the 2,4-D acid standard gave an 80% recovery compared to the 90% recovery determined with the methyl ester standard and reported in Table 1 for the BF_3/methanol modified extraction. The lower recoveries calculated using the 2,4-D acid standard relative to the 2,4-D methyl ester standard may have been due to partial hydrolysis of the methyl ester powder.

In contrast, recoveries determined using standards prepared from the methyl ester powder were substantially lower for the ion-pairing and methanol-modified experiments than those determined using standards prepared from the acid powder. For the methanol-modified experiment, SFE recoveries of 2,4-D determined with the 2,4-D acid standards were 11 and 15%, compared to the 6 and 6% reported in Table 1 based on the methyl ester standards. For the 0.2*N* TFTMPA-modified experiment, SFE recoveries determined with the 2,4-D acid standards were 69 and 71%, compared to the 19 and 14% reported in Table 1 based on the methyl ester standards. We attributed this to the low derivatization yield of 0.2*N* TFTMPA. Under the conditions used in this study, 0.2*N* TFTMPA converted only 24 to 33% of the 2,4-D acid standards in solution to the ester form. Thus, it is possible that the low extraction yields reported in Table 1 for the TFTMPA modifier may have been due to insufficient derivatization.

Hawthorne *et al.*, who obtained a recovery of 2,4-D >90% with TMPA (trimethylphenyl-

ammonium hydroxide), used a relatively high concentration of TMPA (about 20% in methanol) with a 15-min derivatization step and multiple extractions. Thus, with optimization of the esterification process in the GC, ion-pairing extraction followed by thermal decomposition esterification appears promising as an approach for the extraction and quantification of 2,4-D from soils.

CONCLUSIONS

This is the first report of the use of a salt solution to increase extraction efficiencies of polar compounds during SFE. The possibilities for salt-modified SFE look promising for the extraction of polar compounds. However, considerable optimization with respect to salt type, concentration and extraction time is needed before a final recommendation concerning this approach can be made.

ACID–BASE AND DISTRIBUTION EQUILIBRIA OF 5,7-DICHLORO-2-METHYL-8-HYDROXYQUINOLINE IN BRIJ-35 MICELLAR MEDIA SOLUTIONS

J. L. BELTRÁN,* R. CODONY, M. GRANADOS, A. IZQUIERDO and M. D. PRAT

(*Received* 2 *August* 1991. *Revised* 25 *May* 1992. *Accepted* 25 *May* 1992)

Summary—The acid–base equilibria of 5,7-dichloro-2-methyl-8-hydroxyquinoline (HQ) have been examined spectrophotometrically in aqueous micellar solution of the non-ionic surfactant Brij-35. The differences between apparent pK_a values at different surfactant concentrations can be quantitatively explained in terms of the extraction constants of the neutral species HQ and the ion-pair Na^+Q^-. Calculations have been performed by means of SPDIS program, developed in this work to handle multiwavelength spectrophotometric data in micellar systems.

Aqueous micellar media are widely used in different areas of analytical chemistry and several reviews concerning their analytical applications have been published.[1–4] One important property of micelles is their ability to solubilize a wide variety of compounds which are insoluble or slightly soluble in water. The incorporation of a solute into micellar systems can lead to important changes in its molecular properties. Surfactants usually affect spectral parameters: the intensity of the absorption bands can be increased and shifts in the absorption maxima of reagents and complexes are observed.[5,6] Moreover, the acid–base and complexation equilibria involved in these systems are also influenced by surfactants.[7,8]

Several theories have been proposed to account for the changes in spectral parameters and equilibria.[9–15] One of the most successful is the partition model,[12–15] in which it is assumed that micelles act as a separate phase uniformly distributed throughout the solution, and distribution of neutral species and ion associates between the aqueous phase and micelles can occur.

In this work the effect of the non-ionic surfactant polyoxyethylenlaurylether (Brij-35) on the apparent dissociation constants of 5,7-dichloro-2-methyl-8-hydroxyquinoline or chlorquinaldol (HQ) was studied by spectrophotometry. Interest in chlorquinaldol is related to its chelating ability towards metal ions and the enhancement of the fluorescence of some metal–chlorquinaldol complexes observed in non-ionic surfactant media.[16,17]

Although studies of equilibria in micellar media are usually carried out by means of uv–visible spectrophotometry,[5,8,18,19] to date no program has been able to calculate extraction and distribution constants from multiwavelength spectrophotometric data in these systems, where there is no physical separation between the two phases. Therefore, the constants were determined from data obtained at one wavelength and it was impossible to obtain the spectra of the species extracted into the micellar phase.

In order to improve the data treatment of this kind of system, the SPDIS program has been developed. It has been designed to handle spectrophotometric data taking into account the presence of distribution processes between aqueous and micellar phases.

By using SPDIS a quantitative assessment of the equilibria involved in the system studied has been obtained. The proposed model explains the differences observed between the apparent acid–base constants and the aqueous acid–base constants. Additionally, the effect of Brij-35 media on the fluorescence of chlorquinaldol has been studied and the variations in fluorescence intensity have been related with distribution equilibria between micellar and aqueous phases.

EXPERIMENTAL

Apparatus

The spectrophotometric measurements were carried out on a Beckman DU-7 instrument, using a 1.00-cm quartz cuvette. The spectrophotometer was connected to an IBM personal computer for data collection.

For fluorimetric measurements a Perkin Elmer LS-50 spectrofluorimeter, with a 1.00-cm quartz cuvette, was used.

The pH values were measured on a Radiometer PHM84 pH-meter, equipped with a Ross combined pH-electrode (Orion 81-02). The potentiometric system was calibrated prior to use with 4.008, 6.863 and 9.185 buffer solutions, prepared from Merck salts according to DIN 19266.

All spectrophotometric, fluorimetric and potentiometric measurements were made at $25.0 \pm 0.1°$.

Reagents

5,7-Dichloro-2-methyl-8-hydroxyquinoline (Supro, Troponwerke, Köln) was recrystallized twice from ethanol solution. Fresh $10^{-3}M$ solutions were prepared daily by dissolving the reagent in $0.02M$ hydrochloric acid. Brij-35 (Fluka) was used without further purification. All other chemicals were of analytical grade. Buffer solutions were prepared according to Perrin and Dempsey[20] from formic acid and sodium hydroxide, sodium dihydrogenphosphate and sodium hydroxide, and tris(hydroxymethyl)-aminomethane and hydrochloric acid. Ionic strength of the working solutions was kept constant at $0.1M$ by addition of sodium chloride.

Procedures

In order to determine the dissociation constants of chlorquinaldol, several series of solutions were prepared by adding hydrochloric solution of the reagent to 50-ml standard flasks, containing the buffer ($2 \times 10^{-3}M$), the ionic medium and the surfactant. Final concentration of chlorquinaldol was about $2 \times 10^{-5}M$. After thermic equilibration, spectra of the solutions were recorded, from 220 to 450 nm, at 5-nm increments, and finally the pH of the solutions was measured and converted into hydrogen ion concentration, according to the Davies equation.[20] (The activity coefficient calculated for the hydrogen ion was 0.771 at 25° and $0.1M$ ionic strength). Fluorimetric measurements were carried out at $\lambda_{ex} = 350$ nm and $\lambda_{em} = 530$ nm, using excitation and emission slit widths of 5 and 10 nm, respectively.

Data treatment

Dissociation constants. The dissociation constants of chlorquinaldol and the molar absorptivities of its pure species were determined using the program STAR.[21] This program was also used in the determination of "apparent" dissociation constants in micellar media, at different concentrations of surfactant. The apparent dissociation constants (K^*_{a1} and K^*_{a2}) are defined as:

$$K^*_{a1} = \frac{[HQ]^* \cdot [H^+]}{[H_2^+Q]^*} \quad K^*_{a2} = \frac{[Q^-]^* \cdot [H^+]}{[HQ]^*} \qquad (1)$$

where $[H_2Q^+]^*$, $[HQ]^*$ and $[Q^-]^*$ are the total concentration of the cationic, neutral and anionic species of chlorquinaldol, regardless of whether they are in the aqueous or micellar phase.

Taking into account that in micellar media the dissociation constants calculated by STAR are apparent, the molar absorptivities obtained with the program are also apparent. From the variation in the apparent dissociation constants and molar absorptivities, at different surfactant concentrations, the species that participate in distribution processes between the aqueous and micellar phases can be inferred.

Distribution equilibria. For the treatment of the extraction equilibria in micellar phases, the SPDIS program, based on the program STAR, was developed. As SPDIS is written in Turbo-PASCAL (5.0) for personal computers (IBM-PC/AT or compatible). The program was used for the determination of the extraction and distribution constants from absorbance data of micelle-containing solutions. The mathematical background is as follows: in a micellar medium, the volume of the micellar pseudophase (Vm) is given by:

$$Vm = (C_S - \text{cmc}) \cdot V \cdot V\phi \qquad (2)$$

where C_S is the total concentration of surfactant, cmc the critical micelle concentration (both in mole.l^{-1}), $V\phi$ the partial molar volume of micellar phase (l./mole), and V the total volume of the solution ($V = Vm + Vw$, Vw: volume of the aqueous phase). The ratio R, of the micellar volume to the total volume can be written as:

$$R = Vm/V = (C_S - \text{cmc}).V\phi \qquad (3)$$

The absorbance of a solution at a j determined wavelength (A_j) will be:

$$A_j = A_{j(w)} + A_{j(m)} \quad (4)$$

where $A_{j(w)}$ and $A_{j(m)}$ are the absorbances of the aqueous and micellar phases, respectively. Assuming a pathlength equal to 1.00 cm, these absorbances can be written as:

$$A_{j(w)} = \sum_{i=1}^{ni} C_{i(w)} \cdot \epsilon_{j,i(w)} \cdot Vw/V = \sum_{i=1}^{ni} C_{i(w)} \cdot \epsilon_{j,i(w)} \cdot (1 - R) \quad (5)$$

$$A_{j(m)} = \sum_{i=1}^{ni} C_{i(m)} \cdot \epsilon_{j,i(m)} \cdot Vm/V = \sum_{i=1}^{ni} C_{i(m)} \cdot \epsilon_{j,i(m)} \cdot R \quad (6)$$

where ni is the number of absorbing species, $C_{i(w)}$ and $C_{i(m)}$ are the concentrations of the i-species in aqueous and micellar phases, and $\epsilon_{j,i(w)}$ and $\epsilon_{j,i(m)}$ the molar absorptivities at the j-wavelength of the i-species in aqueous and micellar phases.

In this work, the values of R varied from 1.83×10^{-5} to 1.96×10^{-3}, thus the factor $(1 - R)$ in equation (5) can be assumed equal to unity ($V = Vw$).

If we consider that an extraction equilibrium takes place between aqueous and micellar phases we can write:

$$C_{i(m)} = K_{Di} \cdot C_{i(w)} \quad (7)$$

K_{Di} being the distribution constant of the i-species.

The program SPDIS was used for the determination of these distribution constants and the molar absorptivities of the species extracted in micellar phase, from absorbance data. For these calculations, previous knowledgement of the formation constants of the species in aqueous phase, and their molar absorptivities, are advisable.

The algorithms used for the refinement of equilibrium constants, and for the calculation of molar absorptivities, are the same as used in STAR. However, there is a minor change in the description of solution equilibria to take into account the extracted species. For each component of the solution (*e.g.*, the r-component), its total concentration (C_r), is equal to:

$$C_r = \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(w)} \cdot \frac{Vw}{V} + \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(m)} \cdot \frac{Vm}{V} \quad (8)$$

where $sc(i,r)$ is the stoichiometric coefficient of the r-component in the i-species.

Substituting the values $(Vw/V) = 1$ and $(Vm/V) = R$ the following equation is obtained:

$$C_r = \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(w)} + \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(m)} \cdot R \quad (9)$$

And, taking into account equation (7):

$$C_r = \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(w)} + \sum_{i=1}^{ni} sc(i,r) \cdot C_{i(w)} \cdot K_{Di} \cdot R \quad (10)$$

On the other hand, the concentration of each species in aqueous phase is defined as:

$$C_{i(w)} = \beta_{i(w)} \cdot \prod_{k=1}^{nk} X_{k(w)}^{sc(i,k)} \quad (11)$$

Where nk is the number of components, $\beta_{i(w)}$ the formation constant of the i-species in aqueous solution, and $X_{k(w)}$ the free concentration of the k-component in aqueous phase. Rearranging equations (10) and (11) we obtain:

$$C_r = \sum_{i=1}^{ni} sc(i,r) \cdot \beta_{i(w)} \cdot \prod_{k=1}^{nk} X_{k(w)}^{sc(i,k)} + \sum_{i=1}^{ni} sc(i,r) \cdot \beta_{i(w)} \cdot K_{Di} \cdot R \cdot \prod_{k=1}^{nk} X_{k(w)}^{sc(i,k)} \quad (12)$$

In order to simplify computation, the second term on the right side of equation (12) can be treated as the definition of a system with $nk + 1$ components, where R is considered as the $nk + 1$ component, and $\beta_{i(w)} \cdot K_{Di}$ is the extraction constant of the extracted i-species. Therefore equation (12) can be written as:

$$C_r = \sum_{l=1}^{nl} sc(l,r) \cdot \beta_l \cdot \prod_{k=1}^{nk+1} X_k^{sc(l,k)} \quad (13)$$

where nl is the total number of species in aqueous phase and micellar phase.

The stoichiometric coefficient of R for the l-species, $sc(l, nk + 1)$, can only take two values: 0, for species present in the aqueous phase, and 1, for species present in micellar phase.

For any species the formation or extraction constant will be given by:

$$\beta_l = \beta_{l(w)} \cdot K_{Dl} \qquad \text{if } sc(l, nk+1) = 1$$

$$\beta_l = \beta_{l(w)} \qquad \text{if } sc(l, nk+1) = 0$$

The R value is used as a "free concentration", but it is calculated directly after equation (3). Furthermore, as the hydrogen ion concentration is known (as the pH of solution is measured), only $nk - 1$ mass balance equations have to be solved.

Once the mass balance equations have been solved, the program calculates the unknown molar absorptivities by multiple regression,[22] and the constants can be refined by the Gauss-Newton method.[23] As in STAR program, the minimized function is the sum of squared

residuals of the absorbance of n solutions (a maximum of 200 in the SPDIS program) at nj wavelengths (up to 12).

RESULTS AND DISCUSSION

Dissociation constants in water

Chlorquinaldol shows two acid–base equilibria: the first is that of the heterocyclic nitrogen protonation, and the second corresponds to the dissociation of the hydroxyl group.

Chlorquinaldol absorption spectra in aqueous solution, in the absence of Brij-35, at several pH values are shown in Fig. 1. The protonated species exhibits an absorption maximum at 260 nm, the neutral species shows two absorption maxima, at 250 and 280 nm, and for the anionic form the absorption maximum is located at 265 nm. On the other hand all species shows broad bands at visible range, these bands being less sensitive than those in the UV range. The calculated pK_a constants are $pK_{a1} = 3.44 \pm 0.01$ and $pK_{a2} = 7.84 \pm 0.02$.

Apparent dissociation constants in the presence of Brij-35

In order to determine the influence of the non-ionic surfactant Brij-35, a series of experiments were run at different Brij-35 concentrations, above the cmc. The apparent pK_a values of the reagent for each Brij-35 concentration are given in Table 1. These results shows that as the surfactant concentration increases, from $1.1 \times 10^{-4} M$ to $1.9 \times 10^{-3} M$, the apparent pK_{a1} decreases from 3.34 to 2.37, whereas the pK_{a2} increases from 7.92 to 8.53.

The apparent spectra of the protonated form are independent of the surfactant concentration. Nevertheless, apparent spectra of the neutral form are strongly dependent on Brij-35 concentration. As its concentration increases, the intensity of absorption maximum at 280 nm decreases, and the intensity of the 250 nm maximum increases and shows a slight bathochromic shift. At high surfactant concentrations the apparent spectra of the neutral form show the same shape as those obtained when chlorquinaldol is dissolved in organic solvents like chloroform, benzene or isoamyl alcohol.[24] On the other hand, apparent spectra of the anionic species show a bathochromic shift of the maximum at 265 nm, and the band intensity slightly decreases as Brij-35 concentration increases. In Fig. 2 the apparent molar absorptivities, for each Brij-35 concentration, of the species HQ and Q^-, calculated by means of STAR program, are displayed.

Table 1. Apparent dissociation constants of chlorquinaldol in aqueous Brij-35 solutions

$C_{Brij\text{-}35}$ (M)	pK_{a1}*	pK_{a2}*	sigma

*Values in ( ) are three times the estimated standard deviation of pK_a as given by the program.

Distribution equilibria in water-Brij-35 systems

According to the partition model, distribution of neutral species and ion associates between the aqueous solution and the micellar phase can take place. Since Brij-35 is a non-ionic surfactant, in this system ion-pairing can only occur between the charged species of the reagent, Q^- and H_2Q^+, and sodium and chloride ions, from the ionic medium. The effect of ions from buffers was neglected because their concentrations are much lower than those of the sodium chloride used to adjust the ionic strength.

Several equilibria models were checked with the SPDIS program. These models were chosen according to the variations observed in the spectral parameters and acid–base behaviour with the surfactant concentration. Thus, the variations observed in the apparent spectra of the neutral species, and in the apparent pK_a values (pK_{a1} decreases and pK_{a2} increases as Brij-35 concentration increases) suggest that HQ distributes between aqueous and micellar phases, as can be expected. On the other hand some variation in the apparent spectra of the anionic species was detected. In addition the extraction of ionic associates between the anionic form of oxine and derivatives and alkaline ions have been reported in several systems, including micellar solutions of non-ionic surfactants.[14,24] Finally, from the apparent spectra of cationic species obtained at different Brij-35 concentrations no inference can be made about the extraction into the micellar phase of an ion-pair of H_2Q^+. Nevertheless the extraction of this kind of ion-pair of oxine and derivatives into some organic solvents and micellar systems has been detected.[14,24]

In Table 2 the models assayed are listed. The models include, besides the dissociation

and they were taken as 1.070 l./mole[25] and $10^{-4}M$,[4,26] respectively.

If only distribution of the neutral species was considered (model 1) the standard deviation obtained was high (sigmaD = 0.0171) since large differences between experimental and calculated values were obtained, especially in the basic pH-range. When the extraction of the $Na^+.Q^-$ ion-pair was also taken into account (model 2) the fit with the experimental data was clearly improved (sigmaD = 0.0078). Finally model 3, which includes, besides the species of model 2, the extraction of $H_2Q^+.Cl^-$, was checked. Although a slight improvement of the fitting was obtained (sigmaD = 0.0074), the extraction constant of this ion-pair was ill-defined, and this species was found to be formed only to a maximum of 2%. Therefore the extraction of $H_2Q^+.Cl^-$ was not considered further and model 2 was adopted for this system. The calculated values of the constants and the distribution ratio D, defined as ratio of total concentration of chlorquinaldol in the micellar phase to that in aqueous phase, are given in Table 3. Figure 3 shows the species distribution as a function of pH, calculated from the obtained constants (by using a modified version of SOL1 program[27]), for a Brij-35 concentration equal to $1.91 \times 10^{-3}M$. Despite the high values obtained for the distribution ratios ($\log D$ = 3.65 and $\log D = 2.77$ for HQ and Q^-, respectively), the mass of chlorquinaldol in the micellar phase does not exceed 90% because of the low volume of the micellar phase, only 0.2% of the total volume.

The extraction of neutral and anionic species explains the observed differences in the spectra with increasing Brij-35 concentration. The calculated molar absorptivities of the species in micellar phases ($\lambda = 252$ nm; $\log \epsilon = 4.63$ for HQ and $\lambda = 263$ nm; $\log \epsilon = 4.50$ for Q^-) agree with those observed in organic solvents in which the extraction of the anionic species takes place, like isoamyl alcohol ($\lambda = 253$ nm; $\log \epsilon = 4.65$

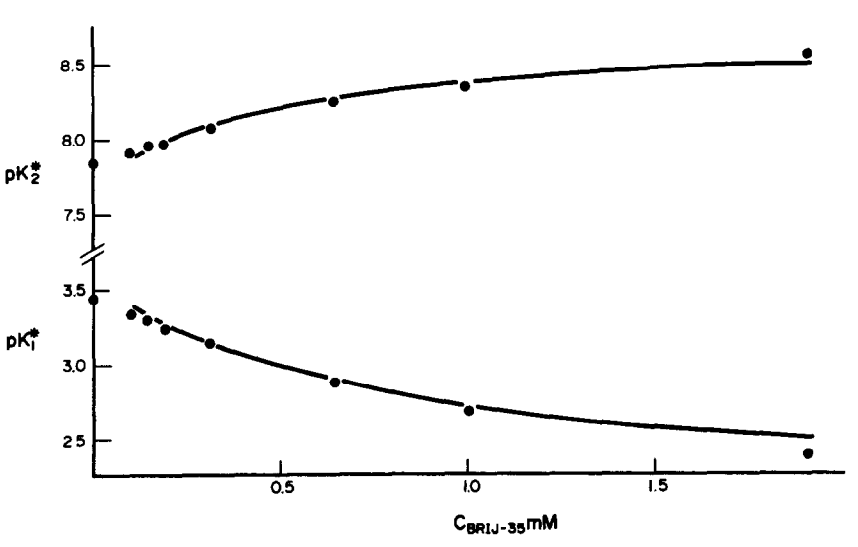

Fig. 4. Apparent dissociation constants as a function of $C_{Brij\text{-}35}$. (●): experimental values, (—): calculated curves using the constants given in Table 3.

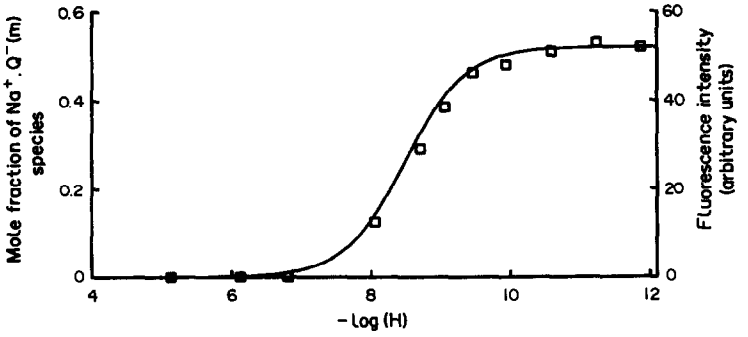

Fig. 5. Relative fluorescence intensities (□) of chlorquinaldol ($4 \times 10^{-5}M$) as a function of pH, at $C_{\text{Brij-35}} = 1.8 \times 10^{-3}M$. Solid line corresponds to molar fraction of $Na^+Q^-_{(m)}$.

for HQ and $\lambda = 260$ nm; $\log \epsilon = 4.51$ for Q^-). On the other hand, the fact that the ion-pair of the anionic form distributes between the two phases, but the cationic form does not, explains the finding that the shifting observed in pK_{a1} values is greater than that observed in pK_{a2} values.

From constant values given in Table 3, the apparent dissociation constants of the reagent, as a function of Brij-35 concentration, were determined. Theoretical and experimental apparent dissociation constant values are displayed together in Fig. 4. The good agreement between experimental and calculated "apparent" pK_a values shows that the proposed model provides a complete description of the effect of Brij-35 on the apparent dissociation constants of the reagent.

Fluorescence of chlorquinaldol in Brij-35 micellar solutions

It is well known that micellar media very often enhance fluorescence. This has been attributed to the solubilization of the fluorophore into the micelles. Preliminary experiments showed that chlorquinaldol does not fluoresce in aqueous solution in the whole pH range, but it does so when dissolved in basic aqueous micellar solutions of Brij-35 surfactant. In order to find a relationship between solubilization of chlorquinaldol into micelles and its fluorescence properties, the influence of pH and surfactant concentration on chlorquinaldol fluorescence was studied.

The pH dependence of the fluorescence intensity, at constant chlorquinaldol ($4 \times 10^{-5}M$) and Brij-35 ($1.8 \times 10^{-3}M$) concentrations is shown in Fig. 5. Points are the experimental relative fluorescence values whereas the solid line corresponds to mole fraction of $Na^+Q^-_{(m)}$ species in this micellar medium. This behaviour clearly indicates that the anionic form in the micellar phase is the only fluorescent species.

The influence of Brij-35 concentration (between 2×10^{-4} and $2 \times 10^{-3}M$) on fluorescence intensity was studied at constant pH (about 11) and chlorquinaldol concentration ($4 \times 10^{-5}M$). It was found that the relative fluorescence intensity is a linear function of the mole fraction of $Na^+Q^-_{(m)}(X_{NaQ})$.

The good correlation between observed fluorescence and calculated X_{NaQ} shows that solubilization of anionic form of chlorquinaldol into the micelles is a determining factor for fluorescence enhancement. Furthermore, the agreement between measured fluorescence intensity values and the proposed model for the equilibria of chlorquinaldol in Brij-35 micellar solutions confirms its validity.

CHEMILUMINESCENCE DURING THE OXIDATION OF ALCOHOLS BY PERMANGANATE: APPLICATION TO THE DETERMINATION OF ETHANOL IN GIN

S. I. MONTALVO* and J. D. INGLE, JR.†
Department of Chemistry, Oregon State University, Gilbert Hall 153, Corvallis, OR 97331-4003, U.S.A.

(*Received* 9 *April* 1992. *Revised* 26 *May* 1992. *Accepted* 26 *May* 1992)

Summary—Chemiluminescence is observed during the oxidation of ethanol with potassium permanganate under very acidic conditions. Factors affecting the chemiluminescence signal are discussed. Based on this chemiluminescence reaction, a method for the determination of alcohol in gin was developed. The method, which has a detection limit of 0.3% (v/v) and a relative standard deviation of about 1% at 40.0% (v/v), was used in the determination of ethanol in three different brands of gin with no sample preparation.

The oxidation of ethanol in acidic solutions by potassium permanganate is well known. This reaction is a two-electron process, which eventually gives acetic acid.[1] According to Banerji,[2] the permanganate-ethanol reaction stoichiometry is 4 to 5. With a large excess of the alcohol, the reaction kinetics are first order in permanganate and ethanol, and the rate of oxidation increases linearly with acid concentration.

Marino and Ingle[3] demonstrated that chemiluminescence (CL) is produced during the oxidation of humic material and polyphenols by permanganate ion in basic solutions. In our laboratory, it was discovered that oxidation of ethanol by permanganate ion produces weak CL and that the CL intensity is greater at very low pHs. Hence, the classic oxidation of simple aliphatic alcohols by acidic permanganate is a CL reaction.

Determination of ethanol (proof) in liquors is mandated by the Department of the Treasury (Bureau of Alcohols, Tobacco and Firearms).[4,5] The specified method, which is also recommended by the AOAC,[6] is based on hydrometer readings which are normalized to 60°F. Ethanol in other types of samples has been determined with many different methods including amperometry,[7] automated densitometry,[8] gas chromatography,[9,10] and titrimetry.[11]

This paper is concerned with using this new CL reaction for the determination of ethanol in gin. Spectral, optimization, and calibration data are discussed.

EXPERIMENTAL

Instrumentation

A discrete-sampling CL photometer described elsewhere[12,13] was used for all quantitative CL measurements. Briefly, it consists of a 1-cm pathlength spectrophotometer sample cell housed in an aluminum sample chamber. A brass temperature-controlled jacket around the same cell is connected to a thermostated water bath. The contents of the sample cell are mixed with a magnetic stirrer and a stirbar. The final reagent is delivered to the cell by means of an automatic pneumatically-activated syringe to initiate the reaction. A portion of the light emitted during the reaction is impingent on the photomultiplier tube (PMT). The resulting photoanodic current is converted to a voltage, electronically filtered, and displayed on a recorder.

Spectrophotometric data were obtained with a HP 8451A diode array spectrophotometer. Chemiluminescence spectra were acquired with a spectrometer based on an intensified diode array detector.[14]

Solution preparation

The water used for dilution of all aqueous solutions and rinsing was deionized water from a Millipore Milli-Q system connected to the house deionized water. All chemicals were

*Present address: Jefferson State Junior College, Brewton, AL 36426, U.S.A.
†Author for correspondence.

reagent grade. Potassium permanganate solutions (30m*M* and lower) were stored in black Teflon bottles in the dark. These bottles were washed and soaked with 1% (v/v) hydrochloric acid and then water to ensure the removal from the bottle walls of manganese dioxide formed during storage of previous permanganate solutions.

Measurement procedure

The general procedure followed for CL analysis involved the addition of 1.0 ml of sample, standard, or blank (water) and then 0.5 ml of acid to the sample cell with Eppendorf pipets. With the sample chamber lid closed and the PMT shutter open, 0.81 ml of the final CL reagent ($KMnO_4$) was injected into the sample cell using the pneumatic injector. CL peaks for the blank were negligible unless otherwise stated. Between runs the reaction cell was cleaned by adding 50% (v/v) hydrochloric acid, letting it stand for 2–3 min, and then rinsing ten times with water. Reaction mixtures and rinsing solutions were removed by vacuum aspiration.

All CL signals were reported as the maximum in the peak-shaped signal in Volts. Generally, the mean and the standard deviation of the CL signal from three or more repetitive runs are reported. The noise filter cut-off frequency was 0.5 or 1.0 Hz, and the cell temperature was controlled to 25°.

RESULTS AND DISCUSSION

Type of acid

The effect of the type of acid on the ethanol CL reaction was studied by using 0.5 ml of 50% (w/v) nitric, phosphoric, acetic, perchloric, or sulfuric acids or concentrated hydrochloric acid in the reaction mixture. Calibration curves over a concentration range of 1–50.0% (v/v) ethanol were obtained. No CL was observed with phosphoric or acetic acid. Apparently the pH of reaction mixture is too high with these acids for the reaction to proceed at a significant rate. The results for the other acids are summarized in Table 1. Hydrochloric acid provides the greatest signal and has the advantage of dissolving the MnO_2 formed during the reaction. However, the precision and linearity are poor. The detection limit with sulfuric acid is worse than that with some of the other acids. Also the reaction rate is slow and there is a potential explosion hazard of this acid when combined with potassium permanganate. The use of perchloric acid has two disadvantages, an imprecise blank signal and a potential explosion hazard when mixed with organic compounds. Nitric acid was finally chosen as the best acid because it yields a relatively high CL intensity, a relatively fast reaction rate, a reasonable detection limit, good precision, no blank signal, and a more linear response at lower ethanol concentrations.

Absorption and chemiluminescence spectra

A time sequence of the absorption spectra of a reaction mixture with ethanol in molar excess relative to permanganate revealed that in the visible wavelength range, MnO_4^- absorbs strongly from about 450 to 600 nm with a tail that extends to longer wavelengths and that most of the potassium permanganate is consumed in 30 sec. With Fe(II) added before injection of the oxidant, the CL signal is enhanced, and the absorbance due to MnO_4^- decreases much more rapidly than that without Fe(II) added due to the reduction of permanganate by this species.

To obtain a crude CL spectra, the CL signal was recorded with different cut-on filters between the reaction cell and the PMT in the CL photometer sample compartment. From the signal attenuations observed, it was esti-

mated that the broad emission band begins at about 500 nm with an apparent maximum at about 660 nm.

For fast CL reactions, the intensified diode array provides a better means to obtain spectral information.[14,15] The successive CL spectra in Fig. 1 show that it takes about 4 sec for the reaction to reach its maximum intensity and the CL spectrum is quite broad. Note that the wavelength of maximum CL intensity (λ_m) shifts to shorter wavelengths as the reaction proceeds. After 1 sec, $\lambda_m \approx$ 650 nm, while $\lambda_m \approx 580$ nm after 4 sec. At 4 sec, the CL emission occurs over the 450–750 nm region. This apparent shift is attributed to the absorption of a fraction of the CL photons by permanganate whose absorption spectrum overlaps the CL spectrum. The strongest absorption occurs in the shorter wavelength region of the CL spectrum. As the reaction proceeds, the permanganate is consumed and the degree of absorption of CL photons of shorter wavelength decreases.

In the presence of Fe(II), the CL reaction proceeds about three times faster (*i.e.*, 1.5 sec to reach maximum intensity) as shown in Fig. 2. Note that λ_m is about 530 nm and emission occurs from about 380 to 800 nm. We postulate that this spectrum represents a truer picture of the CL spectrum. In this case, the Fe(II) reduces all the MnO_4^- almost immediately to lower Mn oxidation states [Mn(III) and Mn(IV)] which do not absorb the CL radiation as strongly but which we believe are responsible for oxidizing the ethanol.[16]

Optimization

In discussing the optimization of the $KMnO_4$ and HNO_3 concentrations, the stoichiometry and absorption of CL radiation by $KMnO_4$ should be kept in mind. If the oxidation proceeds to acetic acid it takes 0.8 moles of

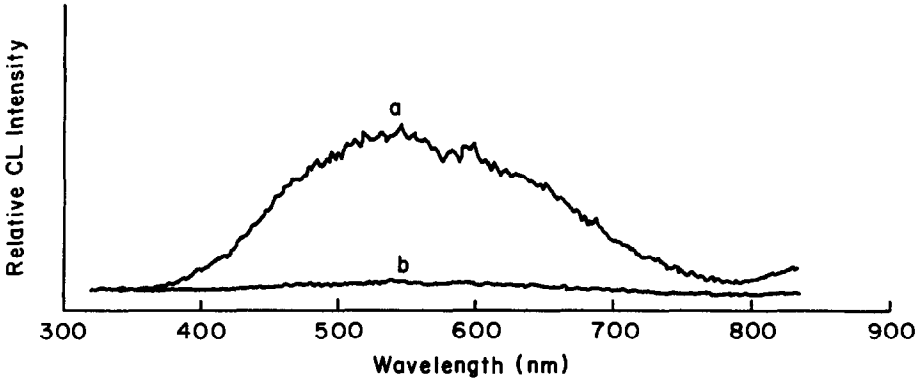

Fig. 2. Chemiluminescence spectra from the oxidation reaction of ethanol with $KMnO_4$ in the presence of Fe(II). Spectra taken 1.5 sec (a) and 3.5 sec (b) after injection. Reaction mixture: 1 ml of absolute ethanol, 1 ml of 0.1*M* Fe(II), 0.5 ml of 95% (v/v) HNO_3, 0.81 ml of 10m*M* $KMnO_4$.

permanganate to oxidize 1 mole of ethanol. If acetaldehyde is the oxidation product, 0.4 moles of permanganate is required to oxidize 1 mole of ethanol. The lowest concentration of ethanol used in the optimization studies was 1% (v/v) or 171m*M*. With 10m*M* permanganate, ethanol is in molar excess relative to permanganate in the reaction mixture by a factor of 21 or greater. Thus, it might be expected that the rate of oxidation and the CL signal would be proportional to the permanganate and ethanol concentrations. Because of the absorption of the CL photons by permanganate caused by the overlap between the CL spectrum and MnO_4^- absorption spectrum, it is also expected that attenuation effects will be more pronounced at higher permanganate concentrations.

The effect of nitric acid concentration on the CL signal for 12.5% (v/v) ethanol with different potassium permanganate concentrations is shown in Fig. 3. In all cases, the CL signal increases with higher acid concentrations. For a given nitric acid concentration, the CL signal increases as the potassium permanganate concentration increases from 1 to 10m*M*, but decreases when the oxidant concentration increases to 30m*M*. The potassium permanganate concentration yielding the highest CL signal depends upon the nitric acid concentration. Only for the case of a potassium permanganate concentration of 1.0m*M*, the dependence of the CL signal on the nitric acid concentration is approximately linear (pseudo-first order). However, at higher concentrations of potassium permanganate, a pronounced positive deviation is observed and is most obvious at 30m*M* potassium permanganate. The above behavior is attributed to the absorption of some of the CL radiation by unreacted potassium permanganate which is

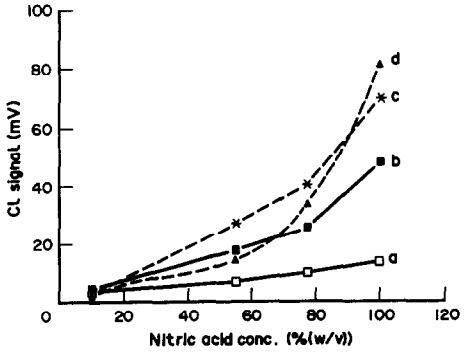

Fig. 3. Dependence of the CL signal on HNO_3 and $KMnO_4$ concentrations. $KMnO_4$ concentration: a, 1m*M*; b, 3.3m*M*; c, 10m*M*; d, 30m*M*; ethanol concentration, 12.5%.

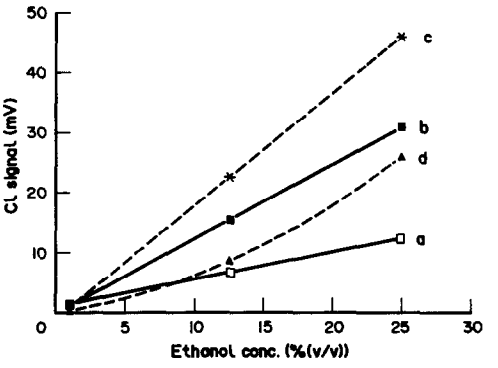

Fig. 4. Effect of $KMnO_4$ concentration on the shape of the calibration curve. a, 1m*M*; b, 3.3m*M*; c, 10m*M*; d, 30m*M*; HNO_3 concentration, 50% (v/v); ethanol concentration, 12.5%.

more significant at higher potassium permanganate concentrations and at lower nitric acid concentrations where the rate of consumption of potassium permanganate is slower. Note that the CL signal is largest with 30m*M* MnO_4^- only with 95% (w/v) nitric acid where the rate of reaction and the rate of disappearance of MnO_4^- is greatest.

Figure 4 shows calibration curves with different permanganate concentrations at a fixed nitric acid concentration of 50% (w/v). The slope of the calibration curve increases as the permanganate concentration increases from 1 to 10m*M*. However, the slope decreases when the permanganate concentration is further increased to 30m*M*. With 30m*M* MnO_4^-, nonlinearity is quite obvious and the calibration slope is less than that obtained with 3.3 or 10m*M* MnO_4^- due to greater absorption by the oxidant. At low ethanol concentrations, this attenuation effect is enhanced because the rate of disappearance of MnO_4^- is less. For example, for the lowest ethanol concentration tested [1% (v/v)], the CL signal with 10m*M* MnO_4^- is smaller than that observed with 1m*M* MnO_4^-. At higher ethanol concentrations, the opposite is true.

With 10m*M* potassium permanganate and 50% (w/v) nitric acid as a starting point, a three-dimensional simplex optimization was performed for a 1.0% (v/v) ethanol solution to find the nitric acid and potassium permanganate concentrations yielding the maximum CL signal. The optimum concentrations were found to be 10m*M* potassium permanganate and 95.0% (w/v) nitric acid. These conditions yielded a signal improvement of a factor of 12 relative to the starting vertex. The detection limit is 0.3%

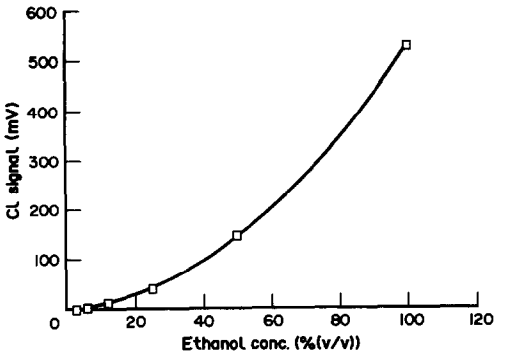

Fig. 5. Ethanol calibration curve with optimized reagent concentrations.

(v/v) based on twice the standard deviation of the blank (dark) signal.

Calibration data

Figure 5 shows a typical ethanol calibration curve under the optimized conditions. Least squares fitting of the data with first, second, and third order polynomials revealed that the second order fit was the best (*i.e.*, minimum standard error). Over a small range of ethanol concentration (±5%), a linear fit may be used.

Figure 6 shows the typical peaks obtained from the ethanol CL reaction. At greater ethanol concentrations, the CL reaction is faster and the peak maximum is higher.

Ethanol determination in gin

Samples of three different brands of gin were analyzed without dilution. Standards with ethanol concentrations of 35.0, 40.0, 45.0, and 50.0% (v/v) were also run. The ethanol concentration in each sample was determined with a two-point calibration curve [two standards that bracketed the concentration in the sample and that differed by 5% (v/v) ethanol] and a three-point calibration curve over a range of 10% (v/v) ethanol. A linear fit was used in both cases.

The results are summarized in Table 2. The bracketing technique yielded excellent results as did the unweighted three-point calibration curve. The results with weighted calibration curves were more in error than the unweighted ones. The RSD in the CL signal for the standards and samples was about 1%.

The standard addition method was also attempted with dilution of the samples to work in the region where the calibration curve is more linear. The standard addition procedure is not recommended because it yielded poorer results because the calibration curve is not perfectly linear.

Wine and beer were briefly studied and their alcohol content determined. The alcohol concentrations found by CL were approximately two-fold that of the expected ones. Apparently other species in these samples were oxidized and contributed to the CL signal. Chemiluminescence is observed under similar conditions with polyphenols.[16]

It was also confirmed that the CL signal from 10% (v/v) ethanol was depressed by about a factor of 2 with 0.01% (w/v) glucose present. Apparently the permanganate concentration is

reduced by reaction with the glucose and indicates that sugar would be a serious interferent for the determination of ethanol. The CL detection limit for glucose is about 0.5% (w/v) and the calibration curve is quite nonlinear.

CONCLUSIONS

The discovery of the chemiluminescence produced during the oxidation of ethanol by permanganate at low pH has lead to a new method to determine ethanol. This CL method is unique compared to most solution CL reactions in that the analyte is a necessary reagent for the CL reaction rather than an activator or acceptor that enhances the CL signal observed without the analyte. Although the CL reaction is class selective for hydroxide-containing compounds, it does not differentiate between many alcohols and phenols. Thus, it is best suited for samples in which the hydroxy-containing analyte is in sufficient excess with respect to other hydroxy-containing compounds or other species that react with permanganate. In this regard the CL determination of ethanol in gin proved to be a near ideal application of the technique. The accuracy was 1% or better with no sample preparation, even dilution, required. The method is rapid because the CL signal is obtained within 2 sec of adding the sample to the sample cell. The new CL reaction has the potential for use in determination of other alcohols or phenols. Some form of sample cleanup or prior oxidation of weaker reductants would be required in many cases. The CL reaction may also be suited for a post-column CL detection in HPLC.

SEPARATION OF THORIUM FROM LANTHANIDES BY SOLVENT EXTRACTION WITH IONIZABLE CROWN ETHERS

H. S. Du, D. J. Wood, Sadik Elshani and C. M. Wai*

(*Received* 28 *May* 1992. *Accepted* 30 *May* 1992)

Summary—Thorium and the lanthanides are extracted by α-(sym-dibenzo-16-crown-5-oxy)acetic acid and its analogues in different pH ranges. At pH 4.5, Th is quantitatively extracted by the crown ether carboxylic acids into chloroform whereas the extraction of the lanthanides is negligible. Separation of Th from the lanthanides can be achieved by solvent extraction under this condition. The extraction does not require specific counteranions and is reversible with respect to pH. Trace amounts of Th in water can be quantitatively recovered using this extraction system for neutron activation analysis. The nature of the extracted Th complex and the mechanism of extraction are discussed.

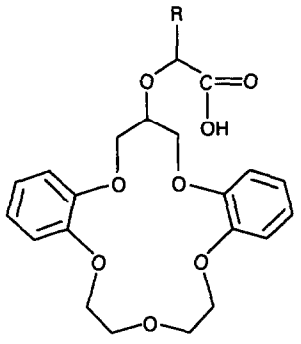
Thorium and the rare earth elements (REE) usually coexist naturally, *e.g.*, thorium is a common component of monazite and REE are generally present in thorite.[1] Separation of thorium from REE is therefore important for the analysis and production of these elements. Recent reports indicate that macrocyclic polyethers with a suitable cavity size and an attached ionizable functional group such as α-(sym-dibenzo-16-crown-5-oxy)acetic acid are selective for the extraction of trivalent lanthanide ions.[2] The extraction does not require specific counteranions and is reversible with respect to pH. In slightly acidic and neutral solutions, the extraction efficiencies of sym-dibenzo-16-crown-5-oxyacetic acid for the lanthanides are 2 to 3 orders of magnitude greater than the alkali metal and alkaline earth metal ions of similar size.[3] The crown ether carboxylic acid appears to behave like a bifunctional ligand which chelates with cations according to their size as well as their chemical nature. Chelation of ionizable crown ethers with thorium has not been reported in the literature. This paper compares the extraction behaviours of Th^{4+} and the two end members of the lanthanide series, La^{3+} and Lu^{3+}, with α-(sym-dibenzo-16-crown-5-oxy)acetic acid (**I**) and its phenyl substituted analogue α-(sym-dibenzo-16-crown-5-oxy)phenyl acetic acid (**II**) (Fig. 1). The nature of the extracted complexes and the conditions for the separation of Th from the lanthanide ions by solvent extraction with the crown ether carboxylic acids are discussed.

*Author for correspondence.

EXPERIMENTAL

α-(Sym-dibenzo-16-crown-5-oxy)acetic acid (**I**) was synthesized in our laboratory according to the procedure reported in the literature.[4,5] α-(Sym-dibenzo-16-crown-5-oxy)phenylacetic acid (**II**) was prepared from α-sym-hydroxydibenzo-16-crown-5 by reaction with α-bromophenylacetic acid in THF in the presence of sodium hydride as a base at room temperature for 24 hr. After that, water was added to destroy unconsumed sodium hydride and THF was evaporated in vacuo. The residue was dissolved in 100 ml of water and extracted with ether to remove unreacted crown alcohol. The water phase was acidified with 6*M* hydrochloric acid and extracted with methylene chloride. The methylene chloride phase was washed with water, dried with magnesium sulphate, and evaporated in vacuo to obtain the crown ether carboxylic acid (**II**). After recrystallization in ethylacetate-hexane, the final product is a white solid with a melting point range of 127–128.5°. Elemental analysis gave C, 67.46% and H, 5.67%, in good agreement with the calculated values for $C_{27}H_{28}O_8$ (C, 67.49%; H, 5.87%).

The nitrates of La^{3+} and Lu^{3+} were obtained from Alfa Chemical Company and that of Th^{4+} was from Mallinckrodt, Inc. All other chemicals used in the experiments were Baker Analyzed reagents. Demineralized water was prepared by



I. R=H α-(Sym-dibenzo-16-crown-5-oxy)acetic acid
II. R=C_6H_5 α-(Sym-dibenzo-16-crown-5-oxy)phenyl acetic acid

Fig. 1. Stuctures of the crown ether carboxylic acids: (I) α-(sym-dibenzo-16-crown-5-oxy)acetic acid and (II) α-(sym-dibenzo-16-crown-5-oxy)phenyl acetic acid.

passing distilled water through an ion exchange column (Barnsted Ultrapure Water Purification Cartridge) and a 0.2-μm filter assembly (Pall Corporation Utipor DFA).

Neutron activation analysis (NAA) was used to determine the concentrations of Th in the extraction experiments. Samples were generally irradiated for two hours in a TRIGA nuclear reactor with a steady flux of 6×10^{12} n/cm^2 sec. Neutron activation of ^{232}Th produces a short lived radioisotope ^{233}Th with a half life of 22.2 minutes. Its daughter product, ^{233}Pa ($t_{1/2} = 27$ days) further decays to ^{233}U with the emission of a 311 keV gamma which was used for quantitative determination of thorium. Radioisotope tracer techniques were used to measure the distribution of La^{3+} and Lu^{3+} in the extraction experiments. The nuclides ^{140}La ($t_{1/2} = 1.68$ days) and ^{177}Lu ($t_{1/2} = 6.74$ days) were produced by irradiation of La and Lu nitrates in the nuclear reactor. The 1596 keV gamma from ^{140}La and the 133 keV gamma from ^{177}Lu were used for quantitation. All samples were counted with a large volume ORTEC Ge(Li) detector with a resolution of 2.3 keV at 1332 keV gamma from ^{60}Co. The detector output was fed into an EG&G ORTEC ADCAM (Model 950A) multichannel analyzer and an IBM-XT computer was used for data processing. Details of the NAA procedures are given elsewhere.[6]

Extraction experiments usually involved 10 ml of a chloroform solution with a known concentration of the ligand and 10 ml of an aqueous solution containing the metal ions placed in a 30-ml Beckman polyvial with a fast-turn cap. The La and Lu solutions were spiked with the radioisotopes ^{140}La and ^{177}Lu, respectively. The mixture was shaken vigorously for 30 min with a wrist action mechanical shaker (Burrell model 75) at room temperature ($22 \pm 1°$). Dilute nitric acid and lithium hydroxide solutions were used for pH adjustment. The equilibrium pH of the aqueous phase was measured by an Orion model 701 pH meter with an Orion model 91-03 semimicro combination glass electrode. The distribution coefficients of La and Lu were determined by gamms counting 4-ml aliquots of the aqueous and organic phase which had been pipetted into 10-ml Beckmann polyvials. For NAA of Th in the aqueous phase, 1 ml of the aqueous solution was pipetted into a 2/5 dram polyethylene vial and heat sealed for neutron irradiation. A back-extraction procedure was used to remove Th from the organic phase into an acid solution prior to neutron activation. In this procedure, 4 ml of the organic phase was mixed with 4 ml of 1M nitric acid, and the mixture was shaken for 10 min to back-extract Th. Only 1 ml of the acid solution was placed in a 2/5 dram polyvial and heat sealed for neutron irradiation.

RESULTS AND DISCUSSION

The efficiency of extraction of Th^{4+}, La^{3+}, and Lu^{3+} from aqueous phase with α-(sym-dibenzo-16-crown-5-oxy)acetic acid in chloroform as a function of the equilibrium pH of the solution are given in Fig. 2(a). In these experiments, the concentration of the ionizable crown ether in the organic phase was fixed at $3 \times 10^{-3}M$, while that of Th^{4+} or trivalent lanthanide ions in the aqueous phase was $1 \times 10^{-4}M$. Sodium acetate at a concentration of $1 \times 10^{-3}M$ was used as a buffer in the aqueous solution. As shown in Fig. 2, the extraction of Th^{4+} occurs at a much lower pH than those of La^{3+} and Lu^{3+}. At pH < 2, Th^{4+} was not appreciably extracted, but the extraction efficiency increases rapidly at pH above 2. The extraction efficiency of Th^{4+} exceeds 95% at pH around 4 and is virtually quantitative at pH above 4.5. At pH above 7, however, the extraction efficiency for Th^{4+} tends to decrease. The extraction efficiencies of La^{3+} and Lu^{3+}, on the other hand, become appreciable at pH above 5 and reach a plateau around pH 6.5. The pH range for the extraction of trivalent lanthanide ions is shifted by approximately 3 pH units relative to that of Th^{4+}. This difference in pH constitutes a basis for their separation.

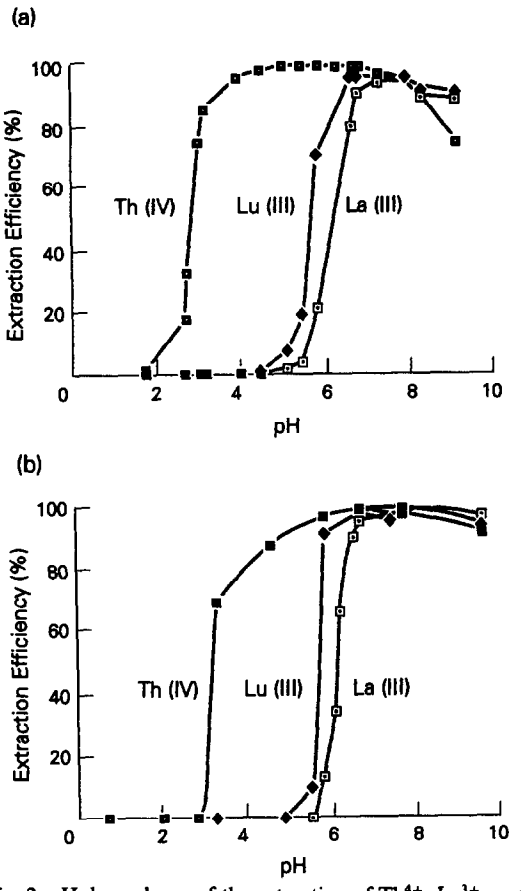


Fig. 2. pH dependence of the extraction of Th^{4+}, La^{3+}, and Lu^{3+} with (a) α-(sym-dibenzo-16-crown-5-oxy)acetic acid and (b) α-(sym-dibenzo-16-crown-5-oxy)phenyl acetic acid.

The cation to ligand ratio of the extracted species can be estimated from the variation of log *D vs.* log HL of the extraction experiments at a fixed pH, where *D* is the distribution coefficient and HL is the concentration of the ligand in the organic phase. Figure 3 shows the log *D vs.* log HL plots for Th^{4+} at pH 5 and for Lu^{3+} at pH 6.3. The slope for the Th^{4+} plot is 2.1 and that for the Lu^{3+} is 2.2, indicating that the ratio of cation to ligand of the extracted complexes is most likely 1:2 in both cases. Since the ligand carries one negative charge, the cationic species extracted into the organic phase must be doubly charged in order to satisfy the charge neutralization requirement. In the case of Th, it is known that hydrolysis of Th^{4+} occurs at pH around 3 leading to the formation of $Th(OH)^{3+}$ and $Th(OH)_2^{2+}$ species, with the latter being the major species in the pH range 3–5.[7] The extraction curve of Th corresponds to the pH range of the formation of $Th(OH)_2^{2+}$ species in the aqueous phase. The correlation suggests that the extracted form of Th is probably $Th(OH)_2L_2$. Hydrolysis of Lu^{3+} occurs at pH around 5–6 with the formation of $Lu(OH)^{2+}$ which also appears to be in the pH range for the extraction of Lu^{3+}. The extracted form of Lu is likely to be $Lu(OH)L_2$. The similarity in the extraction curves of Lu^{3+} and La^{3+} shown in Fig. 1 suggests that the trivalent lanthanide ions are probably all extracted by the ionizable crown ether via the same form.

The extraction curves for Th^{4+}, Lu^{3+} and La^{3+} with crown ether carboxylic acid (II) are given in Fig. 2(b). The results were obtained under experimental conditions similar to those described above for (I). Addition of phenyl group to the side arm of (I) changes the pK_a value and the solubility of the crown ether carboxylic acid in water. According to our measurements, the pK_a values for the crown ether carboxylic acids (I) and (II) are 4.7 and 5.2, respectively. Substitution of a phenyl group to acetic acid is known to lower the pK_a value from 4.77 to 4.31 because of the electron withdrawing of the phenyl group. The increase in

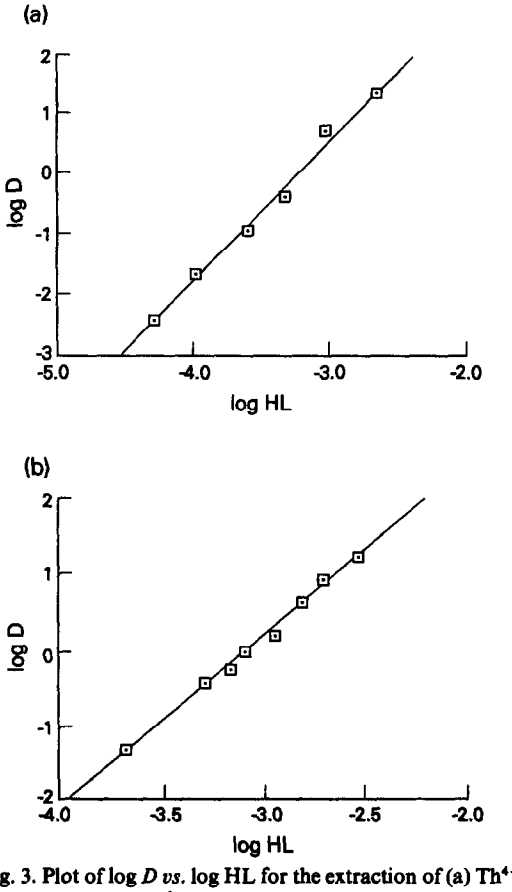

Fig. 3. Plot of log *D vs.* log HL for the extraction of (a) Th^{4+} (at pH 5) and (b) Lu^{3+} (at pH 6.3) with α-(sym-dibenzo-16-crown-5-oxy)acetic acid.

pK_a from (I) to (II) is opposite to the effect of α-substitution on the observed pK_a of acetic acid. It is possible that α-substitution in (II) tends to push the carboxylic acid group towards the cavity resulting in enhanced intramolecular hydrogen bonding with the cavity oxygen, thus increasing the strength of the O—H bond. This intramolecular hydrogen bonding must be stronger than the inductive effect of phenyl on the carboxylic acid. Substitution of phenyl in the side arm of (I) reduces the solubility of the macrocycle in water slightly. The solubility of (I) and (II) in distilled demineralized water at room temperature ($22 \pm 1°$) are $1.1 \times 10^{-4}M$ and $8.9 \times 10^{-5}M$, respectively, according to our experiments.

The extraction curve for Th^{4+} shifted slightly to higher pH from (I) to (II) and those for Lu^{3+} and La^{3+} showed little difference. At pH around 3–4 where Th^{4+} is extracted, the crown ether carboxylic acids should be present primarily in the organic phase. Thus, the extraction of Th^{4+} can be described by the following equation:

$$Th(OH)_2^{2+} + 2HL_{org} = Th(OH)_2L_2 + 2H^+ \quad (1)$$

The extraction constant (K_{ex}) according to equation (1) is given by

$$K_{ex} = [Th(OH)_2L_2]_{org}[H^+]^2/[Th(OH)_2^{2+}][HL]_{org}^2 \quad (2)$$

The concentration of $Th(OH)_2^{2+}$ is determined by the total Th species and the fraction of $Th(OH)_2^{2+}$ present in the aqueous phase. The fraction of $Th(OH)_2^{2+}$ can be calculated from the hydrolysis species of Th^{4+}, *i.e.*,

$$f = Th(OH)_2^{2+}/\Sigma Th(OH)_n^{(4-n)+} \quad (3)$$

with $n = 0$–4. In terms of stepwise hydrolysis constants (K_n) of Th^{4+}, f can also be expressed as

$$f = (K_1K_2/[H^+]^2)/(1 + K_1/[H^+] + K_1K_2/[H^+]^2 + \ldots) \quad (4)$$

The distribution coefficient D, which is the ratio of $[Th(OH)_2L_2]_{org}/\Sigma[Th(OH)_n^{(4-n)+}]_{aq}$, is related to pH and $[HL]_{org}$ by equation (5).

$$\log D = \log K + \log f - 2\log[H^+] + 2\log[HL]_{org} \quad (5)$$

According to equation (5), a plot of log D versus log $[HL]_{org}$ at a fixed pH should yield a straight line with a slope n which equals the ligand to Th ratio.

Both ionizable crown ethers (I) and (II) can be used for the separation of Th from the trivalent lanthanides. The difference in pH range for the extraction of Th and the lanthanides is slightly longer for (I). A suitable pH range for the separation of Th from the lanthanide ions using sym-dibenzo-16-crown-5-oxyacetic acid appears to be between 3–5 where Th is almost quantitatively extracted and the lanthanide ions are virtually not extractable. The best pH value for the separation is around 4.5 which can be easily controlled by means of an acetate buffer. To evaluate the separation efficiency under this condition, an experiment was performed with 50 ml of an aqueous solution at pH 4.5 containing $1 \times 10^{-4}M$ each of Th^{4+}, La^{3+} and Lu^{3+}. The aqueous solution was extracted with 20 ml of chloroform containing $3 \times 10^{-3}M$ α-(sym-dibenzo-16-crown-5-oxy)acetic acid in a separatory funnel. After phase separation, the organic phase was removed and washed with 10 ml of a pH 4.5 aqueous solution containing the acetate buffer. Both of the separated phases were analyzed for Th, Lu, and La by NAA. The purity of Th in the organic phase was found to be better than 99.9%. Only less than 0.1% of the lanthanides were found in the organic phase indicating essentially complete separation after one cycle of extraction. The Th extracted into the organic phase can be quantitatively stripped into a nitric acid solution, *e.g.*, 0.1–1M. For rapid back-extraction of Th from the organic phase for NAA, a 1M nitric acid solution was used.

The crown ether carboxylic acids can be used to preconcentrate trace amounts of Th from water for analytical purposes. To demonstrate this, between 100 and 400 μg of Th were spiked into 100-ml aliquots of a distilled water sample at pH 4.8. The solutions were extracted with 10 ml of chloroform containing $3 \times 10^{-3}M$ of α-(sym-dibenzo-16-crown-5-oxy)acetic acid. After shaking for 15 min, the organic phase was removed and washed. Thorium in the organic phase was back-extracted with 2 ml of a 1M nitric acid solution for NAA. The average recovery of Th was found to be $99.6 \pm 3.5\%$ based on the results of 5 samples. A preconcentration factor of 50 was obtained from this process. Higher preconcentration factors can be obtained by using a larger aqueous to organic phase ratio. Quantitative extraction of trace amounts of Th can be achieved if the aqueous to organic ratio does not exceed 20. The back-extraction step can provide further preconcentration. A total preconcentration factor of

4×10^2 can be easily achieved using the two-step extraction procedure.

This study demonstrates that crown ether carboxylic acids are capable of forming stable complexes with an actinide such as Th. The complexation depends on the oxidation state and hydrolysis species of the actinide present in the aqueous phase. The extraction efficiency thus is a strong function of pH which may be used as a basis for their separation. These types of ionizable crown ethers are potential selective chelating agents for solvent extraction separation of actinides and lanthanides.

SULPHATE ANALYSIS IN URANIUM LEACH IRON(III) CHLORIDE SOLUTIONS BY INDUCTIVELY COUPLED ARGON PLASMA SPECTROMETRY

I. NIRDOSH,* S. LAKHANI† and M. Z. MOHD YUNUS‡
Department of Chemical Engineering, Lakehead University, Thunder Bay, Ontario, Canada P7B 5E1

(*Received* 20 *January* 1992. *Revised* 2 *June* 1992. *Accepted* 3 *June* 1992)

Summary—Inductively coupled Argon Plasma Spectrometry is used for the indirect determination of sulphate in iron(III) chloride leach solution of Elliot Lake uranium ores via addition of a known amount of barium ions and analyzing for excess of barium. The ore contains ~7 wt% pyrite, FeS_2, as the major mineral which oxidizes to generate sulphate during leaching with Fe(III). The effects of pH, the concentrations of Fe(III) and chloride ions and for presence of ethanol in the test samples on the accuracy of analysis are studied. It is found that unlike the Rhodizonate method, removal of iron(III) from or addition of ethanol to the test sample prior to analysis are not required. Linear calibration curves are obtained.

For obtaining environmentally acceptable non-radiotoxic uranium mill tailings, aqueous solutions of iron(III) chloride acidified with the same concentration of hydrochloric acid have proved effective in the simultaneous leaching of radium-226 along with uranium from the ores.[1] These solutions contain nearly 5500 to 27,200 mg/l Fe(III) and 14,000 to 71,000 mg/l chloride. However, some ores contain high concentrations (~7 wt%) of sulphidic minerals, mostly pyrite, which are oxidized to sulphate by the Fe(III) present in the leach solution and concentration of sulphate in the solution gradually builds up upon repeated recycling of the solution for leaching of fresh ore.[1] This increase in the sulphate concentration causes the precipitation of radium sulphate or the coprecipitation of barium radium sulphate during leaching. The precipitate deposits on the finely divided solids whereby the mill tailings acquire low levels of radiotoxicity due to radium-226 and become environmentally hazardous, defeating the main purpose of leaching the ore with iron(III) chloride.

Nirdosh *et al.*[2] studied the removal of sulphate from iron(III) chloride leach solutions of Elliot Lake uranium ores using anion exchange. During this study sulphate was analyzed by the spectrophotometric method described by Vogel[3] wherein a known amount of barium is added to the test sample as aqueous barium chloride in quantities larger than that stoichiometrically needed for precipitating with sulphate. An ethanol matrix is maintained for the stability of the barium sulphate and sodium rhodizonate solution is added to give a coloured complex with the excess barium not precipitated with sulphate. The colour intensity is measured spectrophotometrically as 520 nm and the amount of the residual barium is determined from a calibration curve. The amount, and hence the concentration, of sulphate is then back calculated by difference. The calibration curve can also be plotted directly in terms of sulphate concentration.

Although straight forward, the method is tedious in that it requires complete removal of Fe(III) and other cations by ion-exchange prior to analysis in order to eliminate any possible interference by their coloured complexes such as the iron(III) rhodizonate.

Because this analytical method is primarily based on the quantitative measurement of barium ions in solution, it was thought worthwhile to explore if another simpler method of barium analysis by the Inductively Coupled Plasma Atomic Emission Spectrometry (ICP–AES) may be used without the need for the separation of interfering ions, such as Fe(III), from the test sample prior to analysis.

This paper presents investigations leading to a standardized analytical procedure for the quantitative determination of sulphate by ICP–AES in the presence of Fe(III) and chloride ions. The possible interference in analysis by only these ions was studied because of their usually high concentrations in the iron(III) chloride leach solutions of the Elliot Lake uranium ores, as noted above.

EXPERIMENTAL

A standard solution of barium containing 500 mg/l barium was prepared by dissolving barium chloride bihydrate in demineralized water. From this stock solution, samples were prepared containing varying amounts of barium by dilution with demineralized water. To some of these samples, a known (less than stoichiometric) quantity of ammonium sulphate was added to precipitate some barium as barium sulphate leaving a known residual barium concentration in solution. This was done to check if barium precipitated quantitatively. An Ashland unit model Jarrell Ash ICAP 9000 Inductively Coupled Argon plasma Spectrometer was used for analyzing barium in solution. The unit had an Argon purge of the optical path with other specifications as: forward power = 1000 watts; reflected power < 5 watts; plasma argon flow = 10 ml/min; auxiliary argon flow = 1.2 l/min; nebulizer argon flow = 0.6 l/min; sample uptake = 0.6 ml/min; and observation height = 15 mm above work coil. The analytical wavelength and detection limit for barium were respectively 493.41 nm and 10 μg/l (10 ppb). Calibration curves were prepared by plotting concentration of barium in the solution versus intensity ratio which is defined as the ratio of the intensity of light produced by the emission spectra to the instrument constant. The instrument constant is given by 1000/exposure time which is usually less than 10 sec. The effects of the addition of 95% ethanol, sample pH and the concentration of the Fe(III) or chloride ions in the sample were investigated by the methods outlined below. The concentration of Fe(III) and chloride were varied by adding iron(III) chloride hexahydrate or sodium chloride, respectively, to the standard barium solutions. All chemicals were Fisher Brand Analytical Reagent grade. The solid symbols in all the diagrams represent identical duplicate samples analyzed to check the reproducibility of results. Although many duplicate samples were prepared and analyzed, only a few have been added in the figures for the sake of clarity. In all the equations in the following sections the concentration of barium is expressed in the units of mg/l.

RESULTS AND DISCUSSION

The effect of ethanol addition

Varying amounts of the 500 mg/l barium standard solution in demineralized water were taken in 50 ml standard flasks so as to obtain barium concentrations between 0 to 100 mg/l in the final 50-ml solution. A 19-ml volume of 95% ethanol was added to each flask. This is the usual amount of ethanol added to samples for analysis via the rhodizonate method.[3] The volume was then made up to 50 ml with demineralized water. The flasks were repeatedly inverted to mix the contents and the samples were analyzed for barium.

The results are plotted in Fig. 1 and indicate a considerable scatter with no linear region in the calibration curve. During the course of analysis it was observed that ethanol caused a drift in the instrument which is considered to be due to the "memory effect", *i.e.*, the flame indicated the presence of ethanol (bright yellow flame) even up to 5 minutes after the sample had been analyzed. These results show that the presence of ethanol leads to interference and should be avoided.

The effect of pH

The suitability of the method was investigated at pH values 1 and 4. These pH values were selected because the iron(III) chloride leaching

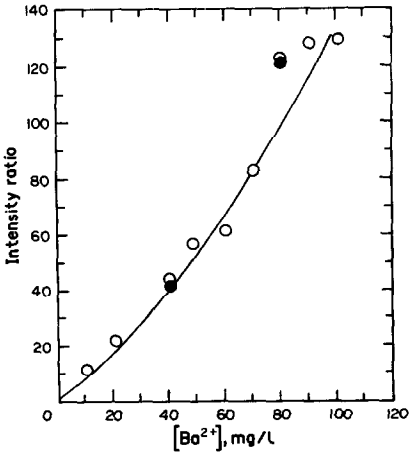

Fig. 1. Variation of intensity ratio with barium concentration in the presence of ethanol.

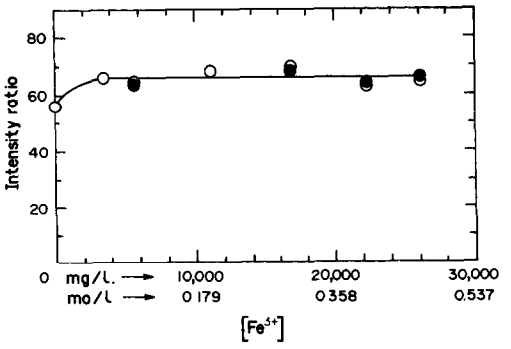

Fig. 2. Effect of Fe(III) concentration on the intensity ratio.

solutions of uranium ores are usually at pH $\leq$ 1 and the rhodizonate method of sulphate analysis works best at pH 4.[2] In each case, eleven test samples were prepared. Aliquots of the standard sulphate solution were taken in 50-ml standard flasks. Known excess amounts of the standard barium solution were then added to precipitate all the sulphate and leave free residual barium in solution. The volume was then made up with pH 1 or pH 4 solution of hydrochloric acid. The contents were thoroughly mixed by shaking the flasks. The precipitate was left to settle and then vacuum filtered using a Millipore unit with a 0.45-μm filter medium. The filtrate was then analyzed for barium. The results indicated that corresponding samples for both pH 1 and pH 4 gave intensity ratios of within $\pm$2–4 units of each other and, in the barium concentration range of 20–100 mg/l, the calibration curves could be described by the following linear equation:

$$\text{Intensity Ratio} = 4.51\ [Ba^{2+}]. \qquad (1)$$

This indicates that pH $\leq$ 4 has little effect on the analysis.

The effect of Fe(III)

Samples 5 ml of a 50 mg/l standard sulphate solution were taken in 50-ml flasks. Aliquots of 1*M* iron(III) chloride solution were added to give varying amounts of Fe(III) in the 50-ml solutions obtained. A 5-ml volume of the 500 mg/l barium standard solution was then added to each flask and the total volume was made up with demineralized water. The contents were mixed and the filtrates analyzed for barium. The results are plotted in Fig. 2. These results indicate that the intensity ratio is not significantly affected by the presence of Fe(III) in concentrations 3350–27,200 mg/l in the test samples.

Another set of calibration data were obtained by analyzing barium in two sets of standard samples. In one set, varying amounts of barium were used whereas in the second set, a fixed amount of 0.02*M* Fe(III) was added to the standard barium solutions of the same barium concentrations as in the first set. The results indicated that the intensity ratios for all the samples in both the sets were nearly the same and the calibration curves could be given by mutually superimposing linear lines given by the equation

$$\text{Intensity Ratio} = 1.08\ [Ba^{2+}]. \qquad (2)$$

These results confirm the findings obtained from Fig. 2 that between 3350–27,200 mg/l concentration range, the Fe(III) ions do not interfere with the analysis of barium.

The effect of chloride

The method was the same as described in Section 3.3 except that instead of the Fe(III) solution, varying amounts of a 3.9*M* standard sodium chloride solution were added to the flasks so as to give samples of chloride concentrations of 0 to 70,000 mg/l. The results are plotted in Fig. 3. A duplicate set of samples was prepared in an identical manner and barium was analyzed with the ICP–AES unit fitted with a high-solids' nebulizer instead of the usual cross-flow nebulizer. The results are included in Fig. 3 for comparison.

The results indicate that chloride ions showed a significant effect on the intensity ratio in the range of 0 to 20,000 mg/l for both types of nebulizers. The results with the cross-flow nebulizer indicate that the effect was more predominant up to a chloride concentration of 20,000

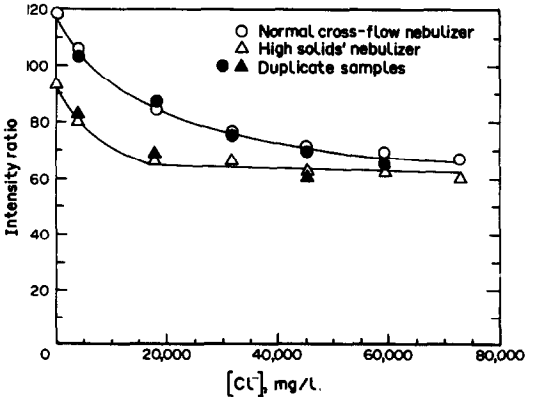

Fig. 3. Effect of chloride concentration on the intensity ratio.

Table 1. Comparison of $[SO_4^{2-}]_{analyzed}$ and the initially known $[SO_4^{2-}]_{known}$ values in demineralized water and aqueous solutions of 0.1M $FeCl_3$

$[SO_4^{2-}]_{known}$, mg/l	$[SO_4^{2-}]_{analyzed}$, mg/l		% Deviation	
	Demineralized water	$FeCl_3$ solution	Demineralized water	$FeCl_3$ solution
40	39	—	2.5	—
60	59	57	1.7	5.0

100	100	104	0.0	−4.0
200	211	213	−5.5	−6.0
300	315	311	−5.0	−3.7
400	412	412	−3.0	−3.0
500	497	492	0.6	1.6

— = not done.

ml/l, after which there was a gradual tapering of the interference. However, with the high-solids' nebulizer, the interference was significantly reduced at chloride concentrations 20,000 mg/l, as is indicated by the lower curve in Fig. 3.

A separate set of calibration data were obtained with the cross-flow nebulizer by preparing samples that all had a chloride concentration of 30,000 mg/l. In this set of analyses, the instrument was flushed thoroughly after testing each sample. The results gave a linear calibration curve which could be described by the equation

$$\text{Intensity Ratio} = 1.31\ [Ba^{2+}]. \qquad (3)$$

These results indicate that high concentrations of chloride ions do not interfere with barium analysis provided a high-solids' nebulizer is used or with the cross-flow nebulizer, the instrument is flushed thoroughly after each test.

Sulphate analysis by the addition of barium ions

A 10-ml volume of a 1430 mg/l stock barium solution was taken in 100-ml standard flasks. To these, varying amounts of a 500 mg/l standard sulphate solution were added so as to obtain 40–500 mg/l sulphate. Two identical sets were prepared. The volumes were then made up with either demineralized water (first set) or a solution of 0.1*M* iron(III) chloride (second set). The barium sulphate was allowed to precipitate and the contents were filtered through a 0.45 μm filter medium. The filtrates were analyzed for barium by ICP–AES and barium concentrations were obtained from appropriate calibration curves. The concentration of sulphate was then calculated and the values, $[SO_4^{2-}]_{analyzed}$, are given in Table 1 along with the initial known sulphate concentrations, $[SO_4^{2-}]_{known}$, of the corresponding samples, and the percentage deviations.

These results indicate that (i) in general there is good agreement between the known and the calculated sulphate concentration values; and (ii) except for one sample containing 200 mg/l sulphate, the deviation is $\leq \pm 5\%$. Within the experimental errors, these deviations also indicate that barium sulphate precipitated quantitatively in the samples tested.

CONCLUSIONS

ICP–AES can be used for the quantitative determination of sulphate in iron(III) chloride leach solutions of uranium ores by precipitating the sulphate in the presence of known excess quantity of barium, analyzing for free barium and back calculating the sulphate concentration.

Interference by Fe(III) ions in concentrations of 3350–27,200 mg/l is insignificant and removal of Fe(III) from solution prior to analysis is not needed rendering the sample preparation much simpler than in the rhodizonate method.

Interference by chloride ions is insignificant at chloride concentrations 20,000 mg/l with a high-solids' nebulizer. When using a cross-flow nebulizer, flushing the instrument between each test is important to prevent interference by chloride.

Presence of ethanol in the test solution causes interference and should be avoided.

The reproducibility of results is within ± 2–4 intensity units and the accuracy is $\pm 5\%$.

The method can be used for aqueous solutions of pH < 4 and containing high concentrations of Fe(III) ($\approx$27,200 mg/l) and chloride ($\approx$71,000 mg/l) usually encountered in commercial oxidative iron(III) leach solutions of

ores with pyrite or other sulphides as significant gangue minerals.

Summary—An analytical method based on microwave decomposition and flow injection analysis (FIA) coupled to hydride generation atomic absorption spectrometry (HGAAS) is described. This is used to differentiate arsenite [As(III)], arsenate [As(V)], monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA) from organoarsenic compounds usually present in seafood. Without microwave digestion, direct analysis of urine by HGAAS gives the total concentration of As(III), As(V), MMA and DMA because organoarsenic compounds such as arsenobetaine, usually found in most seafood, are not reducible upon treatment with borohydride and therefore cannot be determined by using the hydride generation technique. The microwave oven digestion procedure with potassium persulfate and sodium hydroxide as decomposition reagents completely decomposes all arsenicals to arsenate and this can be measured by HGAAS. Microwave decomposition parameters were studied to achieve efficient decomposition and quantitative recovery of arsenobetaine spiked into urine samples. The method is applied to the determination of urinary arsenic and is useful for the assessment of occupational exposure to arsenic without intereference from excess organoarsenicals due to the consumption of seafood. Analysis of urine samples collected from an individual who ingested some seafood revealed that organoarsenicals were rapidly excreted in urine. After the ingestion of a 500-g crab, a 10-fold increase of total urinary arsenic was observed, due to the excretion of organoarsenicals. The maximum arsenic concentration was found in the urine samples collected approximately between 4 to 17 hr after eating seafood. However, the ingestion of organoarsenic-containing seafoods such as crab, shrimp and salmon showed no effect on the urinary excretion of inorganic arsenic, MMA and DMA.

Arsenite [As(III)], arsenate [As(V)], monomethylarsonic acid (MMA), and dimethylarsinic acid (DMA) are widely present in the natural environment[1] and their relative toxicities are As(III) > As(V) > MMA > DMA.[2,3] Many organoarsenic compounds present in the biological system, however, are much less toxic. For example, arsenobetaine is found in many seafoods as the major arsenic compound and it is essentially non-toxic.[4,5] The ubiquitous presence of arsenic compounds in biological systems results in a need for methods that can accurately and easily assess their environmental impact.

A convenient approach to assess occupational exposure is through chemical analysis of urine because urine samples are readily obtained non-invasively. Such an analysis can provide important information about exposure to many chemical species and information about many of the body's metabolic functions. As early as 400 B.C., the Greek physician, Hippocrates, pointed out the importance of urine examinations in health and disease.[6–8] Diagnosing disease by visual examination of urine—referred to as uroscopy—was very popular among ancient medical practitioners. Although they lacked sophisticated equipment, they were able to obtain diagnostic information from such basic observations as color, volume, turbidity, viscosity, odor, and even sweetness. Interestingly, these same urine characteristics are still reported in today's clinical laboratories, although modern urinalysis includes not only the physical examination of urine, but also chemical analysis. In addition to routine chemical analysis, the determination of trace elements in urine has gained much attention[9–11] and has become a useful tool for health assessment.

Urinary excretion is the major pathway for the elimination of arsenic compounds from the body.[12–17] Therefore, urinary arsenic determination is important for assessing occupational exposure.[18–20] Excess exposure to arsenic can occur in occupations such as mining, smelting, glass making, and pesticide manufacture. In the work environment, the exposure to As(III) is mainly from As_2O_3 in non-ferrous smelters and in glass making. Exposure to arsenate arises

*Author for correspondence.

from its use in insecticides, cotton desiccants, and wood preservatives. Exposure to MMA and DMA is due to their use as selective herbicides. Rapid urine excretion of these arsenic compounds from humans,[13,14,17,20–22] monkeys,[15] dogs,[23] and hamsters[24] has been reported. The biotransformation of inorganic arsenic in the body, to DMA and MMA, has also been studied extensively.[13,21,24–29]

Unlike those from occupational exposure, dietary sources of arsenic, particularly from seafood, generally contain more complex organoarsenicals such as arsenobetaine, $(CH_3)_3As^+CH_2COO^-$. Arsenic ingested in this form is not metabolized and is excreted unchanged with a very short half-time.[5,12,16,17] Since arsenic compounds ingested from both occupational exposure and dietary sources contribute to the urinary arsenic excretion, the determination of total arsenic concentration in urine cannot be used to assess oocupational exposure to arsenic. In fact, it has been reported[18] that the total arsenic concentration in urine increased by a factor of 20–30 after ingestion of 100 g of shrimp. Because the two groups of arsenic species, from occupational exposure and from dietary intake of arsenic, are different, it should be possible to develop an appropriate analytical method to distinguish the contributions to urinary arsenic from these two sources. This was the objective of the present study.

In a previous publication,[30] we described a rapid method for arsenic determination based on the decomposition of organoarsenicals by potassium persulfate and sodium hydroxide with the aid of a microwave oven and subsequent determination by hydride generation atomic absorption spectrometry (HGAAS). The organoarsenicals were completely decomposed to arsenate. When the microwave oven was off, only As(III), As(V), MMA, and DMA were measured because organoarsenicals such as arsenobetaine are "hidden" and do not form hydrides upon treatment of borohydride under the commonly used analytical conditions. The difference between the two measurements with microwave power on or off accounts for the hidden organoarsenicals. This method is simple and rapid, with a sample throughput of approximately 100–120 analysis per hour and can be successfully applied to the decomposition of organoarsenicals in demineralized water and seawater. However, when arsenobetaine was spiked into a urine sample the recovery was approximately 40% due to incomplete decomposition. To solve this problem, we investigated simple approaches to achieve the complete decomposition of arsenic compounds in a complex matrix such as urine. Longer decomposition times and higher concentrations of decomposition reagents were found to be necessary. Therefore, a batch type digestion prior to the determination was developed to completely decompose the arsenic compounds in urine. Quantitative recoveries of organoarsenic and inorganic arsenic spiked into urine are achieved. The method developed here is successfully applied to the analysis of urinary arsenic. Urine samples from a research worker who ingested crab meat are analyzed and the excretion patterns of inorganic arsenic and organoarsenic compounds are compared.

EXPERIMENTAL

Instrumentation

A Varian Model AA-1275 atomic absorption spectrophotometer equipped with an air-acetylene flame atomizer, an open-ended T-shaped quartz tube (11.5 cm × 0.8 cm i.d.) mounted in the AA flame, a domestic microwave oven (Toshiba, Japan), and a lab-made new hydride generator as described previously[30] were used throughout this work. (Safety precaution: two holes drilled on one side of the microwave oven for sample inlet and outlet should be shielded with proper metal fittings to prevent any possible microwave leakage.) The experimental layout for flow injection analysis (FIA)/on-line microwave digestion coupled to HG AAS measurement is the same as discussed previously.[30] For most of the present work, however, a batch type microwave digestion was used, and the microwave oven was used off-line. Both the undigested and the digested samples were analyzed by using FIA/HGAAS.

Samples

Urine samples were collected from a 30-year old, healthy male working in an analytical chemistry research laboratory. Live crabs were purchased from a local fish market in Vancouver (Canada) and were steam cooked. After the cooked crab meat was eaten, urine samples were collected for the following 2–3 days. The samples were stored at 4° and were analyzed within 48 hr. No preservative was added.

Table 1. Experimental conditions for microwave digestion and hydride generation

	FIA/HGAAS Direct Analysis	Batch type microwave digestion FIA/HGAAS
Digestion	no	microwave digestion
Urine Samples	100 μl	40 ml
$K_2S_2O_8$	none	4.5 g

HCl Flow Rate	3.4 ml/min	3.4 ml/min
$NaBH_4$ Conc.	0.65*M* in 0.1*M* NaOH	0.65*M* in 0.1*M* NaOH
$NaBH_4$ Flow Rate	3.4 ml/min	3.4 ml/min
Carrier Gas Flow	160 ml/min	160 ml/min
Cysteine	1.0%	none

Reagents

Standard solutions of As(III), As(V), MMA, DMA and arsenobetaine were prepared as described previously.[30] Sodium borohydride (Aldrich) solutions in 0.1*M* sodium hydroxide (BDH) were prepared fresh and filtered prior to use. Potassium persulfate (BDH) solutions in various concentrations of sodium hydroxide were prepared fresh daily for the FIA/microwave digestion/HGAAS determination. For the batch type microwave digestion, appropriate amounts of potassium persulfate and sodium hydroxide were directly added in their solid form into digestion vessels (Erlenmeyer flasks) containing sample solutions. Appropriate amounts of *L*-cysteine (Aldrich) were directly added and dissolved into the test solution when needed.

Procedures

FIA/HGAAS. A 100-μl sample was injected into a carrier stream (H_2O) by means of a Rheodyne six-port sample injection valve fitted with a 100-μl sample loop. The injected sample along with the carrier subsequently met with a continuously introduced hydrochloric acid stream and sodium borohydride stream. Upon mixing with sodium borohydride, hydride generation takes place and continues in the gas/liquid separator apparatus as discussed previously[30] in detail. Inside this apparatus, a continuous flow of carrier gas assists mixing and reaction and subsequently carries hydrides to the quartz tube mounted in the air-acetylene flame for the AA measurement. A peak signal was recorded by using an integrator (Hewlett–Packard 3390A) capable of both peak height and peak area measurements. It was found that the peak height measurement gave better reproducibility and lower standard deviation. Thus the peak height of the signal was measured for quantitation unless stated otherwise.

As(III), As(V), MMA, and DMA have been reported to have different sensitivities upon hydride generation;[31–33] and their maximum sensitivities appear at very different acid concentrations as reaction media. Although compromised acid conditions have often been used, considerable error was present particularly when one standard was used to represent the four species.[32,33] We have found that the use of cysteine in the reaction media shifts the optimum acid concentration to a much lower level;[34–36] and that under the same optimum acid concentration all the four arsenic species give the same maximum sensitivity.[37] Thus the determination error which otherwise arises from the use of compromised condition is eliminated. Upon optimization, 0.1 g of cysteine was added to every 10-ml of urine sample for the determination of As(III), As(V), MMA, and DMA in the urine. For the determination of total arsenic, the microwave decomposition was applied, and arsenic compounds were all converted to arsenate as confirmed previously[30] by using the molybdenum blue colorimetric method. Therefore there is no need to add cysteine in this case, and the optimum acid concentration for determining arsenate was chosen.

The experimental conditions are summarized in Table 1.

FIA/On-line microwave decomposition/HGAAS. A 100-μl sample was injected into the decomposition reagent stream containing potassium persulfate and sodium hydroxide. The stream carries the sample into a 3-m knotted Teflon coil (0.5 mm i.d.) located in the microwave oven which operates at full power (500 W). After microwave decomposition, the solution

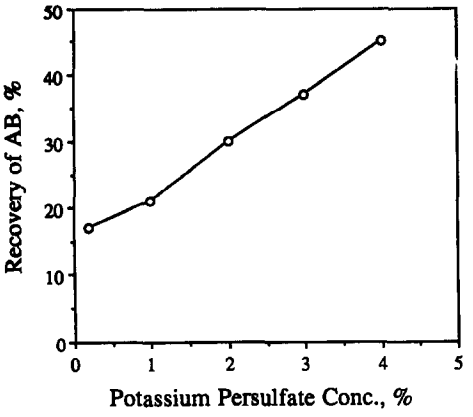

Fig. 1. Effect of $K_2S_2O_8$ concentration on recovery of arsenobetaine in urine by FIA/continuous microwave decomposition/HGAAS measurement.

flow mixes with the continuous acid and borohydride feeds. Hydride generation and gas/liquid separation take place and the evolved hydrides are introduced into the flame-heated quartz tube for AA measurement. The experimental conditions for this mode of operation are the same as described previously.[30]

Batch type microwave decomposition. A urine sample or standard solution (40 ml) and the appropriate amounts of potassium persulfate and sodium hydroxide (Table 1) were combined in a 125-ml Erlenmeyer flask. Six of such sample-containing flasks were placed in the microwave oven at one time. The microwave oven was then operated at full power for 3 min followed by a 2–3 min cooling period. This heating and cooling sequence was repeated for another four cycles. After the samples were cooled to room temperature, they were each diluted to 50 ml with demineralized water. The determination of arsenic was carried out by using FIA/HGAAS as described above. Note that excess potassium persulfate is used. This is not completely soluble in the urine sample prior to the digestion, however, the excess potassium persulfate decomposes in the presence of sodium hydroxide under microwave heating and there is no solid residue present after the decomposition is complete.

RESULTS AND DISCUSSION

By using the on-line microwave decomposition system described previously,[30] initial attempts to completely decompose organoarsenicals in a urine sample matrix were made by optimizing concentrations of the decomposition reagents, potassium persulfate and sodium hydroxide. Figures 1 and 2 show recoveries of spiked arsenobetaine (AB) into a urine sample, determined by HGAAS after on-line microwave decomposition using persulfate and sodium hydroxide of various concentrations. Recovery values were obtained by comparing signals from spiked AB with those of the same amount of an As(V) standard solution. As demonstrated in Fig. 1, increasing the concentration of potassium persulfate from 0.1 to 4% results in continuous improvement of recoveries with a maximum recovery of 45% when the potassium persulfate concentration is 4%. Further increase of persulfate concentration was not studied because of the limited solubility of potassium persulfate in water. Similarly, increasing the sodium hydroxide concentration from 0.1 to 2*M* also leads to higher recoveries in the determination of the spiked AB in the urine sample as shown in Fig. 2. Although recoveries are improved at these higher reagent concentrations, the desired quantitative recoveries are not achieved due to incomplete decomposition of AB. Therefore, in addition to higher concentrations of decomposition reagents, a longer decomposition time appears to be necessary in order to achieve complete decomposition of AB and thereby a quantitative recovery. Use of longer decomposition coils (5 m and 12 m as compared to 3 m used in the previous work) were studied in an attempt to achieve complete decomposition; and recoveries of spiked AB into urine were improved. However, with longer decomposition coils, a higher noise level and poorer signal stability were shown. To solve this problem, a batch mode

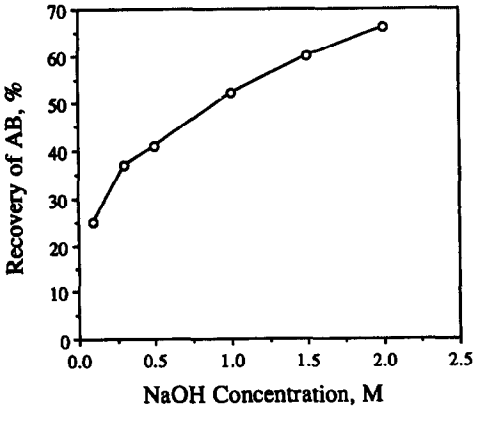

Fig. 2. Effect of NaOH concentration on recovery of arsenobetaine in urine by FIA/continuous microwave decomposition/HGAAS measurement.

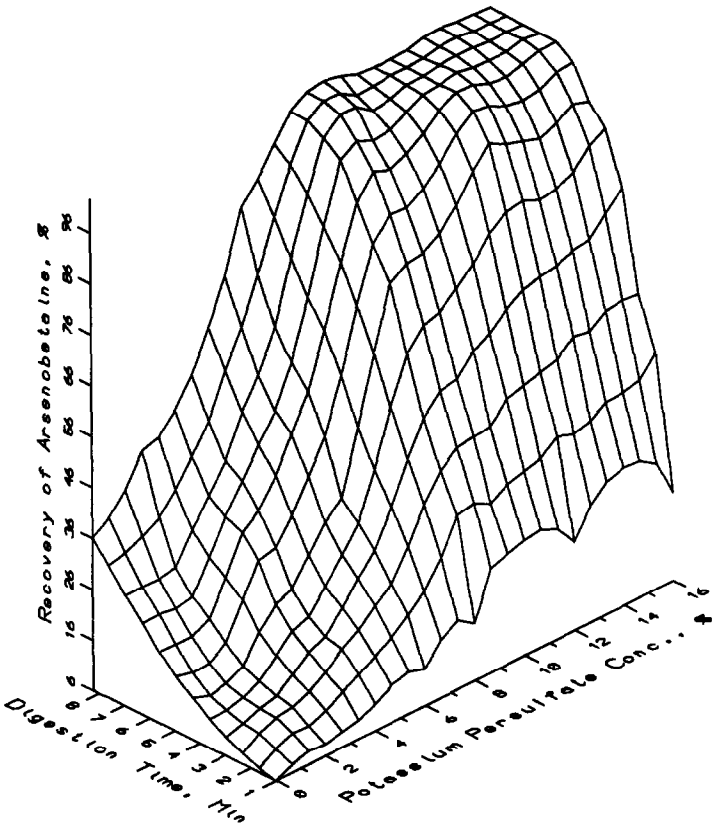

Fig. 3. Effect of microwave digestion time and $K_2S_2O_8$ concentration on recovery of arsenobetaine in urine by batch type microwave digestion and FIA/HGAAS determination.

microwave oven digestion followed by the determination by using FIA/HGAAS was chosen for the rest of this work.

Effect of decomposition time and concentrations of potassium persulfate and sodium hydroxide

Arsenobetaine (AB) is the major arsenic compound found in most seafood, it is excreted unchanged in urine after ingesting seafood, and it is one of the organoarsenic compounds that is most difficult to decompose to a form amenable to hydride generation. AB was chosen as a model compound in order to study the decomposition of organoarsenicals in urine. A measured amount of AB was spiked into a urine sample and the arsenic concentration was measured by using FIA/HGAAS after batch type microwave digestion in open vessels. Recovery was measured by comparing signals obtained from the spiked AB with those of the same amounts of an As(V) standard solution. For this optimization study, two samples at a time were placed in the microwave oven.

The effect of decomposition time and the amount of potassium persulfate on the recovery of AB spiked into a urine sample is shown in Fig. 3. By studying these two factors together, a possible dependence on each other would be revealed. In the present situation, increasing both the digestion time and the concentration of persulfate is beneficial to a quantitative recovery. As the decomposition time and the concentration of potassium persulfate increase, recoveries of AB approach unity. This is because a longer decomposition time and a higher concentration are useful for complete decomposition of AB in the urine sample. The decomposed arsenic product was confirmed to be arsenate,[30] an arsenic compound that readily forms arsine on treatment with borohydride. A contour diagram clearly showed that quantitative recoveries of AB are achieved when the amount of potassium persulfate added is in the range of 10–16 g per 100 ml of urine and the decomposition time is longer than 5 min.

The effect of the concentration of sodium hydroxide and the decomposition time was also studied by varying both of these factors, and the recovery results of AB are presented in Fig. 4. Similarly, recovery of spiked AB improves with

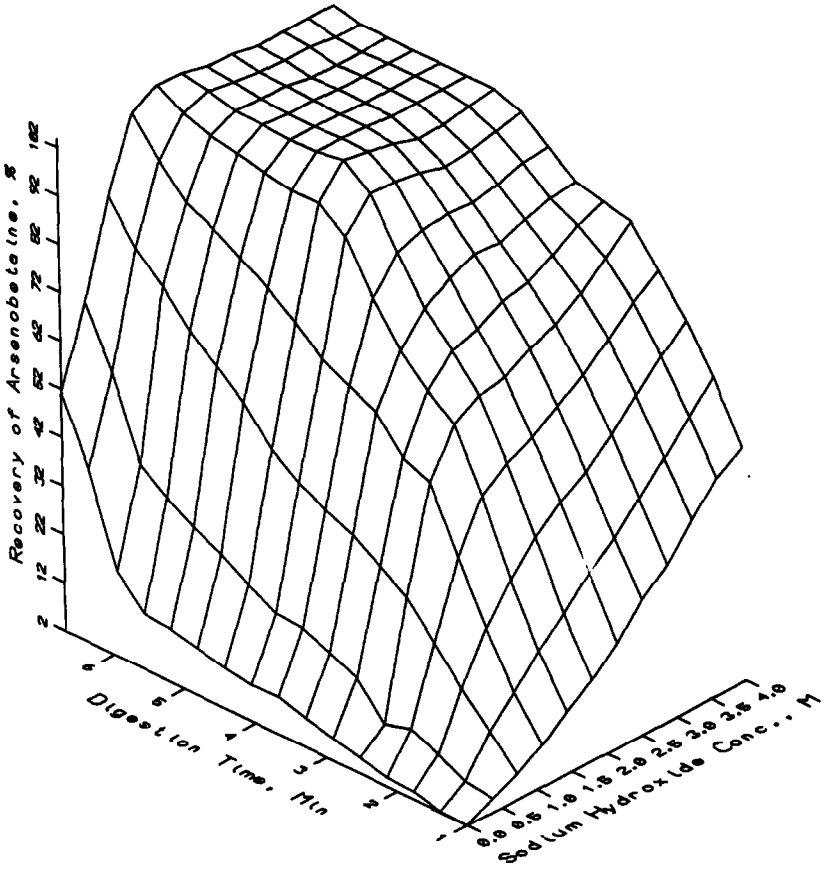

Fig. 4. Effect of microwave digestion time and NaOH cencentration on recovery of arsenobetaine in urine by batch type microwave digestion and FIA/HGAAS determination.

an increase of the sodium hydroxide concentration from 0.1 to 1.5*M* and the decomposition time from 0.5 to 4 min. Complete recovery is achieved with a sodium hydroxide concentration of above 1.5*M* and a microwave decomposition of longer than 4 min.

A six minute microwave decomposition time, 1.7*M* sodium hydroxide and 11% potassium persulfate were chosen as optimum for digesting two samples at one time to ensure complete decomposition and quantitative recoveries of organoarsenicals in urine samples. For a batch of 6 samples a total of 15 min proved to be sufficient and was adopted for further applications.

Calibration and standard addition

For comparison, both As(V) and AB were used as standards in obtaining calibration curves. As shown in Fig. 5, calibration curves obtained from As(V) and AB are superimposable, indicating that AB is completely decomposed to arsenate which forms arsine upon treatment with borohydride in the same way as does As(V). Therefore, either one of them can be used as standard for quantitative analysis. For convenience, As(V) was chosen.

To estimate any possible interference from the sample matrix, a standard addition study

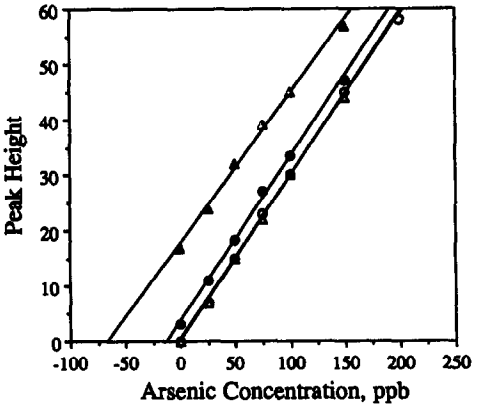

Fig. 5. Comparison of calibration curves of As(V) (○) and AB (△) and standard addition curves of As(V) (●) and AB (▲) spiked into a urine sample. For AB determination, both standards and spiked samples underwent microwave digestion; whereas no digestion was needed for As(V) determination.

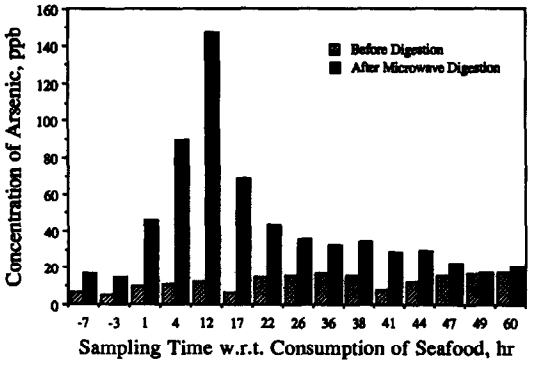

Fig. 6. Concentration of arsenic in urine samples collected from a person at various times with respect to his consumption of crab meat. (▨) sum of As(III), As(V), MMA and DMA, obtained directly by using FIA/HGAAS, without digestion of urine samples (■) total arsenic concentration obtained by using microwave digestion and FIA/HGAAS determination.

was conducted by separately spiking standard As(V) and AB of various concentrations into a urine sample. Samples spiked with As(V) were directly analyzed for arsenic by FIA/HGAAS, whereas the samples spiked with AB underwent microwave decomposition before being analyzed by the same FIA/HGAAS method. The two standard addition curves are also shown in Fig. 5 and they are essentially parallel to the calibration curves. These results demonstrate that there is no interference from the urine sample matrix in the determination of As(V) and AB. When As(III), MMA, DMA, and arsenocholine were spiked into the urine sample, quantitative recoveries were also obtained, indicating that there is no interference in the determination of these arsenic species in urine.

Analysis of a reference urine sample, UriChem (Urine Chemistry Control Level 1, Fisher Scientific), gives arsenic concentrations of 16.2 ± 1.0 ng/ml in the absence of microwave digestion and 26.4 ± 1.3 ng/ml after microwave digestion. No information on the arsenic species is available for comparison although the reference value for total arsenic concentration is 25 ± 19 ng/ml. Our results for total arsenic, 26.4 ± 1.3 ng/ml, is in good agreement with this value.

Standard deviation

Eleven aliquots (40 ml each) of a urine sample (collected approximately 5 hr after the ingestion of some crab meat) were analyzed for the sum of As(III), As(V), MMA, and DMA before microwave digestion and total arsenic concentration after microwave decomposition. Each decomposed sample was measured three times. The relative standard deviation (RSD) from the 11 replicate determinations of arsenic in the urine sample (mean arsenic concentration of 63.4 ng/ml) is 3.0% with peak height measurement and 4.9% with peak area measurement. The sum of As(III), As(V), MMA, and DMA measured before the microwave digestion of the same urine sample is 10.1 ng/ml.

Application

The method described above shows simplicity, accuracy, and is free from interference. Since the ingestion of seafood results in urinary excretion of increased levels of organoarsenic compounds, and the method developed is capable of differentiating these marine organoarsenicals from As(III), As(V), MMA and DMA, the method was used to analyze urine samples collected from a person before and after the consumption of some seafood.

Figure 6 shows the arsenic concentration in urine samples collected at various times encompassing the ingestion of crab meat from a 500-g steam cooked crab. The sum of As(III), As(V), MMA and DMA concentrations measured directly by FIA/HGAAS without digestion and the total arsenic concentration measured after microwave decomposition of the sample are compared. The difference corresponds to the organoarsenicals that normally do not form hydrides upon treatment with borohydride. As shown in Fig. 6, the ingestion of crab meat has very little effect on the concentration of As(III), As(V), MMA and DMA in urine. However, up to a 10-fold increase of total arsenic concentration is observed in urine samples collected after the ingestion of crab meat. This is expected as high concentrations of organoarsenicals such as arsenobetaine have been found in much seafood including crab,[16,25,38] and these organoarsenic compounds are eliminated by kidneys and excreted in urine. Obviously, measuring total urinary arsenic concentration is not acceptable for assessing occupational exposure when the subject has eaten seafood prior to the sampling. Roy[39] stated that the ingestion of seafood at 48–72 hours prior to the sampling would invalidate the use of urinary arsenic as a measure of occupational exposure if the dietary arsenic was not taken into account. In studies by Buchet *et al.*[21,22] the subjects were restricted from eating any seafood before their urine samples were collected. Foa *et al.*[18] and Chana and Smith[19] have further discussed the interference

from dietary arsenic on the biological monitoring of occupational exposure to arsenic. By using the analytical method developed here, however, we are able to differentiate the organoarsenicals due to dietary intake from As(III), As(V), MMA and DMA. Therefore, occupational exposure to inorganic arsenic can be easily assessed by measuring urinary arsenic concentration without interference from the consumption of seafood.

Figure 6 also shows that rapid urine excretion of these organoarsenicals occurs as early as one hour after eating seafood. The excretion of arsenic continues and maximum arsenic concentration appears between 4 and 17 hours after eating seafood. Reproducible excretion patterns were obtained from several replicate feeding experiments including the ingestion of some other seafood such as shrimp and salmon fish. Our results showing rapid urine excretion of organoarsenic compounds are in good agreement with Buchet *et al.*[25] who calculated that the half-time for urinary excretion following crab meat consumption was 18 hours. Freeman *et al.*[17] and Charbonneau *et al.*[15] have also reported that most of the arsenic ingested is excreted in the urine from both men[17] and monkeys[15] within two days of eating arsenic-containing fish. The urinary arsenic excretion pattern and the excretion rate vary with the different arsenic compounds ingested. While the excretion of organoarsenicals present in marine organisms is very fast as can be seen from this work and that of others,[15,17,40] the elimination of inorganic arsenic by the kidney is relatively slow. Buchet *et al.*[25] calculated a biological half-time of 30 hr for the urinary excretion of arsenic following a single ingestion of 3000 μg of arsenic as sodium arsenite. They also reported[21] that after the ingestion of 500 μg of arsenic in the form of arsenite, 45% of the dose was excreted within 4 days, of which 24% was as DMA, 10% as MMA and 11% as inorganic arsenic. Following ingestion of the same amounts of arsenic as MMA or DMA, however, approximately 75% of the dose was excreted in the urine within 4 days. Tam *et al.*[13] reported that in six human subjects who ingested 0.01 μg of arsenic as ^{74}As labelled arsenic acid, 38% of the dose was excreted in the urine within 48 hours and 58% within 5 days, of the latter excreted amount 30% was as DMA, 12% as MMA and 16% as inorganic arsenic. The difference in excretion rate between inorganic arsenic and seafood organoarsenic may be due to the fact that inorganic arsenic is metabolized by the human organism[13,21,25,26,28] whereas organoarsenic such as arsenobetaine is excreted unchanged in urine.[16]

It is also interesting to point out that a trace amount of organoarsenic is found in urine samples collected before the ingestion of seafood as shown in Fig. 6. In another set of experiments where urine samples were collected for 60 hr from the same person under a regular diet which did not include seafood, the arsenic concentration in every urine sample measured after the microwave digestion is higher than or at least equal to that obtained without the digestion. Therefore, this confirms the presence of organoarsenic compounds in the urine of people who do not regularly eat seafood. These results support the findings of Foa *et al.*[18] who reported that unknown organoarsenicals represented up to 70% of the total arsenic in urine samples of a reference population that does not have occupational exposure or does not ingest large amounts of seafood.

CONCLUSION

The present FIA/HGAAS method is rapid, sensitive and easy to use. In addition to the determination of As(III), As(V), MMA and DMA in urine samples described here, the method could be expanded to the analysis of other biological and environmental samples. The addition of cysteine into the sample enables As(III), As(V), MMA and DMA to give the same maximum sensitivity under the same condition. This eliminates the determination errors due to the choice of a compromised acid concentration for the four arsenic species; the optimum acid concentration for DMA is usually much lower than those for As(III), As(V) and MMA. The beneficial effect of cysteine is under further investigation.

Microwave oven decomposition is rapid and efficient. In the presence of potassium persulfate and sodium hydroxide, all arsenic species are converted to arsenate and therefore the total arsenic concentration is easily determined by using the hydride generation technique. The difference in arsenic concentrations obtained after the microwave decomposition and before the decomposition is a measure of the presence of complex organoarsenicals such as arsenobetaine.

Urinary arsenic due to occupational exposure usually consists of As(III), As(V), MMA and

DMA. Ingestion of seafood results in urinary excretion of organoarsenicals unchanged from their original forms present in the seafood. These two pools of arsenic compounds do not interchange. The present method is capable of differentiating these two pools of arsenic compounds and therefore can be used to distinguish the sources of urinary arsenic, occupational exposure or dietary intake.

1-(2-PYRIDYLAZO)-2-NAPHTHOL (PAN) AS EXTRACTANT IN SOLID–LIQUID EXTRACTION OF SOME TRIVALENT RARE EARTH ELEMENTS*

JINZHANG GAO, GUANGLIN HU, JINWAN KANG and GUANGBI BAI
Institute of chemistry, Northwest Normal University, Lanzhou 730070, China

(*Received* 9 *April* 1992. *Accepted* 9 *June* 1992)

Summary—In the present paper, solid-liquid extraction behaviour of RE(III) (RE = La, Ce, Pr, Nd, Sm, Gd, Dy and Yb) by the use of 1-(2-pyridylazo)-2-naphthol (PAN, HL) as an extractant in paraffin (m.p. 48 ~ 50°) has been investigated at 80 ± 0.07°. The effect of equilibrium time, pH of aqueous phase, concentration of extractant in paraffin and solid diluent as well as buffer solution used on the extraction efficiency of RE(III) have been discussed. The extraction reacton is

$$RE^{3+} + 2HL_{(o)} + Cl^- \rightleftharpoons REL_2Cl_{(o)} + 2H^+$$

As a powerful chelant, 1–(2–pyridylazo)-2-naphthol (abbreviated as PAN or HL) can react with the majority of metal ions in the periodic table to form water-insoluble, coloured chelate complexes and has been applied widely to liquid–liquid extraction separation and extraction–photometric analysis in analytical chemistry.[1-3] Liquid–liquid extraction of RE(III) with PAN is reported in the literature.[4,5] Solid–liquid extraction by the use of molten paraffin as diluent has been paid close attention to because this method has some main merits such as no emulsification phenomenon and rapid phase separation and so on.[6,7] In this paper, a study on solid–liquid extraction behaviour of RE(III) (RE = La, Ce, Pr, Nd, Sm, Gd, Dy and Yb) with PAN in molten paraffin was described. The effect of equilibrium time, pH of aqueous phase and concentration of extractant in organic phase as well as solid solvent on the extraction efficiency of RE(III) has been observed.

EXPERIMENTAL

Reagents and apparatus

Preparation of 1-(2-pyridylazo)-2-naphthol (PAN) solution. A calculated amount of PAN (AR) was dissolved in pure acetone and stored in an amber bottle.

Paraffin with ceresin (PC, m.p. 48 ~ 50°) was purified according to the method in Ref. 8. Specific gravity is 0.772 g/ml at 80°.

Dibenyl (m.p. 68 ~ 70°) was of chemically pure grade without further purification.

Buffer solution (triethanolamine–hydrochloric acid) was used for pH adjustment. The ionic strength was maintained at 0.1 ± 0.01 with buffer.

Stock solutions of rare earth metals ($1.0 \times 10^{-2}M$) were prepared by dissolving calculated amounts of the pure oxide (99.99%) in an appropriate amount of $1M$ hydrochloric acid and diluting to the desired volume and then diluted to $1.0 \times 10^{-4}M$ when they were used.

All other chemicals used were of analytical grade.

All solid–liquid extraction experiments were carried out with the aid of the device below (see Fig. 1).

A Model DF-101B magnetic stirrer (Zhejiang, China), a super thermostat (Chongqing, China), model CS501, with an accuracy ± 0.07°, a model 721 spectrophotometer (Shanghai, China), a model U-3400 Hitachi spectrophotometer and a model PHS-10A digital acidity/ionometer (Xiaoshan, China) were also used.

Procedure

The solid–liquid extraction was carried out at 80 ± 0.07° as follows: an aliquot of the slightly acid solution containing definite amounts of

*Project supported by the National Natural Science Foundation of China.

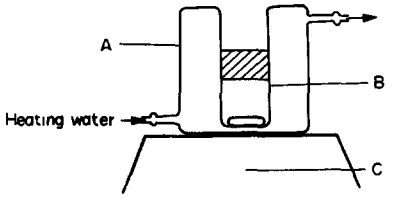

Fig. 1. Solid-liquid extraction device. A: water jacket; B: extraction vessel; C: magnetic stirrer.

rare earth ion was placed in the 30-ml extraction vessel and appropriate amount of PAN solution, buffer solution and solid solvent were added. The ionic strength of the aqueous phase was kept at 0.1 ± 0.01 and the phase ratio was 0.5 v/v. High temperature circulating water was then introduced into water jacket with a super thermostat. When the desired temperature was obtained, the magnetic stirrer was started. After 12 min, the stirring was stopped and the extraction vessel was allowed to cool to room temperature. Finally, the solidified solvent containing the complex extracted was separated.

The pH of the aqueous phase was measured on a pHS-10A digital acidity/ionometer. The amount of RE^{3+} contained in the aqueous phase was measured by Arsenzo III spectrophotometry. The amount of individual RE^{3+} in the organic phase was determined by means of the back-extraction method. Some preliminary results show that single back-extraction with 10 ml of 0.1*M* perchloric acid at 80° for 30 min can transfer completely the RE(III) to the aqueous phase.

RESULTS AND DISCUSSION

Determination of optimum conditions of solid–liquid extraction

Effect of pH. The effect of the pH of aqueous phase on the percentage extraction was examined in the pH range of 6.5 ~ 9.5 and the results are shown in Fig. 2. The extraction conditions were: PC as solid diluent; $(CH_2CH_2OH)_3N$–HCl as buffer; ionic strength 0.1 ± 0.01; extraction time 15 min; $C_{RE} = 2.0 \times 10^{-5}M$ and $C_{PAN(0)} = 2.5 \times 10^{-3}M$. Single solid–liquid extraction of La^{3+} and Ce^{3+} with PAN–PC performs quantitatively, and the pH ranges of quantitative extraction are 9.0 ~ 9.5 and 8.9 ~ 9.2 for La^{3+} and Ce^{3+}, respectively. When pH > 9.25, percentage extraction of Ce^{3+}, decreases rapidly. The percentage extraction of Pr^{3+}, Nd^{3+}, Sm^{3+}, Gd^{3+} and Yb^{3+} reaches the maximum at pH ~ 8.75, 8.20, 8.50, 7.90 and 7.70, respectively. When the pH of the aqueous phase in equilibrium is over the pH of maximum extraction, extraction efficiency of RE(III) (RE = Pr, Nd, Sm, Gd and Yb) decreases gradually. The percentage extraction of Dy^{3+} reaches the maximum at pH ~ 8.25 and decreases within the pH range 8.25 ~ 9.20 with pH increasing due to the hydrolysis of Dy^{3+} in the aqueous phase. When pH > 9.20 the amount of Dy^{3+} in the organic phase increases again due to part adsorption of water-insoluble, neutral

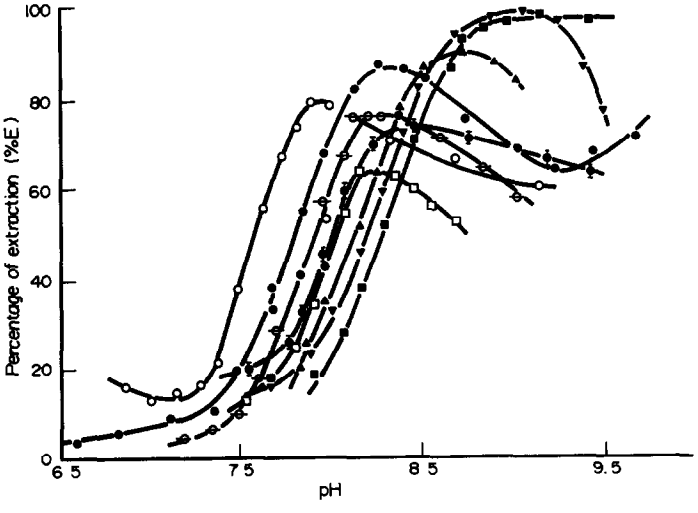

Fig. 2. Plots of %*E* vs pH of aqueous phase. PC as diluent, $(CH_2CH_2OH)_3N$–HCl as buffer, $C_{RE} = 2.0 \times 10^{-5}$ mol/l, $C_{PAN(0)} = 2.5 \times 10^{-3}$ mol/l. (■) La, (▼) Ce, (▲) Pr, (□) Nd, (♦) Sm, (⊖) Gd, (●) Dy, (○) Yb.

hydrolysate onto the surface of PC. The decrease in the percentage extraction when the pH of aqueous phase is over optimum pH is a direct consequence of hydrolysis and turbid phenomenon can be observed in the aqueous phase. Solubility products of $RE(OH)_3$ (RE = La, Ce, Pr, Nd, Sm, Gd, Dy and Yb) are 4.3×10^{-19}, 1.5×10^{-20}, 2.7×10^{-20}, 3.2×10^{-22}, 6.8×10^{-22}, 2.1×10^{-22}, 1.4×10^{-22} and 2.9×10^{-24}, respectively.[9–11] Thus at $C_{RE} = 2.0 \times 10^{-5} M$, precipitation of the hydroxides, without any complexing factors, should take place at pH ~ 9.40, 9.00, 8.40, 8.50, 8.34, 8.28 and 7.72, respectively. They are in essential agreement with the pH at which the percentage of the solid–liquid extraction of individual RE(III) with PAN–PC reaches the maximum, respectively.

Effect of stirring time. The effect of stirring time on the percentage extraction is shown in Fig. 3. In this series of experiments the pH of the aqueous phase was kept at 8.10 with $(CH_2CH_2OH)_3N$–HCl buffer solution and the solid–liquid extraction was carried out at $C_{Dy^{3+}} = 2.0 \times 10^{-5} M$ and $C_{PAN(0)} = 2.5 \times 10^{-3} M$. The equilibrium was established after 8 min. In the further tests 12 min was accepted as the equilibrium time for the extraction.

Effect of PAN concentration in PC. When the amount of $2.5 \times 10^{-3} M$ PAN–acetone solution was varied from 0.5 to 5.0 ml, at a constant pH of 8.20 and 3.86 g of PC (the volume of 3.86 g of PC is 5.00 ml at 80°), the percentage extraction increased, *i.e.*, the higher the initial amount of PAN, the higher the percentage extraction (Fig. 4). The initial concentration of PAN in PC was accepted as $2.5 \times 10^{-3} M$ in the further

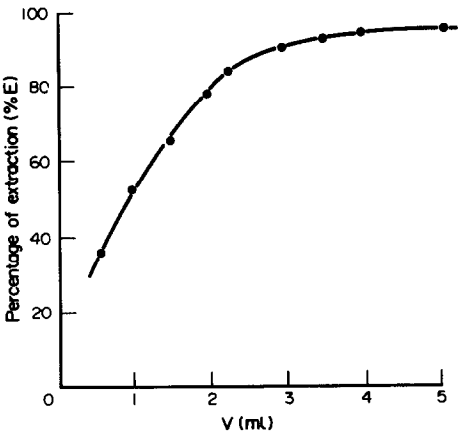

Fig. 4. Plot of the percentage of extraction (%E) vs amount of 2.5×10^{-3} PAN solution. PC as diluent, $(CH_2CH_2OH)_3N$–HCl as buffer, $C_{Pr^{3+}} = 2.0 \times 10^{-5}$ mol/l, pH = 8.20

experiments (except in the experiments discussed on the effect of $C_{PAN(o)}$ on the distribution ratio).

Effect of solid diluent. Paraffin with ceresin, naphthalene or diphenyl was used as solid diluent respectively and $(CH_2CH_2OH)_3N$–HCl buffer was used for the adjustment of the pH of aqueous phase. Figure 5 presents the relationships of the extraction percentage of Yb^{3+} in relation to the pH of the aqueous phase in the presence of different solid diluents. There is no emulsification phenomenon and phase separation is rapid when PC is used as diluent in solid–liquid extraction. Moreover, the extraction efficiency of Yb^{3+} with PAN–PC is higher than that in the presence of naphthalene or diphenyl due to the larger solubility of

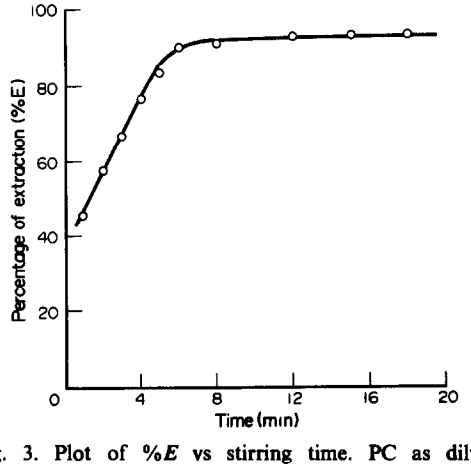

Fig. 3. Plot of %E vs stirring time. PC as diluent, $(CH_2CH_2OH)_3N$–HCl as buffer, pH = 8.10, $C_{Dy^{3+}} = 2.0 \times 10^{-5}$ mol/l, $C_{PAN(0)} = 2.5 \times 10^{-3}$ mol/l

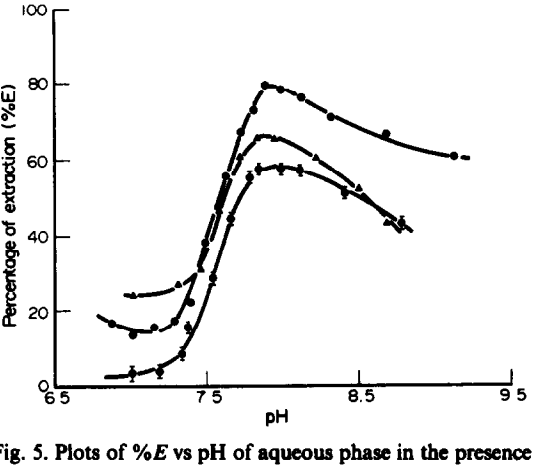

Fig. 5. Plots of %E vs pH of aqueous phase in the presence of different solid diluents. $(CH_2CH_2OH)_3N$–HCl as buffer, $C_{Yb^{3+}} = 2.0 \times 10^{-5}$ mol/l, $C_{PAN(0)} = 2.5 \times 10^{-3}$ mol/l. (●) Paraffin, (▲) diphenyl, (◆) naphthalene.

Yb^{3+}–PAN complex in molten PC. In the presence of naphthalene or diphenyl, solid–liquid extraction, however, has several drawbacks: naphthalene or diphenyl adheres to the extraction vessel after cooling and solidification and naphthalene solidified includes a part of aqueous phase. Hence, paraffin with ceresin was accepted as solid diluent in further experiments.

Effect of the used buffer. Finally, the effect of buffer solution on the percentage extraction of Dy^{3+} was investigated at PC as diluent, $C_{Dy^{3+}} = 2.0 \times 10^{-5} M$ and $C_{PAN(o)} = 2.5 \times 10^{-3} M$ for an extraction time of 12 min. Buffer solutions used for the adjustment of aqueous phase were NH_3–NH_4Cl, $(CH_2CH_2OH)_3N$–HCl and $(CH_2)_6N_4$–HCl, respectively. The results are shown in Fig. 6. The extraction efficiency was found to depend on the buffer that was employed in the following order: hexamethylenetetramine < triethanolamine < ammonia, this result is in agreement with liquid–liquid extraction.[12] The probable reason is that only smaller molecules can partake of coordination for steric hindrance of the big PAN anion. However, the rapid volatilization of ammonia under the experimental conditions decreases the buffer capacity of NH_3–NH_4Cl solution, thus causing difficulties in operation. Therefore, $(CH_2CH_2OH)_3N$–HCl buffer solution was accepted to adjust the pH of aqueous phase in our experiments. Furthermore, the use of $(CH_2CH_2OH)_3N$–HCl buffer solution can inhibit some ions such as Fe^{3+}, Al^{3+} and Mn^{2+} from extracting into organic phase because triethanolamine can form very stable water-soluble complexes with Fe^{3+}, Al^{3+} and Mn^{2+}.

Mechanism of solid–liquid extraction of RE(III) with PAN–PC

Determination of the composition of the extracted complex. Busev and Ivanov[13] had pointed out that, under various conditions of pH, ionic strength and concentration, PAN shows no intermolecular association. The concentration of RE(III) in the aqueous phase was always $2.0 \times 10^{-5} M$ in our experiments. Such concentrations of RE(III) in this phase can eliminate the possibility of polymerization of the RE(III)–PAN complex in the organic phase.[14] Hence, in RE^{3+} ($2.0 \times 10^{-5} M$/$CH_2CH_2OH)_3N$–HCl ($\mu = 0.1 \pm 0.01$)/PAN–PC system, the extraction process may be described by the following equation:

$$RE^{3+} + (x+y)HL_{(o)} + zCl^- \rightleftharpoons REL_x(HL)_y(Cl)_{z(o)} + xH^+ \quad (1)$$

where RE = La, Ce, Pr, Nd, Sm, Gd, Dy or Yb and (o) denotes organic phase.

The extraction constant (K_{ex}) is given by:

$$K_{ex} = [REL_x(HL)_y(Cl)_z]_o[H^+]^x / [RE^{3+}][HL]_o^{(x+y)}[Cl^-]^z \quad (2)$$

Based on the reported data,[15] the influence of ions and molecules present in the aqueous solution which can form non-extractable complexes with RE(III) can be neglected and thereby $[HL]_o$ is equal to the initial

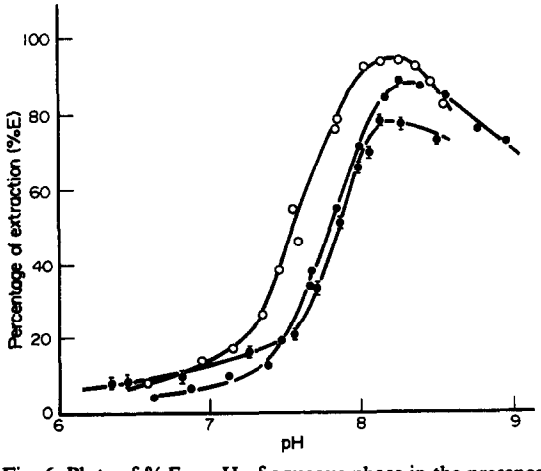

Fig. 6. Plots of %E vs pH of aqueous phase in the presence of different buffers. PC as diluent, $C_{Dy^{3+}} = 2.0 \times 10^{-5}$ mol/l, $C_{PAN(0)} = 2.5 \times 10^{-3}$ mol/l. (○) NH_3–NH_4Cl, (●) $(CH_2CH_2OH)_3N$–HCl, (◐) $(CH_2)_6N_4$–HCl.

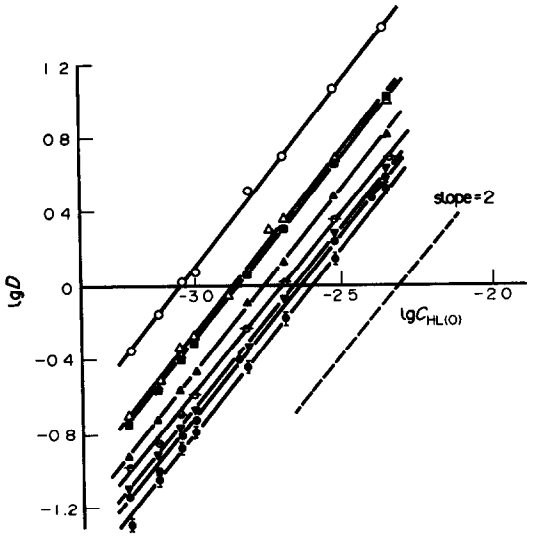

Fig. 8. Effect of the initial concentration of PAN on RE (■) distribution between the aqueous phase and PAN–PC. $(CH_2CH_2OH)_3N$–HCl as buffer; $C_{RE} = 2.0 \times 10^{-5}$ mol/l; La^{3+}: pH = 8.54; Ce^{3+}: pH = 8.30; Pr^{3+}: pH = 8.20; Nd^{3+}: pH = 8.05; Sm^{3+}: pH = 7.90; Gd^{3+}: pH = 7.86; Dy^{3+}: pH = 7.64; Yb^{3+}: pH = 7.50. (○) La, (△) Ce, (■) Pr, (▲) Nd, (▼) Sm, (⊖) Gd, (◐) Dy, (●) Yb.

concentration of PAN in the organic phase $C_{HL(o)}$. Equation (2) can be simplified:

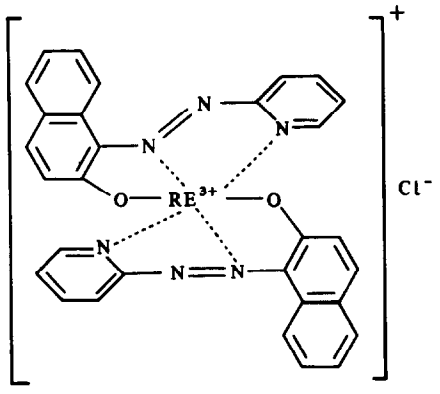
$$K_{ex} = D\frac{[H^+]^x}{C_{HL(o)}^{(x+y)}[Cl^-]^z} \quad (3)$$

or

$$\log D = \log K_{ex} + x\text{pH} + (x+y)\log C_{HL(o)} + z\log[Cl^-] \quad (4)$$

where D denotes the distribution ratio of RE(III). From equation (4) the slope of a log D curve *vs.* pH at constant $C_{HL(o)}$ and $[Cl^-]$ gives the number of protons released on chelation, and the slope of log D *vs.* log $C_{HL(o)}$ at constant pH and $[Cl^-]$ gives the number of reagent molecules involved in the complex.

Figure 7 indicates the dependence of RE(III) extraction with PAN–PC on the pH of aqueous phase. The slope of log D *vs.* pH is approximately 2.0. This fact means that the distribution ratio of RE(III) is proportional to the minus second power of hydrogen ion concentration of the aqueous phase.



Scheme 1

Figure 8 shows the experimental results for extraction of RE(III) with various PAN concentrations in PC (from $6.0 \times 10^{-4}M$ to $8.0 \times 10^{-2}M$) at fixed pH values and $[Cl^-]$. log D *vs.* log $C_{HL(o)}$ give straight lines of slope 2.0. This indicates that two ligand molecules partake in the extraction process.

Within experimental error the results obtained suggest that 1:2 complexes of the rare earth metals with the reagent were formed. This is in accordance with the conclusion obtained in liquid–liquid extraction of RE(III) by Shibata.[4] Assume that only the neutral complexes can be extracted into PC since PC belongs to inert solvent and the affinity of PC is extreme small.[1] However, neutral complex $REL_2(OH)$ cannot be extracted into PC because of the hydrophilicity of $REL_2(OH)$ caused by a hydrogen bond between hydroxy in $REL_2(OH)$ and water molecule. Hence, the composition of the extracted species is proposed to be REL_2Cl. We believe that PAN is a tridentate ligand when PAN forms a complex with RE(III). The probable structure of the complex REL_2Cl is shown above.

The above results indicate that the mechanism of solid–liquid extraction reaction of RE(III) with PAN–PC may be expressed by the equation:

$$RE^{3+} + 2HL_{(o)} + Cl^- \rightleftharpoons REL_2Cl_{(o)} + 2H^+ \quad (5)$$

Table 1. Extraction parameters for the formation of REL_2Cl complexes (at $80 \pm 0.07°$, $\mu = 0.1 \pm 0.01$)

Parameter	Rare earth ions							
	La^{3+}	Ce^{3+}	Pr^{3+}	Nd^{3+}	Sm^{3+}	Gd^{3+}	Dy^{3+}	Yb^{3+}
log K_{ex}	−9.98	−9.85	−9.69	−9.58	−9.47	−9.32	−9.08	−8.72
$pH_{1/2}$ at $C_{PAN(o)} = 2.5 \times 10^{-3}M$	8.10	8.03	7.95	7.89	7.84	7.76	7.64	7.46

Calculation of the values of $pH_{1/2}$ and extraction constant (K_{ex}). Equation (4) can be simplified from equation (5):

$$\log D = \log K_{ex} + 2\text{pH} + 2\log C_{HL(o)} + \log[Cl^-] \quad (6)$$

$pH_{1/2}$ values are defined as the pH at which the distribution ratio (D) of the metal ion is equal to 1. Thus $pH_{1/2}$ is equal to the intercept of the abscissa axis of $\log D$ *vs.* pH (Fig. 6). With the aid of relation (6) the average $\log K_{ex}$ values were calculated by the least-squares method. The constants and $pH_{1/2}$ values at $C_{PAN(o)} = 2.5 \times 10^{-3} M$ are given in Table 1.

The comparison between solid–liquid extraction of RE(III) with PAN–PC and liquid–liquid extraction of RE(III) with PAN. The liquid–liquid extraction behaviour of RE(III) with PAN–CCl_4 or PAN–$CHCl_3$ has been reported in Ref. 5. The results show that under the same conditions and within the studied pH range, the RE(III) extraction efficiency decreases from the heavy RE to the light RE. Particular marked differences in the extraction efficiency of the light and the heavy RE occur when a solution of PAN in CCl_4 is applied to extraction. The light RE(La^{3+}, Ce^{3+} and Pr^{3+}) cannot be extracted into the organic phase, Nd^{3+}, Sm^{3+}, Gd^{3+} and Dy^{3+} can be partly extracted, while Yb(III) is extracted almost completely. PAN–CCl_4 can be used as the group reagent for the separation of RE(III) by the liquid–liquid extraction method. Regarding the RE(III) studied, a PAN solution in $CHCl_3$ is less efficient an extractant than a PAN solution in CCl_4. In the system of solid–liquid extraction, La^{3+} and Ce^{3+} can be extracted quantitatively at higher pH ranges because pH at the beginning of precipitation for La^{3+} and Ce^{3+} are more than those for the other RE(III). The solid–liquid extraction efficiency of RE(III) with PAN–PC is higher than that of liquid–liquid extraction with PAN–CCl_4 (except Yb^{3+}). Furthermore, extraction efficiency decreases slightly from the light RE to the heavy RE. The use of $(CH_2CH_2OH)_3N$–HCl buffer solution for pH adjustment can eliminate interference from Fe^{3+}, Al^{3+} or Mn^{2+}. Therefore, the solid–liquid extraction method with PAN–PC can be used for separation and purification of rare earth elements.

EXTRACTION SPECTROPHOTOMETRIC DETERMINATION OF MANEB WITH 1-(2′-PYRIDYLAZO)-2-NAPHTHOL (PAN)

A. L. J. Rao,* A. K. Malik and Jyoti Kapoor
Department of Chemistry, Punjabi University, Patiala-147002, India

(*Received* 21 *May* 1992. *Accepted* 9 *June* 1992)

Summary—A rapid, sensitive, simple and selective spectrophotometric method has been developed for the determination of micro-quantities of maneb (manganese ethylenebisdithiocarbamate) after extraction of the manganese–PAN complex in isobutyl methyl ketone (MIBK). The complex absorbs strongly at 550 nm. Beer's law is obeyed over the concentration range 0.37–3.75 μg/ml. The molar absorptivity was found to be 4.1×10^4 l.mole^{-1}.cm^{-1}. The developed method has been applied to the determination of maneb in commercial formulations, synthetic mixtures, grain and in the presence of various other dithiocarbamates.

Metallic salts of dithiocarbamic acid, such as nabam, ziram, zineb, ferbam and maneb are used as agricultural fungicides because of their low phytotoxicity and are applied in the rubber industry as vulcanization accelerators and antioxidants. Although several methods have been reported in the literature for estimating these fungicides, the method reported by Clarke[1] is of practical importance which is based on carbon disulphide evolution after decomposing these dithiocarbamates in acidic medium.[2–4] Hall has reported on a collaborative study of determination of maneb using modified versions of the methods of Clarke *et al.*[1] The results obtained from both the methods were inconsistent. Maneb was also determined by spectrophotometric methods,[5] a volumetric method with electrogenerated iodine[6] and by high performance liquid chromatography.[7] However all of the above mentioned methods are time consuming or have low sensitivity. This method is simple, sensitive and selective for the determination of maneb based on the extraction of the Mn–PAN complex into isobutyl methyl ketone. PAN has also been used to determine manganese in high purity Nb, Ta, Mo and W metals.[8]

EXPERIMENTAL

Equipment

An SP-20 Spectrophotometer for absorption measurement and a digital pH meter were used.

Reagents

Pure maneb was prepared by adding a solution of manganese(II) to a solution of disodium ethylenebisdithiocarbamate (Wilson Laboratories, Bombay). The precipitates so formed were filtered and dried over silica gel. The purity of maneb was checked by elemental analysis and by complexometric titration of manganese after decomposition using Thymolphthalexone as an indicator.[9] A 0.1-mg/ml solution of maneb was prepared in dimethyl sulphoxide (DMSO).

PAN solution, 0.1 mg/ml. PAN (LOBA) (10 mg) was dissolved in 100 ml of methanol.

Isobutyl methyl ketone. The purity of the isobutyl methyl ketone was checked spectrophotometrically before use.

Buffer solution. Boric acid and potassium chloride solutions (0.2*M*, 100 ml of each) were mixed, pH adjusted 9.2 with 0.2*M* sodium hydroxide and diluted to 500 ml.

Stock solutions. Stock solutions for interference studies were prepared by dissolving suitable salts in water. Synthetic samples were prepared by mixing suitable salts to give the required composition.

Procedure

To an aliquot containing 37.5 μg of maneb, 2 ml of boric acid buffer (pH 9.2) and 0.7 ml of PAN were added and the total volume was made up to 10 ml with doubly distilled water. The solution was allowed to stand for 2 min, then shaken exactly with 10 ml of isobutyl

*Author for correspondence.

methyl ketone. A second extract with another 10 ml of isobutyl methyl ketone gave negligible absorbance, so the absorbance of the first extract was measured at 550 nm against a reagent blank prepared under similar conditions.

RESULTS AND DISCUSSION

The absorption spectra of manganese–PAN complex in isobutyl methyl ketone were recorded against a reagent blank. The complex absorbs strongly at 550 nm whereas the reagent shows negligible absorbance. The absorbance of the complex was maximum when the pH of the aqueous phase was 8.0–11.0 and 0.7 ml of 0.01% PAN was used. The complex was extracted into isobutyl alcohol, chloroform, carbon tetrachloride, ethyl acetate, isobutyl methyl ketone, amyl alcohol and n-butyl acetate. Maximum absorbance was observed with isobutyl methyl ketone and hence this solvent was selected for the extraction of manganese–PAN complex. The absorbance of the complex remains practically constant for 24 hr.

The Job's method of continuous variation and mole-ratio methods indicated the formation of 1:2 (M:L) complex.

Analytical characteristics

Under the optimum conditions described above the calibration graph was linear over the concentration range 0.37–3.75 μg/ml of maneb at 550 nm. The molar absorptivity was found to be 4.1×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$. Aliquots containing 37.5 μg of maneb gave a mean absorbance of 0.58 with a relative standard deviation of $\pm 0.3\%$.

Interferences

Sample solutions containing 37.5 μg of maneb, the interferences of various anions (as alkali-metal salts) and metal ions were studied after applying the general procedure. Of the anions examined, the amounts (mg) shown in parentheses are tolerable ($\pm 2\%$ error) for thiocyanate (4), orthophosphate (0.37), citrate (47), acetate (450), chloride (18), bromide (16), fluoride (120), sulphate (50), metabisulphite (5), but tartrate and EDTA interfered strongly. Of the metal ions examined Co(II) (0.03), Ni(II) (0.09), Bi (0.15), V(V) (0.2), Th(IV) (0.23), Mo(VI) (0.02) did not interfere. Cu(II), Pb(II), Hg(II), Zn(II) and Fe(II) interfered strongly but could be masked with 1.0 ml of 5% sodium fluoride solution.

Of the dithiocarbamates examined, nabam (sodium ethylenebisdithiocarbamate), dibam (sodium dimethyldithiocarbamate), vapam (sodium monomethyldithiocarbamate), sodium *N*-methylanilinecarbodithioate, *i.e.*, which do not contain any metal ion did not interfere in the determination of maneb. Ferbam, ziram and zineb could be masked with 1.0 ml of 5% sodium fluoride solution.

Simultaneous determination of ziram and maneb, or zineb and maneb

Ziram and maneb, zineb and maneb were taken in various proportions. Equal aliquots of the solution were analysed in the presence and absence of 1.0 ml of 5% sodium fluoride solution. The difference in the absorbance corresponded to the amount of zineb/ziram. The results are given in Table 1.

Applications

The proposed method is one of the most sensitive and selective methods for the determination of maneb and was applied to the determination of maneb in commercial formulations "Dithane M-45" (Indofil Chemicals) with pure samples taken as reference. Five dilutions of the stock solutions were prepared and in all cases the recoveries were between 72.5 and 72.9% by this method, where as the value reported was 73%.

Determination of maneb in grain

This procedure was applied for the determination of maneb in grain. A known amount of maneb was finely crushed with 20 g of grain and was shaken with 100 ml of acetonitrile for an hour. The mixture was filtered and residue was washed with three 10-ml portions of acetonitrile. The extract was evaporated at room temperature by a current of dry air. The residue was dissolved in dimethyl sulphoxide and the maneb content was analysed by general procedure. Untreated samples were taken as reference. The results are given in Table 2.

Table 1. Recovery of maneb from synthetic mixtures

Composition and percentage	Amount of Maneb (μg)		Recovery (%)
	Taken	Found	
Maneb:50	40.0	40.1	100.25
Ziram:50	45.0	44.9	99.7
	42.0	42.3	100.7
Maneb:50	30.0	30.2	100.6
Zineb:50	20.0	19.8	99.0
	35.0	35.0	100.0

Table 2. Recovery of maneb from grain

Amount of maneb added (μg)	Amount of maneb found (μg)	Recovery (%)
10	9.85	98.5
20	19.6	98.0
30	29.7	99.0
40	39.0	97.5
50	49.0	98.0

Comparison of sensitivity

The sensitivity of this method is better than that of the Lowen,[10] Cullen[11] and Chmiel[12] methods which are based on the determination of liberated CS_2. It is also more sensitive than the Rao *et al.*[13] method. According to the latter method a minimum of 2 μg/ml maneb could be determined but according to the present method a minimum of 0.37 μg/ml maneb could be determined. Moreover, this method is more selective since other pesticides like ziram, zineb, ferbam which usually interfere in other methods do not interfere in this method under the experimental conditions.

DIRECT ZINC DETERMINATION IN COMMERCIAL SULPHURIC ACID BY DPASV. COMPARISON OF ROTATING DISC AND STATIONARY GRAPHITE ELECTRODES

IGNACY CUKROWSKI* and EWA CUKROWSKA
University of Transkei, Department of Chemistry, P/B X1, Umtata, Republic of Transkei, South Africa

(*Received* 11 *November* 1991. *Revised* 21 *April* 1992. *Accepted* 22 *April* 1992)

Summary—A striking gas technique employed made a direct Zn determination possible at extremely low pH in commercial acid solutions when a stationary impregnated graphite-based mercury film electrode was used. The original Zn(II) concentrations were determined quantitatively by differential pulse anodic stripping voltammetry on 0.5*M* and 1*M* sulphuric acid solutions by standard addition and were found to be $2 \times 10^{-8}M$ and $4.1 \times 10^{-8}M$, respectively. The influence of mercury ion concentration, pulse amplitude, potential step and pulse repetition time on analytical data was studied and optimized. A rotating disc graphite electrode was also used as a working electrode and was found unreliable for this purpose as hydrogen bubbles were not removed effectively and blocked the working electrode surface.

Stripping analysis, like many forms of ultratrace analytical techniques, is subject to interferences that affect accuracy and precision. The reliability and validity of the analytical data strongly depend on the degree to which contamination and/or loss of the analyte can be minimized. In this respect, the simplification of sample pretreatment steps and the restriction of their number is significant. It is desirable to operate at low pH as the rate of adsorption of metals onto the container and electrode surfaces is very pH-dependent, increasing considerably at high pH.[1] Robertson studied the adsorption of 11 elements in seawater onto various containers and indicated that optimum conditions for storing seawater were achieved by acidifying to pH 1.5 immediately after collection and storing in polyethylene containers.[2] Mart recommended deep-freeze (−20°) storage of the acidified sample to avoid leaching metals from the surface of a containter.[3] Scarponi *et al.* found,[4] investigating the contamination of seawater samples by cadmium, lead and copper during storage of samples, that conventional polyethylene containers can be used for long-term storage of samples at their natural pH (about 8) at 4°, but must be cleaned with acid for at least 1 week and conditioned with prefiltered seawater for at least 2 weeks. At the natural pH, samples were analyzed for labile heavy metals,[5] but the total concentration of metals was determined on rain and seawater samples acidified with concentrated hydrochloric acid to pH 1.5[5,6] or pH 2.[7] The increase in the peak currents observed upon acidification was explained as a result of the release of the metals from complexes[8] or labile complex formation that are "electrochemically available".[9] In addition, the presence of surfactants at low pH values did not affect peak current.[8]

It can be concluded from the above that for various environmental and industrial applications, the acidification of collected samples and direct determination was found to be the best procedure for minimizing contamination or loss of the trace metals. But in the case of the stripping Zn determination at solid electrodes the acidification results in a strong hydrogen evolution which can disable quantitative analysis. To overcome this problem, samples were buffered and Zn was measured at pH 5.8[10] or 4.6[11] while for most metals, seawater was acidified to pH 1.9.[10] DPASV at a GC rotating electrode was employed for Zn determination in Antarctic snow samples at pH 2.9 but further acidification resulted in steeper voltammetric baseline currents and loss of sensitivity for Zn.[12] SWV was found to be more sensitive in comparison with DPASV for Zn determination at SDME in strongly acidic media and for

*Author for correspondence.
New postal address: Univ. of the Witwatersrand, Dept of Chemistry, P.O. Wits 2050, Johannesburg, South Africa.

the determination of Zn lower than 10 μg/l. A 0.01*M* acid solution was recommended, but the highest SWV peak was obtained at pH 1.4.[13]

To acidify the real sample which is to be studied for zinc content one must know what the concentration of zinc is in a commercial acid. In our previous work we have presented the direct quantitative Zn determination at pH 2 by ASV at the epoxy-resin-impregnated graphite electrode (IGE).[14] In this paper, the extension to the DPASV technique with and without a background current correction is reported. The instrumental and analytical parameters were studied and optimized so that a direct Zn determination can be performed at pH ≅ 0, or even higher acid concentration (a calibration curve for Zn in 1*M* sulphuric acid is discussed) despite the solid and stationary electrode used. For comparison, some results of DPASV measurements at a rotating IGE will also be presented.

EXPERIMENTAL

Instrumentation and reagents

Analyses were done with a Polarecord E 506 in the differential mode with a polarography stand E 505 (both Metrohm). The voltammetric cell was a Metrohm universal measuring and titration vessel (6.1415.220) with a vessel lid (6.1414.010 – five electrode apertures). The working electrode (4 mm in diameter) was an epoxy-resin-impregnated graphite electrode for which production and preparation were described elsewhere.[15,16] From this electrode a tip was made which is of the exact shape and size required by Metrohm (6.1204) to fit a Metrohm E 628-50 rotating disc electrode (RDE) which was used in this paper as a RDE drive for a home made IGE disc. Once the working electrode was made no additional chemical, electrochemical or mechanical treatment was done during the whole study presented in this paper. The working electrode was used in two modes during the deposition step of a DPASV measurement: firstly, as a rotating disc (2100 rpm) and secondly, as a stationary one with the aid of the striking gas (SG) technique.[17] SG serves as the source of a metered stream of neutral gas which is used to deoxygenate the sample and stir the solution during the deposition stage. To achieve the latter an additional, two tubes holder was made and fixed in one of the vessel lid apertures. One tube was used to direct the metered gas stream towards the active surface area of the working electrode (the distance between a gas outlet and the electrode working surface was about 10 mm), and the second tube maintained an inert atmosphere over the solution being analyzed. A gas purge tube (Metrohm 6.1443.000) was used only when IGE worked in a rotating mode. Pure argon was used to deaerate and stir the solutions. All measurements were carried out in the three electrode system using a platinum wire counter electrode (Metrohm EA 285) and an Ag/AgCl saturated potassium chloride reference electrode (Metrohm EA 441/5) placed on the electrolyte vessel with a ceramic plug (Metrohm 6.1225.010). Solutions were prepared with analytical reagent grade chemicals and doubly distilled water. Standard solutions of sulphuric acid and metal ion concentrations were prepared by diluting stock solutions and were stored in polyethylene bottles rinsed with acid. Standard additions were made from fix Transferpettes and digital Transferpettors (Rudolf Brand GMBH, Germany). All experiments were done at room temperature 22 ± 2°.

Standard procedure

Except where specified, the experimental parameters and analytical procedure were as follows. A 50-ml volume of the solution to be studied was prepared directly in the voltammetric vessel by mixing appropriate volumes of doubly distilled water with the sulphuric acid, mercury nitrate and zinc nitrate solutions metered from 2.5*M*, $1 \times 10^{-2}M$ and $1 \times 10^{-4}M$ standard solutions, respectively. Samples were deaerated for 300 sec after which −1.4 V potential was applied to the IGE in the stirred solution for 180 sec. Then the potential was changed from −1.4 to 1.2 V and after 5 sec a rest period of 15 sec began during which sensitivity was adjusted from the pre-electrolysis position to a desired one. Scanning was from −1.2 to −0.85 V (E_{pulse} = 40 mV, E_{step} = 3 mV, pulse repetition time 0.4 sec) followed by stripping of any trace metal at 0.00 V for 30 sec in the stirred solution. Three consecutive curves were recorded in one sample and the last one was taken into consideration. The mercury film was removed by wiping the electrode gently with wet filter paper. Prior to the next measurement in a different sample the vessel and electrode system were rinsed with 0.1*M* sulphuric acid and water several times. If only the stirring solution mode was changed from RDE to SG only the mercury film was removed but the solution was unchanged in the vessel. A RDE rotation speed of 2100 rpm and

a gas outflow efficiency[17] of 2 l./min were the same for all experiments.

RESULTS AND DISCUSSION

Preliminary study

The primary aim at this stage was to find out whether any of the studied techniques, RDE and SG, are suitable for a direct Zn determination at extremely low pH using standard experimental parameters. A series of measurements was performed in which the concentration of Zn was kept constant, mainly $1 \times 10^{-7}M$, but mercury ion and sulphuric acid concentrations varied in the range of 5×10^{-7} to $5 \times 10^{-4}M$ and 0.005–2.5M, respectively. The results obtained are presented in Fig. 1 in the form of the bar graph and some selected voltammetric curves in Fig. 2. Despite the complexity of the system studied and the lack of obvious and clear (at the first view) relations presented in Fig. 1, some important conclusions and trends can be drawn up. It is seen that 2.5M sulphuric acid is not the one for the direct Zn determination for both techniques examined. On the other hand, the fact that with SG small peaks of zinc were recorded might suggest the possibility of quantitative analysis, but no attempt was made to do it. It is evident (see Fig. 2) that the Zn peaks recorded using SG are several times higher than those when the RDE mode was used. This fact can be explained by the IGE active electrode surface observations made during the deposition and rest stages. One may easily notice hydrogen bubbles which are not effectively removed during the electrode rotation. The amount of the gas increases with the acid concentration increase, the mercury ion concentration decrease and with a consecutive number of measurements of the same sample or for longer deposition times. Initially, many of these small bubbles are formed, but after several minutes they form a single big hydrogen bubble (rotating together with the electrode) which may cover the working surface of IGE even entirely. The fact of insufficient gas removal makes the RDE system uncertain and unreliable for quantitative analysis of Zn at very low pH. In the case of SG, the above described phenomenon does not take place. Only in 2.5M sulphuric acid during a rest stage, were small

Fig. 1. The influence of solution composition and solution stirring technique on zinc peak height. Blank bar—RDE; filled bar—SG. Zinc concentration: $1 \times 10^{-7}M$. Mercury concentrations: (a) $5 \times 10^{-4}M$; (b) $5 \times 10^{-5}M$; (c) $5 \times 10^{-6}M$; (d) $5 \times 10^{-7}M$. For standard procedure parameters see text. Question mark—no reproducible peak height (see text for full explanation).

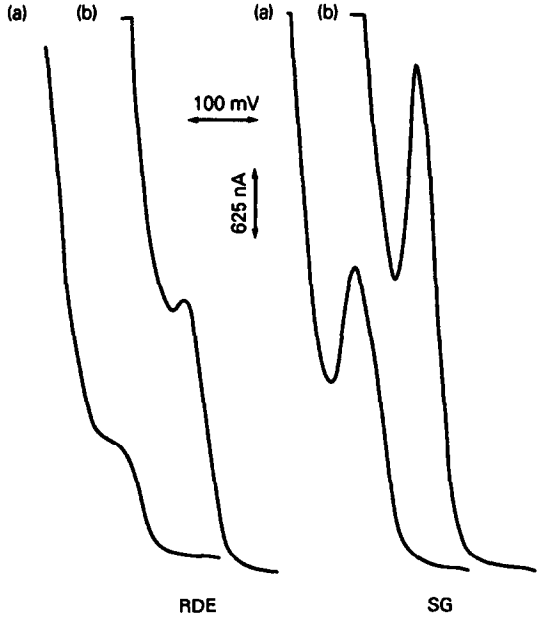

Fig. 2. DPASV peaks of zinc for selected measurements in 0.5M sulphuric acid. Zinc concentration: $1 \times 10^{-7}M$. Mercury concentrations: (a) $5 \times 10^{-5}M$; (b) $5 \times 10^{-4}M$. Standard parameters.

hydrogen bubbles observed. These were removed from the surface during the next deposition step. Even in $0.5M$ sulphuric acid and at the lowest mercury ion concentration studied no gas bubbles were observed during the rest step. For both stirring systems, the lower the pH, the lower the Zn peak height recorded for all mercury ion concentrations except $5 \times 10^{-4}M$, and the higher the mercury ion concentration the higher the Zn peak recorded for all sulphuric acid concentrations. In the solutions of $5 \times 10^{-4}M$ mercury ion and $5 \times 10^{-3}M$ acid, noise and the lack of reproducibility in peak height were observed when curves were recorded. The arrow and the question mark in Fig. 1 indicate a very low accuracy and uncertainty of the measurement performed in that solution, because the mercury nitrate partially played a role of a supporting electrolyte. Its concentration was only 10 times lower than that of the acid and any small vibration or shaking of solution caused the change of the current recorded from a diffusion to a diffusion-migration one. In addition, the superimposed hydrogen reduction and zinc oxidation currents made the system even more sensitive and unstable. The mercury ion concentration of $5 \times 10^{-4}M$ seems to be the best as not only the highest Zn peaks were recorded, but also the Zn peak in the $0.5M$ acid solution is higher than that in the $0.05M$ solution. This might suggest that the observed increase is caused by the Zn content present in the acid appearing as contamination. Furthermore, one may suppose that at such high mercury ion concentration levels, the amount of Hg(II) is a decisive factor when the sensitivity of a measurement is concerned. As a confirmation, the equal Zn peak heights, recorded by SG, in solutions of $5 \times 10^{-3}M$ sulphuric acid $+ 5 \times 10^{-5}M$ Hg^{2+} and $5 \times 10^{-2}M$ sulphuric acid $+ 5 \times 10^{-4}M$ Hg^{2+} may be used. This indicates that in both solutions the main source of Zn was the standard zinc solution added and not impurities in the sulphuric acid or the mercury nitrate standard solutions. For all other mercury concentrations studied, the pH of the solution (hence the acid concentration) limits the height of Zn peak—the lower pH, the lower peak recorded. It was also observed that Zn peaks recorded on acid solutions containing $5 \times 10^{-4}M$ Hg^{2+} are higher and narrower than those obtained at $5 \times 10^{-5}M$ Hg^{2+} or lower mercury ion concentration levels and at the same Zn and acid concentrations—compare two SG curve in Fig. 2.

Peak height assessment

An evaluation of voltammetric data when measurements of Zn content were performed at very low pH is not an easy task. The shape and size of the peak is strongly affected by a steep voltammetric baseline current from hydrogen evolution. In addition, the steepness of the baseline current depends on the acid and mercury ion concentrations, thickness of a mercury film as well as the sensitivity value pre-set before the curve is recorded, which very often must be changed when a standard addition technique is used. We found that at very low Zn(II) levels reliable results could be obtained only when the background current is recorded (without deposition step) just after each voltammetric measurement of Zn. A subtractive DPASV peak is not only much easier for interpretation but also higher, sometimes twice as high as that obtained using the tangent. The following demonstrates how substantial error can arise (the lower peak of metal, the more significant discrepancy) by tangent assessment of a DPASV peak height of zinc. Two experiments were performed on $0.5M$ sulphuric acid with $5 \times 10^{-5}M$ Hg^{2+} at the stationary IGE. The first one was the standard addition of zinc solution and the second one was the study of the height of zinc peak as a function of the deposition time, at $7 \times 10^{-7}M$ Zn^{2+} content. For both relationships straight lines were obtained but with negative values of y-axis interceptions. When corrected by taking the background current as baseline peak it results in curves that have positive y-axis intercepts, better correlation coefficients and larger gradients. For illustration purposes the interception, correlation coefficient and slope of calibration curves for tangent and background current correction were found to be -0.65; 0.975; 0.77 ± 0.06 and 0.10; 0.996; 0.89 ± 0.03, respectively. A tangent approximation of a hypothetical baseline is commonly used in a computerized equipment as it is an easy and quick way of peak height measurement.[13,18] One must realize that this method may often lead to large determination errors, which can be avoided by a subtractive method, or background current correction, or highly-developed mathematical analysis of the peak region.[19] In all further measurements backgrond current is taken into account for data evaluation.

Quantitative Zn determination

For zinc determination only the SG mode was used. The original Zn concentrations in $1M$

sulphuric acid solution with $5 \times 10^{-4}M$ Hg^{2+}, a deposition time of 10 min (sample A) and two $0.5M$ sulphuric acid solutions for 5-min deposition times and at different mercury concentration levels, mainly $5 \times 10^{-4}M$ (sample B) and $5 \times 10^{-5}M$ (sample C) were determined by the standard addition technique. In all cases, the relationships between the peak heights and the added Zn standards were linear but had different slopes. For samples A, B and C slopes were found to be 2.78, 4.48 and 3.81, respectively. The original concentrations of Zn in studied samples were in very good agreement; Zn contents in $1M$ and two $0.5M$ sulphuric acid solutions were found to be $4.1 \times 10^{-8}M$ and $2.0 \times 10^{-8}M$, respectively. The producer specification says that the maximum amount of Zn can be 5×10^{-5}% which corresponds to $3 \times 10^{-7}M$ Zn^{2+} in a $0.5M$ acid solution and is one order of magnitude more than the value found. One must notice the difference in the deposition times which were 5 and 10 min for the 0.5 and $1M$ acid solutions, respectively. From the analytical point of view, data obtained for both sulphuric acid solution concentrations, even when a 10-min deposition time had to be used in $1M$ acid to record peaks sufficiently high, well-shaped and suitable for quantitative determination of Zn, are regarded as fully satisfactory. This experiment also confirms that the higher the acid concentration, the lower the Zn peak recorded and the higher the mercury concentration, the higher the Zn peak recorded in the solution of the same pH, which results in a different slope of the calibration curve.

The effect of extremely low pH

The results of the preliminary study, especially the lack of a Zn peak in $2.5M$ sulphuric acid as well as a significant decrease in peak height in the $1M$ acid (sample A in quantitative Zn determination) suggested the need for a more detailed examination. A series of measurements was performed on one sample containing $2 \times 10^{-7}M$ Zn^{2+} and $1 \times 10^{-4}M$ Hg^{2+} with a stepwise standard sulphuric acid addition. After each acid addition the voltammetric curve was recorded and results obtained are presented in Fig. 3, where two curves are seen. The first one (lower curve) represents the real values of the peaks recorded and the second one (upper curve) was obtained when the dilution of Zn was taken into account. From this relation and the data presented in Fig. 1, where no decrease of Zn peak is observed in $0.5M$ acid solution with

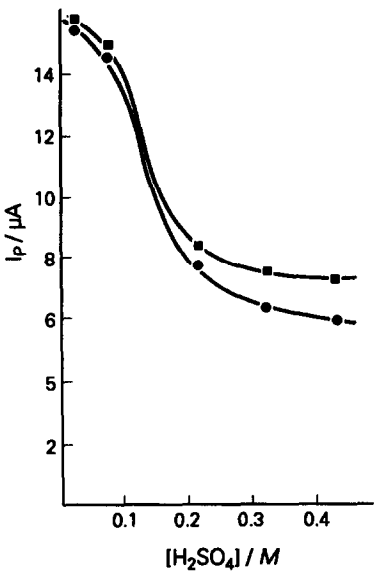

Fig. 3. The effect of acid concentration on zinc peak height. Mercury concentration: $1 \times 10^{-4}M$. Zinc concentration: $2 \times 10^{-7}M$. Standard instrumental parameters. (●) Zn peak recorded; (■) Zn peak recalculated (see text).

$5 \times 10^{-4}M$ Hg^{2+} addition it is clear, that there is no specific pH range at which the Zn peak height dramatically decreases. It depends not only on the acid to mercury ion concentration ratio but also on the working electrode or mode of solution stirring used and must be found experimentally for each system studied. For example, when the quantitative Zn determination

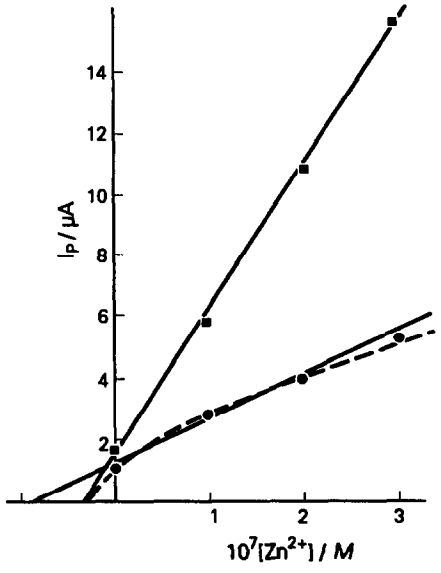

Fig. 4. Comparison of RDE (●) and SG (■) calibration curves for zinc, $0.5M$ sulphuric acid + $5 \times 10^{-4}M$ Hg^{2+}. Deposition time 5 min. Standard instrumental parameters. Dashed line = a real relationship for RDE (for explanation see text).

was performed using the RDE or SG modes in the same sample, two different relations were obtained even when the optimum composition of the solution for SG was chosen, mainly $5 \times 10^{-4}M$ Hg^{2+} in $0.5M$ acid (Fig. 4). One may see, that the original concentration of Zn in the acid solution estimated from RDE curve, presented as a solid line (●), is far too high—compare this result with those discussed in the previous section, *e.g.*, quantitative zinc determination. To explain this result, one must recall the hydrogen evolution phenomenon at RDE discussed earlier and under the circumstances the proper relationships for RDE is presented by a dashed line (●) in Fig. 4.

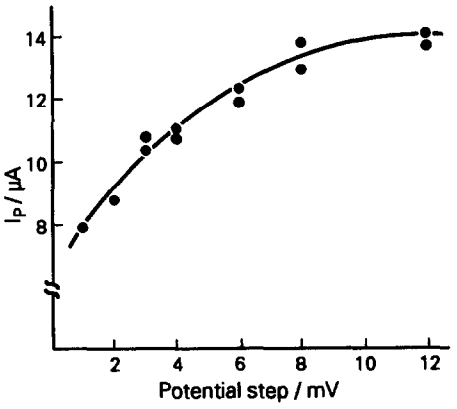

Fig. 6. The effect of potential step on Zn peak height. For details see Fig. 6.

The effect of instrumental parameters

The influence of the DPASV parameters on the analytical data was studied in $2.5 \times 10^{-2}M$ sulphuric acid (pH ≅ 1.6) containing $2 \times 10^{-4}M$ Hg^{2+}. It is not such a critical medium that pH must equal 0 but a very low pH is required and due to the striking gas technique employed we could record very well shaped Zn peaks. The estimated value of the Zn concentration in $2.5 \times 10^{-2}M$ sulphuric acid was found to be $1.07 \times 10^{-9}M$. This is in very good agreement with the results collected for 1 and $0.5M$ sulphuric acid but it was inconvenient, although possible, to study the effect of the instrumental parameters at such a low Zn level. By addition of $2 \times 10^{-7}M$ Zn^{2+} (about 200 times more than the original content) it was possible to obtain a high Zn peak (about 8 μA) at a deposition time of just 60 sec.

Under these conditions, *e.g.*, relatively low pH and relatively high mercury and zinc ions concentrations, one could expect a fairly stable and reliable performance of IGE in a SG mode, so all observed changes could be related to the instrumental parameter change. The influence of pulse amplitude, potential step and pulse repetition time on the peak height was studied. In each experiment, one parameter was varied while the others were kept constant. All measurements were performed in one sample solution. Prior to the series of measurements, a mercury film was plated in 180-sec steps followed by 60-sec steps (for total time of 16 min) to ensure that the electrode was reproducible. For all measurements, deposition potential, start potential and deposition time were −1.4 V, −1.2 V and 60 sec, respectively. The results are presented in Figs. 5–7. From data in Figs. 5 and 6 it is seen that the higher the scan rate the higher the peak recorded which is exactly opposite to the observation reported by Vos *et al.*[7] The pulse repetition time does not influence the peak height up to

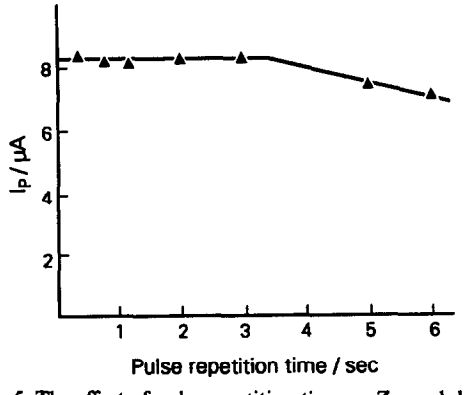

Fig. 5. The effect of pulse repetition time on Zn peak height in sulphuric acid solution. pH ≅ 1.6; mercury concentration $2 \times 10^{-4}M$; zinc concentration $2 \times 10^{-7}M$; deposition time 60 sec. For other instrumental parameters see text.

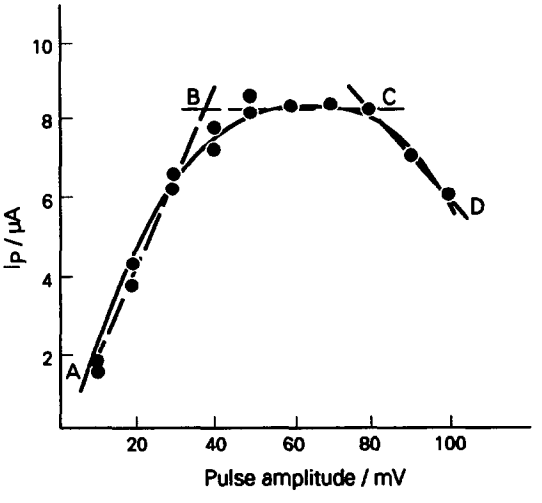

Fig. 7. The effect of pulse amplitude on Zn peak height. For details see Fig. 6.

3 sec. This is a very convenient relationship from the analytical point of view and allows the use of the shortest time available which makes the single measurement a relatively quick one. From the shape of the Zn peak recorded, when the influence of the potential step was studied and from the relation in Fig. 6, we recommend the use of 6 or 8 mV steps. This results in a 15- or 20-mV/sec scan rate at 0.4-sec repetition times. At these scan rate values the peak decreases only very slightly but its shape is much better than for 10 mV or higher steps because for a single Zn peak more points are recorded. In Fig. 7 three regions one may select and from them B–C one, *e.g.*, for pulse amplitude between 40 and 80 mV, which is the most suitable for use as the peak height does not depend on a pulse value and is the highest one. With the pulse amplitude increase, the DPASV zinc peak shifts towards more negative values, we recommend use of 50- or 60-mV pulse amplitudes (for 10 and 100 mV pulse amplitudes Zn peak potentials were -1050 and -1120 mV, respectively). The decrease of the Zn peak for higher pulse amplitude values (region C–D in Fig. 7) was also observed for a SWV zinc peak at SMDE, when the square wave amplitude was higher than 60 mV.[13]

During this study a significantly higher value of the gas outflow efficiency, 2 l./min, was used than that reported previously,[17] as it was necessary to remove effectively a huge amount of gas being evolved at the working surface of the IGE. Fortunately, even under these circumstances, *e.g.*, extremely low pH, very strong gas stream striking IGE and in addition at high mercury concentration (more than one order of magnitude higher than that used before[17]), hence for the thick mercury film formed, there was no single symptom observed which would indicate a destruction or failure of the working electrode and mercury film.

In conclusion, the method described provides a simple approach for direct determination of trace levels of zinc at extremely low pH in commercial acids used to acidify collected samples. Using optimized instrumental parameters, several hydrochloric and nitric acids solutions were analyzed for zinc at pH $\cong 0$ by standard addition. For all samples studied the Zn content was below the level specified by the producer. The detection limit of $1M$ acid solution and 10 min deposition time was estimated to be about $1 \times 10^{-9}M$. The results presented confirm that IGE combined with SG may be used successfully for this purpose and on the other hand, made it obvious that commercially available rotating disc electrodes are not suitable. Bearing in mind the results presented it is easy to explain why the loss of sensitivity for Zn at a pH lower than 2.9 was reported when GC as the working RDE was used (1500 rpm) at a $5 \times 10^{-5}M$ mercury ion concentration level.[12]

RAPID GAS ANALYSES FOR THE INVESTIGATION OF SPONTANEOUS COMBUSTION USING CAPILLARY GAS CHROMATOGRAPHY

W. J. HAVENGA
Research and Development, ISCOR Headquarters, P.O. Box 450, Pretoria 0001, South Africa

(*Received* 13 *April* 1992. *Revised* 10 *June* 1992. *Accepted* 10 *June* 1992)

Summary—A simple and fast but sensitive and precise gas chromatographic method is described for the quantitative determination of O_2, N_2, CO, CO_2, C1 and C2-hydrocarbons for coal research. Gas analyses are necessary to obtain parameters for modelling spontaneous combustion and to predict long term coal behaviour. The method is based on a single PLOT-type capillary column in a single channel gas chromatograph. Using a micro-volume TCD coupled in series with a FID detector containing a capillary methanizer it is possible to determine high and trace level gases simultaneously. Trace quantities of CO and CO_2 can be determined with a single analysis and the detection limits are improved significantly using the capillary methanizer. The detection limit of the described method is approximately ten parts per million CO_2 and one part per million CO. Using the same instrument configuration the O_2/N_2 ratios (major components), as parameter for coal reactivity, are also determined. The proposed approach is restricted to the determination of gases evolved during coal studies and the application to other gas mixtures is not considered.

Spontaneous combustion of coal is always undesirable as it can lead to atmospheric pollution and the loss of a valuable commodity or even life. The oxidation of coal (adsorption of oxygen) in which oxygen reacts with the coal to form what is termed an "oxycoal",[1] is the major source of heat in a heap. The oxycoal contains oxidation products such as carboxylic acids, humic acids, peroxides and hydroxides. These products decompose with time to release product gases such as CO and CO_2. Inherent CH_4 is released mainly due to desorption. These gases are released in relatively small concentrations compared to the total amount of oxygen adsorbed, and are expected to be present in trace levels at low temperatures.

The gas concentrations and temperatures in waste heaps is monitored to investigate the coal reactivity, toxic gas evolution and trace gas distribution in order to implement safety precautions and to make long term predictions. The release of CO is of particular importance as it is very toxic, has no smell and its emission from smouldering or burning heaps is a major hazard. Laboratory research programmes exploring the self-heating potential of coal[2] provide the latest information needed for the safe stockpiling, transportation and disposal of coal or waste material. A typical test is the determination of low temperature coal reactivity as well as the amounts of evolved gases. Typical gas concentrations, as found during laboratory experiments or in waste heaps, are indicated in Table 1.

The gases depicted in Table 1 are traditionally determined using two columns, namely a molecular sieve type packed column for O_2, N_2, CO and CH_4 and a Porapak Q for CO_2 and C2-C4 hydrocarbons. Mindrup[3] summarized most of the methods used for permanent gas and light hydrocarbon analyses. Single column applications, using temperature programming from sub-ambient temperatures[4] and dual column[5] or dual channel operation with column valving,[6–8] have been reported, but they are all complex or have long analysis times. All the above-mentioned techniques are based on thermal conductivity detection (TCD) for CO and CO_2 and therefore also lack the necessary sensitivity. Simplicity, efficiency, precision, sensitivity and ease of operation and ease of troubleshooting were considered important standards in developing an analytical technique for modelling of coal behaviour. Efficiency and resolution can be improved significantly using a capillary column.

The Carboplot 007 carbon molecular sieve type capillary column was employed in this investigation. Inorganic and light hydrocarbon gases can be separated and determined using this column and it was deemed possible to

Table 1. Typical expected gas concentrations

Component	Non-reactive waste heaps	Smouldering heaps	Laboratory low temperature experiments
CO	1–25 ppm	0.05–10%	100–5000 ppm
CO_2	0.05–1.5%	0.1–20%	0.05–2%
CH_4	<1	0.001–3%	10–5000 ppm
C_2H_4	<1	1–1000 ppm	<1
C_2H_6	<1	1 ppm–1%	<1

configure a system around a single column to suit the needs for coal research. This would eradicate the complications involved with dual column systems. A capillary methanizer, based on the principles described by Volman,[9] was used to improve the sensitivity for carbon monoxide and carbon dioxide. The efficiency, sensitivity and precision of this method, as well as its application to gas analysis in coal studies, was investigated.

EXPERIMENTAL

Instrument configuration

A Siemens Sichromat II gas chromatograph with a FID, a TCD with an internal cell volume of 20 μl and a gas sampling valve was used in this investigation. The TCD outlet was connected to the FID inlet using a 0.3-mm diameter fused silica capillary. The system was configured as illustrated in Fig. 1 and the FID capillary insert was packed with a cobalt catalyst as shown in Fig. 2. A CarboPLOT 007 capillary column (25 m × 0.53 mm), operated from ambient to 115°, and a helium carrier gas flow of 15 cm^3/min were employed.

A cobalt catalyst with a high surface area was prepared by soaking Chromosorb M (120 mesh) in a saturated cobalt nitrate solution. The excess liquid was removed by filtering under vacuum. The solid phase was dried overnight at 110° and then heated in air for 5 hours at 350° to obtain cobalt oxide with a high surface area. The catalyst was then packed into the quartz tube, as illustrated in Fig. 2, and installed in the FID of the gas chromatograph. The FID was heated overnight at 350° under a stream of helium gas to activate the catalyst.

Gas monitoring in experimental coal heaps

Gas samples are taken from heaps using gas sampling bulbs (250 cm^3), through probes installed at various points. The samples are introduced into the GC using the gas sampling valve with a fixed 0.25-cm^3 sample loop and analyzed for CO, CO_2, CH_4, C_2H_4 and C_2H_6.

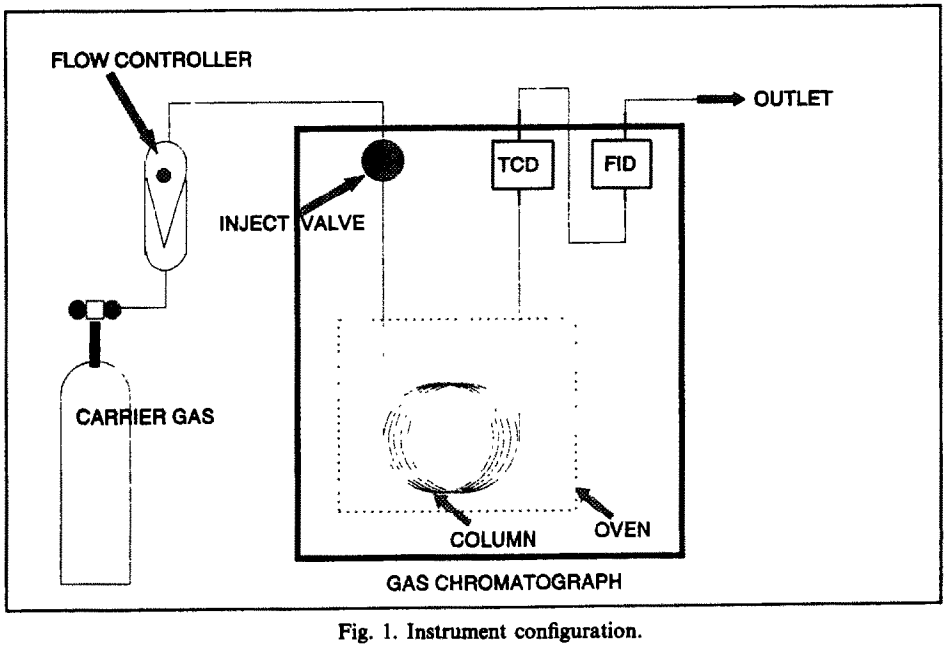

Fig. 1. Instrument configuration.

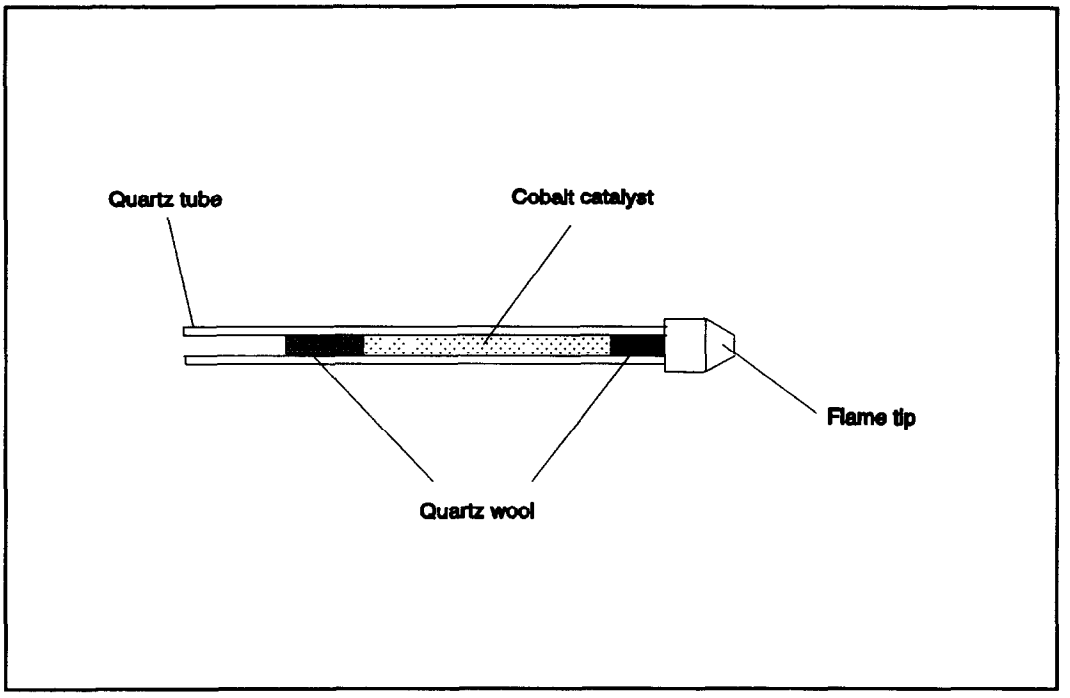

Fig. 2. Cross section of the glass insert in the FID.

The concentration of these gases may vary from trace levels to major components, depending on the temperature in the heap. The FID detector signal is used to quantify low concentration gases and the TCD detector signal for gas concentrations exceeding 1%. The results are expressed as parts per million or percent component present in a specific location in the heap.

Laboratory tests exploring the self heating potential of coal

Sample preparation. The air-dry samples were crushed to 25 mm, mixed, sieved and divided by means of a Jones-riffler to produce four kilogram samples of 1.0–6.3 mm coal particles. These samples were allowed to equilibrate with air at 35° in open trays for twenty four hours.

Apparatus. Reactivity determinations are based on the determination of the rate of oxygen adsorption. For this purpose high density PVC reaction vessels of *ca.* ten litre capacity are used. Each vessel is sealed by a polyurethane gasket located in a machined groove on the flange. The bolt-on lid contains a gas sampling port with a silicone rubber septum and an airtight stop-cock for pressure equalization. Experiments are carried out in a constant temperature room at $35 \pm 1°$ and *ca.* 30% relative humidity.

Method. The coal sample of known mass and density is placed in a reaction vessel of known volume, sealed, and placed in a rotator. The barometric pressure is recorded. Gas samples are removed at intervals through the septum and analyzed by the proposed gas chromatography method to determine the change of O_2/N_2 ratios with time and trace gas levels CO, CO_2 and CH_4 evolved. The test is continued until the O_2 level drops below 15%.

Calculation. The reaction constant of the material with oxygen is calculated from the change in gaseous oxygen content of the sealed container. The formula used is:

$$k = \frac{\ln \dfrac{O_{2i}}{O_{2f}}}{t} \qquad (1)$$

where O_{2i} and O_{2f} are respectively the initial and final O_2/N_2 mole ratio in the reaction vessel, t the time in days and k the rate constant of oxygen depletion (day^{-1}), assuming first order reaction. The reactivity of the material is expressed as normal cm^3 oxygen consumed per kilogram material per day. The formula used is:

$$\text{Reactivity} = k \cdot V_{O_{2i}} \qquad (2)$$

where $V_{O_{2i}}$ is the initial normal cm^3 volume of O_2 available per kilogram coal in the reaction vessel.

RESULTS AND DISCUSSION

System configuration

As indicated by Porter all the necessary conditions for conversion, except the catalyst, are present in the flame ionization detector. Complete conversion of CO and CO_2 to CH_4 is obtained at a FID operating temperature of 350°. Results obtained in this manner are found to be approximately 120 times more sensitive than those obtained employing a TCD. This methanizer configuration is only suitable for conversion of micro-quantities of gases and is therefore only applicable to capillary gas chromatography. The advantage of this method is improved efficiency when compared to traditional packed columns. Simultaneous determination of CO and CO_2 concentrations is also possible.

For simultaneous FID and TCD detection, the series coupling of the detectors was preferred above a parallel arrangement. The latter arrangement would reduce the already low flow rate through the TCD with a simultaneous decrease in resolution and sensitivity. It would also require the installation of a reliable outlet splitter with a very constant split ratio. In the case of the series arrangement it is necessary to use a micro volume TCD to eliminate the possibility of band broadening and resulting loss of resolution of the peaks detected with the FID.

The application of the method to the monitoring of gas concentrations in experimental coal heaps

Gas concentrations in coal waste heaps depend on factors such as the coal type, reactivity, age, moisture content (weather conditions), heap geometry and particle size. The concentration of these gases increase as a function of temperature. In burning heaps CO_2 concentration will typically increase to approximately

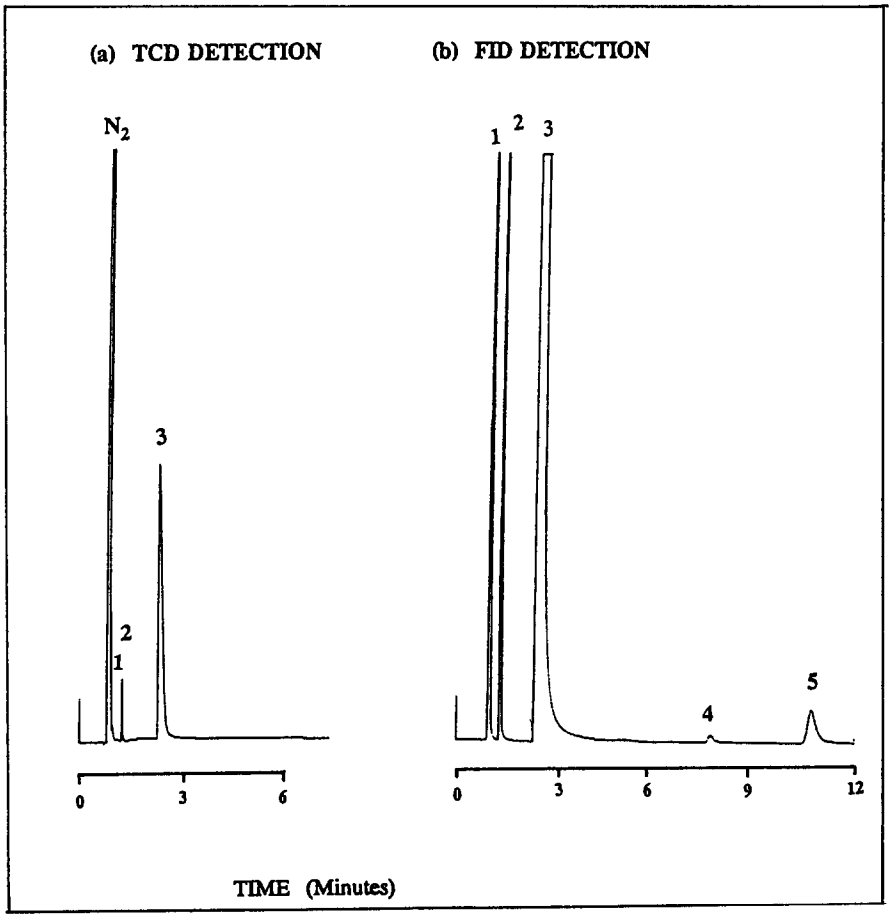

Fig. 3. Separation of gases from a smouldering heap. Column—Carboplot 007, 25 m × 0.53 mm; Oven temperature—90°; Carrier Gas—Helium, flow of 15 cm^3/min; Sample size—size 0.25 cm^3; Detection—TCD coupled in series with the FID, fitted with a capillary methanizer. 1 = 1.01% CO, 2 = 0.95% CH_4, 3 = 15.5% CO_2, 4 = 3.5 ppm C_2H_4, 5 = 43 ppm C_2H_6.

20 percent, methane to 2.5 percent and the C2-hydrocarbons to between 0.001 and 0.15 percent.

Using the Carboplot 007 column, base line separation of CO, CO_2 and CH_4 is achieved at an isothermal column temperature of 90° within an analysis time of 3 min. Ethylene and ethane can also be separated and detected using an extended analysis time of ten minutes, but these components are not normally present in samples and only occur in burning heaps or in high temperature experiments. A typical chromatogram of a sample collected from a waste heap at the Grootegeluk Coal Mine, is illustrated in Fig. 3.

As evident from Fig. 3(a) there is considerable interference (overlap) from the N_2 peak with the CO peak using TCD detection. This problem is solved when CO is converted to methane because the FID is insensitive to N_2 [Fig. 3(b)]. The relative signal intensity differences between Figs. 3(a) and (b) are also illustrated.

The application of the method to determine gas concentrations during controlled laboratory experiments

The low temperature adsorption of oxygen by coal is the main heat-generating step during the oxidation process of coal. The rate of oxygen adsorption, as a measure of coal reactivity, is determined by the gas chromatographic method and calculated according to equations (1) and (2). The reactivity is also used as a parameter for mathematical models used to predict the self-heating potential of coal. A reliable method for determining O_2/N_2 ratios during an experiment is therefore invaluable. For reliable reactivity calculations, the assumption of first order reaction must also be valid. Although a first order reaction is generally assumed for mathematical models of spontaneous combustion in coal stockpiles,[10,11] this is not necessarily the case. Stott[12] described the oxidation by a 0.5 power of the oxygen in the gas stream. Schmal[13] used an experimentally determined order of reaction (n) of 0.7 in the calculations with his moist coal model, and assumed $n = 1$ (as obtained from literature) for calculations with the dry coal model. The order of reaction was also investigated in our laboratory by plotting log O_{2f} versus time. The graphs were constructed from experimental data obtained for various coals and found to be linear. Under our experimental conditions we therefore accepted that chemisorption of oxygen by the coal particle surface proceeds according to a first-order reaction.

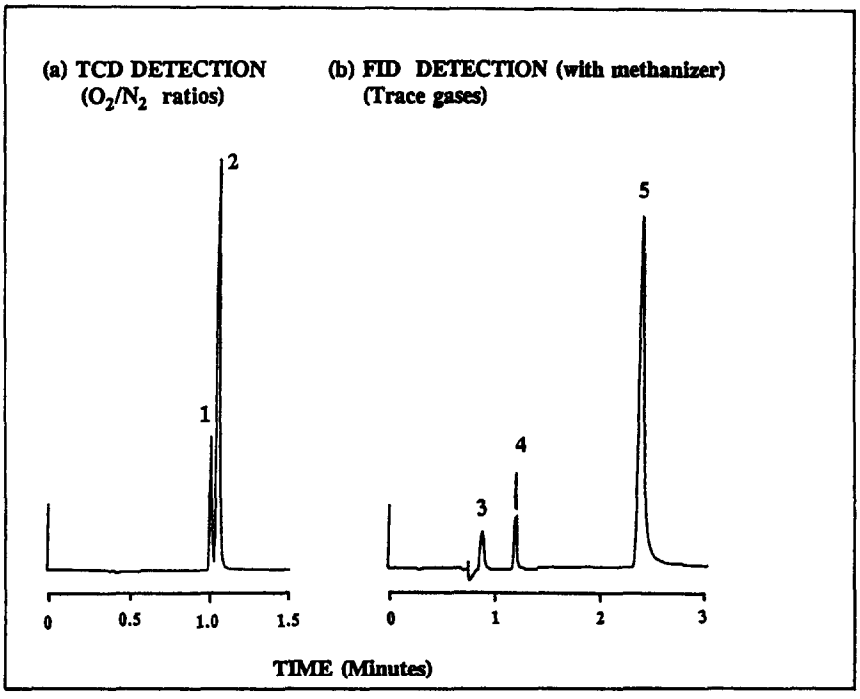

Fig. 4. Separation of gases during a controlled laboratory experiment. Column—Carboplot 007 column, 25 m × 0.53 mm; Carrier gas—helium with flow of 15 cm³/min; Sample size—(a) 10 μl, (b) 250 μl; Oven temp—(a) 30° (b) 90°; Coal sample—Obtained from the Syferfontein Coal Mine in the eastern Transvaal. 1 = 20.9% O_2, 2 = 79.0% N_2, 3 = 17 ppm CO, 4 = 27 ppm CH_4, 5 = 1448 ppm CO_2.

Table 2. Precision of reactivity and gas determinations during a typical laboratory experiment on a Syferfontein coal sample

	Average value X ($n = 11$)	Standard deviation	Coefficient of variation
O_2/N_2 ratios (O_{2i})	0.2562	—	—
O_2/N_2 ratios (O_{2f})*	0.2080	—	—
Reactivity	415 cm^3/kg/day	10.9	2.63
CO	17.8 ppm	0.44	2.49

CO_2	1448 ppm	16	1.10

*Time elapsed = 0.177 days; $V_{O_{2i}} = 352.4$ cm^3.

Gas chromatographic results obtained on coal from the Syferfontein Mine in the eastern Transvaal, are illustrated in this paper. The $O_2:N_2$ ratios were determined using a Carboplot 007 column at ambient temperature and TCD detection. Almost baseline separation of O_2 and N_2 was achieved within an analysis time of under 1.5 minutes. A typical chromatogram is shown in Fig. 4(a).

Trace amounts of gases evolved during this experiment were also determined. A typical chromatogram of trace level gases is illustrated in Fig. 4(b). The final results of this experiment are given in Table 2.

Precision of the method

Data on precision studies was obtained by repeatedly analyzing the gases in the reaction vessel containing the Syferfontein coal (Table 2), as well as the gas sample collected from the Grootegeluk waste heap (Table 3).

As evident from Table 2, variation coefficients better than 2.5 percent were obtained in the case of the controlled laboratory experiment. As evident from the two sets of results obtained for the waste heap sample in Table 3, a considerable improvement is noticed in the case of FID detection. The CO peak could not be integrated on the TCD chromatogram due to overlap with the nitrogen peak. Furthermore the ethane and ethylene concentrations were too low for TCD detection. However, in the case of CO_2 present at a high concentration, the TCD results were found to be more precise. The lower value obtained on the FID could be due to the flattening out of the calibration curve at high gas levels. The combined results indicate that the precision is acceptable for the intended use of the method. Acceptable variation coefficients were obtained for all the trace gases, including the very low carbon monoxide concentration.

Linearity and detection limits

Multipoint calibration curves for each component were determined on the Carboplot 007 column using primary and secondary standards of different component concentrations. Relative response factors were calculated for each gas and were found to be linear over the concentration ranged indicated in Table 1. Other concentration ranges were not considered in this paper. The analytical working ranges for the FID and TCD, as well as the method detection limits (MDL) which can be expected for the trace gases, are indicated in Table 4.

The MDL is defined as the minimum concentration that could be measured with 99% confidence that the analyte concentration is greater than zero. The measurements were based on a maximum sample size of 250 μl that could be used to determine the trace gases with

Table 3. Precision of a gas determination on a reactive heap gas sample from Grootegeluk

	Results obtained on the FID			Results obtained on the TCD

Table 4. Suggested analytical working ranges for the TCD and FID

Component	Analytical working ranges	Type of detector	Method detection limits
O_2/N_2 ratios	0.1–0.26	TCD	—
CO	0–1%	FID (Methanized)	1 ppm
	1–10%	TCD	100 ppm
CH_4	0–1%	FID	1 ppm
	0.1–3%	TCD	100 ppm
CO_2	0–1%	FID (Methanized)	10 ppm
	1–20%	TCD	1000 ppm
C_2H_4	0–1%	FID	2.5 ppm
	0.1–3%	TCD	250 ppm
C_2H_6	0–1%	FID	2.5 ppm
	0.1–3%	TCD	250 ppm

this column, before observing the effects of overloading. Low enough detection limits were obtained with FID detection to allow reliable-results. Unacceptable detection limits were found on the TCD, thus illustrating the advantage of the FID and methanizer for reliable determination of evolved gases in coal research.

CONCLUSIONS

The Carboplot 007 capillary column used in the proposed configuration was found to exhibit superior performance compared to traditional methods. Separation and determination of O_2, N_2, CO, CO_2, CH_4, C_2H_4 and C_2H_6, as major or trace components, can be achieved with a single channel system built around a single column. Combining the efficiency and simplicity of the single capillary column with the detection capability of a capillary methanizer the following is achieved:

Separation of all the gases involved
Short analysis turnover time
Improved sensitivity for CO and CO_2
Wide linear working range of all the involved gases
Simplicity, ensuring ease of operation and ease of trouble shooting

The method can be applied to various investigations, covering a wide range of concentrations for the most important gases, by making inexpensive modifications. The method is particularly suitable for the monitoring of coal reactivity.

DETERMINATION OF PLATINUM IN PLANTS BY EMISSION SPECTROMETRY AFTER PRECONCENTRATION ON MODIFIED SILICAGEL

VÍTĚZSLAV OTRUBA,* MARTA STRNADOVÁ and BLANKA SKALNÍKOVÁ
Department of Analytical Chemistry, Masaryk University, 611 37 Brno, Czech Republic

(*Received* 19 *February* 1992. *Revised* 10 *June* 1992. *Accepted* 10 *June* 1992)

Summary—Silicagel Separon SGX C18 (particle size 7 μm) was suitable for the preconcentration of 2–20 μg of Pt from 0.1*M* hydrochloric acid in the presence of cationic surfactants especially dimethyllaurylbenzylammonium bromide, with subsequent elution with 96% ethanol. The recovery was 86–110% for 2 μg of Pt. The sample matrix corresponding to 2.5 g of average plant ash does not interfere. The final emission spectrometry of platinum was carried out in 15 A dc-arc at Pt I 265.942 nm in the presence of Au as internal standard (Au I 267.595 nm). RSD was 6.3% in average.

The environmental platinum is often due to platinum dust coming from industrial and vehicles' catalyzers. Platinum contents of 37–680 μg Pt/kg were detected in roadside dust on dried plants.[1] Isolated samples of dried plants contained platinum levels of 100–830 μg/kg.[1] Among suitable methods for the determination of platinum the classical emission spectrometry,[2,3] the flame AAS,[4] ETA–AAS[4] or ICP–OES[5] were commonly used.[5] The absolute detection limits are reported to be usually 100 ng of Pt for the classical emission spectrometry[3] and the flame AAS,[4] 0.75 ng of Pt for ETA–AAS[4] or 30 ng of Pt for ICP–OES.[5] Thus, a preconcentration of platinum and its separation from the matrix is necessary when biologic samples are analysed.

Sufficiently low limits of detection can be achieved by using classical emission spectroscopy.

In this paper the simple preconcentration of platinum in the form of platinum(IV)–chlorocomplexes[7] with cationic surfactant on Separon SGX C18 column is used in combination with dc-arc-emission spectroscopy as detection. In this way the detection limit dropped to 10^{-7}% Pt for model samples.

EXPERIMENTAL

Instruments

Spectrograph PGS-2 of Carl Zeiss, Jena, supplied by two gratings, *i.e.*, with 651 lines/mm, blaze angle at 320 nm and reciprocal linear dispersion 0.737 nm/mm in the 1st order, or 1302 lines/mm, blaze angle 265 nm and reciprocate linear dispersion 0.184 nm/mm respectively if used in the 2nd order. A three-lens system with a 5-mm intermediate projection diaphragm was used, the entrance slit was 0.020 mm, the distance between carbon electrodes was 3 mm.

A UBI-1 generator of RFT supplying 15 A dc-arc was used. Carbon electrodes SU 326, SU 304 or SW 304 (carrier), SU 202 (counter electrode as cathode) and graphite powder SU 602 were used, all of Elektrokarbon Topolciany, CSFR.

Exposed photographic plates ORWO WU 2 and WU 3 (Germany) were evaluated on microphotometer MD-100, Zeiss with slit area 0.1 × 15 mm and under 20 times magnification using the P-transformation of characteristic curve and filters with 10% T(internal standard) or 100% T(platinum line).

AAS spectrometer Perkin–Elmer 306 with 10 cm burner, acetylene-air flames with flow rates 22.5 l./min for air and 1.4 l./min for acetylene. Hollow cathode lamp with Pt line 265.942 nm at 30 mA.

Membrane pump MP 2501 was from Laborinstruments Prague with stainless and teflon® fittings.

Chemicals

Standard solutions. Platinum solution (0.326 mg/ml) was prepared by dissolving the metal in *aqua regia* (1 + 9). $AuCl_3$ was prepared with 5.3 mg/ml Au in hydrochloric acid

*Author for correspondence.

(1 + 9). $ZrOCl_2$ was prepared in 1*M* hydrochloric acid with 3.0 mg/ml Zr and GeO_2 in water with 1.075 mg of Ge.

Brij 35 (Merck, Darmstadt). A 2.5% stock solution was used.

Butyltriphenylphosphonium bromide (BTPP). Recrystallized from ethanol.

Cetyltrimethylammonium bromide (CTMA) (Lachema Co., Brno).

Cetylpyridinium bromide (CPB) (Lachema, Brno).

Dimethyllaurylbenzylammonium bromide (Sterinol). 10% Aqueous solution (Galenius Co., Warsaw).

All other chemicals were of analytical grade quality. Matrix model solution: 2.6 g/l. Na (NaCl), 12.0 g/l. Ca ($CaCl_2$), 19.2 g/l. K (KCl), 3.6 g/l. Mg ($MgCl_2$), 1.0 g/l. Fe ($FeCl_3$) and 0.5 g/l. Al ($AlCl_3$) in 0.1*M* HCl. A 1-ml aliquot of such solutions corresponds to 0.1 g of average plant ash or 6.7 g of average plant material.[8]

Glass chromatographic columns 3 × 30 mm of Tessek Co., Prague filled with Separon SGX C18, particle size 7 μm.

RESULTS AND DISCUSSION

Determination of platinum with emission spectroscopy

For determination of platinum the line Pt I 265.942 nm and internal standards with Au I 267.595 nm, Ge I 265.1178 nm and Zr I 267.8636 nm were tested. Sodium carbonate was used as spectral buffer and Brij 35R as wetting agent.

Procedure for calibration. A 2-ml portion of 2.5% Brij 35R, 1 ml of 2.5% sodium carbonate and solutions containing 0–100 μg of Pt, 25μg of Au or 300 μg of Ge or 1000 μg of Zr were pipetted into 1 g of graphite powder in a Teflon® dish, the solution evaporated under an infra-red lamp, the residue thoroughly mixed and filled into carbon electrodes. Excited in 15 A dc-arc and exposed for 120 sec through the graduated gray filter onto plates WU 3 (grating 651 lines/mm) or WU 2 (grating 1302 lines/mm).

Sample procedure. Pipette 0.5 ml of 2.5% Brij 35R, solutions with 6.25 μg of Au, 75 μg of Ge or 250 μg of Zr, 0.25 ml of 2.5% sodium carbonate and a portion of the sample eluate in *aqua regia* into 0.25 g graphite powder in a Teflon® crucible and continue as above.

Best results were obtained when Au was used as internal standard. Using increased spectral resolution, one component of the structured background lies under the platinum line and interferes. Thus, in spite of steeper calibration plots for larger spectral resolution, the detection limit of 0.8 μg Pt/g graphite powder (0.1 μg of Pt in the electrode for determination) was identical in both cases and the grating with 651 lines/mm was observed as fully satisfactory. Some resulting data are collected in Table 1.

Preconcentration of platinum on dynamically modified Separon SGX C18

The column was initially washed with 30 ml of 70% ethanol and 100 ml of water and treated with 5 ml of aqueous solution of quarternary salt (0.33 ml/min) containing 1m*M* BTPP, 1m*M* CPB, 12.5m*M* CTMA or 2.7m*M* Sterinol. A 50-ml solution containing 20 μg of Pt in 0.1*M* hydrochloric acid and 1m*M* BTPP, 1m*M* CPB, 12.5m*M* CTMA or 2.7m*M* Sterinol passed through the column. The elution from the column followed with 70, 85 or 96% ethanol. The flow rate for the sorption and desorption

Table 2. Effect of surfactants on the retention of platinum (20 μg) on Separon SGX C18 from 0.1*M* hydrochloric acid.

Surfactant	Surfactant concentration used, *m*M	Retained Pt (%)	Recovery (%)	Ethanol as eluent
BTPP	1	53	40	75%
CTAB	12.5	80	80–90	75, 85%
CPB	1	»95	86–100	85, 96%
Sterinol	2.7	»95	90–100	85, 96%

being limited by the available column pressure was 0.33 ml/min.

The behaviour of platinum on the sorbents was followed by AAS at Pt 265.942 nm in acetylene-air flames with flow rates 22.5 l./min for air and 1.4 l./min for acetylene respectively (Perkin-Elmer AAS, model 306). The determination limit was 3 μg Pt/ml.

In the presence of BTPP the sorption of platinum (20 μg of Pt) from 50 ml was poor and took place from 53% only and 40% of the total platinum amount was eluted with the first 5-ml fraction of 75% ethanol.

With CTMA the last three 10-ml fractions contained an average of 1.3 μg of Pt which is 6.5% of the total amount applied onto the column. The platinum elution resulted in the first two 5-ml fractions of 75% ethanol.

The sorbent was most effective in the presence of 1m*M* CPB or 2.7m*M* Sterinol and sorbed 20 μg of Pt from 50 ml of 0.1*M* hydrochloric acid quantitatively. Unfortunately 10–15 ml of 85 or 96% ethanol was necessary for the elution of platinum from the column covered by CPB, whereas in the presence of Sterinol the quantitative elution of Pt was already in the first ml of 96% ethanol and the recovery for 20 μg of Pt was 86–100%. Identical results were also obtained from 0.01*M* hydrochloric acid and 2.7m*M* Sterinol. Some results are given in Table 2.

Matrix effects were examined similarly but the solution with 20 μg of platinum in 0.1*M* hydrochloric acid and the quarternary salt in concentrations as above contained 5 or 25 ml of matrix model solution corresponding to 33.5 or 167.5 g of dry average plant material in the total volume of 50 ml. The eluate was evaporated with 0.25 g of powdered graphite. This represents approximately 10^{-7}% Pt in solution corresponding to 167.5 g of dry plant material, if the detection limit of 0.2 μg of Pt for 0.25 g of graphite is assumed.

From the 12.5m*M* CTMA solution with 5 ml of matrix model solution the recovery of platinum was 70–80% but 40% only in the presence of 25 ml of model matrix solution if eluted with 10 ml of 85% ethanol. Moreover the recovery of 2 μg of Pt in 50 ml was 20% only. For 1m*M* CPB and 20 μg of Pt in 50 ml the recoveries were 70–80% in the presence of 5 ml or 65% respectively in the presence of 25 ml of matrix model solution. The recovery of 2 μg of Pt was 50% only. A 10–15 ml amount of 85 or 96% ethanol was necessary for the elution of platinum from the column. Most suitable results were again observed with Sterinol (2.7m*M*). The recovery of even 2 μg of Pt in 50 ml was 100% in the presence of 25 ml of matrix model solution and the elution with 1 ml of 96% ethanol was satisfactory. Results are collected in Table 3.

Glycole–polymethacrylate gels such as Spheron DEAE 1000 (particle size 0.063–0.1 mm, Lachema INC, Brno) as anion exchanger showed no advantage against modified silicagel. Under similar conditions platinum was sorbed in more than 95% (flow rate 0.5 ml/min) from 0.1*M* hydrochloric acid but the recovery of platinum with 3 ml of 0.1*M* hydrochloric acid and 2*M* perchloric acid was 85% only.

The advantage of proposed method is in its high separation selectivity for platinum from accompanying main components of biological material. From the sample matrix, platinum(IV) chloro-complexes are retained only. The sorption of matrix macrocomponents such as aluminium or iron on Separon SGX C18 was

Table 3. Recoveries of minor platinum concentration from matrix model solution

Surfactant	Recovery		
	20 μg Pt for 5 ml*	2 μg Pt for 25 ml†	20 μg Pt for 25 ml†
CTAB	70–80%	20%	40%
CPB	70–80%	50%	65%
Sterinol	100%	100%	100%

*In the presence of 5 ml of matrix model solution (see the text).

†In the presence of 25 ml of matrix model solution.

not observed in contrast to anion exchanger Spheron DEAE 1000. The retention of platinum by Separon SGX C18 takes place from non-aggressive media of 0.1*M* hydrochloric acid and its elution with 85 or 96% ethanol respectively into small (1 ml) volumes of eluent is fast and quantitative. In this way the corrosion of stainless parts of membrane pumps is hindered which is not the case when using 2*M* perchloric acid as eluent from Spheron DEAE 1000.

Acknowledgement—Thanks are due to Professor L. Sommer for his deep interest and valuable comments.

SIMULTANEOUS DETERMINATION OF WARFARIN AND BROMADIOLONE BY DERIVATIVE SYNCHRONOUS FLUORESCENCE SPECTROMETRY

S. PANADERO, A. GÓMEZ-HENS and D. PÉREZ-BENDITO

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

(*Received* 13 *April* 1992. *Revised* 12 *June* 1992. *Accepted* 12 *June* 1992)

Summary—By using second derivative synchronous fluorescence spectrometry the simple resolution of mixtures of the anticoagulant rodenticides warfarin and bromadiolone in the presence of β-cyclodextrin is accomplished, which causes a differential effect on the fluorescence intensity of these compounds. The determination method developed is simple, fast and inexpensive; in addition, measurements are performed in a single scan. Mixtures of warfarin and bromadiolone in ratios between 4:1 and 1:10 were satisfactorily resolved.

Warfarin[3-(3-oxo-1-phenylbutyl)-4-hydroxycoumarin] and bromadiolone{3-[3-(4-bromodiphenyl-4-yl)-3-hydroxy-1-phenylpropyl]-4-hydroxycoumarin} are two coumarin-based anticoagulants used as rodenticides. They impair blood coagulation, leading to hemorrhage as the ultimate cause of death. Warfarin is also extensively used as a clinically effective oral anticoagulant in man; on the other hand, bromadiolone has a much higher acute oral toxicity, so it is only used as a rodenticide. The interest on the determination of these compounds lies in the poisoning hazards for no-target animals owing to their toxicity to all mammals.

Because of their similar spectral features, the determination of these compounds in mixtures has so far been carried out by liquid chromatography[1–3] with fluorimetric detection. However, there are other approaches which allow the simple determination of compounds with overlapped spectra without prior separation. Synchronous spectrofluorimetry offers improved selectivity over conventional spectrofluorimetry thanks to the narrower spectral bandwidth, which in turn depends on the chosen $\Delta\lambda$ value (viz. the wavelength difference between emission and excitation monochromators). Also, derivative synthronous fluorescence spectrometry[4] has proved a highly useful analytical technique[5,6] for the direct resolution of mixtures of different compounds of clinical, biochemical and pharmaceutical interest.

Because the emission spectra of warfarin and bromadiolone are completely overlapped, direct use of derivative synchronous fluorescence spectrometry for their simultaneous determination is obviously precluded. We were thus to seek an alternative way of distinguishing the two compounds and found β-cyclodextrin to increase their fluorescence intensity to a different extent.

Cyclodextrins are reportedly interesting organized systems in terms of fluorescence and room-temperature phosphorescence of use for the determination of organic compounds.[7–10] Because of the internal cavity of these compounds, luminescent molecules can form stable inclusion complexes provided they fit in the cavities. The formation of these complexes is thus reliant on chemical and geometrical factors. The chief practical consequence of this association is that the luminescent molecules are isolated from the environment, so any quenching effects are avoided and their luminescence is enhanced. The inclusion complex of β-cyclodextrin with a coumarin (coumarin C540A) was previously studied[11] and β-cyclodextrin was used to improve the determination of warfarin by circular dichroism[12] and fluorimetry.[10] However, the differential effect of β-cyclodextrin on the fluorescent features of warfarin and bromadiolone is dealt with for the first time in this paper. The combination of this effect and derivative synchronous fluorescence spectrometry allowed the simple resolution of mixtures of these two compounds.

EXPERIMENTAL

Reagents

Stock warfarin and bromadiolone solutions (0.1 mg/ml) were prepared from warfarin (Aldrich) and bromadiolone (Chem. Ser.), respectively, in 0.1*N* sodium hydroxide, and stored at 0–4°. More dilute solutions of both were prepared daily by dilution with distilled water. A β-cyclodextrin solution, $10^{-2}M$, was prepared by dissolving β-cyclodextrin (Aldrich) in distilled water. A borate buffer of pH 9.5 was made from 0.1*M* boric acid and 0.4*M* sodium hydroxide. Reagent-grade chemicals and pure solvents were used throughout.

Apparatus

A Perkin–Elmer MPF-43A fluorescence spectrometer furnished with 1-cm quartz cells and a xenon source was used for fluorescence measurements. The cell compartment was thermostated by circulating water at 25° through it. A spectral band-pass of 8 nm was set for the excitation and emission monochromators. For synchronous fluorescence mesurements, both monochromators were interlocked and scanned simultaneously at 2 nm/sec. Derivative spectra were recorded by electronic differentiation of the signal from a Perkin–Elmer H 200-0507 derivative accessory. Of the six differential time constants available through the mode switch, position 6 was selected for all measurements. The spectrofluorimeter response (time constant) was set to 3 sec. A series of fluorescence polymer samples was used daily to adjust the spectrofluorimeter to compensate for changes in source intensity. A Perkin-Elmer LS-50 luminescence spectrometer controlled via a Hewlett-Packard Vectra computer, running the "Galactic" application program was used to obtain the contour plots.

Procedure

To a sample solution containing warfarin and bromadiolone in a final concentration range between 0.2 and 3.5 μg/ml of each were added 7 ml of $10^{-2}M$ β-cyclodextrin and 1 ml of 0.1*M* borate buffer (pH 9.5). The mixture was made up to 10 ml in a standard flask with distilled water. The second-derivative synchronous fluorescence spectrum was recorded by scanning both monochromators simultaneously while keeping an 85-nm constant difference between their wavelengths ($\Delta\lambda$). The excitation monochromator was scanned from 215 to 375 nm and the emission monochromator from 300 to 460 nm. The instrumental parameters were set as stated above. The second derivative peak-to-peak measurements[13] are given as the relative fluorescence intensity and expressed as ΔI. The derivative signal obtained at 348 nm (ΔI_1) was directly proportional to the bromadiolone concentration and the measurement obtained between 403 and 430 nm (ΔI_{2+3}) resulted from the contribution of both warfarin and bromadiolone. The difference between the total ΔI_{2+3} and ΔI_2, which can be ascribed to the bromadiolone concentration and was determined from a previously constructed calibration plot (ΔI_2 *vs.* bromadiolone concentration) is thus directly related to the warfarin concentration (ΔI_3).

RESULTS AND DISCUSSION

Optimization of variables

The emission spectra obtained in the absence of β-cyclodextrin are completely overlapped and have equal fluorescence intensity (Fig. 1). However, in the presence of β-cyclodextrin, the fluorescence of both compounds substantially enhanced and that of warfarin is higher than the fluorescence of bromadiolone. Both spectra remained stable for at least two hours, but they were also strongly overlapped, so that simultaneous determination of these compounds by conventional spectrofluorimetry was clearly

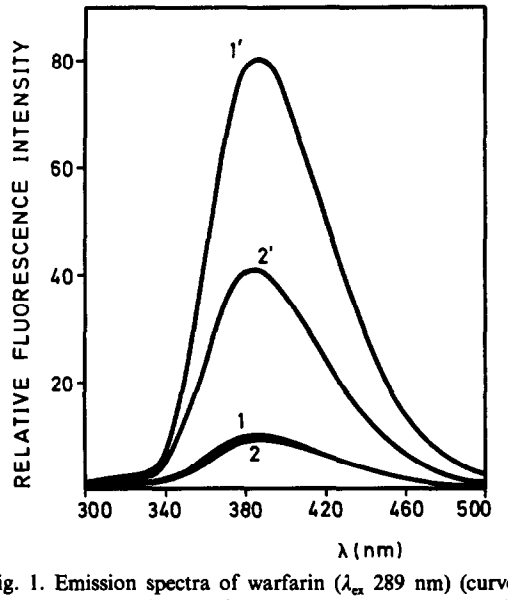

Fig. 1. Emission spectra of warfarin (λ_{ex} 289 nm) (curves 1,1') and bromadiolone (λ_{ex} 278 nm) (curves 2,2') in the absence (curves 1,2) and presence (curves 1,2') of β-cyclodextrin. [warfarin] = [bromadiolone] = 1 μg/ml.

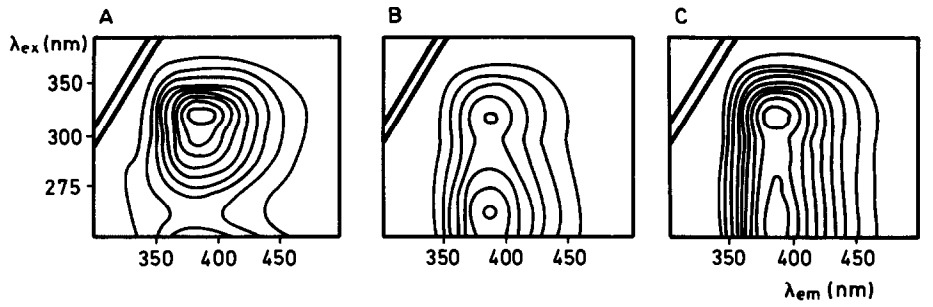

Fig. 2. Contour plots of warfarin (A), bromadiolone (B) and a mixture of both (C). Analyte concentrations as Fig. 1.

unfeasible and a different approach, such as synchronous spectrofluorimetry, was required for this purpose.

A simple way of determining the best $\Delta\lambda$ value for the resolution of a mixture by synchronous spectrofluorimetry involves obtaining the contour plots of the individual components and the mixture. These graphs allow one to choose the best synchronous trajectory to follow in order to avoid spectral overlap. Figure 2 shows these spectra for warfarin, bromadiolone and a mixture of both. As can be seen, warfarin yields a peak that overlaps with one of the two peaks of bromadiolone, so the resolution of this mixture by synchronous spectrofluorimetry is also unfeasible. This is quite apparent from Fig. 3, which shows the overlapped synchronous spectra obtained for the two compounds at $\Delta\lambda = 85$ nm, which according to the contour plots appears to be an appropriate path to use as it passes near the maxima of both compounds with no loss of sensitivity.

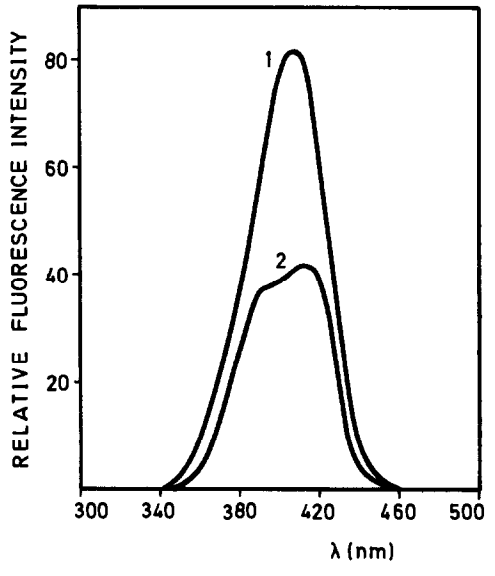

Fig. 3. Synchronous flourescence spectra of warfarin (curve 1) and bromadiolone (curve 2). $\Delta\lambda = 85$ nm. Analyte concentrations as Fig. 1.

In the event of strongly overlapped synchronous fluorescence spectra, as is the case with warfarin and bromadiolone, the technique calls for the additional resolution capability offered by derivative fluorescence spectrometry. Figure 4(A) shows the first-derivative synchronous fluorescence spectra obtained for warfarin, bromadiolone and a mixture of both. The signal obtained between the minimum at 390 nm and the maximum at 418 nm corresponds to the additive contribution of warfarin and bromadiolone, while the small shoulder at 356 nm is due to bromadiolone only. Although this approach could be used to resolve the mixture, the measurements at 356 nm might be inadequately precise. The second-derivative synchronous fluorescence spectra obtained for these compounds and a mixture of both [Fig. 4(B)] show that the bromadiolone concentration is correlated with the signal obtained at 348 nm (ΔI_1) and that the signal between the minimum at 403 nm and the maximum at 430 nm (peak-to-peak measurements) (ΔI_{2+3}) corresponds to the additive contribution of both compounds.

Because the signal-to-noise ratio (SNR) degrades as the derivative order is increased, we compared the SNR values obtained from the first- and second-derivative synchronous spectra. When electronic differentiation was used, the signal was derived with respect to time rather than the wavelength ($dI/d\lambda = dI/dt \times 1/c$, c being the wavelength scanning speed, which was kept constant during the scan), so all variables including the time factor markedly affected the SNR obtained. It was experimentally found that, in using electronic differentiation, the signal obtained from the second-derivative spectrum was higher than that from the first-derivative spectrum, the difference

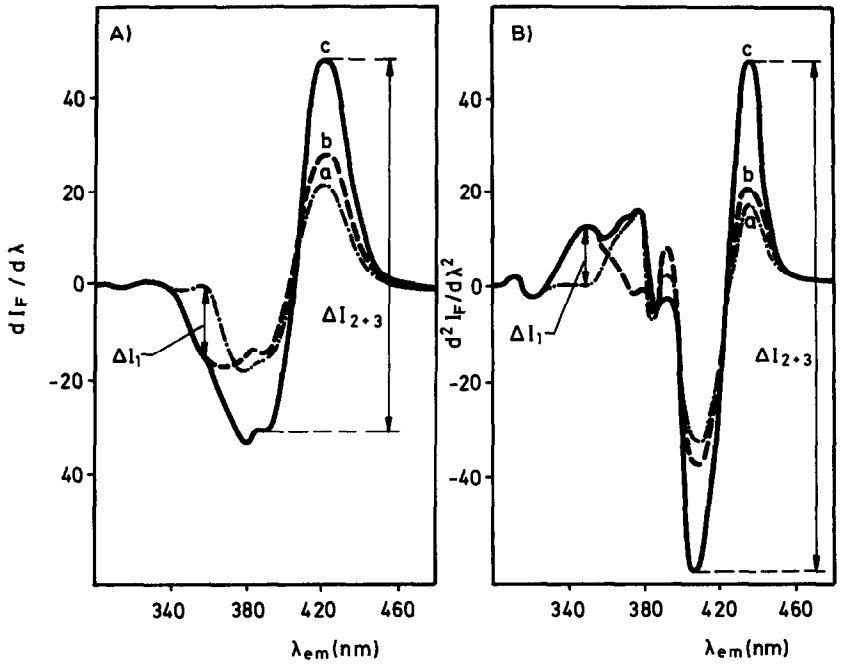

Fig. 4. First- (A) and second-derivative synchronous fluorescence spectra (B) of bromadiolone (curve a), warfarin (curve b) and a mixture of both (curve c). $\Delta\lambda$ = 85 nm. Wavelength scanning speed = 2 nm/sec. Analyte concentrations as Fig. 1.

increasing with increasing wavelength scanning speed.[14] At a scanning speed of 2 nm/sec noise increased from the first- to the second-derivative spectrum by about 30%, however, as the signal obtained from this spectrum was higher, the resulting SNR was only about 10% smaller. This led us to choose the second- instead of the first-derivative spectrum to resolve the warfarin–bromadiolone mixture, thus avoiding the potentially poor precision of the measurements made at 356 nm on the first-derivative spectrum.

Experimental variables were optimized according to the following criteria: 1) the fluorescent signal ΔI_1 should not depend on the warfarin concentration, 2) the fluorescence signal ΔI_{2+3} should be additive for the warfarin and bromadiolone concentrations, and 3) the fluorescence signal of each compound should be as tall as possible.

Instrumental variables ($\Delta\lambda$, wavelength scanning speed, differentiation constant, spectrofluorimeter time constant and slit widths) have a critical effect on the sensitivity and selectivity of the determination as they affect both the resolution and the signal because they modify the wavelength ranges and the number and relative intensity of the peaks making up the derivative synchronous fluorescence spectrum.

Figure 5 reflects the marked dependence of the second-derivative synchronous fluorescence spectra on the chosen $\Delta\lambda$ value. This variable affects the shape of these spectra, which show bathochromic shifts as $\Delta\lambda$ increases, and the ΔI value obtained. The resolution of the warfarin–bromadiolone mixture is only possible when $\Delta\lambda$ is in the range 80–90 nm, where ΔI_1 only depends on the bromadiolone concentration and ΔI_{2+3} is additive for the warfarin and bromadiolone concentrations. $\Delta\lambda$ value of 85 nm was thus chosen.

The shape of the derivative synchronous fluorescence spectra is also affected by the wavelength scanning rate, as it determines the dI/dt value obtained from the electronic differentiation accessory. This variable was studied in the range 0.5–8 nm/sec, and SNR was found to increase with increase in the scanning speed. However, it was impossible to use a high scanning speed because the signal ΔI_{2+3} was not additive for the warfarin and bromadiolone concentrations, so that a speed of 2 nm/sec was eventually chosen. The study of the effect of the differentiation constant showed that the optimization criteria were met at the minimum response speed (mode 6). The shape of the spectra did not change appreciably with the spectrofluorimeter time constant (0.3, 1.5 and 3.0 sec), but the spectra were cleaner when 3 sec

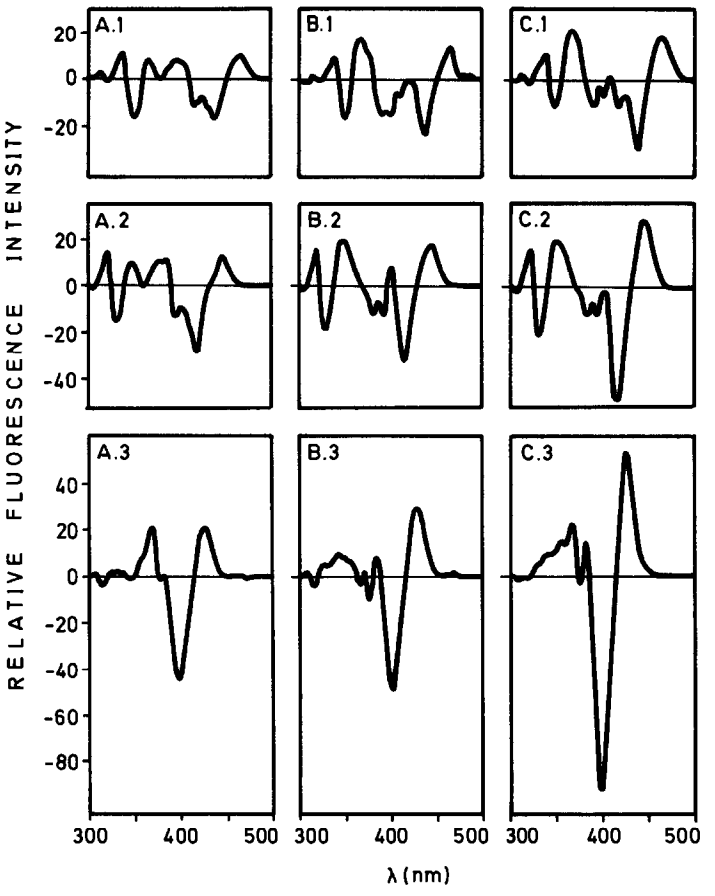

Fig. 5. Effect of $\Delta\lambda$ on the second-derivative synchronous fluorescence spectra of warfarin (A), bromadiolone (B) and a mixture of both (C). (1) 120 nm, (2) 100 nm, (3) 80 nm.

was used. From the different slit widths of the excitation and emission monochromators tested, a width of 8 nm for both monochromators was found to provide acceptable results.

The chemical and physico-chemical variables only affect the sensitivity of the method as they only alter the analytical signal (ΔI). The study of the effect of α- and β-cyclodextrin on the fluorescence of warfarin and bromadiolone showed this compound to raise the fluorescence of both compounds. On increasing the β-cyclodextrin concentration between 10^{-3} and $10^{-2}M$ the fluorescence intensity of both warfarin and bromadiolone increased; however, the effect was virtually negligible above a $8 \times 10^{-3}M$ concentration.

As shown elsewhere,[10] the fluorescence intensity of warfarin in the presence of β-cyclodextrin is constant over the pH range 6.8–11.0. We found the fluorescence intensity of bromadiolone in the presence of β-cyclodextrin to behave similarly towards pH, so we assayed two different buffers (boric acid–borate and ammonium–ammonia) and obtained the same fluorescence intensities. Also, the borate buffer concentrations assayed (5.0×10^{-3}–$2.5 \times 10^{-2}M$) were found to have no effect on this parameter. Decreasing the dielectric constant of the solutions by adding ethanol had no effect on the ΔI_{2+3} signal, but resulted in a loss of correlation between ΔI_1 and the bromadiolone concentration. The spectra were virtually independent of the temperature over the range 25–50°, so this was not a critical factor in choosing the best experimental conditions.

Features of the proposed methods

The main analytical features of the individual methods developed for warfarin and bromadiolone by using second-derivative synchronous fluorescence spectrometry are summarized in Table 1. The detection limits were calculated according to the IUPAC recommendation.[15] The detection limit for warfarin is similar to that achieved by conventional spectrofluorimetry.[9] This can be ascribed to the fact that even though the noise in the second-derivative synchronous spectrum is higher than that in the conventional

Table 1. Features of the individual determination of warfarin and bromadiolone

spectrum, the signal obtained in the former by using electronic differentiation and the optimum instrumental variables is higher than that obtained in the conventional spectrum, so a small degradation of the SNR is the sole loss to be expected from using the second-derivative synchronous spectrum. The relative standard deviation obtained at two different concentrations (1 and 3 μg/ml) of both analytes was less than 3%. A brief study of the selectivity of these methods showed that other rodenticides such as dicoumarol and diphacinone are tolerated at the same concentration levels as warfarin and bromadiolone.

Simultaneous determination of warfarin and bromadiolone

Table 2 summarizes the results obtained in the resolution of synthetic mixtures of warfarin and bromadiolone by second-derivative synchronous fluorescence spectrometry. The determination was carried out in a single scan by using the calibration graphs obtained for each component. Mixtures of warfarin and bromadiolone in ratios between 4:1 and 1:10 were resolved.

The proposed method described could be applied to the analysis of animal tissues in cases of suspected poisoning. Liver is usually the most useful sample for diagnostic analysis; however, as it is a very complex matrix, previous extraction and clean-up processes would be required. Using liquid chromatography for the resolution of mixtures of coumarin anticoagulant rodenticides including warfarin and bromadiolone in animal tissues,[1-3] entails extraction into a chloroform–acetone mixture of ethanol and clear-up of the extracts by gel permeation chromatography or solid-phase extraction with silica columns. Similar separation procedures could be used before the derivative synchronous fluorimetric technique is applied for mixture resolution. The main advantages of the proposed method compared to chromatographic procedures, which call for dedicated and expensive instrumentation as well as, usually, elution gradient, are its great simplicity and low cost. All the synchronous technique requires is a simple switch for simultaneously scanning both monochromators, while the derivative technique can be implemented by incorporating a straightforward electronic accessory (electronic differentiation) or using computer software (numerical differentiation) to obtain derivative spectra.

SOLVENT EXTRACTION OF 8-QUINOLINOLATO–IRON(III) WITH THE AID OF VARIOUS PHENOLS AS HYDROGEN-BONDING DONORS

SHOICHI KATSUTA and NOBUO SUZUKI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980, Japan

(*Received* 26 *May* 1992. *Accepted* 16 *June* 1992)

Summary—Effect of various phenols (ArOH) on the solvent extraction of iron(III) with 8-quinolinol (HQ) has been investigated. Greatly enhanced extraction is found in the presence of ArOH, *e.g.*, the distribution ratio of iron(III) with HQ in carbon tetrachloride is increased 200,000-fold by 0.10*M* 3,5-dichlorophenol. From extraction equilibrium analysis, the enhanced extraction has been ascribed to the formation of association complexes of neutral iron(III) 8-quinolinolate (FeQ_3) with ArOH as $FeQ_3 \cdot n$ArOH (n = 1, 2, 3) in the organic phase, and the association constants ($\beta_{ass,n}$) have been determined. A linear relation is observed between logarithmic values of $\beta_{ass,n}$ and the acid-dissociation constant of ArOH. Existence of the hydrogen bond between FeQ_3 and ArOH is clearly shown by infrared spectroscopy.

While chelate extraction has been studied in depth, little attention has been paid to the role of hydrogen bond interaction between organic proton donors and metal chelates. The authors have recently discovered that halogenated phenols strongly interact with metal acetylacetonates through hydrogen bonding in organic solvents, and enhance the extraction of various metal ions with acetylacetone.[1–6] This novel enhancement effect of phenols as proton donors on the chelate extraction should be analytically important because it is expected to show quite different selectivity from the well-known synergistic enhancement effect of electron donors such as tributyl phosphate and trioctylphosphine oxide.[4–6] However, the effect of phenols has only been examined for the systems using acetylacetone and trifluoroacetylacetone[6] as chelating extractants. Further investigations concerning other chelating extractants are desired.

8-Quinolinol is one of the most familiar and widely used chelating extractants. In this paper, the effect of phenols on the extraction of iron(III) with 8-quinolinol is investigated. The extraction equilibria are analysed in detail, and the interaction between iron(III) 8-quinolinolate [tris(8-quinolinolato)iron(III)] and phenols is quantitatively evaluated. The existence of hydrogen bonding is examined by means of infrared (IR) spectroscopy.

EXPERIMENTAL

Reagents

The radioactive iron(III) solution labelled with ^{59}Fe was prepared as described previously.[4] 8-Quinolinol (Wako Pure Chemical) was recrystallized from ethanol and dried *in vacuo*. 3,5-Dichlorophenol (Wako Pure Chemical) was purified by vacuum sublimation at 35°. 4-Fluorophenol, 4-chlorophenol, 2,3-dichlorophenol, 2,6-dichlorophenol, 2,3-dimethylphenol, and 3,5-dimethylphenol (more than 97–99% purity, Aldrich or Tokyo Kasei) were used as obtained. Tris(8-quinolinolato)iron(III) was synthesied in the usual way, recrystallized from benzene–hexane and dried *in vacuo*, and its identity was established by elemental analysis. The organic solvents used were of spectroscopic grade. Water was doubly distilled. Other reagents used were of analytical grade.

Procedure

An aqueous solution of 1.0×10^{-6}–$1.0 \times 10^{-5}M$ radioactive iron(III) (5 ml) was placed in a 30-ml extraction vial together with an equal volume of an organic solution of $1.0 \times 10^{-2}M$ 8-quinolinol and $1.5 \times 10^{-4} - 2.0 \times 10^{-1}M$ phenol. The vial was mechanically shaken for 5–60 min at 330 strokes/min at 25°. After centrifugation, the equal-volume aliquots of both phases were pipetted out and their γ-activity was measured separately with an NaI(Tl) well-type scintillation counter. The distribution ratio

of iron(III) (D) was calculated as the radioactivity ratio. The pH of the aqueous phase was adjusted with 0.04–0.10M perchloric acid and measured with a glass electrode immediately after shaking. The ionic strength was maintained at 0.10 with perchloric acid and sodium perchlorate.

The distribution of 8-quinolinol, 4-fluorophenol and 4-chlorophenol between carbon tetrachloride and 0.10M sodium perchlorate was also investigated. The organic phase containing these compounds (1.0×10^{-4}–$8.3 \times 10^{-2}M$) was shaken with the aqueous phase for 15 min at 25°. The distribution ratio was determined by measuring the absorbance of the organic phase at 320 nm (8-quinolinol) or 289 nm (phenols) before and after shaking.

IR spectra of 0.10M 3,5-dichlorophenol and a mixture of 0.10M 3,5-dichlorophenol and 0.016M tris (8-quinolinolato)iron(III) in carbon tetrachloride were measured with Jasco IR-810 spectrophotometer using a cell with potassium bromide windows (layer thickness 0.1 mm) against air.

RESULTS AND DISCUSSION

The distribution ratio of iron(III) was independent of the shaking time (5–60 min) and the initial metal concentration (1.0×10^{-6}–$1.0 \times 10^{-5}M$). The recovery of radioactivity from the two phases was always confirmed to be quantitative.

In Fig. 1, the extraction of iron(III) with a mixture of 8-quinolinol (0.010M) and 3,5-dichlorophenol (0.050 or 0.10M) in carbon tetrachloride is shown as plots of log D *vs.* pH together with the extraction with 8-quinolinol alone. Greatly enhanced extraction is found in the presence of 3,5-dichlorophenol: in the whole pH region studied, the distribution ratio is increased 20,000- and 200,000-fold by 0.050 and 0.10M 3,5-dichlorophenol, respectively. This enhancement effect is much larger than that of the phenol on the extraction of iron(III) with acetylacetone previously reported.[4] The synergistic effect of the electron donor, tributyl phosphate (0.050M), was also examined on the extraction of iron(III) with 8-quinolinol, but no effect was observed.

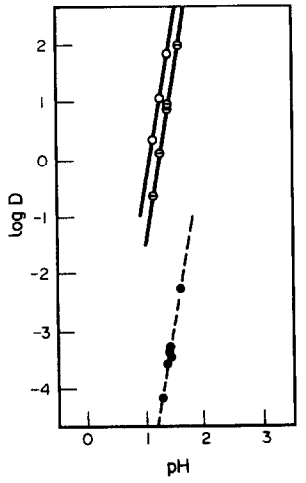

Fig. 1. Extraction of iron(III) with 8-quinolinol in carbon tetrachloride in the presence of 3,5-dichlorophenol. Initial phenol concentration in the organic phase (C_{ArOH}/M): (●) 0; (⊖) 0.050; (○) 0.10. Initial 8-quinolinol concentration in the organic phase (C_{HQ}/M): 0.010.

Table 1. Effect of various phenols (0.050M) on the extraction of iron(III) with 8-quinolinol (0.010M) in carbon tetrachloride at pH 1.40

Phenol	log D	log(D/D_0)*
4-Fluorophenol	−1.89	1.53

*D_0: Distribution ratio of iron(III) with 8-quinolinol alone; log $D_0 = -3.42$.

Table 1 shows the effect of various phenols (0.050M) on the extraction of iron(III) with 8-quinolinol (0.010M) in carbon tetrachloride at pH 1.40. All the phenols exert the enhancement effect, which increases in the following order: 2,6-dichlorophenol < 2,3-dimethylphenol < 2,3-dichlorophenol < 4-fluorophenol < 3,5-dimethylphenol < 4-chlorophenol < 3,5-dichlorophenol. The effect of 3,5-dichlorophenol is conspicuously large in the investigated phenols. The enhancement effect seems to be smaller when a chlorine atom or methyl group is present at the *ortho*-position of the phenol.

Table 2 shows the enhancement effect of 3,5-dichlorophenol (0.050M) on the extraction of iron(III) with 8-quinolinol (0.010M) in several organic solvents. The enhancement effect is remarkably influenced by the solvents and increases in the following order: chloroform < carbon tetrachloride < heptane. This solvent order is the same as that observed in the conventional synergistic extraction systems, *e.g.*, Zn(II)–thenoyltrifluoroacetone–tributyl phosphate system.[7,8] The solvent effect in the chelate extraction including the synergistic extraction has been throughly investigated.[7–11] It is striking that the inert solvents such as carbon

†The distribution ratio was too low to determine.

tetrachloride and heptane, which barely extract iron(III) with 8-quinolinol alone, can quantitatively extract iron(III) in the presence of 3,5-dichlorophenol.

Equilibrium analysis

Equilibrium analysis was carried out for the extraction of iron(III) with 8-quinolinol in carbon tetrachloride in the presence of 4-fluorophenol, 4-chlorophenol, and 3,5-dichlorophenol. The distribution ratio (D_0) of iron(III) with 8-quinolinol (HQ) alone can be expressed as

$$D_0 = \frac{\overline{[FeQ_3]}}{[Fe^{3+}] + \Sigma[FeQ_j^{(3-j)+}]} = \frac{K_{ex} P_{HQ}^3 [Q^-]^3}{K_{HQ}^3 (1 + \Sigma \beta_j [Q^-]^j)} \quad (1)$$

where the bar over the species denotes the organic phase, K_{ex} is the extraction constant defined as $[\overline{FeQ_3}][H^+]^3[Fe^{3+}]^{-1}[\overline{HQ}]^{-3}$, β_j is the overall stability constant of $FeQ_j^{(3-j)+}$ in the aqueous phase, and P_{HQ} and K_{HQ} are the partition coefficient and acid-dissociation constant of the neutral 8-quinolinol, respectively. In a region where the concentration of Q^- is low enough, the chelate species in the aqueous phase can be neglected, and equation (1) is then rewritten as

$$D_0 = \frac{\overline{[FeQ_3]}}{[Fe^{3+}]} = \frac{K_{ex} P_{HQ}^3 [Q^-]^3}{K_{HQ}^3}. \quad (2)$$

The equilibrium concentration of 8-quinolinolate anion Q^- in the aqueous phase is calculated from the following equation:

$$[Q^-] = \frac{C_{HQ} K_{HQ}}{[H^+](P_{HQ} + 1 + [H^+]/K_{H_2Q} + K_{HQ}/[H^+])}, \quad (3)$$

where C_{HQ} represents the initial concentration of 8-quinolinol, and K_{H_2Q} the acid-dissociation constant of the protonated 8-quinolinol H_2Q^+.

The P_{HQ}, K_{H_2Q} and K_{HQ} values were determined in the present study by investigating the distribution ratio of 8-quinolinol as a function of pH, *i.e.*, log $P_{HQ} = 2.02$, p$K_{H_2Q} = 5.03$, and p$K_{HQ} = 9.66$. These values are in good agreement with the literature values.[12,13]

In Fig. 2, a plot of log D_0 *vs.* log[Q^-] is shown. The plot gives a straight line with a slope of 3.0 as is expected from equation (2). The log K_{ex} value was determined to be 3.25 by a linear least-squares method, on the basis of equation (2).

In the presence of phenols (ArOH), if the association of tris(8-quinolinolato)iron(III) (FeQ_3) with ArOH in the organic phase is assumed, the distribution ratio (D) can be expressed as follows:

$$D = \frac{\overline{[FeQ_3]} + \Sigma\overline{[FeQ_3 \cdot n\mathrm{ArOH}]}}{[Fe^{3+}]} = \frac{K_{ex} P_{HQ}^3 [Q^-]^3}{K_{HQ}^3}(1 + \Sigma \beta_{ass,n} [\overline{\mathrm{ArOH}}]^n), \quad (4)$$

where $FeQ_3 \cdot n$ArOH denotes the association complex, and $\beta_{ass,n}$ the overall association constant in the organic phase defined as $[\overline{FeQ_3 \cdot n\mathrm{ArOH}}][\overline{FeQ_3}]^{-1}[\overline{\mathrm{ArOH}}]^{-n}$.

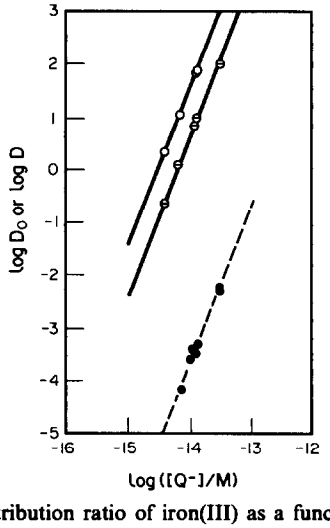

Fig. 2. Distribution ratio of iron(III) as a function of the equilibrium concentration of 8-quinolinolate anion in the aqueous phase. Organic solvent: carbon tetrachloride. C_{ArOH}/M: (●) 0; (⊖) 0.050; (○) 0.10. C_{HQ}/M: 0.010. pH: 1.1–1.6. The broken line indicates the calculated values from equation (2) and the solid lines from equation (4).

Figure 2 also shows plots of log D *vs.* log[Q^-] under the constant concentration of 3,5-dichlorophenol (0.050 and 0.10M). Each plot gives a straight line with a slope of 2.9, which is very close to the theoretical value 3 according to equation (4). This result indicates that the assumption leading to equation (4) is reasonable.

Dividing equation (4) by equation (2) gives

$$D/D_0 = 1 + \Sigma \beta_{ass,n}[\overline{ArOH}]^n. \quad (5)$$

Therefore, the enhancement of the extraction by phenols is quantitatively evaluated by the association constant. The association constants as well as the number of phenols in the association complexes can be obtained by analyzing the $\log(D/D_0)$ *vs.* $\log[\overline{ArOH}]$ plot according to equation (5).

The equilibrium concentration of phenols in the organic phase is calculated from the following equation:

$$[\overline{ArOH}] = \frac{C_{ArOH} P_{ArOH}}{P_{ArOH} + 1 + K_{ArOH}/[H^+]}, \quad (6)$$

where C_{ArOH}, P_{ArOH} and K_{ArOH} denote the initial concentration, partition coefficient and acid-dissociation constant of phenols, respectively. The P_{ArOH} values of 4-fluorophenol and 4-chlorophenol were determined in the present paper to be 0.555 ± 0.000 and 2.26 ± 0.06, respectively, given as the averages of data measured at 3 different phenol concentrations in the range 3.3×10^{-4}–$8.3 \times 10^{-2}M$; that of 3,5-dichlorophenol was previously determined[6] to be 11.6. The pK_{ArOH} values were reported to be 9.89 for 4-fluorophenol,[14] 9.37 for 4-chlorophenol, and 8.25 for 3,5-dichlorophenol.[15] The term $K_{ArOH}/[H^+]$ in equation (6) was practically negligible under the present pH conditions.

It should be pointed out that the equilibrium concentrations, [Q^-] and [$\overline{ArOH}$], can be affected if the mutual association between 8-quinolinol and phenols occurs. Previously, the association of acetylacetone with 3,5-dichlorophenol in the organic phase has been observed and quantitatively evaluated by the solvent extraction technique.[4,6] Therefore, the association of 8-quinolinol with the phenols was investigated in a similar manner, *i.e.*, by determining the distribution ratio of 8-quinolinol as a function of the phenol concentration in the organic phase. The distribution ratio of 8-quinolinol did not change in the presence of 4-fluorophenol and 4-chlorophenol, which indicates no association of 8-quinolinol with these phenols. On the other hand, 3,5-dichlorophenol somewhat enhanced the distribution ratio of 8-quinolinol, and the formation of 1 : 1 association complex of 8-quinolinol with 3,5-dichlorophenol in carbon tetrachloride was indicated. However, its association constant, determined to be 5.01, was relatively small. Consequently, the HQ-ArOH association could be neglected in the calculation of [Q^-] and [$\overline{ArOH}$] under the present pH conditions, 1.1–1.6, where most of 8-quinolinol exists in the aqueous phase as the protonated species.

In each phenol system, the D/D_0 was rapidly increased with an increase in [$\overline{ArOH}$]. The $\log(D/D_0)$ *vs.* $\log[\overline{ArOH}]$ plot for 3,5-dichlorophenol was an almost straight line with a slope of 3 in the higher concentration region of the phenol. In other phenol systems, although no such limiting slope could be observed, the slopes of the plots went up to higher than 2 at high concentrations of the phenols. These results indicate that the maximum number of phenol molecules able to associate with one molecule of tris(8-quinolinolato)iron(III) is 3, which is the same as that observed for the association of tris(acetylacetonato) complexes of scandium(III)[5] and iron(III)[4] with 3,5-dichlorophenol. The association constants were determined by a nonlinear least-squares method (SALS program, University of Tokyo) on the basis of equation (5), and are summarized in Table 3. Calculated D/D_0 values using these association constants were in good agreement with experimental values.

Very large association constants are obtained in the 3,5-dichlorophenol system. These values are larger than those of the association of tris(acetylacetonato)iron(III) with 3,5-

Table 3. Association constants of tris(8-quinolinolato)iron(III) with phenols in carbon tetrachloride at 25°

Phenol	$\log(\beta_{ass,1}/M^{-1})$	$\log(\beta_{ass,2}/M^{-2})$	$\log(\beta_{ass,3}/M^{-3})$
4-Fluorophenol	2.78	4.90	5.97
4-Chlorophenol	3.00	5.14	6.96
3,5-Dichlorophenol	3.55	6.00	8.32

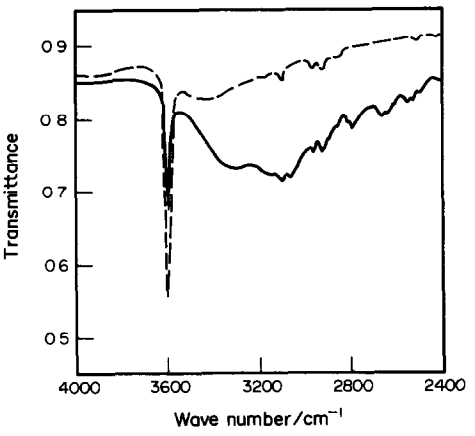

Fig. 3. IR absorption spectra in the O–H stretching vibration region of 0.10*M* 3,5-dichlorophenol (broken line) and a mixture of 0.10*M* 3,5-dichlorophenol and 0.016*M* tris(8-quinolinolato)iron(III) (solid line) in carbon tetrachloride.

dichlorophenol in carbon tetrachloride,[16] *i.e.*, $\log \beta_{ass,1} = 2.64$, $\log \beta_{ass,2} = 4.52$ and $\log \beta_{ass,3} = 5.73$.

The association constant is expected to correlate with the acid-dissociation constant of the phenols if the association is caused by hydrogen bonding of hydroxyl hydrogen of the phenols.[2,3] In a plot of the $\beta_{ass,n}$ ($n = 1$–3) values against the K_{ArOH} value of the phenols, either $\log \beta_{ass,n}$ value linearly increases with an increase in the $\log K_{ArOH}$ value as expected, which supports the existence of hydrogen bonding. Additionally, these linear relations will allow us to estimate the association constants of other various phenols from their K_{ArOH} values, except for *ortho*-substituted phenols. The *ortho*-substituted phenols should have the smaller association constants than expected from the linear plots because the substituents such as chlorine and methyl groups adjacent to the hydroxyl group may bring out the steric hindrance for the hydrogen bonding of the phenols to the chelate.[2,3]

More direct evidence for the hydrogen bonding can be obtained by IR spectroscopy. Figure 3 shows the IR absorption spectra in the O—H stretching vibration region of 3,5-dichlorophenol and a mixture of 3,5-dichlorophenol and tris(8-quinolinolato)iron (III) in carbon tetrachloride. By the addition of the chelate, the sharp band at 3600 cm^{-1} due to a free O—H of the phenol is reduced in intensity, and the broad band in the 3000–3500 cm^{-1} region due to a hydrogen-bonded O—H appears.[17] This is the first and definitive evidence for the hydrogen-bond acceptor ability of the 8-quinolinolato chelate. Since the only oxygen atom has a lone pair of electrons in the chelate, the hydroxyl hydrogen atom of the phenols probably interacts with the oxygen atom of the chelate. The maximum association number of the phenols, 3, is in agreement with the number of oxygen atoms in the chelate.

In conclusion, it was found that phenols form highly stable association complexes with iron(III) 8-quinolinolate through hydrogen bonding, and greatly enhance the extraction of iron(III) with 8-quinolinol. This study strongly suggests such the enhancement effect of phenols *via* chelate–phenol hydrogen bonding should be applicable to various chelate extraction systems.

ION INTERACTION CHROMATOGRAPHY OF NITRILOTRIACETATOCOMPLEXES OF THE RARE EARTH ELEMENTS WITH POST-COLUMN REACTION DETECTION

ROKURO KURODA, TAKEHARU WADA, YOKO KOKUBO and KOICHI OGUMA
Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Yayoi-cho, Chiba 263, Japan

(*Received* 17 *March* 1992. *Revised* 26 *June* 1992. *Accepted* 26 *June* 1992)

Summary—The chromatographic behaviour of nitrilotriacetatocomplexes of the rare earth elements (Sc, Y and lanthanides) on a reversed phase ODS column has been investigated in the presence of 1-octanesulphonate. There is a great difference in selectivity for the ODS among the rare earth nitrilotriacetatocomplexes. Concentration gradient elution with nitrilotriacetic acid (0.005–0.050*M*, pH 3.0) that contains 0.01*M* 1-octanesulphonate allows the rare earth elements to be separated from each other within 30 min at room temperature, except a Gd–Eu pair which is eluted together. Yttrium elutes at about 10 min between samarium and neodymium. Detection and quantitation of the rare earth elements can be achieved by post-column reaction with Chlorophosphonazo III in acid media at 700 nm.

Methods of separating the rare earth elements have been targets of investigation since their discovery. Increasing industrial utilization of the individual rare earth elements and their interest in geochemical roles have enhanced the development of methods for rapid, sensitive, selective determination of individual rare earth elements. Recent advances in the analytical methods for geological materials[1] and in analytical chromatography[2,3] have been reviewed. High performance liquid chromatography (HPLC) with polymer-based cation-exchange resins[4–9] and silica-based ion-exchangers[10–16] has been extensively used for the separation of individual rare earth elements with post-column reaction detectors. On account of the adjustable low ion-exchange capacity nature of ion-interaction chromatography (IIC) it gives more rapid, high resolution separation of the rare earths with gradient elution techniques.[17–25] α-Hydroxyisobutyric acid (HIBA) and lactic acid have been used most frequently as the complexing agent in the chromatographic modes above. One of the disadvantages of using HIBA or lactic acid is that the elution position of yttrium is very near to that of dysprosium or coincides with that of dysprosium.

Goetze and Bialkowski[26] separated the rare earth elements as anionic complexes with EDTA on a reversed phase C_{18} column with tetrahexylammonium chloride for the heavy rare earth group and tetrabutylammonium chloride for La, Nd, Pr and Sm. In this system independent runs are necessary for the heavy (Lu–Eu) and light (La–Sm) rare earth groups and Tb and Gd eluted together. Nitrilotriacetic acid has not been used as the complexing agent in conjunction with HPLC, although it received fairly wide acceptance as an eluting agent for rare earth separation.[27] However, its use was confined to production of large amounts of rare earth compounds.

In this work we report that on-column formation of nitrilotriacetatocomplexes of the rare earth elements in a reversed phase ODS column in the presence of 1-octanesulphonate will provide a high resolution chromatographic system for the separation of individual rare earth elements at room temperature.

EXPERIMENTAL

Apparatus

HPLC system consisted of a Hitachi L-6200 intelligent pump, a Rheodyne Model 7125 syringe loading valve with a 20-μl sample loop and a Hitachi L-4200 UV-VIS detector. Sample injection was made by a 10-μl microsyringe [MS-R25, Ito Co., Ltd., Shizuoka, Japan]. The detector output signal was fed into a Hitachi D-2500 Chromato-Integrator. For pumping the post-column reaction detection reagent,

Chlorophosphonazo III solution, a double plunger type of reciprocating pump [DMX-2300T, Sanuki Industry Co., Ltd., Tokyo] was used. The effluent and the post-column reagent were mixed via a low dead volume tee. The column was packed with ODS silica of 5-μm diameter (Hitachi ODS #3056, 150 × 4 mm i.d.) operated at 20°.

Reagents

All the chemicals used were of analytical reagent grade purity. Stock solutions of the rare earth elements were prepared from their oxides (99.9% purity, Wako Pure Chemical Industries Ltd., Osaka, Japan) to yield 0.1M metal solutions in 3M hydrochloric acid. These stock solutions were standardized by titration with EDTA–2Na using Xylenol Orange as a metal indicator. A mixed rare earth stock solution was 0.002M in each metal and 3M in hydrochloric acid. Sodium 1-octanesulphonate was obtained from Tokyo Kasei Kogyo Co., Ltd., Tokyo. Nitrilotriacetic acid (NTA, Dojindo Laboratories Co., Ltd., Kumamoto, purity >99%) was used for the preparation of eluent (0.005 to 0.05M). Chlorophosphonazo III [2,7-bis-(4-chloro-2-phosphonopheylazo)chromotropic acid, disodium salt] was used as post-column reaction detection reagent. A 0.0001M reagent solution in 0.05M hydrochloric acid was prepared and filtered through a 0.45-μm membrane filter before use.

Chromatographic separation and quantitation

Prior to the sample loading, the column was conditioned by passing 0.005M NTA–0.01M octanesulphonate solution (pH 3.0) for one hour. The mixed rare earths sample solution was prepared so that it contained 0.00005M of each rare earth and 0.01M octanesulphonate, the pH being adjusted to 3.0 with dilute ammonium hydroxide. A 10-μl volume of the prepared solution is loaded onto the column. A linear solvent program was run for the elution from 0.005–0.05M NTA(pH 3.0) usually over 25 min with the octanesulphonate concentration of 0.01M at a flow rate of 1 ml/min. A 0.0001M Chlorophosphonazo III–0.05M hydrochloric acid solution was delivered at a flow rate of 1 ml/min to join the effluent to achieve the post-column reaction detection at 700 nm. The calibration curves were constructed for each rare earth by plotting their concentrations against the peak area up to *ca.* 0.20, 0.23 and 0.26 mg/ml for La, Sm and Yb, respectively.

RESULTS AND DISCUSSION

In Fig. 1 the relationship between the retention time and NTA concentration is shown for La, Ce, Pr, Nd, Y, Dy, Lu and Sc, where 1-octanesulphonate and pH are kept constant at 0.01M and 3.0, respectively. As can be seen, the retention of the rare earth elements depends greatly on the NTA concentration and selectivity differences increase significantly with decreasing concentration of NTA. If concentration gradient elution is conducted, high resolution separation will be expected with low k' at higher NTA concentration, good separation factors (ratio of k' for two rare earth elements) and high plate number reflected by rapid mass transfer in IIC system. Hence, a linear NTA concentration gradient elution was attempted from 0.005 to 0.05M NTA with the gradient time of 15, 25 and 35 min. The chromatograms obtained for mixtures of La, Ce, Pr, Nd, Y, Sm, Eu, Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu and Sc are illustrated in Fig. 2 for respective times. The Sc–NTA complex is not retained on the ODS coated with 1-octanesulphonate in this system, and exists as an anionic or neutral species, and its retention time coincides exactly with that of nitrate anion detected at the 301 nm characteristic

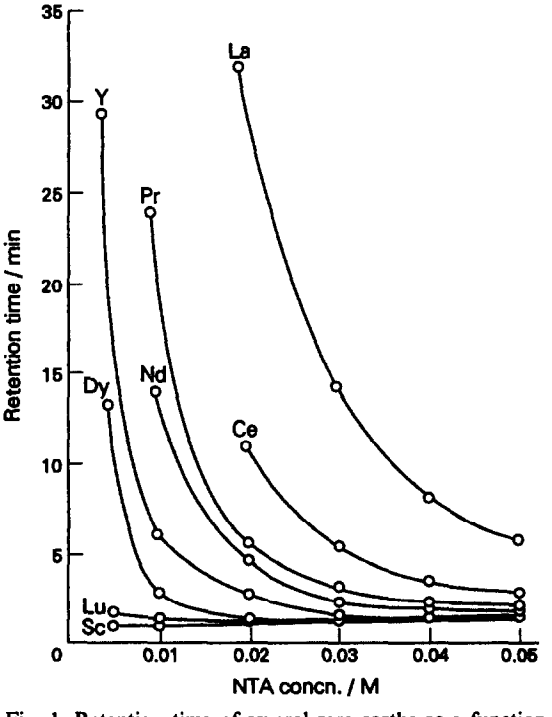

Fig. 1. Retention time of several rare earths as a function of NTA concentration (pH 3.0). Concentration of each rare earth: $5 \times 10^{-5}M$, 1-octanesulphonate concentration: 0.01M. Conducted at 20°.

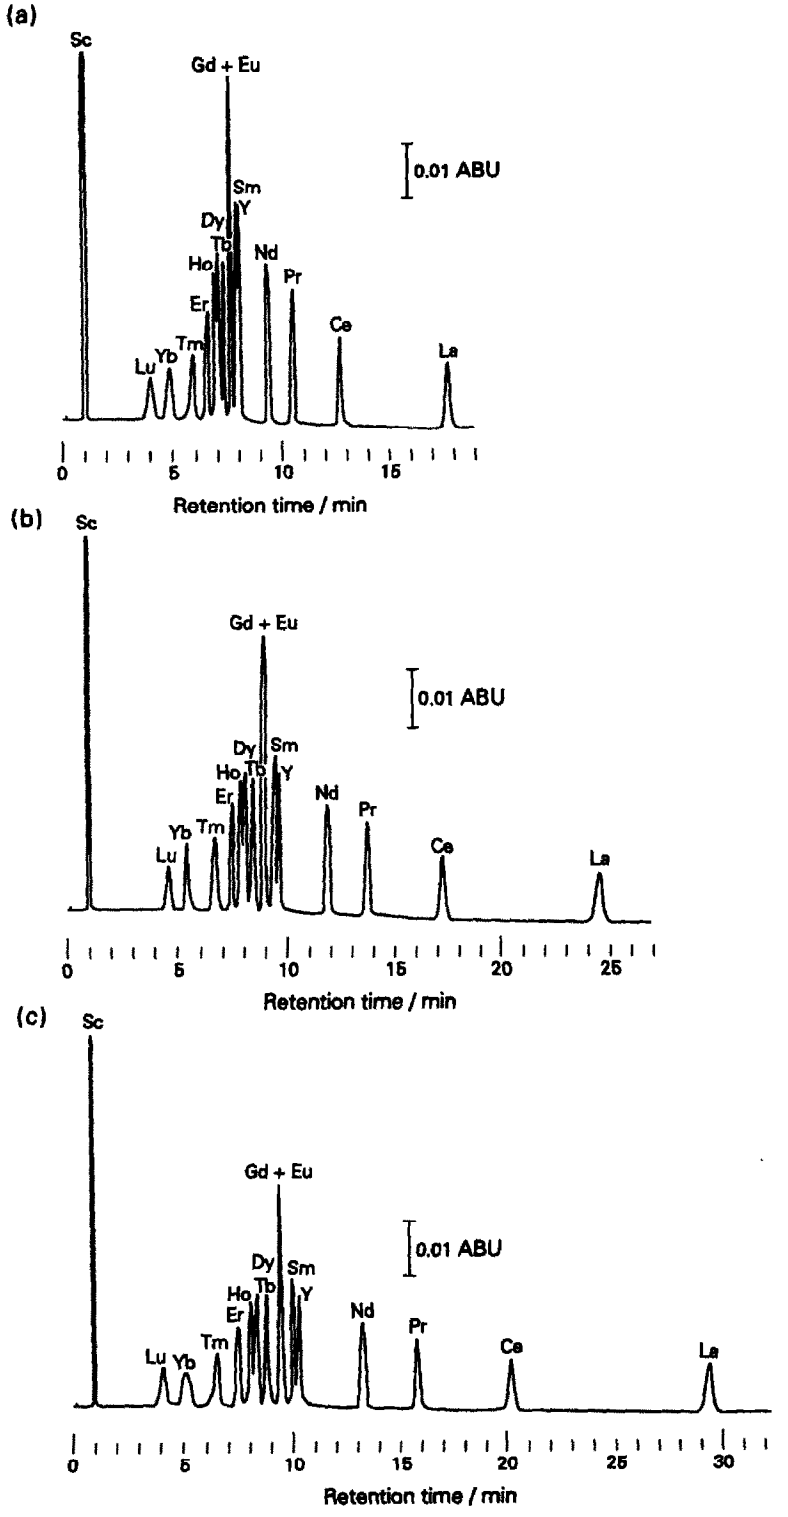

Fig. 2. Gradient elution runs. Concentration gradient elution run over 15, 25 and 35 min with 0.005–0.05*M* NTA (pH 3.0), 20°. Each rare earth concentration: $5 \times 10^{-5}M$. a: 15 min, b: 25 min, c: 35 min.

absorption band. With 25- and 35-min elution the adjacent rare earth elements can be resolved distinctly with the exception of the Eu–Gd pair. Y elutes between Sm and Nd, and this position is convenient for its detection and quantitation, because it usually behaves like heavy rare earth elements and often elutes together with Dy in most cation-exchange chromatography.

In this work 25-min elution was used for further study.

Since the hydrophobic ion, 1-octanesulphonate, interacts with the ODS, absorbs over its surface and controls the apparent ion-exchange capacity, its concentration in the mobile phase must affect the retention times of individual rare earth elements, *i.e.*, the speed of the chromatographic separations concerned. The effect of concentration of 1-octanesulphonate (0–0.03*M*) was thus examined on the retention time during the NTA gradient elution run, when the pH was kept at 3.0. The retention time increased rapidly with increasing concentration of 1-octanesulphonate, reaching a plateau at about 0.01*M* sulphonate for each rare earth. Its absence causes no retention of the rare earths on ODS. The concentration of 1-octanesulphonate exercises a great ion-exchange capacity function. Taking into consideration the selectivity differences, 0.01*M* concentration of 1-octanesulphonate was used.

The effect of pH of the eluent on retention was then tested. The retention times of some representative rare earth elements examined decreased with increasing pH values in the range 2.5–5.0. However, since lighter rare earth elements exhibit high retention times at pH 5 and selectivity differences are not profound as compared to those caused by NTA concentration changes, pH gradient elution would yield inferior results to concentration gradients both in terms of separation time and peak resolution, if it were tried. We used pH 3.0 as a safe value for use of ODS.

One of the factors which control the concentration of hydrophobic ion on the ODS surface is the presence of nonionic molecules such as methanol and acetonitrile in the mobile phase, which compete for the absorption sites on the ODS. The effect of methanol concentration on the retention time of NTA complexes was such that the retention of the complexes decreases with increasing methanol concentration. Methanol concentration gradient elution may be feasible, but increased viscosity of the methanolic mixed solvent media requires increasing the pressure applied to the chromatographic system. Therefore, only an aqueous eluent system was examined in the present study.

The present system provides an excellent medium particularly for the separation of adjacent La–Ce–Pr–Nd–Y–Sm–(Eu,Gd)–Tb–Dy–Ho–Er–Tm–Yb–Lu on a single run at room temperature; Eu–Gd pair is eluted together.

The mobile phase typically includes a complexing agent that can interfere with the post-column reaction detection of the rare earth elements. Commonly used colorimetric reagents for the rare earths are 4-(2-pyridylazo)-resorcinol, Xylenol Orange, Alizarin Red S, Arsenazo I and Arsenazo III,[2] but these reagents are not satisfactory to use in the presence of NTA, because of high stabilities of rare earth-NTA complexes with the conditions for their color development. Hence, Chlorophosphonazo III[28] was selected as the post-column reaction reagent, since it reacts with the rare earth elements in acid media. To avoid the reagent blank contributing to base line drift, detection was made at 700 nm where the detection sensitivity was somewhat lowered, but a stable constant base line level was guaranteed, as seen in Fig. 2.

The calibration curves were constructed for La, Sm and Tb by plotting the peak area against their concentration. The curves for La, Sm and Yb were linear up to 0.20, 0.23 and 0.26 mg/ml, respectively. Detection limits taken as corresponding to S/N ratio 3 are 77, 18 and 80 ng/ml, respectively, for La, Sm and Yb.

In the present IIC system the rare earth elements are introduced into the ODS column as simple ions, not the NTA complexes; the complexes are formed on the column from NTA in the eluent. If prepared complexes are loaded, peaks of early eluted heavy rare earths broaden, split (for Tb) and deteriorate the resolution, depending highly on the excess concentration of NTA. The system may provide an on-column derivatization ion-interaction chromatography for the rare earth elements.

THE INVESTIGATION OF COMPLEX FORMATION EQUILIBRIA AT CONSTANT IONIC STRENGTH

G. ANDEREGG
Laboratorium für Anorganische Chemie, Eidgenössische Technische Hochschule, CH 8092 Zürich, Switzerland

(*Received* 17 *February* 1992. *Revised* 19 *June* 1992. *Accepted* 19 *June* 1992)

Summary—The inert salts used for the investigations of complex formation are briefly discussed in relation to the effects of their ions on the equilibria studied. In general, some association with the inert salt ions cannot be completely avoided. In case of very stable complexes measured at low ionic strength, their effects can be quantified even though they are not caused by the anion if NO_3^- or ClO_4^- are used. In the case of weak complexes, when ionic strengths $I \geq 1$ are used, the concentration of the complex of interest can be 1000 times lower than that of the associates of the same cation with the anion of the inert salt causing difficulties with the investigation of the latter systems. If the experimental results for K_1 of the alkaline-earth metal ions with fluoride in sodium perchlorate and sodium nitrate are correct, as their equilibrium constants have very similar values, it follows that the behavior of two anions is very similar. However, if NO_3^- associates with the above cations, as found, the same behavior is expected for ClO_4^-. A more accurate analysis can only be done if activity coefficients in these solutions are known.

The large volume of stability constant data of metal complexes ML_n in aqueous solution, expressed here for simplicity as K_n and β_n, reported in the last 40 years were obtained using a constant ionic medium in which an inert salt, *i.e.*, a supporting background electrolyte,[1] was introduced to adjust the ionic strength of the medium. This procedure was sometimes criticized because the components of the salt used (AX) are not inert but intervene in the investigated processes as reacting species. This was recently observed by Štulíková.[2] As the cation and the anion of the inert salt and the species studied M and L are charged species, electrostatic interactions with the ions of the inert salt with formation of associates are always possible, these can be either ion-pairs or complexes such as MX, AL and MLX. In a similar way the associate AX could be formed from the components of the inert salt especially at $I \geq 1$ as discussed, for sodium nitrate solutions. These interactions are particularly important in the investigation of weak complexes because the concentrations of the associates with the anion of the inert salt can be equal to or larger than those of the complexes investigated. The equilibrium constants obtained in the presence of an inert salt are concentration quotients as the corresponding activity coefficients are given the value one. With respect to the thermodynamic constants, the concentration quotients can also be considered as being thermodynamic, where the standard state is not pure water but the solution of the inert salt. The ionic strength I is calculated with the expression $I = 1/2\Sigma c_i z_i^2$, in which the sum is extended to all ions c_i present in solution, the concentration normally expressed in molarity (M) or molality (mol/Kg = m) and z_i is the electrical charge of the corresponding species. In the latter case this should be mentioned in order to avoid confusion (see Table 1). The most suitable salts for this purpose are those of univalent cations and anions since the above interactions are much weaker with respect to the case of ions of higher charge. Alkali metal cations and anions such as ClO_4^-, NO_3^-, ClO_3^-, *etc.* and the halide ions, whose conjugate acid should be strong, are used. If the hydrolysis of a metal ion is investigated, sodium perchlorate seems, for instance, to be the inert salt of first choice, because generally ClO_4^- is among the anions forming the weakest complexes. Nevertheless, the list of cations which interact with this anion is quite considerable. Thus, in the case of polyaminopolycarboxylates such as EDTA the above salt is not appropriate because of the formation of the sodium EDTA complex.[3] For this reason a potassium salt was used, but not the perchlorate because of its low solubility. Potassium chloride and nitrate were used and

Table 1. Log K_1 values for the equilibrium: $M^{2+} + F^- \rightleftharpoons MF^+$ at 25°, obtained with fluoride electrode measurements. The K_{18} values at I in molarity scale* are in dm³/mol or else in Kg/mol

Medium†	I [M $(NO_3)_2$]	Mg^{2+}	Ca^{2+}	Sr^{2+}	Ba^{2+}	Ref.
1*M* ($NaClO_4$)	0.09–0.3	1.318 (±0.020)	0.633 (±0.030)	0.146 (±0.035)	−0.222 (±0.230)	7
1*M* ($NaClO_4$)	0.03–0.15	1.380 (±0.019)	0.531 (±0.100)	0.114 (±0.050)	−0.155 (±0.155)	8
1 m ($NaNO_3$)	0.03–0.6	1.318 (±0.004)	0.568 (±0.011)	−0.027 (±0.025)	−0.377 (±0.050)	9
1 m ($NaNO_3$)	0.15–0.9	1.352 (±0.035)	0.682 (±0.023)	0.137 (±0.024)	−0.174 (±0.053)	10
1*M* (Na)NO_3	0.03–0.3	1.31 (±0.03)				11

*The conversion of log K_1 from the molarity to the molality scale[12] is done by substracting either 0.021 ($NaClO_4$) or 0.014 ($NaNO_3$) from each value in 1*M* medium and, for the opposite conversion, ($NaNO_3$) 0.020 is added to the data in molarity scale.

†Parentheses are used if the measurements are made at the given ionic strength reached by addition of the inert salt stated. The constant concentration of the substance or ion stated is given without parentheses.

the preference for the latter is due to its ability to form complexes which are weaker than those with Cl^-. The use of potassium chloride between 1940–1950 can be explained by the fact that its aqueous solution is normally present in the reference calomel (or AgCl) electrode. By using the same solution in the test cell it is possible to eliminate the diffusion potential, which is often the origin of erroneous potentiometric measurements. Perchlorate solutions during the measurements, in the presence of ligands such as 2,2′-bipyridyl, 1,10-phenanthroline or pyridine derivatives, cause the precipitation of insoluble (complex) salts. In the case of Pd(II) and the above ligands nitrate or chlorate were then preferred. The equilibria with Tl^{3+} had to be investigated potentiometrically in 1*M* perchloric acid and, in order to avoid the diffusion potential, a bridge with the same acid was prepared. A calomel reference electrode in 0.99*M* perchloric acid and 0.01*M* hydrochloric acid can be used.

In recent years inert salts containing organic cations with a very low tendency for complex formation were introduced: $N(CH_3)_4Cl$, $N(CH_3)_4NO_3$, $N(C_2H_5)_4ClO_4$, ..., but we have no corresponding substitutes for the anions. It is evident that the choice of a given salt is always the result of a compromise among several possibilities in relation to the system investigated. By using a given inert salt the equilibrium constants obtained refer to the standard state chosen and the species studied such as M, L, and ML_n can contain a variable number of medium components. Their relative concentrations are not affected by the equilibrium investigated and only their sum can be determined. For instance, the concentration of ML, obtained at a given I value attained with AX, is the sum of concentrations of all species

$$\sum_{i=0}\sum_{m=0}\sum_{n=0} [ML(H_2O)_iA_mX_n]$$

containing M and L in the ratio 1:1 and variable quantities of other components of the medium. Similar sums are valid for all complexes as well as for M and L. In order to obtain exact values for the equilibrium constants it is important that the concentrations of the species investigated are negligible with respect to those of the inert salt thus causing a minimal variation of the ionic strength I. This ensures that, when titrating the solution, the activity coefficients of the species studied remain practically constant. The value of the concentration quotient K_1 normally given in the literature corresponds to that obtained directly without corrections for the different species appearing in the three sums for ML, M and L. If K_1 has to be corrected for the presence of an A^+ complex, we have to obtain the corresponding constant in the same medium. The trivial case of different ML species with $n = m = 0$ in the above sum differing in the number of coordinated H_2O molecules and in the structure of ML in equilibrium is also possible and the concentrations of the ML species cannot be separately determined by potentiometric measurements.[4] In principle for a given ligand, for instance EDTA, we have the possible formation of species between A^+ and L^{4-}, HL^{3-}, *etc.* Among such species only those with the unprotonated ligand seem to be normally important as expected for electrostatic reasons because of its larger negative charge. Complex formation by a ligand is often accompanied by a pH decrease in the solution of the protonated ligand in the presence of a cation under study such as A^+. This is shown[3] by the decrease of the pK of HL^{3-} from 10.44 in 0.1 [$(CH_3)_4NCl$] to 10.24 in 0.1 (KNO_3), whereas the pK of H_2L^{2-} is the same in both media. While discussing this change, we have to realize that two different effects are operative and causing the variation of the pK of HL^{3-}: (a) change in the complexing cation of the inert salt

and (b) change in the activity coefficients of the ions and of water. If the I value is low, for instance 0.1, the ionic activity coefficients in the two salt solutions will have very similar values and the variation of the pK can be explained by the complex formation of A^+. In this way it is possible to estimate the value of K_1 for AL^{3-}. In the case of potassium as component of the inert salt, the constant K_1 for the EDTA complex on the basis of the above pK values is estimated[3] to be $10^{0.8} = 6.3$. This value can be used to estimate the reduction in the concentration of the unprotonated ligand $[L^{4-}]_0$ to $[L^{4-}]$ using a potassium salt as the inert salt: $[L^{4-}]_0 = [L^{4-}] + [KL^{3-}] = [L^{4-}](1 + 6.3[K^+]) = [L^{4-}]\Delta$. For instance inserting $[K^+] = 0.1$ one obtains: $[L^{4-}] = [L^{4-}]_0/(1 + 0.63) = [L^{4-}]_0/10^{0.21}$. This implies that the equilibrium constants corrected for potassium complex formation at $I = 0.1(KNO_3)$ are calculated multiplying their values by $\Delta = 1.63 = 10^{0.21}$ which takes into consideration the effective ligand concentration in the presence of the complexing metal ion of the inert salt. Clearly this estimate can be done more exactly if the constant in question has been evaluated more carefully. The effect of nitrate association in $0.1(KNO_3)$ for the EDTA complexes can be estimated using published data for their association with alkaline earth cations[5] and for the divalent first-row transition metal cations.[6] As the values of K_1 are close to 1, in view of the low nitrate concentration, one finds that the metal ion concentration should be divided by Δ values ranging from 1.07 ($=10^{0.03}$) to 1.146 ($=10^{0.06}$), *i.e.*, the corrected stability constant is to be multiplied by these values. Definitively one has an increase of the decimal logarithmic value of the stability constant K_{ML} from 0.03 to 0.06, an amount similar to the error of K_{ML}. Thus the association of nitrate in this case has no significant influence on the stability constants.

In the case of formation of alkaline-earth metal complexes with fluoride and chloride, investigated using sodium nitrate as inert salt, there can be no doubt that one can have a preference for a given medium but, as mentioned by Štulíková,[2] erroneous values for stability constants are obtained. An exact judgement of the situation is only possible if one knows the equilibrium constants for all species appearing in solutions of inert salts used and introduces them in equations like the sum given above, which allow one to quantify the interference of the different salt media. The results reported in references 7–11 at $I = 1$ for the fluorides are given in Table 1 and seem to be of the expected precision. One has two (or three) values available for log K_1 at $I = 1M$ ($NaClO_4$) or $1M$ ($NaNO_3$) medium as well as 1 m ($NaNO_3$) [$\cong 0.97M$ ($NaNO_3$)]. However, although these values are quite close it is not possible to find the same trend for each metal, which would be expected if NO_3^- forms more stable associates than ClO_4^-. It seems that the effects of side-reactions in the two media compensate one another and similar values of K_1 are obtained, although the activity coefficients in the two media are different. The large discrepancy of log K_1 of Mg^{2+} in $1M$ ($NaClO_4$) is commented on in the more recent reference 8 as "good agreement" Some doubts about the accuracy of the results of the first two references in sodium nitrate can be proposed because the concentrations of the reacting metal nitrates[9,10] are changed from values between 0.03 and 0.05 m to 0.2 and 0.3 m, respectively, by a corresponding decrease of the sodium nitrate concentration maintaining $I = 1$ m. The large changes in the concentration of the reacting metal nitrate, and consequently in the concentration of sodium nitrate, cannot ensure a constancy of the activity coefficients of the reacting species within the solutions used for the determination of the same constant K_1. A much lower medium change occurs using solutions with $I = 1M$ $(Na)NO_3$ in which, in accordance with this abbreviation, from 0.01 to $0.1M$ magnesium nitrate solutions sodium nitrate is added to reach $1M$ NO_3^- "maintaining the activity coefficients constant".[11] Among the values of Table 1 in sodium nitrate solutions the most accurate seems to be the last one for Mg^{2+} at $I = 1M$ $(Na)NO_3$ taking into consideration that in this case constant potential values with the fluoride electrode are obtained whereas at $I = 1$ m ($NaNO_3$) a potential drift is mentioned. This drift influences the values of the constants obtained. As Ba^{2+} forms fluoride complexes which are thirty times weaker than those of Mg^{2+}, in order to have the same concentration of BaF^+ as for MgF^+, one would need a $3M$ $Ba(NO_3)_2$ solution at the same free fluoride concentration Further, the above replacement of $NaNO_3$ with $M(NO_3)_2$ at $I = 1$ m ($NaNO_3$) occurs with decrease of the concentration of the nitrate ion from 1 in 1 m $NaNO_3$ to 0.7 in 0.3 m $M(NO_3)_2 + 0.1$ m $NaNO_3$. This could have some effects on the concentrations of the species in equilibrium if nitrate acts as ligand. On the

basis of recent investigations this seems to be the case, $M(NO_3)^+$ and $M(NO_3)_2$ have been detected in $NaClO_4$ solutions.[5] Also the sodium ion seems to associate with nitrate ($K_1 = 0.389$ dm^3/mol) and fluoride ($K_1 = 0.162$ dm^3/mol).[13,14] Considering these equilibria, it is possible to calculate: (a) the concentration of the reacting species M^{2+} and F^- after equilibration with NO_3^- and Na^+. In this calculation the formation of ternary or mixed complexes has not been considered because of the lack of reliable data. A correction factor Δ is then calculated for the published value for K_1; (b) the corrected ionic strength, after formation of the species $NaNO_3$, $M(NO_3)^+$ and $M(NO_3)_2$, NaF being negligible. These calculations have been done for Ba^{2+} because of the more effective nitrate association $\{K_1[M(NO_3)^+] = 1.45$ dm^3/mol; $\beta_2[M(NO_3)_2] = 0.93$ dm^6 mol$^{-2}\}$ in the presence of the lowest and largest quantities of $Ba(NO_3)_2$ in the measurements. The following results were obtained: (1) 0.05 m $Ba(NO_3)_2$: $[Na^+] = 0.66$ m, $[F^-] = 0.72 \times 10^{-3}$ m giving $\Delta = 10^{0.27}$, $[BaNO_3^+] \approx 0.02$ m and $I = 0.74$ m, (2) 0.3 m $Ba(NO_3)_2$: $[Na^+] = 0.086$ m, $[F^-] = 0.99 \times 10^{-3}$ m giving $\Delta = 10^{0.13}$, $[BaNO_3^+] \approx 0.1$ m and $I = 0.65$ m. The concentration of barium fluoride not exceeding 1×10^{-4} m, it seems evident that in these mixtures the side reactions are the more important. Of course the calculated concentrations are only estimates as they were obtained using the published values without correction for the different conditions, but they show that the investigation of weak association is very difficult and very often accompanied by large ionic strength changes as the inert salts form associates. The correction of K_1 is carried out multiplying the corresponding value of Table 1 by Δ. In general, it is expected that the actual value of K_1 is lower in presence of salts which associate with the components being investigated as long as the activity coefficients in the media are the same. In sodium nitrate one obtains K_1 values which are similar to those obtained in sodium perchlorate: it follows that in this latter medium an almost equally significant ClO_4^- association has to be considered. In conclusion, it is obvious that the investigation of weak complexes cannot be done in a reasonable way without taking into account the effects of the inert salt on the equilibria and on the ionic strength.

DETERMINATION OF CHLORINATED HYDROCARBONS INTRODUCED INTO AIR/ACETYLENE FLAMES BY FOURIER TRANSFORM INFRARED EMISSION SPECTROSCOPY

ANTHONY R. KOEBELE and DAVID C. TILOTTA*

Department of Chemistry, The University of North Dakota, University Station, Box 7185, Grand Forks, ND 58202, U.S.A.

(*Received* 26 *March* 1992. *Revised* 23 *June* 1992. *Accepted* 23 *June* 1992)

Summary—A Fourier transform spectrometer is used to record the infrared emission from chlorinated hydrocarbons combusted in an air/acetylene flame. In this manner, the chlorinated hydrocarbons are determined by monitoring the infrared emission of hydrogen chloride at 2653 cm^{-1}. Discussion is presented of the air/acetylene flame background, and the potential spectral interference from the emission of deuterated species. Practical detection limits for chloroform, carbon tetrachloride and methylene chloride in acetone, methanol, and ethanol are solvent independent and are found to be 1.1, 0.80, and 1.0%, respectively. Calibration curves for these three analytes are linear from their detection limits to approximately 55% (v/v). In addition, evidence is presented that flame flicker-noise does not lead to a multiplex disadvantage when the Fourier transform instrument is used for data acquisition.

The acquisition of low-temperature infrared emission spectra from thermally excited materials is experimentally difficult due to low spectral emittance at low temperature. Because of this low emittance, Fourier transform spectrometers (FTSs) are generally used to increase the signal-to-noise ratios of the obtained spectra over conventional dispersive instruments. The throughput and multiplex advantages of the FTS allow a larger solid angle of collection and an increase in the detector irradiance, respectively, over dispersive instruments. Of course, these advantages are enjoyed in the infrared because it is assumed that detection noise, which is independent of the detector-irradiance, dominates over source (flicker) and photon noise.

In a recent paper, Tilotta *et al.* showed that a conventional FTS could be used to detect the infrared emission from the combustion products of organic molecules introduced into flames.[1] In their work, organic compounds were introduced into a hydrogen/air flame via a nebulizer for combustion and vibrational excitation. Since the hydrogen/air flame has been reported to have a temperature of 2380 K,[2] a commercially available FTS equipped with a room temperature tryglycine sulfate (TGS) detector proved to be satisfactory in recording the infrared emission from the flame. Cooled instrumentation, detectors, or special sample heat-transfer devices were not required.

Combustion flames, however, are atypical infrared sources and may be expected to have noise characteristics different from conventional infrared emission sources such as globars or Nernst glowers. It is well known from atomic spectroscopy, for example, that the spectral noise arising from combustion flames and nebulizers is multiplicative, *i.e.*, the noise is carried by the signal.[3] In terms of the application of Fourier transform spectrometry to atomic emission spectroscopy, there is evidence that flame-flicker noise effectively distributes itself across the transformed spectrum and leads to a multiplex disadvantage.[4,5] (It should be pointed out, however, that under some circumstances, an emission multiplex advantage can exist.[4,6])

To a large extent, organic compounds are detected indirectly in flames by the infrared emission from their combustion products. Of course for applications in chromatography or for screening methods for general non-metallic species, this operational principle is satisfactory. Previous studies of the analytical applications of infrared emission from combustion

*Author for correspondence.

flames have employed a miniature hydrogen/air capillary-head burner for combustion and vibrational excitation.[7-10] The hydrogen/air combustion flame was chosen in order to eliminate the spectral interference of CO_2 emission from hydrocarbon fuel gases. However for analysis by infrared emission from a combustion flame in which carbon or CO_2 is not the analyte, such as chlorine from a chlorinated hydrocarbon, a combustion mixture based upon a hydrocarbon fuel should be feasible.

The subject of this paper is the investigation of the application of Fourier transform spectrometry to the determination of chlorinated hydrocarbons by infrared emission from an air/acetylene flame. A commercially available Fourier transform spectrometer is optically coupled to a conventional atomic absorption laminar-flow slot-burner. Chlorinated hydrocarbons are introduced into the flame by a conventional concentric nebulizer and are monitored via their hydrogen chloride infrared emission signal. In addition, this paper investigates the Fellgett (multiplex) advantage when the infrared emissions of the flame are multiplexed by the Fourier transform instrument.

EXPERIMENTAL

Fourier transform spectrometer

All infrared emission measurements were conducted with a Nicolet Model 5-MX FTIR (Nicolet Instruments, Madison, WI., U.S.A.) The FTIR was modified for infrared emission spectroscopy by removing the conventional infrared source and installing a 4.3-cm diameter, f/1.5, aluminum concave reflecting mirror 13.0 cm from the original source location. Figure 1 shows the experimental design. Although the collection mirror was used off-axis, no significant aberrational defects were observed. The FTIR was operated at room temperature with its cover removed in order to admit the infrared emission from the flame into the optical path. In addition, the air circulation fan of the FTIR was disconnected so as not to cause flame turbulence.

A room temperature tryglycine sulfate (TGS) detector was used in the FTIR. All spectra, unless otherwise noted, are the result of 100 co-added scans and required a total scanning time of 3.75 min. Although this FTIR has a theoretically fixed resolution of 4 cm^{-1}, the experimentally observed resolution was approximately 6 cm^{-1}. A triangular

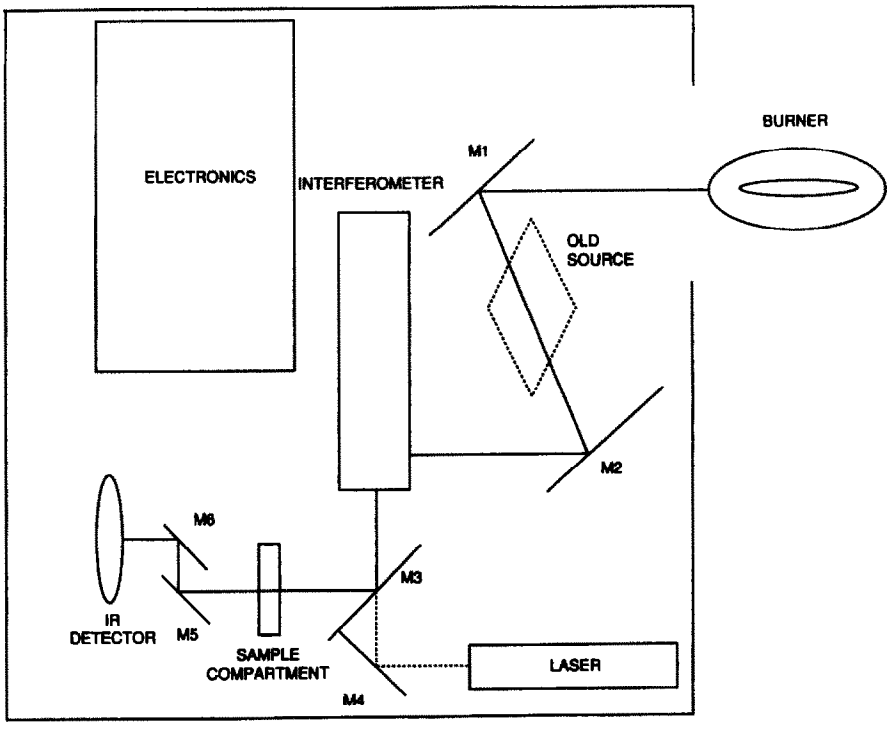

Fig. 1. Schematic diagram of instrumental set-up used to collect infrared emission from the air/acetylene flame. The old source was removed, and concave focusing mirror M1 was added to the optical bench in order to admit the infrared radiation into the interferometer. Mirrors M2, M3, M5 and M6 are concave mirrors and mirror M4 is planar. A 1-cm aperture was added to the sample compartment.

lar apodization function was employed and zero-filling was not utilized. All spectra were acquired with a 1-cm diameter aperture placed in the normal sample compartment. The spectra presented in this paper have not been corrected for the instrument response function.

Burner

A 10-cm long, laminar flow slot burner was obtained from a Perkin–Elmer model 403 atomic-absorption spectrometer (Perkin–Elmer Corporation, Norwalk, CT, U.S.A.) and positioned 30 cm from the FTIR collection mirror. Since the adjusting micrometers were retained, the slot burner could be precisely positioned along three axes. The infrared emissions were viewed over a 1.0-cm vertical section centered at a height of 4.0 cm above the slot-burner top.

The slot-burner utilized air and acetylene as its fuel and oxidant, respectively. Stoichiometric flame conditions were employed with an acetylene flow rate of 1000 ml/min. In order to increase flame stability, triple-stage regulation was utilized for both air and acetylene, and the acetylene tank was replaced when the pressure dropped to three-quarters its initial value. The aspirator uptake rate was 1.0 ml/min.

Reagents

All chemicals, with exception of acetone-d_6, were reagent grade (Fisher Scientific, Fairlawn, NJ, U.S.A.) and were used without further purification. The acetone-d_6 was 99.9% isotopically pure and was obtained from MSD Isotopes (Division of Merck-Frosst Canada Inc., Montreal, Canada). Calibration standards of chloroform were prepared to have concentrations of 5, 10, 20, 30, 50, 70 and 100 percent (v/v) by diluting the appropriate volume of chloroform with either ethanol, methanol, or acetone.

RESULTS AND DISCUSSION

Flame background

Figure 2 shows an infrared emission spectrum of the flame background in the region from 4200–400 cm^{-1}. As can be seen from Fig. 2, the major emission bands in the background spectrum are due to the asymmetric stretching vibration of CO_2 at 2261 cm^{-1} and the bending motion of CO_2 at 671 cm^{-1}. The infrared emission bands of water are significantly less intense than the CO_2 emission bands and occur in the 4075–3200 cm^{-1} and 2100–400 cm^{-1} spectral regions corresponding to stretching and bending motions, respectively. It should be noted, however, that this spectrum has not been corrected for the instrument response function and interspectral comparisons based on emission intensity are difficult. However from an experimental standpoint, the most intense emission band in any spectrum acquired from the air/acetylene flame is generally the asymmetric stretching vibration of CO_2 at 2261 cm^{-1}. During the course of these investigations, no other band was found with a greater intensity.

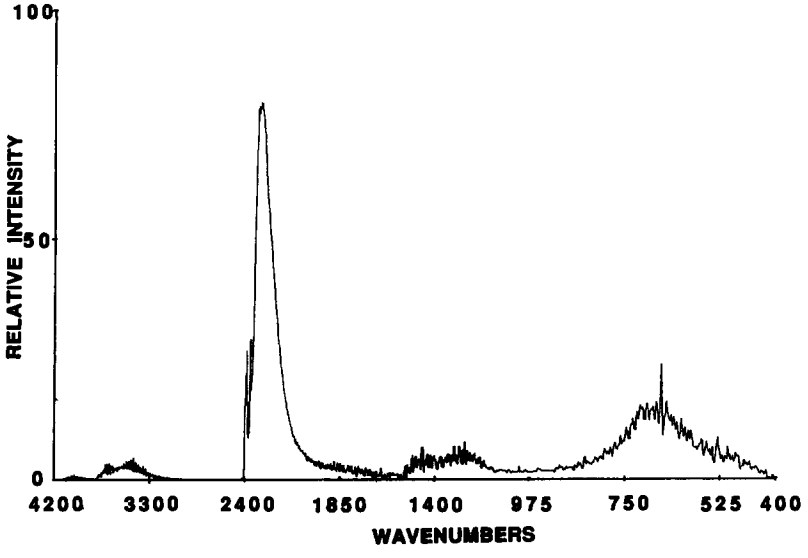

Fig. 2. Infrared emission spectrum of air/acetylene flame background.

It has been reported in the literature that the infrared absorption bands of CO_2 corresponding to the asymmetric stretching vibration and bending vibration occur at 2349 and 667 cm^{-1}, respectively.[11] In addition, a previous study on the infrared emission of CO_2 from a hydrogen/air flame reported the asymmetric stretching vibration to occur at 2262 cm^{-1}; the bending vibration was not observed.[1] The differences between the absorption and emission frequencies for the asymmetric stretching vibration of CO_2 have been accounted for by anharmonic distortion in the vibration, and absorption of the emitted radiation by atmospheric CO_2.[1,12] The presence of the bending vibration in the spectra from the air/acetylene flame (at 661 cm^{-1}) reflects the higher concentration of CO_2 over the hydrogen/air flame. The frequency shifts of the CO_2 bands in the air/acetylene flame (versus the hydrogen/air flame) may be due to a slight red shift because of anharmonicity in the bonds, and absorption of the radiation by atmospheric CO_2 (for the bending vibration at 667 cm^{-1}). However, exact conclusions are difficult to draw because of instrumental resolution considerations.

Flame and burner parameters

The air/acetylene burner may be oriented with its slot parallel to the optical axis or perpendicular to it. With the burner-slot oriented parallel to the optical axis, it may be anticipated that a larger signal would be observed because a larger number of emitting species would be in the optical path. In fact, with the slot burner oriented parallel to the optical axis, the emission intensities (measured by peak heights) were approximately 20% greater. This small improvement is expected because of the difficulty in collecting and imaging such a large amount of radiation from the source. No significant resolution loss due to off-axis radiation was observed.

The fuel/oxidant ratios are critical in flame infrared emission spectroscopy because the flame not only supplies vibrational energy but also thermally decomposes the organic analytes. Since a large number of analyses by flame infrared emission spectroscopy are based on the formation of an analyte derivatized for detection, the choice of flame conditions will depend on the emitting species. For example, the determination of Cl_2, Cl^-, or a chlorine-containing organic compound relies on the formation and emission of hydrogen chloride.[8] Thus, it is anticipated that fuel-rich flame conditions will promote the formation of hydrogen chloride.

It is well-known, however, that organic solvents introduced into air/acetylene flames may cause soot formation due to incomplete

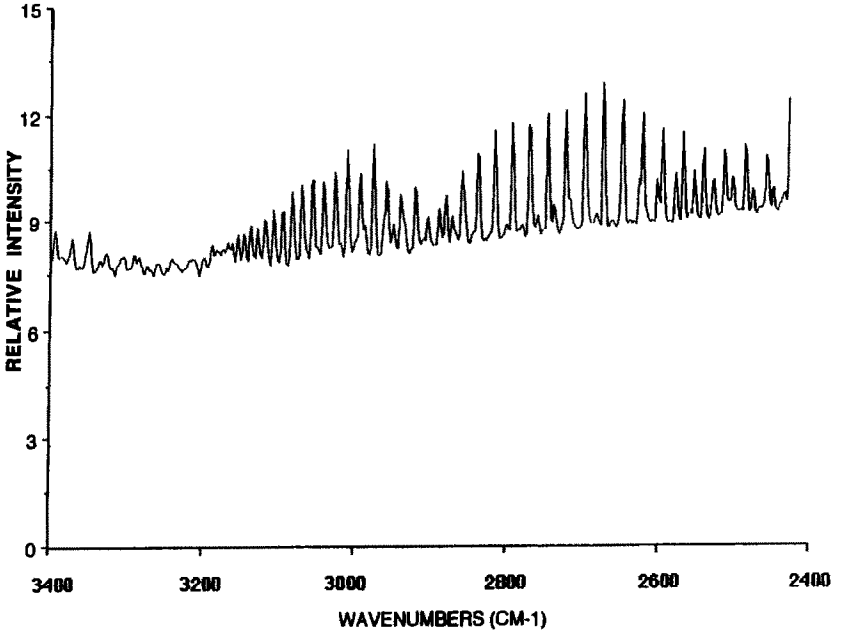

Fig. 3. Infrared emission spectrum of hydrogen chloride obtained when pure chloroform is aspirated into the air/acetylene flame. The baseline offset, to a relative value of 7.5, is due to blackbody radiation from soot particles in the flame.

combustion. In turn, the presence of soot particles in a flame may lead to blackbody radiation. Thus, a fuel-rich flame may interfere with calibration of the emission intensity because of the blackbody radiation from soot particles.

The effect of the fuel/oxidant ratio on the hydrogen chloride emission signal obtained from chloroform was studied by aspirating pure chloroform into the flame. Figure 3 shows the infrared emission spectrum from hydrogen chloride in the region 3600–2400 cm^{-1}. The baseline offset, at a relative value of about 7.5, is due to blackbody radiation from hot soot particles. The blackbody radiation does not affect the magnitude of the analytical calibration signal and can be removed by subtraction. However, it should be pointed out that the amount of blackbody radiation in each spectrum changes with respect to analyte/solvent composition, and it can affect the precision of the measurements because of associated noise.

The intensity of the hydrogen chloride emission line at 2653 cm^{-1} was observed as the air/acetylene ratio was varied. The intensity of this line was corrected for blackbody emission by subtracting the average background obtained from each side of the emission line (approximately ten wavenumbers from the 2653 cm^{-1} line). The most intense hydrogen chloride emission occurs at a fuel/oxidant ratio of 1:1.98 (acetylene:air) and reflects a fuel-rich flame, as expected. However, the adjustment of the air/acetylene ratio is not critical and the optimum ratio affords an hydrogen chloride emission intensity that is only 20% larger than at other ratios.

Noise studies

It is well known from statistical arguments that co-adding spectra leads to signal-to-noise ratio improvements dependent upon the square root of the number co-added, providing the noise is random. Conversely, deviation from this relationship is strong evidence of non-random noise properties. In order to establish the nature of the noise in the background emission bands of CO_2 and H_2O, a graph of the logarithm of the baseline noise (ordinate) versus the logarithm of the number of co-added scans (abscissa) was constructed for the case of 1, 10, 25, 81, and 100 co-added scans of the CO_2 emission band at 2261 cm^{-1}. If the noise is random, it can be shown that the slope of this graph should be equal to $-1/2$. Since, in fact, the slope of the experimentally determined graph was equal to -0.508 ($r = 0.99$), it can be inferred that the noise in the background emission band of CO_2 appears to be random over the range of instrumental parameters used in these experiments. Based on this result, it can be anticipated that the noise in all of the infrared emission bands from the flame is essentially random.

Since the flame utilizes acetylene as its fuel gas, the dominant emission bands in all spectra (even in the presence of analyte bands) are from CO_2 and H_2O. For example, when pure chloroform is aspirated into the flame, the intense emission line of hydrogen chloride at 2653 cm^{-1} is 1/20th the intensity of the CO_2 emission band at 2261 cm^{-1} (although the hydrogen chloride band is broader due to its rotational fine structure). From an experimental standpoint, the noise in the intense CO_2 emission bands significantly impairs the determination of carbon (as CO_2). However, the determination of chlorinated hydrocarbons may still be accomplished providing spectral interferences are negligible and the baseline noise in the spectral region of the analyte emission band is small. In Fourier transform spectrometry, however, the latter criterion may be influenced by the distribution noise of the multiplexing process. Since the air/acetylene flame background is spectrally rich (in fact, nearly continuous), noise localized around the bands and lines may effectively appear "white". Consequently, the noise in the background bands may influence the noise in the analyte bands.

In order to determine if the noise in the major emission bands distributes into the baseline, an experiment was conducted in which the amount of flame radiation reaching the detector was varied by the use of an aperture-stop placed immediately after the beamsplitter. The intensity of the background emission bands were monitored simultaneously with the magnitude of the baseline noise in a region considered to be free of spectral interferences. Since the baseline noise in that region should not directly arise from an infrared emission band, correlation of the signal-to-noise ratio (SNR) of the background emission bands with the optical throughput is strong evidence of detector noise-limited measurements.

The plot in Fig. 4 shows the relationship between the SNR of the CO_2 emission band and

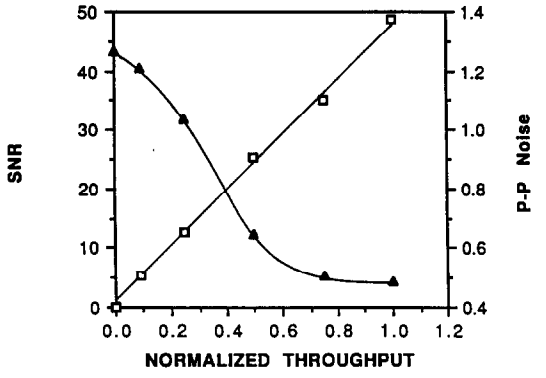

Fig. 4. Dependence of SNR of the CO_2 emission band (noise in the 4200–4300 cm^{-1} region) and peak-to-peak baseline noise on optical throughput. The line denoted by □ is the SNR of the CO_2 emission band and the line denoted by ▲ is the peak-to-peak baseline noise in the 4200–4300 cm^{-1} region. The optical throughput axis has been normalized, and best-fit lines have been drawn through the data points.

the optical throughput of the FT–IR spectrometer. For completeness, Fig. 4 also shows the absolute baseline noise (peak-to-peak) as a function of the optical throughput. The signal of the predominant background emission band at 2261 cm^{-1} was used as a measure of the intensities of all background emission bands, and the flame parameters were adjusted until this band had a relative standard deviation of 25% (constant for all measurements). The peak-to-peak noise in the region from 4300–4200 cm^{-1} was used because no discernible emission bands could be observed, even when 100 spectra were co-added. The SNR values in Fig. 4 are averages from ten single-scan spectra, and the optical throughput values were normalized to the largest value. It should be pointed out that the dynamic range of the CO_2 emission signals was limited by the maximum-attainable throughput of the infrared signal and the minimum detectable signal.

The plot of SNR versus throughput shown in Fig. 4 is quite linear ($r = 0.99$) and exhibits the kind of relationship between the SNR and throughput expected for the case of detector-noise limited measurements.[13] If substantial flicker noise were being distributed to the baseline, then an increase in the optical throughput would lead to virtually no change in the SNR, and, as a result, the slope of the line would decrease (ideally, to zero) at some point in this plot. Thus, it is believed that the dominant noise-source in this system is most likely the FT–IR spectrometer (TGS detector and/or electronics). Of course, other noise sources may also be present in this system and cannot be entirely ruled out. However, it is difficult to speculate on "other" noise sources because of the statistical uncertainty in the measurements. Nonetheless, Fig. 4 clearly shows that a true "multiplex disadvantage" is not present in this system using a TGS detector and $f/3$ collection optics.

Spectral observation windows and spectral interferences

As stated in a previous section, the air/acetylene flame has a number of emission bands due to excited CO_2 and H_2O. Furthermore, these bands are noisy to some degree because of flame turbulence. Thus, it is anticipated that some spectral regions of the air/acetylene flame will be more stable and noiseless than other spectral regions. Of course, those spectral "windows" with lower noise will yield superior detection limits over those windows with greater noise. Thus, an examination of the analytically useful wavelength regions in the air/acetylene flame is worthwhile.

As shown in Fig. 2, the flame background bands cover the entire mid-infrared region. However, clearly there exists certain wavelength regions in the background emission which are reasonably "clean" and can be used for analytical purposes. Based on the criterion of the absence of flame background emission bands, the useful infrared window in the air/acetylene flame occurs in the region of 3133–2400 cm^{-1}. Noise from either H_2O or CO_2 emission (produced by the flame) contributes to the wavelength regions outside of this window. In addition, absorption of radiation by atmospheric H_2O and CO_2 significantly reduce the intensity of emitting species in some regions. However based on experimentally determined results, analytical measurements can be acquired in the regions from 1700–1560 cm^{-1} and 1120–860 cm^{-1}. Of course, higher spectral resolution may be used to resolve the rotational fine structure.

The only species which has been found to give rise to infrared emission bands which overlaps those of the hydrogen chloride emission band are due to D_2O and HDO. As shown in Fig. 5, the infrared emission from D_2O and HDO (obtained by aspirating pure acetone-d_6 into the flame) is easily detected in the 3100–2420 cm^{-1} region. Because of the poor instrument resolution (6 cm^{-1}), assignment of the bands to either HDO or D_2O is

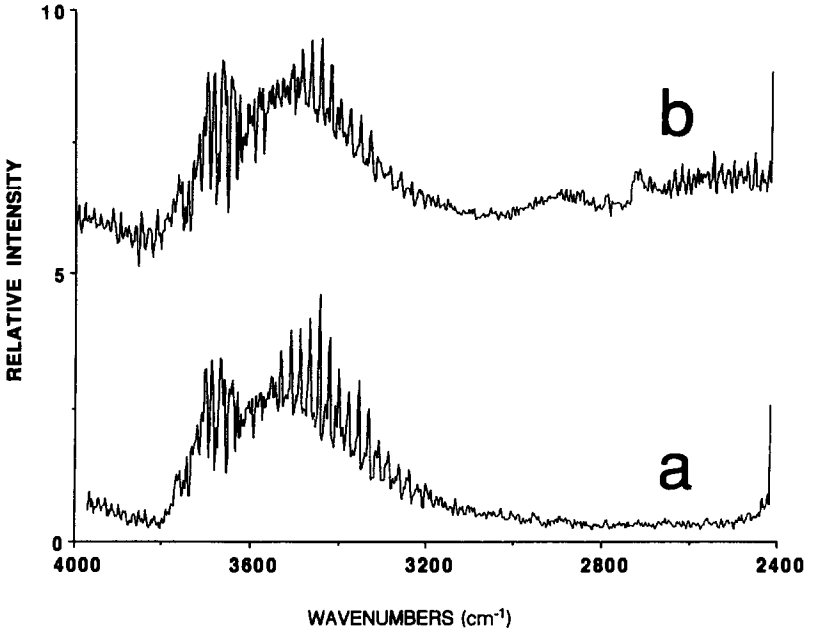

Fig. 5. Spectra showing location of D_2O and HDO infrared emission. Spectrum a is of the air/acetylene flame background and spectrum b is of the air/acetylene flame background when acetone-d_6 is aspirated into the flame (the emittance of spectrum b has been offset 5 arbitrary units). Infrared emission from D_2O and HDO is in the region of 3100–2420 cm^{-1}.

difficult. However, both molecular species are expected to exist at these flame temperatures because of hydrogen exchange.

As will be seen in the proceeding section, the hydrogen chloride infrared emission occurs in the 3100–2420 spectral region in the air/acetylene flame. Thus, the emission signals from D_2O and HDO potentially may spectrally interfere with the hydrogen chloride emission signal. Since elevated levels of deuterated species are generally not found with chlorinated species, this spectral interference should be minor. However, the interfering emission signal may be removed by subtraction as long as the noise in the signal does not significantly impair the precision of the measurement.

Matrix effects and calibration

Although it has been established that the intensity of an analytical emission band (*e.g.*, HCl, HF, CO_2, *etc.*) is directly proportional to analyte concentration, the use of infrared emission from flames as an analytical tool has been confined to detectors for gas chromatography and purge-and-trap analytical methods.[7–10] Since both these techniques isolate the analyte in an inert gas stream, the effect of different sample matrices on the analyte emission signal has not been studied. Figure 6 shows calibration curves for chloroform in ethanol, methanol, and acetone. The concentration axis has been expressed in terms of the percentage of solute in the total volume (percent v/v). Since a number of solvents were available, ethanol, methanol, and acetone were chosen as representative solvents.

The calibration curves of chloroform shown in Fig. 6 were background corrected for blackbody radiation (as described in a previous

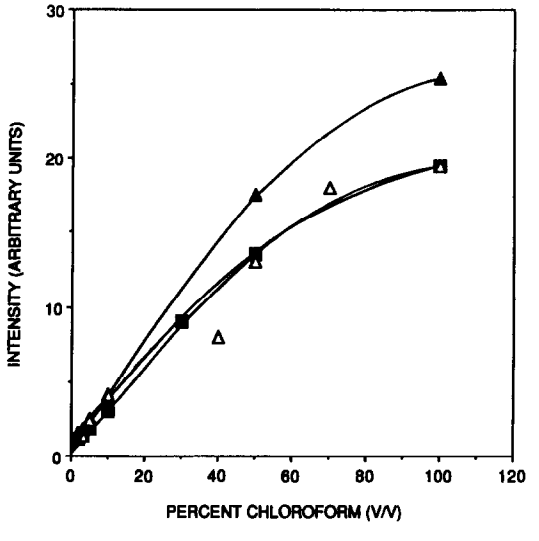

Fig. 6. Calibration curves of chloroform in acetone (△), methanol (▲), and ethanol (■).

section) and are linear from their detection limits to about 55%. Downward curvature at concentrations exceeding 55% is due to either self-reversal of the radiation by cooler hydrogen chloride molecules surrounding the flame, a loss of the hydrogen chloride emission signal from incomplete combustion from a lack of O_2, or a change in the flame conditions due to the introduction of large amounts of analyte. In addition, it is important to note that all curves have nearly the same slope at low concentrations. Thus for these three solvents, the signal from the chloroform (as hydrogen chloride) is approximately independent of solvent in dilute solutions. The detection limits of chloroform in all three solvents were statistically identical and were 1.10% (v/v). In addition, similar results were obtained for carbon tetrachloride and methylene chloride. The detection limits of CCl_4 and CH_2Cl_2 in these three solvents were 0.80 and 1.0%, respectively. Calibration curves for CCl_4 and CH_2Cl_2 were linear from their detection limits to 52% concentration and 60% concentration, respectively.

The detection limits of these chlorinated species in the air/acetylene flame are poor and are believed to be governed by the noise in the FT–IR spectrometer (most likely the TGS detector). A study of the SNR of the CO_2 emission band versus the optical throughput using the baseline noise in the 3000–2420 cm^{-1} region shows a dependence similar to that shown in Fig. 4. The poor detection limits may also be due to the noise present in the infrared emission band of water which slightly overlaps the emission of the HCl and the noise in the background blackbody emission. Further work is needed in order to gain a better understanding of the noise present in this system. Some improvements in the detection limits might be obtained by using a different burner or using a mercury cadmium telluride (MCT) detector. Of course, as shown above, spectral scans may be co-added to improve the detection limits. However, increasing the number of co-added scans increases the total scanning time.

CONCLUSIONS

It has been shown that a conventional Fourier transform infrared spectrometer coupled to an air/acetylene slot burner is suitable for determining chlorinated organic compounds in a variety of sample matrices. The organic compounds may be determined by the infrared emission from hydrogen chloride obtained upon combustion in the flame. The air/acetylene flame background, although spectrally rich, has several optical windows and does not interfere with the determination of the compounds. In addition, it has been shown that the Fourier transform instrument using a TGS detector does not lead to a multiplex disadvantage from flame flicker-noise. Although the detection limits for these chlorinated compounds are poor, it is believed that a better understanding of the noise aspects of this system could improve them.

SUPERSONIC JET SPECTROMETRY OF THERMALLY DECOMPOSED PRODUCTS FROM POLYSTYRENE AND POLYα-METHYLSTYRENE

TOTARO IMASAKA,* MASAMI HOZUMI and NOBUHIKO ISHIBASHI
Faculty of Engineering, Kyushu University Hakozaki, Fukuoka 812, Japan

(*Received* 14 *April* 1992. *Revised* 15 *June* 1992. *Accepted* 15 *June* 1992)

Summary—Polystyrene and polyα-methylstyrene are thermally decomposed, and the products are measured by fluorescence spectrometry and multiphoton ionization spectrometry. The monomers are found to be major products from both the polymers, but many other chemical species, including dimers and trimers, are also observed. The present instrument is applied to a mixture sample containing these two polymers, and the components included are selectively determined using this hyphenated technique.

Constituents of polymers are currently determined by mass spectrometry after pyrolysis of the sample using a heated insertion probe. Such an instrument is already commercially available and has been applied to many polymers, *e.g.*, polystyrene, polycarbonate, polyimide, *etc.*[1] More recently, a laser ablation technique has been used for vaporization of the sample,[2] which is especially useful for a polymer being easily carbonized at an elevated temperature. However, mass spectrometry has limited performance in differentiation of isomers, though some additional information is obtained from the mass fragment pattern, from the excess kinetic energy of ions, and from the daughter-ion mass spectrum obtained by mass spectrometry/mass spectrometry.

In order to overcome this problem, mass spectrometry is usually combined with a separation technique such as gas chromatography. However, standard chemicals are necessary for calibration of each column used. It is noted that each polymer has different characteristics, so that a few polymers are mixed to improve performance; *e.g.*, polyα-methylstyrene is added to polystyrene to improve the thermal properties of the polymer material. Thus a more selective analytical means is required, in order to clarify the constituents of the polymer.

Supersonic jet expansion cools a sample molecule and provides sharp spectral lines. Thus very high spectral selectivity is given by a combination with laser spectrometry.[3–6] This technique allows differentiation of even isomers and isotopes. However, only an analytical application has been reported so far for a polymer sample; polystyrene is measured by laser ablation/supersonic jet/fluorescence spectrometry.[7] In the laser ablation technique, two independent lasers are required, *i.e.*, ablation and excitation lasers, which makes the analytical system more complicated. Moreover, only fluorescence spectrometry has been applied, and therefore information available for assignment of the chemical species is quite limited.

In this study we describe supersonic jet spectrometry combined with fluorescence spectrometry and multiphoton ionization spectrometry. This hyphenated technique is applied to polystyrene, polyα-methylstyrene, and the mixture of these polymers.

EXPERIMENTAL

Apparatus

The supersonic jet spectrometer used in this study is reported in detail elsewhere, and is briefly described here.[8] The polymer sample was heated in a gas chromatograph chamber (Shimadzu, GC-8A). The thermally decomposed products were introduced into the vacuum system from a pulsed nozzle.[9] In the first chamber, the chemical species in a supersonic jet was excited by a dye laser (Quantel, YG581-C20, TDL-50, UVX-2). Fluorescence was measured by using a monochromator (Jasco, CT-25CP) equipped with a photomultiplier (Hamamatsu, R1477). A boxcar integrator (Stanford, SR-250) was used for measurement

*Author for correspondence.

of the signal. The second chamber is separated from the first chamber by a skimmer (Beam Dynamics, 1 mm i.d.). The chemical species in a molecular beam was multiphoton ionized by the same dye laser described above. The ion induced was extracted into the third chamber, *i.e.*, a time-of-flight tube, by a repulsive potential. The ion was detected by an assembly of three microchannel plates; this high-gain detector has a narrow pulse height distribution for a single ion and also removes an external amplifier. The transient signal, *i.e.*, the mass spectrum, was recorded by a waveform digitizer (Iwatsu, DM901). The signal was accumulated 1024 or 2048 times to improve the signal-to-noise ratio. A mass-selected multiphoton ionization spectrum was measured using the boxcar integrator by adjusting the delay time to monitor a specific ion.

Reagent

Styrene and polystyrene were obtained from Wako Pure Chemicals. Other chemicals such as α-methylstyrene and β-methylstyrene were supplied from Tokyo Kasei. Polyα-methylstyrene was purchased from Polyscience. Laser dyes were supplied from Lambda Physik and Exciton.

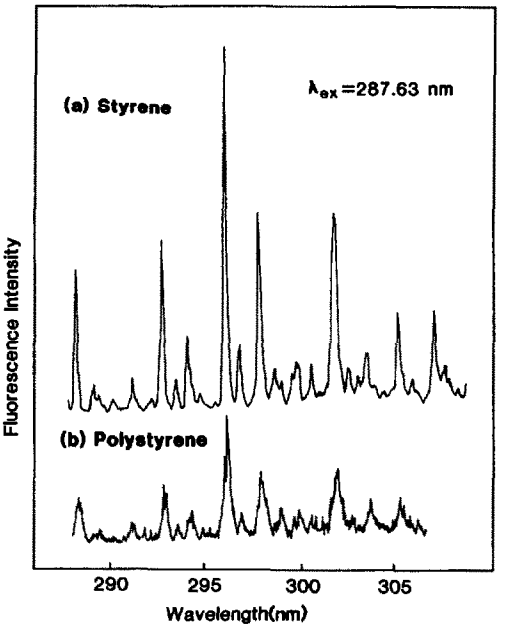

Fig. 2. Fluorescence spectrum for (a) styrene monomer (b) polystyrene; the exciting wavelength is indicated in the figure.

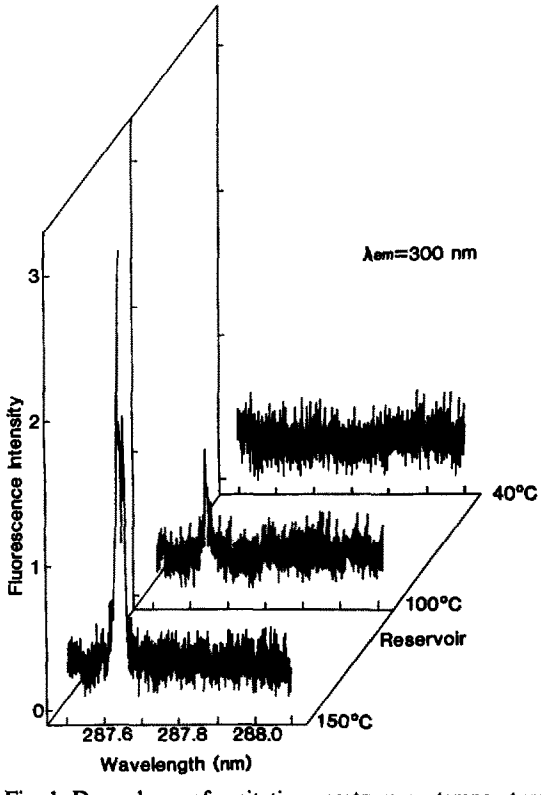

Fig. 1. Dependence of excitation spectrum on temperature for thermally decomposed products from polystyrene; the monitoring wavelength is indicated in the figure.

RESULTS AND DISCUSSION

Polystyrene

The excitation spectrum for thermally decomposed products from polystyrene were measured at various temperatures. The results are shown in Fig. 1. A sharp peak appears at 287.65 nm, which is readily assigned to the 0—0 transition of the styrene monomer from the database constructed by accumulating the data of 0—0 transition for many aromatic hydrocarbons.[10] It is noted that the signal is observed even below 100°. The ceiling temperature, at which the rate of thermal decomposition is equal to that of thermal polymerization, is 220° for polystyrene.[11] The lowest temperature at which the signal appears (100°) is much less than this ceiling temperature. Thus the styrene monomer observed might occur from the monomer included (or dissolved) in the polymer under reduced stagnation pressures (200 Torr). Presence of the styrene monomer in the thermally decomposed product is further confirmed by measuring the fluorescence spectrum, as shown in Fig. 2. The spectrum for polystyrene is identical to that for the styrene monomer. The signal intensity was rather small for a polymer sample, but it became almost identical to that for the

monomer at 350°. This is due to efficient generation of the monomer by thermal decomposition above the ceiling temperature.

Polyα-methylstyrene

The excitation spectrum for polyα-methylstyrene is shown in Fig. 3. The peak corresponding to the 0—0 transition is very weak and three characteristic progressions are observed in the spectrum, as reported.[12] These results are ascribed to the facts that there is a low-energy torsional motion of the methyl group, and that the configuration of the excited state is quite different from that of the ground state. The spectrum observed for the polymer is almost identical to that for the monomer. Thus a major component of the thermally decomposed product is a monomer of α-methylstyrene. The excitation spectrum recorded for β-methylstyrene in the similar spectral region is shown in Fig. 4. Since the band origin is located at longer wavelengths, many irregular peaks are observed in this spectral region, due to the transitions to high vibrational levels in the excited state. Thus the isomer is readily differentiated by the present instrument. The multiphoton ionization spectrum observed for polyα-methylstyrene is shown in Fig. 5, in which a parent ion is monitored. Spectral feature observed is almost

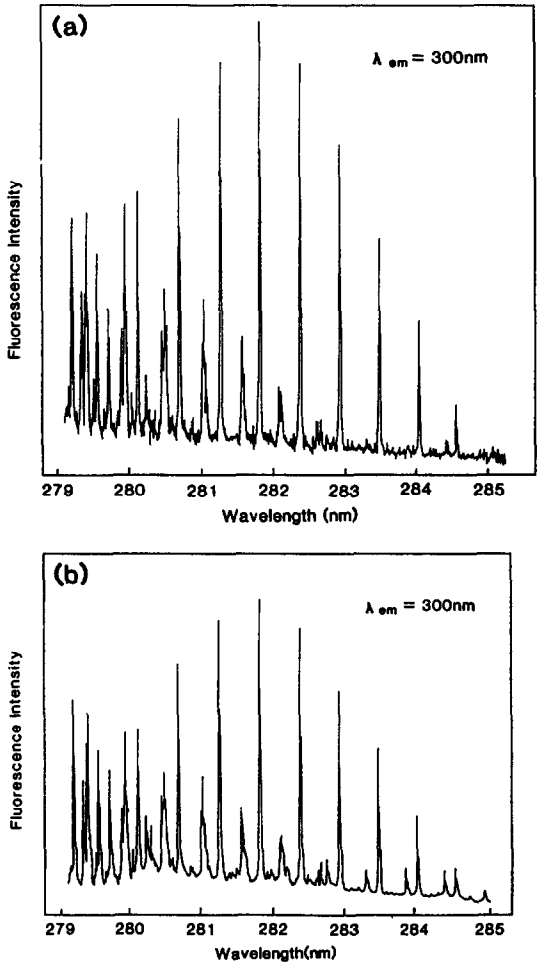

Fig. 3. Excitation spectrum for (a) polyα-methylstyrene (b) α-methylstyrene monomer; the monitoring wavelength is indicated in the figure.

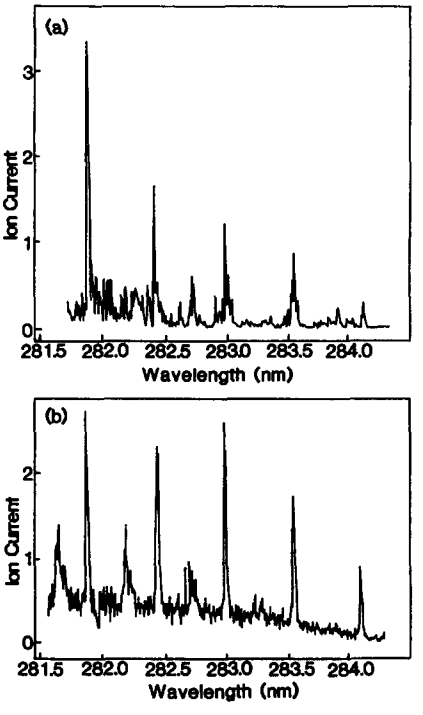

Fig. 5. Multiphoton ionization spectrum for (a) polyα-methylstyrene (b) α-methylstyrene monomer.

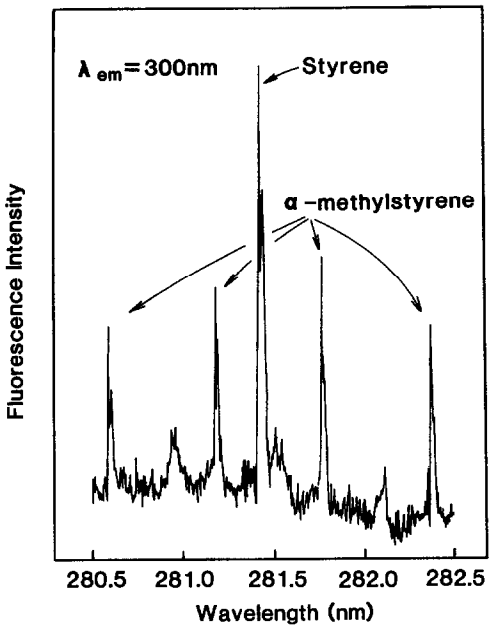

Fig. 6. Excitation spectrum for mixture sample containing polystyrene and polyα-methylstyrene.

identical to that observed in the spectrum for α-methylstyrene. Again, it indicates that α-methylstyrene occurs as a major product from polyα-methylstyrene. It is noted that the spectral shape is almost identical to that obtained in the excitation spectrum. This implies that the efficiency of multiphoton ionization is determined by the excitation step rather than the ionization step.

Mixture sample

In order to demonstrate the figure of merit of the present analytical instrument, a mixture sample containing polystyrene and polyα-methylstyrene was measured. The excitation spectrum obtained is shown in Fig. 6. Several peaks corresponding to the progressions for α-methylstyrene and a single peak corresponding to a transition to a high vibrational level for styrene are clearly observed. Thus the styrene and α-methylstyrene monomers are easily assigned. This assignment is further confirmed by measuring the multiphoton ionization spectrum by monitoring the parent ions at different delay times. As shown in Fig. 7, a sharp peak is observed at 281.55 nm when the ion is monitored between 10.2 ~ 10.6 μsec, corresponding to the parent ion of the styrene monomer (M.Wt. = 104). On the other hand several peaks (progression band) are observed, when the ion is monitored between 11.0 ~ 11.4 μsec, corresponding to the parent ion for the α-methylstyrene monomer (M.Wt. = 118). Thus each component is differentiated on the mass-selected multiphoton ionization spectrum. It is noted that a dip signal observed at 281.55 nm in Fig. 7(b) is attributed to a space charge effect (many styrene monomers are ionized and their charges scatter non-resonantly-ionized α-methylstyrene observed as a background signal) or to overloading the microchannel plate induced by a large number of styrene ions (a millisecond time interval is necessary to recover after the strong saturated signal). In order to avoid these effects, either the concentration of the styrene monomer or the laser power must be reduced. However, they decrease the signal intensity, and therefore the accumulation time should be increased to retain a sufficient signal-to-noise ratio.

A mass spectrum was measured by adjusting the laser wavelength to different values. The result is shown in Fig. 8. When the mixture sample is ionized at 282.04 nm under off-resonance conditions, many peaks appear in the spectrum. The largest peak, corresponding to M.Wt. = 104, is ascribed to the parent ion of the styrene monomer. However, many other peaks appear in the mass regions corresponding to dimers and trimers. When polystyrene is vaporized and ionized by a KrF laser (248 nm) and a ps-UV laser (290 nm),[13] an ArF laser (193 nm)

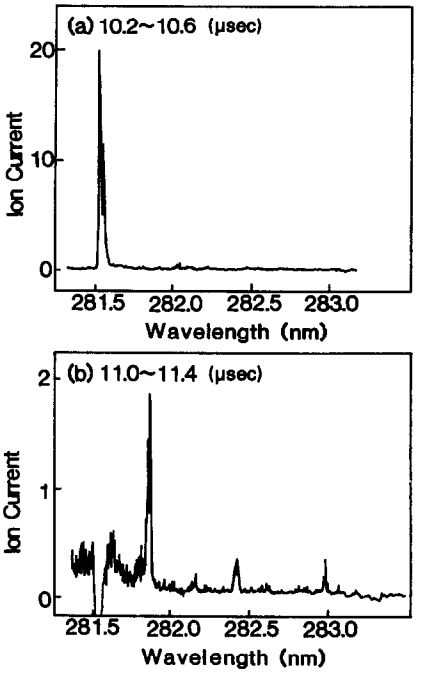

Fig. 7. Multiphoton ionization spectrum for mixture sample containing polystyrene and polyα-methylstyrene; the delay time specified in the figure is adjusted to monitor the parent ion of (a) styrene (b) α-methylstyrene.

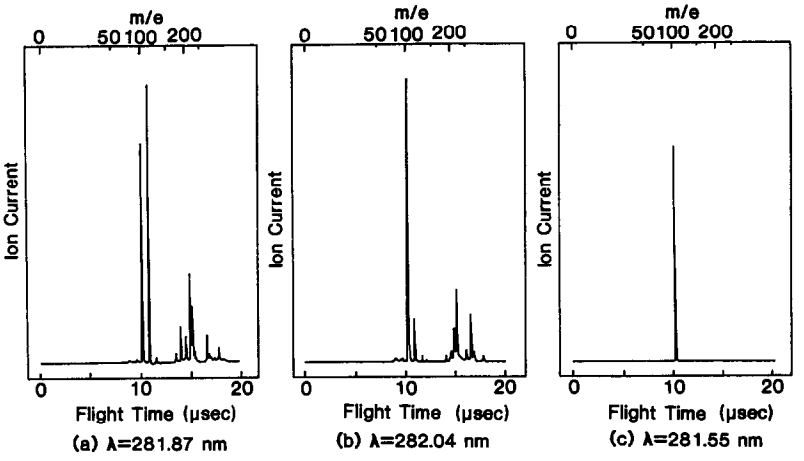

Fig. 8. Mass spectrum for mixture sample containing polystyrene and polyα-methylstyrene; the wavelength of the laser is indicated at the bottom of the figure; (a) on-resonance to α-methylstyrene (b) off-resonance (c) on-resonance to styrene; figure (c) is not presented to scale.

and a vacuum-UV laser (118 nm)[14] and Ar-ion sputtering and a vacuum-UV laser (118 nm),[15] a series of fragments, CnHx ($n = 4,6,\ldots,16$), is clearly observed. Thus thermal vaporization/supersonic jet/multiphoton ionization is more suitable for soft vaporization and ionization. When the mass spectrum is measured at 281.55 nm, which corresponds to the 0—0 transition for a styrene monomer, the peak at M.Wt. = 104 is strongly enhanced; almost a single peak is observed when this peak is presented not to scale out. Thus the strongest peak observed in Fig. 8(b) is confirmed to be due to a styrene monomer. When the laser wavelength is adjusted to 281.87 nm corresponding to one of the progression band for α-methylstyrene, the signal at M.Wt. = 118 becomes strongest among these signal peaks. This fact indicates that the peak at M.Wt. = 118 in Fig. 8(b) originates from a α-methylstyrene monomer. No other peak assignable to fragment species from polyα-methylstyrene is found in this spectrum. This is in contrast to the results obtained by a laser ablation/ionization technique (266 nm/248 nm, 266 nm/193 nm, 248 nm/266 nm); many fragment species are observed in these cases.[16] This result indicates soft vaporization/ionization in the present method, again.

CONCLUSION

As demonstrated in this study, supersonic jet spectrometry combined with a hyphenated spectrometric method is quite useful for determination of thermally decomposed products from polymers, especially for differentiation of the isomers. From the mass spectrum measured under non-resonant conditions, many candidates of the thermally decomposed products are proposed and can be ensured spectrometrically by measuring the mass-selected multi-photon ionization spectrum and excitation/fluorescence spectra. Unfortunately, many fragment species are remained unassigned in this study. In order to assign these chemical species, standard chemicals must be synthesized, since most of the candidates are not commercially available, now.

KINETIC SPECTROPHOTOMETRIC DETERMINATION OF Ga(III)–Al(III) MIXTURES BY STOPPED-FLOW INJECTION ANALYSIS USING PRINCIPAL COMPONENT REGRESSION

M. BLANCO,* J. COELLO, H. ITURRIAGA, S. MASPOCH, J. RIBA and E. ROVIRA

Departamento de Química, Unidad de Química Analítica, Universidad Autónoma de Barcelona, E-08193 Bellaterra, Barcelona, Spain

(*Received* 17 *February* 1992. *Revised* 22 *June* 1992. *Accepted* 29 *June* 1992)

Summary—A multivariate calibration method based on principal component regression analysis is applied to the resolution of mixtures by kinetic methodology. Gallium(III) and Al(III) were determined in mixtures on the basis of their different rate of reaction with 4-(2-pyridylazo)resorcinol in a slightly basic medium by using a stopped-flow injection procedure. Mixtures containing 1–5 mg/l. Ga(III) and 20–100 mg/l. Al(III) were successfully resolved with errors less than 10%.

Flow-injection analysis (FIA) is currently one of the most interesting analytical techniques on account of its potential for solving real problems in a variety of fields.[1,2] Even though all FIA methods are kinetic in nature, this adjective is only customarily employed in relation to those procedures relying on reaction rate measurements.[2] A host of kinetic methodologies are implemented by FIA. That of stopped flow is of special interest on account of its high potential.[3] However, such a potential has scarcely been exploited to date except for analytical determinations of a single analyte.

Mixtures of analytes have been resolved on the basis of their different rate of reaction by using the proportional-equation method[4] or, more recently, by least-squares fitting of kinetic curves[5] or by using the Kalman filter.[6] The inception of diode array spectrophotometers opened up new prospects in this context as they allow full UV–visible spectra to be recorded in a few-tenths of a second, an interval over which few kinetic reactions are bound to develop to a significant extent, so the net result is a simultaneous absorbance measurement at a number of different wavelengths. Rather than the typical (A_i, t_i) data pairs provided by conventional procedures, diode array spectrophotometers yield three-dimensional matrices of the form $(A_{j,w}, t_j, \lambda_w)$ and hence allow wealthier information to be obtained and complex mixtures unaffordable by conventional systems to be readily resolved.[7,8]

Every kinetic method entails a prior calibration. In the above-mentioned mixture resolution methods, such as calibration involves determining the reaction rate of each analyte in the mixture in order to subsequently determine its concentration in the mixture on the assumption that the experimental conditions are preserved, which may not hold inasmuch as the presence of a given analyte may influence the reaction rate of another and the analyte/reagent concentration ratio will not be the same for the analytes alone and in mixtures.

A general kinetic method for mixture resolution thus requires calibration to be carried out on mixtures concerned rather than the individual analytes. This type of calibration is frequently employed with time-independent chemical systems by using one of several procedures that are collectively known as "multivariate calibration procedures" (MCP).[9] Such procedures, however, have scarcely been used in connection with time-dependent reactions.[10]

In this work we used an MCP based on principal component regression (PCR) for the resolution of Ga(III)–Al(III) mixtures by complexation with 4-(2-pyridylazo)resorcinol in a basic medium.

*Author for correspondence.

THEORETICAL BACKGROUND

The absorbance of the product of a pseudo first-order reaction as a function of time is given by

$$A_{w,t} = a_w b C^0 (1 - e^{-kt}) + B_{w,C} \quad (1)$$

where a_w is the absorptivity coefficient at wavelength w, C^0 the initial concentration of the analyte, $B_{w,c}$ the absorbance when $t = 0$, (it includes the absorbance independent of the analytical reaction and the absorbance produced by the analytical reaction before the measurement starting point, consequently it depends both on the wavelength and on the analyte concentrations), b the lightpath and k the rate constant.

For a mixture of two analytes with additive absorbances in the absence of mutual interactions, equation (1) takes the form

$$A_{w,t} = a_{w,1} b C_1^0 (1 - e^{-k_1 t}) + a_{w,2} b C_2^0 (1 - e^{-k_2 t}) + B_{w,C} \quad (2)$$

which simplifies to

$$A_{w,t} = \sum_i K_{(i,w,t)} C_i^0 + B_{w,C} \quad (3)$$

Application of principal component regression (PCR) involves using principal component analysis (PCA) methodology[11] to draw analytically relevant information from the calibration data matrix obtained by recording the absorbance of m mixtures of known composition at n different wavelengths. For this purpose, the data matrix $\mathbf{A}(m,n)$ is broken down as follows:

$$\mathbf{A} = \mathbf{PT} + \mathbf{E} \quad (4)$$

where $\mathbf{P}(m,a)$ is the score matrix, $\mathbf{T}(a,n)$ the loading matrix, and $\mathbf{E}(m,n)$ the residual matrix, a being the number of principal components [$a \leq \min(m,n)$]. This procedure provides a calibration matrix, $\mathbf{B}$, by linear regression from the score matrix.

$$\mathbf{C} = \mathbf{PB} \quad (5)$$

$$\mathbf{B} = (\mathbf{P}^t\mathbf{P})^{-1}\mathbf{P}^t\mathbf{C} \quad (6)$$

The unknown mixture concerned is quantified by determining its scores, p_x, from its spectrum (a_x) and using the loading matrix obtained from the calibration samples. From the scores and matrix $\mathbf{B}$ the different mixture components are subsequently quantified by using the following equations:

$$a_x = p_x\mathbf{T} \quad (7)$$

$$a_x\mathbf{T}^t = p_x\mathbf{T}\mathbf{T}^t = p_x \quad (8)$$

$$C_x = p_x\mathbf{B} \quad (9)$$

EXPERIMENTAL

Reagents

Stock solutions of Ga(III) and Al(III) containing 1 g/l. of either in 1M hydrochloric acid were prepared from their nitrates (Merck *p.a.* grade chemicals) and standardized titrimetrically with EDTA[12].

A $10^{-3}M$ 4-(2-pyridylazo)resorcinol (PAR) solution was also prepared from its monohydrate monosodium salt (Merck, metallochromic indicator).

Finally, a 0.1M decahydrate disodium tetraborate buffer of pH 8.5 adjusted with nitric acid was made from Borax (Merck *p.a.* grade) and recrystallized twice in bi-distilled water.

Apparatus and manifold

The FIA manifold used (Fig. 1) consisted of a Gilson Minipuls 2 HP4 peristaltic pump; a Tecator V-200 variable-volume, two-channel injection valve; a quartz flow-cell of 18 μl inner volume and 10 mm lightpath that was thermostated at 25 ± 0.1°; and a Hewlett-Packard HP 8451A spectrophotometer. The peristaltic pump was connected to a relay and, together with the injection valve, was controlled via a GP-I0 interface connected to the switch of an HP 85 computer.

All tubes used and the injection loop were made of Teflon tubing of 0.5 mm bore.

Procedure

We recently developed a FIA-stopped flow system which allows samples to be injected and the flow to be halted by means of a commercially available Tecator V-200 injection valve.[13] Both the valve and the peristaltic pump were

Table 1. Composition (mg/l.) of the mixtures used for calibration and quantitation

Calibration samples							
	Mixture no.						
	1	2	3	4	5	6	7
[Ga]	2.47	0.00	1.48	2.47	3.45	3.94	4.93
[Al]	0.00	53.00	127.20	79.50	53.00	26.50	10.60
Quantitation samples							
	Mixture no.						
	8	9	10	11	12	13	14
[Ga]	0.99	1.23	1.48	1.97	2.96	4.44	4.44
[Al]	5.30	106.00	63.60	21.20	5.30	42.40	74.20

controlled by the computer of the spectrophotometer running a BASIC programme. On switching the valve, the metal solution was injected into the carrier which merged with the buffer and reagent stream solutions, and, once the plug had reached the detector cell, the flow was stopped and the spectra began to be recorded. Reference was recorded on the reagent stream solution, prior to the metal solution injection. In order to avoid wasting reagent, the peristaltic pump was also stopped.

The absorption spectra of the mixture were recorded over the wavelength range 490–540 nm at 2-sec intervals for 60 sec by using an integration time of 0.3 sec. Data were transferred to an IBM PC-XT computer via an HP/829339A RS232C interface for its mathematical treatment.

Fourteen solutions containing variable amounts of Ga(III) and Al(III) in the ranges 0–5 and 0–130 mg/l., respectively (Table 1), were injected in duplicate and the variation of the absorbance with time was monitored as described above. In order to simplify the calculations involved, the original data matrix was reduced to a representative portion, *viz.* that comprising the data corresponding to six wavelengths (500, 510, 518, 526, 532 and 540 nm) at five different times (6, 10, 14, 20 and 30 sec). The absorbances measured under these conditions were sorted as a function of time for each mixture and injection, and were processed by a principal component regression programme written by the authors that uses the NIPALS algorithm to break down the absorbance matrix.[14]

The values obtained for the five mixtures and the two solutions or pure metal ion were used to construct the calibration matrix, whereas those yielded by the other seven mixtures were employed for validation. Both calibration and validation were done by using the recordings obtained for the two injections.

RESULTS AND DISCUSSION

The kinetics of formation of the Ga(III)–PAR complex in an acid medium is well known.[15] However, the proposed mechanism does not hold for a basic medium owing to the presence of hydroxo complexes, which occur as the major species above pH 3.[16] In earlier work we derived the rate equation for this reaction in a slightly basic medium:[17]

$$v = k[\mathrm{Ga}]\,[\mathrm{H}^+]^{\frac{1}{2}}[\mathrm{PAR}] \qquad (10)$$

At pH 8.5 (Borax buffer) and a PAR concentration of $10^{-3}M$, the reaction can be assumed

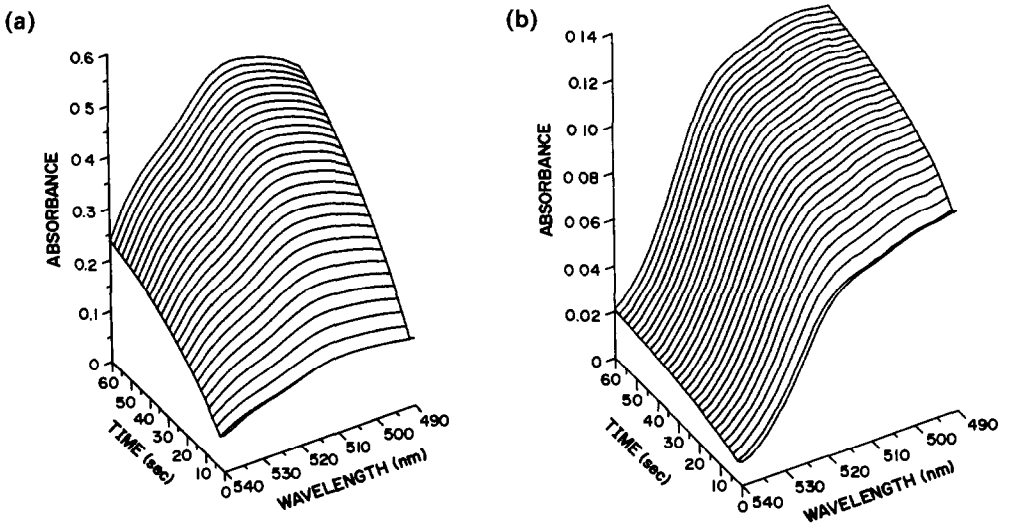

Fig. 2. (a) Kinetic curves of Ga-PAR complex obtained over the wavelength range 490-540 nm. (b) Kinetic curves of Al-PAR complex obtained over the same range.

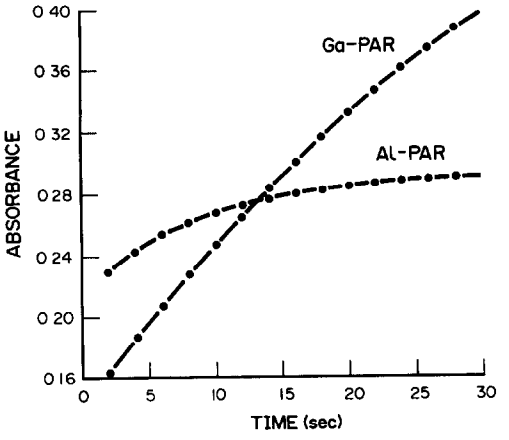

Fig. 3. Kinetic curves. Ga-PAR: 2.5 mg/l, Al-PAR: 100 mg/l. Dashed line: theoretical curve calculated using equation 1.

to be of pseudo first-order in the metal concentration, $v = k_{Ga}[Ga]$, so the corresponding rate constant is $k_{Ga} = (2.45 \pm 0.08) \times 10^{-2}$ sec^{-1}.

Under these conditions, the formation of the Al(III)–PAR complex is also of pseudo first-order in the metal concentration, and the rate constant is $k_{Al} = (9 \pm 1) \times 10^{-2}$ sec^{-1}, as determined by using the programme STATGRAPHICS 5.0 to fit the curves of seven solutions over the Al(III) concentration range 10.6–127.2 mg/l.

Figure 2 shows the variation with time and the wavelength of the absorbance of solutions containing 2.5 mg/l. Ga and 100 mg/l. Al. The corresponding kinetic curves obtained at 510 nm are shown in Fig. 3. The line is the theoretical curve corresponding to the model defined by equation (1) as fitted by STATGRAPHICS. As

Table 2. Variation of the residual variance with the number of principal components (a)

Components	1	2	3	4	5	6	7
$V_y(\cdot 10^4)$	7500	89	105	10	137	68	73

can be seen, the fit is quite good for both ions and thus indicative of pseudo first-order kinetics for the concentration of the two metal ions.

A plot of all the data recorded at the five times used in the calculations for pure solutions of Ga and Al is shown in Fig. 4., The wavelengths chosen for the quantitation of the mixtures are marked with an arrow. It must be remarked the cyclic structure of the data corresponding to the different times.

Determination of the number of principal components

Correct estimation of the number of principal components is crucial to the application of a PCR procedure. In this work we selected the number of factors by means of the cross-validation method.[18] For each factor, the total residual variance of the concentrations predicted by the model, (V_y), was calculated

$$V_{y_{\text{Total}}} = \frac{1}{NM} \sum_{i=1}^{M} \sum_{j=1}^{N} (\hat{C}_{(i,j)} - C_{(i,j)})^2 \qquad (11)$$

where N and M are, respectively, the number of analytes and samples used in the calibration set; $C_{(i,j)}$ denotes the experimental concentration of the analyte i in the sample j, and $\hat{C}_{(i,j)}$ refers to the calculated value. The variation of the residual variance with the number of PC is

shown in Table 2. It is observed that the minimum was found when four components were considered, increasing the value when more factors were used in the model.

Figure 5 shows the scores plot of the second PC versus the first PC; by comparison with data in Table 1, it is observed that PC1 scores increase with the concentration of Ga, whereas those of PC2 do it with the concentration of Al. The particular structure of the data in the calibration matrix, an ordered set of 6 measurements at each one of the 5 different times chosen, is reflected in the plot of the loadings of the four PC used to build the model, as is shown in Fig. 6. PC3 is associated to this cyclic structure, and the plot of the loading values of the 30 variables used for PC3 versus those of PC2 and PC1, Fig. 7, follows the same pattern as the original data. The relationship between PC4 and the data structure is more complex. Along the time, the absorbance recorded for a sample increases depending not only on the initial concentration of both metals but on the different values of the kinetic constants and the absorption coefficients of Ga–PAR and Al–PAR complexes as well. Figure 8 shows the loading values for PC4 at different wavelength versus each one of the 5 times selected and comparing with Fig. 3, it is seen that the minimum appears when the absorbance of Ga–PAR and Al–PAR are similar.

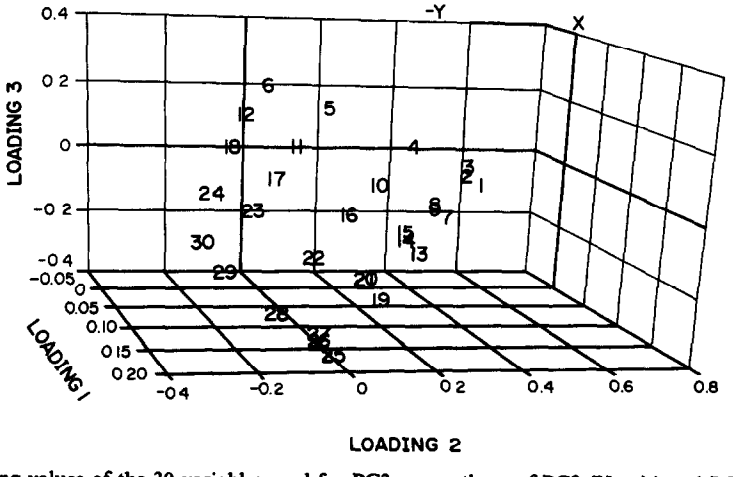

Fig. 7. Loading values of the 30 variables used for PC3 versus those of PC2 (Y axis) and PC1 (X axis).

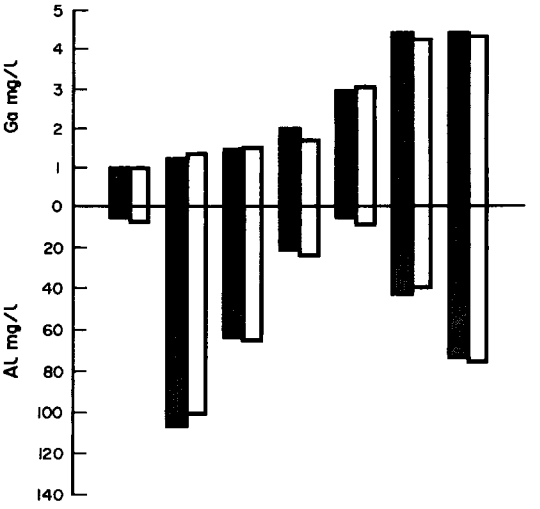

Fig. 9. Mixtures resolution. ■ Added, □ found.

Quantitation of the samples

Once the calibration model was established, analysis of the sample set was performed. The average values obtained are shown and compared with the added metal concentrations, Fig. 9. As can be seen, the mixtures were accurately resolved, with errors smaller than 10% in every case except for Al at concentrations below 20 mg/l., which can be attributed to the low sensitivity of its reaction with PAR under our experimental conditions.

The reproducibility of the proposed method, expressed as the mean relative standard deviation (MRSD), was estimated from the differences between the calculated values for two injections of each mixture according to the following equation,[19]

$$\%\text{MRSD} = 100 \times \frac{1}{\bar{C}}\left[\frac{\sum_{i}^{Z}\sum_{j}^{N}(C_{(i,j)1} - C_{(i,j)2})^2}{2Z}\right]^{\frac{1}{2}} \quad (12)$$

where N and Z are, respectively, the number of analytes and samples used in the validation set; $C_{(i,j)n}$ denotes the calculated concentration of the analyte i in the sample j and the determination n and $\bar{C}$ the mean concentration.

The MSRD was found to be 0.8% for Ga and 1.6% for Al.

We should emphasize that this procedure allows the highly accurate and precise simultaneous determination of GA–Al mixtures in which the latter metal is in a large excess (100:1) over the former.

The literature includes a few methods for the kinetic spectrophotometric resolution of Ga–In mixtures,[20,21] but none for Ga–Al mixtures, the resolution of which has so far been addressed by using spectrofluorimetric methods,[22–24] which obviously afford lower detection limits, but are applicable over narrower Ga/Al concentration ratio ranges (1:10).

In conclusion, multivariate calibration opens up new prospects for the resolution of mixtures on the basis of time-dependent chemical reactions. The procedures involved can be readily implemented in stopped-flow injection manifolds, which further increase the analytical potential of this technique.

Summary–Hybrid least-squares algorithm MINOPT for a nonlinear regression is introduced. MINOPT from CHEMSTAT package combines fast convergence of the Gauss–Newton method in a vicinity of minimum with good convergence of gradient methods for location far from a minimum. Quality of minimization and an accuracy of parameter estimates for six selected models are examined and compared with different derivative least-squares methods of five commercial regression packages.

In literature many regression algorithms and program packages for non-linear regression are described and classified.[1] According to their practical applicability in the chemical laboratory the program's modus operandi may be elucidated using a block structure classification:[2,3] regression program may be divided into functional blocks as INPUT, RESIDUAL SUM OF SQUARES, MINIMIZATION, STATISTICAL ANALYSIS, DATA SIMULATION, ADDITIONAL SUBROUTINES, *etc.* An amount of useful information achieved from program application, efficiency and reliability of results can be deduced from

(i) a numerical point-of-view which concerns ability to reach a minimum of the regression criterion (subroutines of a MINIMIZATION block);

(ii) a statistical point-of-view which concerns quality of statistical information (subroutines of STATISTICAL ANALYSIS block).

According to these two blocks the commonly used programs are not always reliable. Due to a great variability of regression models, regression criteria and data the effective algorithms enabling sufficiently fast convergence to a global extreme are not available. Some algorithms and programs often fail, *i.e.*, converge very slow or diverge.

In this paper we concentrate on procedures of derivative methods for the least-squares (LS) criterion which represents a very large group of methods today.[4] Some numerical aspects of the algorithm MINOPT are presented. Its numerical quality is examined and compared with other derivative methods on selected mathematical models usually found in problems of reaction kinetics and solution equilibria studies.

RESIDUAL SUM OF SQUARES BLOCK

In the classical setting the additive model of measurements is adopted

$$y_i = f(x_i; \beta) + \epsilon_i, \quad i = 1, \ldots, n \qquad (1)$$

In model (1) the y_i is the response (experimental quantity), x_i are non-stochastic explanatory variables (without detriment to generality, x is supposed to be scalar), $f(x_i, \beta)$ is a regression model containing the $(m \times 1)$ parameter vector β and ϵ_i is the so called (experimental) error.

The main task of regression is to find estimators, b, of an unknown parameter vector β. A process of parameter estimation is based on assumptions about errors ϵ: classical presumption requires the errors ϵ to be independent and identically distributed random variables having normal distribution $N(0, \sigma^2)$ with zero mean and constant variance σ^2. Based on these

*Part XIII, *Talanta*, 1988, **35**, 981.

assumptions the sufficient estimates $\hat{b} = \{b_1, \ldots, b_m\}$ can be obtained minimizing the least-squares criterion

$$U(\hat{b}) = \sum_{i=1}^{n} [y_i - f(x_i; \hat{b})]^2, \quad n \geqslant m \qquad (2)$$

MINIMIZATION BLOCK

For minimization of $U(\hat{b})$ criterion a lot of various derivative and non-derivative algorithms exist.[4-8] Derivative algorithms are useful for all model functions which are twice differentiable. In a sequel we concentrate on derivative methods and LS criterion only.

The main disadvantage of derivative methods is a local convergence which depends on a choice of an initial guess $\hat{b}^{(0)}$. All algorithms of this group are of iterative nature. In the i-th iteration a procedure starts from the estimates $\hat{b}^{(i)}$ to which a suitable increment vector $d^{(i)}$ is added:

$$\hat{b}^{(i+1)} = \hat{b}^{(i)} + d^{(i)} \qquad (3)$$

The vector $d^{(i)}$ is considered acceptable if

$$U(\hat{b}^{(i)} + d^{(i)}) \leqslant U(\hat{b}^{(i)}) \qquad (4)$$

Here, the increment vector can be expressed by relation

$$d^{(i)} = \alpha_i V \qquad (4a)$$

where V is directional vector and α is scalar. Some algorithms admit equality or even a small increase of $U(\hat{b}^{(i+1)})$ against $U(\hat{b}^{(i)})$. Procedure of a search of minimum $U(\hat{b})$ consists of the following four steps:

1. *Determination of initial guess of parameters* $\hat{b}^{(0)}$

This step is decisive for many algorithms for successful minimization. From a good initial guess $\hat{b}^{(0)}$ the simple algorithms usually converge. For a very poor initial guess a minimum cannot be found by any methods of this group.

2. *Determination of direction vector* V

Derivative of a LS criterion function $U(\hat{b})$ in a point $(\hat{b} + \alpha V)$ according a scalar α has form

$$\frac{\delta U(\beta)}{\delta \alpha} = \left[\frac{\delta U(\beta)}{\delta \beta}\right]^T \frac{\delta \beta}{\delta \alpha} \qquad (5)$$

For $\alpha \to 0$ we get from equation (5) so called directional derivative

$$S_D = \left.\frac{\delta U(\beta)}{\delta \alpha}\right|_{\alpha \to 0} = g^T V \qquad (6)$$

where g is the gradient vector of $U(\hat{b})$ whose elements g_j are equal to $\delta U(\hat{b})/\delta b_j$. The steepest decrease of a criterion function is in the direction $-g$. The condition of acceptability of the directional vector V requests that the directional derivative is not positive. Any direction for which an inequality $g^T V > 0$ holds is therefore inconvenient. Moreover, if the directional vector V is acceptable the positive regular definite matrix $\mathbf{R}$ exists so that

$$V = -\mathbf{R}g \qquad (7)$$

The directional derivative S_D is then equal to

$$S_D = -g^T \mathbf{R} g \qquad (8)$$

For a positive definite matrix $\mathbf{R}$ their quadrative forms are always positive so that S_D in equation (8) is negative.

3. *Calculation of minimization step* αV

For calculation of the minimization step (also called the optimal increment or the correction vector) $d = \alpha V$ in direction V the approximation of $U(\hat{b})$ by the Taylor series up to a quadratic term can be used. It leads to form

$$U(\hat{b} + \alpha V) \approx U(\hat{b}) + \alpha g^T V + \frac{\alpha^2}{2} V^T \mathbf{H} V \qquad (9)$$

where $\mathbf{H}$ is symmetric Hessian (matrix) having as elements the second derivatives of $U(\hat{b})$. Equation (9) assumes α to be approximately quadratic so that the optimal value of α may be estimated by putting the first derivative $U(\hat{b} + \alpha V)$ according to α to zero. Solving this equation will give

$$\alpha^* = -\frac{\delta U(\hat{b})}{\delta \alpha} \Big/ \frac{\delta^2 U(\hat{b})}{\delta \alpha^2} = -g^T V [V^T \mathbf{H} V]^{-1} \qquad (10)$$

and after substitution from equation (8) we obtain the so called Raleigh coefficient

$$\alpha^* = g^T \mathbf{R} g [g^T \mathbf{R}^T \mathbf{H} \mathbf{R} g]^{-1} \qquad (11)$$

The suitability of Raleigh coefficient α^* is restricted for a region in which the approximation (9) can be used.

For LS criterion $U(\hat{b})$ the gradient g can be expressed in the form

$$g = 2\mathbf{J}^T \hat{e} \qquad (12)$$

and the Hessian $\mathbf{H}$ in the form

$$\mathbf{H} = 2[\mathbf{J}^T \mathbf{J} - \mathbf{W}^T \hat{e}] = 2[\mathbf{J}^T \mathbf{J} - \mathbf{B}] \qquad (13)$$

Here $\hat{e}$ is the residual vector having components

$$\hat{e}_i = y_i - f(x_i; \hat{b}) \qquad (14)$$

$\mathbf{J}$ is the Jacobian (matrix) of dimension $(n \times m)$ with elements

$$J_{ij} = \frac{\delta f(x_i, \hat{b})}{\delta b_k}, \quad j = 1, \ldots, n; \quad k = 1, \ldots, m \quad (15)$$

and $\mathbf{W}$ is a three-dimensional array of dimension $(n \times m \times m)$ which is composed from n layers where the ith one is formed by the matrix $\mathbf{W}_i$ having elements

$$W_{i(j,k)} = \frac{\delta^2 f(x_i, \hat{b})}{\delta b_j \, \delta b_k} \quad (16)$$

4. *Termination of iteration process*

The natural criterion of an optimal estimate $\hat{b}$ is a zero value of the gradient g. Many methods of a minimum search terminate the iterative process when the norm of gradient

$$\| g \|^2 = \sum_{j=1}^{m} g_j^2 \quad (17)$$

is sufficiently small. It is possible to select a critical value of this norm, for example, equal to 10^{-4} *i.e.*, the limit under which the point $\hat{b}^{(i)}$ is considered as a local extreme. Often iterations terminate when too small changes of parameter estimates appear. None of these criteria enable a termination in a minimum. Minimization may terminate less heuristically. From the geometry of LS we get termination criterion as follows: the residual vector $\hat{e}$ is approximately perpendicular on columns of the matrix $\mathbf{J}$. This is equal to condition $\mathbf{J}^T\hat{e} = 0$. For cosines of angle α_j between the residual vector $\hat{e}$ and the j-th column J_j of a matrix $\mathbf{J}$ a simple relation is valid

$$\cos \alpha_j = \hat{e}^T J_j [J_j^T J_j \hat{e}^T \hat{e}]^{-1/2} \quad (18)$$

When a maximal value of $\cos \alpha_j$ is sufficiently small, *e.g.*, smaller than 10^{-9} it is supposed that a minimum $U(\hat{b})$ was reached. Some other termination criteria may be found in Ref. 7.

The following derivative algorithms seem to be dominant in nonlinear regression analysis today:

(a) Gauss–Newton methods;
(b) Marquardt methods;
(c) dog-leg method.

Gauss–Newton methods

For determination of a convenient directional vector V the quadratic approximation of a criterion function $U(\hat{b})$ may be used which also corresponds to equation (9) for $\alpha = 1$. From

$$\frac{\delta U(\hat{b} + V)}{\delta V_i} = 0 \quad (19)$$

the optimal direction vector $V_i = N_i$ in the form

$$N_i = -\mathbf{H}^{-1} g = (\mathbf{J}^T\mathbf{J} + \mathbf{B})^{-1} \mathbf{J}^T \hat{e} \quad (20)$$

is evaluated. Substituting into equation (11) we estimate that $\alpha^* = 1$. Therefore N_i is directly a minimization step d_i and the method is called the Newton–Raphson method. It is obvious that when the criterion $U(\hat{b})$ is a quadratic function (*i.e.*, an elliptic paraboloid) the minimum $\hat{b}$ will be reached in one step. For other forms of criterion function $U(\hat{b})$ and estimates $\hat{b}^{(0)}$ far from β, this method does not converge too fast. Moreover it requires knowledge of an array of second derivatives $\mathbf{W}_i$ for a determination of a matrix $\mathbf{B}$ in equation (13).

Neglecting matrix $\mathbf{B}$ is equivalent to a linearization of regression model and is theoretically acceptable for a case when a residual vector $\hat{e}$ is negligible. The corresponding directional vector L_i has the form

$$L_i = (\mathbf{J}^T\mathbf{J})^{-1} \mathbf{J}\hat{e} \quad (21)$$

and methods are called Gauss–Newton methods. They belong to the simple and the most frequently used procedures of nonlinear regression. When $\mathbf{H} \approx (\mathbf{J}^T\mathbf{J})$ is supplied into equation (11) it leads to $\alpha^* = 1$. From the practical point it is important that the Gauss–Newton method will work well, if some of the following conditions are fulfilled:

I. Residuals $\hat{e}_i = y_i - f(x_i, \hat{b})$ are small.

II. The model function $f(x, \beta)$ is nearly linear *i.e.*, the Hessian $\mathbf{H}$ has a small norm and its elements are nearly zero.

III. Residuals $\hat{e}_i$ have alternate signs so that $\mathbf{B}$ is approximately a zero matrix. It is valid in a vicinity of optimum $\hat{b}$.

Extending a region of convergence of this very simple method is possible to reach by different ways:

(a) The technique of an inversion of the matrix $\mathbf{J}^T\mathbf{J}$ and solution of a set of linear equations

$$(\mathbf{J}^T\mathbf{J})L = \mathbf{J}^T\hat{e} \quad (22)$$

(b) Improving a matrix $(\mathbf{J}^T\mathbf{J})$ in order to be close to Hessian $\mathbf{H}$.

(c) Choice of a suitable length of the step α.

Marquardt methods

The natural selection of a directional vector V_i is the direction of steepest descent $-g$. It corresponds to a matrix option $\mathbf{R} = \mathbf{E}$. For optimal coefficient α^* in this direction it is from equation (11) that

$$\alpha^* = g^T g [g^T \mathbf{H} g]^{-1} \approx g^T g [g^T (\mathbf{J}^T \mathbf{J})^{-1} g]^{-1} \quad (23)$$

The minimization step $d_i = -\alpha^* g$ corresponds to the gradient method.

The gradient methods converge often slowly in a vicinity of an optimum. On the other hand, in cases when $b^{(i)}$ is far from β it enables a direction leading to a minimum to be found. It is effective to use a combination of directions of the Newton method N_i or a direction of linearization L_i together with a direction $-g$ to a construction of the more robust procedures which are also called the hybrid procedures. Known representative is here the Marquardt method which calculates the directional vector $V_i(\lambda)$ by relation

$$V_i(\lambda) = (\mathbf{J}^T \mathbf{J} + \lambda \mathbf{D}_i^T \mathbf{D})^{-1} \mathbf{J}^T \hat{e} \quad (24)$$

where λ is the parameter and $\mathbf{D}_i$ is the diagonal matrix which eliminates an influence of various magnitudes of components of the matrix $\mathbf{J}$. Usually the diagonal elements D_{ii} are equal to diagonal elements of matrix $(\mathbf{J}^T \mathbf{J})$. Convenient selection of a parameter λ ensures:

(1) positive definiteness of a matrix $\mathbf{R} = (\mathbf{J}^T \mathbf{J} + \lambda \mathbf{D}^T \mathbf{D})$ which is necessary for its invertibility;

(2) a shortening step $V_i(\lambda)$ moving from a direction of linearization L_i;

(3) a possibility of a selection between a direction L_i and approximate direction $-g$. Step length in direction $-g$ is however equal to zero;

(4) a restriction of a magnitude of the incremental vector V_i to the certain "admissible" region in a vicinity of $b^{(i)}$.

The necessity of repeated matrix inversion for each λ is a disadvantage of this procedure which is rather time-consuming. Moreover a situation may happen that for large λ a magnitude V_i is too small. Therefore the maximal magnitude of λ is limited. Individual modifications of the Marquardt method differ especially in strategy of the adaptive setting of parameter λ.

Generally it is valid that methods of Marquardt type are for their robustness a standard part of library programs of most computer packages.

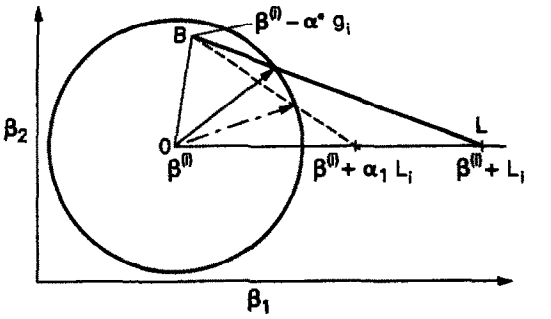

Fig. 1. Geometrical interpretation of dog-leg strategy. The circle shows admissible range of increments. Solid hypotenuse is $V(\mu)$ for $\alpha_1 = 1$ and dotted hypotenuse is $V(\mu)$ for $\alpha_1 = 1$.

Dog-leg methods

Among the main disadvantages of the Marquardt method are:

(a) a necessity of matrix inverse at change of parameter λ;

(b) a small length of vector $V(\lambda)$ for a large λ.

Both these disadvantages are removed in hybrid methods when the optimal directional vector $V(\mu)$ is the convex combination of vectors L and the vector $-\alpha^* g_i$. It holds that

$$V(\mu) = b^{(i)} + (1 - \mu) L_i \alpha_1 - \mu \alpha^* g_i \quad (25)$$

Here α^* is estimated from equation (23) and condition $0 \leqslant \mu \leqslant 1$ is valid. The function $V(\mu)$ for cases $\alpha_1 = 1$ and $\alpha_1 < 1$ on Fig. 1 hypotenuses of right angle triangles with dotted line for $\alpha_1 < 1$ and solid line for $\alpha_1 = 1$. Classical strategy of the Powell dog-leg method estimates an optimal vector $V_i(\mu)$ on the abscissa TB of a triangle defined by vertices $0 = b^{(i)}$; $T = b^{(i)} + L_i$; $B = b^{(i)} - \alpha^* g_i$ where α^* is defined by equation (23).

It is obvious that for $\mu = 0$ the vector $V(\mu)$ is identical with a linearization direction L_i and for $\mu = 1$ with a direction of negative gradient $-g$. The magnitude of a total increment in direction $-g$ correspond to the optimal value α^*.

Dennis and Mei[10] used the "shorter" vector $\alpha_1 L_i$ instead of a vector L_i. The parameter α_1 is determined that the increment in a linearization direction approximately corresponds to a Raleigh point, *cf.* Ref. 10.

$$\alpha_1 = 0.2 + 0.8 \, \|g_i\|^4 \times [g_i^T (\mathbf{J}^T \mathbf{J})^{-1} g_i g_i^T (\mathbf{J}^T \mathbf{J}) g_i]^{-1} \quad (26)$$

From Fig. 1 it is obvious that shortening $L_i \alpha_1$ leads to a directional vector $V_1^*(\mu)$ which is

closer to a linearization direction than the vector $V(\mu)$ calculated at option $\alpha_1 = 1$. MINOPT algorithm[11] uses $V_1^*(\mu)$ directional vector. For solution of matrix inverse problems a rational rank technique (*i.e.*, special pseudoinversion) is adopted. A special heuristic strategy for constraining a maximum step length based on quality of quadratic approximation of $U(\hat{b})$ is used here.

Other blocks as STATISTICAL ANALYSIS, GOODNESS-OF-FIT TEST, DATA SIMULATION, *etc.* will be described in the next contributions of this series.

Software

Program MINOPT from CHEMSTAT package carries out the numerical and statistical analysis of a non-linear regression model $f(x; \beta)$ with use of modified "double dog–leg" strategy. Input consists from the experimental data (x_i, y_i), $i = 1, \ldots, n$, and the initial guess of parameters estimates $\hat{b}^{(0)}$. The user supplies the regression model. All required derivatives are calculated numerically.

Program CHEMSTAT is available from authors on request.

RESULTS AND DISCUSSION

Comparison of some commercial packages for nonlinear regression

In a study of reaction kinetics and solution equilibria, the regression analysis of frequently used nonlinear models requires an estimation of unknown parameters of exponentials or parameter powers. To examine the reliability of MINOPT algorithm six testing problems have been chosen. Models I, II, and III are selected from literature. Models IV and VI are based on simulated data and Model V is based on experimental data. Testing models with their data and available initial guess of parameters are summarized below. To compare parameter estimates $\hat{b}$ and $U(\hat{b})$, no restart or repeated determination with new initial guess of parameters in divergence or failing were allowed. Commercial packages BMDP (*i.e.*, BMDP PC-90), SAS (*i.e.*, SAS version 6.03), SYSTAT (*i.e.*, SYSTAT version 5.01), SPSS (*i.e.*, SPSS PC+ version 3.1), ASYST (*i.e.*, ASYSTANT+ version 1.5), STATGR (*i.e.*, STATGRAPHICS version 5.0) and CHEMSTAT (*i.e.*, CHEMSTAT version 1.25) were used,[11,12] *cf.* Table 3.

Six tested models with data:

Model I. $y = \beta_1 + \beta_2 \exp(\beta_3 x)$

x	1	5	10	15	20	25	30	35	40	50
y	16.7	16.8	16.9	17.1	17.2	17.4	17.6	17.9	18.1	18.7

Model II. $y = \exp(\beta_1 x) + \exp(\beta_2 x)$

x	1	2	3	4	5	6	7	8	9	10
y	4	6	8	10	12	14	16	18	20	22

Model III. $y = \beta_1 \exp\left[\frac{\beta_2}{\beta_3 + x}\right]$

x	50	55	60	65	70	75	80	85
y	34780	28610	23650	19630	16370	13720	11540	9744

SYSTAT	37.5	—
STATGR	50	—
ASYST	8.3	—
SPSS	100	66.6
CHEMSTAT	100	100

Initial guess of parameters (Table 1), parameters estimates (Table 2) and results of convergence (Table 3) for six tested models are summarized. Detailed results may be found in the forthcoming[12] textbook or from the authors. For overall comparison of packages the Performance Index PI was computed

$$PI = \frac{100 * (\text{number of correct results})}{T * (\text{number of used methods in package})}$$

where T is the number of tests. From a numerical viewpoint the greater value of PI indicates the better package. Performance index PI for all tested packages are summarized in Table 4.

CONCLUSION

From this comparative study it can be deduced that the best results have been obtained using MINOPT procedure. Even this comparison may disappoint some users of standard statistical packages as it indicates that errors due to a false optimum, saddle points or a flat $U(b)$ function can often cause failure of the whole regression analysis.

(*Received* 9 *December* 1991. *Revised* 29 *June* 1992. *Accepted* 29 *June* 1992)

Summary—Estimation of nonlinear regression quality leads to examination of quality of parameter estimates, a degree of fit, a prediction ability of model proposed and quality of experimental data. Statistical analysis serves for computation of confidence intervals of parameters and confidence bands, the bias of parameters and bias of residuals. Goodness-of-fit test examines classical residuals using various diagnostics and identifies influential points. Mentioned topics of nonlinear model building and testing contained in MINOPT program from CHEMSTAT package are illustrated.

Practical applicability of regression algorithms and program packages for non-linear regression can be deduced from an ability to reach a minimum of a sum of squared residuals and from a quality and amount of statistical information. Structural classification of regression programs in blocks already introduced in ABLET programs of solution equilibria[1,2] and instrumental methods of analytical and physical chemistry concerns blocks INPUT, RESIDUAL SUM OF SQUARES, MINIMIZATION, STATISTICAL ANALYSIS, GOODNESS-OF-FIT TEST, DATA SIMULATION, *etc.* was also used here.

While a previous paper[3] of this series describes RESIDUAL SUM OF SQUARES and MINIMIZATION blocks, this paper brings a description of two other blocks of MINOPT structure, *i.e.*, STATISTICAL ANALYSIS and GOODNESS-OF-FIT TEST. Procedure of regression model testing[4] is illustrated.

THEORY

Statistical analysis block

Statistical analysis in nonlinear regression depends on an actual model used, measurement errors and a criterion function. Let us concentrate here on the method of maximum likelihood when the searched estimates $\hat{b}$ maximize the logarithm of the likelihood function $l(\beta) = \ln L(\beta)$. If for the additive model of measurement (*cf.* Ref. 3) the independent errors ϵ have the probability density function $p(\epsilon)$ then likelihood function $L(b)$ is defined as

$$L(b) = \prod_{i=1}^{n} p(y_i - f(x_i; b) \qquad (1)$$

In construction of confidence intervals of parameters β or in statistical hypotheses testing the linearization, Lagrange multipliers and likelihood ratio methods may be used.[5]

The least-squares (LS) method is the best case of an additive model of measurement and independent normally distributed measurement errors having constant variance. Gallant[5] shows that the least squares estimator $\hat{b}$ of true value of parameters β in the regression model has asymptotically m-dimensional normal distribution

$$\hat{b} \approx N[\beta, \sigma^2(\mathbf{J}^T\mathbf{J})^{-1}] \qquad (2)$$

Here σ^2 is error variance and $\mathbf{J}$ is the Jacobi matrix (definition, *cf.* ref. 3). The asymptotic normality of estimates $\hat{b}$ determined by the least-squares method does not require a normality of errors ϵ, Ref. 5.

For real experimental data the estimates $\hat{b}$ and other statistical characteristics are biased and therefore application of equation (2) is

limited. Statistical analysis of nonlinear regression models by the least-squares methods then depends on a magnitude of bias which describes a degree of nonlinearity of regression model.

Covariance matrix of parameter estimates. From equation (2) it follows that the asymptotic covariance matrix of estimate $\hat{b}$ is expressed by the relation

$$D(\hat{b}) = \sigma^2(\mathbf{J}^T\mathbf{J})^{-1} \tag{3}$$

where s^2 is estimator of σ^2. There exist many more accurate expressions,[6] but for practical calculations the asymptotic formula [equation (3)] is quite acceptable.

On the base of knowledge of a covariance matrix $D(\hat{b})$ either the variance of individual parameters $D(\hat{b}_j)$ or the correlation coefficients r_{ij} between estimates $\hat{b}_i$ and $\hat{b}_j$ may be estimated.

Bias of parameter estimates. The bias is given by

$$h = E(\hat{b} - \beta^*) \tag{4}$$

For the sake of simplicity we use an expression of parameter bias in the form[7]

$$h = (\mathbf{J}^T\mathbf{J})^{-1}\mathbf{J}^T d \tag{5}$$

where d is the $(n \times 1)$ vector with components

$$d_i = \frac{-\sigma^2 \operatorname{tr}[(\mathbf{J}^T\mathbf{J})^{-1}\mathbf{W}_i]}{2} \tag{6}$$

where tr[·] denotes a trace of matrix and $\mathbf{W}_i$ is the matrix of second derivatives of model function in the i-th point. The vector d is an expected value of difference between the linear and quadratic approximation of a model function.

Similarly the bias of residuals

$$\hat{e}_i = y_i - \mathrm{f}(x_i; \hat{b}) \tag{7}$$

can be defined. When $E(\epsilon) = 0$, the bias of residuals is equal to their mean value $E(\hat{e})$. The mean value of residuals vector

$$E = E(\hat{e}) \tag{8}$$

can be rewritten[7] as

$$E = (\mathbf{E} - \mathbf{P})\, d \tag{9}$$

where $\mathbf{P} = \mathbf{J}(\mathbf{J}^T\mathbf{J})^{-1}\mathbf{J}^T$ is the projection matrix and $\mathbf{E}$ is the unit matrix of order n.

For practical calculation the relative bias of parameter estimates is often used

$$h_{Rj} = \frac{h_j}{\hat{b}_j} 100 \quad [\%] \tag{10}$$

The bias of estimates is considered significant if $h_{Rj} > 1\%$ holds.[7] For such biased estimates the statistical analysis based on linearization of regression model cannot be correctly used.

For expressing the total bias of parameter estimates Box[8] proposed the scalar characteristic

$$\hat{M} = \frac{h^T(\mathbf{J}^T\mathbf{J})h}{m\hat{\sigma}^2} \tag{11}$$

The bias of parameters may be affected by a reparametrization.[9]

Interval estimates of parameters. Points estimates $\hat{b}$ of regression parameters β are, in the statistical view, worthless as they do not mention intervals in which a true value β may be expected. The estimates $\hat{b}$ are random quantities estimated on base of sample, $\{y_i, x_i\}$, $i = 1, \ldots, n$.

In nonlinear regression models for a construction of confidence regions and intervals a linearization is often used for which confidence regions are elliptic. However, a linearization is useful only in cases when a model is not strongly nonlinear and nonlinearity measures, for example, the parameter bias, are small. The more accurate confidence region calculated on the base of Lagrange multipliers or the likelihood ratio can also be constructed. They are generally non-elliptic and are not continuous.

For asymptotic normality of maximum likelihood estimates $\hat{b}$ it follows that the quadratic form

$$Q = (\beta - \hat{b})^T D(\hat{b})^{-1}(\beta - b) \tag{12}$$

has χ^2(m) distribution. The corresponding 100(1–α)% confidence region of parameters β forms a m-dimensional ellipsoid with boundaries expressed by

$$(\beta^* - \hat{b})^T D(\hat{b})^{-1}(\beta^* - \hat{b}) = \chi^2_{1-\alpha}(m) \tag{13}$$

where $\chi^2_{1-\alpha}(m)$ is the $100(1-\alpha)$%th quantile of $\chi^2(m)$ with m degrees of freedom. The center of this ellipsoid is in the point $\hat{b}$.

For the least-squares method the application of equation (13) leads to definition of confidence ellipsoid having the boundary

$$\Delta b^T(\mathbf{J}^T\mathbf{J})^{-1}\,\Delta b = m\hat{\sigma}^2 F_{1-\alpha}(m, n-m) \tag{14}$$

where $\Delta b = \beta - \hat{b}$ and $F_{1-\alpha}(m, n-m)$ is quantile of Fisher–Snedecor distribution.

When a bias of parameters h is calculated, instead of Δb the correction $\Delta b_0 = \hat{b} - h - \beta$ may be used.

For expressing a geometry of confidence ellipsoids the decomposition of the matrix $(\mathbf{J}^T\mathbf{J})^{-1}$ to eigenvalues L_i and eigenvectors Z_i may be introduced

$$(\mathbf{J}^T\mathbf{J})^{-1} = \mathbf{Z}\mathbf{L}\mathbf{Z}^T \tag{15}$$

where $\mathbf{Z}$ is a matrix containing eigenvectors in columns and diagonal matrix $\mathbf{L}$ contains eigenvalues $L_1 \geqslant L_2 \geqslant \cdots \geqslant L_m$ on a diagonal. Using this decomposition the new orthogonal set of coordinates $y = \mathbf{Z}\,\Delta b$ can be defined. This set has an important property that the axes of confidence ellipsoid are identical with the axes of the coordinate system. Introducing notation

$$p^2 = m\hat{\sigma}^2 F_{1-\alpha}(m, n-m) \tag{16}$$

the confidence ellipsoid can be expressed by simple formula

$$\sum_{i=1}^{m} \frac{Y_i^2}{L_i} = p^2 \tag{17}$$

The lengths of half-axes of the ellipsoid are equal to $p\sqrt{L_i}$. For a projection Δ_{jk} of the j-th half-axis into the axis of parameter β_k it holds that

$$\Delta_{jk} = p|Z_{kj}\sqrt{L_j}| \tag{18}$$

where Z_{kj} is the k-th elements of the vector Z_j which is the j-th column of matrix $\mathbf{Z}$.

When dimension of a parameter vector is $m > 2$, a partial confidence ellipsoid can be constructed.[5]

For building the confidence region the Lagrange multipliers or a likelihood ratio may also be used. For example, from properties of likelihood ratio the bound of $100(1-\alpha)\%$ confidence region can be defined by relation

$$2[\ln L(\hat{b}) - \ln L(\beta)] = \chi^2_{1-\alpha}(m) \tag{19}$$

For a least-squares criterion the relation (19) leads to the relation

$$U(\beta) - U(\hat{\beta}) = m\hat{\sigma}^2 F_{1-\alpha}(m, n-m) \tag{20}$$

The confidence region defined by this equation is not generally elliptical or continuous.

With the use of equation (13) the $100(1-\alpha)\%$th confidence interval of parameter β_j in the form

$$\hat{b}_j - \hat{\sigma}\sqrt{C_{jj}}\, t_{1-\alpha/2}(n-m) \leqslant \beta_j \leqslant \hat{b}_j + \hat{\sigma}\sqrt{C_{jj}}\, t_{1-\alpha/2}(n-m) \tag{21}$$

is direct analogy of confidence intervals of the parameters of linear models. An influence of other parameters is neglected. When all diagonal-off elements of the matrix $\mathbf{C} = (\mathbf{J}^T\mathbf{J})^{-1}$ are zero the relation (21) may be used. However, elements of the vector $\hat{b}$ are often mutually correlated so that intervals of equation (21) are under-estimated.

More suitable determination of the confidence interval of parameter β_k is based on the maximal length Δ_k of a projection Δ_{kj} into the parameter axis β_k. The confidence interval of a parameter β_k is then estimated by

$$\hat{b}_k - \Delta_k \leqslant \beta_k \leqslant \hat{b}_k + \Delta_k \tag{22}$$

Instead of projections it is simpler to search directly coordinates of extreme points on the confidence ellipsoid in directions of individual parameter axes.[2] The corresponding confidence interval of a parameter β_k is defined by inequality

$$\hat{b}_k - p\sqrt{C_{kk}} \leqslant \beta_k \leqslant \hat{b}_k + p\sqrt{C_{kk}} \tag{23}$$

holds. For $m = 1$ all confidence intervals[21-23] are identical. Increasing the number of regression parameters m the confidence intervals (22) and (23) are broader than those of (21). All confidence intervals are symmetrical. Using linearization the confidence intervals of prediction $f(x^*; \hat{b})$ and confidence bands can be simply derived.[4] The more accurate confidence bands may be constructed with the use of convenient reparametrization.[9]

Goodness-of-fit tests block

In many regression programs the statistical analysis of residuals represents the main diagnostic tool and a resolution criterion in a search of the "best" model when more than one are possible or proposed. The goodness-of-fit test (which is also called the fitness test) analyses the residual set and examines statistical characteristics.

To application of statistical analysis of classical residuals $\hat{e}$, it should be critically noted that the diagnostic use of classical residuals is not rigorous but of a rather approximate character. The classical residuals do not exhibit a zero mean, they are biased and they are a combination of errors ϵ. Moreover, they are dependent on true values of parameters β which are unknown.

Statistical analysis of classical residuals. Classical residuals are defined as the differences $\hat{e}$ between observation y_i and prediction $\hat{y}_i = f(x_i; \hat{b})$ by equation (7). Graphical and analytical examining residuals check the quality of a

nonlinear model.[4] The following plots are often used in nonlinear models examination:

(1) The overall diagram gives a first view of residuals. If the model is correct these residuals should resemble observations from a normal distribution with zero mean.

(2) Plot type I (also called the index plot) is a scatter plot of residuals $\hat{e}_i$ against an index i in the time order as occurred.

(3) Plot type II (also called the plot against an independent variable) is a scatter plot of residuals $\hat{e}_i$ against the independent variable x_j, $j = 1, \ldots, m$.

(4) Plot type III (also called the plot against a prediction) is a scatter plot of residuals against the prediction $\hat{y}_i$.

The following statistics are used in nonlinear models examination:

(1) The arithmetic mean of residuals known as the estimate of residuals bias, $E(\hat{e})$, should be equal to zero;

(2) The residual variance is calculated from the residual sum of squares

$$\hat{\sigma}^2 = U(\hat{b})/(n-m) \tag{24}$$

The square-root of a residual variance known as an estimate of the residual standard deviation, $s(\hat{e})$, should be of the same magnitude as the (instrumental) error $s_{\text{inst}}(y)$, of dependent variable (observation, measured quantity y), *i.e.*, $s(\hat{e}) \approx s_{\text{inst}}(y)$;

(3) The determination coefficient D^2 is computed from the relation

$$D^2 = 1 - \frac{U(\hat{b})}{\sum_{i=1}^{n} (y_i - \bar{y})^2} \tag{25}$$

where $\bar{y} = 1/n \, \Sigma_{i=1}^{n} y_i$ is the arithmetic mean of response variable. The determination coefficient is for linear models equal to the square of the multiple correlation coefficient. When the determination coefficient is multiplied by 100% we receive the regression rabat in percents, $100D^2$[%]. Determination coefficient D^2 is an increasing function of a number of parameters, therefore, it is not convenient to use as a resolution diagnostic for search of models of different numbers of parameters.

(4) To distinguish between various models proposed the Akaike information criterion AIC is more suitable to apply being defined by the relation

$$\text{AIC} = -\ln L(\hat{b}) + 2m \tag{26}$$

where $L(\hat{b})$ is the likelihood function. The "best" model is considered to be a model for which this criterion reaches a minimal value. Using the least-squares criterion the AIC may be expressed

$$\text{AIC} = n \ln\left[\frac{U(\hat{b})}{n}\right] + 2m \tag{27}$$

(5) The prediction ability of a model proposed may be examined by the mean quadratic error of prediction MEP being defined by the relation

$$\text{MEP} = \frac{1}{n} \sum_{i=1}^{n} (y_i - \text{f}(x_i; \hat{b}_{(i)})^2 \tag{28}$$

The symbol $\hat{b}_{(i)}$ denotes the estimator of parameter β computed without the point (x_i, y_i). Here instead of the parameter estimate $\hat{b}_{(i)}$, the one-step approximation $\hat{b}^1_{(i)}$ defined by following equation (29) may be used. Lower values of MEP criterion give better prediction ability of the model proposed.

Identification of influential points. Influential points can strongly affect some regression characteristics. The points affecting prediction $\hat{y}_i$, for example, may not be influential from the point of view of parameter variance. The degree of influence of individual points should be classified regarding which characteristics are affected.[4] While for linear models all the characteristics for identification of influential points are a function of residuals $\hat{e}$ and diagonal elements P_{ii} of the projection matrix $\mathbf{P} = \mathbf{X}(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T$. For nonlinear regression models the parameter estimates and residuals cannot be expressed so simply as a linear combination of experimental data. When the Taylor type linearization of original nonlinear model is used, all methods of identification of influential points in linear models can be used here. Then in the nonlinear case the matrix $\mathbf{J}$ has the same role as $\mathbf{X}$ in the linear case. For a one-step approximation of the parameter estimate $\hat{b}_{(i)}$ computed without point (x_i, y_i) is valid

$$\hat{b}^1_{(i)} = \hat{b} - (\mathbf{J}^T\mathbf{J})^{-1} J_i \frac{\hat{e}_i}{1 - P_{ii}} \tag{29}$$

Here P_{ii} are elements of a projection matrix $\mathbf{P} = \mathbf{J}(\mathbf{J}^T\mathbf{J})^{-1}\mathbf{J}^T$. With use of equation (29) the variance estimate $\hat{s}^2_{(ii)}$ when leaving out the ith point is defined by

$$\hat{s}^2_{(i)} = \frac{U(\hat{b}) - \dfrac{\hat{e}_i^2}{1 - P_{ii}}}{n - m - 1} \tag{30}$$

Some characteristics of influential points based on linearization and used in program MINOPT are in Table 1. Interpretation of these characteristics may be found in Ref. 4.

To express an influence of individual points on parameter estimates the quadratic expansion of a regression model may be used, too.[10]

Nonlinear measure of an influence of the ith point on the parameter estimates is also represented by the likelihood distance

$$LD_i = 2[\ln L(\hat{b}) - \ln L(\hat{b})_{(i)})] \qquad (31)$$

In case of the least-squares the likelihood distance is expressed by

$$LD_i = n \ln\left[\frac{U(\hat{b}_{(i)})}{U(\hat{b})}\right] \qquad (32)$$

In both equations (31) and (32) the estimate $b_{(i)}$ is calculated by a nonlinear regression when the ith point is left out or the one-step approximation $\hat{b}^1_{(i)}$ of the parameter estimates is used. When inequality $LD_i > \chi^2_{1-\alpha}(2)$ holds, the ith point is strongly influential. The significance level α is usually chosen to be equal to 0.05.

Procedure of nonlinear model testing

A quality of nonlinear model proposed is examined using following criteria.

Quality of parameter estimates. Quality of parameter estimates $\hat{b}_j$ is considered according to their confidence intervals Δ_j, equation (18) and (21) and Δ_{Rj}, equations (22) and (23) or according to their standard deviations $s(\hat{b}_j)$, equation (3), the absolute bias h_j, equation (5) and the relative bias h_{Rj}, equation (10). Often an empirical rule of thumb is used: the parameter β_j is considered to be significant when its estimate $\hat{b}_j$ is greater than its 2 standard deviations, $2s(\hat{b}_j) < |\hat{b}_j|$. High values of parameter standard deviation $s(\hat{b}_j)$ is caused by termination of a minimization process before reaching minimum. Therefore, also inaccuracy of calculation of matrix **J** appears or a high nonlinearity of

Table 1. Three characteristics of influential points based on linearization. Critical level is the value of characteristic exceed this level, the corresponding point is denoted as highly outlying

Name	Form	Critical level
Cook distance D_i	$\frac{(\hat{b}-\hat{b}_i)^T \mathbf{J}^T \mathbf{J}(\hat{b}-\hat{b}_i)}{m\hat{\sigma}^2}$	1
DF_i	$\frac{(\hat{y}_i - \hat{y}_{(i)i})^2}{\hat{s}^2_{(i)} P_{ii}}$	$2\sqrt{m/n}$
Jackknife residual $\hat{e}_{Ji}$	$\frac{\hat{e}_i}{\hat{s}_{(i)}\sqrt{1-P_{ii}}}$	3

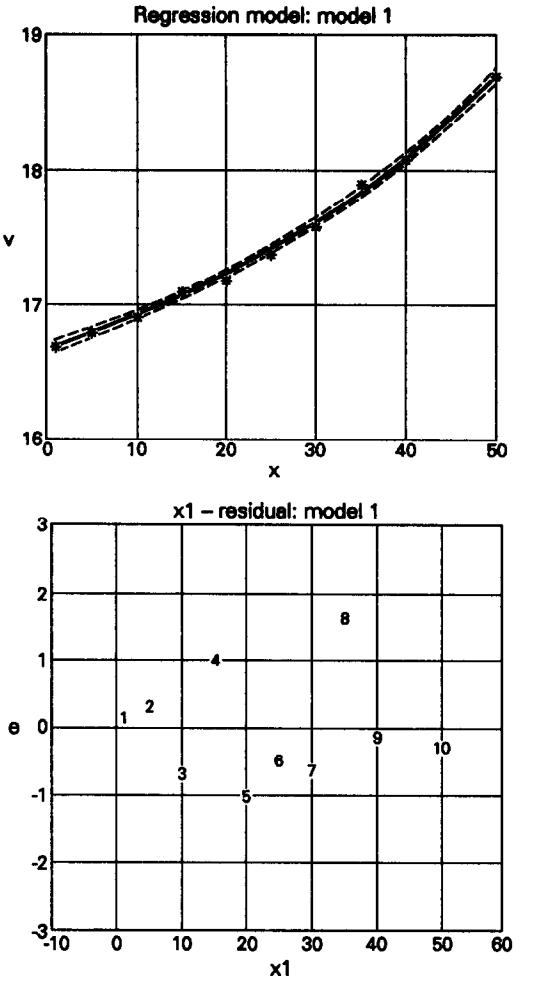

Fig. 1. Non-linear regression of data for Model I: (a) a curve-fitting, and (b) a scatter plot of type II of classical residuals.

regression model exists. The test of statistical significance of each parameter β_j, the null hypothesis $\beta_j = 0$ *vs.* the alternative one $\beta_j \neq 0$, is carried out.

Inter-dependence between parameters. Matrix of paired correlation coefficients of parameters, r_{ij}, expresses a measure of correlation or inter-dependence between two parameters β_i and β_j. If r_{ij} in absolute value is close to one, two parameters β_i and β_j are linearly dependent.

Quality of achieved model fitness. Agreement of proposed model with experimental data is examined by (i) the statistical analysis, and (ii) the goodness-of-fit test.

The statistical analysis of nonlinear regression contains following characteristics: the residual sum of squares $U(\hat{b})$, the regression rabat in percents 100 D^2[%], equation (25), the mean quadratic error of prediction MEP, equation (28), the Akaike information criterion AIC,

Map of parameter sensitivity in model

Parameter j	Relative change $CjR(-5\%)$ [%]	Total sensitivity Cj	Relative change $CjR(+5\%)$ [%]
1	−1.1930E − 08	1.0000E + 00	2.8004E − 08
2	−7.0302E + 00	3.4946E + 00	7.6700E + 00
3	−1.7824E + 01	4.5182E + 03	2.1104E + 01

equations (26) and (27), the standard deviation of prediction $s(y/x)$, the total bias of parameter estimates M, equation (11), a graph of the confidence interval of prediction.

The goodness-of-fit contains: the table of the prediction calculated $\hat{y}$, the standard deviation of prediction $s(\hat{y})$, the residual bias $h(\hat{y})$, equation (9), and classical residuals $\hat{e}$, equation (7). Statistical characteristics describe classical residuals: the residual bias $E(\hat{e})$, equation (8), the norm of residual bias $\|E\|$, the mean of absolute residuals $E(|\hat{e}|)$, the mean of absolute values of relative residuals $100E(|\hat{e}_{rel}|)$ in percents, the estimate of residual variance $s^2(\hat{e})$, equation (24) and its square-root the residual standard deviation $s(\hat{e})$.

Prediction ability of model proposed. Prediction ability of model can be classified by the following procedure: data are divided on two groups, M_1 with indices $i = 1, \ldots, n/2$ and M_2 with indices $i = n/2 + 1, \ldots, n$. Denote estimates of parameters made from points of subgroup M_1 as $\hat{b}(M_1)$ and from subgroup M_2 as $\hat{b}(M_2)$. Prediction ability of the model is expressed by criterion

$$K = \frac{U(\hat{b})}{\sum_{i \in M_1} [y_i - f(x_i; b(M_2)]^2 + \sum_{i \in M_2} [y_i - f(x_i; b(M_1)]^2} \tag{33}$$

The prediction ability of the model is higher when the criterion K is close to one. The mean quadratic error of prediction MEP, equation (28), can also be calculated. The lower the value of MEP the better is the prediction ability of the proposed model.

Quality of experimental data. For examination of quality experimental data an identification of influential points by regression diagnostics is applied: the Jackknife residuals $\hat{e}_J$, the Cook distance D, the diagonal elements of projection (hat) matrix H_{ii}, the test criterion DSF, the normalized distance FDA, and the likelihood distance LD, equations (31) and (32).

Map of parameter sensitivity in model. The total sensitivity C_{Cj} for all parameters β_j and the relative changes caused by 5% change of parameters β_j are computed. Characteristics C_{Cj} and their interpretation are described in a forthcoming book.[4]

Graph of regression curve. A graph of regression curve fitted through given experimental points with the 95% confidence bands and two plots of classical residuals give a graphical overview of fitness achieved: the plot of type II and the plot of type III.

Physical meaning of parameter estimates. In proposed models some restrictions of physical meaning are given on parameter estimates. For example, concentrations or molar absorption coefficients are defined in a range of positive numbers only.

Software

Program MINOPT from CHEMSTAT package carries out the numerical and statistical analysis of a non-linear regression model $f(x; \beta)$ with use of modified "double dog–leg" strategy. This program contains all the above mentioned criteria of nonlinear model quality.

Program MINOPT is a part of CHEMSTAT package and is available from authors on request.

Illustrative examples

For illustration of MINOPT statistical characteristics the example of Model 1 from paper[3] was recomputed. Selected outputs are shown in Table 2.

CONCLUSION

Many problems in the chemical laboratory can be reduced to the problem of finding a correct mathematical model and its unknown parameters. It may be carried out by minimizing a difference between experimental and calculated data. The variety of regression diagnostics introduced here serves as an efficient tool in search of true model.

SHORT COMMUNICATION

DETERMINATION OF DIBENZO [*b*,*f*]-1,4-OXAZEPINE BY EXTRACTION SPECTROPHOTOMETRY

EMIL HALÁMEK, ZBYNĚK KOBLIHA and JAN SOUČEK
Department of Chemistry, Faculty of the Arms, Military University, 682 03 Vyškov, Czech Republic

(*Received* 29 *March* 1992. *Revised* 11 *June* 1992. *Accepted* 11 *June* 1992)

Summary—The spectrophotometric determination of the substance dibenzo [*b*,*f*]-1,4-oxazepine (CR) the form of an ionic associate with the anionactive dyes of the type of azo dyes, sulphonephthaleins and anthraquinones after extraction with chloroform was worked out. Conditional extraction constants K'_{ex} were calculated and equilibrium ratios D and extraction yields E of ionic associates were determined. On the basis of detection limit L_Q, the dyes Alizarine Black S (0.7 μg/ml) and Orange II (0.8 μg/ml) were recommended for extractive spectrophotometric determination of the substance CR.

INTRODUCTION

Dibenzo[*b*,*f*]-1,4-oxazepine (CR) represents a qualitatively higher degree in the development of substances with strongly irritating effects.[1,2]

The substance CR was identified by UV spectrophotometry,[3,4] NMR,[5] gas chromatography,[6] mass spectrometry,[7,8,10] HPLC[9] and—in the case of its metabolites—also by TLC. For the determination of CR, colorimetry and spectrophotometry[11] based on its diazotation splitting in an inorganic acid and organic solvent was used. On the same principle, a detector tube for the detection of CR in the air was designed.[12]

Dibenzo[*b*,*f*]-1,4-oxazepine is an organic heterocyclic base with a protonable nitrogen atom ($pK_H = 3.0$). So its cationic form can associate the anions of the dyes in acid solutions. Up to now, no attention has been given to this property of the substance CR.

The aim of this work is to investigate the formation of ionic associates of dibenzo[*b*,*f*]-1,4-oxazepine with some anionactive dyes[13–15] which may be extracted into chloroform and to elaborate a method of its determination by extraction spectrophotometry.

EXPERIMENTAL

Reagents and apparatus

Dibenzo[*b*,*f*]-1,4-oxazepine was synthesized in the army factory VOZ 072 at Zemianské Kostolany.[16] The azo dyes used [Calcon (C.I.15 705) (I), Eriochrome Black T (C.I. 14 645) (II) and Orange II (C.I. 15510) (III)], the sulphonephthaleins [Bromothymol Blue (IV) and Bromophenol Blue (V)] and a dye of the anthraquinone type [Alizarine Black S (C.I. 67 430) (VI)] were from Merck. The buffers (pH range 1.0–6.0, increments of 0.2 pH) were prepared according to the literature[17] and checked by means of an MV 870 pH-meter. (Präcitronic, Dresden). Chloroform was shaken three times with redistilled water and then distilled as an azeotropic mixture at 60°. The single-beam spectrophotometer Spekol 11 (Zeiss, Jena) was used for spectrophotometric measurements.

Procedures

The absorbance curves of the ionic associates obtained from measurements of the function $A = f(\lambda)$ were measured. A 1.8-ml portion of the pH 2.0 buffer, 0.2 ml of a methanolic solution of the dye ($c_L = 5mM$) and a methanolic solution of the substance CR ($c_{CR} = 5mM$: 100 μl for IV, V, 70 μl for VI, 50 μl for II, 30 μl for III and 20 μl for I) were pipetted into test tubes.

The extractions were performed by shaking the two phases (2 ml each) in glass test tubes at 20 ± 1° in the hand. The extraction time, which was 2 min, was chosen based on the study of the kinetic curves of extraction. The organic phase was measured spectrophotometrically against the blank.

Table 1. Parameters of the ionic associates of the substance CR with Calcon (I), Eriochrome Black T (II), Orange II (III), Bromothymol Blue (IV), Bromophenol Blue (V) and Alizarine Black S (VI)

L_Q, μg/ml	1.1	2.5	0.8	1.4	1.5	0.7

*λ_{max}—Absorption maximum of the ionic associate in chloroform, pH_{opt}—optimum pH for the extraction of the ionic associate into chloroform (†hydrochloric acid, $c_{HCl} = 0.8M$), c_L—optimum concentration of the dye in the aqueous phase, n_{CR}/n_L—mole ratio of the substance CR to the dye, corresponding to the composition of the ionic associate, ϵ—molar absorption coefficient under the conditions of quantitative extraction of the ionic associate, ϵ'—molar absorption coefficient of the ionic associate, r—correlation coefficient, D—distribution ratio, E—extraction yield, K'_{ex}—conditional extraction constant, L_D—detection limit, L_Q—limit of determination.[19]

The effect of the pH of the water phase was arranged similarly to the absorbance curves. The absorbance of the chloroform extracts of the ionic associates was measured for λ_{max} of each dye (see Table 1).

The composition of the ionic associates in the organic phase was determined by measurement of the dependence $A = f(x_L)$, where x_L is the molar ratio of the dye. Volumes ranging from 20 to 180 μl (in steps of 20 μl) of 5m*M* CR were pipetted and then completed to 200 μl with the 5m*M* solution of the dye; 2 ml of the buffer with pH_{opt} (see Table 1) were then added.

The optimum concentration of the dye in the water phase was determined from the dependence $A = f(c_L)$, $c_L = 0.5$ to 10.0m*M*. For the calculation of the molar coefficient ϵ, the dependence $A = f(c'_L)$ was determined. The amounts of 0.1–1 ml of the aqueous dye solution ($c_L = 50\mu M$) were pipetted into the test tubes, the volume was completed to 1 ml with pH_{opt} buffer and 1 ml of the solution of the substance CR ($c_{CR} = 5mM$) with pH_{opt} value was added. The calibration curves were determined by measurement of the dependence $A = f(c_{CR})$. The volumes of 1.8 ml of buffer solutions with pH_{opt} and 0.2 ml of methanolic dye solutions were pipetted into the test tubes. Then 10–100 μl of methanolic solution of the substance CR ($c_{CR} = 2.5mM$ for I, III, VI or 5m*M* for II, IV, V)—by steps of 10 μl—were added by means of the micropipette.

RESULTS AND DISCUSSION

The substance CR forms in the medium of a buffer with study dyes coloured ionic associate which may be extracted into chloroform. Their absorption curves are presented in Fig. 1.

The effect of the pH value of the aqueous solutions on the formation and the extraction of the substance CR is evident from Fig. 2. In dependence on the absorbance of the blank, the optimum pH values of the citrate buffers were

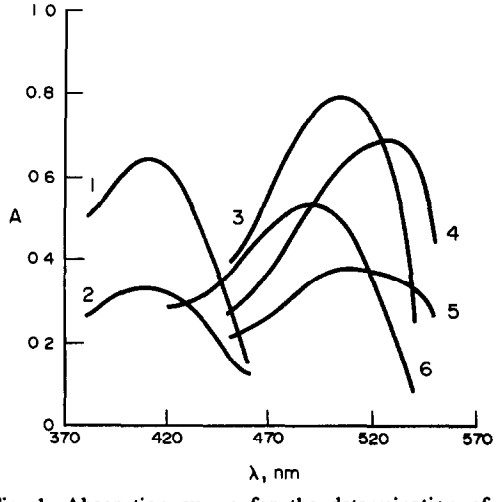

Fig. 1. Absorption curves for the determination of the substance CR with Bromophenol Blue (1) [$c_{CR} = 0.25mM$], Bromothymol Blue (2) [0.25m*M*], Alizarine Black S (3) [0.175m*M*], Calcon (4) [0.05m*M*], Eriochrome Black T (5) [0.125m*M*] and Orange II (6) [0.075m*M*]; $c_L = 0.5mM$, organic phase chloroform.

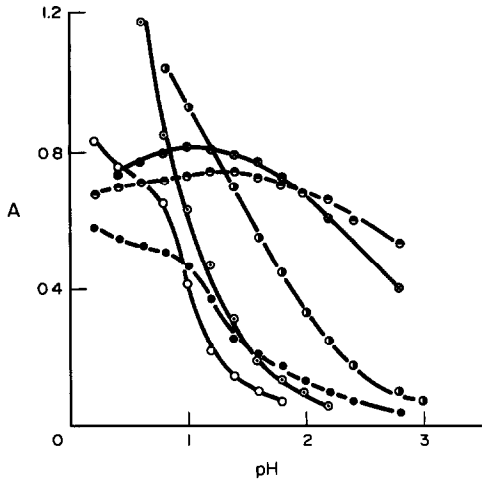

Fig. 2. Dependence of the absorbance of the ionic associate of the substance CR with Orange II (○) [$c_{CR} = 0.075 mM$, A_{480}], Bromothymol Blue (◓) [0.25mM, A_{410}], Alizarine Black S (●) [0.175mM, A_{500}], Eriochrome Black T (⊙) [0.125mM, A_{513}], Calcon (◑) [0.05mM, A_{531}] and Bromophenol Blue (⊗) [0.25mM, A_{413}], on the pH of the reaction medium; $c_L = 0.5 mM$.

determined for the dyes I–V, the optimum medium for VI was 0.8M hydrochloric acid (Table 1). It was found from the dependence of the absorbance variation on the molar ratio x_L of the dye that the substance CR forms ionic associates with all the other investigated dyes in the ratio 1:1.

The optimum concentration of the dye c_L in the reaction mixture is given in Table 1.

The ionic associates of the substance CR with the investigated dyes were extracted into chloroform in the surplus of the base. The molar absorption coefficients ϵ of the dyes (which may be considered constant at the maximum obtainable yield of the extraction) were determined by a simple linear regression. On the other hand, with a surplus of the dye a maximum yield of the extraction is not attained (in dependence on the conditions of the determination) in all cases. The resulting slope is not necessarily identical with the molar absorption coefficient ϵ. It could be considered as the conditional molar absorption coefficient and indicated as ϵ'.

The conditional extraction constants K'_{ex}, equilibrium ratios D and yields of the extraction were calculated according to Souček *et al.*[18]

In the investigated concentration range 25–250μM all measurements comply with the Lambert-Beer law. The extractive spectrophotometric method enables to determine 0.7 or 0.8 μg of substance CR in 1 ml of sample when using the dye III or VI.

BOOK REVIEWS

Handbook of Inductively Coupled Plasma Mass Spectrometry: K. E. JARVIS, A. L. GRAY and R. S. HOUK, Blackie, Glasgow and London, and Chapman and Hall, New York, 1991. Pages xi + 380. £75.00.

It is a pleasant, if rare, experience to review a scientific text written by enthusiastic and knowledgeable authors who still manage to present an easy-to-read, informative and unbiased account of an analytical technique. Jarvis, Gray and Houk, assisted by inputs from I. Jarvis, J. W. McLaren and J. G. Williams, have managed to produce just such a book. A concise introductory chapter on the origins of ICP–MS sets the scene admirably, though it tends to assume a reasonable knowledge of various aspects of atomic spectrometry. This is followed by detailed and fully referenced chapters on instrumentation and on some of the options available to those ambitious enough to engage in development work. John Williams' chapter on sample introduction (other than by pneumatic nebulization) deserves wider readership than just those using ICP–MS, and includes a concise but useful summary of chromatography/plasma interfacing. The following chapter on interferences is up to date and commendably honest. Together with chapter 6 on calibration and data handling, and chapter 7 on sample preparation for ICP–MS, it provides excellent insight for existing or intending users. It is interesting to note that the authors have chosen to collect geological, environmental, nuclear, industrial and biological applications together in chapter 8, but dedicate a separate 22-page chapter to natural water analysis. This very fairly reflects the impact of ICP–MS in this field, where the full detection power, capacity for multi-element analysis and selectivity may be readily exploited. The final chapters are on solids analysis and isotope ratio determinations, the latter being especially valuable to anyone considering employing stable isotope tracer techniques. Some might think this is an expensive book, but if you buy an ICP–MS, this volume may prove to be the accessory providing best value for money. If you're still contemplating purchase, it may prove an even better investment!

M. S. CRESSER

Atomic Absorption Spectroscopy—Theory, Design and Applications: S. J. HASWELL (editor), Elsevier, Amsterdam, 1991. Pages: xx + 529. Dfl 345.00.

Volume 5 in the Analytical Spectroscopy Library (a series of books devoted to the application of spectroscopic techniques to chemical analysis) is a well-produced, comprehensive text which should become a standard handbook for practitioners in AAS. It is essentially a collection of 14 reviews preceded by 3 introductory chapters which deal with basic principles, instrumentation and practical techniques. The editor has not just compiled the reviews from the mainly UK and USA authors but has also written chapters 2 and 3. The close involvement of the editor has resulted in a text with only a minimum of repetition between contributors.

Areas of application covered are: waters, sewage and effluents (45 pages); marine analysis (33 pages); airborne particles (32 pages); food analysis (36 pages); ferrous metals (48 pages); non-ferrous metals (12 pages); geochemical (32 pages); petroleum (20 pages); glasses and ceramics (17 pages); clinical (flame techniques—21 pages, ETA—58 pages); forensic (24 pages); fine, industrial and other chemicals (52 pages) and polluted soils (12 pages).

All of the reviews contain numerous references (up to the year 1989) and a footnote appears on each odd-numbered page of the application chapters directing the reader to where the references are listed. I found this feature surprisingly useful. A subject index is included but it does not do justice to the comprehensive range of topics discusssd in the text, nor does it adequately refer the reader to all occurrences of a single topic. For example, ETA-AAS has advanced tremendously over the last decade and this text extols its virtues in almost every chapter but the index gives only 6 different page numbers for this topic. Another very minor gripe would be that the diagrams in chapter 1 are very small and Table 1 refers to mysterious λ-rays.

A common feature of the book is that it is full of practical details, some reviews such as that on elemental analysis of body fluids and tissues by ETA-AAS (Delves and Shuttler) are excellent, selective and critical. Others, e.g., on forensic science (Dale) and polluted soils (Cresser) are characterized by the ease at which the authors disseminate their extensive knowledge in the subject areas. The ubiquitous nature of samples and elements requiring analysis is shown in the chapter on food analysis (Rains) and extensive sample digestion methods for geochemical samples are given by Thompson and Banarjee. Indeed, there is something here to interest all those involved with AAS. It is a text to be highly recommended.

P. J. Cox

Glycerine—A Key Cosmetic Ingredient: E. JUNGERMANN and N. O. V. SONNTAG (editors), Dekker, New York, 1991. Pages xi + 460. $125.00 (U.S. and Canada), $143.75 (Elsewhere).

This book is the eleventh in Dekker's Cosmetic Science and Technology series and could well be sub-titled 'all you could possibly want to know about glycerine'! It presents a very comprehensive compilation of information about glycerine,

suitable substitutes and related materials. Such a broad spread is to be commended, but also has its drawbacks. One wonders, for example, if a cosmetic scientist requires 80 pages of detail on glycerine manufacture.

The book is well presented in 17 chapters written by a total of 13 authors. As may be expected with such a text, the style of writing varies and there are some minor overlaps of material.

After the introductory chapters, there are two chapters giving very detailed analysis of manufacturing methods and plants, especially in the USA. There follows chapters dealing with the chemical reactions of glycerine, its physicochemical properties, analysis and safety. Generally, these are comprehensive although it is surprising that no IR spectrum is included. Chapter 9 on economics may have sat more easily in the section on production. There follows 6 chapters dealing with aspects of the use and evaluation of glycerine in cosmetics. These are comprehensive, many taking the form of reviews of published work, although in chapter 13 the words 'speculate' and 'surmise' occur too frequently. The least successful chapter is the one dealing with monoglycerides where there are several mistakes, a tendency to repeat material and only 2 references post-1983. The book concludes with two chapters dealing with alternatives to glycerine and its non-cosmetic uses.

Throughout, the book is well referenced, enabling the interested reader to delve further into the subject. The editors have done a commendable job in producing such a text which will be a valuable resource for cosmetic, and other, scientists.

A. J. WINFIELD

Sampling: G. E. BAIULESCU, P. DUMITRESCU and P. GH. ZUGRAVESCU, Ellis Horwood, Chichester, 1991. Pages 184. £45.50.

Short, snappy titles may be eye-catching but they are not necessarily informative and can even be misleading. This is such a case. The authors state quite clearly that they consider the word sampling to apply to all the procedures prior to the measurement step, that is to include sample collection, handling, storage and preparation for analysis. That is acceptable, but the authors then all but ignore that very operation which most people would consider as "sampling"—the taking of a sample. This is admitted in a one paragraph appendix which gives a few references where readers will find relevant information.

Analysts seeking guidance on how to collect particular samples or even how to undertake the analysis will not find it in this book. Indeed it is neither practical nor a reference book but more of a philosophical discussion on the importance of correct sampling in the overall scheme of analysis. There are just five chapters with a few sub-divisions and as a consequence there are large blocks of unbroken text with few figures or tables. The philosophical approach means that there are no sub-divisions for types of analyis or instrumentation, or of an overall consideration of the requirements. Although one could not expect such a book to be comprehensive there are some surprising omissions. Spark source mass spectrometry appears in a list of eight techniques which the authors consider to be the only ones applicable to trace element analysis but there is no mention, here or elsewhere in the book, of other more modern techniques, for example ICP–mass spectrometry which is becoming widely used in multilement analysis. The tendency to simplicity can lead to misleading statements such as the "potted history of mass spectrometry" which appears in one sentence. There is no statistical treatment of the requirements for representative sampling.

In summary, this is a disappointing book. That is not to say it is not worth reading. It is written in a very easy style and would be a useful bed-time book for all analytical chemists because the authors hammer home the importance of sampling within the whole analytical scheme. There is a lot of background information, much of which will be in areas of study other than the reader's own. It will probably make the reader think about their own approach to carrying out analysis and it emphasises the importance of the role of the analyst. The authors repeatedly make the statement that "no analysis is better than the sample itself". If this comes across to the reader then the book is successful but the problem is that the process starts at the sample collection stage and if that is not done properly the rest is meaningless.

J. BACON

Techniques for Characterization of Electrodes and Electrochemical Processes: R. VARMA and J. R. SELMAN (editors), Wiley-Interscience, New York, 1991, Pages xii + 780. £89.70.

This volume collects together fifteen reviews, varying in size between 16 and 96 pages. The techniques covered are ellipsometry, photothermal deflection spectroscopy, surface x-ray absorption spectroscopy, surface enhanced Raman spectroscopy, neutron scattering, Mössbauer spectroscopy and laser interferometry as applied to electrode surfaces. Measurements *in situ* are stressed whenever possible. There are also two reviews on electrochemical impedance spectroscopy, two on modelling techniques, two general surveys (solid electrolytes and molten salts) and a short review on diffraction techniques for determining the structure of liquid electrolytes. To take the reader from fundamentals to applications in an average of some 50 pages is a tall order and I generally found it heavy going in style and content. I found myself wishing for a more elementary approach and an earlier appreciation of the relationship beween the electrochemical phenomena and the measured characteristic. Perhaps lack of space enforced a formal approach. As a whole, however, this volume has value as a substantial source-book for those interested in electrodes, but one would need more extensive texts before adopting these techniques. The electrochemistry is directed towards corrosion and electrode processes rather than analysis. Analytical interest, in a narrow sense, will thus tend to be in the applications of the techniques rather than the electrochemical results presented. The book will clearly have its uses in a large electrochemical research laboratory, but probably not in many analytical laboratories. I doubt if anybody who could use a library would think it *necessary* to have these reviews bound together.

D. MIDGLEY

D. MIDGLEY

Liquid Chromatography Column Theory: R. P. W. SCOTT, Wiley, Chichester, 1992. Pages: xi + 279. £34.95.

Liquid Chromatographic Column Theory by R. P. W. Scott is a valuable addition to the Separation Science Series in that it deals at an essentially theoretical level with the quantitative relationships governing liquid chromatographic column performance. This is a welcome departure from many previous liquid chromatography texts which concentrate on particular applications of separations with no theoretical basis or even rationale for a given chromatographic analysis.

The main volume is free from typographical errors such as the incorrect spelling of theory in the Preface but the typeface used is not easy to read, particularly in terms of the interspersed algebra.

After an introductory chapter which briefly covers factors controlling retention, the physical nature of the column and nomenclature, subsequent chapters give complete coverage of the Plate and Rate Theories of chromatography together with extensions to these as proposed by several leading chromatographers. Chapters 3 and 10 are of particular interest in addressing the important variables of column dead volume and extra column band broadening.

The final four chapters deal with column design. Firstly, a general design protocol is suggested and this is followed by detailed consideration of the design requirements for packed columns, open tubular columns and columns for preparative liquid chromatography. In these chapters, previously derived relationships are applied to ascertain optimum column dimensions, stationary phase diameter and operating conditions. Listings of interactive BASIC computer programs are provided for the calculation of such optimised conditions for specified equipment.

This is not a book to be read but rather to be studied as required. It deals with the fundamental aspects of liquid chromatographic separations that many analysts, who rely heavily on this technique, largely ignore. It will be most useful to those working in analytical method development and may go some way to encouraging individual preparation of columns and to minimising acceptance of commercially offered components.

R. B. TAYLOR

Interfacial Phenomena in Biological Systems: M. BENDER, Dekker, New York, 1991. Pages xiv + 429. $135.00 (U.S. and Canada), $155.25 (Elsewhere).

This book covers some of the rather complicated interfacial aspects encountered in biological systems. The text is divided into five parts with further subdivision within each part. As the editor explains in the preface some physical and chemical principles are shared by more than one of these areas, and the arrangement of various chapters within the specific parts of the text is not always easy to follow.

The first part is titled "Biological surfaces" and includes chapters on the skin, the oral cavity, biomaterials, and plasma proteins. Each chapter reviews some of the current aspects of research within these areas and as throughout there are many useful and up-to-date references given at the end of each chapter to allow further reading and clarification of points where required.

The second part covers membranes, with the first two chapters on water stabilization and electromagnetic field influence being concise and easy to follow. The third chapter dealing with the "non-specific" adsorption of plasma proteins to erythrocytes is rather lengthy and may prove to be rather mathematical for most readers.

The two chapters in part three are covered under the heading "corpuscular" but they do appear to be rather isolated and could perhaps have been included in other parts of the text. Part four covers interactions, where the second chapter on supercomputer simulations again may be rather too specialized for most readers.

The final chapter on transport has two well written chapters, with the second in keeping with the title of the book covering many biological systems. The fact that proteins are covered extensively throughout the text emphasizes the important role they have in the structure of biological systems and also their involvement in transport and adhesion as well.

The text is rather specialized and as such will be of most benefit to researchers in the life sciences. It could also be useful for extended reading as part of certain undergraduate courses including medicine and dentistry. There is detailed coverage of the areas mentioned above but for those requiring even more information there are over 850 references, a large number being recent and published in the eighties.

K. I. CUMMING

Chemistry and Physics of Carbon: P. A. THROWER (editor), Dekker, New York, 1991. Pages xiii + 366. $165.00 (U.S. and Canada), $189.75 (Elsewhere).

Clearly, this well established series is set to "run" well into the future with the recent advances in Buckminster Fullerene and allied molecular carbon chemistry. The current volume 23 comprises four diverse topics in carbon science. This diversity may well appeal to carbon specialists, it will certainly not encourage those from outside this field to purchase this volume.

The first section addresses the characterization of structure and microstructure by magneto-resistance in various carbon materials including highly orientated graphites, cokes, carbon fibres and carbon/carbon composites. The second section reviews the electrochemical carbonization of fluoropolymers documenting chemical and electrochemical reduction of polytetrafluoroethane, and other fluoropolymers. The properties of the resulting electrochemical carbon, which is often electronically doped or contains electrolyte crystals, are discussed and its use in power sources and separation described. In the next section the methods of protection of carbon from oxidation at high temperatures are described. The limitations of the various coatings/incorporations are reported and the possibility of extending significant protection to temperatures above 1500° discussed. The final section addresses methods for assesssing the effectiveness for removing radioactive iodine from accidental nuclear emissions. In particular, the degradation in activity with weathering and/or ageing is considered.

Liquid Chromatography Column Theory: R. P. W. SCOTT, Wiley, Chichester, 1992. Pages: xi + 279. £34.95.

Liquid Chromatographic Column Theory by R. P. W. Scott is a valuable addition to the Separation Science Series in that it deals at an essentially theoretical level with the quantitative relationships governing liquid chromatographic column performance. The two chapters in part three are covered under the heading "corpuscular" but they do appear to be rather isolated and could perhaps have been included in other parts of the text. Part four covers interactions, where the second chapter on supercomputer simulations again may be rather too specialized for most readers.

The final chapter on transport has two well written chapters, with the second in keeping with the title of the book covering many biological systems. The fact that proteins are covered extensively throughout the text emphasizes the important role they have in the structure of biological systems and also their involvement in transport and adhesion as well.

The text is rather specialized and as such will be of most benefit to researchers in the life sciences. It could also be useful for extended reading as part of certain undergraduate courses including medicine and dentistry. There is detailed coverage of the areas mentioned above but for those requiring even more information there are over 850 references, a large number being recent and published in the eighties.

K. I. CUMMING

Chemistry and Physics of Carbon: P. A. THROWER (editor), Dekker, New York, 1991. Pages xiii + 366. $165.00 (U.S. and Canada), $189.75 (Elsewhere).

Clearly, this well established series is set to "run" well into the future with the recent advances in Buckminster Fullerene and allied molecular carbon chemistry. The current volume 23 comprises four diverse topics in carbon science. This diversity may well appeal to carbon specialists, it will certainly not encourage those from outside this field to purchase this volume.

The first section addresses the characterization of structure and microstructure by magneto-resistance in various carbon materials including highly orientated graphites, cokes, carbon fibres and carbon/carbon composites. The second section reviews the electrochemical carbonization of fluoropolymers documenting chemical and electrochemical reduction of polytetrafluoroethane, and other fluoropolymers. The properties of the resulting electrochemical carbon, which is often electronically doped or contains electrolyte crystals, are discussed and its use in power sources and separation described. In the next section the methods of protection of carbon from oxidation at high temperatures are described. The limitations of the various coatings/incorporations are reported and the possibility of extending significant protection to temperatures above 1500° discussed. The final section addresses methods for assesssing the effectiveness for removing radioactive iodine from accidental nuclear emissions. In particular, the degradation in activity with weathering and/or ageing is considered.

Overall, this volume contains a lot of useful information and is, generally, well presented. The sections on fluoropolymer reduction and oxidative protection contain a good deal of interesting science for the more general reader, whereas the other two sections are much more specialized.

J. T. S. IRVINE

Fourier Transform Raman Spectroscopy—Instrumentation and Chemical Applications: P. HENDRA, C. JONES and G. WARNES, Ellis Horwood, 1991. Pages 311. £53.00.

The yellow plastic duck on the cover is not merely to catch the eye. The illustration has been chosen for a very good reason—it sums up many of the advantages of FT Raman spectroscopy discussed in this book: for example, ease of sampling, and the ability to obtain spectra from coloured and fluorescent materials.

The contents fall into two distinct sections. The first third covers the background to vibrational spectroscopy, conventional laser Raman spectroscopy and the development of FT Raman instrumentation. The second two-thirds are used to discuss a large number of applications, stressing those areas where the FT method is superior to conventional laser Raman spectroscopy. Finally there is a fascinating appendix "the processing history of a spectrum—from ADC to VDU" which should be essential reading for anyone who uses FT IR spectroscopy seriously as well as users or potential users of FT Raman instrumentation.

The "applications" chapter covers a very wide range: organic chemistry (alkaloids, explosives, dyestuffs, pharmaceutical materials), polymers (including the duck!), biological samples (membranes, polypeptides, animal, wood and plant tissue), surfaces and catalysts, and inorganic compounds. The treatment, though didactic, is honest and the authors do not avoid the two negative aspects of the present FT Raman systems—sample heating leading to black-body emission and the difficulty of obtaining spectra from aqueous solutions. The chosen examples are well illustrated by spectra and I for one believe that the case is made for FT Raman as a routine analytical technique with wide applicability.

The introductory chapters are also excellent. "The vibration behaviour of molecules" is a good readable account (at senior undergraduate level) of IR and Raman spectroscopy while the chapter on conventional laser Raman spectroscopy contains very useful sections on such practical aspects of the technique as spectral bandwidth and signal-to-noise levels. The chapter on FT vibrational spectroscopy could be read with advantage by all students who use FT IR spectrometers.

I have only two complaints. The quality of the photographs is rather poor and some of them are unnecessary. The diagrams, on the other hand, are universally good—in many cases, however, they are over the page from the text. The publishers could well consider arranging the text so that diagrams and text could be read together without having to turn over the page.

In summary this is a very useful book, not only for those who are contemplating the purchase of an FT Raman instrument but for all users of vibrational spectroscopy. It should certainly be in all Chemistry Department libraries and many vibrational spectroscopists will want their own copy.

R. D. PEACOCK

Adenosine and Adenosine Receptors: M. WILLIAMS, Humana Press, Chichester, 1991. Pages xii + 512. £79.70.

This extremely competent volume edited by Michael Williams comprises five sections and thirteen chapters. The first section written by Michael Williams, himself, is a historical perspective starting with the paper by Drury and Szent-Gyorgyi published in *The Journal of Physiology* in 1929 first describing the physiological actions of adenosine compounds, continuing with the discovery of cyclic AMP in 1960's, nonadrenergic, noncholinergic transmission and ATP in the 1970's and further to the receptor classification of the 1980's. This is a short chapter but provides the reader with a simple introduction to the subject and to the more complicated information which follows in subsequent chapters. The second section is concerned with characterization of the receptor and its binding site. Michael Williams joins with Kenneth Jacobson in the first chapter in this section which is entitled "Radioligand Binding Assays for Adenosine Receptors". Following a brief description of the principles of radioligand binding, the chapter then becomes very technical. They catalogue the many agonist and antagonist radioligands which have been used and this is followed by a section on species differences, receptor autoradiography and the labeling of other adenosine recognition sites. I found this a difficult chapter to read, though the information is there for those who are interested. The second chapter in this section is by Bharat Trivedi, Alexander Bridges, and Robert Bruns and is entitled "Structure-Activity Relationships of Adenosine A_1 and A_2 Receptors". There is a short discussion on the two types of receptors and the chapter provides a copious list of adenosine analogues and their structure activity relationships.

Section three is called "Biochemical Mechanisms of Receptor Action" and contains four chapters. The first chapter in this section is by Dermot Cooper and Kevin Caldwell and is concerned with signal transduction mechanisms for adenosine. This is a long chapter of some thirty-seven pages covering a very large selection of topics. However, it is eminently readable and for this chapter alone, the whole volume is worth having. Thomas Dunwiddie writes a chapter on electrophysiological aspects of adenosine receptor function. The author points out that the physiological basis of responses to adenosine is much more complex than had first been suggested. He points out that there now seems to be several well established models in which adenosine can modulate ionic conductance, reduce calcium currents in some cells and activate potassium conductance in others. He states that at present there appear to be at least three or perhaps more receptors requiring to be postulated to account for the pharmacology observed in different systems. He then suggests how the answers to these questions can be provided. Adenosine release is discussed by Trevor Stone, Andrew Newby and Hilary Lloyd. The authors discuss the results of studies from various tissues in the body which have been shown to release adenosine and to differentiate between neuronal and non-neuronal release. This chapter also discusses the source of adenosine and the mechanisms thought to

Overall, this volume contains a lot of useful information and is, generally, well presented. The sections on fluoropolymer reduction and oxidative protection contain a good deal of interesting science for the more general reader, whereas the other two sections are much more specialized.

There is a short discussion on the two types of receptors and the chapter provides a copious list of adenosine analogues and their structure activity relationships.

Section three is called "Biochemical Mechanisms of Receptor Action" and contains four chapters. The first chapter in this section is by Dermot Cooper and Kevin Caldwell and is concerned with signal transduction mechanisms for adenosine. This is a long chapter of some thirty-seven pages covering a very large selection of topics. However, it is eminently readable and for this chapter alone, the whole volume is worth having. Thomas Dunwiddie writes a chapter on electrophysiological aspects of adenosine receptor function. The author points out that the physiological basis of responses to adenosine is much more complex than had first been suggested. He points out that there now seems to be several well established models in which adenosine can modulate ionic conductance, reduce calcium currents in some cells and activate potassium conductance in others. He states that at present there appear to be at least three or perhaps more receptors requiring to be postulated to account for the pharmacology observed in different systems. He then suggests how the answers to these questions can be provided. Adenosine release is discussed by Trevor Stone, Andrew Newby and Hilary Lloyd. The authors discuss the results of studies from various tissues in the body which have been shown to release adenosine and to differentiate between neuronal and non-neuronal release. This chapter also discusses the source of adenosine and the mechanisms thought to

be involved in its synthesis and release. Concluding this chapter, the authors state "the diverse aspects of adenosine's properties allow it to be viewed in many different ways and to be classified variously as hormone, neuromodulator, protective, or retaliatory metabolite. The overall concept must be that of an ubiquitous, arguably primitive molecule, importantly involved in homeostasis and the control of tissue function and integration". The last chapter in this section is by Jonathan Gieger and James Nagy, "Adenosine Deaminase and [^{3}H] Nitrobenzylthioinosine as Markers of Adenosine Metabolism and Transport in Central Purinergic Systems". This chapter is extremely long, comprising some sixty-four pages. This is a really comprehensive chapter dealing with such different things as sites and control of adenosin's actions in the central nervous system, metabolism of adenosines, its disposition within cells and cytotoxicity. The authors then deal with adenosine deaminase and suggest a possible role for this enzyme in the central nervous system and in the context of this enzyme, they also deal with its inhibition. This is followed with discussion on its cellular and ultrastructural localization and its species differences. The final part of the chapter is concerned with adenosine uptake and transport. Section Four is entitled "Physiological Functions of Adenosine Receptors" and concerns the effects of adenosine on the various systems of the body. This section is the heart of the volume and in a way it can be said that all the preceding sections have been leading up to this section.

Kevin Mullane and Michael Williams discuss the role of adenosine and cardiovascular function, both the direct effects on contractability and cardio arrhythmias and the indirect actions, such as inhibiting adrenergic responses and histamine H_2 mediated effects. The final section of this chapter deals with adenosine and pathophysiology of the cardiovascular system relating to hypertension and ischaemia. The chapter by Paul Churchill and Anil Bidani is concerned with adenosine and renal function and this chapter comprehensively deals with such topics as renal haemodynamics, with a discussion on the effects of adenosine on renal blood flow and glomerular filtration rate. Of particular interest are the sections on the interactions of adenosine with angiotensin II, and the prostaglandins and its involvement with renal secretion. The role of adenosine in respiratory physiology is in the chapter by Timothy Griffiths and Stephen Holgate and they detail the role of adenosine in the immune system with particular reference to the bronchial tree, the effects of adenosine on the central control of respiration, peripheral chemoreceptors and the pulmonary vascular responses. A very comprehensive chapter indeed. Michael Jarvis and Michael Williams have written the chapter on adenosine in central nervous system function. This is a chapter of over fifty pages long, is far ranging and very comprehensive. It covers too many topics to describe briefly here, however, it should be said that as with all the other chapters Michael Williams has had a hand in, this is an extremely lucid and well-written contribution.

In chapter twelve which is the only chapter in Section 5, Receptor Regulation, Bruce Cronstein and Rochelle Hirschhorn discuss adenosine and host defence. The chapter is primarily concerned with the adenosine receptors present in the immune system, and deals with these receptors on such cells as lymphocytes, monocytes and leucocytes and with the role of adenosine receptors in autoimmune disorders. In the final part of the chapter, the authors postulate that adenosine is a modulator on inflammation. The final section again consists of just one chapter, "Adenosine Receptors Future Vistas" is just three and a half pages of text and is another chapter written by Michael Williams. He points the finger forward to the possible development of adenosine and its derivatives in the clinic.

In summary, we have in this volume a very comprehensive coverage of the physiology, pharmacology, biochemistry and pathology of adenosine and its receptors. It is a book to delve into, not one to read all in one go. Some chapters are easy to read and are for a wide audience, others need a specialized background. The amount of information in this book is enormous and with a very comprehensive list of references at the end of each chapter. Anyone interested in the field has everything at their fingertips. Michael Williams must be congratulated for editing such a book. The effort which he must have put into this publication, particularly with his own several contributions, must have been considerable. A book for every University and Research Library and for the desk of those working with adenosine and adenosine receptors.

A. S. MILTON

Chemical Analysis in Complex Matrices: M. R. SMYTH, Ellis Horwood, Chichester, 1992. Pages 295. £50.00. ISBN 0-13-127671-9.

Many texts on chemical analysis minimize the importance of the analyte matrix and, as a result, overemphasize specialist determination techniques. In contrast, this book takes full account of the importance of the matrix in any analytical procedure. This is fully discussed in the initial short chapter describing general analytical strategy and the theme is carried through the subsequent chapters dealing with particular subject areas. These include bioanalysis of drugs, analysis in the brewing and adhesive industries and trace analysis of the atmosphere and of human and animal food.

It is a general rather than a specialist text on chemical analysis and as such it is a welcome addition to the chemical literature. This book may be read to obtain background information on the analytical requirements of various industries including the applications of bioanalysis and the source of atmospheric trace impurities. It also contains considerable analytical information appropriate to the specialist fields and industries included.

In some of the chapters very full accounts are given of the spectroscopic and chromatographic methods which are of general application and in others descriptions are given of more specialist techniques appropriate to the particular industry. While chromatography features strongly in many of the chapters there is no repetition throughout the book and each chapter provides complementary information on particular analytical problems.

The literary style of the book is uniform and clear and it is well produced. It provides a very readable source for a wide range of analytical information. It should be a very useful undergraduate text as well as one which could be profitably read by any analyst with a view to appreciating what is going on in adjacent fields of activity.

R. B. TAYLOR

be involved in its synthesis and release. The Periodic Table for Chromatographers: M. LEDERER, Wiley, Chichester, 1992. Pages v + 129. £60.00.

Although chromatography is often regarded as primarily a separation method for organic compounds, over the years it has played an important role in many inorganic separations. In this reference book Michael Lederer has brought together a collection of over 100 tables containing some 60,000 data values. These are usually presented in the format of the periodic table to illustrate the differences and similarities between the elements.

The values are principally drawn from previously published reports of extractions, ion-exchange separations, paper chromatography, electrophoresis and TLC, almost entirely from the 1960's and 1970's. There are sections on the distribution constants of the elements as undissociated molecules and as chelates with a range of reagents. The ion-exchange data are based on different resin columns and papers and eluent acids. The TLC values come from impregnated cellulose, silica and ion-exchanger phases and different liquid ion-exchange coatings. Finally there is one set of data from electrophoretic separations.

The author admits that the book is a result of a hobby of collecting chromatographic data. However, the problem with this book is that like many hobbies it represents material almost entirely for the specialist. The advent of ion chromatography, conductivity detection and specialised AED, ICP and AAS detection methods means that the separation of ions has advanced considerably over the last 10 years away from these traditional methods. Very few analysts would now contemplate separation of metal ions by TLC as a routine method and even less would think of paper chromatography. This book would therefore mainly appear to be valuable as a compilation of physical data of distribution and separation properties of the elements and their chelates and complexes. However, as the author notes in the Introduction, the values were collected under conditions that might be kinetically controlled rather than under equilibrium conditions.

R. M. SMITH

The Kirk-Othmer Encyclopedia of Chemical Technology: Volume 2, Fourth Edition. Alkanolamines to Antibiotics (Glycopeptides). J. I. KROSCHWITZ, M. HOWE-GRANT, L. C. HUMPHREYS and L. GRAY (editors), Wiley-Interscience, Chichester, 1992 Pages: xxviii + 1018. £135.00.

Inevitably, encyclopedias are referred to for specific items of interest rather than read from cover to cover. The easiest method of locating a desired topic in such a reference work is a simple search amongst items arranged in alphabetical order. Hence this volume, together with volume 1, covers topics beginning with the letter "A". Overall there are 27 volumes to be published, at the rate of one volume every 3 months, to extend coverage to the whole alphabet. A subscription price of 10% discount on individual volume list price is available. If information on a chemical substance is desired then here it is the most common correct name of the substance that is given (followed by its Chemical Abstracts Service Registry Number).

There are numerous topics in volume 2 involving contributions from several authors. Those topics covered at most length include aluminium and its alloys/compounds, amines, and various pharmaceutical agents such as analgesics, antiasthmatic agents and antibacterial agents. There are also extensive sections on amino acids and, ammonia and its compounds. Where appropriate methods of manufacture are covered and process diagrams are presented.

There is a small section on analytical methods which includes a survey followed by current trends and details of hyphenated instruments. This survey informs the reader of analytical techniques that are covered on other volumes of the encyclopedia (the names of the techniques appear in upper case to indicate a separate inclusion in the encyclopedia). The final section on antibiotics starts with a survey and then continues with various classes of antibiotics starting with aminoglycosides and continuing to the glycopeptides. The proposed volume 3 must, presumably, start with the lincomycin antibiotics.

I found browsing through this work and reading sections in depth to be both informative and enjoyable. These volumes will certainly enhance libraries in research, academic, industrial and other public institutions.

P. J. COX

Wilson & Wilson's Comprehensive Analytical Chemistry Vol. XXVII—Analytical Voltammetry: G. SVEHLA (editor), M. R. SMYTH and J. G. VOS (volume editors), Elsevier, Amsterdam, 1992. Pages xxv + 578. US$254.99. Dfl. 495.00. ISBN 0-444-88938.

This book is handsomely bound and properly printed, which is all too rare these days, and has contributions from 14 authors. A chapter by J. F. Cassidy on theory is well-judged for analytical users, with equations set at the right level for understanding without being too intimidating in number. The chapter on instrumentation is short (42 pp) and rather general, avoiding mention of any specific commercial instrumentation that an analyst might use. More space is devoted to modified electrodes than to computer software. I wonder if generalized circuit diagrams are really of any use to the average analyst and I also wish that suspended mercury reservoirs were seen as rarely in books as they are in the laboratory. There follows a chapter (37 pp, 241 references) devoted to "biological" molecules, *i.e.*, largely immunoassay, nucleic acids and proteins. Pharmacy (Bersier and Bersier) gets 184 pages of information on specfic molecules arranged by drug type: a very useful analytical compilation with 514 references. Environmental analysis is divided into inorganic (35 pp, 146 references) and organic and oganometallic (84 pp, 275 references). The former includes speciation, titration and stability constants; in fact there is rather little on direct analysis and that organized by neither sample type nor determinand. Two pages on metals in body fluids seem out of place here. The organics chapter covers air, water and (very briefly) soil analysis,

The Periodic Table for Chromatographers: M. LEDERER, Wiley, Chichester, 1992. Pages v + 129. £60.00.

Although chromatography is often regarded as primarily a separation method for organic compounds, over the years it has played an important role in many inorganic separations. In this reference book Michael Lederer has brought together a collection of over 100 tables containing some 60,000 data values. These are usually presented in the format of the periodic table to illustrate the differences and similarities between the elements.

The values are principally drawn from previously published reports of extractions, ion-exchange separations, paper chromatography, electrophoresis and TLC, almost entirely from the 1960's and 1970's. There are sections on the distribution constants of the elements as undissociated molecules and as chelates with a range of reagents. The ion-exchange data are based on different resin columns and papers and eluent acids. The TLC values come from impregnated cellulose, silica and ion-exchanger phases and different liquid ion-exchange coatings. Finally there is one set of data from electrophoretic separations.

The author admits that the book is a result of a hobby of collecting chromatographic data. However, the problem with this book is that like many hobbies it represents material almost entirely for the specialist. The advent of ion chromatography, conductivity detection and specialised AED, ICP and AAS detection methods means that the separation of ions has advanced considerably over the last 10 years away from these traditional methods. Very few analysts would now contemplate separation of metal ions by TLC as a routine method and even less would think of paper chromatography. This book would therefore mainly appear to be valuable as a compilation of physical data of distribution and separation properties of the elements and their chelates and complexes. However, as the author notes in the Introduction, the values were collected under conditions that might be kinetically controlled rather than under equilibrium conditions.

R. M. SMITH

The Kirk-Othmer Encyclopedia of Chemical Technology: Volume 2, Fourth Edition. Alkanolamines to Antibiotics (Glycopeptides). J. I. KROSCHWITZ, M. HOWE-GRANT, L. C. HUMPHREYS and L. GRAY (editors), Wiley-Interscience, Chichester, 1992 Pages: xxviii + 1018. £135.00.

Inevitably, encyclopedias are referred to for specific items of interest rather than read from cover to cover. The easiest method of locating a desired topic in such a reference work is a simple search amongst items arranged in alphabetical order. Hence this volume, together with volume 1, covers topics beginning with the letter "A". Overall there are 27 volumes to be published, at the rate of one volume every 3 months, to extend coverage to the whole alphabet. A subscription price of 10% discount on individual volume list price is available. If information on a chemical substance is desired then here it is the most common correct name of the substance that is given (followed by its Chemical Abstracts Service Registry Number).

There are numerous topics in volume 2 involving contributions from several authors. Those topics covered at most length include aluminium and its alloys/compounds, amines, and various pharmaceutical agents such as analgesics, antiasthmatic agents and antibacterial agents. There are also extensive sections on amino acids and, ammonia and its compounds. Where appropriate methods of manufacture are covered and process diagrams are presented.

There is a small section on analytical methods which includes a survey followed by current trends and details of hyphenated instruments. This survey informs the reader of analytical techniques that are covered on other volumes of the encyclopedia (the names of the techniques appear in upper case to indicate a separate inclusion in the encyclopedia). The final section on antibiotics starts with a survey and then continues with various classes of antibiotics starting with aminoglycosides and continuing to the glycopeptides. The proposed volume 3 must, presumably, start with the lincomycin antibiotics.

I found browsing through this work and reading sections in depth to be both informative and enjoyable. These volumes will certainly enhance libraries in research, academic, industrial and other public institutions.

Environmental analysis is divided into inorganic (35 pp, 146 references) and organic and oganometallic (84 pp, 275 references). The former includes speciation, titration and stability constants; in fact there is rather little on direct analysis and that organized by neither sample type nor determinand. Two pages on metals in body fluids seem out of place here. The organics chapter covers air, water and (very briefly) soil analysis,

mainly by literature reference. There is also a section on foodstuffs. Future developments are represented by a timely, but not immediately encouraging, review of modified electrodes by Forster and Vos (65 pp, 398 references) and a chapter on amperometric biosensors (40 pp, 207 references). References extend into 1988. The index is inadequate. This is undoubtedly a very useful volume for those concerned with organic analysis. Inorganic analysts will find it interesting, but not essential.

D. MIDGLEY

Trace Metal Analysis and Specification: I. S. KRULL (editor), Elsevier, Amsterdam, 1991. Pages: xvi + 302. Dfl. 240.00.

Although most analysts would first think of atomic-absorption spectroscopy or inductively-coupled plasma emission spectrometry when asked to analyse metal ions, these methods are non-species specific and only give total concentrations. However, in recent years there has been a greater realization of the importance of the form in which a metal is present in the sample. This has led to the rise of a range of coupled techniques in which a chromatographic separation, such as HPLC or GLC has been linked to an element specific detector and these form the backbone of this collection of reviews edited. Despite a larger number of research papers on this field little has been done previously to bring together inorganic chromatographic methods since Schwedt in 1981 and MacDonald in 1985.

The most important advances have been in the general application of plasma detectors, which have provided much greater sensitivity and specificity than ultraviolet spectroscopic detection. The book starts with a review of microwave induced plasma detection for GC by Uden with small sections on LC and SFC. Three chapters on environmental samples by Irgolic and interfacing by Heitkemper and Caruso and also by Houk and Jiang comprehensively cover coupled-LC and GC systems and although there is some overlap it is mainly in the samples being examined. Bilhorn, Pomery and Denton discuss the details of the instrumentation of plasma emission detectors and coupled direct current plasma instruments are described by Krull and Childress.

Alternative approaches are given in a review by Karcher and Krull on the use of complexation and derivatisation techniques and by Bond on electrochemical detection of metal ions. The more specific technique of ion chromatography is reviewed by Gjerde and Mehra.

Overall the book reflects the modern practice in metal ion analysis and emphasises the importance of coupling the more traditional spectroscopic and electrochemical methods with separation techniques. Each section includes numerous relevant examples of the applications of the techniques.

R. M. SMITH

Principles of Environmental Toxicology: S. F. ZAKRZEWSKI (editor), American Chemical Society, Washington, D.C., 1991. Pages xiii + 270. US$59.95 (Hardback) ISBN 0-8412-2125-1. US$ 44.95 (Softback). ISBN 0-8412-2170-7.

There is much more to this book than toxicology. Indeed, the amount of toxicology is disappointingly limited. The author starts by setting the scene in a chapter on world and environmental trends, and then looks at some basics of pharmacological concepts, metabolism of xenobiotics, factors that influence toxicity and chemical carcinogenesis and mutagenesis. As someone with little direct knowledge of toxicology I found these latter chapters quite interesting and useful, although without a background in biochemistry, some of the context is a little obscure. What disappointed me was that the book then went on to deal rather cursorily with air pollution, water and land pollution, pollution control, radioactive pollution, occupational toxicology and regulatory policies. As a specialist in some of these areas I found the treatment sadly limited. For example, the subjects of stratospheric ozone depletion and climate change are covered in a few pages each, without any real indication of toxicological consequences, be there any. The book, therefore, might more properly be called Principles of Environmental Pollution and Toxicology, being about 50% on each topic. The style is relatively light and easy to read and I can commend the book to the beginner in this field as providing a rather shallow but useful introduction to the subject. The book was derived from lectures given by the author and its primary use is likely to be as a teaching text. In this context, the shallowness of treatment of some areas will limit its value, and the discussion of regulatory policies purely in the context of United States law will severely limit the value of this chapter to those in other countries. In summary, a useful introductory level book, but do not be misled by the title.

R. M. HARRISON

Preparative and Process-Scale Liquid Chromatography: G. SUBRAMANIAN (editor), Ellis Horwood, 1991. Pages 286. £55.00.

If you take the papers presented at a short course on Preparative Chromatography and put them together do you get a book on Preparative Chromatography? All that you really obtain are the notes of speakers. As such, you have a very nice set of course notes, but not a book for others to read.

This book, Preparative and Process Scale Liquid Chromatography, is such a collection of course notes, and so, falls short of any target group of readers that would be interested in the subject, either as a novice, user or expert wanting to gain more knowledge of Preparative Liquid Chromatography.

Fourteen authors of different papers are gathered together. They cover a wide variety of subject matter from the design of preparative columns and preparative systems to the media used in the columns to the type of applications that are now being developed and run on preparative systems.

Preparative and Process-Scale Liquid Chromatography: G. SUBRAMANIAN (editor), Ellis Horwood, 1991. Pages 286. £55.00.

If you take the papers presented at a short course on Preparative Chromatography and put them together do you get a book on Preparative Chromatography? All that you really obtain are the notes of speakers. As such, you have a very nice set of course notes, but not a book for others to read.

This book, Preparative and Process Scale Liquid Chromatography, is such a collection of course notes, and so, falls short of any target group of readers that would be interested in the subject, either as a novice, user or expert wanting to gain more knowledge of Preparative Liquid Chromatography.

Fourteen authors of different papers are gathered together. They cover a wide variety of subject matter from the design of preparative columns and preparative systems to the media used in the columns to the type of applications that are now being developed and run on preparative systems.

As such, there is a great deal of overlap from section to section. Sections written by manufacturers of equipment or packing materials are very biased to their equipment and materials. And in general, the data presented in these sections can be found in other journals, procedings of other conferences or even promotional material supplied by the manufacturers.

For me, the most interesting sections were those by industrial presenters who appear to be real users of preparative systems. Sections by Derek Hill, Kevin Connelly and Christopher Goward are well worth reading, as they give a real feel for Preparative Chromatography from real users of the systems, as opposed to people selling equipment or packing materials. In the sections from these presenters you can tell some of the major practical problems they have in Preparative Chromatography.

Overall, a nice set of course notes, but as a book it is lacking a target and so much material is repeated between different authors of different sections. It could also have done with another proof-read before being committed to print.

THE DETERMINATION OF ORGANOTIN COMPOUNDS IN EDIBLE OILS BY GAS CHROMATOGRAPHY-ATOMIC ABSORPTION SPECTROMETRY

D. S. FORSYTH, D. WEBER and K. DALGLISH

Food Research Division, Bureau of Chemical Safety, Food Directorate, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario, K1A 0L2, Canada

(*Received* 14 *May* 1992. *Revised* 4 *August* 1992. *Accepted* 4 *August* 1992)

Summary—An extraction method for butyl-, cyclohexyl-, octyl- and phenyltin compounds from edible oils was developed using 0.05% tropolone in 0.04*M* HCl/methanol. Cooling the methanol extracts in a dry ice/methanol bath removed approximately 64% of nonvolatile coextractives without affecting recoveries. Methyl derivatives formed by Grignard reaction were quantitated by gas chromatography-atomic absorption spectrometry. Edible oils sold in poly(vinyl chloride) containers had ng/g levels of dioctyl- and monooctyltin. GC–MS confirmed the presence of octyltin and did not detect any other organotin compounds in the extracts.

Organotin compounds are used in numerous applications including biocides, poly(vinyl chloride) (PVC) stabilizers and catalysts. Global consumption of PVC stabilizers accounted for 66–75% of all organotin production during the 1970s.[1] Currently, annual consumption is estimated to be 35×10^6 kg world wide.[2]

Dibutyltin is typically added as a heat stabilizer to rigid and semi-rigid PVC products used in industrial applications.

Dioctyltin compounds have low mammalian toxicity[3] and several are used by many countries as stabilizers in PVC drink containers and food packaging.[4] The monoalkyltin analogue is frequently blended with the dialkyltin to produce a synergistic effect in stabilizer performance.[4]

Recent analyses of Canadian wines for organotins[5,6] found butyltins in blended wine products containing imported wines which had been transported in containers constructed of butyltin-stabilized PVC. As edible oils are also shipped in these containers a survey was conducted to determine what alkytins were present in edible oils available to the consumer. Existing methods for determination of alkyltins in edible oil are primarily designed for migration studies using radiolabelled organotin stabilizers[7–9] of known composition or total tin determinations.[10,11] However, the methods found in the literature could not speciate unknown alkyltins in edible oils.

The purpose of this study was to develop a method capable of speciating a variety of alkyltins in edible oils using gas chromatography-atomic absorption spectrometry and to conduct a limited survey of edible oils available from retail outlets.

EXPERIMENTAL

Reagents and standards

Distilled-in-glass grade solvents (Caledon Laboratories Ltd., Georgetown, Ontario) and ACS reagent grade chemicals were used. The methylmagnesium chloride and tropolone were purchased from Aldrich Chemical Co., Inc. (Milwaukee, Wisconsin, U.S.A.). Dioctyltin dichloride (Oc_2SnCl_2) was obtained from MTM Research Chemicals (P.O. Box 1000, Windham, NH).

Dioctyldimethyltin was prepared from Oc_2SnCl_2 using the following procedure. Dioctyltin dichloride (10–20 mg) was weighed into a 10-ml screw cap centrifuge tube; tetrahydrofuran (1 ml) and 100-fold excess (molar basis) of methylmagnesium chloride were added under nitrogen. The reaction mixture was rotary tumbled at 25 rpm for 15 min and then cooled in ice. Hexane (3 ml) and prechilled 0.5*M* nitric acid were slowly added up to a 10-ml total sample volume. The aqueous layer was removed after tumbling (25 rpm, 2 min) and centrifugation (2000 rpm, 2 min). The organic layer was then tumbled (25 rpm, 2 min) once with approx. 8 ml of deionized (18 megohm/cm) water. The

pooled aqueous washings were extracted twice with 2-ml portions of hexane. The pooled organic extracts were then dried over anhydrous sodium sulphate. The dioctyldimethyltin was 97% pure (Sn basis). The source and purity of the other organotin standards have been described elsewhere.[5,12]

Instrumentation

Details of the gas chromatograph (GC)-atomic absorption spectrometer (AAS) system used in this study have been reported elsewhere.[13,14] GC operating conditions in the current study were as follows: glass column (1.8 m × 6 mm o.d., 2 mm i.d.), packed with 3% OV-7 on Chromosorb W, HP 100/120 mesh (Chromatographic Specialties Ltd., Brockville, Ont.); carrier gas, helium, 20 ml/min; transfer line, 0.8 m × 0.25 mm i.d. deactivated fused silica; transfer line temperature, 275°, column temperature program, 75° (0.5 min hold) to 130° (no hold) at 25°/min then to 155° (no hold) at 15°/min, then increased at 25°/min to 310° (5.0 min hold); injector temperature, 225°.

AAS operating conditions were: Hamamatsu Sn hollow cathode lamp (Hamamatsu Photonics K.K.); current, 15 mA; wavelength, 224.6 nm; bandpass, 0.5 nm; quartz T tube furnace temperature, 900°; furnace support gas flow rates, H_2 45 ml/min, air, 45 ml/min.

A Varian VISTA 6000 GC interfaced to a VG Analytical 7070EQ mass spectrometer with EBQQ configuration was used for GC-MS analysis. Using the conventional magnetic sector only, the system was operated in the electron impact mode (70 eV) at a mass resolution of 1000. GC operating conditions have been previously reported.[12] Selected ion monitoring was at m/z 205 and 207 for butyltrimethyltin ($BuMe_3Sn$), 225 and 227 for phenyltrimethyltin ($PhMe_3Sn$), 205 and 207 for dibutyldimethyltin (Bu_2Me_2Sn), 261 and 263 for octyltrimethyltin ($OcMe_3Sn$), 247 and 249 for tributylmethyltin (Bu_3MeSn), 231 and 233 for dicyclohexyldimethyltin (Cy_2Me_2Sn), 261 and 263 for dioctyldimethyltin (Oc_2Me_2Sn), 299 and 301 for tricyclohexylmethyltin (Cy_3MeSn), and 349 and 351 for triphenylmethyltin (Ph_3MeSn).

Analytical methods

Sample collection. A variety of edible oils were purchased from local supermarkets and stored at room temperature until analysis.

Extraction. Five grams of oil were weighed into a 50-ml centrifuge tube. Each sample was then tumbled for 20 min (65 rpm) with 10 ml of 0.05% tropolone in 0.04*M* hydrochloric acid/methanol. Following centrifugation (2000 rpm, 4 min), the sample was placed in a dry ice/methanol bath for 2 min and then briefly centrifuged (3000 rpm, 2 min). The methanol layer was collected with a Pasteur pipette. After the sample had warmed to room temperature, the extraction was repeated. The pooled extract was evaporated at 35° (Brinkmann RotoVapor-R, Brinkmann Instruments) to 1 ml over approx. 4 min. Chloroform (10 ml) was added and the volume reduced to 1 ml over 2–3 min. Hexane (15 ml) was then added and used to wash down the sides of the round bottom flask, and evaporated to 2 ml over approx. 3 min. Solvents were removed at these slow rates to prevent sample bumping and to ensure removal of the methanol, hydrochloric acid and chloroform during the transition to apolar solvent. The hexane was transferred to a 10-ml screw cap centrifuge tube with one 2-ml tetrahydrofuran rinse followed by two 2-ml rinses of hexane. The sample was placed in a water bath at 30° and the solvent volume reduced to 1 ml under a nitrogen stream. Pentane (5 ml) was then added and the sample evaporated to 1 ml.

Derivatization. Tetrahydrofuran (0.9 ml) and methylmagnesium chloride (0.7 ml) were added and the sample capped under nitrogen. After brief vortexing, the sample was rotary tumbled (10 min, 25 rpm). The sample was then cooled in ice and the volume adjusted to 10 ml with prechilled 0.5*M* nitric acid (added slowly initially). Isooctane (0.9 ml) was added, and the sample was tumbled (2 min, 25 rpm), and centrifuged briefly (up to 2500 rpm). The aqueous layer was removed and discarded and the acid wash repeated once. After discarding the aqueous layer, the organic volume was adjusted to 2.0 ml. Residual acid and water were removed by the addition of sodium bicarbonate and anhydrous sodium sulfate (approx. 300 mg each). The sample extract was then transferred to an autoinjector vial.

Analysis. Sample quantitation was by comparison to external standards using GC–AAS. A 10-μl sample volume was injected by autosampler. As a monooctyltin standard was unavailable, a Sn response factor determined from Bu_3MeSn standards was used to quantitate monooctyltin levels. Monooctyltin was identified in the samples by GC–MS. Reagent

blanks were run with each sample series. Method detection limits were 0.2 to 0.4 ng Sn/g (Table 1).

Recovery experiments. Samples of peanut or corn oil were spiked at 2 levels (3.2–5.6 or 16.2–28 ng/g) with $BuSnCl_3$, Bu_2SnBr_2, Bu_3SnBr, Oc_2SnCl_2, Cy_2SnBr_2, Cy_3SnBr and Ph_3SnCl. The percent recovery of each analyte was determined by dividing the mean peak area of the compound found in the spiked peanut or corn oil extracts by the mean peak area of the compound in blank peanut or corn oil extracts spiked just prior to derivatization.

Method development

Tropolone study. The effects of tropolone were evaluated by comparing recoveries from corn oil using (1) two 10-ml methanol extractions or (2) a methanol followed with 0.05% tropolone in methanol (10 ml each) extraction. No hydrochloric acid was added to these samples. Extraction conditions (minus methanol cooling with dry ice bath) were as given in the Extraction section. No chloroform was used during rotary evaporation. A 0.05% tropolone in hexane solution was used to rinse the round bottom flasks. Derivatization was as reported in the derivatization section except 18 megohm/cm water was used instead of the second 0.5*M* nitric acid wash and no sodium bicarbonate was added.

Hydrochloric acid addition. Spiked corn oil samples were extracted (minus methanol cooling step), and rotary evaporated as reported in the Extraction section. Derivatization was as reported in the tropolone study section. The hydrochloric acid content of the 0.05% tropolone/methanol solution was varied from 0 to 0.04*M*.

Sample cleanup. NaOH extraction. a) Nonvolatile Removal. Duplicate sample extracts from spiked peanut oil were taken to a constant volume under a nitrogen stream, desiccated under vacuum for 1 hr and then weighed. Hexane was added to obtain the original 2-ml volume and the sample extracted twice with 5 ml portions of 3% sodium hydroxide (tumbled 20 min, 65 rpm). After centrifugation, the aqueous layer was discarded. The hexane layer was dried over anhydrous sodium sulfate and transferred (with two 2-ml hexane washings) to a preweighed 125-ml round bottom flask, rotary evaporated, dessicated under vacuum and then weighed for comparison to the preextraction weight.

b) Chromatography. Two spiked 5-g peanut oil samples were extracted (minus methanol cooling) as reported in the extraction section. The samples were derivatized as described in the derivatization section with the following modifications. After removing the 0.5*M* nitric acid wash, the samples were extracted twice with 5-ml portions of 3% sodium hydroxide (tumbled 20 min, 65 rpm) followed by a 18 megohm/cm water wash (tumbling time 30 sec). The organic sample volume was adjusted to 2.0 ml, dried over anhydrous sodium sulfate and transferred to autoinjector vials to await analysis.

Dry ice-methanol cooling. Nonvolatile removal. Four 5-g samples of spiked peanut oil were extracted with 0.05% tropolone in 0.04*M* hydrochloric acid/methanol as described in the extraction section. Methanol extracts from two samples were cooled in dry ice/methanol. The pooled methanol extracts of

each sample were rotary evaporated, desiccated under vacuum and then weighed. The weights of the cooled sample extract residues were compared against those of the noncooled extracts.

RESULTS AND DISCUSSION

Extraction method

The method isolated the organotins with minimal coextractives without the expense and equipment requirements of gel permeation or other column chromatography. Recoveries of the organotins (excluding Cy_3SnBr results) from peanut and olive oil averaged 93 and 88% respectively (Table 2). The method also provided qualitative screening for tricyclohexyltin as recoveries were low but consistent (26–32%). Coextractives from the oil matrix did not affect derivatization yields.

The precision of the method, estimated from duplicate determinations of edible oil samples (Table 3), averaged 4.3% relative standard deviation (range 0.9–11.9%).

Initial work indicated the use of tropolone and hydrochloric acid were important factors affecting recovery efficiency. Tropolone (Fig. 1) improved the recoveries of monobutyltin and dicyclohexyltin from 36 to 96% and 29 to 46%

respectively. The presence of hydrochloric acid (Fig. 2) increased recoveries of dicyclohexyltin and triphenyltin from 67 to 82% and from 48 to 85% respectively. Further improvements resulted from optimizing rotary evaporation and sample transfer steps in the procedure.

The derivatization method used previously[6] was modified by replacing 18 megohm/cm water with 0.5*M* nitric acid for the final sample wash to eliminate emulsion formation which occurred in some sample extracts.

Sample cleanup

GC column performance degraded rapidly during chromatography of initial (uncleaned) extracts, resulting in peak broadening of dioctyltin and tailing of triphenyltin [Fig. 3(a)]. The sodium hydroxide cleanup procedure, adapted from Martin-Landa *et al.*[15] removed only 1.2% of total nonvolatile coextractives and only slightly improved column performance [Fig. 3(b)]. However, cooling the methanol extract resulted in 63.6% reduction of nonvolatile coextractives present and improved the peak area/height ratio of both dioctyl- and triphenyltin [Fig. 3(c)]. Column performance could be easily maintained by silylation (using Silyl-8®) followed by a bake-out period (30 min) after every 20–30 injections with samples that had been prepared using the methanol extract cooling procedure.

Edible oil analyses

Monooctyl- and dioctyltin were found in 5 of the 15 oil samples with levels ranging from 5.7–26.9 ng/g and 23.2–118.4 ng/g respectively (Table 3). Canadian food regulations permit no more than 1 μg total octyltin/g.[16] No other alkyltins were found at levels exceeding the GC–AAS method detection limits.

GC–MS analysis of four oil samples confirmed the presence of monooctyltin [as $OcMe_3Sn$ (m/z 263 $[M\text{-}CH_3]^+$)], and dioctyltin [as Oc_2Me_2Sn (m/z 263 $[M\text{-}C_8H_{17}]^+$)] (Fig. 4). No other alkyltins were detected by GC–MS.

None of the oil samples purchased in glass or polyethylene terephthalate containers contained octyltins (Table 3). However, octyltins were present in most of the oils packaged in poly(vinyl chloride) containers (Table 3), indicating the octyltin source was probably the PVC container material. The absence of butyltins in the oil samples indicates that either the oil samples have not been in contact with PVC formulated with butyltin stabilizers or that the oils do not extract these organotin compounds from the PVC shipping containers efficiently.

CONCLUSIONS

Most of the tested organotins were quantitatively recovered from oil by extraction using 0.05% tropolone in 0.04*M* hydrochloric acid/methanol. Edible oil samples sold in PVC containers had monooctyl- and dioctyltin present. No other organotins were detected in the oil samples by GC–AAS or GC–MS.

SEPARATION OF OXYANIONS OF PHOSPHORUS BY SINGLE COLUMN ION CHROMATOGRAPHY

DENISE HATTON and WILLIAM F. PICKERING
Chemistry Department, University of Newcastle, NSW 2308, Australia

(*Received* 4 *June* 1992. *Revised* 21 *July* 1992. *Accepted* 22 *July* 1992)

Summary—Separation of mixtures containing hypophosphite, phosphite, orthophosphate, chloride, nitrate and sulphate ions has been achieved using a Vydac 300 IC 405 column, refractive index detection and eluents which were 2m*M* in *p*-hydroxy benzoic acid or 4m*M* in *p*-amino benzoic acid (adjusted to pH 5.5). Calibration curves were linear over the concentration range 3 to 30 mg P/l.; and the precision (RSD for peak heights in mixtures) was $< \pm 10\%$. Using *p*-hydroxy benzoic acid, detection of eluted peaks by indirect UV absorption was equally satisfactory. In an initial survey, the elution behaviour of nine oxyanions of phosphorus (simple ions and condensed species) was examined, using eluents containing different organic carboxylic acids (six aliphatic and nine aromatic), present at levels of 1 to 5m*M*; with the pH adjusted to values between 3 and 8.6. No suitable conditions for separating mixtures containing condensed phosphates were identified.

A number of industrial processes produce wastes that contain mixtures of the oxyanions of phosphorus and many of the combinations have been analysed successfully using a dual column ion chromatograph and alkaline eluents, with detection of the eluted species being based (in most cases) on conductivity measurements. The mixtures of $H_2PO_2^-$, $H_2PO_3^-$ and $H_2PO_4^-$ found in plating baths have been analysed, for example, using eluents such as 3m*M* sodium carbonate (adjusted to pH 12 with sodium hydroxide[1] or a 3m*M* solution in sodium hydrogen carbonate; 2.4m*M* in sodium carbonate[2] (pH 10.3). To identify the different types of condensed phosphates found in foods elution with 80m*M* sodium hydroxide has been used.[3] Detection based on UV absorption by derivatives formed in post column reactions [*e.g.*, with Fe(III)] has been used in river water analysis (where the eluent was 1.5 to 8m*M* in sodium carbonate; 90m*M* in sodium hydroxide[4]) and in food analysis.[5]

Single column HPLC procedures have not become as well established. In this technique the eluents used are usually weak organic acid solutions and in these acidic conditions many phosphorus species, *e.g.*, hypophosphite, phosphite and orthophosphate, exist predominantly as monovalent ions. Separation of mixtures of these three oxyanions has been achieved using a Vydac 302 column, a conductivity detector and 20m*M* succinic acid (adjusted to pH 3) as the eluent;[6] and using a Hamilton PRP × 100 column, 4-amino-2 hydroxybenzoic acid (4m*M*, pH 5.5–6.5) as eluent and indirect ultraviolet absorption detection.[7] Mixtures of phosphoric, pyrophosphoric and tripolyphosphoric acids have been separated on a single column unit using an eluent composed of trimesic acid (pH 3.4) loaded with a chelating agent, *e.g.*, CyDTA.[8] For the determination of pyrophosphate and tripolyphosphate and detergent granules, an indirect UV detection method was found to be more sensitive than conductometric detection.[9]

Detection based on refractive index measurements appears to be an unexplored variant, hence in our single column ion chromatography study we elected to combine this detection system with separation on a short Vydac column. The eluents tested were a series of carboxylic acids which varied in structure, p*K*a, and pH (range 3–9).

EXPERIMENTAL

HPLC equipment

The unit used contained an ETP Kortech solvent pump (model K35M); a separating column (Vydac 300 IC 405); a sample loop (50 μl); a Refractive Index Detector (model ERC-7510); and a fast speed recorder (FSD 10 mV, operating at a paper speed of 1 cm/min). The eluent flow rate was adjusted to 1–2 ml/min. The room temperature was maintained at 22°.

For comparison studies using indirect UV absorbance detection, the column was connected into a Waters Associates Liquid Chromatograph fitted with a Lambda-Max Model 481 LC Spectro-photometer. The sample loop size in this unit was 10 μl.

Anion solutions

Stock solutions (1mM) of a series of phosphorus oxyanions [NaH_2PO_2; Na_2HPO_3; Na_2HPO_4; NaH_2PO_4; HPO_3; $(NaPO_3)_6$; $Na_5P_3O_{10}$; $Na_2H_2P_2O_7$; and $Na_4P_2O_7$] were prepared from A. R. grade chemicals dissolved in purified water obtained from a Millipore, Milli-Q reverse osmosis system.

Eluent solutions

The weak organic acid solutions listed below were pH adjusted before being filtered through a 0.45-μm membrane filter and degassed under vacuum. Each eluent was run at three pH values (3.5, 5.5 and 8.6), and where additional tests were warranted, solutions having intermediate pH values were prepared. The concentration of acid in the eluting solution was initially 1mM; but with some systems the levels were varied; and the additional concentrations (mM) tested are shown in brackets for (a) aliphatic carboxylic acids: acetic acid; succinic acid (0.5, 5, 20); adipic acid (5); maleic acid (5); fumaric acid (3); tartaric acid (2) and (b) aromatic carboxylic acids: benzoic acid (2); phenylacetic acid (5); *o*-hydroxy benzoic acid (5, 7.5, 10); *p*-hydroxy benzoic acid (2, 3, 4, 5); *p*-amino benzoic acid (2, 4); *o*-toluic acid (3); sulphosalicyclic acid (0.5, 4); phthalic acid (0.5, 2); and terephthalic acid (0.5).

RESULTS AND DISCUSSION

Eluent survey

The eluent strength of weak organic acid solutions tends to be a function of the molecular structure; the relative strength of the acid functional groups; and the system pH. Aliphatic acids have proved useful in some applications, but more widely used are aromatic mono- or di-carboxylic acids. The presence of substituent groups modifies the eluting power of these acids. For example, in a recent study[10] the effect of substituents on the separation of mixtures of monovalent (Cl^-, NO_2^-, Br^-, NO_3^-) and divalent (SO_4^{2-}, SeO_4^{2-}, $S_2O_3^{2-}$, $S_2O_6^{2-}$) inorganic ions was examined. For the pH range 5–7, it was found that the mobile phase eluent strength followed the order:

$$o\text{-sulfo} > o\text{-hydroxy} > p\text{-nitro} > p\text{-amino} > o\text{-amino} > m\text{-amino} = \text{benzoic acid.}$$

A change in pH can alter the affinity of the analyte species for the exchange sites on the column packing (by altering the degree of protonation) while simultaneously altering the level of displacing anion present in the eluent solution, hence in our investigation, we sought to utilise both effects by varying the pH of the acid eluent systems over a wide range (3–9).

Prediction of the effect of pH on elution patterns is difficult, due to the many competing equilibria involved, but many of the trends observed were as expected. For example, the elution times decreased on raising the system pH (or by increasing the eluent concentration) and when the level of displacing anions in the eluent became too high, the analyte species were swept through the column so rapidly that their detector signal became lost in the system peak observed on all chromatograms.

In the preliminary survey, the different oxyanions of P were introduced into the column as single component samples in order to confirm that the various species were being detected by the refractive index measurement unit. Systems or conditions worthy of more detailed study were then selected by comparing oxyanion elution times. A majority of the eluents tested proved to be unsuitable, due to P anions being eluted with the solvent front, or several oxyanions eluted at similar rates, or an analyte yielded multiple peaks. Only three of the organic acids (*para* substituted hydroxy- or amino benzoic acid; and *o*-phthalic acid) could be classified as potentially useful (*e.g.*, for separating mixtures containing $H_2PO_2^-$, $H_2PO_3^-$ and $H_2PO_4^-$) and these were then studied in more detail. Succinic acid was also subjected to further examination because it had been used successfully in an earlier study.[6] No suitable conditions for separating mixtures containing condensed phosphates were identified.

Separation of hypophosphite, phosphite and orthophosphate

Using p-amino benzoic acid or p-hydroxy benzoic acid. As shown on Fig. 1, separation of mixtures containing hypophosphite, phosphite, orthophosphate, chloride, nitrate and sulphate ions has been achieved using a Vydac 300 IC

405 column, refractive index detection and eluents which were 2m*M* in *p*-hydroxy benzoic acid or 4m*M* in *p*-amino benzoic acid (adjusted to pH 5.5). Using *p*-hydroxy benzoic acid, detection of eluted peaks by indirect UV absorption was equally satisfactory. Calibration curves (Fig. 2) were linear over the concentration range 3–30 mg P/l.; but the column was overloaded if mixtures contained more than 15 mg/l. of each component. Repeated analysis of this type of mixture was used to calculate the standard deviation of the various peak heights, and the precision was found to vary with the oxyanion involved. For example, the RSD values obtained using refractive index detection ranged from ±2% (hypophosphite) to ±10% (phosphite); with indirect UV detection (and *p*-hydroxy benzoic acid as eluent) the RSD values increased to < ±12%.

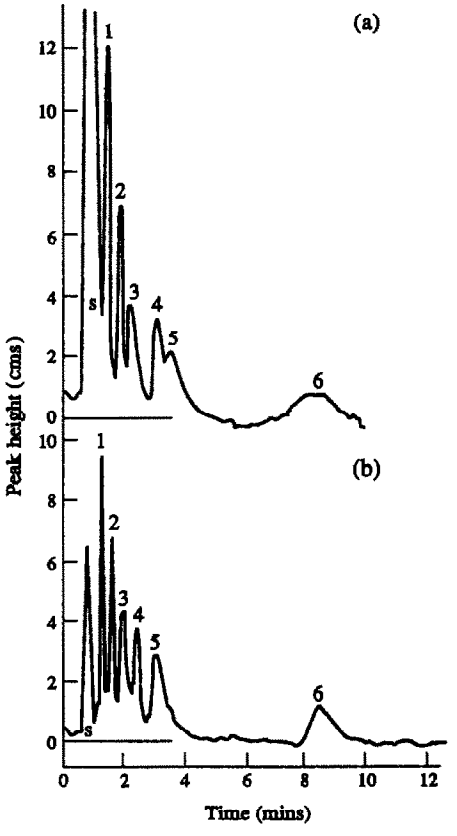

Fig. 1. Chromatograms showing the separation of mixtures containing 1. hypophosphite (250μ*M*); 2. chloride (125μ*M*); 3. orthophosphate (250μ*M*); 4. nitrate (125μ*M*); 5. phosphite (250μ*M*); and 6. sulfate (125μ*M*). s = system peak. Eluents used were (a). 4m*M* 4-amino benzoic acid (pH 5.5); (b). 2m*M* 4-hydroxy benzoic acid (pH 5.5). Flow rate 1.5 ml/min, Vydac 300 IC 405 column, column temperature 22°, refractive index detector. [With the instrument settings used, a peak height of 10 cms corresponds to 1×10^{-6} RI units].

The acid dissociation profiles of *p*-amino and *p*-hydroxy benzoic acid are somewhat similar (pK_a 4.6, 4.9), with both being weaker acids than the 4-amino-2-hydroxybenzoic acid (p*K*a 4.3) used by Mehra and Pelletier[7] for separating mixtures of a similar group of anions. The top phosphorus anion concentration studied by these investigators was 20 mg/l., and the precision achieved with this eluent (expressed as RSD values) was a little better than that achieved in our study.

Effective separation of phosphorous oxyanions by aromatic monocarboxylic acids appears to be influenced more by the type and position of substituents, than by the p*K*a value of the acid group. For example, benzoic acid has a p*K*a value similar to that of 4-amino-2-hydroxybenzoic acid but it did not selectively elute the various oxyanion species. Equally unsatisfactory as eluents were *o*-toluic acid, salicylic acid (p*K*a 3) and sulphosalicylic acid.

Using o-phthalic acid. Elution with *o*-phthalic acid has been reported[6] to yield poor separations of P oxyanions and most of the results obtained in our study were consistent with this opinion. For example, at pH 3.5 the P species signals tended to overlap and/or give dual peaks for a single species. At higher pH the $H_2PO_2^-$ ion travelled close to the solvent peak. It was found, however, that over a narrow pH range (5–5.5) there was separation of phosphite and orthophosphate ions, and with careful control of operating conditions (*e.g.*, 1m*M* eluent, being pumped through the column at 1.5 or 1.0 m/min) separation of the hypophosphite ion from the system peak was sometimes achieved, yielding a separation of the three anions. The sensitivity to operating parameters and overlap of the phosphorous peaks with chloride and nitrate ion signals led to curtailment of further studies on this eluent.

No suitable conditions for separating mixtures of P oxyanions were detected using the 1,4 isomer, terephthalic acid, as eluent.

Elution behaviour using aliphatic carboxylic acids

Succinic acid. Separation of $H_2PO_2^-$, $H_2PO_3^-$ and $H_2PO_4^-$ has been achieved[6] using 20m*M* succinic acid (adjusted to pH 3) as eluent, but small changes in pH were found to have a marked influence (*e.g.*, at pH 3.5 the three peaks totally overlapped). Since at pH 3, only about 8% of the diprotic acid would be ionized it was predicted that more dilute solutions (*e.g.*, 0.5, 1.0 or 2.0m*M*), adjusted to a slightly higher

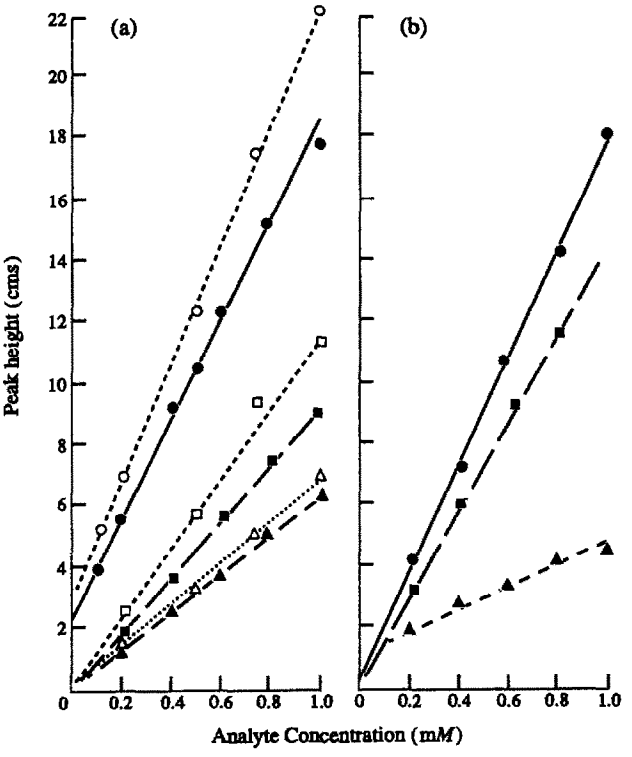

Fig. 2. Calibration curves for hypophosphite (●), orthophosphate (■) and phosphite (▲) ions; eluted at pH 5.5 from a Vydac column (300 IC 405) using an eluent flow rate of 2 ml/min. (a). Eluent, 4-hydroxy benzoic acid (2m*M*), refractive index detector; (indirect UV absorbance detection, dotted lines). (b). Eluent, 4-amino benzoic acid (4m*M*), refractive index detector. [With the instrument settings used, a peak height of 10 cm corresponds to 1×10^{-6} RI units or 2×10^{-3} absorbance units].

pH (*e.g.*, 3.5), could be equally effective. This proved to be a faulty premise, since in our study where we used these different conditions, the hypophosphite ion tended to come out with the solvent peak and the other oxyanions of phosphorus tested were rarely resolved.

Adipic, maleic, fumaric and tartaric acids. These four di-carboxylic acids showed no tendency to selectively elute the various phosphorous oxyanions, but the varied responses again showed the influence of molecular structure effects. For example, the dissociation constants for the two acid groups on adipic acid are reasonably similar to those of *o*-phthalic acid, but the absence of the aromatic ring resulted in greatly different elution behaviour. Tartaric acid has a species distribution pattern (as a function of pH) which is similar to fumaric acid, but these two acids yielded different (but equally unsatisfactory) elution patterns. Maleic acid and fumaric acid are the *cis* and *trans* isomers of the same basic molecule (HOOOC . CH = CH . COOH) but the p*K*a of the acid groups varies between the isomeric forms, and this was reflected in the eluting power.

Mono-carboxylic acid. The p*K*a value for acetic acid is similar to that of the two aromatic acids found to yield satisfactory separation of some P anions but the difference in size and chemical nature of the displacing ion led to completely different results. The introduction of a phenyl group into the base molecule altered elution behaviour, but did not facilitate separations.

Detection of oxyanions of phosphorus

In the survey of single analyte behaviour the refractive index detector yielded peaks for each of the anions tested, but those from condensed phosphates tended to be broad or distorted. The calibration graphs shown on Fig. 2 indicate the different responses observed for $H_2PO_2^{(-)}$, $H_2PO_3^{(-)}$ and $H_2PO_4^{(-)}$ ions and it can be seen that for these three oxyanions, the peak heights for 1m*M* (*i.e.*, 31 mg P/l.) solutions ranged from 0.5 to 2.0×10^{-6} RI units. Detector responses of similar magnitude were obtained using indirect UV detection (*cf.* Fig. 2). A similar type of calibration plot was obtained in an earlier study[7] which also used indirect UV absorbance as the detection mode, but where the eluent was

4-amino-2 hydroxy benzoic acid. As expected, peak width varied with the retention time, which in turn varied with system pH and nature of the eluent. There were occasions when an oxyanion of phosphorus yielded more than one peak, and no satisfactory explanation for this behaviour has been found.

General comments

Examination of the effect of pH on species distribution patterns for the various organic acids studied provided only limited guidance with respect to selecting operating conditions suitable for separating mixtures containing oxyanions of phosphorus. Despite the wide range of eluents tested and pH values used, this investigation did not find any system which effectively separated mixtures of condensed phosphate anions but it did discover two alternative reagent systems for separating hypophosphite, phosphite and orthophosphate mixtures. It also demonstrated that refractive index detection could be used in analyses of this type. The same detector mode proved useful in an earlier study of the separation of sulfite, sulfate and thiosulfate.[11]

Summary—The electrochemical properties of zopiclone, an anxiolytic and hypnotic drug, have been investigated by different techniques. The compound is reduced in two 2-electron steps in the pH range 0–12. The first step, which corresponds to the reduction of the pyrazine ring, is reversible in acidic and neutral solutions. Strong adsorption phenomena accompany the reduction process in acidic and neutral media. Zopiclone can be quantitatively measured over the entire pH range using DC polarography. However, the use of differential pulse and square-wave modes for quantitative measurements is more limited due to a slope modification in the current-concentration relationship. Adsorptive stripping voltammetry can be applied to the determination of low levels of the drug at pH 9, but only short deposition times may be used because large amounts of material accumulated under stirring conditions due to fast adsorption kinetics are rapidly released from the electrode surface. Detection limits are $1 \times 10^{-7} M$ and $2 \times 10^{-10} M$ for polarography and adsorptive stripping voltammetry, respectively. Only the first wave is of analytical interest for both techniques.

Zopiclone (4-methyl-1-piperazine carboxylic acid, 6-(5-chloro-2-pyridyl)-7-oxo-6,7-dihydro-5H-[3,4b]pyrrolo-5-pyrazinyl ester) is a new derivative of the cyclopyrrolone family. This compound has a chemical structure quite different from that of benzodiazepines but exhibits similar pharmacological effects, mainly anxiolytic and hypnotic properties,[1–3] which have often been compared with those of triazolam.[4–6] The piperazinyl carbamate moiety is important for the interaction of the drug at the receptor sites.[7]

A polarographic investigation of zopiclone has been carried out using direct current, differential pulse and square-wave techniques and cyclic and adsorptive stripping voltammetry. The electrochemical properties of the pyrazine ring, which is to be considered as a probable electroactive site of zopiclone, is well documented[8–14] but only the marked influence of small substituents has been investigated. The aim of this work is to determine the redox behavior of this more substituted pyrazine derivative in aqueous solutions and to compare the results with those presented in the literature.

From a pharmacological point of view, the knowledge of the electroanalytical properties of a drug is always of interest for further applications, in raw material or in biological fluids. The optimal conditions for its quantitative determination have also been developed. To our knowledge, only gas[15,16] and liquid[17] chromatographic techniques have been applied to the determination of zopiclone.

EXPERIMENTAL

Apparatus

DC polarographic analysis was performed using a PRG 34 Tacussel instrument equipped with a three electrode cell. The potentials are referred to the saturated calomel electrode (SCE), and unless otherwise stated, the following parameters were applied: drop time: 1.1 sec; scan rate: 5 mV/sec.

DP, SW and adsorptive stripping measurements were performed using a PAR 384B Polarographic analyzer equipped with an SMDE 303A stand and a Houston DMP 40 plotter, the following parameters being employed: DP

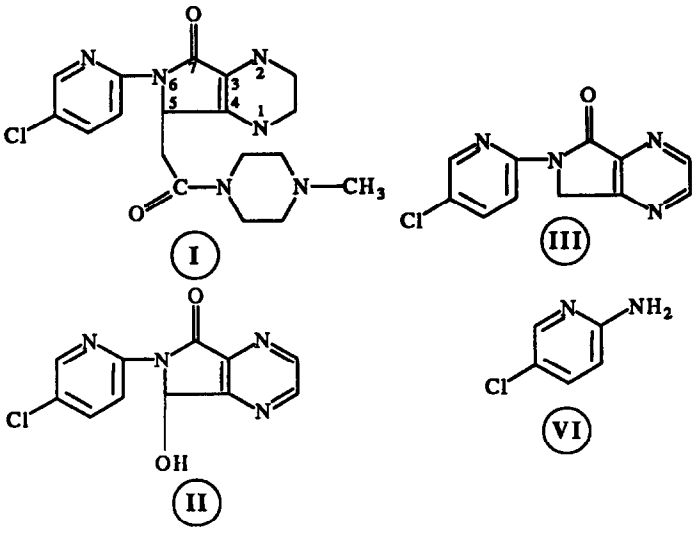

Fig. 1. Structures of Compounds Studied. I. Zopiclone (27.267 RP). II. 6-(5-Chloro-2-pyridyl)-5-hydroxy-7-oxo-6,7-dihydro-5H-[3,4b]pyrrolopyrazine (29.307 RP). III. 6-(5-Chloro-2-pyridyl)-7-oxo-6,7-dihydro-5H-[3,4b]pyrrolopyrazine (48.497 RP). IV. 2-Amino-5-chloropyridine (26.695 RP).

polarography: scan rate: 5 mV/sec, pulse height: 25 mV; SW voltammetry: pulse height 20 mV, frequency: 100 Hz, scan rate 200 mV/sec. Cyclic voltamperograms were recorded with a PAR 174A polarograph coupled with a PAR 175 programmer for scan rates up to 500 mV/sec and with a PAR 273 potentiostat monitored by an IBM XT computer for higher scan rates. These instruments were coupled with a PAR 303 and 303A stand, respectively. DP, SW and cyclic voltamperograms were plotted against a Ag/AgCl/saturated KCl reference electrode.

Reagents

Zopiclone and its precursors were graciously provided by Rhone-Poulenc, Brussels, Belgium. These compounds (Fig. 1) were used without further purification. A 0.1*M* Britton–Robinson buffer adjusted with sulfuric acid or sodium hydroxide was used, the absence of interaction between the investigated compound and each component of the buffer having been verified. A stock $2 \times 10^{-3}M$ solution, renewed daily, was prepared in 2-propanol. The working solutions were prepared by dilution of the stock solution and contained 10% 2-propanol.

RESULTS AND DISCUSSION

Influence of pH

Zopiclone was studied in the pH range 1–12. The drug is reduced at the dropping mercury electrode in two waves of about the same height (Fig. 2). Intensities of both waves decrease to about half of their initial values between pH 9.5 and 10.5 and recover their initial heights above pH 10.5. The first wave decreases slowly with a further increase in the pH. Between pH 9.5 and 10.5, three small additional waves appear before, between and after the main waves (Fig. 2).

First wave

The first wave corresponds to a two-electron transfer as indicated by controlled potential coulometry performed in both neutral and very alkaline solutions. Its half-wave potential is shifted towards more negative values with increasing pH up to pH 10, by 57 mV/pH unit (Fig. 3). A small break appears at this pH value and the slope becomes equal to 36 mV/pH unit at higher pH's.

Electrode mechanism. Logarithmic analysis of the wave in acidic medium exhibits two segments with slopes very close to 30 mV. This slope increases to 39 mV in neutral solution and 48 mV at pH 12.5, indicating that the process is reversible in acidic medium, becomes quasi-reversible at pH 7.0 and irreversible above pH 10. This behavior is confirmed by cyclic voltammetry (Fig. 4). In very acidic medium (1*M* perchloric acid), the well defined reduction peak gives rise to a re-oxidation peak but only at high scan rates, even when the scan is reversed after the first peak. The ratio i_{pa}/i_{pc} remains lower than unity, indicating an EC mechanism.

The linear increase of the reduction peak current with the square root of the scan rate and the independence of $i_p/v^{1/2}$ as a function of log

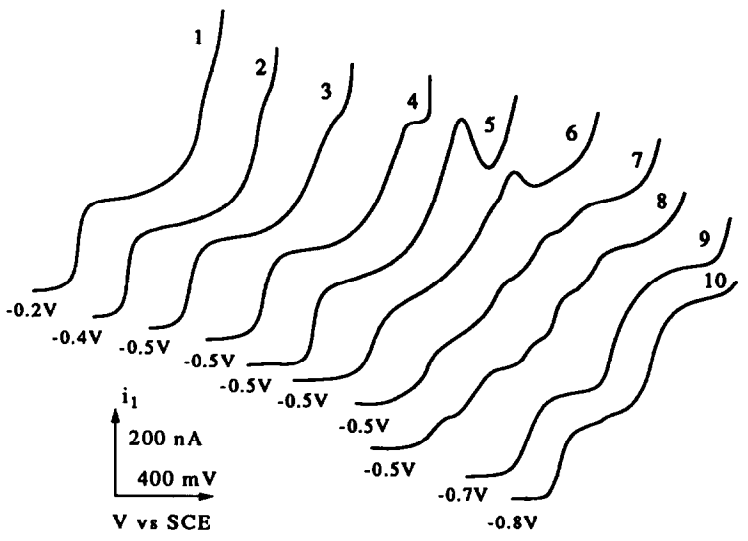

Fig. 2. DC Polarograms of $2 \times 10^{-4}M$ zopiclone in $0.1M$ Britton–Robinson buffer. pH = (1) 2.0; (2) 5.0; (3) 7.0; (4) 8.2; (5) 9.2; (6) 9.8; (7) 10.0; (8) 10.6; (9) 11.0; (10) $0.2M$ NaOH.

v shows the diffusion control of the process. However, adsorption appears at high scan rates (10 V/sec). Reversibility is confirmed by the independence of the peak potential against the scan rate.

Conducting similar experiments with solutions of increased pH shows that adsorption phenomena become more important and result from the adsorption of the reduced species. An adsorption peak precedes the reduction peak at pH 7 while the reoxidation peak becomes sharper [Fig. 4(B)]. The influence of adsorption can be minimized, but not eliminated, by addition of 40% ethanol to the solution [Fig. 4(C)]. The process remains reversible at pH 7 [Fig. 4(B),(C)] but the rate of the chemical reaction involved in the EC mechanism decreases with increasing pH and the i_{pa}/i_{pc} ratio is equal to unity at slow scan rates (< 50 mV/sec) and reaches 1.5 at higher scan rates (see below: second wave).

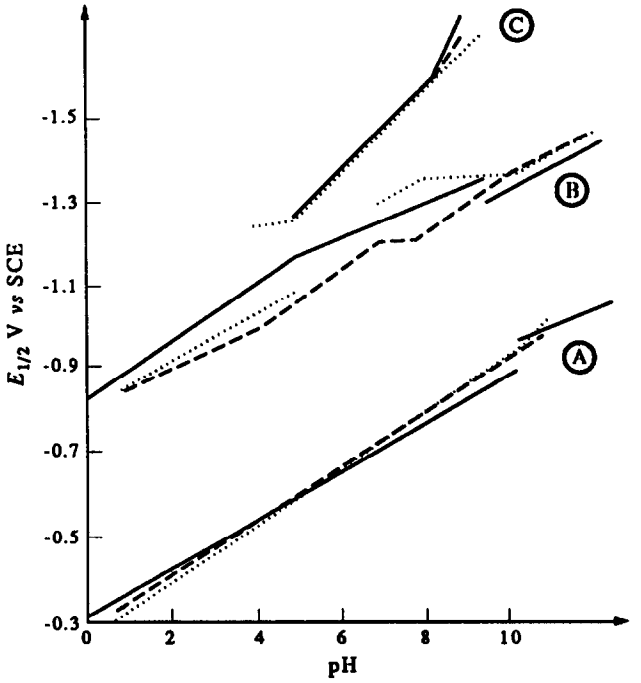

Fig. 3. Half-wave potentials as a function of pH. Zopiclone I, $2 \times 10^{-4}M$ —. Compound II, $2 \times 10^{-4}M$ · · ·. Compound III, $2 \times 10^{-4}M$ – – –. A: Wave 1; B: Wave 2; C: Wave 3.

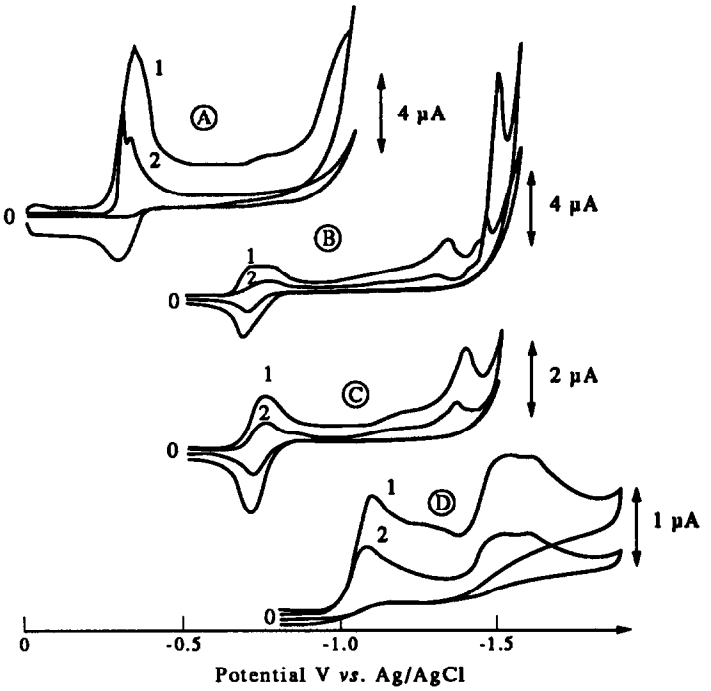

Fig. 4. Cyclic voltamperograms of $2 \times 10^{-4}M$ zopiclone. A: $1M$ $HClO_4$, (1) 500 mV/sec, (2) 100 mV/sec; B: pH 7, (1) 200 mV/sec, (2) 50 mV/sec; C: pH 7 and 40% ethanol, (1) 200 mV/sec, (2) 50 mV/sec; D: pH 12.5, (1) 200 mV/sec, (2) 50 mV/sec.

An inverse situation occurs at pH 12.5 [Fig. 4(D)]. The disappearance of the reoxidation peak and the negative shift of the reduction peak potential with increasing scan rate confirms the irreversibility established by the logarithmic analysis. The decrease of i_p *vs.* $v^{1/2}$ and of $i_p/v^{1/2}$ *vs.* log v with increasing scan rate shows a kinetic complication and the appearance of a CE mechanism. This corresponds to the reduction of the unprotonated form. Protonation takes place at the electrode surface before the electron transfer, as has been demonstrated elsewhere,[8,9] the pK value determination for zopiclone (pK = 10.25) being similar to those established by these authors for substituted pyrazines.

Reduction mechanism. The above described results indicate that the first wave can be attributed to the reduction of the pyrazine ring, giving rise to the corresponding 1,4-dihydropyrazine derivative, according to a reversible two-electron process.[10–13] It has been previously established that such a process is followed by a hydrolysis reaction of the formed 1,4-dihydropyrazine into an amino-aldehyde in acidic medium[13,14] which cannot be reoxidized [see disappearance of the reoxidation peak at slow scan rates, Fig. 4(A)]. By increasing the pH, the kinetics of the chemical reaction are decreased and reoxidation may occur, even at slow scan rates [$i_{pa}/i_{pc} = 1$, Fig. 4(B),(C)]. In alkaline solution, the process becomes irreversible due to a tautomerization reaction of the 1,4-dihydropyrazine into a less oxidizable 1,2- or 1,6-dihydropyrazine.[10,14]

Both the stability of the 1,4-dihydropyrazine and hence the reversibility of the process highly depend on the substituent on the pyrazine ring.[11,13] Electron-withdrawing substituents (pyrazinamide, pyrazine carboxylic acid) enhance the lifetime, while electron-releasing substituents (methylpyrazines) decrease this lifetime. Reversibility of this last group thus appears in a more restricted range of pH and/or scan rates.

In zopiclone, the pyrazine ring is substituted by a hydropyrrolone moiety which is itself substituted at the C5 and N6 atoms. Considering the extended reversibility of the reduction of zopiclone, as well as its reduction potential (intercept of the E–pH relationship at −0.300 V *vs.* SCE), which are similar to those of the unsubstituted pyrazine,[13] the behavior of zopiclone can be regarded as intermediate between pyrazinamide and methylpyrazine.[13] In fact, the hydropyrrolone substituent can be considered as an amido group on C3 and a methyl group on C4 of the pyrazine ring. This explains the stability and hence the wide pH range in which reversibility is observed for zopiclone.

It should be noted that substitution of the hydropyrrolone ring by the 4-methyl-1-piperazine carboxylate moiety does not modify the behavior of the first wave. This has been demonstrated by performing similar experiments on compounds II and III (E–pH relationships in Fig. 3). The main difference is in a more pronounced decrease of the first wave of compound II above pH 10.5 and its disappearance at pH 11.5.

Although most of the electrochemical characteristics of substituted pyrazines are encountered with zopiclone, two different behaviors are unusual. Pyrazine derivatives generally involve a protonation step before the $2e$–2H transfer occurs.[8-13] This appears in the E–pH relationship, the slope of which is about 90 mV/pH between pH 2 and 7. This preprotonation step does not occur or else it occurs in the bulk solution rather than at the electrode during reduction of zopiclone, since a slope of 57 mV/pH is observed between pH 0 and 10, indicating a classical $2e$–2H exchange. On the other hand, pyrazine compounds are often reduced in two one-electron steps in very acidic solutions, *i.e.*, the first wave splits into two separated one-electron waves.[10,12,13] This never occurs with zopiclone, even in 1M perchloric acid.

Second wave

Zopiclone exhibits a second wave over the entire pH range (Figs. 2 and 3). This ill-defined wave appears near the discharge of the supporting electrolyte. It becomes inhibited at pH 8 and exhibits a maximum between pH 8.5 and 10.0. Its intensity is somewhat higher than that of the first wave in acid and neutral medium and it decreases between pH 9.5 and 10.5, as does the first wave, and regains its initial value above pH 10.5. Its height remains constant when the pH is further increased. The half-wave potential of this wave is also shifted negatively with increasing pH [Fig. 3(B)] but the relationship exhibits two slopes, 67 and 41 mV/pH successively, with a break at pH 5. The potential becomes somewhat less negative above pH 10 (pK of the pyrazine ring) and then shifts by 52 mV/pH when pH is again increased.

Between pH 5 and 9 the second wave is immediately followed by a very steep third wave situated very closely to the supporting electrolyte discharge (not represented in Fig. 2). The height of this third wave is similar to that of the second wave and is constant between pH 5 and 8. It strongly decreases at pH 9 and disappears at pH 9.5. Its half-wave potential shifts negatively by 100 mV/pH with increasing pH [Fig. 3(C)]. In the presence of 40% ethanol, this third wave is completely removed and the second wave becomes better defined and of the same height as the first one.

Electrode mechanism. Logarithmic analysis of the second wave exhibits two slopes: 44 and 74 mV/log unit in acidic solutions and 50 and 68 mV/log unit in alkaline medium, demonstrating the irreversibility of the process at all pH values. Cyclic voltammetry confirms these results but brings some additional information. In acidic solutions, the second wave appears as a shoulder to the supporting electrolyte discharge current [Fig. 4(A)], but only at high scan rates (>0.5 V/sec in 1M perchloric acid, >0.2 V/sec at pH 3.25). No reoxidation peak can be seen before that of the first process. At pH 7, a flat peak corresponding to the second wave is followed by a sharp peak corresponding to the third wave [Fig. 4(B)]. This last peak disappears in the presence of 40% ethanol and the second wave becomes more defined and has the same intensity as the first one [Fig. 4(C)].

This means that the second process, developed in this last case with low interference from adsorption phenomena, also involves a two-electron transfer and that the higher intensity of the second wave as well as the presence of the third wave in the absence of ethanol result from adsorption phenomena. In fact, the third wave corresponds to the same process as the second one but from an adsorbed state. When the potential of the third wave is reached, the adsorbed molecules are desorbed and immediately reduced.

A study performed as a function of concentration shows that, if both the first and the second waves increase linearly with this parameter, the third wave appears only for relatively high concentrations. The lowest limit for which this third wave appears depends on the pH since adsorption increases with increased pH and the higher the pH, the lower will be the critical concentrations. Two peaks of similar height are recorded at pH 12.0 where adsorption problems are very low [Fig. 4(D)].

The negative shift of the peak potential with increasing scan rate confirms the irreversible character of the process. Analysis involving the peak current is not possible in acidic medium due to the disappearance of the peak at low scan rates. At pH 7, both the i_p *vs.* v and i_p/v *vs.* log v relationships show that strong adsorption

phenomena are involved but are lowered by ethanol additions. As with the first peak, the second peak exhibits a kinetic character at pH 12 due to a protonation reaction preceding the electron transfer.

Reduction mechanism. Very little information can be found about the second wave, whenever present, of pyrazine derivatives. Volke *et al.*[11] evoke a "probable" further reduction of the 1,4-dihydropyrazine ring leading to the tetrahydro derivative. Armand *et al.*,[14] working in alkaline medium, demonstrated that some 2,3-disubstituted pyrazines undergo a first reversible two-electron transfer giving rise to the 1,4-dihydro derivative, which is further irreversibly reduced to the 1,2,3,4-tetrahydro compound. Nevertheless, the phenomenon with zopiclone allows us to make some observations of the behavior of the second process, but the reduction site cannot be defined definitively.

The fact that the second peak only appears at high scan rates in acidic medium [Fig. 4(A)], meaning that time is too short to allow hydrolysis of the 1,4-dihydro derivative, shows that the second process is related to the pyrazine ring; a further reduction of 1,4-dihydropyrazine, or the reduction of another site (*i.e.*, the hydropyrrolone ring) is possible only when it is next to the intact 1,4-dihydropyrazine ring, but impossible when that ring has been hydrolyzed to the aminoaldehyde structure (in acid solution). A further reduction of the 1,4-dihydropyrazine is doubtful since such a process is irreversible and the reoxidation peak of the first process should be absent. This would mean that another site should be involved.

The structure of zopiclone allows consideration of only the cleavage of the hydropyrrolone ring. Such a reductive cleavage should occur between the C5 and N6 atoms, this bond having reduced stability in the hydro-pyrrolone ring, mainly when next to a rigid cycle (dihydropyrazine) instead of two separated groups (amino aldehyde). Such a behavior has been previously pointed out with piroxicam.[18,19] In such a case, the nature of the substituent at the C5 position should influence the reduction potential of the second wave.

In fact, the removal of the ester group (compound II) or its replacement by a hydroxy group (compound III) modifies the *E*-pH relationship [Fig. 3(B)]. Compound III remains more easily reduced than zopiclone up to pH 9.5, while compound II is reduced at less negative potentials in acidic solutions but at more negative values between pH 7 and 10.5. The wave disappears between pH 5 and 7, but the third wave remains. The third wave of the three compounds are superimposed [Fig. 3(C)], indicating that their reduction potentials are governed by the desorption process and that adsorption results from an identical part of the molecules, *i.e.*, the pyrrolopyrazine moiety.

The situation becomes more complex in alkaline medium where the second wave of each compound (I, II and III) appears at similar potentials and is shifted in the same manner with pH [Fig. 3(B)]. The first hypothesis which comes to mind is that zopiclone undergoes a hydrolysis of the ester function in alkaline solution, giving rise to compound III. This would mean that the hydroxy group has no more influence on the reduction potential between pH 10.5 and 12, in opposition to the marked influence exhibited between pH 7 and 10 [Fig. 3(B), compounds II and III]. While this hydrolysis of the ester function probably occurs, another chemical reaction would take place as indicated by the following experiments. Two samples of zopiclone were treated, respectively, with a pH 9 Britton–Robinson buffer and with 0.05*M* sodium hydroxide. Their dichloromethane extracts were submitted to thin layer chromatographic separation. Both samples show that zopiclone has completely disappeared. Neither compound II nor compound III can be detected, invalidating the above hypothesis, but aminochloropyridine (compound IV) has been formed. Chloropyridine is not detected.

A zopiclone solution treated with 0.05*M* sodium hydroxide has also been investigated polarographically as a function of pH. Two to four waves were recorded, depending on the pH, but they cannot be correlated to any wave of compounds I to III, of pyrazine carboxylic acid, nor those of pyrazinamide recorded under the same conditions. However, the first wave splits into two waves in very acidic solution and the reduction potential of this wave is shifted by 100 mV/pH up to pH 7, meaning that one or more simpler derivatives of pyrazine (*i.e.*, hydroxymethylpyrazine carboxylate) have been formed by a complex reaction involving the hydropyrrolone ring. In such a case, the second wave can no longer be attributed to the cleavage of this ring but to a further reduction of the dihydropyrazine resulting from the first electron transfer.[11,14] This would also explain the unusual positive shift in the potential of the second wave

at pH 9.5 as the pH is increased when this chemical modification occurs [Fig. 3(B)].

Influence of concentration

The influence of zopiclone concentration on the polarographic response was investigated between $1 \times 10^{-6}M$ and $2 \times 10^{-4}M$. The drug can be determined quantitatively, but the results which are summarized in Table 1 depend highly on the pH and on the applied wave form. It can be deduced from Table 1 that DC polarography exhibits a better linearity for each investigated pH and over a wider concentration range, except at pH 11. DP and SW modes generally exhibit a slope modification in this relationship due to the adsorption phenomenon occurring with zopiclone. The higher concentrations offer higher slopes in acidic media, the opposite situation occurring at pH 11. The concentration at which this break in the slope appears depends on the applied wave form.

When it can be used, the SW mode provides a higher sensitivity. Except at pH 11, only the first wave is to be considered for analytical purposes, the second one giving rise in most cases to a non-linear increase of the current with increasing concentration. This is to be attributed to the strong adsorption of the compound produced in the first reduction step in acidic and neutral solutions.

Adsorptive stripping voltammetry

Adsorptive stripping measurements have been performed on the first reduction wave. Preliminary studies have demonstrated the usefulness of the square-wave mode which provides a hundred-fold enhancement in the response.

Influence of pH. An adsorptive study performed as a function of pH shows that the peak intensity remains very low below pH 6 and does not increase linearly with either the concentration or the deposition time. Above pH 6, a well defined peak is recorded, its intensity increasing regularly up to pH 9.5. It decreases abruptly above this value due to the degradation process which takes place. The degradation product of zopiclone is not accumulated in very alkaline medium. Since the solutions are stable enough at pH 9.0 (several hours) to perform adsorptive measurements, this pH value has been selected as providing the highest sensitivity. However, in order to verify that these results are not affected by the degradation process, the experiments on deposition and concentration were repeated at pH 7 where the compound is stable (see below).

Influence of the supporting electrolyte. The nature and the concentration of the supporting electrolyte may strongly influence the voltammetric response. Table 2 summarizes the peak potential and intensity and the half-peak width for seven buffered or unbuffered media. Compared with the values obtained with sodium sulfate or perchlorate from which low adsorption interference is expected, borate and acetate buffers partially inhibit the accumulation process while tris-HCl buffer enhances the peak height. The latter was selected for further investigations.

The highest sensitivity is provided by a $0.1M$ tris-HCl concentration. The peak height decreases below $0.05M$ and above $0.3M$. The same experiment repeated using a constant ionic strength demonstrates that the addition of as low as $1 \times 10^{-4}M$ tris-HCl in a $0.1M$ sodium sulfate solution enhances the peak current by a factor of two, the intensity becoming stable above $1 \times 10^{-3}M$. However, reproducibility is not as good as that observed with $0.1M$ tris-HCl alone.

This behavior may be attributed to a co-adsorption of the buffer molecules which increases the amount of accumulated zopiclone. At high tris-HCl concentrations (above $0.3M$), the adsorption of the buffer becomes competitive and inhibits accumulation of the drug.

Influence of the operating parameters. Maximum accumulation occurs between -0.4 and -0.6 V *vs.* Ag/AgCl for both pH 7 and 9 solutions. A deposition potential of -0.6 V has been selected for both pH values.

Unusual behavior has been observed from studying the influence of the deposition time (Fig. 5). At each investigated concentration, ranging from 1×10^{-9} to $1 \times 10^{-7}M$, at pH 9 a linear relationship exists between the peak current and the deposition time up to 30 sec only, the maximum response being obtained

Table 2. Adsorptive stripping voltammetry of $1 \times 10^{-7}M$ zopiclone. Influence of the nature of the supporting electrolyte ($0.1M$), pH = 7.0, $E_{acc} = -0.6$ V *vs.* Ag/AgCl, $t_{acc} = 30$ sec

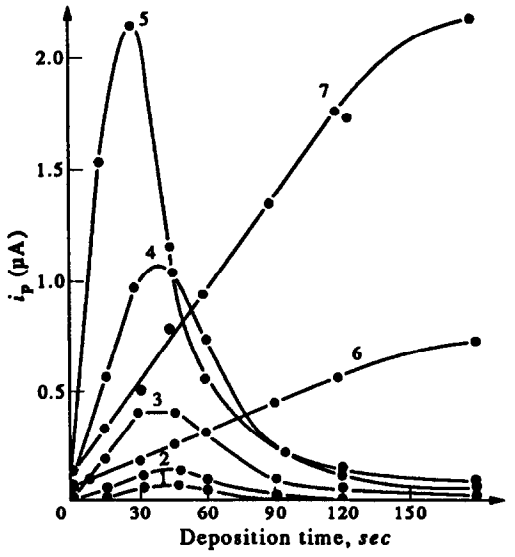

Fig. 5. Adsorptive stripping voltammetry of zopiclone. Peak current as a function of the deposition time. 0.1*M* tris-HCl buffer, $E_{acc} = -0.60$ V *vs.* Ag/AgCl, zopiclone concentration = (1) $1 \times 10^{-9}M$, (2) $3 \times 10^{-9}M$, (3) $1 \times 10^{-8}M$, (4) $3 \times 10^{-8}M$, (5) $1 \times 10^{-7}M$, (6) $3 \times 10^{-8}M$, (7) $1 \times 10^{-7}M$. 1–5: accumulation under stirring; 6, 7: accumulation without stirring.

between 30 and 45 sec. The current decreases rapidly above 45 sec to become negligible after 120 sec. A similar situation occurs at pH 7 using the same buffer; the maximum current is recorded between 30 and 45 sec and decreases after 45 sec as rapidly as observed at pH 9.

The fact that the current increases with the concentration but decreases with time indicates that the behavior is to be attributed to a release of the adsorbed material with time, not to a saturation of the electrode surface.

The same experiments repeated with a deposition step performed without stirring show that linearity is extended up to 120 sec (Fig. 5). With further accumulation time, the current levels off and does not decrease. This means that accumulation performed under stirring conditions gives rise to a metastable adsorbed layer, with a subsequent slow equilibrium provoking the release of a significant portion of the molecules instead of their rearrangement at the electrode surface to give a more stable adsorbed layer. The slower accumulation occurring in quiescent solution gives rise to a stable configuration of the adsorbed molecules. This behavior is observed at both pH 7 and 9.

The same experiment has been performed using three different supporting electrolytes: acetate buffer, sodium sulfate and sodium perchlorate. Again, the voltammetric response in stirred solution exhibits a maximum between 30 and 60 sec, depending on the nature of the supporting electrolyte, but lower currents are recorded (Table 2). This means that this unusual behavior must be attributed to zopiclone itself, not to a surface interaction of the tris-HCl buffer.

Effect of concentration. The above described behavior is also reflected in the plots of the peak current as a function of the concentration for different accumulation times. Tables 3 and 4 compare the characteristics of the calibration curves established at pH 7 and 9. It can be deduced that the neutral pH provides enhanced sensitivity (slope) but with lower precision. For each applied deposition time, a break appears in the linearity range with stirred solutions at $1 \times 10^{-9}M$ at pH 7 and at $1 \times 10^{-8}M$ at pH 9.

*Accumulation performed without stirring.

The slopes at the two pH values are similar before the break, but pH 9 provides a higher slope after the break, giving rise to a better sensitivity. This is attributed to a modification of the adsorption pathway which is strongly influenced by pH, as demonstrated above by polarography and cyclic voltammetry.

Despite the particular adsorptive behavior of zopiclone, the optimal analytical conditions can be summarized as follows: 0.1M tris-HCl buffer at pH 9 with an accumulation step of 30 sec performed at -0.6 V *vs.* Ag/AgCl under stirring conditions and a rest period of 5 sec. A 120-sec collection time without stirring provides a lower sensitivity but a higher precision. If it is required by the analysis conditions, a pH 7 tris-HCl buffer can be utilized with the same conditions but the lower limit is fixed at $1 \times 10^{-9}M$.

It is to be noted that the kinetics of the accumulation process are very fast at both pH values since very low concentrations (1 or $2 \times 10^{-10}M$) can be investigated using a short deposition time (30 sec). Most adsorptive procedures using similar convection conditions require longer times (120–300 sec) for measurements at these concentrations.[20–22] This fast kinetic behavior could be used to advantage to perform adsorptive voltammetric detection in flow injection analysis, as well as for the analysis of complex media (biological or environmental) in which an interfering compound is more slowly adsorbed.

ADSORPTIVE STRIPPING BEHAVIOUR OF MITOXANTRONE ON CARBON PASTE ELECTRODES

JUAN CARLOS CORTINA VILLAR, AGUSTÍN COSTA GARCÍA and PAULINO TUÑÓN BLANCO*
Department of Physical and Analytical Chemistry, University of Oviedo, 33006 Oviedo, Principality of Asturias, Spain

(*Received* 5 *December* 1991. *Revised* 19 *June* 1992. *Accepted* 13 *July* 1992)

Summary—The electrooxidation of mitoxantrone (MXT) on carbon paste electrodes was studied using voltammetric techniques in adsorption conditions. The analyte was accumulated at the working electrode (a carbon paste electrode) under precisely controlled mass-transport conditions and stripped electrochemically in the same solution. An electrode pretreatment is proposed which shows good reproducibility of the analytical signal (0.81%). The stripping step was studied with alternating current voltammetry providing a linear response in the concentration range 5×10^{-11} to $7 \times 10^{-10} M$ in aqueous samples. Finally, a method using the medium exchange and AC phase-selective adsorptive stripping voltammetry technique was proposed for MXT analysis in urine samples.

Mitoxantrone [Fig. 1, 1,4-dihydroxy-5,8-bis (2-(2-hydroxyethl) amino]ethyl amino) 9,10-anthracenedione dihydrochloride] belongs to a new structural class of antineoplastic agents, the anthracenediones. A large series of analogues have been synthesized with structural features predicted to favour intercalation with DNA. After initial studies, MXT was selected for clinical trials on the basis of its potency and excellent antitumour activity in mice.[1–4]

Due to the continued use of MXT in clinical trials several analytical methods have been developed for its determination. The main emphasis has been on chromatographic[5–15] and immunoassay methods[16,17] of analysis. However, some fundamental electrochemical studies dealing with the polarographic behaviour of MXT in the presence of cuprous and cupric salts have been carried out, and a probable explanation of its antitumour activity was put forward.[18] Both electron spin resonance spectroscopy and electrochemical studies have been applied to obtain a better understanding of the metabolism of MXT.[19]

The use of carbon paste electrodes for electroanalysis has gained popularity. One of the primary reasons for this is their applicability to anodic oxidations and the lower charge current involved. Such electrodes thus permit important analytical applications which are not available to the HMDE. On the other hand, the effective utility of solid electrodes is generally hampered by a gradual fouling of the electrode surface. Such loss of electrode activity is usually attributed to the adsorption of reaction products, the analyte itself, or a large variety of electroinactive organic surfactants. A slow decrease in peak current or in extreme cases complete inhibition of the electron transfer may be observed. In these cases the method cannot be used for analysis. To overcome these negative effects, the electrode surface can be treated before the measurement step to obtain a reproducible surface and therefore a reproducible peak current similar to that obtained by the HMDE.[20–24]

In this paper, the electroactivity of MXT on carbon paste electrodes (CPE) was studied using adsorptive stripping voltammetry (ADSV). As far as we know this is the first fundamental work in which the adsorptive stripping signal at a carbon paste electrode is recorded using the alternating current technique. In previous works, other authors[25–28] have reported the differential pulse adsorptive stripping voltammetry of some selected molecules but a poor reproducibility between each measurement and

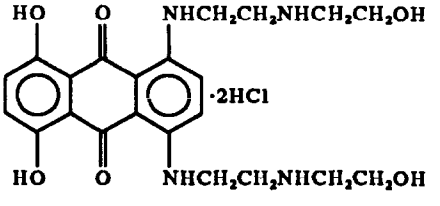

Fig. 1. Mitoxantrone structure.

*Author for correspondence.

higher detection limits were found (above $1 \times 10^{-9} M$).

As is well known, the advantage of ADSV on CPE's is that this technique is readily coupled with the "medium exchange" procedure as the accumulated species are rarely air sensitive. Using this procedure, after accumulation the working electrode can be easily transferred into a blank solution of appropriate composition, where the stripping step is carried out and the voltamperogram is recorded without interference from other non-accumulated electroactive species present in the original sample. Therefore, accumulation and stripping steps may take place under the optimum conditions for each process.[29,30] In this study the above procedure was applied to the analysis of MXT in urine samples to avoid interferences from uric acid. The results obtained showed that the proposed method constituted a valid alternative to others previously reported allowing meaningful physiological concentrations of MXT to be analysed.

This work provided the basis for an FIA method applied to the determination of MXT in urine.[31] The full automatized procedure included a voltammetric detector using AC voltammetry after adsorption of the analyte on CPE and proves to be a fast, reproducible and selective method of analysis.

EXPERIMENTAL

Apparatus

The experiments were carried out in an all-glass cell designed for a three electrode potentiostatic circuit. Linear sweep voltammetry (LSV) and cyclic voltammetry (CV) experiments were performed using a Metrohm E-611 potentiostat coupled to a Metrohm E-612 scanner. Voltamperograms were recorded on a Graphtec WX-4421 X-Y recorder. Alternating current voltammetry (AC) stripping measurements were made using a Metrohm Polarecord E-506. A carbon paste electrode was used as working electrode. The three-electrode cell design was completed with a calomel reference electrode and a platinum wire as the auxiliary electrode. A magnetic stirrer (Agimatic Selecta) and a stirring bar (1 cm long, 2 mm thick) provided the convective transport during the preconcentration step.

Reagents and procedure

MXT was kindly supplied by Lederle Laboratories Division. It is a hygroscopic dark solid normally supplied as a sterile aqueous solution containing mitoxantrone free base, with sodium chloride, sodium acetate and acetic acid as inactive ingredients. The product does not contain anti-bacterial preservatives. Solutions of MXT were prepared daily by dilution of an ampoule in demineralized water. The samples were stored in the dark at room temperature to avoid photochemical decomposition. As MXT reacts with phosphate and borate ions, several buffers (pH 3–11) composed of acetic acid/acetate, bicarbonate/carbonate were used. Alternatively perchloric acid and sodium hydroxide solutions were used when necessary. Carbon paste electrodes (geometric area 12.5 mm^2) which consisted of a teflon tube with an inner core containing a contact with a twist action, were prepared by mixing 1.8 ml of paraffin oil (Uvasol, Merck) with 5 g of spectroscopic grade graphite powder (Ultracarbon, Dicoex, Bilbao, Spain). The carbon paste was packed into the well of the working electrode to a depth of 1 mm and the surface was polished on a white paper sheet placed over a flat glass stand. All solutions were prepared using water purified by distillation and then passed through an ion exchanger. All chemical reagents employed were of analytical grade. Urine samples consisted of aliquots of pooled urine (from at least 15 healthy individuals) to which increasing amounts of MXT were added to give the desired concentrations.

Cyclic voltamperograms were recorded from $1 \times 10^{-6} M$ solutions of MXT in the pH range 0–14 using a preconcentration step of 30 sec and stirring in open circuit conditions. A fresh carbon paste surface was used for each experiment.

The preconcentration step was carried out as follows: 20 ml of buffer solution containing the desired amount of MXT and stirred at 1000 rpm until the solution was homogenous. The working electrode was then immersed into the cell and a preconcentration time in open circuit conditions was implemented. A quiescent period of 10 sec was then allowed before commencing the potential scan (the last 5 sec under electrolysis at the starting potential). Stripping voltammetric experiments in the AC mode were carried out using a fixed frequency of 75 Hz and a scan rate of 10 mV/sec, while in CV it was 100 mV/sec.

RESULTS AND DISCUSSION

Cyclic voltammetry experiments

Cyclic voltamperograms were recorded in the pH range 0–14 using the conditions outlined

above. A typical voltamperogram obtained in 0.1M perchloric acid is shown in Fig. 2, where two anodic peaks can be observed. When the cyclic scan is reversed before the second anodic peak potential is reached one can see a reduction peak corresponding to a reversible process.

The oxidation peak potentials shift to more negative values as the pH increases, following the equations:

1st process:

$$Ep/V = -5.87 \times 10^{-2}\ pH + 0.80;\ r = 0.9991$$
$$(pH = 1\text{–}14)\ (n = 13)$$

2nd process:

$$Ep/V = -6.30 \times 10^{-2}\ pH + 1.023;\ r = 0.9983$$
$$(pH = 1\text{–}13)\ (n = 12)$$

The slope was seen to be similar for both processes (Fig. 3). The first process increases at a rate of 58 mV per unit of pH, in close agreement with a reversible reaction involving two protons and two electrons.

The effect of the electrolyte support on the peak intensity was studied in order to find out the best analytical characteristics. The oxidation peak intensity shows two maximum values: in acid pH an absolute maximum and around pH 7 a relative maximum for both processes. At very alkaline pHs MXT undergoes a decomposition and all processes disappear, at pH 14 in 5 min. The relative signal improvement in acid pH was better than at other pHs (after 30 sec of preconcentration), an enhancement factor of 9.4 was obtained. Also, the difference between anodic and cathodic peak potentials is smaller

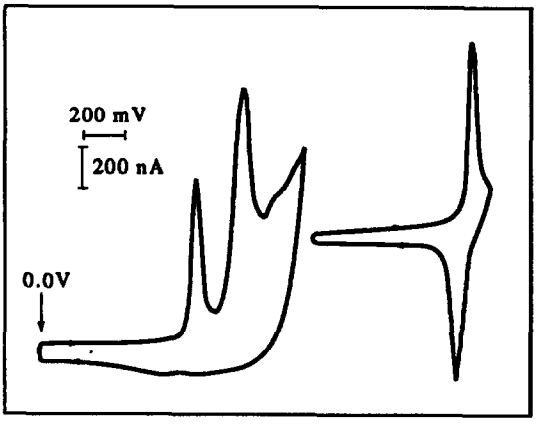

Fig. 2. Cyclic voltamperograms of $1 \times 10^{-6}M$ MXT in 0.1M perchloric acid.

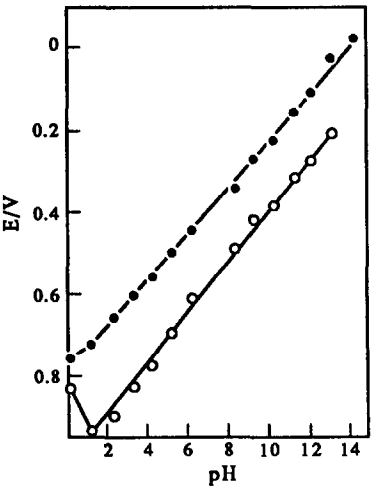

Fig. 3. Effect of pH on peak potential of the first (●) and the second(○) anodic process for a $1 \times 10^{-6}M$ MXT concentration. Scan rate 100 mV/sec.

than in other pHs (55 mV). Therefore, for all subsequent experiments 0.1M perchloric acid was chosen, as at this pH the intensity and morphology of both peaks were at an optimum.

There was no great effect on peak intensity if the preconcentration step was carried out in closed circuit conditions for a wide range of potentials assayed between −0.3 and +0.5 V.

The peak intensity of the first anodic peak increases linearly with the scan rate potential between 10 and 60 mV/sec following the equation:

$$I/\mu A = 0.012v/mV.sec^{-1} + 0.175;$$
$$r = 0.992\ (n = 5)$$

Due to the short range of scan rates where the linear dependence is found, no definitive conclusion about the effective control processes by adsorption can be made. Since from an analytical point of view it is necessary to prove that the molecule is effectively adsorbed on the electrode, the following medium exchange experiments were carried out. The CPE was immersed in a $4.5 \times 10^{-7}M$ solution of MXT for 30 sec while stirring in an open circuit. Then, the electrode was carefully cleaned and transferred to another cell containing only the background electrolyte. A cyclic voltamperogram recorded in the positive direction showed the same anodic processes as those observed when the analyte was in the cell, indicating that the drug had been adsorbed and transported to the new cell on the CPE.

When the analyte preconcentration step was carried out at a more positive potential than

that of the first oxidation peak, the subsequent scan in the negative direction in the blank cell produced a reduction peak which resembled that which had been obtained originally. From this it can be concluded that the product of the oxidation process is insoluble and that it is also adsorbed and transported on the electrode surface. Finally, a third experiment consisted of carrying out the preconcentration step in an open circuit and scanning in the negative direction. The observed reduction peak is similar, once more, to the one obtained in the presence of the analyte, but in this case the intensity of the peak was higher than in the last experiment, showing that the first product of electrooxidation is more soluble than MXT.

Electrode mechanism

In the pH ranges studied, the voltamperograms recorded show two anodic processes, the first almost reversible ($E_{pa} - E_{pc} = 55$ mV in 0.1M pechloric acid) when the scan was reversed before the second anodic process. So, one can expect that the two -OH groups are oxidized to produce the quinone which is in agreement with the 2 H^+ and 2 e^- transferred as shown by the cyclic voltammetric study and the consulted bibliography.[32,33] At higher potentials the amino aromatic groups are probably oxidized irreversibly.[34-36] Other reactions which break the molecule may occur on the electrode surface resulting in a loss of the reduction peak on the reverse scan. In order to confirm the electrode mechanism proposed, some experiments were carried out with N-methylaniline and 5,8-dihydroxy-1,4-naphtoquinone. Figure 4 shows three voltamperograms recorded using different solutions containing $6.3 \times 10^{-7}M$ MXT, $1.10^{-5}M$ N-methylaniline and $1 \times 10^{-6}M$ 5,8-dihydroxy-1,4-naphtoquinone prepared in 0.1M perchloric acid. In the case of 5,8-dihydroxyde-1,4-naphtoquinone a preconcentration step of 60 sec was carried out before starting the potential scan, since that a weak adsorption was observed previously in the study. N-methylaniline doesn't show affinity for the electrode surface.

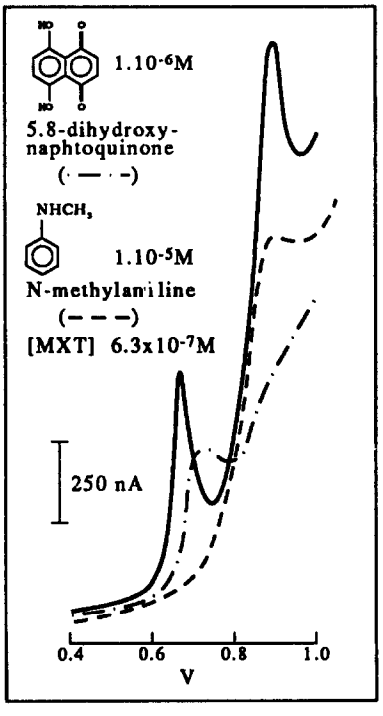

Fig. 4. Voltamperograms of $6.3 \times 10^{-7}M$ MXT, $1 \times 10^{-5}M$ N-methylaniline and $1 \times 10^{-6}M$ 5,8-dihydroxy-1,4-naphtoquinone solutions in 0.1M perchloric acid. Scan rate 100 mV/sec.

Electrode pretreatment

As previously mentioned, activation of carbon paste electrodes is an essential and fundamental part in any CPE study for analytical purposes. In our case, the analyte itself shows a strong adsorption on the electrode which is similar in both open or closed circuit conditions. Consequently, it has been shown that an *in situ* pretreatment in the presence of MXT was difficult. To clean or activate the electrode surface the following procedure was used: after each measurement the CPE was taken and immersed in another cell containing 0.1M perchloric acid. It was held for 30 sec with stirring at -1.5 V. Afterwards the CPE was dried carefully and was ready for the next measurement.

Operating in this way provided excellent reproducibility of voltammetric data and a relative standard deviation of 0.81% ($n = 10$) was obtained for the voltammetric signal. The following experiments were carried out using this activation step before each measurement.

Adsorptive stripping behaviour

In general, increasing amounts of MXT adsorbed on CPE raise the peak current. For the first process, a plot of peak current *vs.* preconcentration time for several concentrations in the range from 5×10^{-9} to $1 \times 10^{-7}M$, scanning with LSV is shown in Fig. 5. It can be seen that for short preconcentration times the peak intensity grows linearly with preconcentration time and the slopes of the linear portions are proportional to the assayed concentrations. For longer accumulation times, peak current stabil-

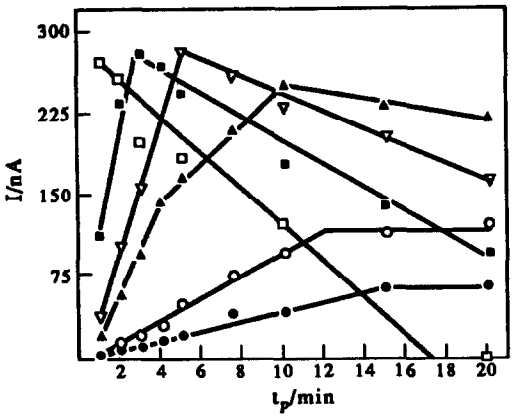

Fig. 5. Effect of preconcentration time upon weak intensity of the first anodic process for different MXT concentrations. (●) 5×10^{-9}, (○) 1×10^{-8}, (▲) 1.5×10^{-8}, (▽) 2.5×10^{-8}, (□) 5×10^{-8} and (□) $1 \times 10^{-7}M$.

ization was observed in all cases and for higher concentrations this decrease was directly proportional to the preconcentration time. This behaviour at low concentrations and low preconcentration time might be explained in terms of a linearized Langmuir isotherm. In fact it can be assumed in these conditions that the electrode surface is homogenous and no interactions between the adsorbed MXT occur. However at high solution activities, a saturation coverage of the electrode by adsorbate (*e.g.*, to form a monolayer) can occur. The decreasing peak intensity can be assumed as being due to the formation of a non-conducting layer of the analyte adsorbed on the electrode surface.

As for the first process, Fig. 6 shows a plot of current intensity *vs.* the product of accumulation time by MXT concentration. From this plot an increasing linear dependence between both parameters is found if the product assumes values less than 1×10^{-7} mol. l^{-1}. min showing that a wide range of concentrations and accumulation times could be used for analytical purposes. Therefore, for the first process a reasonable preconcentration time of 4 min meant that a large linear calibration range with fairly good sensitivity could be obtained.

Stripping with alternating current voltammetry

The first MXT anodic process is almost reversible and is of greater analytical interest. Therefore, the next experiment attempted was the stripping step on the CPE surface with alternating current voltammetry. Exploratory experiments were carried out to optimize the main parameter that controls alternating current voltammetry, that is the effect of the AC superimposed voltage. This was evaluated for a $2.5 \times 10^{-8}M$ MXT solution using a preconcentration time of 30 sec while stirring the solution in an open circuit. The same activation step was used as in the LSV technique. The results showed a linear dependence on the peak current in the range 5–20 mV following the equation:

$$I/\mu A = 0.035\ \triangle E/mV + 0.15;$$

$$r = 0.9980\ (n = 4)$$

At higher amplitude values the peak current remained constant. We also observed that the half-peak width was 55 mV for an amplitude of 20 and 45 mV for an amplitude of 10 mV, so the selectivity losses were small at an amplitude of 20 mV.

Calibration plots

The preconcentration of the drug by adsorption onto the CPE for 1 and 4 mins, in an open circuit under stirring conditions, produced calibration graphs that followed the equations:

1 min: I/nA

$$= 2.28 \times 10^{11}\ [MXT] - 255.0\ (n = 6)$$

$$r = 0.9990\ (1 \times 10^{-9}\text{–}1.5 \times 10^{-8}M)$$

Detection limit $1 \times 10^{-9}M$

4 min: I/nA

$$= 3.74 \times 10^{11}\ [MXT] + 50.4\ (n = 5)$$

$$r = 0.9990$$

1st linear range $(5 \times 10^{-11}\text{–}7 \times 10^{-10}M)$

Detection limit $5 \times 10^{-11}M$

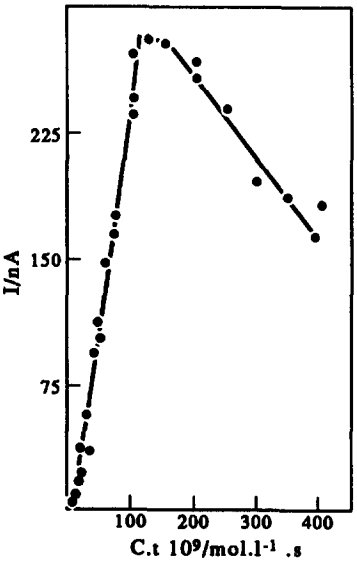

Fig. 6. Peak current *vs.* the product of accumulation time by MXT concentration.

I/nA

$= 7.29 \times 10^{10}$ [MXT] + 262.3 ($n = 4$)

$r = 0.9980$

2nd linear range (7×10^{-10}–$2 \times 10^{-9} M$

Analytical interference

In stripping voltammetry the preconcentration of MXT by adsorption can be hampered by the presence of other surfactants competing for the adsorption sites on the electrode. The influence of four different surfactants was studied using a preconcentration time of 60 sec at 1000 rpm, open circuit conditions and a MXT concentration of $1 \times 10^{-8} M$ (4.4 ppb). The stripping step was carried out with LSV. All of the surfactants suppressed the stripping signal of the drug. The anionic surfactant sodium lauryl sulphate (SLS) caused a greater decrease in the peak than a cationic surfactant such as cetyltrimethylammonium chloride (CTAC). A 29-ppm solution of SLS decreased the MXT peak current by 82% while 32 ppm of CTAC only decreased it by 62%. On the other hand, Triton X-100 (non-ionic nature) showed a strong effect, so 25 ppm caused a peak decrease of 80%. Gelatin was chosen as a model of the surfactants that may occur in biological media since it consists of a mixture of soluble proteins. 25 ppm of gelatin produced a 10% peak decrease and a 1000-fold excess (50 ppm), it being necessary to reduce the stripping peak by 36%. This could be due to the large molar mass of gelatin leading to a lower diffusion rate from the MXT solution to the electrode surface.

The effect of the molecules which interfere in biological fluids, might be reduced by adequate dilution of the sample providing samples in which the concentration of MXT is within the linear range of the method, whereas the concentration of interferents are below the threshold of interference.

Determination of MXT in urine samples

After optimization of the MXT adsorption and stripping steps, the method was applied to the determination of MXT in urine samples. The first experiment was carried out with blank urine sample, 100 μl of urine without any kind of pre-treatment was added to 20 ml of $0.1 M$ perchloric acid and then scanned anodically. The voltamperogram showed an anodic peak at the same potential as that of MXT and this was shown to be due to uric acid. The process was diffusion controlled and it was possible to avoid this interference by doing a "medium exchange" experiment, *i.e.*, the adsorption step and the stripping step were carried out in different solutions, the latter being done in $0.1 M$ perchloric acid without the drug. Following this procedure the interference caused by uric acid was removed. (Fig. 7). In five consecutive determinations of urine samples to which an MXT concentration of $5 \times 10^{-7} M$ had been added a mean concentration of $5.01 \times 10^{-7} M$ was obtained with a standard deviation of 1.51%. This was achieved by injecting 20 μl of the sample into the cell and by using a standard addition method. The estimated detection limit for a ratio s/n = 3 in urine samples following this procedure was $5 \times 10^{-8} M$.

ADSORPTIVE STRIPPING VOLTAMMETRIC BEHAVIOUR OF MITOXANTRONE ON MERCURY ELECTRODES

JUAN CARLOS CORTINA VILLAR, AGUSTÍN COSTA GARCÍA and PAULINO TUÑÓN BLANCO*
Department of Physical and Analytical Chemistry, University of Oviedo, 33006 Oviedo, Principality of Asturias, Spain

(*Received* 5 *December* 1991. *Revised* 19 *June* 1992. *Accepted* 13 *July* 1992)

Summary—The electrochemical behaviour of mitoxantrone (MXT), an important antineoplastic agent, has been studied at mercury electrodes. The nature of the process taking place at the hanging mercury drop electrode (HMDE) was clarified. The electrochemical behaviour observed was in close agreement with theoretical predictions for an adsorbed molecule which is reversibly reduced. Both the molecule and its reduced product appeared to be adsorbed at the surface of the electrode. Adsorptive stripping voltammetry has been proven to be advantageous over any other assay technique, allowing 5×10^{-11} *M* MXT to be detected. The interference arising from surfactants competing for the adsorption sites at the electrode have been studied and the possibility of MXT determination in dilute urine samples has been shown. Some interesting data, such as the MXT adsorbing surface area and the kinetic constant of the associated coupled chemistry reaction were also determined.

Mitoxantrone, 1,4-dihidroxy-5,8-bis({2-[(2-hidroxyethyl)amino]ethyl} amino)-9,10-anthracenedione (Fig. 1) is a substituted anthraquinone with strong DNA binding properties similar to the anthracycline antibiotics.[1] The drug has shown activity *in vitro* and *in vivo* against solid tumours and leukaemia.[2–4]

As far as we know the elemental electrochemical study of MXT at mercury electrodes reported in previous work does not exist.[5] Since the MXT structure has important electroactive functional groups, we have previously reported its oxidation behaviour at the carbon paste electrode[5] and this work is devoted mainly to its reduction behaviour using mercury electrodes. The effect of some parameters such as accumulation time, potential, ionic strength, *etc.*, on the MXT adsorption process was evaluated. The influence of different models of scanning potential were also studied, which included linear sweep voltammetry (LSV), alternating current voltammetry (ACV) and square wave voltammetry (SWV). The AC mode applied to the stripping of the MXT adsorbed gave the most sensitive analytical response, and the preconcentration of the drug in open circuit allowed extended linear calibration plots to be drawn. Finally, two electroanalytical methods applied to the analysis of MXT in ampoules or urine samples have been proposed. In the case of urine samples, a reliable clean up sample procedure is necessary to avoid the interference arising from naturally occurring substances in urine.

EXPERIMENTAL

Apparatus

Linear sweep and cyclic voltammetric experiments were carried out using a Metrohm E-611 potentiostat coupled to a Metrohm E-612 scanner. Voltamperograms were recorded on a graphtech WX-4421 X-Y recorder. Alternating current stripping measurements were made using a Metrohm Polarecord E-506. The square wave voltammetric measurements were obtained using an Inelesca PDC 1212 potentiostat coupled to an Inelesca GOT 1018 scanner assisted by a computer model Acer 500+. As working electrodes for the stripping experiments, a Metrohm EA-410 hanging mercury drop electrode

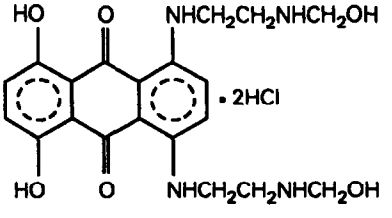

Fig. 1. Mitoxantrone structure.

*Author for correspondence.

(HMDE) and a Metrohm 663 static mercury drop electrode (SMDE) were used as indicated below. Unless otherwise stated, drop areas of 2.20 and 0.57 mm^2 were used with the HMDE and SMDE respectively. The three-electrode cell design was completed with a calomel saturated reference electrode and a platinum wire auxiliary electrode.

Reagents and procedure

The MXT in solid form (84% pure) as well as ampoule form was a generous gift from Lederle Division Laboratories, Cyanamid Iberica, and used as supplied. MXT is a hygroscopic dark blue solid supplied for clinical purposes as a sterile, aqueous solution containing mitoxantrone hydrochloride equivalent to 2 mg/ml ($4.5 \times 10^{-3} M$) mitoxantrone free base, with sodium chloride, sodium acetate and acetic acid as inactive ingredients. Stock solutions ($4.5 \times 10^{-3} M$) were prepared by dissolving the necessary amount of the solid product in water, and were kept at room temperature in the dark to avoid its crystallization and photochemical decomposition.

Several buffers composed of acetic acid, phosphoric acid and sodium hydroxide solutions were used. Also perchloric acid and sodium hydroxide solutions were used when necessary (pH below 3 and above 11). Buffers containing borate ions were excluded because they react chemically with the reduction product of MXT in such a way that the formation of the reversible pair is not allowed.

All reagents were of analytical-reagent grade and demineralized water was obtained by passing distilled water through an ion exchanger.

The background electrolyte (20 ml) was added to the cell and the dissolved oxygen was removed by passing oxygen free argon for 15 min. The stirring applied during the preconcentration step was the maximum allowed which did not produce oscillations of the HMDE or 3000 rpm in the case of the SMDE. A quiescent period of 10 sec was allowed before commencing the potential scan (the last 5 sec under electrolysis at the starting potential when the preconcentration step was done in the open circuit). Stripping voltammetric experiments in the AC mode were carried out using a fixed frequency of 75 Hz, a phase angle $\phi = 0°$ and a scan rate of 10 mV/sec.

The urine samples examined consisted of mixtures of human urine from healthy individuals. Samples consisted of aliquots of 10 ml of pooled urine to which appropriate amounts of MXT were added on order to achieve the desired final concentration.

Sample purification was accomplished by liquid–solid extraction according to the following procedure: 5 ml of urine with the desired amount of MXT previously added was passed through a reversed phase disposable C18 cartridge (Sep-Pak, Waters) previously activated by washing with pure methanol (10 ml) and water (20 ml). The effuent was disposed of, the cartridge washed with 20 ml of water containing 10% methanol, and the retained materials were eluted with 5 ml of acetonitrile:0.1M sodium hydroxide (50%).

RESULTS AND DISCUSSION

Cyclic voltammetry and nature of the electrode process

Cyclic voltamperograms were recorded from a $1 \times 10^{-7} M$ solution in the pH range 0–14. A typical voltamperogram obtained in 0.1M perchloric acid is shown in Fig. 2, where two cathodic peaks were observed; the first one, which is more useful from an analytical point of view, is found to be reversible over all pH ranges studied, when the cyclic scan is reversed before the second cathodic peak potential.

The reduction peak potential shifts to more negative values as the pH increases with different slopes and following the equations:

1st linear range:

$$Ep/V = -0.3 - 0.0844 \times \text{pH} \quad (n = 4)$$

$$\text{pH} = 0 - 3 \qquad r = 0.999$$

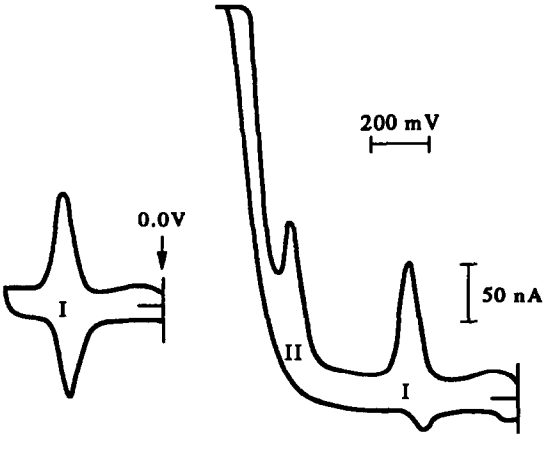

Fig. 2. Cyclic voltamperogram of $1 \times 10^{-7} M$ MXT solution in 0.1M perchloric acid.

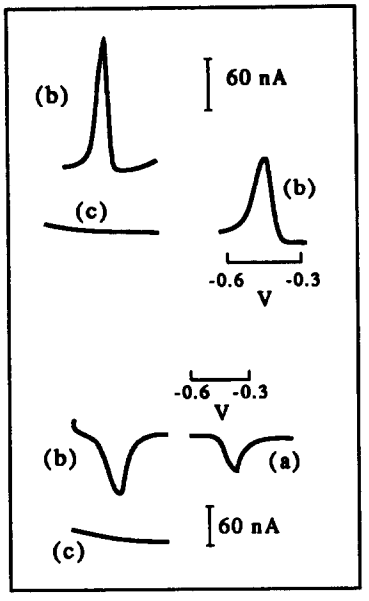

Fig. 3. Medium exchange experiments with a solution $5 \times 10^{-7}M$ of MXT in $0.1M$ perchloric acid. Voltamperograms before (a) and after (b) medium exchange. (c) Voltamperograms recorded in the new medium with a fress mercury drop.

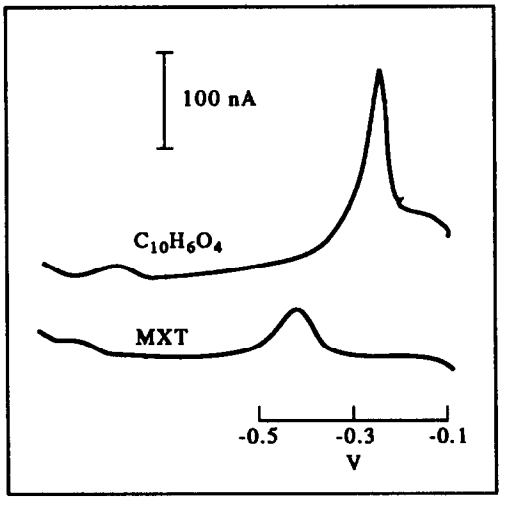

Fig. 4. Voltamperograms of $1 \times 10^{-4}M$ 5,8-dihydroxyde 1,4-naphtoquinone and $5 \times 10^{-7}M$ MXT solutions in $0.1M$ perchloric acid. Scan rate 100 mV/sec.

2nd linear range:

$$Ep/V = -0.4 - 0.048 \times \text{pH} \quad (n = 8)$$

$$\text{pH} = 3 - 12 \quad r = 0.997$$

3rd linear range:

$$Ep/V = -0.985 \quad (n = 3)$$

$$\text{pH} = 12 - 14 \quad r = 0.999$$

It can be seen that the slopes rate between the second and the first linear range is 1.75 (almost 2) indicating that in the first linear range two protons are implicated whereas in the second linear range only one proton is implicated. Similar behaviour was observed for the second process although a displacement of the potential of about 0.4 V is shown.

No strong influence of the pH on the current intensity of the first peak was found for a pH range from 0 to 6. In general, at higher pHs the peak current decreases slightly, and for this reason $0.1M$ perchloric acid was chosen for subsequent experiments.

Although the shape of the cyclic voltamperograms (CV) allows the prediction of an adsorption control of the electrode process, the effective adsorption of both MXT and its product of the electrode reaction on the HMDE was proven by carrying out two different medium exchange experiments. These were to keep the HMDE in contact with a solution $5 \times 10^{-7}M$ in MXT for 30 sec under stirring conditions and in an open circuit. Then, the medium exchange procedure was similar to that followed in previous work[5] and the CV which was started in the positive direction was recorded. The same experiment was carried out after preconcentration at a potential which was more negative than the first cathodic peak. The CV recorded after medium exchange in both cases showed identical peaks to those obtained in the MXT solutions under the same experimental conditions (Fig. 3), indicating that not only MXT but also its reduction product are adsorbed and placed on the electrode surface.

According to the experimental evidence described above, a linear dependence of the peak intensity upon the scan rate was found in the range 10–100 mV/sec and follows the equation:

$$I/\mu\text{A} = 0.53 \times v/\text{mV} \cdot \text{sec}^{-1} + 3.5 \quad (n = 10)$$

$$r = 0.998$$

$$[MXT] = 5 \times 10^{-7}M \quad \text{(SMDE)}$$

On the other hand, when the cyclic scan is reversed before the second cathodic peak potential, it was found that the cathodic peak intensity (I_{pc}): anodic peak intensity (I_{pa}) ratio decreases exponentially with the scan rate. A plot of I_{pa}/I_{pc} *vs.* the time transcurred between both electrochemical processes shows a linear dependence that follows the equation:

$$I_{pa}/I_{pc} = -1.61 \times 10^{-2} t/\text{s} + 0.9977 \quad (n = 8)$$

$$r = 0.997$$

So supposing a first order kinetic for the chemical reaction the corresponding kinetic equation is:

$$v = 0.0161 \times [\text{MXT}]$$

in $0.1M$ perchloric acid as background electrolyte.

Electrode mechanism

As reported previously, MXT shows two cathodic processes in the pH range studied. The first of these is reversible and at acid pHs corresponds to a transference of $2H^+$ and $2e^-$. The electrochemical reaction was attributed to the anthraquinone groups which are reduced to the dihydroxianthraquinone.[6-8] A ECE mechanism was found, *i.e.*, the product of the first cathodic process undergoes a chemical reaction whose products are then reduced in the second cathodic process. Other reactions which break the molecule may occur on the electrode surface resulting in a loss of the oxidation peak in the reverse scan.

In order to prove the main reduction peak of the MXT is due to the anthraquinone groups, the molecule 5,8-dihydroxyde-1,4-napthoquinone containing similar quinonic groups has also been studied. Figure 4 shows the voltamperogram of a $1 \times 10^{-4}M$ solution of 5,8-dihydroxyde-1,4-naphthoquinone prepared in $0.1M$ perchloric acid. In fact, the electrochemical process is similar but the displacement of the peak potential to less negative values occurs. This difference can be accounted for by having in mind that this molecule possesses one less aromatic ring. This results in a poorer adsorption and accordingly a higher energetic level that leads to an easier electrochemical reduction; and on the other hand, a concentration two orders of magnitude higher is necessary to obtain a similar peak intensity that comes to emphasize the better adsorption preconcentration of MXT.

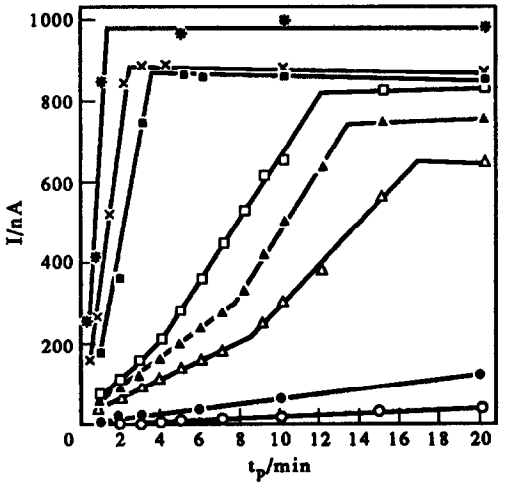

Fig. 5. Effect of preconcentration time upon first cathodic peak intensity for different MXT concentrations. (○) 1×10^{-8}, (●) $2{,}5 \times 10^{-8}$, (△) 5×10^{-8}, (▲) 7.5×10^{-8} (□) 1×10^{-7}, (■) $1{,}5 \times 10^{-7}$, (⊙) 2.5×10^{-7} y (⊖) $5 \times 10^{-7}M$.

Parameters affecting the adsorptive stripping signal

The peak current intensity of the first process is unaffected by changes in the concentration potential (range from -0.3 to $+0.2$ V) or by carrying out the preconcentration step in open circuit. So, the following experiments were carried out using a preconcentration step in an open circuit.

No significant influence on the stripping current was observed when the ionic strength of the background electrolyte was studied in the range 0.1–$0.5M$.

Accumulation curves

As is well known, the mass transport from the bulk of the solution to the electrode surface controls the overall rate of adsorption. When the mass transport is made convectively, *i.e.*, by stirring the solution, the rotation speed affects the magnitude of the stripping peak current. This effect was demonstrated for a $5 \times 10^{-7}M$ MXT solution by varying the rotation speed in the range 90–900 rpm and using a preconcentration time of 60 sec. The stripping current shows a linear dependence on the rotation speed (w) according to the equation:

$$I/\text{nA} = 4.2 \times 10^{-2} \times w/\text{rpm} + 61.24 \quad (n = 6)$$

$$r = 0.996$$

A plot of the peak current *vs.* the preconcentration time for eight different MXT concentrations, in which the preconcentration step was carried out in the open circuit under constant stirring conditions, is shown in Fig. 5. As expected, the peak intensity grows in direct proportion to increasing preconcentration time. At a certain peak current (about 200 nA), the cathodic stripping peak shifts a few millivolts to more negative potentials and becomes sharper. This sharper peak grows linearly with the preconcentration time, as shown in Fig. 6. The appearance of this phenomenon can be explained by Laviron in terms of interactions among the adsorbed molecules,[9] and has been described in other work also.[10]

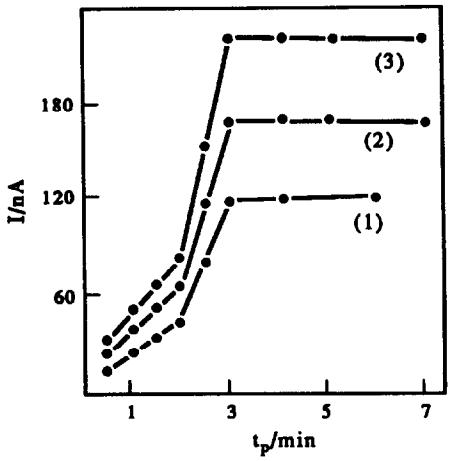

Fig. 6. Effect of preconcentration time upon peak intensity using three different electrode areas. (1) 0.29 mm², (2) 0.44 mm² and (3) 0.57 mm²

At longer preconcentration times, peak current stabilization was observed and we can assume that the electrode surface is saturated by the molecule adsorbed. So this stabilization was achieved at shorter preconcentration times for higher MXT concentrations.

The area of an adsorbed MXT molecule was calculated using a series of preconcentration experiments. These consist of studying the preconcentration time effect for three different drop sizes of the electrode (0.29, 0.44 and 0.57 mm²) and for a $5 \times 10^{-7}M$ MXT concentration. The results showed that for a preconcentration time of 180 sec a monolayer of adsorbed MXT was obtained (Fig. 6). Using Faraday's Law three values for the MXT adsorbed area were calculated (1.53, 1.66 and 1.51 nm²). The mean value was 1.57 nm² with a standard deviation of 5.2%, that is in agreement with others obtained for similar molecules using this method and reported in the literature[10] (folic acid 1.66 nm², blue methylene 1.28 nm²).

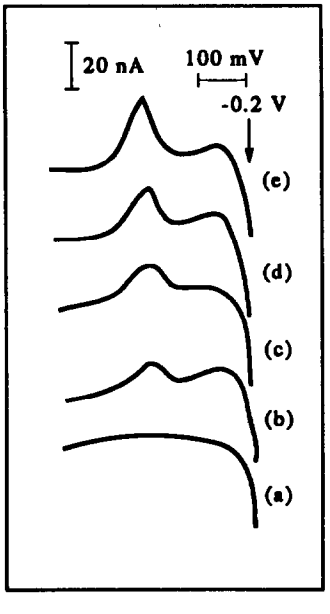

Fig. 7. Determination of MXT in urine samples. (a) Blank, (b) Addition of 1 ml of the organic extract, (c, d, e) Successive additions of 10 μl of $1 \times 10^{-5}M$ MXT standard.

Influence of other surface active compounds

The influence of some surfactants of different nature on the preconcentration-stripping process of MXT was studied in order to determine the optimum experimental conditions for carrying out adsorptive stripping measurements in the presence of a large excess of surface active compounds. A preconcentration time of 60 sec and a MXT concentration of $1 \times 10^{-7}M$ (44.4 ppb) were used in all experiments.

Competition for the adsorption sites of the electrode surface between MXT and gelatin (a known mixture of soluble proteins itself) is solved in favour of MXT; thus, the stripping response obtained in a 1000-fold excess of gelatin is 68% of its original value. The effect of an anionic surfactant, sodium laurylsulphate (SLS), and a cationic surfactant, cetyltrimethylammonium chloride (CTAC), was also studied. CTAC caused greater decreases in the peak than SLS, thus, a 2.6 ppm solution of CTAC or SLS decreased the MXT peak current to 84 and 70% of its original peak value, respectively. The cationic surfactant at bigger concentrations form a white precipitate and current peak increases. Finally, the effect of a non-ionic surfactant such as Triton X-100 was examined. A large excess of Triton X-100 (36 ppm) caused a peak increase of 32% of its original value. At the same time, a change in the peak width was observed. This sharper peak increases in direct proportion with the MXT concentration.

In conclusion, preconcentration in the presence of a large excess or surface active compounds has proved feasible, and well-defined relationships exist between the transferred charge, the preconcentration time and the analyte concentration in the background electrolyte.

Stripping of the MXT adsorbed with different voltammetric techniques

In order to ascertain the most sensitive adsorptive stripping response, several potential scan modes were assayed. Initial experiments were carried out with linear sweep voltammetry (LSV) when the analyte is preconcentrated for

one or five min at a HMDE in open circuit under a stirring rate of 1000 rpm. The intensity follows the equations:

$$I/\text{nA} = 5.94 \times 10^8\ [\text{MXT}] - 0.520\ (n = 8)$$
$$r = 0.9992$$
$$t_p = 1\ \text{min}\quad (5 \times 10^{-9}\text{–}3.5 \times 10^{-7} M)$$

$$I/\text{nA} = 2.76 \times 10^9\ [\text{MXT}] + 0.433\ (n = 4)$$
$$r = 0.9995$$
$$t_p = 5\ \text{min}\quad (1 \times 10^{-9}\text{–}1 \times 10^{-8} M)$$

The accuracy of this technique expressed in terms of the relative standard deviation is 0.53% at a concentration of $1 \times 10^{-7} M$ and using a preconcentration time of 1 min.

Stripping with square wave voltammetry (SWV)

SWV for analytical purposes was applied in the determination of other quinones at low levels by adsorptive stripping voltammetry.[11] Irreversible systems are in general, less attractive than reversible ones for the application of SWV, because of diminished sensitivity and resolution.[12] Therefore, it is possible to obtain good results with the first process of MXT.

The purpose of the first series of experiments was to optimize the parameters of the waveform, such as square-wave amplitude (Esw), potential step (Es) and frequency (f) for a MXT concentration of $1 \times 10^{-8} M$ and using 1 min as preconcentration time. Data obtained for different potential step, while maintaining other parameters of the waveform constant (Esw = 25 mV, f = 150 Hz), showed that for a value of 5 mV the peak intensity was the highest and that between 5 and 25 mV the intensity decreases and peak width increases. Then, voltamperograms for MXT were generated at seven different square-wave frequencies. A plot of peak current *vs.* frequency gave a maximum of between 150 and 165 Hz. At smaller and higher values the current peak quickly decreases. Finally, the effect of the square-wave amplitude upon peak current was shown to have a maximum of 25 mV.

These optimum values of Es and Esw are in close agreement with a reversible $2e^-$, $2\,H^+$ reduction to produce the corresponding hydroquinone.

Using these last optimized parameters and a preconcentration time of 60 sec, a calibration plot was carried out, providing a linear response between 1×10^{-9} and $1 \times 10^{-8} M$ that follows the equation:

$$I/\mu\text{A} = 9.01 \times 10^7\ [\text{MXT}] + 0.187\quad (n = 5)$$
$$r = 0.9996$$

The estimated detection limit ($s/n = 3$) was $3.2 \times 10^{-9} M$

Stripping with alternating current voltammetry (AC)

As is well known, the enhancement of sensitivity when the voltamperogram is recorded with AC mode has been theoretically predicted by Laviron for reversible redox couples with the reactant and product strongly adsorbed under Langmuir isotherm conditions.[13] Therefore, AC voltammetry was applied to the MXT stripping.

The peak current of the AC voltamperograms recorded from $5 \times 10^{-8} M$ MXT solutions, was found to be closely proportional to the superimposed voltage amplitude, ΔE, and no stabilization was observed, as expressed by the following equations:

1st linear range:

$$I/\text{nA} = 12.7 \times \Delta E/\text{mV} + 2.9\quad (n = 5)$$
$$r = 0.9997\quad (1 - 7.5\ \text{mV})$$

2nd linear range:

$$I/\text{nA} = 7.1 \times \Delta E/\text{mV} + 44.8\quad (n = 9)$$
$$r = 0.9990\quad (7.5 - 27.5\ \text{mV})$$

Finally, the effect of MXT concentration upon the peak current was studied using a superimposed voltage amplitude of 25 mV. The conditions and equations can be seen below:

$$I/\text{nA} = 5.6 \times 10^{10}\ [\text{MXT}]\text{–}39.7\quad r = 0.9999$$
$$t_p = 1\ \text{min}\quad (1 \times 10^{-9}\text{–}7.1 \times 10^{-9} M)$$
$$\text{L.D. } 1.5 \times 10^{-9} M$$

$$I/\text{nA} = 1.1 \times 10^{11}\ [\text{MXT}] + 3.5\quad r = 0.9995$$
$$t_p = 5\ \text{min}\quad (5 \times 10^{-11} - 2 \times 10^{-9} M)$$
$$\text{L.D. } 6.3 \times 10^{-11} M$$

Analytical applications

The first of these was the MXT determination in ampoules. A standard addition method using a stock solution $6.3 \times 10^{-3} M$ MXT was used. No preconcentration step was carried out. In these conditions, a linear calibration was done between 7.87×10^{-7} and $7.87 \times 10^{-6} M$, in which

the intensity *vs.* MXT concentration follows the equation:

$$I/\text{nA} = 5.9 \times 10^6\ [\text{MXT}] + 0.2 \quad (n = 7)$$

$$r = 0.9997$$

So, an adequate ampoule dilution was needed (5 μl in 20 ml 0.1M perchloric acid) for to work in the above linear range.

In five consecutive determinations, a mean concentration value of $5.04 \times 10^{-3}M$ was obtained, with a standard deviation of 1.37%.

The MXT determination in urine samples was carried out following the previously mentioned clean-up procedure and 1 ml of the organic extract was injected in 20 ml of 0.1M perchloric acid. A standard addition method was used and the voltapermograms recorded are found in Fig. 7. The recovery of the method was established by processing five urine samples to which MXT had been added and established at $94 \pm 12\%$.

SANDWICH-TYPE FLOW-THROUGH FIBER-OPTIC CELLS FOR OPTICAL ABSORBANCE MEASUREMENTS

PURNENDU K. DASGUPTA,* HARVEY S. BELLAMY and HANGHUI LIU
Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 10 *July* 1992. *Accepted* 10 *July* 1992)

Summary—The sandwich cell described by Pavon *et al.*[1] and a similar sandwich cell, except with angled (45°, confocal) single strand optical fibers and a conventional Z-type cell of 6-mm path length have been studied with respect to their performance for absorbance detection. Both sandwich cells show less susceptibility by one order of magnitude to artifact absorbance signals from RI changes than the Z-cell. The light throughput in the sandwich cells increase by an order of magnitude when an inert metallized reflector is used and this improves S/N. The overall light throughput is substantially greater for the angled entrance single strand fiber optic cell rather than the cell with the bifurcated fiber optic. Attainable limits of detection with these cells appear to be related to the pathlength for the cell dimensions studied.

Pavon *et al.*[1] have recently described in this journal a universal sandwich membrane flow-through cell which can be used for spectrophotometric or chemiluminescence measurements. For absorption measurements, light conducted by one leg of a bifurcated fiber optic cable is brought into the cell through the common leg, passes through the test solution, is reflected by a Teflon^R plate and is carried out back to a detector through the other leg of the fiber optic [Fig. 1(a)]. In some applications, the Teflon plate may be replaced by a porous hydrophobic membrane that can be part of a gas diffusion or phase separation device integral to a flow injection analyzer.

The authors rightly point out that the great virtue of this cell is its simplicity. This results in turn in robustness, and ease of construction, cleaning and repair. They have also indicated its relative freedom from bubble entrapment problems. The emphasis was placed on the versatility of the design in manifold applications rather than what performance limits can be expected. From a practical viewpoint of flow-through optical detection (whether for liquid chromatography or for flow injection analysis), the majority of applications involve straightforward optical absorbance measurement without gas diffusion or phase separation. We believe that the cell design described by Pavon *et al.*[1] is an important advance. Therefore we believe further that it is important to determine the performance limits of such a cell optimized for absorbance measurements and compare the same to the performance of flow-through cells of more conventional design and dimensions. It is of considerable interest, for example, to determine if the short path length of the cell results in a proportionate decrease in the attainable limit of detection (LOD, in terms of concentration), and the quantitative degree to which artifact signals from changes in refractive index may be reduced in this cell.

The purpose of the present note is to address these issues.

EXPERIMENTAL

The universal sandwich cell of Pavon *et al.*[1] was obtained in its commercial version from Alitea U.S.A. (Medina, WA, U.S.A.). This cell was used with a bifurcated fiber optic (common leg bundle diameter 1.6 mm, individual leg bundle diameter 1.1 mm; Dolan-Jenner Industries, Woburn, MA, U.S.A.). Reflective Mylar film (175 μm thick, Marlin P. Jones and Associates, Lake Park, FL, U.S.A.) and transparent Kel-F film (175 μm thick, American Durafilm Co., Natick, MA, U.S.A.) were obtained as indicated. Metallic aluminum was deposited on one side of the Kel-F film by vacuum deposition to form a highly reflective flexible mirror with an inert surface.

A variation of the Alitea sandwich cell was constructed by replacing the original cell front block FB (Fig. 1) with a different block in which

two 1.0-mm holes were drilled at oppositely inclined angles [see Fig. 1(b)] to accommodate 1.0-mm diameter ESKA polymeric single strand optical fibers (Edmund Scientific, Barrington, NJ, U.S.A.) that were polished at the termini and ended flush at the interior surface of FB. The fibers were held in place by epoxy adhesive and jacketed outside with black heat-shrink poly(vinylchloride) tubing. The spacing between the fibers was such that they were confocal at the reflector surface. Experiments with both the original and the modified Alitea cell were conducted with the mylar/Kel-F reflector in place of the Teflon^R reflector supplied with the cell, except as mentioned. A third cell, used for comparison, utilized the common Z-geometry with illuminated dimensions of 6 mm × 1.0 mm ϕ. The cell was constructed of opaque poly(ether ether ketone) polymer with optically flat glass windows and also utilized fiber optic to transmit light back and forth from the cell. This latter cell has been described in more detail elsewhere.[2]

The same electronic and optical arrangement was used to test all three cells (Fig. 2). Except as stated, the light source was a 605-nm high brightness light emitting diode (LED, Stanley HAA5566X, AC Interface, Los Angeles, CA) driven by a 40-mA constant current source. The LED was referenced on the backplane by a photodiode R (S2007, Electronic Goldmine, Phoenix, AZ, U.S.A.) and the reflected/transmitted light was detected by photodiode D, identical to R. Both photodiodes were mounted on a circuit board containing a log ratio amplifier integrated circuit chip (LOG100JP, Burr-Brown, Tucson, AZ, U.S.A.). The optical fibers were directly coupled to the photodiodes. The optoelectronic assembly was enclosed in a metallic, essentially light tight enclosure. The cell and electronics were then further put in a 0.25″ thick-walled brass box to minimize external electromagnetic noise. Power ($\pm$12 V) was supplied by a wall-mounted supply and the amplifier was operated with a fixed gain of 5 V/absorbance unit.

The test arrangement consisted of a pneumatically pressurized reservoir pumping a carrier liquid at 1.1 ml/min through a loop injector (loop volume *ca.* 110 μl), a conduit (0.75 × 750 mm) and the detector. Experiments with bromothymol blue (BTB) were conducted by injecting various concentrations of the alkaline test solute (0.12–100 μg/ml) into an alkaline carrier. Refractive index effects were studied by injecting 50% (v/v) aqueous ethanol into a water carrier.

RESULTS AND DISCUSSION

Increasing light throughput

Replacing the white Teflon^R backplate with a metallized reflector increases light throughput by a factor of 8–10 as evidenced from the detector photocurrent. This results in improved signal/noise, particularly when the incident light intensity is low. For example, for a blue LED emitting at 470 nm the light output is very low and the system noise level was observed to be inversely related to the detector photocurrent. For direct photometric measurements where a membrane is not required, we therefore recommend the use of a metallized reflector. A Kel-F film (transparent down to *ca.* 210 nm) is to be preferred if aggressive reagents/solvents are to be used. Indeed, further use of such a film as the entrance window to the cell (placed between FB and S, Fig. 1, with appropriately

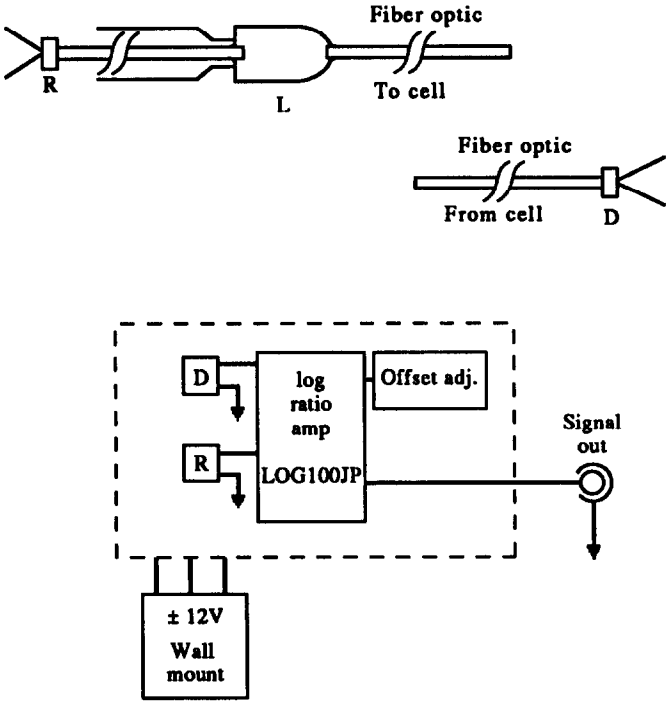

Fig. 2. Optoelectronic test arrangement. L: Light emitting diode; R, D: Reference and Signal Photodiodes.

placed holes punched in the flow path) can serve to prevent direct contact of the fiber optic to the test solutions.

Path length and detection limits

With a 1/32 in. (0.75 mm) spacer, the effective path length of the cell in Fig. 1(a) was 1.5 mm. The computed or nominal path lengths of all three cells studied are listed in Table 1 along with the observed performance parameters. The linear slopes for calibration with BTB correspond reasonably well with the anticipated path lengths, as may be expected. The slightly lower value of linear r^2 for the conventional geometry cell probably results from the higher absolute absorbance values measured by this cell and the lack of perfect correspondence between the relatively broadband emission of the LED and absorption by BTB. The absolute noise levels appear to be related to the overall light throughput for each cell rather than to the path length. In this respect, the angled entrance cell with the single strand fiber optics appears to do a much better job than the bifurcated fiber bundle. With water flowing through each cell, detector diode photocurrents were 45 nA and 360 nA for cells 1(a) and 1(b), respectively. Overall the angled cell thus results in a somewhat better LOD. The longer pathlength of the conventional cell allows it an LOD even lower. The absolute noise levels of the Z-cell and the angled entrance sandwich cell are the same, thus the detection limit is inversely related to the path length. However, quite respectable LODs are obtained by either sandwich cell.

The illuminated volume of the Z-cell is 4.7 μl. In the sandwich cells, the distance to the reflector is small, comparable to or less than the aperture of the light entrance/exit. Thus, if we presently ignore the lateral diffusion of light, the illuminated volumes are 1.5 and 1.3 μl for the straight and angled light entrance sandwich cells, respectively. Doubtless, the actual illuminated volume will be somewhat larger, but this is still very respectable.

Both sandwich cells were found to be immune to bubble entrapment problems.

Refractive index effects

When the injected fluid element has a different refractive index (RI) from that of the carrier stream, virtually all flow-through cells used for optical absorbance measurements produce an artifact signal not related to true absorption. Betteridge *et al.*[3] were the first to clearly illustrate that this occurs because the moving bolus of a fluid element of different RI forms a dynamically changing lens that affects the light transmitted through the illuminated volume. The degree to which a cell is susceptible to

Table 1. Performance comparison of cell designs

	Sandwich cell, perpendicular light entrance/exit	Sandwich cell, angled light entrance/exit	Z-geometry conventional cell
Nominal or calculated pathlength mm	1.5	2.1	6.0

‡50% ethanol injected into water carrier in a FIA system, amplitude of signal from positive to negative excursion.

producing such artifact RI signals is dependent on the cell geometry—a large value for the ratio of the physical path length to the bore (called the aspect ratio) results in an increase in RI sensitivity. By imaging the source on the exit window with focusing optics and using tapered cell construction (light exit diameter < entrance diameter) it is possible to greatly reduce RI sensitivity,[4] albeit it cannot be eliminated altogether. It is also possible to correct for the artifact RI signal by using a second wavelength as a reference.[5] Nevertheless, it would be desirable to reduce the intrinsic sensitivity of a cell to RI changes in the first place. Consideration of the principles laid out by Betteridge *et al.*[3] clearly indicate that as long as the aspect ratio is not overly large (causing light loss to the cell wall), if the incident light goes not just through a single lens element but also through a second lens element oppositely placed, the RI effect can be largely cancelled. In previously unpublished work, we have observed that RI artifacts are indeed greatly reduced in a T-type cell geometry where the source and detector optical fibers are placed in the opposing arms of a tee. In this arrangement, the fluid enters through the short arms of the tee and flows at equal rates around and past the opposing fibers. Opposing lenses are thus created in the illuminated volume by a transient element of a different RI. The reflective sandwich cell of Pavon *et al.*[1] does this in a far simpler and elegant fashion, passing the light through the same optical element in two directions. The great reduction in RI sensitivity compared to a conventional cell is illustrated in Fig. 3. Note that dispersion is very limited in these experiments and the effects are larger than what would be observed in a typical analytical system where the injected plug will undergo greater dispersion in the carrier. While the RI artifact signals appear complex, they are nevertheless highly reproducible. Because alcohol has a refractive index closer to glass (or acrylate fiber) than does water and the overall dispersion in the system is low, the dominant feature is a negative absorbance signal because the presence of alcohol results in less reflection loss at the fluid–fiber or fluid/window interface.

The response of the angled light entrance sandwich cell is particularly complicated apparently because the injected bolus sequentially affects the probe volume of each of the fibers. However, the overall amplitude of the response is essentially the same as that of the original sandwich cell when the greater path length of the angled entrance cell is taken into account.

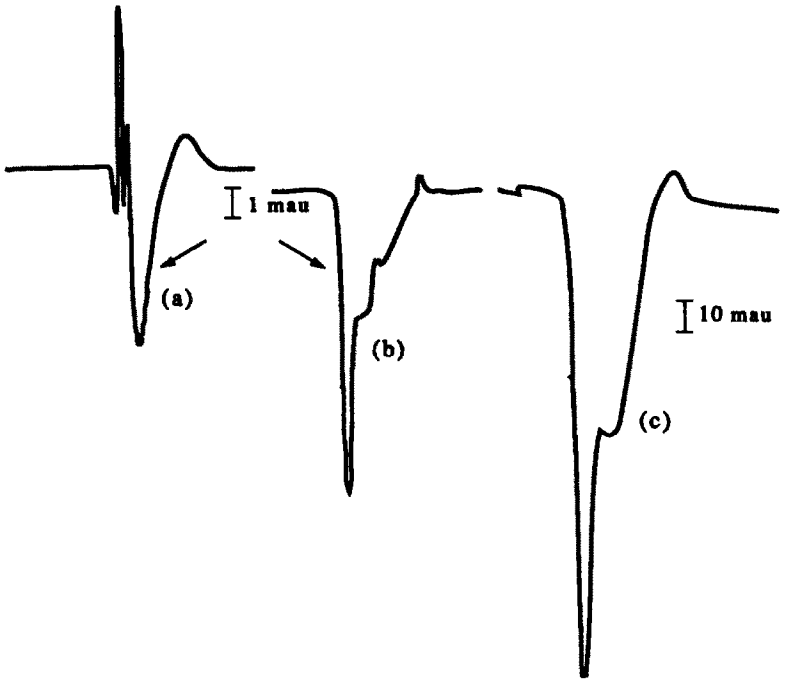

Fig. 3. Artifact absorbance signal arising from the injection of 50% ethanol into a water carrier. (a) Angled light entrance sandwich cell, (b) perpendicular light entrance sandwich cell, (c) Z-configuration cell. Note the order of magnitude different scale in (c).

CONCLUSIONS

In summary, the cell described by Pavon *et al.*[1] combined with a metallized reflective element provides attractive performance in terms of absolute concentration sensitivity, susceptibility to bubble entrapment and RI artifacts and ease of construction and cleaning. In its conceptually simplest embodiment, a thin-walled transparent conduit of glass or silica can be provided with in/out connecting tubes and an opaque enclosure, metallized on one exterior half with a bifurcated fiber optic probe from the other half. If measuring the exact dispersion patterns of a bolus without imposing the influence of the cell itself is important, such a design is expected to produce minimum changes in the flow pattern. The original sandwich design is more robust, however, and may be modified to have flow entrance/exits through the sides of the spacer S to achieve a no-disruption flow geometry. As to the single strand fiber optic pair angle light entrance/exit configuration, it is not a new concept.[6,7] Construction is somewhat more involved than the perpendicular geometry sandwich cell but otherwise it may be more attractive where source light levels are low or in uv applications where single strand 1-mm core silica fibers not only directly provide an inert window but are substantially less expensive than the corresponding bifurcated fiber optic bundles.

Acknowledgement—We thank Alitea U.S.A. for the gift of the sandwich cell. This work was supported by the Office of Basic Energy Sciences, U.S. Department of Energy through DE-FG05-84ER13281. However, this manuscript has not been subject to review by the DOE and no endorsement should be inferred.

APPLICATION OF STANDARDLESS ANALYSIS IN GRAPHITE FURNACE ATOMIC ABSORPTION SPECTROMETRY: DETERMINATION OF CHROMIUM

YANSHENG ZHENG* and XINGGUANG SU
Department of Chemistry, Jilin University, Changchun 130023, P.R. China

(*Received* 15 *May* 1992. *Revised* 9 *July* 1992. *Accepted* 10 *July* 1992)

Summary—Influences of atomization temperatures on the characteristic mass and the atomic absorption coefficient of chromium were studied. The experimental results show that the values of characteristic mass have appeared to be stable to better than 10% when the analyte is atomized in the range of 2500–2800°. The standardless analysis was applied to the determination of chromium in standard sediment and geochemical reference samples and satisfactory results were obtained.

The idea of standardless or absolute analysis[1–4] has attracted attention of spectroscopic workers ever since Walsh's first paper on atomic absorption spectroscopy.[5] There are now several approaches that have been proposed for providing graphite furnace conditions approximate to those that are theoretically required for absolute analysis. Typically, these devices have been called "constant temperature furnaces", a name that seems to have been proposed by Woodriff.[6] However, the Woodriff furnace was very difficult to use for real analysis. At present, in discussions of the development of graphite furnace atomic absorption spectrometry (GFAAS), it is worth while to speak of the method which is known as the stabilized temperature platform furnace.[7] With this system, it has been demonstrated that it is possible to control the experimental conditions so tightly that a unique and constant calibration curve can be assumed as valid. However, any change of sample composition and the formation of stable molecules can be a source of larger errors for application of standardless analysis. Therefore, it is an important condition that a matrix modifier should be used to eliminate interferences for application of standardless analysis in real samples.

In atomic absorption spectrometry, the transient atomic absorption signal of a spectral line is the result of the time-dependent density distribution of the analyte atoms in the analysis volume. The equation which has been derived for GFAAS[1,2] is

$$A(t) = \frac{0.432\sqrt{4\pi \ln 2}e^2 g_i}{m_e c^2 Z(T)\Delta\nu_D s} \times \exp(-E_i/kT)\gamma'\delta f H(a,\omega)\, N(t) \quad (1)$$

Here m_e and e are the mass and the charge of the electron, c is the velocity of light in vacuum, f is the oscillator strength, g_i and E_i are the statistical weight and the energy of the lower level for the analytical line, γ' is a coefficient accounting for hyperfine splitting in the analytical line and the Doppler line width in the light source, δ is a correction factor for adjacent lines in the light source spectrum, $Z(T)$ is the partition function at temperature $T(K)$, k is the Boltzmann constant, $H(a,\omega)$ is the Voigt integral for the point of the absorption line centour distant from the line centre by $\omega = 0.72a$ (here a is the damping constant of the Voigt profile), s is the cross section of the tube, $N(t)$ is the total number of free analyte atoms in the analysis volume at time t.

The atoms need not be distributed homogeneously over the tube length, but they must maintain a homogeneous distribution in the plane perpendicular to the light beam, because otherwise the $A(t)$ measured will not be linearly related to $N(t)$.[8,9] The constant

$$K = \frac{0.432\sqrt{4\pi \ln 2}e^2 g_i \exp(-E_i/kT)\gamma'\delta f H(a,\omega)}{m_e c^2 Z(T)\,\Delta\nu_D} \quad (2)$$

will be called the atomic absorption coefficient.

*Author for correspondence.

In graphite furnace atomic absorption spectrometry, the sensitivity is usually expressed as the characteristic mass (m_0), *i.e.*, the mass of analyte in picogram corresponding to a peak area of 0.0044 $A \cdot s$. As long as the removal of free analyte atoms from the furnace is a first order process, we get for the peak area absorbance (A_i):

$$A_i = KN_0\tau_R/s \quad (3)$$

here N_0 is the total number of analyte atoms deposited in the furnace and τ_R is the average residence time of atoms in the optical path.

We recall that

$$N_0 = m \cdot N_A/M_a \quad (4)$$

Here m is the analyte mass, N_A is the Avogadro number, M_a is the molar mass of the analyte.

Substituting equation (4) into equation (3), we come to

$$A_i = KN_A\tau_R m/sM_a \quad (5)$$

For an absolute analysis, the constant K in equation (2) should be obtained from universal constants. However, it is possible to obtain τ_R experimentally if the process of atom generation is fast in comparison with the removal process.[8,10,11] Therefore, for all practical purposes it is more convenient to measure K in equation (5) from a known quantity of analyte, as is done for the measurement of the molar absorptivity in UV–Vis molecular spectroscopy. The characteristic mass (m_0) was calculated from the mean peak area from the following equation:

$$m_0 = (0.0044/A_i)m \quad (6)$$

Here m is the mass of analyte in picograms for the particular element. It can be seen from equation (5) that the relation between K and m_0 can be expressed as

$$K = 2.30 \times 10^{-14}M_a r^2/m_0\tau_R \quad (7)$$

Here r is the tube radius. If we assume that the temperature in the furnace is constant and that the removal proceeds exclusively via diffusion through the graphite tube ends, the residence time can be expressed as:

$$\tau_R = l^2/8D \quad (8)$$

Here l is the tube length and D is the diffusion coefficient.

Substituting equation (8) into equation (7), we come to

$$K = 1.84 \times 10^{-13}M_a Dr^2/m_0 l^2 \quad (9)$$

In this paper, the influences of atomization temperatures on the characteristic mass and the atomic absorption coefficient of Cr were studied. The method of standardless analysis was applied to the determination of chromium in standard sediment and geochemical reference samples; satisfactory results were obtained.

EXPERIMENTAL

Apparatus

A Hitachi 180–50 atomic absorption spectrometer with a GA-3 graphite furnace was used. Pyrolytically coated graphite tubes (made in China) and solid pyrolytic L'vov platforms and pyrolytic V-shaped boats[12] (made in our laboratory). The size of the graphite tubes used in our experiments is $r = 2.35$ mm and $l = 30$ mm. The slit width was 1.3 nm. A Cr hollow cathode lamp (made in China) was used as a light source and operated at 10 mA. A deuterium arc background system was used throughout. N_2 was used as the purge gas, due to its lower cost than Ar at a flow rate of 150 ml/min and the purge gas was stopped during the atomization step. The 357.9 nm line of Cr was employed for all measurements. The absorption signals were recorded with an XWT-164 (made in China) strip chart recorder. Sample solution was injected into graphite tube with a 20 ml Eppendorf micropipette. The temperature of the furnace was corrected using a MT-2 optical pyrometer (made in China). The graphite furnace operating parameters were as follows: dry 80–120°, 30 sec; ashing 800°, 30 sec; atomization 2700°, 7 sec; cleaning 2800°, 3 sec.

Reagents

Chromium stock solution (1 mg/ml) was prepared by dissolving a suitable amount of $K_2Cr_2O_7$ (analytical reagent grade) in quartz sub-boiling distilled water. The working standards were prepared by appropriate dilution with water prepared in a sub-boiling still.

A 5%(w/v) solution of the ammonium salt of EDTA was prepared by dissolving 5.00 g of EDTA (analytical reagent grade) in sub-boiling distilled water and adding 15 ml of 25% aqua ammonia (analytical reagent grade) and then diluting to 100 ml with water.

Procedure

Standard sediment and geochemical reference samples (made in China) were used in this study. Transfer a weighted amount of the sample into

a polyfluorotetraethylene crucible usually 0.1–0.2 g, carefully add 5 ml and 3 ml of concentrated nitric and perchloric acids, respectively. Heat on a sand bath until near dryness, again add 3 ml of perchloric acid, 5 ml of hydrofluoric acid and 0.5 ml of sulphuric acid and continuously heat to dryness. The residue dissolves in sub-boiling distilled water. Add 0.5 ml of 5% (w/v) ammonium salt of EDTA as a matrix modifier and make the final volume to 25 ml for the determination of chromium by GFAAS.

RESULTS AND DISCUSSION

Influences of atomization temperature on m_0 *and* K

There are parameters influencing the stability of standardless analysis by graphite furnace atomic absorption spectrometry in which the temperature of the atomization step is a main factor.[13] Frech and Baxter[14] have studied the temperature dependence of atomization efficiencies of some elements in the graphite furnace. They pointed out that the atomization efficiency for most elements reaches a plateau, often in the higher temperatures region. We observed the influences of atomization temperatures on the experimental values of m_0 and K when the sample was evaporated from the wall, using the platform and the V-shaped boat techniques. The results are listed in Table 1.

As shown in Table 1, the influences of atomization temperatures on the experimental values of m_0 and K showed basically the same tendency when the samples were evaporated in three different ways. The value of m_0 decreased with an increase in the atomization temperature, and then reached a stable value after 2500°. The stability of m_0 values obtained by vaporizing of the three different ways appeared to be better than 10% in the range of 2500–2800°. However, the m_0 values are the smallest in the V-shaped boat furnace and the m_0 values in the platform furnace are less than that for the wall of the furnace at temperatures higher than 2600°. On the other hand, the value of K increases with increasing atomization temperature in the range of 2200–2800°.

Standardless analysis of Cr

It can be seen from Table 1 that the values of m_0 for Cr appeared to be stable to better than 10% when the analyte was atomized in the range of 2500–2800°. Therefore, we investigated the determination of Cr without standards. The determination of Cr in the standard sediment and geochemical reference samples by the three

methods with 2%(v/v) ammonium salt of EDTA as matrix modifier was carried out. The analytical results are listed in Table 2. They indicate that standardless analysis applied to determination of Cr in practical samples provides satisfactory results. But it must be emphasized that a frequent check of characteristic mass will be a key link which assures accurate analytical results and that use of a matrix modifier to eliminate the interferences will be a necessary condition for application of standardless analyses in a practical sample.

ADSORPTIVE STRIPPING MEASUREMENTS OF TRACE ALUMINUM IN THE PRESENCE OF CUPFERRON

JOSEPH WANG,* JIANMIN LU and ROSSI SETIADJI
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 30 *June* 1992. *Revised* 8 *July* 1992. *Accepted* 8 *July* 1992)

Summary—The adsorptive collection of the aluminum complex with cupferron is exploited for developing a highly sensitive stripping procedure for trace aluminum. Optimal experimental conditions include the use of $2 \times 10^{-4}M$ cupferron in PIPES buffer (pH 7.0), an accumulation potential of -0.40 V and a linear potential scan. With controlled accumulation for 2 min, a detection limit near 30 ng/l. aluminum is obtained. The relative standard deviation (at 5 μg/l.) is 2.9%. Possible interferences are evaluated. The analytical performance compares favourably with that of early adsorptive stripping schemes for aluminum.

Because of the environmental and biological significance of aluminum, a highly sensitive method is required for its reliable measurement. The extremely negative reduction potential of aluminum makes its direct voltammetric quantitation difficult. Indirect polarographic schemes, based on the distinct reduction wave of aluminum, in the presence of di-o-hydroxyazo dyes, have thus been developed (1–3). It is possible to couple this redox behavior with the spontaneous interfacial accumulation of the aluminum/azo-dye complex for developing a highly sensitive adsorptive stripping procedure.[4] A drawback of this procedure is the slow chelate formation that requires a 10-min heating period at 90°. The need to heat the sample (after the ligand addition) has been obviated through the use of another reagent, 1,2-dihydroxyanthraquinone-3-sulphonic acid (DASA).[5] The resulting adsorptive stripping voltammetric procedure permits quantitation down to the nanomolar level, but suffers from interferences due to coexisting zinc and antimony ions.

The present paper describes a highly sensitive adsorptive stripping procedure for determining aluminum by adsorption accumulation and reduction of its complex with cupferron. The cupferron-based procedure compares favourably—in terms of sensitivity, selectivity and simplicity—with earlier adsorptive stripping schemes for aluminum. The utility of cupferron for adsorptive stripping measurements of other trace metals have been reported recently.[6,7]

EXPERIMENTAL

Apparatus and reagents

The equipment used to obtain the voltamperograms (a PAR 264A analyzer with a PAR 303 static mercury drop electrode) has been described in detail elsewhere.[4,6] A medium-sized hanging mercury drop electrode (HMDE) with a 0.016-cm^2 surface area was employed.

All solutions were prepared with doubly distilled water. A 1000-ppm stock aluminum solution (atomic absorption standard, Aldrich) was diluted as required. Stock solutions (0.1M) of cupferron (Aldrich) were prepared weekly and were stored at 4°. A $1 \times 10^{-3}M$ PIPES buffer (pH 7.0) served as supporting electrolyte.

Procedure

Voltammetric stripping experiments were performed in the following matter. The blank solution (10 ml) was pipetted into the cell and purged with nitrogen for 8 min. The preconcentration potential (usually -0.40 V) was applied to a fresh mercury drop while the solution was stirred. Following the accumulation period, the stirring was stopped and after 15 sec the voltamperogram was recorded by applying a linear scan (at 100 mV/sec) in the negative direction; the scan was terminated at -1.55 V.

RESULTS AND DISCUSSION

Response characteristics

Figure 1 shows cyclic voltamperograms for 10 μg/l. (ppb) aluminum, in a medium containing

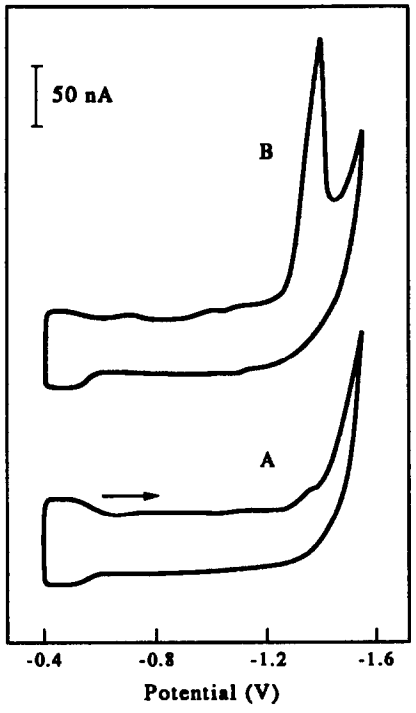

Fig. 1. Cyclic voltamperograms for 10 μg/l. aluminum after O (A) and 90 (B) sec stirring at -0.40 V. Scan rate, 100 mV/sec; solution, $1 \times 10^{-3}M$ PIPES buffer (pH 7.0), containing $2 \times 10^{-4}M$ cupferron.

$2 \times 10^{-4}M$ cupferron and $1 \times 10^{-3}M$ PIPES buffer (pH 7.0). In the absence of prior accumulation, only a small peak from the reduction of the aluminum/cupferron complex is observed at -1.39 V (A). When the experiment is repeated with a 90-sec stirring period (-0.40 V), a significantly (40-fold) larger cathodic peak is observed, indicating an interfacial accumulation of the complex (B). No peaks are observed upon scanning in the positive direction. The cathodic peak (following the stirring period) increased linearly with the potential scan rate (not shown), as expected for the surface-bound species. The peak also decreased rapidly upon repetitive scans, indicating rapid desorption of the complex from the surface. The fact that a well-defined cyclic voltammetric response is observed for μg/l. concentrations indicates the remarkable sensitivity associated with the interfacial accumulation process.

The spontaneous accumulation of the aluminum–cupferron complex can be exploited for effective preconcentration prior to the voltammetric scan. Figure 2 displays voltamperograms for 5.0 μg/l. aluminum after different preconcentration periods (0–60 sec, a–e). While quantitation is not possible without accumulation (a), well-defined peaks are observed after preconcentration. The peak increases rapidly with increasing preconcentration time, indicating (again) an enhancement of the complex concentration on the mercury surface. Also shown in Fig. 2 is the resulting peak-current *vs.* preconcentration time plot for 2.5 (A) and 5.0 (B) μg/l. aluminum. The rapid increase of the current observed at short preconcentration times, is followed by a levelling-off for longer periods. Such profiles reflect the kinetics of the adsorption process.

Various experimental variables affecting the adsorptive stripping response were evaluated and optimized. Figure 3(A) shows the dependence of the aluminum/cupferron peak on the ligand concentration. The peak height increases linearly with the cupferron concentration up to $2 \times 10^{-4}M$, after which it starts to level off. The dependence of the peak height on the accumulation potential is shown in Fig. 3(B). Such behaviour is attributed not only to the complex stoichiometry, but also to competition of the free ligand for adsorption sites. Larger peaks were obtained over the range from -0.40 to -0.50 V, *i.e.*, around the potential of zero charge; the peak decreased rapidly at lower and higher potentials. Other optimal conditions

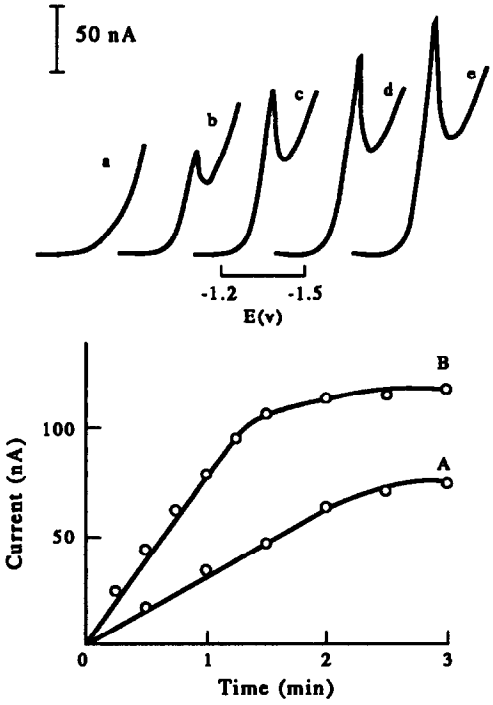

Fig. 2. Stripping voltamperograms for 5.0 μg/l. aluminum after preconcentration for 0 (a), 15 (b), 30 (c), 45 (d), and 60 (e) sec (at -0.40 V with 400 rpm stirring). Also shown are the resulting current *vs.* time plots for 2.5 (A) and 5.0 (B) μg/l. aluminum. Other conditions, as in Fig. 1.

include the use of pH 7.0 and of the linear potential scan mode (at 100 mV/sec).

Analytical performance

Figure 4 shows voltamperograms obtained after increasing the aluminum concentration in 2 μg/l. steps [(a)–(e)]. Well-defined peaks, proportional to the metal concentration, are observed using a 60-sec preconcentration period. Also shown are the resulting calibration plots following 30 (A) and 60 (B) sec of preconcentration. Both plots are highly linear over the entire range examined (slopes, 8.4 and 14.6 nA · l. · μg^{-1}, respectively; correlation coefficients, 0.998). A detection limit of 0.03 μg/l. ($1.1 \times 10^{-9} M$) was estimated from the signal-to-noise characteristics of the response for 0.25 μg/l. aluminum solution (120-sec accumulation). Such a detection limit is lower than that of the azo-dye based stripping procedure[4] and is similar to that of the DASA-stripping scheme.[5] Non-electrochemical methods for aluminum, such as inductively coupled plasma[8] and liquid chromatography[9] are characterised by significantly higher detection limits (of 0.3 and 0.2 μg/l. respectively). The adsorptive accumulation of the aluminum/cupferron complex results in reproducible stripping peak currents. For 22 successive measurements of 5 μg/l. aluminum, the mean peak current was 75.3 nA, with a range of 72.0–78.9 nA and a relative standard deviation of 2.9% [conditions, as in Fig. 2(e)].

The following metal ions (25 μg/l.) were tested and found not to affect the 5 μg/l. aluminum peak: Cu(II), Pb(II), Zn(II), Cd(II), Ni(II), Co(II), Sb(III), Fe(III), Bi(III), Tl(I), Mo(VI), Se(IV), Ga(III), In(III), Pd(II), Zr(IV), Te(VI), Ge(IV), W(VI), Ru(III), and Rh(III). Several of these ions [Cu(II), Pb(II), Cd(II), In(II), Ni(II) and Zn(II)] yielded cathodic peaks at lower potentials that did not affect the response of interest. Indeed, it was possible to simultaneously quantitate aluminum with 4 or 5 of these metals. In contrast, interfering overlapping signals were observed in the presence of U(VI), Cr(VI), and Ti(VI). An appropriate masking or separation step would be required in the presence of elevated levels of these ions. Hence, the cupferron-based procedure offers new selectivity dimensions compared to early adsorptive stripping schemes, that suffer from interferences due to Cu(II), and Fe(III)[4] or Zn(II) and Sb(III).[5] As noted above, these ions do not affect the aluminum/cupferron response.

In conclusion, the method described provides a highly sensitive approach to the determination of aluminum. Such use of cupferron offers an

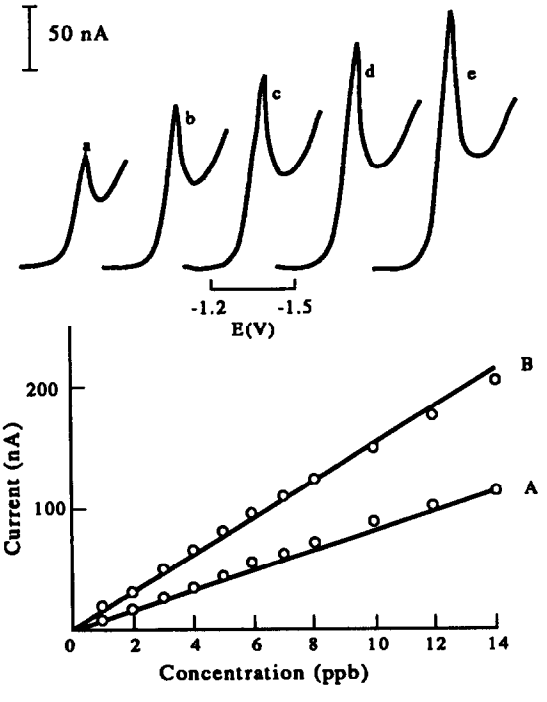

Fig. 4. Stripping voltamperograms for solutions of increasing aluminum concentrations: 2 (a), 4 (b), 6 (c), 8 (d), and 10 (e) μg/l. One-min accumulation at −0.40 V. Other conditions, as in Fig. 1. Also shown are the resulting calibration plots following 30 (A) and 60 (B) sec. accumulation.

alternative adsorptive stripping scheme, which compares favourably with the use of other ligands for the same task. The method successfully addresses the growing needs for measuring trace aluminum in environmental and clinical matrices. Such applications will require a prior removal/destruction of the organic matter. Speciation and on-line monitoring schemes based on this adsorptive stripping procedure are anticipated.

APPLICATION OF NONPARAMETRIC STATISTICS TO THE ESTIMATION OF THE ACCURACY OF MONTE CARLO CONFIDENCE INTERVALS IN REGRESSION ANALYSIS

JOSEPH S. ALPER* and ROBERT I. GELB
Department of Chemistry, University of Massachusetts–Boston, Boston, Massachusetts 02125, U.S.A.

(*Received* 16 *June* 1992. *Accepted* 6 *July* 1992)

Summary—Confidence intervals and their uncertainties for nonlinear regression parameters are obtained using nonparametric statistical methods. The confidence intervals are calculated by means of a Monte Carlo procedure. Their uncertainties depend on the confidence level desired and on the number of Monte Carlo simulations of the data set. They are obtained by calculating the uncertainties in the boundaries of the confidence intervals using a generalization of the nonparametric method used to calculate confidence intervals for medians. The method described here provides reliable confidence intervals at relatively low computational expense. It seems especially suited to the statistical analysis of nonlinear regression problems that are difficult to deal with using conventional methods.

Nonlinear regression analysis of experimental data[1–4] has become a standard procedure in chemistry. This analysis determines the values of the adjustable parameters in a set of model equations (nonlinear in the parameters) that result in the best fit of the model to the experimental data. In addition to the values of the parameters, it is important to obtain estimates of the uncertainty in each parameter value. For the general nonlinear problem, if the experiment were repeated many times, the distribution characterizing the set of values of any one of the parameters will not be normal as it would be in a linear problem. Consequently, traditional parametric estimates of the uncertainties, which rely on the assumption that the parameter values are normally distributed, may not be correct and can lead to significant errors. The appropriate measure of the uncertainty is a confidence interval at some chosen probability level.

In a recent paper, we described a simple nonparametric method for estimating confidence intervals for the values of parameters obtained from nonlinear regression analyses.[5] This method is based on Monte Carlo sampling[6,7] of the universe of possible data sets consistent with the one actually obtained from the experiment. Confidence intervals derived using this procedure are free from assumptions about the distributions of the calculated parameters and about covariances between them. It is the purpose of this paper to determine the number of Monte Carlo sampling points required to achieve any predetermined level of accuracy of the confidence intervals.

EXPERIMENTAL

Determination of confidence intervals

Our procedure for determining confidence intervals for parameters is straightforward. First, the set of experimental data together with estimates of their uncertainties is analyzed using a nonlinear regression algorithm. The algorithm provides optimized values of the adjustable parameters and the value of χ^2, the goodness-of-fit statistic. Assuming that the estimates of the uncertainties in the experimental data are correct, if the model serves as a correct description of the phenomena, then the value of χ^2 will be approximately equal to the number of degrees of freedom. The number of degrees of freedom is equal to the number of data points minus the number of adjustable parameters.

Second, the experimental data set is repeatedly and randomly manipulated to provide N simulated experimental data sets, where N is some suitably chosen number. In earlier work, we employed a Monte Carlo technique to generate these simulated data sets.[5,8] This technique is based on the assumption that the error in each

*Author for correspondence.

experimental datum is derived from some known probability distribution. A random number chosen from this distribution is added to the measured datum resulting in a new datum. A new data set is generated by repeating this process for each datum in the original data set.

The nonlinear regression algorithm is then applied to each of the simulated experimental data sets providing a new set of parameters for each data set. The N values of each parameter are characterized by a distribution which is an approximation to the distribution of the universe of values of that parameter. A confidence interval for each parameter can be obtained directly from the calculated set of values for that parameter by numerically ordering the set of values and then choosing an appropriate percentile to determine the boundary values of the confidence interval. For example, the boundary values at the 5th and 95th percentile levels of the values of an optimized parameter constitute a 90% confidence interval for that parameter.

The percentile method is a direct implementation of the definition of the confidence interval. Using the example given in the previous paragraph, if the experiment were repeated many times, in 90% of the experiments the value of the parameter determined by the nonlinear regression would be expected to lie in the 90% confidence interval bounded by the 5th and 95th percentiles. There are other procedures for generating a confidence interval from the distribution of a parameter, but the simplicity of the percentile method makes it, in our opinion, the method of choice.

Because the set of calculated values for a parameter represents only a finite and possibly non-representative sample of the universe of parameter values, the estimate of the confidence limits from that set of values is subject to error. The overall accuracy of confidence intervals obtained from the procedure outlined above depends on two factors: (1) the accuracy of the calculated parameter distribution obtained from the Monte Carlo simulations and (2) the accuracy of the determination of the location of the percentile levels.

The first factor derives from the inherent limitations in the Monte Carlo simulation. Even if an infinite number of simulations were performed, the calculated distributions might not be equivalent to the true distribution because of the experimental errors in the original data set. We will return to this point below.

We are primarily concerned in this paper with answering the question implicit in the statement of the second factor: assuming that the procedure for generating parameter distributions is correct, how many values, N, of a calculated parameter resulting from N simulations of the original data set are required to provide accurate percentile levels and thus, accurate confidence intervals?

In order to answer this question, we first note that percentiles are so-called "order statistics"; they involve only numbers of points (in this case, the set of calculated values of a parameter) rather than the actual values of these points. Simple nonparametric methods can be used to determine confidence intervals for these statistics.[9] In order to avoid confusion in the following discussion, we will refer to confidence intervals for the percentiles as "ranges". That is, the confidence interval for a given percentile level (which itself is the boundary of a confidence interval) will be called the range of the percentile.

Ranges for order statistics

The order statistics relevant to the study of the uncertainty in confidence intervals are the median and a generalization of the median. In the following discussion of these order statistics, we will assume that a set of values for each of the parameters has been obtained by some random manipulation of the experimental data.

The median. There is a straightforward procedure for determining the range (confidence interval) about the simplest of the order statistics, the median. Consider a set of N data points X_i, $i = 1, N$, randomly chosen from a large population with some unknown distribution. Let the median of the large population be M while that of the N member sample be X_m. The probability that exactly k of the N data points lie at or below the unknown population median is given by the binomial distribution:

$$P(N,k) = \binom{N}{k}\left(\frac{1}{2}\right)^N \tag{1}$$

We can calculate a symmetric range $[X_q, X_{N-q+1}]$ of level $1-\beta$ for the sample median by calculating the cumulative probability that at least q and no more than $N-q$ points lie below the true median. The interval is constructed so that $1-\beta$ is the probability that the population median M lies within the interval.

We thus chose q to be the largest integer such that

$$\sum_{k=q}^{N-q} P(N,k) \geqslant 1-\beta \qquad (2)$$

This interval is symmetric about the sample median X_m because the binomial distribution is symmetric if the probability of each elementary event is 0.5.

This procedure can be illustrated by means of a simple example. We consider a set of $N = 50$ points arranged in ascending numerical order and arbitrarily chose $1-\beta = 0.683$, the value equal to the one-sigma confidence level for a normally distributed variable. Using equation (1) we find:

$$P(50,25) = 0.1123$$
$$P(50,26) = P(50,24) = 0.1080$$
$$P(50,27) = P(50,23) = 0.0960$$
$$P(50,28) = P(50,22) = 0.0788$$
$$P(50,29) = P(50,21) = 0.0598$$

We interpret $P(50,k)$ to be the probability that the population median M lies in the closed interval $[X_k, X_{k+1}]$. This represents a conservative interpretation of the probability measure. The maximum value of q statisfying equation (2) is found to be 21. For this value of q the sum of the probabilities is 0.7975. This sum is the probability that M lies between the 21st and the 30th entries in the list of data points arranged in ascending order.

The interval $[X_{21}, X_{30}]$ constitutes the conservative 0.683 range for the population median. We note that this result is independent of the nature of the distribution of the population from which the sample is chosen and is also independent of the actual values of the members of the population. We now generalize this analysis and apply it to the percentile method for estimating confidence intervals.

The generalized median. The median divides the population so that 50% of the points lie at or below it. We define a generalization median, which we call the p-median, $0 < p < 1$, to be the point X_p such that a fraction p of the points lie below it. The probability that exactly k of a sample of N data points will lie at or below the p-median is given by

$$P(N,k,p) = \binom{N}{k} p^k (1-p)^{N-k} \qquad (3)$$

The binomial distribution is not symmetric about its maximum value if $p \neq 0.5$. Therefore, two integers q and r, $q < r$, are needed to define a confidence interval about a p-median. These integers were chosen so that they define an interval of minimum length (compared with intervals defined by any other pair of integers) while satisfying

$$\sum_{k=q}^{r-1} P(N,k,p) \geqslant 1-\beta \qquad (4)$$

We continue to interpret $P(N,k,p)$ in a conservative manner; the probability refers to the closed interval between the k^{th} and $k+1^{\text{st}}$ points. Consequently, the range for the p-median is given by the asymmetric interval $[X_q, X_r]$ about X_p.

We show in the next section that the p-median is ideally suited for determining the appropriate value of N, the number of values of each parameter needed to achieve some desired degree of accuracy.

Application of the p*-median to confidence intervals*

Suppose that a set of N values of each of the adjustable parameters is determined by the Monte Carlo simulation or some other method. The p- and $(1-p)$-medians of the numerically ordered set of values of each parameter define the $1-2p$ confidence interval for that parameter. For example, the $p = 0.05$ and $p = 0.95$ medians define the 90% confidence interval. For the case of N data points, the position of the upper median is $u = [N(1-p)]$, where $[r]$ denotes the integer part of r. In order that the confidence interval be symmetric with respect to the highest and lowest data point, we set the lower median X_1 at position $N-u+1$.

We now consider the uncertainty in the location of the upper and lower p-medians X_u and X_1. After choosing some arbitrary confidence level $1-\beta$ we calculate the range about X_u using the method described in the previous section. It is important to note that the position of the boundaries of this interval is independent of the actual values of the parameters and their distributions and so can be calculated once and for all. Ranges about the upper and lower p-medians are related by mirror reflection symmetry. If the upper median lies at position u and the confidence interval around it is $X_q \leqslant X_u \leqslant X_r$, then the corresponding range about the lower p-median is $X_{N-r+1} \leqslant X_{N-u+1} \leqslant X_{N-q+1}$. Representative ranges about p-medians for various values of p and N with $1-\beta = 0.683$ are given in Table 1.

Table 1. Positions of the upper p-medians and their 68.3% confidence intervals

Number of Monte Carlo simulations	Confidence levels for the parameters a_j

100	[81, 85, 89]	[88, 90, 94]	[93, 95, 98]
200	[164, 169, 175]	[176, 180, 185]	[187, 190, 194]
300	[247, 253, 260]	[265, 270, 276]	[282, 285, 290]
400	[331, 338, 346]	[355, 360, 367]	[376, 380, 385]

*The $p = 0.842$ median is located at the upper bound of the 68.3% confidence interval for a parameter a_j.

†[40,43,46] means that the $p = 0.842$ median is found at position 43 and that the boundaries of the 68.3% confidence interval for this median are found at positions 40 and 46.

The (1–2p) confidence interval for a regression parameter a_j is given by $[X_l, X_u]$ since it is bounded by the lower and upper p-medians. The uncertainty in this confidence interval can be expressed in terms of the ranges in the positions of X_l and in X_u. Consider, as an example, the 90% confidence interval for a_j calculated using $N = 200$ Monte Carlo simulations. This interval is defined by the 0.05- and 0.95-medians and so is bounded by the 11th and 190th positions in the ordered list of the 200 values of a_j. At a confidence level of $1 - \beta = 68.3\%$ for the uncertainty in the position of each p-median, we see from Table 1 that the 0.95-median is uncertain by $-3, +4$ positions, while the 0.05-median is uncertain by $-4, +3$ positions.

These uncertainties mean that the lower p-median could lie as high as position 14 and as low as 7, while the upper p-median could lie as high as position 194 and as low as 187. Using positions 7 and 194 as the boundaries of a confidence interval implies a confidence level of 94% since 12 values have been struck from each end of the list of 200 values. Similarly, the interval bounded by positions 14 and 187 imply a confidence level of 87%.

We have thus found that the confidence interval $[X_{11}, X_{190}]$ corresponds to a confidence level of 90 $+4, -3$%. To the degree of accuracy required for our analysis of uncertainties, we can approximate the asymmetric uncertainty estimate by the symmetric uncertainty, $90 \pm 3.5\%$. This symmetrization will be applied to all the uncertainties calculated in this work.

We now determine the confidence level of this uncertainty of $\pm 3.5\%$. This confidence level depends only on the confidence level of the uncertainties in the p-medians which we have arbitrarily set at $1 - \beta = 68.3\%$. The probability that either p-median will lie outside its range is β. Since the positions of the 2 p-medians are independent, the probability that both will lie outside their respective ranges is β^2. As explained in the preceding paragraphs, the uncertainty in the 90% confidence interval for a_j was determined by considering the case where both p-medians lie outside the interval defined by positions 11 and 190 and the case where both lie inside. Assuming sufficient symmetry in the binomial distribution, the probability of the occurrence of either of these two cases is approximately $\beta^2/2 = 0.050$, which corresponds to a 95% confidence level.

We conclude that if $N = 200$ Monte Carlo simulations are performed, we can be 95% confident that the confidence level for the 90% interval $[X_{11}, X_{190}]$ is $90 \pm 3.5\%$. We emphasize again that this 95% confidence level depends only on the 68.3% uncertainty in the p-medians. It does not depend on the number of simulations nor on the confidence level or interval for a_j.

The results of this analysis for different values of N is given in Table 2. For each value of N, we show the 68.3, 80, and 90% confidence intervals for a_j as defined by the upper and lower p-medians and the uncertainties in each of these confidence levels.

Suppose we wish to calculate the confidence interval at the nominal level of 80% for the parameter a_j but would be satisfied knowing that the confidence level actually lies in the

Table 2. Boundaries of confidence intervals (as defined by the upper and lower p-medians) and the uncertainties (at the 95% level) in the confidence levels of these intervals

Number of Monte Carlo simulations	Confidence levels		
	68.3%	80%	90%
50	[8, 43]*	[6, 45]	[3, 48]

	±3.8%	±3.0%	±2.3%

*[8, 43] means that the 68.3% confidence interval for any one of the adjustable parameters a_j is bounded by the 8th and 43rd values of that parameter.

†±12% is the uncertainty (at the 95% confidence level) in the 68.3% confidence interval, *i.e.*, the interval [8, 43] represents a confidence level of 68.3 ± 12%.

somewhat wider range 74–86%. Table 2 shows that if $N = 100$, there is a 6% uncertainty in the 80% confidence level. Thus, 100 values of each parameter are sufficient, and the nominal 80% bounds will appear at the 11th and 90th entries of the list of the 100 values of a_j.

There appears to be little practical difference between a nominal 80% confidence level and the range 74–86% obtained using 100 Monte Carlo simulations. Consequently, we conclude that 100 simulations are adequate for an estimation of 80% confidence intervals. Similarly, if the difference between a 68.3% confidence level and the range 60–76% is regarded as unimportant, then 100 simulations are adequate to accurately describe this confidence level. However, for the nominal 90% confidence level, 100 simulations yields a range of 85–95%. This represents a range in the odds from approximately 6:1 to 20:1. This range does seem to represent a significant difference and indicates that a larger number of simulations, say 200, is appropriate. As explained above, for $N = 200$, the nominal 90% level represents the range $90 \pm 3.5\%$ which appears adequately precise for most applications.

These results can be interpreted from a different point of view. Instead of focussing on the uncertainty in the confidence level, we can use the uncertainty in the position of the boundaries of the p-medians to determine the uncertainty in the confidence interval about the parameter. Using the same example, ($N = 200$, 90% confidence interval), we assume that the confidence level of 90% is correct but that there is uncertainty in the interval. This uncertainty can be calculated from the values of the parameters found at 4 positions higher and 3 positions lower from each of the boundaries of the original confidence interval. In constrasting the two points of view, we note that only the first, which analyzes the uncertainty in the confidence level, is independent of the statistical fluctuations involved in using the Monte Carlo for estimating the parameter distributions.

A specific chemical example illustrating the determination of the accuracy of a confidence interval for a parameter may clarify this discussion. We show that for this example, the procedure described above produces, for each regression parameter, a set of values that accurately reproduces the actual distribution of that parameter. Moreover, the procedure provides accurate percentile levels (boundaries of the confidence intervals).

A simulated differential kinetic analysis

A simulated mixture of substances X and Y is analyzed for both components by a differential kinetic method involving the measurement of absorbance versus time. The mixture is treated with a color developing reagent which reacts with the analytes at different rates. We will assume that the rates of product formation are first- or pseudo-first-order in both X and Y and that the products of the reactions involving X and Y are the only light absorbing species in the mixture. The time dependence of the absorbance is given by

$$A(t) = X(1 - e^{-at}) + Y(1 - e^{-bt}), \qquad (5)$$

where $A(t)$ is the absorbance at time t; X and Y are constants proportional to the concentrations of the analytes X and Y, and a and b are the first- or pseudo-first-order rate constants for the reaction of X and Y, respectively, with the color developer. Once values of X and Y are determined, the corresponding concentrations can be obtained from Beer's Law and the appropriate extinction coefficients.

We note that equation (5) is identical in form to one describing a controlled potential chronocoulometric determination of two electroactive species which are reduced or oxidized at different rates. Thus, the quantity of electricity $Q(t)$ passed at time t during the bulk electrolysis of a mixture of substances X and Y under conditions of constant stirring is given by

$$Q(t) = Q_X(1 - e^{-at}) + Q_Y(1 - e^{-bt}) \qquad (6)$$

where Q_X and Q_Y are the quantities of electricity required for complete oxidation or reduction of X and Y and a and b are the corresponding mass-transfer coefficients for these species, which are taken as constants.

An exact data set of $A(t)$ *vs.* t was constructed using 11 values of t: 0.0, 2.0, 4.0, . . . , 20.0. The values of the four parameters were chosen to be $X = 0.50$, $Y = 0.70$, $a = 0.05$, and $b = 0.20$. We simulated an experimental data set by adding to each exact value of $A(t)$ (which varied from 0.0 to approximately 0.9) a normally distributed random error with a mean of 0 and a standard deviation of 0.005.

The simulated experimental data set was analyzed using the Levenberg-Marquardt nonlinear regression technique as implemented by Press *et al.*[4] to obtain the values of the four parameters X, Y, a, and b that best fit the simulated experimental data set. We found $X = 0.518$,

$Y = 0.689$, $a = 0.0493$ and $b = 0.207$. The goodness-of-fit statistic, χ^2, was found to be 7.28, which is approximately equal to 7, the number of degrees of freedom in the regression analysis. Standard error estimates for each of the parameters are obtained from the diagonal elements of the covariance matrix. These error estimates, which we will refer to as parametric estimates, had values of 0.12, 0.50, 0.11 and 0.07 for X, Y, a and b, respectively.

Unfortunately, error estimates of regression parameters obtained from the covariance matrix are unreliable if the model equation is nonlinear in the parameters.[4,5] Examination of equation (5) reveals such a nonlinearity. In order to obtain accurate confidence intervals for the calculated parameters we employ a Monte Carlo simulation method.

In implementing this method, each value of $A(t)$ in the simulated experimental data set is scattered by adding a random normally distributed error with mean 0 and a standard deviation of 0.005. The resulting Monte Carlo data set is analyzed using the nonlinear regression algorithm and a new set of parameters is obtained. This procedure is repeated a total of N times. A confidence interval for each parameter is then derived from the N values of that parameter.[5]

As discussed above, our goal in this work is to determine the number N of Monte Carlo simulations required in order to obtain some predetermined degree of accuracy in the calculated confidence intervals. We examined the 68.3 and 90% confidence intervals for the differential kinetic example using three different values of N (50, 100 and 200). In order to evaluate the reproducibility of our results, we repeated each set of calculations six times. Finally, we made an additional calculation with $N = 4000$. We assume that the confidence interval obtained from this calculation is an accurate approximation of the "true" confidence interval that would be obtained in the limit as N goes to infinity.

The numerical results are summarized in Table 3. An entry in the first row of numbers listed below the value of N is the mean of the 6 Monte Carlo confidence interval half-widths for the specified parameter. The entry below this one is the standard deviation of the 6 values, and the corresponding entry in the third row is the maximum deviation from the mean. Thus, this entry indicates a typical worst value obtained for a confidence interval for a given value of N. For example, the mean of the 6 Monte Carlo 68.3% confidence half-intervals for parameter X calculated using $N = 50$ was 0.037. The standard deviation was 0.006 and the 6 half-interval values fell within the range 0.030 to 0.044.

Table 3. Confidence half-intervals and their uncertainties as a function of the number of Monte Carlo simulations for the differential kinetic analysis example*

90% confidence half-interval			
X	Y	a	b
	$N = 50$		
0.062	0.050	0.0067	0.0124
0.009	0.009	0.0016	0.0023
0.012	0.012	0.0024	0.0040
	$N = 100$		
0.063	0.041	0.0053	0.0112
0.007	0.008	0.0005	0.0013
0.009	0.010	0.0012	0.0023
	$N = 200$		
0.060	0.040	0.0055	0.0108
0.006	0.007	0.0007	0.0012
0.008	0.010	0.0012	0.0030
	$N = 4000$		
0.0617	0.0401	0.0058	0.0115

*For each value of N, each number in the first row is the mean value of the confidence interval half-widths obtained from 6 independent Monte Carlo simulations. The corresponding number in the second row is the standard deviation. The number in the third row is the maximum deviation from the mean value.

RESULTS AND DISCUSSION

The Monte Carlo confidence intervals differ significantly from the parametric estimates, sometimes by a factor of ten or more. For example, the $N = 4000$ Monte Carlo 68.3% interval for parameter Y is 0.0126 which is to be compared with the parametric standard error estimate of 0.50. This discrepancy indicates that this example is one of the typical cases in which parametric estimates of the uncertainties in non-linear regression parameters are in error.

The results of Table 3 indicate that there is little value in extending the Monte Carlo

method beyond $N = 200$. Focussing on the 90% confidence interval for parameter X ($X = 0.52$ from the regression analysis), we find a mean half-width of 0.060 with a standard deviation of 0.006 and a range of values of 0.052 to 0.068. Suppose that the $N = 200$ calculation had been performed only once and that the extreme value of 0.052 had been obtained for the confidence interval half-width. Then, the value of parameter X would be 0.52 ± 0.05 with 90% confidence. There seems to be little or no practical difference between this value and the value of 0.52 ± 0.06 which was obtained using 4000 Monte Carlo simulations.

In order words, the standard deviations of the confidence intervals for $N = 100$ and $N = 200$ are generally only 10–20% of the half-widths of the interval values. The single exception is the $N = 100$ value for parameter Y, where the standard deviation is about 30% of the interval value. For $N = 200$ all of the half-interval standard deviations are less than 25% of the interval values and the extreme values are within 30% of the $N = 4000$ intervals.

As discussed above, the accuracy of a confidence interval can be directly estimated from the ordered set of values of the parameters. We consider the 90% interval for X and examine its values at the 14^{th} and 187^{th} positions and at the 7^{th} and 194^{th} positions. These values lead to minimum and maximum confidence interval half-widths of 0.055 and 0.066, respectively. The "exact" value of 0.617 falls within this range. The corresponding extreme and "exact" intervals for Y are 0.032, 0.050, and 0.0401. These results, together with numerous other similar comparisons, serve to confirm our estimate that the extreme values contain the exact result with about 95% probability.

This example thus illustrates our contention, based on the analysis of generalized p-medians given above, that even if only 100 or 200 simulations are employed, the Monte Carlo 68.3% and 90% confidence intervals provide accurate and practical estimates of the "true" confidence intervals. The relatively minor errors of 10–20% in the Monte Carlo confidence intervals seem especially insignificant in the view of the fact that the parametric estimates of confidence intervals for nonlinear regression parameters can be in error by an order of magnitude or more.

(*Received* 13 *May* 1992. *Revised* 2 *July* 1992. *Accepted* 2 *July* 1992)

Summary—Desorption chemical ionization (DCI) and desorption electron ionization (DEI) of homo- and co-polymers of *N*-alkyl-4-vinylpyridinium triflates having ethyl, n-hexyl and n-dodecyl groups as *N*-alkyl substituents, produce mass spectra that display oligomeric ions. These positively charged ions are singly-charged and result from cleavage of the polymer into neutral oligomers and the loss of a single triflate anion per oligomer. Analogous negatively charged ions, in which each neutral oligomer carries an extra triflate anion, are observed in the desorption chemical ionization mass spectra. Each oligomer within the available mass range is represented in the mass spectra. The formation of cluster ions in which a single, multiply-charged cation is associated with a number of singly-charged anions, as observed for these ammonium polysalts, is unusual. Five major and three minor series of positively charged ions are observed in DCI and DEI methods of ionization. Ions in the different series correspond either to cleavage at different bonds between the constituent monomers or to hydrogen transfer in different directions. Unique and structurally diagnostic fragmentation processes are observed in tandem mass spectrometry (MS/MS) experiments performed using collision activated dissociation of mass-selected oligomeric ions.

Although well-established methods exist for molecular weight determination of polymers,[1,2] there is a need for improved analytical methods for structural characterization. It would also be useful if, unlike the case for existing methods,[1,2] pure samples were not needed for such analyses. Mass spectrometry has increasingly been used for direct analysis of polymers,[3–11] including biopolymers, where tandem mass spectrometry[12,13] can provide structural information on compounds present in mixtures.[14,15] The recent increased use of mass spectrometry in polymer characterization followed the introduction of the desorption ionization[16] and, more recently, spray ionization, techniques.[17] Recent applications of tandem mass spectrometry in polymer chemistry include characterization and monomer sequence distribution of polyalkylisocyanates,[18] the determination of polymer additives,[19] analysis of chemical structures of ions generated from low molecular weight polyglycols,[20] and sequence analysis of polyamides,[21,22] and polyesters.[23] Some of these studies[21–23] utilize chemical degradation to produce suitably sized oligomers while in others,[18] thermolysis accompanies ionization. The work of Bennighoven, Hercules and their collaborators[4] stands out as accessing high molecular weight organic polymers. Fragmentation can be limited and in some cases[4,8] true molecular weight distributions are obtained. The advantages of pyrolysis tandem mass spectrometry include simplicity, speed and sample economy. The limitations of most pyrolysis/MS experiments are the complexity of the mass spectra and the inability to access higher oligomeric ions. However, rapid heating techniques such as desorption chemical ionization (DCI) are known to yield higher mass molecular ions without causing much fragmentation.[24] Therefore the combination of DCI and MS/MS might provide an excellent means of characterization of polymers. Recent successes[18] achieved in characterizing alkylisocyanates by a combination of pyrolysis tandem mass spectrometry and DCI encourage further application of this method to other types of copolymers.

*Author for correspondence.

Poly(*N*-alkyl-4-vinylpyridinium) salts have both hydrophilic and hydrophobic units in their structure and are useful as polyelectrolytes,[25-28] surfactants,[25-27] and artificial enzymes.[28-32] These polymers can be produced, either by direct heating of the monomers, or by an inverse-micro-emulsion process that consists of overnight heating at 45–55° of an emulsion containing a mixture of the monomers, a reaction initiator, and organic and aqueous solvents.[33,34] Despite their potential for various applications, very little is known about the structural characteristics of these polymers. Studies on polyvinylpyridines,[35] monomeric *N*-alkylpyridinium,[36-38] and related organic salts[39-42] using desorption ionization have been reported but there appear to have been no previous structural investigations on the polysalts by mass spectrometry.

The objectives of this study are (i) to develop mass spectrometric methods to ionize poly(*N*-alkyl-4-vinylpyridinium) salts, (ii) to acquire structural information and (iii) to investigate the gas-phase ion chemistry of the pyrolysis products formed from these polymers.

EXPERIMENTAL

Experiments were performed using a Finnigan TSQ 700 mass spectrometer. The samples were dissolved in either methanol or methylene chloride. A drop of sample solution was placed on the loop of rhenium wire which comprises the filament of the desorption probe and dried before introduction into the ion source. The amount of sample on the probe tip was approximately 0.5 μg. Samples were pyrolyzed by heating the probe from 30 to 500° at a rate of 10/sec. At this heating rate, desorption of the sample starts when the temperature of the filament is approximately 200° and continues until the temperature is 500°. The scan speed of the quadrupole is typically 1000 amu/sec. This allows the data system to average 3–5 scans covering a range of 1000 amu. The signal-to-noise ratio can be improved by narrowing the mass range and keeping the scan speed constant. Temperatures of the ion source and the manifold were 150 and 70° respectively. The electron energy was 20 eV during desorption electron impact (DEI), which was performed without reagent gas being present, and 150 eV during desorption chemical ionization (DCI). The emission current of the source filament was 0.2 mA. Isobutane was used as the reagent gas for chemical ionization at a source pressure of 0.5 torr. MS/MS product spectra were obtained by mass selecting a specific ion, using the first quadrupole, Q1, accelerating these ions to a nominal 10 eV in Q2 where collision-activated dissociation (CAD) was performed under multiple collision conditions with argon (2.0×10^{-3} torr) as the collision gas, and finally by performing mass analysis of the resulting fragments using the third quadrupole, Q3. MS/MS parent spectra were obtained similarly, except that Q1 was scanned instead of Q3 which was set to pass a selected fragment ion. An ion derived from the isobutane reagent gas, instead of the sample beam, was used to estimate attenuation because the sample ion beam is stable only for a short period (typically 2–3 sec) due to the rapid desorption. The reagent ion beam (m/z 57) was attenuated to 25% after introducing argon (2×10^{-3} torr) into the collison cell.

Homo and copolymers of *N*-alkyl-4-vinylpyridinium trifluoromethanesulphonates (triflates) containing ethyl, n-hexyl and n-dodecyl groups as the *N*-alkyl chains were examined in this study. Polymer-I, polymer-II and polymer-III are the homopolymers of *N*-ethyl-4-vinylpyridinium triflate, *N*-hexyl-4-vinylpyridinium triflate and *N*-dodecyl-4-vinylpyridinium triflate, respectively. The co-polymer, Polymer-IV was prepared using *N*-ethyl-4-vinylpyridinium triflate (0.83 mole) and *N*-hexyl-4-vinylpyridinium triflate (0.17 mole) monomers, polymer-V was prepared using *N*-ethyl-4-vinylpyridinium triflate (0.80 mole) and *N*-dodecyl-4-vinylpyridinium triflate (0.20 mole) monomers, by the microemulsion method.[33,34] The polymers were synthesized according to procedures described in refs 32, 33, 43, 44 and 45.

RESULTS AND DISCUSSION

Both 20-eV desorption electron ionization (DEI)* and isobutane desorption chemical ionization (DCI) mass spectra of the polymers show monomeric and oligomeric positively-charged ions formed by polymer cleavage and loss of a single triflate anion. Formation of intact cations (C^+) from pyridinium salts

*For brevity, many of the mass spectra are not shown. Interested individuals may request copies of those spectra from the authors.

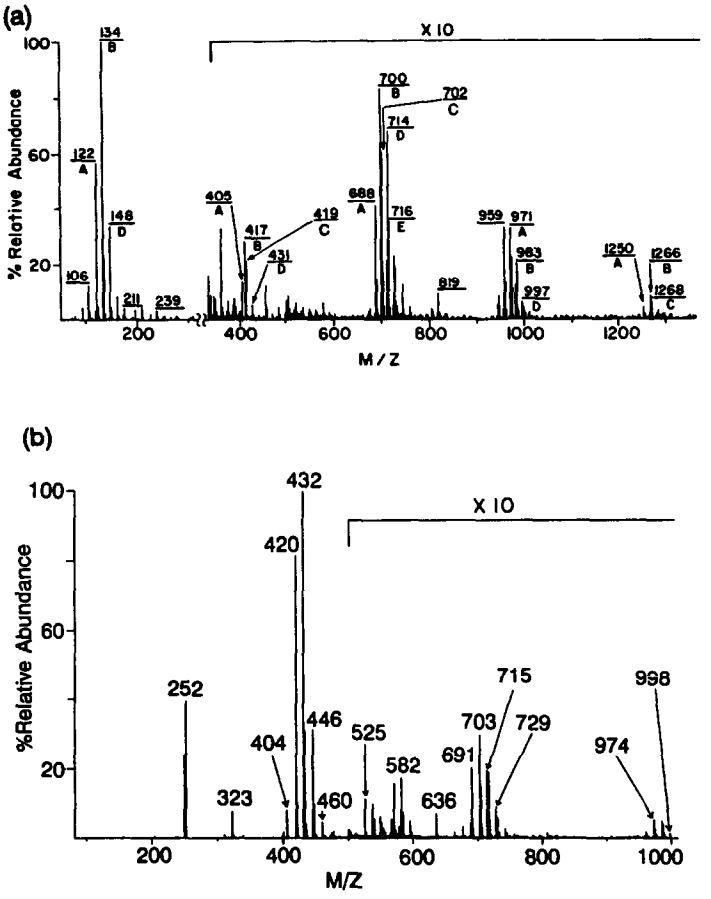

Fig. 1. Mass spectra of polymer-I obtained by (a) positive DCI and (b) negative DCI.

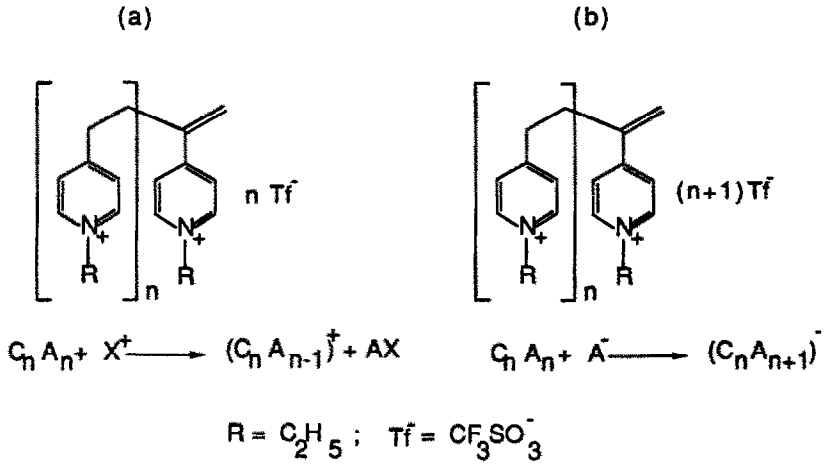
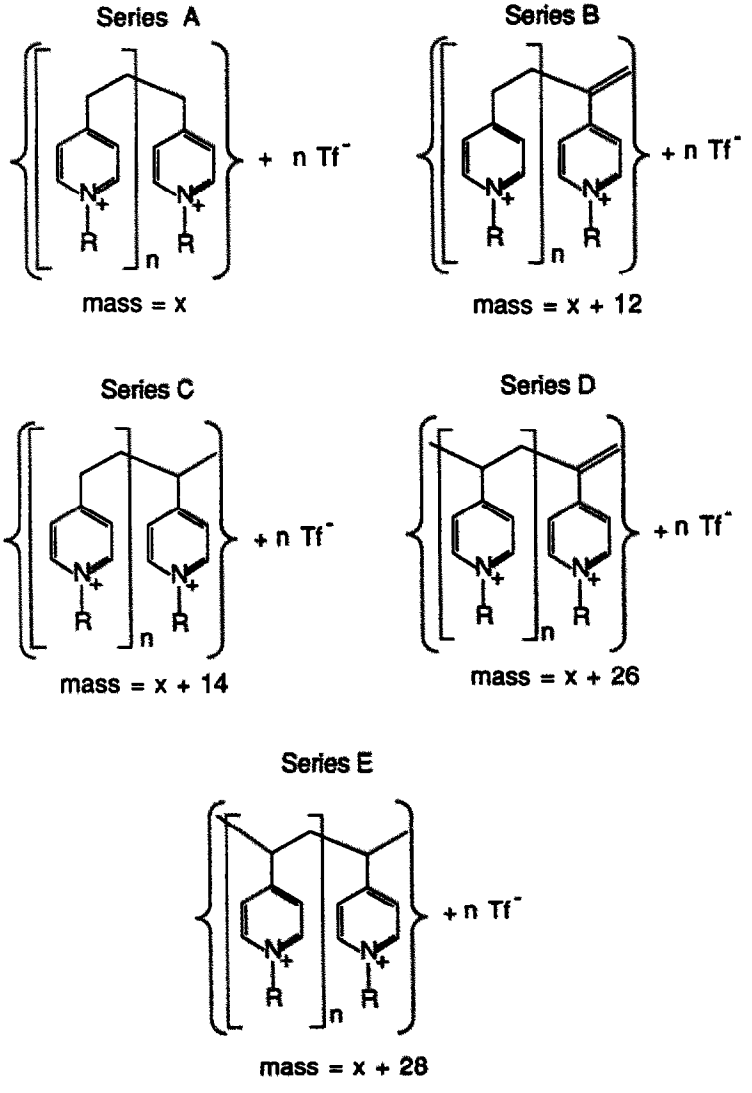
has been reported earlier[41] by both EI and ion bombardment. Thermal desorption of quaternary ammonium and phosphonium salts is well known.[46] The gas-phase ions observed from the present polymers are unique in that they are polycationic species. They include a polycation of n charges associated with $(n-1)$ triflate counter ions. As noted above, positive ion formation from poly(*N*-alkyl-4-vinylpyridinium)triflates occurs by the loss of only one triflate group from the pyrolyzed oligomer fragment. The corresponding negatively-charged ions are also observed and are polysalts with one additional triflate group. Multiply-charged ions formed by the loss or gain of more than one triflate anion are not observed in any of the experiments discussed here.

Typical positive and negative ion mass spectra obtained by DCI of polymer-I [poly(*N*-ethyl-4-vinylpyridinium triflate)] are shown in Fig. 1. The ions are observed as groups of oligomers; for example, the ions m/z 134, 417, 700, 983, and 1266, seen in Fig. 1(a) represent the series $n = 0$, 1, 2, 3, and 4 in the oligomer structure shown in Scheme 1(a). Other peaks are due to homologs and saturated forms of these ions, and they too occur as groups of oligomers as discussed below. Similarly, the negative ions m/z 432, 715, and 998 in Fig. 1(b) may be obtained by substituting $n = 1$, 2, and 3 in the structure shown in Scheme 1(b). Although, these characteristic series of ions may result from several processes, they can be explained by the simplified equations and structures displayed in Scheme 1. The same types of ions are formed by positive ion DCI and DEI except that the series extend to higher mass in the DCI experiments. Formation of higher mass ions during DCI compared to DEI may be due to several reasons, including collisional relaxation of the thermally excited ions in the high pressure CI source.

Since isobutane DCI provides access to higher oligomers, it was chosen for structural investigations discussed in the following sections. Positive ions were chosen over negative ions since they contain smaller contributions due to the triflate counter ion at a given mass.



Scheme 1. Structures of poly(*N*-alkyl-4-vinylpyridinium) triflates and the general mechanism of formation of ions under DCI conditions; (a) formation of positive ions (b) formation of negative ions.



Scheme 2. Major series of positive ions observed under DCI conditions.

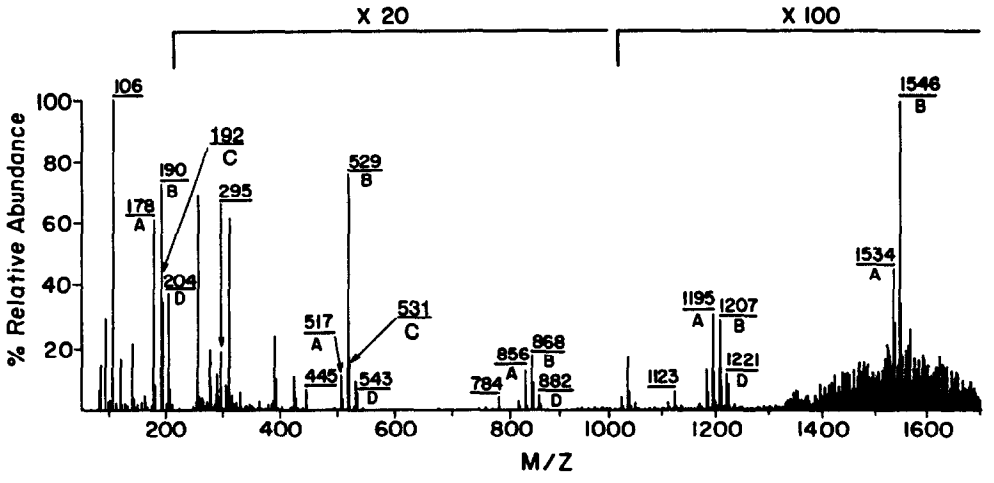


Fig. 2. DCI positive ion mass spectrum of polymer-II.

Five different series of monomer and oligomer ions, as well as their fragments, are observed in the DCI mass spectra and their structures and mass differences are summarized in Scheme 2. Successive members in each series are found to differ from each other by a fixed mass corresponding to the monomer unit, *N*-alkyl-4-vinylpyridinium triflate. In particular cases, structural assignments were confirmed by MS/MS parent and product spectra. The following discussion is subdivided according to the types of ions observed.

Series A ions

Figures 2 and 3 are the DCI mass spectra of polymer-II and polymer-V, respectively. Ions with m/z 178, 517, 856, 1195 and 1534 in the mass spectrum of polymer-II [poly(*N*-hexyl-4-vinylpyridinium triflate; Fig. 2] belong to series A. Structures for these ions may be obtained by substituting $n = 0$, 1, 2, 3, and 4 in the general structure for series A ions in Scheme 2. The MS/MS product spectrum of ion m/z 1195 (Table 1) shows that this ion fragments to produce series A ions of m/z 856, 517, 178 and series B ions of m/z 868, 529, and 190, respectively. Based on this information, fragmentation pathways for series A ions are shown in Scheme 3, using ion m/z 1195 as an example. The MS/MS parent spectrum of m/z 178 [Fig. 4(a)] confirms its origin from series A ions (m/z 517, 856, and 1195), as well as from series C ions (m/z 531 and 870) and another series of ions (m/z 505, 844, 1183).

One fragment ion seen in Scheme 3, m/z 106, is present in the DCI mass spectra of all the polymers and in the MS/MS product spectra of

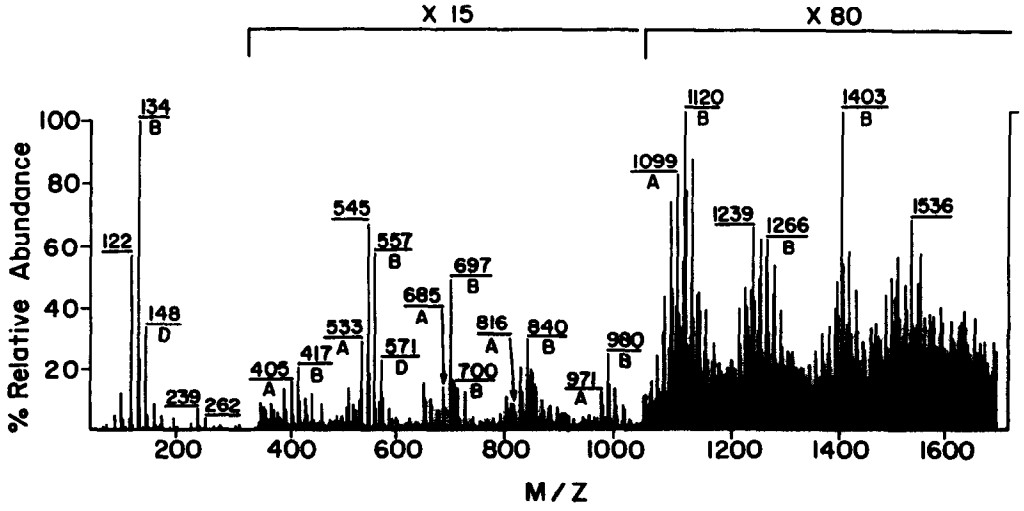

Fig. 3. DCI positive ion mass spectrum of polymer-V.

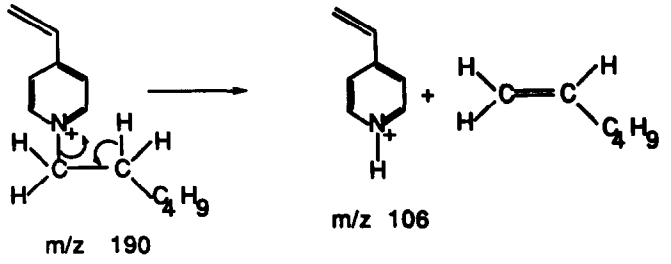
Table 1. MS/MS product spectra of selected ions

Polymer	Selected ion (m/z)	Product ions m/z (%RA)*
Poly(*N*-hexyl-4-vinyl pyridinium)triflate	1195 (A)	106 (5), 178 (15), 190 (53), 517 (95), 529 (100), 856 (16), 868 (13)
	1207 (B)	106 (6), 190 (45), 529 (100), 868 (30)
	1209 (C)	106 (12), 178 (5), 190 (64), 192 (7), 204 (15), 517 (21), 529 (100), 531 (10), 543 (16), 856 (4), 868 (10), 870 (37), 882 (5)
	1221 (D)	106 (12), 120 (3), 190 (37), 204 (12), 529 (82), 531 (3), 543 (100), 868 (11), 882 (40)
	884 (E)	106 (5), 178 (6), 190 (81), 192 (10), 204 (57), 206 (10), 529 (49), 531 (81), 543 (89), 545 (100)
Copolymer having *N*-ethyl and *N*-hexyl groups	1083 (A)	106 (14), 122 (4), 134 (21), 178 (7), 190 (66), 405 (36), 417 (27), 461 (84), 473 (100), 517 (33), 529 (44), 744 (13), 756 (16), 800 (34), 812 (25)
	1095 (B)	106 (10), 122 (4), 134 (17), 190 (24), 417 (26), 473 (100), 487 (3), 529 (25), 545 (3), 756 (6), 812 (7)
	1041 (C)	106 (16), 120 (6), 122 (11), 134 (41), 136 (8), 148 (16), 178 (6), 190 (38), 192 (4), 204 (14), 405 (31), 417 (63), 419 (52), 431 (46), 461 (48), 473 (100), 475 (67), 487 (73), 702 (14), 714 (6), 744 (10), 756 (19), 758 (50), 770 (31)
	1053 (D)	106 (16), 134 (37), 136 (8), 148 (11), 190 (38), 204 (21), 338 (14), 417 (77), 419 (18), 431 (82), 473 (98), 487 (100), 714 (28), 756 (19), 770 (93)
	1111 (E)	106 (26), 122 (18), 134 (30), 136 (23), 148 (14), 178 (15), 190 (40), 204 (23), 309 (15), 417 (13), 419 (12), 431 (18), 473 (32), 475 (44), 487 (24), 489 (30), 501 (38), 758 (16), 772 (18), 800 (11), 814 (12), 826 (12), 828 (13), 840 (25), 961 (10)
Copolymer having *N*-ethyl and *N*-dodecyl groups	1099 (A)	106 (14), 134 (23), 262 (57), 274 (20), 288 (29), 391 (20), 405 (51), 417 (23), 533 (31), 546 (20), 557 (54), 559 (40), 662 (26), 676 (31), 688 (31), 700 (29), 802 (29), 816 (69), 828 (100), 949 (43)
	1123 (B)	106 (37), 120 (11), 134 (33), 148 (12), 162 (12), 212 (11), 262 (24), 274 (56), 288 (24), 323 (12), 338 (13), 417 (24), 459 (18), 557 (19), 636 (55), 700 (100), 714 (33), 840 (25)
	1125 (C)	106 (84), 120 (70), 134 (95), 148 (50), 262 (55), 274 (98), 288 (60), 405 (44), 417 (52), 419 (70), 431 (75), 545 (65), 557 (88), 559 (93), 571 (51), 700 (85), 842 (77), 854 (100), 975 (64)
	994 (D)	106 (10), 134 (9), 148 (15), 274 (85), 288 (70), 507 (18), 557 (30), 571 (60), 697 (60), 711 (100), 723 (12), 844 (20)
	1139 (E)	134 (38), 136 (28), 148 (28), 262 (28), 274 (60), 276 (25), 288 (53), 302 (33), 405 (50), 417 (35), 431 (45), 433 (63), 445 (30), 545 (38), 559 (90), 571 (98), 573 (70), 714 (75), 716 (30), 728 (70), 842 (88), 854 (70), 856 (100), 868 (73), 989 (25)

*Ion abundances are normalized to the most abundant fragment ion in the MS/MS spectrum and are not corrected for isotopic contributions. The standard deviation of the relative ion abundances is 12%.

all five series of ions. It is proposed that this ion is formed by alkene elimination from the *N*-alkyl group of the monomer of Series B (m/z 190 in Scheme 3) as shown opposite.

Turning from polymer-II, we discuss first the other homopolymers and then the copolymers. This discussion continues to focus on A series ions. Series A ions in the DCI mass spectrum of polymer-I [Fig. 1(a)] occur at m/z 122, 405, 688, 971 and 1254, respectively. There appear to be two isomeric ions at m/z 122 and their probable structures and fragmentation pathways, as revealed by MS/MS experiments, are shown in Scheme 4. The product spectrum of ions m/z 122, generated from polymer-I, included m/z 79 (35%), 94 (100%) and 106 (20%) which indicate that these ions are mostly composed of the protonated *N*-ethyl-4-methylpyridine structure, shown in Scheme 4(a). The isomeric ion, protonated 4-isopropylpyridine, m/z 122 shown in



Scheme 4(b), appears to be formed in the DCI mass spectra of the polymers that do not contain the *N*-ethyl group. In these cases the product spectrum of this ion displays the fragments *m/z* 79 (100%), 94 (5%) and 106 (65%), which is consistent with its proposed structure. Note that the formation of the fragment ion, *m/z* 94, is much more favorable

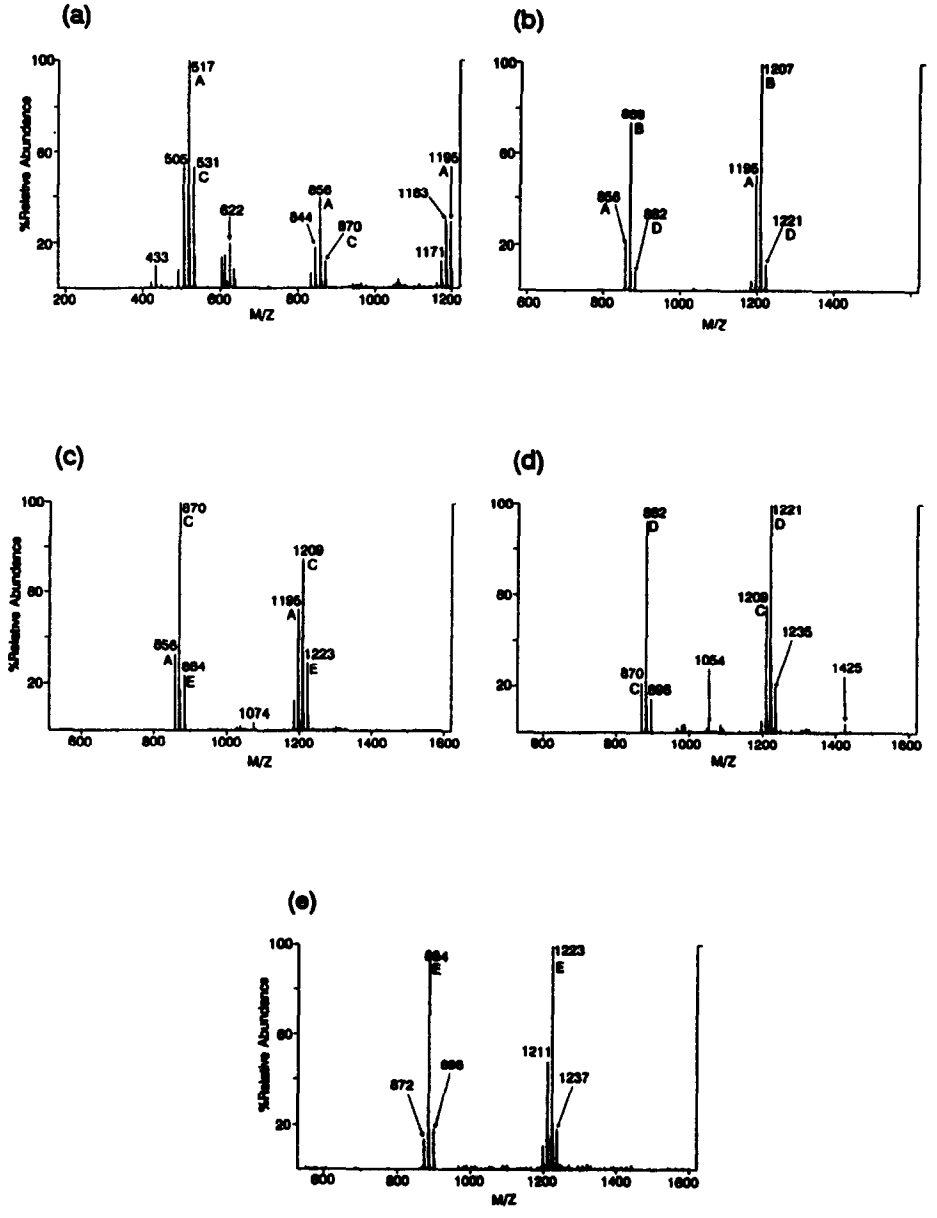


Fig. 4. MS/MS positive ion parent spectra of (a) series A ion *m/z* 178, (b) series B ion *m/z* 529, (c) series C ion *m/z* 531, (d) series D ion *m/z* 543 and (e) series E ion *m/z* 545 from polymer-II.

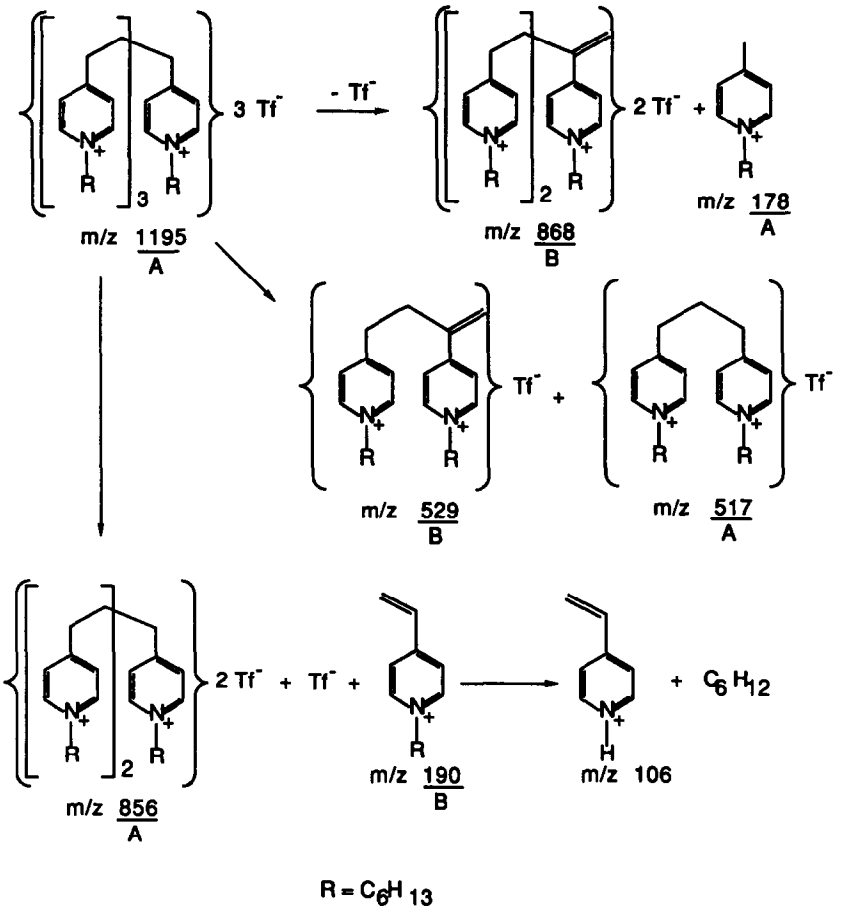
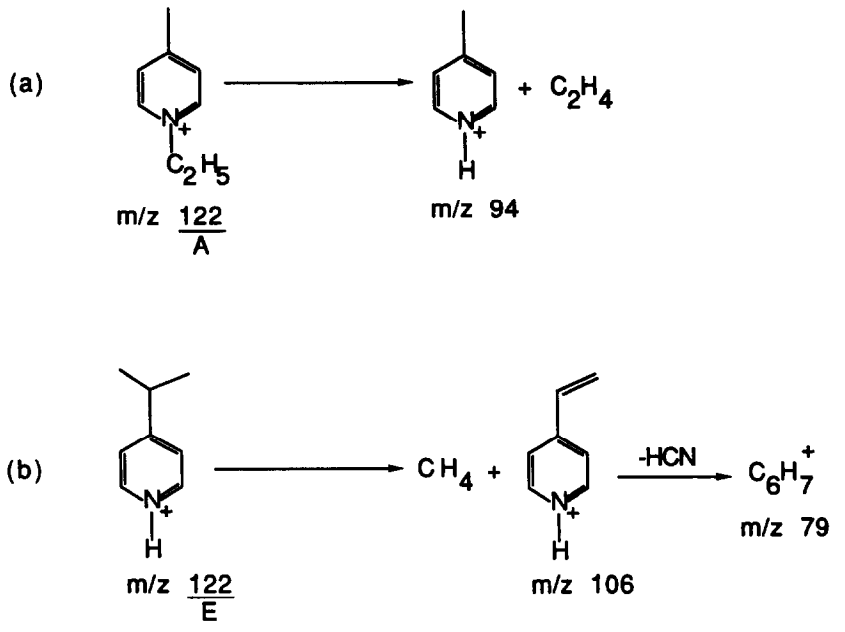


Scheme 3. Proposed fragmentation pathways for Series A ion, *m/z* 1195, determined by MS/MS scans under CAD conditions.

from protonated *N*-ethyl-4-methylpyridine [Scheme 4(a)] than from protonated 4-isopropylpyridine [Scheme 4(b)]. On the other hand, the formation of the fragment ions, *m/z* 106 and 79 is favored from protonated 4-isopropylpyridine [Scheme 4(b)], as indicated by the ion abundances in the product MS/MS spectra. The DCI mass spectrum of polymer-III [poly(*N*-dodecyl-4-vinylpyridinium triflate); not shown here] displays the series A ions *m/z* 262, 685 and 1108 corresponding to $n = 0$, 1 and 2, respectively, in the general formula for series A (Scheme 2).

The copolymers examined by DCI showed ions corresponding to both homo- and hetero-oligomers. For example, Polymer-IV displays the series A ions *m/z* 122, 178, 405, 461, 517, 688, 744, 800, 971, 1027, 1083, 1254 and 1310, respectively, in its DCI mass spectrum (not shown). Ions *m/z* 122, 405, 688, 971 and 1254 are the monomer and homo-oligomers having the *N*-ethyl-4-vinylpyridinium group, *i.e.*, they are the same ions as discussed above in connection with polymer-I, while ions *m/z* 178 and 517 are the monomer and homo-dimer containing the *N*-hexyl-4-vinylpyridinium group. The remaining ions are the hetero-oligomer ions *m/z* 461 (dimer), *m/z* 744 (trimer having two *N*-ethyl and one *N*-hexyl groups), *m/z* 800 (trimer having one *N*-ethyl and two *N*-hexyl groups), *m/z* 1027 (tetramer having three *N*-ethyl and one *N*-hexyl groups), *m/z* 1083 (tetramer having one *N*-ethyl and three *N*-hexyl groups) and *m/z* 1310 (pentamer having four *N*-ethyl and one *N*-hexyl groups), respectively.

Structural compositions of these ions are supported by the MS/MS experiments summarized in Table 1. For example, fragmentation of the ion *m/z* 1083 (Table 1) clearly shows that it consists of two *N*-ethyl and two *N*-hexyl groups. It produces the series A ions *m/z* 800, 744, 517, 461, 405, 178 and 128 having the compositions described earlier. It also produces series B ions at *m/z* 812, 756, 529, 473, 417, 190 and 134. The presence of all these ions in the MS/MS product spectrum of *m/z* 1083 (Table 1) supports the proposed structure for this ion and



Scheme 4. Proposed structures of the two isomeric ions of *m/z* 122 and their fragmentation pathways, as suggested by MS/MS product scans.

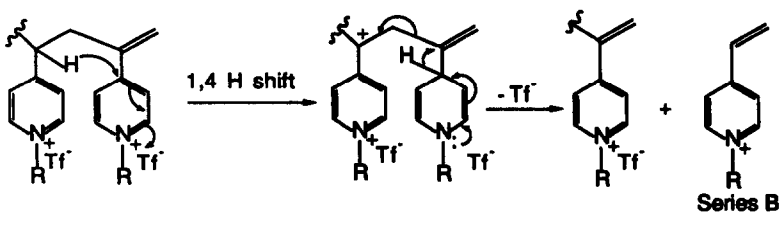
is consistent with the general fragmentation pathways discussed earlier. The MS/MS parent spectrum of the hetero-dimer ion *m/z* 461 shows series A ions *m/z* 744, 800, 1027 and 1083; series C ions *m/z* 758, 1041 and 1097; and ions of the series *m/z* 732, 788, 1015 and 1071 as its precursors. This behavior is analogous to that of the A series N-hexyl ion, *m/z* 178, discussed above.

The DCI mass spectrum of polymer-V (Fig. 3) displays the series A ions *m/z* 122, 262, 405, 533, 685, 688, 816, 971, 1099 and 1239, respectively. The ions at *m/z* 122, 405, 688 and 971 are the homo-oligomers containing *N*-ethyl-4-vinylpyridinium groups, and their structures and compositions have already been discussed. Analogous ions, containing the *N*-dodecyl-4-vinylpyridinium group, appear at *m/z* 262 and 685. The hetero-oligomer ions are *m/z* 533 (dimer), 816 (trimer having two *N*-ethyl and one *N*-dodecyl groups), 1099 (tetramer having three *N*-ethyl and one *N*-dodecyl groups) and 1239 (tetramer having two *N*-ethyl and two *N*-dodecyl groups), respectively. Oligomers having the *N*-dodecyl group display more fragment ions compared to other oligomers due to the multiplicity of C—C linkages in the *N*-dodecyl substituent. The MS/MS product spectrum of the hetero-oligomer ion *m/z* 1099 (Table 1) shows the expected ions of series A and series B.

The mixed dimer ion *m/z* 533 shows series A ions *m/z* 816, 956, 1099 and 1239; series C ions *m/z* 830, 982, 1113, 1265; and the series B ions *m/z* 804, 944, 1087 and 1227 as its precursors in MS/MS parent spectrum (Fig. 5).

Series B ions

Ions of this series are the most abundant in the DCI mass spectra of all the poly(*N*-alkyl-4-vinylpyridinium triflates. These ions have a double bond whose position is not known definitively, but for convenience, it is shown in the original terminal position (Scheme 2) and a probable mechanism of formation, a 1,4 hydride shift followed by a 1,2 shift, is shown below:



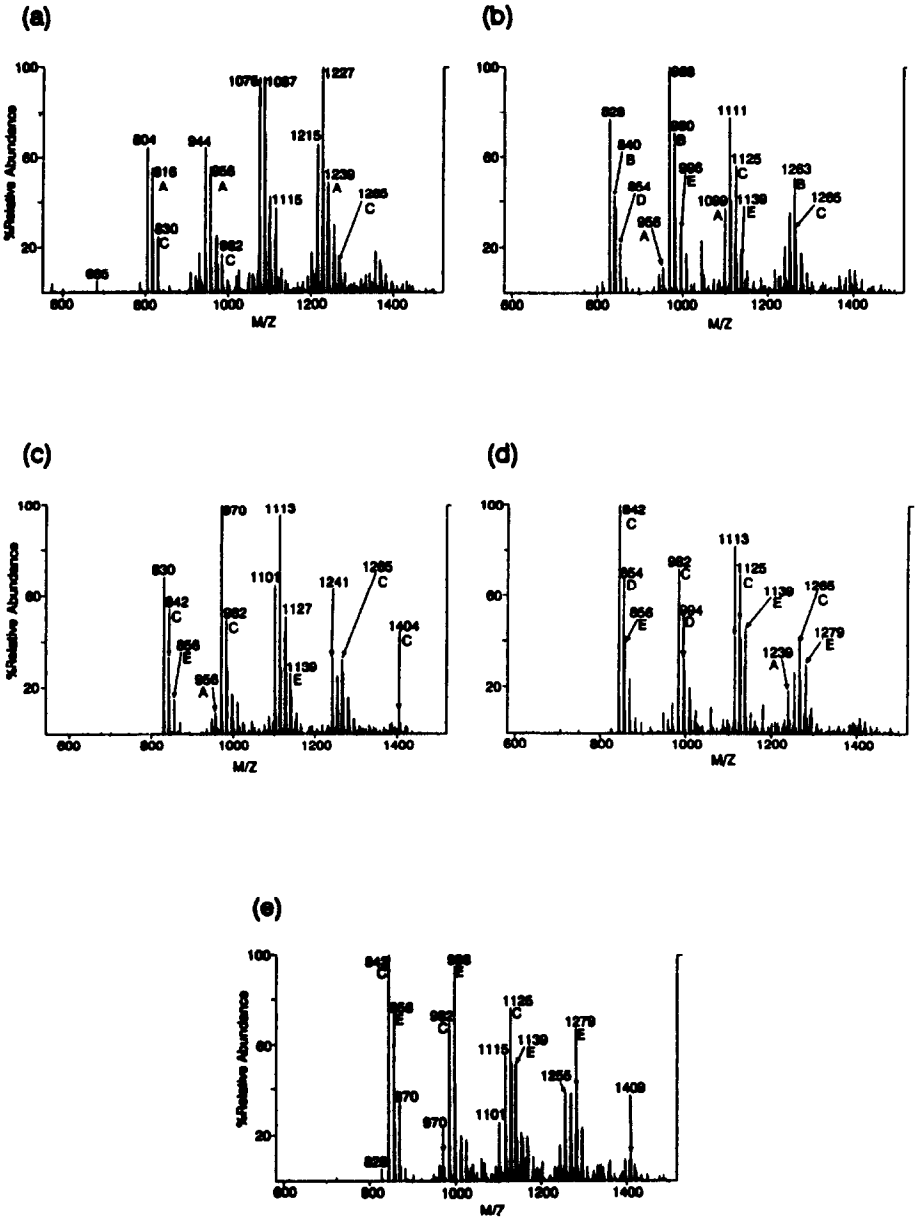


Fig. 5. MS/MS positive ion parent spectra of (a) series A ion m/z 533, (b) series B ion m/z 557, (c) series C ion m/z 559, (d) series D ion m/z 571 and (e) series E ion m/z 573 from polymer-V.

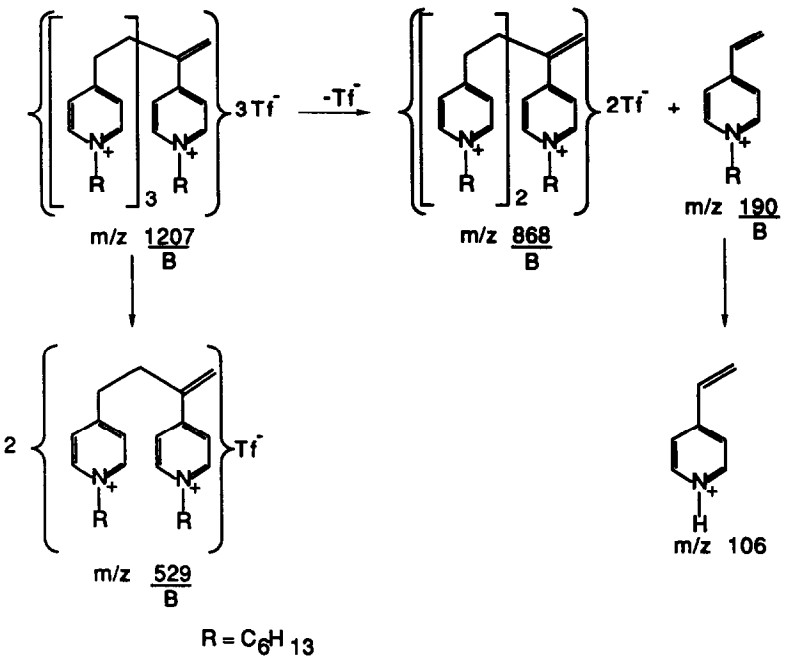
Each ion of this series has a mass 12 daltons higher than the corresponding ion of series A and the lowest member of the series is the monomeric *N*-alkyl-4-vinylpyridinium cation. The DCI mass spectrum of polymer-II (Fig. 2) shows series B ions m/z 190, 529, 868, 1207 and 1546 corresponding to the mono-, di-, tri-, tetra- and pentamer, respectively. Fragmentation pathways of series B ions are the simplest among the five series observed in the DCI mass spectra of the polymers because the series B ions generate mostly lower mass ions belonging to the same series. This is illustrated by the typical fragmentation pathway shown in Scheme 5. The ion m/z 1207 is chosen for this example and data from its MS/MS product spectrum are collected in Table 1. This ion fragments to produce ion m/z 106, the 4-vinylpyridinium cation and other series B ions m/z 190, 529 and 868, respectively. MS/MS parent spectra of series B ions show higher mass ions of series B as the major precursors in combination with ions from all other series. For example, the MS/MS parent spectrum of ion m/z 529, [Fig. 4(b)], shows series A ions at m/z 856 (23%) and 1195 (50%); series B ions at m/z 868 (74%) and 1207 (100%);



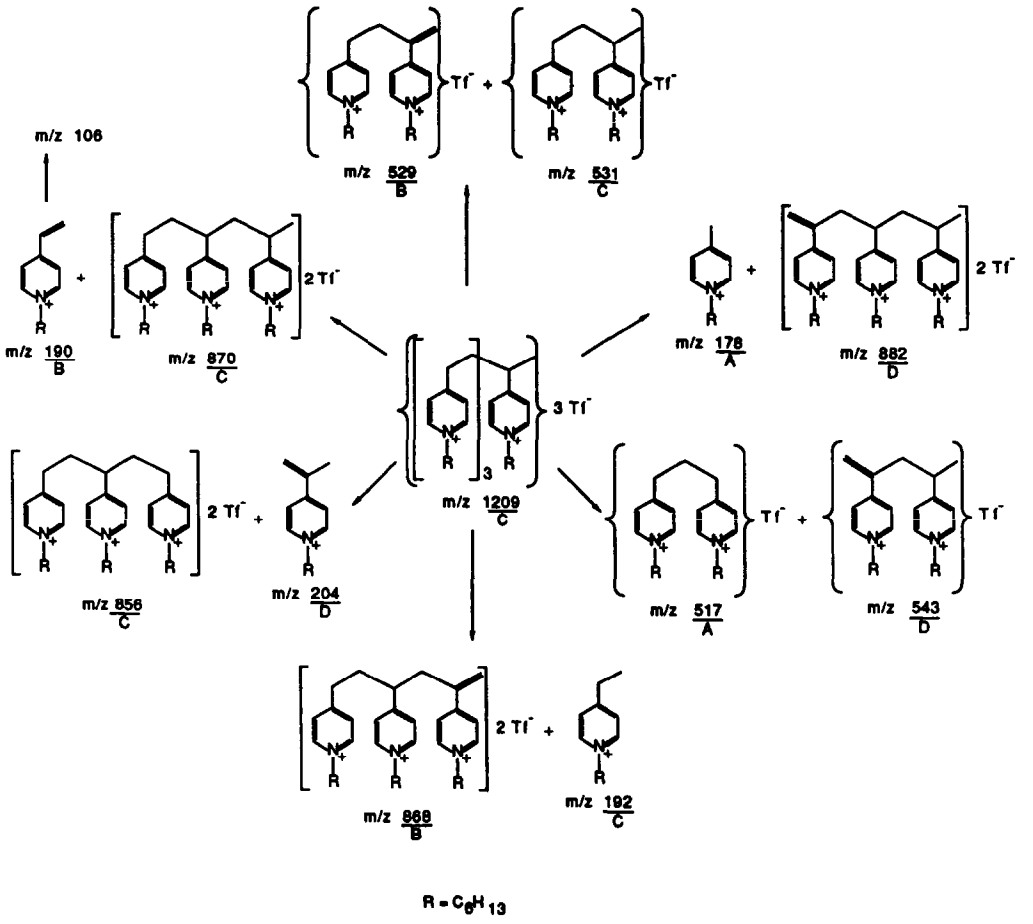
Scheme 5. Proposed fragmentation pathways for Series B ion, *m/z* 1207, determined by MS/MS scans under CAD conditions.

a series C ion at *m/z* 1209 (22%); series D ions at *m/z* 882 (10%) and 1221 (15%); and a series E ion *m/z* 1223 (5%) as its precursors. The ease of formation of series B ions from both saturated and unsaturated polymer chains as suggested below explains their high relative abundances in the DCI mass spectra of the polymers.

The DCI mass spectra of polymers I, III, IV and V show similar ions of B-series to those discussed for polymer II. MS/MS experiments showed many fragment ions in the case of *N*-dodecyl containing oligomers generated from polymer-V because of the ease of dissociation of the complex *N*-dodecyl group, as mentioned above. These fragment ions were again diagnostic of the structural compositions of the oligomers. For example, the MS/MS product spectrum of the ion *m/z* 1123 (Table 1) displays a series A ion at *m/z* 262; series B ions at *m/z* 134 (*N*-ethyl-4-vinylpyridinium monomer, *m/z* 274 (*N*-dodecyl-4-vinylpyridinium monomer), *m/z* 417 (dimer having *N*-ethyl groups); *m/z* 557 (hetero-dimer), *m/z* 700 (trimer having *N*-ethyl groups), *m/z* 840 (trimer consist of two *N*-ethyl and one *N*-dodecyl groups); series D ions at *m/z* 148, 288 and 714, respectively. It is evident from the product spectrum that three *N*-ethyl groups and one *N*-dodecyl group comprise the hetero-tetramer ion, *m/z* 1123. MS/MS parent spectrum of the hetero-dimer ion *m/z* 557 [Fig. 5(b)] shows the series A ions *m/z* 1099 and 1239; series B ions *m/z* 840, 980, 1123, 1263; series C ions 842, 982, 1125 and 1265; series D ions *m/z* 854 and 994; and series E ions *m/z* 996 and 1139, respectively.

Series C ions

This series is the saturated form (with respect to the main carbon chain) of series B and therefore the mass of each member of this series is 2 daltons higher than the corresponding ion of series B. Ions of series C in the DCI mass spectrum of polymer-II (homopolymer of *N*-hexyl-4-vinylpyridinium triflate; Fig. 2) include the monomer (*m/z* 192) through the pentamer (*m/z* 1548) corresponding to $n = 0$, 1, 2, 3 and 4 in the general structure shown in Scheme 2. Collision activated dissociation of these ions yields a rich spectrum with fragment ions belonging to series A, B, C, and D respectively. For example, the MS/MS product spectrum of *m/z* 1209 (Table 1) shows series A ions at *m/z* 178, 517, 856; series B ions at *m/z* 190, 527, 868; series C ions 192, 531, 870; and series D ions *m/z* 204, 543, and 882. The structures of the series A and B ions have already been discussed and the presence of these ions helps to confirm the structure of the C series tetramer, *m/z* 1209. Routes of fragmentation of this ion, *m/z* 1209, are shown in Scheme 6 and are typical of the series C ions.

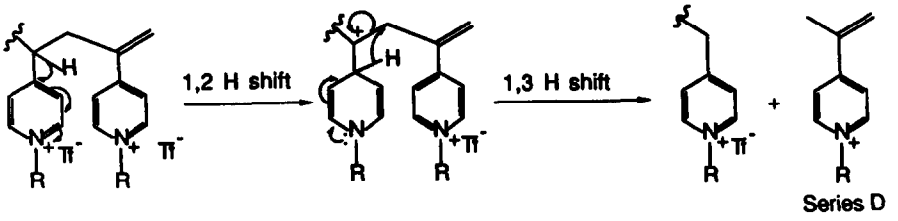


Scheme 6. Proposed fragmentation pathways for Series C ion, *m/z* 1209, determined by MS/MS scans under CAD conditions.

The MS/MS parent spectrum of the dimer ion *m/z* 531 [Fig. 4(c)] shows series A ions at *m/z* 856, 1195; series C ions at *m/z* 870, 1209; and series E ions at *m/z* 884 and 1223, respectively. The parent spectrum clearly proves that series C ions are only formed from series having saturated main chains. Major precursors of *m/z* 531 are the higher mass ions of series C. Polymers I, III, IV, and V show similar behavior with respect to series-C ions in their DCI mass spectra. Ions of series C in the DCI mass spectrum of polymer-V (Fig. 3) are the monomer and homo-oligomers *m/z* 136, 419, 702 and 985 containing *N*-ethyl-4-vinylpyridinium group; ions *m/z* 276, 699 and 1122 containing *N*-dodecyl-4-vinylpyridinium group; and the mixed-oligomer ions *m/z* 559 (mixed-dimer), *m/z* 842 (trimer composed of two *N*-ethyl and one *N*-dodecyl groups), *m/z* 982 (trimer having one *N*-ethyl and two *N*-dodecyl groups), *m/z* 1125 (tetramer comprised of three *N*-ethyl and one *N*-dodecyl groups), *m/z* 1265 (tetramer having two *N*-ethyl and two *N*-dodecyl groups) and *m/z* 1405 (tetramer comprised of one *N*-ethyl and three *N*-dodecyl groups). The MS/MS product spectrum of ion *m/z* 1125 (Table 1) is consistent with the proposed structure of the ion. The MS/MS parent spectrum of the co-dimer *m/z* 559 [Fig. 5(c)] displays high mass ions of series A, C and E as its precursors.

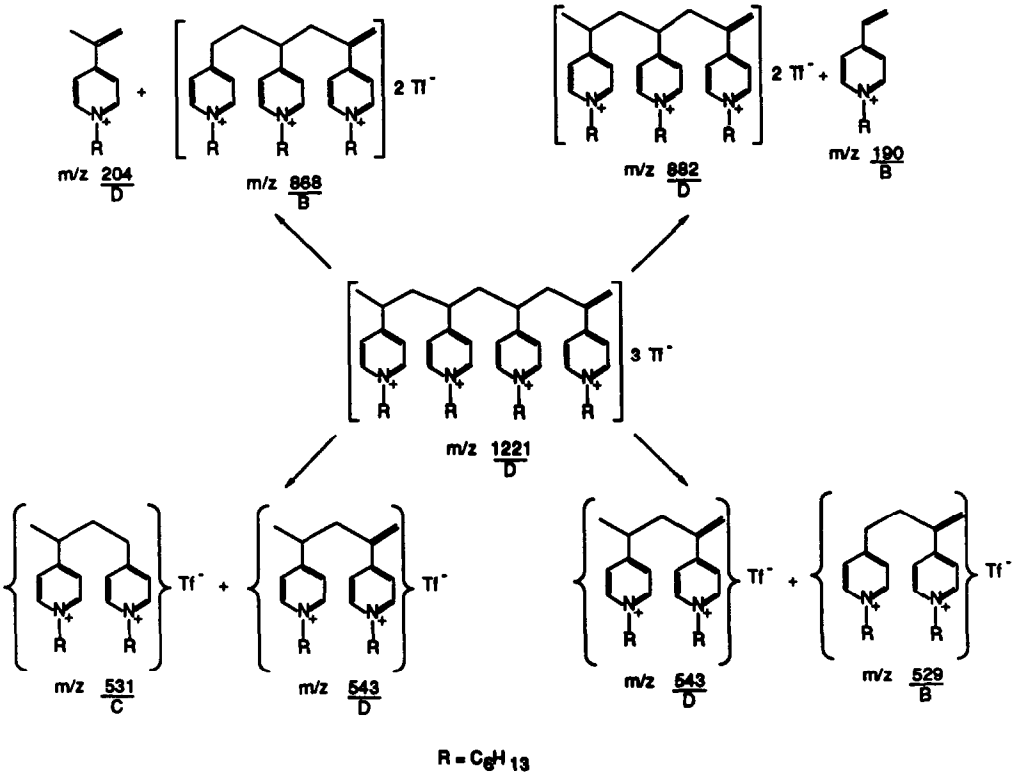
Series D ions

Ions of series D, like their homolog, series B, have a double bond in the main carbon chain. The probable location for the double bond is the terminal vinyl group in the main chain. The formation of these ions may involve a 1,2 hydride shift followed by 1,3 hydride shift as shown in the following tentative scheme, but this remains to be established.



Ions with *m/z* 204, 543, 882 and 1221 corresponding to mono-, di-, tri- and tetramer in the DCI mass spectra of polymer-II (homopolymer having N-hexyl group; Fig. 2) belong to series D. Typical MS/MS fragmentation pathways for this series are shown in Scheme 7 using the tetramer, *m/z* 1221, as an example (Table 1). Ions *m/z* 120 and 106 in the MS/MS product spectrum of *m/z* 1221 are formed by loss of hexene from the *N*-alkyl group of ions *m/z* 204 and 190 as shown in Scheme 7. The ion at *m/z* 543 can be formed by two different channels (Scheme 7) during collision activated dissociation of *m/z* 1221, which helps explain why *m/z* 543 is the most abundant ion in the MS/MS product spectrum. Scheme 7 also shows formation of series B ions at *m/z* 190, 529, 868; a series C ion at *m/z* 531, and series D ions at *m/z* 204, 543, and 882. The MS/MS parent spectrum of the D ion *m/z* 543 [Fig. 4(d)] shows higher members of series D ions viz. *m/z* 882 (80%) and 1221 (100%) as its major precursors along with ion *m/z* 870 (20%) of series C and *m/z* 884 (18%) and *m/z* 1223 (36%) of series E, respectively.

The DCI mass spectrum of polymer-V (Fig. 3) shows series D ions *m/z* 148 (monomer having *N*-ethyl group), *m/z* 288 (monomer having *N*-dodecyl group), *m/z* 431 (dimer having *N*-ethyl group), *m/z* 571 (mixed-dimer), *m/z* 711 (dimer having dodecyl groups), *m/z* 714 (trimer having *N*-ethyl groups), *m/z* 994 (mixed trimer having one *N*-ethyl and two *N*-dodecyl groups), *m/z* 997 (tetramer composed of *N*-ethyl groups) and *m/z* 1134 (trimer composed of *N*-dodecyl groups) respectively. The presence of the ions at *m/z* 711 and *m/z* 571 in the product spectrum of ion *m/z* 994 (Table 1) confirms that the latter is



Scheme 7. Proposed fragmentation pathways for Series D ion, *m/z* 1221, determined by MS/MS scans under CAD conditions.

composed of a trimer having one *N*-ethyl and two *N*-dodecyl groups. The MS/MS parent spectrum of the mixed-dimer, *m/z* 571 [Fig. 5(d)] shows high mass ions of all five series as its precursors.

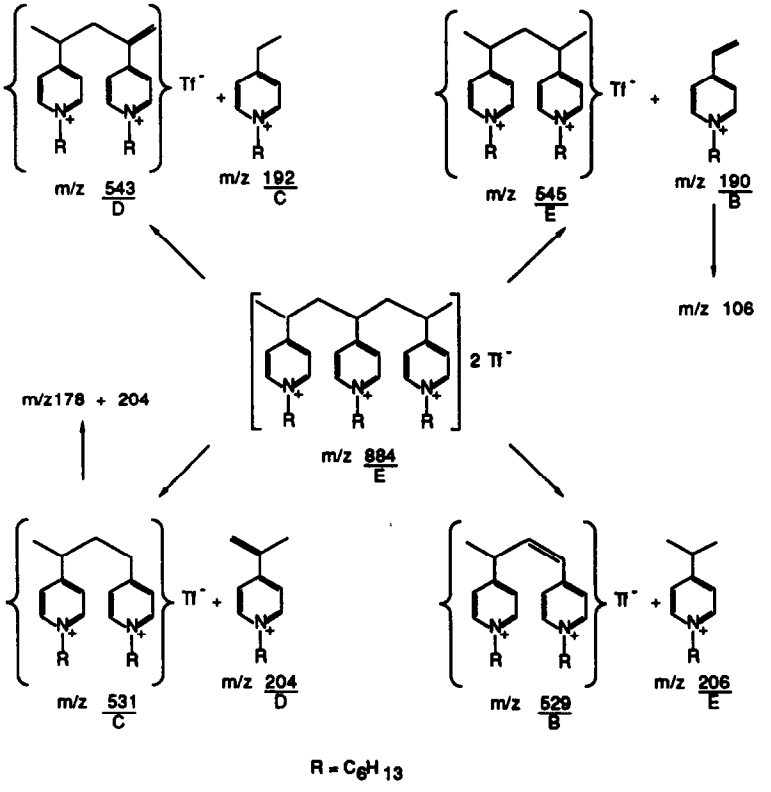
Series E ions

These ions are the saturated forms of the ions of series D. The DCI mass spectrum of polymer-II (homopolymer composed of *N*-hexyl groups; Fig. 2) displays series E ions *m/z* 206, 545, 884 and 1223 the structures of which can be obtained by substituting $n = 0$, 1, 2 and 3 in the general structure of series E ions (Scheme 2). Typical MS/MS fragmentation pathways for this series are shown in Scheme 8 using data taken from the MS/MS product spectrum (Table 1) of the trimer ion *m/z* 884. Ions of all five series are present in the MS/MS spectrum. The parent spectrum of *m/z* 545 [Fig. 4(e)] shows series C ions at *m/z* 870, 1209 and series E ions at *m/z* 884 and 1223 as its precursors. The homopolymers having *N*-ethyl group and *N*-dodecyl group show analogous behavior.

The DCI mass spectrum of polymer-V shows series E ions at *m/z* 150 (monomer having *N*-ethyl group), *m/z* 433 (dimer having *N*-ethyl group), *m/z* 573 (mixed-dimer), *m/z* 713 (dimer having *N*-dodecyl groups), *m/z* 856 (mixed-trimer composed of one *N*-dodecyl and two *N*-ethyl groups), *m/z* 996 (mixed-trimer having one *N*-ethyl and two *N*-dodecyl groups), *m/z* 999 (tetramer composed of *N*-ethyl group), *m/z* 1139 (mixed-tetramer composed of one *N*-dodecyl and three *N*-ethyl groups) and *m/z* 1282 (pentamer composed of *N*-ethyl group), respectively. Collision activated dissociation of *m/z* 1139 (Table 1) produces fragment ions *m/z* 716 (trimer composed of *N*-ethyl groups) and *m/z* 573 (mixed-dimer) among other ions, proving evidence for the structural composition of *m/z* 1139 as a tetramer having three *N*-ethyl and one *N*-dodecyl groups. The MS/MS parent spectrum of the mixed-dimer ion *m/z* 573 [Fig. 5(e)] displays mostly high-mass ions of series C and E respectively.

Other processes

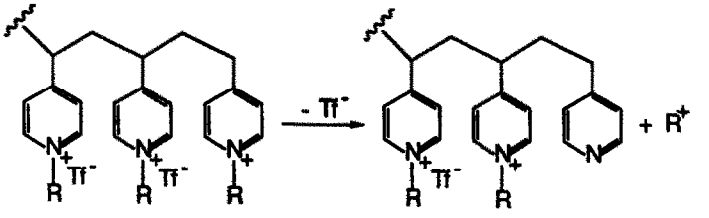
The DCI mass spectra of the polymers display other ions besides those belonging to the five series discussed so far. Most of these ions are the result of simple fragmentation of the series ions. One such fragment ion series has as its lowest member the 4-vinylpyridinium ion, *m/z* 106,



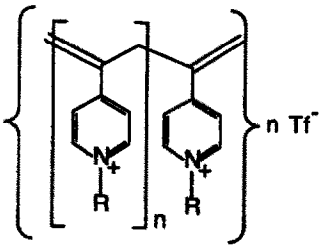
Scheme 8. Proposed fragmentation pathways for Series E ion, *m/z* 884, determined by MS/MS scans under CAD conditions.

shown in Scheme 5. These ions are formed by alkene loss from the *N*-alkyl group according to the mechanism shown in the discussion of series A ions. A similar mechanism has been proposed by Katritzky *et al.* for fragmentation of *N*-alkylpyridinium ions.[36-38] Higher members of this series are present in the DCI mass spectrum of polymer-II (homopolymer composed of *N*-hexyl groups; Fig. 2) and are due to loss of C_6H_{12} *m/z* 445 (series B dimer-C_6H_{12}), *m/z* 784 (series B trimer-C_6H_{12}) and *m/z* 1123 (series B tetramer-C_6H_{12}), respectively.

Another series of low abundance ions in the DCI mass spectra of the polymers are formed by the loss of both a triflate anion and the *N*-alkyl substituent as a carbocation, as shown in the following reaction. These ions have neutral 4-vinylpyridine groups in their structures.



Formation of neutral pyridine and the corresponding carbocation during gas-phase fragmentation of *N*-alkylpyridinium ions has been reported in the literature.[36-38] Ions belonging to this series in the mass spectrum of polymer-I [Fig. 1(a)] are *m/z* 211 (4-vinylpyridinium ion + 4-vinylpyridine), *m/z* 239 (*N*-ethyl-4-vinylpyridinium ion + 4-vinylpyridine), and *m/z* 819 (series D trimer + 4-vinylpyridine). Ions, *m/z* 295 (*N*-hexyl-4-vinylpyridinium ion + 4-vinylpyridine) and *m/z* 634 (series B dimer ion + 4-vinylpyridine), in the mass spectrum of polymer-II (Fig. 2) also belong to this series. The presence of both the ion *m/z* 379 (*N*-dodecyl-4-vinylpyridinium ion + 4-vinylpyridine) and the carbocation *m/z* 169 ($C_{12}H_{25}^+$) in the DCI mass spectrum of polymer-III supports the mechanism proposed in the above reaction. Another minor series of ions having doubly unsaturated main chains corresponds to the unsaturated form of D ions and is also present in the DCI mass spectra of the polymers. These doubly unsaturated ions are clearly displayed at *m/z* 712 in the DCI mass spectrum of polymer-I (Fig. 1(a)), at *m/z* 709 in the DCI mass spectrum of polymer-III and *m/z* 569 in the DCI mass spectrum of polymer-V (Fig. 3). A general structure of these ions is suggested in the following reaction.



Ions two mass units different from the main series ions are apparent in the DCI mass spectra of the polymers. For example, the DCI mass spectrum of polymer I shows the ions at *m/z* 712 and *m/z* 981 which are two mass units below the main series ions, D and E, respectively. These types of ions might be formed by processes involving skeletal fragmentation with hydrogen transfer. These ions contribute isotope to the main series ions.

CONCLUSIONS

The capabilities of DCI mass spectrometry in producing characteristic oligomeric ions and of DCI MS/MS in characterizing the structures of these ions has been demonstrated. The ion chemistry described here should find application in methods for structural characterization of vinylpyridinium polymers. All five series of positive ions observed in the DCI pyrolysis/mass spectra of these polymers are stable species that yield structural information on their constituent monomers by CAD. Series A ions have a saturated main chain and yield mostly low mass ions of series A and series B on gas-phase fragmentation by CAD. The most abundant species in the DCI mass spectra of the polymers, ions of series B, have double bonds along their main chain and are produced as products of CAD of all five

series of ions. They themselves undergo simple fragmentation during CAD, principally forming lower mass ions of series B. Ions of series C are the saturated form of the corresponding ions of series B and form ions of series A, B, C, and D upon collision activated dissociation. These ions show ions of the saturated species, *viz.* series A, C and E, as precursors in their MS/MS parent spectra. Ions of series D and E are the homologs of series B and C ions respectively. DCI mass spectra of the poly(*N*-alkyl-4-vinyl-pyridinium) triflates also show other series of ions that are formed by simple fragmentation at the *N*-alkyl groups. One such series is formed by alkene loss from the *N*-alkyl group of the ions of the major series and another fragment series is found to be generated by loss of the *N*-alkyl group as carbonium ions, leaving a neutral pyridine-substituted oligomer. Another low intensity doubly unsaturated series of ions, corresponding to the unsaturated form of the D ions is also observed in the DCI mass spectra of the polymers.

APPLICATION OF ION-EXCHANGE-RESIN PHASE SPECTROPHOTOMETRY TO FLOW INJECTION ANALYSIS SYSTEM—I. DETERMINATION OF TRACE ZINC IN HAIR OF CHILDREN

REN-MIN LIU, DAO-JIE LIU and AI-LING SUN
Department of Chemistry, Liaocheng Teachers College, Liaocheng, Shandong, P. R. China.

(*Received* 7 *January* 1992. *Revised* 2 *July* 1992. *Accepted* 2 *July* 1992)

Summary—A novel flow injection analysis system with ion-exchange-resin phase spectrophotometric detection is described in this paper. Zincon was presorbed on the ion-exchange resin. The resin was then added to a flow-through cell. When samples pass through the resin, the zincon presorbed on the resin reacts with zinc(II) to form the zincon–zinc(II) complex, which has an absorption maximum at 620 nm in solution, but at 650 nm in the resin phase. The measurements were made at 650 nm. High sensitivity and precision can be obtained by the proposed method. When 4.0 ml of sample solution was used, the sensitivity obtained was more than 10 times higher than that of the corresponding solution method. The proposed method has been successfully applied to the determination of zinc in the hair of children.

Ion-exchange resin phase spectrophotometry is based on the direct measurement of the degree of light absorption by an ion-exchange resin phase that has sorped a sample component. It combines the steps of preconcentration, separation and determination and provides a sensitivity several hundred times greater than that obtained with solution phase spectrophotometry. By direct application of the method, trace elements in water samples can be determined without additional preconcentration. Analytical methods for up to 20 elements have been developed and were summarized in a review.[1–9] Recently, ion-exchanger phase spectrophotometry has been applied to flow analysis.[10–12] This provides a novel means for studying ion-exchanger phase spectrophotometry.

In the present work, ion-exchange resin phase spectrophotometry was applied to a flow injection analysis (FIA) system. The purpose of this study was to apply chelating agent-loaded resin phase spectrophotometry to an FIA system. Zincon was presorbed on the ion-exchange resin. This formed the chelating agent-loaded resin. The resin was then added into a flow-through cell (Fig. 3). When samples pass through the resin beads, the immobilized zincon reacts with zinc(II) to form the zincon-Zn(II) complex, which has an absorption maximum at 650 nm in the resin phase. The proposed method has been applied to the direct determination of zinc in the hair of children.

EXPERIMENTAL

Reagents

Stock zinc solution, 1000 μg/ml.

pH Buffer solution. A 31-g weight of boric acid, 37 g of potassium chloride and 10 g of thiourea were dissolved in 800 ml of water and the pH was adjusted to about 9.0 with 20% sodium hydroxide, and the solution was diluted to 1000 ml.

Eluent solution. Hydrochloric acid (0.20*M*)

Zincon solution, 0.02%. A 0.020-g weight of zincon was dissolved in a 2 ml of 1*M* sodium hydroxide and the solution was diluted to 100 ml.

Ion-exchange resin. 201 × 4(100 ~ 160 mesh) anion-exchange resin in the chloride form (NanKai University) was used. It was conditioned, air-dried at 40° and stored in polyethylene containers.

All chemicals used were of analytical grade and were prepared with demineralized water.

Apparatus

The FIA system is shown in Fig. 1. The peristaltic pump was supplied by the Jiangsu Electroanalytical Instrument Plant. A six-way rotary valve with two PTFE tube loops was used for sample and eluent injection. The connection of the valve is shown in Fig. 2. Sample and eluent solutions were injected into the carrier solution alternately by an asynchronous injection technique. A 721

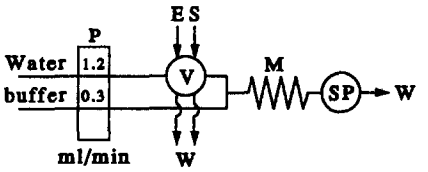

Fig. 1. Schematic diagram of the FIA system. P, peristaltic pump; V, six-way injection valve with two loops (one is 4.0 ml for sample injection the other is 1.0 ml for eluent injection); S, sample; E, eluent; M, mixing coil (100 cm, i.d. 1.0 mm); SP, spectrophotometer; W, waste.

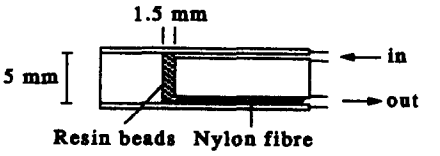

Fig. 3. Schematic diagram of the resin-filled flow-through cell.

spectrophotometer (The Third Analytical Instrument Plant of Shanghai) connected to a XWT-S platform recorder (The Third Automatic Instrument Plant of Shanghai) was used as the detector with a flow-through cell (Fig. 3). the cell had a black side, a 5 mm path and a diameter of 1.5 mm. In order to retain the resin in the cell, the cell was blocked with nylon fibre.

Procedures

Preparation of chelating resin loaded with zincon. One gramme of the anion-exchange resin was stirred with 20 ml of the zincon solution for 30 min and then the resin was collected. The amount of the zincon taken up was determined by measurement of the absorbance at 470 nm. About 7 μmoles of zincon was loaded on 1 g of the resin. The capacity for chelating metal is about 7 μmol/g resin. The chelating resin loaded with zincon has high stability. No zincon can be released even in 1.0*M* sodium chloride and 0.1*M* hydrochloric acid.

Determination. The FIA system is connected with PTFE tubing (1.0 mm i.d.) according to the arrangement shown in Fig. 1 and Fig. 2. Inject the sample solution (4.0 ml) into the carrier (water) solution flowing at 1.2 ml/min and merging with the buffer solution flowing at 0.3 ml/min. Allow the sample slug to pass through the flow-through cell, in which the colour-forming reaction takes place. Read the absorbance in the flow-cell at 650 nm. Inject the eluent solution into the carrier solution when the absorbance steady state has been recorded. When the recorder comes back to its baseline the next sample is then injected and determined as before.

Prepare a series of standard solutions of Zn(II). Inject these solutions into the carrier solution, as for sample solutions, before and after the sample runs.

Use the peak height (maximum absorbance) as a measure of absorbance throughout for the samples and calibrations runs.

RESULTS AND DISCUSSION

Zincon is a sensitive reagent for zinc. It reacts with zinc(II) to form a blue colour complex in the pH range 8.5–9.5. The complex decomposes immediately when the pH of the solution is below 6. As a result, a buffer solution of borate with a pH of 9.0 was employed for complex formation and a 0.20*M* hydrochloric acid solution was employed for the desorption of the zinc from the resin.

Effect of flow-rate

Figure 4 shows the influence of flow-rate (carrier solution and buffer solution together,

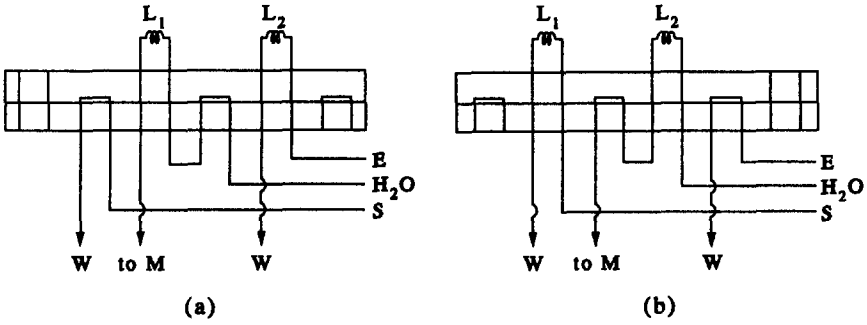

Fig. 2. Schematic diagram of the connection of the valve. (a), Sample injection position; (b), eluent injection position; E, eluent; S, sample; L1, loop for sample; L2, loop for eluent; M, to mixing coil; W, waste.

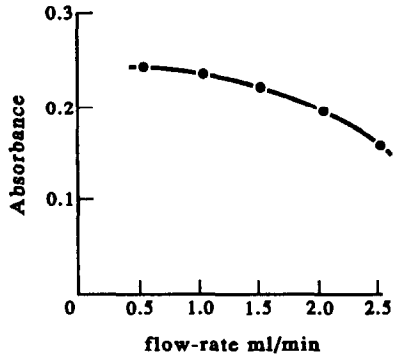

Fig. 4. Effect of flow-rate on sensitivity. Sample volume, 4.0 ml.

the ratio of them is 4:1) on the measurement of a 100 μg/l. Zn(II) solution. It can be seen that a change in the flow-rate from 0.5–2.5 ml/min decreased the sensitivity by 32%. However there was a linear relationship between the measured absorbance and the Zn(II) concentration determined at a constant flow-rate. Measurements at flow-rate lower than 0.6 ml/min took longer than 10 min. In all subsequent experiments, the total flow-rate was maintained at 1.5 ml/min.

Effect of sample volume

The increase of the sample volume resulted in a proportional increase of absorbance. Much higher sensitivity can be obtained by employing a larger volume of sample solution. But more time would be required for each determination. So the selection of sample volume should reflect a consideration of sensitivity and analysis speed.

Calibration and sensitivity

According to the proposed procedure, the calibration graph was established with standard solution of Zn(II) (Fig. 5). The calibration curve is reasonably linear in the concentration range

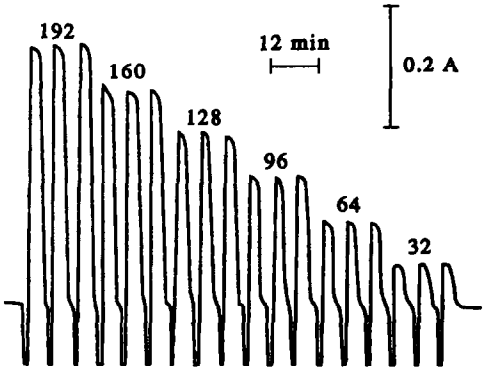

Fig. 5. Recorder signals for standard solution of Zn. Values above the peaks are concentrations of Zn in μg/l.

of 16–360 μg/l. The sensitivity of the proposed method has been compared with that of a conventional FIA method (Table 1). The sensitivity is more than 10 times higher than that of corresponding solution method for a 4.0 ml sample injection.

Precision and detection limit

Precision was measured with a sample solution of 32 μg/l. and 80 μg/l. in Zn(II), respectively. For 10 determinations, the relative standard deviations obtained were 1.4 and 1.1%, respectively. The detection limit, defined as the concentration that produces an absorbance equal to twice the magnitude of the fluctuation in the background was as low as 4.2 μg/l.

Effect of foreign ions

The following ions interfere in the determination of zinc when present in a molar ratio to zinc of 1:1 or more: aluminium, iron(III), chromium(III), cobalt(II), nickel(II), manganese(II), lead(II), molybdenum(VI), cadmium(II), mercury(II) and bismuth(III). These elements in hair samples were also determined by us. The maximum value of these elements in hair are as follows (ppm): aluminum (42.8), iron (37.6), chromium (0.19), cobalt (0.07), nickel (0.42), manganese (1.46), lead (9.72), molybdenum (0.31) and cadmium (0.21). They are not high enough to interfere in the determination of zinc in hair samples. Copper(II) interferes seriously. It can be masked by the addition of thiourea in the buffer solution.

Determination of zinc in hair of children

Hair is an excretive organ of the human body. The content of micro-elements in hair can reflect the cumulative status of micro-elements in the human body.[13] Zinc is an essential micro-element. So the determination of zinc in hair of children is of great interest in the evaluation of nutrient status. The present method has been applied to the determination of zinc in the hair of children. Hair was washed with acetone and

de-ionized water to remove surface contamination and dry-ashed in a muffle furnace at 450°, and the residue was dissolved in nitric acid. The pH of the solution was adjusted to about 9.0 and diluted to 50 ml with demineralized water. The solution was then analysed by the proposed method and an AAS method. The results are listed in Table 2. Table 2 showed that the results of this method are in accordance with those of the AAS method.

SPECTROPHOTOMETRIC DETERMINATION OF GADOLINIUM(III) WITH 2-(5-BROMO-2-PYRIDYLAZO)-5-DIETHYLAMINOPHENOL (5-Br-PADAP)

L. D. MARTINEZ, E. PERINO, E. J. MARCHEVSKY and R. A. OLSINA

(*Received* 14 *November* 1991. *Revised* 2 *July* 1992. *Accepted* 2 *July* 1992)

Summary—Reaction between gadolinium(III) and 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) was studied for delineating optimal conditions for complexation. This reagent can be used for the spectrophotometric determination of Gd(III) in concentrations ranging from 0.04 to 1.2 ppm ($a = 1.76(\pm 0.03) \times 10^5$ (l.$^{-1}$ mole^{-1} . cm). The reaction takes place at a pH between 9.2 and 11.6. In the presence of Triton X-100 this complex is soluble in water. In order to overcome difficulties caused by the presence of other lanthanides, an ion exchange chromatographic technique was used.

For several years, the use of micellar media of ternary metal–chromophore–surfactant systems has been a common practice in the spectrophotometric determination of metal ions, with a view to enhancing sensitivity and/or selectivity.[1–3] The solubilizing power of micellar systems has allowed investigators to speed up and simplify many common analytical procedures when the chromophore or chelate formed is insoluble or only slightly soluble in water, thus avoiding costly and tedious extractions and allowing determination in a homogeneous medium.[4]

The growing importance of the rare-earths elements (REE) in advanced engineering and high-technology ceramics and in special glasses has made it necessary to develop simple and reliable analytical methods for determining traces of these elements.

The analytical application of 2-[(5-bromo-2-(pyridylazo)]-5-diethylaminophenol (5-Br-PADAP) (RH) compounds has been extensively studied. However since the metal chelates obtained are insoluble in water, the methods require aqueous alcohol media or extraction into non-polar solvents.

At present, 5-Br-PADAP can be used in the spectrophotometric determination of many rare earths,[5–9] but it has not been employed for the determination of Gd(III). In this paper, we describe the use of 5-Br-PADAP for the spectrophotometric determination of Gd(III).

The proposed method using the reagent 5-Br-PADAP produces an absorptivity of 1.76×10^5 l. mole^{-1} . cm^{-1} and it is the most sensitive, comparing it with other methods such as arsenazo[6,10] ($a = 5 \times 10^4$ l. mole$^{-1} \cdot$ cm^{-1}) and PAN[11] ($a = 7 \times 10^4$ l. mole$^{-1} \cdot$ cm^{-1}). This circumstance is important for the determination of trace elements in geological samples to solve petrogenesis problems. Selectivity is low, as happens with every chromogenic reagent for REE; a previous separation is unavoidable in any spectrophotometric method. Nevertheless these methods are frequently used for REE determination because of their simplicity, expeditiousness and low cost.

EXPERIMENTAL

Reagents

Standard solutions of Gd(III) were prepared by dissolution of suitable amounts of the oxide (99.99% pure, Aldrich) in small volumes of concentrated hydrochloric acid, followed by dilution with distilled water. Standardization was achieved as described in the literature.[12]

5-Br-PADAP standard solution. The reagent was purified by recrystallization twice from ethanol–water. A solution of the purified reagent ($2 \times 10^{-3} M$) was prepared by dissolution in ethanol. Lower concentrations were prepared by serial dilution.

Octylphenol poly(ethyleneglycol) ether (Triton X-100 Merck) solution. A 5% (v/v) surfactant solution in redistilled water was prepared.

Buffer solution. Ammonium nitrate–ammonia solutions were used for the pH adjustment.

Cation exchange resin. Dowex 50W-X4 (200–400 mesh) was used. All other reagents used were of analytical grade.

Apparatus

A Variant spectrophotometer (model 634-UV–Vis) with 10-mm optical path glass cells was used for the absorptiometric measurements. The pH values were measured with an Orion 701-A pH meter equipped with a glass combination electrode.

The apparatus used for the separation through ionic exchange is that described by Wolfsberg *et al.*[13]

Procedure

An aliquot of the standard metal solution was placed in a 50-ml standard flask. Next, 2.5 ml of an ethanolic solution of 5-Br-PADAP ($2.5 \times 10^{-3}M$), 5.0 ml of buffer solution (pH = 9.8) and 5 ml of surfactant solution (5% v/v) were added. The mixture was then made up to volume with distilled water and mixed well by shaking vigorously. The color intensity was determined against a blank as the reference solution at 580 nm.

The proposed method was applied to Gd(III) determination in standard samples of known composition rocks. The procedure developed was the following:

Take the sample (0.1–0.2 g) in a 50-ml platinum dish and heat gently to drive off moisture. Treat with 7 ml of hydrofluoric acid and 10 ml of nitric acid, cover and digest on the steam-bath. Add more hydrofluoric acid, if necessary, to complete the decomposition. The fluorides of rare earths and calcium are completely precipitated. Allow the precipitate to settle, filter it off on a Whatman No. 40 filter paper and wash with hot water. Transfer the precipitate to the original platinum dish and decompose the paper with nitric acid (steam-bath). Evaporate to dryness, add 5 ml of nitric acid and evaporate to a moist residue. After cooling, dissolve the residue in dilute nitric acid.

Then, continue with the procedures described by Stary[14] and Wolfsberg *et al.*[13] That is, solvent extraction was performed to remove the metals listed in Table 3, followed by ion exchange to separate gadolinium from the rare earths. The sample pH was adjusted to 3 prior to placing on the column. The fraction obtained was collected in the period between 6 and 7.5 hr. A hydrochloric acid–nitric acid solution was added and evaporated to dryness. The treatment was repeated with 5 ml of solution. Then, the residue was taken up with dilute hydrochloric acid solution. The operative conditions were adjusted and the spectrophotometric determination was carried out.

RESULTS AND DISCUSSION

An attempt has been reported to use the reagent 5-Br-PADAP in the determination of REE without finding a proper solution to the inconvenience due to hydrolytic decomposition of the complex. In our work, the coloured complexes were easily obtained by adding a few drops of an ethanolic solution of 5-Br-PADAP to an aqueous solution of metal ion. Different solvents were tried so as to select the best one with respect to its solubilization ability. An increase in the percent organic solvent always produced a loss of sensitivity. It was therefore necessary to introduce a surfactant into the reaction medium in order to solve the solubility difficulties while maintaining sensitivity.

The surfactant, Triton X-100, proved to be most suitable for our system, in a proportion of 0.5% (v/v). Figure 1 shows the influence of the surfactant percentage upon the absorbance of the Gd(III)–5-Br-PADAP complex.

The full purple color of the Gd(III)–5-Br-PADAP complex develops in a few minutes at

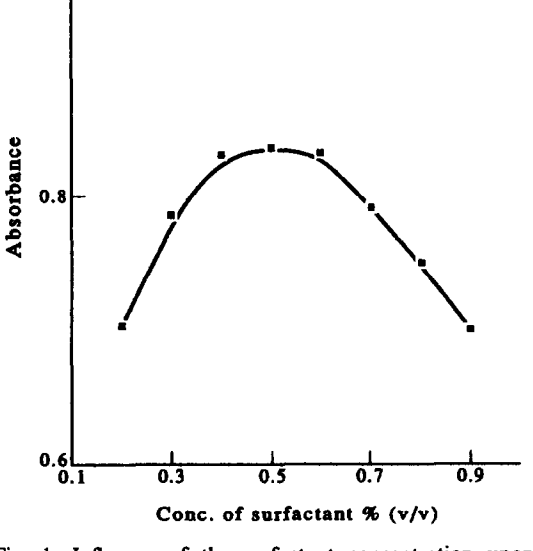

Fig. 1. Influence of the surfactant concentration upon absorbance of metal complex. $C_{Gd(III)} = 4.73 \times 10^{-6}M$, $C_{RH} = 9.5 \times 10^{-5}M$, pH = 9.8; Ethanol–water 5% (v/v); $\lambda = 580$ nm.

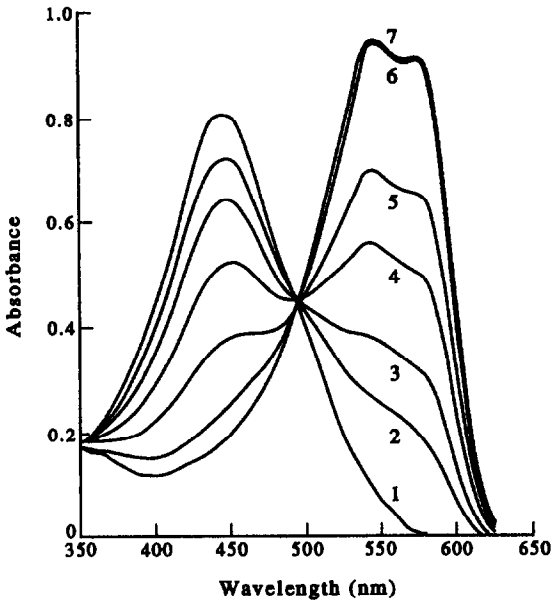

Fig. 2. Absorption spectra of Gd(III)–5-Br-PADAP in 5% (v/v) ethanol–water and 0.5% (v/v) Triton X-100 at various pH values. $C_{Gd(III)} = 1.85 \times 10^{-4}M$; $C_{RH} = 1.85 \times 10^{-5}M$; pH: 1 = 5.0; 2 = 7.6; 3 = 8.2; 4 = 8.8; 5 = 9.2; 6 = 9.6; 7 = 9.8–11.2.

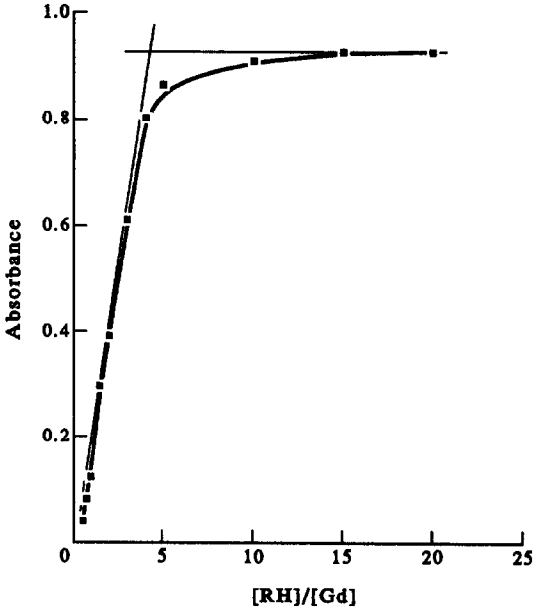

Fig. 4. Dependence of absorbance upon reagent to metal ratio. $C_{Gd(III)} = 5.2 \times 10^{-6}M$; pH = 9.8; λ = 580 nm; $\mu = 0.1$ ($NaClO_4$); Ethanol–water 5% (v/v); 0.5% (v/v) surfactant solution.

room temperature and its absorbance remains constant for up to 72 hr.

Figure 2 shows the absorption spectra of a mixture of reagent, Triton X-100 and Gd(III) at various pH values.

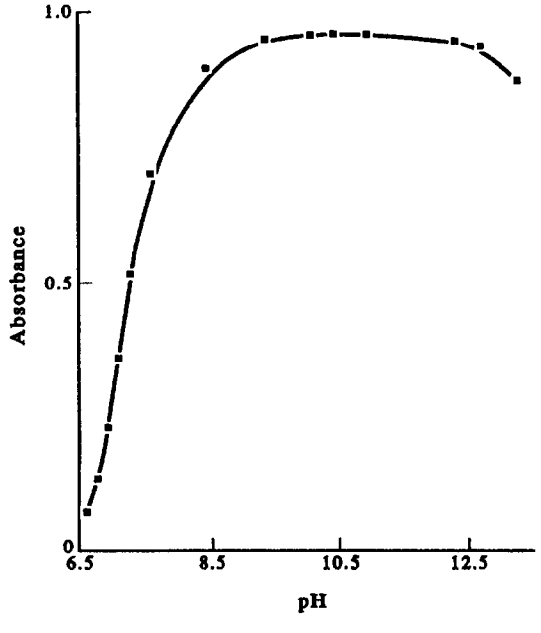

Fig. 3. Influence of the pH upon absorbance of metal complex $C_{Gd(III)} = 5.3 \times 10^{-6}M$; $C_{RH} = 1.1 \times 10^{-5}M$; Ethanol–water 5% (v/v); 0.5% (v/v) surfactant solution; $\mu = 0.1$ ($NaClO_4$).

Our experiments enabled us to determine the optimal pH range for complex formation. The results are shown in Fig. 3.

Reagent concentration and calibration curve

The reagent concentration appropriate for the quantitative work was evaluated by plotting the saturation curve (Fig. 4) at pH 9.8. The Gd(III) concentration was kept constant while the 5-Br-PADAP was changed between 7×10^{-6} and $5.6 \times 10^{-4}M$ with Triton X-100 and ethanol concentrations kept constant at 0.5 and 5.0%, respectively. The absorbance was read at λ_{max} 580 nm.

For a 1:10 Gd(III)–5-Br-PADAP molar ratio, the complete development of the complex is achieved and remains unaltered for proportions up to 1:50. The absorbance at pH 9.8 and ionic strength of $0.10M$, as well as the absorption spectrum, did not change over a 3-day period.

The stoichiometry of the complex was studied at pH 9.8. The method of continuous variations (Job) was used and as can be seen from Fig. 5, the ratio of Gd(III): reagent was 1:4. The mole ratio and slope ratio methods also confirmed this stoichiometric ratio.

Beer's law of the Gd(III)–5-Br-PADAP-Triton X-100 complex was linear in the Gd(III) concentration range of 0.04–1.2 mg/l.

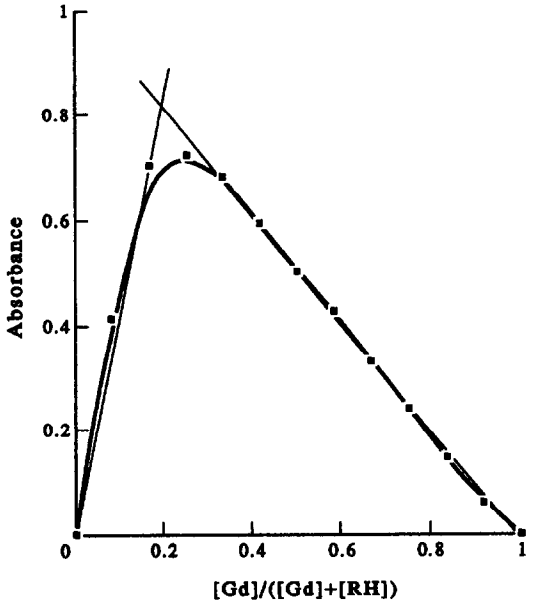

Fig. 5. Continuous variation plots. $C_{Gd(III)} = C_{RH}$; pH = 9.8; Ethanol–water 5% (v/v); 0.5% (v/v) surfactant solution.

Table 1 summarizes the optimal experimental conditions for the quantitative evaluation of Gd(III) ion with the reagent 5-Br-PADAP in the presence of the surfactant, Triton X-100.

Effects of concomitant ions

Under the optimum experimental conditions, the influences of some anions, cations and a number of complexing species that could be applied as selective masking agents were examined.

The influences were studied individually. The potential interferent and gadolinium(III) were put in pH 9.6 buffer solutions of ammonium nitrate–ammonia. The gadolinium(III) concentration was kept fixed while that of the possible interferent was increased until the magnitude of error was *ca.* ±2%, arbitrarily established as the maximum acceptable. Table 2 shows the admissible proportions of several anions and masking agents. EDTA, CTDA and phosphate interfere in a molar ratio lower than 1:1 with respect to gadolinium(III).

Under the conditions required to form the gadolinium(III)–5-Br-PADAP complex, Mn(II), Zn(II), Cd(II), Cu(II), Ni(II), Bi(III), Fe(III), Pb(II), Sb(III) and the elements belonging to the group of rare earths not only consume reagents, thus making the gadolinium(III) complexation incomplete or even null, but they spectrally disturb the spectrometric determination to a large extent. In order to increase tolerances up to values compatible with the composition of some concrete samples, several masking agents—cyanide, diethanolamine, ascorbic acid, tartaric acid, triethanolamine, were tried in their maximum admissible concentration. Results obtained for any of the above

*Two successive extractions ($Vo = Vw$), in aqueous phase of pH 5.5 with diethyldithiocarbamate 0.4M in carbon tetrachloride.

†Ion exchange chromatography—α-hydroxyisobutyric acid adjusted to different pH values was used as an eluent.

mentioned cations showed no significant modifications. Therefore we tested other separation techniques suitable for this case. Liquid–liquid extraction by means of diethyldithiocarbamate dissolved in carbon tetrachloride was chosen to separate interfering cations. The procedure employed was the one suggested by Stary,[14] using pH 5.5. Following extraction, the pH was readjusted to 9.6 and the spectrophotometric method followed. The admissible tolerances thus obtained are shown in Table 3. Most of the rare earth elements react with 5-Br-PADAP, resulting (with this method) in serious interference with the determination of Gd(III). Thus, a separation step must be conducted prior to the spectrophotometric determination of Gd using this method. In order to apply the method developed for the determination of Gd(III) to a mixture of rare earths, ion exchange chromatography was used to separate the constituents. The technique proposed by Wolfsberg[13] to separate a mixture of Eu, Sm, Nd, Ce, La and Gd was considered to be convenient. Synthetic samples of the mentioned ions of different composition were subjected to the separation using a 0.8 × 60 cm column of cation exchange resin and a flow rate of 9 ml/hr. In the initial step, 0.5 molar hydroxyisobutyrate adjusted to the desired pH values (3.4–4.2) by the addition of concentrated NH_4OH was used as an eluent. A value of 3.4 was selected as the initial pH of the eluent because at this pH an adequate separation of 10 mg of Y, 0.5 mg of Gd, and 10 mg of each other ion was achieved in less than 30 hr. Gadolinium is eluted between 6.5 and 7.5 hr after the start of column operation.

The elution of the three different ions was checked by X-ray fluorescence, using a preconcentration technique. The fraction containing Gd(III) was preconcentrated and then taken to a final volume of 50 ml. The spectrophotometric determination was carried out on an aliquot of this fraction with the reagent 5-Br-PADAP using the above-mentioned method. The results were highly satisfactory, obtaining in all cases an error less than 2%, as can be seen in Table 4.

Finally, the results of the method applied to Gd(III) determination in standard samples of known composition rocks are shown in Table 5.

CONCLUSIONS

The analytical applications of the reagent are an original contribution for gadolinium(III) spectrometric determination. Complexation is accompanied by a strong bathochromic effect, about 135 nm, providing a clear contrast between the colors of the free reagent and the one belonging to the gadolinium(III) complex.

The results obtained for a variety of geological reference materials demonstrate that the procedure allows precise and accurate analysis of geological samples for their REE and Y content. The total salt concentration is reduced and potentially interfering elements are eliminated.

The main advantage of the method proposed is the high sensitivity and the low cost of the equipment required.

RAPID AUTOMATED DETERMINATION OF CONSTANTS OF SOLUBILITY PRODUCT AND CRITICAL MICELLE CONCENTRATIONS BY THE FLOW-RATE GRADIENT TECHNIQUE

JULIANA MARCOS, ANGEL RÍOS and MIGUEL VALCÁRCEL
Department of Analytical Chemistry, University of Córdoba, E-14004 Córdoba, Spain

(*Received* 30 *December* 1991. *Revised* 2 *July* 1992. *Accepted* 2 *July* 1992)

Summary—Several straightforward, rapid and automated methods for the determination of the constant of solubility product of various inorganic salts and hydroxides and the critical micelle concentrations of both anionic and cationic surfactants are reported. The underlying methodology relies on the establishment of flow-rate gradients in completely continuous flow systems including a conductometric or potentiometric detector. The results obtained are quite consistent with those reported in the chemical literature.

Unsegmented flow systems have proved to be powerful tools for automating some steps of the analytical process. A host of applications have been developed on the basis of this methodology, as shown in pertinent monographs.[1–3] Such applications usually involve constant experimental conditions where flow rate is one of the major variables. However, in some of the approaches reported in the last few years, manipulation of hydrodynamic conditions in unsegmented flow systems plays a crucial role in developing new automated determinations.[4] Thus, variable flow-rate methodologies allow the automated determination of acidity constants,[5] complex stoichiometries,[6] and the implementation of titrimetric procedures,[7,8] among others.

In variable flow-rate methodologies, the flow-rate is changed throughout the measurement step according to a linear or non-linear mathematical function, the first derivative of which defines the flow-rate gradient (Q) in each case. Linear flow rate–time functions provide constant flow gradients, while non-linear flow rate-time functions give rise to variable flow gradients. Every flow-rate gradient can be used to create a corresponding concentration gradient profile along the flow system. This is very important in as much as it allows one to automatically and gradually change the concentration of one of the analytes with time. Many chemical and physico-chemical properties are dependent on this variable, so one immediate application of this methodology is in the determination of certain parameters or in studying some properties.

In this work we used flow-rate gradients to determine constants of solubility product (K_{sp}) and critical micelle concentrations (cmc) by using a simple manifold in a rapid, automated fashion and monitoring conductivity or pH changes. Both parameters are related to the critical concentration of one reactant, above which dramatic changes in the properties of the system concerned occur (formation of a solid phase, constants of solubility product, or micelles, cmc).

EXPERIMENTAL

Reagents

Aqueous solutions of the following compounds were used at different concentrations and pH values.

Inorganic salts. Zinc(II) nitrate (Riedel), tin(II) chloride (Merck), nickel(II) nitrate (Merck), aluminium(III) nitrate (Riedel), potassium nitrate (Merck), disodium tartrate (Merck), cobalt(II) nitrate (Merck), copper(II) nitrate (Merck), sodium oxalate (Merck), calcium chloride (Merck), potassium iodate (Fluka), lead(II) nitrate (Riedel), and sodium fluoride (Riedel) were used.

Surfactants. A 0.10M sodium dodecyl sulphate solution (Aldrich), 0.010M sodium

Table 1. Constants of solubility product obtained by using the automated flow method with direct introduction of insoluble compound into the system

Compound	n(moles)*	Literature $pK_{sp}^{\dagger}$	pK_{sp} found	r.s.d.(%)
$CaSO_4$	6×10^{-3}	4.6	4.4	1.0
KH-Tartrate	10^{-2}	3.5	3.5	1.3
CoC_2O_4	1.6×10^{-3}	5.4	5.6	0.5

$Ca(IO_3)_2$	5×10^{-3}	6.2	6.4	0.6
PbF_2	6×10^{-3}	7.4	6.4	0.9

*Quantity of moles added to 100 ml of distilled water to prepare the suspension.
†From reference (9) (at 25°).

hexadecyl sulphate (Aldrich), 0.010*M* cetylpyridinium chloride (Serva), 0.010*M* cetyltrimethyl ammonium bromide (Serva), 0.4*M* dodecyltrimethyl ammonium bromide (Aldrich) and 0.010*M* sodium dioctyl sulphosuccinate (Aldrich) were prepared.

Preparation of the suspensions of the insoluble compounds. The insoluble compounds were previously precipitated in a flask, filtered and washed until no conductometric signal was obtained from the last water volumes used to wash the precipitate. Water was used as solvent to prepare those suspensions, taking a certain number of moles of each insoluble compound (see Table 1) for 100 ml of water.

Apparatus

A Gilson Minipuls-3 peristaltic pump controlled by a Commodore 64 microcomputer through a laboratory-made interface was used to set flow-rate gradients.[6] A Gilson Minipuls-2 peristaltic pump was used to provide a constant flow-rate. A YSI conductometer (model 3S) and a FIAtron 721 FIA cell equipped with a glass-calomel microelectrode and connected to a Radiometer pHM 62 pH-meter and a Radiometer REC 80 recorder were used as detectors. The potentiometric detection requires a calibration procedure. This was done by passing through the system standard buffers at pH 4.00 and 7.00. A Tecator TM II chemifold was also employed.

Manifold

The configuration used is depicted in Fig. 1. The two streams used are merged at point C. The programmable pump (PP) is controlled by the microcomputer and the flow rate of solution A is changed linearly with time. The conventional pump (CP) is operated at constant flow-rate. As a result, a flow gradient is created that gives rise to a concentration gradient arising from the different composition of solutions A and B.

The methodology used in this work is based on a completely continuous flow system in which the result of the concentration gradient established along reactor coil R (70 cm length and 0.5 mm i.d.) is continuously monitored with a conductometer or a glass-calomel microelectrode for pH measurements. The signal was automatically recorded on an x-t recorder at an appropriate chart speed to obtain graphically and accurately the parameter determined in each case.

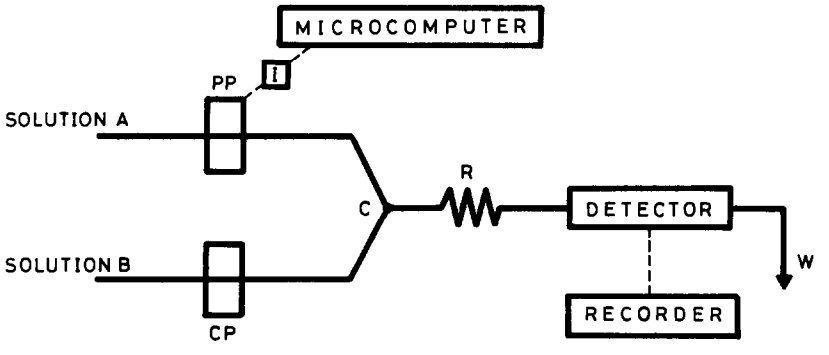

Fig. 1. Manifold used for solubility and critical micelle concentration determinations. [PP = programmable pump; CP = conventional pump; R = reactor coil (length = 70 cm; inner diameter = 0.5 mm); C = merging point; I = electronic interface].

The experiments were carried out at room temperature (18–25°) due to the difficulties to thermostatize all the system.

RESULTS AND DISCUSSION

The manifold in Fig. 1 was used to determine constants of solubility product and critical micelle concentrations, which are dealt with below in separate sections.

Determination of constants of solubility product

Constants of solubility product were determined by direct introduction of the insoluble compound into the system and by *in situ* formation of the compound in the manifold.

Direct introduction of the insoluble compound. A suspension of each insoluble compound studied was used as solution A in Fig. 1. The suspension was prepared as Experimental section reports and was continuously stirred to get the homogeneous suspension that was introduced into the system. The amounts were chosen in order to provide recordings where two zones (before and after K_{sp} value) were clearly shown, but different amounts, in the same range, can be used. The suspensions of those compounds were propelled by means of the programmable pump. To avoid the risk of blocking up the connections and the tubes of the flow manifold a flow-meter was placed at the end of the flow system for the continuous monitoring of the flow-rate. Solution B in Fig. 1 was distilled water in this case. As pump A was operated to obtain a linear positive flow-rate gradient, the insoluble compound concerned was partially dissolved after the mixing point, so the measured conductivity increased as a result of the gradual increase in the amount of insoluble compound dissolved in the system. Thus, as shown in Fig. 2, a linear conductivity-time relationship was obtained up to a point where the slope of the plot started to change. A constant conductivity would be expected after this point as a consequence of the constant dissolved ion concentration in the system when the constant of solubility product is reached. However, the small increase in conductivity in this region can be due to the intrinsic conductivity of the insoluble compound. The time at which the slope changes is denoted by t_p, and represents the situation in which the liquid phase from point C (Fig. 1) is saturated with ions from the precipitate. Therefore, this situation defines the solubility product (K_{sp}) and can be used to calculate it.

The hydrodynamic conditions in this system are determined by the flow-rate of solution A (q_A) which is changed according to the equation $q_A = Qt$ (Q is the flow gradient and t the time), whereas solution B is circulated at constant flow-rate (q_B). It should be noted that this

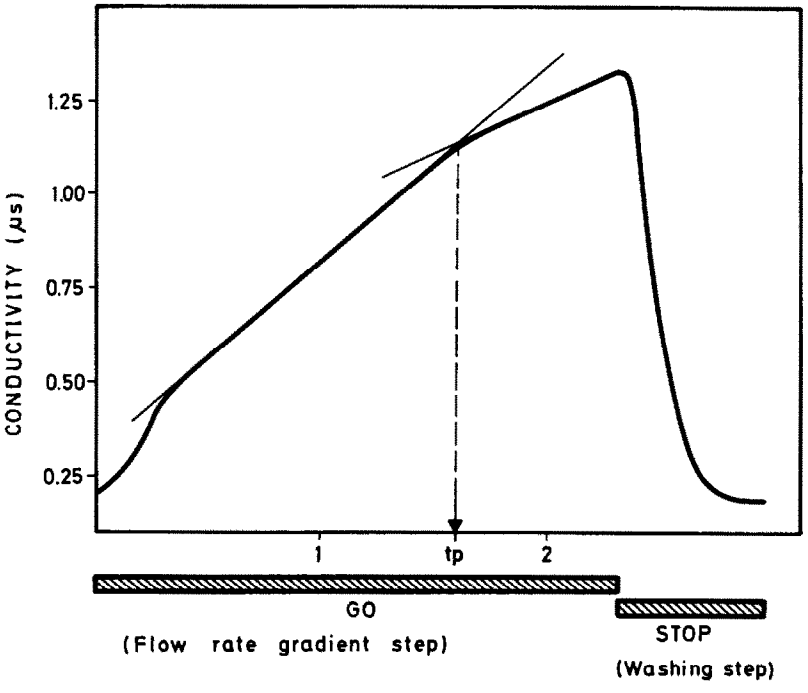

Fig. 2. Recording obtained for CoC_2O_4 by using a suspension of this compound as a solution A (Fig. 1).

methodology involves two different processes, namely: interaction between ions to form the precipitate and dilution through increase in the total flow-rate (q_T) throughout the experiment:

$$q_T = q_B + q_A = q_B + Qt \quad (1)$$

Therefore, the dilution factor (f) of the system will be:

$$f_A = q_A/(q_A + q_B) = Qt/(Qt + q_B) \quad (2)$$

If the maximum flow-rate of solution A[$(q_A)_{max}$] is of similar order than that of solution B, then a linear zone will be obtained only at the initial time period, when $q_A \ll q_B$:

$$f_A \approx q_A/q_B = Qt/q_B \quad (3)$$

However, this factor tends to 1 at great values of time, when q_A is much higher than q_B.

Figure 3 shows the variation of dilution factor with time under two different situations. In all cases the B stream flowed at constant flow-rate (1.5 ml/min); however, the flow-rate for the A stream was changed in the range $0 < q_A < 4.0$ (curve A) or $0 < q_A < 0.6$ (curve B). In practice, the latter conditions (*i.e.*, a linear change in Fig. 3) were required to prevent the dilution process from masking the conductometric signal yielded by the precipitation process. Thus, under this latter condition:

$$f_A = q_A/(q_A + q_B) \approx q_A/q_B = Qt/q_B = (Q/q_B)t \quad (4)$$

Therefore, for a salt of the general type N_mM_n whose solubility is characterized by:

$$K_{sp} = [N]^m[M]^n$$

the concentration of each ion at the time t_p is given by:

$$[\text{ion}] = xC_sq_A/(q_A + q_B) = xC_sQt_p/(Qt_p + q_B) \quad (5)$$

where x is the number of ions resulting from the dissolution of one molecule of salt ($x = m$ for N, and $x = n$ for M), and C_s is the "concentration" of the suspension introduced as solution A. Thus, provided the stoichiometry of the insoluble compound is known, K_{sp} can be calculated from the experimental data. This methodology allows the determination of constants of solubility product greater than 10^{-8}. Lower K_{sp} caused the level of dissolved ions to be too low to be clearly distinguished from the blank. Some of the K_{sp} values thus obtained are listed together with their literature counterparts in Table 1. According to the experimental procedure used the ionic strength within the flow system was very low in all cases, and it can be assumed to be close to zero in order to compare the experimental results with those reported in the literature. The precision of the method as r.s.d. was about $\pm 2\%$ ($n = 11$; $P = 0.05$) referred to pK_{sp}.

In situ *formation of the insoluble compound.* Most hydroxides are special insoluble compounds insofar as they can be generated by changing the pH within a flow system. Various

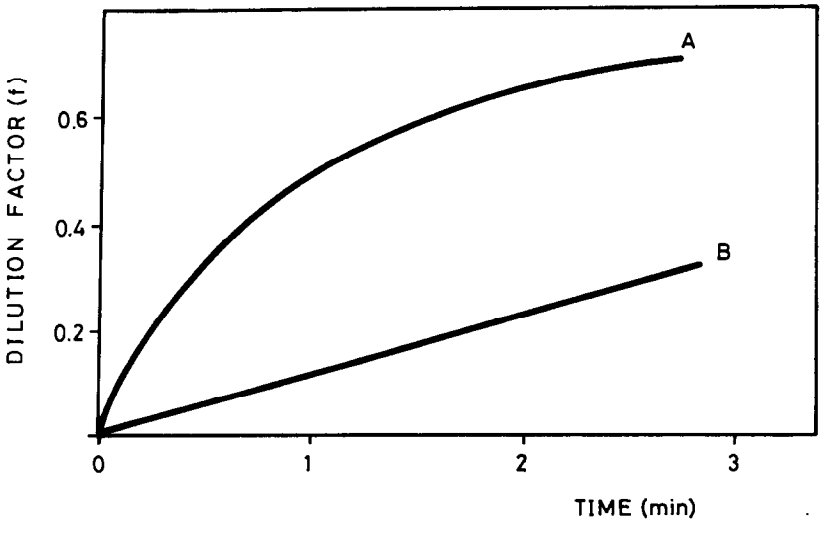

Fig. 3. Variation of the dilution factor (f) in the system as a function of the flow gradient used. Curve A: Q = 1.49 ml/min^2 (q_A changes from 0 to 4.0 ml/min). Curve B: Q = 0.22 ml/min^2 (q_A changes from 0 to 0.6 ml/min). q_B = 1.5 ml/min in all cases.

insoluble hydroxides were studied by using the manifold depicted in Fig. 1 and creating a pH gradient in the flow system. Thus, solution B contained one metal ion (0.010M) in acidic medium (HCl), while solution A was sodium hydroxide at different concentrations in each case (see Table 2). Those concentrations allowed the K_{sp} value to be reached during the experiment. The formation of soluble complexes [like $Al(OH)_4^-$] did not occur because the pH reached in the flow system was not high enough. Precipitates were formed under a pH gradient at a characteristic time dependent on the intrinsic solubility. The process was monitored conductometrically and yielded a recording such as that shown in Fig. 4 (curve A). The conductivity decreased dramatically through disappearance of H^+ ions (highly conductive) by neutralization with OH^- ions (part 1 in curve a). When the product of the ion concentrations equalled K_{sp}, the precipitate started to be formed and the conductivity decreased slowly (part 2 in the curve). Finally, once all the metal had precipitated, OH^- ions were in excess, so the conductivity started to increase (part 3 in the curve). The recordings obtained were quite different from those resulting from replacement of the dissolved metal ion with an acid solution at the same pH (curve B in Fig. 4), which in fact represents an acid–base conductometric titration.

As those precipitation reactions correspond to fast reactions, no kinetic effects were detected. Therefore, the same K_{sp} values were obtained by using different flow gradients. The parameter t_p was changed when the Q value was modified, keeping the constants of the solubility product the same by applying the equations described below.

The process can be better studied by using a conductometric and a potentiometric (pH) detector arranged in series, in order to obtain both conductometric and potentiometric information, as is shown in Fig. 5, where curves A′ and B′ were obtained in the presence of metal ion [0.010M solution of Zn(II) in HCl], whereas curves A and B were recorded in its absence. On comparing curves A and B, and A′ and B′, it is clear that t_p is the time at which the precipitation process starts, so it can be used to calculate the constant of the solubility product:

$$q_T = q_{OH} + q_H = Qt + q_H \qquad (6)$$

where q_{OH} and q_H are the flow-rates of solutions A and B, respectively. At $t = t_p$, $q_{OH} = Qt_p$ and, provided this flow-rate is known, the pH at this time can be readily calculated from the conductivity-time recording.

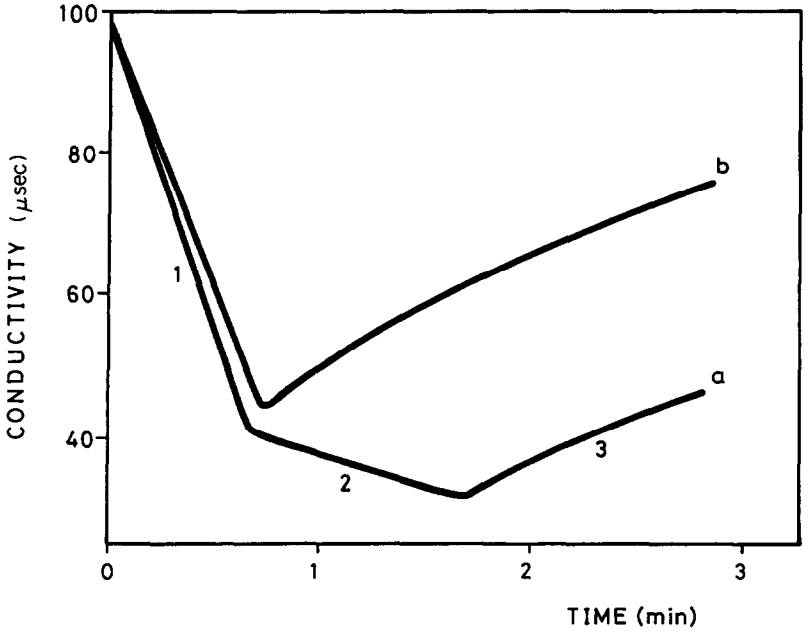

Fig. 4. Conductivity-time recordings obtained by using 0.0246M sodium hydroxide as solution A (Fig. 1), and $10^{-2}M$ $Zn(NO_3)_2$ in $6.3 \times 10^{-3}M$ HCl as solution B (curve a), or in $6.3 \times 10^{-3}M$ HCl alone as solution B (curve b).

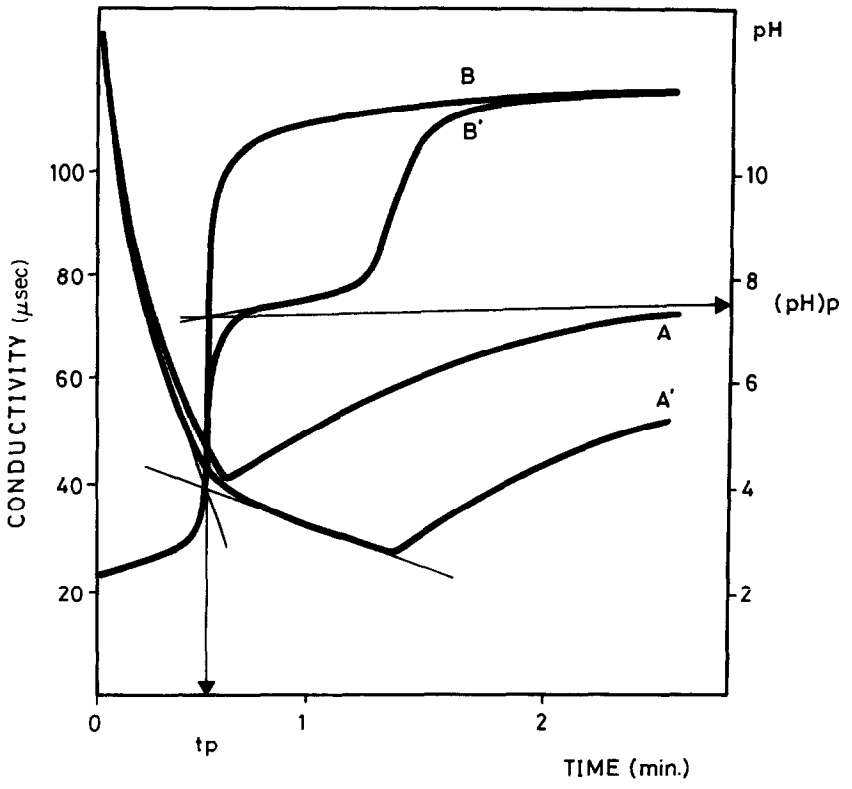

Fig. 5. Conductivity-time (curves A) and pH-time (curves B) recordings obtained for a $10^{-2}M$ $Zn(NO_3)_2 + 6.3\ 10^{-3}M$ hydrochloric acid mixture as solution B (curves A′ and B′), and for a $6.3\ 10^{-3}M$ HCl solution as solution B [curves A and B, which correspond to the experiment performed in the absence of Zn(II)]. $7.58 \times 10^{-3}M$ NaOH was used as solution A in all cases (see Fig. 1).

The concentrations of H^+ and OH^- at the mixing point are:

$$[H^+]_p = [H^+]_0 q_H/(Qt_p + q_H) \quad (7)$$

$$[OH^-]_p = [OH^-]_0 Qt_p/(Qt_p + q_H) \quad (8)$$

If $[H^+]_p \leqslant [OH^-]_p$ the concentration of OH^- after the confluence point is determined as:

$$[OH^-]_{tp} = [OH^-]_p - [H^+]_p \quad (9)$$

If $[OH^-]_p \leqslant [H^+]_p$ the concentration of H^+ after the mixing point is calculated as:

$$[H^+]_{tp} = [H^+]_p - [OH^-]_p \quad (10)$$

then, the OH^- concentration could be determined through:

$$[OH^-]_{tp} = 10^{-14}/[H^+]_{tp} \quad (11)$$

The metal ion concentration at t_p can be calculated from the equation:

$$[M]_{tp} = [M]_0 q_H/(Qt_p + q_H) \quad (12)$$

where $[M]_0$ is the metal ion concentration in solution B. So, the constant of solubility product will be given by:

$$K_{sp} = [M][OH^-]^m = [M]_{tp}[OH^-]^m_{tp}$$

where m is the stoichiometry of the hydroxide.

The use of potentiometric measurements has some advantages over conductometric ones in this case. Thus:

t_p is better defined in the graphs under all conditions.

The pH (concentration of the precipitating reagent) can be obtained directly from the graphs depending on the t_p value. Therefore, no algebraic calculation is required.

Table 2 summarizes the results obtained for three different insoluble hydroxides by using this methodology and two pH gradients along the flow system. The ionic strength was between 0.01 and 0.03 in all cases. As can be seen, the constants are quite consistent with those reported in the literature[9] (ionic strength, $I = 0$), from which the conditional constants were calculated taking into account the ionic strength.

Table 2. Constants of solubility product obtained by the automatic flow method with *in situ* formation of the insoluble compounds

			Constants of solubility product (pk_{sp})			
	Experimental conditions			Literature values		r.s.d. (%)

Determination of critical micelle concentrations

The critical micelle concentration (cmc) is a major physicochemical parameter of surfactant compounds which, like constants of solubility product, represents a point or range of concentrations beyond which dramatic changes in the properties of the compound solution occur. Surfactant micelles are of great chemical and biochemical interest in connection with catalysis of chemical reactions,[10] room-temperature phosphorimetry experiments on liquid samples,[11] studies on their similarities with membranes on globular proteins,[12] and solvents used in liquid chromatography.[13] All these uses required the cmc of the surfactant concerned to be known. It should also be noted that this characteristic parameter changes with the experimental conditions, so the literature values only apply under specified conditions and are thus only guidances.

Traditionally the cmc is determined by measuring some physical property related to the micelle formation (*e.g.*, surface tension, osmotic pressure, refractive index, conductivity[14]). Some cmc determinations are also based on the flow injection analysis with a dilution chamber.[15,16] The continuous flow system depicted in Fig. 1 allows the automated determination of the cmc of ionic surfactants in a straightforward manner. Solution A contains the surfactant at a high concentration (much higher than the cmc), while solution B is distilled water (*i.e.*, the situation is similar to that of the determination of constants of solubility product by introducing an insoluble compound into the flow system). A linear dilution factor is also used in this case. Therefore, a non-linear conductivity-time

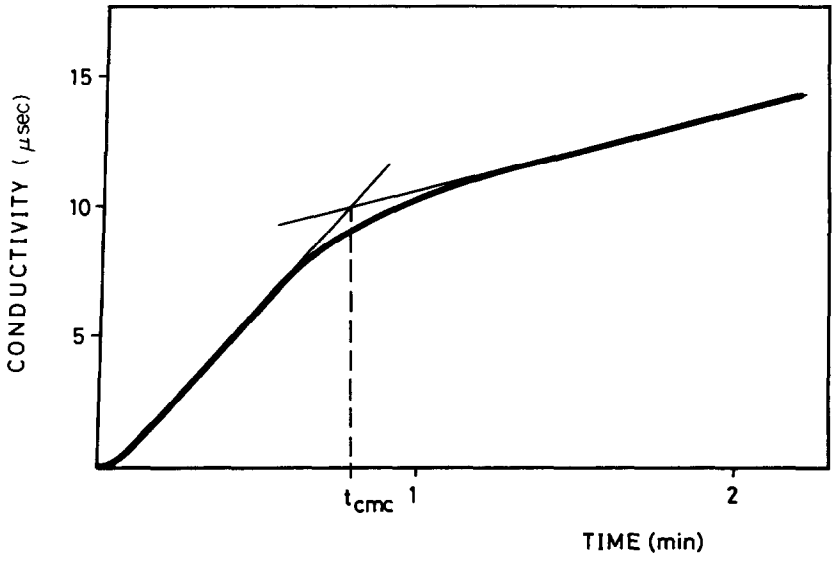

Fig. 6. Conductivity-time recording obtained for sodium dodecylsulphate by using a 0.1*M* solution of this compound as solution A.

Table 3. Critical micelle concentration obtained by using the automatic flow method and the batch procedure

Surfactant	Solution A concentration	cmc Found (m) Flow system	Batch procedure	Literature cmc (M)	r.s.d. (%)
Sodium dodecyl sulphate	0.10	8.4×10^{-3}	7.6×10^{-3}	8.2×10^{-3}	2.8
Sodium dioctyl sulphosuccinate	0.01	3.6×10^{-4}	—	6.8×10^{-4}	4.1
Sodium hexadecyl sulphate	0.01	9.2×10^{-4}	4.7×10^{-4}	7.0×10^{-4}	2.8
Cetylpyridinium chloride	0.01	9.1×10^{-4}	1.0×10^{-4}	9.0×10^{-4}	3.2
Cetyltrimethylammonium bromide	0.01	9.4×10^{-4}	8.6×10^{-4}	9.2×10^{-4}	1.7
Dodecyl trimethylammonium bromide	0.40	1.8×10^{-2}	1.3×10^{-2}	1.6×10^{-2}	5.0

response will be indicative of the occurrence of a process other than dilution, *viz.* micelle formation. Figure 6 shows a typical recording where the two zones of predominance of non-associated molecules surfactants and micelles can be clearly seen. The cmc is related to the time at which the two straight lines intercept (t_{cmc}). The flow-rates are:

$$q_A = Qt_{cmc} \quad \text{and} \quad q_B = \text{constant}$$

so

$$\text{cmc} = [\text{surfactant}]_0 q_A/(q_A + q_B)$$
$$= [\text{surfactant}]_0 Qt_{cmc}/(Qt_{cmc} + q_B)$$

where $[\text{surfactant}]_0$ is the concentration of surfactant in solution A.

The cmc values of various surfactants were determined in this manner and the results obtained are listed in Table 3 compared with those obtained by the batch procedure and those reported in the literature.[14] Under the experimental procedure the ionic strength had a negligible effect due to the low values for this variable. The precision of the automated flow gradient method was ± 2 and $\pm 3\%$ as r.s.d. ($n = 11$, $P = 0.05$).

CONCLUSIONS

As shown in this work, flow gradients in a continuous flow system can be used for the simple, rapid automated determination of physico-chemical parameters. This allows some classical batch determinations to be automated to obtain similar results. This strategy exploits the analytical potential of variable flow-rates in unsegmented flow systems compared to the conventional methods where the flow-rate is kept constant, and expands the possibilities of flow methodologies. The new applications are unaffordable by methods using constant flow-rates. The proposed methodology can also be used to study other properties of chemical systems dependent on the concentration of one of the reactants, as well as perform studies in solvents other than water, taking care of using tubes made out of solvent-compatible materials.

(*Received* 15 *May* 1992. *Revised* 30 *June* 1992. *Accepted* 30 *June* 1992)

Summary—A carbon fibre microelectrode was modified by electrodeposition of a thin copper-heptacyanonitrosylferrate (CuHNF) film on its surface. The film showed the ability to catalyse electrochemical oxidation of ascorbic acid. The catalytic reaction was limited either by diffusion, or by the electrochemical reaction of the catalyst. A linear, cyclic voltammetric response for ascorbic acid was obtained between 5.0×10^{-5} and $6.0 \times 10^{-3}M$. By amperometric measurements the linear range could be extended to 8.0×10^{-6}–$2.0 \times 10^{-3}M$. The modified electrode showed good stability and reproducibility.

There has been a lot of interest in developing different kind of biosensors over the recent years.[1–3] Electrochemical biosensors have a number of advantages in detection of biological substances, such as: simple and inexpensive instrumentation, simple sample treatment and fast response time. Electrochemical biosensors are suitable for both *in vivo* and *in vitro* applications, such as transducers in molecular recognition in biological systems.[4–6] Many attempts have been focused on miniaturization of biosensors, which is an important step in development of compact, high performance automatic analytical systems and sensing devices for artificial organs, especially *in vivo* applications. This trend is due to the attractive features these sensors possess. Firstly, the small electrode size and therefore low background current facilitate *in vivo* electrochemical detections,[7] and even detections in single cells.[8] Secondly, due to the small area of the electrode only very low currents will be measured (as low as 10^{-17}A), and therefore the electrodes can be used in high resistive solvents where electrodes of conventional size would encounter high uncompensated *iR* drops.[9] Low currents also allow the electrodes to be used in ultrafast cyclic voltammetry to study fast electrode processes.[10–13] A good number of papers have been published discussing the use of chemically modified microelectrodes as biosensors. Since the pioneering work of Adams the field of *in vivo* electrochemistry has been subject to considerable development.[14] A lot of efforts have been devoted improving the selectivity of neurotransmitter measurements.[15–19] These include the use of electrochemical pretreated, Nafion coated carbon fibre modified electrodes,[15–17] stearic acid modified microelectrodes,[18] or use of a poly(ester-sulphonic acid) coating to exclude anionic interferences from the electrode surface.[19] Hurrel and Abruña[20] employed polymer modified microelectrodes for amperometric determination of calcium. They reported submicromolar sensitivity for their electrodes and a dynamic range that extends over three orders of magnitude. The selectivity, especially toward magnesium was fairly good. Wrighton and co-workers developed a variety of sensors based on chemically modified microelectrode arrays sensitive to pH,[21] hydrogen and oxygen[22] as well as to other chemical species.[23,24] Kuwana *et al.* designed a microcarbon array enzyme glucose electrode that relied on the catalytic

monitoring of unconsumed oxygen.[25] Dong *et al.* have studied reduction of ascorbic acid with a Prussian Blue modified platinum microdisk electrode.[26]

We have recently reported how the overpotential of reduction and oxidation of hydrogen peroxide at glassy carbon electrode can be reduced by modifying the electrode surface with copper-heptacyanonitrosylferrate, CuHNF.[27] In this work we present the results obtained on electrocatalytic oxidation of ascorbic acid at a carbon fibre microelectrode modified by electrodeposition of a thin film of CuHNF.

EXPERIMENTAL

Chemicals

All chemicals used were of certified analytical grade and used without further purification. The solutions were prepared from double distilled water. Ascorbic acid solution was stored under nitrogen in a refrigerator. Potassium heptacyanonitrosylferrite solution was prepared daily.

Electrode and apparatus

Electrochemical experiments were performed with a low current–low noise potentiostat (Shanming Electronic Factory, Fujian, P.R. of China) equipped with a Type 3086 X-Y recorder (Yokogawa Hokushin Electric, Tokyo, Japan). A three-electrode system consisting of a chemically modified carbon fibre microelectrode (CMCFME), a platinum wire auxiliary electrode and a saturated calomel reference electrode (SCE) were used in all electrochemical measurements. All potentials given in this paper are measured *vs* the SCE. High purity nitrogen was used to remove oxygen from the solutions. Glass sealed carbon fibre microelectrodes were prepared according to the procedure described by Wightman and Vipf.[28] The fibre end is flush with the glass surface, making it easy to polish. Carbon fibres were obtained both from Union Carbide Co (New York) and Amoco Performance Products, Inc. (Greenville, SC).

Modification procedure

Before modification of the surface, the carbon fibre electrodes were polished first with fine polishing paper and then with 0.3- and 0.05-μm alumina. The electrodes were then cleaned in an ultrasonic bath with water and acetone for 10 min. The CuHNF film was then deposited on the surface of the electrodes by scanning them from 0.5 to -0.4 V in an oxygen free $4 \times 10^{-3}M$ $CuSO_4$–1.0M KCl solution with a scan rate of 20 mV/sec and then keeping the potential at -0.4 V for 30 sec. The electrodes were then removed from the solution, rinsed with water thoroughly and transferred into a $5 \times 10^{-3}M$ $K_2(Fe(CN)_5NO)$ solution where they were potential cycled for 10 min in the range of -0.4–0.5 V with a scan rate of 20 mV/sec. After rinsing thoroughly with water, the electrodes were ready for experiments.

RESULTS AND DISCUSSION

Evaluation of the quality of the electrode preparation

In order to obtain highly reproducible results, it is essential, after the electrode preparation, to evaluate the electrochemical behaviour of the electrode as well as its effective radius. Oxidation of hexacyanoferrate(II) at the electrodes in a 1M potassium chloride solution was selected as the evaluation reaction because the diffusion coefficient of this system is known.[29] Figure 1 illustrates a number of cyclic voltamperograms of glass sealed carbon fibre microelectrodes. At low scan rates the voltamperograms have sigmoidal shape due to the steady-state diffusion to the electrode surface and because a significant fraction of the current passes at the edges of the electrode.[28] Equation (1) describes the current under mass transfer limited, steady-state conditions at a microdisk electrode:[28]

$$i = 4nFDrC \qquad (1)$$

where n is the number of electrons transfered, F is the Faraday constant, D is the diffusion

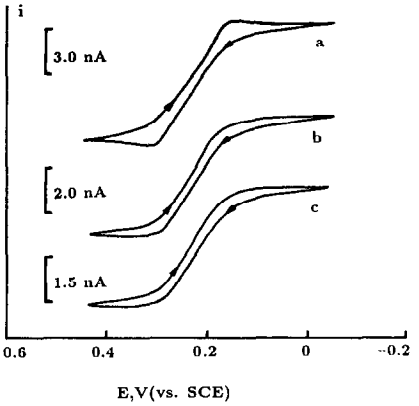

Fig. 1. Cyclic voltamperograms with 50 mV/sec scan rate of 1.0mM $K_3FeCN)_6$ in 1.0M KCl at carbon fibre microelectrodes of different radius: (a) 30, (b) 20 and 15 μm.

coefficient, r is the radius of the electrode and C is the bulk concentration of the depolarizer. Knowing the values of D, C, F, n and measuring the current, the effective radius of the electrode can be determined. In our studies we found the radius to be in good agreement with the values given by the carbon fibre manufacturers.

To study the effect of deposition time of copper at −0.4 V on the behaviour of the modified electrode the following experiment was conducted. After the linear scan from 0.5 to −0.4 V in a 4mM solution of copper sulphate the electrode was held for different lengths of time at −0.4 V before proceeding with the modification procedure as described in the Experimental section. The results of this study are shown in Fig. 2. As can be seen, 30 sec is enough to produce a film with reversible cyclic voltammeric behaviour. When longer deposition times or higher Cu(II) concentrations were used, the stability of the film as well as the amount of modifier on the electrode surface were decreased. With increased deposition time, the cyclic voltammetric response of the film became more sluggish. When a newly formed CMCFMF electrode was cycled in 1.0M potassium chloride, pronounced tailing at the negative end of the voltamperogram was observed. With increasing number of scans the tailing of the i-E curve disappeared gradually. This behaviour of the film may be due to migration of free Cu^{2+} from the lattice of the film to the solution. Due to the larger radius of Cu^{2+}, 3.25 Å, it is more difficult for these ions to be transported through the film than the smaller potassium ions with the radius of 1.25 Å.[30] After several cycles, all the interspatial Cu^{2+} is replaced by potassium ions and a typical steady-state i-E curve is obtained

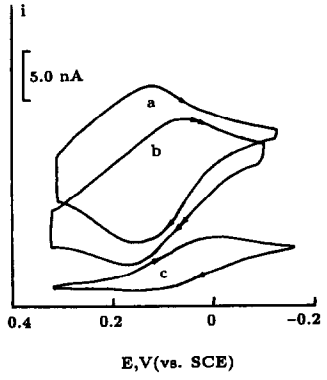

Fig. 2. Cyclic voltamperograms with 50 mV/sec scan rate of the CMCFME ($r = 25$ μm) under different deposition time in 4mM $CuSO_4$–1.0M KCl solution: (a) 30 sec, (b) 60 sec and (c) 240 sec.

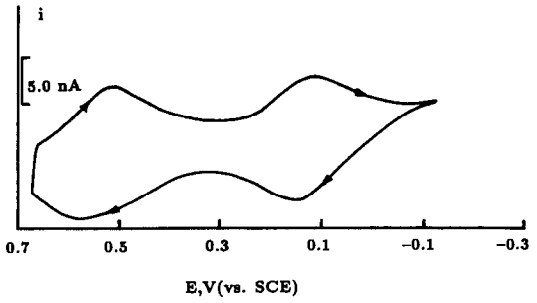

Fig. 3. Cyclic voltamperogram with 50 mV/sec scan rate of CMCFME ($r = 20$ μm) in 1.0M KCl solution.

as shown in Fig. 3. It can be seen that there are two couples of redox peaks in the potential range studied, one at 0.14 V and the other one at 0.59 V. Mössbauer spectra indicated that the redox couples at 0.14 V and 0.59 V are Cu(I)/Cu(II) and Fe(II)/Fe(III), respectively.[31]

It was interesting to notice that when the potential was scanned in the range of −0.5 V to 0.9 V the peak current of the redox couple at 0.14 V decreased markedly and disappeared after a dozen scans. But the peak current of the redox couple at 0.59 V remained unchanged.[27] The reason for this change is not clear yet. It might be that a new structure in the Cu(II)–Fe(III)$(CN)_5NO$ compound is formed and Cu(II) is not capable of undergoing redox reactions any more. As long as the potential, however, was kept less positive than 0.5 V the CMCFME did exhibit stable cathodic and anodic waves at 0.14 V. As will be discussed below, only the redox couple at 0.14 V has the catalytic effect on the oxidation of ascorbic acid. The catalytic ability of the film can be maintained as far as potentials less than 0.5 V are used.

The peak currents of our electrodes at 0.14 V were found to be proportional to the potential scan rate indicating that the modified microelectrode behaves exactly as could be expected of a reversible, surface immobilized redox couple.[32] The cyclic voltamperogram at a CMCFME with radius smaller than 5 μm, however, differed from that of an electrode with larger radius. The peak shaped voltamperogram disappeared and instead, a sigmoidal shaped voltamperogram was observed. In this case, however, it was very difficult to obtain a good CuHNF film on the electrode surface as well.

The electrode behaviour was not found to depend on pH within the range 2–8 in pure electrolyte solutions as long as the solution contained excess of potassium or sodium ions.

Although the shape of the wave at 0.14 V was slightly affected by the pH, the peak potentials were almost the same in pH 2 to 8. Beyond this pH range the CMCFME was unstable and the modified film was rapidly destroyed, especially in strong alkaline media.

Stability of the CMCFME upon scanning was tested in potassium or sodium containing solutions in the pH range 2–8, by performing 100 cyclic voltammetric scans with a scan rate of 50 mV/sec, in the range of −0.5 to 0.5 V. No significant changes either in cathodic or anodic current (<5%) could be observed. The electrode was found to possess additionally good mechanical stability when the solution was stirred with a magnetic stirbar.

Electrocatalysis of ascorbic acid at the CMCFME

The catalytic function of CMCFME upon oxidation of ascorbic acid is shown in Fig. 4. The cyclic voltamperogram obtained in 1*M* potassium chloride, curve (a), is changed in the presence of 0.6m*M* ascorbic acid, curve (b). When the oxidation of ascorbic acid is studied at a naked carbon fibre microelectrode a broad wave, however, is observed, indicating an irreversible electron transfer process.[26] In addition, the electrode reaction of ascorbic acid at a naked carbon fibre microelectrode depends on the electrode pretreatment as well.[33] The peak potential of ascorbic acid oxidation at the CMCFME is also about 200–300 mV less positive

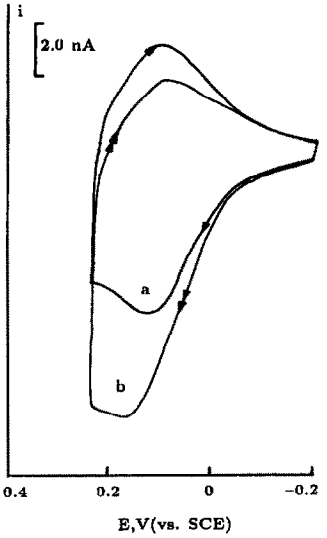

Fig. 4. Cyclic voltamperograms, 50 mV/sec scan rate, of a CMCFME ($r = 20$ μm) in (a) 1.0*M* KCl solution and (b) 0.6m*M* ascorbic acid + 1.0*M* KCl.

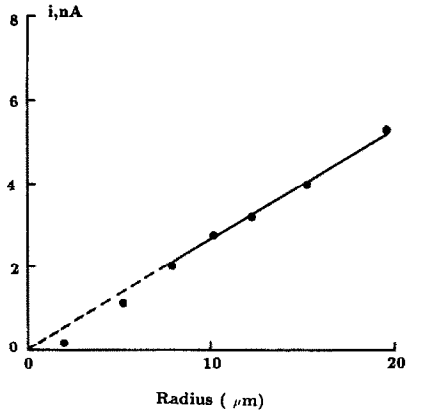

Fig. 5. Cyclic voltammetric peak current of ascorbic acid as function of the radius of the CMCFME in 1.0m*M* ascorbic acid and 1.0*M* KCl. The scan rate used was 10 mV/sec.

than that at the naked carbon fibre microelectrode. The catalytic activity of the redox couple at 0.14 V obviously mediates in the oxidation of ascorbic acid and reduces the high overpotential otherwise observed at solid electrodes. The peak potential of oxidation is not found to be affected by the ascorbic acid concentration.

At low potential scan rates, $v < 10$ mV/sec, the voltamperogram of ascorbic acid oxidation reached the steady state at the CMCFME. With increasing potential scan rate, however, a peak shape voltamperogram appeared indicating that only quasi steady state was reached. By using small radius microelectrodes ($r < 5$ μm) a steady state could be reached even at high potential scan rates. It was interesting to note that the limiting current of ascorbic acid oxidation at the CMCFME (5 μm) was lower than that at a naked carbon fibre microelectrode. This indicates that the overall reaction rate of the system is mainly controlled by the catalytic reaction, not by diffusion of ascorbic acid to the electrode. A similar result was obtained by Dong *et al.* in their studies on PB modified electrodes.[26,34] If oxidation of ascorbic acid at CMCFME is controlled solely by diffusion, the relationship between limiting current of ascorbic acid oxidation and the radius of modified microelectrode would follow equation (1), *i.e.*, the plot of the limiting current *i vs.* the radius *r* is a straight line. Figure 5 shows the plot of the limiting current of ascorbic acid oxidation as a function of the radius of the CMCFME. As can be seen the plot is no longer linear with electrodes with very small radii. This indicates that the overall process of ascorbic acid oxidation changes from diffusion controlled to

catalytic reaction controlled process with decreasing radius of the microelectrode. The same tendency was also observed when the concentration of ascorbic acid is increased but keeping the electrode radius constant.

For quantitative determination of ascorbic acid, a CMCFME with a relative large radius ($r = 20\ \mu m$) was used. Due to the mass transfer limited current of ascorbic acid oxidation at this electrode, a linear calibration curve could be expected. A linear, cyclic voltammetric response was obtained at a scan rate of 50 mV/sec with the ascorbic acid concentration from 5×10^{-5} to $6 \times 10^{-3} M$. A linear least square fit yielded the slope of 6.3 nA/mM with a correlation coefficient of 0.997. The relative standard deviations ($n = 10$) were 3.1 and 6.7% at the high end and at the low end of the calibration plot, respectively.

Amperometric determination of ascorbic acid at CMCFME

Quantitative determination of ascorbic acid was also done amperometrically in a stirred solution. Potential of the electrode was kept at 0.2 V corresponding to the beginning of the limiting current of ascorbic acid oxidation. The amperometric response was measured when a series of successive standard additions of ascorbic acid was made to the solution. Linear response was found in the concentration range 8×10^{-6}–$2 \times 10^{-3} M$. The slope of the calibration graph was 6.55 nA/mM and the correlation coefficient 0.998. The relative standard deviations ($n = 10$) were 2.3 and 5.1% at the high end and at the low end of the calibration plot, respectively.

CONCLUSIONS

Oxidation of ascorbic acid on naked carbon electrodes requires a high overpotential. Normally oxidation takes place in the range 0.4–0.5 V. This results in high background currents and interferences from other substances that are oxidized in this or lower potential range.[5] The CMCFME allows electrochemical detection of ascorbic acid at significantly lower potentials and therefore improves the selectivity of the determination as well as the sensitivity due to the higher signal-to-noise ratio. Amperometric determination of ascorbic acid at CMCFME certainly will find useful applications with biosensors.

FLOW-INJECTION DETERMINATION OF 9,10-PHENANTHRENEQUINONE WITH CATALYTIC PHOTOMETRIC DETECTION

NOBUTOSHI KIBA, HIROSHI SUZUKI, EIICHI GOTO and MOTOHISA FURUSAWA
Department of Applied Chemistry and Biotechnology, Faculty of Engineering, Yamanashi University, Kofu 400, Japan

(*Received* 22 *April* 1992. *Accepted* 30 *June* 1992)

Summary—A catalytic photometric method with a flow-injection system is described for the determination of 9,10-phenanthrenequinone. It is based on the catalytic effect of 9,10-phenanthrenequinone on the redox reaction of 1,2-dinitrobenzene with formaldehyde under alkaline conditions. 9,10-Phenanthrenequinone at the 5.0×10^{-8}–$5.0 \times 10^{-6}M$ level can be determined at a rate of 20 samples/hr. The detection limit is 1.0×10^{-8} M (40 pg in a 10-μl injection).

9,10-Phenanthrenequinone (PQ) has been shown to possess photosensitivity and is used as a photoreceptor and photoinitiator in photoresistors.[1,2] The PQ content in photopolymers influences the sensitivity and stability of the resistors. PQ has been determined spectrophotometrically[3,4] and fluorimetrically,[5] but the methods were unsuitable for the rapid analysis of a large number of samples. PQ catalyses the reduction of 1,2-dinitrobenzene to nitrophenyl hydroxylamine dianion (λ_{max}: 560 nm) in the presence of formaldehyde. The reaction was used for the spot-test of PQ down to 2 ng.[6,7] The catalytic reaction was applied to the determination of catecholamines in alkaline dimethyl sulphoxide as solvent.[8]

Kinetic methods based on catalytic reactions are useful in trace analysis because of the sensitivity and selectivity. Though many batch techniques for kinetic catalytic analysis have been used, care must be exercised to control the reaction time. In a flow-injection system, the reaction time can easily be controlled by varying a flow-rate and length of reaction coil.[9]

In this paper, a flow-injection photometric method for the determination of PQ based on the catalytic effect on the reduction of 1,2-dinitrobenzene with formaldehyde is reported. The conditions for the catalytic reaction were studied in order to adapt it to a flow-injection system. This method was applied to the determination of PQ in photopolymer.

EXPERIMENTAL

Reagents

1,2-Dinitrobenzene (DNB) and 30% formaldehyde (FA), which were obtained from Nacalai Tesque (Kyoto, Japan), were used as received. Dimethyl sulphoxide (DMSO), which was from Wako Chemicals (Tokyo, Japan), was purified by a refrigeration method.[10] All other chemicals were of analytical-reagent grade.

Apparatus and procedure

A schematic diagram of the flow-system is shown in Fig. 1. A sodium hydroxide solution (3M) and reagent solution which consisted of 3mM DNB and 3M FA in DMSO were pumped by a reciprocating pump of the double plunger type (Kyowa Seimitsu, KHU-W-52)

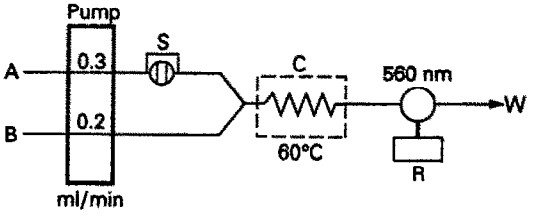

Fig. 1. Schematic diagram of the flow-injection system for the determination of 9,10-phenanthrenequinone. A: reagent solution (3mM 1,2-dinitrobenzene and 3M formaldehyde in DMSO), B: 3M NaOH, S: sample injector with 10-μl loop, C: reaction coil (10 m × 0.5 mm i.d.) kept at 60°, D: spectrophotometer, R: data processor, W: waste.

at a total flow-rate of 0.5 ml/min. Samples were introduced with an injection valve (Sanuki, SV1-SU7) with a 10-μl loop. The reaction coil (10 m × 0.5 mm) was kept at 60° in a water-bath. The absorbance at 560 nm was monitored with a spectrophotometer (Jasco, Uvidec-100-VI), the output being fed to a data processor (System Instrument, Chromatocorder II). The flow channel was assembled from 0.5-mm bore Teflon tubing and stainless steel connectors.

RESULTS AND DISCUSSION

Optimization

The effect of temperature on the reaction was examined over the range 50–70°. As shown in Fig. 2, the response was essentially constant from 60–65°. The decrease in response at higher temperature may be attributed to the thermal lability of the product.

The effect of sodium hydroxide concentration in the reaction coil was examined in the concentration range 0.4–1.2 *M*. The response increased exponentially according to the second power of the concentration (Fig. 3). Above the concentration of 1.3*M*, base line stability was poor because sodium hydroxide is slightly soluble in aqueous DMSO solution.

The response was dependent on the composition of aqueous DMSO solution. The total flow-rate was kept constant at 0.5 ml/min and the ratio of flow-rates for the sodium hydroxide solution and the reagent solution which contained 75% DMSO was changed from 0.5:4.5 to 4.5:0.5. The response increased gradually with increasing content of DMSO in the reaction medium. At higher flow-rates of the reagent solution, the base line was unstable because of incomplete mixing and poor sodium hydroxide solubility. A flow-rate of 0.2 ml/min for the sodium hydroxide solution and a flow-rate of 0.3 ml/min for the reagent solution were selected, as a compromise between sensitivity and base line stability.

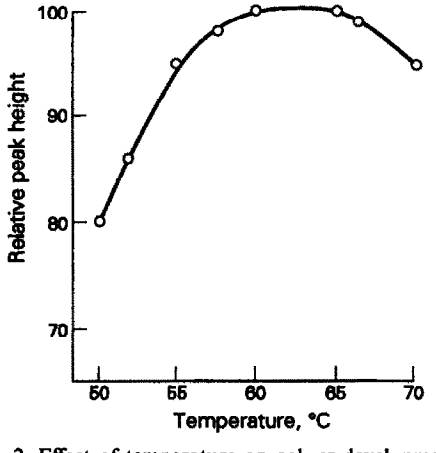

Fig. 2. Effect of temperature on colour development.

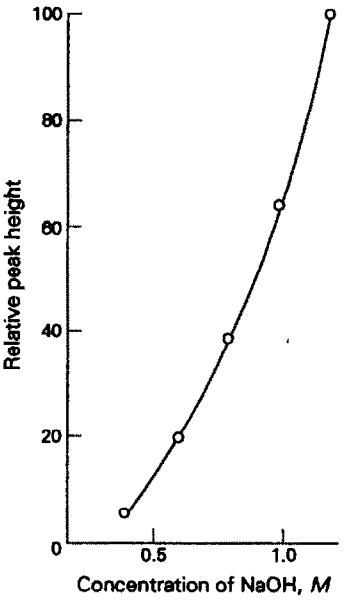

Fig. 3. Effect of NaOH concentration on colour development.

Since the catalytic reaction proceeds with the elapse of time, the peak height depends on the flow-rate and reaction coil length. The lower flow-rates gave higher peaks but the baseline reversion times were increased. A total flow-rate of 0.5 ml/min was selected, taking account of the sensitivity and the rate of sampling. Under the conditions the rate of sampling was 20/hr.

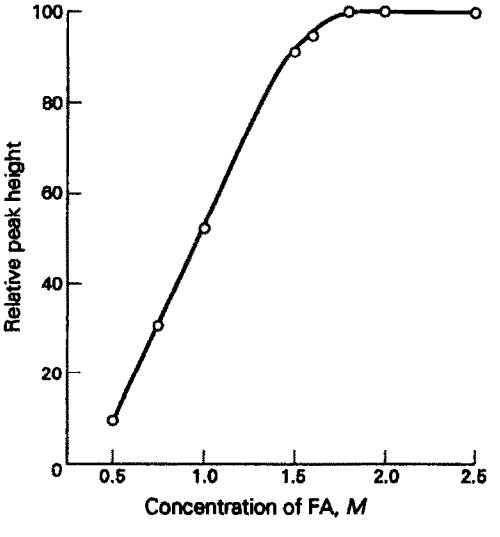

Fig. 4. Effect of concentration of formaldehyde on colour development

Table 1. Interference of various quinones on the determination of 5.0×10^{-7} *M* PQ

Quinones	Concentration ($\times 10^{-7}M$)	Error (%)	Response RSD (%)
1,2-Benzanthraquinone	50	0.0	1.0
Anthraquinone	50	0.0	0.91
1,2-Naphthoquinone	50	2.5	1.3
1,4-Naphthoquinone	50	15.6	1.9
	20	5.3	1.4
2-Methyl-1,4-naphthoquinone	50	5.3	1.5
	20	2.2	1.3
2,3-dichloro-1,4-naphthoquinone	50	3.8	1.4
	20	1.3	1.2

Table 2. Results for PQ in photosensitive resin

Content* %	Peak height† Absorbance	Found %
0.50	0.704 (1.1)	0.51
1.0	0.843 (0.88)	1.00
2.0	0.981 (0.98)	2.01
3.0	1.06 (0.97)	3.00
4.0	1.12 (1.2)	3.99
5.0	1.16 (1.4)	4.98

*Obtained from the data presented by manufacturers.

†All values are means ($n = 9$) with relative standard deviation (%) in parentheses.

The effect of FA concentration on the response is shown in Fig. 4. The response increased as the concentration increased and above the concentration of 1.8 *M* it was constant.

The reaction was found to be independent of the DNB concentration between 1.5–3.0m*M*.

Interference

The selectivity of the reaction was examined by studying the effect that $1.0 \times 10^{-6}M$ concentration of various quinones had on the determination of $5.0 \times 10^{-7}M$ PQ. The results, summarized in Table 1, show that the method provides good precision with relative standard deviation values of less than 2.0% in the absorbance measurements (7 replicates).

Calibration graph

The calibration graph was obtained from different concentrations of PQ under the same conditions as shown in Fig. 1. The graph was linear over the range 5.0×10^{-8}–$5.0 \times 10^{-6}M$. The linear regression equation was $y = 0.460x + 3.751$ with a correlation coefficient of 0.992 ($n = 21$), where y and x are absorbance and log[PQ concentration (M)], respectively.

Application

Table 2 shows the results for the determination of PQ in photosensitive resin prior to photoirradiation, which was coated in a 60-μm thick layer on circuit boards. The resin contains dimethylaminoethyl methacrylate–methyl methacrylate copolymer (56.0–60.5 wt%), pentaerythritol triacrylate (27%), tetraethylene glycol diacrylate (10%), tribromoethylphenyl sulphone (2%) and PQ (5.0–0.5%). The resin (0.1 mg) which was scraped from the boards was dissolved in 10.0 ml of DMSO. The solution (10 μl) was injected into the system.

It is concluded that the flow-injection system with catalytic reaction is useful for the sensitive, rapid and reliable measurement of PQ. The proposed method could easily be used for the determination of PQ in the photopolymer.

ATOMIC ABSORPTION DETERMINATION OF TRACES OF CADMIUM IN URINE AFTER ELECTRODEPOSITION ONTO A TUNGSTEN WIRE

GUIEN ZHANG, JINGHUA LI, DEXUE FU, DAQING HAO and PINGPING XIANG
Dept. of Chem., Henan Normal University, Xin Xiang, Henan, 453002, P.R. China

(*Received* 22 *April* 1992. *Revised* 30 *June* 1992. *Accepted* 30 *June* 1992)

Summary—A three-coil tungsten wire is used as electrode for the preconcentration of cadmium, which is then placed in a graphite tube for atomization and atomic absorption measurement. The heating parameters of the graphite furnace are optimized using the Modified and Weighted Centroid Simplex Method (MWCS), and computer program for automatic calculation. Sulphuric acid is selected as the supporting electrolyte for electrodeposition. The linear range of the calibration graph is 0.00–0.55 ng/ml. The detection limit is 0.01 ng/ml. For 0.1 ng/ml cadmium the coefficient of variation is 3.35% for ten parallel determinations. No interference occurs in the presence of more than 20 coexisting ions. Traces of cadmium in urine of normal people and in river water and the recoveries for cadmium are determined. The results are satisfactory.

There have been numerous reports on the determination of traces of metal ions using preconcentration by electrodeposition together with the graphite furnace atomic absorption method[1–9]. Earlier, researchers tried to increase the sensitivity by deposition on a metal wire followed by atomization in a fire, but that method is only equal in sensitivity for the level of solution sampling in a graphite tube. Czobik[16] placed the cathode with deposited metal directly into a graphite tube and successfully determined Cd of sea water and blood serum. Yet, because the tungsten wire length was limited, the effective area was small and the sensitivity was low. In this paper we present a new approach. Atomic absorption determination is performed using an electrode of tungsten wire with 3 coiled turnings matched with the graphite tube diameter with increased effective area and sensitivity.

The modified and weighted centroid simplex method

MWCS is used to optimize the conditions for the determination, performed automatically using a program on a PB-700 computer. Traces of cadmium in urine of normal people and river water have been determined.

EXPERIMENTAL

Instruments and reagents

The following materials were used: a Dao Jin AA-670 atomic absorption spectrometer, pyrolitically coated graphite tubes (Dao Jin catalog 200–54525-045), a HDV-7 Transistor potentiostat.

Cadmium standard solution, 1 mg/ml. Weigh 0.2282 g of specpure reagent 3 $CdSO_4 \cdot 8H_2O$, dissolve in 0.1*M* sulphuric acid and dilute to 100 ml with 0.1*M* sulphuric acid.

Electrodeposition equipment and procedure

The electrode is made of tungsten wire which is 0.3 mm in diameter and wound to 3 turnings. Before using it, burn the graphite furnace twice till its surface turns shiny. Its absorbance is then zero.

An HDV-7 potentiostat is used as the power source, the three-winding tungsten wire is the cathode, a platinum electrode is the anode, a saturated calomel electrode is the reference electrode, and saturated potassium chloride solution is contained in the reference cell. A potassium chloride salt-bridge connects the electrolysis and reference cell.

Add 20.0 ml of sample solution containing 0.1*M* sulphuric acid to the electrolysis cell, insert the electrodes and then stir the solution. The controlled cathode potential is −1.0 V (*VS.*SCE) and the preconcentration time is 2 min. Remove the electrode without interrupting the power. Use filter paper to carefully remove the electrolyte from the tungsten wire and then place it in the graphite tube in such a way that the light is parallel to the surface of the

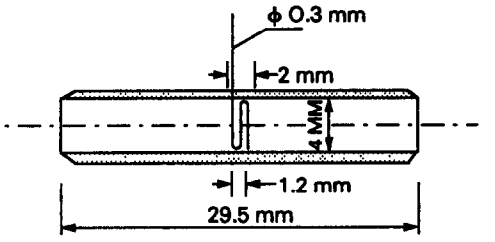

Fig. 1. Tungsten wire shape and match of wire and graphite tube.

three-winding tungsten wire, i.e. passes through the centre of the coil.

Initiate the heating cycle of the graphite furnace, and record the absorbance.

Conditions for atomic absorption measurement

Wave length: 228.8 nm, slit width: 0.3 nm, hollow cathode lamp electric current: 6 mA, argon flow: 1.5 l./min.

The heating program of the graphite furnace was as follows:

dry: 100°, 20 sec; ashing (ramp): 250°, 10 sec; atomization (stair): 1500°, 3 sec; cleaning: 2000°, 2 sec.

RESULT AND DISCUSSION

Study of the shape of the tungsten wire and match of the wire and the graphite tube

Tungsten wire can withstand high temperatures, is chemically stable and can form various shapes. Therefore, tungsten wire is used as the material for the cathode. In order to increase the sensitivity of the analysis and to enlarge the surface area for electrolysis, 3 windings wire are used. The coil is smaller than the diameter of the sampling hole of the graphite tube and its diameter is smaller than the inner diameter of the graphite tube, i.e., 4 mm high long and 1.2 mm wide (Fig. 1). This matches the graphite tube well (Fig. 1). In the graphite tube the surface with three wound wires is placed parallel to the light beam. The blank absorbance of this electrode is nearly zero. The experimental results show that this procedure has high sensitivity and good

Table 1. Effect on Absorbance from numbers of turnings of Tungsten wire (0.3 mm diameter wire)

	0.085	0.129	0.172

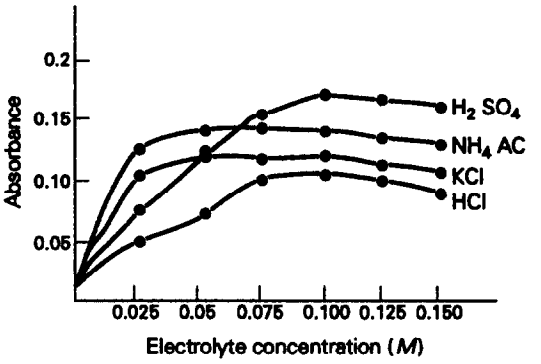

Fig. 2. Effect of different base electrolytes.

reproducibility for the determination of Cd. Table 1 lists the absorbance of Cd after its deposition onto W-wire with different numbers of turnings.

Selection of conditions for electrodeposition[10-15]

In order to optimize the electrodeposition of Cd, the following parameters were investigated.

Supporting electrolyte. Experiments were carried out with four electrolytes: H_2SO_4, HCl, HNO_3 and NH_4AC. The experiments show that at low concentration, absorbance increases with increasing electrolyte concentration, but the absorbance decreases when the concentration has reached a certain value. Interference from nitric acid is serious. In 0.1*M* sulphuric acid, the absorbance is largest and stable, as shown in Fig. 2. So 0.1*M* sulphuric acid is selected as the base electrolyte.

Cathode potential. The influence of the cathode potential between −0.4 and −1.4 V is shown in Fig. 3. For further investigations, the electrodeposition was carried out at −1.0 V.

Effect from electrodeposition time. The yield of the deposition depends strongly on electrolysis time. The absorbance increased from 0.05 at 0.5 min to 0.7 at 3.5 min, with a slight curvature dependence. In order to keep the analysis time

	Best point		250	10	1500	3	

short, a period of 2 min was chosen when the absorbance was 0.4 for the above Cd solution.

Effect of tungsten wire diameter. When tungsten wires of different diameters are examined, the absorbance increases linearly with increasing diameter, increasing from 0.025 at 0.2 mm to 0.33 at 0.6 mm. A wire with 0.3 mm diameter was used in further studies.

Effect of stirrer speed. In order to increase the mass transfer rate and decrease the concentration polarization, stirring is needed during the electrodeposition. After the speed reaches a certain value, the absorbance changes little. So 200 rpm is selected as the speed for stirring.

Selection of atomic absorption conditions

After investigating the effects on absorbance, 6 mA was chosen as the lamp electric current, 0.3 nm for the slit and 1.5 l./min for the argon flux.

Optimization of the condition of the graphite furnace

In order to optimize the measurement parameters for ETAAS, the MWCS technique was applied, using a PB-700 computer and a self-designed program. The parameter ranges and optimum values are shown in Tables 2–4.

Calibration curve

The calibration curve is linear up to 0.6 ng/ml Cd. The equation of the linear regression is $y = 1.647x - 0.0157$; the correlation coefficient is $r = 0.9998$. For 0.1 ng/ml Cd, the standard deviation is 3.35% ($n = 10$). The detection limit is 0.01 ng/ml.

Effect of coexisting ions

Experiments have been carried out with more than 20 coexisting ions. For errors smaller than 5%, the permitted amount of each coexisting ion is shown in Table 5.

Sample analysis

Determination of cadmium in urine of normal people. It is important to determine the cadmium content of urine of normal people in environmental sanitation monitoring. But it cannot be determined directly by ordinary graphite furnace AAS, due to the low concentration of cadmium. After decomposition of urine, Cd can be separated using electrodeposition and determined with ETAAS as described above.

Place 20 ml of urine in a beaker. Digest with one of two methods. Procedure 1: add 4 ml of concentrated perchloric acid and 4 ml of concentrated nitric acid to the sample. Procedure 2: add 10 ml of concentrated nitric acid to the sample. Each digestion requires two such additions of acid and heating. Heat it on an electric-heating plate and digest until white crystals appear and the excess of nitric acid is removed. Remove from the plate and cool. Dissolve and dilute the residue to 100 ml with 0.1*M* sulphuric acid. Take 20-ml portions for the electrodeposition of Cd. Recovery was determined by the standard addition method. The results are listed in Table 6.

Determination of the free cadmium in river water. The cadmium content of the canal of Xinxiang city was determined. Take 50 ml of water, add 5 ml of 1*M* sulphuric acid, to bring the concentration of sulphuric acid to 0.1*M*. Mix well and store overnight. Filter with quantitative filter paper. Take 2-ml filtered portions of liquid in five 100-ml standard flasks, add 0.00, 1.00, 2.00, 3.00, 4.00 ml of standard solution containing 10 ng/ml cadmium. Bring the volume up to 100 ml with 0.1*M* sulphuric acid and determine the Cd concentration by taking 20 ml of each bottle. The results are shown in Table 7.

Atomization mechanism

Figure 5 compares the ashing and atomization curves for the normal solution ETAAS method (curves 1 and 2) with those using the electrodeposition method (curves 3 and 4). Ashing curve (3) has the largest absorbance at 100–300° and changes little in this range. This matches the melting point of Cd (320.9°). When the ashing temperature is above 300°, Cd begins melting, its volatization increases, and nearly all the atoms are lost at 800°; this matches the boiling point of Cd (765°).

Curve (4) in Fig. 5 is the atomization curve for electrodeposition–atomic absorption. Atomization starts at 400°. The absorbance increases with the temperature in the range 400–900°. In this range, partial atomization transforms to full atomization.

Note that ashing temperature effects are similar for both methods but atomization efficiency reaches a maximum at lower temperatures than with the solution deposited in the graphite tube.

SIMULTANEOUS DETERMINATION OF BERYLLIUM AND ALUMINIUM IN MIXTURES USING DERIVATIVE SPECTROPHOTOMETRY

NARINDER KUMAR AGNIHOTRI, HAR BHAJAN SINGH,* RATTAN LAL SHARMA and VINAY KUMAR SINGH

Department of Chemistry, University of Delhi, Delhi 110007, India

(*Received* 16 *April* 1992. *Accepted* 25 *June* 1992)

Summary—The spectrophotometric determination of beryllium and aluminium with 5,8-dihydroxy-1,4-naphthoquinone in the presence of a non-ionic surfactant is reported. Absorption maxima, molar absorptivity and Sandell's Sensitivity of 1:2 (M:L) beryllium and aluminium complexes are, 585 nm and 598 nm, 1.63×10^4 l. mole^{-1}. cm^{-1} and 2.04×10^4 l. mole^{-1}. cm^{-1}, and 0.55 ng/cm^2 and 1.32 ng/cm^2 respectively. Beer's law is obeyed between $7.20–3.96 \times 10^2$ ng/ml beryllium and $1.08 \times 10^1–1.08 \times 10^3$ ng/ml aluminium. A method for simultaneous determination of beryllium and aluminium in their mixture using derivative spectra is described. The range $3.6 \times 10^1–3.6 \times 10^2$ ng/ml beryllium could be determined in the presence of $1.08 \times 10^2–1.08 \times 10^3$ ng/ml aluminium, and vice versa.

Toxicity of beryllium and aluminium as well as the need for sensitive and selective methods for determining these elements are well documented.[1] Several sensitive reagents exist for spectrophotometric determination of beryllium (Beryllon II, III, and IV, Quinalizarin, Erichrome Cyanine R) and aluminium (Chrome Azurol S, Erichrome Cyanine R, Pyrocatechol Violet, Aluminon). These reagents become selective in the presence of a suitable masking agent.[2] Acetyl acetone and 8-hydroxyquinone are the sensitive and selective reagents recommended and practised for extractive spectrophotometric determination of beryllium and aluminium respectively.[3]

Impact of micellar system[4–6] on the photometric parameters, and utility of derivatization[7–8] of normal absorption spectra on the selectivity and sensitivity of the spectrophotometric methods are well established. Simultaneous photometric determination of beryllium and aluminium is hampered due to spectral overlap of their complexes. In such cases spectrometry coupled with derivative techniques is useful in analysis of such mixtures.[9–11]

We now report a rapid, sensitive and inexpensive spectrophotometric determination of micro amounts of beryllium and aluminium using 5,8-dihydroxy-1,4-naphthoquinone (DHNQ), a bidentate ligand capable of forming polychelate(s),[12–14] as a chromogenic reagent, and Triton X-100, a non-ionic surfactant, to generate the requisite micellar medium. Simultaneous determination of beryllium and aluminium, without any pre-separation or masking, has also been carried out using derivative spectra.

*Author for correspondence.

EXPERIMENTAL

Instruments

Absorption measurements were made on a Shimadzu UV-260 recording spectrophotometer using 10-mm fused silica cells and a 1-nm band width taking water as reference. First and second order derivative spectra were recorded with $\Delta\lambda = 2$ and 4 nm respectively. The pH of solutions were measured on an EC digital pH-meter (Model pH 5662) fitted with a combined glass electrode.

Chemicals

All chemicals used were of analytical grade purity. Dilute solution of sulphuric acid and sodium hydroxide were used for pH adjustment. Stock solutions (0.01M) of Be(II) and Al(III) were prepared in decimolar sulphuric acid using $BeSO_4 . 4H_2O$ and $KAL(SO_4)_2 . 12H_2O$ respectively. As DHNQ is sparingly soluble in water, an appropriate amount (7.61 mg) was first dissolved in the minimum amount of 0.2*M* sodium hydroxide with stirring at 40°, which was followed by addition of 4.0 g of Triton

X-100 and acidification. The solution was diluted to 100 ml with water.

Procedure

To study the effect of varying H^+ concentration on the absorbance of each system, two sets of solutions in the pH range 2.0–11.5 were prepared. One of these contained $2 \times 10^{-4}M$ DHNQ, 2% w/v Triton X-100 and $0.01M$ ammonium acetate, while the other, in addition, contained $2 \times 10^{-5}M$ of the metal ion [Be(II) or Al(III)] as well.

The effect of varying surfactant concentration on the absorbance of the complex was studied by increasing the amount of Triton X-100 in a series of solutions, $2 \times 10^{-4}M$ in DHNQ, $2 \times 10^{-5}M$ in metal ion solution and $0.01M$ in ammonium acetate at the pH of maximum complex formation.

Beer's law was studied by adding increasing amounts of the metal ion to a $2 \times 10^{-4}M$ solution in DHNQ, 2% w/v in Triton X-100 and $0.01M$ in ammonium acetate, keeping the ratio $L:M \geqslant 10$.

Simultaneous determination of Be and Al

Concentrations of beryllium and aluminium ions were determined from first/second derivative spectra by measuring derivative amplitudes at isodifferential points and comparing the values with a calibration graph. The calibration graph for beryllium was prepared by measuring amplitudes of the first/second derivative spectra at isodifferential point of aluminium, and vice versa for aluminium.

RESULTS AND DISCUSSION

Absorption spectra and its dependence on pH

DHNQ exhibits maximum absorption at 490 nm which shows a bathochromic shift to 610 nm with pH on account of increasing dissociation of the phenolic groups. Formation of Be(II)–DHNQ–Triton X-100 and Al(III)–DHNQ–Triton X-100 complexes was studied in the pH range 2.0–11.5. The complex formation starts at 5.0 and 5.5 in the case of beryllium and aluminium respectively and increases up to pH 6.5 and 6.6 as evidenced by increase in absorbance. This remains constant from pH 6.5 to 7.4 and 6.6 to 7.6 in the respective cases and further increase in pH, results in decrease of absorbance in both cases. Beryllium and aluminium complexes show absorption maximum at 585 nm and 598 nm respecitvely at pH of maximum complexation. Subsequent studies have been carried out at these λ_{max} wavelengths and pH values (6.8 and 6.9 respectively).

Effect of surfactant

The surfactants investigated include cetyltrimethylammoniumbromide (CTMB), *N*-cetylpyridiniumchloride (CPC), sodiumlaurylsulphate (SLS), and triton X-100. As absorbance of the complex in each case was lesser in the presence of an ionic surfactant than in non-ionic surfactant, either due to increased deprotonation of the ligand or inhibition of complex formation, Triton X-100, a non-ionic surfactant was selected for micelle formation. Concentrations up to 2% (w/v) of surfactant is found to increase the extinction of the complex which decreases with a further increase in the case of both the metal ions. A 2% w/v concentration of Triton X-100 was, therefore, maintained in subsequent studies.

Reversibility of the complexation reaction

Complexation of Be(II) and Al(III) with DHNQ in the presence of Triton X-100 is reversible between pH 6.8 to 11.5, and 6.9 to 11.5 respectively. The colour of the ligand and that of complexes are stable up to twenty four and eight hours respectively at room temperature (20–25°).

Effect of reagent concentration

Absorbance spectra of solutions containing increasing amounts (4×10^{-6}–$2.8 \times 10^{-4}M$) of reagent and fixed amount of the metal ion showed an increase in absorbance at absorption maxima, 585 nm and 598 nm respectively for Be(II) and Al(III) complexes. Since the ligand also absorbs at λ_{max} of the complexes. The corrected absorbance at λ_{max} of each complex was plotted against molar ratio (L:M) of the reagent. The slope of the plot remains constant between 5:1 to 20:1 (L:M) in the case of the beryllium complex and 10:1 to 45:1 (L:M) in the case of the aluminium complex. The reagent concentration in subsequent studies has, accordingly, been kept within the above mentioned limits, wherever possible.

Number of chromogenic species and their composition

A computer program[15] based on matrix rank determination of an absorbance matrix has been used to determine the number of chromogenic

species present in solution. The rank is determined by triangularizing the matrix, based on the method of gaussian elimination and comparison of the diagonal elements with error matrix. Though on this basis three absorbing species (H_2L, HL^-, L^{2-}), are inferred to be present in the ligand solution in the pH range 2.0 to 11.5, existence of only the first two species are of significance up to 8.0 (pH of concern for the present investigation); error matrix $\geqslant 0.0026$. Three absorbing species are shown to be present in the solution of Be(II)/Al(III) complexes for error matrix $\geqslant 0.0030$.

Stoichiometry of the complexes were determined using the method of continuous variations. Plot of absorbance at λ_{max} of the complexes versus mole fractions of the metal ion shows a maximum at 0.33, suggesting the formation of a 1:2 (M:L) complex in each case. The complexes are, therefore, represented as $Be(HL)_2$ and $[Al(HL)_2]^+$, where H_2L represents the molecular form of DHNQ.

Effect of metal ion concentration

Absorbance of solutions having excess of ligand increased linearly with increase in metal (Be(II)/Al(III)) ion concentration [Fig. 1(a) and 2(a)]. Linear regression of absorbance on concentration gave equations with positive intercepts due to absorption by the ligand at λ_{max} of the complexes. The observed absorbance values have, therefore, been corrected in two ways giving corrected absorbances A_I and A_{II} as expressed in equations (1) and (2). These corrected absorbance values show improvement in linear fit (Table 1) which is evident from the regression coefficients.

$$A_I = (A)_{max(C)} - [(A)_{max(C)}/(A)_{max(L)}]_{L.BLK} \times (A)_{max(L)} \quad (1)$$

$$A_{II} = (A)_{max(C)} - [(A)_{max(C)}/V_L]_{L.BLK} \times (V_L - R \times V_M) \quad (2)$$

where $[(A)_{max(C)}/(A)_{max(L)}]_{L.BLK}$ is the ratio of absorbances of the ligand blank solution at λ_{max} of the complex and that of the ligand, V_L and V_M are volumes of equimolar solutions of ligand and metal ion respectively, and R is stoichiometry of the complex.

First and second derivative spectra of the above-mentioned solutions are shown in Figs. 1(b) and (c), and 2(b) and (c). The first derivative spectrum of beryllium shows a peak at 585 nm [Fig. 1(b)] and that of aluminium shows crossover point at 598 nm [Fig. 2(b)] corresponding to λ_{max} of the respective complexes. Heights of the peaks (PH) and depth of the troughs (TD) were measured from the base line of the ligand and plotted against the metal ion concentration. Relationship between PHs or TDs and increasing metal ion concentration at different wavelengths in each case show a good linear fit (Table 1) which is useful in determining these metal ions in solution. Be(II)–DHNQ–Triton X-100 and Al(III)–DHNQ–Triton and X-100 systems obey Beer's law from 7.20–72 ng/ml, 36–396 ng/ml and 10.8–108 ng/ml and 108–1.08 $\times 10^3$ ng/ml beryllium and aluminium ions respectively.

*Recommended for determination, A_I/A_{II} = Corrected absorbance, PH = Peak height, TD = Trough depth, C = Concentration of Be(II)/Al(III).

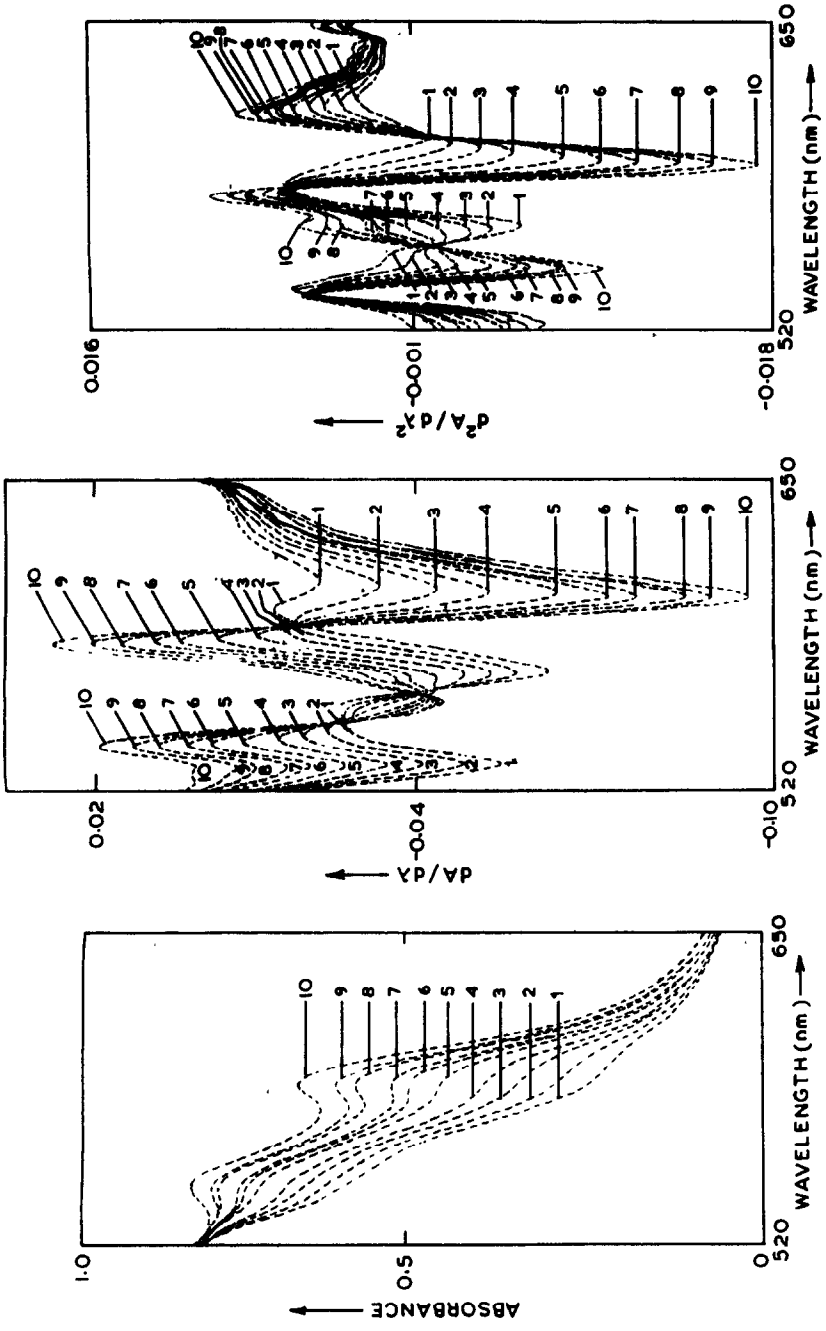

Fig. 1. Spectra of Be(II)–DHNQ–Triton X-100 system containing increasing amount (from 3.60×10^{1}–3.96×10^{2} ng/ml) of Be(II) (No. 2 to 10); No. 1 contains 2×10^{-4} *M* DHNQ (a) Normal, (b) First order and (c) second order derivative spectra.

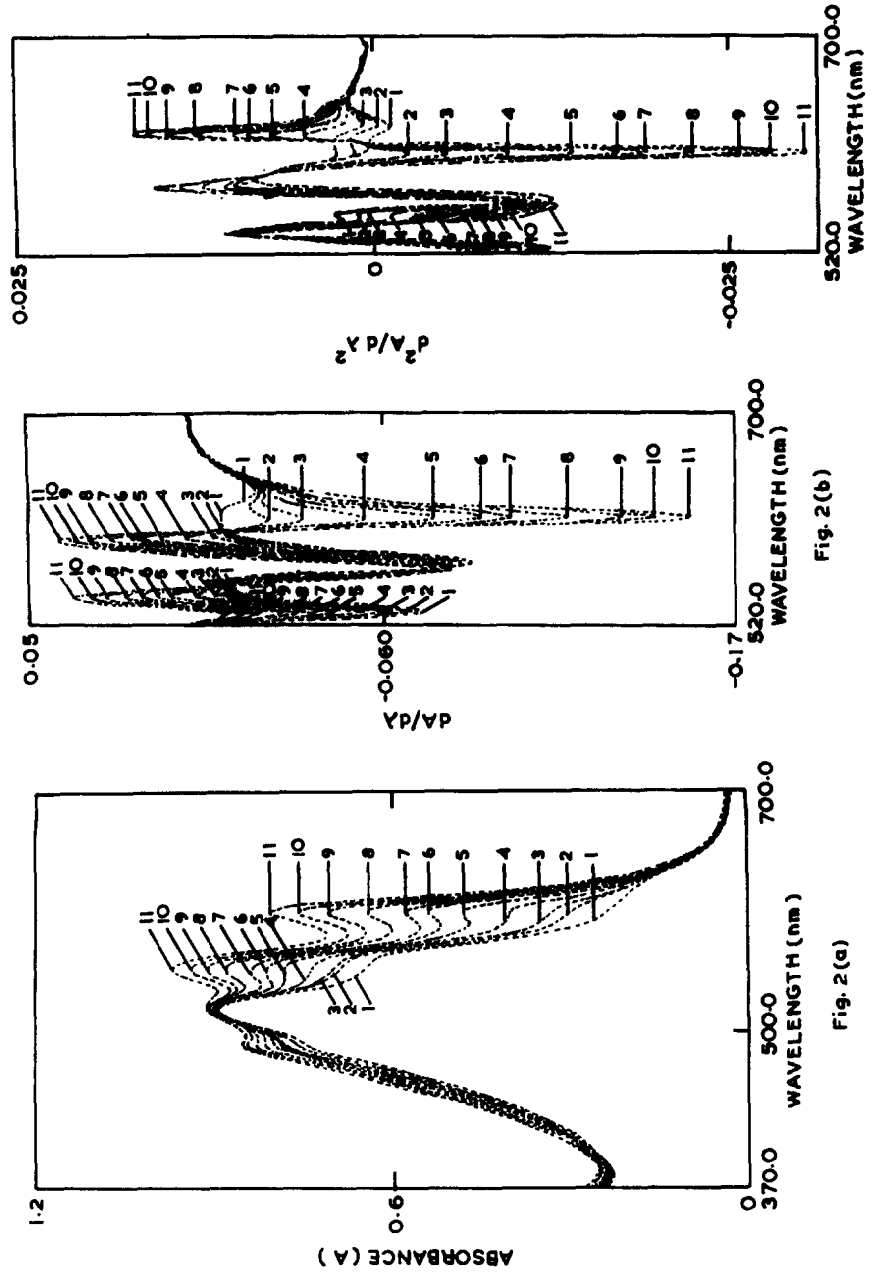

Fig. 2. Spectra of Al(III)–DHNQ–Triton X-100 system containing increasing amount (from 1.08×10^2–1.08×10^3 ng/ml) of Al(III) (No. 2 to 11); No. 1 contains 2×10^{-4} *M* DHNQ, (a) Normal, (b) First order and (c) second order derivative spectra.

Molar absorption coefficient (ϵ), specific absorptivity (a) and Sandell's sensitivity (S) of the complexes under optimal experimental conditions are found to be 1.63×10^4 l. mole^{-1}. cm^{-1} and 2.04×10^4 l. mole^{-1}. cm^{-1}, 1.81 ml g^{-1}cm^{-1} and 0.76 ml g^{-1}cm^{-1}, and 0.55 ng/cm^2 and 1.32 ng/cm^2 respectively. The IUPAC detection limits ($K = 3$)[16] are 0.5 ng/ml for beryllium and 1.0 ng/ml for aluminium.

Conditional stability constant

Conditional stability constants[17,18] of beryllium and aluminium complexes have been determined by taking the following equilibria

$$Be^{2+} + 2H_2L \rightleftharpoons [Be(HL)_2] + 2H^+$$

$$Al^{3+} + 2H_2L \rightleftharpoons [Al(HL)_2]^+ + 2H^+$$

The value of the conditional stability constant (k') for beryllium and aluminium complexes has been found to be 1.58×10^5 l. mole^{-1} and 2.69×10^5 l. mole^{-1} respectively; concentrations have been used instead of activity as the solutions are dilute and a non-ionic surfactant has been used.

Effect of diverse ions

Effect of the presence of diverse ions in the determination of Be(II) and Al(III) using DHNQ was studied under optimum conditions. The analytical results for a series of determinations are given in Table 2. When a precipitate appeared, it was removed by centrifugation before measuring the absorbance of the supernatant liquid. Absorbance measurement in the first and second derivative modes proved useful in overcoming interferences in a number of cases where masking agents like EDTA, tartrate, citrate, oxalate, F^- could not help. For example, very close absorption profiles due to Ce, Th, Au, Al, As, Cr, Fe, Ni and UO_2, and Th, Ce, Au, Cr, Fe, Ga, In, Be, Co, Ni, Sn and UO_2 in case of beryllium and aluminium complexes get resolved from those of the analytes [Be(II)/Al(III)] in higher order derivative modes enabling their determination in presence of such ions.

Simultaneous determination of Be and Al in mixtures

Since absorption spectra of beryllium and aluminium complexes overlap, their photometric determination in mixtures is difficult. Appropriate parameters were selected to record the first and second derivative spectra and determine the positions of isodifferential points.

Be(II) and Al(III) complexes have one isodifferential point in each of the two derivative modes, *viz.*, B′, B″ and A′, A″ which are at 589.5 nm, 601.5 nm, and 597.5 nm, 608.5 nm respectively [Fig. 3(a) and (b)]. The isodifferential points at 601.5 nm, (B″) and 608.5 nm, (A″), are potentially useful for the determination of aluminium and beryllium respectively. Calibration graphs were then made by measuring the distances of the absorption profiles of one metal at the isodifferential point of the other. Figure 3(a) and (b) show the first and second order derivative spectrum of the two series of 24 solutions containing increasing amount of beryllium and aluminium ions. Linear plots are obtained for 3.60×10^{1}–3.60×10^{2} ng/ml beryllium and 1.08×10^{2}–1.08×10^{3} ng/ml aluminium [equations (3) and (4)].

$$D = 1.309 \times 10^{-1}\,[\mathrm{Al}] - 8.936 \quad (r = 0.9989) \text{ at B}'' \quad (3)$$

$$D = 1.005 \times 10^{-1}\,[\mathrm{Be}] + 1.524 \quad (r = 0.9919) \text{ at A}'' \quad (4)$$

Presence of beryllium in a solution of aluminium and that of aluminium in a solution of beryllium, changes the amplitude $d^2A/d\lambda^2$ in second derivative spectra respectively at A″ and B″, the isodifferential points of aluminium and beryllium complex [Figs. 4(a) and (b)]. Concentration of beryllium and aluminium ions is then read from the calibration curve. The results of simultaneous determination of beryllium and aluminium ions are given in Table 3. The mixture containing 3.60×10^{1}–3.60×10^{2} ng/ml beryllium and 1.08×10^{2}–1.08×10^{3} ng/ml aluminium can be analysed with a relative error of $<2.80\%$.

Procedure is developed for determination in aqueous phase of beryllium and aluminium when present either alone or in mixture. Simplicity, sensitivity, large range of linearity besides accuracy and precision are the main advantages of the developed methods.

Summary—A highly sensitive and rapid bioluminescent flow sensor was developed for the determination of the content of *L*-phenylalanine (Phe) in serum by monitoring the reduced form of nicotinamide adenine dinucleotide (NADH), produced by immobilized phenylalanine dehydrogenase (PheDH), with bacterial bioluminescent enzymes immobilized on a separate nylon coil. The L-PheDHs extracted from *Bacillus badius*, *Bacillus sphaericus* and *Rhodococcus sp. M*4 were investigated and the performances of the three immobilized L-PheDH's were analysed. The *B. badius* reactor was found to give higher transformation rate and better sensitivity; the response was linear from 1 to 100μM at 25°, with a detection limit of 10 pmoles (0.5μM). The intra- and inter-assay coefficients of variation were less than 5% and recoveries ranged from 90 to 101%. The results agreed well with those obtained with a chromatographic method for the Phe determination in serum and with the normal reference values.

L-Phenylalanine (*L*-Phe), an essential amino acid for mammals, is of great interest in many fields, occurring naturally in blood, saliva, urine, milk and other body fluids.[1,2] Aberrations of *L*-Phe metabolism lead it to accumulate in the blood of hyperphenylalaninemic patients.[1–4] Therefore, a simple, rapid and sensitive method for the determination of *L*-Phe in very small samples is essential for screening of neonatal diagnosis[3] and dietary management of hyperphenylalaninemic patients[4] and, to this end, a variety of methods have been designed. Among the chromatographic ones, there are high performance liquid (HPLC), ion-exchange with postcolumn derivatization with ninhydrin,[5,6] narrow-bore reversed-phase with precolumn derivatization with *o*-phthalaldehyde (absorbance) or 9-fluorenylmethyl chloroformate (fluorescence),[7] reversed-phase without derivatization,[8] reversed or normal-phase with *p*-nitrobenzoyl and 3,5-dinitrobenzoyl derivatization,[9] and chiral thin-layer chromatography.[10] The chromatographic methods are reliable, but require expensive instrumentation or result in high cost per analysis. Also spectrophotometric methods can be used with second derivative to enhance specificity.[11] However, the most specific methods make use of enzymes such as Phe hydroxylase,[1] *L*-Phe oxidase,[12] amino acid oxidase[13] and *L*-phenylalanine dehydrogenase.[14–19]

Recently several *L*-phenylalanine dehydrogenases were detected and isolated from several microorganisms such as *Bacillus badius*, *Bacillus sphaericus*, *Nocardia*, *Termoactinomyces intermedius* and *Rhodococcus sp. M4*[14–19] and this allowed us to develop several enzymatic assays.[18–20]

Bioluminescent flow sensors have been developed previously for several analytes and enzymes,[21] including lactate dehydrogenase (LDH)[22] and, more recently, *L*-lactate and *D*-lactate present in biological fluids.[23,24] When

*Author for correspondence.

an immobilized enzyme is used in a continuous-flow system, manual handling is minimized and the reproducibility is enhanced, making the analytical system[25] simple and cheap.

In this work, the assay of *L*-Phe was based on bioluminescent monitoring of the reduced form of nicotinamide adenine dinucleotide (NADH), produced by *L*-PheDH immobilised into a nylon coil that preceded the bioluminescent detection coil [see equations (1), (2) and (3)].

$$L\text{-Phenylalanine} + NAD^+ + H_2O \xrightleftharpoons{L\text{-PheDH}} L\text{-Phenylpyruvate} + NADH + H^+ + NH_4^+ \quad (1)$$

$$NADH + FMN + H^+ \xrightleftharpoons{NADH\ oxred} NAD^+ + FMNH_2 \quad (2)$$

$$FMNH_2 + RCHO + O_2 \xrightleftharpoons{luciferase} FMN + H_2O + RCOOH + LIGHT \quad (3)$$

EXPERIMENTAL

Reagents

Luciferase from *Photobacterium fischeri* (EC 1.14.14.3; 15 mU/mg protein), NAD(P)H:FMN oxidoreductase from *Photobacterium fischeri* (EC 1.6.8.1; 100 U/mg protein), NAD^+ (lithium salt), FMN were purchased from Boehringer (Mannheim). n-Decanal and Dithiothreitol (DTT) were obtained from Sigma (St. Luis, MO). *L*-Phenylalanine dehydrogenase from *Bacillus badius* (E.C. 1.4.1.; 34 U/mg protein/3.5 U/mg lyophilized) and *Bacillus sphaericus* (E.C. 1.4.1.; 35 U/mg protein/7.3 U/mg lyophilized) were a gift from Central Glass Co. (Tokyo, Japan), whereas PheDH from *Rhodococcus sp.* M4 (E.C. 1.4.1.; 90 U/mg protein) was from Calbiochem (San Diego, CA). Nylon-6 tubes, 1 mm i.d., were obtained from Portex Ltd (Hythe, U.K.). All other reagents and compounds were analytical-reagent grade.

Preparation of solutions

The working bioluminescent solution was 0.1μM potassium phosphate buffer (pH 6.75), containing 10μM FMN, 27μM decanal and 0.5mM DTT. The solution was prepared 20–30 min before analysis. Decanal was previously dissolved in propanol-2-ol (0.05%, v/v) and was stable for at least 6 weeks at 4°. The working bioluminescent solution showed no detectable degradation after 8–10 hr in the dark at room temperature. Because NAD^+ is unstable in alkaline media, 1mM NAD^+ had to be reconstituted daily with water.

Immobilization of enzymes on nylon

The dehydrogenases (2 mg/ml of phosphate buffer) and bioluminescent enzymes were immobilized on nylon coils that had been activated with triethyloxonium tetrafluoroborate, 1,6-diaminohexane and glutaraldehyde as described previously.[20–23] After removal of the enzyme solutions, the tubes were washed thoroughly with potassium phosphate buffer and stored in 0.1M potassium phosphate buffer (pH 7.0), with 1% m/v bovine serum albumin (BSA), 1mM DTT and 0.02% (w/v) sodium azide, −20° for long-term storage and at 4° for short-term storage.

The activity and the protein content of free and immobilized enzymes were measured as described previously.[20–23] The stability of the immobilized enzymes was determined by measuring the residual activity of PheDH after intermittent use of the coils (analysis at room temperature and storage at 4°) over a period of 4 months.

Apparatus

The manifold developed for bioluminescent continuous-flow determination of *L*-phenylalanine is shown in Fig. 1 and it is similar to those described previously.[21–24]

Chromatographic assay

Analysis of free amino acids in serum was made according to classical Moore's method[5,6]

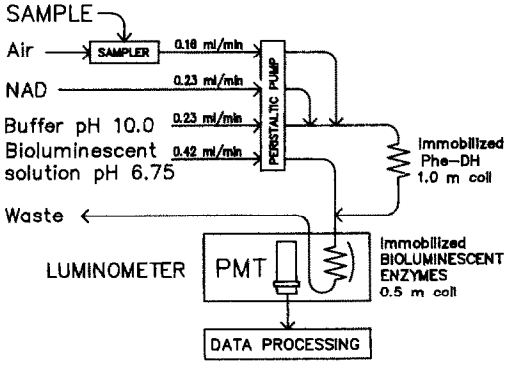

Fig. 1. Manifold for bioluminescent continuous-flow assay of *L*-pheynlalanine.

Table 1. Michaelis constants of free and immobilized enzymes, obtained from Lineweaver-Burke plot

Enzyme	Substrate or coenzyme	K_m of free enzyme, mM	K_m of immob. enzyme, mM
NAD(P)H:FMN	FMN	0.042 ± 0.005*	0.039 ± 0.004

using a 3A30 automatic analyzer equipped with a 3AR/1C/6/10-Li 12 cm ion exchange column (Carlo Erba Instruments, Milano).

Sample treatment

Blood collected from veins without stasis and strictly avoiding haemolysis or standard control sera were used. When the bioluminescent flow sensor was used the serum samples were diluted 1 + 9 to 1 + 49 without deproteinization with the 0.02M pyrophosphate buffer (pH 10.0) used to supply external dehydrogenase reactor. The phenylalanine content was evaluated comparing the samples with graphs obtained by pooled sera treated as above. Three different pooled sera at three Phe levels (42, 136 and 916nM, respectively) were used to determine Phe with respect to the reference interval (0–69nM) and pathological values (>69nM). The standards were stable for 6 days if stored at +4°, and for at least 4 months at −20°.

For the chromatographic method the serum was deproteinized with sulphosalicyclic acid (30/40 mg per ml serum), centrifuged at 3500 rpm for 15 min, stored at −20° and analysed within 6–7 days.

Comparison for phenylalanine content was also made with the spectrophotometric determination,[14] using 0.1M glycine buffer, pH 10.4

RESULTS AND DISCUSSION

Enzyme immobilization

Under the described conditions of coupling 60–70% of added PheDHs (considering both activity and protein content) was bound to the matrix in all the three cases. Apparent Michaelis constant (K_m) values of the immobilized enzyme for substrates and coenzymes were not markedly different from those of the free enzymes (Table 1), and activity recovery (5% for *Bacillus badius* and 4% for *Bacillus sphaericus* and *Rhodococcus sp. M4*) was in agreement with previously published data on nylon-immobilized enzymes.[21–25] Immobilized PheDHs maintained *ca.* 50% of their original activity after 60–90 days of intermittent use. This was to be expected owing to the stability of the covalent bond between the enzyme and the matrix and also to the intrinsic stability of the enzymes.

For short-term storage, the reactors were filled with storage buffer and kept at 4°; for long-term storage they were kept at −20°; in this case they retained the original activity almost completely even after 18 months. Repetitive freeze-thaw cycles, however, should be avoided.

Optimization of experimental conditions

The conditions for maximum light emission for the three PheDHs were selected after preliminary testing including reagent concentration, flow rate, pH and composition of the buffer solutions, and reaction temperature. This also made it possible to optimize precision and peak separation, as reported previously for other analytes.[21–24]

The pH and ionic strength of solutions are important parameters in the continuous-flow system. Experiments were made to establish the optimum pH (about pH = 10.5 for oxidative deamination in batch analysis[15–19]) for the determination of phenylalanine in several buffers (tris[hydroxymethyl]-aminomethane (Tris), *N*-[tris(hydroxy-methyl)-methyl]glycine (Tricine), glycylglycine, pyrophosphate). The influence of coenzyme concentrations was also studied.

The highest activity of immobilized PheDHs was obtained at pH 10 as shown in (Fig. 2) for *Bacillus badius* and *Bacillus sphaericus* in 0.02M pyrophosphate buffer. The nature of the buffer significantly influenced the reactor response with the best results obtained in pyrophosphate buffer (Fig. 3). PheDH from *Bacillus badius*

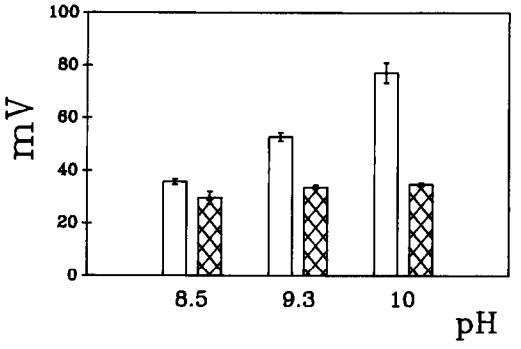

Fig. 2. Effect of pH (0.02*M* pyrophosphate buffer) on the light emission for phenylalanine dehydrogenases from *Bacillus badius* (white) and *Bacillus sphaericus* (hatched), at 1m*M* Phe level.

gave a higher light emission than that of *Bacillus sphaericus* and *Rhodococcus sp. M*4. Therefore pyrophosphate was the buffer of choice and the PheDH from *B. badius* was normally used especially when low Phe concentrations have to be determined.

The pH of the luminescent buffer solution was kept at 6.5 (0.1*M*); the optimum pH for the bacterial luciferase, *ca.* pH 7.0, was achieved on mixing it with the alkaline buffer solution for the Phe determination (pH 10, 0.02*M*).

There was an increase of PheDH activity by increasing the coenzyme concentration in the range of 0.5–10m*M*. However 1m*M* NAD^+ was routinely used in order to reduce cost and because the assay sensitivity was satisfactory also at this concentration.

The transformation yield of the PheDH coil was determined at 1m*M* of Phe and compared with the light emitted from an equal concentration of NADH in different buffers. NADH

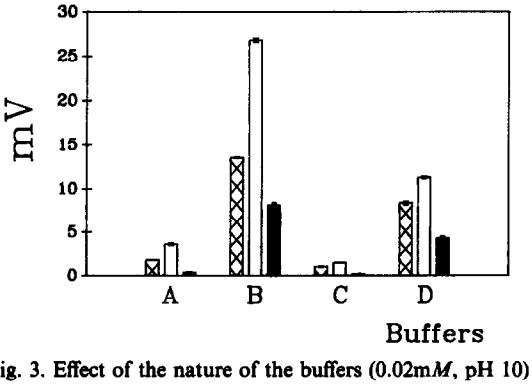

Fig. 3. Effect of the nature of the buffers (0.02m*M*, pH 10) on the light emission for phenylalanine dehydrogenases from *Bacillus sphaericus* (hatched), *Bacillus badius* (white) and *Rhodococcus sp. M*4 (black), at 0.1m*M* Phe level. buffers: A: Tris; B: Pyrophosphate; C: glycilglycine; D: Tricine.

was analysed with the same manifold and in the same conditions as phenylalanine and the transformation yield was taken as the ratio between the response (mV) obtained for Phe and that obtained for NADH. The yields were not very high (maximum 10%) owing to non-equilibrium conditions of analysis and to an unfavourable equilibrium constant.

Determination of L-*phenylalanine*

Using the PheDH reactor, the detection limit of the assay (3σ) was 0.5μM for an injected sample volume of 20 μl. The response, for freshly prepared phenylalanine standard solutions, obtained by the measurement of peak height, was linear between 1 and 100μM; $y = 1.01 \pm 0.02$ mV $(M)^{-1} + 9.09 \pm 0.15$ mV; correlation coefficient $(r) = 0.995$, number of analysis $(n) = 8$; probability (P) < 0.001. The non-zero y intercept for the calibration curve was caused by the background of nylon coil, *i.e.*, light emission when only the working bioluminescent solution flows into the nylon coil.

The relative standard deviation (R.S.D) of the method in the analytical range of Phe was below 5%. The recoveries were between 90 and 101% when phylalanine standards (1–50μM) were added to serum samples of known phenylalanine concentration (916μM) diluted 1 + 19 with pyrophosphate buffer.

The specificity of *Bacillus badius* PheDH coil for a variety of substrates (tested at two different concentrations) is shown in Table 2. Although it was reported that PheDH can catalyze the oxidative deamination of a number of amino acids such as methionine (8% relative activity to *L*-phenylalanine), *L*-tyrosine (9%), *L*-norleucine (19%), *etc.*[19,16] at 10m*M* level, we found no or low activity with the above-mentioned amino acids and also with others (Table 2). Only DL-thienylalanine, normally not present in the serum, gave a high response (33–49%). This suggests that the enzyme recognizes the back of the skeleton of the two molecules, which is similar in two cases.

Serum

L-Phe is generally very stable and freezing-thawing does not change Phe concentration in serum;[1] and it is also possible to analyse Phe without pre-treatment or deproteinization with sulphosalicyclic acid. It should be noted that the use of sulphosalicylic acid would inhibit reactor response and need buffers at high ionic strength to keep the optimal pHs.

* No signal detected

With samples diluted 1 + 1 − 1 + 4 with pyrophosphate buffer a slight inhibition of the luminescent enzymes was observed and the calculated *L*-Phe concentrations are quite different. At higher dilutions (1 + 9 − 1 + 99) little or no interference was found for sera, while *L*-Phe diluted in acid showed a greater inhibition.

Constant addition of 50μM *L*-phenylalanine to different serum diluted from 1 + 19 to 1 + 199 gave a good recovery (87–104%) both with addition after dilution, and addition before dilution. Variable additions of *L*-Phe (10–500μM) to serum constantly diluted to 1 + 19 or to buffer alone gave the same good correlation.

The results of within-day and between-day reproducibility studies with the two sera (normal and pathological) gave R.S.D. values of $< 5\%$. These satisfactory results are also due to the use of an automatic diluter—injector in the treatment and preparation of the sample.

The content of *L*-phenylalanine was assayed with the ion-exchange chromatographic method performed automatically with deproteination and compared with the continuous-flow system. The results obtained with the bioluminescent method agreed well with those from the reference method giving, for normal and pathological *L*-phenylalanine concentrations, the correlation equation: $y = 0.90 \pm 0.02 \times + 0.23 \pm 0.08$; $r = 0.947$, $n = 59$; $P < 0.001$, for the chromatographic (x) *vs.* the bioluminescent (y) method (Fig. 4). Moreover we used the Wilcoxon Test for coupled, not parametric data

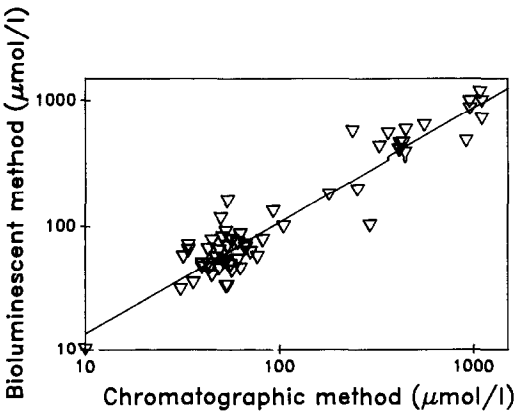

Fig. 4. Comparison between determination of *L*-phenylalanine using bioluminescent flow sensor (y) and chromatographic method (x). Reference range: 0–69μM Phe.

which shows ($P = 0.19$) that the results obtained from the two methods were not statistically different.

CONCLUSIONS

The lifetime and operational stability of immobilized enzymes were satisfactory. The residual activity of the whole enzymic system after 2 months of use and analysis of more than 40 samples per day was *ca.* 50% of the original. The lifetime of the proposed sensor, defined as the time during which accurate results can be obtained within the full calibration range, was about 4 months.

The direct use of serum, without extraction with chaotropic agents such as perchloric, metaphosphoric or sulphosalicylic acid, allows exclusion of the pre-instrumental work-up (only dilution has been made).

Recently Wendel *et al.*[20] have developed a batch method for the control of phenylketonuric patients using PheDH from *Rhodococcus sp. M4*, with a good sensitivity. However the method requires an extraction step from serum with perchloric acid and incubation at 21° for 15 min, which made the procedure more complex and time consuming than that of the luminescent one. The flow sensor makes it possible to reduce the analysis time (1–2 min) in comparison to chromatographic analysis (20–30 min).

The present data agreed well with those reported by other workers[15–19] and the automation of the whole system should allow the use of the bioluminescent flow sensor for the continuous monitoring of *L*-Phe in blood and in foodstuffs. For instance the direct determination of *L*-Phe in paper disc (sent by mail) with blood from newborn for neonatal screening of hyperphenylalaninaemia, or dietary management of phenylketuronic patients should be possible, as well as the quality control of aspartase of which *L*-Phe is a hydrolysis product.

INVESTIGATION OF RELATIVE HUMIDITY EFFECTS ON THE RESPONSE BEHAVIOR OF A pH INDICATOR-BASED OWG VAPOR SENSOR

DANIEL CALLAHAN and DAVID S. BALLANTINE, JR.*
Chemistry Department, Northern Illinois University, DeKalb, IL 60115, U.S.A.

(*Received* 21 *April* 1992. *Revised* 21 *May* 1992. *Accepted* 15 *July* 1992)

Summary—The response of a pH indicator-based optical waveguide sensor was characterized with respect to the effects of relative humidity (RH) on the magnitude of the sensor response, and on the rate of response to both hydrochloric acid and ammonia/ammonium hydroxide vapors. Water vapor constitutes both a chemical and a systematic (optical) interference for the OWG sensor response to hydrochloric acid. Swelling of the polymer films upon exposure to water vapor results in a decrease in the loss of light at the polymer/air interface, resulting in an increase in the sensor signal. In addition, high RH conditions decrease the bromothymol blue indicator response to hydrochloric acid vapor. In contrast, the bromothymol blue indicator response to ammonia increases as the RH increases. High RH levels also increases the rate of diffusion (transport) of hydrochloric acid into (and out of) Nafion films, but does not affect the diffusion rate for poly(vinyl alcohol) polymer films. The RH does not appear to have any significant effect on the rate of transport of ammonia in any of the polymer films studied.

Due to the advantages of microsensor technologies (low cost, rapid and sensitive detection, and portability), there is increasing interest in the development of these devices for a variety of chemical sensing applications. In order to optimize a sensor for detection of a given analyte (or class of analytes) a thorough characterization of the sensor response behavior is required. Such characterization includes evaluation of the coating/reagent materials and their effects on the sensor performance, as well as the sensor response to potential interferences.

A multiple internal reflection optical waveguide (MIR-OWG) sensor for the detection of acidic and alkalescent vapors was recently reported.[1] This sensor employed a pH indicator (bromothymol blue) suspended in an ionic polymer, Nafion. During the initial evaluation of this sensor a dramatic interference from water vapor was noted. In order to eliminate or correct for this interference, the nature of the interference with respect to the response mechanism must be determined. The work reported herein is intended to address this problem. Specifically, the effects of water vapor on the rate and magnitude of sensor response were investigated. The implications of the results reported herein are discussed with respect to the design and construction of similar OWG sensors.

EXPERIMENTAL

Materials

The two indicators studied during this work were thymol blue and bromothymol blue. Both are sulfonic acid-type pH indicators, with structures and effective transition ranges in aqueous solution included in Fig. 1. Thymol blue was obtained from Aldrich, and bromothymol blue was obtained from Fisher Scientific. Both materials were of >95% purity and were used as received. These materials were dissolved in methanol to obtain solutions that were approximately 2 mg (indicator)/ml (solution).

Poly(vinyl alcohol) samples were selected to represent a broad range of molecular weight ranges as well as varying degrees of hydrolysis as indicated in Table 1. Nafion was obtained as a 5% solution from Solution Technologies, Mendenhall, U.S.A.; all other polymers were obtained from Aldrich and were used as received. Solutions were prepared by dissolving the polymers (or in the case of Nafion, by dilution) in methanol/water solution to obtain final polymer concentrations of 2 mg/ml.

Solutions for coating the OWGs were prepared by mixing equal volumes of the selected

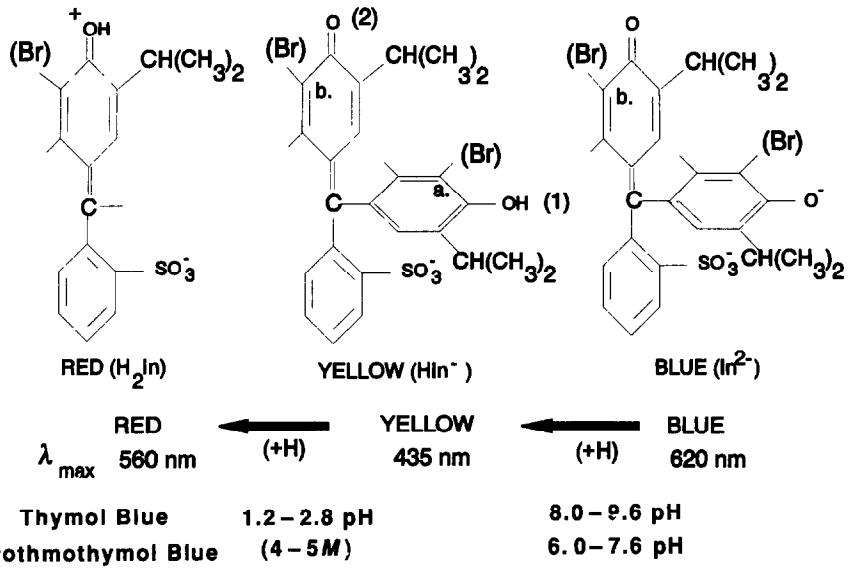

Fig. 1. Representation of the three forms of the pH indicators, thymol blue and bromothymol blue; (a) and (b) indicate sites of the bromines for the BT indicator.

polymer and indicator solutions to obtain final concentrations of 1 mg/ml in each component. These solutions were cast onto either quartz slides, for single-pass spectroscopic measurements, or onto cylindrical quartz capillary tubes for the MIR spectroscopy measurements as described below. The quartz capillaries (100 mm × 0.87 mm o.d.; wall thickness 0.065 mm) were obtained from ChemGlass, Inc. (New Jersey).

Procedures

In the previous study sensor response measurements were performed using the LED-OWG electronics module described previously.[1] Additional measurements during this work were performed using the Minichrom Monochromator system (Optometrics Corp., Ayer MA), equipped with a tungsten lamp source and a photo-multiplier (PMT) detector. Two experimental set-ups were used during these studies and are illustrated in Figs. 2 and 3. Figure 2 represents the single-pass system. The indicator/polymer film was cast onto a thin quartz slide which was, in turn, placed in a flow cell inside the spectrophotometer as indicated. Because light only passes through the sample film once before reaching the PMT detector, the sensitivity of this configuration is limited. Figure 3 represents the MIR-OWG set-up. Light is introduced to one end of the waveguide via optical fibers which are connected to the exit port of the monochromator. Light propagates along the waveguide via internal reflection and exits the opposite end of the waveguide, where it is transmitted to the PMT via a second set of optical fiber couplers. The light may be reflected at more than one interface, as indicated in the inset in Fig. 3. If the refractive index of the polymer is less than that of the waveguide substrate then reflection can occur at the substrate/film interface if the incident angle, θ, is greater than the critical angle, θ_c, determined from Snell's Law. If the refractive index of the polymer is greater than that of the substrate then light is transmitted through the substrate/polymer interface, where it may either be reflected at the film/air interface or lost via transmission through the interface.

Table 1. Polymeric materials

Polymer	PolymerID	MW Range	% Hydrolysis
poly(vinyl alcohol)	PVA-H	105,000–110,000	100%
	PVA-M	31,000– 50,000	98%
	PVA-L1	13,000– 23,000	89%
	PVA-L2	9,000– 10,000	80%
poly(vinyl acetate)	PVAc	High Mol Wt.	0%
Nafion	NAF	—	—

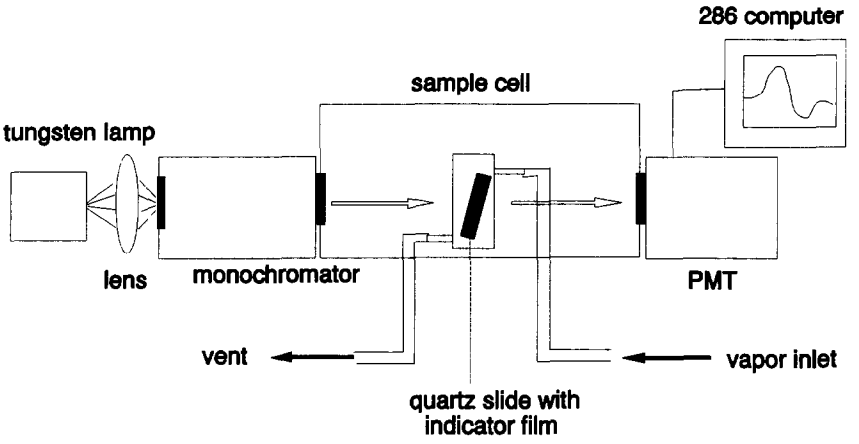

Fig. 2. Instrumental setup used to collect single-pass spectral data for the indicator/polymer films using the Minichrom system.

The Minichrom system was interfaced to a Hyundai 286 personal computer via an RS-232 port. The system is fully programmable and can obtain absorbance spectra in the visible region (300–750 nm), or to monitor PMT voltage at a given wavelength as a function of time. Voltage data from PMT and from the LED-OWG module were collected by computer via an IBM data acquisition and control adapter (DACA) card.

Hydrochloric acid and ammonia vapors were generated by bubbling dry $N_2(g)$ through an aqueous solution of hydrochloric acid or ammonium hydroxide. The vapor output from the bubbler could be sent directly to the quartz slide or the MIR-OWG sample cells illustrated in Figs. 2 and 3, or could be mixed with diluting air/vapor from a VG-400 Vapor Generator System (Microsensor Systems, Inc., Bowling Green KY) before being directed to the sample cells.

RESULTS AND DISCUSSION

Indicator/PVA films were cast onto quartz slides, and spectra were obtained using the

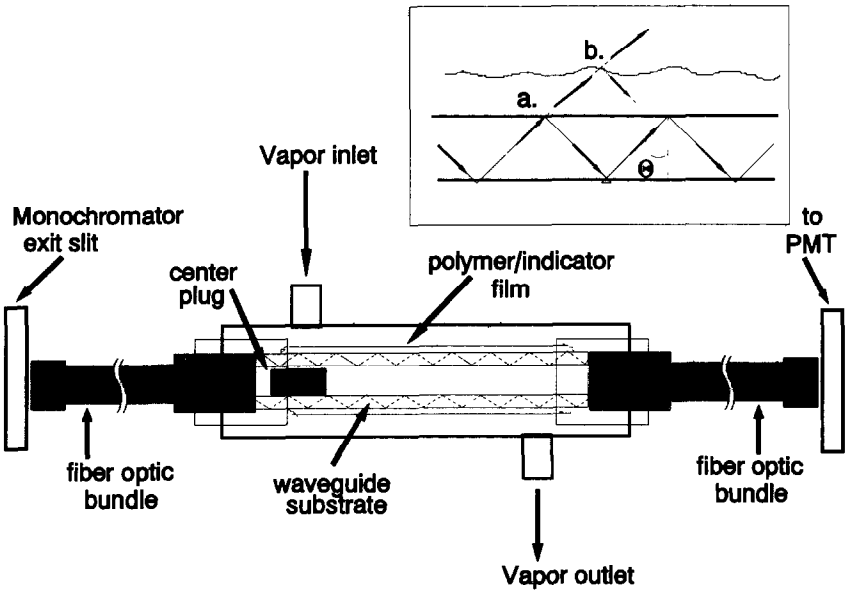

Fig. 3. Fiber optic coupler adaptation used to collect MIR-OWG data using the Minichrom system. The insert illustrates reflection(s) and losses at a) the substrate/film interface and b) the film/air interface.

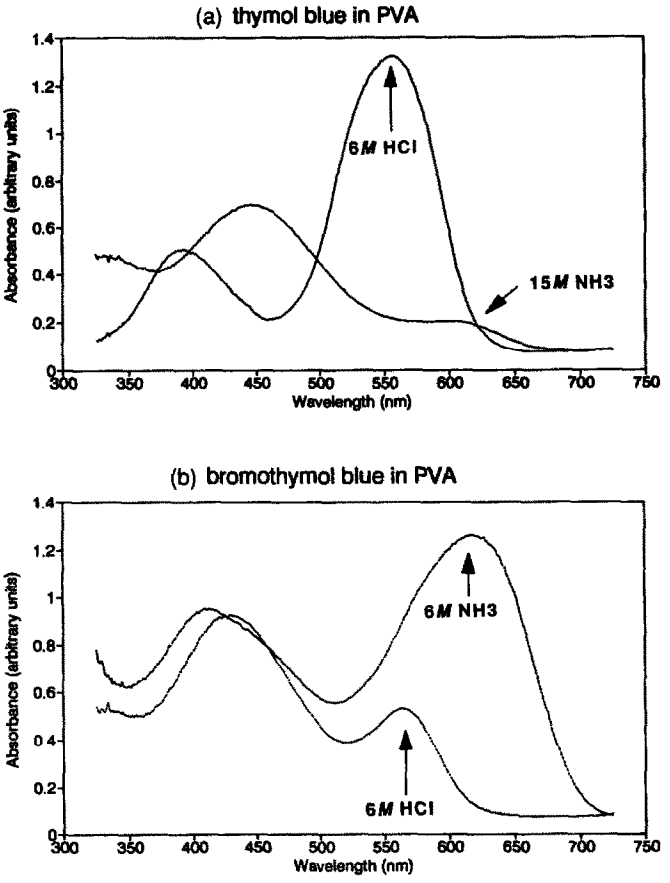

Fig. 4. Single-pass spectra for a) a TB/PVA film (solid lines) and b) BT/PVA film (dashed lines) upon exposure to HCl and NH_3 vapors, as indicated in figure.

single-pass optical configuration in Fig. 2. Typical absorbance spectra for the TB/PVA and BT/PVA films are presented in Fig. 4(a) and (b). Separate spectra were obtained for each film exposed to hydrochloric acid and ammonia vapors from solutions of various concentrations, as indicated in the Figure captions. Note that both indicators exhibit three characteristic forms (H_2In, HIn^-, and In^{2-}), with the predominant form being dependent on the acidity or basicity of the film. Spectral studies for the indicators in Nafion films yielded similar results.

The initial color of the indicator films varied depending on the indicator and the polymer matrix. The bromothymol blue (BT) indicator suspended in PVA polymer exhibited an initial yellow color, typical of the HIn^- form of the indicator. Thymol blue (TB)/PVA films were initially red in color, indicative of the H_2In form; exposure to NH_3 vapors converted the TB to the HIn^- (yellow) form which persisted for long periods of time after removal of the NH_3 vapor. The TB/NAF film also dried in the red form. Exposure to NH_3 vapors could shift the equilibrium temporarily to the HIn^- form, but the indicator reverts to the H_2In (red) form upon removal of NH_3 vapors. This is likely due to the acidic nature of the sulfonic acid groups in the Nafion polymer. The Nafion solution was treated with sodium hydroxide to convert the sulfonic acid sites to the sodium salt before preparation of some NAF/indicator films. In these Na-salt Nafion films, the HIn^- form of the TB indicator was more stable. The TB could then be converted to the H_2In form upon exposure to HCl vapors. In general, the TB indicator films exhibited irreversible response to the HCl vapors; the red color indicative of the H_2In form persisted long after removal of the HCl vapor. It was possible, however, to regenerate the HIn^- (yellow) form of the TB in the Na-salt Nafion film by exposure to NH_3 vapor. The BT/NAF films also dried in the red (H_2In) form, but could be readily converted to the yellow (HIn^-) form by exposure to NH_3, or prolonged exposure to water vapor. Once converted to the HIn^- form, the BT films

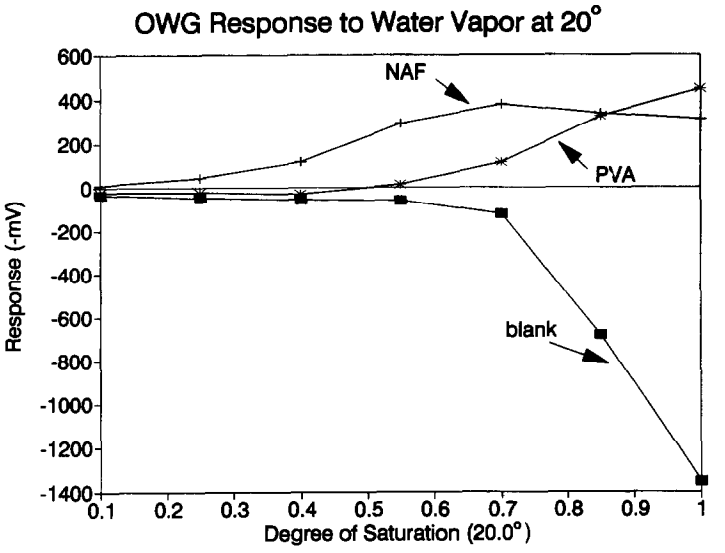

Fig. 5. LED-OWG Response to water vapor at 20° *vs.* % saturation (P/P°) for a blank waveguide and waveguides coated with Nafion and PVA films.

exhibit spontaneously reversible response to both hydrochloric acid and ammonia vapors.

As indicated in the spectra in Fig. 4, the TB films exhibited minimal spectral response to ammonia, but sensitive response to hydrochloric acid vapors. The BT films, on the other hand, exhibited very sensitive response to ammonia and lesser sensitivity to hydrochloric acid vapors. These differences are readily explained by the differences in structure (see Fig. 1) and are consistent with the relative pH transition ranges observed for these indicators in aqueous solution. The spectral behavior of the indicators seemed to be independent of the molecular weight or the % hydrolysis of the PVA polymers. While there was some variation in the intensity of the absorbance peaks, the position of indicator equilibrium (determined as the ratio of the H_2In and HIn^- peaks) seemed fairly consistent in all the PVA and PVAc polymers.

Water vapor effects

The presence of water vapor affects the sensor response in a variety of ways. The observed effects can be generally classified as systematic (optical), chemical, or kinetic effects, as discussed below.

Systematic response effects. In our initial report dealing with an LED-OWG acid vapor sensor it was noted that exposure of the sensor to nearly saturated water vapor resulted in a significant increase in transmittance (*i.e.*, photodetector voltage). Previous experimental results indicated that this effect was due to the water vapor/polymer interactions, and was not due to any change in the absorbance spectra of the indicator.[1] Since this increase in signal is in the opposite direction than the acid–indicator response this effect constituted a systematic interference. We initially proposed a differential approach (dual wavelength or dual sensor) to compensate.[1] As part of the current work this phenomenon was investigated further to determine the source of the effect and to identify other possible means to either compensate for or eliminate the interference.

Typical response data for uncoated (blank) and polymer-coated waveguides exposed to water vapor (using the LED-OWG sensor configuration from Ref. [1]) are summarized in Fig. 5. The data as presented represent the change (increase or decrease) in the photodetector signal upon exposure of the waveguide to water vapor. For the uncoated waveguide the detector signal decreases, whereas for the polymer-coated waveguides the signal increases.

Table 2. Refractive indices for experimental materials

Material	Refractive index (at 589 nm)*
Poly(vinyl alcohol)	1.49–1.53
	1.50
Nafion	—
Borsilicate glass	1.52
Quartz (fused)	1.46
air (@20°)	1.00
water (@20°)	1.33

The refractive index range in the table is from Ref. 2; the value of 1.50 is the value given by Aldrich for the high MW PVA polymer used for the majority of the reported studies. All other values were obtained from Ref. 4. A refractive index for Nafion was unavailable.

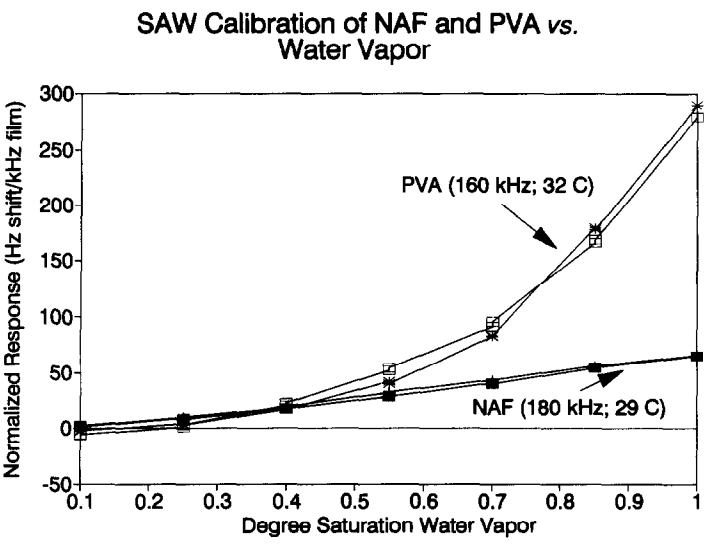

Fig. 6. Normalized response of polymer-coated 158 MHz SAW devices to water vapor between 10 and 100% saturated.

These data can be explained in part by referring to Snell's Law and the refractive indices for the waveguide sensor materials in Table 2. Using the refractive index values (n_i) for the glass capillary and air we obtain a critical angle of 41°. Light having an incident angle *less* than the critical angle will be transmitted through the glass/air interface and lost, whereas light having an incident angle *greater than* this value will be reflected at the interface and will propagate through the waveguide to the detector. The introduction of water vapor will change the effective n_i value of air at the interface; for adsorbed or condensed water vapor, having an n_i value of 1.33, we obtain a critical angle of 61°. This increase in the critical angle translates into a decrease in the cone of acceptance, which would readily account for the observed decrease in the detector signal for the bare waveguide exposed to water vapor.

The polymer-coated LED-OWG response is not as easily explained. For all practical purposes, the refractive indices of the substrate materials and the PVA are close enough in value that nearly all light will be transmitted through the substrate/polymer interface, except for incident angles approaching the grazing angle (90°). A glass capillary coated with PVA, for example, has a critical angle of 80.7°. For such cases the polymer/air interface becomes the reflecting interface. Because the polymer film surface is most likely not as smooth as the glass surface, greater scattering and transmission losses would be expected at this interface. An increase in detector signal upon exposure to water can only result from a reduction in the amount of light lost at this interface. A number of possibilities exist to explain the observed behavior. First, swelling of the polymer results in both a thicker film and, possibly, a smoother film surface. A smoother surface would decrease the amount of scattering and transmission losses. A thicker film would decrease the total number of reflections and thereby decrease the number of opportunities for loss of light at this interface.

In order to quantify the amount of water absorbed into the polymer, surface acoustic wave (SAW) studies were performed. SAW devices were coated with polymer films, and the frequency of the devices were observed while the coated devices were exposed to varying concentrations of water vapor. Results of these studies are presented graphically in Fig. 6. The sensor responses (frequency shift in Hz) are plotted *vs.* the vapor pressure of water (fraction of saturation, P/P°). Note that the sensor responses (frequency shift) have been normalized *vs.* the amount of polymer coating, reported in kHz of frequency shift. Thus the values plotted in the figure represent a *relative* increase in mass; the actual % increase in mass would be equal to the relative increase divided by a factor of 1000. If we assume that the entire SAW response is due to added mass of water vapor, then the polymer swelling can be estimated as follows. Treating the adsorbed vapor as a condensed liquid, the increase in volume can be approximated as the volume of an equivalent amount of this vapor in its liquid form, *i.e.*, from the reciprocal of the liquid density, ρ_L. The %

Table 3. Polymer swelling estimated from SAW sorption data

Water vapor (Rel. sat.)	Poly(vinyl alcohol) (160 kHz film)		Nafion (180 kHz film)	
	Norm. response (*Hz/kHz*)	Estimated % Swelling*	Norm. response (*Hz/kHz*)	Estimated % Swelling
0.10	—	—	2.1	0.21 (0.05)
0.25	2.78	0.28 (0.07)	9.3	0.93 (0.23)
0.40	19.0	1.9 (0.5)	18.2	1.8 (0.45)
0.55	46.9	4.7 (1.2)	30.3	3.0 (0.75)
0.70	87.9	8.8 (2.2)	41.8	4.2 (1.1)
0.85	173	17.4 (4.4)	55.4	5.6 (1.4)
1.00	284	28.5 (7.1)	65.3	6.6 (1.7)

*Figures in parenthesis are corrected for estimated SAW response due to elastic effects.

swelling is then calculated as the product of the % mass increase and $1/\rho_L$. Estimated percent swelling for various water vapor saturation levels are given in Table 3. Swelling for Nafion films is relatively small, with a maximum at saturation of only 6.6%. This is a reasonable estimate when compared to swelling estimates of 13% for Nafion membrane samples in aqueous solution.[5] For PVA the estimated swelling appears to be more significant, approaching 29% when exposed to saturated water vapor.

These estimates should be considered as upper limits only. According to SAW theory, changes in the mass or in the elastic modulus of the coating will produce a shift in the resonant frequency of the device. The increase in mass due to the sorption of water vapor into the polymer film will produce a corresponding decrease in the SAW frequency. If the sorption of water vapor causes swelling of the polymer, with an accompanying decrease in the elastic modulus, then there will be an additional decrease in the SAW frequency. A recent report concluded that the contribution of swelling effects to the observed SAW frequency shift may exceed the mass loading effect by a factor of 4–6.[6] If we take into consideration the contribution of swelling effects the frequency shift due to mass loading is smaller than the total observed frequency shift by a factor of 4 or more, and the actual swelling for PVA is on the order of 7%. These more conservative estimates of swelling are given in parenthesis in Table 3.

Using the swelling data from Table 3, we can estimate the refractive index for the swollen polymer film by considering the volume percents of the polymer and water in the swollen film, such that

$$n_{\text{swelled}} = \left(\frac{V_{\text{PVA}}}{V_{\text{total}}}\right) \cdot n_{\text{PVA}} + \left(\frac{V_{\text{water}}}{V_{\text{total}}}\right) \cdot n_{\text{water}} \quad (1)$$

As noted above, the critical angle for a PVA-coated glass capillary (calculated from Snell's Law) is 80.7°. For a PVA film swelled by 29% a refractive index of 1.44 is calculated using equation 1, with a corresponding decrease in the critical angle to 71°. For the more conservative swelling estimate of 7%, the refractive index and corresponding critical angle are 1.49 and 78.6°, respectively. This reduction in the critical angle implies that more light would be reflected at the substrate/polymer interface, which translates into an increase in the detector signal consistent with the observed OWG responses. This change in the critical angle is rather small, $\approx 2°$–$10°$ for PVA and significantly less for the NAF. Any increases in light due to this phenomenon will likely be too small to account for the large observed increases in detector signal. Therefore, it is proposed that the observed signal increases are predominantly the result of decreases in scattering and transmission losses at the film/air interface due to swelling, as discussed above, with only minor increases due to changes in refractive index.

Since this effect is most likely the result of a decrease in losses at the polymer/air interface, this potential systematic interference may be minimized or avoided by controlling the reflecting interface. The above experiments were repeated using the MIR-OWG configuration of Fig. 3. The fiber-optic couplers introduce light to the waveguide at angles much closer to the grazing angle compared to the LED; using this configuration there is a greater chance for reflection at the substrate/polymer interface. As seen in Fig. 7, the increase in signal of the MIR-OWG upon exposure to water vapor is much smaller, in the order of 10–20 mV. This small increase is consistent with what would be expected due to refractive index changes as a result of swelling, as discussed above.

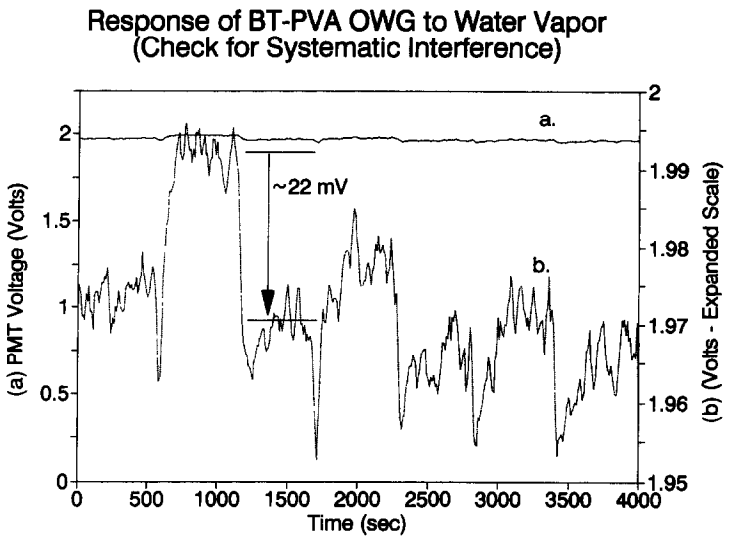

Fig. 7. Response of polymer-coated MIR-OWG sensor to water vapor, illustrating decreased response to water vapor compared to LED-OWG.

Selection of substrate and polymer materials, based on refractive indexes, and the introduction of light into the waveguide can thus be controlled so that the majority of light propagates by reflection at the substrate/polymer interface. Such an OWG sensor will still respond to changes in the absorbance properties of the reagent film via the evanescent wave, but changes in signal due to losses at the film/air interface will be avoided or minimized.

Kinetic effects. In our initial investigation it was reported that the addition of water vapor to the sensor increased the rate of recovery (return to baseline) for a BT-NAF OWG sensor exposed to hydrochloric acid vapor. In order to investigate the effect of water vapor on sensor response time the indicator/polymer films were exposed to hydrochloric acid and ammonia vapors mixed with diluting air from the VG-400 containing varying amounts of water vapor.

Figure 8 summarizes the results for a TB-NAF (base-treated) film exposed to hydrochloric acid vapor from a 0.33*M* hydrochloric acid solution maintained at room temperature (23°). This vapor produced from this solution has an estimated hydrochloric acid concentration of 20 ppb (see calculations and discussion in Ref. 1). The flow rate from the bubbler was approximately 100 ml/min. The bubbler output was mixed with diluting air streams from

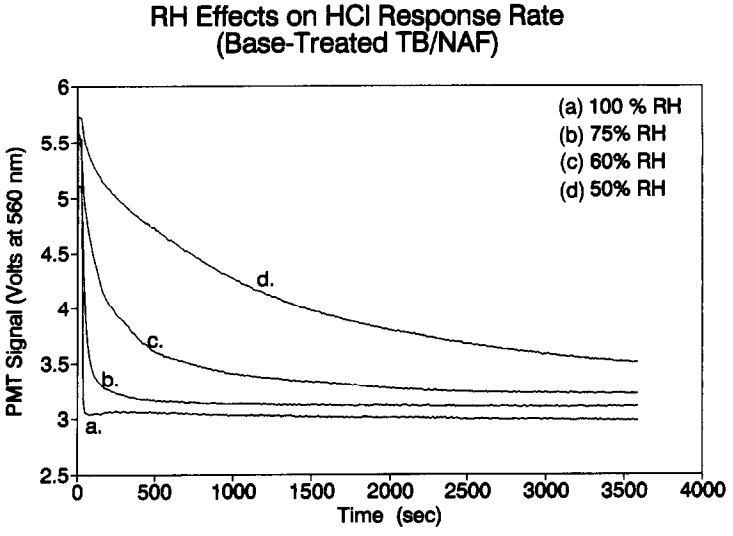

Fig. 8. Rate of response of a TB-NAF (base-treated) film to HCl vapor as a function of RH using the single-pass configuration. PMT signal at 560 nm was monitored during acid vapor exposure.

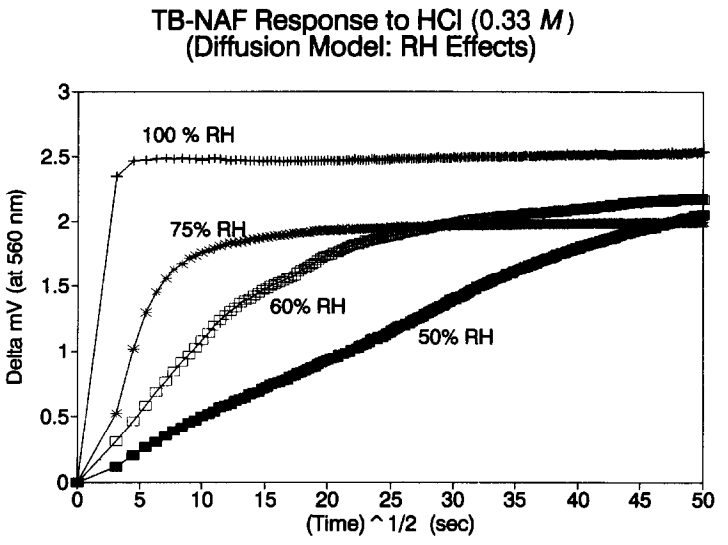

Fig. 9. Data from Figure 8 plotted *vs.* $\sqrt{t}$, indicating the diffusion limited response of the indicator film.

the VG-400 (100 ml/min) that were 100, 50, 20 and 0% saturated in water vapor. Assuming that the bubbler output was saturated with water vapor, then the relative humidity (RH or % saturation) of the resulting streams was 100, 75, 60 and 50% RH, respectively, and the concentration of hydrochloric acid vapor was 10 ppb. These vapor streams were introduced to a TB-NAF film on a quartz slide and signal intensity at 560 nm (in volts) was monitored as a function of time using the single pass configuration in Fig. 2. The results clearly indicate the increase in response rate with increased RH.

If we assume that the indicator response is fast compared to the rate of diffusion then we can characterize the response of the sensor by way of a diffusion model. For a film of uniform thickness the concentration of analyte at some depth in the film as a function of time, $C(x,t)$, can be described using the one-dimensional Fick's Law,

$$\frac{\delta^2 C}{\delta t} = D \frac{\delta C}{\delta x^2} \tag{2}$$

where D is the diffusion coefficient. Assuming that the film response is directly proportional to the vapor absorbed into the film, and that the rate of the indicator reaction is fast compared to the rate of diffusion, then the incremental response (ΔmV) is proportional to $\sqrt{t}$ until the concentration of solution in the film reaches

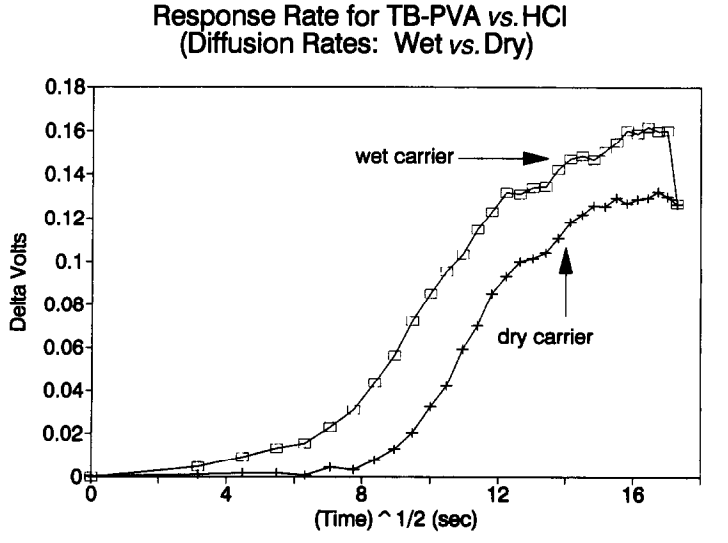

Fig. 10. Response for MIR-OWG TB-PVA film plotted *vs.* $\sqrt{t}$, indicating that rate of response of the PVA films to HCl vapor are not dependent on RH.

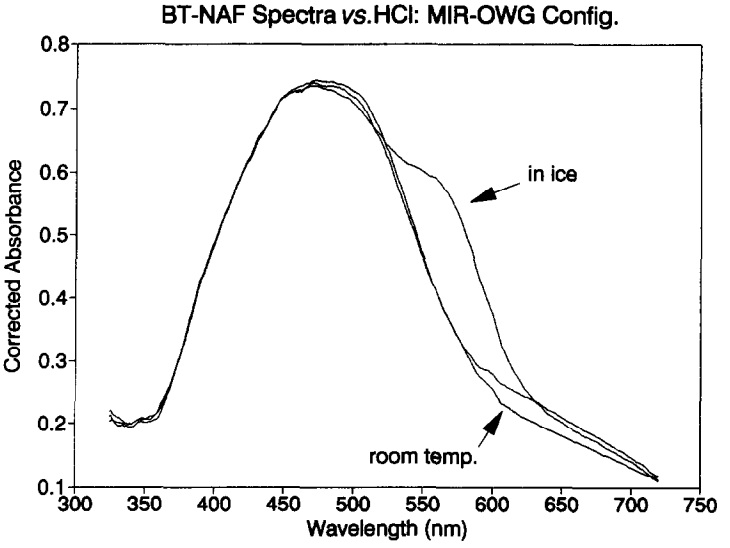

Fig. 11. Spectra for BT/NAF film exposed to water vapor, and HCl vapor from 0.165 M HCl bubbler solution at 0° and 23° as indicated. Spectra were collected using the MIR-OWG configuration from Fig. 3.

approximately 60% of the equilibrium film concentration.[7] Plotting the response data in Fig. 8 as ΔmV *vs.* $\sqrt{t}$ produces the data presented in Fig. 9. The linear initial slopes for the plots in Fig. 9 indicate that the diffusion model fits the observed responses, and that the rate of diffusion of hydrochloric acid into the Nafion film is humidity-dependent. Previous work has demonstrated that gas diffusivity in Nafion polymer films increases as the degree of film hydration increases,[8] which supports the observations reported above.

Similar experiments for hydrochloric acid *vs.* PVA films indicate that the diffusion of hydrochloric acid into these films is not sensitive to humidity. This unique behavior observed for the HCl/NAF system may be explained by the cation-exchange properties of Nafion. When these response studies were performed using the fiber-optic configuration of Fig. 3 the results represented in Fig. 10, plotted as ΔmV *vs.* $\sqrt{t}$, were obtained. The response profiles for the 50 and 100% RH conditions are similar in appearance (although slightly offset in time) indicating that the diffusion of hydrochloric acid into the PVA film is not sensitive to RH. It is worth noting that, unlike the data in Fig. 8, the initial slopes of the ΔmV *vs.* $\sqrt{t}$ plots in Fig. 10 are not linear. This is due to differences in the optical configurations used to collect these data. The data in Fig. 9 were obtained using the single pass configuration, whereas the data in Fig. 10 were obtained using the MIR-OWG configuration. For the single-pass configuration the observed signal is an integrated response through the entire film. As soon as hydrochloric acid diffuses into the film there is a net decrease in the detector signal; as the concentration of hydrochloric acid in the film increases the signal at 560 nm decreases proportionately. In contrast, for the MIR-OWG configuration most of the light is reflected at the substrate/polymer interface, as discussed previously, and probes the film via the evanescent wave. The sensor response arises from interactions of the evanescent wave with the indicator in the film. The effective probing depth of the evanescent wave is generally small compared to the average thickness of the film, so that there is no indicator response until the hydrochloric acid diffuses far enough into the film to be sensed at the substrate/polymer interface.

For the BT-polymer sensors, the rate of response to ammonia vapor was observed to be independent of RH for both the NAF and the PVA films. The magnitude of response, however, was significantly affected by RH for both ammonia and hydrochloric acid. These observations are discussed in the next section.

Chemical (interference/synergistic) response effects. A series of experiments was performed to investigate the effect of water vapor on the indicator response of the OWG sensor. To differentiate between the systematic effects of water discussed previously, complete absorbance spectra were obtained for polymer/indicator films on a quartz capillary tube using

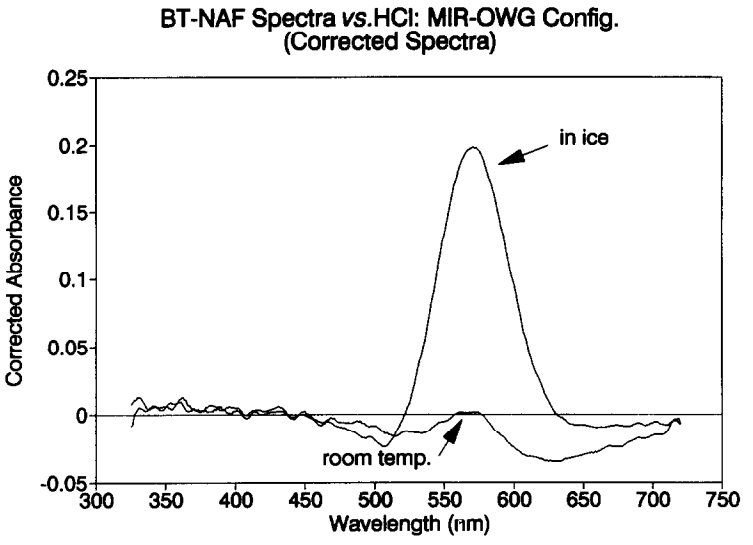

Fig. 12. Corrected spectra for a BT-NAF OWG sensor exposed to HCl vapor as indicated. Spectra were obtained by subtracting the baseline spectra (water vapor) from the HCl vapor spectra in Fig. 11.

the fiber-optic configuration in Fig. 3. Systematic effects will increase the sensor signal at all wavelengths, whereas changes in the indicator response (chemical interferences) will only be observed at the λ_{max} in the absorbance spectra for the relevant indicator form(s).

Complete spectra were collected for a BT/NAF coated waveguide using the MIR-OWG configuration. Spectra were collected for the waveguide exposed to water vapor (no acid), to vapors from 0.165*M* hydrochloric acid solution at room temperature (23°), and to vapors from the same hydrochloric acid solution maintained in an ice bath (0°). These spectra are given in Fig. 11. It should be noted that the optical bandpass using the fiber optic couplers is much larger than the bandpass using the single-pass configuration (exit slit width = 300 μm), which results in a broadening (and shifting) of the spectral features (*i.e.*, absorbance bands). As seen in Fig. 11, the majority of the BT indicator is in the HIn^- (yellow) form, indicated by the broad peak at $\approx$450 nm. Exposure to the relatively small hydrochloric acid vapor concentration (in ice) produces a slight shoulder at 560 nm, but this shift toward the red H_2In form is too small to see a sizable decrease in the 450 peak. At higher hydrochloric concentrations, the decrease in the HIn^- form is readily observed as the response at 560 increases.

To make it easier to identify changes in the absorbance spectra in Fig. 11, corrected spectra were obtained by subtracting the baseline spectra (water vapor) from spectra obtained upon exposure to hydrochloric acid vapors. The corrected spectra for the BT/NAF OWG exposed to hydrochloric acid vapor are given in Fig. 12. It should be noted that, since the large peak due to the yellow form has been subtracted, small increases or decreases in the red (H_2In) form are readily seen in the corrected spectra. Increasing the temperature of the hydrochloric acid bubbler solution should increase the concentration of both hydrochloric acid and water vapor sent to the OWG sensor. Although there is an *increase* in hydrochloric acid vapor, there is a marked *decrease* in the sensor absorbance at 560 nm. As the concentration of water in the polymer increases there will be a slight decrease in the concentration of indicator due to swelling of the polymer, but this factor is too small ($\approx$7%) to account for the factor of 2 observed decrease in absorbance. Similar behavior was observed for BT/PVA response to hydrochloric acid.

The vapor pressures of water at 0° and 23° are 4.6 torr and 21.1 torr, respectively, so that the increase in the bubbler solution temperature represents an increase in water vapor concentration by a factor of 5. The increase in water sorbed into the polymer films can be estimated from the SAW data discussed previously. At an average SAW sensor temperature of 30° the vapor pressure of water is 31.8 torr; vapor pressures of 4.6 torr and 17.5 torr represent saturation levels of 14.5 and 66%, respectively. According to the SAW responses represented in Fig. 6, this 5-fold increase in water vapor concentration translate into a 6–8 fold increase in

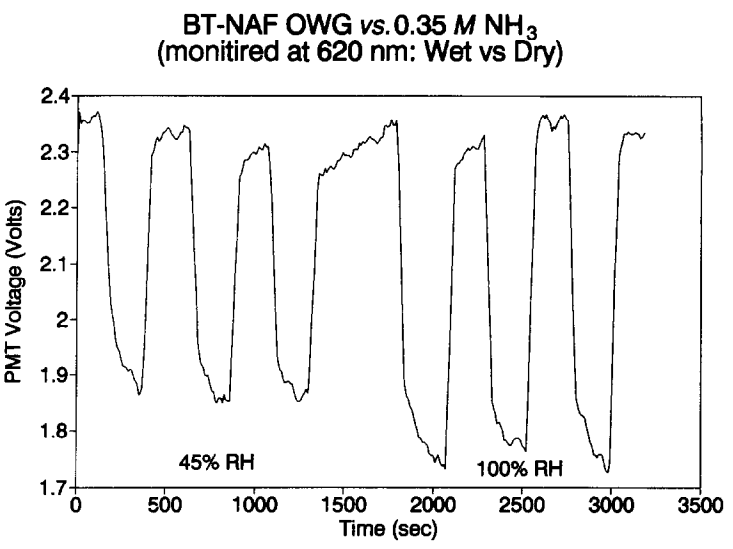

Fig. 13. Response of BT-NAF OWG to vapor from 0.35*M* NH_3 solution mixed with a) dry carrier gas, and b) carrier gas saturated with water vapor.

water in the Nafion film, and a nearly 50-fold increase for PVA. It is suggested that the presence of water in the polymer film acts as a chemical interference by affecting the equilibrium between the hydrochloric acid(g) and the BT indicator. No comparable chemical interference was observed for the TB-polymer films studied.

This behavior can be explained by making reference to the levelling effect of water. Briefly, levelling refers to the fact that strong acids in aqueous solvent will donate protons to water, *e.g.*,

$$HCl + H_2O \longleftrightarrow H_3O^+ + Cl^- \quad (3)$$

so that hydronium (H_3O^+) becomes the strongest acid in the system. This levelling effect is quite apparent for the BT indicator in aqueous solution, where very acidic conditions (4–5*M*) are necessary to protonate the indicator. In the dry polymer films, however, very small concentrations of hydrochloric acid are sufficient to produce the H_2In form. As the concentration of water increases, however, H_3O^+ becomes the predominant species; since H_3O^+ is a weaker acid than the hydrochloric acid, a greater concentration of acid is required to shift the indicator to the H_2In form.

The acid response of the TB *vs.* the BT indicator can be explained by considering the relative ability of the two indicators to act as a base (proton acceptor). Using the p*K* values for the indicator transitions in Fig. 1, then K_a and K_b values for the HIn^- form of the indicators can be calculated for these equilibria in aqueous solution. The ability of TB to act as a base (proton acceptor), is nearly 4 orders of magnitude larger than for BT. This may explain the irreversible formation of the H_2In form under mildly acidic conditions for TB, and the reversible behavior for the BT indicator under similar conditions in the polymer films.

To evaluate the effect of water vapor on the response to NH_3 vapors, various solutions of NH_3 were placed in the bubbler (at room temperature) with a bubbler flow rate of 90 ml/min. The vapor output from the ammonia bubbler was mixed with diluting air from the VG-400 at 100 ml/min. The diluting air was alternated between dry air and saturated water vapor. Again assuming that the output from the bubbler was nearly saturated in water vapor, then the RH of the vapor streams to the sensor were 40% RH (when diluting air was dry air) and 100% RH (when diluting air was saturated water vapor). Typical responses for a BT-NAF film using the MIR-OWG configuration are given in Fig. 13. The responses represent changes in PMT signal at 620 nm while the sensor is exposed to vapor from a bubbler solution of 0.35*M* ammonium hydroxide. The first three responses are in dry diluting air (45% RH), and the second three responses are in saturated water vapor (100% RH). Similar exposures were performed using 0.05, 0.10 and 0.35*M* ammonium hydrochloride solutions, and results for 100% RH and 45% RH conditions are plotted in Fig. 14. Responses to ammonia in 100% RH are generally 15–20% greater than

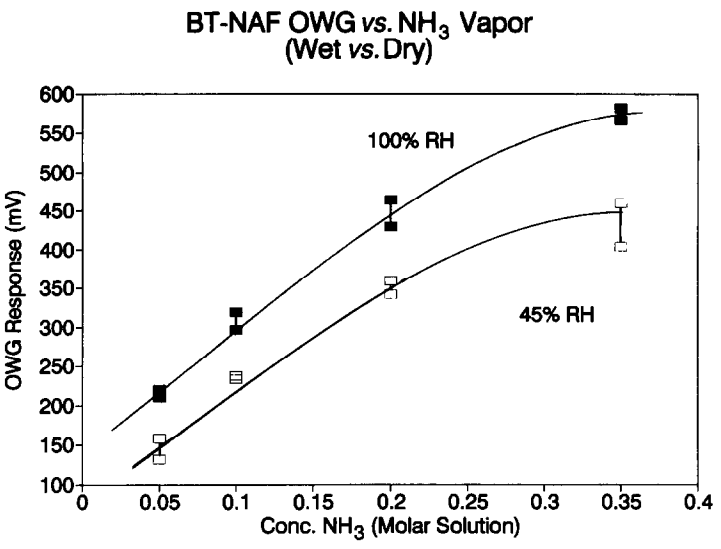

Fig. 14. Calibration curves for BT-NAF OWG response to NH_3 at 45% RH and 100% RH.

responses in 45% RH. Similar ammonia response behavior was observed for BT/PVA films.

This increased ammonia response in the presence of water vapor is interpreted as a chemical effect rather than an optical effect for several reasons. First, optical (systematic) effects would be evident as an *increase* in photodetector signal; this would translate into an increase in the baseline of the sensor when the RH was increased to 100%, whereas the baseline remains fairly constant for the data collected in Fig. 13. Second, there is a net *decrease* in signal when ammonia is introduced, indicating an increase in absorbance at 620 nm, consistent with a chemical effect. Third, the data were collected using the MIR-OWG configuration; as noted earlier, systematic effects are minimized using this configuration.

There are several possible explanations for the observed chemical effect of water on ammonia response behavior. First, water in the polymer film increases the K_a of the indicators, *i.e.*, solvation of the indicators increases their ability to donate protons to the base (ammonia). As the activity of water in the hydrated film increases, the In^{2-} species become more stable than in a dry (non-polar) film and the indicator equilibrium shifts in favor of the blue form. Alternatively, the presence of water increases the solubility of ammonia in the film, increasing the indicator response as a direct consequence.

CONCLUSIONS

The results of the above study have significant ramifications with regard to the design of indicator-based OWG sensors. These considerations are listed below:

1. In the LED-OWG, light is primarily reflected at the film/air interface, whereas for the MIR-OWG light is reflected at the substrate/film interface. The systematic interference from water vapor may be avoided by constructing the OWG sensor to utilize evanescent wave interactions as the predominant response mechanism. In this way losses at the film/air interface are minimized.

2. PVA films would be preferable to the Nafion films to avoid kinetic effects since the response times, *i.e.*, diffusion rates, in PVA are independent of relative humidity.

3. The OWG sensitivity to acidic and/or basic vapors is determined largely by the choice of indicator. For acid vapor sensing, TB-PVA films provide better sensitivity at the expense of reversibility. BT-polymer films provide both sensitive and reversible response to both hydrochloric acid and ammonia vapors. Because humidity tends to decrease the response of the BT-polymer films to hydrochloric acid (at low hydrochloric acid vapor levels), some means of humidity control would be required for reliable trace detection.

(*Received* 5 *May* 1992. *Revised* 10 *June* 1992. *Accepted* 14 *July* 1992)

Summary—The immobilisation of *L*-lactate oxidase at a platinum electrode was achieved by entrapping the enzyme within an *o*-phenylenediamine film at 0.65 V (*vs.* Ag/AgCl). Anodic detection of the product of the enzymatic reaction, i.e., hydrogen peroxide, at 0.75 V (*vs.* Ag/AgCl) was employed for the quantification of *L*-lactate using amperometric batch and flow injection methods. This technique allows the enzyme to be entrapped in a strongly adherent thin membrane. The sensor exhibits a very fast response time, an active enzyme loading of 5 mU/cm^2 electrode surface, and high sensitivity with a detection limit of $2.46 \times 10^{-7}M$. A sample throughput of 180/hr, precision of 3.53% for 25 injections and linearity up to 1.5m*M* were obtained in flow injection analysis studies. The one-step procedure for sensor preparation requires 20 min, and the discriminative properties of the polymer film show great promise as a means of excluding interfering compounds commonly found in serum.

Polymeric coatings have recently become of increasing interest in the modification of electrode surfaces.[1] By appropriate choice of monomer and experimental conditions for film preparation, polymer films with particular desired properties may be achieved. Heineman *et al.*[2] have reported that *o*-phenylenediamine forms polymeric films upon electrochemical oxidation in solutions of neutral/slightly acidic pH, and that the electrode exhibits a nearly Nernstian response with changes in pH.[3,4] The selective permeability can be varied with the nature of the ions dissolved in solution.[5]

Polymer coated electrodes have several attractive features, such as being a convenient means of immobilising an electrocatalyst near the electrode surface in high concentration,[6,7] while preventing interferences and electrode fouling.[8] The electrochemical method of immobilisation permits a controlled method of localisation of biologically active molecules at electrode surfaces. Therefore by this approach the spatial distribution of the enzyme may be readily controlled and thickness of the enzyme film easily varied. The usefulness of sensors based on immobilised enzymes depends on several factors such as the immobilisation method, thickness and stability of the entrapped enzyme, the response time and storage conditions required.

Despite uncertainties as to the mechanism of entrapment, electrochemical deposition offers advantages over the more traditional methods of enzyme immobilisation, particularly in the simplicity and reproducibility of the one-step construction process. Conventional enzyme electrodes employing discrete macroscopic membranes (to overcome problems associated with interferences and electrode fouling) suffer in lack of reproducibility and response times.[9,10]

It has recently been demonstrated that immobilisation of glucose oxidase with an electrochemically generated *o*-phenylenediamine film can be used for the amperometric detection of glucose.[11] A fast and permselective response was thus reported. The objective of the present work was to explore the *o*-phenylenediamine electropolymerisation scheme for effective immobilisation of lactate oxidase.

The determination of *L*-lactate is important in the diagnosis of respiratory insufficiencies, heart disease[12,13] and also in sport medicine. The

†Author for correspondence.

relevant lactic acid concentration in blood occurs in the range 0.3–1.5m*M*.[14] Determination of *L*-lactate also plays an important role in the food industry, *e.g.*, wines and dairy products.[15]

Previous methods for determination of *L*-lactate have involved enzyme reactors,[16] co-immobilisation of lactate oxidase and lactate dehydrogenase in enzymatic amplification schemes,[10] entrapment of the enzyme behind a semi-permeable membrane.[9]

The immobilisation of *L*-lactate oxidase in poly(vinyl alcohol) has also been reported[17] following gamma-irradiation. These methods result however in slower response time, interference problems and prove to be more complicated than the method described here. This paper describes a simple and easily controlled enzyme immobilisation procedure that has application in the development of sensors for this biologically important compound.

EXPERIMENTAL

Apparatus

Amperometric measurements and electropolymerisation of *o*-phenylenediamine were carried out in a 3-electrode cell (Model VC-2, BAS), containing 10 ml of 0.05*M* phosphate buffer as supporting electrolyte. Reference and counter electrodes were Ag/AgCl (Model RE-1, BAS) and platinum wire, respectively. A platinum disk electrode served as the working electrode and all three joined the cell through holes in its Teflon cover. The three-electrode system was then connected to an EG&G PAR Model 264A polarographic Analyser, the output of which was displayed on a strip chart recorder (Model 4500 Microscribe, The Recorder Co.). A magnetic stirrer and bar provided the convective transport. The flow injection system used was equipped with a carrier reservoir, a platinum thin-layer detector (Model TL-10A, BAS) a Rainin Model 5041 sample injection valve (20 μl loop) and interconnecting tubing. A flow rate of 2.0 ml/min was employed throughout.

Reagents

All experiments were conducted at room temperature in 0.05*M* phosphate buffer pH 7.4, and all solutions were prepared with doubly-distilled water. Lactate oxidase (activity 38 Units/mg), *L*-lactate, glucose, nicotinamide adenine dinucleotide (reduced form), uric acid and acetaminophen were obtained from Sigma Chemical Co., St. Louis, MO. The ascorbic acid was obtained from J. T. Baker Inc., Phillipsburg, NY and the *o*-phenylenediamine dihydrochloride from Aldrich, Milwaukee, WI. The cellulose dialysis membrane (MW cutoff 12–14 k) was purchased from Spectrum Medical Industries, Los Angeles, CA. Stock solutions of glucose were allowed to mutarotate at room temperature for 24 hr before use. The nitrogen used to obtain a controlled atmosphere in the electrochemical cell was of high purity grade.

Electrode preparation

Prior to electropolymerisation the platinum disk working electrode was polished firstly with 3 μm of alumina followed by 0.05 μm, after which it was sonicated in distilled water for 5 min to remove any residual alumina. Lactate oxidase/*o*-phenylenediamine films were electrochemically grown on platinum electrodes from a fresh solution of 1m*M* *o*-phenylenediamine and 3.42 units of enzyme in 0.05*M* phosphate buffer, (pH 7.4). Electropolymerisation was initiated by applying a constant potential of 0.65 V (*vs.* Ag/AgCl) in deaerated unstirred solutions for 20 min. The enzyme electrode was thoroughly rinsed with doubly-distilled water after preparation and stored in phosphate buffer pH 7.4 at 4° when not in use.

Procedure

Amperometric responses of the lactate oxidase/*o*-phenylenediamine (LOX/o-PD) electrode to *L*-lactate were measured in batch and flow experiments by application of a fixed potential of 0.75 V to the enzyme electrodes. The background current was allowed to decay before aliquots of the stock *L*-lactate solution were added and the oxidation current due to hydrogen peroxide measured.

An estimation of the activity of enzyme entrapped in the polymer film was carried out amperometrically. A clean polished platinum electrode was held at 0.75 V (*vs.* Ag/AgCl) in stirred solution containing 1.0m*M* *L*-lactate in phosphate buffer, pH 7.4. When a steady state current was achieved, a known activity of lactate oxidase was injected and the current response noted for the production of hydrogen peroxide. A calibration curve was constructed and the activity of each LOX/o-PD electrode expressed as equivalent activity in solution. Enzyme stability within the film was ascertained by measuring the current response over a 20 day period. While not in use, the electrode was stored in phosphate buffer pH 7.4.

RESULTS AND DISCUSSION

Lactate oxidase catalyses the reaction shown below and electrochemical biosensing is based on the amperometric monitoring of the hydrogen peroxide produced.

$$\text{LOX(FAD)} + L\text{-LACTATE} + O_2$$

$$\Leftrightarrow \text{LOX(FADH}_2\text{)} + \text{PYRUVATE} + H_2O_2$$

The response of the LOX/*o*PD electrode to successive additions of *L*-lactate at the bare and modified surfaces, using both amperometric and chronoamperometric measurements, is shown in Fig. 1. Steady state currents were achieved within 15 sec and 2 mins respectively, with high sensitivity for μM concentrations of substrate and a detection limit of $2.46 \times 10^{-7}M$ for both techniques.

The effects of many experimental variables were investigated in order to optimise analytical performance. Optimisation of enzyme loading in the polymer film is shown in Fig. 2. Linearity and response increased with increasing biocatalytic activity in the film, the optimum activity being achieved with 3.42 Units in solution (1.6 mU/electrode). The response to 50μM additions of *L*-lactate resulted in a slope of 4.5 nA/μM and a correlation coefficient of 0.99975 when the electropolymerisation solution contained 1m*M* *o*-phenylenediamine and 3.42 units lactate oxidase.

The effect of operational potential (A) and pH (B) for amperometric experiments is shown in Fig. 3. An increase in oxidation current for hydrogen peroxide, resulting from 0.25m*M* injections of *L*-lactate occurred as the applied potential increased from 0.2 to 0.8 V with a decrease at higher potentials. An optimum current response to 0.5m*M* injections of *L*-lactate was achieved at pH 7.4 and therefore this pH was taken as that providing maximum activity for the operation of this enzyme electrode.

Figure 4(A) shows the effect on anodic response with increasing concentration of *o*-phenylenediamine in the electropolymerisation solution, keeping both enzyme activity and time

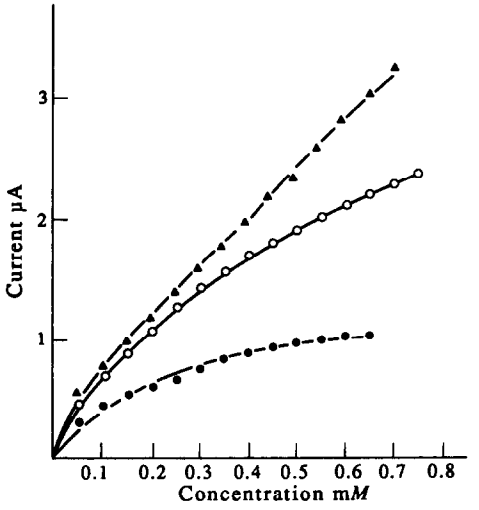

Fig. 2. Current dependance on *L*-lactate oxidase loading in the electropolymerised film upon injection of $5 \times 10^{-5}M$ *L*-lactate. Fig. 3. Effect of applied potential (A) and solution pH (B) on response to $2.5 \times 10^{-4}M$ and $5 \times 10^{-4}M$ injections of *L*-lactate respectively. Electropolymerisation solution containing 10m*M* (A) and 5m*M* (B) *o*-phenylenediamine with 3.04 Units enzyme activity. Enzyme loading-5 mUnits/cm^2. Other conditions as in Fig. 1(A).

constant. The greatest current was observed for the film prepared with 1m*M* monomer solution. A subsequent decrease in response was observed up to 5m*M*, followed by an increase once more up to 10m*M*. A thicker film implies a slower response time and a lowering of sensitivity but results in a wider linear range. A thinner film appears to incorporate more enzyme resulting in a greater response. The diffusion of the product hydrogen peroxide through the film may be the limiting factor as the thickness is increased, the enzymatic reaction occurs more readily in the outer portions of the polymer layer near the solution side than in the interior of the film.

The effect of the electropolymerisation potential on current response is shown in Fig. 4(B). An optimum value was found to be 0.65 V, but

as the anodic potential was increased above this value, the amperometric response decreased. A decrease in conductivity in the film and a loss of activity occurs at high potentials. Destruction of the polymer may be attributed to irreversible deterioration of the film by formation of electroinactive polymer films on the surface. Figure 4(C) shows the effect of polymerisation time on performance of the sensor. The form of the current *vs.* time curve implicates a nucleation and phase growth process in the mechanism of deposition of *o*-phenylenediamine, similar to that of the growth of *m*-toluidine on gold.[18] The monomer appears to oxidise more readily on the poly(*o*-phenylenediamine) film than on the platinum itself. Initial growth requires 5–10 min followed by a rapid increase in current with increasing thickness of polymer film. Saturation of enzymatic activities above 20 min may result in the conformational arrangements of the enzyme within the film. Due to release of protons in the course of polymerisation, the acidic environment produced may lead to denaturation of lactate oxidase at longer electropolymerisation times.

The fast response and stability of the LOX/o-PD electrode makes it an attractive choice in dynamic flow systems. Figure 5 illustrates flow injection peaks for 20-μl samples of increasing *L*-lactate concentration. The peak width of 6 sec allows a sample throughput of 180 samples/hour, with linearity observed up to 1.5m*M* and a limit of detection of $1 \times 10^{-4}M$. Twenty five successive injections of a 5m*M* *L*-lactate solution showed a precision of 3.54%. Under optimum conditions, a precision study employing 10 consecutive separate batch additions of 50μM *L*-lactate resulted in a RSD of 3.23% (not shown).

The potential required to oxidise hydrogen peroxide is sufficiently anodic that several other interfering compounds may contribute to the signal. However, the electropolymerised *o*-PD film appears to be very effective in preventing interferences while allowing hydrogen peroxide to pass through the film. Due to its permselectivity the access of substances such as ascorbate to the electrode surface is blocked. Similar improvements were reported for analogous sensing of glucose.[11]

The selectivity of the LOx/*o*-PD electrode was studied by monitoring the response to 0.5m*M* *L*-lactate alone and in the presence of relevant compounds at the 1.0m*M* level which may interfere by direct electrode oxidation (Table 1). In the case of polypyrrole films[19] anionic species showed enhanced electrochemistry due to the electrostatic interaction with the polymer matrix which contained cationic fixed sites. The relatively high response to uric acid in the case of the *o*-PD polymer was further decreased by an additional cellulose membrane (12–14 k MW cutoff) over the electrode. The polymer film proved effective in further reducing the current signal due to uric acid, ascorbic acid, NADH, and glucose (all at the 1.0m*M* level) while retaining 90 and 64.3% of the *L*-lactate response (0.5m*M*), with and without cellulose membrane respectively.

The oxidation of *o*-phenylenediamine in phosphate buffer shows a completely irreversible oxidation peak at 0.35 V using cyclic

Table 1. Percentage interference response compared to that of analyte (A) without membrane and (B) with cellulose membrane. All interferences at the 1.0m*M* level in presence of 0.5m*M* *L*-lactate. voltammetry, which with continuous scanning between 0.2 and 0.7 V resulted in a decrease in peak current until eventually no current flowed. This behavior is indicative of a non-conductive polymeric film coating the electrode until eventually access of the monomer to the surface is blocked resulting in the formation of a very compact and insulating layer.[20]

The mechanism by which the enzyme is entrapped is uncertain; however adsorption of the lactate oxidase at the platinum surface prior to electropolymerisation could play an important part. Initial film formation is that of a conducting organic film and subsequent formation of a non-conducting film then occurs. *o*-Phenylenediamine forms polymeric films during oxidation at almost all pH values. Most organic electrochemical oxidations of this type form a monocation as the initial electrolysis product, which is involved in the follow-up chemical reaction. The insulating film could then possibly be formed by the polymerisation of the dication formed upon disproportionation. Poly(*o*-phenylenediamine) contains phenazine rings as electroactive sites. The ladder polymer is partially ring opened and involves moieties of the oxidised forms of the quinone-imine type.[21] Under optimum conditions, 5 mUnits/cm^2 electrode surface equivalent to 1.52 Units/ml in the electropolymerisation solution may be incorporated into the film. The estimation of enzyme activity on the surface was carried out by comparison to the rate of hydrogen peroxide production when the enzyme was in solution in the presence of excess substrate. This assumed that the solution kinetics are equivalent to those when the enzyme is in the immobilised form, which is not true due to mass transfer limitations resulting from immobilisation. The activity within the film may be estimated however from the plot of current *vs.* activity in solution.

The upper limit of the electrode response may be improved by placement of a cellulose membrane onto the LOX/*o*-PD film. This restricts the diffusion of *L*-lactate to the underlying enzyme layer and as a result extends linearity. The improvement in linear response was accompanied by a significant decrease in the noise level for injections of μM quantities of substrate. In the presence of cellulose membrane the response has mass transfer as opposed to kinetic limitations, the latter resulting in a levelling off at lower substrate concentrations. This restricts the diffusion of *L*-lactate to the underlying enzyme layer and as a result extends linearity. A LOX/*o*-PD polymer electrode prepared from 1.14 Units enzyme activity and 1m*M* *o*-phenylenediamine solution resulted in an i_{max} (the maximum current, obtained from the intercept of the Lineweaver-Burk plot of 1/current *i* *vs.* 1/[Substrate]) of 1.236 μA and apparent Michaelis-Menten constant (K_m app, calculated from the slope of the graph) of 117.3μM. The same electrode covered with cellulose membrane showed an i_{max} of 1.3528 μA and K_m app of 342.2μM. The additional diffusional restrictions imposed as a result of the membrane causes alteration of basic catalytic properties and results in a shift in the apparent K_m app. The increase in K_m app in the case of the membrane indicates that the immobilisation process generates a loss of affinity to the substrate due to the additional environmental constraints placed on the enzyme.[22] However, this method is useful from the analytical point of view due to extension of the upper limit.

An improvement in linearity was also observed using 10m*M* monomer in the electropolymerisation solution and after film formation, polymerisation once more in the same solution. Linearity in this case was extended up to 1.5m*M* again at the expense of lower sensitivity and slower response time.

The stability of the LOX/*o*-PD electrode with storage at 4° in phosphate buffer (pH 7.5) was investigated. Responses were measured as the oxidation of resultant hydrogen peroxide caused by the addition of 0.5m*M* *L*-lactate at 24-hourly intervals. A 50 and 93% decrease in response was observed after 5 and 20 days respectively.

CONCLUSION

Electrochemically initiated polymerisation has recently received great attention in the modification of electrode surfaces. Polymer film electrodes offer higher inherent chemical and physical stability, higher surface activity and a very sensitive electrochemical response. The electropolymerisation of *o*-phenylenediamine provides simultaneous immobilisation of lactate oxidase and offers the advantage of producing a very thin and self insulating film that can be coated on any conducting surface. The sensor is found to reject physiologically important compounds, *e.g.*, ascorbic acid while incorporating a significant amount of lactate oxidase. The very fast response time, together with the high sensitivity and high sample throughput, are further distinctive features of the described sensor.

The stability and dynamic bahavior of the film allows for application in flowing streams.

NON-ENZYMATIC OPTICAL SENSOR FOR PENICILLINS

HUARUI HE,* HONG LI, GEORG URAY and OTTO S. WOLFBEIS†
Institute of Organic Chemistry, Karl-Franzens University, Heinrich St. 28, A-8010 Graz, Austria

(*Received* 31 *March* 1992. *Accepted* 12 *June* 1992)

Summary—We report on the first penicillin-sensitive fluorosensor not based on the use of an enzyme. Rather, the recognition process relies on the use of an anion carrier (which carries the penicillin anion from the aqueous sample into the membrane), a proton receptor (lipophilic nile blue which accepts the proton, thereby undergoing a change in fluorescence intensity), and a new lipophilic hydroxylic plasticizer material (which facilitates ion transport). All materials are contained in a dyed poly(vinyl chloride) membrane whose fluorescence is monitored. The optical sensor fully reversibly responds to penicillin V over the 0.01–10m*M* concentration range, and to penicillin G from 0.03 to 10m*M*. Potential interferences by about 20 other anions have been investigated. Nitrate, salicylate, and ascorbate were found to interfere significantly. These species are, however, usually not present in penicillin bioreactors or drug formulations where penicillin sensing is most important. The sensor does not respond to penicillins containing an aliphatic amino group (such as amoxicillin). The method has been applied for determination of penicillin G in pharmaceutical formulations.

In view of the large scale production of penicillins there is a considerable interest in continuous sensing of penicillin both during biotechnological production and in quality control. Another attractive application is on-line monitoring of penicillins *in vivo* during therapy and pharmacokinetic studies. Methods for determination of penicillin include flow injection analysis,[1,2] HPLC,[3,4] potentiometry,[5] and spectrophotometry.[6,7] An optical sensor for penicillin and its analogs has been reported by two groups.[8,9] In these, the enzyme penicillinase rather unspecifically hydrolyzes all kinds of penicillins to give penicillic acids. The corresponding decrease in pH is monitored using an optical fiber pH sensor. While this is a promising approach for on-line sensing and has all the advantages of fiber optic biosensors,[10] it suffers from two limitations: the observed pH change also strongly depends on the buffer capacity (which in biological samples can vary to a considerable extent), and the enzyme loses activity with time and at low pH. An alternative and more reliable method was therefore sought.

In a search for non-enzymatic alternatives for optically sensing penicillins, we have found a method which exploits the phenomenon of co-extraction[11] of both an ion and its counter-ion into a PVC membrane. The extraction of organic cations has been described several times in the past two years, but there is only a limited number of reports on the extraction of organic anions into lipid phases.[5,12,13] We report here that penicillin anions can be extracted as well, provided suitable receptor/carriers and plasticizers are incorporated into the membrane.

EXPERIMENTAL

Apparatus

Measurements were performed using an Aminco SPF 500 spectrofluorometer equipped with a tungsten halogen lamp as a light source. Data were transferred onto a HP 9825A desk calculator and plotted. All fluorescence spectra are uncorrected. Sample solutions were pumped through a 100-μl flow-through cell containing the sensing membrane at a rate of 1.5 ml/min, using a Ventilomat autosampler (Fa. Ziegler, Graz, Austria). pH measurements were performed with a Metrohm pH meter (Metrohm, Buchs, Switzerland) calibrated with Aldrich pH standards of pH 4.00 and 7.00.

The flow injection equipment comprises autosampler (Besta, Heidelberg, Germany), pump (Gilson, France), fiber optic photometer (Oriel 3090, Chelsea Instruments, London, UK), data

*On leave of absence from Department of Chemistry, Nankai University, CN-300071 Tianjin, P.R. China.
†Author for correspondence.

acquisition unit (Keithley 575, Taunton, USA), and personal computer. Sample solutions were pumped through the flow-through cell containing the sensing membrane using the autosampler. Fluorescence intensity was measured with the photometer and data were transferred to an acquisition unit controlled by the PC.

Reagents

Penicillin G potassium salt was obtained from Fluka AG (Buchs, Switzerland), while penicillin V and amoxicillin (Fig. 1) were purchased from a pharmacy. For the membrane preparation, poly(vinyl chloride) (high molecular grade) (PVC) bis(2-ethylhexyl) phthalate (DOP), bis(2-ethylhexyl) sebacate (DOS), 2-nitrophenyl octyl ether (NPOE), tri(2-ethylhexyl) phosphate (TOP), tridodecylmethylammonium chloride (TDMAC) and tetrahydrofurane (THF) were obtained from Fluka AG. The new plasticizer (WM3, Fig. 1) was synthesized by Dr. Kriessmann (Fa. VIANOVA, Graz) and was found to be of sufficient purity. The lipophilic N-octadecanoyl nile blue (ODNB) was prepared according to the published procedure.[14] The samples, Penicillin G-Natrium, Antipen, and Retarpen (all from Biochemie GmbH, Vienna, Austria) were purchased from a drug store.

Membrane preparation

The membranes were prepared from a batch of 2.4 mg of PVC, 0.2 mg of TDMAC, 0.6 mg of ODNB and 6.0 mg of WM3. The mixture was dissolved in 1.5 ml of freshly distilled tetrahydrofurane. 0.1 ml of this solution was pipetted onto a 12 × 50-mm dust-free glass plate (Menzel-Gläser, Germany) which was located in THF-saturated atmosphere in a desiccator. After about 5 hr the glass plate with the sensing membrane on it was removed and placed in ambient air for 15 min to dry completely. From the amount of materials used we estimate the membrane to have a thickness of around 1.0–1.5 μm. Before measurements, the sensor membrane was placed, for 10 min, in a freshly prepared 0.1M solution of penicillin G in pH 6.00 buffer (50mM sodium citrate and 50mM sodium tartrate), and another 10 min in plain buffer of pH 6.00 for activation.

Experimental procedure

The glass plate with the PVC membrane of about 1-μm thickness was mounted in a flow-through cell. The measuring system was arranged according to Ref. 15. Standard solutions, freshly prepared from distilled water, were pumped over the sensing membranes, and fluorescence intensity was continuously recorded at excitation/emission wavelengths set to 520/670 nm, respectively.

Optical selectivity coefficients were determined by using a method similar to the separate-solution method (SSM) frequently applied in ion-selective electrodes.[14,16] Solutions of potentially interfering compounds were prepared in proper concentrations (C_I^{n-}), and the fluorescence of the sensing membranes was

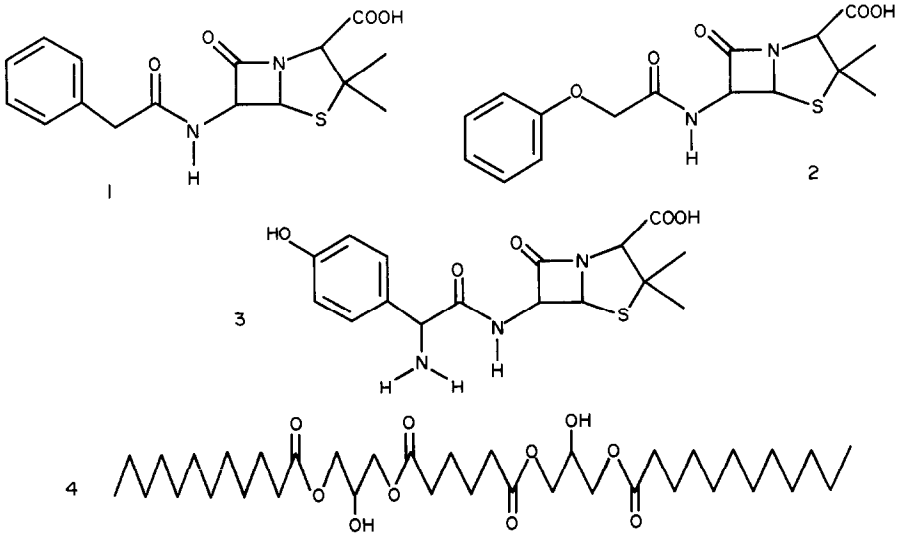

Fig. 1. Chemical structures of the penicillins studied in this work, and of plasticizer WM3. 1: penicillin G, 2: penicillin V, 3: amoxicillin, 4: WM3.

measured under experimental conditions identical to those when establishing the calibration curve. The fluorescence intensities thus obtained were related to the concentration of penicillinate anion ($C_{pncl.}^-$).

The drug samples—three kinds of dry (powdered) penicillin contained in an ampoule—were pretreated according to the following procedure: 40 mg of Penicillin G-Natrium or 80 mg of Retarpen (containing benzathine-penicillin G and polypyrrolidon K 17) or 17 mg of Antipen (containing clemizole-penicillin G and sodium penicillin G) were suspended in 70 ml of a pH 5.50 buffer solution composed of 50m*M* sodium citrate and 50m*M* sodium tartrate. The solution was stirred at room temperature until clear. It was then diluted to 100 ml with the same buffer solution. This solution was used directly for the measurements.

RESULTS AND DISCUSSION

Selection of the plasticizer

In order to function properly, PVC-based membranes for use in either electrochemical and optical sensing require the addition of a plasticizer. It is well known that the type of plasticizer has a dramatic effect on the response behavior of such "liquid membranes". Five plasticizers (DOS, DOP, TOP, NPOE, WM3) with different polarities have been investigated in an initial study.[17] The results showed that tri-dodecyl-methylammonium chloride (TDMAC) along with the plasticizer WM3, whose chemical structure is shown in Fig. 1, is a viable carrier/plasticizer combination for sensing penicillin. Optical transduction is achieved via the PVC-soluble *N*-octadecanoyl nile blue (ODNB). Hence, the membrane whose fluorescence responds to penicillin consists of PVC, TDMAC, ODNB, and WM3 only.

Fluorescence spectra of lipophilized nile blue in plasticized PVC

Figure 2 shows the uncorrected excitation and emission spectra of lipophilized nile blue in a WM3-plasticized PVC membrane as it is used in practice. The emission maximum of the base form is at 670 nm. The maxima are similar to those given in the literature, differences probably arising from the fact that spectral maxima strongly depend on the nature of the additives contained in the membrane material. The red base form of nile blue has a much larger Stokes' shift than the blue (acid) form so that interferences by straylight can be kept to a minimum. Given the longwave absorption and emission of the dye used, the sensor obviously is fully compatible with solid-state opto-electronic components such as LEDs.

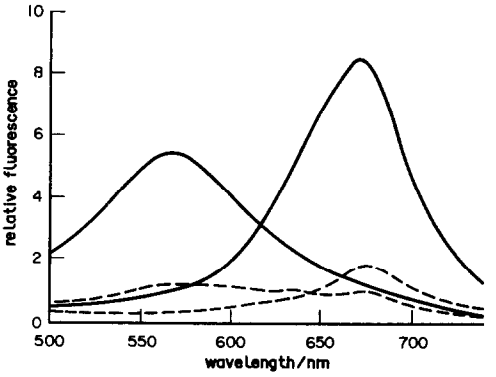

Fig. 2. Uncorrected excitation and emission spectra of lipophilized nile blue in a WM3-plasticized PVC membrane. Fluorescence intensity is given in arbitrary units.

The response of the optrode membrane

The sensing membrane contains an anion exchanger (TDMAC) and a chromo-ionophore (ODNB). When, at any pH between 5.3 and 6.0, the penicillin carboxylate anion is transported into the PVC membrane by the anion carrier, a proton will be co-extracted (rather than a chloride released). The conjugate base form of nile blue contained in the membrane acts as a chromogenic proton carrier. On protonation, it undergoes a significant change in fluorescence intensity. Hence, it also acts as the optical transducer. The response function can be related to the product of the activities of two ions.[11,18] The signal depends only on the activity of the analytes if the pH value of the sample

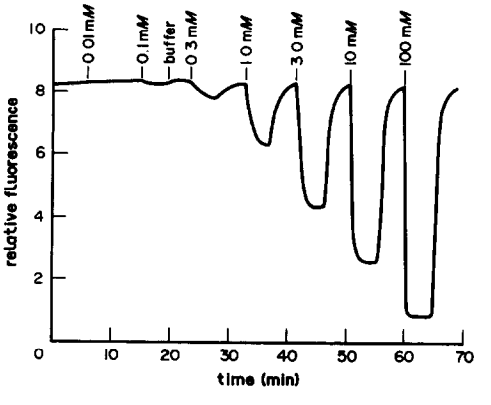

Fig. 3. Response time, relative signal change, and reversibility of the penicillin-sensitive sensor membrane at pH 5.50, with excitation/emission wavelengths set to 520/650 nm.

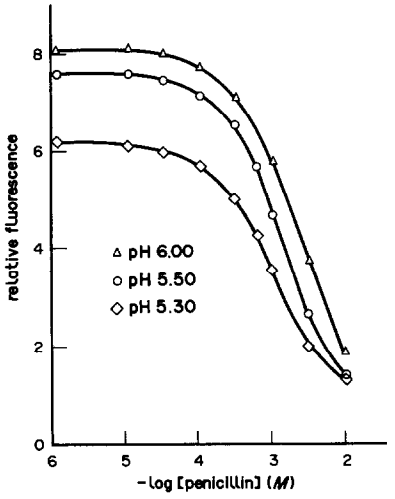

Fig. 4. Calibration curves for the penicillin-sensitive membrane at pH's of 6.00, 5.50 and 5.30 and excitation/emission wavelengths set to 520/650 nm.

solution is kept constant. When exposed to increasing levels of penicillin G, the sensor membrane undergoes a fully reversible colour change from red to blue. Figure 3 shows the response curve of the penicillin G sensor. Response times are about 3 min in the forward direction, but 5 min for the reverse response. The rather sluggish response is due to slow mass transfer in the membrane rather than to the dead volumes of flow-through cell and tubings, respectively.

The fluorescence intensity is a specific function of the analyte (penicillin G) only if the pH value of the sample solution is kept constant. Figure 4 shows the calibration curves of the sensor at different pH values. Clearly, the response is highly pH dependent since the recognition process is coupled to a proton transport mechanism. The dynamic range is shifted to a lower concentration range at lower pH, while the total signal change becomes smaller. The dynamic range is from 30μM to about 10mM, with a detection limit of about 10μM.

Figure 5 shows the response and calibration curves of the penicillin-sensitive membrane plasticized by WM3 and tested with a flow injection analyzer.[19] The linear range is 1–60mM concentration. A comparison with the results of the measurement using the flow-through cell of the fluorometer (see Fig. 4) shows the dynamic range to be shifted to a higher concentration range. This can be attributed to the dilution effect of the flow injection analysis.

The possible response mechanism

The mechanism of the interaction between penicillin, TDMA, and WM3 probably involves (a) formation of hydrogen bonds between the amido groups of penicillin and the hydroxy groups of the plasticizer, and (b) electrostatic attraction between the ammonium ion (TDMAC) and the penicillinate anion. We find only membranes plasticized by some kind of hydroxylated plasticizers (with a ratio of hydroxy groups to carbon atoms in the chain being around 10) to respond to penicillins. Similar effects were found in case of fluorescence-based optical sensors for alkali ions[20] and in other sensors based on the use of synthetic carriers.[17]

Selectivity tests

Interferences by 18 compounds have been investigated using the established method.[12] Optical selectivity coefficients (K^{opt}), defined as the logarithm of the concentration of an interfering species that gives the same response, are summarized in Table 1. They show salicylate,

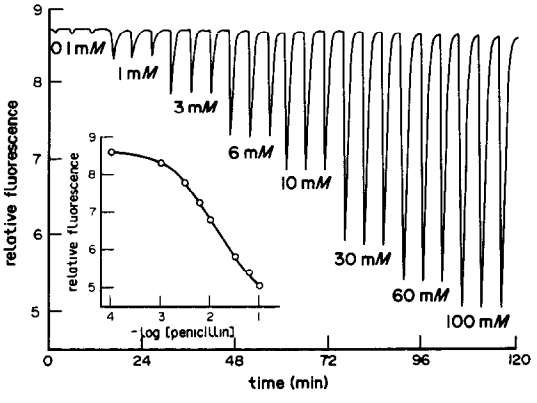

Fig. 5. Response curve of the penicillin-sensitive membrane plasticized by WM3, tested with the flow injection analyzer, and resulting calibration plot (insert).

Table 1. Optical selectivity coefficients (K^{opt}) of the penicillin-selective optical sensor for potentially interfering ions at pH 5.50

Interferent	log K^{opt}
Salicylate	0.30
Nitrite	0.20
Ascorbate	0.15
Benzoate	−0.45
Nitrate	−0.74
Iodide	−1.08
Chloride	−1.83
Acetate	−2.53
Oxalate, phenylalanate	−2.70
Glycinate	−2.80
Glutamate, amoxicillin	< −3
Lactose, glucose	< −3
Sulphate, phosphate, carbonate	< −3

Table 2. Results of 5 replicate determinations of penicillin in 3 kinds of penicillin formulations. SC, specified concentration (in m*M*); AV, average measured value (in m*M*); SD, standard deviation; RSD (%), relative standard deviation; RE (%), relative error

Sample	SC	AV	SD	RSD(%)	RE(%)
Penicillin G-Natrium	1.14	1.17	0.02	1.58	2.93
Retarpen	0.87	0.82	0.02	−2.34	−6.13
Antipen	0.31	0.29	0.01	2.42	−4.68

ascorbate and nitrite to strongly interfere, while nitrate, iodide and chloride have moderate effects. Interestingly, penicillins containing a basic amino group (such as amoxicillin, see Fig. 1) display no response. This high selectivity may be exploited for distinguishing aminopenicillins from other penicillins.

Determination of penicillin G in injection ampoules

Retarpen and Antipen contain benzathine–penicillin and clemizol–penicillin, respectively. Benzathine and clemizol are relative lipophilic organic ammonium ions and capable of forming strong ion-pairs with penicillinate anion. As a result, they are hardly soluble in water. Furthermore, dissolved benzathine and clemizol were expected to interfere due to their much higher lipophilicity than the proton. In order to avoid any errors caused by the co-extraction of benzathine or clemizol with penicillinate anion, they must be masked prior to assay. In earlier work[21] it has been shown that tartrate can form a complex with organic ammonium, and this can be exploited for masking the lipophilic organic ammonium and to keep it in the water phase. Consequently, all measurements were performed in a 50m*M* tartrate medium. The results are summarized in Table 2.

The experimental data are slightly lower than the specified concentrations for Retarpen and Antipen. We think that this is due to the interference of residual benzathine and clemizol cation, both of which may not completely be masked by the tartrate anion in the buffer solution. For Penicillin G-Natrium, the data are slightly higher. The highest relative error observed is −6.1%. If dealing with samples which do not significantly vary from batch to batch (such as in pharmaceutical quality control), this may be corrected for by a correction factor).

BOOK REVIEWS

Advances in Coal Spectroscopy: H. L. C. MEUZELAAR (editor), Plenum, New York, 1992. Pages xx + 416. US $85.00. ISBN 0-306-43796-1.

This publication, the latest in the Modern Analytical Chemistry series, is based on the keynote lectures given at a Utah symposium on coal spectroscopy in June, 1989. The literature of the last 3 years, therefore, is not covered except in a few isolated instances.

The publication has the usual characteristics of symposium proceedings, being disparate and somewhat unfocussed, but providing the reader with accounts of the application of a series of analytical techniques to structural investigations of coals and coal-derived products. In 15 chapters somewhat more recent work in well-established techniques such as proton and ^{13}C NMR, mass spectrometry and gas chromatography are presented along with accounts of work using more specialized techniques such as SEM, XAFS, and laser spark emission spectroscopy. Maceral analysis by fluorescence microspectrophotometry forms the subject of one chapter, while another gives an interesting account of the use of computer-enhanced mass spectrometry in the investigation of coal structure. While the overall emphasis in the book is on the organic structure of coal, ash analysis and combustion behaviour also receive some attention.

The standard of presentation in "Advances in Coal Spectroscopy" is generally good, but the literature surveys are by no means exhaustive, and the work is essentially a series of individual snap-shots of the topics covered. Its readership, therefore, is likely to be drawn from those who are already active in or on the edge of coal chemistry research. At the price set it is also likely to be a library purchase. It can be recommended as a moderately useful institutional acquisition.

W. STEEDMAN

Electroorganic Synthesis—Festschrift for Manuel M. Baizer: R. D. LITTLE and N. L. WEINBERG (editors), Dekker, New York, 1992. Pages xxxiii + 434. $150.00 (US and Canada), $172.50 (elsewhere). ISBN 0-8247-8584-3.

Manuel M. Baizer (1914–1988) was recognised as the foremost international authority on organic electrosynthesis, and this book is a tribute to his memory. The contents comprise the published proceedings of the Manuel M. Baizer Memorial Symposium, held as part of the 177th meeting of the Electrochemical Society in Montreal, May 1990.

However, unlike many conference proceedings in which individual contributions do not always mesh together to give a coherent treatise on a particular subject, this book can be viewed as an excellent review of developments across the range of organic electrosynthesis. This reflects not only Baizer's all-encompassing interest in the subject but also the standing of the contributors, who represent a world-wide theatre.

The book is packed with detail, and after a suitable introduction to Baizer's career and publications enlivened with personal anecdotes there are 48 papers grouped into sections. These papers cover an expansive range of topics including direct electroreductions and electrooxidations, indirect and mediated systems, modified electrodes, alternative electrode materials, biochemical, biomass and natural product systems, mechanistic studies, electrogenerated bases; conducting polymers and electrochemical ion-exchange. The editors are to be congratulated on the tight, condensed style of the papers, which are well referenced; and many are almost mini-reviews of their topics. This book therefore represents a résumé of the current state-of-the-art and as such is invaluable to anyone wishing to assess the present situation.

Baizer's best-known contribution to the subject was his pioneering work at Monsanto on the commercialisation of the electrohydrodimerisation of acrylonitrile to adiponitrile. Since then it is arguable that industrial exploitation of electroorganic processes has failed to attain hoped-for levels, reflecting the particular difficulty in this discipline of scaling up systems that appear promising in the laboratory. Baizer showed that perspicacity and perseverance could overcome these developmental problems and it is to be hoped that the contents of this book will attract others to consider this technology.

This packed little book is not cheap, and it may be that a more lasting monument to Baizer for the general chemist and for newcomers to the field of electrochemistry will be his seminal textbook, edited with Henning Lund: 'Organic Electrochemistry' (Dekker) now in the 3rd edition. However, this Festschrift volume is not only a fitting tribute to a fine scientist, but is also a valuable review in its own right.

D. J. WALTON

Data Fitting in the Chemical Sciences: P. GANS, Wiley, Chichester, 1992. Pages xii + 258. £29.95. ISBN 0-471-93412-7.

The full title of this book is *Data Fitting in the Chemical Sciences by the Method of Least Squares* and this conveys a much clearer picture of its contents than the shorter title which appears on the front cover. The earlier chapters contain a discussion of the application of the method of least squares to both linear and non-linear problems. I was impressed by the wide range of different least squares techniques described and with the thoroughness of their presentation. Model selection and testing are then considered. The later chapters illustrate the application of these ideas in fitting polynomials,

This reflects not only Baizer's all-encompassing interest in the subject but also the standing of the contributors, who represent a world-wide theatre.

The book is packed with detail, and after a suitable introduction to Baizer's career and publications enlivened with personal anecdotes there are 48 papers grouped into sections. These papers cover an expansive range of topics including direct electroreductions and electrooxidations, indirect and mediated systems, modified electrodes, alternative electrode materials, biochemical, biomass and natural product systems, mechanistic studies, electrogenerated bases; conducting polymers and electrochemical ion-exchange. The editors are to be congratulated on the tight, condensed style of the papers, which are well referenced; and many are almost mini-reviews of their topics. This book therefore represents a résumé of the current state-of-the-art and as such is invaluable to anyone wishing to assess the present situation.

Baizer's best-known contribution to the subject was his pioneering work at Monsanto on the commercialisation of the electrohydrodimerisation of acrylonitrile to adiponitrile. Since then it is arguable that industrial exploitation of electroorganic processes has failed to attain hoped-for levels, reflecting the particular difficulty in this discipline of scaling up systems that appear promising in the laboratory. Baizer showed that perspicacity and perseverance could overcome these developmental problems and it is to be hoped that the contents of this book will attract others to consider this technology.

This packed little book is not cheap, and it may be that a more lasting monument to Baizer for the general chemist and for newcomers to the field of electrochemistry will be his seminal textbook, edited with Henning Lund: 'Organic Electrochemistry' (Dekker) now in the 3rd edition. However, this Festschrift volume is not only a fitting tribute to a fine scientist, but is also a valuable review in its own right.

Data Fitting in the Chemical Sciences: P. GANS, Wiley, Chichester, 1992. Pages xii + 258. £29.95. ISBN 0-471-93412-7.

The full title of this book is *Data Fitting in the Chemical Sciences by the Method of Least Squares* and this conveys a much clearer picture of its contents than the shorter title which appears on the front cover. The earlier chapters contain a discussion of the application of the method of least squares to both linear and non-linear problems. I was impressed by the wide range of different least squares techniques described and with the thoroughness of their presentation. Model selection and testing are then considered. The later chapters illustrate the application of these ideas in fitting polynomials,

exponentials and various other functions to experimental data. A chapter on Fourier transform techniques is included and a rather specialised chapter on least squares interpretation of potentiometric titrations, a topic clearly dear to the author's heart, provides a conclusion.

The statistical theories which underpin the techniques discussed are presented, but in a rather unsystematic way: propagation of error formulas are given in Chapter 2 but the reader is referred to an Appendix for a derivation and the Central Limit Theorem makes only a fleeting appearance on page 107. Most readers are likely to apply the methods discussed by acquiring a computer program rather than by writing one but there is no guide to selection of suitable routines from the large number of program packages now commercially available. Crystallography, something of an adventure playground for the least squares specialist, gets only a passing mention.

I strongly recommend this book to research workers who already have some experience of least squares methods, possibly through use of an applications package, and who want a more detailed and wider understanding of what these methods can deliver. The complete novice and anyone with a dislike for matrix algebra should look elsewhere.

K. W. MUIR

High Performance Liquid Chromatography: Second Edition. S. LINDSAY, Wiley, Chichester, 1992. Pages xxii + 337. Softback £17.50, ISBN 0-471-93115-2. Hardback £39.93, ISBN 0-471-93180-2.

The appearance of the second edition of Sandie Lindsay's text is both timely and appropriate. As part of the Thames Polytechnic Analytical Chemistry by Open Learning (ACOL) series, this highly revised edition will be welcomed by students and practitioners of High Performance Liquid Chromatography. One particularly annoying fault in the first edition—and indeed in a number of first edition texts in the ACOL series—the lack of an index, has been rectified.

For those unfamiliar with the ACOL philosophy, it is "... a convenient and flexible way of studying for people who, for a variety of reasons, cannot use conventional education courses." At various stages in the text the reader is asked to answer questions, draw graphs or perform calculations. Self assessment questions (SAQs) are also included to enable the reader to establish whether or not he or she has understood what has been studied. The author's response to each SAQ is provided at the end of each chapter. Summaries, and lists of objectives respectively keep the reader abreast of important points covered, and of goals to be achieved.

The number of pages has been increased by almost one hundred over the first edition, and the number of chapters has doubled from five to ten. More important of course, is the new arrangement and content of these chapters. For example, "Columns" and "Detectors" now appear, rightly so, as independent chapter headings. Other new chapter headings are "Retention and peak dispersion", "Solvent delivery and sample injection", "The mobile phase", and "Method development". The tenth chapter is a short one on additional topics such as small bore columns, enantiomer separation, flash chromatography, preparative HPLC, SFC, and LC–MS.

Chapter 6 on "The mobile phase" is particularly useful in that it describes methods (sequential, predictive, iterative) of mobile phase optimization in ternary and quaternary systems. This is undoubtedly one aspect of HPLC which has progressed considerably since the first edition of this book was published, thanks to advances in computing, and its inclusion is not only valuable but essential. Indeed, the important contribution of microcomputers to HPLC is rather underplayed, here and in other sections of the book, for example when discussing photodiode array detectors. This, however, is a minor criticism.

The book is well written, is pitched at the correct level for its intended readership, is certainly good value for money, and can be thoroughly recommended.

(*Received* 1 *December* 1991. *Accepted* 25 *July* 1992)

The earliest successful amperometric gas sensor of modern design was the Clark electrode used for oxygen determination.[1,2] A detailed description of various types of Clark electrodes and their applications can also be found elsewhere.[3,4] While the analytical reactions for many toxic gases like SO_2, Cl_2, Br_2, NO_2 and HCN at solid electrodes has been known,[5] practical gas sensors were not constructed because there was no convenient way to package the electrodes and electrolytes for field or laboratory use.

A breakthrough came in the late 60s as the result of the development of fuel cell technology. The use of Teflon-bonded noble metal catalyzed gas-diffusing electrodes to constrain the aqueous electrolytes made modern amperometric gas sensors possible for a wide range of toxic gases. In addition, the use of a Pt/air reference electrode by Oswin in 1969[6] significantly simplified sensor design and led to practical field gas sensors for alcohol,[7] CO,[8–10] nitrogen oxides,[10,12] H_2S,[11] and SO_2[13] that were introduced in the 70s. A variety of two- and three-electrode amperometric gas sensors were introduced during the same period. For example, SO_2,[14] H_2CO,[15] ozone,[16] cyanide,[17,18] ammonia[19] and hydrazine[20–22] sensors have been addressed, as well as variations on these sensors.

A combination of the Teflon-bonded gas-diffusion electrode and a solid polymer electrolyte (SPE) membrane (*e.g.*, Nafion) was used to provide an alternative design for the amperometric gas sensor. Sensors for H_2,[23] CO[23–25] and nitrogen oxides[24,25] were introduced and, later, a sensor for O_2.[26] Recent studies of the electrochemistry of the SPE system indicate that CO_2[27] and alcohol[28] sensors are possible.

Amperometric gas sensors with non-aqueous electrolytes have been reported for Cl_2,[29] CH_4[30,31] and CO_2.[32,33] Commercial non-aqueous sensors have been available since the mid 70s. The amperometric gas sensor has seen widespread use in industrial hygiene and safety,[34] environmental and medical applications, and, recently, indoor air pollution studies.[35]

The amperometric gas sensor is often described in the literature using terms such as polarographic, electrolytic, voltammetric, amperometric, or micro-fuel cell. This use of diverse and sometimes inappropriate nomenclature confuses the method of sensor operation, the description of the sensor design, and the application. Most amperometric gas sensors are not polarographic because they do not contain a mercury electrode. Many are not electrolytic but rather are galvanic cells and none generate sufficient power to be called a fuel cell. The method most frequently employed in these gas sensors is "constant potential amperometry". Therefore, the term "amperometric gas sensor" is preferred and it can be modified by an appropriate adjective to yield a precise description of the method of operation of the electrochemical sensor. The name "amperometric gas sensor" will also distinguish the "current"

*Present address: Dow Chemical Company, Midland, MI 48640, U.S.A.

measurement from the "potential" measurement in potentiometric systems and "amperometric gas sensor" will be used throughout this discussion.

AMPEROMETRIC GAS SENSOR

An amperometric gas sensor is a device designed to measure the concentration of gaseous compounds. The gas sensor is an electrochemical cell and the detection of gases and vapors is performed either by electro-oxidation or electro-reduction of the compound at an electrode surface that is in contact with a liquid, solid polymer, or gel electrolyte. Typically, the sensing electrode is a noble metal catalyzed gas-diffusing electrode which is capable of keeping the electrolyte in the cell and yet is porous enough to allow the gas phase to diffuse to the electrode/electrolyte interface.

By choice of a suitable geometry for gas exposure and electrolyte confinement, materials for membranes, electrolytes, electrocatalysts, and useful operating conditions (*e.g.*, electrode potentials and sample flow rates), the sensor can be made quite sensitive for a particular gas component and quite insensitive to others.

A potentiostat is usually applied to provide a fixed or controlled potential for the sensing or working electrode relative to a reference electrode which is placed in the same electrolyte. In a three-electrode system the potentiostat is employed to energize and control the electrochemical cell as well as amplify the sensor's signal. The three-electrode configuration allows for precise operation even with microelectrodes. The reference electrode is used to maintain the sensing electrode at a known electrochemical potential and must be stable in the electrolyte of the sensor. The sensor is designed such that the magnitude of the current generated by the electrochemical reaction of the analyte is directly proportional to the analyte concentration in the gas stream being sampled. Some work has been performed using the cyclic voltammetric technique for gas detection, but the success of this approach for gas sensors is not well documented.[22]

In amperometric gas sensors, a sampling system, usually a pump or diffusion tube, is used to transport the reactive gas to the sensing electrode. A major problem often exists in obtaining a representative aliquot of the sampled environment so that the observed sensor current has analytical significance. It is not critical that efficient sampling take place; however, repeatable sampling is required to make the sensor signal a meaningful representation of the concentration.

A membrane is often employed to cover and protect the sensing (working) electrode. The membrane can also slow the diffusion of unwanted gases to the sensing electrode and decrease the flow rate dependence of signal magnitude. In a number of cases, the rate of mass transfer through the membrane is the main factor controlling the limiting current output of amperometric gas sensors.

The counter electrode completes the electrochemical cell by performing the half cell reaction, the nature of which is preferably in opposition to the sensing electrode reaction in order to minimize net chemical changes in sensors. Two electrode systems for O_2 and CO are common and in these sensors the counter (or auxiliary) electrode serves as both counter and reference electrode.

The electrolyte should be chosen carefully. It must carry the ionic current efficiently, solubilize the analyte effectively, support both counter and sensing electrode reactions, form a stable reference potential with the reference electrode, and be compatible with the materials of construction. Sensor signals are often observed to decay as electrolytes evaporate. Such instabilities often can be controlled by a judicious choice of the electrolyte and the operating conditions of the system.

SENSOR STRUCTURE

Figure 1 is a schematic diagram of an amperometric gas sensor system. The sensor may consist of six major parts (see Fig. 1); filter, membrane (or capillary), working or sensing electrode, electrolyte, counter electrode, and reference electrode. Each part of the sensor influences the overall performance and analytical characteristics of the sensor. Choosing appropriate materials for sensor construction and selecting an efficient sensor geometry is critical to sensor operation. The "minor" details of sensor design can have a profound influence on the accuracy, precision, response time, sensitivity, background current, noise, stability, lifetime and selectivity of the resulting sensor. Often the choice of optimum sensor materials and geometry for a given application are not obvious.

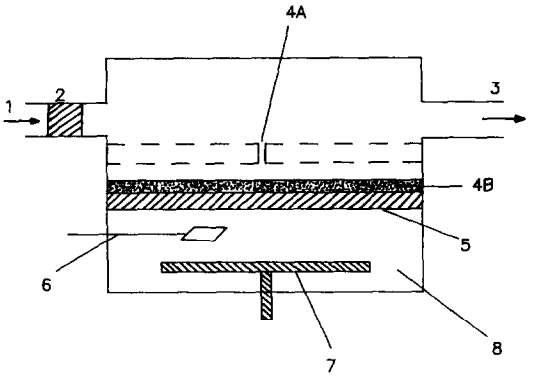

Fig. 1. Schematic diagram of the amperometric gas sensor system.

Definite relationships must exist among materials of construction, sensor geometry, specific electroanalytical method employed, and the performance characteristics of gas/vapor sensors. However, such relationships are still poorly defined. An adequate general model of the amperometric gas sensor does not exist and guidance in the design and application of these sensors is still very much an art.[36] Insight into the mechanism of the amperometric gas sensor, however, can be obtained by examining the reactivity of specific sensor systems.

Various types of amperometric sensor structures can be classified in different ways. The simplest way would be to classify them as two-electrode or three-electrode systems. However, such classification gives no insight into the nature of the sensing electrode and the main process controlling the magnitude of the sensor signal. In the following sections, sensor structures are classified according to the type of sensing electrode employed and the geometry of the gas-permeation path and the ion-conducting phase (electrolyte).

Membrane-covered planar electrode system (Clark sensor)

The Clark sensor is the most published and widely used membrane-covered planar electrode amperometric gas sensor. It usually works as a two-electrode system, although three-electrode configurations of the same sensor are also feasible.

The Clark sensor was first introduced to measure oxygen fugacity in medical applications. A schematic diagram of the Clark cell[1,2] is illustrated in Fig. 2. The container houses the electrolyte, the cathode, and anode. The external electrical circuit consists of a variable voltage source and a current meter to measure any current flowing between the two electrodes. A gas permeable membrane separates the electrolyte from the oxygen sample. When the cathode is made negative enough with respect to the anode (by adjusting the circuit), dissolved oxygen molecules at the cathode are electrochemically reduced and a current flows in the external circuit. The magnitude of this current is a measure of the concentration of oxygen in the sampled gas.

A practical illustration of a typical Clark sensor[37] is given in Fig. 3. The membrane fits closely over the end of the electrode, leaving a thin layer of electrolyte (typically 5 μm–15 μm thick) between the cathode surface and the membrane. Suitable membrane materials are polypropylene, polyethylene, Teflon, or Mylar. In general, polypropylene or polyethylene are the materials of choice, and the membrane thickness is typically 20–25 μm. Both plastic membrane materials are good electrical insulators and their permeability to oxygen is practically unchanged in the presence of water vapor.[38] This makes them ideal in medical applications where relative humidities may vary substantially from sample to sample.

The reference/counter electrode in the Clark sensor is most frequently a silver–silver chloride electrode and the electrolyte is typically a buffer solution with the addition of some sodium

chloride to stabilize the potential of the reference/counter electrode. The electrolyte can be a potassium chloride solution and, in industrial applications, glycol can be added to reduce the possibility of electrolyte freezing. Gelling agents (*e.g.*, methacrylate) can be added to enable convenient handling of the electrolytes. In medical applications, an electrolyte of pH = 7 is generally chosen[39] and the complete system is thermostated at 37° so that the blood–gas pO_2 measurements are made at normal body temperature.[40]

Gas-diffusion electrode gas sensor system

Gas-diffusing electrodes used in amperometric gas sensor systems are usually[7] of the semi-hydrophobic type. These electrodes are prepared by mixing Teflon emulsion with high surface area noble metal catalyst powder, and then depositing the slurry on a metal wire screen or on the surface of a totally hydrophobic porous Teflon film or a hydrophillic SPE membrane. The resulting gas-diffusing electrode consists of highly interlocked matrices of gas pores, electrolyte channels, electronically conducting paths and electrocatalytic surfaces. It is porous enough to effect efficient gas permeation, has sufficient metal catalyst to be a good electronic conductor, and is hydrophilic enough to make intimate contact with the electrolyte for ionic conduction and electrochemical reactions involving gases. Gas-diffusing electrodes are especially valuable in those cases when the kinetics of electrochemical reaction are very slow, such as the oxidation of hydrocarbons.

Free electrolyte sensor. Figure 4 illustrates the structure of a gas sensor that uses a Teflon-bonded gas-diffusion electrode.[31] The gas chamber that exposes the working electrode to the analyte stream allows easy pnuematic connections for the sample. For convenience, the working and counter/reference electrode are often positioned vertically and located at opposite ends of the electrolyte chamber. The vented gas exposure chamber for the counter and reference electrode insures a nearly constant reference potential, since the counter and reference electrode reactions may also involve the reaction or production of a gas, such as the evolution or reduction of oxygen. In other cases, metal/metal oxide (such as Pb/PbO) or metal/metal halide (such as Ag/AgCl) electrodes are used as counter and reference electrodes, and a gas-diffusing electrode is employed only as the sensing electrode. The primary reasons that the Pt/Air reference electrode is used in most industrial sensors are that: (1) it is a convenient size, (2) can be made rugged (no glass), and (3) its reference potential (about 1.0 V *vs.* NHE), even though not reversible, is stable (constant) enough to be used as a reference electrochemical voltage for the three-electrode sensor! The fully enclosed Pb/PbO_2 electrode may come close to these features but is consumed during operation and therefore, not catalytic.

One of the principal benefits of the free electrolyte sensor is the high buffering capacity of the electrolyte, which helps to keep the composition and pH value of the electrolyte

nearly constant over a long period of continuous operation. In addition, the position of the "three-phase boundaries" within the gas-diffusing electrode are more stable when the latter is in contact with the free electrolyte. However, localized changes at the sensing electrode (dehumidification, carbonization, pH change, *etc.*) may still occur in pores adjacent to the gas chamber. Carbonization of alkaline electrolyte is especially harmful since precipitation of crystallites of carbonates not only weaken the hydrophobic character of the electrode, but also form crystals that pierce it. Therefore, the long-term performance of sensors employing gas-diffusion electrodes is usually better when an acidic or neutral salt electrolyte is used.

Solid polymer electrolyte (SPE) sensors. A problem of the free electrolyte sensor is possible electrolyte leaks. Attempts to by-pass this situation include stabilization of the electrolyte in various porous matrices or gels. By far the most successful attempt seems to be the use of a solid polymer electrolyte (SPE) membrane for the electrolyte and the Nafion membrane is commonly employed for this purpose.[24,25,41]

Nafion is a copolymer of polytetrafluoroethylene (PTFE) and polysulfonylfluoride vinyl ether containing sulfonic acid groups. The sulfonic acid groups are chemically bound to the perfluorocarbon backbone as illustrated in Fig. 5(a).

The equivalent weight (EW) of an ion-exchange resin is defined as the weight of resin which neutralizes one equivalent of base. Ion exchangers are also characterized by their ion exchange capacity (IEC) and the IEC is given by the milli-equivalents (meq) of sulfonic acid/dry weight of membrane. The relationship between IEC and EW can be expressed as:

$$\text{IEC} = 1000/\text{EW}$$

Generally, IEC is determined by titration of the resin with base and measurement of the gravimetric weight. Upon exposure to water, the sulfuric acid groups are solvated, the mobility of proton is enhanced, and the Nafion becomes a good proton conductor, *i.e.*, an acidic electrolyte.

In the Nafion electrolyte sensor design, a thin Nafion solid polymer film is used both as the electrolyte and as a support for the electrode structure. The electrodes can consist of high surface area metal powder together with

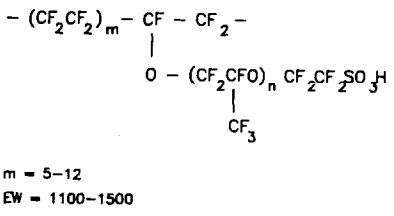

Fig. 5(a). Structural formula of Nafion (1000 series).

some form of current collector attached to the Nafion substrate using heat or chemical bonding techniques. The specific design [see Fig. 5(b)], construction, and performance of the Nafion system have been described in the literature.[24,25,41]

Apparently, a good contact between catalyst particles and the "solid" polymer membrane is vital to the performance of the electrode. The contact area could be improved either by impregnation of the catalyst layer with a Nafion solution,[42,43] or by *in-situ* formation of crystallites of a noble metal catalyst within the surface layer of the membrane.[44–46] The noble metal catalyst/Nafion membrane interface is chemically very stable, which seems to be the main reason for the long-term stability of some sensor designs employing a Nafion membrane. However, the water content of the membrane must be carefully controlled in order to avoid drowning or drying-out of the electrode-membrane assembly. Under- or over-humidification will not only influence the ionic conductivity of the SPE membrane, but also affect the coverage and thickness of liquid film on the surface of the catalyst, resulting in deterioration of the

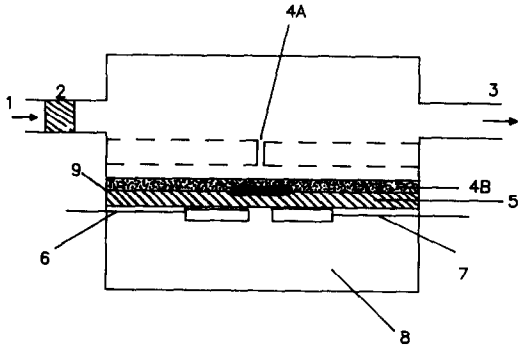

Fig. 5(b). Schematic diagram of sensor using a thin sheet of Nafion as the electrolyte.

analytical characteristics of the sensing electrode. Usually, a water reservoir, as shown in Fig. 5(b), can insure a constant humidification of the system.

BASIC OPERATING MECHANISM OF THE AMPEROMETRIC GAS SENSOR

General mechanism of electrochemical gas reactions

The response of an amperometric gas sensor can be described by the following eight steps in light of the Fig. 1 schematic:

1. Introduction of the gas or vapor phase compound to the sensor through the filter. [The filter can act to enhance the selectivity of the sensor system by removing unwanted electroactive contaminants and protect the sensing electrode from particulate contamination.]
2. Transfer of the reactant from the gas chamber to the back of the sensing electrode and diffusion to the gas/electrolyte interface. [Laminar flow characteristics dominate in gas chambers of typical geometries. There may be a membrane or capillary somewhere between the gas chamber and the electrode, and transfer across the membrane or capillary is usually characterized as a diffusion process.]
3. Dissolution of the electroactive species in the electrolyte. [Rate of mass transfer across the gas/liquid boundary and solubility of the gas in the electrolyte can affect sensor sensitivity and response time.]
4. Diffusion of the analyte to the electrode/electrolyte interface (in the liquid phase).
5. Adsorption onto the electrode surface.
6. Electrochemical reaction.
7. Desorption of the products
8. Diffusion of the products away from the reaction zone to the bulk of electrolyte or gas phase.

Any of these steps can be rate limiting, thus determining the ultimate response characteristics of the amperometric sensor. The parameters that most frequently influence the observed analytical characteristics of a sensor include: sample flow rate, working electrode composition, type and amount of electrolyte, membrane porosity and permeability, and the electrochemical potential of the sensing electrode. By controlling these parameters, the sensor engineer can often achieve the desired and/or optimum sensor response characteristics for a particular compound in a given situation.

Steps 5, 6 and 7 in the proposed mechanism are especially important since they involve the electrocatalytic phenomena. It is often appropriate to consider steps 5, 6 and 7 as a single but rather complex electrocatalytic event. The precise mechanism of the electrochemical process can be worked out by careful analysis of the transient and steady-state current response and the build-up of intermediate and final reaction products. The response of an electrode may also be complicated by electrode poisoning processes and/or auto-catalytic reactions (observed as a change of steady-state signal response time and magnitude).

In addition, the electrochemical reaction mechanism may change with sensor operating conditions. For example, at low analyte sampling rates, the sensor may electro-oxidize all of the available analyte and act as a coulometric device being limited by the supply of analyte. Conversely, at high analyte flows, diffusion through the electrolyte may limit response; and at low electrocatalytic activity, the rate of reaction at the electrode surface may limit the observed current (*i.e.*, signal). Before an appropriate model can be developed for the sensor, the nature of the rate-limiting step must be determined.

Theory of the limiting current: steady-state sensor response

It is usually preferable that a sensor works in the "limiting current region" in which the magnitude of the sensor signal is practically independent of the electrode potential. In theory, the limiting current region can be achieved in any case when the rate-limiting step is a step prior to electron transfer. In sensor design, diffusion-limited current operation is by far the most commonly employed for analytical applications in the field.

There are several possibilities for realization of diffusion limited current. First, the rate of electrode reaction may be limited by the rate of diffusion through a membrane or a capillary which is placed somewhere between the gas stream containing the analyte and the catalyst layer of the electrode. The limiting current, i_{lim}, (not current density), according to equation (1), can be written as

$$i_{lim} = \frac{nFD_s AC_s^0}{\delta} \tag{1}$$

where n is the number of electrons involved in the electrochemical reaction per molecule of the

diffusing species, F is the value of the Faraday, A is the effective area of the membrane or the cross section of the capillary, and δ is the thickness of the membrane or the length of the capillary. The diffusion constant also represents the gaseous diffusion constant for s in the medium of the membrane or capillary.

Second, the current can be limited by the rate of diffusion across the diffusion layer in solution. An expression similar to equation (1) can be used to calculate the current. However, in this case A in equation (1) is the effective surface area of the electrode, D_s is for diffusion of s in solution, and δ is the thickness of the diffusion layer in solution at the electrode surface (this is the typical interpretation of Fick's equation in polarography).

There are other ways to realize a potential independent limiting current which is not governed by the diffusion process. The current may be limited by transport to the sensor from the outside world. In this case, 100% of the electroactive species that enters the gas sensor reacts and the limiting current is related to the sample in a "coulometric" way. This method of sensor operation has been used successfully to determine the electrochemical characteristics for several gas sensor reactions.[9,47,48]

If the rates of diffusion processes are much faster than the rate of reaction at the electrode surface, then the current is controlled by the rate of the electrode kinetics. In this case an expression for the current will take the form

$$i = nFKA[P]^n[Q]^m \exp(\alpha nF/RT\eta) \qquad (2)$$

where K represents the standard rate constant, n and m represent the order of the reaction for concentration of reactants P and Q respectively, α and η are the transfer coefficient and overvoltage of the electrode reaction. This behavior has been observed for an NO_2 gas sensor with a very low surface area electrode[49] in acid electrolyte.

Theoretically, the above model has several interesting consequences. If the kinetics of transport of reactant to the electrode surface (up to step 5) are significantly slower than all other steps, the limiting current should be potential independent. Conversely, a strong potential dependence should be observed for sensors wherein the electrocatalytic reaction limits the observed current and this "electrode-reaction" limited sensor should produce limiting currents that are independent of external events such as analyte flow rate. These predictions have been recently confirmed for the electrochemical reaction on NO_2 at a gold electrode in acid electrolyte.[41]

To appreciate the differences in the limiting current mechanisms, it is useful to discuss specific sensors and several are presented in the following sections.

The Clark cell (oxygen sensor)

The Clark oxygen gas sensor is probably the most widely used, most thoroughly studied, and best characterized of the amperometric gas sensors. Figure 6 represents the one-dimensional model, showing the transport of oxygen from the sample (concentration C_s) to the cathode surface of a Clark sensor. Assuming an even distribution of current density at the electrode surface, it is easy to prove that the steady-state limiting diffusion current density at the cathode of the Clark sensor can be expressed as

$$I_{lim} = (1/I_{lim(m)} + 1/I_{lim(l)})^{-1} \qquad (3)$$

where $I_{lim(m)}$ and $I_{lim(l)}$ represent the limiting diffusion current densities across the membrane (m) and thin electrolyte film (l) respectively:

$$I_{lim(m)} = \frac{nFD_m C_m}{\delta_m} \qquad (4)$$

$$I_{lim(m)} = \frac{nFD_l C_l}{\delta_l} \qquad (5)$$

where δ_m and δ_l represent the thicknesses of membrane and electrolyte layer respectively, and subscripts "m" and "l" are used to denote parameters D and C in different layers.

I_{lim} in equation (3) may be predominantly determined by either $I_{lim(m)}$ or $I_{lim(l)}$ if one of them is significantly smaller than the other. In most sensor designs found in industrial applications,

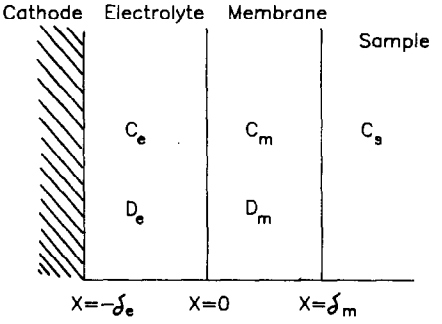

Fig. 6. The one-dimensional diffusion model, showing the transport of oxygen from the sample (concentration C_s) to the cathode surface, where it is electrochemically reduced.

the rate of mass transport across the membrane is the limiting factor, and $I_{lim(l)} > I_{lim(m)}$.

Mancy *et al.*[50] have provided a comprehensive solution for the E *vs.* t behavior of this sensor by solving the transient form of Fick's law of diffusion for the system shown in Fig. 6. The main conclusions of their work can be summarized as follows.

Within a very short time interval after the start of polarization, diffusion in the electrolyte layer alone is rate limiting and the current density at the cathode is given as:

$$I = nF\frac{K_b}{K_o}C_s\left(\frac{D_e}{\pi t}\right)^{1/2} \times\left[1+2\sum_{n=1}^{\infty}\exp\left(\frac{-n^2\delta_l^2}{D_e t}\right)\right] \quad (6)$$

where K_o is the distribution coefficient for the electrolyte-membrane interface, and K_b is the distribution coefficient for the sample-membrane interface.

Since typically δ_l is about 10 μm and D_e is 0.1 m^2/sec, equation (6) will only hold for $t < 0.1$ sec, since the diffusion layer must be confined to the electrolyte film. In this short initial time interval ($t < 0.1$ sec) the exponential terms in equation (6) can be neglected, so we have

$$I \cong nF\left(\frac{K_b}{K_o}\right)C_s\left(\frac{D_e}{\pi t}\right)^{1/2} \quad (7)$$

After that short initial time interval, the diffusion layer enters the membrane and, if we assume $\delta_m/\sqrt{D_m} \gg \delta_e/\sqrt{D_e}$, the rate of mass transfer within the membrane will soon turn out to be the predominant rate limiting step and the current density equation becomes

$$I = nFK_bC_s\left(\frac{D_m}{\pi T}\right)^{1/2} \times\left[1+2\sum_{n=1}^{\infty}\exp\left(\frac{-N^2\delta_m^2}{D_e t}\right)\right]^{1/2} \quad (8)$$

This equation can be reduced to a simpler form by noting that typical values for δ_m and D_m are <20 μm and 10^{-3} m^2/sec, respectively. Thus, for $t < 10$ sec,

$$I = nFK_bC_s\left(\frac{D_m}{\pi t}\right)^{1/2} \quad (9)$$

Because, in both cases, it is diffusion transport alone which controls the magnitude of the observed current density, equations (9) and (7) are similar.

At longer time intervals, the diffusion layer will spread into the membrane layer, approaching the outer face of the membrane. Under these conditions, the current density is given by

$$I = nFK_bC_s\frac{D_m}{\delta_m} \times\left[1+2\sum_{n=1}^{\infty}\exp\left(-\frac{n^2\pi^2D_m t}{\delta_m 2}\right)\right] \quad (10)$$

After 20 or 30 sec, the exponential term becomes negligible and equation (10) reduces to steady-state current density:

$$I = \frac{nFK_bC_sD_m}{\delta_m} \quad (11)$$

which is the same ($c_m = K_bC_s$) as equation (4) since only transport in the membrane is of importance.

Other investigators have developed models to explain the precise shape of the i *vs.* E behavior of the Clark oxygen gas sensor. Mochizuki[51] developed a much simplified one-dimensional model which included a reaction rate term to describe the destruction of oxygen at the cathode surface. Hahn[52] further developed this model to include not only one-dimensional but spherical and cylindrical coordinate steady-state geometries. Using this approach, Hahn was able to produce oxygen concentration profiles in the electrolyte and membrane layers as well as at the cathode surface at various polarizing voltages. A complete representation of the theroetical i *vs.* E behavior was obtained in this manner and compared well with experimental observations.

However, the basic assumption of the one-dimensional model, *i.e.*, uniform distribution of current density at the surface of the sensing electrode, could hardly be totally realized at Clark electrodes of practical size. If the diameter of the electrode exceeds 1–2 mm, lateral ionic conduction through the thin electrolyte film and removal of reaction products from the central part of the electrode would be difficult, so the current density near the center of the electrode could be lower. On the other hand, for very small electrodes, the "edge effect" can enhance the rate of mass transfer at the periphery of the electrode. Limiting current density at an electrode with a radius smaller than 100 μm can be significantly higher than that predicted by the one-dimensional model.[53–55]

Sensors using gas-diffusion electrodes

Analysis of the polarization behavior of gas-diffusion electrodes has been performed.[56,57] When a diffusion barrier (membrane or capil-

lary) is placed somewhere between the gas stream and the catalytic layer of the gas-diffusion electrode, potential independent limiting current may appear if the kinetics of the electrochemical reaction are much faster than the rate of mass-transfer through the diffusion barrier. Such a diffusion barrier can make amperometric sensors more stable. If the reaction is fast over a range of potentials, no potential control is required in the gas sensor. A simple two-electrode system provides adequate analytical performance because, even though the thermodynamic potential can drift during sensing, no change in the analytical signal (the steady-state current) is observed. When the electrode reaction is slow, the potential of the sensing electrode must be precisely controlled (as in the three-electrode system) to avoid drift in the sensor current.

The gas-diffusion electrode can be an efficient electrochemical device and, often consumes a significant portion of the gaseous reactant by Faradaic reaction. When this condition exists, the magnitude of the sensor's signal will vary with the flow-rate (or input) of the gas stream. Sedlak and Blurton[9] studied the limiting current in a three-electrode amperometric gas sensor by measuring the flow rate dependence of the sensor signal for carbon monoxide at various concentrations. They reported an empirical analysis of these data that included consideration of both the mass transfer and electrochemical processes occurring in the gas sensor. The overall mass transfer equation for the electrochemical reaction in the sensor was given as:

$$\frac{dc}{dt} = -V\left(\frac{dc}{dx}\right) - k\int\frac{\delta c}{\delta t}\,dt \qquad (12)$$

where c denotes the concentration of reactant, V represents the linear velocity of the gas stream, and k is the overall rate constant for transfer of reactant to the catalytic electrode. The first term on the right hand side of equation (12) refers to the convectional transport of the gaseous analyte and the second term refers to ("unsteady-state") mass transfer of gaseous reactant through the electrode and membrane structure. The solution to this differential equation for a gas path geometry as defined in Fig. 7 is given

$$c(x,t) = c^{\circ}[1-\exp(-\lambda t)] \times \exp[(\lambda - k)whx/G] \qquad (13)$$

where c° denotes the initial concentration of the reactant, λ is a time constant arising from

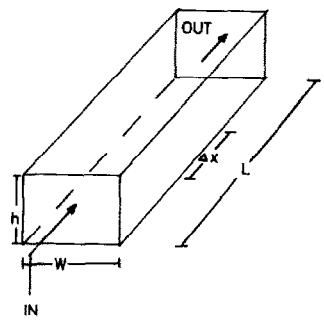

Fig. 7. Schematic of gas pathway in sensor. The gas-diffusion electrode is placed at downside of the box.

solution of the continuity equation, and G is the volumetric gas flow-rate ($G = whV$).

Faraday's law must apply to the sensor current (if no gas losses or side reactions are assumed to occur in the sensor and the effect of build-up of concentration in the gas chamber can be ignored), then the observed current, i, is

$$i(t) = -(nFG/V)[C(L,t) - C(0,t)]$$

and

$$i(t) = (nFC^{\circ}F/V)[1-\exp(\lambda - t) \times (1-\exp[(\lambda - k)whL/G])] \qquad (14)$$

The steady state value of i is attained at sufficiently large values of $\lambda\, t$:

$$i = (nFC^{\circ}G/V) \times (1-\exp[(\lambda - k)whL/G]) \qquad (15)$$

Equations (14) and (15) were sufficient to describe the experimental data that they reported but the physical significance of the constants is not entirely clear. This approach does not offer a plausible mechanism of response. Critical examination of these data can be revealing.

Figure 8 (curve a) shows a response time curve for 48 ppm CO using a flow rate of 700 cm^3/min. As predicted by equation (15), the sensor signal increases with time to a steady-state value at large values of t. Figure 8 (curve b) shows the current decay with time after the CO analyte flow through the sensor had ceased. The rapid return of the current to zero supports the assumption used in the derivation of equation (16) that all the CO migrating through the porous electrode is electro-oxidized. Curve (c) illustrates the data for a curve plotted in the form $-\log(1 - i/i_{lim})$ *vs.* t. The slope of this plot equals λ. The values calculated from these data gave $\lambda = 0.18 \pm 0.02$ sec^{-1} for $300 < G < 1500$ cm^3/min. Similar semi-logarithmic plots were obtained with the current decay results and they

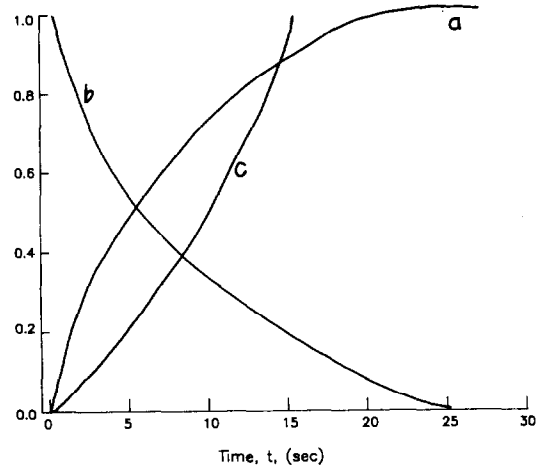

Fig. 8. Sensor response characteristics: (a) I/Ilim vs t(sec) for signal rise; (b) I/Ilim vs t (sec) for signal decay; (c) $-\log(1 - I/Ilim)$ vs t (sec) for signal rise. Ilim: limiting current.

gave a value of $\lambda = 0.16 \pm 0.02\ \text{sec}^{-1}$ in the same flow-rate range. Thus, the time constants for rise and decay of the sensor signal are essentially equal and are independent of flow rate supporting the first order response model for the transient current.

Sedlak and Blurton[10] also measured current *vs.* flow rate behavior for 39 ppm NO and compared the current to the theoretically predicted values (if 100% oxidation of analyte in the electrode is assumed for all flow rates). It follows from equation (15) that, as $G \to 0$,

$$\lim(i/G) = nFC^{\circ}/V \qquad (16)$$

Thus, as the flow rate is decreased, a point is reached at which all of the NO entering the sensor reacts. Therefore, current measurements at very low flow rates permit calculation (or estimation) of C° at known n or n at known C° (concentration). Notice that equation (16) describes the analyzer current only when oxidation or reduction of the sample gas is obtained with "perfect" Faradaic efficiency. This method has been used to determine "n" for several gaseous reactions[10,21] using an amperometric gas sensor.

At the typical flow rates used in the amperometric gas sensor, coulometric reaction efficiency is rarely achieved and sometimes as little as 2% of the gas is reacted during its passage through the gas sensor. However, the fraction of analyte reacted in the sensor is always constant as long as conditions (*e.g.*, flowrate, geometry, potential, *etc.*) are held constant. One need not achieve quantitative reaction to use the sensor as a quantitative analytical tool. However, suitable calibration of the steady-state current must be performed regularly, since the performance of the gas-diffusion electrode can change gradually with time. These changes may be due to losses in electrocatalyst activity, electrolyte concentration changes or contamination, or even clogging of the pores of the gas porous diffusion membrane.

For many gas sensor designs, it is reasonable to assume that all of the analyte entering the electrolyte is consumed with Faradaic efficiency and the current is limited by mass transport of gas across the membrane separating the gas sample chamber and the electrode/electrolyte interface. This was confirmed by several studies of CO, NO_2, and hydrazine reactions and the "coulometric" characteristics of the "steady-state" current was observed during sensor operation.[21,47,48]

Equation (16) can also be used to describe the mass transport limited response of the solid polymer electrolyte sensor. However, if the surface reaction of analyte is slow or the effective surface area of the electrode is small, then the response of the electrochemical sensor will be limited by the rate of the electrocatalytic (electrode) reaction and the observed limiting current will be proportional to the surface area of the electrode. In this case, equation (16) will be inadequate to describe the flowrate *vs.* i and i *vs.* concentration behavior of the sensor.

Low surface area Au electrodes have been examined for an NO_2 reduction reaction.[49] The limiting currents were compared to a high surface area Au electrode. The i *vs.* E behavior was different for these two different surface area sensing electrodes. The results illustrated that the observed current is limited by diffusion to the high surface area electrode. At the low surface area electrode, the observed current is dependent upon the rate of the electrochemical reaction at the electrocatalyst surface, and in this case:

$$i_{\text{lim}} = K[NO_2][O_2][A] \qquad (17)$$

where A is the surface area of the catalyst. Equation (17) is a typical expression of the kinetics of a chemical reaction and K is the Arrhenius constant and contains the temperature dependence of the reaction.

Concluding remarks on limiting currents and sensor models

An accurate model of sensor response should include the ability to describe all of the obser-

vations in all regions of sensor performance. Such a model does not yet exist. However, it is clear that the signal (time dependent and steady-state parts) of any gas sensor is limited by either Fickian diffusion, membrane mass transport (permeation and/or diffusion), or the kinetics of the electrocatalytic process. Each of these can be viewed as a "resistance" to current passage that must be overcome to generate the observed sensor signal. The controlling resistance for the system can then be expressed as follows:

$$1/R(\mathrm{s}) = 1/R(\mathrm{d}) + 1/R(\mathrm{m}) + 1/R(\mathrm{k}) \quad (18)$$

where $R(\mathrm{s})$ represents the system resistance, $R(\mathrm{d})$ is diffusion resistance, $R(\mathrm{m})$ is membrane (electrolyte solubility and mass-transport) resistance, and $R(\mathrm{k})$ is the resistance of the electrocatalytic reaction.

Equation (18) allows for any of the processes to be dominant and ultimately control the rate of the reaction in the sensor. Each of these terms may be expressed in terms of the parameters previously described for the sensor current.

Usually, all the $R(\mathrm{d})$, $R(\mathrm{m})$ and $R(\mathrm{k})$ terms are inversely proportional to the concentration of reactant C°, so the reciprocal of the resultant resistance $R(\mathrm{s})^{-1}$ is directly proportional to C°. Therefore, linear response to the concentration of reactant could be realized regardless of whether the kinetics of the electrode process is controlled by a single step or controlled simultaneously by several steps. However, it would be much easier to design and predict the sensor response under various circumstances if the kinetics of the sensing electrode is governed by a single step, wherein the rate of that step is independent of the electrode potential.

APPLICATIONS AND EXAMPLES OF AMPEROMETRIC GAS SENSORS

Amperometric gas sensors have been used to design instruments for chemical detection, and a wide variety of both portable and fixed-site toxic gas monitors are now commercially available. These instruments have found applications in monitoring industrial atmospheres, medical gases, compressed air lines, process streams, and pipe line gas. Gas chromatographic instrumentation, ventilation controllers, energy management systems, environmental pollutant control equipment, chemical research instrumentation, and analytical laboratory gas analyzers also utilize amperometric gas sensors. The sensors are found everywhere from space shuttles to the rim of volcanoes.

The practical capabilities of some present day industrial electrochemical gas sensors are summarized in Table 1. The first sensors were developed for the more common atmospheric pollutants namely CO, NO, NO_2, H_2S and SO_2. Sensors have also been developed for some special cases such as the hydrazines,[20,21] Cl_2,[29] CH_4,[30] O_3[16] and alcohol,[7] and, of course, the medical application for the detection and measurement of N_2O,[33,58,59] O_2, CO_2[32] and $CHClBrCF_3$.[33] Table 2 lists several classes of compounds which have been analyzed in real-time using commercially available electrochemical sensors and associated instrumentation.

Commercial instrumentation with ppm-level sensitivity has already been developed for the detection and measurement of CO, NO, H_2S, SO_2, O_2, N_2H_4, $(CH_3)N_2H_2$ and $(CH_3)2N_2H_2$. Other candidates for analysis by amperometric gas sensors (many of which have been performed) include all electrochemically active compounds like acetylene, alcohols, aldehydes (acetone), phosphine, arsine and phosgene. These compounds are often encountered as interferences on present day commercial instruments.

The application of amperometric sensors has been extended to compounds (like benzene, methane, pyridine, and trichloroethylene) electrochemically inactive at the potentials traditionally used in gas sensors.[50] Thus, the ultimate applications are only limited by the imagination of the analyst. However, the analytical characteristics of each individual sensor will determine the ultimate success of the specific application. Analysis for selected compounds has been extended into the ppb range.[10,11,29,35,41,49,60]

Examples of the electrochemical reactions that are used as the basis for analyzing gases in amperometric sensors are given in Table 3. Reactions for NO_2, N_2O, CO_2 and O_2 analyses

Table 1. Exemplary capabilities of electrochemical detectors

Detection principle	Gas/vapor measured	Approximate detection level (ppm)	Ref.
Constant potential Amperometry	CO	1–3000	8
	NO	1–100	61
	NO_2	1–500	60
	H_2S	1–5000	14
	SO_2	1–100	15
	Cl_2	0.1–50	29
	MMH	0.1–500	20, 21

Table 2. Classes of gaseous compounds analyzed amperometrically

1	Hydrocarbons and carbon/oxygen compounds	CO, CO_2, C_2H_4, C_2H_5OH, EtO
2	Oxides of nitrogen	NO, NO_2, N_2O
3	Sulfur compounds	H_2S, CH_3SH, C_2H_5SH, SO_2
4	Reduced nitrogen	NH_3, N_2H_4, $(CH_3)N_2H_3$, $(CH_3)_2N_2H_2$
5	Other	O_2, H_2, Cl_2, O_3, PH_3, As_3, HCN, $CHClBrCF_3$

are electrochemical reductions while the other examples utilize electro-oxidation to produce the analytical signal. The complementary reaction at the counter electrode with oxidation at the working electrode is typically oxygen reduction:

$$O_2 + 4H^+ 4e^- = 2H_2O$$

while the reverse reaction may occur at the counter electrode during reduction reactions of analyte at the sensing electrode. The cell reactions and specific mechanism are not well defined for all sensor systems and this is an area that requires study in the future.

ANALYTICAL CHARACTERISTICS OF SPECIFIC SENSOR SYSTEMS

The amperometric sensor requires only small amounts of power and is relatively small. This makes it ideal for portable and fixed-site analyzer applications. The four characteristics that limit the successful application of the amperometric gas sensor technology are: (1) stability of the electrochemical system with time and with environmental fluctuations, (2) the response time, (3) the specificity or selectivity (*i.e.*, degree to which one reaction occurs relative to the others which occur in the same sensor), and (4) the lower detection limit [*i.e.*, signal to noise (S/N) and/or signal to background (S/BKG) ratio]. The following discussion addresses the relationship between the desired analytical characteristics and sensor design as well as suggesting ways that have been used to overcome sensor limitations. The response time of the sensor has been discussed in previous sections.

Lower detection limit

The lower detectable limit for a particular gaseous compound is related to several factors including mass transport of the compound within the detection system, electrocatalytic activity (the catalyst material, form, and potential of operation), Faradaic equivalents per mole transferred during reaction, analyte solubility and mobility in the electrolyte, the physical geometry of the sensor, and the "method" of operation (including semipermeable membranes or filters). It is the optimization of these parameters which leads to the maximum S/N for a given analytical system.

Sensitivity is typically not limited by the Faradaic or electrocatalytic signal. For example, using Faraday's law [equation (16)], the current achieved (*i.e.*, sensitivity) by reacting a one ppm CO/air mixture at 1% efficiency in a

Table 3. Examples of amperometric gas sensor reactions

Gas analyzed	Electrochemical reaction proposed	Electrocatalyst	Ref.
NO_2	$NO_2 + 2H^+ + 2e = NO + H_2O$	Au	60
CO	$CO + H_2O = CO_2 + 2H^+ + 2e$	Pt	8
H_2	$8\ H_2 + 4H_2O = 8\ O_4^{2-} + 10H^+ + 8e$	Au	14
MMH	$(CH_3)N_2H_3 + 4OH^- = CH_3OH + N_2 + 3H_2O + 4e$	Au	21
NO	$NO + 2H_2O = NO_3^{2-} + 4H^+ + 3e$	Au	61
O_2	$1/2\ O_2 + 2H^+ + 2e = H_2O$	Au, Ag, Pt	62, 63
CO_2	$CO_2 + H_2O + 2e = HCOO^- + O - H^-$	Ag	32, 33
N_2O	$N_2O + H_2O + 2e = N_2 + 2OH^-$	Ag,Pt	33, 59

gas stream of 600 cm^3/sec would be *ca* 1 μA. Clearly, a current of 1 μA can be easily measured with existing electronic capabilities. However, the background current and fluctuations thereof cause most sensors to have a detection limit in the low ppm range. Thus, the practical lower detection limit for most sensors is the relatively large magnitude of the background and noise current and not the size of the signal.

The possible causes of background current in amperometric gas sensors can include:

1. impurities in the electrolyte such as traces of dissolved oxygen, and/or slow oxidation or reduction of solvent at the sensing electrode, such as the slow evolution of hydrogen or oxygen from an aqueous solution,
2. corrosion of the electrode, such as the slow growth of the oxide layer on the surface of a noble or passivated metal electrode catalyst in the anodic potential range, and
3. diffusion of the reactant or reaction products from the counter electrode, such as the diffusion of dissolved peroxide toward the sensing electrode from an oxygen-reducing counter electrode.

Lower detection limits for current amperometric gas sensors has been extended to ppb levels for certain analytes like NO_2,[10,35,41,49,60] Cl_2,[29] and H_2S.[11]

Selectivity

Typically, ppm levels are easily analyzed by an amperometric gas sensor. Interferences can be generally kept to an acceptable level either by selecting the proper electrocatalytic conditions or by using a selective adsorbent in the instrument inlet to remove undesirable electrochemically active contamination. The selectivity of amperometric gas sensors can be improved by careful manipulation of thermodynamic and/or kinetic reaction parameters. Examples have been discussed[8,11] and a brief example is offered here. Carbon monoxide oxidation occurs on a platinum electrocatalyst at 0.9–1.5 volts *vs.* NHE. However, the CO reaction proceeds 100 to 1000 times slower on a gold electrocatalyst. On the contrary, H_2S reactivity is high for both Au and Pt electrocatalysts. Thus, H_2S can be monitored even in the presence of CO by using a gold electrocatalyst. This is an example of kinetic selectivity. The NO oxidation reaction on gold does not occur at potentials below about 1.0 volt *vs.* NHE, but NO_2 can be reduced at potentials about 0.8 volts *vs.* NHE. Thus, NO_2 can be detected even in the presence of NO using a gold electrocatalyst operated at 0.8 volts *vs.* NHE. This is an example of thermodynamic selectivity with the constant potential amperometric gas sensor. Favorable kinetics or thermodynamics are the only two sources of inherent sensor selectivity. All methods of achieving selectivity can be put into these categories except those involving external devices (*e.g.*, pre-filtration or pre-treatment of the gaseous analyte prior to sensor entry).

Precision and accuracy

The accuracy of amperometric gas sensors is typically limited by the preparation of standards while the precision is a function of the operating conditions, the concentration of analyte, and the care taken by the operator.

In field monitoring situations there is often no opportunity for repeat readings and, indeed, the sensor must often operate unattended gathering data over a long period of time. Instrument precision must be known in order to quantify the analyte and assess the reliability of each independent measurement. The precision of amperometric gas sensors for a variety of gases has been evaluated and for signals that are 10–100 times larger than the background current, precision is typically within 1% of the signal.[7,11,20]

The accuracy of an individual datum point is often limited by the ability to calibrate the instrument. Calibration is achieved when an unambiguous relationship between the instrument signal and the actual gas concentration is established. For an electrochemical sensor system we may assume that the response *vs.* concentration function is linear (if the sensor materials and geometry are properly chosen) over about two orders of magnitude. Typical least squares representations of signal *vs.* concentration data produce nearly ideal slopes and intercepts with correlation coefficients of near unity.[55,64]

The range of linear response of the sensor varies with the particular gas or vapor being monitored. In most cases linear response is observed in the low ppm range and may extend to as high as 5000 and 10,000 ppm. For example, the linear response of a hydrogen sulfide sensor was evaluated[11] in the concentration range 0–0.277 ppm and 0–153 ppm and the signal is directly proportional to the H_2S concentration.

Often determinations of linearity are limited by the ability to synthesize an accurate calibration for gas mixtures. For highly reactive gas mixtures such as hydrazine, it is difficult to prepare an accurate gas mixture even under ideal laboratory conditions. NBS gas standards are available with an accuracy certified as $\pm 2\%$ for certain mixtures such as CO/air.

In conclusion, the accuracy, precision, and typical linear response of the amperometric gas sensor system is very important because it makes the following possible:

1. reliable and accurate instrument calibration with only a single datum point, *i.e.*, only one standard gas sample is necessary making field use simple,
2. simplified electronic design to measure, amplify, record, manipulate, and report (display) the output signal, and
3. simple additivity of responses when used in a sensor array where one records responses to various compounds and simple mixtures of compounds.

Stability

The stability of an amperometric gas sensor relates to its ability to retain its original response characteristics over long time intervals and under changing environmental conditions. Stability is generally divided into short-term fluctuations and long-term fluctuations. The stability for certain sensors has been reported.[10,11,20,21]

The causes of zero drift (*i.e.*, drift in background current) and span drift (*i.e.*, fluctuations in signal magnitude or changes in the steady-state current) are not well characterized. It is known that drift can be caused by temperature fluctuations, sensor operation at extreme relative humidities over long time periods (under or over-humidification of the membrane or the gas-diffusion electrode), catalyst degeneration or fouling, and electrolyte contamination. Besides, if the counter electrode reaction consumes an electroactive substance of limited supply (such as the metal/metal oxide electrode), the lifetime of the sensor will be limited and extreme drift can be observed near the end of the sensor life. Even the input current of an operational amplifier can exhaust the capacity of a small size reference electrode after long term continuous operation.[65] In spite of such problems, amperometric sensors may last many years in demanding industrial environments and retain good analytical performance.

RECENT ADVANCES AND FUTURE POSSIBILITIES

It is inevitable that advanced amperometric gas sensors will be designed which provide improvements in practical detection limits, stability, and selectivity as well as in the total number of compounds which can be measured.[62] The improvements will be a result of an extension of our knowledge about these sensors as well as improvements in the materials, geometries, and electroanalytical methods that become known and used.

Electrochemical sensor arrays

Amperometric gas sensors respond to a limited number of compounds and each one responds with its own characteristic selectivity. One way to overcome these limitations and improve the sensor's versatility and selectivity is to construct sensor arrays made from sensors with the most orthogonal response possible.[66,67]

Information is created in a sensor by its reaction to a chemical stimulus. This reaction of the sensor to the type of chemical and its concentration creates an analytical signal that is transduced into an electronic signal by the sensor. More specifically, if chemicals are to be identified on the basis of their relative electrochemical reactivities, then the sensor array must be designed so that the information necessary to accomplish this task is generated. It must contain sensors that record a different electrochemical response for each chemical species. Thus, to achieve the most effective array for a given problem, the sensor array and the analytical problem must be considered together.

A sensor array consisting of four electrochemical sensors and two hot wire filaments has been evaluated.[68–70] The array was constructed to both identify and quantify a toxic chemical vapor in a few minutes using a portable, battery-operated, lightweight instrument. The electrochemical sensors are combined with a heterogeneous catalyst (which transforms non-electroactive compounds into electroactive fragments) that allows the electrochemical sensors to respond to a very broad range of chemicals. The four electrochemical sensors were chosen to have two working electrodes of Au and two of Pt. One Au and one Pt electrode are operated at anodic potentials to facilitate oxidations and one of each catalyst are operated at cathodic potentials to facilitate reductions. By comparing the signals from the sensors in the array, one can tell whether the sample contains electro-

oxidizable or electro-reducible constituents. The size of the signal is related to the analytes electrokinetic processes, pyrolysis kinetics in the filament reactor, and the analyte concentration. Thus, the signals from these sensors provide a set of chemical parameters related to the vapor's catalytic and electrocatalytic properties. Hence, the term "chemical parameter spectrometry" or CPS was chosen to describe this technique. The term "pyrolysis amperometry" has also been used[71] in connection with the detection of gases and vapors by this technique, however, "catalytic oxidation" followed by amperometric detection of the products is actually occurring.

It is possible to "tune" the array for sensitivity to specific reagents by choosing appropriate sensors and useful operating conditions. The technique of utilizing sensor arrays is effective when coupled with computer data acquisition and algorithms for data analysis[72] (*e.g.*, pattern recognition methods). Multivariate statistical methods can be used to evaluate how well the array can identify compounds and suggest improved approaches as well as be an operational tool for field instrumentation. Recent sensor arrays have been combined with neural networks to simulate an artificial nose.[73]

Coulometry

Amperometric gas sensors produce data that can be interpreted coulometrically. The theory and method of a "dynamic" coulometric technique using amperometric gas sensors has been discussed.[47,48] It can take several forms, but usually uses two amperometric gas sensors (a and b) with sample chambers connected in series with a means for reversing the direction of gas flow through the sensors. By measuring the steady-state (currents) signals from both sensor electrodes with the gas flow first in a forward and then in a reverse direction, the absolute concentration of the reactant species can be calculated by using the following equation:

$$X_{af} = CI_{af}I_{br}(I_{af} + I_{bf})/(I_{af}I_{br} - I_{ar}I_{bf}) \quad (19)$$

where $C = RT/nFPV$ and the subscripts f and r refer to the forward and reverse flow directions, I is the measured current, P is the sample pressure, V is the volumetric flowrate, and X_{af} is the concentration of species X entering sensor "a" in the forward direction, and so forth.

The technique assumes 100% Faradaic efficiency for all analyte arriving at the sensing electrode and proportionality of the current signals to the reactant concentration for both sensors, *i.e.*, linear sensor response *vs.* concentration. This method is a fast and simple way to use the gas sensor to determine the concentration in an unknown sample gas. Since the concentration is determined from a coulometric calculation, it eliminates the need for a reference gas standard and can serve as a primary method of measurement of concentration for unknown gas samples. The method can be applied in modified form to the analysis of various electrochemically active species in electrolyte solutions.

Future possibilities

The continuing publications concerning chemical sensors and in particular, amperometric sensors[74–76] underscore the continuing importance of this electroanalytical approach in the fabrication of practical gas sensors. Advanced amperometric gas and vapor monitors will be designed which incorporate improvements in present practical detection limits as well as in the total number of compounds which can be measured.[62] The field of sensors is interdisciplinary and future advances are likely to occur by combinations of advanced technologies in other fields with the known useful electrochemistries.

Microelectronics has produced a variety of physical and chemical sensors but only very few can be considered amperometric and these structures usually do not contain the electrolyte. Most microsensors are potentiometric and the more common amperometric gas sensors (*e.g.*, CO, H_2S, NO, NO_2, *etc.*) have not yet been microfabricated. It is believed that microelectronic fabrication techniques are well suited for the production of amperometric gas sensors. The need for a geometrically well-defined sensing electrode surface area is well-recognized. Photolithographic reduction and other mask making techniques can be used to produce identical, highly uniform and well-defined electrode structures. Thin and thick film metallization as well as sputtering techniques can be applied to produce the metallic electrode elements. Chemical and plasma etching techniques can be used to delineate geometrically well-defined electrode surfaces. These microelectronic fabrication techniques provide a fruitful way to prepare sensors with specific geometries. These techniques have only begun to be explored at this time.[54]

Sensor arrays are not well developed but hold promise to vastly improve sensor selectivity especially when combined with advanced computational techniques like neural networks. New electrolyte materials must be found so that integrated sensor structures can be built. This is an exciting time for sensor research and, in the near future, amperometric sensors will be more sensitive, more selective, smaller, and less expensive.

ESTIMATION OF pH AND AUTOPROTOLYSIS CONSTANTS IN MIXTURES OF ALIPHATIC AMIDES WITH WATER: MEDIUM EFFECT ON THE 4-AMINOAZOBENZENE SYSTEM

AGUSTIN G. ASUERO,* MARIA A. HERRADOR and A. GUSTAVO GONZALEZ
Department of Analytical Chemistry, Faculty of Pharmacy, The University of Seville, 41012-Seville, Spain

(*Received* 24 *March* 1992. *Revised* 14 *August* 1992. *Accepted* 26 *August* 1992)

Summary—Correction factors to the glass electrode and autoprotolysis constants of mixtures of aliphatic amides with water: *N,N*-dimethylformamide (DMF), *N,N*-dimethylacetamide (DMA), *N*-methylformamide (NMF), *N*-methylacetamide (NMA), formamide (F) and acetamide (A), have been determined. The acidity constants of 4-aminoazobenzene referred to the standard state of the mixtures of these aliphatic amides with water as well as the medium effect on the 4-aminoazobenzene system have been evaluated from spectrophotometric measurements.

Amide–water mixtures are useful polar reaction media and solvents for a variety of purposes. In spite of this, there is relatively little data[1–4] available on the analytical use of mixtures of aliphatic amides with water. Correction factor to be made to the glass electrode, autoprotolysis constants and acidity constants of 4-aminoazobenzene (HB) in mixtures of aliphatic amides with water: *N,N*-dimethylformamide (DMF), *N,N*-dimethyl-acetamide (DMA), *N*-methylformamide (NMF), *N*-methylacetamide (NMA), formamide (F) and acetamide (A), have been evaluated in this paper. An attempt has been made to interpret the medium effects on the basis of hydrophobic interactions.

EXPERIMENTAL

Apparatus

All titrations were made with a Crison digilab 517 pH-meter and an Ingold electrode (order No. 0402311) assembly (glass–AgCl/Ag) (CH-8902 Urdorf/Switzerland). In order to avoid the glass membrane dehydration, the electrode was soaked in water when not in use. Prior to the measurement of pH, the electrode was soaked in a solution of the desired solvent composition. Titration vessels used consisted of tall beakers sealed into a water jacket through which water circulated from a Techne C-100 water bath. Temperature was controlled at $25 \pm 0.1°$ by means of a Selecta 320-R water bath. Titrations were carried out by using 2.0-ml micro burette with magnetic stirring. In the determination of densities, a Paar DMA 60 densimeter fitted with a Paar DT 100-20 densitothermometer, a Tecam 1000 heat interchanger and a Techne C-400 circulator were employed.

A Spectronic 2000 Bausch & Lomb spectrophotometer equipped with silica cells of 1-cm path length was used for the absorbance measurements. 4-Aminoazobenzene was synthesized according to the method indicated by Vogel.[5] The crude product was recrystallized from methanol and its melting point was 127° (reported value 128°). The purity of the dye was checked by thin layer chromatography as described by Vytras *et al.*[6] Solutions of 4-aminoazobenzene at 0.1% v/v in the various pure liquid amides were prepared. In the case of acetamide, a solution containing 50 mg of 4-aminoazobenzene in 50 ml of 10*M* acetamide in water was employed.

Reagents

N,N-Dimethylformamide, *N,N*-dimethylacetamide, *N*-methylformamide and *N*-methylacetamide (E. Merck Darmstadt), acetamide (Merck Schuchardt) and formamide (Normasolv, Ferosa, Barcelona) were stored in 4 Å molecular sieves for at least one week. Analytical reagent potassium monohydrogenphthalate (Riedel–Häen) was used in the

standardization of alkaline solutions. Potassium chloride (Merck, Darmstadt) was used for the adjustment of ionic strength.

Procedures

Correction factors. In 50-ml standard flasks prepare three solutions containing a suitable volume (or weight in the case of acetamide) of amide, 1, 2.5 and 5 ml of a 0.01064*M* solution of hydrochloric acid, respectively, and distilled water to the mark. Measure the pH at $25 \pm 0.1°$.

Autoprotolysis constants. In a 100-ml standard flask add a suitable volume (or weight in the case of acetamide) of amide, 10 ml of 1*M* potassium chloride, 1.3 ml of 1*M* hydrochloric acid and distilled water to the mark, at $25 \pm 0.1°$. Transfer 75 ml of this solution to the titration vessel and titrate with 1*M* potassium hydroxide. Measure the pH at $25 \pm 0.1°$.

Procedure for the evaluation of acidity constants. Solutions for absorbance and pH measurements were prepared in 25-ml standard flasks by mixing 1 ml of $7.61 \times 10^{-4}M$ stock solution of 4-aminoazobenzene in the appropriate amide, 2.5 ml of 1*M* potassium chloride, the necessary volume of pure amide to give the required solvent composition in the final mixture, a few drops of hydrochloric acid or sodium hydroxide at different concentrations and distilled water to the mark. Absorbance was measured at 489, 496 and 505 nm, against a solvent blank and the pH checked after the absorbance measurements. The temperature was kept at $25 \pm 0.1°$.

RESULTS AND DISCUSSION

Reversibility of electrode assembly

Plots of potential cell against pH-meter reading (in mV) for each solvent mixture at the various acid concentrations and ionic strength tested give straight lines whose slope values (from 60.15 to 58.32) are very close to the theoretical nernstian slope (k) value of 59.16. By using the t-test[7] on the slopes one may assume that the behavior of the electrode is reversible.

Correction factors

The relative permittivity of the mixtures of amides with water have been previously reported[8] (Table 1). The amide molar fraction X_{AM} was determined from

$$X_{AM} = \frac{1}{1 + \left(\frac{100 d_m}{V_{AM} d_{AM}} - 1\right)\frac{MW}{18}} \qquad (1)$$

where d_{AM} and d_m are the densities of the pure amide[9] and the mixture containing V_{AM} percentage v/v of amide, respectively, and MW is the amide relative molar mass. The d_{AM} values obtained for the different mixtures studied are compiled in Table 2.

The correction factors to the glass electrode, δ, for transforming the pH-meter readout, R, (when the calibration is done with aqueous buffers) in the logarithm of the proton activity in the studied medium, pH*, $\delta = R - pH^*$, obtained for the different

*Taken from Ref. 2.

solvent mixtures assayed are compiled in Table 3. The relatively small standard deviation observed in most cases indicates that the liquid junction potential is practically constant[10] for each solvent composition tested. However, the reproducibility of measurements in formamide–water mixtures is somewhat poor, and measurements in water–NMF and water–A at high v/v amide to water ratio (or w/v in the case of A) also suffer some dispersion.

This behavior may be qualitatively explained because all mixtures studied are more basic than pure water; the hydrogen ion is expected to be more stabilized in these media, owing to specific interactions between the hydrogen ions and the basic amides. The free standard energy of transfer from water to the mixed solvent, $\Delta G_t^0(H^+)$, will be negative and hence, the medium effect, $\log f_H$, also $[\Delta G_t^0(i) = 2.303\ RT \log f(i)]$.

The presence of alkyl substituents on a nitrogen atom enhances its basicity. Therefore, the theoretical order of basicity of amides studied—which is based in the facility to donate the electron pair of the nitrogen atom—should be

$$\text{DMF} > \text{NMF} > \text{F} \quad \text{DMA} > \text{NMA} > \text{A}.$$

However, an opposite arrangement is found, surprisingly, if we take into account "the virtual basicity" indicated by the values of δ

$$\text{DMF} < \text{NMF} < \text{F} \quad \text{DMA} \simeq \text{NMA} < \text{A}.$$

This fact may be attributed to some other interactions that take place between the hydrogen ions and the various solvent species such as ion–multipole interactions, structural effects or other solvatation effects. Nevertheless, a positive value of δ does not necessarily imply a negative medium effect on the hydrogen ions since the liquid junction potentials are unknown.

Autoprotolysis constants

The pK_s values obtained for the different amide–water mixtures are compiled in Table 4. In the case of water–F mixtures, the cologarithm of the autoprotolysis constant passes through a minimum as the percentage of liquid amide in the mixed solvent increases, unlike the behaviour shown by the other water–amide mixed-solvent mixtures.

The standard deviations of the pK_s values were smaller than 0.04. It can be shown (as expected) that a minimum in the pK_s value is found between pure water and 10% v/v of amide composition (0.0–4.96% molar in the case of acetamide) with the exception of the water–F system. The influence of the relative permittivity of the medium on the autoionization of mixed aliphatic solvents has been envisaged. Several different types of correlation[11,12] between the autoprotolysis constants and acidity constants of weak acids, respectively, and solvent composition have been suggested. The Born equation[13] predicts a

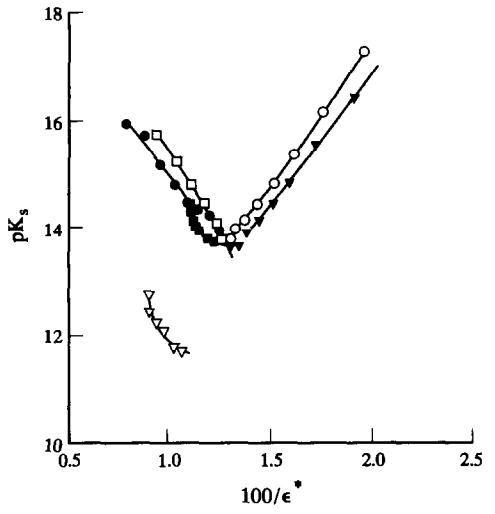

Fig. 1. Dependence of pK_s with the reciprocal value of the permittivity for several water–formamide derivative mixtures: (○) water–DMF mixtures, (●) water–NMF mixtures, (▽) water–F mixtures, (▼) water–DMA mixtures, (□) water–NMA mixtures and (▼) water–A mixtures.

linear relationship when the pK_s is plotted against the reciprocal of the permittivity. Plots of this kind are depicted in Fig. 1, showing a linear behavior with the exception of the A and F–water mixtures. Thus, in a first approach this fact may suggest a predominance of electrostatic effects on the ionization of aqueous mixtures of DMF, NMF, DMA and NMA.

Evaluation of acidity constants

4-Aminoazobenzene may undergo a prototropic tautomeric solvent dependent azonium-ammonium[14] equilibria

$$\underset{\mathbf{I}}{H_3N^+ - C_6H_5 - N = N - C_6H_5} \rightleftarrows \underset{\mathbf{II}}{H_2N - C_6H_5 - N = N^+H - C_6H_5}.$$

The S-shaped form of the absorbance versus pH* graphs obtained in all cases suggests a single ionization process. According to the basic properties of the mixed solvents studied and the greater facility of protonation of the amine–nitrogen with respect to the azonitrogen form I seems to be stabilized. Previous UV–visible and H^1 NMR spectra[15] of 4-aminoazobenzene and similar azodyes in polar solvents such as water–amide mixtures also indicates the potentially tautometric dye exists as true aminoazo species.

4-Aminoazobenzene in its ionization is quite strong and it is not entirely cationic even at pH 1. The pK_a^* (K_a^* being the acidity constant at the standard state of the mixed solvent) values in the media studied are collected in Table 5 and were spectrophotometrically evaluated[1] taking into account that the limiting absorbance of HB^+ is unavailable. The standard deviations were smaller than 0.06 except for the case of acetamide– and formamide–water mixtures whose values were somewhat superior.

Estimation of the medium effect

The solvent effect in the dissociation process of HB^+ can be expressed as follows[16]

$$\Delta G_t\,|HB^+/B|_{sys} = \Delta G_t^0(H^+) + \Delta G_t^0(B) - \Delta G_t^0(HB^+) = 2.303RT \log f\,|HB^+/B|_{sys}. \quad (2)$$

If we assume that the electrostatic effects may be estimated by using the Born model,[17] we have

$$\log f\,|HB^+/B|_{sys} = \log f_{non}\,|HB^+/B|_{sys} + \frac{Ne^2}{2}\left(\frac{1}{r_{H^+}} - \frac{1}{r_{HB^+}}\right) \times \left(\frac{1}{\epsilon^*} - \frac{1}{\epsilon}\right) = pK_a^* - pK_a \quad (3)$$

where $\log f_{non}\,|HB^+/B|_{sys}$ is the non electrostatic contribution to the medium effect.

†The pK_a value of aminoazobenzene in water was found to be 2.95.
§Taken from Ref. 1.

The medium effects in the various mixtures studied are reported in Table 6. The permittivity contribution depends on the difference in the ion sizes of H^+ and HB^+ ions. That the permittivity plays such a minor role in the dissociation process is confirmed by plotting ΔpK_a against the difference of reciprocal permittivity values $(1/\epsilon^* - 1/\epsilon)$ (Fig. 2). In the case of acetamide derivatives and DMF, non linear graphs are obtained. Nevertheless, though in the case of F and NMF solutions a linear plot is observed, the estimation of r_{HB}^+ (given that $r_H^+ = 1.7$ Å) yields meaningless results. This behaviour indicates that the non-electrostatic interactions will play a primary role. Since all ΔpK_a values in the different media are negative ($pK_a^* < pK_a$), taking into account the predominance of the non electrostatic terms, we may assume that

$$\log f_{non}\,|HB^+/B|_{sys} < 0 \qquad (4)$$

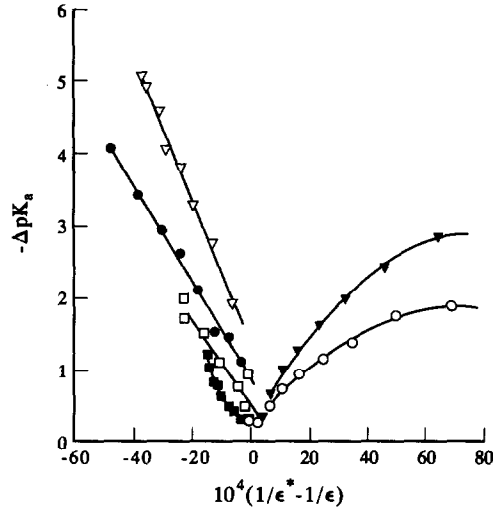

Fig. 2. Dependence of $-\Delta pK_a$ (medium effect) against 10^4 $(1/\epsilon^* - 1/\epsilon)$ for several water–formamide derivative mixtures: (○) water–DMF mixtures, (●) water–NMF mixtures, (▽) water–F mixtures, (▼) water–DMA mixtures, (□) water–NMA mixtures and (■) water–A mixtures.

and then

$$\Delta G_t^0(H^+) + \Delta G_t^0(B) - \Delta G_t^0(HB^+) < 0. \qquad (5)$$

The $\Delta G_t^0(H^+)$ values are negative because of the major basicity of partially aqueous mixtures with respect to pure water. Assuming[17] that the liquid junction potential is $\ll \delta$ we may calculate the $\Delta G_t^0(B) - \Delta G_t^0(HB^+)$ values. In all cases $\Delta G_t^0(B) < \Delta G_t^0(HB^+)$. Thus, the neutral species B is more stable than the charged one HB^+ in the solvent mixtures studied.

The 4-aminoazobenzene is sparingly soluble in water, but soluble in the water–aliphatic amide mixtures studied. Though a theoretical discussion concerning the specific solvation by part of the mixed solvents exceeds the frame of this paper, a brief discussion on the basis of the basic nature of cosolvent and hydrophobic interactions would explain the results obtained in a qualitative way.

According to the virtual basicity of cosolvents indicated above, and considering that this feature plays a capital role in the solvation process, the more basic the solvent mixture the more the 4-aminoazobenzene would display its acidic features (less pK_a value). Thus, at a first insight the acidity of 4-aminoazobenzene is expected to be in the same arrangement as the virtual basicity of cosolvents. This is found for the formamide family

$$F > NMF > DMF.$$

However, in the case of acetamide derivatives the sequence is

$$DMA > NMA > A.$$

In consequence, some other effects in addition to solvent basicity seem to play an important role in this context. The virtual basicity of the formamide family is hierarchically greater than that of the acetamide one. Accordingly so, the basicity may be considered as the most

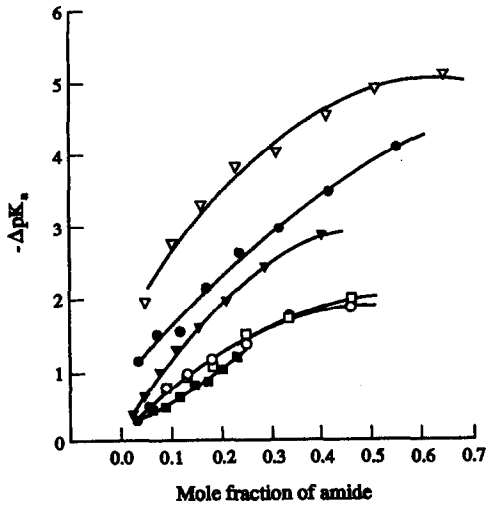

Fig. 3. Dependence of $-\Delta pK_a$ (medium effect) with the mole fraction of amide for several water–formamide derivative mixtures: (○) water–DMF mixtures, (●) water–NMF mixtures, (▽) water–F mixtures, (▼) water–DMA mixtures, (□) water–DMA mixtures and (■) water–A mixtures.

important factor for explaining the acidity of 4-aminoazobenzene in mixtures of F, NMF and DMF with water. Conversely, in the acetamide family, hydrophobic interactions would be competitive against basicity and the outcome agrees with the experimental arrangement.

Hydrophobic interactions contribute to a more negative value of medium effects.[1] These hydrophobic interactions occur between the "aniline moiety" of the uncharged 4-aminoazobenzene (B) and the methyl groups of the acetamide derivative (hydrophobic interactions cancel with the left hand ring in HB^+ and B species). Accordingly, the acidity of 4-aminoazobenzene will increase as the number of methyl groups in the amide molecule increases and therefore agrees well with the experimental sequence. Consequently, by hook or by crook the presence of aliphatic amides as cosolvents enhances the acidity of the 4-aminoazobenzene system. The plots of pK_a^* versus mole fraction of amide were non linear in all instances as shown in Fig. 3.

(*Received* 16 *March* 1992. *Revised* 3 *August* 1992. *Accepted* 26 *August* 1992)

Summary—From the precipitation borderlines in the pBi′–pH diagram, determined experimentally under CO_2-free conditions, the stability constants of bismuth hydroxide, bismuthoxynitrate and bismuthoxyperchlorate have been established. The following values have been found

Nitrate-medium:	Perchlorate-medium:
$\log {}^*K_{s0}(OH) = 5.2$	$\log {}^*K_{s0}(OH) = 5.2$
$\log {}^*K_{s0}(NO_3) = -1.2$	$\log {}^*K_{s0}(ClO_4) = -0.9$
$\log {}^*\beta_2 = -4.0$	$\log {}^*\beta_2 = -4.1$
$\log {}^*\beta_3 = -10.0$	$\log {}^*\beta_3 = -9.9$
$\log {}^*\beta_4 = -21.5$	$\log {}^*\beta_4 = -21.5$
$\log {}^*\beta_{1,0,1} = 1.2$	$\log {}^*\beta_{1,0,1} = 3.5$

The constants refer to precipitates equilibrated for 30 min, prepared at room temperature ($23 \pm 0.5°$) in sodium perchlorate or sodium nitrate medium with an ionic strength of 1.00 ± 0.01. Concerning error propagation it is stated that pBi′ values calculated with these constants will have a standard deviation of about 0.1 log unit.

The hydrolysis of bismuth (III) has been studied by many authors.[1–8] The hydroxide-complex formation constants were estimated from the difference between the amount of hydroxide added and the hydroxide found (pH) after equilibrating. A disadvantage of such a procedure is that the measurements are performed in small limited pBi′–pH regions. Formation constants of hydroxide complexes present only outside such a region cannot be determined. Complexes formed at low concentration inside such a pBi′–pH region easily escape observation because of the limited accuracy inherent to the procedure in which pH-measurements have to be converted into H_3O^+ concentrations. Usually a restricted number of hydrolysis constants is found in this way.

A better procedure appeared to be the determination of the precipitation area in the pBi′–pH diagram. The theory has been described in previous publications,[4,9] but is extended in this paper for the more complex case in which two precipitates may be formed. The simple procedure has been applied successfully to the determination of the complete set of the hydrolysis constants of seven tervalent lanthanides Ce(III), Sm(III), Gd(III), Yb(III), Er(III), Nd(III) and La(III), of which constants were unknown hitherto.[9–16]

Faced with erroneous results in the determination of Bi(III) in 1*M* nitrate medium we supposed that the hydrolysis constants of Bi(III) and especially the solubility product of Bi-oxynitrate found in the literature[17] were disputable.

Recalculation of the solubility product of $BiONO_3$ from the original publication of Swinehart and Garrett[17] showed that they made a mistake with the introduction of the ion-activity coefficients and moreover they did not consider the possible formation of $BiNO_3^{2+}$ ions in solution. $\text{Log } {}^*K_{s0} = 0.25$ was found (instead of -2.55). Swinehart and Garrett[17] did not perform their experiments at constant ionic strength and constant nitrate concentration, but this fact cannot explain the large discrepancy in the log values above.

We decided to determine the formation constants of the bismuth-oxy-compounds with

nitrate, perchlorate and chloride (and to check the constants of bismuth hydroxide if possible) applying our precipitation technique that was so successful for the lanthanides.

In the following it will be shown that there is no reason to doubt the solubility product of $Bi(OH)_3$ and the formation constants of the complexes $Bi(OH)_3$ and $Bi(OH)_4^-$.

The formation constants of BiOCl could not be determined as the rather strong formation of Bi-chloride in solution interfered in the photometric complex formation titration of Bi.

THEORY

The reactions for hydroxide formation can be written as follows:

$$\begin{array}{ccccccc} & & BiOA_{solid} & & & & \\ & & \downarrow\uparrow & & & & \\ BiA^{2+} & \rightleftharpoons & BiOA & & & & \\ \downarrow\uparrow & & \downarrow\uparrow & & & & \\ Bi^{3+} & \rightleftharpoons & BiOH^{2+} & \rightleftharpoons & Bi(OH)_2^+ & \rightleftharpoons & Bi(OH)_3 \rightleftharpoons \cdots \\ & & \downarrow\uparrow & & & & \downarrow\uparrow \\ & & Bi_6(OH)_{12}^{6+} & & & & Bi(OH)_{3\ solid} \end{array}$$

In this reaction scheme A stands for the anions nitrate, perchlorate and chloride. First we will only consider the side reactions with hydroxide. The side reactions with the anion A will be considered later in this paper.

The above system has two independent variables. The concentrations of the various species depend on the total concentration of Bi and the pH. If an additional constraint is set, only one degree of freedom remains which implies that a relationship exists now between metal ion concentration and pH. A curve reflecting the particular constraint can be drawn in the pBi′–pH plot. Areas with predominating species so arise in the pBi′–pH diagram: by setting $[Bi(OH)_i] = [Bi(OH)_{i+1}]$ for different values of i, we get the borderlines of the regions of predominance of the various $Bi(OH)_i$ species; by setting $p.[Bi_p(OH)_q] = [Bi(OH)_i]$ for different values of i, p and q, the borderline for polynuclear complex formation is obtained; and by restricting $Bi(OH)_3$ to a maximum value assuming that excess of $Bi(OH)_3$ precipitates and that the remaining $Bi(OH)_3$ is in equilibrium with the precipitate, we get the precipitation line as function of the pH.

According to Ringbom[18] a system of coexisting equilibria can be described with one main reaction and competitive side-reactions, covering all other reactions. The parameter [Bi′] the total concentration of Bi in solution, is much more useful than the concentration $[Bi^{3+}]$ of the free metal ion, to which it is related by Ringbom's side-reaction coefficient

$$\alpha_{Bi} = [Bi']/[Bi^{3+}]. \quad (1)$$

By substituting in equation (1) the relevant equilibria equations in the so-called H-form (defined in accordance with the IUPAC notation):

$$^*\beta_i = [Bi(OH)_i][H]^i/[Bi^{3+}] \quad (2)$$

this leads to the general equation for only OH side reactions:

$$\alpha_{M(OH)} = 1 + 10^{(pH + \log {}^*\beta_1)} + 10^{(2pH + \log {}^*\beta_2)} + \cdots + 10^{(mpH + \log {}^*\beta_m)} \quad (3)$$

The pH-range can be divided into distinct regions with one of the hydroxide complexes predominating in each region. In each particular region the corresponding term in equation (3) will be the largest. For this particular area in the pBi′–pH plot the side reaction coefficient can be approximated by

$$\log \alpha_{Bi} = i\,.\,pH + \log {}^*\beta_i \quad (4)$$

In the case when a polynuclear complex like $Bi_6(OH)_{12}$ [which can be written in the general form $Bi_p(OH)_q$] predominates the equation can be written as[4]

$$\log \alpha_{Bi} = [q\,.\,pH + \log({}^*\beta_{qp}) + \log(p) - (p-1)\,.\,pBi']/p \quad (5)$$

This principle can be extended if other species—*e.g.*, $Bi(NO_3)_j$—are formed in solution. This component may be considered as a special case ($p = 1, q = 0$) of the more general form: $Bi_p(OH)_qA_j$.

If its formation constant is defined as $^*\beta_{jqp}$ analogously to equation (2) the equation will be:

$$\log \alpha_{Bi} = [q\,.\,pH + \log({}^*\beta_{jqp}) + \log(p) - (p-1)\,.\,pBi' - j\,.\,pA]/p \quad (6)$$

In practice we deal with a mixture of species with the general formula $Bi_p(OH)_qA_j$.

For every species defined by (p, q, j) equation (6) can be written down. The value of $\log \alpha_{Bi}$ is in good approximation equal to the largest value of all possible combinations of p, q and j. Its exact value is found by taking the logarithm of the sum of powers of 10 with the rightside of equation (6) as the exponent [see also equations (15) and (16)].

The precipitation of $Bi(OH)_3$

The uncharged species $Bi(OH)_3$ has a limited solubility. If a precipitate is present in solution under equilibrium conditions, a maximum is set to the concentration of $Bi(OH)_3$ in solution, hence to $[Bi^{3+}]$ and consequently to the overall concentration [Bi']. Using $^*\beta_3$ and maximizing $Bi(OH)_3$ we find: $pBi^{3+} = -\log(^*K_{so}) + 3pH$ from which follows together with equation (1):

$$pBi'_{max} = -\log(^*K_{so}) + 3pH - \log \alpha_{Bi} \quad (7)$$

Substitution of equation (6) in (7) gives

$$pBi'_{max} = (3p - q) \cdot pH - p \cdot \log(^*K_{so}) - \log(^*\beta_{qpj}) - \log(p) + j \cdot pA \quad (8)$$

Equation (8) gives rise to a set of straight lines in the pBi'–pH diagram. Each line represents an equilibrium between the $Bi(OH)_3$ precipitate and the species $Bi_p(OH)_qA_j$ in solution.

From equation (7) and the fact that we have to take the maximum value of $\log \alpha_{Bi}$ it follows that the real value of pBi'_{max} is the minimum value given by the set of straight lines (8). The lines enclose the precipitation region of $Bi(OH)_3$ in the pBi'-pH plot. A line only contributes as borderline if the species predominates in solution; not all lines are involved. If $Bi_p(OH)_qA_j$ predominates in solution in that particular pH region, line (8) will be the borderline in that pH region (Figs. 1 and 2).

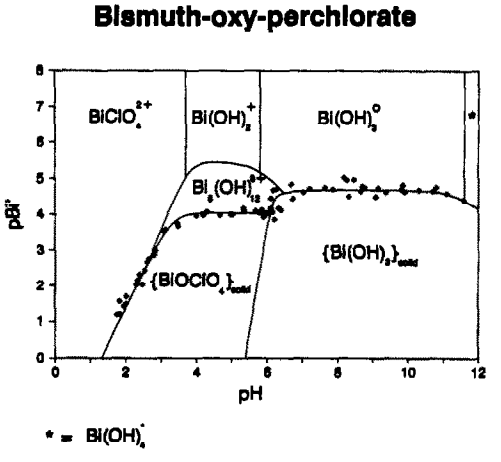

Fig. 1. The pBi'–pH diagram for bismuth in the presence of 1*M* perchlorate. The dots denote the experimental results. The envelope curves of the precipitation regions of $Bi(OH)_3$ and $BiOClO_4$ are found by adapting the curves to the experimental points. From the resulting equilibrium constants follows the position of the regions of predominance above the precipitation regions. The regions are indicated with the respective predominating ions.

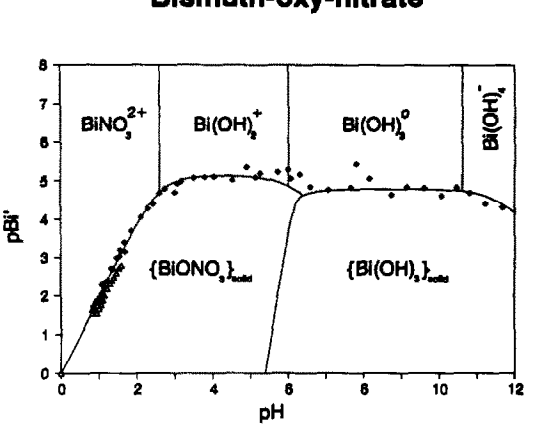

Fig. 2. The pBi'–pH diagram for bismuth in the presence of 1*M* nitrate. The dots denote the experimental results: ◆: own results, △: results of Swinehart and Garrett.[17] The envelope curves of the precipitation regions of $Bi(OH)_3$ and $BiONO_3$ are found by adapting the curves to the experimental points. From the resulting equilibrium constants follows the position of the regions of predominance above the precipitation regions. The regions are indicated with the respective predominating ions.

The precipitation of the mixed hydroxide $Bi(OH)_2A$

It is known that Bi(III) forms precipitates of the composition BiOA in which A stands for nitrate, perchlorate or chloride. For the equilibrium considerations it is not a restriction to write $Bi(OH)_2A$ instead of BiOA. The uncharged species $Bi(OH)_2A$ has a limited solubility. If a precipitate is present in solution under equilibrium conditions, a maximum is set to the concentration of $Bi(OH)_2A$, hence to $[Bi^{3+}]$ and consequently to the overall concentration [Bi']. Using $^*\beta_{121}$ for the formation constant of $Bi(OH)_2A$ and maximizing its concentration we find:

$$pBi^{3+} = -\log(^*K_{so}) + 2pH - p[A] \quad (9)$$

from which follows together with equation (1):

$$pBi'_{max} = -\log(^*K_{so}) + 2pH - p[A] - \log \alpha_{Bi} \quad (10)$$

Substitution of equation (6) into (10) gives

$$pBi'_{max} = (2p - q) \cdot pH - p \cdot \log(*K_{so}) - \log *\beta_{qpj} - \log p + (j - p) \cdot pA \quad (11)$$

Equation (11) gives rise to a set of straight lines in the pBi′–pH diagram. Each line that participates in shaping the precipitation region, represents an equilibrium between the precipitate $Bi(OH)_2A$ and the species $Bi_p(OH)_qA_j$ predominantly present in solution. Again not all lines may be involved [similar to the previous case for $Bi(OH)_3$].

EXPERIMENTAL

At low and moderate concentrations of nitrate and perchlorate Bi(III) does not form complexes with these ions. Under these conditions the regions of predominance in solution are restricted to the species Bi^{3+}, $Bi(OH)^{2+}$, $Bi(OH)_2^+$, $Bi(OH)_3$, $Bi(OH)_4^-$ and $Bi_6(OH)_{12}^{6+}$ and only one precipitate $Bi(OH)_3$ is formed.

At higher concentration (1*M* nitrate or 1*M* perchlorate) a second precipitate is formed of which the precipitation region lies on the acid side of the other precipitation region. The precipitate has a different appearance with a fine crystalline structure. For perchlorate and nitrate the ratio bismuth:oxygen:anion is 1:1:1. If this precipitate was filtered off and then brought into a basic solution, a slow recrystallization into $Bi(OH)_3$ was observed.

Depending on the experimental conditions only one of the two possible precipitates will be in equilibrium with the solution.

The formation of the precipitate was equal to the procedure as described for gadolinium.[11] In a glove box under nitrogen a CO_2-free sodium hydroxide solution is added slowly and carefully to the acid solution of bismuth. The experimental conditions are 1*M* NO_3^- or 1*M* ClO_4^-. The ionic strengths are kept at 1.00 ± 0.01. The temperature was kept constant at $23.0 \pm 0.5°$. The time left to the system to reach equilibrium was kept at 30 min, after which the precipitate was removed by centrifugation. Preliminary experiments revealed that after 30 min changes of both pH and pBi′ in one batch were negligible compared to the reproducibility of the precipitate formation.

The pH-meter was calibrated in concentration units.[9,11,14] Hence if pH is written, actually $-\log[H^+]$ is meant and not the activity of H^+. It implies that the determined formation constants are full concentration products. The Bi concentration has been determined in the supernatant centrifuged solution by complex formation titration with EDTA as the titrant with photometric endpoint detection using Semi-Xylenol Orange as the indicator.[19,20]

RESULTS

For both $BiONO_3$ and $BiOClO_4$ the precipitation regions have been determined. The experimental results are presented as points in Figs. 1 and 2. The precipitation region of the $Bi(OH)_3$ species is enclosed by the following three straight lines in the pBi′–pH plot:[4]

$$pBi'_{max} = 4.75 \quad (12)$$

$$pBi'_{max} = -pH + 16.30 \quad (13)$$

$$pBi'_{max} = 6pH - 32.33 \quad (14)$$

The other lines from the set as described by equation (8) do not contribute; they lie at least 1 log unit higher in the diagram. The lines (12)–(14) hold for both 1*M* nitrate and 1*M* perchlorate solutions. It implies that the hydroxide formation constants are the same in both experiments.

Initially we assume that the value for $Bi_6(OH)_{12}^{6+}$ ($\log *\beta_{6,12} = 0.33$) is correct ($I = 0.1$ and 3).[5–8] Introducing this value in equation (8) and setting $j = 0$ we conclude with equation (14) for $\log *K_{so} = 5.20$. From this and the equations (12) and (13) follows: $\log *\beta_3 = -9.95$ and $\log *\beta_4 = -21.50$. These data are not very dependent on errors in $\log *\beta_{6,12}$ [a change of 0.3 has a negligible influence (0.05) on the other data]. The data found for $*K_{so}$, $*\beta_3$ and $*\beta_4$ are in agreement with the literature data ($I = 0.1$).[5–8] Because of this confirmation we adopt the literature values of $\log *\beta_1 (-1.4)$ and $\log *\beta_2 (\approx -4)$ as holding for both matrices. (The value of $\log *\beta_1$ could not be confirmed from our experimental data; $\log *\beta_2$ has later been selected as 4.0 and 4.1 for better fits to the data for nitrate and perchlorate media respectively.)

The precipitation region of the $BiOClO_4$ precipitate is enclosed by the lines:

$$pBi'_{max} = 4.09 \quad [\text{in equilibrium with } Bi_6(OH)_{12}^{6+}] \quad (15)$$

$$pBi'_{max} = 2pH - 2.63 \quad (\text{in equilibrium with } BiClO_4^{2+}) \quad (16)$$

The precipitation region of the $BiONO_3$ precipitate is enclosed by the lines:

$$pBi'_{max} = 4.9 \quad \text{[in equilibrium with } Bi(OH)_2^+\text{]} \quad (17)$$

$$pBi'_{max} = 2pH \quad \text{(in equilibrium with } BiNO_3^{2+}\text{)} \quad (18)$$

The set of constants presented in Table 1 turned out to be the only set with which it is possible to get a fit to the experimental data for both the nitrate experiments and for the perchlorate experiments with nearly the same set of constants for hydroxide formation.

Deducing these constants from all lines which can be drawn in the pBi'–pH plot is like solving a puzzle. The lines which arise after substitution of the constants in equation (8) and (11) should either be borderlines of the precipitation region or lie at least one log unit higher.

In Table 2 a survey is given of all possible lines which originate from equation (8) and (11) for the perchlorate system in which we deal with two possible precipitates $Bi(OH)_3$ and $BiOClO_4$.

The real curves in Figs. 1 and 2 for the precipitates regions have been found with the mathematically correct equations:

$$pBi'_{max} = -\log[10^{-3pH+5.2} + 10^{-2pH+3.8} + 10^{-pH+1.1} + 10^{-4.7} + 10^{pH-16.3} + 10^{-6pH+32.33} + 10^{-3pH+8.70}]. \quad (19)$$

$$pBi'_{max} = -\log[10^{-2pH-0.87} + 10^{-pH-2.27} + 10^{-4.97} + 10^{pH-10.77} + 10^{2pH-22.37} + 10^{-4.09} + 10^{-2pH+2.63}] \quad (20)$$

In Table 2 asterisks (*) indicate which predominating ion is in equilibrium with the specific precipitate. The equations (*) in the right column of Table 2 are equivalent to equations (15) and (16). The corresponding terms in equation (20) predominate and determine the shape of the precipitation region. The same holds for the equations in the left column, which lead to dominating terms in equation (19). It should be noted that all equations are mutually dependent on each other as all constants appear in all equations. It is surprising that the system actually has only one satisfactory set of constants.

An analogous set of equations hold for the nitrate system.

Table 1.

Nitrate-medium	Perchlorate-medium
$\log {}^*K_{so}(OH) = 5.2$	$\log {}^*K_{so}(OH) = 5.2$
$\log {}^*K_{so}(NO_3) = -1.2$	$\log {}^*K_{so}(ClO_4) = -0.9$
$\log {}^*\beta_1 = -1.4$	$\log {}^*\beta_1 = -1.4$
$\log {}^*\beta_2 = -4.0$	$\log {}^*\beta_2 = -4.1$
$\log {}^*\beta_3 = -10.0$	$\log {}^*\beta_3 = -9.9$
$\log {}^*\beta_4 = -21.5$	$\log {}^*\beta_4 = -21.5$

$\log {}^*\beta_{1,0,1} = 1.2$	$\log {}^*\beta_{1,0,1} = 3.5$
Ionic strength = 1.00 ± 0.01	Temperature = $23 \pm 0.5°$

DISCUSSION

In Fig. 2 the jump in experimental points near pH 6 indicates that before that pH value the $BiOClO_4$ precipitate is present and while above pH 6 the Bi $(OH)_3$ precipitate occurs.

Both precipitates are formed by neutralizing the acidic bismuth solutions with hydroxide. This implies that the $BiOClO_4$ precipitate is formed first in the experiments. The precipitate converts into the $Bi(OH)_3$ precipitate after reaching higher pH values. The reaction proceeds slowly because of its heterogeneous character. Near pH 6 it takes hours to reach equilibrium in an acceptable way and in that region the position of the experimental points will be less precise compared to the experimental points related to lower and higher pH.

This consideration holds also for the nitrate system although it is less obvious from Fig. 2 as the horizontal parts of both precipitation lines lie approximately at the same level (≈ 5); there is no jump detectable in the experimental points.

Table 2.

$Bi(OH)_3$-precpt		$BiOClO_4$-precpt	
$pBi'_{max} = 3.pH - 5.20$:	Bi^{3+}	$pBi'_{max} = 2.pH + 0.87$:	Bi^{3+}
$= 2.pH - 3.80$:	$Bi(OH)^{2+}$	$= pH + 2.27$:	$Bi(OH)^{2+}$
$= pH - 1.10$:	$Bi(OH)_2^+$	$= +4.97$:	$Bi(OH)_2^+$
$= +4.70$:	$^*Bi(OH)_3$	$= -pH + 10.77$:	$Bi(OH)_3$
$= -pH + 16.30$:	$^*Bi(OH)_4^-$	$= -2.pH + 22.37$:	$Bi(OH)_4^-$
$= 6.pH - 32.33$:	$^*Bi_6(OH)_{12}^{6+}$	$= +4.09$:	$^*Bi_6(OH)_{12}^{6+}$
$pBi'_{max} = 3.pH - 8.70$:	$Bi(ClO_4)^{2+}$	$pBi'_{max} = 2.pH - 2.63$:	$^*Bi(ClO_4)^{2+}$

In principle the horizontal parts of BiOA precipitation lines can also be explained by assuming that $Bi(OH)_2A$ is the predominating species in solution. However, this is unlikely as then $Bi_6(OH)_{12}^{6+}$ should not be present and this complex is essential for explaining the jump in the precipitation lines near pH 6 in Fig. 1.

The experimental points found by Swinehart and Garrett[17] are also drawn in Fig. 2. Obviously these points do not deviate much from our measurements. This is remarkable as they did not work at constant ionic strength; their experiments were performed at a different temperature and 2–3 weeks were used to let the system reach chemical equilibrium.

Concerning the accuracy, the position of the individual experimental points has a precision of ± 0.5 log units in the pBi′ (vertical) direction if the borderline is (nearly) horizontal. The points have a precision of ± 0.5 log units in the pH direction if the borderline is (nearly) vertical. The borderlines themselves are close to the mean position of the points and hence are defined more precisely. The standard deviation of the line position may be estimated by 0.1 log unit. The sets of constants in Table 1 are deduced from the position of these lines, but as many constants work together in defining one line, the constants are not mutually independent in a statistical sense. Actually a covariance matrix should be given, but this is difficult to estimate from the calculation procedure and makes no sense. More relevant is to conclude that for a given pH value a pBi′ value calculated using the set of constants will have a standard deviation of about 0.1 log unit.

Attempts to determine a similar way the constants of the Bi–Cl system were finally given up. The solubility of BiOCl is very low while at the same time soluble strong BiCl complexes interfere in the titrimetric determination of Bi. Determinations are only possible at chloride levels below $0.07M$. Perhaps the determination of Bi in the presence of Cl will succeed with atomic spectroscopic techniques like ICP–AES or AAS, but no attempts have been made.

For direct application in an analysis procedure the precipitates $BiONO_3$ and $BiOClO_4$ are not of interest. Knowledge about precipitate formation however is of indirect value in analytical chemistry. Colloidal formed BiOA reacts rather slowly and even behaves rather inert when it sticks to the vessel wall. It explains why in some related cases bismuth escapes from being analysed. It also explains why bismuth and its alloys sometimes dissolve very slowly in strong acid. It is then passified by a layer of BiOA on its surface.

Acknowledgements—We are indebted to Annelies de Wit, Pauline Lobé and Renata Tel for their meticulous contribution to the time-consuming determination of the experimental points in the diagrams.

LIQUID CHROMATOGRAPHIC DETERMINATION OF THE KNOWN LOW LEVEL IMPURITIES IN LOVASTATIN BULK DRUG: AN APPLICATION OF HIGH–LOW CHROMATOGRAPHY

ANTHONY HOUCK, SCOTT THOMAS and DEAN K. ELLISON
Merck Sharp & Dohme Research Laboratories, P.O. Box 2000, Rahway, NJ 07065, U.S.A.

(*Received* 11 *February* 1992. *Revised* 20 *August* 1992. *Accepted* 20 *August* 1992)

Summary—High–low chromatography in combination with gradient elution and multiple wavelength detection is a rapid and sensitive technique that can be used to assay low level impurities in lovastatin. The method is reproducible and can be applied to samples containing as little as 0.1% of any known impurity.

Monitoring low levels of impurities in pure bulk drugs is a critical but often difficult task.[1] Lovastatin, an effective cholesterol reducing agent,[2] is an example of a highly purified drug which contains a number of known low level impurities (see Fig. 1). The production of pure lovastatin involves isolation and purification from a complex fermentation broth.[3] Impurities which are shown in Fig. 1 are either carried over from the fermentation process or produced during the isolation procedure. As a result, these impurities must be routinely monitored throughout the production process. Assaying each impurity individually against reference standards would take a significant amount of time and also require a large supply of analytical standard for each impurity. Rather than optimize analytical methodology for the assay of each individual impurity, we have applied a novel combination of high–low chromatography, gradient elution and multiple wavelength detection to monitor these impurities.[4] To our knowledge, this is the first time this combination of chromatographic techniques has been reported. We demonstrate here that we can obtain reproducible and quantitative results in a short period of time for monitoring known low level impurities in the drug lovastatin.

EXPERIMENTAL

General

HPLC-grade acetonitrile and reagent grade phosphoric acid were purchased from Fisher Scientific and J.T. Baker Chemical Company, respectively. The standards L-154,803, L-154,819, L-637,312, L-642,257, L-154,883, L-665,624, were obtained from the Merck Sample Collection located in Rahway, N.J. Asterric acid was kindly provided by Dr Tom Verhoeven, Merck and Co.

Chromatographic instrumentation

The HPLC system for the high–low impurity assay consisted of a Spectra Physics Model 8700 pump, a Spectra Physics Model SP8500 dynamic mixer, a Spectra Physics Model 8710 autosampler fitted with a 10 microliter injection loop, and two Kratos Model 757 variable wavelength detectors connected in series. A Hatachi column heater, Model 655A-52, was used to maintain the column temperature at 30°.

Lovastatin chromatographic procedure

Reversed-phase separation of impurities in lovastatin was accomplished using a 25.0-cm × 4.6-mm i.d. column packed with C-8 chemically bonded silica (5 micron) Partisil (Whatman) Column. The following gradient system was used: 40:60 water (0.1% v/v H_3PO_4, pH = 2.2):acetonitrile to 20:80 in four minutes, then 10:90 in three minutes and hold for five minutes. The flow was 1.5 ml/min with dual wavelength detection at 200 and 238 nm. All samples were diluted in acetonitrile at a concentration of 2.0 mg/ml.

Quantitation

Two injections of lovastatin standard (0.3 mg/ml) were followed by two injections of

sample (2 mg/ml). Impurities in the sample are identified by retention times and the area counts for each impurity are averaged. The impurity percentages in the sample are then calculated as follows:

$$\text{Wt\% impurity} = \frac{\text{RFS} \times 100}{\text{RFST} \times \text{RRF}}$$

Where: RFS, the response factor of a given impurity in the sample, is calculated by dividing the average area count of impurity in the sample by the concentration of the sample (typically 2.0 mg/ml); REST, the response factor of the lovastatin standard, is calculated by dividing the average area count of the lovastatin standard by its concentration (typically 0.3 mg/ml). This response factor was checked approximately every 10 injections; and RRF, the relative response factor, is a correction factor which accounts for a difference in response (both a function of retention time and UV characteristics of a given impurity) between a given impurity and the lovastatin standard. The RRF is calculated by dividing the response factor of a given impurity by the response factor of standard. This factor must be determined experimentally using authentic samples of impurities. We typically check the RRF daily using a

lovastatin sample which contains a known amount of each impurity.

RESULTS AND DISCUSSION

To routinely monitor low level impurities in lovastatin, it was important to develop a rapid and sensitive analytical method for detecting low level impurities (see Fig. 1). The assay would be useful for release testing of the pure bulk drug and monitoring impurity levels throughout the lovastatin production process.

Wavelength selection

Lovastatin has a strong absorption band in the UV range with an A 1% 1 cm of 634 at its wavelength of maximum absorbance, 238 nm. This absorption is attributed to the diene conjugation (Fig. 1). All of the impurities, with the exception of asterric acid and dihydrolovastatin, contain the same diene functional group and also have a maximum absorbance at 238 nm. As a result, UV detection at this wavelength should provide adequate sensitivity for the impurities with the diene system. The dihydro and asterric acid have very little absorbance at 238 nm, but each does absorb significantly at 200 nm (see response in Table 1). Consequently, we chose to monitor 200 nm also, in order to detect these two impurities with improved sensitivity.

Separation

Our initial reverse phase separations indicated that each impurity could not be base line resolved from each other in a reasonable amount of time using isocratic conditions. This is consistent with the wide range of polarities which exist among the various impurities (see Fig. 1). Gradient chromatography, however, allowed us to base line resolve each impurity within a short chromatographic run-time (see Fig. 2). There are unknown impurities which appear on the chromatogram between known impurities I and III and between known impurities VII and II. These impurities are occasionally detected in some samples, however, because the levels are much less than 0.05%, these impurities have not been identified.

Detection limit

We needed a limit of quantitation (LOQ) of less than 0.1% for each impurity.[5] Our approach was to determine the LOQ for each impurity and then use that value to determine

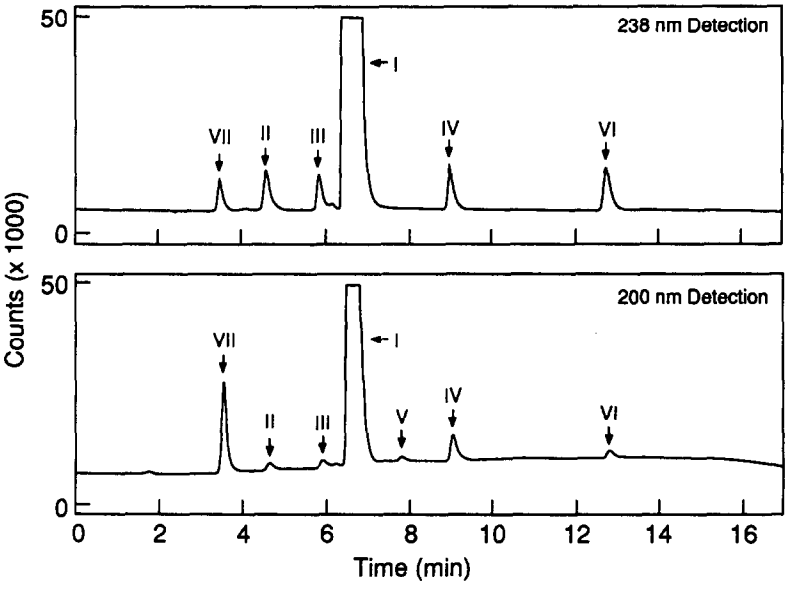

Fig. 2. Chromatographic separation of known impurities spiked at the 0.5% level in a 2-mg/ml lovastatin sample. Conditions are as described in the experimental section.

the amount of sample which would be needed to be injected onto the column. For example, we determined our LOQ to be $\geqslant 3000$ area counts. The average area count responses for each impurity are shown in Table 1. The dihydrolovastatin gives the least sensitive response, 3528 area counts for a 0.02-μg on-column injection because it has low UV absorption even at 200-nm detection (no diene chromaphore). This 0.02-μg level of dihydrolovastatin corresponds to a 20-μg level on column injection of sample in order to get 0.1% quantitation limit. All other impurities are well above the 3000 area count criteria at the 0.02-μg injection level.

Linearity

The area count response of the dihydrolovastatin impurity as a function of concentration is linear across the concentration range of 0.002–0.2 mg/ml (correlation coefficient greater than 0.9999). This concentration range of 0.002–0.2 mg/ml corresponds to a weight percent ([weight of impurity/weight of sample] $\times$ 100%) of 0.1–10% for a 2-mg/ml sample concentration. We selected this concentration range because our experience with lovastatin has suggested that no impurity will be above the 10% range. We performed an identical linearity test with the other impurities shown in Fig. 1 and in each case the correlation coefficient was better than 0.9999.

Reproducibility

The percent relative standard deviation as a function of impurity is also shown in Table 1. The standard deviation was calculated using five successive injections of each solution. In all cases the % RSD was below the 3% level. We consider percent relative standard deviations of less than 20% acceptable for assaying low level impurities in bulk drugs.

Advantages

We have noted three significant advantages of using this method of analysis as compared to methods which routinely employ reference standards for assaying each known impurity; 1) high sensitivity, 2) shorter analysis time, and 3) less frequent use of impurity standards. Because we are able to load more sample on to the column without worrying about going above the linear range of the main component, lovastatin, our sensitivity towards low level impurities in lovastatin is increased by more than five times. A significant amount of time is saved by quantitating each impurity relative to a lovastatin standard, as opposed to assaying each impurity individually. This feature also avoids the excessive use of standards which are often available in limited quantity.

CHROMATOGRAPHIC DETERMINATION OF COPPER SPECIATION IN JET FUEL

DANIEL B. TAYLOR and ROBERT E. SYNOVEC*
Department of Chemistry, BG-10, University of Washington, Seattle, Washington 98195, U.S.A.

(*Received* 22 *July* 1992. *Revised* 19 *August* 1992. *Accepted* 19 *August* 1992)

Summary—A method is described that allows one to distinguish and quantitate two different classes of copper compounds in the same hydrocarbon sample. This will enable the study of the effects of different copper compounds on the performance and stability of petroleum samples. Copper *N,N'*-disalicylidene-1,2-propylenediamine (CuDMD) and several copper carboxylates were preconcentrated from a hydrocarbon matrix using a column packed with polyvinylpyrrolidone, $(C_6H_9NO)_x$, a novel polymeric stationary phase. The copper complexes were then sequentially eluted using a step gradient program beginning with hexane/isopropyl alcohol as the eluent and ending with an acetic acid/isopropyl alcohol eluent. The copper complexes were detected by serial UV absorbance and flame atomic absorbance (FAA) detection. With on-column preconcentration and FAA detection, the limits of detection were 7 and 40 ppb copper for CuDMD and the copper carboxylates respectively. With this method, it was possible to distinguish between the two different classes of copper compounds in the same hydrocarbon sample, which will help to provide an understanding of the catalytic activity of different copper compounds, leading to a better understanding of the factors causing fuel instability. The method promises to be a valuable tool in the analysis and characterization of copper compounds in petroleum samples.

INTRODUCTION

Recently there have been several articles about the speciation of metals in aqueous samples.[1–4] For the purpose of this report, speciation will be defined as the distribution of a metal among different ligands to form complexes. The speciation of a metal is defined by the ligands attached to the metal, therefore, if two metal atoms have different ligands attached, the metals have different speciation. Metal speciation is also important for petroleum systems like jet fuel but the methods used to determine the speciation of metals in aqueous samples cannot be used for petroleum samples. Metal complexes in hydrocarbon matrixes are not retained, relative to the major constituent of the fuel, by the reversed-phase columns typically used to determine the speciation of metals in aqueous samples, but are eluted by the non-polar components in the fuel. Thus, reversed-phase chromatography cannot be used to preconcentrate and separate the copper compounds in petroleum samples. In this manuscript we describe a normal-phase chromatographic method for the determination of copper speciation in jet fuel.

The presence of copper in jet fuel, even at concentrations as low as 40 ppb, can have a detrimental effect on fuel stability.[5,6] It is believed that the copper dissolved in jet fuel degrades the stability of the fuel by acting as a catalyst for the free radical oxidation of the fuel, which leads to the formation of varnishes, gums and sediments.[7,8] This is especially noticeable when the fuel is in contact with hot surfaces, such as heat exchangers. The gums and sediments can cause many problems when they form within an engine. They can clog fuel filters, reduce the efficiency of heat exchangers causing engines to overheat or thermal break down of cooling oil, and clog nozzles in the combustion chambers of engines and change the fuel spray pattern.[7,8] The adverse effect of copper on fuel stability can be reduced by adding DuPont Metal Deactivator (DMD) to the fuel.[6,7] The active ingredient in DMD is *N,N'*-disalicylidene-1,2-propylenediamine which chelates all of the copper in the fuel, and thus, reduces its catalytic activity. The chemical structure of DMD and the CuDMD complex are shown in Fig. 1.

In order to determine whether the copper present in a jet fuel sample will degrade the stability of the fuel, one needs to be able to differentiate between CuDMD and the other forms of copper which will catalyze fuel oxidation. An analytical technique that can

*Author for correspondence.

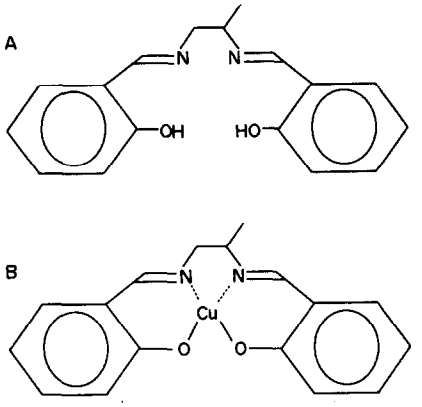

Fig. 1. Chemical structures of (A) the active ingredient in DuPont Metal Deactivator (DMD) and (B) the copper DMD complex.

accomplish this differentiation is needed. A technique that can determine both the speciation and concentration of copper at low parts per billion (ppb) concentrations is needed, because both copper concentration and speciation determine how the dissolved copper will affect fuel stability.

We have developed a method capable of distinguishing between CuDMD and the catalytically active copper carboxylates. The method has enabled us to separate the copper complexes into two classes: strongly bound copper of the CuDMD complex, and the weakly bound copper of the copper carboxylates. This method is significant, because it makes it possible to distinguish between the copper that will have a detrimental effect on fuel stability and cause the fuel to degrade, and the copper which has been "passivated" by DMD and will not affect fuel stability. The technique we have developed for determining the speciation of copper involves preconcentrating and separating the different classes of copper compounds using normal-phase chromatography. The copper compounds are detected by serial ultra-violet absorbance and flame atomic absorption (FAA) detectors. It is important that the speciation is not disturbed during the preconcentration or separation of the two classes of copper compounds, because if the speciation of the copper is changed the information about the catalytic activity of the copper in the jet fuel is lost.

Initially the suitability of the traditional stationary phase alumina for the normal-phase preconcentration and separation of the copper compounds in jet fuel was investigated. The copper in hexane solutions was retained by the alumina, but could not be eluted unless strong acid was added to the eluent. The acidic eluent eluted all of the copper species at the same time. The eluted copper, regardless of its original speciation, had the same response factor for the UV absorbance detection at 300 nm. We interpreted this to mean that alumina acts as an ion-exchanger that displaces the native ligands when the copper adsorbs on the stationary phase. All of the copper was being eluted as the same compound, which is why the response factor was the same for every copper compound. We had developed a method capable of preconcentrating copper from jet fuel with a limit of detection of 0.07 ppb, but all information about copper speciation was lost. So, the method would not be useful in determining the effect of copper speciation on fuel stability.

Alumina could not be used as a stationary phase for the determination of the speciation of copper in jet fuel, because alumina was too polar, and acidic eluents converted it into an ion-exchange phase. We were also concerned about silica based packing materials because of their similarity to alumina. Even the derivatized packing materials have residual silanol groups that could retain the copper. A stationary phase polar enough to allow preconcentration and elution of the copper complexes in the jet fuel, but not polar enough to act as an ion-exchanger and displace the native ligands, was needed. One such stationary phase is polyvinylpyrrolidone[9] (PVP), $(C_6H_9NO)_x$. The chemical structure of the PVP polymer is shown in Fig. 2. A column was packed in house with commercially available packing material with a nominal diameter of 50 μm, because traditional HPLC columns packed with PVP are not commercially available. The column was used to evaluate the feasibility of using PVP as a stationary phase in the normal-phase chromatographic separation of copper complexes in jet fuel. On-column preconcentration of copper complexes and maintenance of their speciation was studied with the PVP stationary phase. Future work should employ smaller diameter PVP particles, to minimize peak broadening.

EXPERIMENTAL

Reagents

N,N'-disalicycline-1,2-propylenediamine, active ingredient in DMD, was purchased from Pfaltz & Bauer, Inc. Technical grade copper naphthenate was purchased from Chem Service. The copper cyclohexanebutyrate was purchased from Pfaltz & Bauer. Reagent grade copper acetate was purchased from Aldrich. Copper powder was purchased from J. T. Baker. Because the copper naphthenate and cyclohexanebutyrate were of unknown purity, solutions of all three carboxylates were made and the copper content was determined by FAA. The isopropyl alcohol, and hexane were Baker Analyzed HPLC Reagent grade solvents (J. T. Baker). The water was purified in house using a Milli-Q Reagent Waters System (Millipore Corporation, Bedford, MA, U.S.A.). The jet fuels analyzed in this study were provided by the Fuels Research Branch at Wright-Patterson Air Force Base (Dayton, OH, U.S.A.).

Column

The column was a 5 cm × 4.3 mm PEEK column with ultra-high molecular weight polyethylene frits (Upchurch Scientific Inc. Oak Harbor WA, U.S.A.). The PVP stationary phase came from Dionex Onguard-P solid phase extraction cartridges (Dionex Corp. Sunnyvale, CA, U.S.A., p/n 039597). The average nominal diameter of the PVP was reported to be 50 μm. The column was packed by slurrying the PVP with isopropyl alcohol, and transferring the slurry into the column with an eyedropper. The excess isopropyl alcohol was removed by a small pump (Fluid Metering Inc. Oyster Bay, NY).

Apparatus

The HPLC system was a Dionex BioLC system with a variable wavelength absorbance detector. The system provides a metal-free eluent flow path which has ensured no sample contamination by the chromatographic system and a low baseline. The HPLC was coupled to the FAA spectrophotometer by connecting the variable wavelength absorbance detector outlet tubing to the FAA nebulizer with an 18 gauge blunt tip needle and 20 gauge Teflon tubing.

A Perkin–Elmer 403 flame atomic absorbance spectrophotometer (Norwalk, CT, U.S.A.) with manual controller, a spoiler nebulizer and 10.5 cm 3-slot burner was used as an element specific detector. The operating conditions for the FAA are listed in Table 1.

The final solvent program was: 0–3 min, 30% hexane, 70% isopropyl alcohol, with a 1.25-ml sample injection at 0.5 min. The eluent from 3 min to the end of run was 5% acetic acid and 0.5% water in isopropyl alcohol.

Data acquisition and control

The data acquisition and system control were done using an IBM AT computer with an IBM DACA board (Boca Raton, FL, U.S.A.). The data acquisition and system control software was written in-house using Microsoft Quick Basic. (Microsoft Corp., Bellevue, WA, U.S.A.).

RESULTS AND DISCUSSION

The PVP stationary phase was evaluated by injecting hexane solutions of the copper complexes listed in Table 2 onto the PVP column.

Table 2. Capacity factor (k') *vs.* percent acetic acid, by volume, on a PVP stationary phase

Species	LOG stability constant[11]	Percent acetic acid in eluent by volume 0	1	2	3	5
Copper acetate	3.63	*	3.0	2.5	2.1	2.4
Copper cyclohexanebutyrate	2.98	*	3.1	2.7	2.4	2.3
Copper naphthenate	†	*	3.2	2.4	2.2	2.4
CuDMD	20.5	0.8	0.6	0.5	0.4	0.5

*The copper carboxylates had a capacity factor greater than 40 for eluents without any acetic acid.

†The stability constant of copper naphthenate is unknown but should be in the same range as the copper acetate and copper cyclohexanebutyrate.

We needed to determine whether the copper compounds would be retained by PVP. If they were retained, we then needed to determine how strongly they were retained and under what conditions they were eluted. It was also important to determine whether the copper speciation was preserved or whether the ligands were displaced from the copper during retention and elution, specifically, if the same copper compound injected was eluted, or if ligand loss or exchange had occurred during retention and separation. This can be substantiated by comparing the ratio of UV and FAA responses for different compounds.

The CuDMD complex was used as a test compound, because it is the dominant copper compound present in fuels containing copper that have been treated with DMD. Figure 3 shows the capacity factor, k', of the CuDMD complex on PVP for different combinations of isopropyl alcohol and hexane. From Fig. 3 we can see that the retention time of the CuDMD complex increases as the hexane concentration increases and the mobile phase becomes less polar. This means the CuDMD complex will be strongly retained by the PVP as long as the mobile phase is non-polar. Since jet fuel is nearly as non-polar as hexane, the capacity factor of CuDMD can be estimated from Fig. 3 to be near 100 when jet fuel flows through the PVP column, which means on-column preconcentration will be feasible.[10]

The other copper compounds investigated in this study were copper carboxylates. Copper carboxylates are copper compounds which might be present in jet fuel that would degrade fuel stability. The copper carboxylates tested had a capacity factor greater than 40 on PVP for all the combinations of hexane and isopropyl alcohol. The copper carboxylates were effectively eluted by a mixture of acetic acid, water and isopropyl alcohol. The water appeared to be necessary for UV detection of the copper carboxylates, which undergo an absorbance shift when hydrated, but changes in the concentration of water in the eluent did not affect the capacity factors of the copper compounds. When the concentration of water in the eluent was greater than 3%, the column back pressure became excessive. The pressure increase is thought to be due to water induced swelling of the PVP.

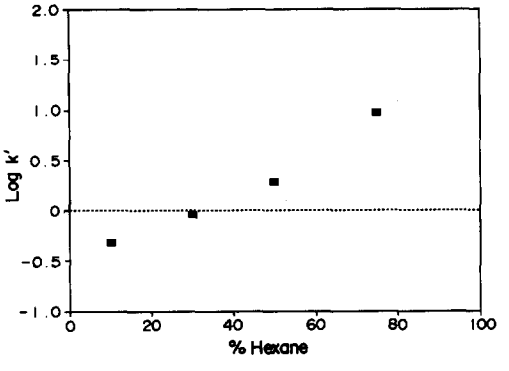

Fig. 3. Log k' of CuDMD complex as a function of percent hexane (by volume) in isopropyl alcohol, where k' is the capacity factor.

The capacity factors of the copper compounds for different combinations of acetic acid and isopropyl alcohol are listed in Table 2. None of the copper carboxylates eluted unless the eluent contained acetic acid. The data in Table 2 indicates all of the copper carboxylates have similar capacity factors for each acetic acid concentration. We believe this is because all the copper carboxylates were eluting as the same species: copper acetate. It seems the copper complexes were intact when they adsorbed on the PVP, but the copper carboxylates underwent ligand exchange during elution. Changing the concentration of acetic acid in the eluent did not significantly change the capacity factors of the copper carboxylates. The peaks just got wider as the acetic acid concentration decreased. This result is thought to be due to the kinetics of the ion exchange process.

The first column in Table 2 lists the logarithms of the stability constants in water,[11] of the copper compounds studied in this investigation. Stability constants, K_s, or formation constants, K_f, describe the strength of a metal ligand complex. The smaller the stability constant of a metal complex, the more likely the complex is to dissociate into metal and ligand ions. This information is significant, because it provides an indication of the likelihood the copper will dissociate while it is being separated. The logarithms of the stability constants listed are for metal complexes in water. The copper complexes should be less prone to dissociate in the solvent systems used in the separation, because they do not support ions as well as water. The CuDMD complex is several orders of magnitude more stable than the copper carboxylates. The copper carboxylates all have similar stability constants, because all the ligands are bound to the copper ion by the same functional group. This is significant, because the stability constant of a copper complex may be related to its

catalytic activity in jet fuel.[5-8] The stability constant of a copper complex may be inversely correlated with the catalytic activity of the copper in jet fuel, because the copper of the more labile species is more available to interact with the components in the fuel, is not as stabilized in one oxidation state, and can act as a catalyst.

Once we had demonstrated that the copper compounds were adequately retained by the PVP to effect a separation, while the majority of the non-polar constituents of jet fuel passed through essentially unretained, we developed a separation of the two classes of copper compounds using the information in Table 2 and Fig. 3. The separation enabled us to distinguish between the copper that would adversely affect fuel stability and the copper that would not. The separation uses a mixture of hexane and isopropyl alcohol to carry the sample to the column and elute the CuDMD. Then a step gradient to a 3% acetic acid in isopropyl alcohol is used to elute the other copper compounds in the sample. Figure 4 is the absorbance chromatogram at 280 nm of a 1.25-ml hexane injection that illustrates the solvent program used to separate the copper compounds. The disturbance between 1 and 3 min is the injection disturbance and the refractive index effects due to the hexane passing through the system. Since acetic acid absorbs weakly at 280 nm, the increase in absorbance between seven and eight minutes is proportional to the acetic acid concentration. This solvent program enabled us to separate the copper complexes into two classes:

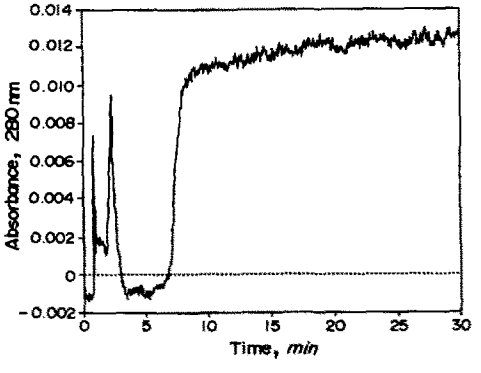

Fig. 4. Solvent program used in normal-phase separation of copper complexes in jet fuel. Absorbance of mobile phase at 280 nm is proportional to the concentration of acetic acid present. The program was 70% isopropyl alcohol/30% hexane from 0–3 min, with sample injection at 0.5 min, 3-end of run was 5% acetic acid and 0.5% water in isopropyl alcohol. The disturbance between 2–3 min is explained in the text.

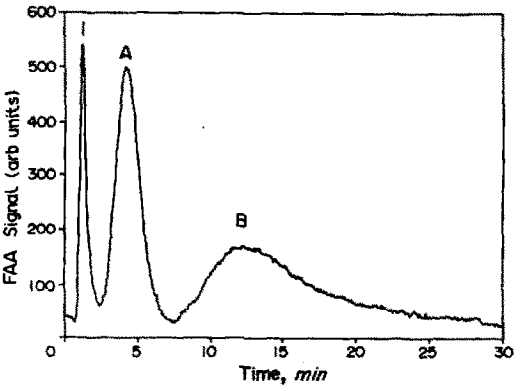

Fig. 5. Normal-phase separation of on-column preconcentrated copper complexes in hexane followed by FAA detection of the Cu signal: (A) CuDMD and (B) Copper carboxylate with (I) injection disturbance explained in text.

CuDMD and the copper carboxylates. This is significant because it enabled us to distinguish, for the first time, the weakly bound copper complexes that would have a detrimental effect on fuel stability from the strongly bound copper complex (CuDMD) that does not affect fuel stability.

Figure 5 shows the separation of two copper compounds in a hexane solution with copper-specific FAA detection. The peak at 4 minutes is CuDMD, the peak at 12.5 min is a copper carboxylate, and the spike at one minute is due to the combustion of the hexane plug, which makes the flame richer; the soot particles of the hexane flame scatter the light.

Having established that the test copper complexes can be separated with a PVP stationary phase, we needed to lower the limit of detection (LOD) to the point where we could detect copper at an adequate level to detect copper concentrations that would cause stability problems. We considered on-column preconcentration,[10] since the copper complexes are readily preconcentrated at high k' while the non-polar constituents of the fuel pass through at low k'. On-column preconcentration was accomplished by injecting a larger volume of jet fuel. Table 3 shows the detected volume of the copper peaks for two different injection volumes. Injecting a

Table 3. On-column preconcentration study: effect of injected volume on eluted peak volume at the base

Volume Injected	25.0 μl	1.25 ml
Peak width, CuDMD	1.61 ml	3.0 ml
Peak width, copper acetate	6.20 ml	13 ml

Table 4. Limit of detection (LOD) for copper carboxylates and copper DMD

Copper complex	Conc. LOD, *ppb*	Mass LOD, *ng*	Relative response factor*	Peak width, *min*
CuDMD	7	9	1.00	3
$Cu(OAc)_2$†	40	50	0.14	13

*This ratio indicates the relative response of the flame AA detector to a copper solution after separation.[12]
†$Cu(OAc)_2$ is copper acetate

sample volume fifty times greater only increased the peak width by a factor of two. This loss of column efficiency is acceptable for the method, because more than adequate chromatographic resolution is achieved with the solvent program to distinguish between the different classes of copper compounds. Thus, the limit of detection (LOD) was substantially improved by on-column preconcentration of a large sample volume.

The injected concentration and mass LODs for the different copper complexes are listed in Table 4. The LODs were the concentrations of copper required to give a signal three times the standard deviation of the baseline noise. The LODs for the different copper species were influenced by the width of the peak and the solvent used for elution.[12-14]

Once we had demonstrated the method could separate and detect the two classes of copper complexes at sufficiently low concentrations to be useful in the evaluation of the stability of fuels, the method was used to analyze several jet fuel samples in order to demonstrate its ability to identify and quantitate strongly and weakly bound copper complexes in real samples. The chromatograms of the jet fuel samples are shown in Fig. 6. Figure 6(A) shows the FAA signal for a fuel sample that has been double clay treated (DCT), a process which removes all the metals from the fuel. This is consistent with the chromatogram that does not indicate the presence of copper. This sample was taken as the baseline, and subtracted from the subsequent fuel samples. Figure 6(B) shows the

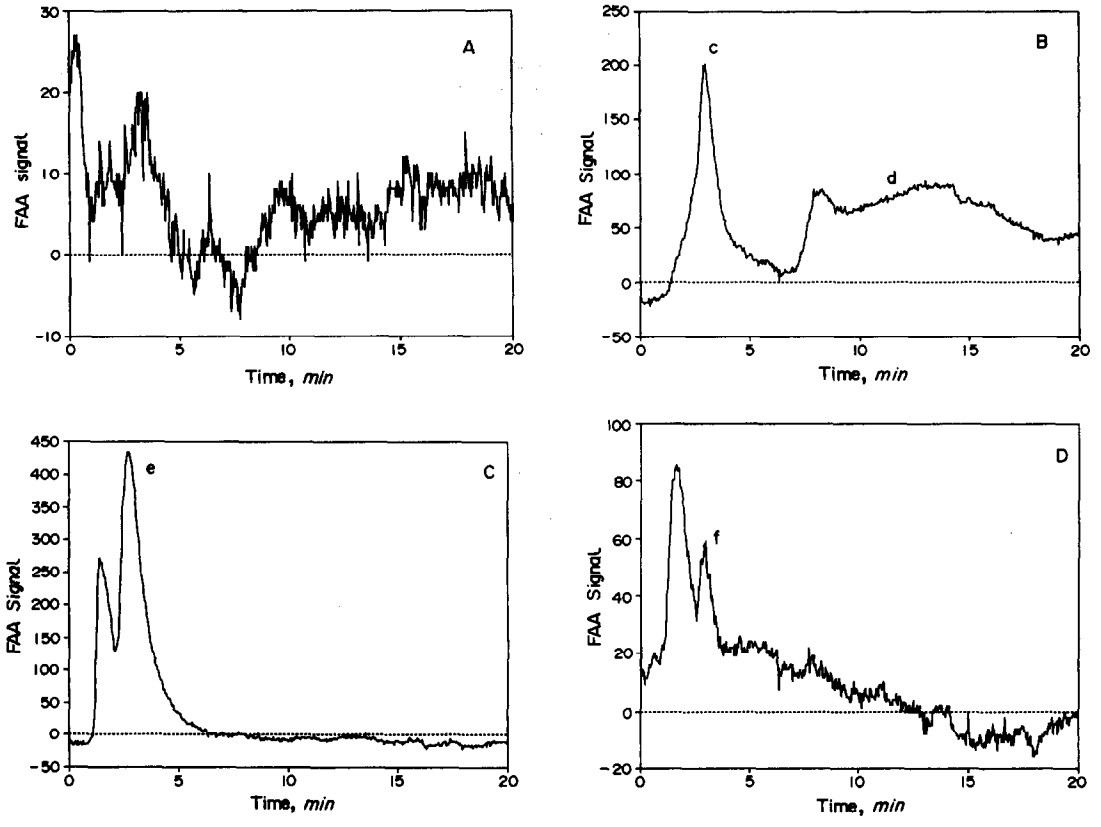

Fig. 6. FAA detection of the normal-phase separation of on-column preconcentrated jet fuel samples run as in Fig. 5, with quantitative results summarized in Table 5 for the labeled features: (A) chromatogram of double clay treated JP-8 with all metals removed, (B) chromatogram of JP-8 that had been standing over copper for 18 hours, (C) chromatogram of Mobil Oil Co. jet fuel, (D) chromatogram of POSF-2691, JP-4.

chromatogram of a JP-8 sample that had been standing over copper powder for 18 hours. The chromatogram shows almost 400 ppb of copper was solvated by the fuel, with 95 ppb Cu solvated into a strongly bound form similar to CuDMD and 300 ppb as weakly bound copper. This shows the propensity of jet fuel to solvate any copper with which it is in contact. Figure 6(C) shows the chromatogram of a Mobil Oil Company JP-5 sample from Tarrance Co. The chromatogram shows that the fuel contains 200 ppb of tightly bound copper, probably CuDMD. Figure 6(D) shows the chromatogram of the JP-4 sample POSF-2691, which contains 14 ppb copper in a form similar to CuDMD. Table 5 is a summary of the information about the copper complexes found in the fuel samples.

CONCLUSIONS

We have developed a method capable of differentiating between the copper species that will cause fuel instability and the copper that has been passivated by DMD, with LODs of 40 and 7 ppb respectively. This is the first reported analytical method capable of determining copper near the level where it can cause stability problems while differentiating between the copper that will cause stability problems and the copper that is no longer catalytically active.

(*Received* 1 *June* 1992. *Revised* 19 *August* 1992. *Accepted* 19 *August* 1992)

Summary—The complexation reactions between Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) ions and benzo-15-crown-5, dicyclohexyl-18-crown-6, dibenzo-18-crown-6 and 1,10-diaza-18-crown-6 have been studied in dimethylsulphoxide solution at 25° by means of a competitive spectrophotometric method using murexide as a metallochromic indicator. With the exception of Pb(II)(benzo-15-croqn-5)$_2$ the stoichiometry of the resulting complexes was found to be 1:1. The formation constants of the complexes were determined, and found to follow the Irving–Williams rule for the cations of the first transition series. It was found that the metal ion-18-crown interactions are strongly dependent on the nature of the substituents on the ring.

Since Pedersen's discovery of macrocyclic polyethers (crowns) capable of forming stable and selective complexes with the alkali and alkaline earth cations,[1] the studies of these ligands and their complexes become an import field of research. During the past two decades, intensive efforts have been undertaken to understand the factors which control the thermodynamic and kinetic stability and selectivity of the resulting complexes in solution.[2–6] However, most of the investigators have concentrated their efforts on the study of alkali and alkaline earth-crown ether complexes, and the corresponding macrocyclic complexes with transition and heavy metal ions, especially in non-aqueous solutions, have received much less attention.[6]

Because of the low stabilities of most crown ether complexes with the cations of the first transition series,[4,6] as well as the serious interference by hydrolysis of these cations in aqueous crown and cryptand solutions,[7] we chose to study the corresponding complexation reactions in dimethylsulphoxide (DMSO) solution. Using DMSO as a dipolar aprotic solvent removes difficulties associated with transition metal ion hydrolysis.[8] Moreover, in this solvent, the different transition metal salts and crown ethers used are readily soluble and, more importantly, the resulting murexide solutions in DMSO are quite stable (in contrast to the corresponding aqueous solutions).

We have recently reported a spectrophotometric method for the study of the murexide complexes with Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) ions in dimethylsulphoxide solution.[9] In this paper, we employed murexide as a metallochromic indicator to study the resulting complexes between these cations and benzo-15-crown-5 (B15C5), dicyclohexyl-18-crown-6 (DC18C6), dibenzo-18-crown-6 (DB18C6) and 1,10-diaza-18-crown-6 (DA18C6) in dimethylsulphoxide solution by means of a competitive spectrophotometric method.

EXPERIMENTAL

Reagent grade cobalt chloride, nickel chloride, copper chloride, zinc chloride, cadmium nitrate and lead nitrate (all from Merck) were dehydrated and dried as described elsewhere.[9] Reagent grade tetraethylammonium perchlorate (TEAP, Fluka) and murexide (Mu, Merck) were of the highest purity available and were used without further purification except for vacuum

*Author for correspondence.

drying over P_2O_5 for 72 h. Crown ethers B15C5, DC18C6, DB18C6 and DA18C6 (all from Merck) were purified and dried by the previously described methods.[10,11] Spectroscopic grade dimethylsulphoxide (DMSO, Merck) was used as received. All spectra were obtained with a Model 2100 Shimadzu UV-Vis spectrophotometer at $25 \pm 1°$.

The formation constants of the resulting complexes between the crown ethers and metal ions used were determined by the absorbance measurements, at λ_{max} of each murexide–metal ion complex,[7] of solutions in which varying concentration of metal ions (2.0×10^{-4}–$1.0 \times 10^{-3} M$) were added to a fixed concentration of murexide ($2.0 \times 10^{-5} M$) and crown ethers (0.005–$0.03 M$) in DMSO. The ionic strength of all solutions was kept constant at $0.1 M$ using TEAP. All solutions were neutral and, hence, the ligand existed in its monovalent form throughout.[9,12] Attainment of equilibrium was checked by the observation of no further change in the spectra after several hours. It should be mentioned that none of the transition metal complexes with crown ethers used show any absorption band in the visible region in the concentration ranges studied.

As it was pointed out before,[9] in the case of 1:1 complex formation between murexide and a metal ion, M, the following linear relation exists between $(A/A_0 - 1)/C_M$ and A/A_0

$$(A/A_0 - 1)/C_M = \epsilon_{Mu}/\epsilon_{MMu} K'_{MMu} - K'_{MMu} A/A_0 \quad (1)$$

where $A_0 = \epsilon_{Mu} C_{Mu}$ and A, ϵ_{Mu}, ϵ_{MMu}, C_{Mu}, C_M and K'_{MMu} are the absorbance at λ_{max} of complex, molar absorptivity of murexide, molar absorptivity of complex, total concentration of murexide, total concentration of metal ion and apparent formation constant of MMu, respectively. It should be noted that under the neutral conditions used, murexide exists only in its monovalent form[12] and can only form 1:1 complexes with metal ions;[9,13,14] thus, when no other complexing agent is present, K'_{MMu} would be actually equal to the absolute formation constant K_{MMu}. According to equation (1), the value of K'_{MMu} could be obtained from the intercept of the linear plot of $(A_0/A - 1)/C_M$ *vs.* A_0/A.

However, in the presence of a crown ether, as a buffer ligand, the metal ion can also form 1:1 and 2:1 (ligand to metal) crown ether complexes with respective stepwise formation constants

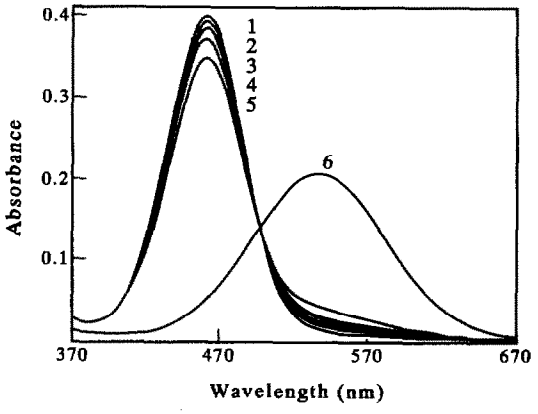

Fig. 1. Plots of $(K_{MMu}/K'_{MMu} - 1)/C_{B15C5}$ *vs.* C_{B15C5}. MMu: 1, Pb–murexide: 2, Zn–murexide.

K_{MC} and K_{MC_2}. In this case, the murexide–metal ion apparent formation constant, K'_{MMu}, can be related to its absolute formation constant, K_{MMu}, by

$$K'_{MMu} = K_{MMu}/\alpha_M \quad (2)$$

Under the experimental conditions $C_C \gg C_M \gg C_{Mu}$, that is the fraction of free metal α_M is given by

$$\alpha_M = 1 + K_{MC} C_C + K_{MC_2} C_2^2 \quad (3)$$

where C_C is the total concentration of crown ether.

Combination of equations (2) and (3) results in

$$\frac{1}{K'_{MMu}} = \frac{1}{K_{MMu}} + \frac{1}{K_{MMu}} (K_{MC} C_C + K_{MC_2} C_C^2) \quad (4)$$

Rearrangement of equation (4) then gives

$$(K_{MMu}/K'_{MMu} - 1)/C_C = K_{MC} + K_{MC_2} C_C \quad (5)$$

According to equation (5), a plot of $(K_{MMu}/K'_{MMu} - 1)/C_C$ *vs.* C_C provides information about the stoichiometry and stability of the metal ion–crown ether complexes. The existence of a linear relation between $(K_{MMu}/K'_{MMu} - 1)$ and C_C reveals the formation of both 1:1 and 2:1 complexes in solution, from the intercept and slope of which K_{MC} and K_{MC_2} could be obtained, respectively. While in the cases where only a 1:1 complex is formed, the (K_{MMu}/K'^{-1}_{MMu}) *vs.* C_C plots give horizontal lines, the intercept of which is equal to K_{MC} (Fig. 1).

RESULTS AND DISCUSSION

The spectra of murexide and its complexes with Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and

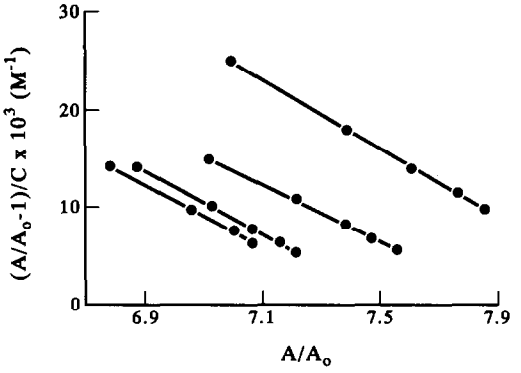

Fig. 2. Visible region spectra for titration of $2.0 \times 10^{-5}M$ murexide with Zn(II) in the presence of $0.01M$ B15C5 and ionic strength of $0.1M$ in DMSO. [Zn(II)]: 1, $4.0 \times 10^{-4}M$; 2, $5.9 \times 10^{-4}M$; 3, $7.9 \times 10^{-4}M$; 4, $9.9 \times 10^{-4}M$; 5, $1.2 \times 10^{-3}M$; 6, murexide alone.

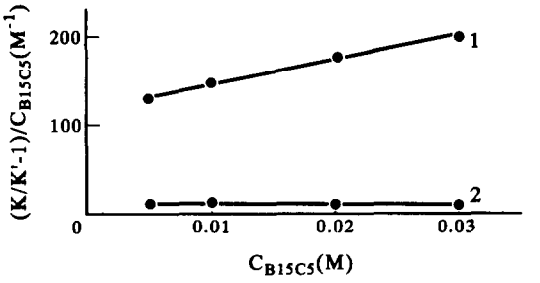

Fig. 3. Plots of $(A/A_0 - 1)/C_M$ *vs.* A/A_0 for Zn(II)–murexide at different concentrations of B15C5 in DMSO. C_{B15C5}: 1, $0.005M$; 2, $0.01M$; 3, $0.02M$; 4, $0.03M$.

Pb(II) ions in DMSO solution are reported elsewhere.[9] All of the resulting complexes are distinguished by a strong spectral shift of about 18–73 nm toward shorter wavelengths, in comparison to the free murexide. In order to determine the stoichiometry and stability of metal ion complexes with B15C5, DC18C6, DB18C6 and DA18C6, the spectra of a series of solutions of fixed murexide and crown ether concentrations and varying amounts of the metal ions were recorded. All spectra presented satisfactory isobestic points. The deviations of spectra from isobestic points were at the most $\pm 5\%$. The spectra of mixtures of murexide and zinc ion in the presence of B15C5 in DMSO solution are shown in Fig. 2 and the corresponding $(A/A_0 - 1)/C_M$ *vs.* A/A_0 plots are given in Fig. 3. The apparent formation constants of metal–murexide complexes were obtained from the slopes of such linear plots. The stoichiometry and stability of different metal–crown ether complexes were determined using the corresponding plots of $(K_{MMu}/K'_{MMu} - 1)$ against C_C. Two samples of the resulting plots are shown in Fig. 1.

With the exception of Pb(II)–B15C5 system, all metal ion–crown ether complexes examined showed a 1:1 stoichiometry. However, in the case of Pb(II) ion, evidences for the formation of both 1:1 and 2:1 (ligand to metal) complexes in DMSO solution was observed. B15C5 has a cavity size (1.7–2.2 Å)[15] that is too small for Pb(II) ion (2.38 Å).[16] Therefore, the cation can only partially penetrate inside the cavity of the ligand and, consequently, a second ligand can approach the cation from the other side to form a 2:1 sandwich complex.[17] In all other cases studied, the size of the cations used (Table 1) are smaller than the cavity size of the three 18-crowns tried (2.6–3.2 Å)[15] and, therefore, the formation of 1:1 complexes is not unexpected.

All calculated formation constants of the resulting complexes between the cations and crown ethers used in DMSO solution are summarized in Table 1. The previously reported stability constants for Cu(II) and Pb(II) complexes with DA18C6 in DMSO are also included for comparison.[18] It should be noted that the Ni(II)–DA18C6 and Zn(II) DA18C6 systems in DMSO showed an unexpected spectrophotometric behaviour (probably due to the

existence of a third equilibrium in solution) and, therefore, the corresponding formation constants cannot be determined by the proposed method. As it is seen, the sequence of stability of the first transition series with all crown ethers tried (*i.e.*, Co(II) < Ni(II) < Cu(II) > Zn(II)) follows the Irving–Williams order,[19] which generally holds for the equilibrium constants of transition metals. On the other hand, Pb^{2+} ion forms more stable complexes[5] than Cd(II) ion with 18-crowns used, mainly because of the better fitting condition of this cation inside the macrocyclic ligands' cavity.

Comparison of the data given in Table 1 shows that among 18-crowns used, where the ring frame remains the same, metal ion–crown ether interaction is strongly a function of the nature of substituents on the ring which control both the electron-pair donicity and the flexibility of the ligand molecules. It is seen that DA18C6 forms the most stable complexes and DB18C6 the least stable ones in the series. The two nitrogen atoms of DA18C6 ring, as soft bases, would interact more strongly with the transition metal ions as soft or intermediate acids[20] than oxygen atoms, as hard bases. It should be noticed that DA18C6 has also the most flexible structure among the 18-crowns used, so that the macrocyclic molecule can easily wrap itself around the cations, inducing more stability to the resulting complexes.

Table 1 shows that, substitution of two benzo groups on the 18C6 ring lowers the stability of the resulting complexes in comparison to DC18C6. This behaviour may be attributed to some combination of the electron-withdrawing property of benzo groups which weakens the electron-donor ability of the oxygen atoms of the ring, and reduced flexibility of the ligand which prevents the macrocyclic molecule wrapping itself around the cation.[10,11]

SPECTROPHOTOMETRIC DETERMINATION OF URANIUM USING ASCORBIC ACID AS A CHROMOGENIC REAGENT

K. K. GUPTA, P. G. KULKARNI, GEORGE THOMAS, N. VARADARAJAN, R. K. SINGH* and M. K. T. NAIR

Fuel Reprocessing & Nuclear Waste Management Group, PREFRE Plant, B.A.R.C., Tarapur, India

(*Received* 9 *April* 1992. *Revised* 19 *August* 1992. *Accepted* 19 *August* 1992)

Summary—A spectrophotometric method has been developed for the determination of uranium(VI) using ascorbic acid. Uranium in the hexavalent state forms a reddish-brown coloured complex with ascorbic acid. The colour intensity of the complex is maximum at pH 4.2–4.5 and is stable for 24 hr. The absorbances of uranium(VI)–ascorbic acid complex at 360 and 450 nm are used for its quantification. Uranium in the range 8–200 μg/ml has been determined with good precision. The method allows the determination of uranium in the presence of many metal ions present as impurities. The described method is simple, accurate and applicable to uranium concentration relevant to the PUREX process and thus can be used for analytical control purposes.

The PUREX process is employed commercially to recover uranium and plutonium by reprocessing spent nuclear fuels. The uranium concentration is determined in various streams for process control in plant operations. Spectrophotometric methods are the most commonly and widely used analytical techniques for uranium determination. In general, these methods are based on the colour reaction of U(VI) with two types of chromogenic reagents. These are intensely coloured organic reagents forming chelate types of complexes and inorganic reagents containing oxygen and sulphur donors, forming simple coordination complexes with U(VI). Methods based on the former type of reagents like dibenzyolmethane (DBM), 1-(2-pyridylazo)-2-napthol (PAN), 5-dimethylamino-2-(2-thiazolyazo) (TAM), arsenazo(III) and 8-hydroxyquinoline are highly sensitive but less specific and therefore have poor tolerance for trace level impurities present in the sample.[1–5] In the application of such methods the prior chemical separation of U(VI) is, therefore, mandatory. The chemical separation steps are often time consuming and tedious in nature, making such methods unsuitable for process control analysis purposes.[6] On the other hand methods based on the latter type of chromagenic reagents are relatively simple and rapid. Two such methods currently in use are based on the colour reactions of uranyl ion with hydrogen peroxide and alcoholic ammonium thiocyanate.[7,8] The peroxide method finds limited application owing to its poor sensitivity and selectivity. The alcoholic ammonium thiocyanate method has relatively good sensitivity and selectivity. However, the waste generated in this procedure causes serious concern. The corrosive nature and relatively high concentration of thiocyanate pose typical waste management problems. The alcohol fraction of the waste constitutes a fire hazard and necessitates additional precautions, while storing or disposing. To circumvent these problems, a new spectrophotometric method has been developed for the estimation of uranyl ion in aqueous as well as organic streams of the PUREX process. The method involves the use of ascorbic acid as a chromogenic reagent for uranyl ion in aqueous media. The results of analysis of some synthetic samples and actual PUREX process samples are reported here.

EXPERIMENTAL

Apparatus

Absorbance measurements were made with a Shimadzu UV–Vis-160 double beam microcomputer-controlled recording spectrophotometer with 1 cm path glass cells. A glass electrode pH meter was used for pH measurements.

*Author for correspondence.

Reagents

Standard uranium solution. A uranium(VI) stock solution (5 mg/ml) was prepared by dissolving nuclear pure grade U_3O_8 powder (obtained from Uranium Metal Plant, B.A.R.C.) in 1:1 nitric acid and standardized by a modified Davis & Gray method using potentiometric end point detection.[9]

Ascorbic acid solution. *L*-Ascorbic acid, $C_6H_8O_8$ (Polypharm, Bombay), was dissolved in distilled water to make a 1*M* solution and filtered through Whatman 41 paper.

Sodium carbonate solution. Sodium carbonate, Na_2CO_3 (Qualigens fine Chemicals, Bombay), was dissolved in distilled water to make a 0.5*M* solution.

Chromogenic reagent. Chromogenic reagent was prepared as and when needed by mixing 1*M* ascorbic acid solution, 0.5*M* sodium carbonate solution and distilled water in the proportion 7:4:9 to the required total volume.

All chemicals used were of analytical reagent grade.

Preparation of synthetic acidic uranium sample. Fixed aliquots of U(VI) standard solution were evaporated to dryness in different vials. The residue of each of these vials was dissolved in nitric acid of varying strength keeping the volume constant.

Procedure and calibration

A weighed or volumetric aliquot of the sample solution up to 0.5 ml in volume and containing not more than one milli equivalent of nitric acid was transferred quantitatively into a 25 ml capacity standard flask. The solution was made up to the mark with freshly prepared chromogenic reagent. The content of the flask was mixed well by shaking and the absorbance of the resultant solution was measured at 360 nm (0.2–1.0 mg U) or 450 nm (1–5 mg U) against a reagent blank. The amount of uranium present in an aliquot can be computed with the following equations:

$$U = 1.4887\ A_1 + 0.0098 \text{ (360 nm)}$$

or

$$U = 4.2696\ A_2 + 0.0001 \text{ (450 nm)}.$$

Here U is the uranium amount (mg) present in the sample aliquot and A_1 and A_2 are the measured absorbances at 360 nm and 450 nm, respectively.

Ten weighed aliquots of the standard uranium solution covering the range from 0.2–5 mg were evaporated to dryness into separate beakers and the content of each beaker was

transferred quantitatively into separate 25 ml standard flasks using chromogenic reagent. The absorbance of the developed colour was measured according to the procedure described earlier. The calibration equations were obtained by regression analysis.[10]

RESULTS AND DISCUSSION

Absorption spectra

Uranium forms a 1:1 complex with ascorbic acid. The instability constant of the complex $[UO_2HA]^+$ at 20° is 3.3×10^{-3} as reported.[11] The complex has the maximum absorption at 335 nm (Fig. 1). At this wavelength the chromogenic reagent itself has significant absorption and hence absorbance measurements are made at 360 and 450 nm which obey Beer's law. The complex has a molar extinction coefficient of about 4000 at 360 nm and 1400 at 450 nm. The complex is stable for 24 hours.

Effect of pH

The complex formation and its absorbance is influenced by the pH of the medium (Fig. 2). At the pH range 4.2–4.5 the absorbance is constant. There is no need for preneutralization of acidic samples since the chromogenic reagent itself acts as a buffer possessing sufficient buffer capacity, hence the system needs no external buffer for pH control.

Amount of chromogenic reagent

At the fixed ratio of ascorbic acid to sodium carbonate, the optimum amount of the chromogenic reagent necessary for the quantitative complexation of uranium is evaluated (Fig. 3).

Analysis of the synthetic samples

Analysis results of synthetic samples are reported in Table 1.

Interferences

Iron, zirconium and plutonium are the potential interferents expected in the uranium determination in PUREX process stream samples. The effects of these metal ions has been studied and the results are listed in Table 2. It can be seen from the data that Zr and Fe do not interfere up to a 1:1 ratio (w/w). The method is also free from Pu interference up to a 1:2 ratio (w/w). Nitric acid influence on uranium estimation has been studied and the results are summarized in Table 3. No significant interference is observed up to 1 meq. nitric acid in the sample aliquot. Interference caused by some anions like sulphate, phospate and fluoride has been reported.[10] These ions are rarely encountered in significant amount in PUREX process streams and hence were not tested in this work.

U.P.—Uranium Product
*Value in mg/g.

Reliability

Aged ascorbic acid solution introduces a bias in the method. To avoid this, ascorbic acid solution should be prepared daily.

The precision of the method (RSD, 11 determinations) is found to be ±2% and ±1% at 0.5 and 5 mg levels respectively.

Acknowledgements—The authors express their sincere thanks to Shri A. N. Prasad, Director, F.R. and N.W.M. Group for his keen interest and encouragement given during the work. The authors are also thankful to the members of the mass spectrometry group and Shri Pintu Sen for their help and cooperation provided at various stages of the work.

SIMULTANEOUS DETERMINATION OF MULTICOMPONENTS BY FLOW INJECTION ANALYSIS

DETERMINATION OF COPPER AND ZINC IN SERUM BY USING ZINCON AS COLOURING REAGENT

REN-MIN LIU, DAO-JIE LIU and AI-LING SUN

Department of Chemistry, Liaocheng Teachers College, Liaocheng, Shandong, People's Republic of China

(*Received* 5 *March* 1992. *Revised* 19 *August* 1992. *Accepted* 19 *August* 1992)

Summary—A flow injection system is described for the simultaneous determination of copper and zinc with a single detector. Two sample plugs are injected into the same carrier stream sequentially. One is for zinc determination and the other is for the sum of copper and zinc. For zinc determination, copper masking reagent is simultaneously injected into a parallel carrier stream and merged with the sample plug by using the merging zone technique. Zincon is used as the colour reagent for the spectrophotometric determination of copper and zinc. The results for the analysis of serum by the proposed method correspond well with those obtained by an AAS method. The rate of analysis is about 45 samples/hr.

Flow injection analysis (FIA) has increasingly been used in various fields, owing to its high sample throughput, cost effective performance and versatility. Whereas in the initial development of FIA, methods were focussed on finding selective methods of detection, a recent trend has been the design and optimization of measuring systems for the simultaneous determination of two or more components, *e.g.*, multicomponent determination.[1–5]

Copper and zinc are essential micro-elements in the human body. The determination of copper and zinc, especially their ratio, in serum is of great interest in clinical chemistry.[9] Several FIA atomic spectroscopy methods have been reported for the simultaneous determination of copper and zinc in serum,[6–8] whereas few methods have been based on spectrometric detection.

Zincon is a sensitive reagent for copper and zinc. In the present work, zincon is used as the reagent for the determination of copper and zinc by using a flow injection analysis system. A three-loop system is used to sequentially inject two samples, one of which is merged with a copper masking solution. In this manner, two FIA peaks are sequentially recorded, one the sum of copper and zinc, the other zinc only.

EXPERIMENTAL

Reagents

Standard stock solution of copper. 1.0 mg/ml.

Standard stock solution of zinc. 1.0 mg/ml.

Copper masking reagent. A 5% (m/V) solution of thiourea.

Buffer solution (carrier). A 12.4-g weight of boric acid, 13 g of potassium chloride, 3.1 g of sodium citrate, 1.5 g of sodium triphosphate and 0.13 g of 1,10-phenanthroline were dissolved in 800 ml of water and the pH was adjusted to 9.0. The solution was then diluted to 1000 ml.

Zincon solution. 0.05% aqueous solution.

Apparatus

The flow injection manifold used is shown in Fig. 1. A Hitachi 220A spectrophotometer equipped with a flow cell was used as the detector. A dual six-way rotary valve (provided by Yellow Sea Fisheries Research Institute, Chinese Academy of Fisheries Sciences) with three loops was used for sample and copper masking reagent injection. The connection of the valve was shown in Fig. 2.

Procedure

The FIA system is connected up with PTFE tubing (1.0 mm i.d.) according to the arrange-

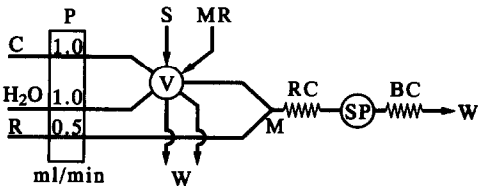

Fig. 1. Schematic diagram of FIA system. C, carrier (buffer solution); R, zincon solution; P, peristaltic pump; S, sample; MR, copper masking reagent; V, injection valve (PTFE); M, confuence point; RC, reaction coil (1.0 mm i.d., 120 cm long); BC, back-pressure coil (0.5 mm i.d., 2.0 m long); SP, spectrophotometer; W, waste.

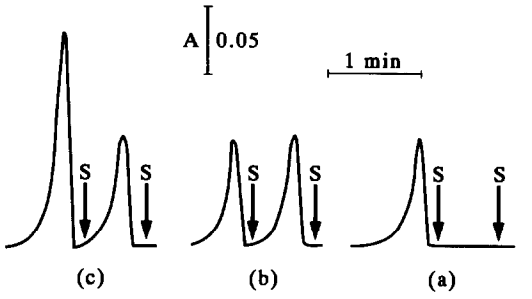

Fig. 3. Typical recordings for copper and zinc, (a) 1.0 μg/ml copper alone; (b) 1.0 μg/ml zinc alone; (c) 1.0 μg/ml copper and 1.0 μg/ml zinc in a mixture. The first (right) peak is for the sample in loop 2 and the second is for the sample in loop 3. S marks the time of injection for each sample plug.

ment shown in Fig. 1. The connection and operation of the injection valve is shown in Fig. 2. Three loops are mounted on the injection valve. Two are for samples and one is for the copper masking reagent. The sample plugs are injected into the carrier solution sequentially for separate spectrophotometric measurements. One is for zinc determination and the other is for the sum of copper and zinc. For zinc determination, the copper masking reagent is simultaneously injected into another carrier (water) and merges with the sample plug by the merging zones technique. The absorbance is red in the flow-cell at 606 nm. Two peaks are observed for the two separate injections, shown in Fig. 3(b). The first peak corresponds to zinc and the second to the sum of copper and zinc. Using the peak height as a measure of absorbance, copper absorbance can be calculated by the difference between the two peaks.

Prepare a series of mixed standard solutions of Cu(II) and Zn(II). Inject these solutions into the carrier solution as described for sample solutions, before and after the sample runs.

RESULTS AND DISCUSSION

FIA manifold for simultaneous determination

In the present approach, two sample plugs were injected into the same carrier solution sequentially. The second is injected after the signal for the first is recorded. One is for zinc determination and the other for the sum of copper and zinc. For the determination of the sum of copper and zinc, only the sample plug was injected into the carrier, and for the determination of zinc, the copper masking reagent was merged with the sample. A 120-cm reaction coil for colour-reaction was found to be suitable both for the determination of zinc and the sum of copper and zinc. The peak separation of the two sample plugs can be controlled by adjusting the interval of the injections. Good separation of the two peaks as shown in Fig. 3 can be obtained when the injection interval is 30–40 sec.

Determination of zinc and copper with zincon.

Zincon reacts with zinc and copper to form blue complexes. The absorption spectra of these

Injection valve and loop configurations, (a) state of determination of zinc; (b) state of determination of the sum of copper and zinc; L1, loop for copper masking reagent injection (120 μl); L2, loop for sample injection in determination of zinc (80 μl); L3, loop for sample injection in determination of the sum of copper and zinc (80 μl). Other symbols are as for Fig. 1.

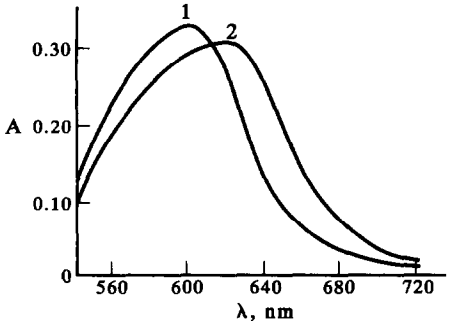

Fig. 4. Absorption spectra of Cu(II)–zincon and Zn(II)–zincon complexes, (1) 0.8 μg/ml of copper; (2) 0.8 μg/ml of zinc.

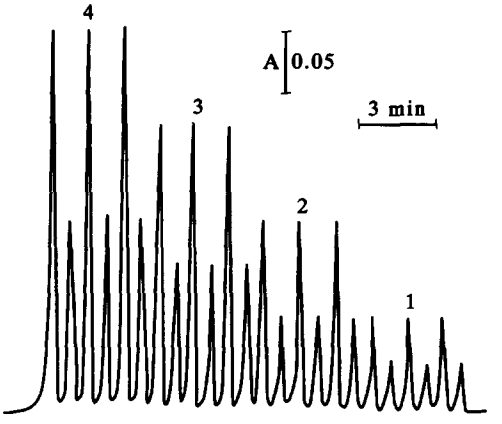

Fig. 5. Recorded signals of mixed standard solutions of copper and zinc. The first (right) peak corresponds to zinc and the second to the sum of copper and zinc. 1, 0.5 μg/ml copper and 0.5 μg/ml zinc; 2, 1.0 μg/ml copper and 1.0 μg/ml zinc; 3, 1.5 μg/ml copper and 1.5 μg/ml zinc; 4, 2.0 μg/ml copper and 2.0 μg/ml zinc.

complexes, as shown in Fig. 4, intersect at 606 nm, at which their absorption coefficients are equivalent ($a_{Cu} = a_{Zn} = a$). The absorbance at this point in the zinc determination in the FIA system can be described as:

$$A = a_{Zn} \cdot b \cdot C_{Zn} = a \cdot b \cdot C_{Zn}$$

The absorbance in the determination of the sum of copper and zinc can be described as:

$$A = a_{Zn} \cdot b \cdot C_{Zn} + a_{Cu} \cdot b \cdot C_{Cu}$$
$$= a \cdot b(C_{Zn} + C_{Cu})$$

A wavelength of 606 nm was chosen both for measurement of zinc and the sum of copper and zinc.

For this simultaneous determination, it was desirable for the zinc signal to be obtained separately in addition to the signal of the sum of copper and zinc. It was decided to mask copper with thiourea. Experiments at pH 9.0 with borate solution indicated that copper could be masked by thiourea since only one peak was obtained when the solution containing only copper was injected [Fig. 3(a)].

Zincon reacts with copper at pH 5–9.5 and zinc at 8–9.5.[10] The effect of the concentration of buffer solution was also studied. Maximum peak heights can be obtained when 0.20*M* borate solution was used. As a result, a pH of 9.0 for complex formation and a buffer solution of 0.20*M* borate were employed.

The effect of the concentration of zincon on the peak height was studied by injecting a mixed solution of 2 μg/ml zinc and 2 μg/ml copper. The peak height was found to be almost independent of the concentration of zincon in the range 0.025–0.075%. A 0.05% solution of zincon was chosen for this study.

Calibration

Under the conditions described, mixed standard solutions of zinc and copper (mass ratio 1:1) were measured (shown in Fig. 5). The calibration graph was linear in the range 0–5 μg/ml for the sum of copper and zinc. The linear ranges of the individual elements are also 0–5 μg ml.

Mixed standard solutions of different ratios of copper and zinc between 0/50 and 50/0 were also measured. The slopes of the calibration curves for copper and zinc were in good agreement with those of the corresponding calibration graphs for the individual elements. Recoveries of copper and zinc in synthetic mixtures were determined (Table 1). Table 1 indicates good recoveries of zinc and copper in synthetic mixtures can be obtained, even at

*Values in the parentheses are the relative standard deviations in percent of six determinations.

differing ratios. The relative standard deviations for 0.5 μg/ml copper and zinc in a synthetic mixture were 0.9 and 0.7%, respectively.

Interference

Iron(III), manganese(II), nickel(II), cobalt (II), aluminum(III) and cadmium(II) interfere in the determination.[11] The interference of these elements at levels present in serum can be masked by the addition of sodium citrate, sodium triphosphate and 1,10-phenanthroline in the carrier solution.[11] Iron(III), aluminum(III), manganese(II), and cadmium(II) can be masked by citrate and triphosphate. Cobalt(II), nickel(II) and cadmium(II) can be masked by 1,10-phenanthroline.

Application

The proposed FIA method was applied to the determination of zinc and copper in serum samples of healthy people and leukosis patients. Mix 1.0 ml of serum and 1.0 ml of 2.0*M* hydrochloric acid. Shake and allow to stand for 10 min. Then add 0.5 ml of 20% trichloroacetic acid and heat for 10 min in a 90–95° water-bath with continued stirring. Cool with water and centrifuge at 3000 rpm. Adjust the pH of the supernatant liquid to about 7.0 and analyse by the proposed method. The results are listed in Table 2.

Table 2 shows that the ratio of Cu/Zn of healthy people and leukosis patient had a significant difference.

The samples listed in Table 2 were also determined by an AAS method. The results of the proposed method were in good agreement with those of the AAS method. The results of four samples are listed in Table 3.

EQUILIBRIA AND SPECTROELECTROCHEMICAL STUDIES ON THE FORMATION OF MULTIBRIDGED TRIS(BIPYRAZINE) RUTHENIUM(II) COMPLEXES WITH RUTHENIUM–EDTA GROUPS

HENRIQUE E. TOMA* and ROSANA L. SERNAGLIA
Instituto de Química, Universidade de São Paulo, Caixa Postal 20780, CEP 01498, São Paulo, SP, Brazil

(*Received* 30 *June* 1992. *Revised* 18 *August* 1992. *Accepted* 18 *August* 1992)

Summary—The tris(bipyrazine) ruthenium(II) complex forms a series of complexes containing $[Ru^{II/III}EDTA]^{2-/-}$ groups coordinated to the peripheral nitrogen atoms of the bipyrazine bridging ligand. These groups exhibit similar redox potentials ($E^0 = 0.38$ V *vs.* SHE) and a very weak electronic coupling through the central complex. When the peripheral Ru(III) groups are reduced to the Ru(II) state, strong charge-transfer bands appear at 490 and 670 nm and the stability constants increase by 7 orders of magnitude due to d_π–p_π^* back-bonding interactions involving the peripheral ions and the bipyrazine ligand.

Binding of ruthenium–EDTA and related complexes to a central bridging unity such as the meso-tetrapyridylporphyrin, TPyP,[1–4] has provided a useful approach for the design of multibridged systems displaying unusual chemical and electrocatalytical properties. Another interesting system is the multibridged complex $[Ru(bpz)_3\{Fe(CN)_5\}_n]^{2-3n}$ (bpz = bipyrazine), which exhibits photoinduced multinuclear charge-transfer reactivity[5] when confined in modified nickel-electrodes. In this work we report the analytical characterization and determination of the equilibrium constants of a new series of multibridged species (Fig. 1) obtained from the reaction of $[Ru(bpz)_3]^{2+}$ with $[(EDTA)Ru(III)/(II)]^{-/2-}$ complexes.

EXPERIMENTAL

The complexes $[Ru(bpz)_3]Cl_2$ and $[Ru(HEDTA)(H_2O)]$ were prepared by literature methods.[6–8] The $[Ru(bpz)_3(RuEDTA)_n]^{2-n}$ complexes were generated in aqueous solution, under an argon atmosphere, by the reaction of $[Ru(bpz)_3]Cl_2$ and $[Ru(HEDTA)(H_2O)]$, using appropriate amounts of each species. The pH of the solutions was kept at 4.7 using acetate buffer. Sodium trifluoroacetate (NaTFA) was used as supporting electrolyte, and to keep the ionic strength around 0.25*M*.

The electronic spectra were recorded on a Hewlett-Packard 8452A diode-array spectrophotometer. Cyclic voltammetry was carried out with a Princeton Applied Research Corp. (PARC) instrumentation, consisting of a model 173/179 potentiostat and a model 175 universal programmer. A glassy carbon working electrode was employed for the measurements, with use of a Luggin capillary arrangement with a Ag/AgCl (1M KCl) reference electrode. The measured potentials were converted to the SHE scale by adding 0.222 V. For the spectroelectrochemical measurements, the PARC potentiostat was used in parallel with the HP 8452A spectrophotometer. A three electrode system was designed for a rectangular quartz cell of 0.025 cm optical path length. A gold minigrid was used as transparent working electrode, in the presence of

RESULTS AND DISCUSSION

The $[Ru(bpz)_3]^{2+}$ (Ru_c) and $[RuEDTA]^-$ (P^-) complexes react yielding a series of multibridged $[Ru^{II}(bpz)_3(Ru^{III}EDTA)_n]^{2-n}$ species, here denoted $[Ru_cP_n]^{2-n}$, containing $[Ru^{III}EDTA]^-$ groups attached to the peripheral nitrogen atoms of bipyrazine. The reaction leads to an enhancement of the absorption band at 298 nm ascribed to internal $\pi \rightarrow \pi^*$ transitions in the bpz ligand, and of the absorption bands at 412 and 442 nm ascribed to Ru_c(II)-to-bpz, $d_\pi \rightarrow p_\pi^*$ charge-transfer transitions.[6] These bands are shifted to 436 and 474 nm in the presence of excess of $[RuEDTA]^-$ ions.

Spectrophotometric titration exhibited no evidence of saturation in the absorbance versus concentration plots, even in the presence of a fifteen times excess of $[RuEDTA]^-$ (around 15mM) over $[Ru(bpz)_3]^{2+}$.

Electrochemical behavior of the reduced species

The cyclic voltamperograms of the polymetallated complexes are shown in Fig. 2. The characteristic wave with $E_{1/2} = 0.38$ V *vs.* SHE was ascribed to the $[Ru(bpz)_3(Ru^{III/II}EDTA)_n]$ redox couples. The redox potential of the $[Ru(bpz)_3]^{2+/3+}$ center is higher than 2.0 V and the corresponding redox waves can not be observed in aqueous solution.[6] A broad, irreversible wave was observed around −0.9 V, involving the reduction of the bipyrazine ligands.

Starting from the reduced complexes at −0.3 V, the anodic peak currents $i_a(1)$ corresponding to the peripheral $[RuEDTA]^{2-}$ groups in the polimetallated species increased almost linearly with the ratio $q = [Ru^{III}EDTA^-]/[Ru(bpz)_3^{2+}]$, as shown in Fig. 3(A). Some dissociation of the polymetallated complexes can be detected above $q = 4$ from the rise of the small anodic wave (2) at 0 V, corresponding to the free $[Ru^{II}EDTA]^{2-}$ species as well as from the deviations of linearity in Fig. 3(a). On the other hand, saturation is observed slightly above $q = 6$, indicating that

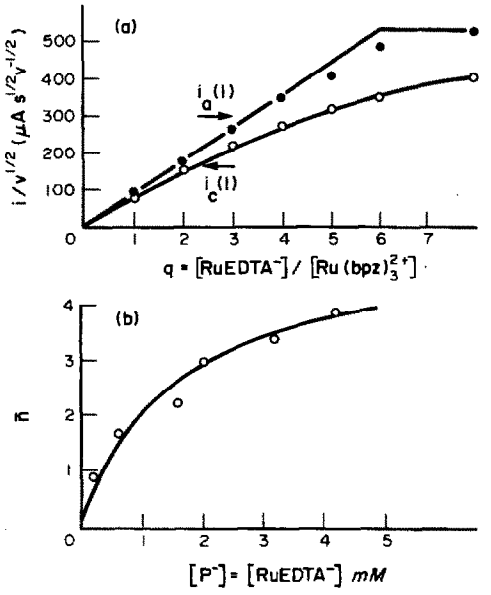

Fig. 3. (a) Plots of the anodic and cathodic peak currents from Fig. 2(A) and 2(B), *vs.* the molar ratio q, including additional points above $q = 6$; (b) plot of $\bar{n}$ versus [RuEDTA$^-$], employed for the evaluation of the equilibrium constants.

the formation of the reduced species is almost quantitative.

The increase of $i_a(1)$ with the number of coordinated [Ru^{III}EDTA$^-$] ions is consistent with the general behavior observed for polynuclear and polymeric systems[9] containing identical, non-interacting redox groups. In this case, it has been shown that the current–potential responses exhibit the same shape as that obtained with the corresponding molecule containing a single center, but the magnitude of the current is enhanced by the presence of additional electroactive centers.

Electrochemical behavior of the oxidized species

In the reverse scan, as shown in Fig. 2(B), the cathodic peak (1) was followed by a second peak around −0.1 V, corresponding to the reduction of [Ru^{III}(EDTA)(H$_2$O)]$^-$ species generated from the dissociation of the oxidized polymetallated complexes.

The voltamperograms of the oxidized complexes involve a series of equilibrium reactions, expressed by equation (1),

$$[Ru(bpz)_3]^{2+} + n[Ru^{III}EDTA]^- \overset{\beta_n}{\rightleftharpoons} [Ru(bpz)_3(Ru^{III}EDTA)_n]^{2-n} \quad (1)$$

In order to evaluate the equilibrium constants β_n, we started at 0.6 V, as shown in Fig. 2(B), with the polynuclear complexes in equilibrium condition. In contrast to the case of the reduced complexes, the plot of the cathodic peak currents, $i_c(1)$ *vs.* q (Fig. 3) exhibited no evidence of saturation, indicating that the oxidized complexes are rather weak.

The use of the relative intensities of the successive waves, $i_c(1)$ and $i_c(2)$, in Figure 2(B) for calculation of β_n is rather complicated, requiring a careful deconvolution of the voltamperograms. For this reason, we preferred to calculate the equilibrium constants based on the difference of $i_a(1)$ in Fig. 2(A), for the [Ru^{II}(bpz)$_3$(Ru^{II}EDTA)$_n$]$^{2-2n}$ species, and the corresponding cathodic peak currents, $i_c(1)$ shown in Fig. 2(B). In both cases the starting solutions are in equilibrium condition and in the absence of dissociation, these two currents would be equivalent, because of the expected similarity between the diffusion coefficients of the oxidized and reduced complexes. It should be noted that kinetic effects become important at low scan rates, *e.g.*, < 100 mV/sec, due to the lability of the [Ru^{III}EDTA] species.[10] However, at scan rates above 500 mV/sec, the ratios of the cathodic peak currents $i_c(1)$ and $i_c(2)$ become constant within 5%. Therefore, the kinetic effects can be neglected at high scan rates. For this reason, a scan rate of 1000 mV/sec, was employed in the equilibrium calculations.

The peak currents are proportional to the number of peripheral groups. In Fig. 2(A), $i_a(1)$ should correspond to the total amount of [RuEDTA]$^-$, since the dissociation of the reduced complexes is negligible, at least when $q < 5$. As q approaches 6, this is only approximate, and extrapolated currents, $i'_a(1)$, from the linear plot in Fig. 3(a), would be better employed in the calculations, in order to correct for the dissociation process. In this way, the concentration of free [Ru^{III}EDTA$^-$] ions, or [P$^-$], can be evaluated from the difference of the extrapolated currents, $i'_a(1)$, and $i_c(1)$ in Fig. 3(a).

The successive equilibria (1) can be analysed based on the Bjerrum[11] function $\bar{n}$,

$$\bar{n} = \frac{[P^-_{total}] - [P^-_{free}]}{[Ru_c]} \quad (2)$$

which is given by

$$\bar{n} = \frac{\beta_1[P^-] + 2\beta_2[P^-]^2 + 3\beta_3[P^-]^3 + \cdots}{1 + \beta_1[P^-] + \beta_2[P^-]^2 + \beta_3[P^-]^3 + \cdots} \quad (3)$$

The plot of $\bar{n}$ against [P$^-$] is shown in Fig. 3(b), indicating that when $q = 6$, the

average number of attached $[Ru^{III}EDTA]^-$ groups is smaller than 4.

Equation (3) can be rearranged in the following way:

$$\frac{\bar{n}}{(1-\bar{n})[P^-]} = \beta_1 + \beta_2\frac{(2-\bar{n})}{(1-\bar{n})}[P^-] + \beta_3\frac{(3-\bar{n})}{(1-\bar{n})}[P^-]^2 + \cdots \quad (4)$$

From the linear plot of $\bar{n}/(1-\bar{n})[P^-]$ against $(2-\bar{n})[P^-]/(1-\bar{n})$ shown in Fig. 4(a), β_1^{III} was estimated as $4 \times 10^3/M^{-1}$ (intercept) and $\beta_2^{III} = 8 \times 10^6 M^{-2}$ (slope).

A second rearrangement of equation (3) leads to

$$\frac{\bar{n}-(1-\bar{n})\beta_1[P^-]}{(2-\bar{n})[P^-]^2} = \beta_2 + \beta_3\frac{(3-\bar{n})}{(2-\bar{n})}[P^-] + \cdots \quad (5)$$

The plot of equation (4) shown in Fig. (4b) is practically linear. From this plot, β_2^{III} and β_3^{III} were estimated as $8.0 \times 10^6 M^{-2}$, and $8 \times 10^9 M^{-3}$ respectively. Based on the linear trend observed for β_1^{III}, β_2^{III} and β_3^{III}, the extrapolated values for β_4^{III}, β_5^{III} and β_6^{III} were $4 \times 10^{12} M^{-4}$, $1.0 \times 10^{15} M^{-5}$ and $1.3 \times 10^{17} M^{-6}$ respectively.

In the case of the reduced complexes, the equilibrium constant β_1^{II} can be calculated from the thermodynamic cycle:

$$\begin{array}{ccc} [Ru^{II}EDTA]^{2-} + [Ru(bpz)_3]^{2+} & \overset{\beta_1^{III}}{\rightleftharpoons} & [Ru^{II}EDTARu(bpz)_3] \\ \Big\downarrow E^0[Ru^{III}EDTA]^- & & \Big\downarrow E^0[Ru^{III}EDTARu(bpz)_3]^+ \\ [Ru^{III}EDTA]^- + [Ru(bpz)]_3^{2+} & \overset{\beta_1^{III}}{\rightleftharpoons} & [Ru^{III}EDTARu(bpz)_3]^+ \end{array}$$

where

$$E^0[Ru^{III}EDTARu(bpz)_3]^+ = E^0[Ru^{III}EDTA]^- + 0.0591 \log \frac{\beta_1^{II}}{\beta_1^{III}}$$

The calculated β_1^{III} is comparable to that report by Matsubara and Creutz[10] for the related pyrazine complex, *e.g.*, $1.0 \times 10^4 M^{-1}$.

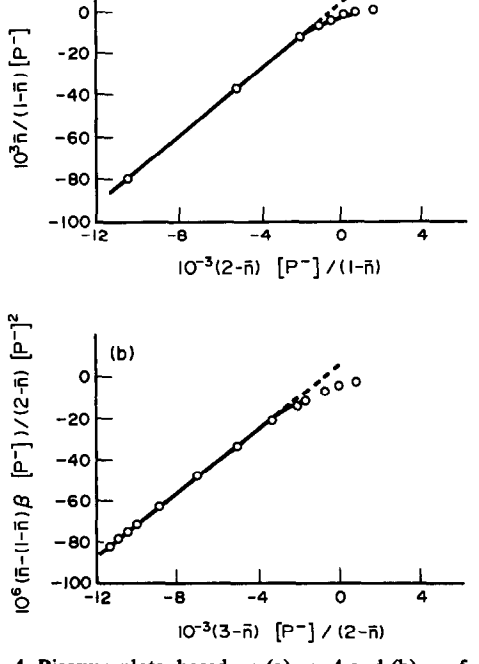

Fig. 4. Bjerrum plots, based on (a) eq. 4 and (b) eq. 5, for the evaluation of β_1, β_2 and β_3.

Since $E^0[Ru^{III}EDTARu(bpz)_3]^- = 0.38$ V, $E^0[Ru^{III}EDTA]^- = 0.04$ V, and $\beta_1^{III} = 4 \times 10^3 M^{-1}$, one can calculate $\beta_1^{II} = 5 \times 10^{10} M^{-1}$. This result is slightly higher than that reported in the literature[10] for the $[Ru^{II}EDTA(pyrazine)]^{2-}$ complex, *e.g.*, $1.7 \times 10^8 M^{-1}$. The difference of 7 orders of magnitude in the stability constants of the Ru^{III} and Ru^{II} species, reflects the importance of π-backbonding interactions in the [Ru^{II}EDTA–bipyrazine] moiety. A similar behavior is expected for the successive β_n^{II} constants, with respect to β_n^{III}.

Spectroelectrochemical behavior

The polynuclear complexes exhibit reversible spectroelectrochemical behavior in aqueous solution, a shown in Fig. 5. The reduction of the $[Ru^{II}(bpz)_3(Ru^{III}EDTA)_n]^{2-n}$ complexes around 0.38 V, is responsible for the rise of two strong absorption bands at 490 and 670 nm. These bands were ascribed to charge transfer transitions from the peripheral $Ru^{II}EDTA^{2-}$ groups to the π_1^* and π_2^* levels of the bridging bipyrazine ligand, by analogy to the systems previously reported in the literature.[12] The plots of absorbance against $q = [RuEDTA^-]/[Ru(bpz)_3^{2+}]$ were typically linear, exhibiting a

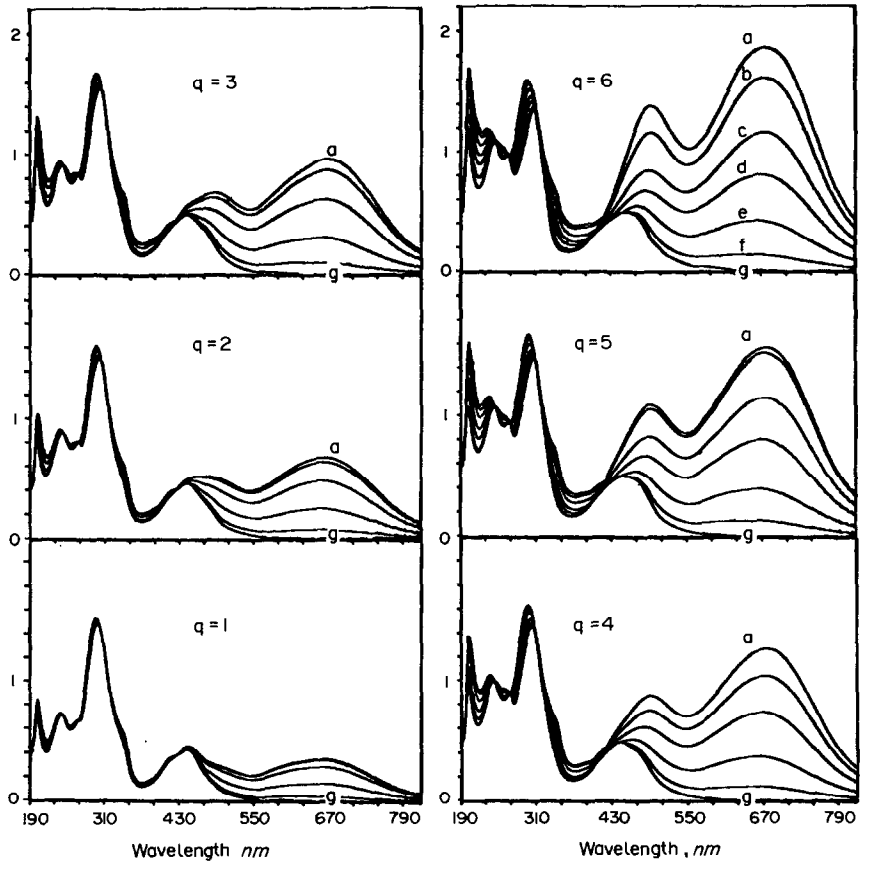

Fig. 5. Spectroelectrochemical behavior of the $[Ru(bpz)_3(RuEDTA)_n]^{2-n}$ complexes (1m*M*) in aqueous solution, for several values of $q = [RuEDTA^-]/[Ru(bpz)_3^{2+}]$. Applied potentials: (a) −578, (b) 172, (c) 272, (d) 322, (e) 372, (f) 422 and (g) 622 mV; [NaTFA] = 0.25*M*, pH 4.5, 25°.

saturation point when this ratio is 6, corresponding to the hexametallated species. The titration plot confirms that the reduced species $[Ru^{II}(bpz)_3(Ru^{II}EDTA)_n]^{2-2n}$ are quite stable, and that metallation reaction is nearly quantitatively under the conditions of this work, in agreement with the electrochemical results.

The Nernst plots, (*E vs.* log [ox]/[red]), for the several values of q employed in the experiments were linear. When $q = 1$, the Nernst slope coincided with the theoretical value of 0.059 V/decade, for a monoelectronic redox equilibrium, with $E^0 = 0.36$ V, in agreement with the cyclic voltamperograms. However, for $q = 2$, 3, 4, 5 and 6, the Nernst slopes were 0.071, 0.077, 0.088, 0.104 and 0.132 V/decade, and the corresponding E^0 were 0.35, 0.34, 0.33, 0.32 and 0.30 V, respectively.

The trends observed in the E^0 values are consistent with the statistical considerations for equivalent multisite redox processes reported in the literature.[9] The increase of the Nernst slope as a function of q cannot be explained in terms of the number of electrons involved, since the cyclic voltamperograms were consistent with $n = 1$. This type of behavior is determined by the dissociation equilibrium involving the oxidized polymetallated complexes. As a matter of fact, by using a fifteen times excess of $[Ru^{III}(EDTA)(H_2O)]^-$ over $[Ru^{II}(bpz)_3]^{2+}$ in order to repress the dissociation of the $[Ru^{II}(bpz)_3(Ru^{III}EDTA)_n]^{2-n}$ species, the Nernst slope decreased from 0.132 ($q = 6$) to 0.100 ($q = 15$) V/decade.

CONCLUSION

The chemistry of the $[Ru^{II}(bpz)_3(RuEDTA)_n]^{2-n}$ complexes is characterized by a complex dynamic equilibrium in solution, and by a very weak interaction between the peripheral [RuEDTA] groups. The stability of the polynuclear complexes is strongly enhanced in the reduced state, as a consequence of the d_π–p_π^* backbonding interactions involving the

peripheral ruthenium(II) groups and the bipyrazine bridging ligand.

(*Received* 21 *February* 1992. *Revised* 18 *August* 1992. *Accepted* 18 *August* 1992)

Summary—The interaction between Ca^{2+} and two well-characterized fulvic acids (Armadale and Laurentide FA) has been studied at 0.100 and 0.010*M* sodium nitrate using a fixed concentration of fulvic acid (100 ppm) and varying amounts of calcium (0.005–0.020 mmoles). Free calcium concentration was determined by *in situ* measurements employing a calcium electrode. For Armadale FA, free calcium was additionally determined via an ultrafiltration technique followed by atomic absorption measurements. For both fulvic acids, Ca^{2+} binding was observed to be decreased by an increase in the ionic strength of the system. At the lower ionic strength, the tendency for binding is dependent on the fulvic acid-to-metal ratio while at the higher ionic strength, the binding is insensitive to changes in the fulvic acid-to-metal ratio (an observation corroborating the contention that calcium binding to humic substances is primarily electrostatic). Comparison of the computed overall complex formation functions shows that values obtained from the ultrafiltration method were higher than those obtained using the calcium electrode. The binding of calcium was similar for the two fulvic acids.

The interaction between Ca^{2+} ions and humic substances has normally been considered in the light of the influence of Ca^{2+} on the binding of other heavy metal ions (e.g., Pb^{2+}, Cu^{2+}, Cd^{2+} and Zn^{2+}) by humic substances.[1,2] To predict the competitive role of Ca^{2+} ions in the binding of other heavy metal ions by humic substances, one has to understand how Ca^{2+} itself is sequestered by these organic acids. A number of earlier researchers have sought to achieve this objective,[3–5] but even though it has been postulated that Ca^{2+} binding by humic substances is primarily electrostatic, their studies have predominantly been performed at only a single ionic strength (0.100*M*). In this paper, the binding of Ca^{2+} by humic substances has been studied as a function of metal-to-fulvic acid ratio, pH and ionic strength for two well characterized fulvic acids using a calcium electrode. For one of the fulvic acids, an additional method involving the separation of the free metal from the complex was employed. The results have been analysed both as the fraction of metal bound and the overall complex formation function varying pH, ionic strength and metal-to-fulvic acid ratio.

EXPERIMENTAL

Materials and instrumentation

Two well characterised fulvic acids, Armadale Horizons Bh fulvic acid, AFA and Laurentide fulvic acid, LFA, isolated from peat, were obtained from Concordia University, Canada.[6–8] Results of the titratable acidic moieties (the active sites involved in metal interactions) are presented in Table 1. A further discussion of these results has been reported by Ephraim *et al.*[7] Standard sodium hydroxide was prepared from analytical concentrates obtainable from J. T. Baker Chemicals and standardized using potassium hydrogen phthalate. Analytical grade NaCl, $NaNO_3$ and $Ca(NO_3)_2$ were supplied by J. T. Baker Chemicals. An Amicon Model 8050 ultrafiltration cell (cell capacity = 50 ml; hold-up volume 0.5 ml) using an Amicon Diaflo membrane YM2 (diameter 43 mm) was used to

Table 1. Comparison of acidic capacities of Armadale Bh Horizons fulvic acid and Laurentide fulvic acid

FA Sample	Titratable acid, meq/g FA			
	Aqueous	Non-aqueous		
		−COOH	−OH	Total
Armadale FA	5.60 ± 0.15	4.15 ± 0.05	1.84 ± 0.06	5.99 ± 0.03
Laurentide FA	7.72 ± 0.05	5.60 ± 0.01	2.13 ± 0.01	7.73 ± 0.01

separate free Ca^{2+} from FA bound calcium and free FA. A Perkin-Elmer Model 503 Atomic Absorption spectrophotometer was used to determine free Ca^{2+} after ultrafiltration. An Orion ionanalyzer, Model 901, was used for pH and pCa measurements employing, respectively, a glass combination pH electrode and a model F2112 Ca, calcium-ion selective electrode from Radiometer A/S.

Procedure

The binding of Ca^{2+} to Armadale and Laurentide FAs was studied at 0.010 and 0.10*M* sodium nitrate using a calcium ion-selective electrode and an ultrafiltration technique.[9] In the ion selective electrode technique (ISE), two approaches were used. In the first approach, the removal of Ca^{2+} in solution was measured during neutralization of FA with base starting with a fixed initial ratio of FA to Ca^{2+}. In the second approach, the initial degree of dissociation of the FA was fixed by adding an appropriate amount of base and the ratio of FA to Ca^{2+} was changed stepwise by titration with calcium. A calibration curve was prepared (at the desired bulk electrolyte concentration) just before and immediately after each experiment.

A complete description of the ultrafiltration method and its adaptation to metal–humate binding studies is given elsewhere.[9] In a typical ultrafiltration experiment, a batch approach was employed where a number of solutions (volume = 50 ml) each containing known concentrations of FA and Ca^{2+} at a defined ionic strength (0.010 and 0.10*M* sodium nitrate) were adjusted to desired pH values with standard base and allowed to equilibrate by placing them at ambient temperature in a dessicator for about 24 hr. The solutions were allowed to equilibrate in a dessicator containing ascarite to ensure a CO_2-free atmosphere. After equilibration, the pH of each solution was determined and 10% of the solution was removed by ultrafiltration under pressure of 3.5 bars. The first 5% of the filtrate was discarded and the next 5% collected for Ca^{2+} ion concentration determination using the Atomic Absorption Spectrophotometer. Total filtrate was limited to 10% of the solution to minimize disturbance of the system. To obtain reliable results, both the calcium electrode and the ultrafiltration membrane were specially handled.

Special handling of the calcium electrode

At pHs between 5 and 8.5 the response of the calcium electrode was independent of pH and followed the Nernstian relationship, but below pH 5, the mV reading decreased progressively as the pH was lowered. To obtain meaningful results at PHs below 5, it was necessary to prepare special calibration curves. A family of calibration curves was prepared by following the response of the electrode at a fixed calcium concentration as a function of pH in the pH range 3–8.5. A typical set of these curves is shown in Fig. 1(a) and (b). Plots of potential *vs.* pCa indicate that the electrode response was Nernstian even at pH 4.0. By using these continuous calibration curves it was possible to extend the study pH range to as low as 4.0 with reproducible results. The calibration curves were obtained at the desired ionic strengths (0.10 and 0.010*M* sodium nitrate) and no significant effect of Na^+ ions on the electrode readings was observed.

Conditioning of the ultrafiltration membrane

An unconditioned YM2 membrane, molecular weight cut-off of 1000 Daltons, selectively retained Ca^{2+} while allowing easy passage of water. A bigger pore-size membrane, YM5 with a molecular weight cut off of 5000 Daltons was permeable to FA molecules as well. Proper conditioning of the YM2 membrane was attained for use in the experiment by filtering $Ca(NO_3)_2$ through it until its retention coefficient for Ca^{2+} was zero [Fig 2(a) and (b)] while that for FA was determined to be unity via the use of an UV–Vis spectrophotometric method.[9]

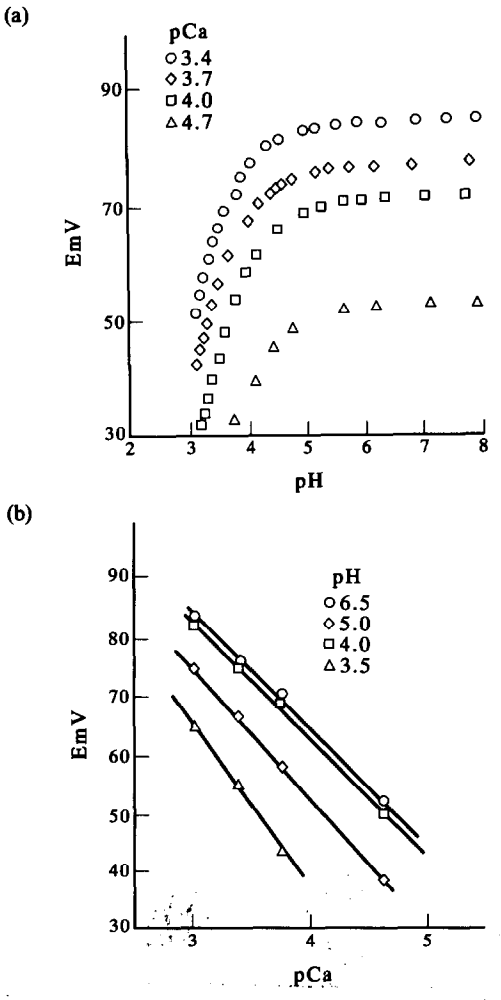

Fig. 1. (a) The response of the calcium electrode as a function of pH for different concentrations of Ca(II). (b) The Nernstian response of the calcium electrode at different pHs, points picked from Fig. 1(a). (Temperature = 23°; ionic strength = 0.10M $NaNO_3$.)

RESULTS AND DISCUSSION

Results of calcium binding to AFA and LFA expressed as fraction of calcium bound, Ca_b/Ca_t, where Ca_b is calcium bound and Ca_t is total calcium, as a function of pH are shown in Figs 3–5. Table 2 gives a detailed relationship between the logarithm of the complex formation function (log β_{ov}) and pH, where β_{ov} has been defined as follows:

$$\beta_{ov} = \{(\Sigma M_b)\gamma_{Mb}\}/\{(M_f\gamma_{Mf})(\Sigma A^- \gamma_{A-})\} \quad (1)$$

In the above equation, ΣM_b and M_f are the total metal bound and free metal respectively, γ_{Mb} is the activity coefficient of the metal-fulvate complex, γ_{Mf} is the single ion activity coefficient of the free metal ion obtained from Kielland,[10] ΣA^- is the total ionized free form of the fulvic acid at the given pH and γ_{A-} is the activity coefficient of the fulvate ion. To facilitate the resolution of the above expression [equation (1)], it is assumed that the activity coefficients of the metal–fulvate complex, γ_{Mb}, and the fulvate ion γ_{A-} are equal thus allowing their cancellation to yield the following:

$$\beta_{ov} = \{(\Sigma M_b)\}/\{(M_f\gamma_{Mf})(\Sigma A^-)\} \quad (2)$$

In Table 2, column 1 describes the composition of the solution studied and the method used, column 2 indicates the pH range studied, column 3 gives the complex formation function arrived at by linear regression analysis, column

(b) A comparison of the concentrations of free Ca^{2+} in the filtrates, retentates and the original standard solutions after membrane conditioning. (Ultrafiltration cell = Amicon Model 8050; Membrane = YM2; ionic strength = 0.10M $NaNO_3$; temperature = 23°; pressure = 3.5 bars.)

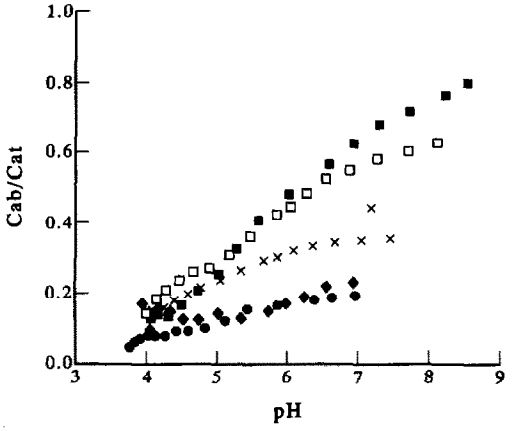

Fig. 3. Fraction of Ca bound as a function of pH, FA-to-metal ratio and ionic strength for Armadale Horizon Bh fulvic acid; method = ISE: Cab = calcium bound = $Ca_{total} - Ca_{free}$; Cat = total calcium. ■ $FA/Ca^{2+} = 6/1$; $I = 0.010$, □ $FA/Ca^{2+} = 3/1$; $I = 0.010$, × $FA/Ca^{2+} = 1.5/1$; $I = 0.010$, ◆ $FA/Ca^{2+} = 3/1$; $I = 0.10$, ● $FA/Ca^{2+} = 1.5/1$; $I = 0.10$.

4 gives the correlation coefficient and the last column gives the number of points used in the analysis. Generally, the complex formation function was found to be dependent on pH and ionic strength of the medium and the values agreed appreciably well with other reports.[5] There was a similar positive dependence on pH for both the ISE and ultrafiltration methods even though the ultrafiltration method gave slightly higher values. The log β_{ov} values which averaged from 2.8 to 3.1 in the pH range 4 to 8 are comparably lower than the log β_{ov} for a strongly complexing cation like Cu^{2+} to FA which is about 8 at pH 5.[11,12]

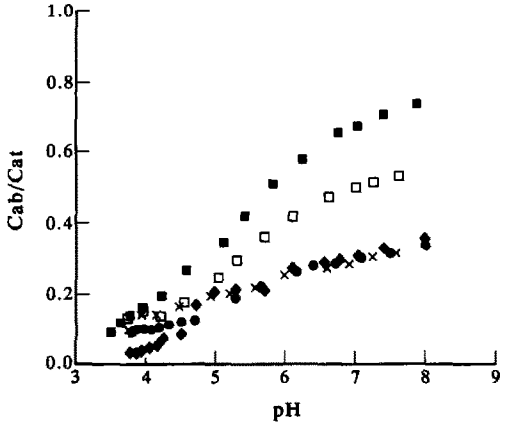

Fig. 4. Fraction of Ca bound as a function of pH, FA-to-metal ratio and ionic strength for Laurentide fulvic acid; method = ISE: ■ $FA/Ca^{2+} = 7.7/1$; $I = 0.010$, □ $FA/Ca^{2+} = 3.8/1$; $I = 0.010$, × $FA/Ca^{2+} = 1.9/1$; $I = 0.010$, ◆ $FA/Ca^{2+} = 7.7/1$; $I = 0.10$, ● $FA/Ca^{2+} = 3.8/1$; $I = 0.10$.

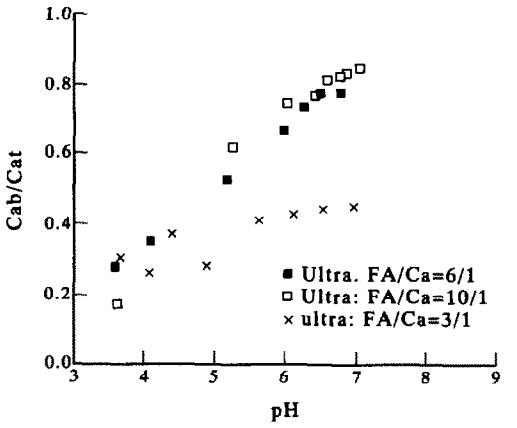

Fig. 5. Fraction of Ca bound as a function of pH, FA-to-metal ratio and ionic strength for Armadale Horizon Bh fulvic acid; method = ultrafiltration: ■ $FA/Ca^{2+} = 6/1$; $I = 0.010$, □ $FA/Ca^{2+} = 10/1$; $I = 0.010$, × $FA/Ca^{2+} = 3/1$; $I = 0.010$.

Effect of FA to Ca^{2+} ratio

For both FAs, the fraction of calcium bound, Ca_b/Ca_t, increased significantly with increase in the ratio of FA to calcium in 0.010*M* sodium nitrate solutions especially at pH values greater than 5 for low FA/Ca ratio and greater than 6 for high FA/Ca ratio (Figs 3 and 4). This could be attributed to an increase in the binding sites relative to Ca^{2+} concentration. At the higher ionic strength, 0.10*M* sodium nitrate, the fraction bound seemed to have no dependence on the ratio of Fa to Ca^{2+} because even though there is an increase in binding sites with an increase in the FA/Ca^{2+} ratio, the Ca^{2+} ions are not effectively bound because of screening by the Na^+ ions.

Effect of ionic strength

The fraction of calcium bound was distinctly higher in 0.010*M* sodium nitrate than in 0.10*M* solutions. A high concentration of Na^+ ions seemed to reduce the accessibility of the binding sites on the FA to Ca^{2+} and hence the observed reduction in the fraction bound. This would suggest that Ca^{2+} binding to FA is mainly in the form of weak electrostatic associations comparable to Na^+–FA associations. This conclusion is further supported by the apparent insensitivity of the fraction of Ca^{2+} bound at high bulk electrolyte concentrations (0.10*M* sodium nitrate) with increasing ratios of Ca^{2+} to fulvic acid. This behavior mimics an ion exchange mechanism where Ca^{2+} ions exchange with Na^+ ions already on the polymer surface. The counterion concentrating properties of the fulvic acid molecule are not considered in this paper.

Table 2. Complex formation functions for Ca^{2+} binding to Armadale (AFA) and Laurentide (LFA) fulvic acids. $\beta_{ov} = \Sigma M_b/\{M_f \gamma \Sigma A^-\}$ (Eq^{-1})

System	pH range	Log β_{ov}-pH relationship	r	n
AFA; Ultra; $Ca^{2+} = 1.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	3.6–6.8	$\log \beta_{ov} = 2.70 + 0.20$ pH	0.990	7
AFA; Ultra; $Ca^{2+} = 6.0 \times 10^{-5} M$; $I = 0.010 M$ $NaNO_3$.	5.0–7.1	$\log \beta_{ov} = 2.89 + 0.18$ pH	0.990	8
AFA; Ultra; $Ca^{2+} = 2.0 \times 10^{-4} M$ $I = 0.010 M$ $NaNO_3$.	3.7–6.7	$\log \beta_{ov} = 3.49 \pm 0.14$	—	8
AFA; ISE; $Ca^{2+} = 1.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	4.0–8.5	$\log \beta_{ov} = 1.78 + 0.28$ pH	0.993	15
AFA; ISE; $Ca^{2+} = 2.0 \times 10^{-4} M$ $I = 0.010 M$ $NaNO_3$.	4.0–8.1	$\log \beta_{ov} = 2.38 + 0.18$ pH	0.978	16
AFA; ISE; $Ca^{2+} = 4.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	4.0–7.4	$\log \beta_{ov} = 2.69 + 0.11$ pH	0.979	15
AFA; ISE; $Ca^{2+} = 2.0 \times 10^{-4} M$; $I = 0.100 M$ $NaNO_3$.	3.9–6.9	$\log \beta_{ov} = 3.07 \pm 0.11$	—	13
AFA; ISE; $Ca^{2+} = 4.0 \times 10^{-4} M$; $I = 0.100 M$ $NaNO_3$.	3.7–7.0	$\log \beta_{ov} = 2.83 \pm 0.15$	—	15
AFA; ISE; $Ca^{2+} = 7.9 \times 10^{-4}$–$7.9 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	6.2–6.7	$\log \beta_{ov} = 3.35 \pm 0.18$	—	19
LFA; ISE; $Ca^{2+} = 1.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	3.5–7.8	$\log \beta_{ov} = 1.81 + 0.28$ pH	0.988	14
LFA; ISE; $Ca^{2+} = 2.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	3.7–7.6	$\log \beta_{ov} = 2.08 + 0.20$ pH	0.981	12
LFA; ISE; $Ca^{2+} = 4.0 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	3.7–7.5	$\log \beta_{ov} = 2.62 + 0.08$ pH	0.991	11
LFA; ISE; $Ca^{2+} = 1.0 \times 10^{-4} M$; $I = 0.100 M$ $NaNO_3$.	3.8–8.0	$\log \beta_{ov} = 1.28 + 0.31$ pH	0.915	17
LFA; ISE; $Ca^{2+} = 2.0 \times 10^{-4} M$; $I = 0.100 M$ $NaNO_3$.	3.8–8.0	$\log \beta_{ov} = 2.31 + 0.14$ pH	0.975	16
LFA; ISE; $Ca^{2+} = 4 \times 10^{-5}$–$7.5 \times 10^{-4} M$; $I = 0.010 M$ $NaNO_3$.	6.2–6.6	$\log \beta_{ov} = 3.52 \pm 0.08$	—	19
LFA; ISE; $Ca^{2+} = 1.6 \times 10^{-4}$–$5.9 \times 10^{-4} M$; $I = 0.100 M$ $NaNO_3$.	6.9–7.0	$\log \beta_{ov} = 3.03 \pm 0.44$	—	12

Note: Ultra. = ultrafiltration; ISE = ion selective electrode; AFA = Armadale FA; LFA = Laurentide FA; r = correlation coefficient; n = number of points; 100 ppm of FA was used for all trials.

Comparison of Armadale FA and Laurentide FA

There was no significant difference in the binding of calcium to the two fulvic acids as long as the ratio of FA to calcium was high but as the proportion of calcium increased the fraction bound to AFA tended to be higher than the fraction bound to LFA (Figs 3 and 4). The apparent extra binding affinity of calcium to AFA might be attributable to the extra acidity that was observed in the non-aqueous titrations of AFA.[7] This extra acidity was not observed in LFA (Table 1). It is, therefore, being postulated that the enhanced binding in AFA could be due to this extra acidity. The log β_{ov} values were, however, identical within the limits of experimental error. This is despite the fact that the acid–base capacities of the two fulvic acids are significantly different (LFA = 7.7 and AFA = 5.6 meq/g). A careful comparison of Figs 3 and 4 shows that the effect of ionic strength on the fraction of calcium bound was more pronounced in AFA than in LFA.

Comparison of the ultrafiltration and the ISE methods

The ultrafiltration method indicated slightly higher binding as compared to the ISE method, *i.e.*, the log β_{ov} obtained by ultrafiltration were greater than those obtained by the ion selective electrode by 0.5 log units in the pH range of 4–5. This difference, $[\log \beta_{ov,(ultra)} - \log \beta_{ov,(ise)})]$, reduces to ~0.25 around pH 7 (Fig. 6). The fraction of Ca^{2+} bound, (Ca_b/Ca_t), obtained by both methods showed a similar dependence on pH and the ratio of FA/Ca^{2+}. The discrepancy between binding constants obtained from the two methods (Fig. 6) which was similarly observed in Cd^{2+}/FA binding studies has been attributed to the intrinsic problems of determining free metal ion concentration associated with each method.[13–15] The ion selective electrode technique determines free metal ion concentration *in situ* while in the ultrafiltration, free metal is separated from the complex before its analysis. The narrow detection limit of the ion

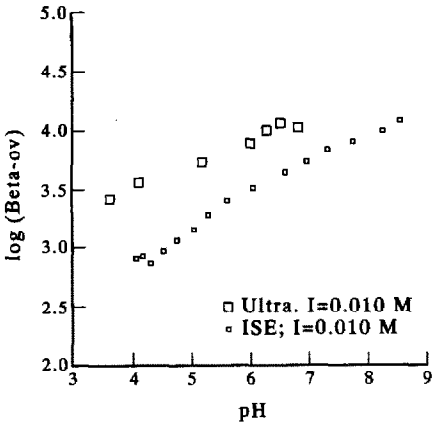

Fig. 6. Comparison of overall complex formation function obtained from ultrafiltration and ion selective electrode methods

specific electrode (not lower than $1.0 \times 10^{-6}M$) and the fact that the method is limited only to ions for which an ion selectrode is available, offer a limited application of the method to metal–humate systems that are close to environmental conditions. On the other hand, the ability to study metal–humate interactions with low concentrations of both fulvic acid and metal ions coupled with the fact that it can be used in studies involving most metal ions for which no easy *in situ* analyses of the free metal ion are available make the ultrafiltration technique a promising technique to complement studies of metal–humate interactions.

CONCLUSION

The log β_{ov} values which are presented in Table 1 are in good agreement with earlier published results.[3,4,5,16,17] The exact magnitude of the values obtained can be affected by the method employed, *e.g.*, with the ultrafiltration method the log β_{ov} values on the average ranged from 3.6 to 4.1 as compared to 2.8 to 3.5 for the ISE method. The low log β_{ov} values suggest that Ca^{2+} will have minimal interference in the interactions of strongly complexing heavy metals like Cu^{2+} with FA, but could reduce the binding of weak complexing metals like Cd^{2+} and Zn^{2+}.

Artefacts in metal–humate binding studies may be identified, reduced or eliminated by employing different methods for the study of the same metal–humate system. Under ideal conditions, different methods used in studies of the same metal–humate system must yield similar results if the methods are measuring the same kind of reaction. Discrepancies in results of well-adapted methods to metal–humate interactions might lead to insight into the existence of different "windows" of the reaction sequence. In this respect, it is suggested that the ion selective electrode and the ultrafiltration techniques may be used as complementary methods rather than as mutually exclusive methods.

A NEW METHOD FOR THE EVALUATION OF THE OXIDIZING EQUIVALENT OF MANGANESE IN SURFACE FRESHWATERS

DAVID JOHNSON and BARRY CHISWELL
Department of Chemistry, University of Queensland, Qld 4072, Australia

(*Received* 19 *February* 1992. *Revised* 30 *July* 1992. *Accepted* 30 *July* 1992)

Summary—The suitability of application of a number of previously used methods for the evaluation of the oxidizing equivalent (OE) of manganese in natural waters is compared with a new method, which depends upon colour development of the dye *N,N'*-diethyl-*p*-phenylenediamine (DPD) upon oxidation by oxidized forms of manganese. The effect of introducing a commonly used metabolic poison, azide, into the most reliable of these determinations of OE has also been assessed.

It is found that, although the methods described by other workers involving redox titrations (*viz.* oxalic acid and iodometric) gave good results when undertaken upon a synthetically prepared (concentrated) manganese (IV) oxide colloid, all such methods involving colour development by oxidation of dyes gave poor results. On the other hand, the new DPD colorimetric method gave results comparable with the titration methods, but was found to be much more sensitive and faster than either titration technique.

All of the methods, apart from the new DPD method, give poor results upon manganese samples in tests undertaken on naturally occurring waters with high OE values.

The importance of microorganisms in mediating change in the oxidation state of manganese in natural waters has been a topic of wide discussion for some years. In work undertaken in our laboratories to assess the relative importance of microbiological and chemical oxidation/reduction of manganese in dam waters, out of necessity, we have developed methods of calculating the oxidation state of manganese in natural waters. In this work we have assessed the methods previously used to arrive at a statement of the oxidation speciation of the manganese and developed a new method of determining the manganese oxidizing equivalents (O.E.).

In natural waters, manganese exists in the oxidation states, II, III and IV. As the oxidation states III and IV cannot be distinguished by redox or colorimetric methods, they are usually expressed together as the sum total oxidising equivalents, which themselves are measured by redox titration or colour forming ability with a colorimetric reagent. A measure of the ratio O/Mn can be obtained as a value x by using equation (1). The total manganese

$$x = 1 + \frac{\frac{1}{2}[\text{O.E.}]}{[\text{MnOx}_{\text{tot}}]} \qquad (1)$$

where $[\text{OE}] = 2[\text{Mn(IV)}] + [\text{Mn(III)}]$ and $[\text{MnOx}_{\text{tot}}] = [\text{Mn}_{\text{tot}}] - [\text{Mn(II)}]$; concentration ($\text{Mn}_{\text{tot}}$) can be obtained by atomic absorption spectroscopic measurements of acidified solutions of the sample, while the manganese(II) concentration can be found by analysis of the dissolved manganese in the sample by use of the colorimetric reagent $\alpha,\beta,\delta,\gamma$-tetrakis(4-carboxyphenyl)porphine [T(4-CP)P].[1]

Equation (1) can only provide the average oxidation state of the manganese present in the sample and there are no commonly accepted methods of determining the individual manganese(IV) and manganese(III) concentrations. The O/Mn ratio has the values 1.0, 1.5 and 2.0 for pure samples of manganese(II), (III) and (IV), respectively.

Since techniques such as atomic absorption spectrometry, voltammetry and neutron activation analysis, traditionally used for elemental analysis of naturally occurring waters, are incapable of distinguishing between the reduced manganese(II) species on one hand and mixed higher oxidation state manganese species on the other hand, the most suitable techniques for such a problem are necessarily redox or colorimetric, the latter using redox dyes.

Table 1. Common redox methods

Redox method	References
Ferrous iron	2–4
Iodate	4, 5–7
Oxalate	4, 8–11

Table 1 lists the most commonly used redox methods for the determination of the oxidation state of manganese oxides, while Table 2 lists common colorimetric reagents used by researchers for the determination of manganese oxidation state. Many such colorimetric reagents, although accurate in laboratory situations, suffer severe interference when used in the analysis of natural waters.

Various colorimetric dyes react stoichiometrically with oxidized manganese, and in such reactions the triphenylmethane dyes such as leuco Berbelin Blue (LBB) and leuco Crystal Violet (LCV) undergo two electron oxidations to form the dyes Berbelin Blue and Crystal Violet. The *p*-aminobiphenyl dyes *o*-tolidine and benzidine also undergo instantaneous two electron oxidations to their coloured forms.[28]

It is the purpose of this paper to evaluate redox and colorimetric methods currently available for manganese oxidation state determination and to compare them with a new colorimetric method using *N,N* diethyl-*o*-phenylenediamine (DPD), a dye not previously used for the determination of the oxidation state of manganese.

EXPERIMENTAL

Reagents

1M *Potassium fluoride.* A 5.81-g weight of potassium fluoride was dissolved in 100 ml of Milli-Q water.

1M *Manganese(II) sulphate.* A 84.51-g weight of manganous sulphate monohydrate was dissolved in 500 ml of water.

2.5×10^{-2}M *Potassium permanganate.* A 0.3951-g weight of potassium permanganate was dissolved in 100.0 ml of Milli-Q water.

2.75×10^{-1}M *Sodium thiosulphate.* A 6.82-g weight of sodium thiosulphate was dissolved in one litre of Milli-Q water.

5×10^{-3}M *Sodium thiosulphate.* A 1.24-g weight of sodium thiosulphate (Aldrich) was dissolved in one litre of Milli-Q water.

3.341×10^{-4}M *Potassium iodate.* A 7.14976-g amount of potassium iodate (Aldrich), previously dried in an oven at 120°, was dissolved in one litre of Milli-Q water to give the stock solution. A 10.0-ml portion of this solution was then further diluted to one litre.

7.5×10^{-4}M *Oxalic acid.* A 1.35054-g weight of oxalic acid (Aldrich) was dissolved in 100.0 ml of Milli-Q water. This solution was then diluted by 1 in 200 to provide the final concentration, approximately $7.5 \times 10^{-4}M$.

DPD Reagent. A 0.10-g weight of *N,N*-diethyl-*p*-phenylenediamine (Aldrich) was dissolved in 30 ml of Milli-Q water and 0.8 ml concentrated perchloric acid and then diluted to 100.0 ml. The solution was stable in light for at least two weeks.

Acetate buffer. A 250-ml amount of glacial acetic acid (AnalaR, Ajax Chemical) was diluted to one litre and titrated to pH 4.0 with 5*M* sodium hydroxide.

1×10^{-3}M *Sodium bicarbonate.* A 0.084-g sodium bicarbonate was dissolved in 50 ml of Milli-Q water and diluted to one litre.

LCV Reagent. A 0.10-g amount leuco Crystal Violet (Aldrich) was dissolved in 30 ml of Milli-Q water and 0.80 ml of concentrated perchloric acid and then diluted to 100.0 ml. The solution was stable in light for up to one month.

o-*tolidine reagent.* A 0.20-g amount of *o*-tolidine (Aldrich) was dissolved in 200.0 ml of Milli-Q water.

T-(4-CP)P reagent[1]. This was prepared directly by refluxing a propionic acid solution, 0.24*M* in both 4-carboxybenzaldehyde and pyrrole, for two hours. Upon cooling, purple crystals of T(4-CP)P separated out and were recrystallized from a methanol/chloroform mixture.

2×10^{-4}M *T-(4-CP)P solution.* A 79.1-mg weight of reagent was dissolved in 5 ml of 0.1*M* sodium hydroxide and diluted to 500 ml with Milli-Q water. The solution is stable for up to six months if stored in a darkened container.

6×10^{-4}M *Cadmium(II) solution.* A 0.0505-g weight of cadmium(II) chloride was dissolved in 500 ml of water.

Table 2. Common colorimetric reagents for OE determination

Colorimetric dye	References
o-tolidine	4, 12–15
Leuco Crystal Violet	4, 14, 16, 17
Leuco Berbelin Blue	18–22
Benzidine	21, 23–26
Leuco Malachite Green	13, 27

Borate buffer (pH 8.0/0.15M *in imidazole).* A 50-ml portion of $2.5 \times 10^{-2}M$ (9.525 g/l)-sodium tetraborate was added to 20 ml of $0.1M$ hydrochloric acid in a 150-ml beaker. A 1.0212 g weight of imidazole in 25 ml of water was added and the pH adjusted to 8.0 using $0.1M$ hydrochloric acid. The solution was transferred to a 100.0-ml standard flask and made up to the mark.

Preparations

Manganese(III) fluoride.[29] The $1M$ potassium fluoride and manganous sulphate solutions were mixed with 250 ml of $4M$ sulphuric acid and 50 ml water, and $2.5 \times 10^{-2}M$ potassium permanganate solution was added slowly with constant stirring. This yielded a solution containing approximately $0.01M$ manganese(III) fluoride as determined by iodometric titration using $0.275M$ sodium thiosulphate. Appropriate dilution of the solution was made prior to use. It should be noted that this solution contains an excess of Mn(II).

Colloidal manganese(IV) oxide. A stock manganese(IV) oxide suspension was prepared by the method of Murray *et al.*[4] The total concentration of manganese in the colloidal solution prepared was found to be 2.01 mg/l. by atomic absorption analysis of acidified aliquots; the colloid was shown to have an oxidizing equivalent of 4.01 as determined by iodometric titration using $5 \times 10^{-1}M$ sodium thiosulphate. Analysis for the presence of Mn(II) in solution using the colorimetric reagent $\alpha,\beta,\gamma,\delta$-tetrakis(4-carboxyphenyl)porphine gave a zero result, and the colloidal solution was calculated by equation (1) to have a value of $x = 1.99$.[11] At this concentration and pH, the suspension was stable for more than two years with no evidence of flocculation, as confirmed by periodic standardization. Standardization using $7.5 \times 10^{-4}M$ oxalic acid was also undertaken; this method gave a value of x for the MnO_x colloid of 2.

Murray *et al.*[4] have characterised this MnO_x product by X-ray photoelectron spectroscopy and have shown it to have values of x between 1.90 and 1.98.

Instrumentation

UV–Vis spectrophotometer. Optical densities of LCV, DPD and *o*-tolidine solutions were measured on a Hewlett-Packard HP845OA, UV–Vis spectrophotometer using 1-cm quartz cuvettes.

Calibration of the HP-845OA was undertaken using colloidal manganese dioxide oxidized DPD, LCV, or *o*-tolidine standards prepared by appropriate dilutions of a 2 mg/l. stock manganese(IV) oxide suspension. Concentrations were determined by colorimetry, by comparison against the calibration curve prepared from these standards.

Atomic absorption spectrometer. Atomic absorption spectroscopy determinations of manganese were made using a Varian AA 875 spectrometer or a Varian SpectrAA 300 spectrometer. An oxidizing air-acetylene flame was used and the wavelength was selected according to concentration. For manganese in the range 10–2000 μg/l., 279.5 nm was used, and for concentrations in the range 2–10 mg/l., 403.2 nm was used.

Calibration standards were prepared by appropriate dilutions from commercial, 1000 mg/l., AAS standard (BDH) supplied in $1M$ nitric acid.

Determination of total manganese concentrations ($[Mn_{tot}]$)

These values were determined for the standard colloidal manganese(IV) oxide and dam water samples by the use of AAS, following acidification of the sample to pH 1.0 using concentrated hydrochloric acid.

Determination of manganese(II) concentrations [Mn(II)]

These were found for the standard colloidal manganese(IV) oxide colloid (effectively a blank) and dam water samples by the following method: 5.00 ml of sample solution was placed into 25-ml standard flasks which had been painted black except for 0.5 cm either side of the volume mark. A 1.0-ml aliquot of $2 \times 10^{-4}M$ T-(4-CP)P solution and 1.0 ml of borate buffer were then added followed by 3.0-ml of $6 \times 10^{-4}M$ cadmium(II) solution. The absorbance at 468 nm was measured between 5 and 20 min after mixing.[30]

Determination of oxidising equivalents of colloidal manganese(IV) oxide, manganese(III) fluoride and of dam water samples

Oxalic acid method. In each determination the value of OE is the mole value of either the titrant used, or the dye consumed in the reaction. As noted above, this method was used to standardize the colloidal MnO_2. The method

was also applied to 100-ml aliquots of dam water samples.

Iodometric method. A 100-ml volume of the colloidal manganese(IV) oxide, Mn(III) fluoride, or the dam water sample were used. An excess of potassium iodide (Ajax) was added to this aliquot followed by 5 ml of 0.1*M* sulphuric acid. The liberated iodine was determined by titration against $5 \times 10^{-3}M$ thiosulphate previously standardized against $3.341 \times 10^{-4}M$ potassium iodate. The end-point determination was aided by the addition of starch solution late in the titration.

Leuco Crystal Violet (LCV) method. Suitable aliquots of the stock manganese(IV) oxide colloid, or dam water samples were added to approximately 12.5 ml of sodium bicarbonate solution in 25-ml standard flasks. To each sample, 0.50 ml of LCV reagent was added followed by 1.0 ml of buffer solution. The solution was mixed and stood for 5 min before making up to the mark with reagent water. The 1 cm absorbance was determined at 590 nm against a reagent blank.

o-*Tolidine method.* Measured volumes of manganese(IV) oxide colloid were added to 100-ml standard flasks. A 25-ml volume of 3*M* perchloric acid and 10 ml of *o*-tolidine solution were added and solutions made up to the mark after mixing. The 1-cm absorbance of the yellow solution was measured at 440 nm.

N,N-*Diethyl*-p-*phenylenediamine (DPD) method.* Suitable aliquots of stock manganese(IV) oxide colloidal suspension or 5.00 ml of unknown samples were added to approximately 12.5-ml aliquots of the sodium bicarbonate in 25-ml standard flasks. To each sample, 0.50 ml of DPD reagent was then added followed by 1.0 ml of buffer solution. The solution was then mixed and left to stand for at least five minutes. The resulting pink coloured solutions were made up to the mark with reagent water and the 1-cm absorbance was determined at 552 nm against a reagent blank.

RESULTS AND DISCUSSION

Determination of OE

Oxalic acid method. The oxalate method involves the addition of a known amount of excess oxalic acid to the sample, with subsequent back titration of the non-oxidized oxalate with permanganate at 60°. Murray *et al.*[4] found that this method gave results for samples of his synthetic MnO_x of $x = 1.99 \pm 0.02$. Results from this study for the analysis of the colloidal manganese (IV) oxide agreed well, with $x = 1.98 \pm 0.01$.

This method was tested, on a series of natural water samples. On all occasions samples consumed more permanganate than did the oxalate standard alone, giving titration results up to 117% of the oxalate standard value.

Because of its interaction with many components present in natural waters, other than manganese, permanganate has to be considered as being too powerful as an oxidizing agent to determine the oxidizing equivalents in such cases; for this reason the oxalate method was not investigated further.

Iodometric method. The iodometric method had similar success to the oxalate method for Murray *et al.*,[4] yielding typical values of x of 1.98 ± 0.05. Although this technique uses the much weaker reducing agent, iodide ion, when the same series of dam samples that were used in the oxalic acid method were measured by iodometric titration using 100-ml volumes, problems were encountered in determination of the end-point. The samples were yellow/brown in colour because of the presence of colloidal organic material and MnO_x, which lead to total inability to detect any end-point.

Leuco Crystal Violet (LCV) method. The method of Kessick and Morgan[12] was used in this investigation.

Figure 1 shows the results of a kinetics experiment measuring the stability of the colour of crystal violet when reacted with standard MnO_2 and manganese(III) fluoride. Thermodynamics predict that both manganese(IV) and (III) will

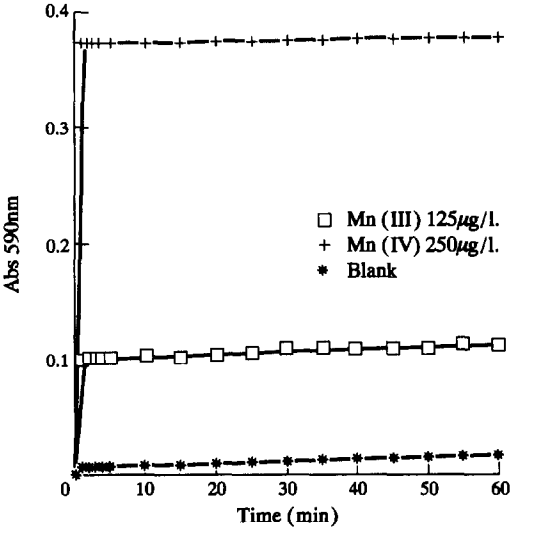

Fig. 1. Reaction of LCV with Mn(III) fluoride and Mn(IV) oxide.

oxidize LCV, however some evidence exists that the kinetics of such reactions may differ. Morgan and Stumm[13] have stated that manganese(III) reacts somewhat more slowly with *o*-tolidine than does manganese(IV).

From Fig. 1 it can be seen that both Mn(III) and Mn(IV) immediately oxidize LCV to a maximum absorbance. The absorbance values remained relatively constant over the period of 1 hour with no real increase observed, indicating that the dye does not react slowly with synthetic MnO_2 or manganese(III) compounds, nor does atmospheric oxidation play any significant role. No difference in stability of colour is observed between the reactions of manganese(III) and (IV).

De Vitre *et al.*[31] have used the method of Kessick *et al.*[12] and compared it with two other methods for the determination of MnO_x concentrations in lake samples; they found it to have three major drawbacks:

(i) the measured absorbance is a function of the kinetics of the reduction of MnO_x by LCV (from Murray's[4] data),
(ii) analysis of turbid samples required scattering corrections of up to 80% of the measured value, and,
(iii) when sulfide concentrations are significant, the LCV forms polymeric solutions resulting in the formation of a cloudy suspension.

In the study undertaken in work reported in this paper, point (i) was found to be insignificant if measurements were taken in under one hour. Point (ii) was found only to be a problem when sediment samples or samples very close to the sediment were taken; scattering caused by analysis of water column samples was measured and found to be negligible; measurement of OE in sediments was not undertaken. Point (iii) was found to be the major problem and was particularly prevalent during periods of stratification. This phenomenon also occurred frequently in samples from other levels of the dam. LCV could therefore not be used at all to measure OE in hypolimnetic samples.

A further problem associated with the use of LCV to determine OE was encountered when azide was used in our experiments to poison and thus prevent microbiological oxidation. Azide is often used as a poison in such work where one wishes to distinguish microbial from chemical reactions; its operation appears to be as a relatively non-specific block on the operation of terminal oxidases within cytochrome chains.[32]

Azide interference was found to be high when measuring the concentration of MnO_x by the LCV method. Two solutions containing the same concentration of colloidal MnO_x standard, one of which contained 15 m*M* NaN_3 and one without the poison, were measured and compared by the LCV method. Figure 2(A) presents the typical visible spectrum of the leuco Crystal Violet dye, oxidized by MnO_2. In the presence of 15 m*M* azide, (Fig. 2(B)) the spectrum is very clearly altered, and marked interference, and complete disappearance of the 591 nm peak, is observed. Such background interference appears to be due to the formation in the LCV

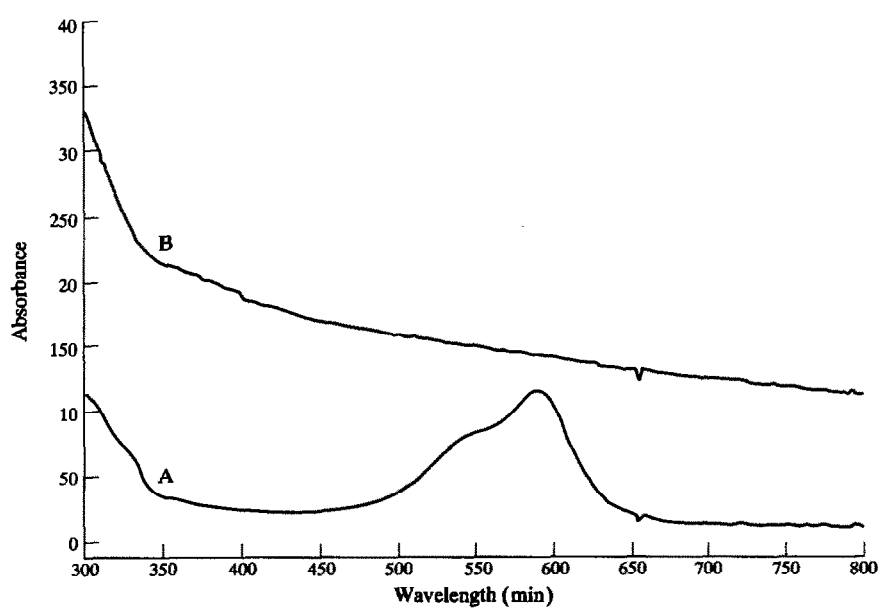

Fig. 2. Absorption spectrum of LCV (A) without azide, and (B) with azide.

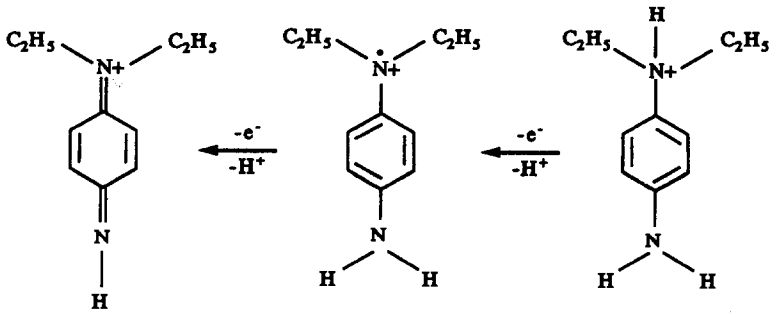

Fig. 3.

solution of a cloudy suspension in the presence of azide.

A number of papers describe the use of the dyes leuco Berbelin Blue (LBB) and LCV to measure OE in the presence of the metabolic inhibitor, azide. In such cases, failure to observe an absorbance peak at 591 nm for LCV and similar peak LBB, has been interpreted in terms of the poison inhibiting microbial oxidation and consequent non-production of oxidized manganese to oxidize the dye and produce the absorbance. Thus, in a study into the oxidation of manganese by cells of *Leptothrix Discophora* SS1, Boogerd and De Vrind[20] measured MnO_2 concentration colorimetrically using LBB, showed that azide inhibited the influence of this strain on the oxidation process. As LBB is of similar structure to LCV, it is clearly likely that azide reacted similarly with LBB, to give a suspension which led to light scattering and no observable absorbance peak.

De Vrind *et al.*[22] in an investigation into manganese oxidation by spore coats of a marine *Bacillus* species, found that the spores oxidized manganese to MnO_2, as measured by LBB. When NaN_3 was present no oxidation could be measured. Again, if the reaction of azide with LBB is similar to that with LCV, one would expect that no absorption peak would be obtained.

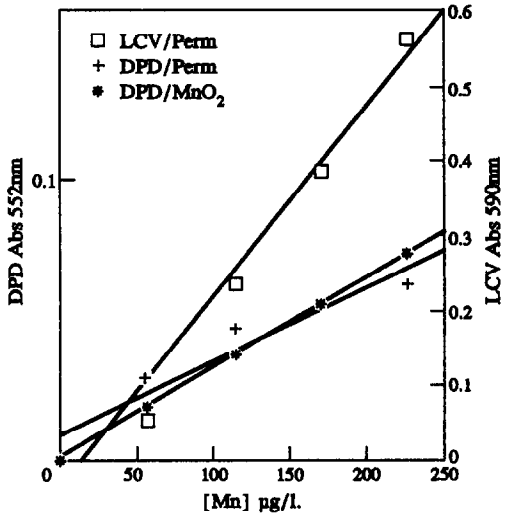

Fig. 4. Standardization of DPD and LCV. LCV/Perm., $r = 0.9898$; DPD/Perm., $r = 0.9582$; DPD/MnO_2, $r = 0.0008$.

o-*Tolidine method.* The method of Morgan and Stumm[13] using *o*-tolidine to determine manganese OE in a colloidal manganese(IV) oxide suspension was attempted in this work on several occasions, but the reagent appeared to react non-quantitatively with standard MnO_2 suspension, providing calibration coefficients of no better than 0.97. Although the purity of the reagent used may be responsible for the deviation from linearity, no attempt was made to purify the reagent as previous experience has shown this to be very time consuming, with very limited improvements.[33] Furthermore, being a *p*-aminophenyl molecule, as is LCV, NaN_3 may also interfere in similar experiments. For these reasons no further work was attempted using *o*-tolidine to determine OE.

N,N-*diethyl*-p-*phenylenediamine, (DPD) method.* DPD is most often currently used for the determination of chlorine residuals in treated water.[34] Figure 3 illustrates the sequential oxidation reactions that DPD undergoes at pH 4.0.

In contrast to LCV, LBB and *o*-tolidine, DPD initially undergoes a one electron oxidation. The semiquinoid intermediate product is a cationic radical, and it is this species, known as Wurster's dye,[35] that provides the pink colour when oxidation of DPD occurs.

DPD provided much improved stoichiometrical results upon colloidal manganese(IV) oxide suspensions compared with those obtained using *o*-tolidine; commonly, correlation coefficients of 0.9999 were achieved. Being only a one electron oxidation, one mole of MnO_2 is able to provide two moles of the cationic radical; this somewhat offsets the lower molar absorptivity.

Table 3. Comparison of Redox and Colorimetric Methods for the Determination of MnO_x

Method	"x" value
LCV	1.65 ± 0.06
o-tolidine	2.36 ± 0.06
LBB	2.13 ± 0.08
Oxalate	1.99 ± 0.05
Iodine	1.98 ± 0.05
DPD	1.98 ± 0.03
Iodine	1.98 ± 0.04

Comparison of the DPD, LCV and iodometric methods

In a comparison of the DPD and LCV methods it was first concluded that permanganate is unsuitable for use as a standard for both reagents. Figure 4 shows that Beer's law plots, using permanganate to standardize both dyes, are far from linear. Significant deviation from linearity occurs indicating that MnO_4^- is being consumed by impurities present in the dyes. It is also possible that the high oxidation state of manganese in MnO_4^- provides problems when used as a redox/colorimetric standard. The reduction of MnO_4^- occurs stepwise, through to the stable IV oxidation state. Full reduction to the Mn(II) state occasionally may not occur rapidly on the timescale required for measurements to be made.

The deviation from linearity is not observed when colloidal MnO_2 is used as the standard in corresponding concentrations.

DPD shows vast superiority in reproducibility over *o*–tolidine and LCV, when used to measure MnO_2 concentration, the standard deviation for measurement of 100 μg/l. MnO_2 being only 5 μg/l.

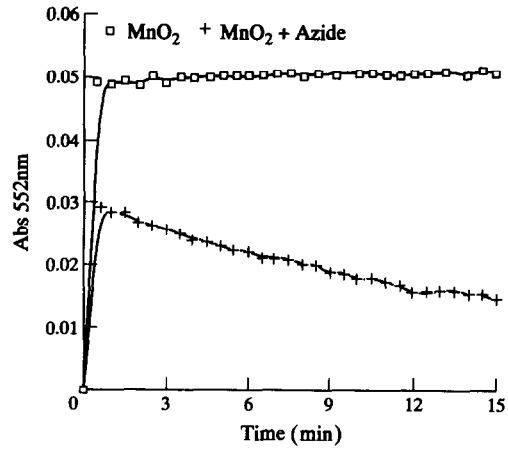

Fig. 5. Stability of DPD absorbance in the presence of azide.

One mole of permanganate should be capable of oxidizing five moles of DPD and thus should give absorbances $\frac{5}{2}$ those of the corresponding MnO_2 concentrations. However, this was not observed. The extinction coefficient of the permanganate line, 1.49×10^4 $l \cdot mole^{-1}$ cm^{-1}, is only $\frac{3}{4}$ that for the MnO_2 line, 1.97×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$. It is worth noting in this context that Tipping *et al.*[35] found that permanganate gave an extinction coefficient of only 2.5×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ with *o*-tolidine, compared to 3.3×10^4 $l \cdot mole^{-1} \cdot cm^{-1}$ when a synthetic manganese(IV) oxide was used. This discrepancy, according to Tipping, almost exactly accounted for the high oxidizing equivalents obtained by Murray *et al.*[4]

Since permanganate cannot be used as a colorimetric standard it is necessary to use MnO_2 standards for the DPD method. To compare the iodine and DPD methods it was

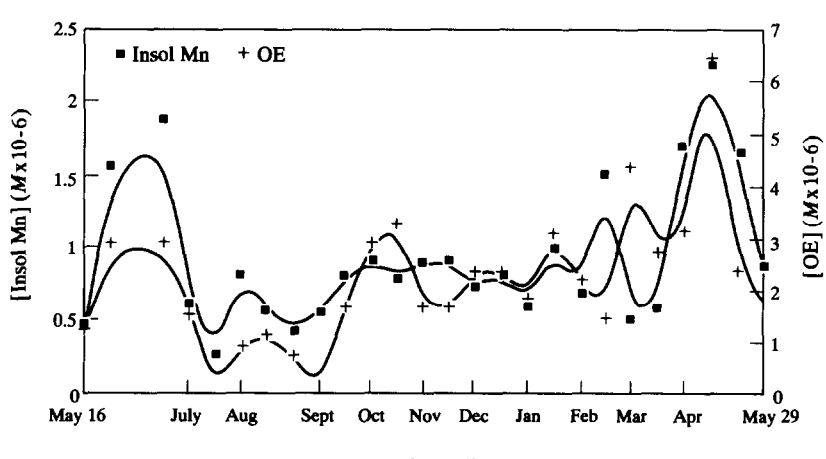

Fig. 6. OE values by DPD method and insoluble manganese concentrations for freshwater dam samples over one year.

therefore necessary to standardize the stock MnO_2 colloidal suspension using the oxalate method. The iodine and DPD methods could then be compared by analysis of a second synthetic MnO_2 colloidal suspension.

Results showed great consistency. The second colloidal suspension was found to be 2020 ± 15 μg/l. using the iodine method and 2010 ± 20 μg/l. using the DPD method.

Table 3 lists the results of Murray *et al.*[4] for the determination of the x value of a synthetic MnO_x suspension and compares them to the results for DPD obtained in this work.

It is clear that DPD is an excellent dye for use in these circumstances. Results compare extremely favourably with the redox titration methods and with other colorimetric methods. It has advantages over the redox methods in sensitivity, time required for each determination, ease of performance and only small sample volumes are required.

To investigate the effect of the poison NaN_3 on the DPD determination of OE, an experiment was run that involved the measurement of a known amount of MnO_2 in the presence of azide by comparison of the absorbance value at 552 nm against a series of standards. The absorbance values used were taken less than 30 sec after DPD had been added to the samples. The final value obtained of 295 μg/l., an average of five individual readings, was within 1.7% of the desired value, 300 μg/l. Figure 5 illustrates the effect of leaving the DPD to react for 15 min with 15 mM NaN_3. It is seen that the DPD colour is again very stable for at least this time period in the absence of azide, but when azide is added the colour is rapidly removed. However, if a measurement is taken within one minute, a value within 1% can be obtained in the presence of azide.

The method was used to find the OE of freshwater dam samples, collected from a depth of three metres, over the year May 1990–May 1991. Figure 6 shows the results obtained and offers a comparison between OE and concentration of insoluble manganese (defined as being retained by a 0.05-μm filter membrane) in the water sample. At this water depth, the majority of the oxidized manganese will be associated with the insoluble fraction of the metal, however it is not necessarily the case that a high OE and a large concentration of insoluble manganese should occur together. Further analysis of this relationship will be taken up in continuing studies.

SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF VANADIUM IN URANIUM RICH HYDROGEOCHEMICAL SAMPLES USING PYRIDYL AZO RESORCINOL (PAR)

G. CHAKRAPANI,* D. S. R. MURTY, B. K. BALAJI and R. RANGASWAMY
Chemical Laboratory, Atomic Minerals Division, Department of Atomic Energy, Nagarbhavi, Bangalore 560072, India

(*Received* 1 *June* 1992. *Revised* 23 *July* 1992. *Accepted* 23 *July* 1992)

Summary—A simple and precise method has been developed for the determination of traces of vanadium(V), using 4-(2 pyridyl azo) resorcinol, in natural water samples, containing very high concentrations of uranium. CDTA–pyrophosphate buffer has been used for masking interferants, including uranium which otherwise interferes above 125 ppb. The reaction of vanadium with PAR in the presence of buffer requires a waiting period of 45 min. The Sandell sensitivity of the method is 0.003 μg/ml, at 545 nm at an optimum pH of 6.5 ± 0.2. The precision of the method is ±15% at the 100 ppb level of vanadium(V). The method has been successfully applied to a number of natural water samples during hydrogeochemical exploration.

The determination of vanadium in hydrogeochemical samples assumes significance, as it is a path finder[1] element for identifying uranium deposits. The presence of vanadium in potable water, in trace quantities has been found to have beneficial effects on the health of individuals.[2] In general, the vanadium in natural water samples varies up to a maximum of 1400 ppb.[3] Various methods that have been reported[4–7] for the determination of vanadium in traces, mostly involving preconcentration, are either cumbersome or the tolerance limits for various ions are poor or their determination levels high. In the method reported for vanadium(V) using PAR and CDTA,[8,9] uranium interferes seriously. Amongst others, uranium(VI) also forms a complex with PAR,[9,10] under identical conditions and thus acts as a major interferant in the determination of traces of vanadium in water samples containing high uranium. During the course of hydrogeochemical surveys in the Cuddapah basin, Andhra Pradesh, India, natural water samples showed anomalous uranium values varying up to a maximum of 5550 ppb.[11] Therefore, a simple and precise analytical procedure for the estimation of vanadium in the presence of high uranium, in hydrogeochemical samples has been developed and the results are presented in this paper.

*Author for correspondence.

EXPERIMENTAL

Instrumentation

A Shimadzu UV-240 graphicord double beam spectrophotometer with 10-mm path length quartz cells and an Orion analyser model 407 A pH meter were used.

Reagents

Vanadium solution. (1 ml = 100 μg of V). Dissolve 0.2309 g of ammonium metavanadate A.R (Renna, Budapest, Hungary) in water, add 15 ml of 1:1 nitric acid and dilute to 1000 ml. From this, prepare a fresh vanadium standard solution of 1 ml = 1 μg of V.

CDTA (0.014M)–pyrophosphate (0.4M) (buffer). Dissolve 1.25 g of 1,2 amino cyclohexane *NNNN*-tetra acetic acid, CDTA (Pro analysis, Merck) in a minimum amount of dilute sodium hydroxide and adjust to pH 6.5 (solution 1). Dissolve 44.69 g of tetra sodium pyrophosphate (Analar, BDH) in a minimum amount of dilute nitric acid and adjust to pH 6.5 (solution 2). Mix solutions 1 and 2 and make up to 250 ml.

PAR solution (0.004M). Prepare 0.1% 4-(2 pyridylazo) resorcinol by dissolving 0.1 g of the sodium salt of PAR (Loba Chemie GR) in distilled water and adjust the pH between 6.5 and 7.0. All the other reagents used are of Analar grade.

Table 1. Tolerance limits in μg for various ions in the determination of 3 μg of vanadium in the presence of CDTA pyrophosphate

Interferant	μg/Aliquot*
K^+	48,000
Na^+	40,000
Ca^{+2}	10,000
Mg^{+2}	10,000
Mo^{+6}	5,000
Zn^{+2}	300
UO_2^{+2}	300†
Cu^{+2}	100
Fe^{+3}	20†
Mn^{+2}	500
As^{+3}	10

F^-	50

*The interference effect beyond the concentration given was not studied.

†Fe^{+3} and UO_2^{++} interfere beyond the concentration given. Aliquot, maximum 10 ml; Buffer, 10 ml of 0.4*M*; PAR 2 ml of 0.1%; total volume of 25 ml.

Procedure

To an aliquot of a natural water sample (maximum 10 ml) containing 1–10 μg of vanadium(V), add 10 ml of CDTA–pyrophosphate buffer, adjust to pH 6.5 ± 0.2 if necessary, and add 2 ml of PAR at the end. Dilute to 25 ml and after 45 min measure the optical density of the solution at 545 nm. Draw a calibration graph by treating 1, 2, 3 and 5-μg vanadium standards in a similar way. Beer's law is obeyed in the range of 40–400 ppb of vanadium.

RESULTS AND DISCUSSION

The sequence of addition of reagents, should be the addition of CDTA pyrophosphate buffer, followed by pH adjustment, where necessary, and addition of PAR at the end. Any precipitate formed after the addition of buffer dissolves while adjusting to pH 6.5 ± 0.2. However, in a situation where the precipitate does not dissolve, if Ca is present in >1000 ppm, smaller aliquots are to be taken.

The CDTA reagent is a well known complexing agent.[12] The presence of CDTA prevents the reaction of many metal ions like Ca, Mg, Al, Mn, Mo, Co, Cr, Cu, Zn, Pb, Ni, *etc.*[8,13] with PAR, making the method one of the most selective for the determination of vanadium. The selective masking reaction of CDTA was attributed to its thermodynamic effect.[14] CDTA has a special action towards the vanadyl ion, in that it does not form a stable complex, in contrast to other metal ions.[15,16] The reaction of vanadium with PAR in the presence of buffer is not instantaneous and requires a waiting period of 45 min. Probably the lower stability constant[14] of the VO_2–CDTA complex ($K = 10^{16.59}$) eventually paves the way for the formation of the more stable VO_2-PAR complex ($K = 10^{18.81}$), thus requiring a waiting period of about 45 min.

$$VO_2 - CDTA + PAR \leftrightharpoons VO_2 - PAR + CDTA^{14}$$

The stability of the VO_2–buffer–PAR complex alone and in the presence of various cations and anions was studied from 45 min to 4 hr. During the period of study the complex was found to be stable. Thus, various metal ions and other anions as indicated in Table 1 do not interfere, during this period.

The tetra sodium pyrophosphate is a well known complexing agent and has been used in the determination of uranium in water samples, using laser induced fluorimetry.[17]

The complexing/buffering property of pyrophosphate for uranium has been made use of as

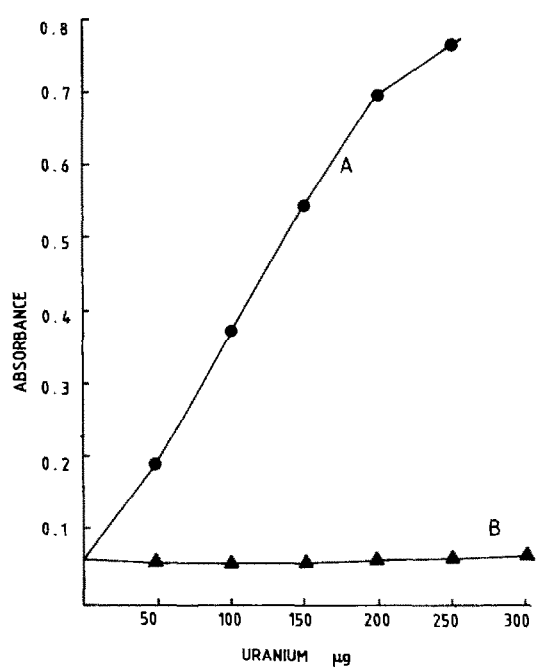

Fig. 1. Effect of uranium on vanadium determination; 3 μg of vanadium with varying concentration of uranium in a total volume of 25 ml. A, in the presence of 10 ml of 0.014*M* CDTA only. B, in the presence of 10 ml of 0.014*M* CDTA–0.4*M* pyrophosphate buffer.

Table 2. Recovery studies for vanadium on synthetic water samples

Synthetic water samples	Composition in 25-ml volume	Vanadium added (in 25 ml)	Vanadium found (in 25 ml)
SYWS-1	Ca and Mg (10 mg each) Cl, SO_4, Na and K (40 mg each)	3 μg	2.85 μg
SYWS-2	SYWS-1 + HCO_3 (25 mg) added at pH 6.5	3 μg	2.90 μg
SYWS-3	SYWS-1 + F (50 μg)	3 μg	3.25 μg
SYWS-4	SYWS-3 + Zn (300 μg) Cu (100 μg) Fe (20 μg) Mn (500 μg) As (10 μg) Ni (100 μg) Pb (1000 μg) Se (3μg)	3 μg	3.30 μg

a masking effect in the proposed spectrophotometric determination of vanadium in the presence of high concentrations of uranium. Thus, the shortcoming of the V–PAR method[8] in which uranium interferes even in the presence of CDTA has been overcome by using pyrophosphate buffer. While determining vanadium in the presence of uranium using PAR, the reaction due to U-PAR is completely suppressed by pyrophosphate, and not by CDTA (Fig. 1). Because of the excellent buffering capacity of pyrophosphate, there is no need to adjust the pH of natural water samples, whose pH will generally be around 6.5–8.5.

The concentrations of various cations and anions, as given in Table 1, were fixed, for interference studies, keeping in view the anomalous values for cations and anions that are likely to be present in anomalous natural water samples. The interference effects of these ions beyond the concentrations given in Table 1, were not studied, except in the case of Fe(III) and U(VI); studies indicate that if Fe(III) is present in more than 20-μg amounts in 10 ml of water sample, it interferes seriously. U(VI) also interferes, if present in more than 300 μg/10 ml. The tolerance limits were fixed as being able to accommodate 5% change in the standard value. As Pb is a general co-existent of uranium, it is probable that Pb will often occur with uranium and hence its interference effect has been studied up to 1000 μg/10 ml. Lead does not interfere even at this high concentration. Fe, U, Pb and other cations and anions are not likely to exist in natural waters above the levels indicated in Table 1.

The optimum concentration of CDTA (0.014*M*) and pyrophosphate (0.4*M*) has been fixed, keeping in mind the natural water samples containing anomalous concentrations of cations and anions as given in Table 1. Uranium present in water samples above 125 ppb interferes in the determination of vanadium, if not masked. Uranium at 100 ppb gives a value equivalent to 15 ppb vanadium.

In Fig. 1, the interference effect of uranium (from 50 μg to 300 μg) on the determination of vanadium (3 μg) is shown in the presence of 0.014*M* CDTA alone and in the presence of both 0.014*M* CDTA and 0.4*M* pyrophosphate buffer mixture. It is very clear from the graph that in the absence of pyrophosphate buffer and in the presence of CDTA alone, uranium interferes seriously [see rising line (A)] *i.e.*, increasing absorbance values for the same concentration of vanadium (3 μg) with an increase in uranium concentration. On the contrary, the interference effect of uranium is not seen in the presence of CDTA–pyrophosphate buffer, as shown by the flattened line (B). Thus, the studies indicate that 10 ml of 0.4*M* pyrophosphate buffer can completely mask uranium (either as UO_2^{2+}, U^{4+} or both) up to 300 μg and CDTA plays no role in complexing uranium. Hence, vanadium can be determined in water samples containing anomalous concentrations of uranium even in the order of 10,000 ppb and greater without interference from it.

In the absence of the naturally available water samples, having anomalous concentrations of various ions as given in Table 1, synthetic water samples were prepared in order to study the recoveries by the present method. Good recoveries of vanadium have been obtained (>90%) on synthetic water samples, SYWS-1, SYWS-2, SYWS-3, and SYWS-4, as given in Table 2.

Natural water samples (Bore well waters), having a very high concentration of uranium (approx. from 1000 to 5000 ppb) have been selected for the determination of vanadium, so as to indicate the extent of uranium interference on vanadium, in the presence of only CDTA and in the absence of pyrophosphate buffer. The vanadium values in these samples,

*Vanadium determined after preconcentration by evaporation.
†Vanadium values given are the average of six determinations.

determined by the present method and by ICP–AES,[18] are tabulated in Table 3 for comparison. The values given in ppb are the average of six determinations. In the same samples, vanadium values, determined by using only CDTA, are very high due to interference from uranium. This explains clearly the role of the buffer. The uranium values in the above samples were determined by laser induced fluorimetry.[17] The relative standard deviation of the method at 100 ppb vanadium is within ±15%.

Two separate aliquots of natural water samples were taken and one portion of it was analysed after treating with an oxidizing agent, keeping both V and U in +5 and +6 states respectively. Another portion of it was analysed directly without adding any oxidizing agent. The vanadium values obtained in both cases were found to be the same and hence the addition of an oxidizing agent is not essential. It is also reported that vanadium[19,20] and uranium[21] mostly exist in +5 and +6 states respectively.

CONCLUSIONS

The present method is simple and precise, involving only the addition of CDTA-pyrophosphate buffer and PAR to natural water samples. Vanadium down to 100 ppb can be determined in the presence of high concentrations of uranium and dissolved solids, without preconcentration and/or isolation from interferants.

(*Received* 17 *June* 1992. *Accepted* 22 *July* 1992)

Summary—Experimental and theoretical vibrational Raman optical activity (VROA) spectra of (2*R*,3*R*)-2,3-dimethylthiirane in the 200–1500 cm^{-1} region are presented. The level of agreement obtained for the observed and predicted VROA signs suggests that the absolute configurations of chiral molecules can be determined confidently using VROA.

Raman optical activity in vibrational transitions, known as vibrational Raman optical activity (VROA), was theoretically formulated[1,2] and experimentally observed[3] in the early 1970's. However, as the effect is very small (usually a few parts in 10^4 units of ordinary Raman cross sections, which themselves are weak) and the phenomenon is one of higher order perturbations, the experimental measurements remained difficult and theoretical predictions appeared hopeless. Two recent developments[4–11] have changed this gloomy situation and the course of VROA spectroscopy. It was recognized that VROA can be predicted[4–10] from first principles using *ab initio* quantum theoretical methods and at about the same time the VROA instrumentation in Glasgow has been improved dramatically so that VROA spectra can be obtained routinely with excellent signal-to-noise ratios.[11] As a result, important chemical problems are beginning to be addressed now using VROA spectroscopy. One of these is the determination of absolute configurations of chiral molecules. Since optical activity is being probed in the vibrational transitions and since each vibrational transition of a chiral molecule in principle can exhibit VROA, the informational content in a VROA spectrum contains the complete stereochemistry of a molecule in the solution phase. Extraction of this information from a given experimental spectrum is not quite straightforward and in this context the reliability of the theoretical models employed plays a key role. In order to be able to use VROA spectroscopy as a practical tool for stereochemical studies, VROA research at this time is directed towards establishing this reliability. As part of this development we investigated the experimental and theoretical VROA of enantioenriched *trans*-2,3-dimethylthiirane. These results are presented and critically analysed in this paper.

*Authors for correspondence.

THEORY AND EXPERIMENTAL

The enantioenriched *trans*-2,3-dimethylthiirane used in the present study was characterized earlier[12] and had $[\alpha]^{23-25}D + 105°$ (neat). Thus, based on the highest rotatory power reported for either enantiomer, this sample of thiirane had an enantiomer excess of 81%. The VROA spectra were obtained on a second new Raman spectrometer developed at Glasgow which will be described in detail elsewhere (this is a 90°-scattering version, for small organic molecules, of the backscattering VROA instrument for biological samples described in Ref. 11).[13] A brief description is as follows. The incident laser beam from an Ar^+ laser, at 488 nm with ~750 mW power at the sample, is modulated between right and left circular polarizations using a KD*P electro-optic modulator at ~1 Hz. The depolarized light scattered in the 90° direction with polarization in the

scattering plane was collected and dispersed on to a CCD detector by a 0.25-meter spectrograph (JY HR250S). A holographic notch filter (Kaiser Optical Systems) enabled the spectra to be measured down to ~ 100 cm^{-1}. The detector is a Peltier-cooled back thinned CCD camera (Wright Instruments Ltd. Model AT1) with an exceptional quantum efficiency ($\sim 80\%$). The light scattered during the left circular polarization excitation was subtracted from that during the right circular polarization excitation and this difference spectrum represents the depolarized VROA, $I_z^R - I_z^L$. For comparison of magnitudes with the theoretical predictions this difference is normalised with the corresponding sum, $I_z^R + I_z^L$, and the normalized circular intensity difference is denoted Δ_z. Typical exposure time was 0.8 sec with total data acquisition time of one hour. The experimental difference and sum spectra are displayed in Fig. 1.

The *ab initio* quantum theoretical predictions of Δ_z were obtained from the expression[1,14]

$$\Delta_z = \frac{I_z^R - I_z^L}{I_z^R + I_z^L} = \frac{24(\gamma^2 - \delta^2/3)}{12\ \beta^2} \qquad (1)$$

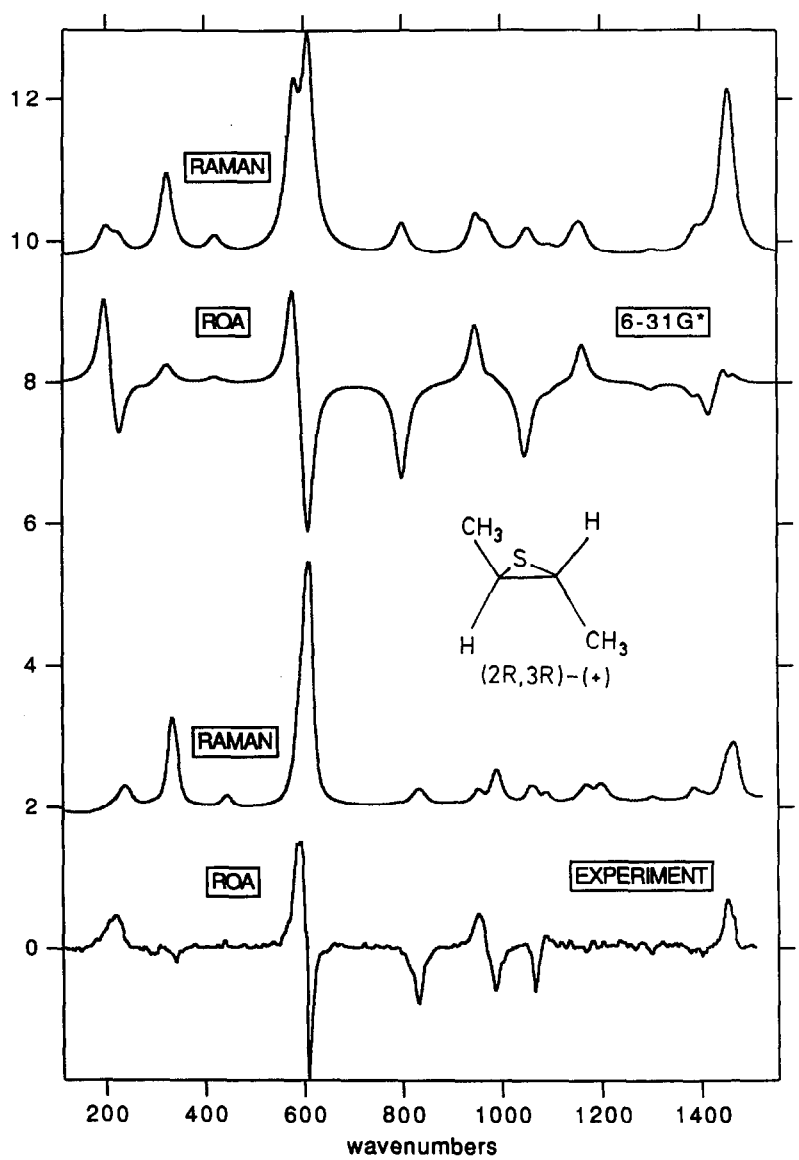

Fig. 1. Experimental (bottom two traces) and *ab initio* theoretical (top two traces) Raman and VROA spectra for (+)-*trans*-2,3-dimethylthiirane and (2*R*,3*R*)-2,3-dimethylthiirane, respectively. The theoretical spectra were obtained with the 6-31G* basis set and the calculated frequencies were multiplied by 0.89 to bring them closer to the experimental frequencies. All spectra are presented on arbitrary intensity scales.

where

$$\gamma^2 = \frac{1}{2}\left[3\frac{\partial\alpha_{\alpha\beta}\partial G'_{\alpha\beta}}{\partial Q\ \partial Q} - \frac{\partial\alpha_{\alpha\alpha}\partial G'_{\beta\beta}}{\partial Q\ \partial Q}\right] \quad (2)$$

$$\delta^2 = \frac{\omega}{2}\frac{\partial\alpha_{\alpha\beta}\partial A_{\gamma\delta\beta}}{\partial Q\ \partial Q}\epsilon_{\alpha\gamma\delta} \quad (3)$$

$$\beta^2 = \frac{1}{2}\left[3\frac{\partial\alpha_{\alpha\beta}\partial\alpha_{\alpha\beta}}{\partial Q\ \partial Q} - \frac{\partial\alpha_{\alpha\alpha}\partial\alpha_{\beta\beta}}{\partial Q\ \partial Q}\right] \quad (4)$$

by evaluating the polarizability derivatives $\partial\alpha_{\alpha\beta}/\partial Q$, $\omega^{-1}\ \partial G'_{\alpha\beta/\partial 2}$, $\partial A_{\alpha\beta\gamma}/\partial Q$ numerically. Here Q is the vibrational normal coordinate; $\alpha_{\alpha\beta}$ is the electric dipole electric dipole polarizability, $G'_{\alpha\beta}$ is the electric dipole magnetic dipole polarizability and $A_{\alpha\beta\gamma}$ is the electric dipole electric quadrupole polarizability. These tensor derivatives were obtained in the static limit by evaluating the tensors at the equilibrium geometry and at the geometries displaced by 0.005 Å along each cartesian coordinate. The procedure for obtaining the $\omega^{-1}\ G'_{\alpha\beta}$ tensor in the static limit is due to Amos[15] as implemented in the CADPAC program[16] which simultaneously evaluates the $\alpha_{\alpha\beta}$ and $A_{\alpha\beta\gamma}$ tensors. The above mentioned tensor derivatives were obtained with the 6-31G* basis set[17] at the fully optimized geometry. Vibrational frequencies and normal mode descriptions were also obtained[12] with the same basis set. The predicted spectra were simulated with Lorentzian band shapes using 12 cm^{-1} half-width at half-height. The resulting theoretical spectra are compared to the corresponding experimental spectra in Fig. 1 where the theoretical frequencies are multiplied by 0.89 to bring them closer to the experimental frequencies. The experimental Δ_z values corrected to 100% enantiomeric excess are given in Table 1.

RESULTS AND DISCUSSION

The experimental data for the (+)-*trans*-2,3-dimethylthiirane and the theoretical data for the enantiomer with the 2*R*,3*R* configuration are used in the following discussion. Also the theoretical frequencies cited in the discussion are those scaled down by 0.89.

The two resolved experimental Raman bands at 1458 and 1446 cm^{-1} are composed of four

¶The experimental Δ_z values are the averages of two measurements and are corrected to 100% enantiomeric excess and thus the listed values are for the pure enantiomer.

normal modes arising from the bending motions of the methyl groups. A single positive VROA envelope is observed for these two bands but if the bands could be resolved better, the predictions indicate a positive-negative-negative-positive substructure in this region. Although the order of the predicted modes here cannot be verified from the available experimental data, the predictions indicate net positive VROA in agreement with the experimental observation. The experimental band at 1398 cm^{-1}, associated with a methyl bending motion coupled to CH_3 bending, has weak negative VROA. This is also the sign predicted for this mode. The predicted VROA intensities differ somewhat from the observed values for the bands discussed above. The two umbrella type bending modes of the CH_3 groups are associated with the unresolved experimental band at 1380 cm^{-1}. These two modes are predicted to have opposite VROA signs cancelling each other due to their overlap and giving a net negative VROA. This is also the sign seen in the experimental spectrum for the 1380 cm^{-1} band. The 1297 cm^{-1} band in the experimental spectrum has weak negative VROA which is supported by the theoretical predictions for the corresponding theoretical mode at 1301 cm^{-1} associated with a —C*—H bending motion.

The C*—C* stretching motion is associated with the experimental band at 1198 cm^{-1}. The VROA associated with this band is weak and positive. Although the same sign is predicted for the corresponding theoretical mode at 1163 cm^{-1}, the predicted intensity is somewhat higher. The neighboring experimental Raman band at 1170 cm^{-1} has weak negative VROA which again is in agreement with the theoretical predictions for the corresponding mode at 1148 cm^{-1}. The predicted and observed VROA signs do not agree for the two experimental bands at 1089 and 1052 cm^{-1} which are associated with —C*—H bending motions. However, since the intensities associated with these two bands are small the predictions can probably be improved here if higher levels of theory are utilized. The experimental Raman band at 1068 cm^{-1} is associated with the C*—C stretch coupled to CH_3 rocking motion and is seen to have significant VROA. This observation is faithfully reproduced in the predicted spectrum where the corresponding theoretical mode is situated at 1049 cm^{-1}. The C*—C stretching coupled to CH_3 rocking motion mode and a —C*—H bending mode are predicted to be responsible for the 991 cm^{-1} experimental Raman band. While this experimental Raman band has negative VROA of substantial intensity, correspondingly large negative VROA is not found for the theoretical modes. Out of the two theoretical modes associated with the 991 cm^{-1} experimental Raman band, the one at 981 cm^{-1} is strongly polarized and has very weak Raman intensity while the other at 972 cm^{-1} is depolarized and has somewhat higher Raman intensity. Therefore the observed VROA at 991 cm^{-1} is most likely due to the calculated mode at 972 cm^{-1} which has negative but weak VROA. Therefore the predicted and observed VROA signs also match here but the intensities differ substantially. The positive VROA at 953 cm^{-1} and the negative VROA at 837 cm^{-1} in the experimental spectrum match very nicely with those of the corresponding theoretical modes at 949 and 801 cm^{-1}, respectively, in both signs and intensities.

The unresolved Raman band at 600 cm^{-1} is associated with the symmetric and antisymmetric C*—S stretching modes. The VROA spectrum however clearly shows bisignate bands here indicating the importance of VROA spectroscopy in yielding additional information. The antisymmetric stretch is associated with the negative part and the symmetric stretch is associated with the positive part of this bisignate couplet. The negative band is slightly more intense than the positive and both are much stronger than any other band in the 200–1500 cm^{-1} region of the VROA spectrum. The theoretical predictions here match with the experimental observations quite satisfactorily, and this agreement is by far the most reliable test for verifying the theoretical model employed.

In the region below 500 cm^{-1}, the experimental spectrum has six Raman bands, but only the band assigned to the symmetric methyl torsion mode has significant VROA. The sign and magnitude for this VROA band are seen to match with those in the predicted spectrum. As discussed elsewhere,[18] methyl torsion VROA is particularly useful for stereochemical deductions. The predicted VROA spectrum also shows strong negative VROA for the two modes at 213 and 226 cm^{-1}, but the experimental spectrum does not have the corresponding feature. This appears to be the only strong disagreement between the predictions and experimental observations.

CONCLUSIONS

The experimental VROA spectrum for (+)-*trans*-2,3-dimethylthiirane is seen to compare remarkably well with that predicted for 2*R*,3*R* configuration, but some differences between the observed and predicted intensities are noticed. As in our earlier studies of alanine[8,9] and tartaric acid,[10] the best agreement between calculations and experiment is found in skeletal vibrations in the range ~ 500–$1000\ cm^{-1}$ which are dominated by stretch coordinates and which reflect the stereochemistry most directly. For the purpose of predicting the absolute configurations, however, it is essential that the signs for corresponding experimental and calculated VROA bands be the same, but differences in relative intensities for corresponding bands are less important. Since observed VROA signs indeed match with the predicted ones for a majority of the bands, this agreement then establishes the reliability for utilizing VROA as a valuable new technique for stereochemical studies.

(*Received* 18 *May* 1992. *Revised* 21 *July* 1992. *Accepted* 21 *July* 1992)

Summary—Three large fragments (A, B and C) of human serum albumin (HSA) were produced by cyanogen bromide digestion of HSA in order to investigate the specific binding sites. The fragments were isolated by use of gel filtration, followed by high performance ion exchange chromatography. The isolated fragments were examined by use of UV/Vis, steady-state fluorescence, and circular dichroism spectroscopy. The study was extended to examine the interactions of bilirubin and two anionic drugs, warfarin and naproxen, with HSA and the three fragments. The primary bilirubin binding site on HSA molecule appeared to be located between fragment A and fragment C. The results also suggest the binding sites of the two anionic drugs to most likely be located in fragment C of HSA molecule.

Human serum albumin (HSA) is the most abundant plasma protein in the body. A large number of low molecular weight compounds, including several drugs, bind reversibly to HSA, which functions as the major transport protein in the body. In certain instances, the albumin binding of a drug is a significant factor for the pharmacokinetics, and the displacement of one drug by another from the albumin binding sites can contribute to the phenomenon of synergistic drug interaction. Knowledge of the HSA binding sites is important for rational understanding of albumin binding and for any approach to systematize such interactions. Furthermore, detailed knowledge about the specific location of the ligand-binding sites of HSA will improve the understanding of general mechanisms of ligand-protein interactions since the number of binding sites of the HSA molecule is rather small. For example, HSA is the dominant transport protein for acidic drugs, and it is believed that there are two main binding sites for acidic drugs.[1,2] It is well established that aromatic-acidic drugs that bind to site I are mostly bulky heterocyclic molecules with a negative charge at the center of a large nonpolar molecule. In contrast, drugs that bind to site II have an extended configuration, and the negative charge is located at one end of the molecule, away from the nonpolar region. One possible approach to locate binding sites on HSA is to cleave the HSA into several fragments and study the ligand binding to various fragments of HSA. Thus, the necessary information about the microenvironment of the binding sites on HSA may be obtained. There are two main protein fragmentation methods: (1) enzymic cleavage and (2) chemical cleavage. One of the most widely used methods is chemical cleavage, which cleaves proteins at the methionine residues using cyanogen bromide. In this method, relatively large fragments, high selectivity, and high cleavage yield are obtained.[3] Several studies of protein structure and drug-binding sites have been performed by use of this fragmentation method.[4–9] Sjöholm and Liungstedt[8] used the low ultraviolet region of circular dichroism spectral data of HSA CNBr fragments to calculate the quantitative contribution of the α helical and β structure in the fragments. They found that large parts of the ordered structures in HSA are preserved in the fragments. Thus this cleavage method should be a meaningful tool for studying the protein conformation and ligand binding sites.

†Author for correspondence.

Bilirubin is one of the most important compounds in the human body that binds to HSA. A high concentration of free bilirubin normally causes jaundice for newborn babies, and this risk decreases when the molecule is bound to HSA. Several studies investigating the binding properties of bilirubin with HSA[10-16] have been reported. The binding site is reported to be specific, and there is some evidence about the location of the bilirubin binding site on the HSA molecule. However, there is no conclusive information in this regard.[16]

Although its amino acid sequence has already been elucidated, and the crystallographic data[17,18] revealing some information about the three dimensional structure of HSA, the binding mode of HSA to certain therapeutic drugs is still not well-understood. Numerous experimental approaches have so far been unable to fully clarify the detailed tertiary structure of HSA and its influence on the binding properties of HSA. Although the detailed high resolution three dimensional structure of HSA is still not available, the crystallographic studies have provided us with more evidence of the physical properties of HSA.[17,18] However, if the detailed structure of certain crystalline forms of HSA is revealed, the real tertiary structure of HSA in solution may not be the same as observed in crystalline form. Therefore, without the exact knowledge of the tertiary structure of HSA both in crystalline form and in solution, the ligand-HSA binding modes can be explained in various ways. Many ligand-HSA binding models are based on the three-domain model proposed by Brown,[19] which has been recently confirmed by Carter.[17] Using crystallographic methods Carter[17] has demonstrated the binding of HSA to small molecules to be within the subdomains IA and IIA. However, this model does not provide sufficient evidence for the binding properties of bulkier ligands such as bilirubin.[20]

In this paper, we report the use of cyanogen bromide to cleave human serum albumin into three main fragments. These fragments were isolated by use of size exclusion and ion exchange chromatography. The three fragments were then examined using UV/Vis, fluorescence, and circular dichroism spectroscopic methods. Furthermore, bilirubin and two acidic drugs, warfarin and naproxen, were used as probe molecules to investigate the complexing ability of the isolated fragments. In particular, warfarin and naproxen were chosen because of their reported preference to bind specifically at site I and site II of HSA, respectively.[1,2] The ligand–protein interactions were monitored by use of fluorescence and circular dichroism spectroscopic techniques. The binding characteristics were compared with those of the intact albumin molecule with the aim of specifying the location of the various binding sites.

EXPERIMENTAL

Materials

Human serum albumin (crystallized and lyophilized), cyanogen bromide, formic acid (99%), propionic acid (99%), bilirubin, warfarin, and naproxen were all purchased from Sigma Chemical Co. (St Louis, MO). Sephadex G-25, G-100 media and mono S HR5/5, mono Q HR5/5 and Fast Flow Sephorose Q XK16/20 ion exchange columns, and a Gel Filtration LMW calibration kit were purchased from Pharmacia LKB Biotechnology Inc., (Piscataway, NJ).

Apparatus

The analytical scale ion-exchange separations were conducted on a high performance ion-exchange chromatography (HPIC) system. This system contains a Bio-Rad model 700 gradient module and workstation equipped with a 2-ml injection loop and a model 1706 UV/Vis detector. The preparative ion-exchange separations were performed on a chromatographic system containing two Beckman 114 pumps, a Beckman 141 gradient controller, a Dionex UVM fixed wavelength UV/Vis detector and an HP 7450 integrator. The absorbance measurements were obtained using a Shimadzu UV/Vis scanning spectrophotometer. Fluorescence studies were performed by use of a Spex model F2T21I spectrofluorometer equipped with a thermostated cell housing and a cooled photomultiplier tube. The circular dichroism (CD) spectra were obtained on a Jasco J-600 spectropolarimeter. All measurements were conducted at $20 \pm 0.1°$.

Methods

Cleavage reaction. The CNBr cleavage reaction was performed following the procedure reported by McMenamy *et al.*[5] Briefly, HSA was dissolved in 80% formic acid and reacted with an equivalent weight of CNBr in the dark at 0–4° for 24 hr. Fragments consisted of residues 298-584, 1-123 and 124-297 of the primary structure of HSA and were labelled as A, B and C, respectively.[5]

Isolation of the fragments. The digested solution was passed through a G-25 column (2 × 8 cm) in 1% propionic acid to remove the salts, and 50 mg (2 ml) of the protein was fractionated on a Sephadex G-100 column. Three fractions (I, II, and III) were collected [Fig. 1(a)] The molecular weight calibration was conducted by use of a gel filtration LMW calibration kit, which covered the molecular weight range of 13,700–67,000. The elution fraction I collected from G-100 column contained the aggregate and monomer of HSA. The elution fraction II containing fragment A was dialyzed against Tris-HCl buffer (20m*M*, pH = 7.5). Fragment A was further purified by using an anion exchange Mono Q column [Fig. 1(b)], and then the fragment was scaled up to preparative quantity by using the Fast flow Sephorose Q column. The elution fraction III was dialyzed against citric acid buffer (20m*M*, pH = 5.0), and fragments B and C were separated by injecting fraction III onto a mono S HR5/5 cation exchange column [Fig. 1(c)].

Characterization and ligand-binding of the fragments. All of the isolated fragments were dialyzed against phosphate buffer (20m*M*, pH = 7.5). As a comparative study, the ligands and the fragments were mixed on a 1:1 ratio by volume at pH 7.5. In addition, the original HSA ($1.54 \times 10^{-5}M$) was used in the complexing studies with the ligands. All ligand-fragment mixture solutions were buffered at pH 7.5 using the phosphate buffer. The concentrations of the ligands were 3.8×10^{-5}, 5.0×10^{-5}, and $2.7 \times 10^{-6}M$ for bilirubin, warfarin, and naproxen, respectively. The UV, circular dichroism, and fluorescence spectroscopic measurements were used to determine the

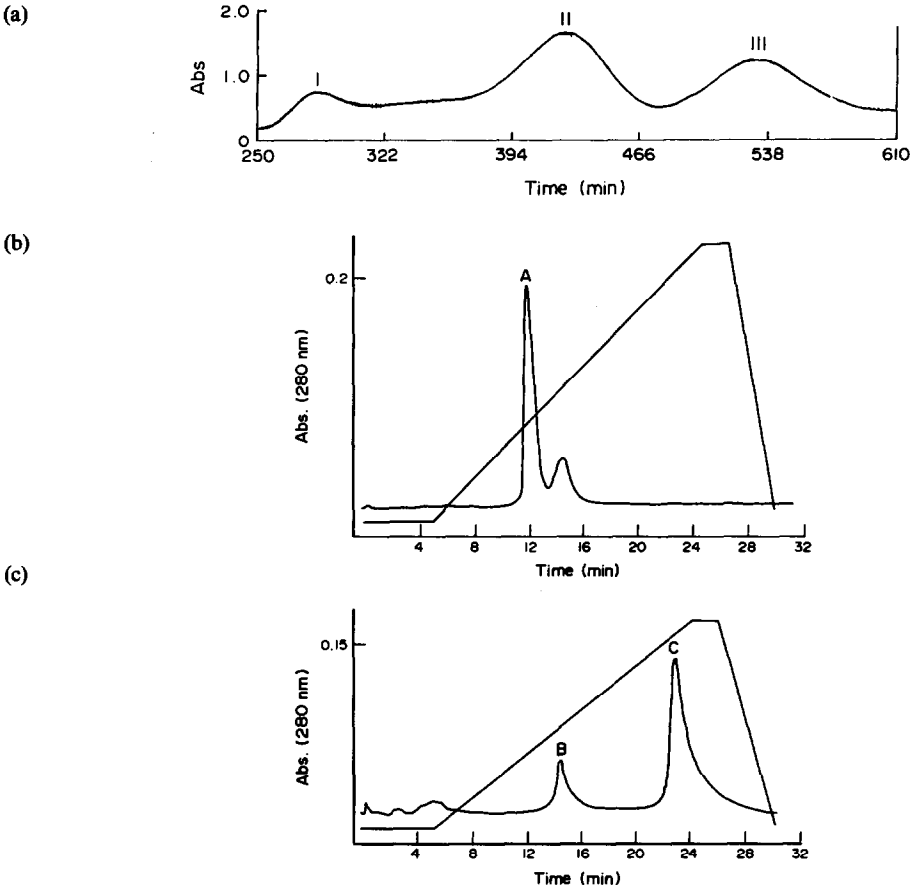

Fig. 1. (a) Elution of CNBr fragments of HSA (50 mg of HSA digest) from a Sephadex G-100 column (2.5 × 50 cm) with 5% propionic acid, 0.1*M* NaCl, flow rate 15 ml per hour. The components in the II and III fractions were further isolated by high performance ion chromatography (HPLC) [See Fig. 1.(b) and 1.(c)]. (b) Isolation of fraction II [from Fig. 1.(a)] on a Mono Q column (0.5 × 5 cm), 0–1.0*M* NaCl gradient in 20m*M* Tris-HCl, pH 7.5, flow rate 1.0 ml/min. (c). Isolation of fraction III (from Fig. 1.(a)) on a Mono S column (0.5 × 5 cm), 0–1.0*M* NaCl gradient in 20m*M* citric Acid, pH 5.0, flow rate 1.0 ml/min.

characteristics and ligands binding of the fragments. In fluorescence measurements, the emission spectra of the fragments are subtracted.

RESULTS AND DISCUSSIONS

Isolation of the fragments

Figure 1(a) shows the chromatogram of the fragments obtained from the size exclusion chromatography column (Sephadex G-100). The molecular weight calibration study suggests that the molecular weight of fragment A is approximately 37,000 and those of fragments B and C are approximately 18,000. McMenamy *et al.*[5] have reported observing the presence of impurities from the commercial HSA used in their study. In this study, the chromatogram of the commercial HSA does not show the presence of impurities compared with that obtained using fresh HSA. Hence, results in this study were conducted using HSA from Sigma. HPLC was used for further isolation of the fragments from the gel filtration column, in order to improve the resolution of the fragments and separation time. A better resolution and a shorter separation time was achieved when using HPLC, compared with a separation using a soft gel ion exchange column[5] [Fig. 1(a) and (b)]. As the separation time decreased, the fragments were concentrated after elution from the HPLC columns. For example, after injecting 8 ml of the fraction III sample on mono S column, the elution volume of fragments B and C were about 1 and 2 ml, respectively.

Spectroscopic properties of the fragments

The concentrations of the fragments were estimated from UV spectral data, and the values were 3.2×10^{-5}, 5.0×10^{-5}, and $3.6 \times 10^{-5} M$ for fragments A, B and C, respectively, using molar absorptivities reported by Gamblir and McMenamy.[7] As we expected, fluorescence is well suited for distinguishing these fragments. According to the amino acid sequence of HSA, fragment C contained the only tryptophan amino acid residue in HSA. Thus, the fluorescence spectrum showed predominately the spectrum of tryptophan. Fragment A contained some tyrosine amino acid residues, and thus, had a predominate tyrosine fluorescence spectrum. Fragment B contained fewer aromatic amino acid residues, and had almost no fluorescence. Circular dichroism (CD) studies were conducted to better understand the conformation of the fragments, especially, the secondary structure. Knowledge of the conformation of the fragments is important for predicting and better understanding the interactions between HSA and the fragments with the drugs in solution. The CD spectra of the fragments were similar in all respect to that of pure HSA molecule, regardless of the concentrations. This in turn suggests that the fragments still retained some secondary structure of the native HSA molecule.

Ligand-fragment binding study

Bilirubin-fragment interaction. Neither pure bilirubin nor HSA solution show a CD signal between 350–550 nm region. However, when HSA is added to a bilirubin solution, the HSA-bilirubin complex has a negative and a positive band at 410 and 460 nm, respectively. This suggests a strong HSA-bilirubin interaction giving rise to induced CD signals. To ascertain whether the specific binding center was limited to any of the CNBr fragments, the CD spectra of bilirubin-fragment complexes were measured in the same region as that of the bilirubin-HSA complex (Fig. 2). The interaction of the fragments with bilirubin seemed to be significantly different from that of the bilirubin–HSA complex. Upon addition of fragment A to bilirubin, a small positive band and a large negative band at 460 and 495 nm were observed, respectively. In contrast, fragment C induced a positive band and a broad negative band at 415 and 460 nm, respectively. The interaction of bilirubin and fragment B induced only a very weak CD signal. These marked differences between the CD spectra of HSA and bilirubin and that of the fragments with bilirubin suggest that the integrity of the original binding site of HSA is not contained in any of the individual CNBr fragments.

The above data suggest that the interaction mechanism in the native HSA molecule, which is probably responsible for the spatial configuration of the binding sites, is lost in bilirubin-fragment interactions. In addition, the induced CD signal of bilirubin with the fragments indicates that the fragments are still active in the binding of bilirubin. The weak intensity of the induced CD signals suggests that the interaction of fragment B probably does not correspond to the high affinity binding site of HSA. This interaction may represent the secondary site of the HSA molecule, which binds bilirubin after saturation at the main binding site. This also suggests that the binding site of bilirubin involves a region of the tertiary structure on the

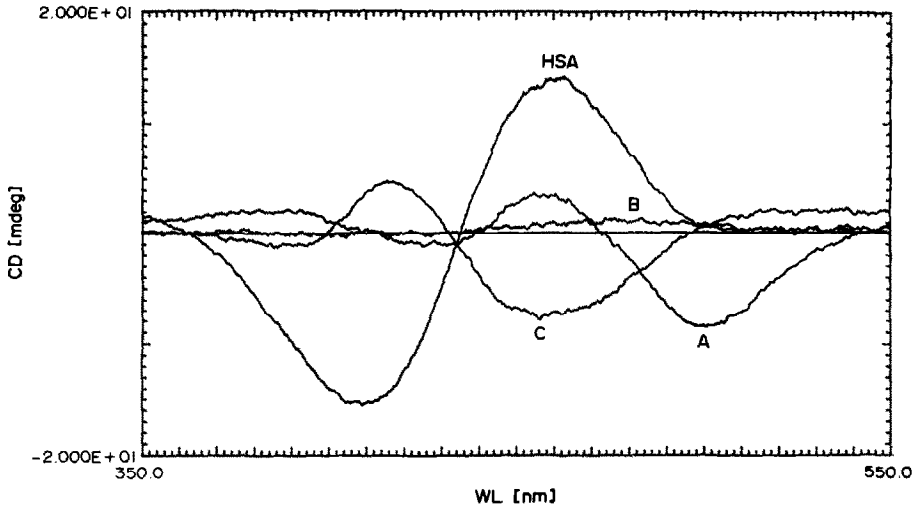

Fig. 2. Circular dichroism spectra of bilirubin with HSA and HSA fragments, respectively, in 20m*M* sodium phosphate, pH 7.5.

HSA molecule which is most likely located between the regions of fragments A and C. In contrast, the results reported by several other studies[12,13,15,16] concluded that bilirubin is most likely bound to the region of residues 180–250. This region is located only in fragment C of the CNBr digestion.

Fluorescence measurements were conducted in an attempt to obtain more evidence of the location of the binding site of bilirubin on HSA. Bilirubin is a weak fluorophore and upon addition of HSA, the fluorescence intensity increases dramatically. Figure 3 clearly shows the influence of fragments A and C on the fluorescence emission of bilirubin. Upon addition of fragment A or C to a solution containing bilirubin, the fluorescence emission of bilirubin is enhanced. Gitzelmann-Cumarasamy *et al.*[10] reported the presence of two HSA peptides labelled with a reactive bilirubin analogue (residues 124–297 and residues 446–547) located in fragments C and A, respectively. Geisow and Beaven[13] concluded that the labelling region of residues 446–547 by bilirubin could represent one of the weaker binding sites in the HSA molecule. In contrast, the results obtained in this study support the assumption that the high affinity binding site of bilirubin on HSA is located between fragments A and C. In summary, both the CD and fluorescence data suggest a strong association between bilirubin and HSA molecule. However, according to Brown's model,[19,20] the bulky bilirubin molecule cannot completely penetrate into the cavity of the helix cylinder of HSA. Therefore, our results could be explained in terms of partial insertion of the bilirubin molecule inside the cavity of HSA helix cylinder. In addition, because of the homologous structure of the domains II and III,[18] and the folding of protein in solution, it is most likely for bilirubin to interact with both domains II and III. This in turn will result in the

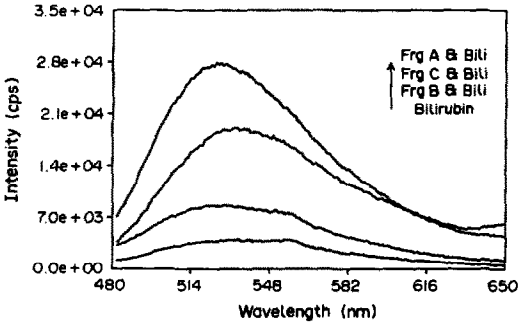

Fig. 3. Fluorescence spectra of bilirubin with HSA and HSA fragments, respectively, in 20m*M* sodium phosphate, pH 7.5, $\lambda_{ex} = 450$ nm.

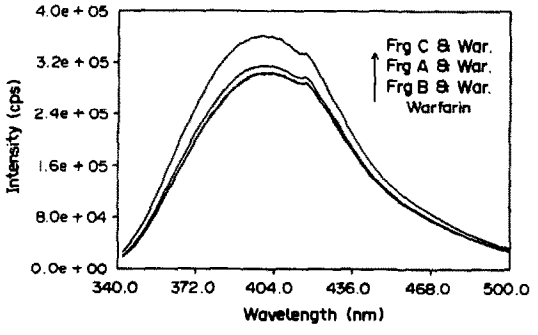

Fig. 4. Fluorescence spectra of warfarin with HSA fragments, respectively, in 20m*M* sodium phosphate, pH 7.5, $\lambda_{ex} = 320$ nm.

formation of an integral binding center, which changes its symmetry and flexibility, giving rise to a CD signal and enhanced fluorescence emission. In contrast, after fragmentation, domain II and III are separated into two different fragments, C and A, which binds bilirubin differently with the intact HSA molecule.

Anionic drug-fragment interaction

The HSA molecule has at least two different anionic binding sites.[1,2] For site I, warfarin is a typical binding drug. Chignell[21] has observed an increase in the fluorescence quantum yield of warfarin upon binding to HSA molecule. When we added fragment C to solutions containing warfarin, the intensity of the fluorescence emission spectrum of warfarin was enhanced (Fig. 4). In contrast, upon addition of fragment A or B in solutions containing warfarin, no significant changes of its fluorescence emission was observed. This also suggests that binding site I is located in fragment C of HSA.

Naproxen is reported to bind favorably to site II of the HSA molecule.[1] The addition of fragment C to a solution containing naproxen showed an increase in the fluorescence intensity of naproxen (Fig. 5); no significant change in the narpoxen spectrum was observed upon addition of either fragment A or B. This suggests that binding site II is also located in fragment C of HSA. The fluorescence signals of the fragments are weaker compared to that of the native HSA molecule.

CONCLUSION

There are several different binding sites on HSA for different types of drugs. To specify more closely the sites, we used the CNBr cleavage method to cleave HSA into three main fragments: A, B, and C. These fragments were isolated employing size exclusion and ion exchange chromatography and then examined by use of UV, fluorescence, and circular dichroism. The fragments were easily distinguished by using fluorescence measurements. Our CD data showed the fragments still retained some secondary structure of HSA. Finally, we investigated the interaction of bilirubin and two anionic drugs (warfarin and naproxen) with the fragments. The bilirubin data suggest that the binding site of bilirubin might be formed by a cooperative effect between the A and C fragments. The anionic-drugs suggest that both binding site I and II on HSA could be in the same fragment, *i.e.*, fragment C. The weaker interaction observed from our fragment-drug data also shows a drawback for using the fragment-drug interaction to locate binding sites in complex protein. From this study and others,[8,12,13] it could be inferred that the drug-binding mechanism in the native HSA molecule is probably a result of a combination of several types of forces, such as electrostatic, hydrogen bonding, and hydrophobic interactions. Most likely, the combination of these forces is destroyed during fragmentation; hence, only a weak fluorescence signal is observed for the fragments. Alternatively, the binding center is totally destroyed during the fragmentation process, and the fragments probably rearrange to form a new binding site that does not exist in the native HSA molecule. However, this binding site has a lower affinity than the native HSA, and hence, weaker interaction for the drugs is observed.

DYNAMIC COATING ION-INTERACTION CHROMATOGRAPHIC SEPARATION OF SOME TRACE IMPURITIES IN OXYGEN-FREE ELECTRONIC COPPER (OFEC) BY PRE-COLUMN CHELATION WITH 4-(2-THIAZOLYLAZO)RESORCINOL

RAJANANDA SARASWATI and T. H. RAO

Instrumental Analysis Division, Defence Metallurgical Research Laboratory, Kanchanbagh P.O., Hyderabad, 500 258, India

(*Received* 23 *March* 1992. *Revised* 16 *June* 1992. *Accepted* 16 *June* 1992)

Summary—Deleterious trace impurities like Mn, Fe, Co, Ni, Zn, Bi and Pb in oxygen-free electronic copper (OFEC) were separated and determined by dynamic coating ion-interaction chromatography (IIC) with spectrophotometric detection using pre-column reaction methods. 4-(2-Thiazolylazo)resorcinol (TAR) was used as pre-column chelating agent. The requirements for sample preparation and the conditions for pre-column chelation reaction are discussed. The optimum conditions for the sensitive detection of these trace metal ions after ion-chromatographic separation are set. The pH of the chelating medium and the eluent, the concentration of TAR and the composition of the eluent were investigated. The detection limits achieved were 2.0, 2.8, 0.6, 0.8, 1.2, 2.6 and 3.0 ng for Mn, Fe, Co, Ni, Zn, Bi and Pb, respectively. The results obtained by IIC methods compare well with those of graphite furnace atomic-absorption spectrometry and the certified values of Mur Bundy Hamil (MBH Analytical Ltd, U.K.).

Studies on the influence of various impurities on the annealability and electrical conductivity of oxygen-free electronic copper have shown that the higher the impurities the higher will be the softening temperature and the lower will be the electrical conductivity.[1–5] For example, the presence of every 5 ppm of lead content in 0–25 ppm range reduces the electrical conductivity of copper by about 0.1% in the international annealed copper society standard (IACA). Similarly, every increment of 5 ppm antimony content in the 0–25 ppm range lowers the conductivity by 0.15% IACS. The presence of Fe in the order of 0.001% (at Cu purity 99.999%) will result in intergranular fracture due to microcracks and micropores and results in embrittlement of Cu at even low stress levels. Therefore, the accurate determination of trace impurities in Cu has become increasingly important. Several schemes for the systematic analysis have been described in the literature.[6] None of the schemes includes the determination of all trace impurities in a single sample, although several independent procedures have been proposed. With the advent of atomic-absorption spectrometry, many procedures for the determination of trace impurities in copper have appeared. However, the detection limits of AAS procedures are severely restricted by matrix effects. In this context, the ion-interaction chromatography (IIC) separation and detection technique seems to be one of the promising tools.

In recent years, this technique has become an attractive method for trace metal determinations.[7–10] The advances that have taken place in column and detection techniques[11–15] have explained the capability of IIC to characterize a wider range of anions and cations. Since individual metals and metal compounds form distinct ions with differing retention times, it is possible to analyze several of them in a single run. The separation and simultaneous determination of metal ions as their chelates with organic reagents by IIC has received much attention. A wide variety of organic reagents have been used to complex metal ions prior to separation.[10,16,17] 4-(2-Thiazolylazo)resorcinol (TAR) is one such reagent which has been used extensively for the spectrophotometric determination of numerous ions. TAR and its chelates with metal ions are insoluble in water. However, they are readily soluble in some solvents that are miscible with water and they can be extracted into solvents that are immiscible with water. Therefore, most metal chelates with TAR can be separated by IIC and can be detected spectrophotometrically.

Though several ion chromatographic methods are available for the separation of transition metals, no reports on the separation and detection of trace impurities in oxygen-free electronic copper as chelates with TAR using IIC have been reported.

In previous communications,[18–20] the separation of transition and rare earth metals present in low-alloy and stainless steel samples using PAR and Arsenazo-III as post-column chelating agents are discussed. Our current research efforts, as described here, are focused on the separation and determination of trace impurities in OFE copper (MBH CRM 17867B, 17868B, 17869B and 17870B) in a single sample by dynamic coating ion-interaction chromatography using TAR as a pre-column chelating agent.

EXPERIMENTAL

Apparatus

The Waters Ion Chromatography system consists of Model 501 pumps with a Waters U6K injector. A Spherisorb S-5 ODS I separation column was employed. A Waters 486 tunable absorbance UV-Vis spectrometric detector with a 12-μl flow cell was used to monitor the effluent from the column. A Waters maxima 820 chromatography workstation along with a printer was employed.

The labware was used after conditioning in an ultrasonic cleaner and equilibrating in reagent grade water (18 Ω resistance) from a Millipore Milli Q water system, having total metallic impurities less than 1 ppb.

Reagents and solutions

High-purity 'Suprapure' grade chemicals from Merck were used. Solvents were further purified using isothermal sub-boiling distillation in a laminar flow fume hood having class 100 condition with a total lab facility maintained at class 10,000 level to overcome dust and particulate contamination. Pure metals from Johnson Matthey (JMC) and Certified Reference Materials from Mur Bundy Hamil (MBH) were used for the preparation of standard solutions and eluents.

Standard solutions of ions were prepared by dissolving known amounts of pure metals and diluting to the required levels. Elution was performed with $1 \times 10^{-3}M$ sodium octane-1-sulphonate (54 mg in 250 ml)–$0.023M$ tartaric acid solution at a flow rate of 1 ml/min. Calibration graphs were obtained with the chosen parameters with injecting standards separately and in mixtures and recording the peak heights for the respective ions.

Sample preparation and matrix separation

A 10-g sample (which was previously washed with methanol and dried with an IR lamp) was dissolved in a requisite amount ($\sim$40 ml) of nitric acid (1 + 1), covering the beaker and heating below the boiling point. After the sample was dissolved, the solution was boiled to get rid of nitrogen oxides. The solution was cooled and then diluted to approximately 100 ml. The sample solution obtained contains a high concentration of copper matrix. This may have a detrimental effect on the chromatographic column and the separation of impurities. Therefore, separation of the copper matrix is a prerequisite for achieving reliable trace element determinations when IC procedures are used. This matrix separation was achieved by subjecting the sample solution to electrolysis at 0.6A using platinum gauze electrodes and a magnetic stirrer. The solution was covered and heated on an electrothermal plate to concentrate it by evaporation, and then the solution was made up to the mark of a 25-ml standard flask and diluted further if required. A 20-μl portion of the solution was used for injection after filtering this solution through a 0.45-μm filter.

Preparation of metal chelates

A 10.0-ml portion of $1.0M$ tartrate buffer (pH 6.0), 4.0 ml of TAR ($5 \times 10^{-3}M$) solution and 4.0 ml of methanol were mixed with a known volume of the above sample solution. The mixture was diluted up to 25.00 ml with water. In order to accelerate the colour development of the chelates such as Fe–TAR and Bi–TAR the solution had to be heated in a boiling water bath. A time study at different temperatures with a mixture of the metals show that 20–25 min at 60–75° is required for the colour development of all the chelates. Then the solution was cooled to room temperature before injection.

Separation of the chelates and reagent

The ODS column was equilibrated with sodium octanesulphonate ($1 \times 10^{-3}M$)–water (50:50 v/v containing $0.023M$ tartrate buffer, pH 6.0). A 20-μl aliquot of the prepared test solution was injected into the ODS column and the complexes were eluted at a flow rate of 1.0 ml/min. The detection wavelength was set at 580 nm.

*Values in [ ] are obtained by GFAAS; and values in ( ) are the MBH certified values.

Instrumental methods

A GBC Model 902 atomic absorption spectrophotometer was used, equipped with a GBC Model GF 2000 graphite furnace. A deuterium lamp was used for background correction. Visimax II hollow cathode lamps were used as light sources. Solutions were injected by a GBC PAL-2000 auto-sampling system. All absorbances were measured as peak heights and were recorded with an Epson Lx-800 printer. The system was operated by a Philips Model P-3105 data station connected on line.

A 1-g amount of sample was dissolved in 5 ml of dilute nitric acid (1 + 1), and the solution was made up to 100 ml with water, and further diluted as required, for atomic-absorption spectrometry.

RESULTS AND DISCUSSION

The results for four sample materials are presented in Table 1. For comparison, the values (wt%) obtained by graphite furnace atomic-absorption spectrometry (GFAAS), and the certified values from MBH are also given. The agreement between the results is excellent as are the relative standard deviations.

Several organic solvents, such as methanol, ethanol, acetonitrile, tetrahydrofuran, isopropyl-alcohol and sodium ocatanesulphonate combined with water, were investigated as binary and ternary mobile phases. A simple methanol–water, ethanol–water or acetonitrile–water binary system mobile phase gave tailing peaks and low sensitivities, and the unreacted reagent appeared as two peaks which overlap with the peaks of Ni^-, Cu^- and Fe–TAR chelates. However, the sodium octanesulphonate–tartaric acid system gave excellent peak shapes and high sensitivities for the separation of Mn, Fe, Co, Ni, Cu, Zn, Bi and Pb metal chelates with TAR which was found to be a good colour forming pre-column reagent. The effect of the concentration of sodium octanesulphonate in the mobile phase on the retention of the chelates is shown in Fig. 1. The chromatograms were recorded at 580 nm as all chelates showed significant adsorption at this wavelength. However, below this wavelength there was an indication of overlap of the peaks of the unreacted reagent and the Ni–TAR chelate peak.

As the pH of the mobile phase shows, the absorption spectra were recorded under mild acidic conditions and it was observed that the absorption of these metal–TAR red chelates was influenced by the hydrogen ion concentration. The absorption of these chelates was found to be maximum around pH 6.0. Below this pH there is marked decrease in the absorption which may be due to protonation equilibria as found in the case of the Cr–PAR chelates.[21]

Various buffers like tartrate, oxalate, citrate, KH_2PO_4–Na_2HPO_4, and Tris-(hydroxymethyl)-aminomethane (Tris) were used to determine

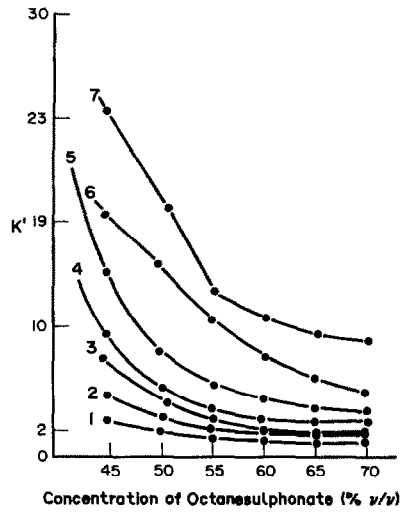

Fig. 1. Effect of sodium octane-1-sulphonate concentration on the retention times of the TAR chelates; buffer, tartrate ($2.308 \times 10^{-2}M$); pH 6.0; flow rate 1 ml/min; TAR ($2.5 \times 10^{-4}M$); column length, 300 × 3.9 mm ID (Spherisorb S-5 ODS-I); detection wavelength, 580 nm.

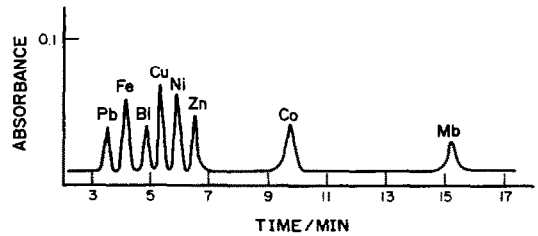

Fig. 2. Separation of some trace elements in OFE copper sample (CRM 17867B) by IC using TAR as pre-column chelating reagent. Octanesulphonate ($10^{-3}M$) with tartrate buffer ($2.308 \times 10^{-2}M$) mobile phase; pH 6.0; flow rate, 1 ml/min; TAR ($2.5 \times 10^{-4}M$); column length, 300 × 3.9 mm ID (Spherisorb S-5 ODS-I); detection wavelength, 580 nm.

the optimum pH range of the mobile phase. Tartrate was found to improve the peak shapes and produce higher peak heights for the TAR chelates of Fe, Co, Ni, Mn and Cu. Tris and KH_2PO_4–Na_2HPO_4 had no beneficial effect on the separation, and the retention of these metal–TAR chelates changed very little, but that of Fe^{-} and Co–TAR chelates increased markedly in the pH range 6.0–7.0. The effect of buffers like tartrate, oxalate, and citrate on the absorbance of these chelates is given in Table 2. As can be seen, the maximum absorption was obtained in the tartrate buffer. It was also found that the absorption of the metal–TAR chelates was influenced by the concentration of tartrate added. With the increase in tartrate concentration, the absorption increases progressively and then decreases. A possible explanation is, in a weakly acidic medium, the concentration of hydroxy groups would be low; hence the hydroxy groups coordinated to metal ions could be replaced by tartrate. As a result, coloured ternary (M–tartrate–TAR) complexes would be formed. Therefore, the absorbance increases as the tartrate concentration increases. However, at high concentrations of tartrate, the coordinated TAR would be replaced by tartrate which would lead to a decrease in the absorbance. The optimum concentration for the maximum absorption of M–TAR chelates was obtained when the concentration of tartrate was about $2.3 \times 10^{-2}M$ and the concentration of TAR was kept at $2.5 \times 10^{-4}M$.

Table 2. Absorption characteristics of the metal–TAR chelates in various buffers

Chelate	Tartrate	Oxalate	Acetate
	(molar absorptivity/10^4 l^3 mol^{-1}. cm^{-1})		
Pb–TAR	3.2	2.1	2.5
Fe–TAR	4.3	2.6	1.9
Bi–TAR	3.5	2.4	2.3
Cu–TAR	4.6	3.0	2.8
Ni–TAR	4.4	2.1	1.8
Zn–TAR	4.5	2.2	2.4
Mn–TAR	4.0	2.1	1.5
Co–TAR	4.2	2.9	2.0

Buffer concentration, $2.3 \times 10^{-2}M$; pH 6.0; flow rate 1 ml/min; TAR ($2.5 \times 10^{-4}M$); column length, 300 × 3.9 mm ID (Spherisorb S-5 ODS-I); detection wavelength, 580 nm.

The chromatograms obtained for some of the trace impurities are illustrated in Fig. 2. Based on the spectrophotometric studies described above, the complete separation of these elements requires about 15 min. Pb was separated at about 3 min 30 sec, followed by Fe (4 min 10 sec), Bi (4 min 50 sec), Cu (5 min 25 sec), Ni (5 min 50 sec), Zn (6 min 30 sec), Co (9 min 30 sec) and Mn (15 min 15 sec).

As the optimum performance of silica based bonded columns occurs in the pH range 3.5–7.0, the effect of variation of the pH of the eluent was carefully studied within this range. It was observed that the retention time increases with a decrease in pH. This may be because increased acidity decreases the ionization of tartrate, which in turn decreases the degree of metal complexation, thereby increasing retention times.[22] It was found that a pH of 6.0 gave the best separation and detection.

The peaks that appearing in the chromatograms were identified by spiking with authentic (*i.e.*, known) metal ion solutions. Quantitative measurements were done by plotting calibration

graphs for individual elements, taking peak heights at different concentrations and comparing with the result for samples. The absolute detection limits, calculated as the amount of injected metal ion that gave a signal that was three times the background noise (*i.e.*, signal-to-noise ratio of 3:1) were 2.0, 2.8, 0.6, 0.8, 1.2, 2.6 and 3.0 ng for Mn, Fe, Co, Ni, Zn, Bi and Pb, respectively.

The other trace elements that are normally present in OFE copper are Se, Te, Mg, Sb, As and Sn and are not detectable using TAR.

No significant change in peak width was observed during the separation of ions using the same sample solution volumes, indicating excellent column performance throughout the analysis.

CONCLUSION

By using TAR as a pre-column chelating agent, some of the trace impurities in OFE copper can be successfully separated and determined by ion-interaction chromatography. This method is fairly selective and sensitive and can be applied to other metallurgical samples for trace analysis at sub-ppm levels.

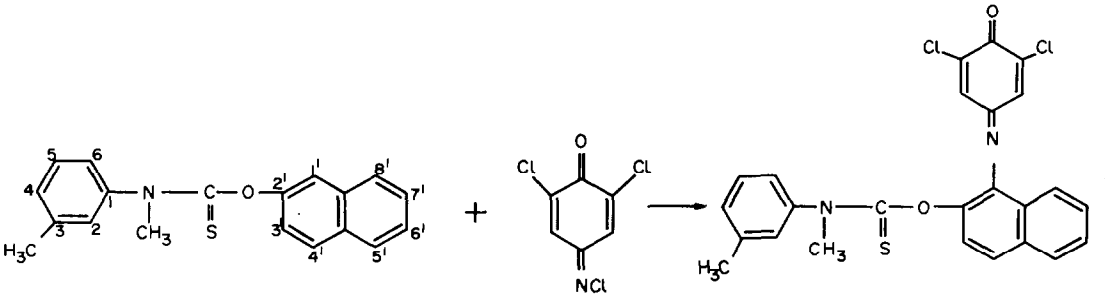
(*Received* 28 *October* 1991. *Revised* 12 *February* 1992. *Accepted* 22 *February* 1992)

Summary—Two simple and sensitive visible spectrophotometric methods (methods A and B) for the determination of tolnaftate in bulk samples and formulations are described. Method A (λ_{max} 490 nm) involves the reaction of tolnaftate with 2,6-dichloroquinone-4-chlorimide (DCQC: Gibb's reagent), while method B (λ_{max} 530 nm) is based on a similar reaction of the drug with *p*-*N*,*N*-dimethylphenylene diamine in the presence of chloramine-T. Both these methods are applicable to pure samples as well as formulations of the drug.



Scheme 1

Tolnaftate (TNF), (*o*-2-naphthyl *N*-methyl-*m*-tolyl thiocarbamate, Scheme 1) finds wide use in the form of topical solutions and creams in the treatment of cutaneous mycoses caused by a number of organisms belonging to the genera trichophyton, epidermophyton, microsporum and malassezia. It is ineffective against candida. The drug is less effective in the presence of hyperkeratotic leisons. It is often formulated in combination with other antibacterial and antifungal agents such as gentamycin and iodochlorohydroxyquinoline and steroid drugs such as betamethasone.

Tolnaftate is officially listed in B.P.[1] and U.S.P.[2] UV spectrophotometric determination at 258 nm is the basis of both the official methods. A survey of literature revealed that no visible spectrophotometric methods are reported so far for the estimation of tolnaftate. Two such methods (methods A and B) now developed are described in this paper. Method A utilises the oxidative coupling reaction of tolnaftate with 2,6-dichloroquinone-4-chlorimide (DCQC), the well known Gibb's reagent,[3] to produce a chromophore with λ_{max} at 490 nm. In method B, tolnaftate undergoes a similar coupling reaction with the *N*-chloroquinone diimine (NCQDI) [produced *in situ* by the action of chloramine-T (CAT) on *p*-*N*,*N*-dimethylphenylene diamine (DMPD)] to give a coloured product with λ_{max} at 530 nm. The two methods now proposed are applicable to bulk samples as well as formulations of TNF.

EXPERIMENTAL

Apparatus

A Systronics model 106 digital visible spectrophotometer with 1-cm matched glass cells was used for absorbance measurements in the visible region. A Milton Roy spectronic 1201 UV–Vis spectrophotometer was used for absorbance measurements in the UV region. An Elico model LI-120 digital pH meter was used for pH measurements.

*Author for correspondence.

Reagents

All aqueous solutions were prepared with doubly distilled water. All the chemicals and solvents used were of Analytical Reagent Grade.

Aqueous solutions of DMPD dihydrochloride (0.1% w/v) and CAT (0.1% w/v) and isopropanolic solution of DCQC (0.1% w/v) were prepared. They can be used for one week when stored at 5°. Buffer (pH 7.0) was prepared by mixing 612 ml of 0.067*M* disodium hydrogen phosphate solution with 388 ml of 0.067*M* potassium dihydrogen phosphate solution and adjusting the pH to 7.0.

Standard drug solutions. A stock solution of tolnaftate (500 μg/ml) was prepared in methanol. Working standard solutions (40 μg/ml for method A and 100 μg/ml for method B) were prepared by appropriate dilution of the stock solution with methanol.

Procedure for bulk samples. Method A. Aliquots of standard drug solution ranging from 0.5–4.0 ml (representing 20–160 μg of the drug) were pipetted out into a series of 10-ml standard tubes. The volume in each tube was adjusted to 4.0 ml by the addition of the appropriate amount of methanol to each tube. A 1-ml portion of DCQC reagent was added to each tube and the tubes were heated in a water bath at 80° until complete evaporation of the solvent in all the tubes (approximately 20 min). The tubes were then taken out, cooled and the residue in each tube was dissolved in isopropanol and the volume adjusted to the mark with the same solvent. The absorbances of the red coloured solutions were measured against a reagent blank after 5 min and before 50 min. The amount of the drug was calculated from its calibration graph.

Method B. Aliquots of standard tolnaftate solution ranging from 0.5–4.0 ml (representing 50–400 μg of the drug) were pipetted out into a series of 20-ml standard flasks. The volume in each flask was adjusted to 4.0 ml by the addition of an appropriate amount of methanol to each flask. A 9-ml portion of pH 7.0 buffer was added to each flask followed by 0.5 ml of DMPD solution and 1 ml of CAT solution. The volume was made up to the mark with distilled water. The contents of each flask were well mixed. The stoppered flasks were stored for one hour to allow full colour development. The absorbances were measured within the next 60 min at 530 nm against a reagent blank prepared simultaneously by omitting the drug solution. The amount of drug was calculated from the calibration graph.

Procedure for formulations. A quantity of cream or a volume of solution meant for topical use, equivalent to about 20 mg of TNF, was dissolved in about 50 ml of chloroform and transferred to a separating funnel. The chloroform solution was washed successively with 0.1*N* sodium hydroxide (2 × 25 ml), 0.1*N* hydrochloric acid (2 × 25 ml) and distilled water (1 × 25 ml). The chloroform solution in the separating funnel was then filtered into a 250-ml beaker through a chloroform washed cotton plug. The aqueous layer was extracted with chloroform (2 × 25 ml) and each chloroform extract was filtered into the same 250-ml beaker. The solvent in the beaker was evaporated and the residue dissolved in 40 ml of methanol and carefully transferred into a 100-ml standard flask. The beaker was washed with methanol (3 × 10 ml) and the washings were added to the standard flask. The volume in the flask was made up to 100 ml to obtain a solution of about 200 μg/ml of TNF. This stock sample solution was diluted stepwise with methanol to provide working sample solutions containing about 100 μg/ml (method B) and 40 μg/ml (method A) of TNF.

The sample solutions were then analysed by the procedures of the methods A and B.

RESULTS AND DISCUSSION

The absorption spectra of the reaction products in methods A and B show characteristic λ_{max} values (Figs 1 and 2). The reaction conditions were established by varying one parameter at a time and observing its effect on the absorbance of the coloured species.

In method A, addition of 1 ml of DCQC reagent and a heating time of 15–20 min at 80° was found to give maximum colour intensity. The suitability of organic solvent medium for colour development using methanol, acetone, isopropanol or dioxane as solvent was studied, as aqueous medium did not give a clear solution. A stable colour with maximum intensity was attained only with isopropanol and so it is preferred. The coloured species was found to be stable up to 45 min. In method B, constant absorbance values were noticed when the volume of DMPD solution added ranged from 0.25–0.75 ml and the volume of CAT solution from 0.5–1.5 ml. Volumes of 0.5 ml of DMPD

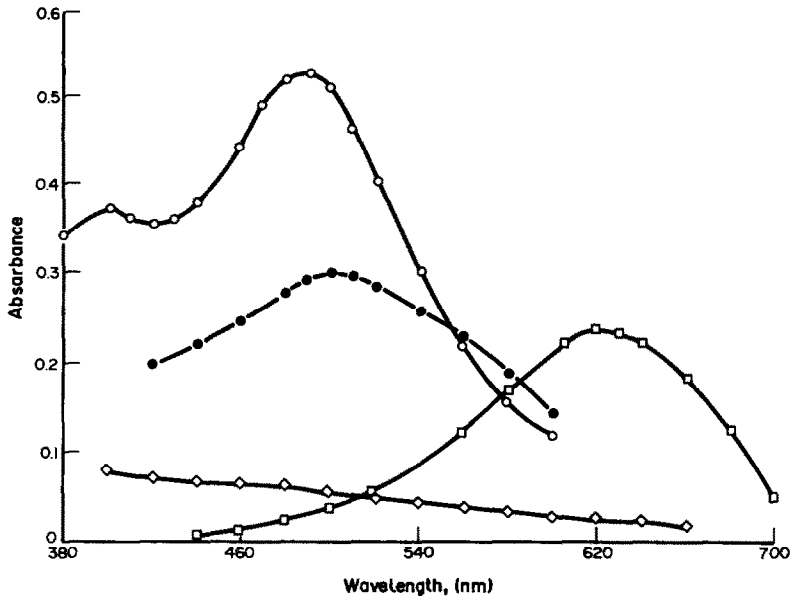


Fig. 1. Absorption Spectra of TNF (○——○); reagent blank *vs.* distilled water (◇——◇), β-naphthol (●——●) and *N*-methylaniline (□——□) with DCQC systems (concentrations of TNF $4.553 \times 10^{-5}M$; β-naphthol $3.468 \times 10^{-5}M$; *N*-methylaniline $4.665 \times 10^{-5}M$; DCQC $4.760 \times 10^{-4}M$).

and 1 ml of CAT were fixed as the optimum amounts to be added. Addition of 9 ml of buffer solution was found to be necessary to maintain the pH at 7.0 for maximum colour development. The colour intensity was found to increase up to one hour and then remained stable for a period of one hour.

The optical characteristics such as Beer's law limits (subject to an absorbance of at least 0.04 and a deviation of 2% from the linear portion in a plot of absorbance *vs.* concentration, μg/ml) molar absorptivity, Sandell's sensitivity (number of μg converted to the coloured product, which in a column

Absorption spectra of TNF (●——●); reagent blank *vs.* distilled water (◇——◇), β-naphthol (○——○) and *N*-methylaniline (□——□) with DMPD–CAT systems (concentrations of TNF $6.505 \times 10^{-5}M$; β-naphthol $6.936 \times 10^{-5}M$; CAT $2.195 \times 10^{-4}M$; pH 7.0; *N*-methylaniline $6.997 \times 10^{-5}M$; DMPD $1.170 \times 10^{-4}M$).

Table 1. Optical characteristics, precision and accuracy of the proposed methods for tolnaftate

Data	DCQC A	DMPD–CAT B
λ_{max} (*nm*)	490	530
Beer's law limits ($\mu g/ml$, x)	2.0–14.0	2.5–20.0
Molar absorptivity (l.mole^{-1}.cm^{-1})	1.155×10^4	5.72×10^3
Sandell's sensitivity ($\mu g/cm^2$/0.001 adsorbance unit)	0.026	0.053
Optimum photometric range (μg/ml)	3.0–7.0	8.0–20.0
Regression equation ($mx + b$)		
Slope (m)	3.75×10^{-2}	1.86×10^{-2}
Intercept (b)	-1.73×10^{-3}	-1.19×10^{-3}
Correlation coefficient (r)	0.9999	0.9999
% RSD*	0.74	0.62
% Range of error (confidence limits)		
0.05 level	0.78	0.65
0.01 level	1.23	1.02
% Error in bulk samples† (tolnaftate without additives usually present in formulations)	+0.51	−0.42

*Calculated from six determinations.

†Average of three determinations considered. Taken 1 mg each time and diluted suitably.

solution of cross section 1 cm^2 shows an absorbance of 0.001) and optimum photometric range (calculated as μg/ml from linear portion in a plot of percent transmission *vs.* logarithm of the concentration) are given in Table 1. The regression equation and the correlation coefficient obtained by linear least squares treatment of the results in each case are also recorded in Table 1. The precision of the two methods was tested by estimating six replicates of the drug within Beer's law limits (100 μg/10 ml for method A and 400 μg/20 ml for method B). The percent relative standard deviation and the percent range of error at 95% confidence level are given in Table 1.

Commercially available formulations (creams and topical solutions) of TNF were successfully analysed by the proposed methods. The values obtained by the proposed and reference methods are given in Table 2. Application of t- and F-tests to the results obtained by the proposed and reference methods revealed no significant differences between the calculated and theoretical values (95% confidence limit) thus establishing their close similarity in precision and accuracy. The results of the recovery experiments by the proposed methods are also listed in Table 2.

The following additives generally used in the formulations of creams and solutions were found not to interfere in the colour development of methods A and B when added in excess fold (compared to the drug) as mentioned in parentheses; stearic acid (70), cetyl alcohol

Table 2. Assay of tolnaftate in pharmaceutical formulations

*Average ± standard deviation of six determinations; the t- and F-values refer to comparison of the proposed methods with the reference method. Theoretical values at 95% confidence limit, $t = 2.57$, $F = 5.05$.

†After adding 10 mg to each pharmaceutical formulation, each value is an average of three determinations.

(10), glyceryl monostearate (50), sodium lauryl sulphate (10), propyl paraben (5) and glycerin (25). Betamethasone valerate, gentamycin and iodochlorohydroxyquinoline often included in some of the commercial formulations of TNF were found not to interfere in the two proposed methods.

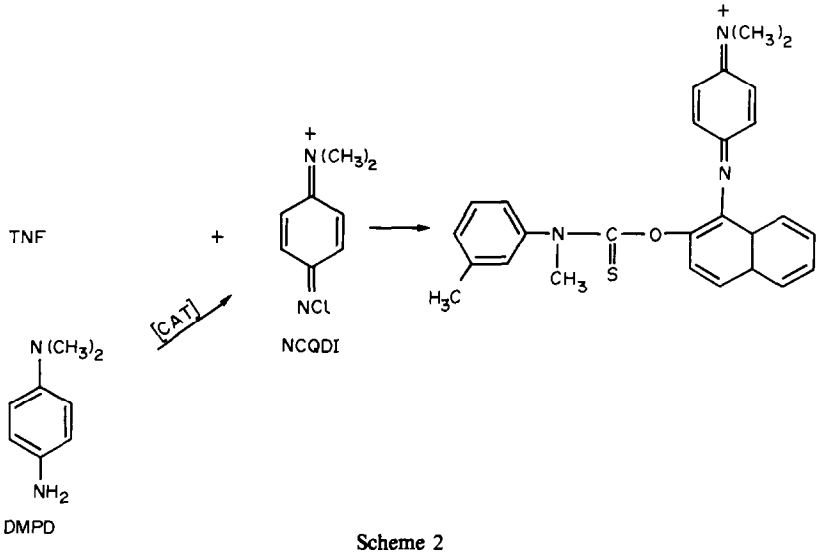
Thus the proposed procedures constitute at the first reported visible spectrophotometric methods for the determination of TNF in pure samples and formulations. Among the two proposed methods, method A is more sensitive than method B, while the λ_{max} is found to be higher for method B. The stability period of the coloured species was also found to be greater in method A.

Chemistry of the coloured species

The reactions of amines and phenols with *N*-halosubstituted quinoneimines to yield coloured coupling products are well known.[4,5] Since TNF possesses both substituted toluidine and substituted naphthol moieties, it can be expected to undergo similar coupling reactions to give the coloured coupling products as follows.

Method A. In tolnaftate there are two possible sites for the coupling reaction to take place, namely position 4 of the *N*-methyl-*m*-toluidine moiety (which is para to the substituted amino grouping) and position 1′ of the naphthyl moiety (which is ortho to the substituted hydroxyl grouping). It is rather difficult to predict which of the two possible products is being formed under the experimental conditions. It is, however, reasonable to assume that only one of the two possible products is being formed during the course of the reaction since the coloured species exhibits only one well defined maximum at 490 nm. In order to settle the point of attachment during coupling, Gibb's reagent was treated with β-naphthol and *N*-methyl aniline separately under the experimental conditions of the reaction. The product in the former case exhibited a λ_{max} at 500 nm (which is very close to the 490 nm shown by the TNF: Gibb's reagent product) while the latter had λ_{max} only at 620 nm. This strongly suggests the involvement of naphthyl moiety (through position 1′) of TNF in the formation of the coloured coupling product as shown in Scheme 1.

Method B. The reaction of TNF with DMPD requires the presence of an oxidant. Among the various oxidants (IO_4^-, $S_2O_8^-$, CAT, $Cr_2O_7^{-2}$) tried in conjunction with DMPD, only CAT is able to generate the coloured species. It is therefore reasonable to assume the initial *in situ* formation of *N*-chloroquinone diimine (NCQDI) by the reaction of DMPD with CAT (as already reported in the case of *p*-aminophenol and sodium hypochlorite in the estimation of dulcin[4]) and the subsequent coupling of NCQDI with TNF. The point of coupling of TNF and NCQDI was settled as in the case of method A by examining the reaction products of β-naphthol and *N*-methyl aniline with DMPD–CAT reagent. As in the case of method A, the spectral characteristics of the reaction product of β-naphthol are very similar to those of the coloured species of method B (530 nm), while *N*-methylaniline reaction product had a λ_{max} only at 630 nm. Thus the generation of the coloured species in method B may be depicted as shown in Scheme 2.



Scheme 2

The proposed methods are found to be simple, selective (when compared to the reported UV method) and sensitive and can be used for routine determination of tolnaftate in pure samples and formulations. The greater sensitivity and the stability observed in method A may be attributed to the presence of the electron withdrawing halogen atoms in the Gibb's reagent which enhance its oxidative coupling tendency. The procedure of method A is simpler in that it requires no oxidizing agent whereas the reaction mixture of method B contains NCQDI, unreacted DMPD and excess oxidant besides the other drug and non drug components of the formulation. None of the additives existing in solution (in methods A and B) and cream (in method A) formulations of tolnaftate interfere, even when the sample solution was prepared as under the bulk sample. However, some of the additives existing in creams separate out in method B (being aqueous medium) and so cause interference. It can be avoided by removal of such interfering components. The recommended procedure for formulations was designed keeping this in view. None of the components in the blank of cream (*i.e.*, without tolnaftate) produced colours with the proposed reagents.

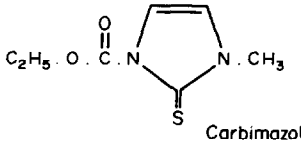
(*Received* 8 *August* 1991. *Revised* 29 *November* 1991. *Accepted* 20 *February* 1992)

Summary—Direct bromometric titration of carbimazole using *N*-bromosuccinimide (NBS) in the presence of methyl red as indicator and three indirect titrations using NBS, potassium bromate and dibromohydantoin (DBH) are developed. The direct procedure can be adopted for quantities of carbimazole ranging from 2–12 mg with mean accuracies of 100.2 ± 0.5. The indirect procedures can be used for quantities of the drug ranging from 1–6 mg using NBS and DBH and 2–16 mg using potassium bromate with mean accuracies of 100.11 ± 0.3, 100.49 ± 0.31 and 100.26 ± 0.51 respectively. The proposed procedures have been successfully applied for the analysis of the drug in tablet form and their validity has been checked using the standard addition technique. The reaction products were separated by TLC methods and their structure was elucidated using IR and NMR spectroscopy. The stoichiometry and the possible pathways of the reaction were postulated and presented.

Carbimazole, ethyl-3-methyl-2-thioxo-4-imidazoline-1-carboxate, Neo thyrostate, is an antithyroid drug used in the treatment of thyrotoxicosis or Graves' disease.[1] It produces its effect by blocking the biosynthesis of thyroxines T_3, T_4.[2]



Carbimazole

Several spectrophotometric methods were applied to the determination of the drug in pure and tablet forms.[3–5] A direct titrimetric method, using ceric sulphate as titrant and 5,7 diiodo-8-quinolinol as indicator was reported.[6] Various chromatographic procedures were used for the detection and determination of carbimazole and its metabolite.[7–9]

The present work describes simple, rapid, inexpensive and accurate procedures for the determination of carbimazole and its tablet form, moreover excipients and additives do not interfere. The method is based on the reaction of the drug with various brominating reagents using direct or indirect titrations. The indirect procedures depend on the addition of a known excess of the brominating reagent to the drug and determining the excess reagent iodometrically.

EXPERIMENTAL

Samples

Authentic sample of carbimazole, BP batch No. 97609, was kindly supplied by Nicholas Laboratories Ltd, London. It was dried and its purity was proved to be 100.7% according to BP 1988[3] (Table 1).

The pharmaceutical formulation "Neo-mercazole" consists of tablets; each tablet is claimed to contain 5 mg of carbimazole, batch No. 1089114, 389110 and 389111 manufactured by CID Co., Cairo, A.R.E.

Stock solutions of carbimazole are prepared to contain 0.2 mg/ml and 0.4 mg/ml of carbimazole in water.

Apparatus

^{1}H NMR spectra were recorded on EM-390 90 MHz varian NMR spectrometer.

Infra-red spectra were made on Pye-unicam IR sp 1100 spectrophotometer.

A 5-ml semimicroburette accurate to 0.02 ml was used.

Materials and reagents

Standard potassium bromate; 0.1N.

Standard NBS, 0.01M, standardized against 0.01N sodium thiosulphate.

Potassium iodide solution, 10% w/v.

Potassium iodobismuthate. Dilute solution, according to BP 1988.[3]

Silica gel G; PLC plates (20 × 20 cm, 2 mm thickness).

Procedures

Bromometric determination of carbimazole using N-*bromosuccinimide.* Direct procedure. Measure accurately an aliquot of the stock solution (0.4 mg/ml) equivalent to 2–12 mg of carbimazole into a 500-ml conical flask, complete to 30 ml with distilled water, add 20 ml of hydrochloric acid, 10 drops of methyl red indicator and mix well. Titrate with continuous stirring using 0.01*M* NBS solution till the red colour of the indicator disappears.

Calculate the amount of carbimazole from the equivalent factor each one millilitre of 0.01*M* NBS = 0.6207 mg of carbimazole. The results obtained are presented in Table 2.

Indirect procedure. Measure accurately an aliquot of the stock solution (0.2 mg/ml) equivalent to 1–6 mg of carbimazole into a 500-ml glass stoppered conical flask, complete to 30 ml with distilled water, then add 20 ml of hydrochloric acid and 25 ml of 0.01*M* NBS. Moisten the stopper with potassium iodide and allow to stand at room temperature for 1–5 min, then add 10 ml of 10% potassium iodide; and wash the stopper with 20 ml of water. Titrate with 0.01*N* sodium thiosulphate using starch as indicator. Simultaneously, carry out a blank experiment.

Calculate the concentration of carbimazole from the equivalent factor, one millilitre of 0.01*M* NBS = 0.6207 mg of carbimazole. The results are illustrated in Table 2.

Bromometric determination of carbimazole using bromate–bromide. Measure accurately an aliquot of the stock solution (0.4 mg/ml) equivalent to 2–16 mg of carbimazole into a 500-ml glass stoppered conical flask, complete to 40 ml with distilled water, add 10 ml of 0.1*N* potassium bromate, 5 ml of 10% potassium bromide and 20 ml of hydrochloric acid. Moisten the stopper with potassium iodide and allow to stand at room temperature for about 15–20 min. Add 20 ml of 10% potassium iodide, wash the stopper with 20 ml of water and titrate with 0.05*N* sodium thiosulphate using starch as indicator. Simultaneously, carry out a blank experiment.

Calculate the concentration of carbimazole from the equivalent factor, each one millilitre of 0.1*N* potassium bromate = 3.1033 mg of carbimazole. The results obtained are shown in Table 2.

Bromometric determination of carbimazole using dibromohydantoin. Measure accurately an aliquot of the stock solution (0.2 mg/ml) equivalent to 1–6 mg of carbimazole into a 500-ml glass stoppered conical flask, complete to 30 ml with distilled water. Add 20 ml of hydrochloric acid and 50 ml of DBH reagent. Moisten the stopper with potassium iodide and allow to stand at room temperature for 1–5 min. Add 10 ml of 10% potassium iodide and wash the stopper with 20 ml of water. Titrate with 0.01*N* sodium thiosulphate using starch as indicator. Simultaneously, carry out a blank experiment.

Each one millilitre of $2.5 \times 10^{-3}M$ DBH equivalent to 0.3103 mg of carbimazole. The results obtained are shown in Table 2.

Determination of carbimazole in tablet form. Weigh 20 tablets and calculate the average weight of a tablet. Take the calculated needed weight of the powdered tablets to prepare stock solutions containing 0.2 mg/ml of carbimazole.

Apply the prementioned procedures as given before.

The results obtained are shown in Table 1.

Table 2. Determination of authentic samples of carbimazole using NBS, bromate–bromide and DBH

RESULTS AND DISCUSSION

The direct titration of carbimazole with NBS was successful in hydrochloric acid medium using methyl red as indicator, in addition the indirect titration was suitable for any of the previously mentioned brominating reagents.

The different factors affecting the indirect titration of carbimazole, such as acidity of the medium and the duration of the reaction were studied.

It was found that 20 ml of 20% (v/v) hydrochloric acid in a total volume of about 55 ml in the bromate–bromide procedure, while 20 ml of 20% (v/v) hydrochloric acid in a total volume of about 55–80 ml in the NBS or DBH procedure were optimal. A big change in the concentration of the acid will lead to irreproducible results.

The reaction time between carbimazole and the reagents is critical. It was found that 15–20 min in contact with bromate–bromide mixture and 1–5 min in contact with NBS or DBH were optimal. Lower or higher results are obtained if the reaction proceeds for less or more than the specified period.

Adequate results were obtained with all procedures by allowing the reaction to proceed at room temperature; higher temperature would lead to lower results.

The volume of excess reagent to be added in the bromate–bromide and DBH procedures should be at least double that consumed in the reaction; low results would otherwise be obtained.

Under the experimental conditions used, the molar ratios relating carbimazole to bromate, NBS and DBH were found to be 1:1, 1:3 and 2:3 respectively. It was of interest to note that NBS reacts with carbimazole either indirectly or directly by the same ratio.

When the proposed methods were applied to the determination of authentic carbimazole, the results demonstrate good precision as shown from Table 2 where the average recoveries were 100.3 ± 0.5 for carbimazole adopting the bromate–bromide titration, 100.3 ± 0.5 and 100.1 ± 0.3 applying the direct and indirect titrations with NBS respectively and 100.5 ± 0.3 using DBH titration.

*Average of five different determinations.

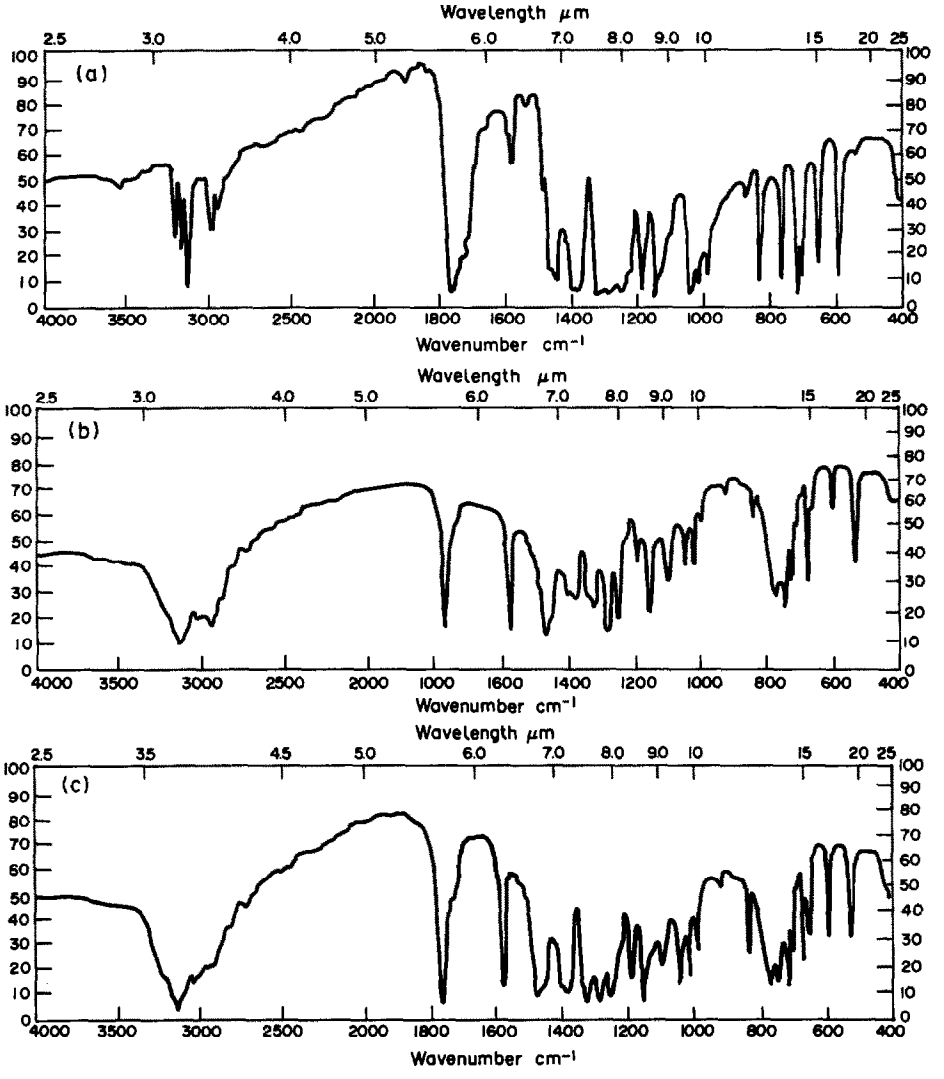

Fig. 1. IR spectra of (a) carbimazole, (b) major product and (c) minor product in KBr.

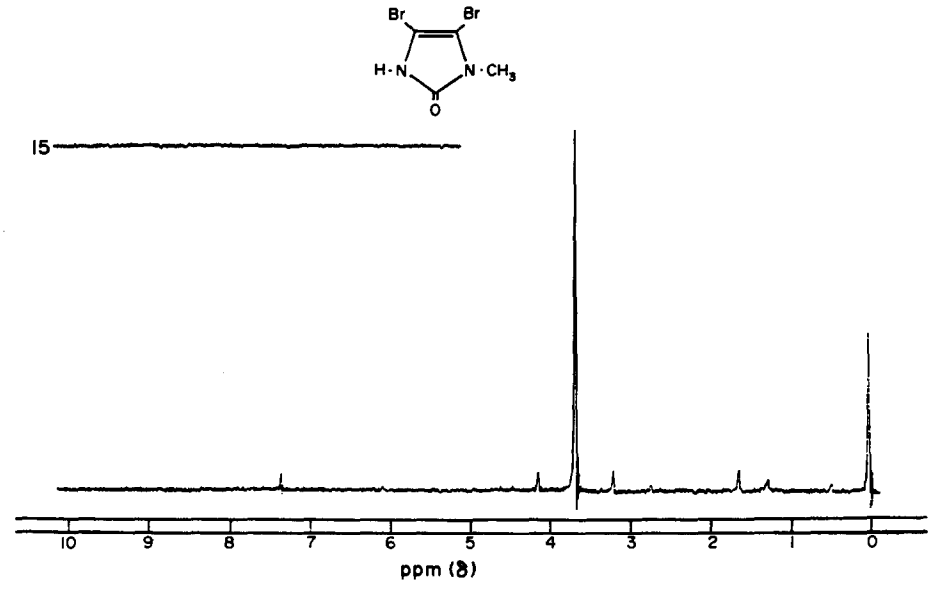

Fig. 2. ^{1}H-NMR of the major product, in $CDCl_3$.

Carbimazole (Neo-mercazole) tablets were analysed for carbimazole content by the proposed titrimetric procedures, before and after filtration from insoluble excipients and additives. It was found that the determination of a suspension of carbimazole powdered tablets gave more or less similar results to that obtained using filtered extracts of tablets. This means that excipients and additives used for their manufacture do not interfere with the proposed procedures. Nevertheless, filtration was preferred for all determination to ensure complete extraction and accuracy of the final volume, providing more clear detection of the end point, and this was adopted in Table 1.

The validity of the proposed procedures was assessed by applying the standard addition technique. The results obtained are presented in Table 3. Further comparative determination of carbimazole in its tablet form by the proposed titrimetric methods and the official BP 1988

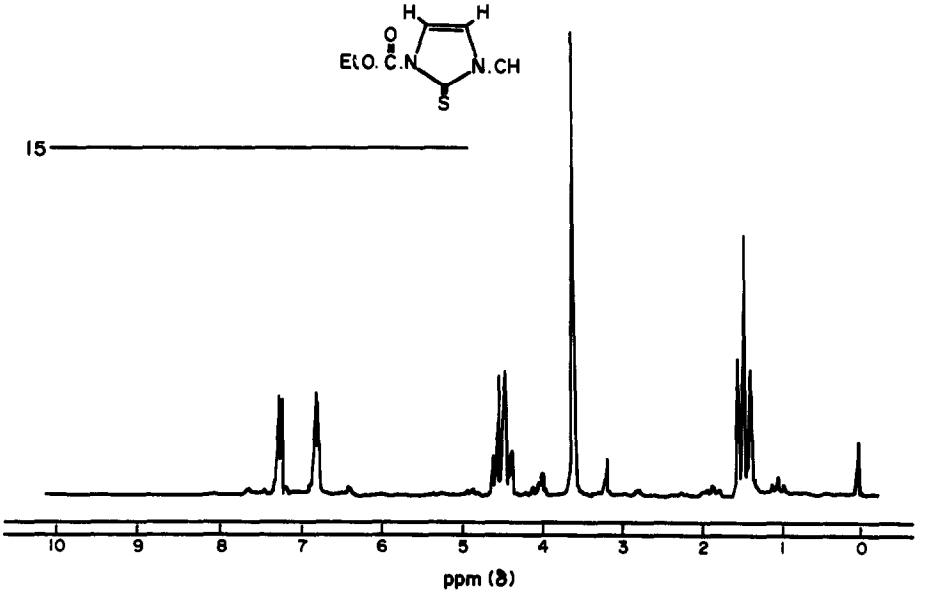

Fig. 3. Effect of reagent concentration.

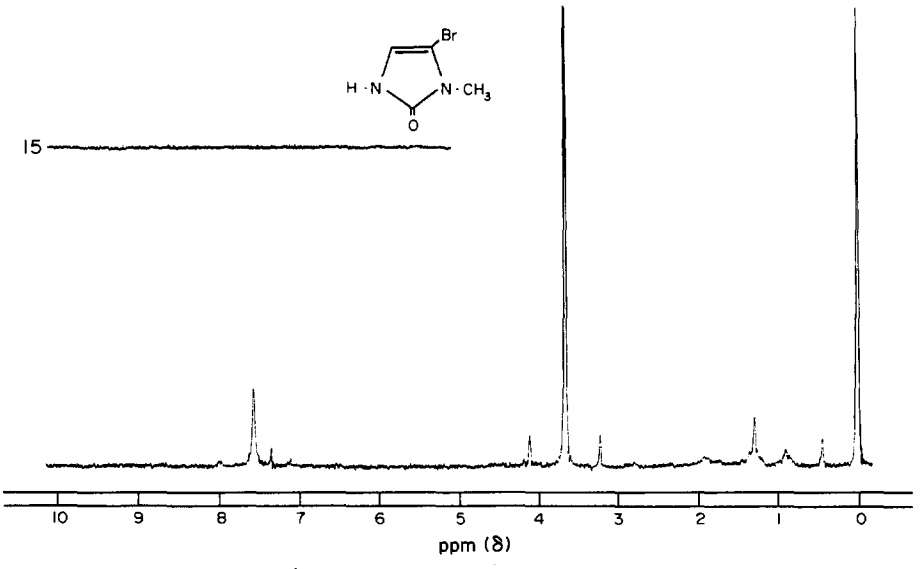

Fig. 4. ^{1}H-NMR of the minor product, in $CDCl_3$.

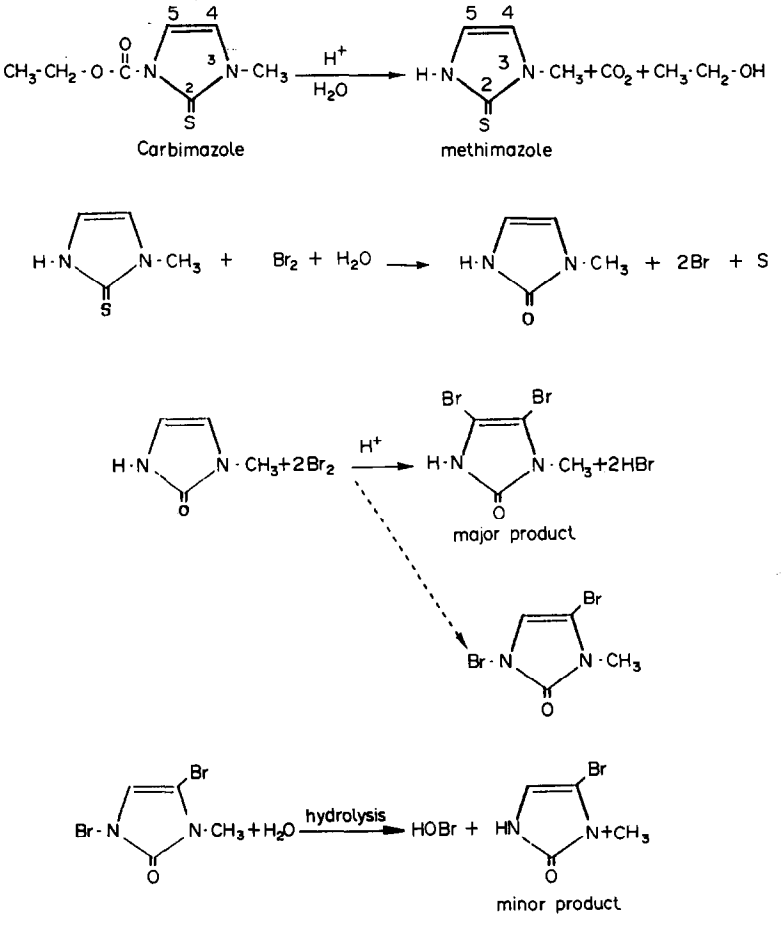
method has been done. The results obtained were illustrated in Table 2.

The studies of the reaction products, after applying the different bromometric procedures were carried out. The reaction products obtained from each bromometric procedure were compared on TLC plates with a spot of the authentic material. Different developing



systems were tried[7] and chloroform–acetone (4:1) was found to be the most suitable one. Various methods for visualization were studied[10,11] and the most suitable one being dilute solution of potassium iodobismuthate. It was found that all the procedures gave the same products.

Isolation of the reaction products

The bromate–bromide procedure was carried out as before using 80 mg of carbimazole and suitable needed amounts of the other reagents. The reaction between carbimazole and bromine was then stopped after 15 min using concentrated ammonia solution. The products were extracted with chloroform, evaporated, then separated on PLC plates using chloroform–acetone (4:1) as solvent system. The spots were visualized using dilute potassium iodobismuthate solution. The bands corresponding to the products were scratched and then extracted with chloroform. The products obtained after evaporation of the chloroformic extract were identified by IR, Fig. 1, and NMR, Figs 2–4.

Mechanism of the reaction

According to the molar ratios of the reaction and from IR and NMR data it may be suggested that the reaction proceeds (on p. 582).

^{1}H-NMR Fig. 2 of the major product in comparison with that of the parent compound, Fig. 3 showed no ethyl function and no aromatic protons, a fact which suggests that the starting material was subjected to hydrolysis followed by decarboxylation and bromination at positions 4 and 5 to give 4,5 dibromo-3-methyl-2-oxo-4-imidazoline.

^{1}H-NMR of the minor product (4-bromo-3-methyl-2-oxo-4-imidazoline), Fig. 4 showed a singlet at 7.6 p.p.m. corresponding to (^{1}H, 5-H).

Considering the absence of ethyl function from ^{1}H-NMR and the presence of a carbonyl absorption band in IR at 1760 cm^{-1}, Fig. 1, we might suggest that desulpherization of the starting compound occurs during the course of the reaction. In addition, IR spectrum showed an absorption band at 3120 cm^{-1} which could be an —NH or —OH. Furthermore, detection of sulphur in the products by Lasaigne sodium test,[12] proved to be absent.

SPECTROPHOTOMETRIC DETERMINATION OF KETOPROFEN IN PHARMACEUTICAL PREPARATIONS BY MEANS OF CHARGE TRANSFER COMPLEX FORMATION

M. EL-SADEK, S. EL-ADL, M. ABOU-KULL and S. M. SAKR
Pharmaceutical Chemistry Department, Faculty of Pharmacy, Zagazig University, Zagazig-Egypt

(*Received* 27 *May* 1991. *Revised* 27 *September* 1991. *Accepted* 30 *September* 1991)

Summary—A spectrophotometric determination of ketoprofen based upon oxime formation followed by charge transfer complexation with *o*-chloranil has been developed. Different variables affecting the complexation process have been studied. Beer's law is obeyed in the concentration range 10–80 μg/ml. The method has been successfully applied to the determination of ketoprofen in pure form and in pharmaceutical dosage forms in the presence of its impurities.

Ketoprofen is an anti-inflammatory anti-rheumatic agent widely used in pharmaceutical practice. Many methods were reported for its determination including titrimetry,[1] spectrophotometry,[2,3] polarography[4] and chromatography.[5–7] Most of the aforementioned methods are not sufficiently selective for the determination of ketoprofen in pharmaceutical preparations in the presence of its degradation products and impurities during the manufacturing process. In order to obtain the necessary sensitivity and selectivity, the proposed method is developed based on the reaction of hydroxylamine with the ketonic group of ketoprofen to form ketoprofen oxime. Upon reaction with *o*-chloranil, a charge transfer complex is formed. Although the proposed method is more complicated than the existing procedures, it distinguishes itself by the required characters and therefore, promises to be a valuable achievement in practical application.

EXPERIMENTAL

Apparatus

A Schimadzu UV–Vis self-recording spectrophotometer with 1-cm quartz cuvettes was used.

Materials and reagents

Ketoprofen; profenid capsules: labelled to contain 50 mg of ketoprofen per capsule; profenid vials: labelled to contain 100 mg of ketoprofen per vial (Rhone Poulenc, France); *o*-chloranil; hydroxylamine hydrochloride; sodium acetate; chloroform; pure ketoprofen oxime solution (100 mg g/50 ml in chloroform) and *o*-chloranil solution ($10^{-4}M$ in chloroform).

Procedures

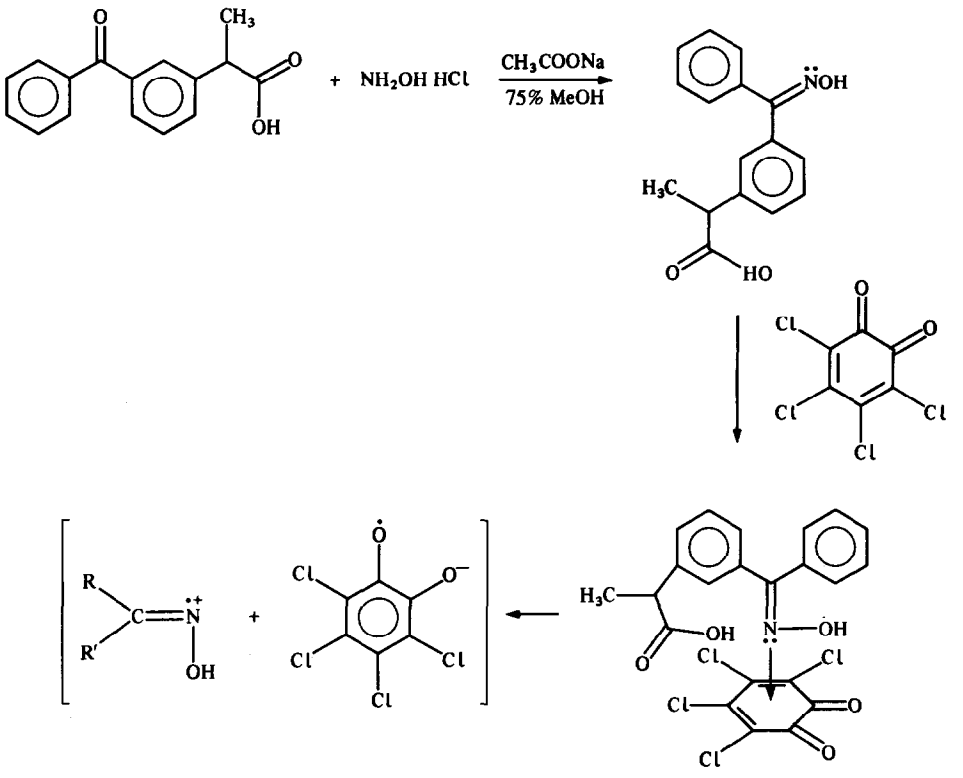
Oximation procedure. To a 50-mg ketoprofen sample, 10 ml of hydroxylamine hydrochloride and 25 mg of sodium acetate was added and the mixture was dissolved in 30 ml of methanol (75%). The mixture was refluxed for 30 min, cooled and extracted with three successive 10-ml portions of chloroform; the chloroformic extract was collected in a 50-ml standard flask and diluted to volume.

Complexation with o-*chloranil.* A suitable aliquot of ketoprofen oxime equivalent to 0.1–0.8 mg was transfered into a 10-ml standard flask, 5 ml of *o*-chloranil was added and the mixture was allowed to stand for 5 min and then diluted to volume with chloroform. The absorbance was measured at 530 nm against a blank prepared in the same way but in the absence of ketoprofen.

Pharmaceutical dosage forms. The contents of 20 capsules or 6 vials were throughly mixed and a quantity equivalent to 50 mg of ketoprofen was added. The procedure was completed as mentioned for the above procedures.

RESULTS AND DISCUSSION

Due to the presence of the ketonic functional group in ketoprofen, it interacts with hydroxylamine hydrochloride to form ketoprofen oxime.



Scheme 1

The formed ketoprofen oxime has an iminic group with a lone pair of electrons on the nitrogen atom, thus it acts as an electron donor (n-donor). On the other hand, *o*-chloranil (3,4,5,6-tetrachloro-*o*-benzoquinone) is highly reactive as an electron acceptor (π acceptor), so it forms an n-π charge transfer complex with ketoprofen. The outer intermediate complex is formed immediately within 60 sec after mixing donor and acceptor. This intermediate is stable in the dark under a nitrogen atmosphere and in a non-polar solvent. It changes to the inner complex in light and in the presence of a relatively polar solvent (chloroform). From elemental and spectroscopic analyses the pathway is proposed in Scheme 1.

Upon studying the absorption curves for ketoprofen, ketoprofen oxime, *o*-chloranil and the ketoprofen oxime–*o*-chloranil complex, different maxima were exhibited at 260, 325, 240 and 530 nm in chloroform respectively; another indication of charge transfer complex formation.

Variable parameters affecting the complexation process were studied. The effect of reflux

*Average of 3 experiments.

time on the oximation processs was examined and it was found that reflux for 30 min afforded complete oximation when using the TLC technique. Also, 5 ml of $10^{-4}M$ *o*-chloranil achieves maximum colour intensity which is stable for up to 40 min. The molar ratio of ketoprofen oxime and *o*-chloranil by the continuous variation method[8] was found to be 1:1.

Beer's law is obeyed in the range 10–80 μg/ml, with the least square method. The absorption graphs were described by the following regression equation:

$$A_{530nm} = 0.002 + 1.233X$$

where X is the concentration in μg/ml in the final solution.

The proposed method was successfully applied to the determination of pure ketoprofen, the results obtained were compared with the official titrimetric method[1] (Table 1). Statistical analysis of the results revealed that there is no significant difference between them.

The effect of degradation products and impurities which may be present: 2-(4-aminophenyl)propionic acid, 2-(4-mercaptophenyl)-propionic acid, 2-iodobenzoic acid and 2-(3-carboxyphenyl)propionitril was experimentally studied and results obtained showed no interference, indicating selectivity of the method.

Pharmaceutical preparations containing ketoprofen were analysed by the proposed method and the results were compared with UV spectrophotometric method[9] (Tables 2 and 3). Statistical analysis of the results showed both methods are equally precise and accurate.

The above study shows that the proposed method is more sensitive than the official B.P. 1980 method. It is sensitive down to 10 μg/ml compared with 200 μg/ml for the official method. Also, the proposed method is a selective one depending upon the presence of an intact molecule and not the hydrolytic products, so it can be used as a stability-indicating assay for ketoprofen in the presence of its impurities for different pharmaceutical dosage forms.

BOOK REVIEWS

Element Specific Chromatographic Detection by Atomic Emission Spectroscopy: P. C. UDEN (editor), American Chemical Society, Washington, D.C., 1992. Pages x + 350. U.S. $74.95. ISBN 0-8412-2174-X.

Increasing demand on trace analysis of complicated samples have fuelled the developments of 'hyphenated' systems. One basic requirement of a 'hyphenated' system is the successful interfacing of component techniques within the system. The same applies to 'chromatograph–atomic emission spectroscopy' systems in which the most common problems lie in ensuring the efficient transfer of the separated analyte to the AES detector and in maintaining a good detector response in a chromatographic environment (e.g., with respect to mobile phase and eluted forms of the analyte).

This book is developed from the 1990 ACS symposium at Boston. It consists of 19 chapters covering mainly gas chromatography–atomic emission spectroscopy (11 chapters), high performance liquid chromatography–atomic emission spectroscopy (3 chapters), supercritical fluid chromatography–atomic emission spectroscopy (2 chapters) and gas chromatography/high performance ligand chromatography–mass spectrometry (3 chapters). Some are review chapters but most chapters are specific discussions of particular aspects, illustrated with studies from the authors' own laboratories. These include discussions on the modes of excitation (mainly on microwave-induced plasma but a few on inductively-coupled plasma and one chapter each on direct current plasma and alternative current plasma) and on detector optics (including a chapter on photo-diode array detection and another on fibre-optic sensor specific to chlorine).

The book is a timely publication of the state-of-the-art of element-specific detection for chromatographic systems. The book is contributed to by researchers, many of whom are experts in the field of chromatographic science, from a variety of backgrounds (academic, industrial and instrument manufacturers) and countries (*e.g.*, US, Germany, Japan). Although some subject areas (*e.g.*, microwave-induced plasma excitation) are common, the emphasis in the papers is sufficiently varied to make the book a comprehensive account of diversed aspects (*e.g.*, technical, fundamental and applied) of a 'hyphenated' technique. Examples are chapter 6 which is more technical on solving optic problems, chapter 9 (technical) on the instrumentation of capacitively coupled plasma, chapter 2 (fundamental) on the development of LC/SFC–AES for non-metals and chapter 15 (applied) on analysis of Se in food and water sample. The diversity is enhanced by the inclusion of discussions on less commonly used techniques such as chapter 8 on a 'doubly-hyphenated' system (GC–AES–MS), chapter 11 on surface-wave plasma and chapter 12 on He discharge detector.

The scientific quality of the chapters is generally high although the first two-thirds of the book appears to be better than the rest. The papers were submitted camera-ready but generally the typeface and chapter formats are quite consistent throughout and quite good too, except for a few chapters which used crowded pitch and single line spacing, making reading rather difficult. The text in the chapters are usually adequately illustrated, well referenced and current. The tables, diagrams and figures are generally clear and well presented.

Overall, this book is informative, up-to-date, well presented and reasonably priced. It should be useful to all those who work with chromatography-element specific detection systems.

Precision and Resolution in Spectroscopic Model Fitting: J. H. SWARTE, Delft University Press, Delft, The Netherlands, 1992. Pages xiii + 198. ISBN 90-6275-756-6 (Softback).

The Dutch PhD thesis is a model most countries would do well to follow: the final product is a compact paperback book with all the obvious advantages. Some theses are subsequently distributed as books, and this volume is one of them. It is concerned with the problem of obtaining accurate peak positions, and resolving peak overlaps in any one dimensional spectroscopic problem.

It begins with a survey of traditional methods of obtaining peak parameters, and is suitably provocative particularly concerning Fourier transform and second-order derivative techniques. This section is followed by a short chapter on the use of model fitting to obtain peak parameters. There are then two chapters concerning precision and resolution in spectroscopy; the first of these is qualitative, the next a more mathematical approach exclusively concerned with non-linear least squares. The final theory section deals with the incorporation of measurement errors into non-linear least squares model fitting, and chapter 6 applies this theory to a series of 22 spectroscopic problems. Finally there are two short chapters containing discussion and conclusions.

The whole work is quite clear, the English is competent, but I am very surprised that maximum entropy methods received no mention anywhere. There are good theoretical reasons for preferring them to non-linear least squares, and they should at least appear in discussions in a publication of this sort. This aside, the book will provide interesting, specialist reading for spectroscopists concerned with quantitative analysis.

C. J. GILMORE

Contemporary Electroanalytical Chemistry: A. IVASKA, A. LEWENSTAM and R. SARA (editors), Plenum, New York, 1990. Pages x + 458. US$120.00. ISBN 0-306-43818-6.

This book contains 53 papers presented by 106 authors at the ElectroFinnAnalysis Conference at Turku-Åbo, Finland, in June 1988. The papers have been grouped into seven sections, though the allocation in some cases has been made quite arbitrarily.

The first section, headed 'Electrochemical Instrumentation and Methods', contains eight papers, half of which deal with 'fast' techniques, i.e., fast electrochemistry, FT-faradaic admittance, fast potentiostats, and FFT-filtering, whilst the other four papers deal with photoelectroanalytical chemistry, reverse pulse voltammetry, multiple sensor arrays, and simultaneous ESR-electroanalytical investigations. Regardless of one's particular interest, most electrochemists will find this section of interest for the papers highlight the advances being made in several techniques. The second section deals with 'Industrial Applications' of electroanalytical techniques to process and product control, and environmental monitoring; products cited include sodium hydroxide, explosives, and those from fermentation and plating processes.

Although most of the papers in this book deal with sensors in one form or another, the ten papers in the section 'Electrochemical Sensors' deal with the structures and responses of solid-state devices, such as ISFETs, SFETs, MOSFETs, and chemically-modified electrodes and ion-selective membrane electrodes. The papers in the fourth section, 'Electrochemical Flow Analysis', concentrate mainly on flow injection analysis, and the modification of electrode systems for use in flow analysis.

Most of the papers in the sections 'Clinical Applications' and 'Pharmaceutical Applications' deal with the use of ion-selective electrodes and adsorptive stripping voltammetry. In the final 'General' section, there are more papers dealing with the use of adsorptive stripping voltammetry, and some with differential pulse polarography.

With the large number of papers, it is inevitable that the quality of the publications varies, but, on the whole, the quality is reasonably good. All of the papers are clearly written, informative, and up-to-date at the time of the conference: there are a number of mis-spellings but these do not diminish the overall quality of the book. This book can be recommended to those who wish to be aware of the progress made in the many related fields of electroanalytical chemistry.

J. B. CRAIG

The Kirk-Othmer Encyclopedia of Chemical Technology: Volume 3, Fourth Edition. Antibiotics (β-Lactams) to Batteries. J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley-Interscience, Chichester, 1992. Pages xxviii + 1121. £135.00. ISBN 0-471-52671-1 (v. 3).

A review of the first volume of the fourth edition of this encyclopedia appeared in *Talanta*, 39, 1063. The current volume completes an extensive section on antibiotics (continued from volume 2) and the contents then proceed alphabetically to a 158-page dissertation on batteries. As with the two previous volumes numerous authors from industry and academia have contributed to this tome.

Elements and compounds of antimony, arsenic and barium are covered in a concise manner with details of production and economics. Much general chemistry associated with these elements is also included. The importance of pharmaceutical compounds is very much in evidence for as well as the section on antibiotics there are details of antiobesity drugs, antiparasitic agents and antiviral agents. Indeed, almost half of this volume is concerned with pharmaceutical agents.

There is a small section on automated instrumentation which is devoted to descriptions of analysers used in clinical chemistry and hematology. Analysis is also mentioned in the section concerning asbestos. An attempt to locate atomic-absorption spectroscopy in the encyclopedia results in a referral to the section on spectroscopy in a future volume. Some of the other topics in volume 3 include antifreezes, antioxidants, atmospheric modelling, azo dyes, bakery processes and barrier polymers.

Overall the volume maintains the high standard of previous volumes with many up-to-date references, competent and easy-to-understand descriptions of technological processes and much interesting chemistry.

SPECTROPHOTOMETRIC DETERMINATION OF CHROMIUM WITH IODONITROTETRAZOLIUM CHLORIDE AND TETRAZOLIUM VIOLET

M. KAMBUROVA
Department of Chemistry, Higher Institute of Agriculture, 4000 Plovdiv, Bulgaria

(*Received* 5 *December* 1991. *Revised* 9 *March* 1992. *Accepted* 21 *April* 1992)

Summary—The interaction of Iodonitrotetrazolium chloride and Tetrazolium Violet with chromium(VI) has been studied and the formation of ion-associates with a 1:1 composition in hydrochloric acid medium established. Extraction photometric methods for determination of chromium in steels and soils have been developed.

A characteristic feature of chromium as a transition element is its ability to form a great number of complex compounds of different structure and chromium oxidation state.[1–4] Various reagents have been suggested for photometric determination of chromium, and solvent extraction of ion-pairs of Cr(VI) anions with organic cations has been described by several authors.[5–14] Several of the organic reagents for spectrophotometric determination of chromium were mentioned in an earlier paper on determination of chromium(VI) by extraction with Methylene Blue;[15] others that have been proposed include sodium 2′-bromo-4′,5′-dihydroxyazobenzene-4-sulphonate,[16] fluphenazine hydrochloride,[17] 4-(2′-thiazolylazo)resorcinol,[18] 4-(2-pyridylazo)resorcinol,[19] *o*-hydroxyquinolphthalein,[20] *o*-nitrophenylfluorone[21] and gallacetophenone.[22] Diphenylcarbazide is considered to be one of the most sensitive spectrophotometric reagents for chromium,[23] but suffers from various interferences.

Tetrazolium salts have been used to provide cations for the formation of ion-associates of various anions in the determination of a number of metals, including Co, Zn, Au, Sb, Nb, Mo, W, Re, Tl and Ga,[24–34] but only triphenyltetrazolium chloride has so far been used as a reagent for determination of chromium.[13,35,36] Here we report on the use of Iodonitrotetrazolium chloride (INT) and Tetrazolium Violet (TV) as counter-ions for formation of ion-association complexes with the chlorochromate anion (CrO_3Cl^-) and determination of chromium(VI).

EXPERIMENTAL

Apparatus

A Zeiss VSU 2-P spectrophotometer and a Specord UV-VIS spectrophotometer were used with 1-cm light-path cuvettes.

Reagents

Iodonitrotetrazolium chloride (INT), $1 \times 10^{-4}M$; Tetrazolium Violet (TV), 1×10^{-5} and $1 \times 10^{-4}M$; potassium chromate, 1×10^{-4} and $1 \times 10^{-5}M$; sulphuric acid, 18 and $0.18M$; hydrochloric acid, 12 and $1.2M$; nitric acid, 17 and $1.55M$; perchloric acid, $9M$; hydrofluoric acid, concentrated; 1.2-dichlorethane.

Procedure

In a 100-ml separatory funnel, $1.2M$ hydrochloric acid (1.2 ml for INT or 0.9 ml for TV), 2 ml of $1 \times 10^{-4}M$ INT or 1 ml of $1 \times 10^{-4}M$ TV and a known amount of chromium(VI) were mixed and the solution was diluted to 10 ml with distilled water and then shaken with 3 ml of dichlorethane for 1 min. The organic layer was transferred through a dry filter paper into a 1-cm cuvette and its absorbance measured at 250 nm for INT or 230 nm for TV. Corresponding blanks containing the same solutions but no chromium were prepared.

RESULTS AND DISCUSSION

Optimization of conditions

With chromium(VI), in hydrochloric acid medium, Iodonitrotetrazolium chloride and

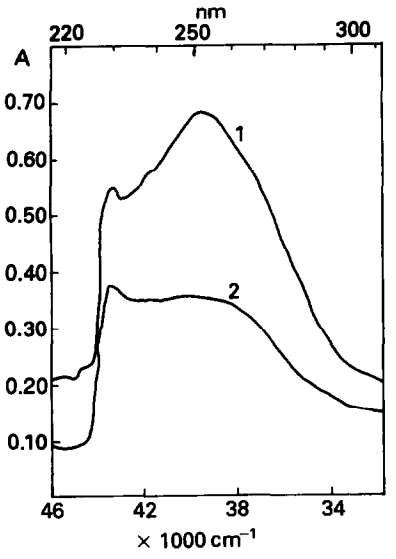

Fig. 1. Absorption spectra (in dichlorethane) of ion-association complex of Cr(VI) with INT (1) and of INT (2); $C_{Cr(VI)} = 1 \times 10^{-5}M$, $C_{INT} = 1 \times 10^{-5}M$, $C_{HCl} = 0.14M$.

Tetrazolium Violet form ion-associates with compositions $INT^+ \cdot CrO_3Cl^-$ and $TV^+ \cdot CrO_3Cl^-$ respectively. This composition is in agreement in earlier reports on the nature of chromium(VI) complexes in hydrochloric acid media.[37-41].

Our studies show that the ion-associate of Cr(VI) with INT or TV is quantitatively extracted into dichlorethane. With other solvents, such as chloroform, benzene, nitrobenzene, ether, the compound is not extractable.

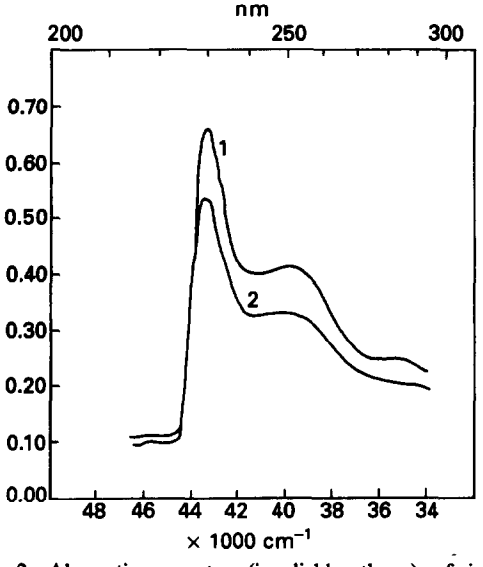

Fig. 2. Absorption spectra (in dichlorethane) of ion-association complex of Cr(VI) with TV (1), and of TV (2); $C_{Cr(VI)} = 7 \times 10^{-6}M$, $C_{TV} = 7 \times 10^{-6}M$, $C_{HCl} = 0.01M$.

The INT ion-associate has absorption maxima at 230 and 250 nm (Fig. 1). The intensity of the second maximum is considerably the higher so 250 nm is used as the working wavelength. The TV ion-associate has an absorption maximum at 230 nm (Fig. 2).

Maximum extraction of the chromium ion-associates is reached with a shaking time of 30 sec, and the ion-associates are stable for five days.

The composition of the ion-association complexes was determined by the Asmus, molar ratio and equilibrium shift methods,[42] and found to be 1:1. Under the optimal conditions the molar absorptivities, determined by the Komar method[42] were $\epsilon_{250} = (8.8 \pm 0.05) \times 10^4$ $1.mole^{-1}.cm^{-1}$ (for INT) and $\epsilon_{230} = (1.22 \pm 0.03) \times 10^5$ $1.mole^{-1}.cm^{-1}$ (for TV). Beer's law is obeyed over the chromium concentration 0.02–0.3 μg/ml. From these data it is seen that the reaction of chromium with INT and TV is highly sensitive.

To establish the optimal conditions for extraction and complexation we studied the relationship between light-absorption and the concentration of the tetrazolium salts INT and TV (Fig. 3). The optimal concentration of tetrazolium salt for formation and extraction of the associate was found to be $[INT] \geq 2 \times 10^{-5}M$, and $[TV] \geq 1 \times 10^{-5}M$, for 3 μg of chromium.

The acidity of the aqueous phase and the nature of the acid are also important conditions in extraction of these two ion-association complexes, especially the nature of the acid. The influence of hydrochloric, sulphuric, nitric and perchloric acids on the extraction process was studied (Fig. 4). The light-absorption was

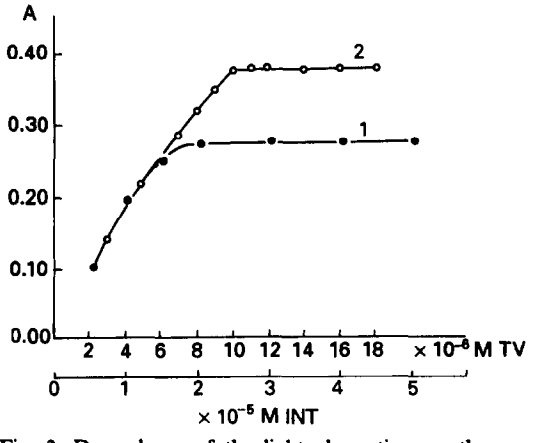

Fig. 3. Dependence of the light absorption on the concentration of (1) INT and (2) TV; (1) $C_{Cr(VI)} = 0.3$ μg/ml, $C_{HCl} = 0.14M$; (2) $C_{Cr(VI)} = 0.3$ μg/ml, $C_{HCl} = 0.11M$.

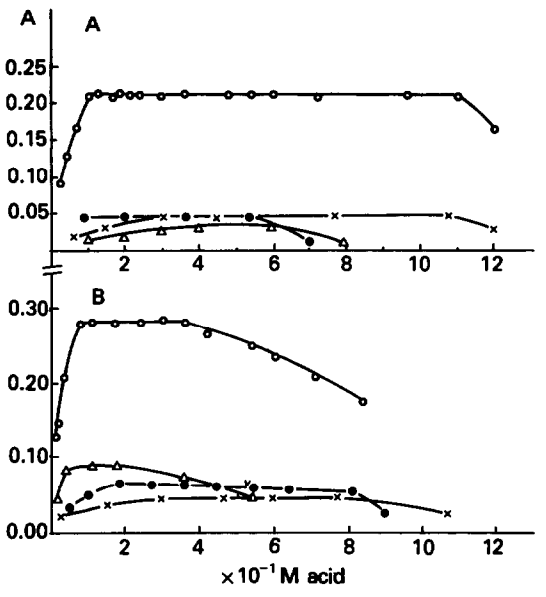

Fig. 4. Investigation of the influence of acidity and acid type on the extraction of Cr(VI) with (A) INT, $C_{INT} = 1 \times 10^{-5}M$, $C_{Cr(VI)} = 7 \times 10^{-6}M$ and (B) TV, C_{TV} lw = $7 \times 10^{-6}M$, $C_{Cr(VI)} = 7 \times 10^{-6}M$. ○—HCl, ●—$HClO_4$, ×—$HNO_3$, △—$H_2SO4$.

greatest when hydrochloric acid was used. CrO_3Cl^- is quantitatively formed in the solution,[37-40,43-45] and the best results were obtained with 0.07–0.36M hydrochloric acid for TV and 0.1–1.1M hydrochloric acid for INT. Use of too high an acidity leads to a decrease of the light absorption because of some reduction of Cr(VI) to Cr(III).

Interferences

Table 1 lists the effects of certain elements and complexing agents on the determination of 2 μg of Cr(VI). Most of the ions studied did not interfere, but Hg(II), Al(III), Ca(II), Na(I) and Br^- interfered in the determination of chromium(VI) with INT, and Hg(II) interfered in the determination of chromium(VI) with TV. As masking reagents, ammonium fluoride, tartaric acid and ascorbic acid were used. The method for determination of chromium with INT was found to be selective in the presence of W(VI) and Mo(VI). The method with TV was found to be selective in the presence of Fe(III) and V(V). We should point out that in the determination of chromium with diphenylcarbazide[23] (the most sensitive and selective method), these four ions interfere.

Table 1. Effect of foreign ions on determination of 2 μg of chromium
