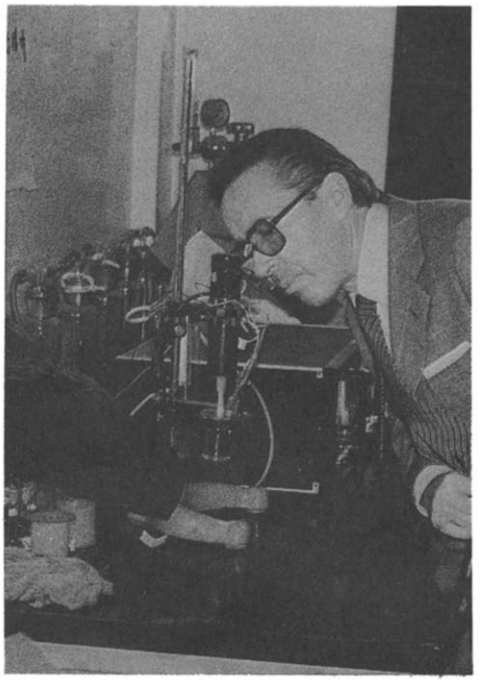
OBITUARY

Professor Dr.Dr.h.c. Wilhelm Simon (1929–1992)



Wilhelm Simon had scarcely arrived in New Orleans for the 1992 Pittsburgh conference on 7 March when he was admitted to hospital. Colleagues and friends from all over the world were shocked by the news. On 17 November he passed away, released from 8 months of weakness and disability. He had not feared anything so much as being physically and mentally disabled in his old age. Consequently, during his illness, he retrained his memory by remembering the names of related persons, doctoral students, postdocs and collaborators all over the world, One day, when he realized his condition, he said to me: "I will tell you some day if it was a 'highlight' to save me from death!" However, in spite of this doubt, he fought optimistically for his recovery.

Wilhelm Simon was born in Fahrwangen on 26 September 1929, a small village in the canton of Berne in Switzerland. He grew up in a family of social modesty which was an attitude he never lost. He worked hard for his education and training, he cultured his language and created his own very effective, exquisite and appropriate vocabulary. Every letter was examined several times. Every lecture was prepared to highlight the relevant and fundamental points, and was enlivened with spontaneous inspiration.

He graduated in chemistry from the Swiss Federal Institute of Technology in 1953 and in the same year married his wife Agnes. He completed his diploma work although he was suffering from severe tuberculosis and was ill for several months during his studies. His enthusiasm for chemistry was supported by his teacher and Mentor Prof. Leopold Ruzicka (retired 1957) who visited him in the clinic in Leysin (Wallis) and encouraged him to stay at the ETH for his Ph.D. He received the latter in 1956 at the Department of Organic Chemistry of the Swiss Federal Institute of Technology in Zűrich (ETH). The doctoral thesis has the ETH – number 2590 and is entitled "Über die Mikrobestimmung scheinbarer Dissoziationskonstanten in nichtwässrigen Medien". At this time he regularly used his bicycle for transport and later he urged his students "I prefer to teach racers, not common cyclists!" During this period he was already teaching analytical chemistry and the application of spectroscopic techniques in organic chemistry and was developing

analytical instruments. His creativity was promoted by Prof. V. Prelog his "doctor father" and his Mentor Prof. E. Heilbronner, who was much more than an authority to him. He remembered many exciting moments when turning over the pages of fascinating books and discussing papers of well-known foreign authors.

During his studies in chemistry he strongly inclined to medicine and was registered at the University of Zürich for basic medical lectures. He was especially fascinated by the lectures in pathophysiology of Prof. W. Siegenthaler, the so called "Sigirama" where real "cases" were discussed and demonstrated. This medical interest structured his research projects throughout.

In 1965 he became an assistant professor in instrumental methods for chemical analysis at the ETH. Since 1970 he had been a full professor in organic chemistry. His instrumental developments, during this first period of research, initialized a typical field of analytical science. Swiss Industries did not utilize the chance. Though a chemist at heart he was, however, very grateful to belong to the field of organic chemistry, especially later in his career when he had the idea to imitate nature, without using complicated enzymes, to recognize compounds by synthetic molecules for analytical use. Thus he had the opportunity to synthesize the compounds planned by himself: "imitate nature, but do it better!"

Four years ago in 1989 the celebration of his 60th birthday was an unforgettable event, assembling all his doctoral students, 115 to date, as well as his promotors at the ETH, Prof. V. Prelog and Prof. E. Heilbronner. Plenty of typical daily events were remembered: the aversion to ferrets in the laboratory ("a pain in the neck!"), the fight against reading the daily press in the lab and many further events showing his enthusiasm and spontaneity. However, the last period of his life in the clinic in "Zihlschlacht" (SG) revealed his strong love of nature, especially of birds and their song.

ACHIEVEMENTS

To date his name is mainly connected to the development of optical and potentiometric sensors as well as potentiometric microdetectors. However, a list of more than 450 papers and 500 talks shows the spectrum of his productivity and opus. Some of his earliest accomplishments are less known. His earliest contribution derives from the title of his thesis. The scope was the development of the instrumentation for the micro-determination of the dissociation constant of organic compounds using glass electrodes and the interpretation of the results related to the constitution by the Hammett acidity function.[1-3] Microtitrations gave input in clinical chemistry in 1961 for the titration of free fatty acids in body fluids.[4] His glass electrodes were based on a broad collection of glasses of different compositions such as germanium dioxide[5] which were processed to electrodes by his friend Willy Möller, who still cultivates the art of manufacturing glasses for various different applications.

The automation of elemental analysis of organic compounds (C, H, N) resulted in a large space-filling instrument, which had a strong input in the industrial evolution of elemental analysis.[6,7] Further accomplishments were made in gas chromatography[8] and Currie-point pyrolysis gas chromatography.[9,10] The instrumental analysis of organic compounds was one of his main fields of research which he followed up for the whole period of his creative work.[11-13] He recognized the gain in information by combined analytical techniques. In 1964 he presented the first papers on combined spectroscopic techniques for the analysis of the structure of organic compounds[12] and presented the coupled GC–MS technique in 1966.[14] In 1967 the accessory to the polarimeter for magneto-optic rotation dispersion (MORD) was published and added to the coupled techniques.[15]

The development of the instrumentation for vapor phase osmometry resulted in a commercially successful product.[16-18] In a subsequent period Willy Simon was mainly concerned with the interpretation of spectra.[19-22]

Few scientists have the vision of a building before it is completed, he was such a visionary. He always realized his plans and concepts in a very early, but final, way. In most cases a commercial instrument was the product of his creative activity in analytical sciences. One of the most convincing examples for his purposeful, systematic procedure is the development of the magnesium-selective carriers over about 20 years.[23] This purposeful behaviour even assisted in opening the doors of industrial sponsorship. With the financial support of companies and different funds it was possible for him to employ assistants for his lectures and students for his research group. His achievements, in many cases, did not hit the headlines, but they were

valued much later; he was honored by awards of four medals and five honorary professorships.

The valinomycin based potassium-selective electrode, for example, is widely used all over the world and in various types of instruments. Willy Simon estimated sales of 64 million potassium sensors worldwide for 1990. The history of this accomplishment sounds close to the story of the recovery of penicillin by Alexander Fleming published in 1929. Valinomycin and rat liver mitochondria were used as tools for metabolic studies.[24] It was suggested that the oxidative phosphorylation of these cells is decoupled by cation transport through the membranes. Cation carriers were suspected of being responsible for this transport by Moore and Pressmann.[25] Experiments *in vitro* were started. Working with buffered solutions of valinomycin a precipitation occurred and was assumed to be due to a complexation of potassium by valinomycin. The first data based on X-ray structure analysis of valinomycin-potassium complexes were published stimulated by Willy Simon.[26] The cation specificity of valinomycin was shown earlier by Shemyakin *et al.*[27] In 1966 the *in vitro* behaviour of macrotetrolides as ion-selective compounds and of valinomycin, especially, as a potassium-selective compound was confirmed potentiometrically by use of artificial membranes.[28–30] In 1969 these sensors were listed under the heading "miscellaneous" and denoted as "even more exotic systems!" The potassium-selective electrode was published and applied to blood serum measurements in 1970.[31,32] At this time I had the chance to contribute to the success by first measurements of the potassium selectivity in serum and by comparison to FAES. I was then employed in my first position in clinical chemistry at the University Hospital Zürich. Much later I noticed the great success but also the trouble created by the ion-selective electrodes and undertook comparisons between electrolyte measurements by ISEs and FAES. I had just evaluated the first potassium-selective optical test by solid state, or so-called "dry chemistry" assays in 1985. It was at this time, nearly 20 years later, that I first met with Prof. Willy Simon personally at a meeting where I presented my results. He was fascinated by the results of these test strips and initialized the optode programme.

The design of ion-selective carriers was accelerated in the subsequent period. Many successful synthetic carriers were evaluated for monovalent and divalent cations, as well as anions. The tailoring of carriers lastly resulted in carriers for neutral compounds coupled to optical transduction as well. Even the sodium-selective glass electrode was born in his kitchen.[33] Also in the field of ion-selective electrodes, research and development were permanently followed up by the industrial contacts. In 1972 the first clinical analyser, using a valinomycin based sensor, was commercialized (STAT-ION, Technicon/Photovolt Corp., USA). The potentiometric as well as optical ion-selective principle of chemical sensors were treated theoretically over all the years.[34–37]

PERSONALITY

For lunch with guests a special place was selected, very frequently on top of a building. One of his favourite places was the "Dozenten-Foyer" at ETH where I remember fascinating discussions with guests from all over the world. As important as the meal, however, was the view of the mountains. On such an occasion he instructed me on the theories of Manfred Eigen, whose papers on thermodynamical properties of electrolyte solutions fascinated him. I was instructed on the dependence of the rate of substitution of solvent molecules in the inner coordination sphere of a metal ion related to the charge and the radius of an ion. I was confronted with ion hydration theories during my studies in the field of plant physiology, taught by Prof. A. Frey-Wyssling at the ETH-Zürich, related to ion uptake by roots. In 1971 and the following years W. Simon presented some papers on calculations of free enthalpies of hydration of ions related to the stability constants and the influence of the medium on the complexation of ions.[38,39] Based on these early thermodynamic calculations Clementi stimulated the calculations of interaction energies and early programs for molecular modelling calculations were written in his laboratory.[40] After teaching me, Willy Simon shifted to the educational and social situation in South Africa. Such appointments were completely dedicated to exciting discussions, more commonly than enjoyment of the meal.

In his heart Willy Simon felt a deep affinity with Japan. Beside his travels for teaching, he had strong respect for some famous chemists as H. Kobayashi, K. Kimura, S. Kamata, T. Shono and others. He considered moving to Japan after his retirement for part of the year. He was learning the Japanese language and

could converse. However he always felt a deep responsibility for his own country, the Swiss products as well as the chemical industry and the education of chemists in Switzerland. His trip around the chemical companies in Switzerland, his talks collecting and presenting the news of Pittsburgh Conference each year, were a main event for all his colleagues and students. Also in our laboratory at the ETH we looked forward to these reports as out of the ordinary and I never learned as much analytical chemistry in a shorter time.

He opened his laboratory to guests from Eastern Europe during a period of a general intensive inclination of science in Europe to the USA. At this time a visit to the Shemyakin Institute of Technology in Moskow was regarded by some as tantamount to being a traitor to his country. The strong relations with Hungary and a deep friendship with Prof. Ernö Pungor and his group, paved the way for him to relax and enjoy his success. Some publications derived from joint projects. Willy Simon was able to accept and enjoy the achievements of his colleagues as well, and was stimulated by these sound relationships which flourished with forward-looking scientific discussions that appealed so much to his temperament.

He opened his laboratory to Chinese researchers, whose intensive and productive attitude I seriously learnt to respect during the last years. Many other coworkers, more than 72 all over the world, have taken the opportunity to share experiences, moments of recognition and fascinating discussions in Willy Simon's elegant office or the "documentation" reserved for internal meetings. In these sessions we got to the bottom of the projects with fundamental considerations and questions. Occasionally young outsiders and shy, sensible newcomers lost the thread, startled by his flow of ideas and his delicate humour. His critical mind and the broad field of his experiences made him a member, advisory and honorary editor of in total 18 editorial boards, 26 scientific committees and a demanded, but occasionally inconvenient, member of different societies.

His responsibility for the technical development and future of Switzerland was his main motivation to activate the last, strongest, efforts for the realization of the "Swiss Centre of Chemical Sensors" in the area of Technopark Zürich. This idea was based on his belief that his country should invest manpower as well as ideas for developments in the field of high technology. He formulated a speech for ILMAC'90: "Es müsste aber das Ziel sein, selbst wieder durch eine Vorwärtsstrategie die Speerspitze des Fortschrittes zu bilden und die Spielregeln selbst zu bestimmen, statt sie aufgezwungen zu bekommen".[41] It happened during the last years that he felt afraid of his own courage and became tired: "Was bringt's?" Nevertheless the phrase above probably puts in words his last will concerning his research area and country.

A great scientist has left the arena leaving behind 20 doctoral students, his coworkers and plenty of plans and projects. In Switzerland his loss is followed by a tragic loss of position in education, training and research in analytical chemistry. Even when he stayed in Switzerland he was mentally participating in projects globally. All over the world colleagues, friends, scientists and analysts will mourn the loss of his strong and fair personality. All over the world his friends and colleagues will miss his humorous, stimulating and sensitive friendship and his compassion, he was a hard working analyst as well as a serious and fascinating teacher.

DOUBLE ARMED CROWN ETHERS AND ARMED MACROCYCLES AS A NEW SERIES OF METAL-SELECTIVE REAGENTS: A REVIEW

HIROSHI TSUKUBE

Department of Chemistry, College of Liberal Arts & Science, Okayama University, Okayama 700, Japan

(*Received* 10 *December* 1992. *Accepted* 9 *February* 1993)

Summary—Various double armed crown ethers and related macrocycles are presented as metal-selective reagents characterized by macrocyclic ligands and metal-ligating sidearms. They exhibit unique metal binding and recognition functions via macroring-sidearm cooperative action. Since they form three dimensional complexes suitable for metal-sensing and separation, we can develop a new series of metal-selective reagents via armed macrocycle strategy. Polymerization and immobilization of the armed macrocycles further enhance the usefulness in analytical science. This review focuses primarily on the molecular design, host–guest chemistry, and analytical applications of the armed macrocycles, and clearly indicates that these macrocycles provide new options in designing a metal-selective reagent.

Because crown ethers and other macrocyclic reagents are known to selectively bind metal cations, they have considerable potential as metal-selective reagents in sensing and separation science.[1,2] They are employed as the carriers in metal-selective extraction, phase transfer catalyses, membrane transport, and related processes. Literally thousands of macrocyclic reagents have been prepared which provide a variety of donor atoms, ring sizes, and ligand geometries.[3] Crown ethers and cryptands were particularly well-recognized as useful metal-selective reagents. Recently, "armed macrocycles" were developed as a new type of metal-selective reagent which are characterized by a parent macrocyclic ligand and a cation-ligating sidearm.[4,5] They topologically lie between crown ethers and cryptands and exhibit both the kinetically fast complexation properties of crown ethers and the three dimensional binding characteristics of cryptands. These metal binding features are similar to those of naturally occurring ionophores which effectively and selectively transport several metal cations across a biomembrane.[6] Because of their great advantages of facile synthesis and versatile molecular structures, a variety of metal-selective reagents were designed along this line and successfully employed in analytical science.

This review describes: (1) strategy for molecular design, (2) recognition of metal cations, and (3) analytical applications of the double armed crown ethers and other armed macrocycles. Their carrier activities in membrane systems are particularly detailed, because there is a wealth of valuable and interesting chemistry to be understood and applied to practical separation problems. We deal here with only a limited number of armed macrocycles; other types of metal-selective reagents have been reviewed elsewhere.[7]

STRATEGY FOR MOLECULAR DESIGN OF ARMED MACROCYCLES

Armed crown ether strategy

Double armed crown ethers[8] are typical examples of the armed macrocycles which are composed of two flexible cation-ligating arms and a parent crown ring. In this class of compounds, the donor group on the flexible sidearm provides further coordination of a guest cation trapped in the crown ring. The crown ring enforces a rudimentary "hole size" selectivity on the complexation, while sidearm donor provides three dimensional solvation. Their complexation behaviors are schematically shown in Fig. 1. We can design a metal-selective reagent of this type by choosing a combination of parent crown ring structure and functionalized sidearm.

Double armed crown ethers occupy an intermediate position between crown ethers and cryptands. The former affects rapid and circular coordination for guest cations, while the latter forms rigid and encapsulated complexes. Since

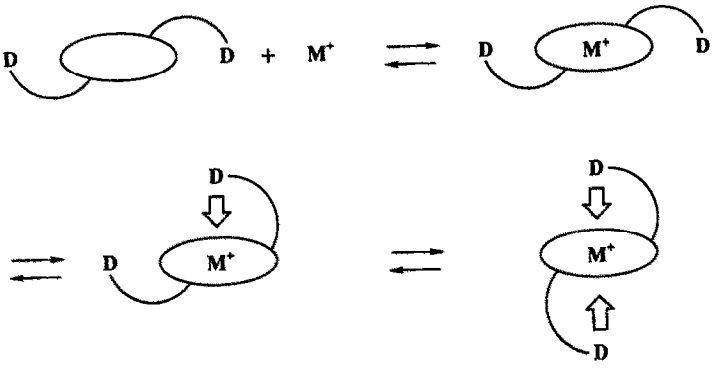

Fig. 1. Cation binding of double armed crown ether.

double armed crown ethers are stronger cation binders than the crown ethers and more flexible than the cryptands, they offer great promise in broad areas of metal-sensing and separation processes. A typical example is the facilitated transport of metal cation.[6] The rates of the carrier-mediated transport, in graphic terms, generally display a bell-shaped dependence on extraction or stability constants: the rate decreases when there is either too little extraction at the entry or too much extraction at the exit of the membrane.[9-11] Both crown ethers and cryptands are excellent cation binders but inadequate as membrane carriers. The monocyclic crown ethers are two dimensional and flexible binders, while the bicyclic cryptands form three dimensional and rigid complexes. Since an effective carrier is required to offer kinetically fast and three dimensional complexation, the double armed crown ether is most suitable and promising for this purpose. This has a flexible molecular structure to wrap a guest metal cation completely. Several kinds of armed crown ethers have already been demonstrated to mediate specific membrane transport of various metal cations.

Structural variation of the sidearm functionalities have been made to enhance usefulness in analytical applications. Introduction of an anionic metal-chelating group on the sidearm generally increases metal extraction activity of a macrocycle, because of the lack of requirement for a lipophilic counter-anion.[12] Addition of a chromophore on the sidearm makes possible colorimetric metal detection,[13] while addition of a signal-responsive group allows the use of signal-switching to control the solvent extraction and membrane transport.[14] Double armed crown ethers, therefore, provide a wide variety of possible uses in metal-sensing and separation processes. Their interesting metal binding and recognition behaviours have been illustrated on a molecular basis in solution and in solid state and are discussed below.

Armed macrocycles

In addition to the crown ethers, other kinds of macrocyclic ligands are available as parent macro-rings. Macrocyclic polyamines, polysulphides, cyclic peptides, calixarenes, cyclophanes, and cyclodextrins are potential candidates. Basic host–guest chemistry and

Table 1. Basic host–guest chemistry of parent macrocycle

Macrocycle	Major guest	Structural diversity*	Guest selectivity*
Crown ether	Na^+, K^+, Ca^{2+} Ba^{2+}, Ag^+, Pb^{2+} NH_4^+, RNH_3^+	A	A
Macrocyclic polyamine	Cu^{2+}, Ni^{2+}, Co^{2+} Polyanion	A	B
Macrocyclic polysulfide	Ag^+, Pb^{2+}	C	A
Cyclic peptide	Ca^{2+}, Ba^{2+} Cu^{2+}, Zn^{2+}	C	B
Calixarene	Na^+, K^+, Cs^+ Organic substrate	A	B
Cyclophane	Organic substrate	C	C
Cyclodextrin	Organic substrate	B	C

*A: excellent, B: fair, C: not good.

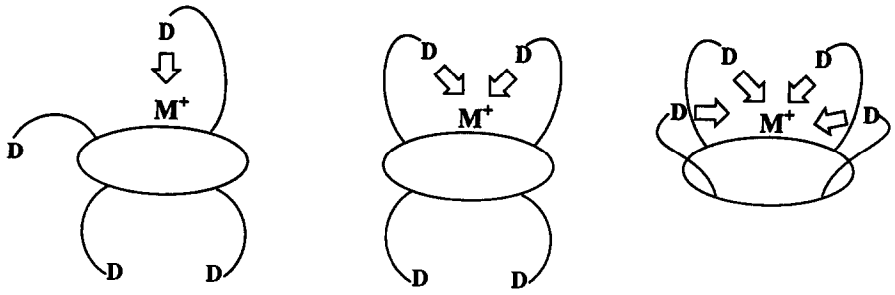

Fig. 2. Cation binding of armed macrocycle.

other characteristics of these macrocycles are summarized in Table 1. Polyamines and polysulphides have soft donor atoms effective for binding of soft metal cations, though crown ethers favour hard metal cations. Cyclic peptides complex with various metal cations, while calixarenes, cyclophanes, and cyclodextrins bind organic substrates. Many attempts have been made to attach the ligating sidearm groups to various macrocyclic ligands.[15] Several examples exhibited different guest selectivity from the armed crown ethers. Their target guest species included alkali, alkaline earth, heavy, and transition metal cations as well as organic substrates.[16] Such armed macrocycles often used a varying number of ligating sidearms for cation binding as schematically shown in Fig. 2, and offered various kinds of host–guest complexations. Since the nature of the parent macroring greatly influences the guest recognition profile of the armed macrocycle, we have many options in designing metal-selective reagents of these types.

HOST–GUEST COMPLEXATION OF ARMED MACROCYCLE

Solid-state structure of metal complex with armed crown ether

Three dimensional complex structures of the armed crown ethers have been demonstrated in the crystal state. Gokel *et al.* reported crystal structures of K^+ complexes with diaza-18-crown-6 **1**, lariat ether **2**, and double armed crown ether **3** (Fig. 3).[17] In the complex of lariat ether **2**, the guest K^+ cation is coordinated to donor atoms of both crown ring and sidearm. The crown ring donor atoms are disposed in a chair conformation with K^+ ion distinctly above the plane of four ether oxygen atoms. Its sidearm oxygen is located underneath the plane in an apical position. Since counter-anion

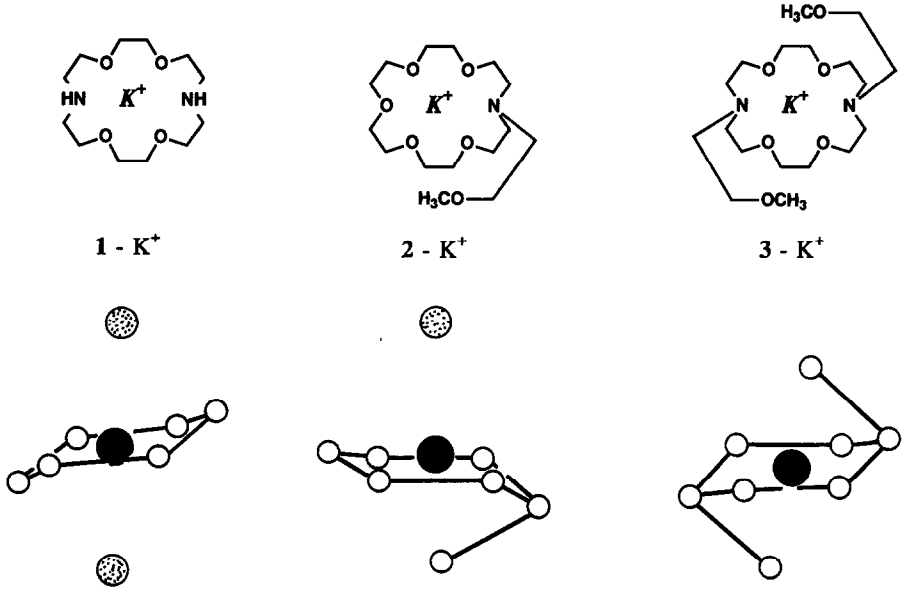

Fig. 3. Crystal structures of KI complexes with diaza-crown ether **1**, lariat ether **2**, and double armed crown ether **3**.

occupies the opposite apical position, the coordination number of the K^+ cation increases to eight. The K^+ ion is also octacoordinated in the double armed crown ether **3** complex, though anion does not contact the K^+ ion. The donor atoms of the crown ring adopt the chair conformation, but oxygen atoms of the sidearms are located above and below the mean plane of the crown ring. The K^+ ion is completely accommodated in a three dimensional cavity, which is topologically similar to those of cryptands. In contrast, the parent diaza-18-crown-6 **1** accommodates K^+ ion in a circular cavity and its encapsulation is not as complete as those with the lariat ether and the double armed crown ether. The solid-state structures of these complexes confirm the "armed crown ether strategy" described above, and suggest promising uses of the armed crown ethers in the metal-sensing and separation processes.

Armed crown ether–metal ion interaction in solution

The effect of functionalized sidearm on the complex stability was clearly demonstrated by comparing double armed crown ether with parent diaza-crown ether. Tsukube *et al.* found that attachment of pyridine-functionalized arms to the diaza-crown ring significantly increased binding constants for Ca^{2+} and Cu^{2+} ions.[18] As shown in Table 2, the stability constant of pyridine-armed diaza-18-crown-6 **4** for Cu^{2+} ion was an order of magnitude greater than that of the unsubstituted diaza-18-crown-6 **1**. Since only slight enhancement was observed for binding of Na^+ ion, the pyridine nitrogen atoms of the double armed crown ether **4** provided more effective coordination with divalent Ca^{2+} and Cu^{2+} ions than with monovalent Na^+ ion. Pyridine-armed crown ether **5**, which has all the structural elements present in the rest of the series, nonetheless behaved differently, because its pyridine nitrogen atoms are too remote to interact with the crown-bound metal cations. Pyridine-armed diaza-15-crown-5 and diaza-21-crown-7 derivatives similarly exhibited large enhancements for binding of several divalent metal cations. One precondition for cation binding enhancement is that the potential donor groups must be appropriately situated on the sidearms to provide effective coordination with the guest cation trapped in the parent crown ring.

Table 2. Stability constants of double armed crown ethers

	Log K in H_2O

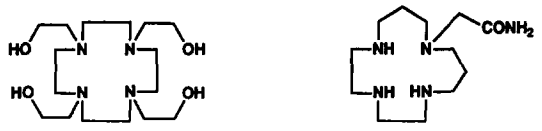
Cation inclusion behaviour of the pyridine-armed crown ether **4** was characterized by a ^{13}C NMR titration experiment.[18,19] Addition of $Ca(ClO_4)_2$ salt to a solution of pyridine-armed crown ether **4** caused significant and continuous shifts of the signals for both pyridine and crown ring carbons, indicating that the pyridine nitrogen atom on the sidearm effectively coordinated with Ca^{2+} ion trapped in the diaza-crown ring. This armed crown ether offered three dimensional but kinetically slow complexation with Zn^{2+} ion. When 0.5 equiv. of Zn^{2+} ion was present, each carbon exhibited two split signals corresponding to the free and complexed forms. This did, however, affect circular coordination for Na^+ cation in the same way as did simple crown ethers, because only the signals for crown ring carbons were shifted in the presence of Na^+ cation. Thus, the pyridine-armed diaza-crown ether **4** provides different coordination characteristics toward Na^+, Ca^{2+} and Zn^{2+} cations, which may explain the enhanced binding for Ca^{2+} and Zn^{2+} cations.

Cation binding of armed macrocycles

Armed aza- and thia-macrocycles form encapsulated complexes with the guest cations in different coordination modes. Dale *et al.* demonstrated that cyclen **6** having four hydroxyethyl-functionalized arms formed three dimensional complexes with Li^+, Na^+ and K^+ cations.[20] This used a varying number of ligating sidearms and accommodated its molecular cavity to the size and shape of the guest metal cation. Macrocyclic polyamines are not good ligands for these hard metal cations, but cooperative binding of the sidearm and the polyamine ring offered effective inclusion of the uncommon metal cations. Kaden *et al.* prepared transition metal complexes with the armed polyamine **7**, in which amide-functionalized sidearm was significantly involved in the metal encapsulation.[21] Since ring-size and donor atom of parent macrocyclic ligand, number and nature of arm donor group,



6 7

Fig. 4.

and shape of molecular cavity are variable factors, a large number of metal-selective reagents can be derived from various macrocycles.

Double armed crown ethers and related armed macrocycles have great advantages of facile synthesis and versatile molecular structures. We can tune the metal selectivity of these compounds by considering a combination of parent macroring and ligating sidearm. Their specific complexation behaviours satisfactorily meet the level required of metal-selective reagents available for multi-purposes. Their promising uses are discussed below from the viewpoint of analytical science.

ANALYTICAL APPLICATIONS

Depending on the structural characteristics, armed macrocycles bind several metal cations with varying strength. Since their metal selectivity is easily controlled through molecular architecture, they can be used to enrich, separate, mask and determine the concentration of metal cations. Their analytical applications include membrane transport, extraction separation, spectroscopic determination, electrochemical sensing, and chromatographic analysis as well as biomembrane mimetic processes. Typical examples of the armed macrocycles exhibiting characteristic metal-selectivity are described below.

Carrier in liquid membrane

Liquid membrane transport is a useful process for metal separation and enrichment, because there is no necessity for the separation of carrier and guest metal salt.[22] In principle, metal cation is moved from one aqueous phase through a lipophilic liquid membrane into a second aqueous phase. Selective transport of the metal cation is effected by a metal-selective reagent embedded in the membrane phase. Several useful carriers were designed by considering:

1. size and shape of cavity for guest encapsulation
2. nature of guest binding force
3. coordination geometry
4. solubility and stability of carrier and complex
5. molecular flexibility and binding dynamics.

Membrane transport produces different requirements for the carrier to be used from those of extraction and other metal separation processes. The effective carrier should not form too strong a complex with a transported metal ion. Double armed crown ethers and armed macrocycles are recognized as the most suitable candidates for effective carriers.[6] They have intermediate stability constants between crown ethers and cryptands and offer very high transport rates. Their three dimensional ligand topology provides highly lipophilic complexes with specific metal cations, while the high mobility of ligating sidearm promises fast kinetics of complexation. These binding features are common to several naturally occurring ionophores which specifically transport metal cations across a biomembrane. Thus, by careful selection of parent macrocycle and functionalized sidearm, we can prepare an armed macrocycle specific for encapsulation and transportation of metal cation.

Tsukube *et al.* first presented systematic studies on cation transport properties of double armed crown ethers.[23,24] They attached benzene, furan (oxygen atom), and thiophene (sulphur atom) rings to the diaza-18-crown-6 system as well as pyridine (nitrogen atom) ring. Interestingly, furan-armed crown ether **9** showed much larger transport rates for K^+, Ba^{2+}, NH_4^+ and Pb^{2+} ions than simple crown ether **8**, though other alkali and alkaline earth metal cations were only slightly transported. In contrast, thiophene- and pyridine-armed crown ethers **12** and **4** offered enhanced transport rates for heavy and transition metal cations such as Pb^{2+}, Cu^{2+} and Zn^{2+} ions.[18] Arm-functionalization of crown ether largely increased transport efficiencies especially for complementary guest cations. Transport selectivity was modified by varying ring-size of the parent crown structure: furan-armed 15-crown-5 **10** effectively mediated Na^+ ion transport, while a 21-crown-7 **11** was a good carrier of K^+ and Cs^+ ions. Therefore, double armed crown ethers have a "tunable" guest-selectivity both in complexation and transportation processes. By considering ring-size of the parent crown ring and coordinating character of donor arm groups, we can easily draw the molecular structure of a carrier specific for a target guest cation.

Fig. 5.

Other examples of metal-selective armed crown ethers **13–15** are shown, together with their favourite metal cations.[9,25,26] Among them, thiazole-armed diaza-crown ether **14**, recently prepared via high pressure SNAr reaction, is notable.[26] This specifically formed a binuclear complex with Ag^+ ion. In this complex, two Ag^+ ions were cooperatively coordinated by thiazole-functionalized sidearms and parent diaza-crown ring, and the Ag....Ag' separation was shorter than the intermetallic distance.[27] Such a unique metal complexation attained a high Ag^+ ion-specificity in extraction and transport processes.

Attachment of an ionizable sidearm to the crown skeleton offers other possibilities in the design of useful carriers. Kimura *et al.* reported that phenoxide anion-armed 14-crown-4 derivative **16** was a specific carrier of Li^+ ion; this recorded an extremely high Li^+/Na^+ selectivity.[28] When the anion-armed crown ether is employed as a carrier, transfer of the metal cation into an organic medium does not require concomitant transfer of a counter-anion. Thus, crown ether ring and anion-charged sidearm act as cooperative complexing functions. Crown ethers having acidic functionalities such as **17** are effective for proton-driven active transport ("uphill transport") whenever guest ion is pumped against a concentration gradient.[29] The carrier shuttles back and forth between the metal-rich and the proton-rich aqueous phases, coupled with proton-transport. A similar coupled cation transport is often observed in the biomembrane processes. Nakatsuji *et al.* prepared crown ether **18** having $-NH_2$ group on the sidearm and demonstrated active transport of K^+ ion.[30] Since the $-NH_2$ group is readily protonated, this crown ether forms intramolecular "tail-biting" complexation of the crown ring with $-NH_3^+$ moiety under acidic conditions. This means that it strongly binds the K^+ cation under basic conditions and rapidly releases under acidic conditions. Such a unique binding realized uphill transport of the K^+ cation.

More interesting for practical applications and theoretical investigations are switchable transport processes, which can be turned on and off by photochemical, electrical, or other energy. Armed crown ethers such as **19**[31] and **20**[32] were designed so that they could be activated either electrochemically or photochemically and thus induce a change in the carrier activity. By

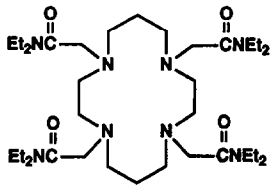
triggering a switch at the membrane interface, the membrane transport of the metal cation can be increased, changed to another ion or interrupted.[33]

Armed macrocycles have characteristically shaped-cavities for effective metal encapsulation. Tsukube *et al.* demonstrated that cyclams **21** bearing amide-functionalized sidearms had unique transport ability for Ba^{2+} ion, though the parent 1,4,8,11-tetraazacyclotetradecane ring favoured soft transition metal cations.[34] This formed a three dimensional, 1:1 complex with the hard Ba^{2+} ion, which was located on the polyamine ring and effectively coordinated both amide and macroring nitrogen groups. On the other hand, pyridine-armed cyclam **22** accommodated a hard Na^+ ion nicely in its molecular cavity and effectively transported it.[35] Since selective binding and transport of Ba^{2+} and Na^+ ions over K^+ ion are not attained by common crown ether-type carriers, unique donor combination and ligand geometry led to the new carrier functions. Furthermore, thiophene-armed thia-macrocycle **23** exhibited specific carrier activity for Ag^+ ion, while Na^+, K^+ and NH_4^+ cations of similar ion-sizes were rarely transported.[36] Although selective transport of Ag^+ ion was observed with the parent thia-macrocycle, its transport efficiency was much lower. Arm-functionalization greatly modified metal recognition profiles of the parent macrocycles and enhanced their carrier performances.

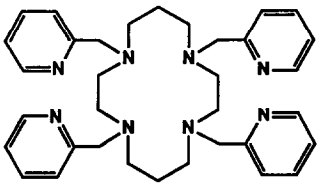
McKervey and Chang chose calixarenes as the parent macro-rings for a new series of metal-selective carriers.[37,38] Calixarenes are cyclic oligomers from *p*-tert-butylphenol and easily prepared in good yields. Chemical functionalization of intraannular OH groups of the calixarene is apparently effective in constructing a locked molecular cavity suitable for specific metal accommodation and transportation.[39] For example, ester derivative **24** from calix[4]arene existed in any one of four conformations: cone, partial cone, 1, 2-alternate, or 1, 3-alternate. Its moderately rigid skeleton allowed satisfactorily high Na^+ cation selectivity, but its conformational freedom assured high binding dynamics.

Ionophore in sensory system

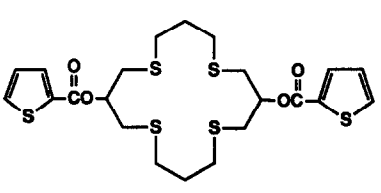
The chemistry of double armed crown ether and armed macrocycle also provides the basis for constructing new spectroscopic and electrochemical sensory systems. When a chromophore is introduced to the armed macrocycle in a proper position, selective inclusion of metal cation greatly influences the spectral characteristics of the chromophore. Thus, detection and determination of a target metal cation are monitored visually or spectrophotometrically. Takagi *et al.* presented a pioneering work on this subject. They prepared a series of proton-dissociable crown ethers in which various chromophores were introduced on the sidearms.[13] When the anion produced upon deprotonation/complexation was singly charged, the resulting armed crown ether formed a neutral complex with a monovalent metal ion to be extracted from aqueous to water-immiscible organic



21

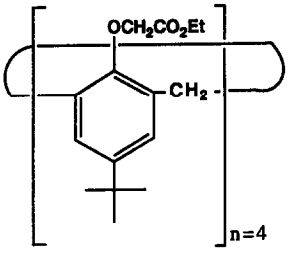


22



23

Fig. 9.



24

Fig. 10.

solvent. The introduction of two anionic sidearms allowed efficient extraction of divalent metal cations. These armed crown ethers were called "chromoionophores"[40,41] and were employed in selective extraction photometry of alkali and alkaline earth metal cations. Typically, armed crown ethers **25** and **26** exhibited high Na^+ cation selectivities for practical use. Their guest selectivities were significantly determined by the structures of crown ring and sidearm as described above.

Fluorimetric methods are useful for the assay of metal ions, especially in medicinal analysis, and several types of armed macrocycles were designed for this purpose. Double armed crown ether **27** is a commercially available reagent for determination of K^+ cation in the biocell.[42] Its principle is similar to that of Takagi's chromoionophore. Armed macrocycles **28**[43] and **29**[44] were recently developed as new metal-specific fluorescent probes, in which cation binding was coupled to emission changes of covalently anthracene fluorophores. Another example is Eu^{3+} or Tb^{3+} complex with bipyridine-armed macrocycle **30**.[45] Three dimensional topology of this macrocycle provided excellent protection against the deactivating action and offered high luminescence quantum yields of lanthanide cations even in water.

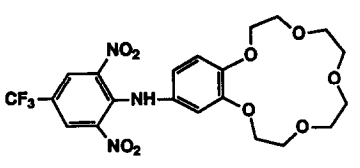
Armed macrocycles exhibited excellent performances, especially in the electrochemical sensory systems. An ion-selective electrode is a typical example and is of high analytical interest for selective determination of metal concentrations. The electrode membrane contains a lipophilic metal-selective reagent and responds to a specific metal ion. In such a system, a metal-selective reagent should have similar properties to those required for membrane carriers:[46] (1) high complexation or extraction selectivity for a given metal cation; (2) enough conformational flexibility for rapid ion exchange; (3) high lipophilicity to remain in the membrane; and (4) moderate molecular weight to allow high mobility. Many armed macrocycles have these features and are recognized as useful.

Kimura *et al.* reported that armed 14-crown-4 derivative **31** exhibited high Li^+ ion selectivity in the PVC membrane electrode.[47] Introduction of dodecyl sidearm prevents a sandwich type 2:1 complexation (crown:metal) due to the steric hindrance, and further coordination of the amide group attached enhances Li^+ cation binding. Actually, the electrochemical selectivity (K_{LiNa} value) was observed as 4.4×10^{-3}. Armed calix[4]arene **32** was also reported to be a potential carrier for Na^+ ion selective electrode.[48] Incorporation of cation-ligating ester group into the calixarene backbone enhanced Na^+ ion selectivity as described above, K_{NaK} value being 4.0×10^{-3}. A similar approach was used in the design of armed oligopeptide carrier **33** of Ca^{2+} ion.[49] These have practical applicability.

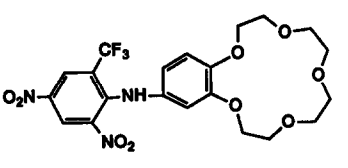
Polymeric "armed crown ethers" as metal-selective reagents

There is great expectation that the incorporation of an armed macrocycle into a polymer system may enhance its usefulness, and several attempts to polymerize and/or immobilize the armed macrocycles have been reported.

Tsukube *et al.* prepared poly(double armed crown ether) **34** and characterized its carrier profile for alkali metal cations in the liquid membrane system.[50] Transport ability of poly(diaza-crown ether) was clearly enhanced by attaching hydroxyethyl sidearms. Since the guest selectivity of the polymeric carrier was significantly controlled by the host–guest chemistry of the monomeric unit, a variety of polymeric armed macrocycles can be derived

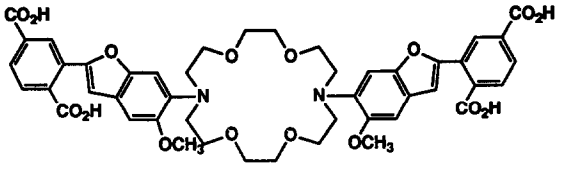


25

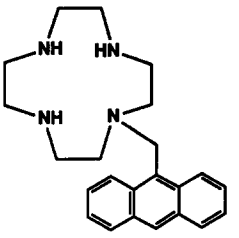


26

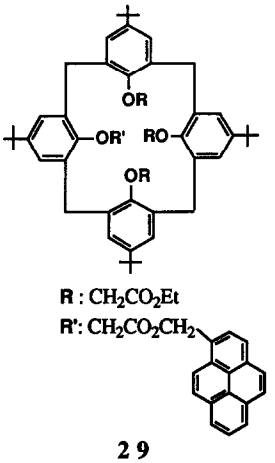
Fig. 11.



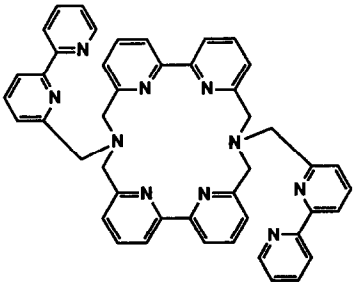
27



28



29



30

Fig. 12.

from well-characterized armed macrocycles. Cast film of this polymer also showed an interesting metal-selectivity.[51] The response in conductivity to the alkali metal cations was specific and further application is envisaged.

Bartsch *et al.* applied poly(crown ether) **35** bearing carboxylic acid-functionalized sidearm to the column concentration of Na^+ cation.[52] Column concentration is based on a single-stage sorption and requires strong binding of a specific metal cation. The proton-dissociable crown ether polymer fitted these requirements well. The participation of carboxylate anion on the sidearm significantly increased the binding ability and enhanced the guest selectivity. Since the polymer-bound metal cation was easily stripped with aqueous HCl, this type of polymer became a good stationary phase for selective metal concentration.

Polymer resin **36** was readily made from armed cyclam.[53] Its adsorption ability of Cu^{2+} and other transition metal cations from aqueous solution was much higher than those with common polyamine resins. A further combination of macrocyclic structure, functionalized sidearm, and polymeric backbone may offer other excellent polymeric reagents for metal-sensing and separation.

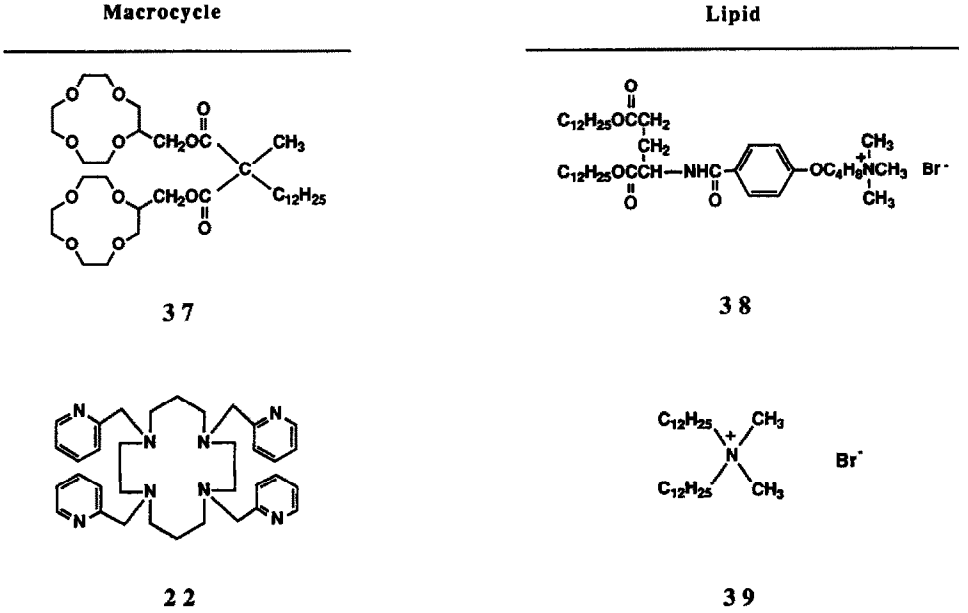
Armed macrocycles in membrane assembly

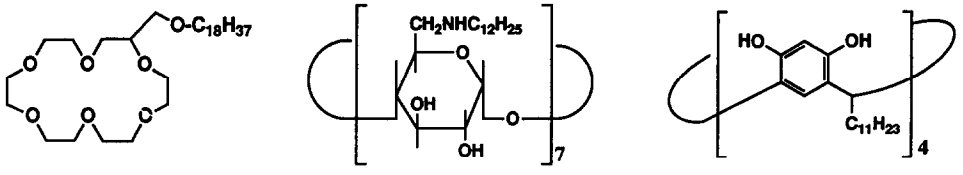
Lipid-like membrane assembly is formed from a variety of surfactants and possesses interesting properties similar to those of biological lipid membranes.[54] This acts as a useful vehicle for the ordering of metal-specific reagents and provides a variety of structurally organized and functionally integrated molecular systems. In particular, a specific



37 38

22 39

Fig. 15.



40 41 42

Fig. 16.

metal complexation on the membrane assembly is important for developing a new application in analytical science,[55] because remarkable amplification and modification of metal-sensing are realized in the biomembrane assemblies.

Nakashima *et al.* developed a highly Na^+ ion-selective membrane assembly which was composed of lipophilic bis-12-crown-4 **37** and chiral lipid **38**.[56] Its cation recognition process was monitored by circular dichroism spectroscopy. They noted that Na^+ ion-selectivity of the bis-12-crown-4 was remarkably amplified in such a bilayer-type membrane assembly.

Tsukube *et al.* reported that a lipid-bound armed macrocycle exhibited different metal selectivity from that observed in the usual liquid/liquid extraction system.[57] This membrane assembly was simply prepared by dispersing an aqueous solution of a lipophilic armed cyclam **22** and a quaternary ammonium surfactant **39**. It extracted Cu^{2+} ion very effectively from a bulk aqueous phase into the lipid-like membrane, while Ni^{2+}, Co^{2+}, and Zn^{2+} ions were rarely extracted. The resulting Cu^{2+} complex was immediately precipitated with lipid-aggregate by addition of $Mg(ClO_4)_2$ salt and easily separated from the aqueous solution by filtration. Since the armed macrocycle employed bound various transition metal cations in the solution systems, the membrane assembly may provide a unique microenvironment for specific metal extraction and recognition.

A variety of membrane assemblies was formed by crown ethers,[58] cyclodextrins,[59] calix arenes,[60] and related surfactants.[61] Some of them **40–42** were reported to show specific guest responses at the air–water and water–electrode interfaces. Since armed macrocycles recognize the guest species in various membrane assemblies, a wide variety of applications may be envisaged.

CONCLUSIONS

Double armed crown ethers and armed macrocycles are of particular interest because they generate many opportunities for analytical science. Since the synthetic strategies for this class of compounds have been presented, a variety of new metal-selective reagents has been designed for membrane transport, liquid–liquid extraction, spectroscopic determination, electrochemical sensing, chromatographic analysis, and so on. These offered good examples of metal-sensing and separation based on molecular recognition. Combinations of armed macrocycle chemistry with membrane chemistry, supramolecular chemistry, and related knowledge provided further possibilities in building up new sensing and separation systems. Development of this magnitude allows us to see a new horizon of metal-sensing and separation science.

Summary—Mercuric ions (Hg^{2+}) can be extracted from solid samples (cellulose matrix) using methanol modified supercritical CO_2 containing the fluorinated chelating agent lithium bis(trifluoroethyl)dithiocarbamate (LiFDDC). Methylmercuric chloride (CH_3HgCl) and dimethylmercury [$(CH_3)_2Hg$] can be extracted by supercritical CO_2 without chelating agent and modifier. The solubility of $Hg(FDDC)_2$ in supercritical CO_2 has been determined to be $5 \times 10^{-3}M$ at 50°C and 150 atm, which is about 3 orders of magnitude greater than that of the non-fluorinated analogue $Hg(DDC)_2$. Use of methanol (5%)-modified CO_2 further enhances the solubility of $Hg(FDDC)_2$ by a factor of 2.4. A small amount of water added to the sample matrix tends to facilitate the extraction of $Hg(FDDC)_2$ and CH_3HgCl. Potential applications of this *in situ* chelation-supercritical fluid extraction method for the preconcentration of mercury species and treatment of mercury contaminated wastes are discussed.

Supercritical fluid extraction (SFE) has become an attractive alternative to conventional solvent extraction for the recovery of organic compounds from environmental and biological samples because of several advantages, including increased speed, better recovery, and the reduction in both solvent usage and solvent waste generation.[1–4] To date, most of the published SFE work has focused on organic compounds, and few reports have dealt with SFE of metal ions and organometallic compounds. Wai and coworkers first reported the extraction of Cu^{2+} from liquid and solid materials using supercritical carbon dioxide containing lithium bis(trifluoroethyl)dithiocarbamate (LiFDDC) as an extractant.[5] These authors also showed that the solubilities in supercritical CO_2 of some metal–FDDC complexes, including those of Cu^{2+}, Ni^{2+}, Co^{3+}, and Bi^{3+}, are 2–3 orders of magnitude greater than those of the non-fluorinated analogues.[6] The use of fluorinated ligands for SFE of metal ions appears necessary in order to achieve significant recoveries of metals from liquid and solid materials. Addition of a modifier such as methanol to supercritical CO_2 alters the polarity of the fluid phase which may also enhance the extraction of metal chelates. However, no quantitative information regarding the effect of modifiers on the SFE of metal chelates is available in the literature. This paper reports an *in situ* chelation method for the extraction of Hg^{2+} from solid materials with supercritical CO_2 and methanol-modified CO_2, both containing LiFDDC as a chelating agent. The extraction of CH_3HgCl and $(CH_3)_2Hg$ from solid materials by supercritical CO_2 is also described.

EXPERIMENTAL

Reagents and materials

Lithium bis(trifluoroethyl)dithiocarbamate was synthesized according to a procedure outlined in the literature.[7] The starting material, bis(trifluoroethyl)amine, was obtained from PCR Chemicals (Gainesville, FL). Other chemicals used in the synthesis, including *n*-butyllithium (2.5*M* in hexane), carbon disulfide, and isopentane were obtained from Aldrich Chemical Co. (Milwaukee, WI). Sodium diethyldithiocarbamate, NaDDC, was purchased from Fisher Scientific Company (Pittsburgh, PA). The $Hg(FDDC)_2$ and $Hg(DDC)_2$ were prepared by mixing LiFDDC or Na(DDC) with an excess amount of Hg^{2+} in a buffered aqueous solution at pH 3. The resulting precipitate was extracted with chloroform, and the organic phase was washed with deionized water after phase

separation. Purification of $Hg(FDDC)_2$ and $Hg(DDC)_2$ was achieved by recrystallization from chloroform/ethanol (1:1 v/v) at 60°C. After evaporation of the chloroform, the crystals of mercury chelates were collected by filtration. An aqueous Hg^{2+} solution was prepared by dissolving a known amount of solid $Hg(NO_3)_2$ in deionized water.

Methylmercuric chloride standard solution and dimethylmercury (Alfa Chemical Co., Ward Hill, MA) were used as received. For the extraction of mercury compounds from the solid matrix, a known amount (usually 10 μg) of Hg^{2+}, CH_3HgCl or $(CH_3)_2Hg$ was spiked onto a cellulose-based filter paper (Whatman 42, 0.5 × 2 cm in size). For the preparation of standard samples of mercury for neutron activation analysis, we found it necessary to add a small amount of LiFDDC solution to the sample spiked with the Hg^{2+} compound in order to stabilize the Hg^{2+}. Otherwise, loss of mercury might occur during neutron irradiation and analysis.

Apparatus

All experiments were performed with a laboratory-built supercritical fluid extraction apparatus. SFC-grade CO_2 or CO_2 with 5% methanol (Scott Specialty Gases, Plumsteadville, PA) was delivered to the system using a microprocessor-controlled high-pressure pump (Haskel Inc., Burbank, CA). The pressure of the system was monitored to ±5 psi using a Setra Systems (Acton, MA) pressure transducer. The extractor consisted of an inlet valve (SUPELCO, Bellefonte, PA) and an outlet valve connected to a 3.5 mL commercial extraction cell (Dionex, Sunnyvale, CA). The extraction cell was placed in an oven that was temperature controlled by a thermostat. Fused-silica tubing (Dionex, 50 μm i.d. and 20 cm in length) was used as the pressure restrictor for the exit gas. The SFE system allows static and dynamic extractions to be performed by use of the outlet and inlet valves.

Extraction procedures

A glass tube plugged at the forward end with a piece of glass wool was used as a sample holder. Into the rear end of the glass tube, a filter paper spiked with 10 μg of Hg^{2+} was inserted, and 10 mg of solid LiFDDC was added. The rear end was plugged with glass wool and the sample tube was placed in the extraction cell. The extraction cell was immediately installed in the oven, heated to 50°C, and pressurized to 100 atm. After 20 min of static extraction, the exit valve was opened and the sample was extracted dynamically for 10 min. The tube was removed from the extraction cell and the filter paper was placed into a polyethylene vial which was then heat sealed for neutron irradiation. A standard consisting of a filter paper spiked with 10 μg of Hg^{2+} was also sealed in a polyethylene vial and irradiated together with the samples under identical conditions. The extraction efficiencies, as reported here, are the activities of ^{197}Hg found in the extracted samples times 100, divided by the activity of ^{197}Hg found in the standard. The SFE conditions for CH_3HgCl and $(CH_3)_2Hg$ were the same as in the Hg^{2+} experiments, except no LiFDDC was added to the sample.

Solubility measurements

A weighed amount (around 100 mg) of $Hg(FDDC)_2$ or $Hg(DDC)_2$ was placed in a glass sample tube. The sample tube was then plugged with glass wool at both ends and inserted into an extraction cell of known volume (0.57 mL). The sample was extracted at 50°C under 150 atm of CO_2 for 30 min. After this static extraction, the fluid phase was vented into a collection vial containing 4 mL of chloroform. The sample tube was removed from the cell and the empty cell was reinstalled into the oven. The system was then flushed with CO_2 for 20 min to collect any mercury complex that had precipitated within the system during depressurization. The total amount of the mercury complex collected in the chloroform solution was back-extracted with 2 mL of 50% Ultrex HNO_3. Aliquots of 0.5 mL of the acid solution were sealed in polyethylene vials for neutron activation analysis. The solubility was calculated from the amount of mercury collected in the chloroform divided by the volume of the extraction cell.

Neutron activation analysis (NAA)

All samples and standards were irradiated for 1 h in a 1 MW TRIGA nuclear reactor at a steady flux of 6×10^{12} n cm^{-2} s^{-1}. After irradiation, the samples were cooled for 24 h before counting. Each sample was counted for 200 s in a large-volume ORTEC Ge(Li) detector with a resolution (FWHM) of about 2.3 keV at the 1332 keV ^{60}Co peak. The 77.6 keV gamma peak from ^{197}Hg ($t_{\frac{1}{2}} = 65$ h) was used for the detection of mercury. The detector output was fed to a Nuclear Data 4096-channel pulse-height

analyser. The details of the NAA procedures are given elsewhere.[8]

RESULTS AND DISCUSSION

Solubilities of Hg(FDDC)$_2$ in supercritical CO$_2$ with and without modifier

Supercritical fluid extraction of metal chelates in CO_2 has received little attention in the literature. This is believed to be caused by the low solubilities of these compounds in supercritical fluids. Several studies have been reported on the separation of metal chelates by supercritical fluid chromatography using CO_2 as a mobile phase, but no solubility data were given.[9,10] In a recent study, we observed that a number of metaldiethyldithiocarbamates (DDC) exhibited limited solubilities in supercritical CO_2.[11,12] It was also found that if fluorine was substituted for hydrogen in the ligand, as in the case of bis(trifluoroethyl)dithiocarbamate (FDDC), the solubilities of the fluorinated metal chelates of Cu, Co, Ni, and Bi in supercritical CO_2 at 50°C and 100 atm were increased by 2–3 orders of magnitude. The solubilities of these metal–FDDC complexes were measured by their absorption in the UV–Vis region using a high-pressure view-cell described previously.[6] The spectroscopic analysis method can not be applied to Hg(FDDC)$_2$ because it does not have characteristic absorption peaks in the UV–Vis region. Therefore, we measured in this study the solubility of Hg(FDDC)$_2$ by NAA as the amount of the metal chelate dissolved in a known volume of CO_2 in an extractor at fixed T and P. The procedure described in the experimental section for the solubility measurement was tested with Cu(FDDC)$_2$ whose solubility in supercritical CO_2 had previously been determined by the spectroscopic method.[6] The chemical analysis method gave a solubility value for Cu(FDDC)$_2$ within 5% of that determined by the UV–Vis spectroscopic method, thus proving the reliability of the method used in this study. The solubilities of Hg(DDC)$_2$ and Hg(FDDC)$_2$ determined at 50°C and 150 atm are $(8.2 \pm 0.6) \times 10^{-6} M$ and $(5.0 \pm 0.4) \times 10^{-3} M$, respectively. Thus, the solubility of the fluorinated complex Hg(FDDC)$_2$ in supercritical CO_2 is about three orders of magnitude greater than that of the nonfluorinated analogue Hg(DDC)$_2$ under the conditions used.

Another factor that affects the solubility of metal chelates in supercritical CO_2 is the presence of a polar modifier such as methanol. The solubilities of Hg(FDDC)$_2$ and Hg(DDC)$_2$ increased by a factor of 2.4 and 3.6, respectively, when 5% methanol was added to CO_2 (Table 1). The critical temperature and pressure for the methanol (5%) modified CO_2 are known in the literature ($T_c = 41.8$°C and $P_c = 73.6$ atm).[13] Our experimental T and P were kept significantly higher than the T_c and P_c of the modified fluid phase to ensure that the extraction occurred in the supercritical fluid region. The strong solubility increase when methanol is added as a modifier is a useful feature for the SFE of metal-chelates.

Effects of methanol modifier on the extraction of mercury

The efficiency of the SFE of solutes from solid matrices generally depends on at least the following three factors: (1) the analyte solubility in the supercritical fluid, (2) the interactions between the substrate and the analytes, and (3) the kinetics of the fluid to transport analytes from active sites on the matrix. In this study, a cellulose-based filter paper was used as a solid support where both strong chemical and physical interactions between solute and matrix can lead to slow extraction of ionic analytes. In our initial SFE experiments with mercury compounds, we used 10 μg Hg^{2+} (about 5×10^{-8} moles) spikes on 2 × 0.5 cm filter paper and 10 mg LiFDDC (3.8×10^{-6} moles) as the chelating agent. The ligand was in large excess relative to the mercury ions in these experiments. A static extraction time of 20 min at 50°C and 100 atm, followed by a dynamic extraction for 10 min at the same T and P was chosen for extraction efficiency studies. The results of the SFE of Hg^{2+} with CO_2 under these conditions are summarized in Table 2. The extraction efficiency of Hg^{2+} from filter paper with pure CO_2 in the absence of LiFDDC was insignificant (<2%). With the addition of LiFDDC, some Hg^{2+} was extracted by CO_2, but the extraction efficiency was low (8–12%) for dry samples. This could

Table 1. Solubility of Hg(FDDC)$_2$ and Hg(DDC)$_2$ in pure and modified CO_2 at 150 atm and 50°C

Metal chelate	Solubility (*mol/L*)	Ratio (*FDDC/DDC*)

CO_2 + 5%MeOH	10 *mg*	Wet	99.5 ± 2.0

*Average value of three runs.

not have been caused by a solubility limitation because the Hg^{2+} spike amounted to less than 1% of the solubility limit of $Hg(FDDC)_2$ in the fluid phase. This low extraction efficiency is probably due to strong interactions between Hg^{2+} and the cellulose matrix.

The extraction efficiency for Hg^{2+} increased from 10 to 84% when a small amount of water (10 μL) was added to the filter paper. The presence of water probably facilitates the chelation and transport of $Hg(FDDC)_2$ from the cellulose matrix to the fluid phase. The water may also serve as a matrix modifier by blocking active sites of the matrix and thus reducing sorption of the solute on the active sites of the polar matrix. Similar observations were reported in the literature for the extraction of polar compounds from polar matrices by supercritical CO_2.[14]

The efficiency of extracting Hg^{2+} can be further enhanced when methanol is added to the fluid phase. The results of extracting Hg^{2+} using a commercially available SFC grade CO_2 containing 5% methanol are also summarized in Table 2. The methanol-modified CO_2 increases the extraction efficiency of Hg^{2+} from 10% to 92% under dry conditions and from 84 to >99% under wet conditions. The large increase in SFE efficiency is most likely due to enhanced interactions between the solute and the modified solvent. Thus, quantitative extraction of Hg^{2+} directly by supercritical CO_2 from a cellulose matrix becomes possible with methanol as a solvent modifier and water as a matrix modifier.

The rate of extraction of Hg^{2+} from the filter paper using this *in situ* chelation/SFE approach was measured using CO_2 modified with 5% methanol and 10 μL water deposited into the matrix. The extraction process consisted of a 20 min static extraction step, followed by a dynamic extraction step of varying time lengths. The experimental results show that quantitative extraction of Hg^{2+} was virtually achieved after 5 min of dynamic extraction. Variations of the static extraction time as shown in Fig. 1 (with a constant dynamic extraction time of 5 min) indicate that the efficiency increases rapidly in the first 10 min of extraction, with over 80% of Hg^{2+} removed after 5 min and about 90% of Hg^{2+} removed at the end of 10 min. After 20 min of static extraction and 5 min of dynamic extraction, over 97% of the spiked Hg^{2+} was removed. The standard extraction times we decided to use were therefore 20 min of static extraction followed by 10 min of dynamic extraction.

Extraction of methylmercury and dimethylmercury with supercritical CO_2

Interest in the speciation of mercury in environmental analysis stems from the marked

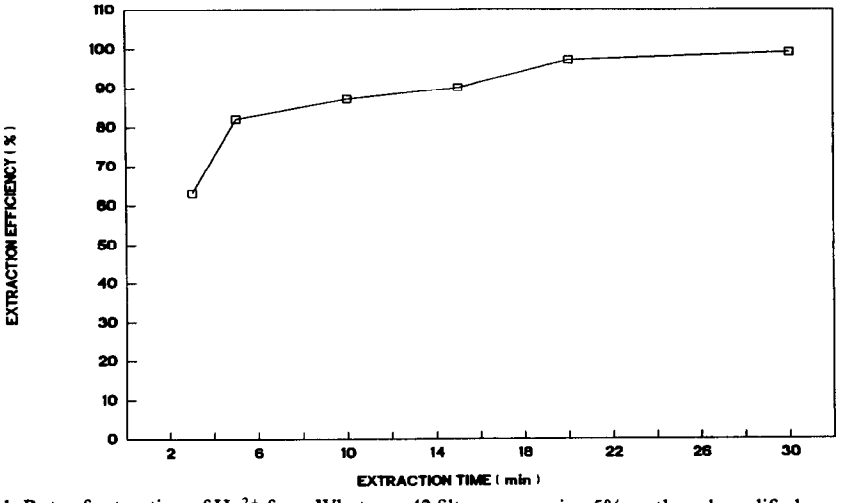

Fig. 1. Rate of extraction of Hg^{2+} from Whatman 42 filter paper using 5% methanol-modified supercritical CO_2 containing LiFDDC at 50°C and 100 atm. Extraction conditions: 10 μg Hg^{2+}, 10 mg LiFDDC, 10 μL H_2O, and 5 min of dynamic flushing following each of the specified static extraction times.

difference in toxicity between Hg^{2+} and organomercurial compounds.[15-17] The methylmercury compounds have been implicated in a number of mercury poisoning episodes.[18] Supercritical fluid extraction of CH_3HgCl and $(CH_3)_2Hg$ was investigated in this study by spiking each methylmercury compound separately on the cellulose based filter papers. The extraction efficiencies for CH_3HgCl and $(CH_3)_2Hg$ from the filter paper by supercritical CO_2 at 100 atm and 50°C are given in Table 3. The samples were prepared by spiking 10 μg of CH_3HgCl or $(CH_3)_2Hg$ on the filter paper similar to that described for the Hg^{2+} experiments. Methylmercuric chloride was spiked with the standard CH_3HgCl solution obtained from Alfa Chemical Company. Dimethylmercury (boiling point 93°C at 1 atm) is a liquid at room temperature, therefore it was introduced directly onto the filter paper in its pure liquid form. The samples were extracted under the same conditions (20 min static followed by 10 min dynamic extraction) as the Hg^{2+} experiments except no LiFDDC was added. The results indicate that methylmercury can be quantitatively extracted from the filter paper by pure CO_2 when 10 μL of water is used as a matrix modifier. Apparently, CH_3HgCl is soluble in supercritical CO_2 and no ligand is needed for its extraction from the filter paper. For dimethylmercury, quantitative extraction from the filter paper by supercritical CO_2 can be achieved even without the presence of water. In this study, the extraction efficiencies were determined by comparing the extracted sample with a standard filter paper treated by the same analytical procedures. The filter papers were sealed separately in polyethylene vials during irradiation and counted without opening the container to avoid volatilization of the mercury compounds. Since monomethylmercury and dimethylmercury can be extracted directly by supercritical CO_2 without the use of a ligand, this method may be used to separate the methylmercury compounds from Hg^{2+} in environmental samples.

Table 3. Extraction efficiency of CH_3HgCl and $(CH_3)_2Hg$ from the filter paper with supercritical CO_2 at 100 atm and 50°C

Sample No.	Matrix condition	Extraction efficiency (%)
	CH_3HgCl

#3	Wet	99.2 ± 1.0
#4	Wet	100.0 ± 1.0
	CH_3HgCH_3	
#1		99.2 ± 1.0
#2		99.0 ± 1.0

CONCLUSIONS

Methylmercuric chloride and dimethylmercury can be extracted directly from cellulose based filter paper with neat supercritical CO_2. Mercuric ions (Hg^{2+}) adsorbed on the filter paper can be effectively extracted by an *in situ* chelation/SFE technique using LiFDDC as a chelating agent. Water and methanol can significantly improve the extraction efficiency of Hg^{2+} from the polar matrix. The solubility of $Hg(FDDC)_2$ in supercritical CO_2 at 50°C and 150 atm is about three orders of magnitude greater than the non-fluorinated analogue $Hg(DDC)_2$. The choice of ligand is important for this *in situ* chelation/SFE technique. LiFDDC happens to be moderately soluble in supercritical CO_2 and complexes effectively with Hg^{2+} to form a stable chelate which also has a sufficient solubility in the fluid phase. The polar cellulose matrix used in this study should resemble other polar matrices in biological samples such as plant and animal tissue. The SFE technique described in this paper thus offers a potential new approach for the preconcentration of mercury ions (Hg^{2+}) and methylmercury compounds from environmental samples for analytical purposes and for treatment of mercury contaminated wastes.

HIGH PERFORMANCE OPTICAL ABSORBANCE DETECTORS BASED ON LOW NOISE SWITCHED INTEGRATORS

HANGHUI LIU, PURNENDU K. DASGUPTA* and HONG J. ZHENG
Department of Chemistry and Biochemistry Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 11 *February* 1993. *Revised* 17 *March* 1993. *Accepted* 18 *March* 1993)

Summary—Optical absorption detection is the most common analytical measurement principle in liquid phase analysis. The current state-of-the-art of commercially available detectors exhibit peak-to-peak (p–p) noise levels in the range of 1×10^{-5}–2×10^{-5} absorbance units (10–20 μAU). Using circuitry based on newly available switched integrator integrated circuit (IC) packages, it is possible to construct inexpensive absorbance detectors with p–p noise levels as low as 3 μAU under actual use conditions. The necessary electronics are described and performance data are reported with light emitting diodes (LEDs) as light sources. Even in the capillary format with a rectangular capillary (50 × 1000 μm cross section) with a slitwidth < 50 μm and with the 1000 μm dimension as the nominal pathlength, p–p noise levels of 10 μAU are observed, from which a concentration limit of detection (LOD) of 10 n*M* for bromothymol blue (BTB) can be estimated with a 660 nm light source.

The wide use of colorimetric methods for analysis first came into vogue in the 1940s. Snell and Snell[1] report that 23% of all articles on analytical chemistry published in 1946 utilized colorimetry. Even today the measurement of optical absorbance (typically following separation, selective reaction, *etc.*) is the most common principle used for quantification in liquid phase analysis. Current practice commonly involves absorbance measurement in a flowing stream, *e.g.* in flow injection analysis (FIA) or high performance liquid chromatography. Relative to static measurements, the detection of a transient signal due to the analyte over a continuously measured background is not only more convenient and more easily automated, significant improvement in limits of detection results. Assuming that flow-induced noise of the background absorbance is not the limiting factor, the intrinsic detector noise becomes the parameter that determines LOD. A survey of specifications of flow-through optical absorbance detectors available from major manufacturers (Applied Biosystems, Beckman Instruments, Dionex Corp., Perkin-Elmer Corp., Shimadzu Scientific, Spectra-Physics Analytical, Varian Associates, Waters Associates) available at the time of this writing indicate that p–p noise levels with integration time ≤ 1 sec are 10–20 μAU. This is equivalent to a change in light intensity of 2–3 parts in 10^5 and is particularly striking when one considers that at the transducer level what is being monitored is a small decrease in a large standing current. Using an 814 nm LED with an output of 35 mW, voltage–frequency conversion and measurements in a static solution, Imasaka *et al.*[2] were able to achieve a record low noise level of 0.75 μAU. This used an integration time of 50 sec, however, unacceptably large for flow-through applications. Further, to eliminate power supply noise, it was necessary to operate the system with batteries; which was not always practical.

When absorbance detection must be accomplished in the capillary format, *e.g.*, for micro-column liquid chromatography or capillary electrophoresis, very narrow slit widths must be used to minimize stray light. The resulting decrease in light throughput further degrades S/N performance. Thermo-optical absorbance detection methods with a laser source are capable of very low noise levels.[3] These methods do not involve a simple measurement of the change in transmission of a probe beam of the desired wavelength. For the same absorbance change, the change in the signal is much greater at the transducer level in such measurements relative to that in conventional measurements of

*Author for correspondence.

transmission intensity. Unfortunately, practical affordable variable wavelength absorbance detectors based on the thermo-optical principles are not on the horizon.

All high sensitivity absorbance detectors use a reference measurement of the incident light (or some portion thereof) and a log ratio circuit then produces the absorbance output from the reference photodetector and transmission photodetector current inputs. It is desirable to keep these photocurrents at a relatively high level (*i.e.* use a bright light source) to minimize the relative contributions of noise picked up from a multitude of sources. It has recently been shown that sufficiently high light intensities can be obtained by operating LEDs in a pulsed mode (these sources are essentially monochromatic) and it is possible to reach very low noise levels using high speed personal computer based data acquisition and digital integration.[4] In this study, it was shown that at a sampling rate of 22 kHz, the standard deviation of the measured absorbance decreases linearly with the square root of the integration period, reaching 2 μAU at an integration period of 0.5 sec. No further improvement was observed at longer integration periods, presumably other sources of noise, that are not adequately compensated for by this type of integration, become the limiting factor.

Precise measurement of low levels of current is also important in many other fields. A pressing need, for example, was perceived for the improvement of precision in the measurement of pA level X-ray induced photocurrents in computerized tomography scanners. In this case, any increase in measurement precision translates into a reduction of the necessary exposure of the patient to ionizing radiation. A low noise (10 μV rms), wide dynamic range (120 dB) low bias current (100 fA) switched integrator was expressly developed for this purpose.[5] These relatively inexpensive IC packages are also ideal for photocurrent measurements in optical absorbance detectors. Each package contains two independent integrators, one can be devoted to the reference and the other to the transmission photodetector and the respective integrator outputs are then processed by the log ratio converter. In this note, we describe an

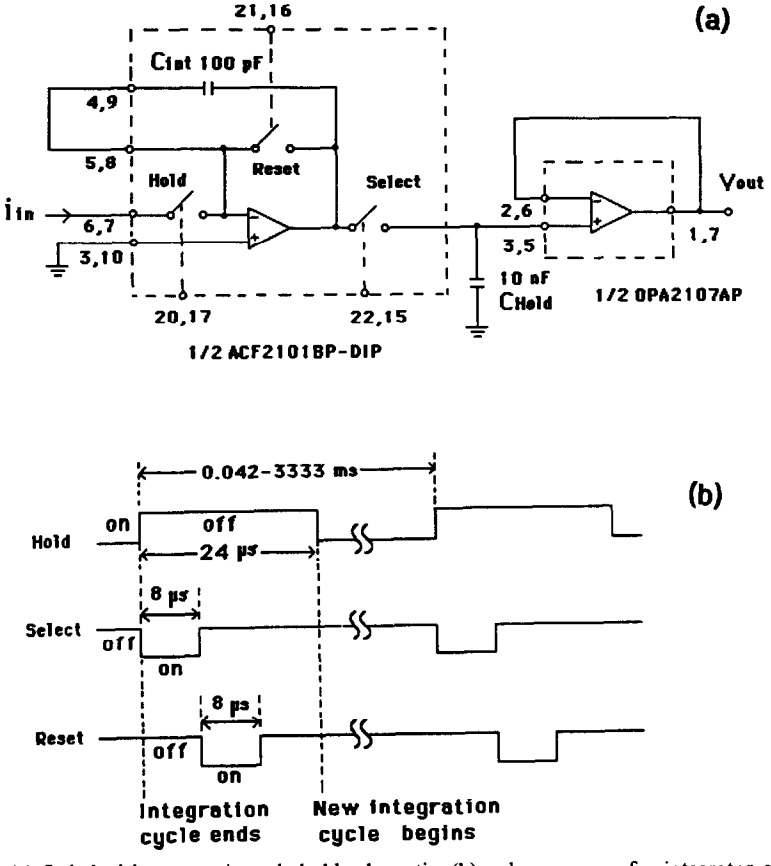

Fig. 1. (a) Switched integrator/sample-hold schematic; (b) pulse sequence for integrator operation.

absorbance detector based on the switched integrator and evaluate its performance.

EXPERIMENTAL

Detector electronics

The dual in-line package version of the ACF2101 IC (ACF2101BP-DIP, Burr-Brown, Tucson, AZ) was used. The block diagram of half of a ACF2101 device with its output processed by a high input impedance operational amplifier ($\frac{1}{2}$ OPA2107) is shown in Fig. 1a. The designation of the pinouts indicate individual halves of each device, *i.e.*, pin 21 is the reset input for one half of the integrator and pin 16 is that for the other half, *etc.* Each integrator has three logic operated switches: hold, reset and select. With the hold switch on and the reset switch off, the device is in the "integrate mode". Under this condition, the integrator output slews to the maximum permissible negative voltage (~ -10 V) at a rate depending on the input current and the integration capacitance. The IC contains an on-board 100 pF integration capacitor, this can be augmented by external capacitors if desired; additional capacitance was not used in the present design. When the hold and reset switches are both off, the device is in the hold mode, the output of the integrator remains constant (except for droop). When the reset switch is enabled, the integration capacitor is discharged and the integrator output drops to zero. The hold switch, the hold capacitor and the sample and hold amplifier (OPA2107) together effectively constitute a low noise (the integration process is very effective at sampling frequencies greater than 60 Hz for rejecting power line noise), high gain current–voltage converter without the use of high value feedback resistors and conventional transimpedance amplifier designs that are prone to leakage current errors and noise pickup. Figure 1b shows the pulse sequence. At the end of an integration cycle, the hold switch is opened to hold the output of the integrator constant. This value is transferred to the 10 nF hold capacitor by closing the select switch. The select switch then opens and the output of the OPA2107 remains constant during the next integration cycle; in effect the select switch, the hold capacitor and OPA2107 form a sample/hold circuit. After the select switch is opened, the integrator is reset by a brief pulse and the hold switch then closes to begin integration. The integration cycle repeats with a frequency of 0.3–24,000 Hz, the value is chosen depending on the input current level (*vide infra*). A longer integration period is chosen for low currents; using overly long integration periods at higher current levels can saturate the integrator output. The integration period is typically in the millisecond time scale whereas the hold, select and reset pulses are, respectively 24, 8 and 8 μS wide. Except at the higher end of the sampling frequency range used, each integration cycle is dominated by the integration period.

The general functional diagram is shown in Figure 2. Figure 3 shows the actual implementation of each functional component. The fundamental clock frequency of 24 MHz is generated by a crystal oscillator (U1, Bomar Crystal oscillator). A series of 10 decade counters (U2–U6, 74LS390) then reduce the initial clock frequency in steps all the way to 0.3 Hz. The range of 0.3–12 Hz sampling frequency is necessary only for very low levels of photocurrent and when pulses of these low frequencies are generated on-board, the noise in the overall instrument output is dominated by noise pickup from this source unless precautions are taken. In normal operation, we therefore use switch S1 to bypass U2 unless sampling frequencies in the range of 0.3–12 Hz are of interest—thus the lowest frequency available in this mode is 30 Hz.

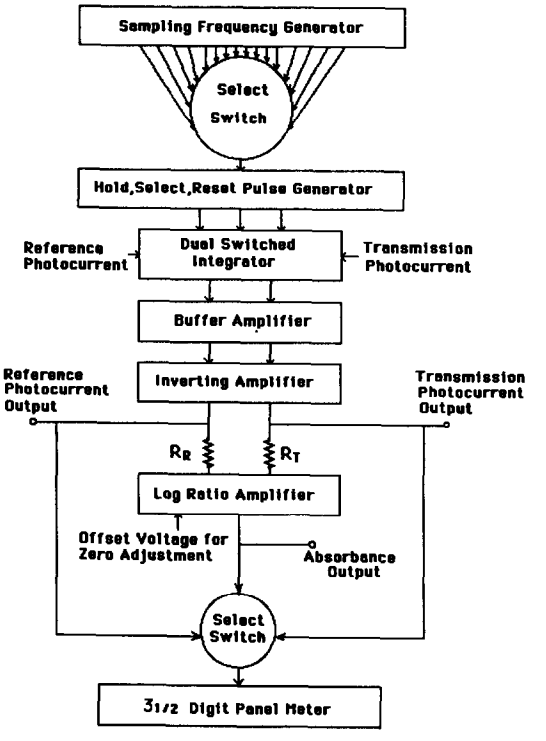

Fig. 2. Block diagram of instrument.

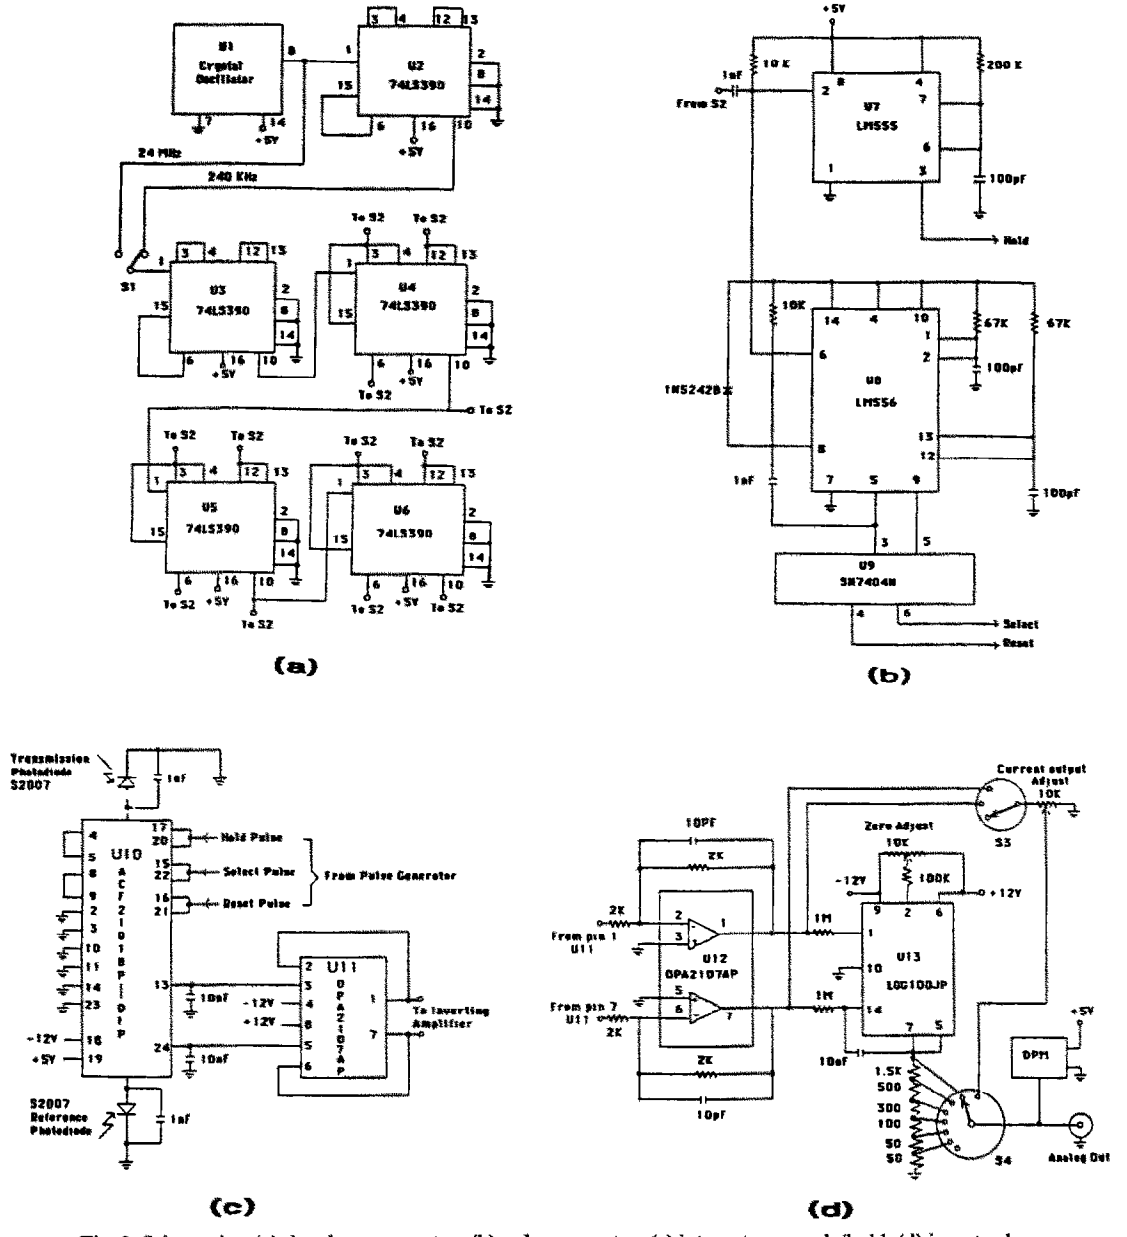

Fig. 3. Schematics: (a) time base generator; (b) pulse generator; (c) integrator-sample/hold; (d) inverter-log ratio amplifier-display.

Further, we isolate the entire frequency generator and selector switch portion (Fig. 3a) in a separate board and a small grounded metallic enclosure which is put inside the main enclosure housing other components. Note that frequencies above 24 KHz are not used at all. For those interested in building such a device it may be preferable to use a lower frequency time base and fewer decade counters.

Indicated frequency outputs are connected to switch S2 (not shown in Fig. 3, a 12-position rotary switch) that connects any one selected frequency to the pulse generator circuit utilizing a 555 timer and a 556 dual timer as shown in Fig. 3b. The desired pulse trains shown in Fig. 1b are generated by this circuit, the reset and select pulses need to be inverted with a inverter (SN7404N) before transmission to the integrator. Note that the hold, select and reset pulses are connected in common to both halves of the integrator.

Photodiode inputs are connected to the integrator (U10, Fig. 3c) using 1 nF input capacitors. In our specific detector, there are provisions for providing either fiber optic or photocurrent inputs (through shielded leads

terminating in BNC connectors) to the front panel. This input is selected by a DIP switch. When fiber optic inputs are connected (SMA connectors), photodiodes mounted inside the instrument and sealed from extraneous light provide the photocurrents to U10. The printed circuit board housing U10 contained imprinted guard loops to protect critical pins from noise pickup as suggested by the manufacturer. The U10 output is processed by U11, operating with unity gain as a sample/hold amplifier. The output of U11 is negative and it is necessary to invert this before processing by the log ratio amplifier that accepts only positive inputs. This task is accomplished by U12 (Fig. 3d). The log ratio amplifier (U13) accepts current inputs. Voltage outputs from U12 are converted to current by reference resistor R_R and transmittance resistor R_T. Both were 1MΩ in this application but if reference and transmittance currents are vastly different (this is dependent on the flow cell design), R_R and R_T should be so chosen as to have essentially equal current inputs into pins 1 and 14 of U13. U12 outputs are also sent to switch S3. Either one (or none) of these photocurrent outputs may be selected by this switch and the value can be scaled by a 10 kΩ potentiometer, displayed and output at analog output terminals if so selected by switch S4 (switch S4 and S3 are actually separate decks of a multi-tier switch). A 10 kΩ potentiometer provides the zero adjust control for U13 which is configured to have an output of 5 V/AU (DIP switch selectable to 1 and 3 V/AU as well). If selected by S4, the absorbance is scaled by a voltage divider, output to the digital display (0.04–1.999 AUFS, readability 0.05% of FS) and to the analog output socket.

Power to the electronics is provided by a wall-mounted power supply (±12 V, +5 V). The instrument is enclosed in a metallic enclosure (30 × 17.5 × 10 cm). The component cost for fabrication of the detector electronics is under $350. A commercial version of this detector is available from Bern Tech-Lite Corp. (Lubbock, TX).

Flow cell designs

The detector electronics was tested with several different flow cell designs previously described[4] and the modified sandwich cell.[6,7] The absorbance noise levels appeared independent of cell design. No difference was perceived between the results when the cell was dry and with water flowing under gravity through the cell.

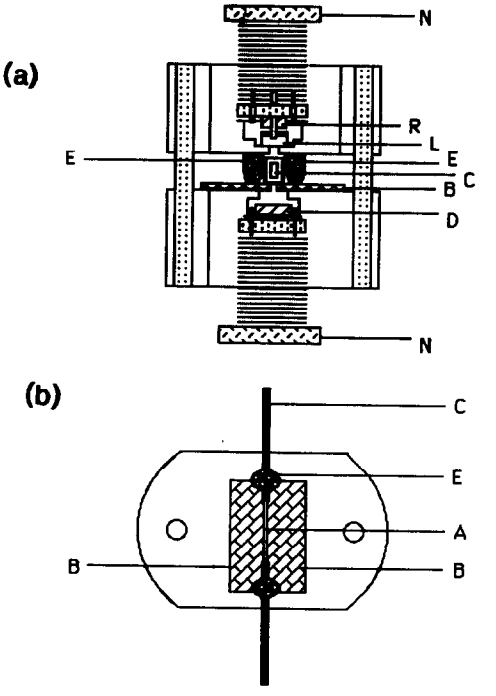

Fig. 4. Design of the capillary flow cell. Except as stated, the reported data were obtained with a 605 nm LED as the light source in demountable Z-path flow cell as shown in Fig. 9 of Ref. 4.

An LED-based detector design using the present electronics was also tested for use with rectangular capillaries used for capillary electrophoresis.[8] The design is shown in Fig. 4. First, the relevant area of the glass capillary is

completely covered with opaque epoxy adhesive (made by mixing a generous amount of activated carbon with epoxy adhesive). After curing, a small area of the epoxy is removed with a sharp scalpel blade from opposing sides of the capillary to create optical slits on the narrow edge. This is then mounted in the cell arrangement shown in horizontal cross section in Fig. 4a. The cell is composed of two aluminum blocks held together by screws. On one side, LED L (660 nm, H-1000-L, I.I. Stanley Co., Battle Creek, MI) sits over the reference photodetector R (which makes use of the light retroreflected from the front dome of the LED). In the second block is mounted detector D (R and D are both polymer encapsulated silicon photodiodes, S2007, Electronic Goldmine, Phoenix, AZ). Rectangular capillary C passes between the two blocks (through the plane of the paper). An excess amount of epoxy E both holds the capillary in place and acts as a spacer to keep the capillary from being crushed by the two blocks. Components are held in place by, and necessary cables exit through, hollow knurled fittings N on either side. The slit and affixing arrangements on the second block are shown in vertical cross section in Fig. 4b. An initial slit of 100–150 μm is created by two razor blades B. The epoxy covered capillary, with the optical slit already created on it, is now appropriately positioned, oriented and then cemented on the gap between the two razor blades. More opaque glue is now applied to eliminate stray light. The two blobs of adhesive E act as the spacer. After the cell is fully assembled, all exposed areas are covered up by opaque tape to eliminate extraneous light.

*Dry cell test conditions.

Approximately 1 mm length of the capillary is illuminated, constituting the optical aperture A.

The LEDs were operated in the DC mode (continuously on) from a constant current power supply. No efforts were made to use a battery operated power source to further reduce noise and drift originating in the power supply. The drive current was changed to simulate different light levels so that the performance could be evaluated at different light levels.

Identical experiments were performed with a tungsten lamp filtered with a 590 nm interference filter (half bandwidth 15 nm) for purposes of comparison.

RESULTS AND DISCUSSION

The sampling frequency chosen is based on the photocurrent level and the ranges used are shown in Table 1. The performance of the instrument even as a picoammeter is attractive. Figure 5 depicts the reference and transmittance photodiode currents measured as a 605 nm LED was driven over a current range of 5μA–50 mA. Note that at the low end, essentially no emission is visible to the naked eye. Table 2 contains the important noise specifications. It will be apparent that the observed noise levels are essentially independent of the specific wavelengths of the LED and are dependent on the absolute level of the photocurrents, reaching a noise level of 2–3 μAU when the photocurrent levels reach several μA. Figure 6 shows the noise levels observed with photocurrent levels of several nA to several hundred nA, respectively. Performance data for both the new design and the older design involving direct photocurrent to voltage conversion and processing by a log ratio amplifier are shown for comparison.

High intensity continuum sources coupled to high throughput low-resolution monochromators are typically used in commercial detectors; microampere levels of detector photocurrent are typical in such instruments. What is striking is that even at sub-nA photocurrents, the present electronics still provides very usable noise levels (10^{-4} AU). This would allow the use of both sources and detectors well beyond ranges within which they, respectively emit and respond optimally.

The improved performance of the present design is not dependent on the use of an LED as the light source. Figure 7 shows that at comparable photocurrent levels, noise levels obtained with an LED and a tungsten lamp source are essentially the same, albeit admittedly the baseline drift is greater with the latter source.

Actual outputs from the detector, both with a cell of conventional dimensions (path length 6 mm) and with the rectangular capillary are shown in Figs 8a and b, respectively. The noise level in the capillary cell is 10 μAU under dry

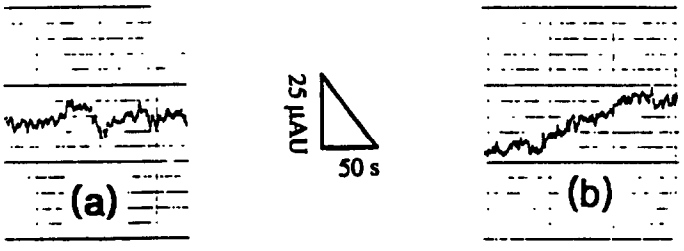

Fig. 7. Noise levels. (a) 605 nm LED: $I_{ref} = 310$ nA, $I_{transm} = 250$ nA; (b) W-lamp, 590 nm interference filter: $I_{ref} = 260$ nA, $I_{transm} = 255$ nA.

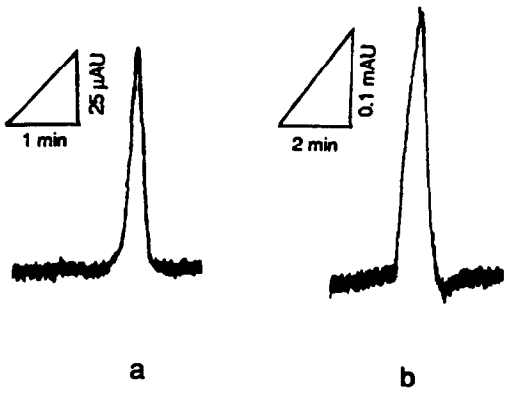

Fig. 8. Detector performance: (a) conventional flow cell (6 mm pathlength), 4.8 n*M* bromothymol blue injected, estimated dilution factor at peak maximum is 2. Carrier is dilute NaOH flowing under gravity. (b) Rectangular capillary flow cell (1 mm path length), 95 n*M* bromothymol blue injected, sample is essentially undiluted at peak maximum.

cell test conditions. With liquid flow in the cell this noise increases marginally but still permits an LOD of 10 n*M* for BTB even though the absorption of BTB ($\lambda_{max} = 615$ nm) is not well matched to the emission of the 660 nm emitter used. This performance exceeds that of any commercially available detector available for use with capillaries. For the conventional cell, the noise level is even lower, 3 μAU. We feel therefore that the dual switched integrator based absorbance measurement approach is a particularly attractive and simple technique that can provide performance levels surpassing those of current commercially available detectors.

(*Received* 5 *February* 1993. *Revised* 22 *March* 1993. *Accepted* 22 *March* 1993)

Summary—The dissociation equilibria of di(2,4,4-trimethylpentyl) phosphinic acid, mono(2,4,4-trimethylpentyl)phosphinic acid, di(*n*-octyl)phosphinic acid and mono(*n*-octyl)phosphinic acid have been studied in ethanol–water mixtures by potentiometric titration at 25°C. These data have been analysed both graphically and numerically using the program LETAGROP-ZETA.

The obtained pK_a values have been correlated with the corresponding values in water, determined both indirectly by means of extraction measurements and by estimation using the suitable Hammett equation.

Organophosphorus acid compounds have attained importance in recent years in the separation by solvent extraction of many metal ions on a commercial scale.[1–3] Among these, alkylphosphinic acids have been reported to possess higher separation factors for successive members of chemically similar groups such as lanthanides[4,5] actinides,[6] cobalt and nickel[7,8] and other metal ions.[9,10,11]

In solvent extraction chemistry the knowledge of the acidity constants as well as the interaction constants between the components of an extracting system is essential in order to clarify the processes that take place in solution and to ascertain the stoichiometry of the extracted species. With such knowledge it is possible to design optimal conditions for separation or purification steps in various technical applications.

However, the low water solubility of long-chain organophosphorus acid compounds prevent the determination of pK_a values in water. Nevertheless, it is possible to evaluate the extracting behaviour of an organophosphorus acid compound towards a particular metal[12] from the pK_a in 75% (v:v) ethanol–water. For this purpose, the following empirical relationship has been proposed:

$$pH_{0.5} = A\,pK_a + B\nu_{P=O} - C$$

where $pH_{0.5}$ is the pH at 50% of extraction of a given metal, pK_a and $\nu_{P=O}$ are the acidic dissociation constant in 75% (v:v) ethanol–water and the characteristic frequency of infrared absorption for P=O group, respectively. A, B and C are constants which depend on the extracted metal.

In the present work the acidity constants of some alkylphosphinic acids in mixtures of ethanol–water have been determined potentiometrically. These constants have been correlated with the pK_a values in water, determined indirectly by distribution measurements and, alternatively, with the values estimated by means of the Hammett equation.

EXPERIMENTAL

Reagents and solutions

Mono(2,4,4-trimethylpentyl)phosphinic acid (H[(TMP)(H)P]), mono(*n*-octyl)phosphinic acid (H[(O)(H)P]) and di(*n*-octyl)phosphinic acid (H[DOP]) were synthesized and purified as described elsewhere.[13]

Bis(2,4,4-trimethylpentyl)phosphinic acid (H[DTMPP]) were supplied by Cyanamid as Cyanex-272 and purified as described in the literature.[14]

Sodium hydroxide solution (Merck p.a.) were prepared in ethanol–water mixture and was standardized against perchloric acid.

Procedure

Potentiometric measurements. The acidity constants of different organophosphinic acid compounds were determined by potentiometric titration of an ethanol–water solution of the corresponding acid with 0.1 mol/dm^3 NaOH at 25°C.

The mef measurements were determined in the range $3 < pH < 7$ using a CRISON Digilab 517 pH meter equipped with a Metrohm AG 9100 combined glass electrode. The concentration of acids HA was varied from 0.006 mol/dm^3 to 0.050 mol/dm^3. Previously the electrode was standardized using Gran plots.[15]

Extraction measurements. The distribution experiments were carried out by shaking mechanically, in special stoppered glass tubes, 10 cm^3 of organic phase (toluene) containing C mol/dm^3 of an organophosphinic acid, with an equal volume of an aqueous phase having composition 0.05 mol/dm^3 (Na^+, H^+) NO_3^-, until the equilibrium was achieved. The concentration of the organophosphinic compound was determined in the aqueous phase, analysing the phosphorus concentration by ICP spectrometer, and the pK_a was determined as described in the literature.[16]

TREATMENT OF DATA

From the experimental values of emf (E) and volume V_T, values of z and $-\log[H^+]$ were determined for each initial concentration of acid C_A, where z is the formation degree[17] defined as:

$$z = \frac{H_{TOT} - [H^+]}{C_A} \quad (1)$$

where $[H^+]$ is the hydrogen concentration calculated with the equation

$$E = E_0 + g \log[H^+],$$

$$g = 59.15 \text{ mV at } 25°C \quad (2)$$

and H_{TOT} is the hydrogen concentration calculated as:

$$H_{TOT} = \frac{V_0 H_0 + V_A C_A - V_T C_T}{V_0 + V_A + V_T} \quad (3)$$

where V_0, V_A and V_T are the initial, acid, and NaOH volumes, respectively, C_T is the NaOH concentration and H_0 is the initial concentration determined previously using Gran plots.

An example of z *vs.* pH plot is given in Fig. 1.

The experimental data obtained have been treated graphically by using normalized curves.[18] Afterwards, a numerical treatment by means of the program LETAGROP-ZETA[19] has been performed in order to confirm the proposed model and refine the values of the constants obtained graphically.

As $z \leqslant 1$ and polynuclear complexes have been excluded because plots of z *vs.* $-\log[H^+]$ are independent of the total concentration of organophosphorus compound, it can be assumed that only HA and A^- species of organophosphinic acids are in solution and the dissociation equilibria can be written as:

$$HA = A^- + H^+ \quad (4)$$

and K_a is the dissociation constant defined as

$$K_a = \frac{[A^-][H^+]}{[HA]}. \quad (5)$$

Taking into account the mass balance equations

$$H_{TOT} = [H^+] + [HA], \quad (6)$$

$$C_A = [A^-] + [HA], \quad (7)$$

and substituting equations (5), (6) and (7) in equation (1) the following expression can be written:

$$z = \frac{[HA]}{[HA] + [A^-]} = \frac{[H^+]K_a^{-1}}{1 + K_a^{-1}[H^+]}. \quad (8)$$

Defining a normalized variable $u = [H^+]\,K_a^{-1}$ and substituting, the expression (8) can be written as:

$$z = \frac{u}{1+u}. \quad (9)$$

Comparing the experimental curves z *vs.* $-\log[H^+]$ with the theoretical curves z *vs.* $\log u$, from the position of best fit the value of K_a can be determined as the difference:

$$-\log K_a = -\log[H^+] + \log u.$$

Once the estimated values of the constants were obtained graphically for each acid, the experimental data were treated numerically using the program LETAGROP-ZETA in order to confirm the proposed model and refine the graphical values.

In this program the computer searches for the best set of constants that minimizes the sum of squares errors, defined by

$$U = \Sigma(z_{exp} - z_{calc})^2 \qquad (10)$$

where z_{exp} is the value obtained experimentally and z_{calc} is the calculated value obtained by solving the mass balance equation. The program also calculates the standard deviation

$$\sigma(Z) = (U/N_p - 1)^{1/2}$$

where N_p is the total number of experimental points.

RESULTS AND DISCUSSION

The obtained experimental results in hydroalcoholic solvents are given in Table 1. The two calculation methods used show a very good agreement and the standard deviation values are satisfactory. All the obtained pK_a values are in the range 3.6–5.5. Although Danesi *et al.*[20] point out approximate pK_a values of 6 for phosphinic acids in alcohol–water mixtures (75% v:v), these values are not directly comparable with those obtained here because it is not clear what alcohol has been used in their work. Dialkylphosphinic acids show pK_a values 1.4–1.8 units higher than those of the corresponding monoalkylphosphinic acids. This fact can be explained by means of the higher electron-donor capacity of the alkyl group with respect to the hydrogen, that destabilizes the anionic species. In the same way, the higher electron-donor ability of the branched substituents, compared to their linear homologous, explains why the pK_a value increase with the substituent steric complexity. Consequently, the acid strength of organophosphinic acids decreases in the order: linear monoalkylphosphinic > branched monoalkylphosphinic > linear dialkylphosphinic > branched dialkylphosphinic.

Although the dissociation constants of these acids in water are very important parameters to elucidate the metallic complex extraction processes when these acids are used as ligands, it is not possible to determine them by means of common potentiometric or spectrophotometric methods because of their very low solubility in water. Therefore, two different methods have been used in order to estimate these constants. The first one is an indirect experimental approach based on distribution measurements that leads to the values shown in Table 2. The second one is the estimation of the pK_a values in aqueous solution using the Hammett equation for substituted phosphorus acids of type

Table 2. Acidity constants in water of some organophosphinic acids

*Estimated by means of the Hammett equation.
†Determined from distribution measurements.

XYPOOH using the suitable tabulated constants.[22,23] The obtained values are given in Table 2. As expected, the experimental values are always slightly higher than the estimated ones, because the extraction diluent, toluene, is water-saturated (solubility of water in toluene at 25°C is 0.072% wt or 0.040 mol/dm^3) and here the water shows basic behaviour. In fact, the value of the Kamlet–Taft basicity parameter, β, is 0.11 for toluene and 0.18 for monomeric water.[24] Since for pure water, with polimeric structure, a revised value of 0.47 has been proposed,[25] an intermediate value slightly higher than 0.18 may be assumed for the very dilute solution of water in toluene used as the extractant solvent.

Both the estimated and experimental values are linearly correlated and show that the estimation of dialkyl-derivative dissociation constants leads to a better agreement with the experimental values.

Because the pK_a of *n*-octyl phosphinic acids have been determined in two different ethanol–water mixtures with very different molar fraction values, the Born equation[26] has been tested by plotting the pK_a values in different ethanol–water mixtures as a function of the reciprocal of the relative permittivity, $1/\epsilon$ using both estimated and experimental values in aqueous solutions. Good correlations have been obtained for the two acids from the values in Table 3, as can be seen in Fig. 2.

In fact, the standard free energy of dissociation is made up of two terms, an electrostatic one, which includes specific solute–solvent interactions, and solvation phenomena. When the electrostatic effects predominate, a straight line should be obtained in the plot of pK_a *vs.* the reciprocal relative permittivity as it occurs with the studied *n*-octyl phosphinic acids.

The pK_a values of the four studied phosphinic acids in ethanol–water mixtures (75% v:v) have been plotted *vs.* the pK_a in water both, experimental and calculated, and good correlations have been obtained. As expected, the slope is slightly higher than unity (1.4) showing a better resolution for these acids in the hydroalcoholic solvent, which shows a relative permittivity value approximately half that of water, and a wider pH scale.[28] Finally, the pK_a of the mono and di *n*-octyl derivatives have been plotted *vs.* the polarity parameter[29] $E^N_{T(30)}$ of the solvent and a straight line has been obtained for both acids using the values in Table 3. The literature shows only a theoretical attempt to relate the electrolyte pK_a variation with the variation of solvent polarity $E^N_{T(30)}$ in binary solvents, and a linear equation with the change of solvent composition was proposed.[30] But, unfortunately, the experimental work covers the variation only until about 20% of water added to isopropyl alcohol. In fact, linear correlations have been obtained using both experimental and calculated values. Because only three experimental points can be used, the difference in the obtained regression coefficients $r = 0.969$ and $r = 0.995$ for experimental and calculated pK_a values in water, respectively, are not significant.

As a conclusion, the Hammett equation developed for phosphorus acids allows a very good estimation of pK_a in water of octyl, both linear and branched octyl derivatives of phosphinic acids and can be used for pK_a estimation for this kind of non water-soluble acids. Nevertheless, if experimental pK_a values (such as those given in Table 2) are available, they should be chosen for solvent extraction uses because they show the acid behaviour in solvent extraction processes better than the estimated

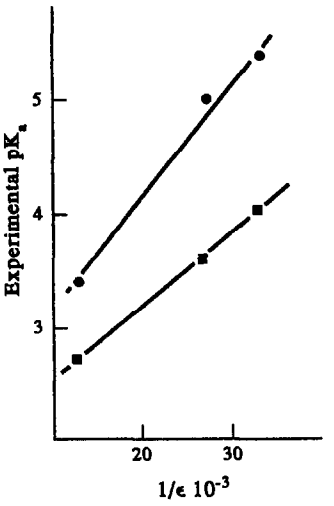

Fig. 2. Experimental pK_a values of mono(*n*-octyl)-phosphinic acid (■) and di(*n*-octyl)phosphinic acid (●) *vs.* the reciprocal of permittivity.

values. In addition, the linear relationship between pK_a values in ethanol–water (75% v:v) and in water can also be used successfully to estimate the pK_a in water of new members of this series of phosphinic acids.

THE SEPARATION OF TELLURIUM AND SELENIUM BY POLYURETHANE FOAM SORBENTS

I. I. STEWART and A. CHOW*
Department of Chemistry, University of Manitoba, Winnipeg, MB, Canada R3T 2N2

(*Received* 14 *January* 1993. *Revised* 1 *March* 1993. *Accepted* 3 *March* 1993)

Summary—Tellurium and selenium can be sorbed from hydrochloric acid and hydrobromic acid solution by both polyether and polyester-based polyurethane foam. Although some acid is needed, the substitution of sodium chloride or sodium bromide increases the extraction significantly. Tellurium is extracted rapidly with > 99% sorbed in 2 min from 1.0/5.0*M* and 2.0/4.0*M* hydrochloric acid/sodium bromide. Selenium can also be sorbed quantitatively but much more slowly so that a separation is possible based on the relative rates of extraction. The capacity of polyether foam is 3% by weight of tellurium.

The use of polyurethane foam as an extractant for organic and inorganic compounds has been developed over 20 years through the publications of H. Bowen in the U.K., T. Braun in Hungary, and workers at the University of Manitoba. Polyurethane has been shown to be a very versatile material for analytical purposes acting as a solid "solvent extractor" in some instances and by a more complex sorption mechanism for the extraction of anionic species. Two books[1,2] and several reviews[3–8] of this field give an excellent overview of the development of this area.

The two general types of polyurethane foam material available are a polyether-based and a polyester-based polyurethane. Each of these has been used as a sorbent for compounds from aqueous solution, although several differences between the polyurethane types have been noted and related to the structure of the polymer. In particular, the polyester-based material acts through a solvent extraction type of mechanism, while the polyether-based material indicates a more complicated process. In some circumstances the polyether-based polymer indicates a solvent extraction mechanism; in others, a cation chelation mechanism predominates as evidenced by the effect of alkali metal ions on the extraction which mimics a crown ether extraction process.

Selenium and tellurium are of analytical interest because of the difficulty in their separation. One element can be determined in the presence of the other by spectrometric methods although large ratios may present some difficulties in analysis. Preconcentration of these elements would be of interest because of the concern of very low concentrations of selenium in the environment, however there is very little recently published literature in this area.[9–10]

In this paper the extraction of tellurium and selenium by both polyether- and polyester-based polyurethane foam is reported and the separation of the two elements is evaluated. The effects of varying concentrations of different acids and salts, concentration of element and length of extraction time are surveyed.

EXPERIMENTAL

Apparatus

All analytical data were obtained with a Varian Spectra AA-20 atomic absorption spectrophotometer equipped with Hamamatsu hollow cathode lamps. The sample solutions were shaken with a modified Burrell wrist-action shaker, where the clamping arms were removed and replaced with baskets to hold the sample containers.

Reagents

All of the chemicals used in these experiments were of reagent grade. The water used in the preparation of all solutions was purified by reverse osmosis and then circulated through a Barnsted Nanopure II™ system. The stock solutions were prepared from; Se powder 99.9% (Alfa Products), SeO_2 99.4% (Alfa Products), TeO_2 99.995% (Aldrich), and Te powder 99.5% (Matheson, Coleman and Bell). The halide salts

Foam weight 1.00 ± 0.05 g; samples were 50.0 ml of 60 ppm tellurium solution.

used were; NaCl (Mallinckrodt), NaBr (Shawinigan), NaI (Fisher), and KCl (Mallinckrodt).

There were two types of polyurethane foams used, a polyether-type, primarily an 80% PEO/PPO polyol, 20% polystyrene/acrylonitrile copolymer + TDI 105 index (5000 m.n.) and a polyester-type obtained from Canlab, Winnipeg, Canada, in the form of diSPo™ plugs.

Procedure

Two 1000 ppm tellurium stock solutions were prepared from tellurium powder and tellurium oxide. For one solution 1.0001 g of tellurium powder was dissolved in 60 ml of a 1:1:1 mixture of $HCl/HNO_3/H_2O$ on a hot plate. The cooled mixture was then diluted to 1000 ml with water. The stock solution made from tellurium oxide was prepared by dissolving 1.2548 g in 100 ml of HCl and then diluting to 1000 ml with water. The selenium stock solutions were prepared similarly except that 1.0119 g of selenium powder and 1.4264 g of the oxide were used.

The sample solutions were prepared from combinations of stock acid and salt solutions. The various matrix combinations were normally prepared by mixing the appropriate amount of acid and salt solutions, before addition to the samples. When preparing the standards and samples for the experiments, a volume of stock solution was placed in a 50 ml volumetric flask and diluted with a solution of the appropriate matrix.

The two types of foam were washed individually. The foam was first placed into 1*M* HCl, squeezed regularly for 2 hr and then rinsed and squeezed repeatedly with water to remove all of the residual acid. After thoroughly squeezing to remove all excess water, the foam was placed in a Soxhlet extraction apparatus and was refluxed in acetone for 6 hr. The foam was squeezed gently to remove the bulk of the acetone and then ground in a stainless steel container on a Waring™ blender. The foam was then air dried and stored out of the light in a covered plastic beaker.

	0.494	10	150	84.9	43.4	0.66

Solution volume 50.0 ml.

Both the sample and standard solutions were prepared in identical matrices at the same time in all cases. The extraction experiment was carried out by placing a measured quantity of foam into a 50 ml plastic bottle with screw cap and then adding the 50 ml sample solution. The bottles were then placed in the baskets of the wrist-action shaker and shaken for the appropriate time. The sample was then removed and the liquid and foam components separated by filtering the solution through Whatman No. 541 paper prior to analysis. The foam was normally discarded except for a few experiments where it was collected quantitatively and the recovery experiments attempted.

The analysis of tellurium was carried out by atomic absorption spectroscopy with the lamp at 10 mA, a slit width of 0.2 nm, and a wavelength of 214.3 nm. For selenium analysis the lamp was operated at 10 mA, a slit width of 1nm, and at a wavelength of 196.0 nm. Where solutions were low in salt concentration, five replicates were performed and where there was a high salt concentration four replicates were used. In all cases the measurement time was 4 sec, with a time constant of 0.05 sec. An air–acetylene flame was used with a Varian Mark VI™ burner head. Depending on the viscosity of the solutions the sample uptake pressure was adjusted to ensure a smooth aspiration. The instrument was zeroed with water, and the particular blank was based on the type of matrix used for the set of samples. Background correction was used for all samples.

The efficiency of a system may be calculated either as the percent extraction of the species ($\%E$), or the distribution coefficient (D):

$$\%E = 100(C_0 - C_{eq})/C_0;\ D = (VE)/W(100\text{-}E)$$

where C_0 is the initial species concentration in ppm before extraction, C_{eq} is the species concentration after the extraction period, V is the volume of solution in ml, and W is the mass of the foam sample in grams.

The distribution coefficient expressed in ml/g (or alternately in l/kg) is a ratio of the species concentration in the foam to the concentration of the sample solution. This ratio should become a constant when the extraction process has attained equilibrium. The distribution coefficient is not always useful, especially with very high or very low percent extractions, because the coefficients may become extremely large or small with only a slight incremental change. Because the foam samples used were about 1.0 g, the distribution coefficient for samples having greater than 95.0% extraction, or less

Extraction from 50.0 ml solution with two consecutive 1.05 ± 0.05 g samples of polyether foam for 10 min each.

than 5.0% extraction become less significant due to inherent errors.

Although this study primarily focuses on the extraction of tellurium–halide species, selenium–halide species were also examined to a lesser extent, as well as the separation of these two species from solution.

The first system examined was the tellurium–chloride system in matrices of varying HCl concentrations from $\sim 0.1M$ to $7M$. Preliminary experiments showed that the extraction was very rapid so the extraction time periods were varied from about 2 min up to 3 hr as shown in Table 1.

The results with polyether foam show that there is essentially no extraction until reaching an acidity of $\sim 3.0M$, and then there was increasing extraction up to $7.0M$, with a secondary maximum at $4.0M$. The experiments at $4.0M$ HCl and $5.0M$ HCl were repeated to confirm this. It was expected from results with other elements that the extraction would increase with acidity. It should also be noted that for $0.0M$, and $2.0M$ HCl there was some small, irregular extraction.

The polyester foam also shows some interesting properties with the extraction increasing with increased acidity as expected. However increasing the acidity also has a negative effect because it degrades the foam. For polyester foam a maximum is achieved before 180 min, but for samples in greater than the $3.0M$ HCl degradation of the foam caused a decrease in the extraction. This effect is especially severe in the $7.0M$ system where the effects of degradation were seen in as little as 5min.

A double extraction of tellurium (30–150 ppm), was carried out using 50 ml solutions, which were shaken for about 2 min with two different samples of foam in succession. The

*n.d. = not determined.

results shown in Table 2 indicate that the extraction process resembles a solvent extraction, where the same percentage of the species is extracted with each separation step. From the data for tellurium in 7*M* HCl (Table 1), the extraction of the 60 ppm solution is 55% after 2 min for the polyether foam. If under these conditions the extraction is repeated where 55% is extracted each time, approximately 48 ppm total will be extracted, and an 80% extraction is obtained. This value agrees quite well with sample 2 from Table 2, which is 82%. Similarly for polyester we obtain 90% upon calculation, which also agrees with the 92% obtained in sample 7, as shown in Table 2. From these data we may conclude that to obtain a near quantitative extraction at least three extractions would have to be performed under these conditions.

The capacity of polyether and polyester foam was evaluated by varying the tellurium concentration in 7*M* HCl solutions and the data are given in Table 3. The data were extrapolated and it was found that the capacity for tellurium was approximately 0.70% by weight for polyether foam and 0.85% by weight for the polyester foam. Although the polyester foam has a greater capacity for tellurium than does the polyether foam under these conditions, it is not as useful as the polyester degrades.

Studies on analogous selenium systems yielded negligible extraction from solutions containing 0–7*M* HCl. This system was then studied in order to see if separation could be achieved.

The results in Table 4 demonstrate that the two elements may be separated. The effect of large concentrations of selenium on the extraction of tellurium was studied and it was found that there was no appreciable effect. Under these conditions it would require multiple extractions to obtain a quantitative separation. The data from Table 5 show that as expected, at least three extractions would be required for the 6*M* HCl solutions and at least four for the 4*M* HCl solutions. The separation could be done quantitatively in either case, although inconveniently.

As the extraction process resembles a solvent extraction the effect of salting out the tellurium species was studied. As shown in Table 6 it was found that the presence of sodium chloride in the system enhanced the extraction of the tellurium species significantly.

The data from Table 6 show that the salting-out effect is significant in the extraction of the tellurium species, increasing the extraction in comparison with acid alone. However, some acid must be present for the extraction to be effective. This was further investigated.

Solution volumes 50.0 ml; extraction time 15 min.

As chloride is a good extraction matrix, the effect of bromide on the extraction of tellurium was similarly investigated. It can be seen from the data in Table 7 that the extraction is quantitative in most cases. The 0*M* HBr/6*M* NaBr system is not entirely free of hydrochloric acid since there is about 0.1*M* HCl, from the acid in the original stock solution. These results suggest that a minimum acidity is required for the extraction to proceed. The rapid increase to essentially 100% extraction in the 2*M* HBr/4*M* NaBr system would indicate that an acidity somewhere between 0 and 2*M*, might give a rapid and complete extraction of the tellurium species. The above data also suggest that the extraction is independent of the acid type, but proceeds quite well with the sodium bromide salt. The study of a mixed HCl/NaBr system was then examined and the results are listed in Table 8.

The above data indicate that for rapid, complete extraction a minimum acidity of between 0.5*M* and 1.0*M* HCl is required. Other trials have shown that quantitative extraction may be achieved in systems with lower than 6*M* balance of halide. In a 1*M* HCl/2*M* NaBr system 75% extraction (45 ppm) was obtained in 2 hr.

A capacity study was then performed on the 2*M* HCl/4*M* NaBr system where the most rapid extraction was obtained and the results given in Table 9. These data show that the polyether foam has a high capacity for tellurium species from this matrix. When the data are extrapolated the capacity was determined to be approximately 3.00% by weight of foam. If this is compared with the data obtained from polyether foam in HCl it can be seen to be approximately four times as great. This system would seem ideal for the extraction of larger amounts of tellurium from solution.

The extraction of selenium was observed in analogous systems and the data are listed in Table 10. From these data, it is observed that the extraction of selenium still goes to completion under the same conditions although more slowly than for tellurium. It is interesting to note that the extraction seems slower in the lower acid matrix and that after 2 min there is only 11% extracted (6.60 ppm). With this in mind a separation of tellurium from selenium

Table 10. Extraction of selenium from HCl/NaBr solution

HCl	NaBr	Time (*min*)	Original concentration (*ppm*)	Final concentration (*ppm*)	% Extraction

was performed under these matrices and the results listed in Table 11.

It can be seen that the separation is not complete in 4*M* HCl/2*M* NaBr but one species is extracted completely and the other partially. This system would seem inefficient for the quantitative separation of these elements. A more quantitative separation is achieved in a lower acid matrix, and for a 2 min rapid extraction, it is possible to extract the tellurium species quantitatively in the presence of selenium with minimal extraction of the other. The extraction of selenium is reduced in the lower acid matrix, however the extraction of tellurium is slowed and becomes less quantitative.

As chloride and bromide both provided suitable extraction matrices, we investigated iodide. The results for tellurium were essentially 100% extraction for a 2*M* HCl/4*M* NaI matrix in 5 min and 100% extraction for a straight 0*M* HCl/6*M* NaI matrix in 10 min, (there was 0.1*M* residual HCl from the stock solution present). When selenium was investigated under similar conditions a precipitate formed, presumably Se_2I_2. Therefore a separation of these two elements in this matrix could be done by filtering the sample solution to collect the precipitate and then running the extraction with the polyether foam to collect the tellurium.

Table 12. Effect of nitric acid on selenium extraction

Time (*min*)	% Extraction from HNO_3	% Extraction from "clean" system
2	4.5; 5.8	11.0
5	9.3; 9.0	22.3
10	10.7	32.0
15	14.3	47.8

Solutions were 50.0 ml of 60 ppm selenium in 2.0*M* HCl/4.0*M* NaBr; extraction with 1.05 ± 0.05 g polyether foam; acid samples were digested for 1 hr in 0.30 ml HNO_3/50 ml sample prior to extraction; "clean" data from Table 10.

In previous studies both tellurium and selenium metals were dissolved in a HCl/HNO_3 mixture, to prepare their respective stock solutions. When this was done it was noticed that there seemed to be negligible extraction of selenium in the HCl/NaBr matrices before 1 hr. However when the extraction was performed in similar matrices with nitric acid-free stock solutions, prepared from dissolving the oxide in HCl there was a much greater and consistent extraction over 3 hr, as shown in Table 10. With this in mind a series of experiments were performed where a volume of HNO_3 was introduced to the nitric acid free selenium stock and the solutions was then left to sit before the matrix was added. Once the matrix solution was added, the extraction was carried out immediately.

From Table 12 it can be seen that there is a marked difference in the extraction of the Se in the presence of HNO_3. A more extended investigation into this effect and its kinetics might lead to a more quantitative separation of the elements.

The reverse extraction of tellurium was investigated and it was found that if the foam was left to sit for a period of greater than 3 hr water with gentle, periodic squeezing the tellurium could be removed quantitatively from the foam. Other investigations also showed that acetone and 1% sodium hydroxide solutions could also be used

to recover completely, the sorbed tellurium species.

CONCLUSIONS

The sorption of tellurium from hydrochloric acid solutions as concentrated as 7*M*, is not quantitative and there is no extraction below 3*M* with polyurethane foam. Although a multiple step procedure or a larger amount of foam would provide a more quantitative sorption, this would be somewhat inconvenient. Under these conditions polyester foam shows a higher extraction than polyether and the capacities are 0.85% and 0.70%, respectively; under similar conditions, selenium is not sorbed so a reasonable separation of the two elements is possible with little contamination of the tellurium on foam by selenium.

The addition of sodium chloride to the hydrochloric acid solutions increases the sorption of tellurium to a maximum of about 80% when both are 3*M*. The use of hydrobromic acid and sodium bromide increases the sorption even more with >95% sorbed by polyether foam in 10 min or more over a range of acid and salt concentrations. Similarly, a mixture of hydrochloric acid and sodium bromide gave excellent and rapid extraction of tellurium with >99% sorbed in 2 min from 1.0/5.0*M* and 2.0/4.0*M*. Under these conditions the capacity of polyether foam is about 3% by weight of tellurium.

The sorption of selenium from 2.0/4.0*M* and 4.0/2.0*M* HCl/NaBr solutions is also quantitative by polyether foam but requires 2 hr for complete extraction. The sorption of both elements under similar conditions prevents a "clean" separation. However by varying the conditions to less than ideal for tellurium, it is possible to take advantage of the difference in the rates of sorption of the two species; in this situation an extraction of >95% of tellurium is obtained with about 6% co-extraction of selenium. The presence of nitric acid has a considerable effect on the rate and percentage extraction of selenium. A more detailed study of the nitric acid system will be undertaken in the future.

Overall it is apparent that polyurethane foam can be used to sorb selenium and tellurium from halo-acid solutions. The presence of some acid is required with higher concentrations more effective, but the presence of larger concentrations of sodium halide salts facilitates a quantitative extraction. A reasonable separation of tellurium from selenium is possible and this method is rapid, efficient and inexpensive.

Further investigations in this area would focus on the separation of selenium and tellurium using polyurethane foam sorbents in columns, the sorption and separation of trace levels of the metals from more complex matrices and a more extensive study of the effects of different acids on the separation process.

SPECTROFLUOROMETRIC STUDY OF THALLIUM (I) COMPLEXES WITH SEVERAL MACROCYCLIC LIGANDS IN METHANOL SOLUTION

HOOSHANG PARHAM and MOJTABA SHAMSIPUR*
Department of Chemistry, Shiraz University, Shiraz, Iran

(*Received* 12 *January* 1993. *Revised* 1 *March* 1993. *Accepted* 1 *March* 1993)

Summary—The fluorescent signal of Tl^+ was employed as a sensitive probe to study the complexation reactions between this cation and several macrocyclic ligands in methanol solution at 20°C. The stability constants of the resulting 1:1 complexes were determined and found to vary in the order C222 > C221 > 18C6 > DC18C6 > DB30C10 > DB18C6 > 15C5 > DA18C6 > B15C5 > DA15C5. The influence of a number of members in the macrocycle, the nature of substituents on the polyether ring and of the dimensionality of the ligands on the stability and selectivity of the complexes is discussed.

The monovalent thallium ion has been suggested as a probe for potassium ion in biological systems.[1,2] It can substitute for K^+ in activation of some important enzymes such as ATPase[3] and pyruvate kinase.[4] Thus, the stability and selectivity of Tl^+ complexes with macrocyclic ligands are of special interest with this respect. Among different spectroscopic and electroanalytical methods used for the study of Tl^+ complexes,[5] the fluorescent properties of the cation, well characterized by Steffen and Sommermeyer in aqueous solution,[6] possess some promising features for such studies in both aqueous and nonaqueous media.

We have been currently involved in the study of the thermodynamics[7–11] and kinetics[12–14] of metal ion complexes with macrocyclic ligands in nonaqueous and mixed solvents. In this paper we report the use of the fluorescent signal of Tl^+ ion as a very sensitive probe to study its complexes with crown ethers 15-crown-5 (15C5), benzo-15-crown-5 (B15C5), 1,7-diaza-15-crown-5 (DA15C5), 18-crown-6 (18C6), dibenzo-18-crown-6 (DB18C6), dicyclohexyl-18-crown-6 (DC18C6), 1,10-diaza-18-crown-6 (DA18C6) and dibenzo-30-crown-10 (DB30C10) and cryptands C221 and C222 in methanol solution at 20°C.

EXPERIMENTAL

Reagent grade thallium nitrate (BDH) was of the highest purity available and used without any further purification except for vacuum drying over P_2O_5. Macrocyclic ligands B15C5, 18C6, DB18C6, DA18C6 (all from Merck) and DB30C10 (Parish) were purified and dried using the previously reported methods.[7,9,10] Macrocycles 15C5, DA15C5, C221 and C222 (all from Merck) were used after vacuum drying over P_2O_5. Spectroscopic grade methanol (MeOH, Merck) was used as received. Fluorometric measurements were made using a Shimadzu RF-5000 spectrofluorometer at 20 ± 1°C.

The formation constants of 1:1 complexes between Tl^+ ion and macrocyclic ligands used were determined by the fluorescence intensity measurements, at the maximum emission wavelength of 354 nm, of solutions in which varying concentration of ligand (1.6×10^{-6}–$2.1 \times 10^{-4} M$) were added to a fixed concentration of thallium ion ($3.2 \times 10^{-5} M$) in MeOH. Attainment of equilibrium was checked by the observation of no change in the spectra after several hours.

When Tl^+ ion reacts with a macrocyclic ligand, L, to form a 1:1 complex, the formation constant is given as

$$K_f = \frac{[TlL^+]}{[Tl^+][L]}. \quad (1)$$

The mass balance equations and the observed fluorescence intensity, $(F1)_{obs}$, are given by

$$C_{Tl^+} = [Tl^+] + [TlL^+] \quad (2)$$

$$C_L = [L] + [TlL^+] \quad (3)$$

$$(F1)_{obs} = K'_{Tl} + [Tl^+] + K'_{TlL} + [TlL^+] \quad (4)$$

*Author for correspondence.

where C and K' values are the analytical concentration and fluorescence constant of the species indicated, respectively. The mass balance equations can be solved in order to obtain an equation for the free metal ion concentration, $[Tl^+]$ as

$$K_f[Tl^+]^2 + (1 + K_f(C_L - C_{Tl^+}))[Tl^+] - C_{Tl^+} = 0. \quad (5)$$

For the evaluation of the formation constants from fluorescence intensity *vs.* mole ratio data (7–14 points), a non-linear least-squares curve fitting program KINFIT was used.[15] The program is based on the iterative adjustment of the calculated values of the fluorescence intensities to the observed values by using either the Wentworth matrix technique[16] or the Pawell procedure.[17] Adjustable parameters are K_f and K'_{TlL^+}.

The free Tl^+ concentration was calculated from equation (5) by means of a Newton–Raphson procedure. Once the value of $[Tl^+]$ had been obtained, the concentration of all other species involved were calculated from the mass balance equations (2) and (3), by using the estimated values of the formation constant at the current iteration step of the program. Refinement of the parameters is continued until the sum-of-squares of the residuals between calculated and observed values of the fluorescence intensity for all experimental points is minimized. The output of the program KINFIT is comprised of refined parameters, the sum-of-squares and the standard deviation of the data.

RESULTS AND DISCUSSION

The present study showed that the fluorescent signal of Tl^+ ion in methanol solution can be used as a convenient and very sensitive probe for macrocyclic complexation of the cation. The fluorescence spectra of Tl^+ ion at different excitation wavelengths were obtained and a wavelength of 232 nm was selected as the most convenient excitation wavelength for further studies. Maximum fluorescence emission occurs at 354 nm. The fluorescence intensity of Tl^+ ion in methanol solution was found to be independent of the nature of the anion, which indicates that an ion pair formation would be negligible in the concentration range studied.

The formation constants of different Tl^+-macrocycle complexes were determined as described in the Experimental section. A sample spectrum is shown in Fig. 1. As is seen, increasing the macrocycle concentration results in a decrease in the fluorescence intensity at 354 nm and appearance of a fluorescence signal at 308 nm, indicating the formation of a new Tl^+ species. It should be noted that, only in the cases of 18C6 and DC18C6 the 308 nm band was so intense and comparable with the 354 nm band. In all other cases, however, the intensity of this signal was about 1/10th of the original Tl^+ band at 354 nm. In all cases studied, the resulting fluorescence intensity–mole ratio data showed the best computer fitting to the 1:1 Tl^+-macrocycle stoichiometry. A sample computer fit of the data is shown in Fig. 2. Moreover, the existence of a well defined isosbestic

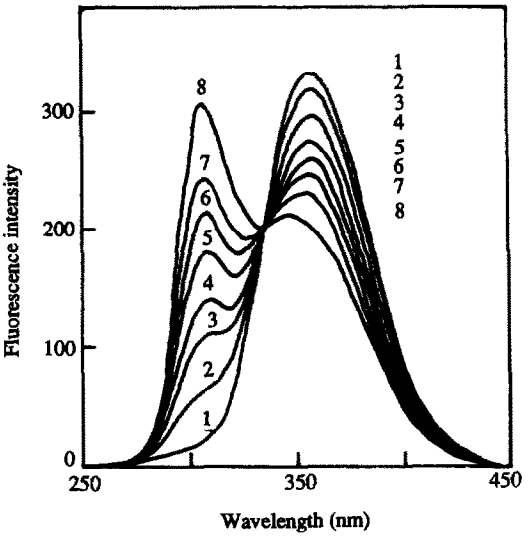

Fig. 1. Fluorescence spectra of Tl^+ ($3.2 \times 10^{-5}M$) upon titration with DC18C6 in MeOH at 20°C. [DC18C6] is: 1, 0.0; 2, $4.1 \times 10^{-6}M$; 3, $8.3 \times 10^{-6}M$; 4, $1.2 \times 10^{-5}M$; 5, $1.7 \times 10^{-5}M$; 6, $2.1 \times 10^{-5}M$; 7, $2.5 \times 10^{-5}M$; 8, $3.3 \times 10^{-5}M$.

*Ref. 19. †Ref. 20. ‡The corresponding solution was neutral and the protonation constants were not taken into account in the process of determining the stability constant.

point in the fluorescence spectra of Tl^+ upon titration with ligand is further evidence for a simple complexation equilibrium.

All the calculated formation constants for different TL^+-macrocycle complexes in MeOH at 20°C are summarized in Table 1. As can be seen, in the cases of C221 and C222 cryptates, the formation constants were greater than 10^6 and their precise values could not be determined by our technique. It is obvious that, the relative size of Tl^+ ion (3.0 Å)[18] and the cavity of polyether rings,[19,20] as well as the nature of substituents on the macrocyclic ring, plays an important role in the complexation reactions. Among different crown ethers used, 18-crowns form the most stable complexes with thallium ion, most probably because of the suitable fitting of Tl^+ ion inside the cavity of these ligands. However, among 18-crowns used, the stability of the resulting Tl^+ complexes vary in the order 18C6 > DC18C6 > DB18C6 > DA18C6.

The presence of two cyclohexyl groups in DC18C6 would cause some reduced stability, in comparison with 18C6, probably because of the reduced flexibility of the ligand. On the other hand, the addition of the two benzo groups to 18C6 lowers the stability of Tl^+ complex markedly. This behaviour may be attributed to some combination of the electron withdrawing property of the benzo groups which weakens the electron donor ability of the oxygen atoms of the ring, and reduced flexibility of the ligand which prevents the macrocyclic molecule from 'wrapping itself' around the cation. Finally, despite the soft character of the two nitrogen atoms of DA18C6 ring which is expected to favor its interaction with Tl^+ ion as a soft acid,[21] this ligand forms the least stable complex in the series. A possible cause of this unexpected behavior would be the existence of a specific interaction between protic solvents such as water and methanol and macrocyclic ligands containing nitrogen atoms, via hydrogen bonding of the solvent with >N–H groups of the ring.[22,23]

It is interesting to note that in the case of 15-crowns used, where the resulting Tl^+ complexes are less stable than those with 18-crowns because of the too small cavity size of the macrocyclic rings for the metal ion, the same trend of stability can also be observed (i.e. 15C5 > B15C5 > DA15C5).

On the other hand, although the cavity of DB30C10 seems too large for Tl^+ ion, it forms a stable 1:1 complex with cation (i.e. in the order of DC18C6). This result is not surprising, since it has been shown that large crown ethers such as DB30C10 can easily twist around a cation of suitable size (such as K^+ ion, ionic size 2.86 Å)[18] to form a stable three-dimensional "wrap-around" complex in which all oxygen atoms of the ring participate in the bond formation with the central cation.[9,10,13,24]

From the stability constant listed in Table 1, it is obvious that the macrobicyclic ligands C222 and C221, despite their small cavity sizes for the complete accommodation of the cation,[20] form more than their corresponding macrocyclic ligands DA18C6 and DA15C5. This rapid increase in stability, obtained by connecting another $-CH_2CH_2-O-CH_2CH_2-O-CH_2CH_2-$ bridge onto the macrocyclic ligands DA18C6 and DA15C5 (to form the corresponding macrobicyclic ligands C222 and C221), is well known as the "cryptate effect".[11,24]

Summary—A liquid chromatographic method is described for the evaluation of Astemizole purity. The method is also applicable for the analysis of pharmaceutical dosage forms of Astemizole using indole as internal standard. Separation was achieved with a μ bondapak C_{18} column and phosphate buffer (pH 6.0):acetonitrile (50:50 v/v) as eluent, at a flow rate of 1.5 ml/min with UV detection at 280 nm. The method is suitable for estimating the possible impurities if any present in Astemizole up to 0.05% for 1a and 0.25% for 1b. The method is simple, rapid and accurate for the analysis of Astemizole.

Astemizole [1-[(4-fluoro phenyl)methyl]-*N*-[1-[2-(4-methoxy phenyl)ethyl]-4-piperidinyl]-1H-benzimidazol-2-amine; 1, Fig. 1] is a new antihistamine of current interest that differs structurally from other antihistamines. Astemizole was found to be a long-acting non-sedating antihistamine with major clinical implications for the treatment of allergic diseases.

Currently Astemizole and its pharmaceutical dosage forms are not found in any pharmacopoeia. However an analytical profile[1] was found in a survey of the literature which include elemental analysis, radioimmunoassays and HPLC.

The synthetic route to Astemizole was described in two patents[2,3] where in both 2-chloro-1-[(4-fluoro-phenyl)methyl]-1H benzimidazole (1a, Fig. 1) and 1-(2-(4-methoxy phenyl)ethyl)-4-aminopiperidine (1b, Fig. 1) were allowed to react to give the expected product (1). Our investigation examined the product for the presence of both reactants as potential impurities. As the quantitative analysis[1] of Astemizole was already published, our aim was to develop an HPLC procedure suitable for detecting these impurities in Astemizole and to apply the same procedure for the analysis of this drug at various stages in the production of Astemizole. Also we want to apply these parameters for the assay of pharmaceutical dosage forms of Astemizole.

A study of several combinations of different solvents and buffer systems, different types of stationary phases and suitable internal standards for proper quantification, led to the described analytical conditions giving sharp and well resolved peaks.

EXPERIMENTAL

Apparatus

The HPLC (Waters Associates) instrument was equipped with a model 501 pump, U6K injector, model 481 variable wavelength UV detector. Separations were performed on a μ bondapak C_{18}, 10 microns stainless steel column (Waters USA) 300 × 3.9 mm at ambient temperature. The flow rate of the system was maintained at 1.5 ml/min with UV detection at 280 nm. The attenuation was set at 2.0 AUFS (Absorbance units full scale) with a chart speed of 0.25 cm/min. Chromatographic peaks were electronically integrated and recorded with a model 745 (Waters Associates) computing integrator.

*Author for correspondence.

Reagents

Chromatographic grade acetonitrile, analytical reagent grade Potassium dihydrogen orthophosphate, dipotassium hydrogen orthophosphate, perchloric acid, and indole and Milli Q water were used throughout these experiments.

Mobile phase

The mobile phase was composed of 50:50 v/v phosphate buffer pH 6.0 and acetonitrile.

Buffer solution was prepared by mixing the solutions of 0.022*M* potassium dihydrogen orthophosphate and 0.003*M* dipotassium hydrogen orthophosphate, and the pH of the solution adjusted to 6.0 with 0.01*M* perchloric acid.

Indole standard solution

A 0.5-mg/ml mobile phase solution of Indole was used as the internal standard.

Astemizole standard solution

A 1.0-mg/ml mobile phase solution of Astemizole was used as the drug standard.

Mixed indole and astemizole standard solution

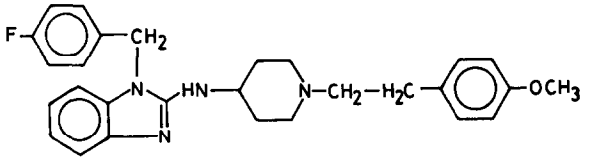
Four millilitres of Astemizole solution and 1.0 ml of Indole solution were transferred to a 10-ml standard flask and diluted to the mark with mobile phase.

Sample preparation

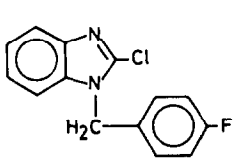
A mass of powdered tablets equivalent to 25 mg of Astemizole was suspended in 25 ml of mobile phase and vortexed for 10 min. The insoluble portion, if any, was removed by filtration and the filtrate analysed after 4.0 ml of this solution was added to 1.0 ml of Indole standard.

Procedure

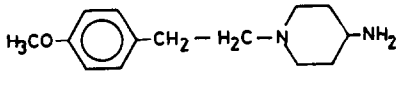
Five microlitres of the mixed standard or sample were injected into a universal injector using a 10-μl Hamilton Syringe. Each injection was done at an interval of 15 min to ensure complete elution of the previously injected material. Sample and mixed standard solutions were injected in triplicate. Quantitative determinations were made by comparison of the peak area ratio of Astemizole and Indole (Internal standard) for a sample injection to the



[ASTEMIZOLE, 1]



[2-CHLORO-1-[(4-FLUOROPHENYL)METHYL]-1H BENZIMIDAZOLE, 1a]



[1-(2-(4-METHOXY PHENYL) ETHYL)-4-AMINOPIPERIDINE, 1b]

Fig. 1.

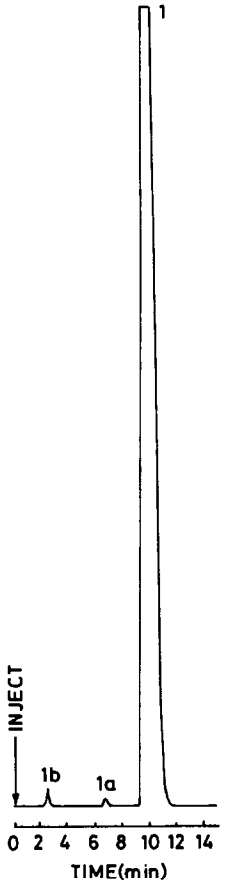


Fig. 2. HPLC separation of astemizole (1), 1(a) and 1(b).

corresponding area ratio for a mixed standard injection. Blank samples showed no interfering peaks.

Impurity analysis of Astemizole

To demonstrate HPLC resolution of Astemizole, 1(a), and 1(b), mobile phase solutions were prepared by adding known amounts of 1(a) and 1(b), 0.05 to 1.0%, to Astemizole. The impurity levels were also determined by comparison of peak area ratios for solutions of 1(a) and 1(b) at the levels up to 0.05 and 0.25%, respectively.

RESULTS AND DISCUSSION

The systematic study of the operating parameters that would optimize the HPLC resolution of chemical compounds involved in the synthesis of Astemizole led to the procedure.

As shown in Fig. 3, Astemizole and Indole (Internal standard) are distinctly eluted having retention times of 10.76 and 4.88 min, respectively. The ratios of peak area of Astemizole to that of Indole (Internal standard) were plotted against concentrations of Astemizole. The plot

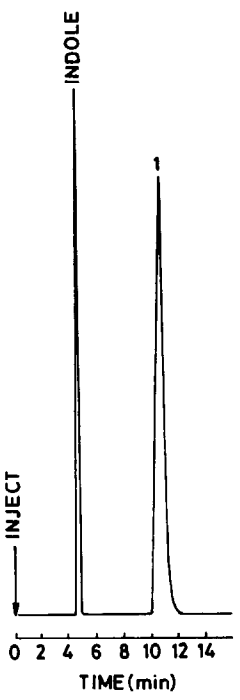

Fig. 3. Separation of indole and astemizole (1) by HPLC on μ bondapak C_{18} column.

was linear over the range 0.125–3.0 μg with a standard deviation of 0.137.

As shown in Fig. 2, Astemizole, 1(a) and 1(b) were distinctly eluted having retention times of 10.76, 7.80 or 2.78 min, respectively, with detection limits of 0.05% for 1(a) and 0.25% for 1(b).

Tablets of Astemizole were analysed by the proposed and reference HPLC methods and the results are tabulated in Table 1. The accuracy of the method was further ascertained through recovery studies by adding known amounts of Astemizole to placebo tablet powder and analysed by HPLC. Recovery was found to be 99.4–99.8%. These values indicate a lack of interference by the tablet diluents and lubricants. The precision of the method was found to

Table 1. Assay of Astemizole in pharmaceutical dosage forms by the proposed method

1	Tablet	10	99.4	99.3
2	Tablet	10	99.8	99.8
3	Tablet	10	99.6	99.5
4	Tablet	10	99.8	99.8
5	Tablet	10	99.6	99.6

*HPLC method reported for pharmaceutical dosage forms in the analytical profile of Astemizole.

be 99.4–99.7% with a standard deviation of 0.04, giving evidence of excellent precision.

In conclusion, the proposed HPLC method allows rapid separation and determination of starting materials 1(a) and 1(b), which may be present in crude Astemizole. The method is also useful for the determination of Astemizole and its pharmaceutical dosage forms and results are comparable with the reported HPLC method.[1]

Acknowledgement—The authors are grateful to Dr. B. Saida Reddy of Dr Reddy's group for providing samples of Astemizole and its intermediates.

Department of Analytical Chemistry, University of Murcia, Murcia, Spain

(*Received* 15 *December* 1992. *Revised* 22 *February* 1993. *Accepted* 19 *March* 1993)

Summary—A flow-injection configuration for the fluorimetric determination of trimeprazine and trifluoperazine is proposed. The procedure is based on oxidation of the drugs by cerium(IV). The fluorescence of cerium(III) formed in the oxidation of trimeprazine or trifluoperazine is monitored. Lineal calibration graphs were obtained between 2×10^{-7} and $1 \times 10^{-5} M$ for both trimeprazine and trifluoperazine with a sampling rate of 60 samples/hr. The relative standard deviations were over the ranges 0.78–1.16 and 0.84–0.97% for trimeprazine and trifluoperazine, respectively. The applicability of the method to determination of trimeprazine and trifluoperazine was demonstrated by investigating the effect of potential interferences and by analysis of commercial pharmaceutical preparations.

Trimeprazine (*N*,*N*,*β*-trimethyl-10-H-phenothiazine-10-propanamine) and trifluoperazine (10[3-(4-methyl-1-piperazinyl)propyl]-2-(trifluoromethyl)-10-H-phenothiazine) are phenothiazines derivatives. These compounds have a profound psychotherapeutic activity,[1] trimeprazine being widely used as an antipruritic agent and trifluoperazine for the treatment of various mental illnesses. The importance of phenothiazine tranquilizers has prompted many investigators to look for methods for their rapid determination. The use of such drugs in chemotherapy and methods for their determination have been revised.[2–4] Titrimetric,[4] spectrophotometric,[5–9] chromatographic[3,10–12] and kinetic[13,14] methods have been used. A variety of methods based on the fluorescence of both unoxidized and oxidized compounds have also been used and cover a wide range of concentrations. Oxidation of phenothiazine drugs has been carried out with chemical reagents (H_2O_2, MnO_4^-, etc.) and photochemical decomposition.[15–18] Despite the large number of manual methods available, there are very few automated procedures. In recent years, flow-injection analysis (FIA) has found wide application in the determination of phenothiazines. Flow-injection procedures generally involve the use of chemical[19–22] or photochemical[23–26] oxidation of phenothiazines and use photometric and fluorimetric detection of their oxidized form. Other procedures using amperometric detection[27] and pseudo-titration in a non-aqueous medium[28] have also been reported.

Cerium(IV) has been used as an oxidizing agent for the determination of trimeprazine[20] and prometazine[21,22] in flow-injection systems. The red colour produced by the oxidized species of these drugs has been monitored spectrophotometrically. However, no method has been found dealing with the indirect determination of phenothiazines by measuring the fluorescence of cerium(III) formed.

In this paper the development of a spectrofluorimetric flow-injection method for the determination of trimeprazine and trifluoperazine and its application to routine are presented. The determination is based on the oxidation of these drugs by cerium(IV) and the parameter measured is the fluorescence of the Ce(III) formed during the reaction. The procedure is very simple, inexpensive and fast and allows the determination of these two drugs in pharmaceutical formulations.

EXPERIMENTAL

Apparatus and manifold

A Hitachi F-3010 spectrofluorometer equipped with a plotter unit and 1 × 1 cm quartz cell was used for recording spectra; excitation and emission spectra were corrected.

The flow-injection system consisted of a Tecator FIAstar 5020 flow-injection analyser

*Author for correspondence.

equipped with an injection valve and a peristaltic pump (40 r.p.p.). A Hitachi F-3010 spectrofluorometer connected to a plotter unit was used as a detector with a Hellma 176.052 QS flow cell (inner volume 25 μl). The manifold used is diagrammed in Fig. 1.

The cerium(IV) solution, $10^{-3}M$ (1M in H_2SO_4) was pumped at a flow rate of 0.8 ml/min. Trimeprazine, or trifluoperazine, covering the range of 2×10^{-7}–$1 \times 10^{-5}M$, were prepared by dilution of stock solutions and injected (158 μl) into the manifold; the peak heights were measured and recorded at 355 nm with excitation at 255 nm. The spectrofluorometer was set with excitation and emission slits at 10 nm.

Reagents

All reagents were of analytical reagent grade and were used as received. Doubly distilled water was used throughout. Aqueous $10^{-2}M$ trimeprazine and trifluoperazine stock solutions were prepared from the pure products (Sigma). Cerium(IV) solutions, $10^{-2}M$, were prepared by dissolving $Ce(SO_4)_2 . H_2O$ (Merck) in 1M sulphuric acid. Sodium bismuthate was added when Ce(IV) solutions were prepared in order to oxidize any Ce(III) present in the Ce(IV). The excess of sodium bismuthate was eliminated by filtering.

All phenothiazine and cerium(IV) solutions were stored in amber-coloured bottles. The drugs solutions were kept refrigerated to ensure stability. Working solutions were freshly prepared from stock solutions by suitable dilution.

Determination of trimeprazine and trifluoperazine in pharmaceutical formulations

Tablets of the pharmaceuticals were ground in an agate mortar to a fine powder and dissolved in water with the help of ultrasonic mixing and filtrated through Whatman No. 42 filter paper. The filtrate was diluted in a standard flask and an aliquot (158 μl) was injected into the flow-system.

For analysis of pharmaceuticals in solution the requisite volume of the solution was transferred to a 100-ml standard flask and diluted to the mark with doubly-distilled water.

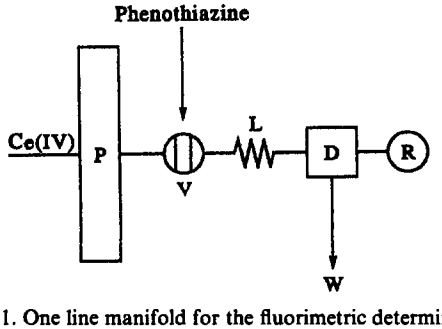

Fig. 1. One line manifold for the fluorimetric determination of phenothiazines.

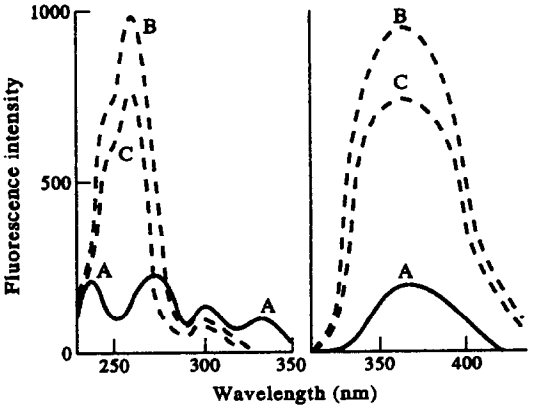

Fig. 2. Excitation and emission spectra of (A) Trimeprazine, $10^{-5}M$; $KMnO_4$, $2 \times 10^{-5}M$ and H_2SO_4, 1M. (B) Trimeprazine, $10^{-5}M$; Ce(IV), $10^{-4}M$ and H_2SO_4, 1M. (C) Ce(III), $10^{-5}M$; Ce(IV), $10^{-4}M$ and H_2SO_4, 1M.

RESULTS AND DISCUSSION

The oxidation of phenothiazines by Ce(IV) occurs in two steps and has already been described as an example of transient redox effects.[13] In excess of Ce(IV), the redox reaction is very fast and phenothiazines are completely oxidized to their sulphoxide form. The development of the reaction can be monitored by fluorescence of the Ce(III) or the sulphoxide formed. However, Ce(III) is more than 4 times as fluorescent as the oxidized phenothiazines, and so the measurement of its fluorescence can be used as a very sensitive indirect fluorimetric method for the determination of phenothiazines.

In addition, some oxidized phenothiazines also show excitation and emission maxima in the same spectral region where Ce(III) fluoresces; in such cases, an additional enhancement of the fluorescence readings is achieved. The excitation and emission spectra of oxidized trimeprazine (Fig. 2) clearly demonstrate this.

On the other hand, trimeprazine and trifluoperazine can be easily oxidized in a flow system by injecting the drugs, which react with the Ce(IV) solution flowing on line. A single-line FIA manifold with fluorimetric detection is suitable for the determination of both drugs.

The manifold schematized in Fig. 1 was used to investigate the effect of chemical and FIA variables on the peak height (fluorescence signal at λ_{em} 355 nm with a λ_{exc} 255 nm). The studies were performed by altering each variable in turn while keeping the others constant.

Chemical variables

The composition of the Ce(IV) stream had strong influence on the peak height. Three different acids (HNO_3, HCl and H_2SO_4) were tested to determine which was the most suitable for optimum reaction development. The nitric acid could not be used owing to the inhibitory effect of nitrate ions of the fluorescence of Ce(III).[29] In the presence of hydrochloric or sulphuric acid the reaction rate and the fluorescence of Ce(III) were high. Since cereus ions were always present to some extent in the Ce(IV) solutions, the fluorescence intensities of cerium(IV) solution were also measured to obtain appropriate blank corrections. In this study, sulphuric acid was selected because the baseline was less in this medium than in hydrochloric acid.

The influence of sulphuric acid concentration is shown in Fig. 3. The recommended concentration was 1*M*, because the fluorescence intensities obtained for trimeprazine and trifluoperazine remained virtually constant with slight changes in the concentration of sulphuric acid.

The effect of the concentration of the cerium(IV) stream was studied in the range 1×10^{-4}–$1.5 \times 10^{-3}M$. As can be seen from Fig. 4, the analytical signal increased with increasing reagent concentration up to $9 \times 10^{-4}M$ above which it remained virtually constant. The concentration selected was $1 \times 10^{-3}M$.

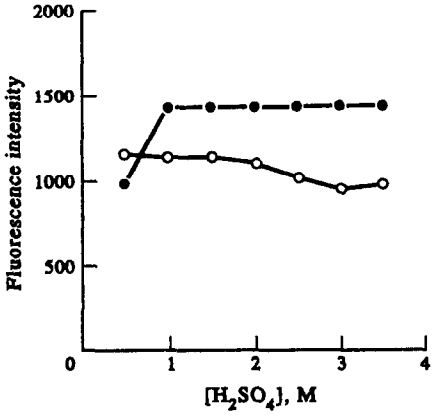

Fig. 3. Influence of sulphuric acid concentration on fluorescence intensity. Curves: (1) trimeprazine; (2) trifluoperazine. Sample injected = 158 μl of $10^{-5}M$.

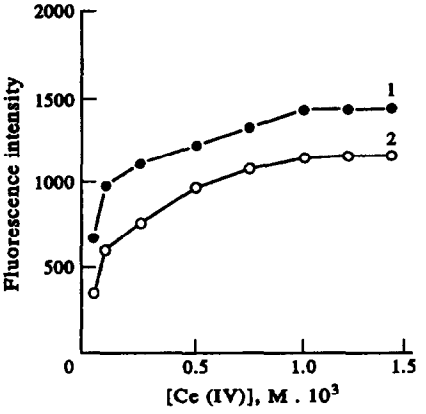

Fig. 4. Influence of Ce(IV) concentration on fluorescence intensity. Curves: (1) trimeprazine; (2) trifluoperazine. Sample injected = 158 μl of $10^{-5}M$.

The influence of temperature on the peak height was studied over the range 25–45°. The signal decreased slightly with an increase in temperature. In the FIA procedure this variable was controlled at 30°.

Optimization of the FIA variables

Because the oxidation of trimeprazine and trifluoperazine by Ce(IV), under the recommended conditions is very fast, a simple manifold using cerium(IV) sulphate solution in 1*M* sulphuric acid as carrier was found to be the most suitable. Optimization of the different variables influencing the FIA system was carried out. Figure 5 shows the effect of the pumping

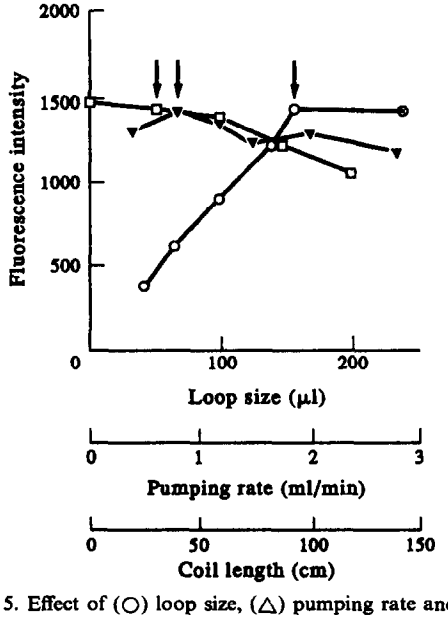

Fig. 5. Effect of (○) loop size, (△) pumping rate and (□) coil length on fluorescence intensity. Sample injected = $10^{-5}M$ trimeprazine. The arrows mark the values of the parameters selected.

Table 1. Features of the calibration graphs for the determination of trimeprazine and trifluoperazine

Parameter	Trimeprazine	Trifluoperazine
Determination range	2×10^{-7}–$1 \times 10^{-5} M$	2×10^{-7}–$1 \times 10^{-5} M$
Slope/I_F, M^{-1}	7.2×10^7	7.6×10^7
Intercept/I_F (%)	159	185
Correlation coefficient*	0.9967	0.9989
RSD%†	±1.16; ±0.78	±0.976; ±0.84

*The correlation coefficients were calculated using 11 different concentrations of each analyte.

†Relative standard deviations ($n = 10$), [phenotiazine] = $2 \times 10^{-6} M$ and $1 \times 10^{-5} M$.

rate, loop size and length of coil. The selected values of the FIA variables are: flow rate, 0.8 ml/min; injection volume, 158 μl and reactor length, 30 cm. The inner diameter of the coil was 0.5 mm. These values allow the phenothiazine drugs to be oxidized by the time the sample plug passes through.

Determination of trimeprazine and trifluoperazine

A series of standard solutions of trimeprazine or trifluoperazine were pumped in triplicate to test the linearity of the calibration graphs. The calibration graphs have a linear range (Table 1), from which the excellent sensitivity of the proposed method is evident. A statistical study was performed on 10 samples ($P = 0.05$) by triplicate injections of 2×10^{-6} and $1 \times 10^{-5} M$ levels of each analyte. The sampling rate was 60 samples/hr.

‡Tolerable W/W ratio.

Interferences

An interference study aimed at the determination of trimeprazine and trifluoperazine in pharmaceutical preparations was performed. Samples containing a fixed concentration of each phenothiazine, $10^{-5} M$, and various concentrations of foreign substances were injected into the FIA system. A substance was considered not to interfere if the variation in the peak height of the phenothiazine was less than ±3% in its presence. The results are shown in Table 2.

The foreign substances tested were substances and excipient generally present in pharmaceutical preparations. Under the reaction conditions used most of them do not interfere. However ascorbic acid, acetylsalicylic acid and sodium sulphite interfere and must therefore be eliminated.

	1.50	1.47 ± 0.05	98.0

*See Table 3.
†Average of three determinations ± SD.

Applications

The proposed methods were applied satisfactorily to the determination of trimeprazine and trifluoperazine in pharmaceutical preparations. Table 3 summarizes the data obtained.

The recovery was determined by adding various amounts of trimeprazine or trifluoperazine to pharmaceutical preparations and subtracting the results obtained for pharmaceuticals prepared in a similar manner but to which no phenothiazine has been added. The results are shown in Table 4.

CONCLUSIONS

The results obtained clearly demonstrate the suitability of monitoring the fluorescence of Ce(III) liberated during the oxidation of trimeprazine and trifluoperazine by Ce(IV). The high tolerance level for foreign species can be ascribed to the kinetic aspect of the flow-injection methods; as a consequence, unwanted reactions do not develop to any significant extent in the short measurement period.

The versatility and simplicity of this method allows its adaption to the type of analysis in which a large number of samples of very similar composition have to be analysed, *e.g.*, testing the uniformity of pharmaceutical preparations (required for all solid formulation with < 50 mg of drug).

When this method is compared with other methods that measure the fluorescence of phenothiazines, it can be seen that its sensitivity is as good as those methods which use photochemical oxidation[23–26] but much greater than those based on chemical oxidation.

The method has been successfully applied to the determination of trimeprazine and trifluoperazine in pharmaceutical preparations.

Summary—Cyclodextrins (CDs) can be bound on silica to prepare chiral stationary phases (CSPs) for liquid chromatography. The cyclodextrin ring is connected to a spacer previously bonded on the silica surface. Three different CD-CSPs were prepared with three different spacers. (i) A dimethylethoxysilane with a linear 6 carbon chain produced a monomeric layer. The bonded CD units can move and rotate freely. (ii) The corresponding trimethoxysilane produced a polymeric layer. The bonded CD units were not located at the same distance of the silica surface, but they could still move and rotate freely. (iii) The third spacer contained a cyclohexyl ring that may introduce some conformational rigidity in the CD connection to silica. The three CSPs prepared contained a CD surface coverage of about 0.3 μmol/m^2 which is approximately half of the maximum theoretical CD coverage. The first spacer was the most efficient to bond CDs with an average value of 1.7 spacers per CD ring, whereas 5.5 spacers per CD ring were needed with the two other spacers. The chiral recognition capabilities of the three phases were compared using 14 racemic compounds. No pronounced differences were noted, but the CSP prepared with the dimethylethoxysilane monomeric spacer seems to be the most efficient for chiral recognition.

Stereoisomeric or chiral separations are a very challenging analytical problem. Liquid chromatography (LC) and gas chromatography (GC) are the most powerful techniques in enantiomer separations.[1,2] A chiral stationary phase (CSP) is most often used together with a classical achiral mobile phase. Among the available CSPs for LC are the polymeric chiral phases, the crown ether phases, the protein phases,[3] the π-complex, hydrogen bond phases (Pirkle type),[4] and the cyclodextrin (CD) bonded phases.[1,5] The latter type of CSPs were introduced and developed by Armstrong and DeMond in 1984.[6] To date, three underivatized or native CD–CSPs and nine derivatized CD–CSPs have been marketed. Some derivatized CD–CSPs are multimodal: they can work with non-polar (normal mode) mobile phases and polar (methanol–water or acetonitrile–water) mobile phases which is known as reversed phase mode.[1] The underivatized CD–CSPs can work with reversed mobile phases and with polar but purely organic mobile phases (acetonitrile–methanol phases). The latter mobile phases used together with native CD stationary phases are very effective for chiral separations.[7]

Cyclodextrins have an internal toroidal and relatively non-polar cavity. It can easily accommodate molecules or parts of molecules having the size of an aromatic ring. The secondary 2- or 3-hydroxyl groups of each glucopyranoside ring in the CD are located axially at the mouth of the cavity. They form a polar crown that is most important for chiral recognition. CD rings are not bonded directly on the silica surface to prepare a CD–CSP. Rather, a primary hydroxyl group of the CD is used to graft it on a spacer which was first attached on the silica surface.[5] The aim of this work is to prepare different CSPs with β-CD and different spacer molecules and to investigate the effect of the spacer on the chiral recognition ability of the CSPs. Three β-CD–CSPs were prepared with three different spacers bonded on the same silica base. They were tested with a variety of chiral compounds to determine which spacer gives the best chromatographic performance.

EXPERIMENTAL

Chemicals

The silica base used to prepare the three CSPs was Spherisorb silica from Phase Separations Inc. (Norwalk, CT, U.S.A.). It is a 5-μm spherical bare silica, 220 m^2/g surface area, 8 nm pore diameter and 0.44 cm^3/g pore volume.[8] The three silanizing reagents were three epoxydized methoxysilanes whose full structures and names are presented in Fig. 1. They were obtained from Petrarch Systems as viscous liquids of ~93% purity (Bristol, PA, U.S.A.) and used as received. Toluene, methanol and other usual solvents were obtained from Aldrich (Milwaukee, WI), Sigma (Saint Louis, MO) and Fisher (Pittsburgh, PA, U.S.A.). Water was demineralized and filtered on a Barnstead D8922 system. The chiral solutes were obtained from Sigma as racemates. Fluoxetine is a drug under pharmaceutical investigation at Eli Lilly (Indianapolis, IN). It was kindly supplied by Thomas L. Jeatran.

Bonding procedure

Spacer bonding. Four grams of Spherisorb silica were dried overnight at 110° in a drying gun under vacuum. The dried silica was placed in a flask with approximately 100 ml of anhydrous toluene. Water was further removed at 84° as an azeotrope by distillation of 25 ml into a Dean-Stark trap. Next, 10 ml of the appropriate epoxysilane was added and the solution was maintained at 90–95° for 4 hr. The bonded sorbent was collected on a fritted glass filter and washed with dry toluene followed by methanol and air-dried.

Cyclodextrin bonding. The epoxy bonded sorbent was dried overnight at 60° in a drying gun under vacuum. Four grams of β-CD (3.5 mmoles) were similarly dried in another drying gun. The dried CD was dissolved in approximately 100 ml of anhydrous dimethylformamide (DMF) and 1 g of sodium hydride (NaH, 42 mmoles), as an 80% suspension in paraffin oil, was carefully added. After 15 min at room temperature, the hydrogen gas release stopped. The solid (excess NaH or sodium hydroxide) was filtered off and the solution was added to a round bottom flask containing the dried epoxy bonded sorbent in DMF. The mixture was refluxed for 4 hr. The cyclodextrin bonded sorbent was filtered on a fritted glass filter and washed with the sequence DMF, toluene, methanol, water, methanol again and air-dried.

The silane A (Fig. 1) can only produce a monomeric bonded layer. The two other silanes, B and C, could produce a polymeric layer if some water was introduced at the end of the spacer bonding reaction. Water molecules hydrolyze methoxysilane groups to generate methanol and silanol groups which can further

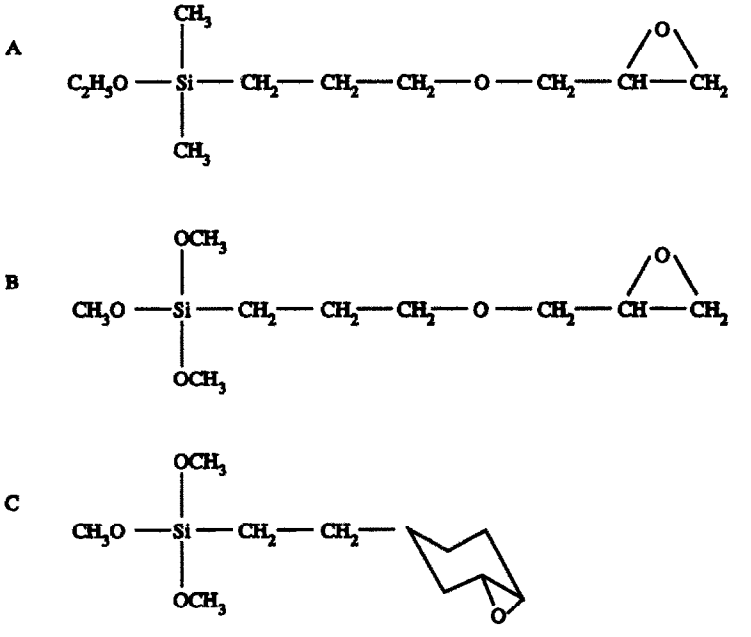

Fig. 1. Structure of the three silanizing reagents. A—3-glycidoxy-propyldimethylethoxysilane. B—3-glycidoxypropyltrimethoxy silane. C—2-(3,4-epoxycyclohexyl)ethyltrimethoxysilane.

Table 1. Characteristics of the chiral phases prepared

Phase type	Bonding agent (Fig. 1)	Spacer bonding		CD bonding		Aver. spacer per CD
		%C	μmol/m²	%C	μmol/m²	
Monomeric	A	1.26	0.6	4.87	0.35	1.7
Polymeric	B	2.59	1.7	5.83	0.32	5.5
Cyclohexyl	C	2.81	1.4	5.47	0.26	5.5

react with the original silane reagent. The reaction with Spacer C was done without any trace of water. At the end of the reaction, water was used in the washing sequence. The residual methoxysilane groups may then be hydrolyzed. Thus, the monomeric bonded spacer C probably bears two silanol groups close to the silica surface. A polymeric CD–CSP was prepared using Spacer B by Tom Beesley at Astec (Advanced Separation Technologies, Whippany, NJ, U.S.A.). The first step was identical to the Spacer C bonding procedure. Next, trace amounts of water were added to hydrolyse some methoxysilane groups and to create silanol groups. Then, more fresh Spacers B were introduced to react with the newly created silanol groups. These steps were repeated four times.

The carbon elemental analysis were done by Galbraith Laboratories Inc, Knoxville, TN, U.S.A.

Chromatographic system

The CD–CSPs were slurry packed in three 25 cm × 4.6 mm i.d. stainless steel columns. A Shimadzu chromatographic system was used with a LC-6A pump, a SPD-6A UV detector, a SCL-6B controller and a CR5A integrator.

RESULTS AND DISCUSSION

The stationary phases

The β-CD ring is more likely attached to the epoxy end group by one of its seven primary hydroxyl groups. These seven more acidic groups protrude on the external side of the CD ring when the less acidic secondary hydroxyl groups are all 21 gathered at the CD mouth. Linkage could occur through secondary hydroxyl groups, but primary hydroxyl groups are less sterically hindered. Table 1 lists the carbon analysis of the three stationary phases after the spacer grafting and after CD addition. The corresponding organic coverage was calculated using

$$\frac{\dfrac{\%C}{12n_c \times 100}}{S\left(1 - \dfrac{\%C}{12n_c \times 100} \times M\right)}$$

in which %C is the carbon mass percentage in bonded sorbent, obtained by elemental analysis, n_c is the number of carbon atoms in the bonded moiety ($n_c = 8$, 6, 8, 42 for Spacers A, B, C and CD, respectively), M is the molecular weight of the bonded moiety ($M = 173$, 175, 187 and 1135 for Spacers A, B, C and CD, respectively) and S is the bare silica surface (220 m²/g).

The bonding density for Spacer B, which produces a polymeric layer, is indicated for comparison and corresponds to an average of 1.7 μmol/m² of 3-glycidoxypropylsilane. From a chemical point of view, Spacer A is the most efficient to link a CD unit to the silica surface. An average value of 1.7 Spacer A units was needed to bond one CD ring. An average value of 5.5 Spacers B and C were necessary to link one CD unit. However, the CD surface concentration was 0.3 μmol/m² for approximately the three phases prepared.

The 0.3 μmol/m² CD surface concentration is more than 10 times lower than the usual surface concentration, in the 3 μmol/m² range,[8] proposed by the manufacturers of classical C18, C8 and C1 LC column packings. The maximum bonding density for linear alkyl chains is close to 5 μmol/m².[9] The height of a CD ring is 0.79 nm and the external diameter of the β-CD ring is 1.53 nm, corresponding to a 1.84×10^{-18} m² area. If the CD ring stands flat on the silica surface, it occupies a square area of about 2.34×10^{-18} m². On a square meter, 4.27×10^{17} CD rings could be packed, which corresponds to 0.7 μmol/m². If the CD ring is placed sideways on the silica surface, the area occupied is about 1.21×10^{-18} m², corresponding to a maximum theoretical bonding coverage value of 1.37 μmol/m². With these data, the 0.3 μmol/m² CD coverage that we obtained experimentally corresponds to

approximately 50% of the maximum CD flat coverage and 22% of the maximum CD sideways coverage. The 220 m^2/g surface area given by the manufacturer includes the surface area of small pores that are not accessible to β-CD rings. This means that it may be very difficult to increase substantially the 0.3 $\mu mol/m^2$ CD bonding coverage obtained using the procedure described in the Experimental section.

Chiral separations

Table 2 lists the results of the separation of 14 compounds already separated by a β-CD phase in a recent study.[10] All drugs were separated on the three stationary phases, adjusting the mobile phase composition (acetonitrile–water + 0.1% triethylammonium acetate) so that the k' values were similar.

The chiral recognition by CD cavities depends on the sp^2 hybridization of the groups attached to the chiral center.[11,12] If the chiral center is part of a ring structure, the chiral recognition by CDs is enhanced.[10,11] The effect of the solvent, the pH and the solute substituents are also very important, as described in other works.[13,14] The highest enantioselectivity factors were obtained with the solutes mephenytoin ($\alpha = 1.42$) and chlorthalidone ($\alpha = 1.19$) in which the chiral center is part of a ring and bears two sp^2 hybridized carbons. The lowest enantio-selectivity factors were obtained with the solutes propranolol ($\alpha = 1.02$) and metoprolol ($\alpha = 1.01$), in both compounds the chiral center is not part of a ring and not connected to sp^2 hybridized carbons. Note that aminoglutethimide has a chiral center in a ring structure with two sp^2 hybridized carbons; however its chiral recognition is very low ($\alpha = 1.02$). Table 2 shows some differences in the enantioselectivity factor of a given compound on the three different phases as discussed below.

Spacer influence

Spacer A is the linear monofunctional spacer of the patented procedure used to prepare the commercialized β-CD-CSP.[5] Spacer B was chosen to obtain a polymeric bonded layer with spacer arms similar to A. Both spacers A and B do not hold the CD ring tightly. They allow some motion that may orientate the CD cavity in any direction. Spacer C contains a cyclohexyl unit that renders the structure more rigid. The CD ring orientation may be limited with this spacer.

Table 2 shows that the enantioselectivity factors for a given compound are not drastically different on the three β-CD CSPs. However, there are some differences. For 10 compounds α is slightly (~0.02 unit) higher on the Spacer A β-CD phase while four compounds have their highest α value on the Spacer B β-CD phase. The chiral recognition seems somewhat more limited on the Spacer C β-CD phase. Figure 2 shows the separation of *N*-dansyl phenylalanine on the three different β-CD CSPs. The racemate is almost baseline resolved on the Spacer B β-CD phase. These small differences in chiral recognition may be due to the difference in CD coverage listed in Table 1.

Table 2 also lists *R*s, the resolution factor between the two enantiomers. The resolution factor combines k', the capacity factor, α, the enantioselectivity factor, and N, the peak efficiency (in plate number). The efficiency was measured by hand using $W_{0.6H}$, the peak width at 60% of the peak height and computed as $N = 4(t_r/W_{0.6H})^2$. Again, the efficiency obtained on the Spacer A β-CD phase is higher, in general,

than the one obtained on the two other phases. Only four compounds showed the highest efficiency on the Spacer B β-CD phase (Table 2). The low efficiency observed with the Spacer C β-CD phase may be due to the silanol groups present at the foot of the spacer after hydrolysis of the two remaining methoxy groups (Fig. 1). The efficiency is especially low with the solutes chlorpheniramine (700 plates) and fluoxetine (1200 plates) which both contain an amino group, but it is equally low (1000 plates) with suprofen, which does not. The fluoxetine separation on the three CSPs is shown in Fig. 3. The selectivity factor is similar on the three phases ($\alpha = 1.06$). The resolution is almost baseline with the Spacer A phase ($Rs = 1.16$ with 7000 plates) and it is very weak with the Spacer C phase ($Rs = 0.41$ with 1200 plates) due to peak broadening. It is known that basic compounds are sensitive to residual silanol groups and produce broad peaks. However, also metoprolol and propranolol have a secondary amino group in their molecule and the observed efficiencies are good (5500 and 6600 plates, respectively). The mobile phase pH was adjusted by triethylamine (0.1% v/v) and acetic acid. Triethylamine was used to shield possible residual silanols.

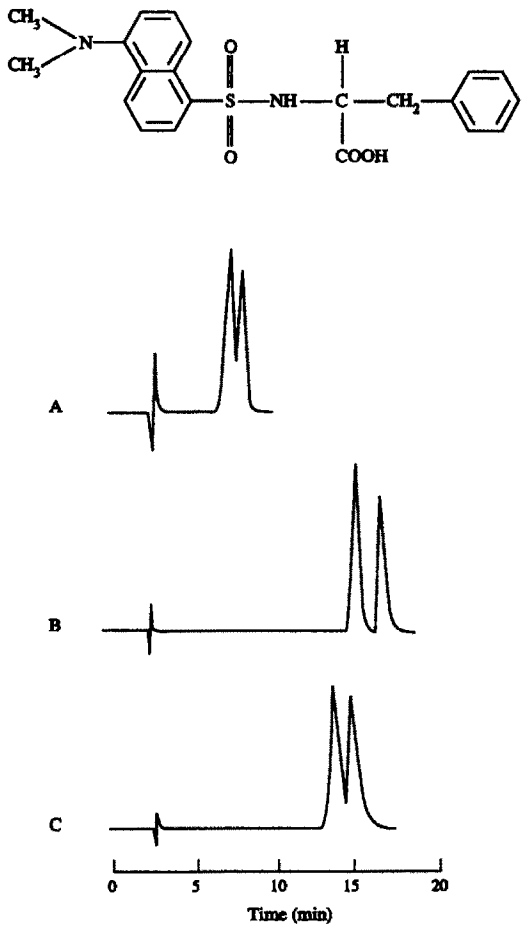

Fig. 2. Enantiomer resolution of *N*-dansyl phenylalanine on the three stationary phases prepared. Mobile phase: 0.1% v/v triethylamine, pH adjusted to 4.1 with acetic acid, water–acetonitrile. A—buffer 70%–ACN 30% v/v; B—buffer 50%–ACN 50% v/v; C—buffer 60%–ACN 40% v/v. Flow rate 1 ml/min. Detection UV = 254 nm.

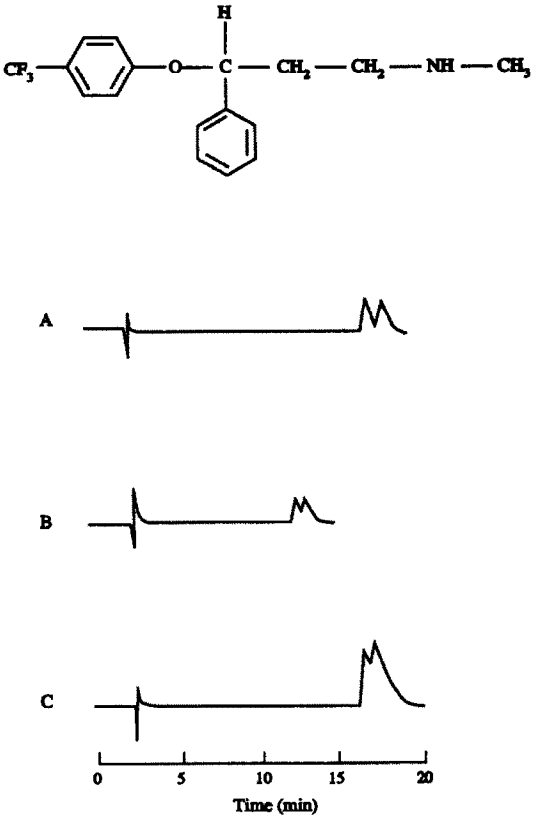

Fig. 3. Enantiomer resolution of fluoxetine on the three stationary phases prepared. Mobile phase: 0.1% v/v triethylamine, pH adjusted to 7.1 with acetic acid, water–acetonitrile. A—buffer 60%–ACN 40% v/v; B—buffer 70%–ACN 30% v/v; C—buffer 60%–ACN 40% v/v. Flow rate 1 ml/min. Detection UV = 254 nm.

CONCLUSIONS

Spacer A produces a monomeric layer. An average value of 1.7 Spacer A molecule is needed to bond one cyclodextrin rings on the surface of silica against 5.5 molecules for the two other spacer studied. From an economical point of view, Spacer A seems the most appropriate to prepare a chiral stationary phase for liquid chromatography. The CD coverage obtained (0.35 μmol/m^2) is close to 50% of the maximum theoretical coverage. The CD coverage obtained with the two other spacers

is similar. However, the Spacer B bonding procedure, that produces a polymeric bonded layer, is more difficult than the two others. The Spacer C phase bears residual silanol groups that may be a problem in a number of chiral separations.

From a mechanistic point of view, this study does not give conclusive advice on the accessibility of the CD rings and on the rigidity of CD bonding to silica. The Spacer A and Spacer B phases join the CD ring to the silica surface with a flexible arm. The CD ring can rotate and take any orientation in the three dimensions. With the Spacer A monolayer bonding, all CD rings may be located at the same distance from the silica surface. With the Spacer B polymeric bonding, the CD rings may be more or less buried in the bonded layer. No significant difference in chiral recognition capabilities were noted with these two phases. The cyclohexyl group in the Spacer C molecule makes the link between the CD ring and the silica surface more rigid. The chiral recognition by the Spacer C phase was somewhat lower than the one obtained with the two other phases. An end-capping treatment would reduce the number of residual silanol groups and may balance the chiral recognition capability of the three phases.

KINETIC SPECTROPHOTOMETRIC DETERMINATION OF LOW LEVELS OF NITRITE BY CATALYTIC REACTION BETWEEN PYROGALLOL RED AND BROMATE

ALI A. ENSAFI* and M. SAMIMIFAR
College of Chemistry, Isfahan University of Technology, Isfahan, Iran

(*Received* 4 *December* 1992. *Revised* 19 *March* 1993. *Accepted* 22 *March* 1993)

Summary—A kinetic spectrophotometric method for the determination of trace nitrite (0.003–1.000 μg/ml) based on its catalytic effect on the reaction between potassium bromate and pyrogallol red in acidic media is described. The reaction is monitored spectrophotometrically by measuring the decreasing colour of pyrogallol red at 467 nm by the fixed-time method. At a given time of 3.0 min at 30°, the detection limit is 0.001 μg/ml and the relative standard deviation for 0.010 μg/ml nitrite is 1.8% ($n = 8$). The method is free from most interferences, especially from large amounts of nitrate and ammonium. The procedure was successfully applied to the determination of trace nitrite in natural water without preconcentration.

In recent years, there has been growing concern about the role of the nitrite ion as an important precursor in the formation of *N*-nitrosamines, many of which have been shown to be carcinogens.[1] The occurrence of nitrite salt in the environment and their use as food preservatives is widespread. Thus there has been an increasing need for a highly sensitive and relatively selective method for the determination of trace nitrite in different natural and artificial samples.

Recent developments in the determination of trace nitrite have been reviewed,[2–4] but not all are suitable for routine trace determination. A spectrophotometric method based in the formation of azo dyes has been investigated.[5–7] These methods suffer from poor sensitivity, interference from other substances, and they typically involve long reaction time and toxic reagents. Other methods such as pulse polarography,[8–10] chromatography[11,12] and spectrofluorometry[13] are also used but suffer from more or less time-consuming procedures and complicated instrumentation. The catalytic kinetic methods[14,15] are one of the most attractive methods for the ultra trace determination of nitrite. Its advantantage is that only a spectrophotometer is required as the main instrumentation.

Few methods for nitrite based on kinetic procedures have been published.[16–18] The bromate oxidation of pyrogallol red (PGR) has been used for the kinetic determination of vanadium[19] and osmium.[20] The present work describes the application of a catalytic method based on the indicator reaction between PGR and potassium bromate in the determination of nitrite. The reaction is monitored spectrophotometrically. The method has been applied satisfactorily to the determination of nitrite in water.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade and were used without further purification. Doubly distilled water was used for the experiments.

Potassium bromate solution ($7.5 \times 10^{-3}M$) was prepared by dissolving 0.313 g of $KBrO_3$ in doubly distilled water in a 250-ml standard flask.

Sodium nitrite was dried at 110° for 4 hr. A 1000-μg/ml nitrite solution was prepared by dissolving 0.375 g of $NaNO_2$ in water in a 250-ml standard flask. A few milligrams (50–100) of sodium hydroxide were added to prevent its decomposition and 0.1 ml of chloroform was also added to prevent bacterial growth. The stock solution was kept in a refrigerator and diluted as required.

PGR solution ($2.50 \times 10^{-4}M$) was prepared by directly dissolving 0.0100 g of PGR (Merck) in methanol in a 100-ml standard flask. The solution is stable for at least 1 month.

Sulphuric acid ($1.35M$) was prepared from concentrated H_2SO_4 (98%, Merck).

*Author for correspondence.

Apparatus

A UV-240 spectrophotometer (Shimadzu) was used for measurements of absorption spectra. A model 35 spectrophotometer (Perkin-Elmer) with 1.0-cm glass cuvettes was used to measure the absorbance at a fixed wavelength (467 nm).

A thermostat (Gallenkamp Griffin, BJ-420-V) was used to keep the reaction temperature at 30°. A stop-watch was used for recording the reaction time.

General procedure

Into a 10-ml standard flask, introduce an aliquot of sample containing 0.03–10 μg of nitrite, 1.0 ml of 1.35M sulphuric acid and 2.0 ml of $2.5 \times 10^{-4}M$ PGR. Dilute the mixture to *ca.* 7 ml. Add 2.0 ml of $7.5 \times 10^{-3}M$ bromate solution, and dilute to the mark with distilled water. Time was measured from just after the addition of the bromate solution. The blank solution was prepared by the same procedure. Keep the sample and blank tube at $30 \pm 0.1°$ in a thermostat bath. After 3.0 min, add 0.1–0.2 g of solid urea to the solution to stop the catalyzed reaction. Transfer the solutions into 1.0-cm glass cuvettes and measure the absorbance of the solutions against water. Label the absorbance of the sample and blank A and A_0, respectively. Then determine the amount of nitrite from a calibration graph.

RESULTS AND DISCUSSION

It was found that some oxidants such as bromate could oxidize PGR in acidic media at a very slow rate.[17,20] On the other hand, the oxidation of PGR by bromate in acidic media is increased in the presence of ultra-trace amounts of nitrite. This reaction can be followed spectrophotometrically by monitoring the change in absorbance at 467.0 nm. Figure 1 shows the absorption spectra of PGR at different times.

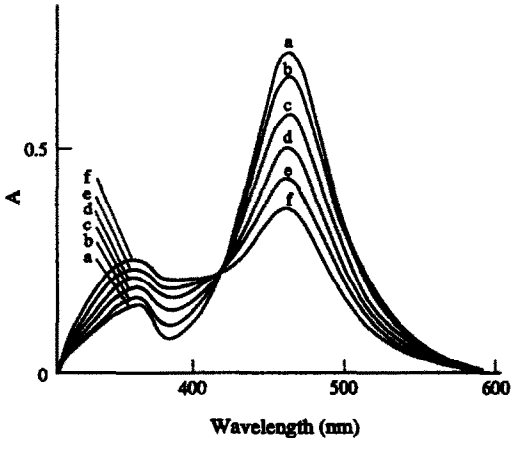

Fig. 1. Variation of PGR–BrO_3^- oxidation system with time in the presence of nitrite; at the optimum conditions with 0.10 μg/ml of nitrite after a. 30 sec; b. 130 sec; c. 230 sec; d. 330 sec; and f. 430 sec, from initiation of the reaction.

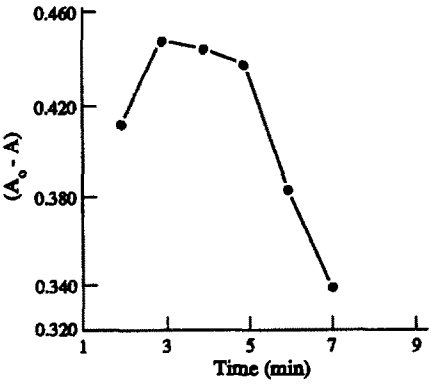

Fig. 2. Effect of time on the reaction rate; conditions: H_2SO_4, 0.0135M; PGR, $4.8 \times 10^{-5}M$; BrO_3^-, $1.5 \times 10^{-3}M$; nitrite, 0.400 μg/ml.

There are many methods such as fixed-time, initial rate and rate constant method for measuring the catalytic species. Among these, the fixed-time method is the most conventional and simple, involving the measurement of A_0 and A at 467.0 nm. Figure 2 shows the relationship between A_0–A and reaction time for the reaction. From the results, 3.0 min was chosen as the optimum interval reaction time.

Effect of variables on the rate of reaction

Experimental results showed that the catalytic reaction can proceed only in strongly acidic media (pH < 3). Among sulphuric, hydrochloric

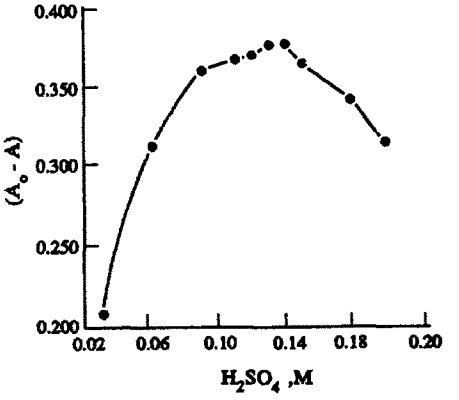

Fig. 3. Effect of sulphuric acid concentration on the reaction rate; conditions: PGR, $7.5 \times 10^{-5}M$; BrO_3^-, 0.001M; nitrite, 0.400 μg/ml and reaction time, 3.0 min.

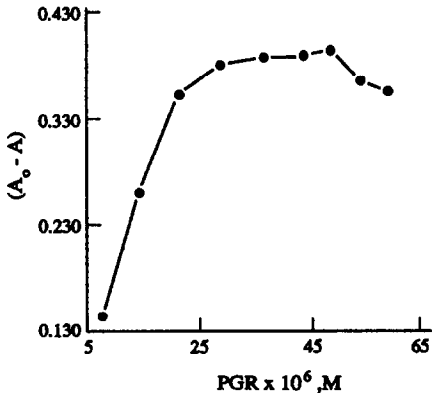

Fig. 4. Effect of BrO_3^- concentration on the rate of reaction; conditions: H_2SO_4, 0.135M; PGR, $5 \times 10^{-5}M$; nitrite, 0.400 μg/ml and reaction time, 3.0 min.

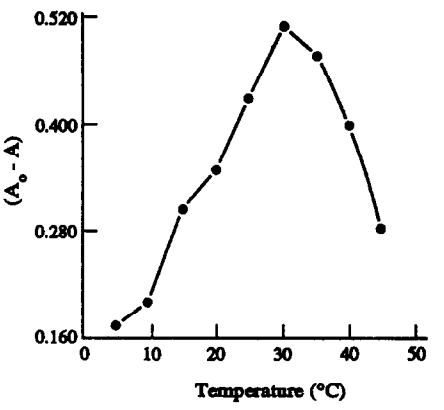

Fig. 6. Effect of temperature on the rate of reaction; conditions: H_2SO_4, 0.135M; PGR, $5 \times 10^{-5}M$; BrO_3^-, $1.5 \times 10^{-3}M$; nitrite, 0.400 μg/ml and reaction time, 3.0 min.

and phosphoric acid, 0.135M sulphuric acid was the optimum as shown in Fig. 3.

The effect of $KBrO_3$ concentration on obtaining maximum sensitivity was investigated. Figure 4 shows that the optimum concentration of $KBrO_3$ is $1.5 \times 10^{-3}M$. Thus $1.5 \times 10^{-3}M$ $KBrO_3$ was used for the study.

The effect of PGR concentration on the rate of catalyzed and uncatalyzed reaction was studied. Figure 5 shows that the A_0–A increases with increasing PGR concentration, thus $5.0 \times 10^{-5}M$ PGR was adopted.

The effect of reaction temperature was studied in the range 5–45°. Figure 6 shows that below 30°, A_0–A increases with temperature, but at higher temperatures it decreases, owing to the decrease in A_0; this means that the rate of the uncatalyzed reaction increases with temperature to a greater extent than the catalyzed reaction and the difference between the rate of the catalyzed and uncatalyzed reaction (equivalent to A_0–A) diminishes at high temperature. The drop in absorbance difference (A_0–A) could also be due to a change in reaction mechanism. The optimum reaction temperature was fixed at 30°.

Rapid cooling, or the use of a chemical inhibitor, can be used to stop the catalytic reaction, which may be required in the fixed-time method in practical applications. It was found that urea is a very good inhibitor which decomposes nitrite rapidly. Addition of 0.1–0.2 g of urea quenches the catalyzed reaction almost completely and very rapidly dissolves in 10 ml of the solution. The absorbance of the solution remains constant for at least 5 min in the presence of urea.

The effect of ionic strength on the rate of reaction was studied by using $NaNO_3$ (3M). The results indicate that, the rate of reaction increases very slightly when ionic strength increases from 0.01 to 1.0M (Fig. 7).

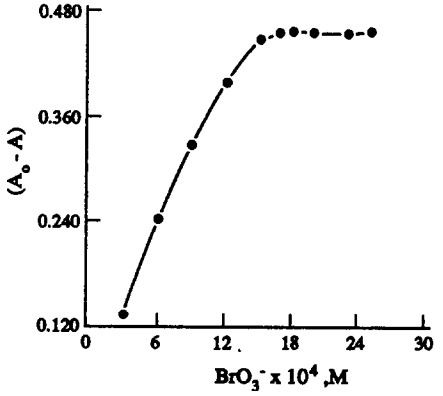

Fig. 5. Effect of PGR concentration on the rate of reaction; conditions: H_2SO_4, 0.135M; BrO_3^-, $1 \times 10^{-3}M$; nitrite, 0.400 μg/ml and reaction time, 3.0 min.

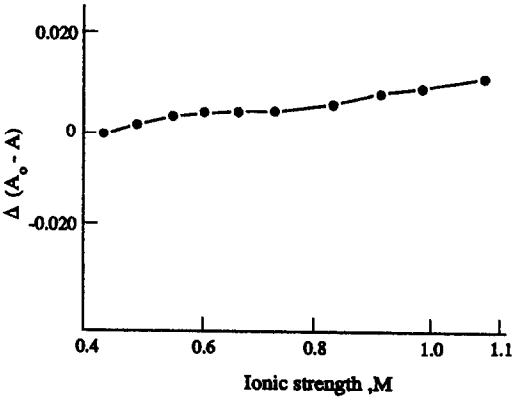

Fig. 7. Effect of ionic strength on the rate of reaction (at the optimum conditions with 0.400 μg/ml nitrite).

Table 1. Determination of nitrite in water ($n = 6$)

Sample	Amount of nitrite found ($\mu g/ml$)		
	This method	Reference value	RSD%*
River Water	0.020	0.022	1.2
Lake Water	0.110	0.105	1.3
Tap Water	0.035	0.034	1.0
Waste Water	0.250	0.258	1.4

*For the proposed method.

Calibration

Under the optimum conditions described above, and the concentration range 0.003–1.000 μg/ml the following regression equation was obtained:

$\log(A_0/A) = -4.116 \times 10^{-3} + 0.934C$ ($n = 5$ and $r = 0.9993$), where C is the concentration (μg/ml) of nitrite.

The experimental limit of detection is 0.001 μg/ml. The relative standard deviation is 1.8 and 1.2% for 0.010 and 0.500 μg/ml nitrite, respectively.

Interferences

More than 50 ions were tested for their possible interference with the determination of nitrite. The results showed that at least 10,000-fold alkali and alkaline earth metal ions and Al(III), Zn(II), Cu(II), U(VI), La(III), Th(IV), Co(II), Cd(II), Mn(II), Zr(IV), Ni(II), acetate, citrate, $B_4O_7^{2-}$, tartarate, CO_3^{2-}, F^-, ClO_4^-, CN^-, $C_2O_4^{2-}$, 1000-fold Cl^-, $S_2O_5^{2-}$, Ir(III) do not interfere, but more than 30-fold Mo(VI), Bi(III), Ce(III), Ag(I), Cr(III), Fe(III), SCN^-, I^-, Br^-, S^{2-}, Hg(II), and 5-fold V(V), V(III), Ce(IV), As(III), IO_4^- interfere. It is important to note that up to 10^6-fold nitrate has little effect, making possible the determination of trace amounts of nitrite in nitrate. The interference of ions may be due to the complex formation of PGR with metal ion or due to the catalytic effects of metal ion (such as V(V) and Ce(IV)) on the reaction.

Determination of nitrite in real samples

Four samples of water were analyzed by the above procedure.

For analysis of real samples some pretreatment is necessary. All suspended particles should be removed by suitable procedures. For tap water analysis, chlorine should also be removed to prevent oxidation of PGR.

For waste water samples, precentrifugation was used. For river water samples, 1 ml of a saturated solution of aluminum hydroxide was added to precipitate the suspended particles, then a mixed solution was filtered and the filtrate used for analysis. The results agreed well with those given by the standard method,[21] and the recovery was also good enough for practical use, as shown in Table 1.

Summary—Four amphetamine derivatives bearing a methylenedioxy group at positions 3 and 4 of the benzene ring and differing in their substitution at C(6) were studied by differential pulse voltammetry in aqueous media. These experiments showed a single oxidation peak for the C(6)-H, -Br and -Cl compounds, while the C(6)-NO_2 analogue was not oxidized. The oxidation peak is interpreted as due to the removal of one electron from the aromatic electrophore with formation of a radical cation stabilized by the dioxole ring. The linear relationship between the peak current and the concentration of the derivatives is appropriate for development of a quantitative method for their determination. pK′ values were determined using both electrochemical and spectrophotometric methods.

The last few years have seen a renewal of interest in the psychotropic drugs 1-(3,4-methylenedioxyphenyl)-2-aminopropane or 3,4-methylenedioxyamphetamine (MDA) and its *N*-methyl and *N*-ethyl analogues (MDMA, "XTC", or "Adam", and MDEA or "Eve", respectively), owing to their disputed use in psychotherapy and to their neurotoxicity.[1,2] MDMA may be regarded as the prototype of a new class of drugs called "entactogens"[3,4] whose mechanism of action and structural requirements are almost totally unknown. It is only clear at this time that their subjective effects differ from those of the structurally similar phenylalkylamine hallucinogens, and that these effects are mainly due to their (S) isomers while the more potent hallucinogens possess the (R) configuration. Thus far, the exploration of this group of compounds has been limited to variations of the amine chain keeping the 1-(3,4-methylenedioxyphenyl) moiety intact and devoid of additional substitution, and has only very recently been extended to include the aminotetralin and aminoindan analogues.[3–5] Nevertheless, it is known that the bromination of MDA to afford 1-(6-bromo-3,4-methylenedioxyphenyl)-2-aminopropane leads to a non-hallucinogenic compound whose subjective effect was interpreted almost twenty years ago as "amphetamine-like" although this was only observed in the rather high dose range which is also required for MDA, MDMA and MDEA.[6,7]

As part of a synthetic program related to the known "entactogens", MDA and the above mentioned bromo derivative were prepared once more, as well as another two compounds substituted at C(6) of the benzene ring with a chlorine atom or a nitro group, respectively. In order to round out our vision of substituent effects on the electrochemistry of amphetamine analogues, obtained with a series of 1-(2,5-dimethoxyphenyl)-2-aminopropane derivatives substituted at C(4),[8] we have now studied the voltammetric behavior of MDA and its congeners.

The electrochemistry of amphetamine derivatives is an unexplored field of research. There are only three published papers related to: the nitro-reduction of 2,5-dimethoxy-4-nitroamphetamine (DON)[9] and 4,5,-dimethoxy-2-nitroamphetamine,[10] and the electrochemical behavior of several 4-substituted 2,5-dimethoxy-amphetamine derivatives.[8] From this latter work it is possible to conclude the existence of a correlation between the ring substitution and the oxidation potential. As the ring substitution in the amphetamine derivatives play an important role in their pharmacological activity, it may be possible to find empirical relationships between oxidation potentials and pharmacological activities.

EXPERIMENTAL

Reagents

MDA and its C(6)-bromo analogue were synthesized following published procedures.[6,7] Melting points are uncorrected. ^{1}H NMR spectra were recorded at 60 MHz in D_2O unless stated otherwise (chemical shifts in ppm from TMSPA-d_4).

1-(3,4-methylenedioxyphenyl)-2-aminopropane. (3,4-MDA)hydrochloride. M.p. 193.5–194.5° (i-PrOH-EtO); ^{1}H NMR (TFA) δ (from TMS) 1.53 (3H, d J = 6.4 Hz, C-CH3), 3.0 (2H, m, CH2), 3.8 (1H, m, CH), 6.02 (2H, s, OCH2O), 6.85 (3H, br s, ArH).

1-(3,4-methylenedioxyphenyl-6-nitrophenyl)-2-aminopropane. (3,4-MD-6-NA) nitrate. 1-(3,4-methylenedioxyphenyl)-2-aminopropane (2.00 g) was dissolved in 2*N* HNO_3 (5.5 ml) and treated dropwise, with efficient stirring and cooling, with 65% HNO_3 (6 ml). After several minutes the product separated out as a thick creamy precipitate which was diluted with water (18 ml), collected by filtration, resuspended in water, filtered again and dried. The yield was practically quantitative, m.p. 171° (decomp.) (EtOH); ^{1}H NMR δ (DMSO-d6) 1.19 (3H, d J = 6 Hz, C-CH3), 3.10 (2H, d J = 6 Hz, CH2), 3.5 (1H, m, CH), 6.27 (2H, s, OCH2O), 7.10 (1H, s, ArH), 7.67 (1H, s, ArH). Anal. C, 41.94; H, 4.59; N, 14.49%; calc. C10H13N207; C, 41.82; H, 4.56; N, 14.63%.

1-(6-bromo-3,4-methylenedioxyphenyl)-2-aminopropane(6-Br-3,4-MDA) hydrochloride. M.p. 221–222° (i-PrOH-acetone); ^{1}H NMR δ 1.32 (3H, d J = 6.5 Hz, C-CH3), 3.00 (2H, app. d Japp = 7 Hz, CH2), 3.7 (1H, m, CH), 6.00 (2H, s, OCH2O), 6.85 (1H, s, ArH), 7.12 (1H, s, ArH). Anal. C, 40.73; H, 4.49; N, 4.40%; calc. C10H13BrClNO2; C, 40, 76; H, 4.45; N, 4.75%.

1-(6-chloro-3,4-methylenedioxyphenyl)-2-aminopropane (6-Cl-3,4-MDA) hydrochloride. Prepared by LiAlH4 reduction of 1-(6-chloro-3,4-methylenedioxyphenyl)-2-nitropropene in Et_2O and precipitation of the salt; m.p. 222.5–223.5° (i-PrOH); ^{1}H NMR δ 1.33 (3H, d J = 6.4 Hz, C-CH3), 2.97 (2H, app. d Japp = 7 Hz, CH2), 3.7 (1H, m, CH), 6.01 (2H, s. OCH2O), 6.87 (1H, s, ArH), 7.00 (1H, s, ArH). Anal. C, 47.85; H, 5.28; N, 5.28%; calc. C10H13Cl2NO2: C, 48.02; H, 5.24; N, 5.60%.

Voltammetric experiments were carried out in buffered aqueous solutions containing 0.02*M* phosphoric acid with 0.02*M* acetic acid for pH 1–8.5 or 0.02*M* Na_2CO_3 for pH 8.5–12. The ionic strength was raised to 0.3*M* with $NaNO_3$.

For spectrophotometric experiments the Universal UV Spectroscopy buffer containing 0.1*M* in citric acid, potassium monophosphate, sodium tetraborate, TRIS and potassium chloride was used.

For both buffers, the pH was adjusted using HCl or NaOH. All reagents were p.a. grade.

The solid electrodes were routinely cleaned with chromic acid solution for 10 sec. This procedure permit to increase the reproducibility considerably.

Apparatus

A Tacussel CPRA thermostatic cell with three different working electrodes (platinum, glassy carbon and carbon paste) was employed. A platinum wire and a saturated calomel electrode were used as auxiliary and reference electrodes. A TACUSSEL model EDI rotating electrode assembly was used with platinum and glassy carbon electrodes. A METROHM carbon paste electrode with a geometric area of 38.5 mm^2 was also used.

Electrochemical data were obtained from an Inelecsa assembly equipped with the following elements:

(a) a generator–potentiostat type PDC-210.

(b) an interface containing 12-bit A/D and D/A converters, connected to a microprocessor with suitable software for fully automated control of the experiments and data acquisition. A Multitech, Apple II Plus-compatible microcomputer was used for data control, acquisition and treatment.

UV-Vis spectra were recorded using a SHIMADZU UV-160A spectrophotometer with 1 cm quartz cells.

A VARIAN Anaspect EM-360 (60 mHz) NMR spectrometer for NMR measurements was used.

RESULTS AND DISCUSSION

The present paper deals with the study of the voltammetric behavior of 3,4-methylenedioxyamphetamine (MDA) and its 6-chloro, 6-nitro and 6-bromo derivatives (Fig. 1).

In aqueous solution, using platinum, glassy carbon and carbon paste electrodes as working electrodes, MDA and the 6-chloro and 6-bromo derivatives produce an anodic peak which is

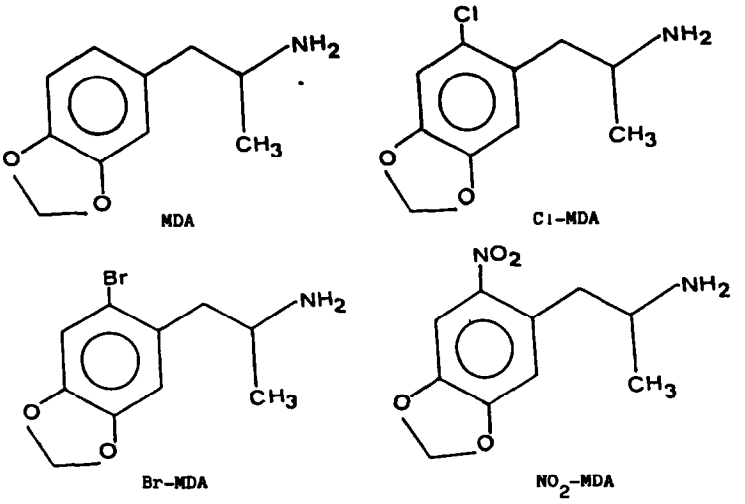

Fig. 1. Molecular structures of 3,4-methylenedioxyamphetamine (MDA) and its 6-chloro (Cl–MDA), 6-nitro (NO_2–MDA) and 6-bromo (Br–MDA) derivatives.

best resolved using differential pulse voltammetry. Unlike these compounds, the 6-nitro derivative of MDA did not reveal any anodic peak under these conditions. For comparative purposes, we also examined the electrochemical behavior of unsubstituted amphetamine and 2-methoxy amphetamine. No oxidation peaks were obtained for these compounds, suggesting that the anodic process observed with the other analogues does not involve the amine-substituted side chain but rather the 3,4-methylenedioxy-substituted benzene ring. In earlier work,[8] similar behaviour was observed for the 2,5-dimethoxyamphetamine derivatives.

The MDA and its chloro and bromo derivatives exhibited a single voltametric peak over the entire pH range studied, extending from pH 1 to 12. The peak potential (E_p)–pH plots (Fig. 2) show two linear segments for each compound, indicating that the electrode process is pH-dependent over the whole range. E_p decreases linearly with increasing pH; therefore, these compounds are oxidized more easily in more alkaline solutions as expected for common oxidative behavior. Moreover, the breaks in the E_p–pH plots can be ascribed to the voltammetric pK' values, showing that, when $pH < pK'$ the dominant chemical species is the protonated amine and when $pH > pK'$ the free base is more abundant. In order to confirm the above assumption we also studied the pH influence on the UV absorption spectra of the derivatives. In Fig. 3 we can observe the UV spectra of the amphetamine derivatives at two different pHs, displaying the strong pH-dependence of their UV band at approximately 210 nm. In the Fig. 4 plots of the absorptivity as a function of pH for the band at 210 nm are shown. From these curves we estimate the UV spectrophotometric pK_a values, which can be found in Table 1. The

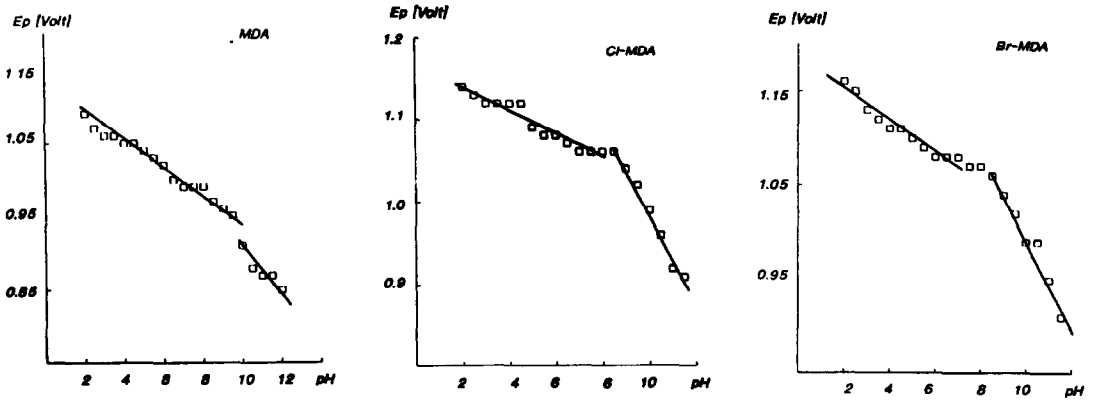

Fig. 2. Variation of the peak potential (E_p) with pH for the differential pulse voltammetric oxidation of the 3,4-methylenedioxyamphetamine derivatives. Voltammograms obtained on glassy carbon electrode.

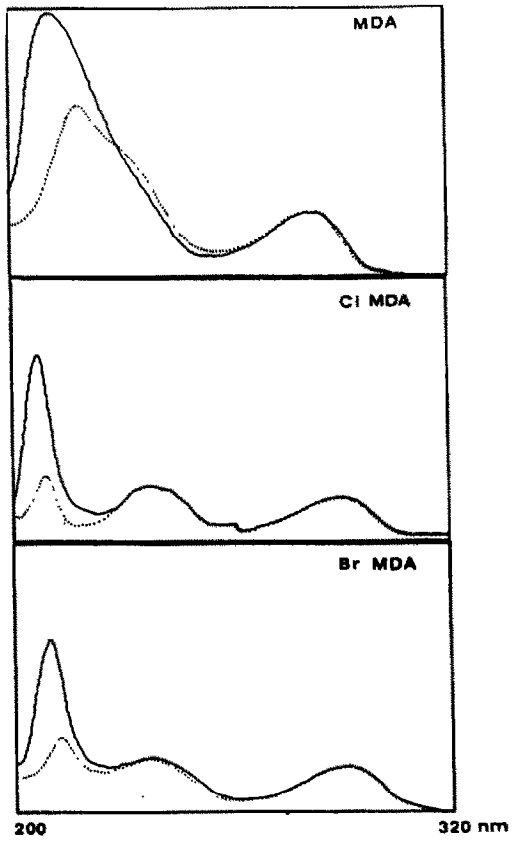

Fig. 3. UV spectra for the 3,4-methylenedioxyamphetamine derivatives. Solid line, pH = 2. Dashed line, pH = 10.

agreement between the voltammetric and the UV values supports the validity of the above assumption.

Examination of the peak current (i_p) values indicates that these fall (Fig. 5), and the peak broadens, as the pH rises. This may be due to a decrease in the heterogeneous rate constant affected by proton transfer.[11]

We also studied the electrochemical behavior of all derivatives under two different experimental conditions: a) variation of the temperature using a glassy carbon electrode as a working electrode, b) the effect of a platinum rotating disk electrode as a working electrode, maintaining a constant temperature (25°). From these experiments it was concluded that I_p does not exhibit variation with temperature or the rate of rotation, indicating that the oxidation rate is controlled by charge transfer without participation of the diffusion of the electroactive species to the electrode surface.

Table 1. pK' values obtained by voltammetric (glassy carbon and carbon paste electrodes) and spectrophotometric methods

Drug	Voltammetric C.P.E.	Voltammetric G.C.E.	Spectrophotometric
MDA	9.15	9.20	9.21
Cl–MDA	9.10	9.30	9.02
Br–MDA	8.75	8.80	9.12

One of the goals of this work was to evaluate the incidence of the C-6 substituent on the electrochemistry of these drugs. The experimental evidence here shown indicates that the electron acceptor or donor character of this substituent is directly related to the greater or lesser ability of oxidation. A simple explanation is that the electron-donating substituent increases the electron density of the aromatic ring π system, making it easier to remove an electron, thus producing a cation radical which is stabilized by the methylenedioxy group at C-3 and C-4. Consistent with this latter interpretation, the lowest E_p value was found for MDA itself, which lacks any substituent at C-6. Conversely, the chloro- and bromo-derivatives present higher E_p values. In these cases, the oxidation of the ring system is presumably more difficult due to the decreased stability of the resulting cation radical. In Fig. 2 we can see that

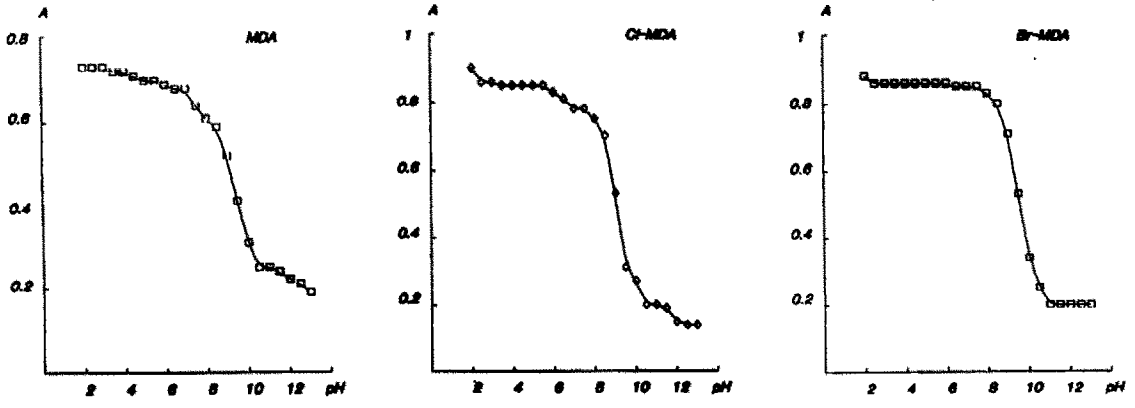

Fig. 4. Absorbance–pH plots for the band at 210 nm for the 3,4-methylenedioxyamphetamine derivatives.

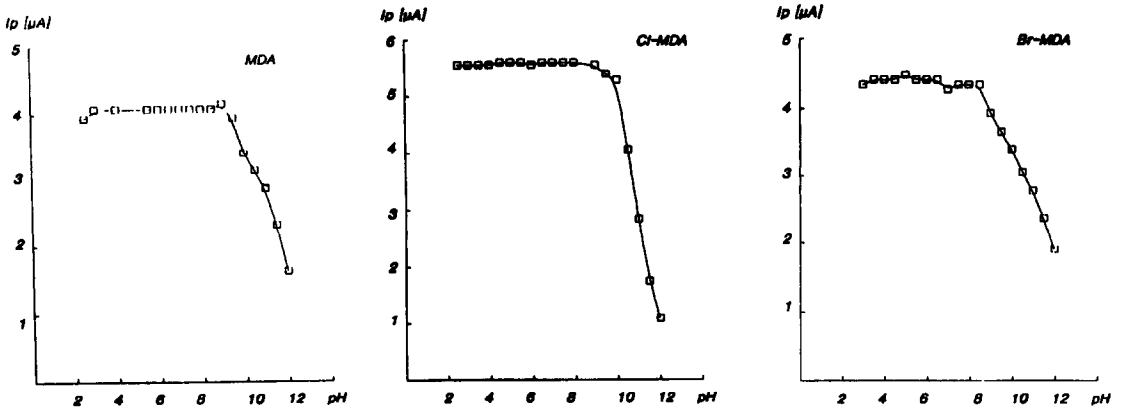

Fig. 5. Peak current–pH dependence for the amphetamine derivatives. Glassy carbon electrode, 25°.

in all the pH range the E_ps follow the order: MDA < Cl MDA < Br MDA. From the above results, it seems obvious that direct oxidation of the aromatic ring, influenced by the C-6 substituent, is occurring. Although, the suggestion that a carbocation is formed in an aqueous medium is arguable, it is quite justified in this case due to the stabilizing effect of the methylenedioxy group. This effect is well documented for a similar substituent, the methoxyl group.[12]

Linear sweep cyclic voltammetric experiments showed a single oxidation peak for all drugs, recording the voltammograms at sweep rates between 50 mV/sec and 5 V/sec at pH 7. From this study it can be seen that the potential peak shifts anodically by about 30 mV for each 10-fold increase in sweep rate. These results agree with an EC mechanism[13] with a one-electron transfer in the electrochemical step and a subsequent chemical reaction, *e.g.*, the electrochemical formation of a cation radical with a subsequent chemical reaction of this species. The chemical reaction of the cation radical is fast enough for the reduction of the cation radical not to occur in the time scale of the experiment.

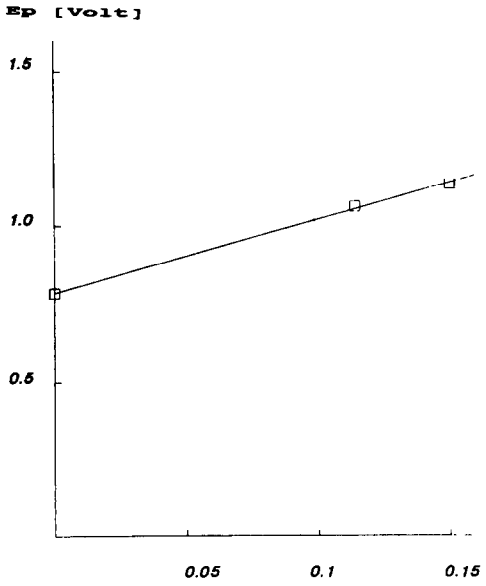

Fig. 6. Linear relationship between the extra-thermodynamic parameter, σ_p^+, and the peak potential of the amphetamine derivatives. pH 7 on glassy carbon electrode.

In order to confirm the relationship between E_p and the effect of the C-6 substituent on the oxidizable moiety, we consider σ_p^+ as an extra-thermodynamic parameter which combines the inductive and resonant effects of the substituents on the benzene ring. This factor can be applied to oxidation reactions involving resonance stabilization of a positive charge in an aromatic ring.[14] As can be seen in Fig. 7, there is a linear relationship between the σ_p^+ factor of the C-6 substituents and the E_ps experimentally obtained by differential pulse voltammetry. From the above behavior it is possible to extrapolate an E_p value for the 6-nitro derivative. The extrapolated value was 1460 mV, which is located in the discharge zone of the support electrolyte, explaining the absence of any oxidation peak for this derivative.

The voltammetric technique also can be used as an analytical tool to quantify these derivatives in aqueous solution. For this purpose we studied the dependence of the voltammetric peak on the concentration of the amphetamine derivatives. A linear relationship between the peak current and the concentration of the derivatives for 0.01 m*M* and 0.1 m*M* solutions at pH 7 were found (Table 2).

Peak potentials were independent of the concentration indicating that no adsorption or second order processes are involved. Reproducibility studies were carried out with the carbon

Table 2. Linear relations between peak current and concentrations of the drugs for 10 points between 0.01 m*M* and 0.1 m*M*. pH = 7.0, 25° and CPE as the working electrode.
i_p (μA) = slope × C (*M*) + intercept

Drugs	Intercept	Slope × 10^{-5}	Correlation
MDA	1.306	1.668	0.996
Br–MDA	−0.168	1.625	0.994
Cl–MDA	−0.938	1.386	0.995

paste and glassy carbon electrodes, obtaining an average CV = 0.5 and 0.4% for the peak potentials and a CV = 3.8 and 3.4% for the peak currents, respectively. These results indicate good reproducibility and accuracy to develop a quantitative voltammetric assay for these derivatives. Furthermore, the behavior presented here would be useful for developing a method of HPLC with electrochemical detection. On the other hand, stability assays allow us to conclude that aqueous solutions of these compounds remain unchanged after 30 days at room temperature under normal room light.

SCREENING OF URINARY COPROPORPHYRIN USING CLOUD POINT EXTRACTION AND CHEMILUMINESCENCE DETECTION

WILLIAM J. HORVATH and CARMEN W. HUIE

Department of Chemistry, State University of New York at Binghamton. P.O. Box 6000, Binghamton, NY 13902-6000, U.S.A.

(*Received* 23 *November* 1992. *Revised* 2 *March* 1993. *Accepted* 3 *March* 1993)

Summary—A simple screening test was developed for the sensitive and selective measurement of urinary coproporphyrin. In this screening test, efficient and selective extraction/pre-concentration of coproporphyrin from the aqueous medium(urine) into a much smaller volume phase containing a common non-ionic surfactant (Triton X-100) and ethyl acetate was accomplished by the addition of a relatively large amount of a cloud point depressing electrolyte (K_3PO_4) into the sample solution to effect cloud point separation. Sensitive and selective detection of coproporphyrin in the mixed Triton X-100 and ethyl acetate phase was performed via chemical excitation using the peroxyoxalate chemiluminescence reaction. The effects of surfactant and cations (from the cloud point depressing electrolyte) on the chemiluminescence intensity of coproporphyrin were briefly investigated. Furthermore, the spectrum of urinary coproporphyrin obtained using the present chemiluminescence method was briefly compared with that obtained from fluorescence method.

Measurement of porphyrins present in biological materials is important for the diagnosis of a group of disorders known as porphyrias.[1–5] These diseases can be inherited or acquired and are usually linked to a deficiency in enzyme activities associated with the heme bio-synthetic pathway. In most clinical laboratories determination of elevated levels of porphyrins in biological fluids such as urine usually involves simple screening tests. Most of these tests consist of an extraction procedure involving the use of talc[5] or organic solvents,[6] *e.g.* ethyl acetate, followed by visual observation of the fluorescent color of the extract under ultraviolet (UV) light. Recently a sensitive and selective method based on the use of flow injection analysis and visible laser fluorimetry has been developed for the rapid screening of a large number of untreated urine samples.[7]

A major limitation of conventional screening tests lies in their inability to estimate the individual concentrations of the two major urinary porphyrin components, *i.e.* coproporphyrin and uroporphyrin. This is an important problem because it is often necessary to distinguish coproporphyrinuria from uroporphyrinuria; the former is more common and its occurrence usually signifies a number of significant diseases such as malignancies, alcohol cirrhosis, infectious hepatitis, lead poisoning, hereditary coproporphyria and variegate porphyria.[1–5] Relatively simple chromatographic procedures have been employed to separate urinary coproporphyrin from uroporphyrin;[8] however, these procedures add extra complexities, costs and time to the screening tests. A possible solution to this problem involves the use of ether to extract coproporphyrin but not uroporphyrin from urine, followed by fluorimetric excitation of the ether layer using UV light.[9] However, this method lacks sensitivity, and perhaps more importantly, efficient and selective extraction of coproporphyrin into the ether layer is highly sensitive to pH and matrix effects. Moreover, ether presents a fire hazard in clinical laboratories.

In recent years analytical methods based on chemiluminescence(CL) have been shown to be highly sensitive and selective for the determination of a large number of biologically important molecules.[10,11] In particular CL based methods are especially well suited for routine analyses in clinical laboratories due to their simplicity and low cost. Albrecht *et al.*[12,13] have recently exploited the advantages of CL and developed a sensitive and highly selective screening test for urinary porphyrins based on the peroxyoxalate CL reaction. When compared to one of the most commonly used screening tests, *i.e.* talc test, the sensitivity of the

porphyrin-sensitized peroxyoxalate CL test was quite similar (visual detection limit ~250 μg/l. of porphyrins in urine). Unfortunately, as in the talc test, this particular CL-based screening test was not selective for coproporphyrin. Positive CL results (orange or red CL emission) can arise from elevated levels of coproporphyrin and/or uroporphyrin due to chemical excitation involving the oxidation of bis(2,4-dinitrophenol) oxalate (DNPO).

In this paper a simple screening test capable of highly sensitive and selective detection of urinary coproporphyrin based on the use of cloud point extraction and peroxyoxalate CL reaction is reported. The use of a relatively stable peroxyoxalate CL reagent—bis(2,4, trichlorophenyl) oxalate (TCPO)—to generate relatively strong and long lasting CL emission from urinary coproporphyrin was made possible by extracting and pre-concentrating the coproporphyrin from urine into a smaller volume phase containing a common non-ionic surfactant (Triton X-100) and ethyl acetate.

EXPERIMENTAL

Reagents

Coproporphyrin, pentacarboxylporphyrin, hexacarboxylporphyrin, heptacarboxylporphyrin and uroporphyrin were all obtained from Porphyrin Products (Logan, UT, U.S.A.). Analytical grade Triton X-100 and imidazole were obtained from Sigma (St Louis, MO, U.S.A.). Acetonitrile(HPLC grade), tri-potassium phosphate, sodium and potassium monohydrogen phosphate, 30% hydrogen peroxide, ethyl acetate, magnesium sulfate, ammonium sulfate, and zinc sulfate were obtained from Fischer Scientific (Fairlawn, NJ, U.S.A.). Di-sodium sulfate was obtained from Baker (Phillipsburg, NJ, U.S.A.). DNPO was obtained from Fluka (Lake Ronkonkoma, NY, U.S.A.). All water used was doubly distilled and deionized.

TCPO was prepared by the method of Mohan and Turro[14] and recrystallized from benzene to ensure purity. TCPO solutions ($1.3 \times 10^{-3} M$) were prepared by dissolving appropriate amounts of TCPO in ethyl acetate. H_2O_2 solutions ($1 \times 10^{-2} M$) were prepared by diluting 30% hydrogen peroxide with acetonitrile. The chemiluminescence reagent solution was prepared by combining equal volumes of both TCPO and H_2O_2 solutions. This solution is unstable and should be used within 15 min of mixing. Surfactant solutions (1% Triton X-100 v/v) were prepared by dissolving appropriate amounts of Triton X-100 in doubly distilled deionized water. Stock solutions of porphyrin standards were prepared by dissolving in acidified (pH 1) doubly distilled deionized water and then stored at 5° in the dark.

Urine samples were collected from a healthy male over a 24 h period and were preserved with sodium carbonate (5 g/l. urine) and ethylenediaminetetraacetate (3 g/l. urine) and stored under refrigeration in the dark at 5°. To prepare urine samples spiked with various known concentrations of porphyrin standards naturally occurring porphyrin was removed by employing the talc extraction procedure described in literature.[15] Urine was readjusted to its previous pH after porphyrin removal.

Apparatus

Fluorescence measurements used to determine extraction efficiencies ($E\%$) were taken with a SLM 8000 photon-counting spectrofluorometer (Amico, Urbana, IL, U.S.A.) The bandwidths of the emission and excitation monochromator were set at 16 nm. The excitation wavelength of all the measurements was set at the Soret band at ~400 nm. The sample solutions were placed in a 1-cm pathlength quartz cell.

CL spectra were obtained using a home-made fiber optic device connected to a Perkin-Elmer fluorescence spectrometer (model 650-10M, Norwalk, CT, U.S.A.) with the light source turned off; for purposes of comparison, fluorescence spectra were obtained using the same spectrometer with the light source turned on. CL was initiated in the test tubes by the addition of CL reagent solution using a syringe. One end of the fiber optic was placed next to the meniscus of the solution on the outside of test tube. The other end of the fiber optic was connected to a monochromator that was interfaced to a photomultiplier tube. To acquire CL and fluorescence spectra scan speed and bandwidth of the monochromator were set at 480 nm/min and 16 nm, respectively.

Procedure

A 10 ml urine sample spiked with porphyrin standards was placed into a test tube and diluted with an equal volume of surfactant solution (Triton X-100, 1% v/v). A small amount of ethyl acetate (~0.5 ml) was then poured into the tube so that a small layer of ethyl acetate just covers the meniscus of the sample solution

(alternatively, the ethyl acetate can be added to the top surfactant layer after phase separation has occurred). To maximize the solubility of the salting-out agent the tube was warmed in a beaker of hot water. After a few minutes the tube was removed from the water bath and 9 g of K_3PO_4 (4*M*) was added. The solution was thoroughly mixed to completely dissolve all of the salt. The tube was then left to stand for 5 min or more. Centrifugation may be required depending on the conditions of the experiment. Centrifugation for 10 min at 4000 rpm (2500 G) was more than adequate to effect phase separation. Afterward 2–3 ml of the chemiluminescence solution was added with a pipet to the top layer of the tube. The chemiluminescence signal varied from a very pale pink to a bright red depending on the concentrations of coproporphyrin.

RESULTS AND DISCUSSION

In our previous paper[16] it was reported that both the hydroxide and phosphate anions can be used as salting-out agents to effect separation of the non-ionic surfactant (Triton X-100) from the aqueous medium based upon the cloud point phenomenon. Highly efficient extractions ($E\% > 95\%$) of a number of hydrophobic porphyrins (hematoporphyrin, protoporphyrin and coproporphyrin) from the aqueous into the surfactant phase were obtained once a certain threshold concentration of the cloud point depressing electrolyte was added to the aqueous non-ionic surfactant solutions. On the other hand the $E\%$ was found to be dramatically lower ($< 3\%$) for the extraction of a hydrophilic porphyrin, *i.e.* uroporphyrin. These findings indicated that the use of hydroxide or phosphate anion as the salting out agent could provide a means by which coproporphyrin could be extracted from urine samples and pre-concentrated into the smaller volume surfactant phase with good efficiency and selectivity, while the majority of the uroporphyrin fraction would remain in the aqueous urine medium.

Table 1 shows the $E\%$ values for coproporphyrin and uroporphyrin in spiked human urine using the phosphate anion as the salting-out agent. The high $E\%$ values for coproporphyrin (and low $E\%$ for uroporphyrin) were obtained immediately after the samples were centrifuged at 4000 rpm for about 10 min (2500 G). These results indicate that the phosphate anion is useful as a salting-out agent for the cloud point extraction and preconcentration of coproporphyrin from real biological matrices. In addition to the two major urinary porphyrin components, Table 1 shows that $E\%$ of the three minor urinary porphyrin components: penta-, hexa-, and heptacarboxylporphyrins.

Table 1. Extraction efficiencies of major and minor porphyrin components (400 μg/l. each) by Triton X-100 (1% v/v) in spiked urine samples using 4*M* K_3PO_4 as the salting-out agent

copro-	penta-	hexa-	hepta-	uro-
93.9%	82.4%	61.2%	22.1%	3.7%

Although the concentrations of the minor urinary porphyrin components in normal urine are negligible when compared to coproporphyrin and uroporphyrin, significant amounts of the minor components, in particular penta- and heptacarboxylporphyrins, can be found in urine samples from patients suffering from different types of porphyrias.[1–5] Since relatively high $E\%$ were obtained for the extraction of pentacarboxylporphyrin into the surfactant phase as shown in Table 1, one would expect that this minor urinary porphyrin component could represent an interferent for the measurement of coproporphyrin when present in high concentrations as occurs in some forms of coproporphyrinuria. Fortunately the increase in urinary pentacarboxylporphyrin level is usually accompanied by a significantly higher levels of coproporphyrin in almost all cases of coproporphyrinuria.[5] This suggests that false positive results originating from signals obtained from pentacarboxylporphyrin in the screening of coproporphyrinuria would be unlikely. On the other hand, significant amounts of heptacarboxylporphyrin can be found in some forms of uroporphyrinuria. Although the $E\%$ of heptacarboxylporphyrin was found to be much lower than that of pentacarboxylporphyrin as shown in Table 1, the existence of elevated levels of heptacarboxylporphyrin in urine, *e.g.* 1000 μg/l., could represent a major interference problem for the screening of coproporphyrinuria. The rise in heptacarboxylporphyrin concentration is usually correlated with that of uroporphyrin, which is the major marker for uroporphyrinuria.

In the present method, potential interference problems for the selective measurement of coproporphyrin in urine due to the presence of elevated levels of minor urinary porphyrin components, in particular from heptacarboxylporphyrin, was minimized by employing a two

step extraction procedure as follows: using 10 ml of urine containing Triton-X-100 (1% v/v), selective extraction of coproporphyrin from uroporphyrin into a very thin surfactant layer (~0.1 ml) sitting on top of the higher density urine medium can be achieved with good $E\%$ using phosphate anion as the salting out agent as shown in Table 1. To achieve selective extraction of coproporphyrin from the minor urinary porphyrin components, a few drops of ethyl acetate (~0.5 ml) was added to the sample solution. The ethyl acetate serves to loosen the viscous surfactant layer, which allows for better mixing with the peroxyoxalate CL reagents and, more importantly, it allows for the major hydrophobic porphyrin component, *i.e.* coproporphyrin, to partition into the mixed organic and surfactant layer (top layer) with good efficiency.[1] The majority of the minor porphyrin components, *e.g.* heptacarboxylporphyrin, remain at the interface of the two layers and/or in the aqueous medium and are not amenable to chemical excitation by the peroxyoxalate CL reagents (*vide infra*).

The present experimental conditions are designed to give rise to a net pre-concentration factor of ~15 for the porphyrins extracted into the top layer and to provide a just barely detectable CL emission at the average normal concentration of coproporphyrin in urine, *i.e.* ~50 μg/l. At this concentration of coproporphyrin in urine, which corresponds to ~750 μg/l. in the top layer, the CL emission from coproporphyrin appeared pale orange in color (negative result). When urinary coproporphyrin concentrations were adjusted to the range of 100–200 μg/l. and 200–400 μg/l., the CL emission becomes light orange and orange-red (positive results), respectively. At concentrations of 400 μg/l. and higher, the top layer appeared intensely red. The color of this visible emission corresponds to the characteristic spectral region of porphyrins ($\lambda_{max} = 610$–650 nm) and the duration of the emission lasted for about 30 sec. To evaluate the effectiveness of the present method in minimizing interference signal due to the presence of abnormal concentrations of heptacarboxylporphyrin, large amounts of heptacarboxylporphyrin (~1000 μg/l.) was spiked into urine and the characteristics of CL emission from the top layer was examined. Importantly, it was found that even at this excessive level of heptacarboxylporphyrin, no discernable CL emission from porphyrins was observed, suggesting that abnormal concentrations of heptacarboxylporphyrin found in most cases of uroporphyrinuria would not give rise to significant numbers of false positive results.

For purposes of comparison, the peroxyoxalate CL reaction involving the oxidation of DNPO was used for the chemical excitation of urine spiked with coproporphyrin. As expected DNPO yielded a relatively strong CL signal (orange) from the top layer even at a coproporphyrin concentrations of ~50 μg/l. At concentrations lower than 50 μg/l. of coproporphyrin, the CL emission appeared slightly greenish-yellow in color. Similar emission has also been reported by Albrecht *et al.*[12] in the use of the DNPO-based peroxyoxalate system for the screening of urinary porphyrins. They postulated that this signal arose from bilirubin and/or other related species in urine. Fortunately, this greenish-yellow is relatively weak and spectrally far away from the orange–red emission of coproporphyrin, such that it does not present an interference problem especially when using TCPO-based systems. As reported by Albrecht *et al.*[12] in the investigation of 1000 serum samples (500 controls and 500 pathological samples) using their porphyrin-sensitized peroxyoxalate CL test, other pathological or physiological components of urine did not show any CL emission in the characteristic spectral region of porphyrins. These results indicated that peroxyoxalate CL reaction is not only sensitive but highly selective for the detection of urinary porphyrins.

Some major difficulties encountered in the analytical applications of the peroxyoxalate CL reaction are directly related to the insolubility and instability of TCPO or DNPO in aqueous solutions.[10,11] In the present method these particular problems are minimized as a result of the extraction of the fluorophore(porphyrins) from urine into the surfactant-rich phase, thus allowing for enhanced CL signal (high intensity and longer lifetime) due to the more reproducible and efficient mixing of the CL reagents and the porphyrins, and to less TCPO hydrolysis. Figures 1(a) and (b) show that when compared to ethyl acetate alone, which is the solvent of choice for most analyses involving the peroxyoxalate CL reaction, the CL intensity of coproporphyrin dissolved in ethyl acetate containing 10% Triton X-100 (resembles the chemical composition of the top layer) is even slightly higher. Moreover, Fig. 1(c) shows that with the use of small amounts of imidazole as a catalyst,[17] the

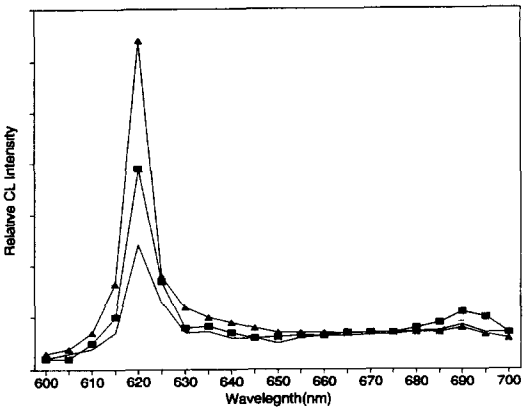

Fig. 1. Relative CL intensity of 400 μg/l. coproporphyrin dissolved in (a) ethyl acetate (□), (b) ethyl acetate and 10% Triton X-100 (■) and (c) ethyl acetate and 10% Triton X-100 in the presence of imidazole (▲). TCPO, H_2O_2 and imidazole concentrations were $1.3 \times 10^{-3}M$, $1 \times 10^{-2}M$ and $3 \times 10^{-2}M$, respectively.

CL intensity of the coproporphyrin dissolved in ethyl acetate containing 10% Triton X-100 was further increased.

It should be noted that addition of non-ionic surfactant at concentrations above those of the critical micelle concentration (CMC) into aqueous solutions (resulting in the formation of normal micelles) have been shown to enhance the CL intensity of certain fluorophores.[18] However, under the experimental conditions described in Fig. 1(b), the non-ionic surfactants probably form dynamic aggregates of reversed micelles in which the hydrophobic portion (alkyl group) of the Triton X-100 extended into the bulk non-polar solvent (ethyl acetate), whereas the polyoxyethylene functional groups formed the hydrophilic core of these aggregates.[19] It is important to note that the observed enhancement of CL as shown in Fig. 1(a) and (b) was accompanied by an increase in the fluorescence intensity of coproporphyrin. This suggests that the coproporphyrin molecules were somehow associated with the micellar assemblies, resulting in a change in their micro-environments, *e.g.*, micro-viscosity, local pH, polarity *etc*, and an increase in the fluorescent quantum yield. However, an enhancement in the CL intensity of coproporphyrin due to increases in the chemical excitation efficiency and rate of reaction are also possible. Finally, it should be noted that the use of reversed micelles to prolong the duration of the light emission generated from the peroxyoxalate CL reaction has been reported.[19]

Table 2 shows the effects of different sulfate and phosphate salts on the relative CL intensity of coproporphyrin. It can be seen that for identical concentrations of sulfate salts ($2.5M$), the salts containing Na^+ yielded the greatest CL intensity while those containing NH_4^+, Zn^{2+} and Mg^{2+} provided lesser CL intensity. It should be noted that although the sulfate anion concentrations were identical the concentrations of the cations were different for singly and doubly charged cations. Similarly for identical concentrations of various phosphate salts ($3.5M$), it was found that the relative CL intensity obtained from using the monohydrogen phosphate salt containing Na^+ was slightly higher than that containing K^+ However, K_3PO_4 yielded the highest relative CL intensity at identical salt concentration and was used as salting-out agent in most of the experiments in this work due to its ease of dissolution in the sample solutions.

The effect of different cations (from the salting-out agents) on the relative CL intensity could be explained in part by their influence on the E% of coproporphyrin. It has been postulated in our previous work[16] that a doughnut-like complex may form between the porphyrin and Triton X-100 molecules. This complex may be stabilized by the chelation of the cation with the oxygen atoms of the polyoxyethylene functional groups (cation chelation mechanism) and could result in the concomitant interaction of this moiety with the porphyrin nucleus and in differing degrees of E% for different cations.

Table 2. Effects of different cations from different sulfate and phosphate salts on the relative CL intensity of coproporphyrin extracted from spiked urine samples (urinary coproporphyrin concentration: 75 μg/l.). TCPO and H_2O_2 concentrations were $1.3 \times 10^{-3}M$ and $1 \times 10^{-2}M$, respectively

Sulfate Salts ($2.5M$)	Relative CL intensity	Phosphate Salts ($3.5M$)	Relative CL intensity
Na_2SO_4	100.0	K_3PO_4	100.0
$(NH_4)_2SO_4$	65.1	Na_2HPO_4	89.2
$ZnSO_4$	47.3	K_2HPO_4	73.5
$MgSO_4$	36.6		

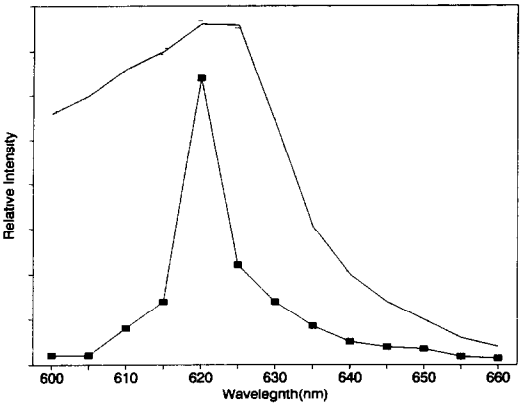

Fig. 2. Comparison of (a) chemiluminescence (■) and (b) fluorescence (□) spectra of coproporphyrin extracted from spiked urine samples. (Urinary coproporphyrin concentration: 75 μg/l.) TCPO and H_2O_2 concentrations were $1.3 \times 10^{-3}M$ and $1 \times 10^{-2}M$, respectively.

Another possibility is that the cation coordinated to the polyoxyethylene groups may provide an electrostatic attraction for the peroxyoxalate reaction species to penetrate the micelles more efficiently,[18] thus allowing for enhancement in CL intensity. More detailed and systematic investigations are necessary to provide insight into the effects of cations on the E%, chemical excitation efficiency, and kinetics of the peroxyoxalate CL reaction in aqueous and non-aqueous solutions.

Figure 2 compares the fluorescence and CL spectra of coproporphyrin extracted from spiked urine samples. It is clear that the intensity of fluorescence signal was slightly higher than that of the CL at the peak maximum (at ~620 nm); however the band-width of the fluorescence spectrum was broader than that of the CL spectrum. It is important to note that the CL spectrum of coproporphyrin extracted from urine samples is very similar to that obtained from coproporphyrin dissolved in ethyl acetate and 10% Triton X-100 as shown in Fig. 1(b). This observation suggests that the broadening effect of fluorescence measurement could arise from fluorescent interferent species present in the urine samples such as riboflavin and/or bilirubin-related compounds[20] and that CL is a more selective method for the detection of urinary coproporphyrin.

In summary, this work demonstrates that cloud point extraction coupled with peroxyoxalate CL reaction provides a highly sensitive and selective method for the detection of urinary coproporphyrin. With the rise in the number of cases of porphyrin related diseases this simple and inexpensive method may prove valuable for the rapid screening of elevated levels of urinary coproporphyrin in clinical laboratories.

SIMULTANEOUS DETERMINATION OF TARTRAZINE AND SUNSET YELLOW BY DERIVATIVE SPECTROPHOTOMETRY AND RATIO SPECTRA DERIVATIVE

J. J. BERZAS NEVADO,* J. RODRIGUEZ FLORES and M. J. VILLASEÑOR LLERENA
Department of Analytical Chemistry and Foods Technology, University of Castilla-La Mancha, 13071 Ciudad Real, Spain

(*Received* 16 *November* 1992. *Revised* 28 *January* 1993. *Accepted* 2 *February* 1993)

Summary—Two methods for determining Tartrazine and Sunset Yellow in mixtures by first derivative spectrophotometry and by first derivative of the ratio spectra are described. The procedures do not require any separation step. By the first method, the measurements are obtained in the zero-crossing wavelengths and the calibration graphs are linear up to 20 μg/ml of Tartrazine and up to 40 μg/ml of Sunset Yellow. The determinations of Tartrazine and Sunset Yellow are also done by the first derivative of the ratio spectra. The methods are applied for determining both compounds in four commercial food products.

Tartrazine (T) is an azo dye available as yellow powder. This colorant must be named in a list of ingredients after an extensive study[1] of the genotoxicity of food, drug and cosmetic color. Sunset Yellow (S), the other determined colorant, is a synthetic azo dye. Derivative spectrophotometry, particularly with digital processing,[2] is an analytical technique of great utility for resolving some mixtures with overlapping spectra. The fundamental principles have been described in the pioneering work of O'Haver and Green,[3] Fell *et al.*[4-6] and others.[7]

Recently, Salinas *et al.*[8] developed a new method for resolving mixtures of chromophores with overlapped spectra. This method is based on the use of the first derivative of the ratio of the spectra. The absorption spectrum of the mixture is divided by the absorption spectrum of a standard solution of one of the chromophores (amplitude by amplitude at each wavelength) and the first derivative of the ratio spectrum is obtained. The concentration of the other component is then determined from a calibration graph previously obtained.

The aim of this work was to demonstrate the ease in which the derivative methods (first and ratio spectra) circumvent the problem of overlapping spectral bands, allowing the simultaneous determination of these two colorants (Tartrazine and Sunset Yellow) without prior separation. The two methods yield accurate and reproducible results in different commercial products.

EXPERIMENTAL

Apparatus

A Beckman Instruments DU-70 spectrophotometer connected to an IBM PS/2 fitted with Beckman Data Leader Software[9] and an Epson FX-850 printer were used for all the measurements and treatment of data.

Solutions

All solvents and reagents were of analytical reagent grade. Tartrazine (T) and Sunset Yellow (S) aqueous solutions were prepared from Sigma products. Their Sigma numbers are T 0388 and O 1625, respectively. T and S solution stocks have a concentration of 200 μg/ml. Acetic acid/sodium acetate buffer solution (0.5*M* and pH = 4.5) was made of analytical reagent grade.

Procedures

(a) First derivative spectrophotometry. Samples were prepared in 25 ml calibrated flasks containing 2–20 μg/ml of T or 4–40 μg/ml of S or their binary mixtures, 5 ml of pH 4.5 buffer solution, and were diluted with water to the mark. The absorption spectra of the samples thus prepared were recorded, and by measuring the signal of their first derivative spectra (obtained with $\Delta\lambda = 8$ nm) at 481.6 ($^1D_{481.6}$),†

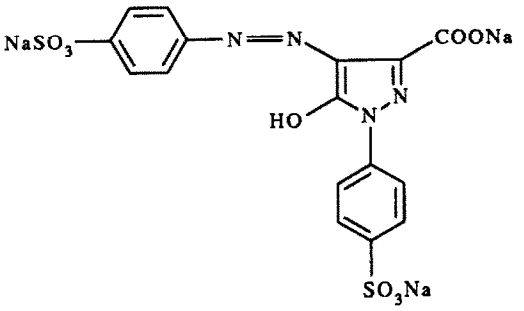
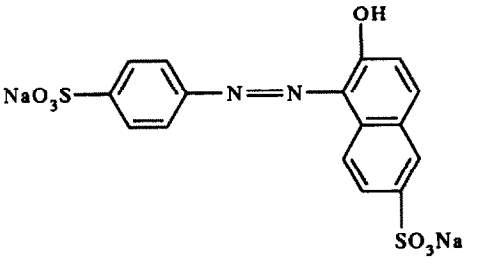
†$^{\text{order derivative}}\text{Derivative}_{\text{wavelength measure}}$.

Tartrazine (E-102)



Sunset Yellow (E-110)



Scheme 1

(zero-crossing point for Sunset Yellow) and by using an appropriate calibration graph, their concentration could be determined. These calibrations were done by varying the concentration of a colorant, without the presence of the other colorant. The S content was also determined by measuring the signal at 426.5 nm ($^1D_{426.5}$) or 538.0 ($^1D_{538.0}$) (zero-crossing points for Tartrazine). Eventually, these spectra were treated with a smoothing of 11 experimental points. (All the spectra have been multiplied by 100 in order to obtain an increase in the accuracy measure.)

(b) First derivative of the ratio spectra. By this method for determining T, the stored spectra were divided by a standard spectrum of S of 16.0 μg/ml. From the ratio spectra thus obtained, first derivatives were calculated with $\Delta\lambda = 6$ nm. The concentration of T was proportional to the amplitude of the maximum at 445.0 nm ($^1DD_{445.0}$)* or at the minimum at 397.0 nm ($^1DD_{397.0}$). For the determination of S, the stored spectra were divided by a standard spectrum of T of 8.8 μg/ml. From the ratio spectra thus obtained, first derivatives were calculated with $\Delta\lambda$ of 8 nm. The concentration of S was proportional to the amplitude of the maximum at 528.0 nm ($^1DD_{528.0}$) or at the minimum at 503.0 nm ($^1DD_{503.0}$) and to the addition of these two signals ($^1DD_{528.0+503.0}$).† All these spectra were smoothed with different experimental points for each of the two dyes.

RESULTS AND DISCUSSION

Method development

The influence of pH on the absorption spectra of T and S was studied. The best results for analytical purposes were obtained at pH = 4.5 (acetic acid/sodium acetate buffer solution) because the T and S absorption spectra were stable in the range pH 4.0–7.0.

Samples were prepared in aqueous solution at pH = 4.5. Under these conditions diluted solutions of T and S were stable for 12 hr at least.

Derivative spectrophotometry

In Fig. 1 the zero order spectra of T and S in the 350–600 nm wavelength range are shown. It can be seen that the absorption spectra of T and S are very overlapped and as a result, the determination of the two colorants cannot be possible for reliable direct absorbance measurements. Derivative spectrophotometry can be suitable to obviate this problem. The "zero-crossing method" is the most common procedure for the preparation of analytical calibration graphs.

In practice, the measurement selected is that which exhibits the best linear response, gives a zero or near zero intercept on the ordinate of the calibration graph, and is less affected by the concentration of any other component. The

shape of the first derivative spectra is adequate for determining T in the presence of S and vice versa. Figure 2 shows the first derivative absorption spectra, respectively, of a solution of T, a solution of S and their mixture. (These spectra are multiplied by 100 as we mentioned in the Experimental section.)

It can be seen that due to the overlapping spectra of these compounds in a determined region, the zero-crossing method is the most appropriate for resolving mixtures of these compounds and it was used in this work with satisfactory results.

Preliminary experiments showed that the signals of the first derivative at 481.6 nm (working zero-crossing wavelength of S) are proportional to the T concentration and the signals of the first derivative at 426.5 and 538.0 nm (working zero-crossing wavelengths of T) are proportional to the S concentration.

Selection of optimal instrumental conditions

The main instrumental parameters that affect the shape of the derivative spectra are the wavelength scanning speed, the wavelength increment over which the derivative is obtained ($\Delta\lambda$) and the smoothing. These parameters need to be optimized to give a well resolved large peak *i.e.*, to give good selectivity and larger sensitivity in the determination. Generally, the noise level decreases with an increase in $\Delta\lambda$ thus decreasing the fluctuations in the derivative spectrum. However, if the value of $\Delta\lambda$ is too large, the spectral resolution is very poor.

Therefore, the optimum value of $\Delta\lambda$ should be determined by taking into account the noise level, the resolution of the spectrum and the sample concentration. Some values of $\Delta\lambda$ were tested. By first derivative 8.0 nm was selected as the optimum in order to give a satisfactory signal-to-noise ratio. In this way, a smoothing of 11 experimental points function was used.

Having established the experimental conditions, the calibration graphs were tested between 2.0 and 20.0 μg/ml of the T concentration at 481.6 nm for the first derivative spectra, without the presence of S (Fig. 3). Equally, the calibration graphs were tested between 4.0 and 40 μg/ml of the S concentration, in the absence of T, at 426.5 and 538.0 nm for the first derivative spectra (as can be seen in Fig. 4). Good linearities were observed in all cases.

First derivative of the ratio spectra

The use of the "zero-crossing" method in derivative spectrophotometry for resolving a mixture of chromophores with overlapped spectra produces a considerable loss of accuracy and sensitivity. This problem is due to the fact that the measurements are taken at a very critical wavelength, the localization of which is sometimes very difficult and whose value is sometimes very small for obtaining a good analysis.

The named "ratio spectra derivative" permits the determination of a component in their mixture at the wavelengths corresponding to a maximum or minimum and, also, the use of the peak to peak between consecutive maximum and minimum. The values of absorbance in these points permit one, in some cases, to reach a better sensitivity.

The influence of the $\Delta\lambda$ for obtaining the first derivative was tested and an $\Delta\lambda$ of 6 nm was considered as suitable for the T determination and a value of 8 nm for the S determination. The concentration of the S solution used as divisor could be modified and different calibration graphs were obtained. A standard spectrum of 16 μg/ml of S was considered as suitable for the T determination and a standard spectrum of 8.8 μg/ml of T as divisor was considered as suitable for the S determination.

In Fig. 5A a calibration graph of T when the divisor is a spectrum of 16 μg/ml of S, in the

absence of Sunset Yellow, is shown. These spectra were derived and the $\Delta\lambda$ used was 6 nm. Eventually, all the spectra were smoothed with a value of 13 experimental points. In Fig. 5B a calibration graph of ratio spectra derivative of T is shown.

Figure 6A shows the ratio spectra of different S standards (spectra divided by the spectrum of a 8.8 μg/ml T solution) in acid medium and in Fig. 6B their first derivatives are calculated, without the presence of T. The first derivative amplitudes at a given wavelength are proportional to the S concentration. Due to the noise levels, a smoothing of 23 experimental points function is used.

A calibration graph was established at a wavelength of 445.0 nm, corresponding to a maximum. Straight lines up to 20.0 μg/ml were obtained for the Tartrazine determination. Calibration graphs were established at wavelengths 528.0 and 503.0 nm, corresponding to a maximum and minimum, and also at the addition of these two signals for the Sunset Yellow determination. Straight lines up to 40.0 μg/ml were obtained for this colorant.

STATISTICAL COMPARATIVE STUDY

In Table 1 summary of the most characteristic statistical data obtained from the different calibration graphs and from the reproducibility of the reagent-blank and a standard by eight successive scans are shown. In all cases good results were obtained.

The best detection limits were obtained from the first derivative at 481.6 nm for T determination and at 528.0 nm for S determination. Nevertheless, in general, the method that used the first derivative of the ratio spectra shows better accuracy and comparable limit detections.

APPLICATIONS

The proposed methods were applied for resolving the determination of T and S, in

*With measurements at the "zero-crossing".

artificial mixtures. The results corresponding to these determinations are summarized in Tables 2 and 3. The obtained recoveries were very good in general. The recoveries (%) by the first derivative spectrophotometry were of the order of 99% except when the ratio T:S was 5:1 and 1:7.5 (0.13). In this case the recovery was poorer, due to the low concentration of one of the colorants in the presence of high concentrations of the second colorant. Similar results were obtained by the first derivative of the ratio spectra method as can be seen in Table 3. The recoveries for the determination of S were in the same range. In conclusion, the first and the ratio spectra derivative methods gave good results for the simultaneous determination of Tartrazine and Sunset Yellow.

The proposed methods were also applied for the determination of T and S in four different food commercial products. These were a **spice** named *Colorante Alimentario* from Granja San Francisco (Spain), two different **gelatin desserts**: orange and lemon flavours, and in **light custards** from Royal Brands S.A.

The percentage of these two dyes can be seen in Table 4 and they were calculated by the method of standard addition, with measuring at "zero-crossing" and by the methods mentioned in this paper.

In all cases, these determinations were made with good recoveries, which were higher than 90% with regard to the data supplied by the companies aforementioned.

VOLATILIZATION OF METHYL BORATE IN IRON MATRIX. DETERMINATION OF BORON IN STEEL BY ICP ATOMIC EMISSION SPECTROMETRY

A. LOPEZ MOLINERO,* A. FERRER and J. R. CASTILLO

Department of Analytical Chemistry, Sciences Faculty, University of Zaragoza, 50009 Zaragoza, Spain

(*Received* 27 *October* 1992. *Revised* 29 *January* 1993. *Accepted* 29 *January* 1993)

Summary—A rapid and reliable method for the determination of boron by ICP–AES in steels is described. The procedure is based on a discontinuous generation of methyl borate, in concentrated sulphuric acid and phosphoric acid medium, after injecting 45 μl of methanol in 20 μl of sample. The gaseous methyl borate and excess methanol are fed into the ICP torch via the intermediate tube by a flow of 430 ml/min Ar carrier gas, without disturbing the discharge. This work simplifies drastically the existing methodology of boron analysis in steels. Acid-soluble boron has been determined, but acid-insoluble boron can also be determined. The determination is carried out without iron interferences, with a reproducibility of 1.90% r.s.d. for a concentration of 20 μg/ml, and an absolute detection limit of 20 ng of total boron, working with a solution volume of 20 μl.

The microdetermination of boron is especially important in steels, where the addition of small amounts of the element, in the order of the micrograms per gram noticeably improves their hardness and toughness.

Even though the analysis of boron can be undertaken by techniques such as Molecular Absorption Spectrophotometry,[1] Atomic Absorption Spectrometry[2] or Flame Atomic Emission Spectrometry[3,4] the Atomic Emission Spectrometry with an inductively Coupled Plasma (ICP–AES) technique yields adequate[5] detection limits (L.D.) (4.8 ng/ml) to approach this problem.

The limitation for the boron determination by ICP–AES in ferric matrix lies in the fact that iron has emission lines at 249.77 nm Fe(II), 249.65 and 249.70 nm Fe(I), which produce spectral interferences for the more sensitive lines of boron at 249.77 and 249.67 nm.

The microdetermination of boron in ferric alloys relies on avoiding the iron interference. This has been carried out by means of:

(a) Fe elimination; through: (a.i) Fe extraction;[6] (a.ii) precipitation[7] and electrodeposition,[8]
(b) Boron extraction,[9,10]
(c) Boron volatilization or distillation mainly through the methyl borate,[11] although there are other boron volatile phases.[12]

Utilizing the last methodology (c), the boron distillation from a ferric matrix of steel[11] has been applied as a preconcentration method and thus it is possible to reach an L.D. of 0.0036 μg/ml when the absorption aqueous solution containing the boron distillate is analysed by ICP–AES. However, to perform this, a considerable experimental manipulation is necessary. In a more simplified method, Novozamsky *et al.*[13] have described a continuous-flow technique for generation and separation of methyl borate with subsequent determination of boron by ICP–AES. An L.D. of 0.05 μg/ml was obtained, but with this assembly serious difficulties prevent practical work. So the excess of methanol must be removed to prevent quenching of the plasma and experimental difficulties of working with a continuous flow of concentrated sulphuric acid are found.

In the present paper, the discontinuous introduction of methyl borate into an ICP spectrometer through its intermediate tube is proposed, enabling a great stabilization of the discharge in spite of the injection of relatively high amounts of methanol. The methodology has been applied to the boron volatilization in an iron matrix (steel).

Methyl borate generation assembly

The flow chart for generation of the methyl borate is shown in Fig. 1. The apparatus consists of a 3 ml reaction vessel made of PTFE. A rubber stopper, pierced with two stainless steel needles and fitted to the reaction vessel, is used. Methanol is injected with an FIA injection valve (Omnifit) equipped with a loop of 45 μl. A two-way valve is utilized to lead the Ar carrier gas either to the reaction vessel or to the plasma. Nylon tubes of 2 mm O i.d. are used and are joined with quick connectors (Clifco series PM).

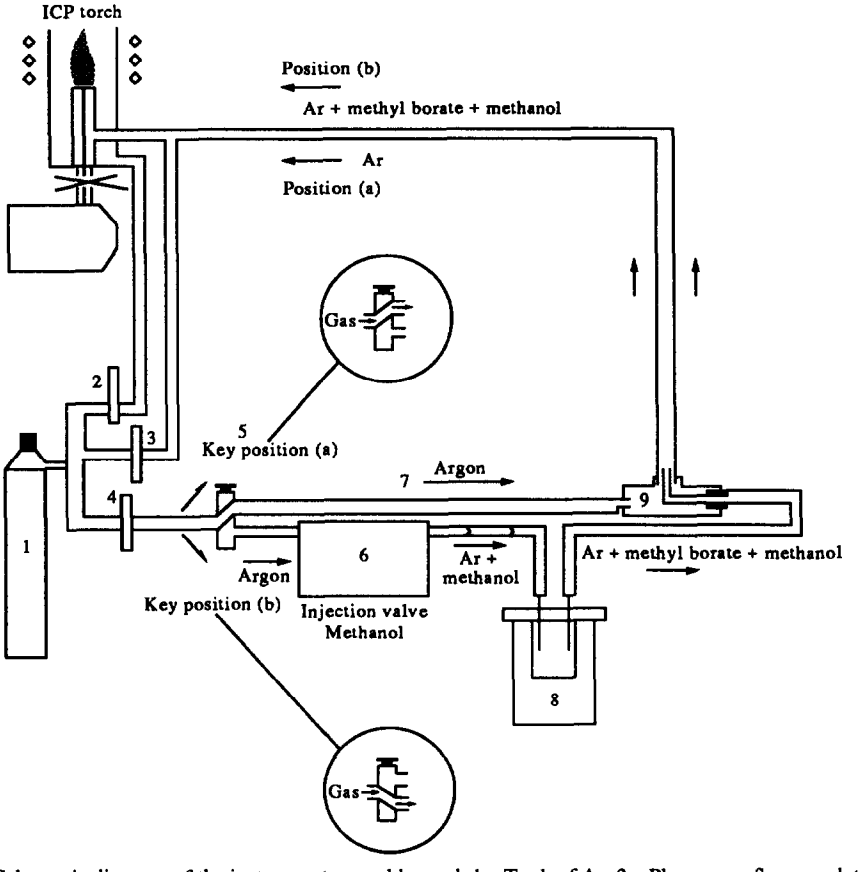

Fig. 1. Schematic diagram of the instrument assembly used. 1—Tank of Ar. 2—Plasma gas flow regulator. 3—Intermediate gas flow regulator. 4—Injector or carrier gas flow regulator. 5—Two-way key. 6—Injection valve for methanol. 7—Nylon tube. 8—Reaction chamber. 9—Three-port quick connector.

Procedure of methyl borate generation

Concentrated sulphuric acid (200 μl) and the sample solution containing boron (20 μl) are placed in the reaction vessel. After stoppering the vessel, the Ar carrier gas (a steady flow of 450 ml/min is maintained) is channelled throughout it, and passed to the top of the liquid surface. By setting the key (5) to position (b) (see Fig. 1) the gas is first passed through the FIA valve, then through the reaction vessel and finally directed to the torch. A brief period of time is needed to stabilize the plasma (30 sec) prior to the injection of methanol (45 μl) via the FIA valve.

The atomic line of boron at 249.773 nm is chosen to measure the emission intensity, which is continuously recorded and thus transient peaks are obtained. Once the recording of boron emission has finished, the flow of Ar carrier gas through the FIA valve and the reaction vessel is interrupted utilizing the key (5), which is rotated to its position (a), re-directing the flow of gas to the torch. With this last configuration, a stable plasma is maintained during the time a new sample is being prepared for analysis. In all instances, Ar flow is fixed and controlled by a flow regulator (see its position on Fig. 1).

Procedure for steel dissolution

Two grams of steel were dissolved in a similar way to the literature[14] and subsequently diluted to 20 ml in a volumetric flask. Using this procedure only acid-soluble boron can be determined.

Procedure for boron determination in steels

Boron in steels is determined according to the following procedure: 200 μl of concentrated sulphuric acid and 20 μl of concentrated phosphoric acid followed by 20 μl of the steel solution are placed in the reaction vessel. The mixture is shaken until homogenized and methanol (45 μl) is injected. The gaseous methyl borate is carried into the plasma torch.

Reagents

All chemicals used were of analytical grade. Deionized water, quality Milli Q, was utilized in all dilutions. A standard solution of boron (1000 μg/ml), made from boric acid was prepared and stored in a polyethylene bottle. Methanol, concentrated sulphuric acid, phosphoric acid and iron nitrate were used.

Standard reference steels from BCS No. 458 and 459 were utilized.

RESULTS

Experiment assembly

The introduction of gaseous methyl borate into an ICP spectrometer, generated by reaction of borate with methanol in concentrated sulphuric acid, presents considerable experimental difficulties.[13] In our paper a new method for gas introduction (methyl borate and methanol in excess) has been accomplished, through the intermediate tube of an ICP torch. It allows one to work with a stable discharge and at the same time, good analytical values are obtained.

In ICP measurements it has been demonstrated that the excess of methanol injected must be removed to prevent quenching of the plasma. We have verified that plasma is able to accept a higher amount of methanol if it comes through the intermediate gas instead of being introduced through the central channel. Up to 90 μl of pure methanol have been injected in this way, against a maximum volume allowed of 20 μl if fed through the central axial channel of the discharge. According to our configuration, a green aureole is produced in the plasma, from its periphery, surrounding and compressing the plasma.

In our assembly (see the scheme of Fig. 1) the nebulizer gas acts as carrier gas and it is channelled directly to the torch via the intermediate tube, using key (5) in position (a), or else it can be passed through the FIA valve and the reaction vessel using key (5) in position (b).

Our proposed method introduces a considerable advantage by being able to maintain stable plasma with a relatively simple gas switching strategy.

We have studied the instability of the discharge during the change which must be fast. This has been carried out by measuring the carbon emission (present in the Ar gas), at its 193.091 nm line, before and after the change of the gas. The signal stability is reached 30 sec after the production of that change. In consequence all analytical measurements have a waiting time of 30 sec, prior to the methanol injection.

Conditions for ester generation: water, methanol, sulphuric acid

The optimum ratios of water, methanol and sulphuric acid for methyl borate generation, have been studied as seen in the bibliography.[2,4] In these works, it is postulated that the exothermic reaction between methanol and sulphuric

acid generates considerable heat. So the temperature of the reaction medium rises, even over the boiling temperature of the methyl borate (b.p. 68°C). However, we have worked with very small volumes of reagents and consequently the thermal effect is limited. So we have tried to evaluate the temperature in the reaction mixture.

A theoretical calculation of the temperature increase (ΔT) generated under the optimum reaction conditions provides a value of $\Delta T = 9$°C. This value was obtained by calculation for dilution of 200 μl of concentrated sulphuric acid (36M) with 20 μl of water (dilution heat 0.146 kcal/mol[15] and for a density of 1.8 kg/l and a specific heat of 0.33 cal/g for the concentrated sulphuric acid).[16] Therefore the reaction mixture is far from reaching the methyl borate b.p. temperature.

This value has been checked experimentally, determining the temperatures in the reaction vessel by means of a Thermistor Thermometer-Digitec model 5831 (type 704 YSI) thermic sounding line. In this way a temperature value for sulphuric acid prior to the reaction of 26.07°C is obtained and after the addition of water (waiting for 30 sec corresponding to the plasma stabilization), a temperature of 36.0°C is measured.

At these temperatures the vapour pressures of methanol (b.p. = 65°C) and of methyl borate ester (b.p. = 68°C) are 220.1 and 222.4 torr, respectively.[17] It has been proved that, under these conditions, boiling point of the methyl borate is not reached but high volatilization of the methyl borate is observed. It can be said that temperature is not the only effect that facilitates the methyl borate volatilization.

However because temperature effects have been profusely argued as being responsible for methyl borate volatilization we have experimented with higher temperatures of both the reaction mixture (an isothermic bath was used at 50 and 60°C) and the carrier gas. In these experiments improvement in sensitivity was not obtained.

On the other hand, boric acid esterification in the presence of phosphoric acid (its dilution heats are lower than those of sulphuric acid) also leads to boron emission. However, the peak signals are less pronounced and wider, and they show lower sensitivity (based on peak height) than those produced in sulphuric medium.

It can be concluded that the high sensitivity obtained in methyl borate volatilization with our set up, depends on the temperature effect and on a very important "sweep effect" produced by the carrier Ar flow.

Optimization of variables

The variables studied can be classified as two types.

—Variables of the reaction. That is: concentrated sulphuric acid volume, water volume, methanol volume.
—Instrumental parametres of detection. That is: injection gas flow (carrier gas), observation height, photomultiplier voltage.

These variables were optimized by means of the Simplex, MSM method,[18] and the following optimum values were adopted: 45 μl of methanol were injected into a solution of 200 μl of sulphuric acid and 20 μl of water. The Ar carrier gas was set at 430 ml/min, the observation height of 20 mm above the coil selected and the PM voltage adjusted to 450 V.

In the same way, the effect of other variables was studied, and they are discussed below.

Firstly, a cylindrical shape for the reaction chamber was chosen and different sizes were tested (varying in section and height). The optimum vessel is shown in Fig. 2.

The effect of the transport length between the reaction vessel and the ICP torch was studied. In our assembly we have worked with a

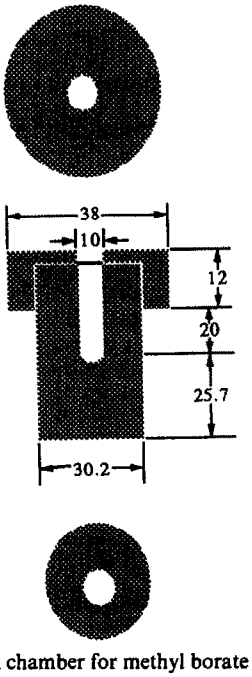

Fig. 2. Reaction chamber for methyl borate generation. The dimensions are given in millimetres.

Residence time—T	= 2–8 sec
Peak height—H	= 1–12 cm

minimum distance of 15 cm. For a distance of 25 cm, a signal loss of 17% with respect to the one obtained at 15 cm was observed. In the same way the reproducibility decreased (10.3% r.s.d., for 20 μg/ml of boron).

Methanol injection by means of a microsyringe was tested and its results compared to FIA injection. The first method of injection presents high irreproducibility (up to 20% r.s.d.) and so FIA injection was chosen.

The effect of surface-active agents, as favouring the methanol transport and injection (Triton × 100 at 0.1% in methanol), as well as the presence of sodium bicarbonate as favouring a greater gaseous emission (methanol saturated with sodium bicarbonate) showed very little modification in the ICP signal of methyl borate, but increased its irreproducibility.

The method of methyl borate introduction into the ICP torch has been studied. Firstly, the vapour stream was fed into the ICP at the torch entrance normally used for the nebulizer gas (the injector tube), but using the nebulizer gas as carrier gas, and secondly, according to an experimental arrangement used by us previously in the study of hydrides.[19] The results obtained with these two approaches showed a low tolerance to methanol, and the injection of 20 μl of pure methanol produced quenching of the plasma.

Characterization of boron emission signal

The flow conditions through our assembly can be characterized by the following data: working pressure of gases (Ar) of 5.5 atm; carrier gas flow average of 430 ml/min through a section of 2 mm i.d.; values of the Reynolds number of the order of 1800. With these values we are under conditions of laminar flow, and the signal obtained by the measurement of the emission intensity of boron at 249.773 nm *vs.* time, shows a profile which has been defined by the parameters of a FIA peak. That is to say: t_a (appearance time), Δt (base line–base line time), H (peak height), T (residence time).

Valcarcel[20] has proposed a characterization of the parameters of a FIA peak from a multiple regression, among the logarithmic values of the manifold hydrodynamic variables [length (L), diameter (d) of conduction and carrier gas flow (q)] and parameters of FIA peak [t_a, Δt,H,T].

The application of the model in our experience (after experimental measurements carried out with the variable ranges shown in Table 2), allows us to characterize and define the signals obtained by the following mathematical expressions:

$$\log t_a = 2.446 + (0.603 \log L) - (0.140 \log d) - (3.253 \log q)$$

$$\log \Delta t = 1.351 + (0.546 \log L) + (0.095 \log d) - (0.450 \log q)$$

$$\log H = -3.229 + (1.248 \log L) + (3.411 \log d) + (0.828 \log q)$$

$$\log T = 2.639 + (0.539 \log L) + (0.263 \log d) - (2.937 \log q).$$

Iron interference

Before beginning the boron determinations on practical samples of steels, boron was determined in a synthetic solution whose Fe and B content was similar to a standard steel. So a simple method (method (a), see Table 3) based on the addition of sulphuric acid and methanol was applied to the boron determination. In these experiments, it was observed that the addition of concentrated sulphuric acid to the steel solution produces precipitation of iron (III) sulphate (by supersaturation) with boron adsorption on precipitate preventing a later reaction of it with methanol. Thus, boron was not detected when analysed.

The addition of phosphoric acid (this is method (b), until the dissolution of the iron (III) sulphate precipitate, obtains the recovery of the

Table 3. Recovery of boron from synthetic iron solution

Analysis method	[Fe] present (μg/ml)	[B] present (μg/ml)	[B] found (μg/ml)	% r.s.d.
Method (a)	100,000	20.00	not found	—

boron signal. According to the results obtained by the two methods ((a), (b)) (see Table 3), the addition of phosphoric acid is proposed to complex iron and to eliminate its interference.

Performance of the method

A linear calibration graph $Y = 5.05 + 0.145X$ between 5 and 1000 μg/ml of boron was found with a regression coefficient of 0.996. Y is the intensity of the boron emission in relative units and X is the concentration of boron in solution in micrograms per millilitre. Typical peak shapes obtained in this experiment are shown in Fig. 3. From this experiment, instrumental detection limit (D.L.) of 1.0 μg/ml can be derived considering that the D.L. is the concentration at which the analyte signal is equal to the mean blank signal plus three times the standard deviation of the blank solution. The standard deviation of the background has been approximated by $(3 \times 0.01 \times I_B)$[21] ($I_B$, being the emission signal corresponding to the blank solution, with a value of 5.05 from the above equation). Sensitivity of the analytical procedure expressed as the slope of the calibration graph of 0.145 was used in this calculation.

This detection limit, obtained with 20 μl of sample, corresponds to an absolute limit of detection of 20 ng. This value is excellent and significantly lower than the detection limit reported so far.[11,13] The reproducibility of the method is 1.90% r.s.d. based on six measurements of 20 μg/ml B.

Using our proposed technique, analysis time for boron is shortened considerably. The signal evolution is not time consuming, and its shape can be seen in Fig. 3. The "limiting step" in the analytical measurement (without decomposition step) is determined by the plasma stabilization between measurements and this only takes 30 sec. All of these factors as well as the simplicity of the experimental device yield a method that can be advantageously applied to the boron determination in steel.

In the work described here, analytical grade reagents were used (Merck). However boron is a common contaminant and for this reason a high content of boron was found in the blank solution (35.7 μg/ml). Considerable effort has been made to reduce this signal and to reproduce it. The best results have been obtained working always with the same batch of reagents.

Application

To test the reliability of the proposed method, the analysis of two certified BCS steel samples, Nos 458 and 459, was carried out by both direct interpolation in a calibration graph, and standard addition methods. In these tests only acid-soluble boron was determined. The results are given in Tables 4–5. In Table 4 it is observed

Table 4. Determination of boron in BCS steels

Sample	Amount dissolved (g)	Dilution (ml)	Boron found* in solution (μg/ml)	Boron found in solid (w/w)%	Boron certified (w/w)%
BCS 458	4.0138	20	9.83 ± 0.10	0.0049 ± 2e-4	0.006
BCS 459	2.0065	20	11.55 ± 0.70	0.011 ± 7e-4	0.010

*Results are expressed as the average of four determinations ± standard deviation.

Table 5. Recovery of boron added to BCS steel solution

Sample	Boron in solution (μg/ml)	Boron added (μg/ml)	Boron found* (μg/ml)	Recovery (%)
BCS 458	9.83	19.6	29.21 ± 0.26	98.88
BCS 459	11.55	19.6	30.76 ± 0.00	98.01

*Results are expressed as the average of four determinations ± standard deviation.

that for steel BCS No. 458 there is a significant difference between the certified and the found boron content. This discrepancy can be explained by a boron loss in the process of steel dissolution. That is, boron is not completely dissolved in the acid attack, in agreement with what other authors have published about this steel.[6,22] However, on the other hand, standard addition of boron to the steel solution previously analysed, reveals a high level of recovery of boron added.

Steel BCS 459 shows a good agreement between the values found and the certified ones. In the same way the standard addition test confirms the results already obtained.

A t-test applied to compare the experimental mean found in BCS steel No. 459, with its certified value revealed no significant difference at $P = 0.05$. That is the "null hypothesis" can be retained: there is no evidence of systematic error in our new analysis method.

DETERMINATION OF TRACE AMOUNTS OF COBALT BY SOLVENT EXTRACTION—SECOND DERIVATIVE SPECTROPHOTOMETRY*

M. INÉS TORAL,† PABLO RICHTER and LORENA SILVA

Department of Chemistry, Faculty of Sciences, University of Chile, Las Palmeras 3425, P.O. Box 653, Santiago, Chile

(*Received* 19 *October* 1992. *Revised* 21 *January* 1993. *Accepted* 3 *February* 1993)

Summary—A sensitive derivative spectrophotometric method is described for the determination of microamounts of cobalt based on the integration of liquid–liquid separation and reaction, in dichloroethane, of the analyte with 3-(4-phenyl-2-pyridinyl)-5-phenyl-1,2,4-triazine (PPT) and 2,4,6-trinitro-phenol (picric acid). Cobalt was thus determined in the range 7.2–500 ng/ml. The method has a high selectivity with a detection limit of 2.2 ng/ml. The relative standard deviations were 3.2 and 1.5% for 20 and 100 ng/ml cobalt, respectively. The proposed method was applied to the determination of the analyte in vitamins.

The analytical chemistry of cobalt has been developed considerably in recent years, which is indicated by the large number of studies reported in the literature. Cobalt is not only of interest in the environment but also in human bio-chemical metabolism,[1] because it is present in the essential vitamin B_{12}. This vitamin is concerned with a wide variety of metabolic processes which include factors affecting growth, hemopoiesis and the maintenance of the integrity of nerve cells.

On the other hand, it is known that some metals that are essential nutrients, can also exert a toxic action, depending on their concentration levels. For these metals a narrow concentration difference exists between the toxic and the essential levels. As a result, knowledge of the metal content in various matrices, together with the development of reliable analytical methods for determination at trace levels are mandatory.

A number of analytical techniques have been used to determine cobalt in different types of samples at ultratrace[2–3] and trace[4–15] levels. Direct batch spectrophotometric methods,[11–15] using organic chelates, have shown some drawbacks as regards sensitivity, selectivity or simplicity. On the other hand, the use of derivative spectrophotometry offers a useful means for enhancing sensitivity and selectivity.[16] However, while derivative methods reported for the determination of cobalt are more selective than those using classical spectrophotometry, these show serious interferences principally from iron, copper and nickel when no masking agents are used.[6,9]

In this context, the purpose of this work was to develop a reliable, inexpensive and selective derivative spectrophotometric method for the determination of cobalt which is based on the integration of liquid–liquid separation and reaction in 1,2-dichloroethane of the analyte with PPT and picric acid, and on the subsequent derivative spectrophotometric measurement.

EXPERIMENTAL

Apparatus

A Shimadzu UV-160 spectrophotometer with 10 mm cells was used for measurements of the absorbance and derivative absorption spectra. An Orion Research Digital Ion-Analyzer 701 with glass and satured calomel electrodes was used for pH determinations.

Reagents

All reagents were of analytical reagent grade and the solutions were prepared with high-purity water from a Millipore Milli-Q Water Purification system device.

Standard cobalt (II) *solution (Titrisol Merck*, 1000 μg/ml. A 10 μg/ml working solution was prepared by diluting standard solution and other cobalt concentrations were prepared by appropriate dilution.

*In memory of Professor Alfonso Morales.
†To whom correspondence should be addressed.

3-(4-phenyl-2-pyridinyl)-1,2,4-triazine (PPT) solution. A 1×10^{-3} *M* solution was prepared by dissolving 0.3104 g of the compound (Merck) in 100 ml of DCE.

Picric acid solution. A 0.01 *M* solution was prepared by dissolving 2.291 g of picric acid in 1000 ml of water. Picric acid was previously purified by recrystallization.

Sodium acetate–acetic acid buffer solution ($pH = 5$). Prepared by adding acetic acid to 2.0 *M* sodium acetate solution until pH 5 was reached.

Foreign ion solutions. Solutions of diverse ions for the interference studies were prepared by dissolving the calculated amount of each compound in order to give 10–1000 μg/ml solutions of each species.

All these solutions were stored in polyethylene containers.

1,2-Dichloroethane (DCE) extrapure (sp. gr. 1.25).

Procedure

Ordinary spectrophotometry. To an aliquot of sample solution containing less than 50 μg of cobalt in a 250 ml separating funnel, 1 ml of the buffer solution and 4 ml of picric acid solution were added and the total volume adjusted to 100 ml. This was mixed and set aside for 2 min. Then 5 ml of 1×10^{-3} *M* PPT solution in dichloroethane was added and the funnel shaken for 2 min. The phases were allowed to separate and the organic layer run into a dry flask. The spectra of the brown DCE extract were recorded over the range from 700 to 350 nm against a reagent blank prepared under the same experimental conditions, using 10 mm cells.

Derivative spectrophotometry. The extract was prepared as above and the second derivative spectra recorded over the range from 700 to 350 nm against a reagent blank at a scan speed of 480 nm/min with $\Delta\lambda 5$.

RESULTS AND DISCUSSION

Spectral characteristics

The absorption spectra of the ion-association complex cobalt(II)–PPT–picrate, of the binary combinations cobalt(II)–PPT, cobalt(II)–picrate, PPT–picrate extracted into DCE and of the PPT solution in DCE were measured against DCE (Fig. 1). It can be observed in Fig. 1 that the spectrum of the PPT solution shows one band at 380 nm. This spectrum was not altered

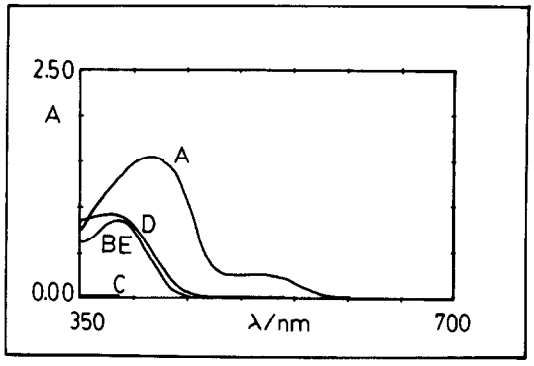

Fig. 1. Absorption spectra of DCE extract of the Co(II)–PPT–pic complex, the binary combinations of reactants and the PPT solution in DCE, measured against DCE. (A) Co–PPT–pic; (B) Co–PPT; (C) Co(II)–pic; (D) PPT–pic and (E) PPT.

when cobalt was added in aqueous phase, which indicates that cobalt remained in aqueous phase and the cobalt(II)–PPT binary complex was not extracted into DCE.

The introduction of a third component, picric acid, leads to the formation of an ion-association complex. The absorption spectrum of the extract of Co(II)–PPT–picrate ternary complex showed two bands at 350–480 nm and 500–600 nm. Based on the spectroscopic behavior of other metal–ferroine–picrate complexes[17–21] the first band can be assigned to the absorption of picrate and PPT and the second to the absorption of the chromophore Co–PPT. However, significant changes in both bands were observed when the concentration of cobalt was increased (Fig. 2), indicating that probably Co–PPT presents not only absorption at 500–600 nm but also another band which is overlapped with the absorption of PPT and mainly of picrate. In order to obtain more information, derivative spectrophotometry,

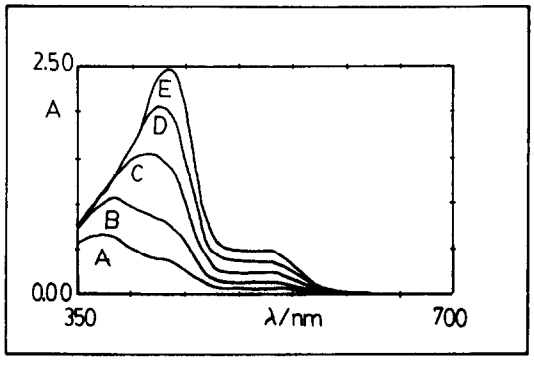

Fig. 2. Effect of cobalt concentration on absorption spectrum of DCE extract of Co(II)–PPT–pic, measured against a reagent blank. Aqueous phase cobalt concentrations (ng/ml) (A) 50; (B) 100; (C) 200; (D) 300; (E) 400. All other conditions as in the text.

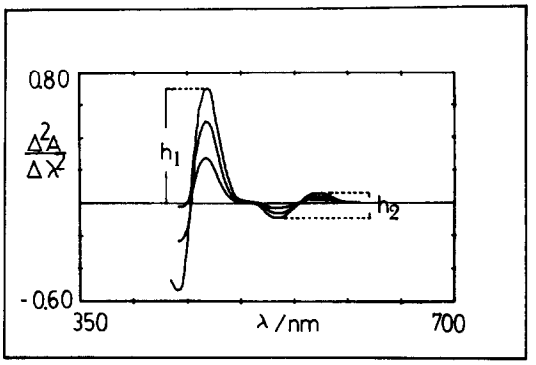

Fig. 3. Second-derivative spectra of DCE extract of the Co–PPT–pic complex measured against a reagent blank. Aqueous phase cobalt concentrations (ng/ml) (A) 100; (B) 200; (C) 300. All other conditions as in the text.

which provides higher spectral resolution, was used. The second-order spectrum shows that the absorption at 350–480 nm is split into two contributions and the portions of the derivative spectrum between 430 and 480 nm and between 500 and 600 nm could be used to measure the cobalt concentration (Fig. 3). On the other hand, if perchlorate is used instead of picrate, the second derivative spectrum of the Co–PPT–perchlorate complex showed similar, but less sensitive, absorptions at 430–480 nm and 500–600 nm, which indicates that both correspond to the absorption of the chromophore Co–PPT.

In order to make the determination more sensitive and reproducible, second-derivative spectrophotometry was adopted and the value of the vertical distance from the base line to peak values at 470 nm or from trough to peak values between 500 and 600 nm can be used for analytical purposes (Fig. 3).

Optimization of variables

Variables were optimized by the univariate method. Table 1 shows the optimum values found for the chemical and spectral variables and the range over which they were studied. The signal increased with the concentration of PPT and picrate to reach a maximum and constant value over 6.2×10^{-4} *M* PPT and 1.6 ml of 1×10^{-2} *M* picric acid in the aqueous phase. An increase in the concentration of both reagents had no influence in the blank and in the analytical signal, and the optimum values were selected by taking into account that foreign cations can be present in the samples with the evident consumption of both reagents. Similarly, the signal was at a maximum at pH = 2.5–9.0. At pH <2.5, formation of the ion pair was incomplete owing to protonation of the picrate ($pK_a = 1.6$). In all subsequent experiments a buffer system of acetic acid–acetate pH 5 was used.

Table 1. Optimization of variables

Variable	Range studied	Optimum value
Chemical		
pH	1.0–12.0	5.0
PPT solution (10^{-4} *M*)	0.6–12.0	10.0
1×10^{-2} Picric acid solution (*ml*)	0.2–6.0	4.0
Aqueous/organic phase ratio	2–24	20
Spectral		
Derivative order	0–4	2
$\Delta\lambda$	1–9	5
Analytical wavelength (*nm*)	700–350	470

It was found that the liquid–liquid separation and reaction of the analyte with PPT and picric acid can be carried out in 1,2-dichloroethane, chloroform and dichloromethane (DCM). The signal values for DCE and DCM solutions were higher than those for chloroform solutions. DCE was selected because it is less volatile than DCM.

The aqueous–organic phase ratio was chosen in order to obtain the maximum enrichment factor. A value of 20 was selected as optimum because miscibility occurred when higher ratios were selected.

The main spectral variable affecting the shape of the spectra was the order of the derivative value. Zero and first order did not resolve the large overlap between absorption of the reagents and complex at 350–480 nm (Fig. 1). However, when the second derivative is used the spectrum is sufficiently resolved for analytical purposes (Fig. 3) and both h1 and h2 signals can be used for measurement. In our spectrophotometer $\Delta\lambda$ values can be selected between 1 and 9. Generally the noise level decreases with an increase of $\Delta\lambda$, thus decreasing the fluctuation in the derivative spectrum. However, if the $\Delta\lambda$ value is too high, the spectral resolution is deteriorated. Therefore, the optimum value of $\Delta\lambda$ should be selected by taking into account the signal-to-noise ratio and the resolution of the spectrum. A $\Delta\lambda$ value of 5 was selected as optimum in order to give the best resolution and signal-to-noise ratio. The wavelength scanning speed has no influence on the signal, because the differentiation is obtained digitally. Hence, a fast value of 480 nm/min was selected.

Calibration graph, sensitivity and precision

Two calibration graphs were obtained by plotting the second-derivative value (h1 or h2, Fig. 3), with $\Delta\lambda = 5$ nm, *vs* the cobalt concentration. The equations for the lines using the least squares method were found to be:

$$h1 = 2.35 \times 10^{-3} (Co)_{ppb} + 0.010 \quad (r = 0.9998)$$

$$h2 = 5.33 \times 10^{-4} (Co)_{ppb} + 0.001 \quad (r = 0.9989)$$

where h is the second derivative value in derivative units.

The precision of the method was tested with solutions of 20 and 100 ng/ml cobalt and the relative standard deviations were found to be 3.2 and 1.5%, respectively.

By using the first equation, the determination range was over 7.2–500 ng/ml and the limit of detection (3σ) was found to be 2.2 ng/ml.

Interference studies

In order to investigate the analytical applications of this method, the effect of several foreign ions that are usually present with cobalt in real samples were examined. The tolerance limits for various species are shown in Table 2. A deviation of more than 5% of the signal was taken as a sign of interference. The results indicate the good selectivity achieved. The most serious cationic interference is from iron which interferes at concentrations twice those of cobalt. However, this problem can be resolved if both ions are determined simultaneously by using an equation system at two wavelengths, taking into account that cobalt does not interfere in the determination of iron with PPT and picrate.

Application of the method: determination of cobalt in vitamins

The content of 2 ml ampoules of vitamin injection were decomposed in a Kjeldahl flask by heating with a mixture of concentrated nitric and sulphuric acids (10 + 1), first at low temperature to avoid violent reaction, then more strongly until the acids were evaporated. Dropwise addition of concentrated nitric acid and boiling were continued until either a colorless or pale yellow residue was obtained. The residue was diluted and heated gently in water, and then was diluted to an appropriate volume (100 ml). The cobalt content of this solution was determined by the recommended procedure, using 5 ml of aliquot solution. The results are presented in Table 3.

Table 3. Determination of cobalt in vitamin B_{12}

CONCLUSIONS

A relatively simple and inexpensive extraction–derivative–spectrophotometric method for the determination of cobalt has been developed. It provides a high sensitivity with a determination limit of 7.2 ng/ml. Compared with previous direct and derivative spectrophotometric methods, the proposed approach is more

*Maximum tested.

selective and simpler because it requires neither separation nor masking of foreign species. Compared with continuous flow injection–chemiluminescence methods,[2,3] which are highly sensitive (limit of detection 0.00006 ng/ml), this method is less sensitive but cheaper and less complicated in terms of assay procedure and equipment used. Finally the method was successfully applied to the determination of cobalt in vitamin.

Summary—The chemical equilibria involved in nine mixed ligand systems Zn(II)–*L*-cysteine (Cys)/*D*-penicillamine(Pen)/*L*-cysteic acid(Cya)(A)–imidazole(Him), histamine(Hist) and *L*-histidine(His)(B) have been investigated in aqueous perchlorate medium by pH titrimetry at 37° and ionic strength, $I = 0.15M$ ($NaClO_4$). The mixed ligand complex species of the types $ZnABH_2$, ZnABH, ZnAB or $ZnAB_2$ have been detected in addition to various binary species due to ligands A and B. The results obtained for the ZnABH type of species indicate that the site of protonation is the amino group of Cys/Pen ligands in the Zn(II)–Cys/Pen(A)–Him, Hist and His(B) systems, and the amino group of Hist/His secondary ligands in the Zn(II)–Cya(A)–Hist and His(B) systems. In the $ZnABH_2$ type of species, one proton is attached with the primary ligand (A) and the other with the secondary ligand(B). In both ZnAB and $ZnAB_2$ type ternary species in all the systems, the primary ligand binds the metal in a bidentate manner and the secondary ligands Him, Hist and His bind the metal, respectively in a uni, bi and terdentate manner.

The studies on the interaction of sulphur containing amino acids such as cysteine, penicillamine and cysteic acid with zinc(II) are important both from the chemical and biological points of view.[1] This point becomes more clear, if one considers the fact that the zinc core consisting of Zn(II) cysteine–histidine residue has an important biochemical role[2,3] in the stabilization of the 'zinc fingers' that bind to DNA. The ligands *L*-cysteine and *D*-penicillamine increase their complex forming tendency via the soft mercapto sulphur atoms. These soft ligands generally form thermodynamically more stable complexes with transition metal ions such as Ni(II) and Zn(II). However, copper(II) complexes with cysteine and penicillamine are readily oxidised. The oxidative product of *L*-cysteine is *L*-cysteic acid. The Zn(II)–cysteic acid complexes are very useful in the field of pharmaceutical chemistry. Considerable attention has been paid in recent years to the studies of Zn(II) complexes with cysteine and its derivatives.[1–6] In continuation of our research work on sulphur containing amino acids,[7] the present paper deals with the systematic equilibrium studies on Zn(II)–*L*-cysteine(Cys)/*D*-penicillamine(Pen)/*L*-cysteic acid(Cya) (A)–imidazole (Him), histamine(Hist) and *L*-histidine(His)(B) mixed ligand systems by pH titrimetry at 37° and $I = 0.15M$ ($NaClO_4$). The Zn(II)–Cys, Pen and Cya(A) binary systems have also been investigated under the present experimental conditions.

EXPERIMENTAL

All the ligands, used were obtained from Fluka. The stock solution of zinc(II)

†Author for correspondence.

perchlorate and other reagents were prepared and estimated as described earlier.[8] All the measurements were carried out as described elsewhere.[7] The electrode system was calibrated by the method of Irving *et al.*[9] For the ternary systems, the pH titrations have been carried out using 50-ml solutions containing low concentrations of $Zn(ClO_4)_2$, ligand A and ligand B in 1:1:1, 1:2:1 or 1:1:2 ratios with known volumes of standard carbonate free NaOH. Nitrogen was used throughout the titrations to maintain an oxygen-free atmosphere. The stability constants of the various binary and ternary complex species were derived from the pH titration data by the MINIQUAD-75 computer program[10] on a CYBER 180/830A computer. The binary stability constants for the Zn(II)–Cys, Pen and Cya(A) systems have been re-estimated under the present experimental conditions and reported in Table 1. The titrations for the binary systems were carried out on 50-ml solutions containing the metal perchlorate and the ligand in 1:1, 1:2 and 1:5 ratios. The binary stability constant data of Zn(II)–Him, Hist and His(B) systems have been reported previously.[8] The results obtained for the mixed ligand systems are given in Table 2. The charges of all the complex species reported in this paper are omitted for clarity.

RESULTS AND DISCUSSIONS

Zn(II)–Cys, Pen and Cya(A) binary systems

The formation of different types of complex species in solution depends upon the experimental conditions used. Thus, though in the Zn(II)–Cys and Pen(A) systems the polynuclear binary complexes in addition to the ZnA, ZnA_2 and their corresponding protonated complex species have been reported,[6,11,12] in the present experimental conditions the Zn(II)–Cys(A) system showed the presence of ZnA, ZnA_2H_2, ZnA_2H and ZnA_2 types of binary complex species, while in the Zn(II)–Pen(A) system the binary complexes of stoichiometry ZnAH, ZnA, ZnA_2H_2, ZnA_2H and ZnA_2 have been found to be present. The Zn(II)–Cya(A) system showed only ZnA and ZnA_2 types of binary species to be important.

As reported earlier[1,13] the $\log \beta_{ZnA}$ values obtained in the present study in the Zn(II)–Cys and Pen(A) systems (Table 1) correspond to the bidentate binding of these ligands through the mercapto and primary amino groups. In the Cr(III)–Cys system also, where the metal prefers to have a stable coordination number of six, Cys binds the metal through the sulphur and nitrogen atoms.[14] Since $\log K_1/\log K_2$ values obtained in both the above systems approaches unity, it can be inferred that in the ZnA_2 species also, Cys/Pen ligands bind the metal in a bidentate manner as in the case of ZnA Cys/Pen species. Of course, the 1:2 species will be more stabilized due to the ability of sulphur to accept electrons from the metal ion by π-bonding, thereby facilitating the addition of a second sulphur atom to the metal. The protonated species of the types ZnAH, ZnA_2H_2 or ZnA_2H in the Zn(II)–Cys/Pen(A) systems have been found to be favoured at low pH values. Hence, as

described elsewhere[15,16] it can be concluded that the S,O coordination plays an important role in the lower pH range, with the extra proton residing with the primary amino group of the coordinated ligand. Thus, in the ZnAH species in the Zn(II)–Pen(A) system, Zn(II) binds the ligand through the mercapto and carboxylato groups and the proton occurs with the primary amino group of the ligand. In the $Zn(AH)_2$ species type in the Zn(II)–Cys/Pen(A) systems, both the ligands should bind the metal through the mercapto and carboxylato groups and the primary amino group of both the ligands will be

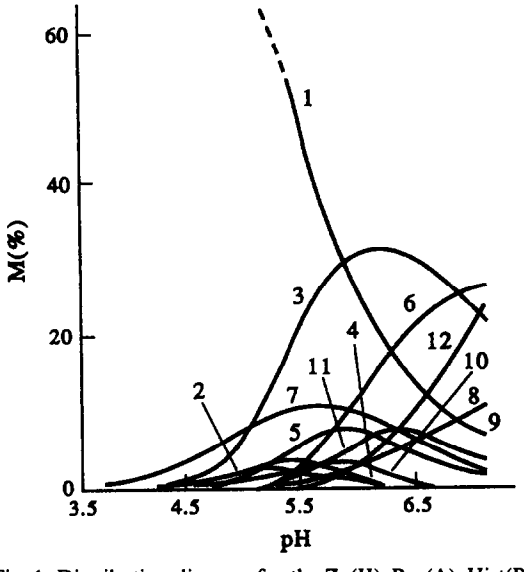

Fig. 1. Distribution diagram for the Zn(II)–Pen(A)–Hist(B) system ($C_{Zn} = 3.062 \times 10^{-3}$, $C_A = 3.042 \times 10^{-3}$, $C_B = 3.045 \times 10^{-3} M$). 1) Unbound Zn(II), 2) ZnAH, 3) ZnA, 4) ZnA_2H_2, 5) ZnA_2H, 6) ZnA_2, 7) ZnBH, 8) ZnB, 9) ZnB_2, 10) $ZnABH_2$, 11) ZnABH, 12) ZnAB.

protonated. In the Zn(AH)A type of species in the above two systems, one ligand will bind the metal through the mercapto and primary amino groups and the other ligand with the protonated amino group binds the metal through mercapto and carboxylato groups. Thus the ambidentate behaviour of Cys and Pen ligands are well demonstrated by the results obtained for Zn(AH)A species in the Zn(II)–Cys/Pen(A) systems. The same type of protonation sites have been suggested for the Ni(CysH)(Cys), $Cd(CysH)_2$ and $Cd(PenH)_2$ complexes.[7,17,18]

The stability constant studies on the Zn(II)–Cya(A) system appear to be more interesting. In this system, ZnA and ZnA_2 types of species with respective $\log K_1$ and $\log K_2$ values of 3.77 and 2.25 have been detected in the present study. The stepwise stability constant values for the formation of ZnA and ZnA_2 types of species in the Zn(II)–glycine system[11,12] are, respectively 5.3 and 4.2. The $\log K_1$ value obtained in the Zn(II)–Cya(A) system is *ca.* 1.6 log units lesser than that expected for the glycine-like mode of binding of Cya with Zn(II). This shows that in the ZnA Cya species no chelate is formed, *i.e.*, the metal should bind any one of the three donor groups, *viz.*, sulphonic acid, primary amino or carboxylato groups. In case it binds through sulphonic acid or carboxylato groups, the $\log K_1$ value should be in the range of two. But the value obtained here is 3.77. This indicates that the metal should bind the ligand through the primary amino group. In the ZnA_2 Cya species also, both Cya ligands should bind the metal through the two primary amino nitrogen atoms. This is supported by the fact that

the $\log \beta_{ZnA_2}$ value of 6.02 obtained in the Zn(II)–Cya(A) system bears favourable comparison with the $\log \beta_{ZnA_2}$ value of 6.3 reported[19] in the Zn(II)–methylamine system, where the metal binds the ligands through the primary amino nitrogen atoms.

Zn(II)–Cys/Pen/Cya(A)–Him, Hist and His(B) ternary systems

The various types of ternary species detected in the title systems are indicated in Table 2. Sovago *et al.*[16] in their studies on Zn(II)–Cys/Pen(A)–Hist and His(B) systems at 25° and 0.2*M* (KCl) could detect only the ZnAB type of species. Kayali and Berthon[20] studied Zn(II)–Cys(A)–Hist and His(B) systems and reported the formation of ZnABH and ZnAB types of species. Reddy *et al.*[3] reported the stability constants of ZnAB and $ZnAB_2$ types of species in the Zn(II)–Cys(A)–Him(B) system, ZnAB type of species in the Zn(II)–Cys(A)–Hist(B) system and ZnAB and ZnA_2B_2 types of species in the Zn(II)–Cys(A)–His(B) system. The types of ternary species reported above under different experimental conditions differ from the results obtained in the present study. Thus, in the Zn(II)–Cys(A)–Him(B) system, the formation of ZnABH ternary species in addition to ZnAB and $ZnAB_2$ species could also be detected. The present results in the Zn(II)–Cys(A)–Hist(B) system agree well with Kayali and Berthon.[20] In the Zn(II)–Cys(A)–His(B) system, the presence of $ZnABH_2$ type of ternary species also in addition to ZnABH and ZnAB species could be detected in the present study. In the Zn(II)–Pen(A)–Hist and His(B) systems, we could detect the presence of $ZnABH_2$ and ZnABH species in addition to ZnAB species reported by Sovago *et al.*[16] The stability constant data reported by these groups of workers bear favourable comparison with the present results after giving due allowance for the change in the experimental conditions.

Stability and structure of ZnAB and $ZnAB_2$ types of species

In the ZnA binary species in the Zn(II)–Cys/Pen(A) binary systems, the ligands bind the metal through the mercapto and amino groups. Hence, it may be expected that in the ZnAB species in the Zn(II)–Cys/Pen(A)–Him, Hist and His(B) systems, Cys/Pen primary ligand would bind the metal in a bidentate manner through its mercapto and amino groups. This becomes clearer by noting that the $\log K^{ZnB}_{ZnAB}$ values obtained in these systems (Table 2) compare favourably with the respective $\log \beta_{ZnA}$ values obtained in the Zn(II)–Cys/Pen(A) systems (Table 1). In the Zn(II)–Cya(A)–Him, Hist and His(B) systems, the $\log K^{ZnB}_{ZnAB}$ values obtained (Table 2) are higher than the $\log K^{Zn}_{ZnA}$ value of 3.77 obtained in the Zn(II)–Cya(A) binary system by ~ 1.5 log units, where Cya binds the metal only through its primary amino group. This probably suggests that in Zn(II)–Cya(A)–Him, Hist and His(B) ternary systems, Cya primary ligand binds the metal in a glycine-like mode. The higher $\log \beta_{ZnAB}$ values obtained in the Hist secondary ligand systems compared to that in the Him secondary ligand systems suggest that Hist in its ZnAB species in the Zn(II)–Cys/Pen/Cya(A)–Hist(B) systems bind the metal in a bidentate manner through its imidazole and amino nitrogen atoms. Thus, ZnAB species in the Hist secondary ligand systems would have a coordination number of four. The $\log \beta_{ZnAB}$ values obtained in the Zn(II)–Cys/Pen/Cya(A)–His(B) systems are higher than those values obtained in the corresponding Hist secondary ligand systems. This indicates that His in its ZnAB species in the above systems binds the metal in a terdentate manner. However, the difference in the $\log \beta_{ZnAB}$ value between those obtained in the His and Hist secondary ligand systems in the range of ~ 1 log unit suggests that the binding of the carboxylato group in the His secondary ligand systems is very weak.

In the $ZnAB_2$ type of species in the Zn(II)–Cys/Pen/Cya(A) Him(B) systems, the coordination number of the metal ion would be four due to the bidentate binding of Cys/Pen/Cya primary ligands and the involvement of two imidazole nitrogen atoms in the two Him secondary ligands. The $\log \beta_{ZnAB_2}$ values in the Zn(II)–Cys/Pen/Cya(A)–Him(B) systems and $\log \beta_{ZnAB}$ values in the Zn(II)–Cys/Pen/Cya(A)–Hist(B) systems, where both the species have tetrahedral geometry, can now be compared. Owing to the chelate effect and higher basicity of the Hist ligand, one would expect higher $\log \beta_{ZnAB}$ values in the later systems compared to the $\log \beta_{ZnAB_2}$ values in the former systems, where the binding of two imidazoles does not result in the formation of a chelate ring. Actually this is the trend in the corresponding binary systems where the $\log \beta_{ZnB}$ value is 5.39 in the Zn(II)–Hist(B) system and $\log \beta_{ZnB_2}$ value is 4.98 in the Zn(II)–Him(B)

system (Table 1). Due to the chelate effect and higher basicity of Hist, one can expect still higher differences between the above $\log \beta_{ZnB}$ and $\log \beta_{ZnB_2}$ values. The lesser difference of ~ 0.4 log units between the above two parameters suggests that the π-acceptor property of the two imidazole ligands in the ZnB_2 imidazole species makes this species have higher stability than those expected. This trend is even higher in the ternary systems involving Cys/Pen/Cya primary ligands and Him and Hist secondary ligands, *i.e.*, the higher $\log \beta_{ZnAB_2}$ value in the Zn(II)–Cys/Pen/Cya(A)–Him(B) systems compared to the $\log \beta_{ZnAB}$ value in the Zn(II)–Cys/Pen/Cya(A)–Hist(B) systems can be due to the fact that π-acceptor property of two imidazole ligands in the $ZnAB_2$ species overcomes the chelate effect and the basicity of Hist ligand in the ZnAB species in presence of Cys, Pen and Cya primary ligands.

$$ZnA + ZnB_2 \rightleftharpoons ZnAB_2 + Zn \quad (1)$$

$$\Delta \log K_{ZnAB_2} = \log \beta_{ZnAB_2} - (\log \beta_{ZnA} + \log \beta_{ZnB_2}) \quad (2)$$

$$ZnA_2 + ZnB_4 \rightleftharpoons 2ZnAB_2;$$

$$X_{ZnAB_2} = [ZnAB_2]^2/([ZnA_2][ZnB_4]) \quad (3)$$

$$\log X_{ZnAB_2} = 2 \log \beta_{ZnAB_2} - (\log \beta_{ZnA_2} + \log \beta_{ZnB_4}) \quad (4)$$

$$ZnA + ZnB \rightleftharpoons ZnAB + Zn \quad (5)$$

$$\Delta \log K_{ZnAB} = \log \beta_{ZnAB} - (\log \beta_{ZnA} + \log \beta_{ZnB}) \quad (6)$$

$$ZnA_2 + ZnB_2 \rightleftharpoons 2ZnAB;$$

$$X_{ZnAB} = [ZnAB]^2/([ZnA_2][ZnB_2]) \quad (7)$$

$$\log X_{ZnAB} = 2 \log \beta_{ZnAB} - (\log \beta_{ZnA_2} + \log \beta_{ZnB_2}). \quad (8)$$

Now, if one compares the $\Delta \log K$ and $\log X$ values obtained for the $ZnAB_2$ species [equations (1)–(4)] with those values of ZnAB species [equations (5)–(8)] in the Zn(II)–Cys/Pen(A)–Him(B) systems, it may be noted that these parameters are more positive for the $ZnAB_2$ species compared to those for the ZnAB species (Table 2) demonstrating that $ZnAB_2$ species are having higher stability compared to ZnAB species. This can probably be accounted for by considering the fact that the primary ligand in each of the above systems results in the formation of the five membered chelate ring and hence the formation of $ZnAB_2$ species is not sterically unfavourable as in the case of Cu(II) ternary complex systems.[23]

The $\Delta \log K$ values [equations (5) and (6)] obtained for the ZnAB type of species in the Zn(II)–Cys/Pen(A)–Him, Hist and His(B) systems are more positive compared to their statistical values[21,22] showing preference for the formation of ternary complexes compared to the binary analogues. The positive values obtained for this parameter in some of the systems show that the secondary ligand prefers to add on to the ZnA complex rather than the aquated metal ion. The $\log X_{ZnAB}$ values [equations (7) and (8)] obtained in these systems (Table 2) also follow these trends. The $\Delta \log K$ and $\log X$ values for the ZnAB species in the Zn(II)–Cya(A)–Him, Hist and His(B) systems could not be computed because only stability constant data for the monodentate binding of Cya with Zn(II) is available both in the ZnA and ZnA_2 type of species (Table 2) while it is bidentate in the ternary species.

Stability and structure of ZnABH and $ZnABH_2$ species

As indicated initially, the protonated ternary species of the type ZnABH has been found to be present in the Zn(II)–Cys/Pen(A)–Him, Hist and His(B) and Zn(II)–Cya(A)–Hist and His(B) systems under study in the lower pH ranges. The protonated binary species have been detected in the Zn(II)–Cys/Pen(A) systems but not in the Zn(II)–Him(B) system (Table 1). Hence, in the ZnABH species in the Zn(II)–Cys/Pen(A)–Him(B) systems, it can be expected that the proton resides with the Cys/Pen primary ligand, possibly with its amino group as is the case with the ZnA_2H_2 and ZnA_2H Cys/Pen species as described in the beginning. The pK^{H}_{ZnABH} values (Table 2) obtained in the Zn(II)–Cys(A)–Him, Hist and His(B) systems are comparable to each other indicating the same protonation site in the ZnABH species in all these three systems, *i.e.*, as is the case for the ZnABH species in the Zn(II)–Cys-Him(B) system, in the corresponding Hist and His secondary ligand systems, the extra proton in the ZnABH species is attached with the Cys primary ligand, possibly by its primary amino group. This argument appears to be more reasonable because when the extra proton in the ZnABH species in the Zn(II)–Cys(A)–Hist(B) system is attached to the Hist secondary ligand, the binding of the Hist ligand would not result in the formation of any chelate ring and hence would lead to lower

stability. Conversely, the Cys ligand with the protonated amino group can bind the metal through the mercapto and carboxylato groups resulting in a six-membered chelate ring. From similar arguments for the Zn(II)–Pen(A)–Him, Hist and His(B) systems, it can be concluded that the extra proton in the ZnABH species in the above systems resides with the Pen primary ligand.

Of the ternary systems containing Cya primary ligands, the Zn(II)–Cya(A)–Hist and His(B) systems gave rise to the formation of ZnABH type of species. Of the Zn(II)–Cya(A) and Zn(II)–Hist and His(B) binary systems, the protonated binary species have only been detected in the latter. Hence, it may be inferred that in the ZnABH type of species in the Zn(II)–Cya(A)–Hist and His(B) systems, the possibilities are more for the attachment of the extra proton with the Hist/His secondary ligand possibly to their primary amino group. Since the $\log \beta_{ZnABH}$ values obtained in the Zn(II)–Cys/Pen/Cya(A)–His(B) systems are higher by about one log unit compared to those in the Zn(II)–Cys/Pen/Cya(A)–Hist(B) systems (Table 2), it may be concluded that in the ZnABH species in the His secondary ligand systems the carboxylato group is also involved in the metal-ligand binding.

$$ZnAH + ZnB \rightleftharpoons ZnABH + Zn \qquad (9)$$

$$\Delta \log K_{ZnABH} = \log \beta_{ZnABH} - (\log \beta_{ZnAH} + \log \beta_{ZnB}) \qquad (10)$$

The $\Delta \log K_{ZnABH}$ [equations (9) and (10)] values obtained (Table 2) in the Zn(II)–Pen(A)–Him, Hist and His(B) systems are more positive compared to the statistical values,[21,22] indicating higher stability for the ZnABH species. Again the $\Delta \log K_{ZnABH}$ values in the Zn(II)–Cya(A)–Hist(B) system has not been calculated because of the reasons outlined in the case of ZnAB species in the above system.

The $ZnABH_2$ type of species has been detected in the Zn(II)–Cys(A)–His(B) and Zn(II)–Pen(A)–Hist and His(B) systems. In this species it may be expected that the two protons should reside, respectively with the primary and secondary ligands possibly with their amino groups. The $\log \beta_{ZnABH_2}$ values in these two systems differ only by *ca.* 0.20 log units, showing that the binding of the carboxylato group in the His secondary ligand system is very weak.

Species distribution plots

The distribution of various binary and ternary complexes (in terms of the percentage bound total metal ion as a function of pH) has been calculated for all the mixed ligand systems under study. The concentration of the $ZnABH_2$ ternary species never exceeded 10% of the total metal ion. About 30% of the total metal ion has been found to be present in the form of ZnABH species. In all the title ternary systems the ZnAB type of species occurs in higher concentrations than the binary analogues, indicating the preference for the formation of ternary species, which is in agreement with the predictions made from the $\Delta \log K$ values. The formation of $ZnAB_2$ species in the Zn(II)–Cys/Pen/Cya(A)–Him(B) systems has been found to be maximum in a 1:1:2 solution of metal, ligand A and Him. The diagram obtained for the Zn(II)–Pen(A)–Hist(B) system at a metal, ligand A and ligand B ratio of 1:1:1 is given in Fig. 1.

FLUORIMETRIC DETERMINATION OF DIACETYL AND 2,3-PENTANEDIONE WITH ISONIAZIDE AND A ZIRCONIUM SALT

RAFAEL J. GARCÍA-VILLANOVA* and ROSA M. GARCÍA ESTEPA
Departamento de Nutrición y Bromatologia, Facultad de Farmacia. Universidad de Granada, 18012 Granada, Spain

(*Received* 3 *August* 1992. *Revised* 25 *March* 1993. *Accepted* 26 *March* 1993)

Summary—Diacetyl and 2,3-pentanedione react with isoniazide in acidified solutions to give the corresponding hydrazones which, by reacting with a zirconium (IV) salt, form fluorescent complexes. Both reactions have been studied separately. Variables such as pH, heating time, and excess of reactives are discussed. The method may be used for the determination of these compounds in foods.

INTRODUCTION

Diacetyl was the first α-diketone to be reported as an important agent responsible for flavour in many foods[1] with 2,3-pentanedione and pyruvic aldehyde being reported subsequently (in fact, one of the functions of the latter is aldehyde). Awareness and, above all, control of the levels of these compounds in foods are of considerable interest since their occurrence determines the quality of many foods; in some cases they may be considered as indicators of optimum maturation, while in others they may be indicators of spoilage. Diacetyl is normally a major compound, with methyl glyoxal appearing in much lower amounts and is rarely a matter for determination. Few references may be found in the literature on this subject and many authors who proposed methods for the determination of α-diketones were probably unaware of its occurrence.

The first colorimetric method[2] to appear was a modification of the well-known Voges–Proskauer reaction, with creatinine and α-naftol in potassium hydroxide; this was followed by many modifications on that method. Other methods include those derived from the reaction with hydroxylamine: UV or visible spectrophotometry[3] after forming complexes with Ni(II)[4] or Fe(II)[5] (the latter procedure being the most common)[6] usually after distillation. Gas chromatography has been used to quantify both diacetyl and 2,3-pentanedione separately using either flame ionization[7–9] or an electron-capture detector.[10–12] The latter has proved to be 1200-fold more sensitive.[13] The head-space technique is the most commonly applied to differentiation in beers.[14,15] Only one fluorimetric method, based on the reaction of diacetyl with 3,4-diaminoanysol to yield a fluorescent quinoxaline, has been reported;[16] nothing has been found on 2,3-pentanedione.

The method reported in the present work is based on the previous synthesis of diacetyldiisonicotinoyl hydrazone (dDIH) and a study of its complexes with Sn(II) and (IV), Y(III), Sc(III), and Zr(IV).[17] The complex/complexes formed with excess Zr(IV) is/are fluorescent and we conclude that the structure in Fig. 1 is the most likely for it/them.

Although we suspect the coexistence of several stoichiometries in aqueous solution, the prevailing one is most likely 1 : 1 [dDIH : Zr(IV)]. 2,3-pentanedione yields a product with very similar features, suggesting that the two reactions are alike. Figure 2 shows the reaction leading to the formation of these complexes.

EXPERIMENTAL

Reagents

0.06*M* zirconyl chloride A.G. (Merck) was prepared by adding hydrochloride acid (viable for no longer than 20 days). A 0.035*M* isoniazide (Sigma) solution was freshly prepared. Solutions of Diacetyl (Merck) and 2,3-pentanedione (Fluka) were prepared from freshly

*Departamento de Química Analítica, Nutrición y Bromatología, Facultad de Farmacia, Universidad de Salamanca, 37007 Salamanca, Spain.

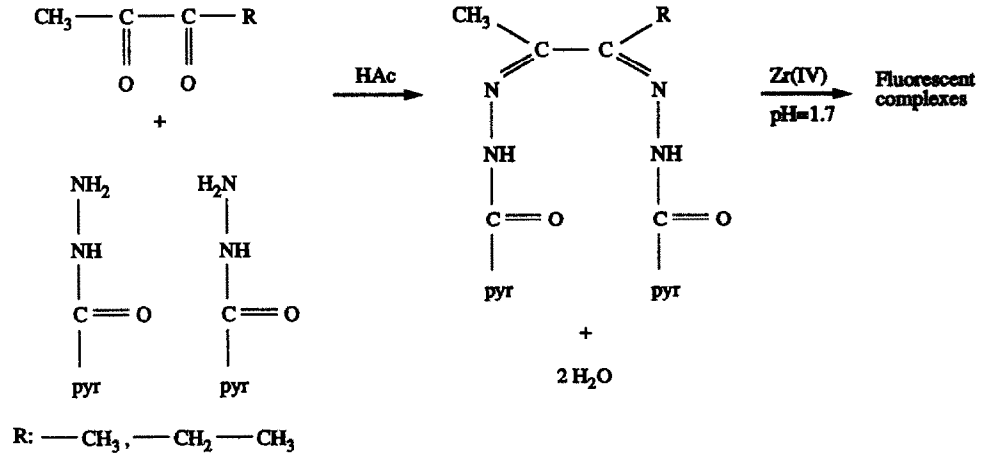

Fig. 1.

rectified reagents. Acetic acid, 4*M* sodium hydroxide, and 3*M* hydrochloric acid solutions were also employed. Other reagents used in this work, but not necessary for the analytical procedure, are noted in the text.

Apparatus

A Radiometer 26 pH-meter and a Perkin-Elmer mod. 204 Spectrofluorimeter with a xenon lamp, 10 nm slit width and 10 × 10 mm quartz cells at room temperature were used. Except where indicated, all measurements were performed with both "0" and "100" knobs turned top right. Just before measurements, air was removed from the reaction mixtures by bubbling nitrogen for a few seconds.

Glass distillation apparatus: 250–500 ml (Ø = 14/23) boiling flask; distillation tube with a vertical-delivery recovery bend; Liebig condenser, connected vertically (effective length = 150 mm); tapered water-tube adapter to dip below the liquid level contained in a 100 ml beaker receiver.

Procedure

$1.0 \times 10^{-5}M$ diacetyl (or 2,3-pentanedione) was added to 10 ml of 0.035*M* isoniazide solution, acidified with a few drops of acetic acid. After several minutes, 5 ml of 0.06*M* Zr(IV) salt was added; the pH was adjusted to 1.7 ± 0.1 with 3*M* HCl and 4*M* NaOH. The solution was transferred to a 50 ml volumetric flask and diluted with water. After approximately 30 min, fluorescence was measured against a blank prepared under similar conditions using excitation and emission wavelengths of 410 and 510 nm, respectively. Calibration curve: A curve was plotted with final diacetyl concentrations between 20 and 200 ppb. The "0" knob was adjusted with a blank and the "100" knob with the higher-concentration solution.

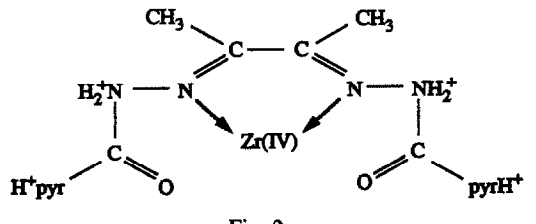

Fig. 2.

RESULTS AND DISCUSSION

Fluorescence spectra

Uncorrected excitation and emission spectra of the complexes were obtained with final concentrations of 0.0023 m*M* diacetyl and 0.0010 m*M* 2,3-pentanedione. In both cases, 10 ml of 0.0523*M* isoniazide, a few drops of acetic acid, and 5 ml of 0.025*M* Zr(IV) were added. pH was adjusted to 1.7 ± 0.1 with HCl and NaOH solutions and both reaction mixtures were diluted to 50 ml in a volumetric flask. After about 30 min, excitation and emission spectra were recorded (Fig. 3). Bands with maximum at 410 and 510 nm, respectively, were observed. Optimization of each reaction was based on the measurement performed at these wavelengths.

Optimum pH value

Following the same protocol, different pH values were studied for the formation of the complexes. A value of 1.7 ± 0.1 was confirmed

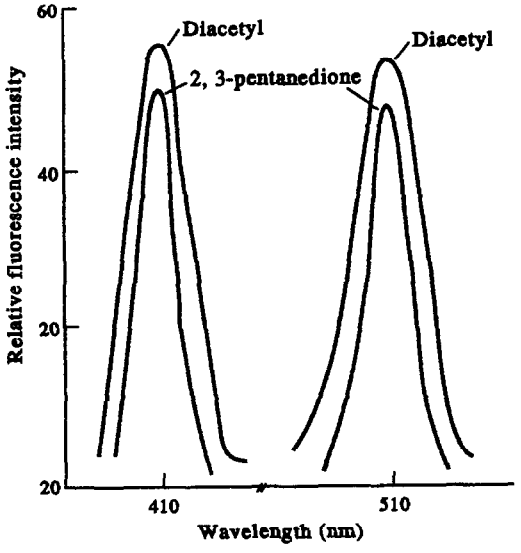

Fig. 3. Uncorrected excitation and emission spectra of both final-reaction mixtures: 0.0023 m*M* diacetyl and 0.0010 m*M* 2,3-pentanedione.

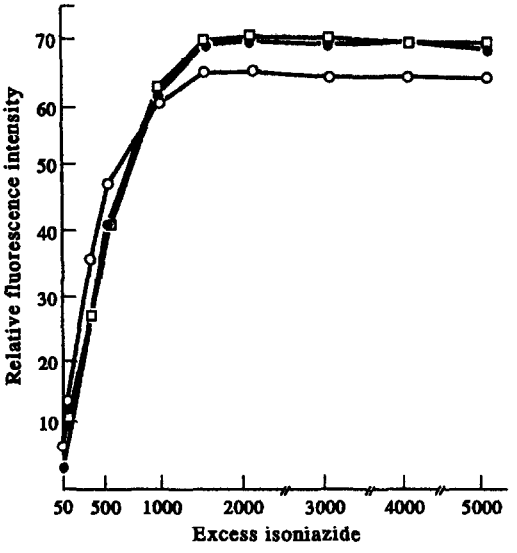

Fig. 4. Excess of isoniazide and time required for formation of diacetyl hydrazone (● just prepared, □ 15 min, ○ 30 min).

as optimum for both reactions, that being the equilibrium state with the maximum complexes formation and the minimum protonation of azomethynic nitrogen atoms and the minimum formation of Zr(IV) hydrocomplex species.

Excess of isoniazide and time for the formation of hydrazones

A preliminary experiment was carried out to establish the amount of Zr(IV) necessary to form the dDIH:Zr(IV) complex. Increasing amounts of Zr(IV) salt were added to a synthesized dDIH solution until a constant value of relative fluorescence intensity was reached. This corresponds to a 2500-fold excess of Zr(IV) in relation to the molar amount of α-diketone. This experiment is necessary to fix the Zr(IV) variable so that the study on excess isoniazide can be accurate. We later fixed the optimum excess of Zr(IV) salt for the determination of vicinal diketones.

The excesses of isoniazide indicated in Figs 4 and 5 in relation to the stoichiometry (2:1) were added to solutions of diacetyl (0.0052 m*M* final concentration) and 2,3-pentanedione (0.005 m*M* final concentration) plus a few drops of acetic acid. After the indicated time, 2500-fold excesses of Zr(IV) were added; pH was adjusted to 1.7 ± 0.1, and measurements were performed 30 min later. Minimum isoniazide excesses of 1500-fold for diacetyl and 4000-fold for 2,3-pentanedione were found to be optimum, and these amounts also resulted in an almost instantaneous formation of hydrazones.

Zirconium (IV) excess, time and temperature for the formation of complexes

Excesses of Zr(IV) ranging from 500- to 5000-fold were added to solutions of diacetyl (0.0052 m*M* final concentration) and 2,3-pentanedione (0.0050 m*M* final concentration). After addition of excess isoniazide (1500- and 4000-fold, respectively), a few drops of acetic acid and adjustment of pH to 1.7 ± 0.1, the reaction mixtures were either let to stand at room temperature or heated to 70–75°C for 15, 30, 45, or 60 min. In Fig. 6 only those experiments providing optimum results are reported, which were 30 min at room temperature for diacetyl, and the same time and heating for 2,3-pentanedione. For both compounds, the optimum amount of Zr(IV) was found to be in excess of 2500-fold.

Analytical features of the reactions

These are reported in Table 1. The calibration range is taken from the detection limit to the

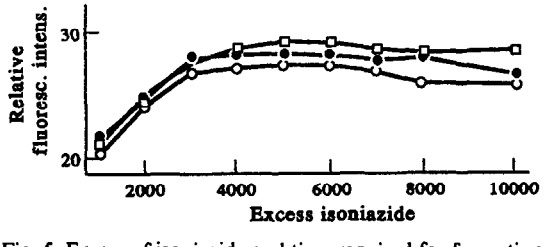

Fig. 5. Excess of isoniazide and time required for formation of 2,3-pentanedione hydrazone (● just prepared, □ 15 min, ○ 30 min).

beginning of fluorescence quenching. There is no way of distinguishing between the factors responsible for the quenching. It was possible to ascertain that Zr(IV) is not the cause, but it was not possible to determine the concentrations at which either the fluorophore or the excess isoniazide are responsible.

Precision was determined at four levels of concentration for both diacetyl and 2,3-pentanedione. The results are shown in Table 2.

Recovery

In separate aliquots, 5 ml of $1.0 \times 10^{-5}M$ diacetyl and 5 ml of $1.0 \times 10^{-5}M$ 2,3-pentanedione were diluted to 50 ml and then distilled to about 30 ml. Six similar distillations were performed for each sample. Three of the distillates were collected into water, and the other three into an excess of isoniazide and acetic acid and compared with three non-distilled controls. All the samples were analysed according to the method outlined in the Procedures section. In the first case, recovery for diacetyl was $81.0 \pm 1.0\%$, while in the second $98.6 \pm 0.3\%$. For 2,3-pentanedione, recovery with water was $87.9 \pm 1.0\%$, while with isoniazide it was $99.6 \pm 0.4\%$.

	8.00	1.39
	12.00	0.86
	16.00	0.70

*Mean $n = 10$ determinations.

Recoveries were also studied in a vinegar model system. Two solutions of vinegar were prepared as follows:

Diacetyl or 2,3-pentanedione = 5.0 mg;
Acetoin = 250 mg;
2,3-butanediol = 300 mg;
Tartaric acid = 2.5 g;
Acetic acid = 40 g;
Ethanol 96°C = 12.5 ml;
Water = up to 1000 ml.

Ten millilitre solutions of vinegar were diluted to 100 ml with water. Three 10 ml aliquots of each solution were neutralized with NaOH, diluted to 50 ml, and distilled to about 30 ml. The distillates were collected into solutions of isoniazide acidified with acetic acid (see Procedures). Recoveries of $98.0 \pm 0.0\%$ and $98.3 \pm 0.6\%$ were obtained for solutions with diacetyl and 2,3-pentanedione, respectively.

Application: determination of vicinal diketones

Any colorimetric method for determining diacetyl based on condensation reactions with diacetyl's carbonyl groups inevitably also determines 2,3-pentanedione since it reacts in exactly the same manner. What is thus being measured are vicinal diketones.

We therefore propose a method for the determination of vicinal diketones according to the reaction conditions reported for diacetyl. Although the method chosen does not give the best results for 2,3-pentanedione, we have nevertheless chosen it for the following reasons: (1) diacetyl is almost always the major (if not the only) vicinal diketone present. (2) Flavourwise, the 2,3-pentanedione taste-threshold is some 10-fold higher than that of diacetyl[19] (the same sensory response requires a 10-fold higher concentration of 2,3-pentanedione) and hence diacetyl is of major analytical interest.

Results are therefore expressed as diacetyl and plotted on a calibration curve ($r = 0.9998$).

Table 3. Recovery of diacetyl from store-bought vinegar

Diacetyl added (μg)	Diacetyl found (μg)	Recovery* (%)
1.000	0.985	98.5
2.000	1.998	99.9
3.000	2.988	99.6

*Mean of three determinations.

In order to confirm its effectiveness, the method was applied to determine the α-diketones in store-bought vinegar.

The vinegar was diluted to 10%, from which 10 ml were taken. Known quantities of diacetyl were added to the 10 ml sample, and the whole was then further diluted to 50 ml. After this, the sample was distilled until around 30 ml of distillate was collected into a solution of isoniazide acidified with acetic acid (see Procedures). Untreated samples were taken as references. The results are given in Table 3.

By the present method it is possible to estimate values as low as 0.02 mg/ml.

The major advantage of using this spectrofluorimetric method, as opposed to other colorimetric methods is therefore the former's greater sensitivity, thus allowing the determinations to be carried out with a very small sample.

THE BINDING OF STRONTIUM AND EUROPIUM BY AN AQUATIC FULVIC ACID—ION EXCHANGE DISTRIBUTION AND ULTRAFILTRATION STUDIES

MARIA NORDÉN, JAMES H. EPHRAIM and BERT ALLARD
Department of Water and Environmental Studies, Linköping University, S-581 83 Linköping, Sweden

(*Received* 20 *July* 1992. *Revised* 15 *February* 1993. *Accepted* 8 *March* 1993)

Summary—The complexation of an aquatic fulvic acid, FA, with Sr^{2+} and Eu^{3+} was studied at 0.10 and 0.01*M* $NaClO_4$ using trace levels of metal ($[Sr^{2+}] = 10^{-9}M$ and $[Eu^{3+}] = 10^{-11}M$) and a constant FA concentration (0.12 g/l) by an ultrafiltration technique (UF) and an ion exchange distribution method (IEDS). The overall complex formation function, β_{ov}, for the two metals was calculated and its dependence on pH, ionic strength and method was investigated. The absolute value of log β_{ov}, the pH dependence and the influence of the ionic strength on the complexation differed depending on the metal ion and experimental technique employed. By considering the functional group heterogeneity of the FA molecule, it was possible to predict the most predominantly bound site (keto–enol) and resolve the complex formation function for this site and Eu^{3+} (IEDS: 9.43 ± 0.29 l/eq at 0.10*M* and 10.58 ± 0.72 l/eq at 0.01*M*; UF: 7.19 ± 1.51 l/eq at 0.10*M* and 6.88 ± 0.91 l/eq at 0.01*M*). The results are discussed in the light of possible intrinsic problems of the two experimental methods.

The need to describe the dispersion of radionuclides from waste repositories due to possible leakage has mandated the study of typical radioisotopes and their interaction with natural organic acids. Earlier simulations of metal dispersion/speciation have normally left out the role of natural organic acids in this important exercise. However, in recent studies[1] it has been shown that small amounts of these ubiquitous natural organic acids have strong affinities for metal ions, thus their contribution to the mobility of radioisotopes cannot be neglected. Attempts to incorporate the role of these organic acids, have been stymied by a lack of a conceptual interpretation of their solution chemistry.

To describe metal ion binding by humic substances, complex formation functions (β) have been widely applied.[2] These functions are highly conditional, *i.e.* dependent on the ratio of metal ion to humic substance, ionic strength, pH and method of study.[3,4,5] In broad terms, models that have been proposed to describe metal–humate interactions may be categorized as the discrete ligand and the continuous distribution model.[6] Our approach may be categorized as a discrete ligand approach but emphasizes the need to incorporate contributions due to ionic strength effects and functional site heterogeneity.

This paper has been written to satisfy three objectives. The first is to address the role of natural organic acids in the mobility of radionuclides. The elements Sr and Eu were chosen as model elements for the study because as fission products in spent uranium, they also have properties similar to other long-lived radionuclides, *e.g.* Ra(II), Pu(III), and Am(III). The second objective is to compare results, expressed as overall complex formation functions at two ionic strengths and varying pH values, obtained by two different methods. The third objective is to describe the metal–fulvate interaction by considering the functional group heterogeneity of the fulvic acid. The complex formation function for the interaction between Eu and the acid site presumed to be the strongest, was determined. Comparison of this value with the literature-reported value[7,8] for the interaction between Eu and the functional group closely resembling the strongest site is made to justify the assignment of functionality to this site. In this exercise Sr was neglected because of its low binding affinity for fulvic acid.

EXPERIMENTAL

Chemicals and equipment

A well-characterized aquatic fulvic acid isolated from surface water in a bog area

(Bersbo, about 200 km south of Stockholm) was used.[9,10] In the ion exchange distribution studies, the sodium form of a Dowex 50 WX8 (mesh 50–100) was employed as the cation exchanger. The isotopes, ^{85}Sr (in aqueous solution) and ^{152}Eu (in 0.10M HCl), were purchased from Amersham. Milli-Q water was used in preparing all solutions. Analytical grade chemicals were employed. An Amicon ultrafiltration cell, 8050, was used in conjunction with a YM2 (1000 cut-off) Diaflo membrane. Radioactivity measurements were carried out using a LKB (Wallac) 1282 Compugamma counter. A radiometer pHM 85 precision pH-meter and a pH-combination glass electrode, GK 2402B, were employed for pH determinations. The experiments were performed at two ionic strengths (0.10M and 0.01M $NaClO_4$), a fixed total concentration of FA (0.12 g/l, corresponding to a total capacity of 5.6×10^{-4} eq/l), and initial metal ion concentrations of $[Sr^{2+}] = 10^{-9}M$ and $[Eu^{3+}] = 10^{-11}M$. The pH-adjustments were effected with $HClO_4$ or NaOH without the use of buffering agents. All experiments were performed at an ambient temperature of 22°C.

Procedure

The ion exchange distribution method has previously been developed for the determination of overall complex formation functions of metal–ligand systems.[11] In a typical IEDS experiment, 5 ml of the metal or fulvic acid–metal solution was added to a carefully weighed amount of the cation exchanger (0.005–0.100 g) in polyethylene tubes. The pH was adjusted with $HClO_4$ or NaOH and after equilibration on a shaking-table for approximately 24 h the pH was determined and aliquots were taken out for radioactivity measurements. To separate the solid from the liquid phase adequately the solutions were centrifuged for about 10 min at an appropriate speed.

The ultrafiltration experiments were performed following the procedure outlined previously.[12] The performance of the membrane, YM2, was checked by ascertaining that the rejection coefficient of the fulvic acid was unity, whereas that of the metal ion was zero.[13] A detailed description of the ultrafiltration method may be found elsewhere.[12,13]

MODE OF COMPUTATION

The classical expression for the conditional stability constant[14] has been the basis for the calculation of the overall complex formation function, β_{ov} as follows:

$$\beta_{ov} = \frac{\Sigma M_b}{M_f \Sigma A^-} \quad (1)$$

where ΣM_b is total metal bound, M_f is metal free in solution and ΣA^- is the summation of ionized acidic species.

In the IEDS the quotient $\Sigma M_b / M_f$ is calculated according to equation (2):

$$\frac{\Sigma M_b}{M_f} = \frac{D_0 - D}{D} \quad (2)$$

where D_0 and D are the respective distribution coefficient of the metal in absence and presence of FA. The D_0 was obtained from a linear regression analysis performed on the results of an experiment where D_0 was investigated as a function of the concentration of bulk electrolyte ($NaClO_4$), Table 1.

$$D = \frac{(wt_s A_c) - ((wt_s + wt_{NaOH} + wt_{HClO_4})A_s)}{(A_s wt_{sp})} \quad (3)$$

where wt_s is weight of solution, A_c is specific activity of the control solution (cpm/g), wt_{NaOH} is weight of added base, wt_{HClO_4} is weight of added acid, A_s is specific activity of the reaction solution (cpm/g) and wt_{sp} is weight of solid phase.

ΣA^- has been defined as:

$$\Sigma A^- = \alpha_{ov} HA_T - \Sigma M_b \quad (4)$$

where α_{ov} is overall degree of neutralization (dissociation) of the fulvic acid molecule and HA_T is total titratable acid in aqueous medium at the ionic strength of study. HA_T is derived at by multiplying the acid capacity (4.65 meq/g FA) with the amount of FA used (0.12 g/l). In these experiments only trace quantities of metal ions have been used and therefore $\Sigma M_b \ll \alpha_{ov} HA_T$ and equation (4) reduces to:

$$\Sigma A^- = \alpha_{ov} HA_T. \quad (5)$$

Table 1. The distribution coefficient of the metal in absence of fulvic acid, D_0, derived from linear regression analysis

Linear relationship: $y = mx + c$ where $y = \log D_0$ and $x = \log\{NaClO_4\}$.*
r = correlation coefficient and n = number of points.

Metal	m	c	r	n
Eu^{3+}	−2.974	2.071	0.9993	5
Sr^{2+}	−2.058	1.716	0.9955	7

*Kielland's (1937)[15] individual ion activity coefficients, γ, have been used for the conversion of concentration to activity.

For the two ionic strengths α_{ov} was calculated using third degree polynomials derived from potentiometric titrations.[16]

$$\alpha_{ov} = 1.035 - 0.644\text{pH} + 0.177(\text{pH})^2 - 0.0125(\text{pH})^3, \quad I = 0.10M \text{ NaClO}_4 \tag{6}$$

$$\alpha_{ov} = 0.4020 - 0.2461\text{pH} + 0.0874(\text{pH})^2 - 0.0060(\text{pH})^3, \quad I = 0.01M \text{ NaClO}_4. \tag{7}$$

In the ultrafiltration experiments $\Sigma M_b/M_f$ is calculated according to equation (8):

$$\frac{\Sigma M_b}{M_f} = \frac{A_o - A_f}{A_f} \tag{8}$$

where A_o is specific activity of the original (unfiltered) solution (cpm/g) and A_f is specific activity of the filtered solution (cpm/g).

Heterogeneity considerations

The description of the interaction between europium and fulvic acid may, however, be achieved by considering the various acidic moieties of the fulvic acid molecule. The fulvic acid employed has been characterized via the comprehensive physicochemical approach outlined by Marinsky.[17,18] In this approach, the fulvic acid is conceptualized as an assemblage of relatively small hydrophobic moieties that are slightly different, but composed of four to five predominant separate acidic sites with each site characterized by a distribution of acid strengths which may be averaged. The characteristics of Bersbo fulvic acid are summarized in Table 2.

Following an earlier treatment of the interaction between Eu^{3+} and a soil fulvic acid and reconciling with the envisaged acid spectrum in Bersbo fulvic acid (Table 2) it has been postulated that Eu^{3+} is predominantly sequestered by the keto–enol-like site.[20] Consequently, the complex formation function for this interaction has been computed by first subtracting the contributions of metal bound by the other acidic functionalities from the experimental value of metal bound. The contribution of the acidic functionalities has been estimated using literature values of stability constants[7,8] describing the interaction between Eu^{3+} and the acidic functional group that resembles the active sites in the fulvic acid molecule (Table 2).

Table 2. The characteristics of Bersbo aquatic fulvic acid.[9,19]

Elemental Analysis (%)	C	H	N	O	S	Ash
	52.5	3.6	1.1	38.8	1.0	3.0
Acidity (meq/g FA)	Aqueous			Non-Aqueous		
				-COOH	-OH	Total
	4.65			4.78	1.35	6.13
Extra acidity due to chelation (% of aqueous capacity)	Cu^{2+}			La^{3+}		
	65-70			25-30		
Molecular weight (Gel Permeation Chromatography)	M_n	M_w	M_w / M_n			
	1750	2650	1.51			
Site Characterization	Acid Site	pK_a	Abundance	Functionality		
	1	1.7	0.20	unidentate -COOH		
	2	3.3	0.25			
	3	5.0	0.30	unidentate -COOH		
	4	6.5	0.20			
	5	7.0	0.05			

The unidentate complexation between the metal ion and the acid site with a pK_a of 1.7 has been described as follows:

$$-R\text{–}COO^- + Eu^{3+} \rightleftharpoons -R\text{–}COOEu^{2+}. \quad (9)$$

The (M_b/M_f) due to this site is estimated from the mass action relationship as follows:

$$\left(\frac{M_b}{M_f}\right)_I = \beta_I(R\text{–}COO^-) \quad (10)$$

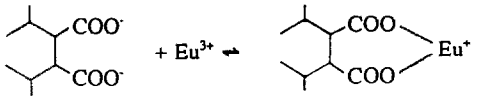
where $\beta_I = 10^{2.13}$ and $(R\text{–}COO^-)$ is the concentration of the ionized form of the acid site obtained by the following:

$$R\text{–}COO^- = \alpha_i Ab_i HA_T \quad (11)$$

where α_i is equal to the degree of neutralization for a specific site and might be expressed as in equation (12). The abundance of a specific site is in equation (11) written as Ab_i.

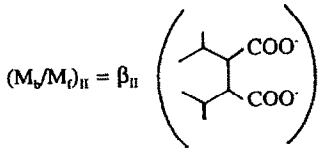
$$\alpha_i = \frac{1}{1 + 10^{pK_a - pH}} \quad (12)$$

Since the acid site with pK_a 1.7 is considered adjacent to the $-R\text{–}COO^-$ site with pK_a of 5.0, an additional mode of interaction is anticipated by envisaging a chelation as follows:



(13)

from which $(M_b/M_f)_{II}$ is computed by the relationship:

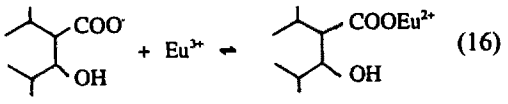


(14)

where $\beta_{II} = 10^{3.70}$ and the concentration term is obtained by considering the ionization of the second –COOH ($pK_a = 5.0$) as the limiting factor. The extra 10% of the acid site with pK_a of 5.0 is considered to complex the Eu^{3+} ion in an unidentate fashion and its contribution was estimated as:

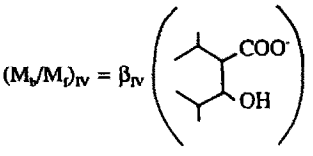
$$\left(\frac{M_b}{M_f}\right)_{III} = \beta_{III}(R'\text{–}COO^-). \quad (15)$$

The acid site with a pK_a of 3.3 and an abundance of 0.25 which was considered to mimic a salicylic acid like site where a very weak –OH ($pK_a = 13.4$) is adjacent to a weak –COOH ($pK_a = 3.3$) was considered to bind the Eu^{3+} in two fashions. The first involved the unidentate complexation between the –COOH and the Eu^{3+} ion, as follows:



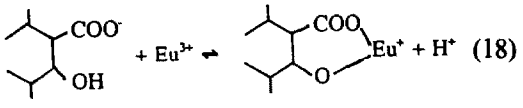
(16)

$(M_b/M_f)_{IV}$ is thus estimated from the mass relationship as follows:



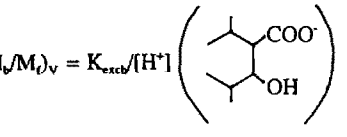
(17)

The other envisaged possible reaction is the chelation involving the $-COO^-$ and the –OH with the subsequent removal of a proton as follows:



(18)

The $(M_b/M_f)_V$ computed from the mass action relationship as follows:



(19)

indicates the small contribution of such an envisaged mode of complexation.[21] The K_{exch} is β for Eu^{3+}–salicylic acid ($10^{4.44}$) multiplied with K_a for the –OH group in this site ($10^{-13.4}$).

The complex formation function for the keto–enol site has been calculated according to equation (20):

$$\beta_{k-e} = \frac{\left(\frac{\Sigma M_b}{M_f}\right)_{exp} - \left(\frac{\Sigma M_b}{M_f}\right)_{i,cal}}{A^-_{k_e}} \quad (20)$$

where A^-_{k-e} is the ionized form of the keto–enol site given by:

$$A^-_{k-e} = \frac{HA_T Ab_{k-e}}{1 + 10^{pK_a - pH}} \quad (21)$$

HA_T is the total titratable acid and Ab_{k-e} is the abundance of the keto–enol site in the fulvic acid molecule. $(\Sigma M_b/M_f)_{exp}$ is experimentally

derived (according to the above) and $(\Sigma M_b/M_f)_{i,cal}$ is obtained as follows:

$$\left(\frac{\Sigma M_b}{M_f}\right)_{i,cal} = \left(\frac{M_b}{M_f}\right)_I + \left(\frac{M_b}{M_f}\right)_{II} + \left(\frac{M_b}{M_f}\right)_{III} + \left(\frac{M_b}{M_f}\right)_{IV} + \left(\frac{M_b}{M_f}\right)_V. \quad (22)$$

RESULTS AND DISCUSSION

Ion exchange distribution studies

The results of the IEDS for the interaction between Sr and Eu and aquatic FA shown in Fig. 1 indicate that Eu binds more strongly to FA than Sr. Whereas the log β_{ov} for the Eu is dependent on pH (in the pH range 3–6.5 (0.10M) and 3.5–5 (0.01M)) the values for Sr are pH-independent. The log β_{ov} for the Eu–FA system at 0.10M may be described by an equation obtained by linear regression analysis. A similar relationship between pH and log β_{ov} for the Eu–FA system at $I = 0.01M$ can be used (Table 3). A constant value of 9.16 ± 0.02 is obtained after pH of 5.5 in the 0.01M system whereas a no clear cut average could be obtained for the 0.10M system. The corresponding values for the Sr–FA system are also reported in Table 3. The dependence of log β_{ov} on the ionic strength is greater in the case of Sr–FA than Eu–FA (Δ log $\beta_{ov,Sr(0.10-0.010M)} \approx 2.0$ while Δlog $\beta_{ov,Eu(0.10-0.010M)} \approx 1.5$).

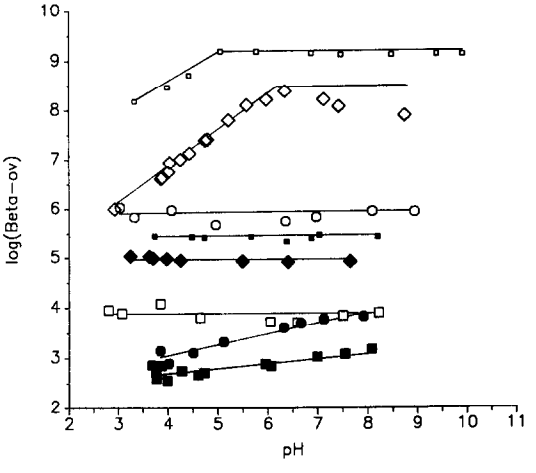


Fig. 1. The effect of pH and ionic strength (0.10 and 0.01M $NaClO_4$) on the overall complex formation function, β_{ov} for Eu^{3+} and Sr^{2+} and Bersbo aquatic fulvic acid investigated by ion exchange distribution studies (IEDS) and ultrafiltration (UF). Note that for IEDS, Eu^{3+} in 0.10M $NaClO_4$, the line has been drawn as above to conform with results in 0.01M $NaClO_4$ because a similar pattern of interaction is expected. IEDS: □ Sr^{2+} in 0.10M, ○ Sr^{2+} in 0.01M, ◇ Eu^{3+} in 0.10M, □ Eu^{3+} in 0.01M; UF: ■ Sr^{2+} in 0.10M, ● Sr^{2+} in 0.01M, ◆ Eu^{3+} in 0.10M, ■ Eu^{3+} in 0.01M.

Ultrafiltration

The UF results also attest to the fact that Eu is more strongly bound by the FA than Sr. The log β_{ov} values for the Eu–FA system showed an insensitivity to pH whereas the Sr–FA system yielded values slightly dependent on pH. The log β_{ov} values obtained for the Eu–FA system at 0.10M and 0.01M $NaClO_4$ maybe averaged to give 4.97 ± 0.04 and 5.44 ± 0.04, respectively. For the Sr–FA system at 0.10M and 0.01M $NaClO_4$ the log β_{ov} may be described by equations obtained by linear regression analysis (Table 3). The effect of ionic strength on the log β_{ov} seems the same for the two metal–humate systems (Δlog $\beta_{ov,Sr(0.10-0.010M)} \approx 0.6$ while Δlog $\beta_{ov,Eu(0.10-0.010M)} \approx 0.5$).

Comparison of methods

The comparison of results obtained from the two methods shows interesting discrepancies. The values of log β_{ov} for both metals obtained by the ion exchange method are invariably higher than those obtained by the ultrafiltration method (Fig. 1). For the two metals this discrepancy in absolute value is more pronounced at the lower ionic strength, 0.01M than at 0.10M $NaClO_4$. The interesting observation, however, is that the effect of method on the behaviour of the resolved log β_{ov} is reversed for the two metals. Whereas for the Eu the log β_{ov} obtained by the IEDS was dependent on pH that obtained by the UF was not. On the other hand the log β_{ov} obtained for the Sr–FA system by the IEDS showed no dependence on pH but those resolved from the UF showed a pH dependence. This discrepancy is not completely understood but similar observations have been made by earlier researchers.[3,22] In addition, the ionic strength effect on log β_{ov} is more enhanced in the IEDS than in the UF and this behaviour is the same for both metals. Sources of error in the IEDS are the accuracy of the determination of D_0 and the possible ion–dipole interactions between the ion exchange resin and the fulvic acid molecule.[20]

An explanation for the low log β_{ov} values obtained in the UF method as compared to the IEDS is the hypothesis of possible fragmentation of the fulvic acid molecule in the presence of the metal ion. These "small" fragments which might pass through the membrane with some

Table 3. Overall complex formation functions for Eu^{3+} and Sr^{2+} binding to Bersbo aquatic fulvic acid. Ionic medium $NaClO_4$. r = correlation coefficient and n = number of points

System	pH range	log β_{ov}–pH relationship (l/eq)	r	n
IEDS, Eu^{3+}, $I = 0.10M$	2.93–6.35	log $\beta_{ov} = 3.84 + 0.74$ pH	0.99	13
IEDS, Eu^{3+}, $I = 0.01M$	3.33–5.06	log $\beta_{ov} = 6.17 + 0.59$ pH	0.98	4
IEDS, Eu^{3+}, $I = 0.01M$	5.78–9.92	log $\beta_{ov} = 9.16 \pm 0.02$	—	6
IEDS, Sr^{2+}, $I = 0.10M$	2.80–8.22	log $\beta_{ov} = 3.87 \pm 0.12$	—	8
IEDS, Sr^{2+}, $I = 0.01M$	3.04–8.94	log $\beta_{ov} = 5.88 \pm 0.12$	—	8
UF, Eu^{3+}, $I = 0.10M$	3.25–7.65	log $\beta_{ov} = 4.97 \pm 0.04$	—	8
UF, Eu^{3+}, $I = 0.01M$	3.74–8.20	log $\beta_{ov} = 5.44 \pm 0.04$	—	8
UF, Sr^{2+}, $I = 0.10M$	3.69–8.08	log $\beta_{ov} = 2.30 + 0.10$ pH	0.72	13
UF, Sr^{2+}, $I = 0.01M$	3.85–7.92	log $\beta_{ov} = 2.17 + 0.22$ pH	0.93	8

metal ions would bring about an over-estimation of the free metal ion concentration which will translate into a reduced estimate of bound metal and thus a smaller log β_{ov}. It has been observed for an Al^{3+}–FA system investigated with a dialysis technique that an increase in metal load caused an increase in fulvic acid concentration outside the dialysis membrane.[23] In a calculation, based on UV–visible spectroscopy experiments, of the over-estimation of the free metal ion concentration it was found that less than 10% of the fulvic acid has to bind 64% of the Sr^{2+} ions and 98% of the Eu^{3+} ions to achieve log β_{ov} values of the same order as the IEDS. This exercise appears to indicate that smaller fragments of fulvic acid predominantly bind the metal ion at the expense of the larger fragments, a conclusion that is contrary to observed results.[24]

The difference in ionic strength effects in the two methods may be attributed to the effect of bulk electrolyte concentration on the measured parameters (*i.e.* D_0 for IEDS and M_f for UF). While the effect of bulk electrolyte concentration on D_o is very pronounced (Table 1) its effect on the estimated M_f is negligible. The parameter M_f is apparently not affected as much by the ionic strength of the system as D_0 and this situation is postulated to account for the decrease in ionic strength effects in the UF method.[25]

The results from two recent studies[25,26] indicate that overall complex formation functions can be both dependent and independent on changes in pH. In one of the studies[25] two methods were employed, IEDS and UF, and log β_{ov} exhibited a dependence on pH for IEDS but not for UF (IEDS: log $\beta_{ov} = 6.65$ l/eq (pH = 4), log $\beta_{ov} = 7.40$ l/eq (pH = 5), log $\beta_{ov} = 8.15$ l/eq (pH = 6), log $\beta_{ov} = 8.95$ l/eq (pH = 7); UF: log $\beta_{ov} = 5.10$ l/eq (pH = 4–7); $I = 0.10M$ $NaClO_4$ for both methods). In the other study[26] using the same FA (Bersbo FA)[25] and laser induced fluorescence, LIF, as a method, no significant variations of log β_{ov} (6.34 ± 0.16 l/eq) was observed in a pH range of 2.7–6.5 and ionic strength of $0.1M$ $NaClO_4$. The results from this study agree with previously reported values.[25] Very few studies of Sr–FA systems with calculated log β_{ov} values are reported in the literature. However, one reported log β_{ov} of 4.53 l/eq for a Sr–HA system at a pH = 5 and $I = 0.1M$[27] is higher than values obtained in this study using both methods.

Heterogeneity considerations

The binding of Eu^{3+} and Sr^{2+} ions by the fulvic acid molecule has additionally been explained by considering the interactions between the metal ions and the various discrete acid sites that have been employed to describe the acid–base properties of the fulvic acid molecule.[9] The Eu^{3+} is considered to be mainly sequestered by the keto–enol-like site[9,25] and the complex formation function for this reaction has been computed. The results of this exercise (Table 4) show the influence of ionic strength effect, which is only significant in the ion exchange distribution studies, and the

Table 4. Complex formation functions for the selective binding of Eu^{3+} by the keto–enol site of the Bersbo aquatic fulvic acid. Employed methods are Ion Exchange Distribution Studies, IEDS and Ultrafiltration, UF

Metal ion	Bersbo fulvic acid (g/l)	Ionic strength, $NaClO_4$ (M)	Method	pH range	log β (1/eq)
Eu^{3+}	0.12	0.10	IEDS	3.87–7.43	9.43 ± 0.29
Eu^{3+}	0.12	0.01	IEDS	3.33–8.48	10.58 ± 0.72
Eu^{3+}	0.12	0.10	UF	3.25–7.65	7.19 ± 1.15
Eu^{3+}	0.12	0.01	UF	3.74–8.2	6.88 ± 0.91

difference between the methods. The values of log $\beta_{\text{keto-enol}}$ obtained in the ion exchange distribution studies agree with earlier results where a similar mode of analysis was employed.[20] The values of complex formation function obtained in this exercise compare well with literature values for the interaction between Eu^{3+} and the probable functionalities, *e.g.* log $\beta_{\text{Eu-catechol}} = 11.17$ l/eq and the log $\beta_{\text{Eu-kojic acid}} = 6.14 \pm 0.02$ l/eq (both measured at $I = 0.1M$ and at 25°C).[7] That the values are not exactly the same as those published in the literature may be explained by considering that the extent of complexation of the envisaged sites might be perturbed by adjacent functional groups.[28]

CONCLUSIONS

The results of this study, though confirming the fact that Eu^{3+} is more strongly bound by fulvic acid than Sr^{2+}, indicate that the overall complex formation functions obtained by the different methods are different both in absolute values, behaviour with respect to pH changes and ionic strength. The influence of method on the overall complex formation function is additionally illustrated by the results of a study where the Bersbo fulvic acid–Eu system studied with LIF[26] yielded values different from UF and IEDS.

In an exercise to determine the speciation of the Eu–FA system using an arbitrary concentration of $10^{-8}M$ (a typical trace metal ion concentration) for the initial total free metal ion, varying concentrations of FA (1, 50, 120 mg/l), log $\beta_{\text{Eu-carbonate}} = 5.93$ l/eq[29] and log $\beta_{\text{Eu-hydroxy}} = 7.45$ l/eq determined from our own data by considering the relationship between D_0 and pH[30], it was shown that with as little as 1 mg/l of FA in the Eu–FA system, the metal ion was predominantly sequestered by the FA ($\geqslant 90\%$ in the pH range of 3–7.5). In the above-mentioned exercise, log β_{ov} values from the IEDS were employed (*i.e.* the highest log β_{ov} values of the two methods were selected). This exercise shows that very small amounts of natural organic acids can have significant effects on the mobility/speciation of trace metals in the environment.

By considering the functional group heterogeneity of the fulvic acid molecule the site which predominantly binds Eu^{3+} has been computed. Comparison of this value with the literature value gave credence to the functionality assigned to the most active site.

The approach outlined in this paper is yet another testimony emphasizing the need for a thorough characterization of the fulvic acid as a ligand in order to facilitate a comprehensive description of metal–fulvate interactions.

SUITABILITY OF NITRIC–SULPHURIC ACID DECOMPOSITION FOR THE DETERMINATION OF TUNGSTEN AND MOLYBDENUM IN GEOCHEMICAL EXPLORATION

G. S. REDDI, C. R. M. RAO and H. S. MURALIDHAR
Chemical Laboratory, Geological Survey of India, Madras-600 032, India

(*Received* 29 *May* 1992. *Revised* 17 *December* 1992. *Accepted* 28 *December* 1992)

Summary—A mixture of nitric and sulphuric acids is used for the decomposition of geochemical samples for the estimation of tungsten. In the resulting sample solution tungsten is determined colorimetrically by the dithiol method. The decomposition procedure suggested works well for scheelite mineral. However wolframite is only partially decomposed. The same sample solution is used for estimation of molybdenum by the thiocyanate method. The method is suitable for batch analysis and results in a high throughput.

Tungsten estimation in geological materials is usually accomplished by fusing the sample with the alkali mixture (Na_2CO_3, NaCl, KNO_3),[1,2] by fusion with pyrosulphate,[3] or by acid decomposition using HF and $HClO_4$[4,5] and the final determination is achieved by colorimetric methods involving thiocyanate or dithiol. A review on the colorimetric method involving thiocyanate has been published.[6] Tungsten in higher quantities is generally determined by the gravimetric method using cinchonine.[7] Tungsten is less sensitive than other elements by the atomic absorption method and is normally not included in the suite of elements determined by the AAS method. Tungsten has also been determined by an energy dispersive X-ray determination method in a suite of nine elements.[8]

Visual colorimetric methods, with detection limits in the same range as the crustal abundance levels, are utilized in many geochemical laboratories around the world, especially since, with many of these methods, the per-man-day output is high.

Many geochemical exploration programmes require the determination of both tungsten and molybdenum. These two elements have been determined after a pyrosulphate fusion with different hydrochloric acid aliquots.[9] Pyrosulphate fusion process has been reported to cause problems in the molybdenum estimation[10] and it also does not suit organic or sulphide rich samples as there is no oxidizing agent in the fusion process.[11]

A sulphuric and nitric acid mixture has been suggested as a suitable decomposition medium for the estimation of molybdenum.[12] In this communication we report the appropriateness of the same decomposition for the determination of tungsten thereby facilitating the determination of both tungsten and molybdenum after a single decomposition step.

EXPERIMENTAL

Apparatus

Spectrophotometer Model No. GS8660 ECIL, India.

Reagents

Analytical Reagent Grade (BDH) H_2SO_4, HNO_3, HCl, $SnCl_2$, NaOH, ethyl alcohol, thioglycollic acid, sodium tungstate and reagent grade zinc dithiol (BDH) are used.

Zinc dithiol solution. 0.3 g of zinc dithiol is dissolved in 2 ml of ethyl alcohol followed by five pellets of sodium hydroxide and 1 ml of thioglycollic acid. The solution is made to 100 ml with distilled water and filtered using Whatman No. 41 paper.

Stannous chloride solution. 15 g of stannous chloride is dissolved in 100 ml of concentrated hydrochloric acid.

Standard tungsten solution. 0.1794 g of sodium tungstate is dissolved in 100 ml of water to obtain 1000 μg/ml of W solution. From this necessary dilutions are made to obtain 5.0 μg/ml working solution.

Table 1. Comparison of values obtained by the proposed method with pyrosulphate fusion method

Sample		Values obtained in ppm (RSD %) Present method W	Mo	Pyrosulphate method* W	Mo
1	Test sample 1 (scheelite-bearing calcgranulite)	10 (4)	<2	10 (6)	<2
2	Test sample 2 (scheelite-bearing calcgranulite)	50 (4)	20 (6)	52 (3)	18 (4)
3	Internal standard, W-01 (wolframite in quartz vein)	21 (2)	<2	25 (2)	<2

*Ref. 5.

Table 2. Values of standard samples obtained by the proposed method

Sample	Values obtained in ppm (RSD%) Mo	W	Certified values in ppm Mo	W
Flue dust (AMDEL-24610)	360 (3)	55 (6)	370	50
Granite (AMDEL-BH1)	330 (3)	0.432% (3)	330	0.422%
Low grade tungsten ore (AMDEL-3131)	307 (5)	1.038% (6)	300	1.042%

PROCEDURE

Up to 0.5 g of the sample is weighed into borosilicate beakers (50 ml capacity with marking at 20 ml). Ten millilitres of concentrated nitric acid and 5 ml of 1:1 sulphuric acid are added from an automatic dispenser. The beakers are heated on an electric hot plate to strong fumes of sulphuric acid and then to a syrupy stage. Ten millilitres of concentrated hydrochloric acid are added to the cooled contents and digested for half an hour at low heat. The remains are then made up to 20 ml with concentrated hydrochloric acid. From the solution above the settled constituents of the beaker a 5 ml aliquot is transferred into a borosilicate tube with ground glass stopper. A 4 ml portion of stannous chloride solution is added and the contents are mixed. The tubes are then placed in boiling water for 20 min. To the warm contents of the tube, 1 ml of dithiol solution is added. The contents are mixed well. A 0.3 ml volume of benzene is added and the stoppered tubes are thoroughly shaken. The colour of the organic layer is visually compared against standards.

Preparation of standards

To five different borosilicate test tubes containing 4 ml portions of pure hydrochloric acid, 0.25, 0.5, 0.1, and 3.0 μg of tungsten is transferred using the 5 μg/ml standard working solution. Four millilitres of stannous chloride solution is added to each of the test tubes and the procedure continued as described above.

For a 0.5 g sample made to 20 ml, when 5 ml aliquot is taken for analysis, a minimum value of 2 ppm is obtained. When the colour of the organic layer exceeds that of the highest standard the procedure is repeated with a smaller aliquot. For samples with W content exceeding 250 ppm, the spectrophotometric method is adopted measuring the absorbance at 640 nm.

For the molybdenum estimation 2 ml aliquot of the sample solution is transferred in to a borosilicate tube containing 4 ml of distilled water. One millilitre of 10% potassium nitrate solution in water and 1 ml of 25% sodium tartrate solution in water are added and the thiocyanate complex developed, after a stannous chloride reduction step. A visual comparative method is adopted as per the recommended procedure.[12]

RESULTS AND DISCUSSION

The results obtained for some of the test samples and laboratory standards are given in Table 1. Good agreement is seen between the values obtained by the proposed method as compared to the pyrosulphate method. Good precision figures are obtained. Accurate values

Table 3. Results of tungsten in mineralized samples

Sample	W values obtained by the pyrosulphate method in % (RSD%)	W values obtained by the suggested method in % (RSD%)
Test sample 1 (scheelite)	0.329 (5)	0.325 (3)
Test sample 2 (wolframite)	0.430 (7)	0.239 (16)
Test sample 3 (wolframite)	0.971 (2)	0.623 (20)

were obtained for the three reference samples analysed (Table 2).

Applying the suggested decomposition technique to high mineralized samples it was found that while scheelite ($CaWO_4$) is attacked fully, wolframite ($FeMnWO_4$) is only partially attacked (Table 3).

The method is adaptable for batch analysis and especially suits exploration programmes where both tungsten (occurring as scheelite) and molybdenum are required to be analysed.

Acknowledgements—The authors wish to thank Shri C. R. Narayanan, Deputy Director General (Geochemistry), Geological Survey of India, for his keen interest and support in the project and to two unknown referees whose critical comments have greatly improved the manuscript.

POTENTIOMETRIC RESPONSE OF POLY(3-OCTYLTHIOPHENE), POLY(3-METHYLTHIOPHENE) AND POLYTHIOPHENE IN AQUEOUS SOLUTIONS

JOHAN BOBACKA, ANDRZEJ LEWENSTAM and ARI IVASKA*
Laboratory of Analytical Chemistry, Åbo Akademi University, SF-20500 Turku-Åbo, Finland

(*Received* 29 *January* 1993. *Revised* 1 *March* 1993. *Accepted* 1 *March* 1993)

Summary—The potentiometric response of some polythiophenes in aqueous solutions has been investigated. Polythiophene (PT), poly(2,2′-bithiophene) (PBT), poly(3-methylthiophene) (PMT), poly(3-octylthiophene) (POT) and poly(4,4′-dioctyl2,2′-bithiophene) (POTd) were electrochemically deposited on platinum in 0.1*M* $LiBF_4$-propylene carbonate solution containing the corresponding monomer or dimer. Polymer electrodes were also prepared by solution casting of chemically synthesized poly(3-octylthiophene) (POTc) dissolved in chloroform. After film deposition (electrochemical or chemical) the polymer coated electrodes were used as indicator electrodes in potentiometric measurements. The open-circuit potential of the polymer electrodes was measured in aqueous solutions containing inorganic salts (10^{-1}–$10^{-4}M$). Interestingly, all the polythiophenes studied were found to give a cationic response to monovalent cations such as H^+, Li^+, Na^+, K^+ and NH_4^+ (Cl^- salts). The slope, calculated from the linear part of the response curve, was found to depend on the polythiophene used but always remained lower than that predicted for a Nernstian response. The polythiophenes also showed some sensitivity to divalent cations such as Mg^{2+} and Ca^{2+} (Cl^--salts). POT was used as the polymer to study the influence of the polymerization conditions on the potentiometric response. By investigating different polymers from the polythiophene family it was possible to evaluate how the starting material (monomer or dimer) and the presence of alkyl side-chains influence the potentiometric response of the polymer membranes.

INTRODUCTION

Polythiophene (PT) and poly(3-methylthiophene) (PMT) belong to the group of conducting polymers that are environmentally stable both in their doped (electrically conducting) and undoped states.[1] Furthermore, poly(3-alkylthiophenes) containing relatively long alkyl chains (PATs) are processable, which makes them particularly attractive for technological applications.[2–5] One possible application is in the field of electrochemical sensors.[6] Considering the possible use of polythiophene and its derivatives as sensors their electrochemical behaviour in aqueous solutions is of interest.

A number of investigations concerning the electroactivity of polythiophenes in aqueous solutions has been reported.[7–10] Tourillon *et al.*[7] have demonstrated that PT and PMT can be reversibly doped in aqueous solutions. The doping level and conductivity were similar to those obtained in acetonitrile. More recently, Sunde *et al.*[8,9] found that the electrochemical doping process of PT and PMT is sensitive to the anion in aqueous electrolyte solutions, which also is of interest in sensor applications.

Although PT and PMT can reversibly be doped in aqueous solutions, this is not the case of PATs.[9,10] No current response was observed for poly(3-octylthiophene) (POT) in aqueous solutions when studied by cyclic voltammetry in the potential range 0–2 V.[9] The POT film remained red in colour, indicating that the oxidation (doping) process was inhibited.[9] This behaviour is in contrast to that observed in organic solutions where the PATs can be reversibly oxidized.[3,11–18] Roncali *et al.*[10] suggested that the increased hydrophobicity, due to the long alkyl chains, is responsible for the low electroactivity of PATs in aqueous media. It is likely that the hydrophobic PATs are poorly swollen in water, which obviously has an inhibiting influence on the doping process. The apparent electroinactivity of PATs in aqueous solutions may be considered as a limitation for these materials, especially in applications based on the reversible doping reaction. It will be shown below that, in spite of its low voltammet-

*Author for correspondence.

ric activity in aqueous media, POT nevertheless gives a fast and reproducible potentiometric response towards several monovalent and divalent cations in aqueous solutions.

The present work is an extension to our previous studies on the electrochemical characteristics of poly(3-octylthiophene) film electrodes in organic solutions.[14-17] The main objective of the present work is to study the potentiometric response of poly(3-octylthiophene) and some other polythiophene derivatives in aqueous solutions of inorganic salts. The chemical structure of the polythiophenes investigated are schematically shown in Fig. 1. Our preliminary investigations indicated that poly(3-octylthiophene) is sensitive to cations. To the best of our knowledge, this is a new feature of polythiophenes and has not been considered earlier. Therefore we decided to study this behaviour more thoroughly. Anion sensitivity of polypyrrole (PPy), another conducting polymer, is, however, well documented.[19,20] The response mechanism for the polythiophenes will be discussed. Finally, some conclusions will be drawn regarding the potential usefulness of the polythiophenes from an analytical point of view.

EXPERIMENTAL

Chemicals

Thiophene, 3-methylthiophene (Aldrich, 99 + %) and 2,2′-bithiophene (Aldrich, 97%) were used as received. Chemically synthesized poly(3-octylthiophene) (POTc) and 3-octylthiophene were used as received from Neste Oy (Research Centre, SF-06850 Kulloo, Finland). The 4,4′-dioctyl-2,2′-bithiophene was synthesized from 3-octylthiophene as described elsewhere.[14] Propylene carbonate (Aldrich, anhydrous), $LiBF_4$ (Fluka, pract.), $NaBF_4$ (Fluka, purum), $NaClO_4$ (Aldrich, 99 + %), HCl, LiCl, NaCl, $NaNO_3$, KCl, NH_4Cl, $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6] \cdot 3H_2O$ (Merck, p.a.), $CaCl_2 \cdot 4H_2O$ (Merck, suprapur) and $MgCl_2 \cdot 6H_2O$ (Merck, p.a.) were used as received. Distilled deionized water was used to prepare the solutions for potentiometric measurements.

Electrode preparation

Electrochemical polymerization was performed by using a one-compartment and three-electrode electrochemical cell (Metrohm 663 VA Stand). The working electrode was a Pt disc (area = 0.07 cm^2) and a glassy carbon (GC) rod was used as the auxiliary electrode. For comparison, Au and GC discs were also used as working electrodes in some cases. The reference electrode was an aqueous Ag/AgCl/KCl(3*M*) electrode that was connected to the cell via a bridge filled with 0.1*M* $LiBF_4$-propylene carbonate ($LiBF_4$-PC). Prior to the polymer deposition, the electrode surface was polished with 0.3 μm alumina and rinsed with water and chloroform.

PT, PBT, PMT, POT and POTd (Fig. 1) were deposited by galvanostatic polymerization of thiophene (0.1*M*), 2,2′-bithiophene (0.1*M*), 3-methylthiophene (0.1*M*), 3-octylthiophene (0.1*M*), and 4,4′-dioctyl-2,2′-bithiophene (0.005*M*), respectively, in 0.1*M* $LiBF_4$-PC. The galvanostatic polymerization was performed by

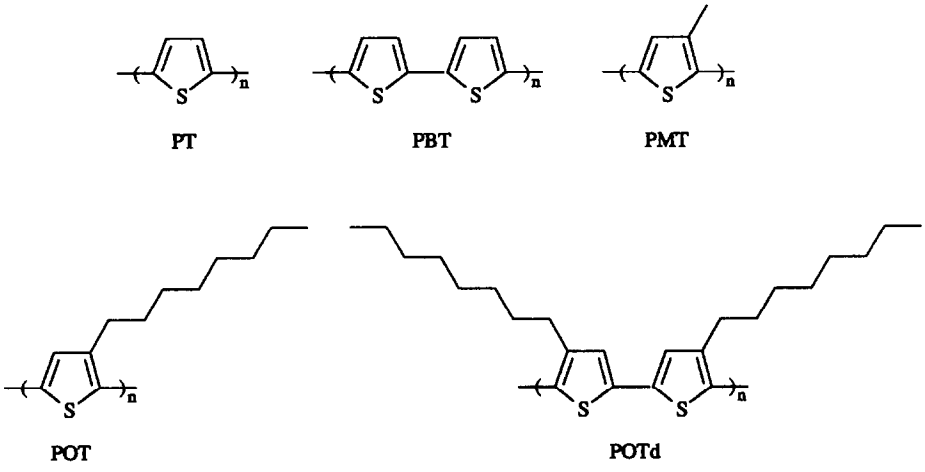

Fig. 1. Chemical structure of the polythiophenes studied. PT = polythiophene, PBT = poly(2,2′-bithiophene), PMT = poly(3-methylthiophene), POT = poly(3-octylthiophene), POTd = poly(4,4′-dioctyl-2,2′-bithiophene).

using a Metrohm type E211 coulometer supplying a constant current of 0.1 mA (1.43 mA/cm^2). The amount of charge passed during polymerization of PT, PMT and POT was 8 mC. The film thickness for POT prepared under these conditions has been estimated to 0.25 ± 0.1 μm by using a Sloan Dektak II profilometer.[17] This gives an indication of the film thicknesses also for the other polythiophenes prepared by using the same polymerization charge. In the case of PBT and POTd only 4 mC was used since the starting materials were dimers. The cell solution was purged with nitrogen and the working electrode was rotated at about 1500 rpm during polymerization which was performed at room temperature (23 ± 2°C).

After polymerization the potential of the polymer electrodes were kept at 0 V for 1 min in the polymerization solution in order to reduce (undope) the polymer films. After undoping, the electrodes were rinsed with PC and water and stored in an aqueous solution ($10^{-1}M$ KCl) for at least two days prior to the potentiometric measurements.

Chemically prepared poly(3-octylthiophene) (POTc) was dissolved in chloroform (0.475 mg/ml) and films of POTc were prepared by solution casting. The average film thickness was estimated to 3 μm by using a density of 0.9 g/cm^3 for POTc.[15]

Potentiometric measurements

Potentiometric measurements were done by using an Orion Research Expandable Ion Analyzer EA 940. The polymer electrodes were used as indicator electrodes in conjunction with the Ag/AgCl/KCl($3M$) reference electrode, connected to the cell via a bridge filled with the test solution ($10^{-1}M$). The liquid junction potential arising from the concentration difference between the reference bridge ($10^{-1}M$) and the test solution (10^{-1}–$10^{-4}M$) were taken into account and the potential values reported in this work have been corrected by using the Henderson equation.[21] Due to the low selectivity of the polythiophenes studied, the measurements were performed in unbuffered solutions.

Prior to the measurements the polymer electrodes were conditioned in $10^{-1}M$ solution of the salt to be tested. The measurements were performed in the concentration range 10^{-1}–$10^{-4}M$, and the polymer electrodes were equilibrated for 2 min in each solution in order to ensure the equilibrium conditions. The electrode was rotated (500 rpm) during the 1st min in order to speed up the equilibration and the potential was read 1 min after the rotation was stopped. The response time of the POT electrode was in the order of a few seconds in the concentration range studied. Film conditioning and potentiometric measurements were performed at room temperature (23 ± 2°C) in open air. The slopes that will be presented in this work have been calculated by linear regression using three points spanning a concentration range of 2 decades (usually 10^{-1}–$10^{-3}M$). The correlation coefficient (r) will be given together with the slopes.

RESULTS AND DISCUSSION

Effects of polymerization conditions on the potentiometric response of POT

Electrode rotation. When POT was electrochemically deposited on the Pt disc without rotation, the outmost layers of the polymer formed were loosely bound to the rest of the film and were removed during rinsing of the electrode in PC after polymerization. The polymer remaining on the electrode after rinsing gave a cationic response to K^+, but the slope was only 23.4 mV/decade ($r = 0.956$). When the Pt disc was rotated at 1500 rpm during deposition of POT, the polymer film was strongly attached to the substrate and no dissolution of the film was observed when rinsing in PC. The potentiometric response of six POT electrodes prepared under the same experimental conditions (rotation rate = 1500 rpm) on different platinum substrates gave a potentiometric response with a slope of 49.7 ± 2.5 mV/decade ($r = 0.999$) during measurements in KCl solutions. It has been observed previously that the yield of POT on the electrode is lower when the electrode is rotated during polymerization.[15] Due to convection at the rotating electrode, oligomers of POT are obviously swept away before they are attached to the Pt or to the growing polymer. Not only the yield but also the morphology of the polymer formed at the rotating electrode may therefore be different from that prepared in a quiescent solution. Since rotation seems to be advantageous for the cationic response of Pt/POT, the electrode is rotated at 1500 rpm during all electrochemical polymerizations in the rest of this work.

Substrate material. In order to study the influence of the substrate material, POT was electrochemically deposited on Pt, Au and GC. The slopes of the potentiometric response

Table 1. Slopes of the potentiometric response curves for POT in KCl solution as function of current density (and potential) used during galvanostatic polymerization. The correlation coefficient $r \approx 0.999$

Current density (mA/cm^2)	Potential (V)	Slope ($mv/decade$)
0.43	1.4	36.1
1.43	1.5	47.4
4.29	1.7	52.1
14.3	2.4	22.9*

*$r = 0.964$.

measured in KCl solutions were 50.3 and 52.6 mV/decade ($r \geq 0.9997$) for Au/POT and GC/POT, respectively. These slopes are similar to those observed for Pt/POT (49.7 ± 2.5 mV/decade, $n = 6$) indicating that the substrate material has only a little influence on the slope. This also confirms that the cationic response is due to the polymer and not due to the substrate, since the slopes observed for the bare electrodes in KCl solutions were -15.1, 26.0 and 31.9 mV/decade ($r \geq 0.995$) for Pt, Au and GC, respectively. Also in the case of polypyrrole (PPy) electrodes, the ionic response is attributed to the PPy layer and not to the Pt substrate.[22] In the following of this work, Pt is used as the substrate material for all the polythiophenes studied.

Current density. POT was polymerized on the rotating Pt disc by using four different current densities but keeping the polymerization charge constant at 8 mC. The potentiometric slopes of the four POT electrodes were then measured in KCl solutions and the results are summarized in Table 1. The results show that the potentiometric slopes increase with increasing current density in the range 0.43–4.29 mA/cm^2. The highest current density used (14.3 mA/cm^2) is obtained at such a high potential (2.4 V) that side-reactions and overoxidation may take place during polymerization.[15] This may be the reason for the low value of the potentiometric slope (22.9 mV/decade) observed for this electrode. Our results can be compared with those obtained by Roncali *et al.* using visible absorption spectroscopy.[11] Their results indicate that the conjugation length and yield of PATs increase with increasing current density (0.5–10 mA/cm^2) during electropolymerization on indium–tin oxide electrodes. It is thus possible that the slope of the cationic response observed for POT increases due to the increasing conjugation length and/or yield of POT, keeping in mind that also other effects may be involved. It will be shown below that the slope depends on the film thickness and this may explain why the slope increases with increasing current density during electropolymerization. One additional effect of the increasing current density might be the increasing degree of crosslinking between polymer chains, and this is regarded as the reason for the low solubility of electrochemically prepared POT.[11,14] A current density of 1.43 mA/cm^2 is used throughout the remaining experiments in this paper, since this value gives a reasonably big slope and since this current density has been used also in our previous works on POT.[14–17]

Film thickness. The effect of film thickness was studied by varying the charge used in polymerization of POT on the rotating Pt disc at the current density of 1.43 mA/cm^2. The results are shown in Fig. 2. It is assumed that the film thickness increases linearly with the amount of charge passed during electropolymerization.[15] By measuring the potentiometric response for the POT electrodes in KCl solutions the slopes can be plotted as function of charge, as shown in Fig. 2. The results indicate that the slope increases sharply with increasing film thickness up to a polymerization charge of about 8 mC and then gradually decreases. In the remaining part of this paper, a polymerization charge of 8 mC (114 mC/cm^2) is used (4 mC when starting from the dimer) for all the polythiophenes studied.

Stability and redox sensitivity of POT

The same POT electrode was used for potentiometric measurements in various aqueous solutions (HCl, LiCl, $LiBF_4$, NaCl, $NaBF_4$, KCl, NH_4Cl, $MgCl_2$, $CaCl_2$) during a time period of 5 weeks. Thereafter the POT electrode was conditioned for about 5 weeks in 0.1M KCl and the potentiometric response to K^+ was then

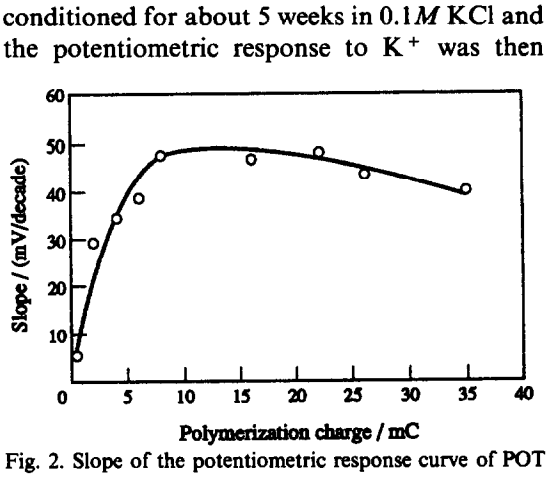

Fig. 2. Slope of the potentiometric response curve of POT in KCl solutions as function of the polymerization charge.

measured again. The slope observed was 46.7 mV/decade ($r = 0.9995$) which is comparable to the slope observed for the freshly prepared polymer electrode (47.4 mV/decade, $r = 0.999$). These results indicate that the POT film is stable and remains attached to the Pt substrate for at least 10 weeks in aqueous solutions although the thickness of the film is only about 0.25 μm. During potentiometric measurements, the potential of the POT electrode is in the range where POT is in its undoped, semiconducting state,[15-17] and therefore one can expect that there is no risk for overoxidation.[15] Furthermore, the polythiophenes are relatively stable to O_2 also in their undoped state, in contrast to PPy.[1] These factors certainly contribute to the good stability of POT observed in our experiments.

The redox sensitivity of POT was studied by measuring the potentiometric response to K^+ in solutions containing different total concentrations of the redox couple, $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$. The concentration ratio, $[Fe(CN)_6^{3-}]/[Fe(CN)_6^{4-}]$, was kept constant = 1/1. The potassium concentration was varied by using KCl and the contribution originating from the redox couple was considered when calculating the final potassium concentrations. The following slopes in mV/decade ($r \approx 0.999$) were obtained for the different total concentrations of redox couple (C_{Fe}): 49.0 ($C_{Fe} = 0$ mM), 48.3 ($C_{Fe} = 0.01$ mM), 49.1 ($C_{Fe} = 0.1$ mM), 40.2 ($C_{Fe} = 1$ mM). It can be seen that the redox couple does not interfere at $C_{Fe} \leqslant 0.1$ mM, but at $C_{Fe} = 1$ mM the slope is reduced. This may be due to electron transfer between POT and the redox couple in solution, giving rise to a mixed ionic and redox sensitivity in analogy to that observed for PPy.[23,24] It can be mentioned, however, that POT seems to be less redox sensitive than PPy.[24] This can be related to the difference in the oxidation potential between these two polymers, i.e. PPy is in its doped (conducting) state,[1] while POT is in its undoped (semiconducting) state,[15-17] at the redox potential of the $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple. Therefore the electron transfer between the polymer and the redox couple in solution is faster for PPy than for POT.

Potentiometric response of some polythiophenes

Cation sensitivity. The potentiometric response of PT, PBT, PMT, POT, POTd and POTc to several cations were investigated and the results are summarized in Table 2. Interestingly, all polymer electrodes give a cationic response to the monovalent cations studied but the slopes are always lower than the theoretical value of 58.7 mV/decade (23°C) as expected for a Nernstian response. Also for the divalent cations, the slopes are smaller than the theoretical (29.4 mV/decade) and for PMT even a slight anionic response to Cl^- is observed in $MgCl_2$ solutions. It can be seen in Table 2 that each polymer responds to several cations, i.e. the selectivity is poor, although small differences in slopes can be observed. In general the polythiophenes, especially PMT, are less sensitive to divalent cations than to monovalent cations. Among the polythiophenes studied, POTc gives the biggest sensitivities to Na^+, K^+, NH_4^+, Mg^{2+} and Ca^{2+}, while PT and POT are most sensitive to H^+ and Li^+, respectively. It is remarkable that POT gives very similar slopes (44.4–47.4 mV/decade, $r \approx 0.999$) for all the monovalent cations studied. On the other hand, the slopes for PT, PBT, PMT, POTd and POTc increase in the following order: $Li^+ < Na^+ < K^+$, i.e. with increasing crystal ionic radii and decreasing hydrated ionic radii for these cations.[25] The slopes as a function of the hydrated ionic radii are shown in Fig. 3. These results indicate that the potentiometric response of the polythiophenes studied (except POT) is influenced also by the size of the cation.

Table 2. Slopes of the potentiometric response curves for some polythiophenes deposited on platinum in Cl^- solutions of different cations. The correlation coefficient $r \geqslant 0.994$

Polymer	Slope (*mV/decade*)						
	H^+	Li^+	Na^+	K^+	NH_4^+	Mg^{2+}	Ca^{2+}
PT	48.2	39.4	41.8	42.4	44.9	13.6	13.7
PBT	10.6	29.6	34.9	38.5	40.8	5.3*	6.0*
PMT	22.3	30.7	37.4	38.1	38.8	−2.0	3.5
POT	44.4	46.6	46.2	47.4	45.0	17.5	11.7
POTd	42.8	35.5	39.1	43.5	46.2	12.3	12.6
POTc	41.3	45.6	50.4	51.4	50.1	20.6	18.2

*$r = 0.976$.

Anion influence. In the experiments described above, Cl^- was the anion of the salts. When BF_4^- was used as the anion, the slopes observed for POT were only 20.5 and 14.3 mV/decade ($r \geqslant 0.998$) for Na^+ and Li^+, respectively. This

It should be mentioned that the measured potential values for all polymer electrodes in 0.1M HCl solution were in the range 0.47–0.61 V, which is significantly higher than the potential values (0.22–0.46 V) in the other solutions used (0.1M). These results show that H^+ shifts the standard potential of the polythiophene electrodes in the positive direction.

clearly indicates that also the anion influences the potentiometric response and this may contribute to the sub-Nernstian response found in Cl^- solutions. The BF_4^- anion, however, seems to cause more interference than Cl^-. For POTc, the slopes for Li^+ and Na^+ were 2.3 mV/decade ($r = 0.445$) and 12.2 mV/decade ($r = 0.944$), respectively, when BF_4^- was used as the anion. This anion effect cannot only be related to the fact that BF_4^- was used as the doping anion during electrosynthesis of POT, since both POT and POTc give smaller slopes in the presence of the BF_4^- anion.

The measured potential values for POT and POTc were found to be significantly higher in the BF_4^- solutions than in the corresponding Cl^- solutions. This was investigated further by measuring the equilibrium potential for the POT electrode in 0.1*M* NaCl, $NaNO_3$, $NaClO_4$ and $NaBF_4$. In Cl^-, NO_3^- and ClO_4^- solutions, the equilibrium potential (0.26 V) was reached immediately. In BF_4^- solution, however, the potential continuously increased for several hours and finally stabilized at 0.55 V. When the electrode, after measurements in BF_4^- solution, was transferred to 0.1*M* NaCl the potential started to decrease and finally stabilized at 0.42 V. This indicates that an irreversible chemical transformation (doping) of POT occurred when the electrode was exposed to BF_4^- in solution. Hotta *et al.*[26] have also observed that BF_4^- behaves differently from ClO_4^- when used as dopant for PMT in nitrobenzene.

Response mechanism. An examination of the results presented in Table 2, allows some conclusions to be drawn regarding the mechanism of the potentiometric response. A cationic response is observed for both electrochemically prepared POT and chemically prepared POTc. Therefore the cationic response seems to be an inherent property of poly(3-octylthiophene) and not as the result of, e.g. residual doping anions (BF_4^-) or solvent (PC) originating from the electrochemical polymerization step. Polymerization of 4,4′-dioctyl-2,2′-bithiophene takes place at a relatively low potential (1.1 V) compared to 3-octylthiophene (1.5 V). Therefore one can expect POTd to be less overoxidized than POT.[14] Furthermore, due to the symmetrically substituted dimer (4,4′-dioctyl-2,2′-bithiophene), POTd is expected to be more stereoregular than POT.[27,28] Nevertheless POTd gives smaller slopes than POT towards most of the cations studied. This indicates that a regular polymer structure does not improve the potentiometric response. Due to the high polymerization potential of thiophene (1.7 V) in comparison to 2,2′-bithiophene (1.2 V), PT is expected to be more overoxidized than PBT.[29] The bigger slopes observed for PT thus indicate that overoxidation may even be beneficial to the cationic response. PMT gives smaller slopes than PT, especially towards the divalent cations, while POT and POTd give slightly bigger slopes than PT and PBT, respectively. This indicates that the presence of octyl groups (in contrast to methyl groups) slightly improves the cationic response, but the effect is small. These observations lead to the conclusion that the cationic response may be attributed mainly to the interaction between the cations and the polythiophene backbone. Therefore the oxidation level of the polymer is expected to influence the potentiometric response.

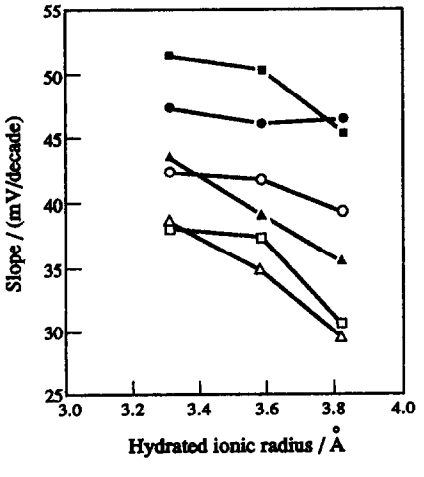

Fig. 3. Slope of the potentiometric response curves of PT (○), PBT (△), PMT (□), POT (●), POTd (▲) and POTc (■) as function of the hydrated ionic radii of the cations: K^+ (3.31 Å), Na^+ (3.58 Å) and Li^+ (3.82 Å).

The oxidation potentials for the polythiophenes studied have been determined by cyclic voltammetry in organic electrolyte solutions.[14,30,31] The oxidation potential of PT, POT, POTd and POTc are very similar (1.1 V) and higher than those of PBT and PMT (0.7 V). In the potentiometric measurements in this work, potentials of the polymer electrodes were in the range of 0.1–0.6 V. The upper limit, 0.6 V, is well below the oxidation potential of PT, POT, POTd and POTc, and therefore these polymers are believed to remain in their undoped state during the potentiometric measurements in the Cl^- solutions. Furthermore, cyclic voltammetry have shown that POT cannot be electrochemically oxidized even at 2 V in

aqueous solutions.[9] In presence of the BF_4^- anion, however, chemical oxidation may influence the potentiometric response characteristics.

For PBT and PMT the upper potential limit in the measurements was rather close to their oxidation potential. Therefore it is possible that PBT and PMT are partly oxidized during the potentiometric measurements. This would mean that there are some positive charges (polarons, bipolarons) on the PBT and PMT backbones decreasing interaction with cations and increasing interaction with anions. Although the slopes were slightly smaller for PBT and PMT, in comparison to the other polythiophenes studied (Table 2), both PBT and PMT give a definite cationic response. It can thus be suggested that the electrostatic repulsion is sufficiently small to still allow interaction between the polythiophene backbones and the cations. The sulphur atoms of the thiophene rings may act as electron donors and thereby increase interactions with cations.[32]

According to this reasoning, an anionic response can be predicted for PPy when used in its oxidized state, in agreement with experimental results.[19] However, in the case of PPy, the anionic response was found to be influenced also by the cation.[20] Incomplete discrimination between anions and cations thus seems to be quite general for conducting polymers, resulting in a mixed ionic response.[23,24] Furthermore, the low selectivity of the polythiophenes studied in this work and of PPy in Ref. 20, indicates that the binding sites in these polymers, e.g. polarons and bipolarons for anions and electron donating S atoms for cations, are rather non-specific.

CONCLUSIONS

The polythiophene electrodes were found to give a fast but non-selective cationic response to several cations in aqueous solutions. This cation sensitivity is unique for the polythiophenes and different from the anion sensitivity observed for, e.g. polypyrrole.[19,20] The polythiophenes showed excellent stability, since they were used in their undoped, semiconducting states. It was suggested that the cationic response may originate from interactions between the cations and the electron donating sulphur atoms of the thiophene rings. The low selectivity will naturally limit the use of polythiophenes (as such) as specific cation sensors. On the contrary, the electronic conductivity and non-selective cation sensitivity of polythiophenes may be useful in combination with traditional ion-selective materials. Following the idea presented by Cadogan *et al.*[33] one may suggest that the polythiophenes can be suitable as the intermediate layer connecting the ion-selective membrane to the metal substrate in solid-state cation-selective electrodes. This kind of electrode has several advantages, compared to traditional ion-selective electrodes with the internal filling solution, e.g. simplicity of design, lower costs and possibility of miniaturization.[33] Furthermore, the interface between the ion selective membrane and the metal will not be blocked, which is an advantage compared to coated-wire electrodes.[33] In view of such applications, the potentiometric response of polythiophene and its derivatives may be of interest to researchers in the field of analytical chemistry.

ATROPINIUM SCOPOLAMINUM INTEGRATED MICROCONDUITS IN A POTENTIOMETRIC ANALYTICAL SYSTEM

CUI HONGBO
Institute of Applied Ecology, Academia Sinica, Shenyang, People's Republic of China

(*Received* 28 *December* 1992. *Revised* 26 *January* 1993. *Accepted* 4 *March* 1993)

Summary—The preparation of the flow-through tubular atropinium and scopolaminum electrodes and assemblage of the integrated microconduit potentiometric analytical system with tubular ISEs, microvalve, chemfold, electrostatic and pulse inhibitors are described. Electrochemical characteristics of new atropinium scopolaminum integrated microconduit FIA–ISEs were studied. The contents of atropine and scopolamine in drugs could be determined at almost equilibrium state at sampling rates of 120/hr. The standard deviation over the linear range was about 0.1 mV (N = 11).

Atropinium and scopolaminum in drugs are routinely determined by the extraction–spectrophotometric method which are complicated, overloaded, consuming and require considerable organic reagent consumption. We have constructed a novel integrated microconduit system with tubular electrodes, microvalve, coil, inhibitors for flow injection potentiometric determinations of atropine and scopolamine in drugs. The proposed method has a high sampling rate (120/hr), good precision (±0.1 mV) and low sample and reagent consumption. Meanwhile, the overall volume of the FIA system was extremely reduced by integration of the flow parts. The detection can be executed exactly within a tubular electrode integrated into the FIA channel, where the dispersion, flow rate and other conditions of an individual assay are optimal.[2]

In this work, the preparation of the flow-through tubular atropinium and scopolaminum electrodes and assemblage of the integrated microconduit potentiometric analytical system are described. The performance characteristics of the electrodes in different experimental conditions were studied. The contents of atropine and scopolamine in drug were determined using the micro device. The analytical results agreed well with those obtained by the extraction–spectrophotometric method.

EXPERIMENTAL

Apparatus

A schematic diagram of the FIA–ISE manifold used in this study is shown in Fig. 1(a). An Orion Research 901 microprocessor ion analyzer connected to a Dahua recorder is used. The home-made peristaltic pump with Tygon pump tubes was used to propel the carrier and to aspirate the sample solution. The integrated microconduit analytical system was used to precise sampling volume, reproducible transport, detection on line.

Tubular flow-through electrodes

Composition. The electrodes consisted of 1.0% atropinium–tetraphenylboron or scopolaminum–tetraphenylboron, 68.0% dibutyl phthalate, 31.0% PVC w/w.

Preparation of the atropinium tetraphenylboron. Pipette 1 ml of 0.1 *M* atropine sulphate solution and 1 ml of 0.1 *M* sodium tetraphenylboron. Extract the precipitate with 10 ml of 2-nitrotoluene. Wash organic phase twice with water and dry thoroughly with anhydrous sodium sulphate.[3]

Preparation of the scopolamine tetraphenylboron. Weigh 0.22 g of scopolamine and add 25 ml of water. Heat to 50°, add 45 ml of 0.6% sodium tetraphenyl boron solution (50°) very slowly and leave to stand overnight. Then, filter through a G-5 glass crucible and wash 3 times with water and alcohol successively. Dry for 6 hr at 50° and store in a dryer.[4]

Construction. The basic cell design and construction were the same as those described previously.[5] Atropinium and scopolaminum tubular electrodes were prepared by replacing part of the wall of a small piece of PVC tubing (1.5 cm long, 0.5 mm i.d., 1.5 mm o.d.) with the

conforming sensing membrane (0.25 mm^2). They were then placed into the Perspex housing as shown in Fig. 1(b). The housing was filled with 0.1 *M* NaCl–10^{-2} *M* atropinium or 0.1 *M* NaCl–10^{-2} *M* scopolaminum inner solution with saturated AgCl into which a Ag/AgCl wire was inserted to serve as the inner reference system. This piece tubing acts as potentiometric flow-through detector with zero dead volume.

Assemblage of the integrated microconduit system

Atropinium electrode (i_1) and scopolaminum electrode (i_2) are placed in a single-channel of the integrated microconduit Perspex block ($10 \times 30 \times 50$ mm) and very close to the injection position in order to minimize sample dispersions (Fig. 2). A common Ag/AgCl reference electrode is placed in a side channel fed by stream B, and the combined streams are ultimately led to waste, W. The microvalve with two channels is placed into microconduit right and fixed with small screw. The connection between the microvalve and the electrode was made with a 0.5-cm length stainless steel tube which was grounded to prevent interference from static electricity earthed by the pump roller.[5]

Reagents

Analytical reagent grade organic and inorganic chemicals were used without further purification. Doubly distilled water was used throughout. The standard 0.1000 *M* solution of atropine and scopolamine were prepared by dissolving the appropriate amount of substance in 0.05 *M* $Mg(CH_3COO)_2$. Working solutions were prepared by appropriate dilutions with 0.05 *M* $Mg(CH_3COO)_2$. Carrier solution was 0.05 *M* $Mg(CH_3COO)_2$.

RESULTS AND DISCUSSION

Sample preparation

Pipette 0.1, 0.2, 0.4, 0.6, 0.8 and 1.0-ml scopolamine injections into 50-ml flasks and dilute with 0.05 *M* $Mg(CH_3COO)_2$ to 50 ml.

Grind 10 tablets of atropine sulphate into powder. Thoroughly mix and accurately weigh 50, 100, 150, 200, 250 and 300 mg of the powder into 50-ml flasks and dilute with 0.05 *M* $Mg(CH_3COO)_2$ to 50 ml.

Electrode characteristics

In order to study the response characteristics of atropinium and scopolaminum electrodes in different experimental conditions, a rod electrode and a tubular flow-through electrode integrated microconduits with the same sensing membrane were made and tested separately in the static state and in the flow state at 25°. These results are summarized in Table 1. The results show that the characteristics of a tubular electrode under hydrodynamic flow conditions differ from those observed under static conditions. Rapid response (5–10 sec), high reproducibility (±0.1 mV) and good stability (overall EMF drift of 0.2 mV/hr over at least 8 hr) were obtained by the microdevice under flow conditions. This is due to the stable experimental conditions for precise sampling volume,

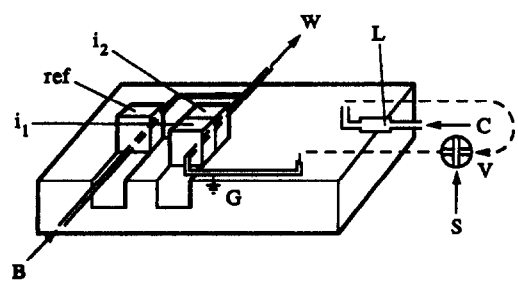

Fig. 2. Details of the integrated microconduit; shown within the dotted lines in Fig. 1(a).

Table 1. Electrode response characteristics (25°)

Type	Condition	Linear range (M)	Response time (sec)	Repeatability ($N = 11$) (mV)	Detection limit (M)	Slope (mV/pX)	Selectivity coefficient (separate solution method)		
							K^{AH^+,K^+}	$K^{AH^+,Ca^{++}}$	$K^{AH^+,Mg^{++}}$
Atropine (AH^+)	Static	10^{-1}–10^{-5}	10–30	±0.5	10^{-6}	59.2	3.6×10^{-4}	2.3×10^{-3}	9.0×10^{-5}	9.5×10^{-5}
	Flow	10^{-1}–2×10^{-5}	5–10	±0.1	2×10^{-6}	58.8	3.4×10^{-4}	1.4×10^{-3}	1.0×10^{-4}	1.1×10^{-6}
Scopolamine (SH)	Static	10^{-1}–10^{-5}	10–40	±0.4	2×10^{-6}	58.0	6.2×10^{-3}	1.5×10^{-2}	4.6×10^{-4}	4.9×10^{-4}
	Flow	10^{-1}–2×10^{-5}	5–15	±0.1	4×10^{-6}	57.3	1.2×10^{-2}	1.8×10^{-2}	1.2×10^{-4}	4.7×10^{-4}

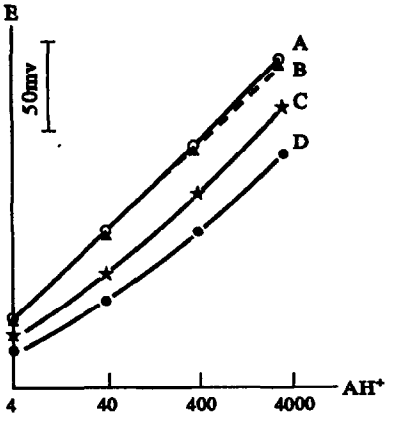

Fig. 3. Calibration curves for the atropinium electrode. A. Steady state measurement; B. response by injecting 120 μl sample volume; C. response by injecting 80 μl sample volume; D. response by injecting 30 μl sample volume.

reproducible transport, constant flow in the system were obtained. Meanwhile, the possibility of preventing the periodical exposure of the electrode to ambient atmosphere which could cause error due to temperature changes, variation in dry and wet conditions at the surface of the electrode, changing solutions, chemical and physical effect was reduced.

Selectivity coefficient values of the electrode under flow conditions differ slightly from those obtained under static conditions. A plausible

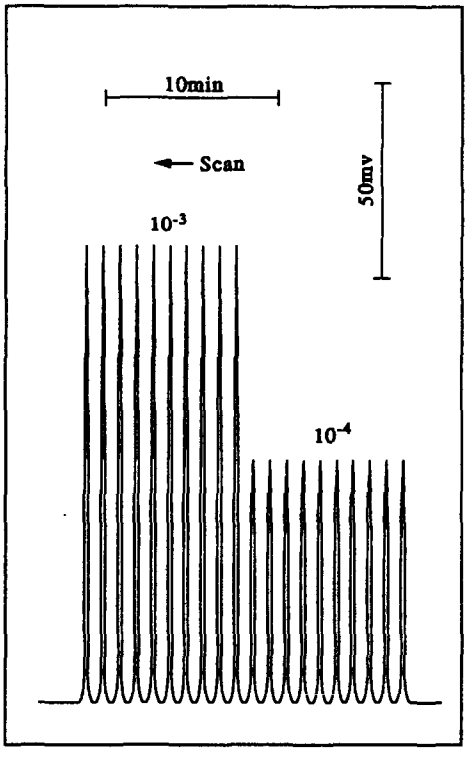

Fig. 4. Repeated determinations of two atropinium standard solution with the system depicted in Fig. 1.

explanation is that the contact time between the interference solution and the membrane is much shorter under dynamic conditions than in static measurement. It is shown that adsorption, desorption and response speed on the sensing membrane may be different. By adjusting experimental conditions, changing carrier components or using FIA treatment on line, the effect of interference ions on the results may be decreased.

Calibration curves of atropinium electrode obtained by injecting sample volumes of $S_v = 120$ μl, $S_v = 60$ μl, $S_v = 30$ μl and static state measurement are shown in Fig. 3. For the lower sample volume, the maximum potentials (peak heights) are lower than those obtained by static state measurement, revealing the influence of the sample dispersion and response time on the readout. The slope value of calibration curve B (58.8 mV/pAH$^+$ differs slightly from the slope value of curve A (59.2 mV/pAH$^+$) from that based on static state measurements. For $S_v = 30$ μl (curve D), a markedly lower slope is observed.

Standard and sample measurement

The integrated microconduits manifold was connected according to Fig. 1(a). The conditions selected were; the sampling volume $S_v = 120$ μl, the pumping rate for the indicator electrodes $Q = 1.2$ ml/min and for the reference electrode $Q = 0.24$ ml/min. The system was calibrated with a series of standard solutions. The results show excellent agreement between the proposed method and extract spectrophotometric method. The accuracy of the proposed method was also tested by the standard additions method. Known amounts of atropinium or scopolaminum were added to samples which were processed before and after the additions. Integrated microconduit FIA–ISEs system gave recoveries of 98–102%.

Typical outputs for reproducibility measurement of two standard solutions are shown in Fig. 4, which represents a sampling rate of about 120/hr. The standard deviation over the linear range with tubular electrodes was about 0.1 mV ($N = 11$).

POTENTIOMETRIC MONITORING OF PROTEINS—PART 6. INDIRECT POTENTIOMETRY

MICHAEL L. HITCHMAN and FRAZIER W. M. NYASULU*
Department of Pure and Applied Chemistry, University of Strathclyde, 295, Cathedral Street, Glasgow G1 1XL, U.K.

(*Received* 28 *December* 1992. *Revised* 26 *January* 1993. *Accepted* 4 *March* 1993)

Summary—In a study of the indirect potentiometry of amino acids and proteins with metal ions it has been discovered that electrode potential responses to organic ligand concentrations can be linear over a range of tens of millivolts. In this paper the reasons for this are considered and a general model is presented in terms of an electrode of the second kind. Experimental results for the indirect potentiometry of a number of amino acids and proteins are then presented and are discussed in the context of the model derived. Applications to flow injection analysis and to the determination and identification of proteins eluting from a gel chromatography column are also considered.

Proteins have a high affinity for some metal cations and this feature is the basis of several methods for protein determination. Metal ions which have proved most useful are copper(II) and silver(I). The use of Cu^{2+}, for example, in the biuret[1] and Lowry *et al.*[2] determinations is well known. Direct and indirect potentiometric determinations of amino acids with copper electrodes have been described,[3,4] and we have reported on the extension of copper based potentiometry to the determination of proteins.[5–8] Copper based potentiometric detection has in addition been used for monitoring in both liquid chromatography[4] and flow injection analysis.[5] Determinations based on silver[9–12] have also been examined, but have received rather less attention from the point of view of applications, probably because only thiol containing proteins give a satisfactory response.[13–16]

Direct potentiometry enjoys the advantage of being a non-destructive technique, but the inherent insensitivity of a semi-logarithmic relationship between potential and concentration leads to poor precision. Indirect potentiometry, which uses an excess of a reagent with the analyte, still, in principle, relies on a Nernstian relationship but it has an advantage in that electrode potentials measured before and after addition of the analyte to the reagent are usually with respect to relatively simple cations or anions and so problems of slow electrode response and irreproducibility often associated with complex analyte molecules[8,11] are minimised. In a previous paper[5] we reported on the application of indirect potentiometry to protein monitoring and we showed that a sufficient level of precision was attainable for quantitative analysis. However, we have also discovered that for indirect potentiometric determination of proteins and amino acids at low concentrations that electrode responses are linear in ligand concentration and that this linearity can extend over a potential range of as much as ~60 mV. This is to be welcomed for it further assists in improving sensitivity, but it is rather surprising that a potentiometric response can be linear for such a large potential range. In this paper the reasons for this are considered.

We also report on results for indirect potentiometry of amino acids and proteins and discuss the experimental data in the context of the model derived. Application to flow injection analysis and to the determination of proteins eluting from a gel chromatography column are considered, and, in particular, the ratio of the responses for copper based and silver based potentiometry is shown to be useful for the identification of proteins eluting from the column.

THEORY

Model based on electrode of the first kind

For a metal electrode in contact with ions of the metal in a solution of concentration C_{mi}, the

*Present address: Department of Chemistry, University of Washington, Seattle, WA 98196, U.S.A.

electrode potential (E_i) is given by the very simple form of the Nernst equation:

$$E_i = E^0 + k \ln C_{mi} \quad (1)$$

where $k = RT/nF$. On adding a complexing species such as a protein or amino acid to the solution the potential (E_e) corresponding to the equilibrium concentration (C_{me}) of metal ions after reaction with the ligand can be represented by

$$E_e = E^0 + k \ln C_{me} \quad (2)$$

If y cations are bound per ligand molecule (Pr) according to

$$\mathrm{Pr} + y\mathrm{M}^{n+} \overset{K}{\rightleftharpoons} \mathrm{M}_y\mathrm{Pr}^{n+} \quad (R1)$$

the metal ion mass balance is

$$C_{mi} = C_{me} + yC_{mpe} \quad (3)$$

where C_{mpe} is the equilibrium concentration of the metal–ligand complex. Using the above equations equation (2) becomes

$$E_e = E^0 + k \ln\{C_{mi}[1 - yC_{mpe}C_{mi}^{-1}]\} \quad (4)$$

If experimental measurements are taken as the difference between a blank solution and that with added ligand then

$$\Delta E = E_e - E_i = k \ln[1 - yC_{mpe}C_{mi}^{-1}] \quad (5)$$

From the metal–ligand equilibrium (R1)

$$C_{mpe} = KC_{pe}C_{me}^{y} \quad (6)$$

The ligand mass balance is

$$C_{pi} = C_{pe} + C_{mpe} \quad (7)$$

where C_{pi} is the ligand concentration before reaction. Expressing metal ion and ligand mass balances in terms of C_{me} and C_{pe} and substituting into equation (6) leads to

$$C_{mpe} = K(C_{pi} - C_{mpe})(C_{mi} - yC_{mpe})^{y} \quad (8)$$

Expansion yields

$$C_{mpe} = \mathrm{K}C_{mi}^{y}(C_{pi} - C_{mpe})[1 - y^2C_{mpe}/C_{mi} + y^3(y-1)C_{mpe}^2/2!C_{mi}^2 - \ldots..] \quad (9)$$

The maximum value of $C_{mpe} = C_{pi}$, *i.e.*, 100% conversion of the ligand to metal–ligand complex. Normally for indirect potentiometry one would have $C_{mi} \gg C_{pi}$ and so $C_{mpe} \ll C_{mi}$. Now provided that y is not too large, and this is usually the case for metal–protein and metal–amino acid complexes,[17] then equation (9) can be approximated by

$$C_{mpe} \simeq C_{pi}C_{mi}^{y}(K^{-1} + C_{mi}^{y})^{-1} \quad (10)$$

Thus

$$\Delta E \simeq k \ln[1 - yC_{pi}C_{mi}^{y-1}(K^{-1} + C_{mi}^{y})^{-1}] \quad (11)$$

The formation constants for silver and copper with proteins are usually large. For example, it has been reported[18] that the equilibrium constant for the reaction between Cu^{2+} and human serum albumin is 1.6×10^{16}, and we have recently determined[17] that for Ag^+ complexation with protein stability constants are equally large. With $K \gg 1$ and then expressing the logarithmic term in equation (11) as a power series and simplifying leads to

$$\Delta E \simeq -kyC_{pi}/C_{mi} \quad (12)$$

This equation predicts that for an initial metal ion concentration much greater than the initial ligand concentration and for a large formation constant for the metal–ligand complex then for a given initial metal ion concentration the potential difference before and after complexation will be linearly dependent on the initial ligand concentration.

Let us consider, though, the potential range over which we would expect equation (12) to be valid. If a discrepancy of up to 10% between a logarithmic expression of the form $\ln(1-x)$ and the linear approximation of $-x$ is taken as being acceptable then it is required that $x \leqslant 0.2$. For the case above this means $yC_{pi}/C_{mi} \leqslant 0.2$ and equation (12) will be valid for $\Delta E \leqslant 5.1/n$ mV where n is the charge on the metal ion. Thus for complexation with Ag^+ linearity between the observed potential difference and initial ligand concentration will only be linear over a range of ~ 5 mV whilst for complexation with Cu^{2+} it will only hold for ~ 2.5 mV. In practice, as mentioned above, we find linearity over a potential range up to ~ 60 mV. Furthermore, we have also found that for linearity it is not essential that the condition assumed above of $C_{mi} \gg C_{pi}$ holds. For example, we have obtained the surprising result that linearity for indirect potentiometry of bovine serum albumin (BSA) with $0 \leqslant [\mathrm{BSA}] \leqslant 0.08\mathrm{m}M$ and $[Cu^{2+}] = 0.1\mathrm{m}M$ (*i.e.*, a value of C_{pi}/C_{mi} up to 0.8) extends over a range of ~ 30 mV [see Fig. 5(a)]. Even more surprising is the result for complexing of *L*-histidine (*L*-hist) with $0 \leqslant [L\text{-hist}] \leqslant 0.45\mathrm{m}M$ and again with $[Cu^{2+}] = 0.1\mathrm{m}M$ (*i.e.* a ratio of ligand to metal ion concentration of up to 4.5) of a linear potential plot over a range of 56 mV (see Fig. 4). Clearly the simple metal electrode model

considered above is inadequate to explain the experimental observations. The linear response in the presence of excess ligand in the case of *L*-histidine together with our earlier results for the direct potentiometry of proteins with copper electrodes would suggest that we might have an electrode of the second kind. This electrode at low concentrations of ligand responds to the excess metal ions, the concentration of which is a measure of the ligand concentration, but it then responds to the ligand itself at higher concentrations. Such a model which takes into account both indirect and direct potentiometry is now discussed.

Model based on electrode of the second kind

The half cell for the metal ligand system can be represented as

$$\begin{array}{cccccc} \alpha' & & \lambda & \delta & \beta & \alpha \end{array}$$

$$\mathrm{Pt|Reference\ electrode\|M^{n+},Pr|M_{y}Pr^{n+}|M|Pt}$$

where the Greek symbols are used to distinguish the different phases. The potential difference (U) between the two platinum wires is given by

$$FU = \mu_{e^-}(\alpha') - \mu_{e^-}(\alpha) \qquad (13)$$

At equilibrium for the chemical potentials of the metal ions (μ_m) and ligands (μ_p) one has

$$\mu_m(\delta) = \mu_m(\lambda) \qquad (14)$$

and

$$\mu_p(\delta) = \mu_p(\lambda) \qquad (15)$$

Combining equations (13)–(15) and using the classical expression for chemical potential gives

$$\bar{\mu}^0_{mp} - \mu^0_{mp} = RT\ \ln(K_{sp,mp}/\bar{a}_{mp}) \qquad (16)$$

where $\bar{\mu}^0_{mp}$ and μ^0_{mp} are the standard chemical potentials for the metal–ligand complex in the solid phase δ and in the solution phase λ, respectively. The solubility product ($K_{sp,mp}$) is for the equilibrium (R1) and is given by

$$K_{sp,mp} = a^{y}_{m} a_p \qquad (17)$$

and the activity ($\bar{a}_{mp}$) of the complex in the solid phase is related to the activities of the individual species by

$$\bar{a}_{mp} = \bar{a}^{y}_{m} \bar{a}_p \qquad (18)$$

Now for an electrode/solution interface not just the chemical potential has to be considered but also the electrochemical potential. If this is done and at the same time account is taken of the asymmetric coupling between the metal and the ligand [cf. equation (R1)] then an equation for the interfacial potential difference is obtained:

$$\bar{\phi}_m - \phi_m = \Delta\phi_m = y(RT/nF) \times \ln(K^{1/y}_{exm} a_m/\bar{a}_m) \qquad (19)$$

where K_{exm} is the extraction coefficient for metal ions and is related to the chemical potentials of the metal ions by

$$K_{exm} = \exp[\mu^0_m - \bar{\mu}^0_m)/RT] \qquad (20)$$

K_{exm} is essentially a traditional partition coefficient modified by the effect of an electric field at the interface [cf. the exponential form of equation (19)] and is a measure of the standard electrochemical potential for the metal ions [cf. equations (19) and (20)].

What determines the activity of metal ions in solution is now considered. This activity (a_m) will be made up of contributions from the excess metal ions left over after the addition of the ligand and from the dissolution of the complex M_yPr^{n+}. If these two contributions are denoted by a_{mx} and a_{md} then

$$a_m = a_{mx} + a_{md} \qquad (21)$$

and equation (17) for the solubility product becomes

$$K_{sp,mp} = (a_{mx} + a_{md})^{y} a_{pd} \qquad (22)$$

where a_{pd} is the ligand activity arising from dissolution of the complex. In terms of concentrations equation (22) can be written as

$$K_{sp,mp} = \gamma^{1+y}_{\pm}(C_{mx} + C_{md})^{y} C_{pd} \qquad (23)$$

where $\gamma_{\pm}$ is the mean ionic activity coefficient for M_yPr^{n+}. Implicit in equation (22) is the assumption that all the ligand is complexed and so $a_{pd} = a_{md}$ and equation (23) becomes

$$K_{sp,mp} = \gamma^{1+y}_{\pm} C_{md} C^{y}_{mx}[1 + (C_{md}/C_{mx})]^{y} \qquad (24)$$

If the binomial expansion is now used and powers greater than unity are neglected then equation (24) for C_{md} can be readily solved:

$$C_{md} \simeq [-C^{y}_{mx} \pm (C^{2y}_{mx} + 4yC^{y-1}_{mx} K_{sp,mp}/\gamma^{1+y}_{\pm})^{1/2}]/2yC^{y-1}_{mx} \qquad (25)$$

The approximation of neglecting higher powers of C_{md}/C_{mx} assumes that the metal–ligand complex has a low solubility, but this is probably not unreasonable in view of the fact that an electrode of the second kind is being considered.

The total activity of the metal ions is given by equation (21) which in terms of concentrations is

$$a_m \simeq (\gamma_+/2y)[C_{mx}(2y-1) + (C_{mx}^2 + 4yK_{sp,mp}C_{mx}^{1-y}/\gamma_\pm^{1+y})^{1/2}] \quad (26)$$

Note that only the value of C_{md} with the square root added to $-C_{mx}$ is used since it is obvious that only this solution can give a positive value for C_{md}.

Substituting back into equation (19) gives

$$\Delta\phi_m \simeq y(RT/nF)\ln\{\gamma_+ K_{exm}^{1/y}/2y\bar{a}_m][C_{mx}(2y-1) + (C_{mx}^2 + 4yK_{sp,mp}C_{mx}^{1-y}/\gamma_\pm^{1+y})^{1/2}]\} \quad (27)$$

With $y = 1$ this equation corresponds to a symmetric 1:1 complex. A simple, common example would be for the formation of AgCl. In this case equation (27) is identical in form to that derived by Buck[19] for the potential of a solid state silver halide membrane electrode in contact with excess silver ions.

Of course, equation (27) is for the interfacial potential difference when the electrode responds to metal ions. In practice in indirect potentiometry what one measures is the difference in electrode potential (ΔE) before and after addition of the complexing agent [cf. equation (5)]. Replacing the subscript x on C_m by a subscript i to represent the initial conditions and subtracting the resulting equation from equation (27) leads to the expression for ΔE. Equation (28) gives this with C_{mx} replaced by $(C_{mi} - yC_{pi})$ to emphasise that it is the relationship between electrode potential and ligand concentration that is of interest.

Before these rather cumbersome equations are examined further let us obtain the corresponding equations for when the electrode responds directly to the added ligand; *i.e.*, once all the metal ions have been complexed.

The analogous equation to equation (19) is

$$\bar{\phi}_p - \phi_p = \Delta\phi_p = -(RT/nF)\ln(K_{exp}a_p/\bar{a}_p) \quad (30)$$

K_{exp} is the extraction coefficient for ligand. Using equation (16) for $K_{sp,mp}$, equation (20) for K_{exm} and the corresponding equation for K_{exp} the following relationship is obtained

$$K_{exp} = \bar{a}_m^y \bar{a}_p / K_{sp,mp} K_{exm}^y \quad (31)$$

Therefore equation (30) becomes

$$\Delta\phi_p = -(RT/nF)\ln(\bar{a}_m^y a_p / K_{sp,mp} K_{exm}^y) \quad (32)$$

Now, as in the case of excess metal ions one has to consider what determines the activity (a_p) of the electroactive species. Again it will be made up from contributions of excess unreacted species, such as protein, and from the dissolution of the complex $M_y Pr^{n+}$; *i.e.*,

$$a_p = a_{px} + a_{pd} \quad (33)$$

The solubility product is now given by

$$K_{sp,mp} = \gamma_\pm^{1+y}(C_{px} + C_{pd})C_{md}^y \quad (34)$$

Following a similar line of argument to that used for the cation case the expression for the interfacial potential difference is arrived at:

$$\Delta\phi_p \simeq -(RT/nF)\ln\{[\gamma_- \bar{a}_m^y / 2K_{sp,mp}K_{exm}^y] \times [C_{px} + (C_{px}^2 + 4K_{sp,mp}C_p^{1-y}/\gamma_\pm^{1+y})^{1/2}]\} \quad (35)$$

For the case of a 1:1 complex this equation reduces to that given by Buck[19] for the anion response. The difference in electrode potential between the point when just enough ligand has

$$\Delta E_m \simeq \frac{yRT}{nF}\ln\left\{\frac{(2y-1)(C_{mi}-yC_{pi}) + \left[(C_{mi}-yC_{pi})^2 + \dfrac{y(4K_{sp,mp}/\gamma_\pm^{1+y})}{(C_{mi}-yC_{pi})^{y-1}}\right]^{1/2}}{(2y-1)C_{mi} + \left[C_{mi}^2 + \dfrac{y(4K_{sp,mp}/\gamma_\pm^{1+y})}{C_{mi}^{y-1}}\right]^{1/2}}\right\} \quad (28)$$

If the ligand concentration added is a fraction $0 \leqslant \alpha \leqslant 1$ of the initial metal ion concentration then $C_{pi} = \alpha C_{mi}$ and equation (28) becomes

$$\Delta E_m \simeq \frac{yRT}{nF}\ln\left\{\frac{(2y-1)C_{mi}(1-y\alpha) + \left[(C_{mi}^2(1-y\alpha)^2 + \dfrac{y(4K_{sp,mp}/\gamma_\pm^{1+y})}{C_{mi}^{y-1}(1-y\alpha)^{y-1}}\right]^{1/2}}{(2y-1)C_{mi} + \left[C_{mi}^2 + \dfrac{y(4K_{sp,mp}/\gamma_\pm^{1+y})}{C_{mi}^{y-1}}\right]}\right\} \quad (29)$$

been added to complex with all the metal ions and for subsequent additions of ligand is given by

$$\Delta E_p \simeq -(RT/nF)\ln\{(C_{px} + [C_{px}^2 + (4K_{sp,mp}C_{pd}^{1-y}/\gamma_{\pm}^{1+y})]^{1/2}/(4K_{sp,mp} \times C_{pd}^{1-y}/\gamma_{\pm}^{1+y})^{1/2}\} \quad (36)$$

In order to examine further the dependence of potential on the ligand solution concentration it is convenient to take a simpler form. This is obtained for the case when $y = 1$ (*i.e.*, a symmetric complex), the activity coefficients are unity and the ionic charge $n = \pm 1$. First equation (27) is considered where some of the constants are lumped together to give

$$\Delta\phi_m \simeq (RT/nF)\ln\{A[C_{mx} + (C_{mx}^2 + 4K_{sp,mp})^{1/2}]\} \quad (37)$$

The constant A will have an effect on the absolute value of $\Delta\phi_m$, but will not affect the general shape of a plot of potential *vs.* concentration. If the simplification is now continued by taking a specific value for 4 $K_{sp,mp}$ (*e.g.*, 10^{-10}) then a plot of $\Delta\phi$ *vs.* concentration is readily made. This is shown in Fig. 1. The classical Nernstian region is obvious for $C_{mx} > \sim 2 \times 10^{-5}M$ but for concentrations below this curvature sets in, not because the Nernstian response breaks down, but rather because the concentration of electroactive species is not solely determined by that deliberately added to the solution. The dissolution of the metal complex gives additional metal ions in the solution and so the potential is less than that expected on the basis of the added ions. At very low concentrations of added ions ($\sim 10^{-7}M$) the dissolution of the complex is the major source of ions and so the potential becomes independent of the added ion concentration.

In general one may readily show that for, say, a 5% deviation from Nernstian linearity it is necessary that $C_{mx}^2 > 40K_{sp,mp}$. For the case considered here with $4K_{sp,mp} = 10^{-10}$ then it is required that $C_{mx} \geqslant \sim 3 \times 10^{-5}M$ and this is what is found on closer inspection of the plot in Fig. 1. For the potential to become within 5% of being independent of C_{mx} the condition is $C_{mx}^2 < 10^{-2}K_{sp,mp}$. For $4K_{sp,mp} = 10^{-10}$ this means $C_{mx} \leqslant 5 \times 10^{-7}M$. Again the plot of Fig. 1 verifies this.

If one now takes the potentials calculated from equation (37) for the curved region of Fig. 1 (*i.e.*, for $0.1 \times 10^{-6}M \leqslant C_{mx} \leqslant 30 \times 10^{-6}M$) and plots them as a linear function of C_{mx} then Fig. 2 is obtained. The result is a gentle curve, but it can be seen that at low values of C_{mx} (*i.e.*, $C_{mx} < \sim 14 \times 10^{-6}M$) the curve can be approximated by a straight line with all points within 5% of the curve over a total potential range of ~ 30 mV. Thus experimental data which may often be no more precise than a few percent, especially in the case of complex species, could well appear to show potential linearity over a range of up to 30 mV. This can be shown in a different manner by using equations (29) and (36). Again a simplified version is taken with y, n and $\gamma_{\pm}$ all equal to unity and with $4K_{sp,mp} = 10^{-10}$. In addition a fixed value for the initial metal ion concentration is taken; *e.g.*, $10^{-5}M$. Equation (29) then becomes

$$\Delta E_m \simeq (RT/F)\ln\{0.414(1-\alpha + [1 + (1-\alpha)^2]^{1/2})\} \quad (38)$$

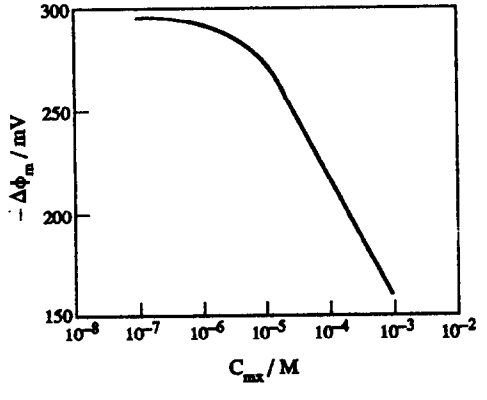

Fig. 1. Plot of equation (37) with $4K_{sp,mp} = 10^{-10}$.

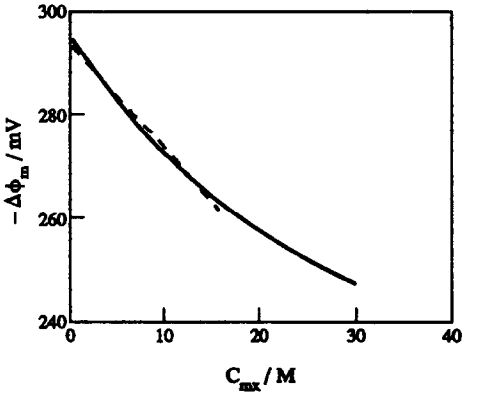

Fig. 2. Plot of potentials from Fig. 1 for $0.1 \times 10^{-6}M \leqslant C_{mx} \leqslant 30 \times 10^{-6}M$ as a linear function of C_{mx}

——— Values taken from Fig. 1.

– – – – – Linear plot through the values from Fig. 1.

Equation (36) simplifies to

$$\Delta E_p \simeq (-RT/F)\ln\{(C_{px} + [C_{px}^2 + 10^{-10}]^{1/2})/10^{-5}\} \quad (39)$$

Or if C_{px} is related to the concentration of ligand (C_{pi}) when it is equal to the initial metal ion concentration by $C_{px} = \beta C_{pi}$ with $\beta \geq 0$ then

$$\Delta E_p \simeq (-RT/F)\ln\{\beta + [\beta^2 + 1]^{1/2}\} \quad (40)$$

Figure 3 shows the plots for these two equations. For $C_{pi} \leqslant 10^{-5}M$ (*i.e.*, $\alpha \leqslant 1$) the response of the electrode is to the metal ions; the plot analogous to that in Fig. 2 for $0 \leqslant C_{mx} \leqslant 10^{-5}M$. For ligand added in excess of $10^{-5}M$ (*i.e.*, $\beta > 0$) the electrode response is for ligand and the potentials are additive to those calculated up to that point. Following on from the analysis of Fig. 2, each mode will show approximate linearity over a potential range of ~ 30 mV thus giving a total linear range ~ 60 mV, as is shown by the dashed line.

The analysis given above is quite general for potentiometric systems involving cations and anions or ligands which constitute the components of an electrode of the second kind. In order to illustrate the effect the cumbersome equations have been simplified and only the 1:1 symmetric case has been considered. To try and illustrate the effect with very general equations [*e.g.*, equations (29) and (36)] would be complicated and probably not very helpful. Results will now be considered for the indirect potentiometry of some amino acids and proteins.

EXPERIMENTAL

The flow injection system, the potentiometric detection cell and the potential measuring equipment used in this work have all been described in detail previously.[5] Briefly, the flow injection system consisted of a reservoir of reagent, a peristaltic pump, a pulse damping system, an injection valve and the detector cell all in series. They were all connected together with silicone rubber tubing. For indirect potentiometry it is clearly necessary that enough time is allowed for adequate mixing of the sample and the reagent and yet not to have too long a time which would allow excessive dispersion of the injected sample. It was found that both these conditions could be met with a short distance (3 cm) between the injection valve and mixing junction and a longer distance (20 cm) from the junction to the detector. Depending on the sample injection volumes (V_i) typical values of the dispersion (D_t) were found to lie in the range 2.5–9.7 for $300 \times 10^{-6} \geqslant V_i \geqslant 50 \times 10^{-6}$ dm^3. In order to maximise sensitivity all determinations were done with the highest sample injection volume. This was found to give a baseline to baseline time of 30 sec which would thus allow a sampling rate of ~ 120/hr. The detector cell consisted[5] of a small beaker with an inlet and overflow outlet. In the cell were three electrodes. The working or indicator electrode was a high purity copper or silver wire and the reference electrode was a double junction Ag/AgCl electrode. The third electrode was a platinum wire coiled around, but insulated from, the indicator electrode. This platinum coil was used for the electrochemical cleaning procedure (see below). Potential measurements were made simply with a high impedance digital voltmeter.

The flow system for indirect potentiometric detection with a chromatography column was essentially the same as that used for flow injection analysis. The column (Pharmacia LKB C10/40) had a packing of Sephacryl S300. The mobile phase was a buffer solution (pH 7) with, in addition, $0.5M$ sodium nitrate. A high level of inert electrolyte reduces the ionic interactions between proteins and the stationary phase and this enhances separations.[20] It also keeps the ionic strength of the eluting solution effectively constant which is necessary for potentiometric detection. The recommended[20,21] inert electrolyte is $0.5M$ sodium chloride, but since it has been shown that[5,16] chloride ions in excess of $\sim 10^{-1}M$ can interfere with protein

potentiometry using Cu and Ag electrodes the chloride anion was replaced by nitrate: no deleterious effect on the separation of the proteins was observed. The output from the detector cell was recorded as a function of time with a chart recorder.

The amino acids and proteins used in this study were all obtained from Sigma Chemical Company and were used without further purification. They were *L*-histidine, *L*-cysteine, ribonuclease A, phosvitin, ovalbumin, bovine serum albumin, human serum albumin, lysozyme and γ-globulin.

The effect of pH on potential response has been reported earlier.[5] It was shown that the optimum value of pH was ~7 and so all solutions were buffered to this value. The electrochemical cleaning of the electrodes was done as has been described before.[5-8,10,12] Essentially the cleaning consisted of a cathodic current pulse applied to the indicator electrode. The purpose of this electrochemical treatment was to remove excess oxide from the surface of the indicator electrode.[6,8] This technique has been shown to lead to significantly improved reproducibility and response for metallic electrodes when monitoring proteins and amino acids.

RESULTS AND DISCUSSION

Figure 4 shows the dependence of electrode potential on amino acid concentrations for *L*-histidine and *L*-cysteine as measured using the flow injection system and with an initial Cu^{2+} concentration of $10^{-4}M$. The reason for choosing these two particular amino acids initially was that it had been previously shown[3,22] that *L*-histidine gave consistent and reproducible results with a copper electrode, whilst *L*-cysteine had been found by some workers[3] to give less successful results. They thus represented two extreme possibilities of electrode reference. With the cathodic cleaning technique which we have developed[1,5-8,10,12] the problem of reproducibility of electrode response is significantly diminished.

It can be seen that for both amino acids the data points lie approximately on straight lines with zero intercepts. For *L*-histidine the linearity extends up to ~0.07 mg/cm³ corresponding to a concentration of $\sim 4.5 \times 10^{-4}M$. For *L*-cysteine the plot is linear up to 0.10 mg/cm³ or $8.3 \times 10^{-4}M$. Thus the linear relationships hold for amino acid to metal ion ratios of 4.5 for *L*-histidine and 8.3 for *L*-cysteine. The dotted

$[Cu^{2+}] = 10^{-4}M$; flow rate = 60 cm³/hr.

lines in each case have been calculated using the formulae derived above for the electrode response with equation (29) being used for $C_{pi} < 10^{-4}M$ and equation (36) for $C_{pi} > 10^{-4}M$. In using these formulae there is the question of which species the electrode responds to. For low concentrations of added ligand there will be excess metal ions and one might expect a simple metal/metal ion electrode. However, as the ligand concentration increases then for strong complexation the potential of the metal electrode could also depend on equilibria between the metal electrode and the metal complex. For both *L*-histidine and *L*-cysteine we have recently obtained[8] good evidence that there is strong complexing between the amino acids and copper and that the potential of a copper electrode in the presence of the complexes will

depend on the equilibrium between the soluble complexes in solution and the copper surface. This type of mechanism has also been suggested by Alexander *et al.* for the response of a copper electrode to complexing inorganic ions[13] and for the potentiometric monitoring of α amino acids with copper wire and tubular electrodes.[3] If the metal–ligand complex is very insoluble then there will be a transition from an electrode of the first kind to one of the second kind, as has been discussed above in the Theory section. For the two amino acids used it has been reported[23] that, indeed, the complexes with Cu(II) are rather insoluble so such a transition might be expected to be observed. However, the situation could be complicated even further if at the same time there is a changeover in the number of electrons involved in the electrochemical couples. At low ligand concentrations with Cu^{2+} in solution then the simple couple

$$Cu^{2+}(aq) + 2e^- \leftrightharpoons Cu(s) \qquad (R2)$$

could operate. As the ligand concentration increases and an insoluble complex is formed then the electrochemical equilibrium might be

$$CuL(s) + H^+(aq) + e^- \leftrightharpoons Cu(s) + HL(aq) \qquad (R3)$$

Such a couple also gives a 1:1 complex which will allow the use of simpler forms of equations (29) and (36). For the interaction of the amino acids with a copper surface 1:2 complexes have been suggested,[6] but when interaction can take place in solution there will be less steric constraints and a higher ratio of copper to ligand may be possible; there is certainly good evidence for 1:1 complexes in solution in the case of *L*-histidine.[24] Thus in applying the derived equation we have taken $y = 1$ in all cases and $n = 2$ when $C_{pi} < C_{mi}$ and $n = 1$ when $C_{pi} > C_{mi}$. There will clearly not necessarily be a sharp changeover, but in the absence of more detailed investigations we make this simplifying assumption. It has also been assumed that activity coefficients are always unity. This then leaves in the equation a choice of values for the solubility product $K_{sp,mp}$ for the complexes. For the case of *L*-histidine and $[Cu^{2+}] = 10^{-4}M$ a value of $K_{sp,mp}$ of 8×10^{-9} gives the best fit while for the same value of C_{mi} for *L*-cysteine a value of 8×10^{-8} is chosen. The fits are quite good over the whole range of values of amino acid concentrations which correspond to amino acid to metal ratios of greater than unity. Thus in spite of the various approximations and assumptions made the concept of an electrode of the second kind responding to both metal ions and the ligand is seen to be consistent with the data. The relatively low values of the solubility products for the two amino acid complexes are consistent with the observed[23] low solubilities and with the strong complexing[8] already mentioned.

If the initial copper ion concentration is changed to $9.5 \times 10^{-4}M$ linear plots of potential *vs.* amino acid concentration are obtained over the same concentration range as before but the slopes are reduced in both cases by a factor of about 9.5. Calculating the expected dependence of potential on concentration with the same values of $K_{sp,mp}$ as used above gives a plot for *L*-histidine with a slope of ~ 8 less than that of $[Cu^{2+}] = 10^{-4}$. This is in reasonable accord with

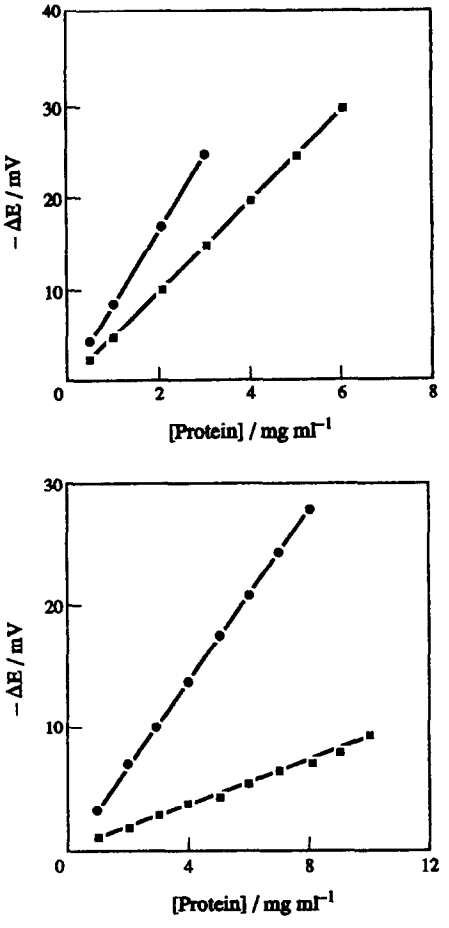

Fig. 5. Dependence of electrode potential on added protein concentrations

Ovalbumin			41.8	2.4×10^{-7}
γ-Globulin			13.2	2.6×10^{-7}

experiment. For *L*-cysteine the calculated plot gives a slope which is only reduced by a factor of ~ 3. This may be due to the fact that the experimental data corresponds to a more complicated changeover in electrochemical couples, as mentioned above; this discrepancy is being investigated further.

Notwithstanding the lack of a complete quantitative agreement between the model and experiment, the concept of an electrode of the second kind responding to either the metal ions or the ligand does offer a semi-quantitative explanation for a linear relationship over several decades of millivolts between electrode potential and ligand concentration. We now consider the case of proteins complexing with copper ions.

Figure 5 shows results comparable to those given in Fig. 4 but for four different proteins. The situation here, though, will be even more complicated than in the case of the amino acids. This is illustrated by the different results obtained for human and bovine serum albumin. These two proteins are very similar in structure, size and amino acid sequence[25] and for direct potentiometry with a copper electrode we have, in fact, obtained[6] very similar responses. Here, however, if one takes the slope of the plots as indicative of the number of binding sites [cf. equation (29)] then bovine serum albumin would appear to bind only $\sim 60\%$ of the copper that human serum albumin binds. This also highlights the fact that proteins have multiple binding sites[27] and thus y may be >1 in equations (29) and (36). So that although the maximum protein concentrations added to the Cu^{2+} solution give, except for ribonuclease A, values of $\alpha < 1$($\alpha \sim 0.4$ for human serum albumin, ~ 0.8 for bovine serum albumin and ~ 0.1 for γ globulin) this does not necessarily mean that the electrode is primarily functioning as a Cu^{2+}/Cu couple, as postulated for the amino acids when $\alpha < 1$. The multiple binding sites of proteins give a further complication in that the sites are not necessarily equivalent,[26] and so the model on which the theory is based of one type of metal complexation is probably oversimplistic. Complexation between metals and proteins is clearly far from straightforward and for this and the various reasons mentioned above it is difficult to interpret the data of Fig. 5 in terms of the derived equations. Nevertheless, the different responses of the various proteins, particularly for ribonuclease A where the maximum concentration used corresponds to $\alpha \sim 6.3$, together with the range of up to 30 mV over which direct linearity between electrode potential and protein concentration is observed, suggest that a mechanism based on an electrode of the second kind is operating.

Table 1 summarises the response indices in terms of mV $(mg/cm^3)^{-1}$ for the data in Fig. 5 and also, from similar plots, for other proteins with either different initial concentrations of Cu^{2+} and/or flow rate. For the results from Fig. 5 it is clear that, maybe apart from γ globulin, the technique is suited for flow injection analysis determination at the mg/cm^3 level; *i.e.*, for concentrations as low as 10^{-4}–$10^{-5}M$. The sensitivity can be improved by lowering the flow rate to reduce the dispersion of the injected samples and by reducing the initial copper ion concentration. With the last set of conditions given in Table 1 a sensitivity of ~ 0.1 mg/cm^3 is readily achievable.

Table 2. Measurements of precision at the 95% confidence level

Concentration mg/ml	$\Delta E \pm$ error mV	
	Human albumin	Phosvitin
0.2	2.61 ± 0.08	2.85 ± 0.07
0.3	3.85 ± 0.09	4.30 ± 0.07
0.4	5.21 ± 0.07	5.71 ± 0.09
0.5	6.44 ± 0.05	7.13 ± 0.08

Note: $[Cu^{2+}] = 10^{-4}M$; Flow rate = 23 cm³/hr.

Table 2 shows examples of the precision attainable with the technique. Ten measurements were made randomly with respect to concentration and each protein. In all cases the error is less than 3% of the average value. For direct potentiometry of albumins a precision of ± 0.4 mV at the 95% confidence level was found[6] for $\Delta E \sim 20$ mV. So the two techniques give comparable levels of precision in terms of potential measurements; this is prehaps not too surprising since if the technique described here is relying upon the interaction between the protein ligand and an electrode of the second kind then it is exactly equivalent to the direct potentiometric measurements reported earlier. However, in terms of concentration measurements the precision of the "indirect" method is higher because of the linear dependence of concentration on potential. A given error in mV will be less critical than if there is an exponential dependence of concentration on potential, as is the case of the classical Nernstian response.

A summary of the detection limits computed on the basis of Midgley's statistical definitions[27] are also shown in Table 1. The limit corresponds to a 5% chance of failing to detect the determinand. The limits are generally one to two orders of magnitude lower than those found with direct potentiometry,[6] and this is because we are making use of the non-linear part of the classical Nernstian plot (cf. Fig. 1).

Similar results to those obtained with flow injection analysis for amino acids and proteins with Cu(II) in solution and with a copper electrode have also been found with Ag(I) in solution and a silver electrode. Table 3

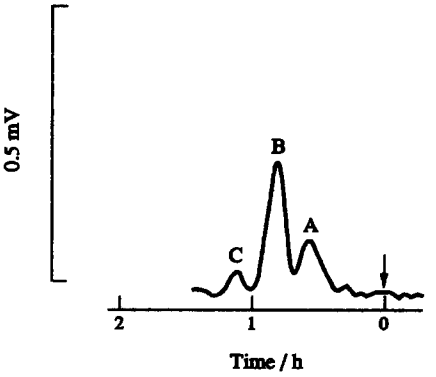

Fig. 6. Typical chromatogram obtained with a potentiometric detector
A catalase
B bovine serum albumin
C lysozyme

[Protein] = 20 μg/cm⁻³;$[Cu^{2+}] = 10^{-5}M$; Flow rate = 23 cm³/hr.

summarises some typical results for the response indices and the detection limits. The response indices are higher and the detection limits are lower than those for the corresponding proteins with Cu(II), which could indicate more binding by Ag^+ than with Cu^{2+}; this is being investigated further.[17]

The technique described for the determination of proteins with Ag^+ and Cu^{2+} has been used for the detection of proteins eluting from a gel chromatography column. An example of a typical chromatogram for an artifical mixture of catalase, bovine albumin and lysozyme is shown in Fig. 6; it was found that the lowest level of the signals which could be readily discerned from the background noise were 10 μg/cm³, 5 μg/cm³ and 20 μg/cm³ for the three proteins, respectively. In accordance with the data in Table 3, limits of detection about one order of magnitude lower were generally attainable when using the Ag^+/Ag systems. The background noise mainly arose from the pulsating action of the peristaltic pump, and a pulse free pump together with signal amplification would probably allow determination at the sub μg/cm³ to be made. A comparison with chromatograms recorded with a UV detector showed that the

Table 3. Response indices and detection limits for potentiometric determination of proteins with Ag^+

Protein	Response Index $mV(\mu g/cm^{-3})^{-1}$	Detection limits M
Human albumin	1.4	1.0×10^{-8}
Ovalbumin	1.2	1.0×10^{-8}
γ-Globulin	0.6	8.0×10^{-9}

Note: $[Ag^+] = 10^{-5}M$; Flow rate = 23 cm³/hr.

Table 4. Ratio of silver:copper response indices

Protein	Response index ratio
γ-Globulin	45
Ovalbumin	29
Bovine albumin	19
Human albumin	11

Note: $[Cu^{2+}] = [Ag^+] = 10^{-5}M$; Flow rate = 23 cm³/hr.

potentiometric method was more sensitive for the proteins with molecular weights less than 50 kamu (*e.g.*, ribonuclease A), but that otherwise results from both techniques were comparable. An advantage of the potentiometric technique over UV detection is that by carrying out simultaneous determinations with both the Ag^+/Ag and Cu^{2+}/Cu systems protein identification could be achieved. Table 4 gives the ratio of the Ag:Cu response indices and it is seen that these are unique for each protein. This procedure for identifying proteins worked well, as long as the proteins were well separated in the chromatogram. A disadvantage of the potentiometric technique compared with UV analysis is the need for post column addition of reagents, which may lead to band broadening. However, this problem could be avoided by chronocoulometric generation of the Cu^{2+} and Ag^+.

Summary—The construction and performance characteristics of a double-membrane ephedrine selective electrode are described. The electrode is based on the use of an internal conducting membrane made of tetrabutylammonium bromide and another external electroactive membrane containing the ionic pair ephedrine-tetraphenylborate in a poly (vinyl chloride) resin (with some plasticizers incorporated) as an inert matrix. The ephedrine electrode exhibits linear Nernstian response within the range 10^{-2}–$5 \times 10^{-5}M$ of ephedrine, with a slope of 58.2 ± 0.5 mV decade^{-1} at $25 \pm 0.2°$. The detection limit is $10^{-4.5}M$. The reproducibility (coefficient of variation) was 0.54% ($n = 10$ determinations) and the stability of its potential is 2.3 mV/24 h. The selectivity coefficients for 15 ions were calculated. The electrode was applied to the determination of ephedrine in some pharmaceutical preparations with satisfactory results.

Ephedrine is a drug that stimulates both α- and β-adrenergic receptors. It is used in therapeutic doses at the level of 15–60 mg to produce pheripheral vasoconstriction, to raise blood pressure, to prevent hypotension and treat allergic states, catalepsy and myasthenia gravis. It is also utilized as an antidote for poisoning by the central nervous system.

Ephedrine (EPH) has been determined by some instrumental methods[1] like spectrophotometry, polarography and potentiometry.

We have described a double-membrane ion-selective electrodes based on the coated-wire technique (CWEs) for the determination of nitrate,[2] potassium[3] and metoclopramide[4]. This paper proposes the preparation of a double-membrane ephedrine selective electrode that improves the reproducibility and stability of measured potentials.[5] The internal membrane contains a conducting substance, tetrabutylammonium bromide (BrTBA) over an inert matrix of a poly (vinyl chloride) resin (VCR). The outer selective membrane contains ephedrine ion as ion pair complex ephedrine-tetraphenylborate (TPB). The active external membrane composition is a determinant for obtaining a Nernstian slope. The electrode has been applied to the determination of ephedrine in some pharmaceutical preparations.

EXPERIMENTAL

Reagents

Ephedrine clorhidrate, sodium tetraphenylborate (NaTPB), tetrabutylammonium bromide, pH solution buffers, potassium nitrate, potassium chloride and tetrahydrofuran (THF) were all provided by Merck. The poly (vinyl chloride) resin used as inert matrix was provided by FAL S.A. Industries (Zaragoza, Spain) and had the following composition (% (w/w)); poly(vinyl chloride) resin (FAL S.A. Industries) (40.3), Chemigun resin (FAL S.A. Industries) (20.2), stabilizer H-260 (FAL S.A. Industries) (1.2), $CaCO_3$ (4.0), primary plasticizer (dioctylphtalate) (20,2), secondary plasticizer (epoxidaded oleum soha) (FAL S.A. Industries) (2.0) and polymer plasticizer (paramoll) (FAL S.A. Industries) (12.1).

The pharmaceutical products containing ephedrine were obtained from local drug stores.

Stock interference ion solutions were prepared at $1M$ concentrations

*To whom correspondence should be addressed.

Solutions of 0.1M ephedrine as standard stock solution, 2M KCl for studying the influence of ionic strength on the electrode response and 10% (w/v) KNO_3 for filling the outer chamber of the reference electrode were also prepared.

The ephedrine-TPB ion pair precipitate was prepared by mixing 50 ml of a $10^{-3}M$ aqueous solution of ephedrine with a $10^{-3}M$ solution of NaTPB. The precipitate was then filtered, washed with high purity water and finally left to dry at room temperature.

High purity water was obtained from a Millipore Milli-Q Water System.

Apparatus

The determination was carried out at $25 \pm 0.2°$ in a double-walled vessel with a circulating Haake thermostat bath, using a Crison Model 2002 pH-millivolt meter. The standard and test solutions were stirred magnetically (30 r.p.m.) with a Teflon bar for 1 min.

A Commercial Instruments Cedar Grove Industrial Instruments INC. electrolyte conductivity meter was used for the determination of the electrode resistance.

A double junction Ingold Model 31451 was used as external reference electrode, with aqueous 4M KCl and 10% (w/v) KNO_3 as internal and external filling solutions. The membranes were coated on an Ingold Pt cylindrical ring electrode (with a flat surface with a diameter of about 5 mm). So the electrode cell is: Pt | internal membrane | external membrane | sample solution || 10% (w/v) KNO_3 | 4M KCl | AgCl, Ag.

Procedure

The Pt electrode, washed with THF and left to dry, it was dipped in a mixture of BrTBA and a 10% (w/v) solution of poly (vinyl chloride) resin in THF. The optimum composition of internal membrane was BrTBA:resin/THF in weight proportions of 5:95. The thickness of the resulting membrane is about 0.1 mm.

After being left to dry for 12 h, the internal membrane was coated with the active membrane by dipping in a mixture of EPH^+ TPB^- and a 10% (w/v) solution of poly (vinyl chloride) resin in THF. The optimum composition of the external membrane was in weight proportions of 40:60. The total thickness is about 0.3 mm. Once dry, the electrode was conditioned for 1 h in a $10^{-4}M$ EPH solution.

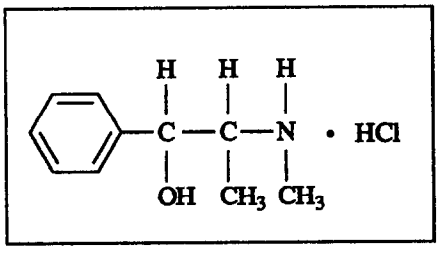

Fig. 1. The formula of ephedrine clorhidrate.

RESULTS AND DISCUSSION

Construction of the EPH electrode

The conducting properties and response time of the electrode seem to depend on the mobility of TBA^+ in the poly(vinylchloride) matrix.[6] The absence of this internal membrane gives rise to bad reproducibility and time-stability.

The principal electrode characteristics (slope, linear response and detection limit) depend on the composition and thickness of the active external membrane. Figure 2 shows the variation in the calibration graph slope as a function of the active membrane composition. A membrane made with a mixture of EPH^+–TPB^- and poly(vinyl chloride) resin in weight proportions of 40:60 exhibits the best results, with a slope of 58.2 ± 0.5 mV decade^{-1}.

It is important when preparing the EPH electrode to control the thickness of both internal and external membranes. If the thickness of the internal membrane is maintained constant, between 0.1 and 0.2 mm, the electrode response depends on the thickness (δ) of the external active membrane. The best results were obtained with $\delta = 0.1$ mm. For values above 0.1 mm the electrode behaviour is subNernstian and the linear response is shorter.

Response characteristics of the electrode

The effect of ionic strength on the electrode response was studied to determine the optimum parameters for the principal electrode characteristics. The calibration graphs were plotted using EPH solutions and dilute solutions of KCl for ionic strength adjustment (ISA). The results are given in Table 1. The ionic strength used was $\leq 0.01M$, where the electrode had a Nernstian slope.

The selectivity coefficients ($K_{EPH,M}^{POT}$) of the EPH electrode were calculated graphically by the mixed solutions method from potential measurements on 20 ml of a solution containing

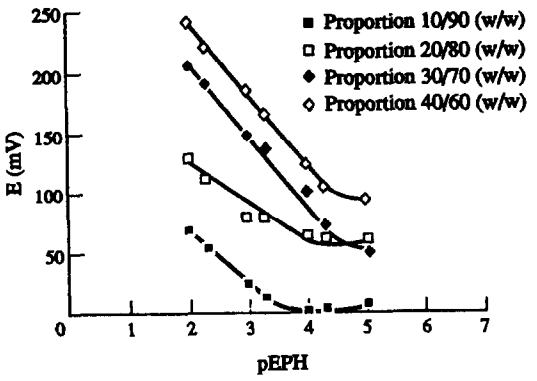

Fig. 2. Effect of the active membrane composition on the double-membrane ephedrine-selective electrode response. The proportion of EPH^+ TPB^-–VCR/THF in%(w/w).

Table 2. Selectivity coefficients for the EPH electrode

Ion (M)	$K^{POT}_{EPH,M}$
Na^+	7.5×10^{-3}
K^+	1.5×10^{-2}
NH_4^+	1.1×10^{-2}
Mg^{++}	5.9×10^{-3}
Ca^{++}	6.7×10^{-3}
Dextrometorphane bromhidrate	0.9
Alanine	2.7×10^{-3}
Acetamide	3.5×10^{-3}
Aminobenzoic acid	1.2×10^{-2}
Nicotinic acid	1.4×10^{-2}
Caffeine	1.0
Sucrose	6.4×10^{-3}
Tetrabutylammonium bromide	1.7×10^{-2}
Oxalic acid	3.3×10^{-3}
Citric acid	6.7×10^{-3}

a fixed ephedrine concentration ($10^{-4}M$) (C_{EPH}) and varying the interfering ion concentration by adding small volumes (0, 0.5, 1.0, 1.5 and 2.0 ml) (V) of $1M(C_M)$ solution of interfering ion.

The selectivity coefficients for 15 ions were calculated. The values obtained with $C_{EPH} = 10^{-4}M$ and $C_M = 1M$ are shown in Table 2. Dextrometorphane bromhidrate and caffeine appear to be the principal interferences.

The effect of the pH on the potential response was studied. To 10 ml of $10^{-2}M$ ephedrine solution, equal volumes of different buffer solutions were added up to 100 ml with distilled water. Values lower than 4 or higher than 8 produce a sharp drop in electrode potential. Results are shown in Fig. 3.

Analytical performance of the electrode

Stability of electrode potential with time was studied ([EPH] = $10^{-4}M$). A drift of 2.3 mV was formed in 24 hr and it is mainly due to the temperature changes.

The response time of electrode (t_R) depends on EPH activity, ranging from 1 min (for [EPH] $\geq 10^{-3}M$) to 5 min (for [EPH] $< 10^{-3}M$). Influences on the electrode response are time and speed of stirring before potential measurement, ionic strength, air bubbles in the membrane of the EPH electrode or reference electrodes, etc. The appropriate control of these variables shortens the response time of the electrode.

The reproducibility (10 replicate determinations) in the determination of $10^{-3}M$ EPH was also studied. The coefficient of variation was 0.54%.

The electrode was stored dry if not in use. Otherwise it deteriorates and its performance impaired. Kept dry, electrode life time was about 21 days. Nevertheless, conditioning of electrode before use for 1 h in a solution $10^{-3}M$ of EPH is essential. Otherwise, the response time is long and the reproducibility is poor.

The electrical resistance of the electrode was measured. The total resistance of the EPH electrode was approximately 10 MW.

The principal analytical characteristics of the EPH electrode were calculated. Employing an ionic strength $\leq 0.01M$ as ionic strength adjustment, the sensitivity (determined by the slope of the calibration graph) was 58.2 ± 0.5 mV (10 different electrodes made) within the concentration range 10^{-2}–$5 \times 10^{-5}M$ and the detection limit calculated according to the IUPAC

Table 1. Effect of ionic strength on the response of the EPH electrode

Ionic strength (M)	Slope ($mV\ decade^{-1}$)	Linear range ($pEPH$)	Detection limit ($pEPH$)
<0.01	59.9	2–4.3	4.5
0.01	58.4	2–4.3	4.5
0.05	52.5	2–4.0	3.7
0.10	44.8	2–3.3	3.7

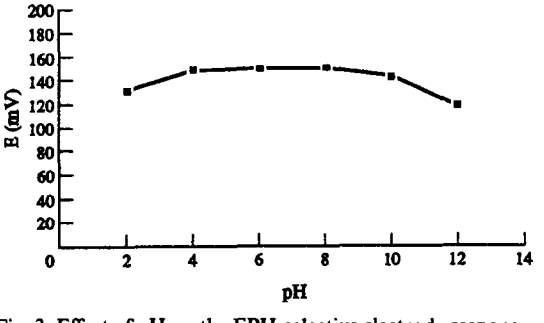

Fig. 3. Effect of pH on the EPH-selective electrode response.

Table 3. Results obtained in the determination of ephedrine in some pharmaceutical preparations

Drug	Certified value (*mg*)	Calibration graph		Standard addition	
		EPH calculated	Standard deviation (%)	EPH calculated	Standard deviation (%)
Tedral	48.0	49.3	2.7	48.9	1.8
Amidrín	8.0	7.6	1.4	7.9	1.3
Toscal	12.5	12.7	1.5	12.7	1.7
Fluidín	1.0	1.0	4.0	1.0	1.5
Bisolvón	1.5	1.6	3.3	1.5	1.3

recommendation[9] is $10^{-4.5}M$ of EPH. The least-squares equation obtained from the calibration data is $E(\text{mV}) = 58.2\ \text{pEPH} + 2.4$ (coefficient of correlation, $R = 0.9999$).

The electrode was applied to the determination of ephedrine in some pharmaceutical preparations by its interpolation on the calibration graph and standard addition methods. In the case of Tedral (solid drug), a pill weighing approximately 0.46 g with 48 mg of EPH was weighed, ground in a mortar and dissolved directly with high purity water to 0.5 l in a volumetric flask. For the other pharmaceutical products (liquid drugs), high purity water of up to 100 ml was added to a volume of 10 ml of drug. The results obtained are given in Table 3 (mean of five determinations) and show a good agreement with the certified EPH concentrations.

POTENTIOMETRIC DETERMINATION OF CHLORIDES WITH AN "AIR-GAP" CYANIDE SENSOR

RYSZARD BARANOWSKI and TOMASZ KUBIK
Department of Analytical and General Chemistry, Silesian Technical University, PL 44-101 Gliwice, Poland

(*Received* 4 *October* 1991. *Revised* 19 *November* 1991. *Accepted* 9 *March* 1993)

Summary—A new electroanalytical method for determining chloride ions with an Air-Gap cyanide sensor system is described. The method is based on the reaction of chloride with mercury(II) cyanide in dilute sulphuric acid. This reaction leads to hydrogen cyanide which can be determined with an Air-Gap cyanide sensor. Optimum concentrations of mercury(II) cyanide and sulphuric acid were established and an analytical curve was prepared for 1×10^{-1}–$1 \times 10^{-5} M$ Cl^-. The slope of the calibration curve was equal to 62.8 mV/log C. The correlation coefficient (R) was equal to 0.9992. The method can determine chloride with good results in high saline solutions and in the presence of surfactants, which is in contrast to direct potentiometry with a chloride electrode. The method was applied for chloride determination in fuses used for initiating explosions. The chlorides were determined both in the raw materials used to prepare the fuse braids and in the other fuse components. Chloride was also determined in drinking water and river water. In dependence of source, chloride amount analyzed in drinking water was in the range 2.18–182.6 mg/l. and 25.8 mg/l. in river water. A comparative analysis was carried out. In the first case, chloride was determined by a turbidimetric method, whereas in the second one by potentiometric titration against a chloride–ISE.

The chloride anion occurs widely in nature. Small quantities of chloride present in natural water and soils are necessary for plants and animals to function correctly. Chlorides participate in oxygen release in photosynthesis, increase hydration of colloids, and influence water balance in plants. They act as a stimulant on plants by influencing the swelling of plasma colloids. The plants absorb chloride from a soil solution through their root system. Chloride anion content in plants is variable and depends on the plant species and organs.

Mechanical processing of plant raw materials such as flax and hemp used in the textile industry removes only adsorbed chlorides. Chlorides as components in cellular plasma and combined in organic compounds are not removed during processing. Flax and cotton fibres are contained in fuses used to initiate explosion, when construction elements in high pressure industrial boilers for the nuclear power industry are connected. Due to the corrosive action on construction materials, the fuse components contain as little chloride as possible.

For a number of plants, high concentrations of chlorides in soil are toxic. Potassic fertilizers, used for soil manuring, usually contain some of chlorides ballast. These excessive chloride concentrations can penetrate natural watercourses and reservoirs, considerably increasing their salination.

The natural environment, rivers and water underflows are permanently contaminated with some surfactants, coming from municipal and food industry wastes, which unfortunately are not completely biodegradable. The possibility of ion determinations in the presence of surface active agents has been considered in other works.[1–5]

The concentrations of the contaminants in the present work was selected based on actual amounts in environmental samples from Upper Silesia. Two potentiometric sensors, for chloride determination, were applied (an Ag_2S/AgCl cell and an Air-Gap cyanide sensor).

Many industrial electrochemical processes, *e.g.*, copper plating, nickel plating, metals electropurification, aluminum electropassivation, require constant chloride concentration. An excess of chloride leads to irregular build-ups on the electroplating surface (fir-tree crystal formation) so the quality of coppering surfaces gets worse. The presence of chloride causes the anodic dissolution velocity to increase. This way an increasing cathodic current density is possible while electroplating. The oxygen evolution

from the electrolyte solution and the passivation process of the anode is observed while the concentration of chlorides is too small. One method of aluminum electropassivation requires the Cl^- level to be less than 20 mg/l.[6] If Fe^{3+} is present, then Cl^- amounts as low as 4 mg/l. lead to formation of pits on the electropassivated aluminum surface.[6] Chloride determination in these baths was made with two ion-selective electrodes: $Ag_2S/AgCl$ cell and the Air-Gap cyanide sensor.

The method described in this paper consists of potentiometric determination of chlorides by applying an Air-Gap cyanide sensor system. Our studies were based on the reaction of mercury cyanide with chloride anions in sulphuric acid, described in the literature[7]

$$Hg(CN)_2 + 2H^+ + 2X^- = HgX_2 + 2HCN$$

where

$$X^- = Cl^-, Br^-, I^-, SCN^-.$$

Hydrogen cyanide is formed in this reaction. As a weak acid it diffuses from acid solution to the gaseous phase. We proposed to determine the evolving hydrogen cyanide by means of the Air-Gap cyanide sensor system. Therefore, studies have been carried out to determine the analytical parameters such as the concentrations of reagents taking part in the above reaction and the response time of the cyanide sensor.

Mercury(II) cyanide has a high stability constant $10^{34.7}$,[8] which is exploited in this method. In the literature, it is stated that this complex undergoes decomposition in sulphuric acid solution whose concentration exceeds $0.56M$.[9] The studies performed by other authors prove that a mercury(II) cyanide does not undergo decomposition in diluted acid solution even at an elevated temperature.[10] Besides sulphuric acid, other acids like tartaric, nitric, phosphoric were examined. It was found that they do not cause mercury(II) cyanide to decompose, but that the complex decomposes in diluted hydrochloric acid solution. Adding chloride, bromide, iodide or thiocyanate to $Hg(CN)_2$ solution in diluted sulphuric acid also caused decomposition of mercury(II) cyanide with hydrogen cyanide evolution.[10]

The design and principle of operation of the Air-Gap cyanide sensor system has been described in the literature.[11] The cyanide sensor has previously been used to determine cyanides at low concentrations and mercury.[9]

EXPERIMENTAL

Reagents

Analytical grade reagents and reagents and redistilled water were used in the studies. Mercury(II) cyanide was synthesized by a literature method.[12] From weighed samples of mercury cyanide, solutions with concentrations from 0.1 to 2.0% were prepared. Solutions of 0.1 and $0.3M$ sulphuric acid, $0.1M$ nitric acid, $0.01M$ silver nitrate and $0.1M$ sodium chloride were prepared. Sodium chloride solutions in concentrations from 0.01 to $10^{-5}M$ were obtained by successive dilutions from $0.1M$ stock sodium chloride solution. The electrolyte, $0.01M$ potassium dicyanoargentate in 1% methylcellulose, was buffered by addition of borax to pH 9.3.

The following reagents were used for investigating the influence of surfactants on chloride analysis:

—an anionic SULFAPOL (sodium alkylbenzosulphonate)

—a weak anionic ROKSOL (block copolymer made from ethylene oxide, propylene and polyoxyethylated alcohols phosphoric acid ester)

—a nonionic ROKANOL K-20 (made from addition of ethylene oxide to unsaturated fat alcohols)

—a cationic KAMINOX L-11 (alkylpolyoxyethylenemethylammonium sulphate).

Apparatus

The Air-Gap OCN-01 METRON cyanide sensor system and type CT1 ELFA-JOT magnetic stirrer with CP-311 ELMETRON microcomputer pH/mV meter were used. For turbidimetric determination of chlorides, a Spekol spectrophotometer with a TK Carl Zeiss Jena attachment was used. Chlorides were also determined by a potentiometric method using a CRYTUR chloride ISE or RADELKIS chloride ISE or Polish private manufacture chloride ISE and a Ag/AgCl reference electrode with electrolytic nitrate bridge.

Mineralization of the examined samples

The raw materials used to manufacture fuse braids and its components were mineralized in an oxygen-bomb calorimeter. Approximately 0.5 g samples were placed in a quartz crucible containing wire coil resistors. Wire ends were attached to electrodes. Redistilled water (5 ml), in which combustion products were absorbed, was placed in the bomb calorimeter. The bomb

calorimeter was filled with oxygen up to 2.5 MPa. After combusting the sample and cooling the bomb, the solution containing the mineralization products was quantitatively transferred to a 25-ml measuring flask.

Procedures

About 5 μl of electrolyte (potassium dicyanoargentate, see Reagents) was placed between an Ag/AgCl reference electrode and a silver electrode of the Air-Gap cyanide sensor system. Next, 1 ml of mercury(II) cyanide solution, 1 ml of standard sodium chloride solution or sample and 1 ml of sulphuric acid solution were pipetted into a 5-ml sample cell. The sample cell was then closed with a ground-in stopper. A magnetic stirrer was started. After 2 min, the stopper was replaced with the cyanide sensor connected to a millivoltmeter. The response time of the sensor was recorded, *i.e.*, the time elapsed from sensor insertion to the moment when the potential was constant for 1 min. The potential was read with a precision of 1 mV. Each measurement was repeated five times and the average value was calculated. After each measurement, the sensor was taken out of the sample cell, the electrode was rinsed with redistilled water, dried with filter paper and a new electrolyte portion was poured in. The sensor was kept in a vertical position in the neck of a 100-ml measuring flask containing about 50 ml of distilled water. After each measurement, the test solution was poured out of the sample cell. The cell was flushed with redistilled water, and then rinsed with methanol and thoroughly dried.

Turbidimetric determination of chlorides

Turbidimetry was applied to determine chlorides in raw materials for manufacturing the fuse braids and other fuse components after mineralization of the samples in a bomb calorimeter. The solutions were filtered by hard filters free of chlorides, and then chlorides were determined as AgCl using the Spekol spectrophotometer with TK attachment.[13]

Potentiometric titration of chlorides

Potentiometric titration was applied to determine chlorides in drinking and river water. The interfering species were removed from water samples,[14] and then the chlorides were titrated with 0.01M silver nitrate solution until the largest difference in potential was reached at a constant insignificant increase of the added titrant.

Preparation of investigation baths for analysis

The samples of copperizing and aluminum electropassivation baths were neutralized with 1M sodium hydroxide and then diluted 10-fold with distilled water. The sample of nickel electroplating baths was also diluted 10-fold, then an additional 100-fold with distilled water.

RESULTS AND DISCUSSION

The effect of mercury(II) cyanide concentration at constant concentration of sulphuric acid and chloride ions on the potential and response time of the Air-Gap cyanide sensor system was studied. Mercury(II) cyanide solutions with concentrations from 0.1 to 2.0%, 0.3M sulphuric acid and standard 0.1–10^{-5}M sodium chloride solutions were used in the studies. Figure 1 presents the relationship of sensor potential *vs.* mercury(II) cyanide solution concentration at a constant sulphuric acid concentration in standard chloride solutions from pCl = 1–5. For pCl = 1 to 3, the cyanide sensor potential decreases with increasing mercury(II) cyanide concentration from 0.1 to 0.5%. However, for mercury(II) cyanide solutions from 0.5 to 2.0% concentration, the cyanide sensor potential is constant. Hence, there is no need to use a mercury(II) cyanide solution, whose concentration exceeds 0.5%. It can be, therefore, expected that mercury(II) cyanide reacts quantitatively with chloride ions. When the effect of

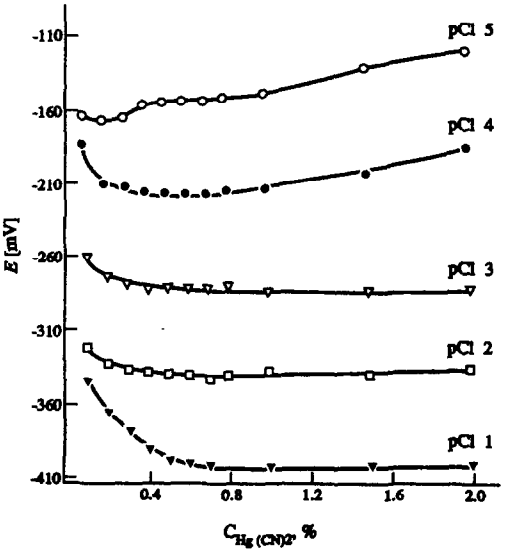

Fig. 1. The effect of mercury(II) cyanide concentration on the potential of the Air-Gap cyanide sensor.

$Hg(CN)_2$ concentration on a cyanide sensor response for chloride solutions of pCl = 4 and 5 was examined, a stable potential was observed in the more narrow concentration range of 0.4–0.8%. Due to these facts, a 0.5% $Hg(CN)_2$ solution was used in further studies. The effect of $Hg(CN)_2$ concentrations on the response time of the cyanide sensor was examined. Also in this case, 0.1–2.0% $Hg(CN)_2$ solutions, 0.3*M* sulphuric acid solution and chloride solutions from pCl = 1 to 5 were used. This relationship is illustrated in Fig. 2. For chlorides of pCl = 1 and 2, the increasing $Hg(CN)_2$ concentration did not cause any change in response time of the cyanide sensor. In each case, the response time was 2 min. The effect of $Hg(CN)_2$ solution concentration on the response time of the cyanide sensor for chloride solutions from pCl = 3 to 5 is more important. The shortest response times were recorded for $Hg(CN)_2$ solutions from 0.3 to 0.5% concentration. For higher concentrations, the response time was doubled. This study proved that the 0.5% $Hg(CN)_2$ solution is suitable for determination of chlorides.

The effect of sulphuric acid solution concentration on the replacement of cyanide ion by chloride ion with simultaneous evolution of hydrogen cyanide from a liquid phase to a gaseous one was investigated. The cyanide sensor potential was recorded *vs.* mercury(II) cyanide concentration at pCl = 3, for 0.3 and 0.1*M* sulphuric acid. The relationship is illustrated in Fig. 3. In case of 0.1*M* sulphuric acid, the measured cyanide sensor potentials dropped

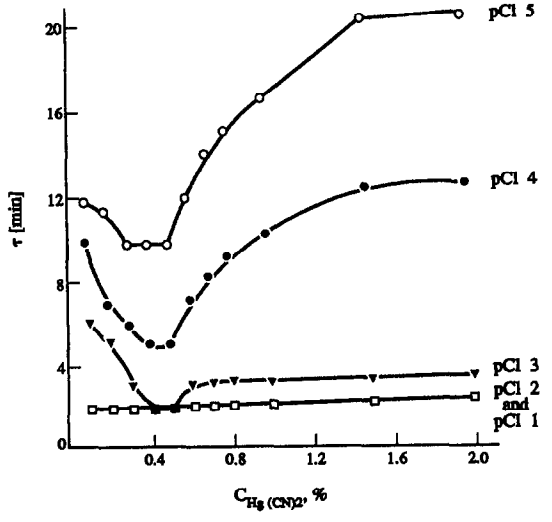

Fig. 2. The effect of mercury(II) cyanide concentration on the time response of the Air-Gap cyanide sensor.

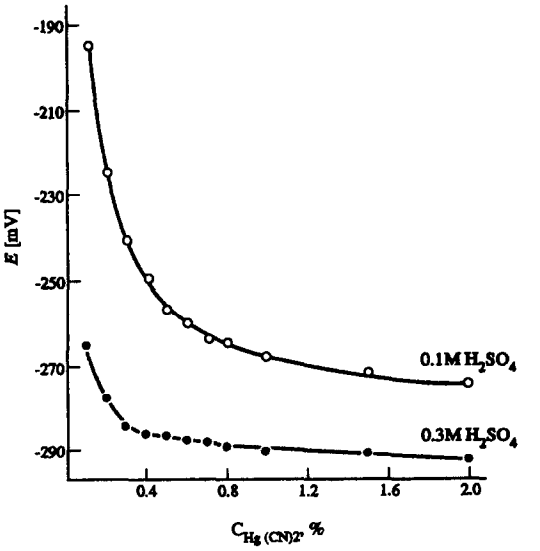

Fig. 3. The effect of mercury(II) cyanide concentration on the potential of the Air-Gap cyanide sensor in various sulphuric acid concentrations.

sharply with increasing mercury(II) cyanide concentrations. This potential became stable at a concentration above 1.6%, but with a prolonged response time. When a 0.3*M* H_2SO_4 solution was used, the potentials underwent slight variations within a wide range of concentrations from 0.4 to 2.0%.

As in this case, the application of >0.8% mercury(II) cyanide causes a considerable extension of sensor response time. The 0.5% solution is considered to be optimum.

The analytical curve for determining the chlorides within a concentration range of $0.1–10^{-5}M$ was plotted for a 0.5% mercury(II) cyanide solution. Its equation is $E = 62.8 \cdot pCl - 467.5$. A correlation coefficient of 0.9992 enables us to determine chlorides within a specified concentration range with high precision.

Studies were performed to define the effect of other ions on the determination of chloride. The results are collected in Table 1. Each ion was introduced to 35.5 μg/ml chloride solution at molar ratios of 1:1, 1:10 and 1:100.

The anions recorded in the table do not significantly affect the determination of chloride even at 100-fold excess. However, interferences are observed in the presence of halides and pseudohalides.

The suitability of the Air-Gap cyanide sensor system for determining chlorides is evaluated in Table 2 by comparing the results with a standard method. When chlorides are determined in raw materials for fuse braids and other

Table 1. Interferences from various anions [A^-] in determination of chloride anion (35.5 μg/ml)

Anion	SO_4^{2-}	NO_3^-	BO_3^{3-}	$H_2PO_4^-$	HPO_4^{2-}
$[A^-]/[Cl^-]$	1–100	1–100	1–100	1–100	1–100

components, the best conformity of the test results was achieved for chlorides in braid 2. This braid was cleaned before determination many times by repeated boiling in distilled water to remove chlorides adsorbed on the surface. Similarly, satisfactory agreement of the test results was achieved, when chlorides were determined in braid 3 by the two methods. In the remaining case, slight differences in determinations were found to be due to a distinct inhomogeneity of the tested materials.

Chloride was also determined in river and drinking water by the Air-Gap cyanide sensor and by potentiometric titration. The results in Table 3 show good agreement. Small differences lie within experimental error. A low chloride amount in water samples taken from a deep well, required, that titration with an ISE be carried out in a mixed solvent system whereas the newly developed method determine chlorides in aqueous medium with good accuracy, without additions.

The possibility of applying the Air-Gap cyanide sensor to chloride analysis in the presence of surfactants was studied. The analysis of chloride with widely available ISE ($Ag_2S/AgCl$) was made to compare the results obtained. Four surfactants were used for these studies: anionic, weak anionic, cationic and nonionic. The 0.1, 0.01 and 0.005% solutions of these agents of 35.5 mg/l. each, were investigated. Results are compiled in Table 4. The surfactants added to the analysed solutions considerably disturbs the results of chloride determination when the ISE was used, because of the influence of the surfactant on the membrane material. Only the nonionic surface active agent did not cause a negative interference. Chloride analysis with an

Air-Gap cyanide sensor in solutions containing surfactants was not subject to significant error. Good results are obtained because the Air-Gap electrode is not in contact with the solution.

The possibility of applying the Air-Gap cyanide sensor to chloride determination in copperizing, nickel electroplating and aluminum electropassivation was also studied. The results of chloride analysis with the Air-Gap cyanide sensor and an ISE in three of the electrolytic baths are shown in Table 5. These baths are equivalent to those applied in industry. Those baths contain high metal concentration, *e.g.*, copperizing baths contain 170–200 g of $CuSO_4 . 5H_2O$ in 1 l. and the nickel plating bath contained 250 g of $NiSO_4 . 7H_2O$ and 30 g of $NiCl_2 . 6H_2O$ in 1 l. In spite of 10-fold dilution, or 100-fold dilution in the case of the nickel bath, the concentration of anions and cations was so large that chloride analysis with ISE was impossible. A very large error was observed because of interaction between dissolved ions and the ion selective electrode membrane material. In the case of the Air-Gap cyanide sensor application, the chlorides were determined in solutions 1–3, with a relative error not higher than 5.6%. The other anions and cations present in the solution did not interfere because the sensor was not directly connected to the solution.

In an acidic (pH 1) solution of mercury(II) cyanide, when hydrogen cyanide was generated as a result of the reaction with chloride, the cyanide complexes of other metals cannot be formed, so measurements by the Air-Gap cyanide sensor were correct.

The above results show the advantage of the developed chloride method in high saline

solution as compared to direct potentiometry. Our investigations show that an Air-Gap cyanide sensor could be applied to chloride ion determination in such systems where the classical ion selective electrode action is disturbed by some active agents, *e.g.*, surfactants or highly concentrated electrolytes.

CONCLUSIONS

A new indirect electroanalytical method for determining the chlorides using the Air-Gap cyanide sensor system has been developed. It has a number of advantages. The method is quick, not requiring the expensive analytical equipment. Owing to simple construction, the cyanide sensor can be made at low expense, even in laboratories that are not equipped for regular manufacture of such equipment. The small dimensions of the sensor, measuring cell and magnetic stirrer permit analysis of trace chlorides in small volume solutions. The use of a milli-voltmeter and battery supplied magnetic stirrer enables the method to be performed in the field. This new method makes it possible to determine chlorides over a wide concentrations range *i.e.*, $0.1–10^{-5}M$.

The suitability of the Air-Gap cyanide sensor for chloride analysis in high saline solutions and surfactant-containing solutions was demonstrated in comparison to the direct method with ISE. The advantages of this method make it more competitive than other well-known methods. Furthermore, it extends the applicability of the Air-Gap cyanide sensor system used until now solely in the analysis of cyanides and mercury, to trace chlorides.

BOOK REVIEWS

Anionic Surfactants—Biochemistry, Toxicology, Dermatology: Second Edition, C. GLOXHUBER and K. KÜNSTLER (editors), Dekker, New York, 1992. Pages ix + 471. $160.00. ISBN 0-8247-8621-1.

This second edition includes significant amounts of new data and reflects the current thinking in the many areas which have been included. The material has been well structured into nine chapters with some major topics such as dermatological considerations appearing in many of these.

The first chapter covers the interaction of the anionic surfactants with proteins and their effect on enzymes and membranes is also discussed with numerous references being provided for further reading. The following three chapters include details of absorption, excretion, toxicity and tolerance studies again providing experimental techniques along with data and references for further reading. The fifth chapter which comprises a third of the total text gives extensive coverage of local tolerance in animal tests. It provides many tables of data for a large number of surfactants from different manufacturers, although there are others which are not covered.

Dermatological observations in humans is well presented in the next chapter with permeation and irritation being discussed in some detail. The number of references from the late 1980s indicates the current interest in this particular field. A review of test procedures and data for carcinogenic, mutagenic and teratogenic properties are then presented in Chapter 7. Again a tremendous amount of information is presented here in the appendices but the text does try to highlight the difficulties involved in the interpretation of such data in many cases. The final chapter on pharmacological properties presents some good examples but is rather brief and could have been expanded.

This is a rather specialized text and although certain areas may be of interest to many scientists the vast majority of the data presented will only be of real interest to those working or researching in this particular field. To these researchers however it may well prove to be a valuable reference source.

K. I. CUMMING

Voltammetric Determination of Molecules of Biological Significance: W. F. SMYTH, Wiley, Chichester, 1992. Pages x + 133. £35.00. ISBN 0-471-93345-7.

This short monograph offers a critical review of recent applications of electrochemical methods for determination of traces of organic, organometallic and inorganic molecules, mainly, but not exclusively, of biological interest. The main techniques included are differential-pulse polarography (DPP), square-wave voltammetry (SWV), anodic, cathodic and adsorptive stripping voltammetry (ASV, CSV and AdSV), electrochemical detection coupled with flow-injection analysis (FIA-ED), ion chromatography (IC-ED), and high-performance liquid chromatography (HPLC-ED), electrochemical immunoassay, and amperometric biosensors. The molecules are considered according to the hetero atom or functional groups they contain, namely, nitrogen, sulphur, oxygen, C—C multiple bonds, halogens, phosphorus, mercury, tin, lead and arsenic. Some inorganic molecules are also included. The critical assessment of methods includes comparisons with competing methods.

MARY MASSON

Successful Management of the Analytical Laboratory: O. I. MILNER, Lewis Publishers (Division of CRC), Boca Raton, Florida, 1992. Pages 162. £35.00. ISBN 0-87371-438-5.

According to the preface, the book " ... reviews the operation of an analytical laboratory from the standpoint of the manager's responsibilities ... and should be particularly helpful to relatively new and potential managers by defining problems they are likely to encounter and offering possible solutions to them".

There are 12 chapters. The first two deal, respectively with the functions and organization of a typical industrial analytical laboratory. Succeeding chapters deal with managerial problems related to staffing, management and development of personnel, communication (oral and written), employee safety and environmental concerns, sample handling, workload management, quality performance, budgeting the cost control, capital investments, and information management (LIMS).

There are three chapters which form the backbone of the book. The first two are, quite rightly, those devoted to staffing the laboratory, and managing laboratory personnel. In the former, the author writes at length on the process of recruitment, from advertisement of the post, through reviewing job applications, the interview and decision, to orientation of the new employee. In the latter, he concentrates on the motivation of employees, delegation of responsibility, communicating with employees, handling personnel problems, managerial power and control, performance evaluations, handling "marginal" employees (i.e., those who are willing but unable, those who are able but unwilling, and those who are in a rut) training and continuing education, and promotion of a subordinate. This chapter also contains seven of 17 short case histories, included to illustrate practical solutions to the kind of personnel and technical problems encountered in a laboratory.

The third main chapter is on quality performance. It is defined as " ... the generation of required information as accurately, rapidly, and inexpensively *as warranted by its intended use* ..." (*Sic*). The latter qualification is sometimes disregarded by chemists, whose scientific training has usually stressed the need always to be as accurate as possible. To

In the former, the author writes at length on the process of recruitment, from advertisement of the post, through reviewing job applications, the interview and decision, to orientation of the new employee. In the latter, he concentrates on the motivation of employees, delegation of responsibility, communicating with employees, handling personnel problems, managerial power and control, performance evaluations, handling "marginal" employees (i.e., those who are willing but unable, those who are able but unwilling, and those who are in a rut) training and continuing education, and promotion of a subordinate. This chapter also contains seven of 17 short case histories, included to illustrate practical solutions to the kind of personnel and technical problems encountered in a laboratory.

The third main chapter is on quality performance. It is defined as " ... the generation of required information as accurately, rapidly, and inexpensively *as warranted by its intended use* ..." (*Sic*). The latter qualification is sometimes disregarded by chemists, whose scientific training has usually stressed the need always to be as accurate as possible. To

some, the quote will be passed off as common sense, but I suspect to the majority of trainee and new managers, in particular those making the transition from bench science to the ranks of management, the voice of experience will come as a breath of fresh air.

This book is relatively short, but it is short and to the point. It is very well written indeed, interesting and easy to read, and pitched at the correct level for its intended readership. References at the end of each chapter are largely American in origin, but their U.K. or European equivalent should be quite obvious.

D. F. RENDLE

Emerging Strategies for Pesticide Analysis: T. CAIRNS and J. SHERMA (editors), CRC Press, Boca Raton, Florida, 1992. Pages 352. $74.95 (U.S.A.), $90.00 (elsewhere). ISBN 0-8493-7991-1.

This volume comes as part of a series on 'Modern Methods for Pesticide Analysis' and contains 16 chapters in three sections. The first section (Chapters 1–3) covers extraction and clean-up, the second section (Chapters 4–9) covers multi-residue analysis and the third section (Chapters 10–16) covers emerging techniques.

The 'Development of Microextraction Methods in Residue Analysis' covers an old subject in a fresh and enlightening way. Analysts rarely refer to the extraction theory to predict the efficiency of the method. This chapter redresses that balance by giving clear guidelines on the microextraction techniques that can be used for a wide range of polarity of solute and solvent mixtures. The chapter on solid-phase partition is only an overview and is rather limited in detailed information. Likewise Chapter 3 on 'Supercritical Fluid Extraction' is a useful overview, but, in a book on emerging strategies, more space could have been devoted to the very important area.

Chapters 4–7 and Chapter 9 cover specific multiresidue methods for specific groups of pesticides in foodstuffs and environmental matrices. They are primarily a review of current practices rather than 'emerging techniques', but nevertheless are a valuable contribution to our knowledge on the current state of the art. The 'Multi-residue Analysis of Fruit and Vegetables' (Chapter 4) covers the basic requirement in a method to comply with monitoring and regulatory requirements. Chapters 5 and 9 cover more specific areas of carbamate analysis in foodstuffs and headspace analysis for dithiocarbamates, while Chapters 6 and 7 include methods for the determination of organophosphorus pesticides in water, soil, sediment and biological samples, and the multiresidue methods for organonitrogen pesticides. Each of these chapters are well written and, collectively, are useful overviews of present methodology.

Chapter 8 on two-dimensional gas chromatography should, in my view, be placed in the section on emerging techniques, but this should in no way detract from the value of this contribution. It reports the recent developments well and gives a broad spectrum of examples in an area where this technique has been invaluable in the identification or confirmation of the determinand. It does not, however, discuss the difficulties associated with obtaining good quantitative data, particularly with the use of internal or surrogate standards, in the 'heart-cut' mode.

Chapter 10 covers 'Fibre Optic Spectroscopy', Chapter 11 'Enzyme Linked Competitive Immunoassay' and Chapter 12 Ion-Trap Mass Spectrometry'. Each of these contribution are short overviews which perhaps do not do justice to the extensive literature on these subjects, and I missed any attempt to evaluate the use of these techniques in the future. Chapters 13 and 14 cover 'Hyphenated Methods' and 'Liquid Chromatography–Mass Spectrometry' which gave an alternative approach to much of the information given in the previous 'compound orientated' chapters. Chapter 15 gave an overview on 'Immunochemical Methods' and contained a small section on 'Emerging Concepts'.

The book is well written by many of the relevant authorities in their field with good examples of recent work; however, I think that some of the chapters appear in the wrong place. It is a valuable reference for anyone wishing to grasp the present state-of-the-art in pesticide analysis, but the title of 'Emerging Strategies' and the actual content of the book do not altogether lie well with each other.

D. E. WELLS

Basic Solid State Chemistry: A. R. WEST, Wiley, Chichester, 1988 (reprinted 1991). Pages x + 415. £17.50 (softcover). ISBN 0-471-91798-2.

Professor Tony West has produced a succinct text covering the basics of solid state chemistry which is suitable for students, teachers and practitioners. It is clear that this book has been written by an author with great enthusiasm for his subject area.

As expected the emphasis throughout is on inorganic structures and explanations are generally descriptive rather than rigorously mathematical. As molecular structures are three-dimensional, numerous figures are used to aid the concepts of crystal packing arrangements. I believe computer programs and hand held models are very useful in this context and the author has included templates for the tetrahedral and octahedral structures in the Appendices along with details of constructing packing arrangements with polystyrene balls.

There are eight chapters which cover topics that might well be incorporated into eight separate books! The first three chapters cover crystal structures, bonding in solids, and crystallography and diffraction techniques. Other techniques are then explained; microscopy, spectroscopy and thermal analysis. Crystal defects, non-stoichiometry and solid solutions are introduced from both theoretical and practical viewpoints. Interpretation of phase diagrams are restricted to one- and two-component systems.

The final two chapters cover electrical properties, and magnetic and optical properties. Here the explanations of observed phenomena are supplemented with details of the relevance of properties such as superconductivity to current and future technology.

some, the quote will be passed off as common sense, but I suspect to the majority of trainee and new managers, in particular those making the transition from bench science to the ranks of management, the voice of experience will come as a breath of fresh air.

Details of further reading, restricted to text books, is given for each chapter and numerous questions (without answers) are included at the end of the book. An extensive index is included. The book is keenly priced and is an excellent introduction to solid state chemistry.

P. J. Cox

Electrochemical Oxygen Technology: Kim Kinoshita, Wiley, Chichester, 1992. Pages ix + 431. £105.00. ISBN 0-471-570-435.

The author has harvested most or all of the published information on the electrochemical reactions of oxygen and distilled it into a very useful, comprehensive, reference book. After a brief chapter on the physicochemical properties (solubility, diffusion, etc.) of oxygen species, the author discusses the reaction rates and mechanisms of oxygen reduction, at low and high temperatures, and of oxygen evolution, paying particular attention to the role of electrocatalysts. The third chapter deals with the types and structures of oxygen electrodes. The remaining chapters deal with the many applications of oxygen in electrochemical processes, such as those in fuel cells, metal/air and rechargeable batteries, and in industrial electrochemical processes.

The book is well constructed, comprehensive, up-to-date, and maintains the tradition of quality of the former books sponsored by the (American) Electrochemical Society. I recommend this book to all those, academic and industrial, involved in oxygen electrochemistry.

J. B. Craig

Preparative and Production Scale Chromatography: G. Ganetsos and P. E. Barker (editors), Dekker, New York, 1993. Pages xiv + 786. $195.00. ISBN 0-8247-8738-2.

Sometimes, when you ask a number of scientists to write chapters for a book on their own specialist subject, the total result can be very fragmented and a poor book may be produced. In this book, however, the editors, have carefully added introductions to most of the sections, which bind together the contributions from each individual author and make this a very practical, informative book that will be of great interest to anyone involved in separation science—from engineers to graduates.

The book covers all aspects of preparative chromatography from packed columns (with all the different separation processes of normal phase), reverse phase, size exclusion and ion exchange. Counter current and moving bed reaction chromatography are also covered. With the methods, real examples are given on separations and then further detailed studies are given on the separation of proteins, amino-acids and hydrocarbons.

The book, however, covers far more areas than the title would suggest by including sections on the theory of the chromatographic process, and extending this in other chapters to the modelling of the process. A very informative view is provided of the problems involved in taking a procedure from the analytical separation stage to both pilot scale and process scale separation. This makes the book an excellent practical reference guide that is suitable for the practitioner involved in analytical through to process scale chromatography. It will be welcomed in all disciplines from pharmacy to bioprocessing technology.

P. Myers

Spectroscopy of Advanced Materials: R.J.H. Clark and R.E. Hester (editors), Wiley, Chichester, 1991. Pages xix + 405. £133.00. ISBN 0-471-929-816.

The 19th volume of the *Advances in Spectroscopy* series by Clark and Hester is dedicated to the use of spectroscopic methods in the rapidly growing research field of advanced materials. A total of six chapters, by an international team of authors, review a wide field of advanced materials including charge transfer crystals, molecular conductors, non-linear optical polymers, thin film semi-conductors and polyconjugated materials. The battery of techniques, including vibrational, pulsed neutron, photoluminescence and photoexcitation spectroscopies, used to study these materials is discussed in depth. All chapters include references up to 1990 and most quote references up to 1991.

The use of infrared and Raman spectroscopy in materials science is discussed in Chapters 1 and 5, the former concentrating on strong charge transfer crystals and organic molecular conductors and the latter on investigating electrical phenomena in polyconjugated polymers, with particular attention given to the theoretical basis underlying the interpretation of data.

Non-linear spectroscopy of conjugated polymers is dealt with in Chapter 2, with detailed discussions on the effect of excited state structure on NLO spectra, third harmonic generation and the interpretation of two photon absorption spectra. Chapter 3 reviews the applicability of pulsed neutron spectroscopy to study advanced materials. The authors provide details on the experimental aspects of the technique before describing new work on magnetic transitions in rare-earth, actinide and 3*d* transition-metal systems and in following proton dynamics in molecular spectroscopy and tunnelling spectroscopy.

The characterization of thin-film semiconductors using photoluminescence spectroscopy is reviewed in Chapter 4, and covers the basic theory of the technique and its application to thin-film semiconductor systems based on GaAs, InP and ZnSe. Finally, Chapter 6 is devoted to the spectroscopy and photoexcitation spectroscopy of polyaninlines and related polymers, and provides a fundamental understanding of why these materials exhibit different behaviour compared to other polymers.

Overall, this is a well-written book and provides valuable information to researchers on the application of advanced techniques to investigate new materials.

R. Raval

Luminescence Spectroscopy of Proteins: E. A. PERMYAKOV, CRC Press, Boca Raton, 1993. Pages iv + 164. $79.95 (U.S.A.), $95.00 (elsewhere). ISBN 0-8493-4553-7.

The book by Permyakov is an excellent, *brief* summary of luminescence spectroscopy. For example, in 29 pages, the author covers an Introduction (Chapter 1—four pages), and fundamentals of luminescence including an introduction to quantum mechanics (Chapter 2—25 pages). The instrumentation is discussed in about four pages and is therefore extremely weak. The majority of the book is devoted to the spectroscopic properties of isolated protein chromophores (tryptophan, tyrosine and phenyl alanine) in Chapter 3 (20 pages) and to protein luminescence in Chapter 4 (130 pages) (position and shape of spectra, quantum efficiencies, fluorescence decay of proteins fluorescence parameters, intermediate states, the effect of temperature, pH, ionic strength and denaturants on protein fluorescence, the interaction of protein with low mass compounds, selective fluorescence quenching and low temperature luminescence). Chapter 4 is well-written with considerable useful information, concepts, and procedures and certainly makes buying the book worth while. The references seem incomplete; for example, there are only 31 references for Chapter 4 of which the majority of references refer to Burstein and/or Permyakov. Overall, the book is worth while, especially Chapters 3 and 4, reads well, and is worth purchasing despite its high price.

DETERMINATION OF MERCURY IN ZINC ORE CONCENTRATE REFERENCE MATERIALS USING FLOW INJECTION AND COLD-VAPOR ATOMIC ABSORPTION SPECTROMETRY

RAJANANDA SARASWATI,* CHARLES M. BECK and MICHAEL S. EPSTEIN†
Inorganic Analytical Research Division, Chemical Science and Technology Laboratory, National Institute of Standards and Technology, Gaithersburg, MD 20899, U.S.A.

(*Received* 22 *March* 1993. *Accepted* 21 *April* 1993)

Summary—A flow-injection, cold-vapor atomic absorption spectrophotometric method was developed for the determination of trace amounts of mercury in a proposed zinc ore concentrate Standard Reference Material (SRM 113b). The samples were digested with nitric and hydrochloric acids in closed Teflon digestion vessels. The experimental details for sample preparation and the flow injection method are discussed. The effect of matrix and various acid concentrations on the extraction and subsequent analysis of mercury were also studied. The method has a detection limit of 0.08 μg Hg/g in the sample. A certified reference material (CZN-1) was analyzed and the results obtained agreed well with the certified value.

Of the various techniques that have been developed for the determination of low mercury levels in geological and metallurgical samples, such as radiochemical neutron activation analysis, fluorescence spectrometry and cold-vapor mercury generation atomic absorption spectroscopy (CVAAS),[1-3] the latter is the most cost-effective and popular. Flow injection analysis (FIA) methodologies can be combined with CVAAS to improve the speed, precision, and sensitivity of that method even further. The concept behind FIA is to both miniaturize and automate large-scale and manual analytical procedures. FIA has been applied in many fields,[4-8] and its use is rapidly increasing because of the simplicity of the method.

The aim of the present work was to develop a rapid and accurate analytical method for the determination of mercury in a proposed Standard Reference Material (SRM) zinc ore concentrate (SRM 113b) by FIA and CVAAS. The method is based on the reduction of mercury ions by tin(II) followed by sweeping the free mercury atoms into an absorption cell and detection at 253.7 nm. FIA has recently been shown to be an efficient way to apply CVAAS to the determination of mercury.[9]

EXPERIMENTAL

Instrumentation

Absorption measurements were made using a commercial FIA system interfaced to an atomic absorption spectrometer. Specific information about the instrumentation and operating parameters is presented in Table 1. The FIA is computer-controlled with two peristaltic pumps, four switching valves, a sample injection loop, a mixing coil, and a liquid–gas separator. Dilute hydrochloric acid, 3% (v/v), is used in the carrier stream to sweep the sample from the injection loop to the mixing coil where it reacts with a solution of 1.1% (w/v) stannous chloride. The reaction produces free mercury atoms which are separated from the solution phase (in the liquid–gas separator) as an atomic vapor carried by argon gas. The argon gas stream sweeps the mercury vapor to a heated (200°C) quartz absorption cell mounted in the light path of a mercury electrodeless discharge lamp in the atomic absorption spectrometer. Because of the short residence time of the mercury atoms in the absorption cell, peak height measurements can be accurately used for quantification.

Reagents

High-purity acids obtained by a sub-boiling distillation process at NIST and high-purity de-ionized water (18 MΩ/cm) were used for preparing solutions. All glassware used for the

*On leave from the Defense Metallurgical Research Laboratory, Hyderabad, India.

†Author to whom correspondence should be addressed.

preparation and storage of solutions was precleaned by soaking in 20% nitric acid for 1 hr followed by a rinse with high-purity de-ionized water. Standard solutions of mercury were prepared by serial dilution of SRM 3133 (Mercury Spectrometric Standard Solution) to the required levels (1–10 ng Hg/g). The reductant solution was prepared by dissolving 11 g reagent grade stannous chloride ($SnCl_2 . H_2O$) in 30 ml of concentrated hydrochloric acid and subsequent dilution to 1 l by the addition of de-ionized water. Some batches of stannous chloride required filtering after dilution to obtain a particle-free solution. This was done using vacuum filtration through a 0.45 μm Millipore filter. Fresh reagent solutions were prepared daily.

Sample preparation

Two accurately weighed samples of approximately 0.25 g, were taken from each of four bottles of the zinc ore concentrate. Two samples of the control material, Certified Reference Material (CRM) CZN-1 were also taken. Samples of the zinc ore concentrate were dried at 105°C for 1 hr, and CRM CZN-1 was dried for 2 hr. Undried samples of the zinc ore concentrate were also analyzed to confirm that no mercury loss occurred during the drying procedure. Samples were placed in Teflon microwave digestion vessels, 2.5 ml of nitric acid and 2.5 ml of hydrochloric acid were added, and the vessels were capped to prevent vapor loss. The vessels were heated in a water bath at 60°C for 3 hr and then cooled to room temperature. The contents were then transferred to 250-ml volumetric flasks with the addition of 0.75 ml of 1% potassium dichromate solution as an oxidative stabilizing agent.

Analysis

Sample solution concentrations were determined by: (a) direct comparison to a calibration curve prepared using solutions from 1 to 10 ng Hg/ml that were matched in acid and stabilizer concentration to the samples and (b) the method of standard addition, in which a sample is diluted 1:1 with either a blank or a standard of known mercury concentration, and the recovery of the standard mercury concentration in the sample matrix is used to calculate the sample mercury concentration. Method (b) was repeated on three separate days for the results to be used for certification.

RESULTS AND DISCUSSION

Because of the extremely low mercury concentrations involved in these analyses, sample handling procedures were optimized to avoid mercury contamination. The closed digestion conditions used in this experiment not only reduced possible loss of mercury, but also dissolved the ore concentrate sample more rapidly than under the open digestion conditions used for a previous determination of zinc using an EDTA titration.

In order to determine the optimum acid concentration for the digestion and analysis, both the effect of acid concentration on (a) the FIA-CVAAS determination of mercury and (b) the extraction of mercury from the ore concentrate during the digestion had to be considered. The former would be correctable by the method of standard addition, although severe suppression of the mercury signal could drastically reduce the measurement precision. The latter was critical to the success of the experiment, since incomplete extraction of mercury from the matrix could not be tolerated.

The effect of acid concentration on the recovery of mercury in standards was first determined by varying one of the two acid concentrations while holding the other constant at 1% (v/v). The effects of varying either the nitric acid or the hydrochloric acid concentration are shown in Fig. 1. The acid concentrations shown on the x-axis are the percentage of acid in the final sample volume of 250 ml. The optimum concentrations of both acids appear to be in the 2%–3% range, with the hydrochloric acid concentration being the more critical. An excessive amount of hydrochloric acid is known to generate chlorine, which leads to the loss of volatile

mercury chlorides.[10,11] The effect of varying the concentration of a 1:1 mixture of the acids is shown in Fig. 2, with an optimum again around 2%.

The effect of acid concentration on extraction of mercury from the samples was then examined by digesting identical ore concentrate samples with varying concentrations of a 1:1 acid mixture. The results are also plotted in Fig. 2 to allow comparison to the effect of the acid concentration (described in the previous paragraph) on the generation of the mercury vapor using the FIA. The maximum mercury absorption signal was obtained when the acid mixture concentration was approximately 2–3% (corresponding to 5–7.5 ml of acid mixture and a sample weight of 250 mg in the digestion vessel). The lower recovery of mercury at acid concentrations less than 2% is likely to be caused by inefficient extraction during digestion. At higher concentrations of acid, the decreased signal is an interference on the generation of mercury using the FIA cold-vapor system. Apparently, the combination of sample matrix with the higher acid concentrations reduces the efficiency of mercury release. The optimum digestion time using a 1:1 mixture of acids at a concentration of 2% was found to be 3 hr, as shown in Fig. 3. A period of at least 3 hr of digestion at 60°C was required to extract all the mercury from the sample using a combined acid concentration of 2%.

The calibration curve prepared in the range 1–10 ng Hg/ml was linear. However, the method

The curves are normalized to the maximum signal for comparison.

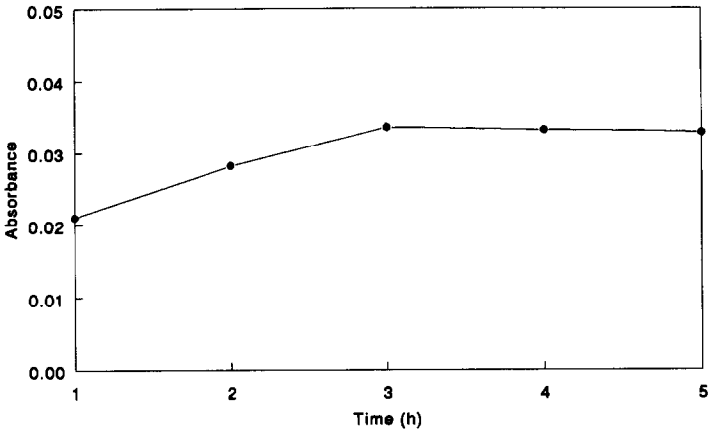

Fig. 3. Effect of digestion time on the signal for Hg in SRM 113b.

of standard addition revealed a suppression of the mercury signal of approximately 10% in the presence of the sample matrix. Therefore, all results are corrected for spike recovery. For the instrumental conditions used in this analysis, the detection limit, defined as the mercury concentration corresponding to three times the standard deviation of the blank, is 0.08 ng Hg/ml, corresponding to a detection limit in the sample of 0.08 μg Hg/g.

The accuracy of this method was tested by the determination of mercury in a certified zinc ore concentrate reference material (CRM CZN-1) produced by the Canada Center for Mineral and Energy Technology.[12] The analysis of this material yielded a value of 44.7 ± 0.1 μg Hg/g (95% confidence interval), in excellent agreement with the certified concentration of 43 ± 4 μg Hg/g. Analysis of the proposed NIST SRM zinc ore concentrate yielded a value of 0.55 ± 0.06 μg Hg/g (95% confidence interval).

Samples of both the zinc ore concentrate and CRM CZN-1 were analyzed with, and without, oven drying at 105°C. Weight loss on drying was 0.21% for CZN-1 and 0.06% for the zinc ore concentrate. No significant difference was observed in the mercury concentrations of dried and undried samples.

CONCLUSION

The high accuracy, precision, and sensitivity of the FIA-CVAAS system when combined with an optimized sample preparation method is apparent from the results obtained in this study. Acid concentration and digestion time are critical for efficient extraction of mercury from the ore concentrate or minimum matrix interference in the generation of mercury using FIA-CVAAS.

Summary—The behaviour of the copper complexes of glycyl–L-histidyl–glycine (GHG) was investigated using cyclic voltammetry and differential pulse voltammetry after their adsorptive accumulation on the surface of a hanging mercury drop electrode (HMDE). The nature of the observed cathodic and anodic peaks was established and optimum conditions were found for the differential pulse cathodic stripping voltammetric determination of GHG at the $1 \times 10^{-8} M$ concentration level using adsorptive accumulation at −0.20 V *vs.* Ag/AgCl reference electrode and the cathodic stripping peak around −0.4 V (pH 8.3). This peak corresponds to the reduction of the Cu(I)–GHG complex formed at the HMDE surface as an intermediate in the reduction of Cu(II)–GHG to Cu(O)amalgam.

The electrochemical behaviour of copper(II) complexes with various oligopeptides is of current interest since these substances mimic the specific Cu(II) transport site of several proteins. Using a small molecule, which represents a simplification of the natural binding site sequence of a larger molecule, it is possible to carry out many important studies which are not feasible with a protein molecule. It is well known that the stabilities of the copper(II) complexes of oligopeptides are considerably enhanced by the presence of a histidyl residue in position three[1–4] from the end of the peptide because of the formation of a very strong tetradentate chelate. In our previous paper[5] this fact was utilized in developing an extremely sensitive cathodic stripping voltammetric method for determining glycylglycyl–L-histidine. Similarly, the presence of the histidyl residue in the second position from the end of the peptide produces a strong tridentate chelate as is demonstrated in the case of glycyl–L-histidylglycine.[4] This tripeptide, because of its histidyl residue within the chain, is also important as a model for further studies of the basic interactions between proteins and copper ions.[4] For this reason the Cu(II)–GHG complexes have been investigated as useful models of copper–protein interaction both in solution[2–7] and in the solid phase[8] and it has been proved that copper(II) is coordinated via the 1-nitrogen of the imidazole ring and the nitrogen atoms of the peptide and amide groups.

Therefore, it is quite clear that the position of the histidyl residue in oligopeptide molecules may cause remarkable differences in both the modes of their complex formation and in their polarographic and voltammetric behaviour. There are relatively few papers on the polarographic behaviour of Cu(II)-oligopeptides.[8–12] The appearance of one predominant cathodic peak, which corresponds to the reduction of the Cu(II) complex to Cu(O)amalgam, has been reported for complexes with glycylglycylglycine,[10] glycyl–L-histidyl–L-lysine and glycyl–L-histidyl–glycine,[11] and glycylglycyl–L-histidine.[5,12] This is in agreement with the well known fact[10] that the electrochemical reduction of copper(II) preferentially occurs by two electrons to form Cu(O)amalgam. When

complexation stabilizes copper(I), however, this can give rise to a one-electron reduction of copper(II) occurring more readily than the two-electron reduction. This results in two successive and distinct single electron transfer steps being obtained, as has been reported for copper(II) complexes of histidine and β-alanyl–L-histidine.[13] Our previous studies on the cathodic stripping behaviour of copper(II) complexes of imidazole,[14] histidine[15] and glycylglycyl–L-histidine[5] have led to extremely sensitive methods for the determination of copper(II) and the latter two biologically significant organic substances.

So far, no detailed study of the cathodic stripping behaviour of the copper complexes of glycyl–L-histidylglycine (GHG) has been reported. For this reason the present study was carried out and its results are reported with the aim of increasing the understanding of the electrochemical behaviour of these biologically interesting systems and of developing a sensitive method for the cathodic stripping voltammetric determination of GHG which is itself polarographically inactive.

EXPERIMENTAL

Apparatus and reagents

Cathodic stripping voltammetry was carried out with a Metrohm 626 Polarecord and a 663 VA-Stand, or with a Metrohm 646/647 VA Processor, using a multi-mode electrode in the HMDE mode. The three-electrode system was completed by means of a glassy carbon auxiliary electrode and an Ag/AgCl (3*M* KCl) reference electrode. All potentials given are relative to this Ag/AgCl electrode. The cyclic voltammetric experiments were carried out by connecting the electrodes on the Metrohm 663 VA-Stand to a PAR 174A polarographic analyser (Princeton Applied Research); the multimode-electrode (HMDE) was still activated by means of the Metrohm 626 Polarecord.

Supporting electrolytes and buffers were prepared using analytical grade reagents supplied by BDH. A $1 \times 10^{-2}M$ solution of glycyl–L-histidylglycine was prepared by dissolving precisely weighed amounts of pure substance supplied by Sigma in 5 ml of 0.2*M* HCl using sonication. It was kept in a refrigerator and prepared freshly each day. Standard solutions of copper(II) were prepared by diluting SpectrosoL atomic absorption standard solution (BDH). Stock solutions of copper(I) were prepared by dissolving copper(I) chloride in hydrochloric acid according to Svehla.[16] Hydrogencarbonate supporting electrolyte solution (0.1*M*) was used for voltammetric measurements at pH 8.3.

Procedures

The general procedure used to obtain cathodic stripping voltammograms was as follows. A 20 ml aliquot of 0.1*M* hydrogencarbonate supporting electrolyte solution was placed in a voltammetric cell and the required amounts of standard GHG and copper(II) solutions were added. The stirrer was switched on and the solution was purged with nitrogen for 5 min. After forming a new HMDE, accumulation was effected for the required time at the appropriate potential while stirring the solution. Maximum drop size and stirrer speed were used throughout with the Metrohm 626 (medium drop size—nominally 0.40 mm^2—with the 646). At the end of the accumulation period the stirrer was switched off, and, after 20 sec had elapsed to allow the solution to become quiescent, a negative potential scan was initiated between the accumulation potential and −0.8 V. When the adsorptive accumulation was carried out at more negative potentials, the potential was changed immediately to −0.1 V from where a negative potential scan was initiated.

Cyclic voltammetry was carried out either immediately after forming a new HMDE or after preceding accumulations at different potentials for different times while stirring the solution. Either negative or positive scans were initiated after accumulation depending on the potential of accumulation. Sampled direct current polarography was performed using the static mercury drop electrode (SMDE) mode with drop time 1 sec and scan rate of 5 mV/sec.

In carrying out medium exchange experiments the PAR 174A instrument was switched to 'off' on the front control panel whilst the solution was being changed: this puts the cell onto open circuit. The cell was reconnected with the accumulation potential being applied.

RESULTS AND DISCUSSION

GHG was found to be electroinactive over the pH range of 5–12 in which range the 1:1 complex is known to be formed.[1-7,17] Sampled DC polarography of a solution containing $1 \times 10^{-4}M$ copper(II) and a five-fold excess of GHG gave two waves which are not well separated at higher pH. Takehari and Ide[11] reported

only a single two-electron reduction process for copper(II)–GHG on the basis of orientative cyclic voltammetry measurements. However, they used equimolar solutions of copper(II) and GHG with relatively high net concentrations of the complex. Under these conditions the two steps mentioned above probably coalesce into one two-electron step. In a $0.1M$ $NaHCO_3$ solution containing $1M$ KCl, which stabilizes Cu(I), the second wave increased after addition of Cu(I) chloride solution prepared according to Svehla,[16] thus confirming that it corresponds to the reduction of the Cu(I)–GHG complex to Cu(O)amalgam. Two main peaks were observed in differential pulse polarograms of a solution containing $1 \times 10^{-4}M$ Cu(II) and $5 \times 10^{-4}M$ GHG, their peak potentials shifting in this pH range from -0.15 to -0.20 V and from -0.36 to -0.47 V. These potentials correspond to the half wave potentials of the above mentioned DC polarographic waves. At a lower pH, a peak at -0.07 V corresponding to reduction of uncomplexed copper(II) was also observed. A polarographic maximum appeared around neutral pH: this was easily removed by the addition of Triton X-100. The best developed, and highest, peaks were observed at pH values of approximately 8. Therefore, further studies were carried out using $0.1M$ hydrogencarbonate supporting electrolyte (pH 8.3). The formation of the 1:1 Cu(II):GHG complex at pH 8.3 was confirmed by the fact that the height of the polarographic wave of a $1 \times 10^{-5}M$ solution of uncomplexed copper(II) decreased to one half of its original value in the presence of $0.5 \times 10^{-5}M$ GHG and disappeared completely in the presence of $1 \times 10^{-5}M$ GHG.

Cyclic voltammetric behaviour of copper complexes of glycyl–L-histidyl–glycine

The effect of GHG concentration on the cyclic voltammograms of Cu–GHG complexes after preceding accumulation at -0.6 V in a pH 8.3 hydrogencarbonate supporting electrolyte, is shown in Fig. 1. Three cathodic and three anodic peaks are observed, the exact position and heights of which depend on both the GHG and Cu(II) concentrations, the accumulation potential and the accumulation time, and on the scan rate, direction and switching potentials of subsequent cyclic voltammetric scans. On the basis of the cyclic voltammetric behaviour of free copper(II) (in the absence of GHG) under these conditions, the first cathodic peak at -0.12 V can be assigned to the reduction of free copper(II) to copper(O)amalgam, while the most positive anodic re-oxidation peak at -0.07 V can be assigned to re-oxidation of Cu(O)amalgam back to free copper(II). On the basis of the DC and DP polarographic behaviour of the Cu(II)–GHG complex, the second cathodic peak around -0.2 V and the third cathodic peak around -0.4 V can be assigned to a stepwise one electron reduction of the Cu(II)–GHG complex to the Cu(I)–GHG complex (peak around -0.2 V), followed by the reduction of the Cu(I)–GHG complex to Cu(O)amalgam (peak around -0.4 V). The morphology of the observed peaks and their dependence on the scan rate suggest that the first cathodic and the most positive anodic peak correspond to diffusion-controlled processes, while the second and third cathodic peaks and

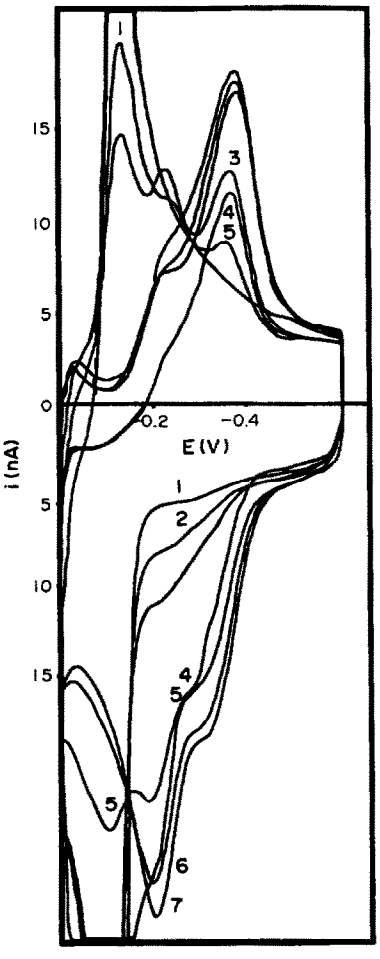

Fig. 1. Effect of GHG concentration on the cyclic voltammograms of Cu–GHG complexes: $1 \times 10^{-6}M$ Cu(II); pH 8.3; scan rate 50 mV/sec; accumulation potential -0.6 V; accumulation time 2 min in stirred solution; [GHG]: (1) 0; (2) 2.5×10^{-6}; (3) 5×10^{-6}; (4) 1×10^{-5}; (5) 2×10^{-5}; (6) 3×10^{-5}; (7) 4×10^{-5}.

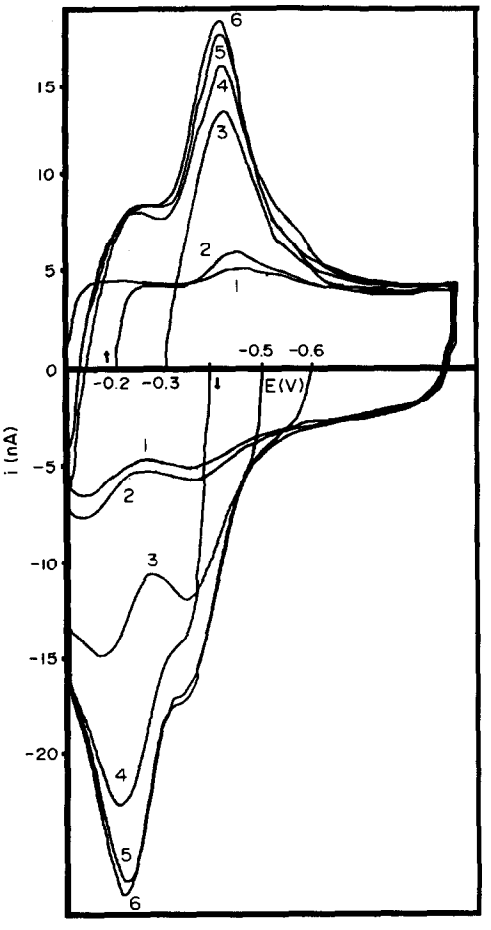

Fig. 2. Effect of accumulation potential: $1 \times 10^{-6}M$ Cu(II); $1 \times 10^{-5}M$ GHG; pH 8.3; scan rate 50 mV/sec; accumulation time 2 min in stirred solution; accumulation potential: (1) −0.1 V; (2) −0.2 V; (3) −0.3 V; (4) −0.4 V; (5) −0.5 V; (6) −0.6 V. The arrows show the direction of the scan initiated after the accumulation step.

the remaining anodic peaks correspond to the reduction and oxidation of adsorbed species.

The above assignment of the observed cathodic peaks is in agreement with the reported electrochemical evidence for the formation of the copper(I) complexes as intermediates in the reduction of Cu(II) complexes of glycine[18] and of histidine and carnosine[13] and with the polarographic behaviour of the copper(I)–histidine complex.[19]

The effect of accumulation potential on the cyclic voltammograms obtained is shown in Fig. 2. The third peak around −0.4 V was very small at accumulation potentials more positive than −0.3 V, which supports the assumption that it corresponds to a species formed at the electrode surface at potentials between −0.2 and −0.3 V (increasingly near −0.3 V). Furthermore, it is clear that during accumulation at −0.1 and −0.2 V no Cu(O)amalgam is formed as the anodic peak at −0.07 V is absent during the subsequent anodic scan. This is not apparent from Fig. 2 as the potential −0.07 V is out of the range shown. Therefore, the product of the reduction of Cu(II)–GHG complex at −0.2 V is not Cu(O)amalgam, and this was further proved by an experiment with medium exchange. In this experiment, after accumulation at −0.25 V in a solution containing $1 \times 10^{-5}M$ GHG and $1 \times 10^{-6}M$ Cu(II), the HMDE was transferred to a solution containing only $0.1M$ $NaHCO_3$ supporting electrolyte and an anodic scan was initiated. No anodic peak that would have indicated the dissolution of Cu(O)amalgam could be detected. However, the peak around −0.4 V is clearly seen after accumulation at −0.25 V. This means that the species formed at −0.25 V is further reduced which supports our assumption that the second and third peaks correspond to stepwise one-electron reductions of the Cu(II)–GHG complex.

To establish the nature of the anodic peaks, a medium exchange experiment was carried out using an accumulation potential of −0.7 V. After accumulating in the presence of excess of GHG and transferring the HMDE into a solution containing only hydrogencarbonate supporting electrolyte solution, only the peak at −0.07 V corresponding to the re-oxidation of Cu(O)amalgam was observed during the subsequent anodic scan. Therefore, it can be assumed that Cu(O)amalgam is formed at −0.7 V, and that GHG is not adsorbed sufficiently strongly at this potential—repulsion of the negatively charged GHG molecule by the negatively charged HMDE surface would be expected—and is removed during medium exchange. This medium exchange experiment confirms that the third cathodic peak around −0.4 V can be assigned to the reduction of the Cu(I)–GHG complex to copper(O)amalgam in accordance with our previous finding. A similar medium exchange experiment using Cu(O)amalgam accumulated at −0.7 V in the absence of GHG followed by an anodic scan after addition of GHG clearly showed that the anodic peaks around −0.2 and −0.3 V can be assigned to a stepwise oxidation of Cu(O)amalgam to the Cu(II)–GHG complex via the Cu(I)–GHG complex.

The cyclic voltammograms in Fig. 3 show that accumulation at −0.7 V in a solution containing a 1:10 metal ion to ligand concentration ratio yields two reduction peaks at

−0.24 and −0.42 V and two related anodic peaks at about −0.19 and −0.36 V, which increase in height with collection time from 0 to 120 sec. The relative position of these cathodic and anodic peaks indicate a degree of irreversibility for both the Cu(II)–GHG/Cu(I)–GHG and the Cu(I)–GHG/Cu(O)-amalgam systems. A small shift in the more positive anodic peak from −0.16 to −0.22 V with increasing accumulation time can be explained by the increase of concentration of GHG at the HMDE surface. When the accumulation was performed at 0 V, only very small cathodic and anodic peaks were observed. The height of these peaks did not increase with increasing accumulation time thus confirming our findings on the nature of these peaks.

Multiple scan cyclic voltammograms after accumulation at −0.1 and −0.7 V are shown in Fig. 4. After accumulation at −0.1 V, only very small cathodic peaks were observed during the first cathodic scan (see Fig. 4(a)). The anodic peaks obtained during the first anodic scan were much higher than the cathodic peaks thus confirming our assumption that copper(O)-amalgam is accumulated during the scans at potentials more negative than that of the cathodic peak around −0.4 V. This assumption is further confirmed by the observed increase of all cathodic and anodic peaks with subsequent scans. It is possible that the Cu(I)–GHG complex can be formed at the HMDE surface not only as an intermediate in the reduction of the Cu(II)–GHG complex to Cu(O)amalgam but also via the reaction of Cu(O)amalgam with the Cu(II)–GHG complex. The decreasing height of all observed cathodic and anodic peaks with subsequent scans after accumulation at −0.7 V (see Fig. 4(b)) can be explained by the desorption of the accumulated species at the switching potentials which are sufficiently far away from the potential of the electrocapillary zero where maximum adsorption of the metal–peptide complexes would be expected to occur.

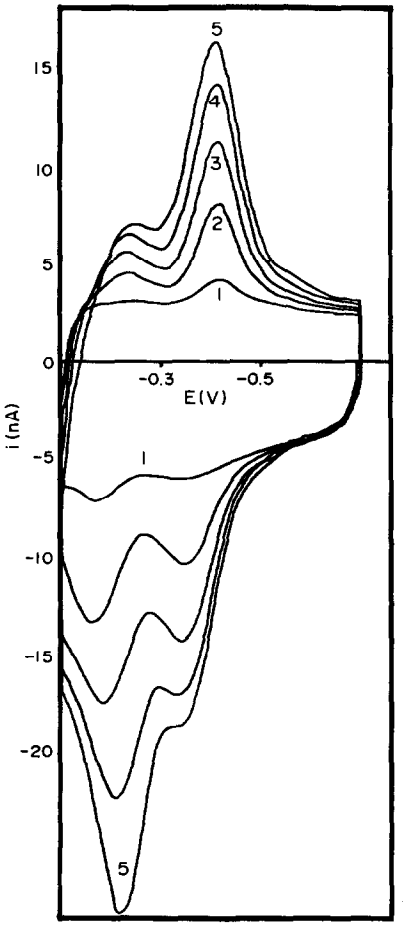

Fig. 3. Effect of accumulation time: $1 \times 10^{-6}M$ Cu(II); $1 \times 10^{-5}M$ GHG; pH 8.3; scan rate 50 mV/sec; accumulation potential −0.7 V; accumulation time: (1) 0; (2) 30; (3) 60; (4) 90; (5) 120 sec.

Differential pulse cathodic stripping voltammetric determination of glycyl–L-histidyl–glycine

Hydrogencarbonate supporting electrolyte solution (pH 8.3) was used for this determination as it gives a smaller background current in the presence of excess of copper(II). In a solution containing $1 \times 10^{-6}M$ Cu(II) and $1 \times 10^{-7}M$ GHG and using an accumulation potential of −0.2 V, the height of the peak around −0.3 V increases rectilinearly with accumulation time up to 3 min; the peak potential shifts from −0.27 to −0.31 V with increasing accumulation time. It should be noted that in the presence of $1 \times 10^{-6}M$ Cu(II) and an equal amount of GHG under otherwise identical conditions, the height of the peak around −0.32 V is not a linear function of accumulation time thus indicating that the HMDE surface is becoming saturated. Under these conditions, the peak potential shifts from −0.24 to −0.27 V for accumulation times increasing from 15 sec to 2 min. Note that the differential pulse voltammetric peaks are shifted towards more positive potentials compared with the cyclic voltammetric peaks in agreement with theory.[20]

On the basis of the above results, the following optimum conditions were chosen for the determination of GHG in the concentration region $(1 - 12) \times 10^{-8}M$: $0.1M$ $NaHCO_3$ (pH 8.3) as a base electrolyte, concentration of

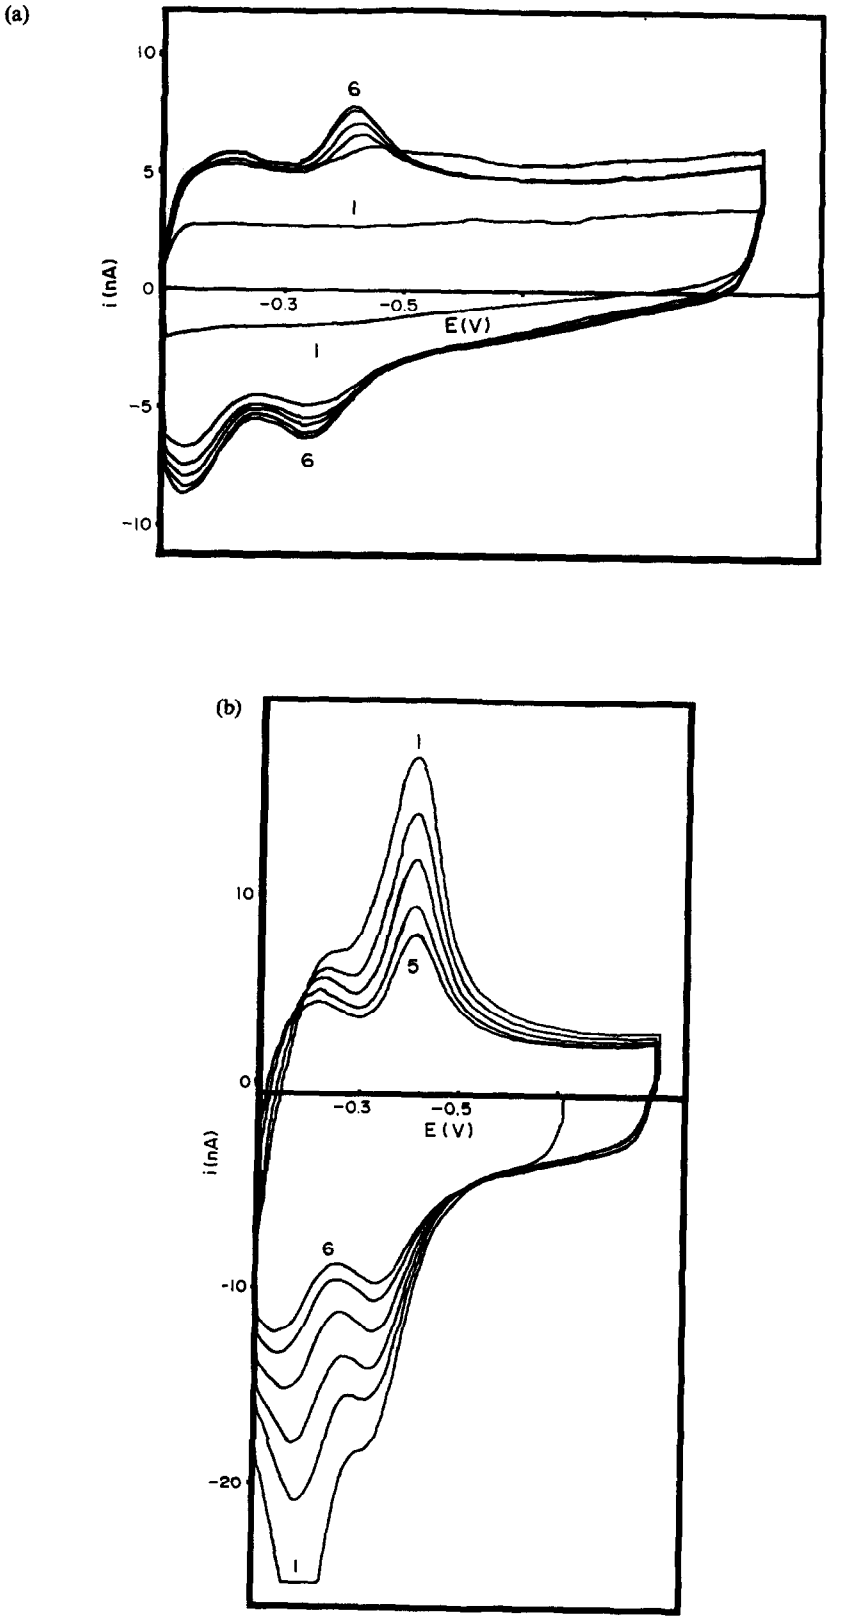

Fig. 4. Effect of accumulation potential on multiple scan cyclic voltammograms of the Cu(II)–GHG complexes: $1 \times 10^{-6}M$ Cu(II); $1 \times 10^{-5}M$ GHG; pH 8.3; scan rate 50 mV/sec; accumulation time 2 min in stirred solutions; accumulation potential -0.1 V (a) and -0.7 V (b). The numbers on the plots indicate the sequence of the scans.

copper(II) = $5 \times 10^{-6}M$, accumulation potential = -0.2 V *vs.* Ag/AgCl reference electrode, accumulation time = 2 min in stirred solution. The height of the peak at -0.37 V, which corresponds to the reduction of Cu(I)–GHG complex to Cu(O)amalgam, was measured. Calibration graphs obtained in this way after subtraction of the blank were rectilinear with a slope of 0.10 A/M and an intercept of 0.2 nA. Coefficients of variation at the $2 \times 10^{-8}M$ level were typically <3% (five determinations). The limit of detection calculated as three times the standard deviation of the determination of GHG at the $2 \times 10^{-8}M$ level was about $0.5 \times 10^{-8}M$. Typical differential pulse cathodic stripping voltammograms for obtaining a calibration graph for the determination of GHG are shown in Fig. 5. It should be noted that this method of determining GHG is not as satisfactory as that for determining GGH, which was described previously.[5] The peak currents obtained in the determination of GHG using the present method are much lower than those obtained for an equivalent amount of GGH, and the peak potential is at a less negative potential. Therefore in the present method at the $10^{-8}M$ level blank peaks can be quite high relative to the sample peaks. The blanks appear to be caused by traces of a complexable material in the buffers used. UV irradiation of suitable buffers to remove organic material might be tried to improve this situation.

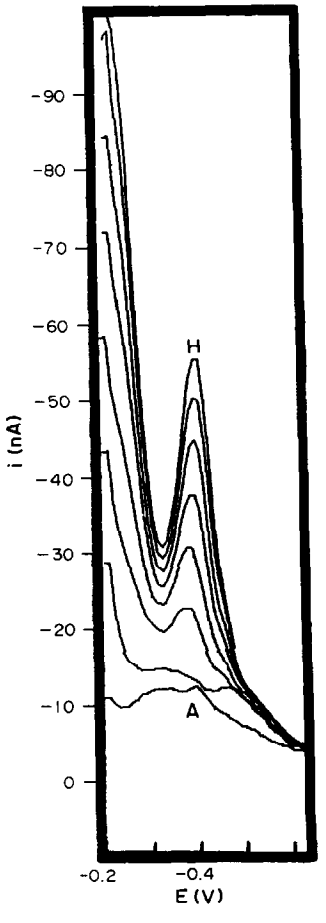

Fig. 5. Differential pulse cathodic stripping voltammograms obtained for preparing a calibration graph for the determination of GHG. Accumulation potential: -0.2 V; scan rate: 10 mV/sec; accumulation time: 2 min; A–I. 0.1M pH 8.2 hydrogen carbonate supporting electrolyte. B–I. $[Cu^{2+}] = 5 \times 10^{-6}M$. GHG concentration = C. $1 \times 10^{-7}M$, D. $2 \times 10^{-7}M$, E. $3 \times 10^{-7}M$, F. $4 \times 10^{-7}M$, G. $5 \times 10^{-7}M$, H. $6 \times 10^{-7}M$.

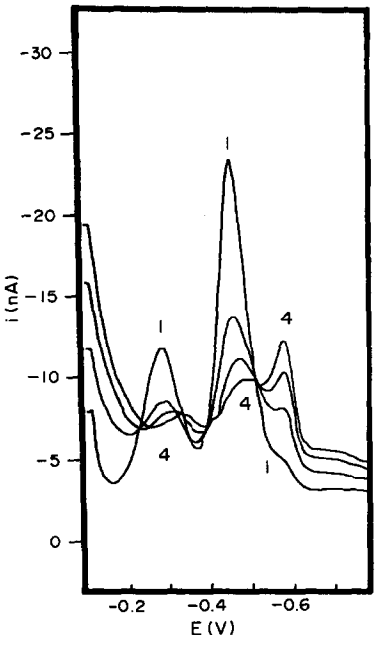

Fig. 6. Differential pulse cathodic stripping voltammograms of the Cu–GHG complexes at pH 10.5: $1 \times 10^{-6}M$ Cu(II); $1 \times 10^{-4}M$ GHG; 0.1M borate supporting electrolyte (pH 10.5); scan rate 50 mV/sec; modulation amplitude 50 mV; accumulation potential -0.1 V; accumulation time: (1) 0; (2) 15; (3) 30; (4) 45; (5) 60; (6) 75; (7) 90 sec.

Considerably different cathodic stripping voltammetric behaviour of the Cu–GHG complexes was observed at pH 10.5 (Fig. 6). Two peaks, at -0.29 and -0.46 V were observed without accumulation. However with increasing accumulation time these two peaks gradually disappeared as a third peak, at about -0.6 V, appeared. This mechanism has not been studied here, but clearly some change in the composition of the complex is occurring on the electrode surface. The presence of isosbestic points seems to indicate a conversion of one species into another single species.

CONCLUSIONS

The sampled DC polarographic, cyclic voltammetric and cathodic stripping voltammetric characteristics of the Cu–GGH complexes described above have some significant differences from those of the Cu–GHG complex investigated in our previous communication[5] in terms of the peak potentials and the relative position of the copper(I) and copper(II) peaks. Nevertheless, use of the peak around −0.4 V (copper(I) → copper(O)) provides a very sensitive method for the differential pulse cathodic stripping voltammetric determination of polarographically inactive GHG. The selectivity of this determination is limited by the interference of surface active substances, by polarographically active substances reducible around −0.3 V, and by substances which can form complexes either with copper (such as some amino acids[13,15] or peptides[10–12]) or with GHG (such as some other bivalent cations[1,17]). A preliminary separation step would be required in the presence of these interferents. Many model biological studies, however, are carried out in a simple matrix, and the voltammetric method developed here can provide a very sensitive tool for determining trace amounts of the GHG. Furthermore, it was confirmed by the present study, that cathodic stripping voltammetry can give us a useful insight into the redox behaviour of biologically interesting complexes of copper with various oligopeptides, when these are adsorbed on the surface of the HMDE. The HMDE can be considered to mimic a hydrophobic physiological redox site. It can be expected that further relevant information, clarifying the role of Cu(II)–peptides complexes in redox processes in biological systems, can be obtained in this way.

WATER–ORGANIC SOLVENT SYSTEMS IN COUNTERCURRENT CHROMATOGRAPHY: LIQUID STATIONARY PHASE RETENTION AND SOLVENT POLARITY

ALAIN BERTHOD* and NATHALIE SCHMITT
Laboratoire des Sciences Analytiques, UA CNRS 435, Université de Lyon 1, 69622 Villeurbanne cedex, France

(*Received* 11 *February* 1993. *Revised* 26 *March* 1993. *Accepted* 26 *March* 1993)

Summary—Countercurrent chromatography (CCC) is a separation technique in which the stationary phase is a liquid. The liquid stationary phase retention is a critical problem in CCC. The retention of 18 organic solvents in a hydrodynamic CCC apparatus was measured with an aqueous mobile phase, the centrifuge spin rate and the mobile phase flow rate being constant, 800 rpm and 2 ml/min, respectively. Conversely, water retention was measured when the 18 solvents were the mobile phases. A direct relationship between the liquid stationary phase retention and the phase density difference was found. The liquid phase density difference is the most important parameter for stationary phase retention in a hydrodynamic CCC apparatus with coiled tubes. The chromatographic retention of formanilide was measured in biphasic systems and expressed as the formanilide partition coefficient. It is shown that the partition coefficient correlates with the Reichardt polarity index of the organic solvent when the liquid stationary phase retention volume does not.

Countercurrent chromatography (CCC) is an emerging technique for preparative purification and extraction of a wide variety of solutes.[1–5] CCC is a technique in which the stationary phase is a liquid. The mobile phase is also a liquid.

The main advantages of CCC are (i) high loadability, (ii) unique selectivities and (iii) robustness. In classical liquid chromatography, the injected solutes can access only the surface of the solid stationary phase. In CCC, the whole volume of the liquid stationary phase is used for solute partitioning. Tannins (4.3 g) were separated in one run with a 180 ml CCC apparatus.[6] The chromatographic selectivity is due to solute partition between the two immiscible liquid phases. The combination of solvents that produces two-phase systems is almost infinite. It is possible to use two, three or more solvents, which means that it is possible to adjust the selectivity by additions of a solvent that has some affinity for the two phases of a biphasic system.[7] The robustness of CCC is due to the liquid character of the stationary phase. Overload and irreversible adsorption problems are common in preparative liquid chromatography. Irreversible adsorption cannot occur in CCC. If a solute is retained too long, it is possible to switch the phase role: the mobile phase becomes stationary and the liquid stationary phase is pushed out of the CCC apparatus with the solute.

Liquid stationary phase retention by the CCC "column" is the most important problem in CCC. The liquid stationary phase should be retained while the mobile phase is pushed through. Many CCC apparatuses contain a continuous open tube coiled on one or several spools which are rotated in a centrifuge. The centrifugal field holds the liquid stationary phase tightly so that the liquid mobile phase can be pumped through it. Stationary phase retention depends on the CCC apparatus design, the operating conditions and the liquid system used. More than 20 different CCC apparatuses were designed by Ito.[1–3,5,8] Most of them contain coiled Teflon tubing. The liquid stationary phase retention capabilities of these apparatuses are difficult to compare. A constant observation with different CCC apparatuses is that liquid stationary phase retention increases with the centrifuge rotation speed and decreases with the flow rate.[7] Liquid stationary phase retention also depends on the liquid system used. Ito and

*Author for correspondence.

co-workers studied the CCC retention behaviour of several liquid systems.[9-12]

This work presents the behaviour of water–organic solvent biphasic liquid systems. In CCC, the liquid stationary phase should be retained somewhat to obtain solute retentions and separations. First, a systematic study of liquid stationary phase retention was done by limiting the numerous parameters as follows: (i) only one CCC apparatus with coiled Teflon tubes was used; (ii) the spin rate was kept constant at 800 rpm; (iii) the mobile phase flow rate was 2 ml/min in all experiments; (iv) the biphasic liquid systems studied were made with two pure solvents only; and (v) one of the two pure solvents was water. In such conditions, the retention of 18 organic solvent stationary phases was measured with the aqueous phase being the mobile phase. The retention of the aqueous phase was also measured when the 18 different organic phases were the mobile phases. The collected data were compared to different physico-chemical properties of the binary liquid systems. Second, the retention of a solute, formanilide, expressed as the liquid–liquid partition coefficient, was studied and related to the organic solvent polarity.

EXPERIMENTAL

Chromatographic system

The CCC apparatus was the Model CPHV 2000 from Société Française de Chromato Colonne (SFCC, 95610 Eragny, France), which is a coil planet centrifuge apparatus first designed by Mandava and Ito.[2] It contains three multilayer coils connected in series spinning with a planetary motion around a central axis. A special gear arrangement is designed to avoid any rotary seal. The apparatus was described in a recent publication.[13] Each spool was filled with 133 turns of PTFE tubing, i.d. 1/16 in. (1.6 mm), length 26 m, coiled in seven layers of 19 turns. The Ito β value is the ratio of the coil radius, r, to the spool revolution radius, R. The β ratio was 0.37 for the first inner layer with $r = 2.2$ cm and $R = 6$ cm. It was 0.75 for the outermost visible layer with $r = 4.5$ cm and $R = 6$ cm. The average β value for this CCC apparatus was 0.56. The internal volume of one coiled spool was 52 ml. The three-coil apparatus had a total internal volume, V_T, of 158 ml. The whole system was housed in an air-thermostatted box. The temperature was regulated to 22 ± 0.5°C.

A Shimadzu LC6A pump was used to fill the CCC apparatus with the stationary phase and to push the mobile phase at a flow rate of 2 ml/min. A Shimadzu SPD-6A UV detector was used at 254 nm with a CR5-A recorder integrator.

Chemicals

The 18 solvents are listed in Table 1. They were obtained from Merck (Darmstadt, Germany), Fluka (Saint Quentin Fallavier, France), Prolabo (Paris, France) and Laurylab (Chassieu, France). Methyl-2-cyclohexanol acetate and trimethylbenzene (TMB or mesitylene, trimethyl-1,3,5-benzene) were industrial solvents (80% average purity) supplied by ELF-Atochem (Vernaison, France). Ethane trichloro-1,1,2-trifluoro-1,1,2 is also called Freon 113. Formanilide was used as a test solute of intermediate polarity and was soluble in many of the 18 solvents tested. It was supplied by MTM (Lancaster Synthesis, Strasbourg, France). Reichardt's dye, 2,6-diphenyl-4-[2,4,6-triphenylpyridinio]-phenolate inner salt, was obtained from Sigma (St Louis, MO, U.S.A.).

Physico-chemical measurements

Densities were estimated simply by weighing a known volume of the liquid phase. Surface tension and interfacial tension were measured using a Du Nouy Tensiometer (Krüss, Hamburg, Germany) with a 15 mm diameter platinum ring. The measurements were performed at 21 ± 0.5°C. The physico-chemical data of the pure liquids are listed in Table 1.

Method

The water–organic solvent was equilibrated overnight to obtain an aqueous phase saturated in organic solvent and a water-saturated organic phase. The apparatus was first filled with the liquid chosen to be the stationary phase. This took about 25 min at 8 ml/min flow rate. Next, the centrifuge was turned on up to a stable rotation speed of 800 rpm. The pump was rinsed with the mobile phase. The mobile phase was pushed into the apparatus at 2 ml/min. The mobile phase entered through the tail of the apparatus if it was lighter than the liquid stationary phase and vice versa. As long as the apparatus was not equilibrated, the stationary phase was pushed off the apparatus and collected in a graduated cylinder. Once the immiscible mobile phase appeared at the exit of the apparatus, two liquid layers were seen in the

M, molecular weight; b.p., boiling point; m.p., melting point; vap. P., vapour pressure; *d*, density; surf. t., surface tension; dielectric constant is dimensionless; dip. mom., dipole moment, at 20°C.

Data from C. Reichardt, *Solvents and Solvent Effects in Organic Chemistry*. VCH, Weinheim, Germany, 1988, and from R. Weast, *Handbook of Chemistry and Physics*, 67th edn. CRC Press, Boca Raton, FL, 1987.

graduated cylinder, and equilibrium was reached. The CCC "column" was then ready and the displaced liquid stationary phase volume was measured. This volume, V_0, corresponds to the mobile phase volume inside the apparatus. The stationary phase volume inside the apparatus, V_s, is:

$$V_s = V_T - V_0.$$

The stationary phase retention is quantified by:

$$\%\text{ret} = V_s/V_T \times 100.$$

The test solute, formanilide, was injected in aqueous solution. Its retention volume, V_r, is linked to its liquid–liquid partition coefficient, P, by:

$$V_r = V_0 + PV_s = V_T + (P-1)V_s.$$

The peak efficiency was roughly estimated using:

$$N = 4(V_r/W_{0.6h})^2,$$

in which N is the peak efficiency expressed in plate number and $W_{0.6h}$ is the peak width at 60% of the peak height.

RESULTS AND DISCUSSION

Table 2 lists the stationary phase retention for the two sets of experiments: water mobile phase, organic stationary phase and vice versa. The driving pressure indicated corresponds to the equilibrated CCC "column", *i.e.* mobile phase leaving the apparatus. The partition coefficient and peak efficiency of formanilide are also listed in Table 2. They will be used in the solvent polarity discussion.

Solvent stationary phase retention

The first set of experiments was to push the water phase through the different organic stationary phases. The solvent miscibility in water was low enough so that the aqueous phase density and viscosity were close to 1 g/cm^3 (Table 3) and 0.9 cP (not measured), respectively. The interfacial tension varied from 1.3 (butanol) to 44.8 dyne/cm (heptane, Table 3).

The highest retention percentage, 82%, was obtained with the chloroform stationary phase. Similarly high retention percentages, 81%, were obtained with methyl tert-butyl ether and Freon 113 liquid stationary phases. The lowest retention percentages, 12% and 16%, were obtained with tributylphosphate and dibutylphthalate. Table 1 shows that chloroform and Freon 113 have the highest densities; tributylphosphate and dibutylphthalate have density values close to unity. The density difference between the organic stationary phase and the aqueous mobile phase seems to be an important parameter for CCC liquid stationary phase retention. To calculate exactly the phase density difference,

Delta, Hildebrand solubility parameter in $J^{1/2}cm^{-3/2}$; E_0, solvent strength parameter according to Snyder; E_T, solvent polarity index according to Reichardt; interfacial tension measured in dyne/cm; density of the organic phase saturated in water and the aqueous phase saturated in solvent, accuracy 4%; capillary wavelength in cm, see text.

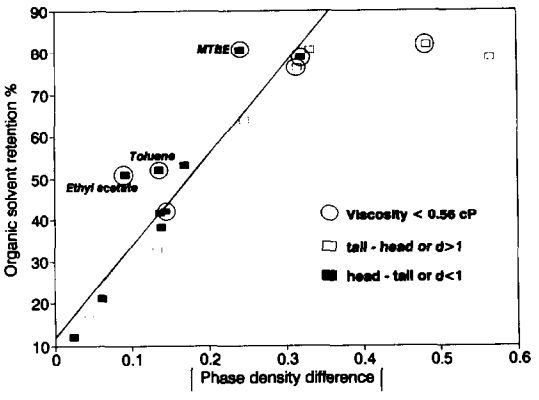

Fig. 1. Organic stationary phase retention percentage *vs.* the phase density difference. Flow rate: 2 ml/min; rotation speed: 800 rpm. Data listed in Tables 2 and 3. Closed squares: $d < 1$ solvents, the aqueous phase enters through the head of the CCC apparatus. Open squares: $d > 1$ solvents, see text. The circled points correspond to low-viscosity pure solvents (Table 1). The regression line equation is given in the text.

Δd, the density of both phases saturated in the other were measured (Table 3). The difference between pure solvent density and water-saturated solvent density is due to mutual solubility. If the water solubility in a given solvent is low, the saturated solvent density is very close to the pure solvent density (Table 3).

Figure 1 shows a plot of the organic solvent retention percentage, %ret, *vs.* the absolute value of the phase density difference, Δd. For absolute Δd values lower than 0.35, there is a linear increase of the retention percentage with Δd. The regression equation is:

$$\%\text{ret} = 222\Delta d + 11$$
$$(\pm 20)\,(\pm 8)$$
$$n = 16,\ r^2 = 0.876.$$

The retention percentage reaches a maximum of about 85% for Δd values higher than 0.40.

The circled points of Fig. 1 correspond to pure organic solvents with a viscosity lower than 0.56 cP (Table 1). The retention percentage of the stationary phase could be inversely related to the stationary phase viscosity. Multiple linear regression analysis of the data set was performed. However, it was not possible to establish a clear relationship between viscosity, density and stationary phase retention. Only the linear relationship density difference *vs.* percentage retention was confirmed. Three low-viscosity solvents, ethyl acetate, toluene and MTBE, have retention percentages higher than the regression line (Fig. 1). Four other low-viscosity solvents, chloroform, dichloromethane, heptane and MEK, are well fitted by the regression line (Fig. 1). A high viscosity of the stationary phase does not affect the retention percentage as illustrated by octanol and tributylphosphate, 7.4 and 3.4 cP, respectively, whose retention percentages are well located on the regression line.

The open squares of Fig. 1 correspond to solvents with a density higher than 1 g/cm^3. In a test tube, these solvents are the lower liquid phase. When the organic solvent is used as the stationary phase in CCC, water, the mobile phase, should enter through the tail side of the apparatus. The three low-viscosity solvents already mentioned and pointed out in Fig. 1 were also low-density solvents. This parameter may partly explain their higher than average retention percentages.

Water stationary phase retention

The next step was to push the organic phases through a water stationary phase. In this way, the mobile phase viscosity and density changed as listed in Tables 1 and 3. Figure 2 shows the plot of water retention percentage, %ret, *vs.* the phase density difference. The trend noticed in Fig. 2 is similar to that in Fig. 1: the water stationary phase retention percentage increases with phase density difference up to $|\Delta d| = 0.35$, where a plateau at percentage retention $\sim$85% is reached. However, the scattering of the data in Fig. 2 is much higher than that in Fig. 1. The

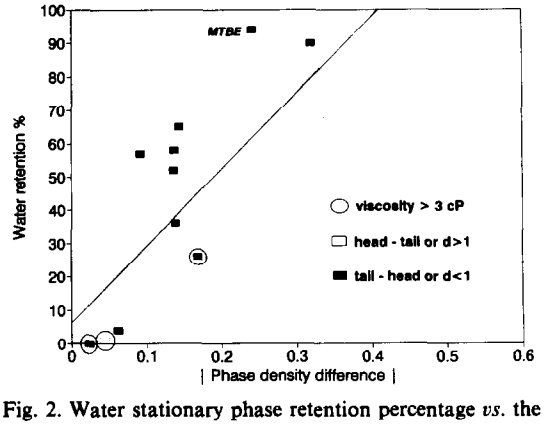

Fig. 2. Water stationary phase retention percentage *vs.* the phase density difference. Flow rate: 2 ml/min; rotation speed: 800 rpm. Data listed in Tables 2 and 3. Closed squares: $d < 1$ solvents, the organic phase enters through the tail of the CCC apparatus. Open squares: $d > 1$ solvents, see text. The circled points correspond to high-viscosity pure solvents (Table 1). The regression line equation is given in the text.

regression line was computed for $|\Delta d|$ values lower than 0.35:

$$\%\text{ret} = 230\Delta d + 6$$
$$(\pm 60)\,(\pm 20)$$
$$n = 16,\ r^2 = 0.540.$$

If the slope and intercept values are similar, the standard errors are too high and the regression coefficient is too low to be acceptable. With organic mobile phases and a water stationary phase, the stationary phase viscosity is almost constant. The circled points in Fig. 2 correspond to highly viscous (>3 cP) mobile phases. The corresponding water retention percentages seem to be below the regression line. For low-viscosity solvents, higher water retention percentages were obtained, *e.g.* methyl tert-butyl ether (MTBE, 0.27 cP) with a 94% water retention percentage. A viscous solvent seems to push more aqueous stationary phase out of the CCC apparatus than a low-viscosity solvent. As already noted, a low-viscosity liquid stationary phase is favourable for retention, although no direct relationship can be defined.

The same notation as in Fig. 1 was used. The open squares correspond to organic solvents denser than water. If water is the stationary phase, a denser liquid must enter the CCC apparatus through the head; a lighter liquid ($d < 1$) must enter the apparatus through the tail and leave it exiting out of the head. Ito has shown that the rotation of a coiled tube filled by a liquid produced a pressure difference between the two ends of the tube due to a "screw effect".[2,3] When two immiscible liquids are loaded in a coiled tube, the rotation also produces a pressure difference. For most binary liquid systems, the lighter liquid accumulates on the high pressure side of the rotating coil, called "head". The denser liquid is located on the low pressure side of the coil, called "tail", where it pushes the lighter liquid towards the head.[1-3] Table 2 lists the experimental pressures. For all solvents denser than water ($d > 1$ g/cm^3), the pressure is lower with the water mobile phase than with the corresponding organic mobile phase. With $d > 1$ organic phases, the water mobile phase entered the CCC apparatus through the tail, the lower pressure side. The corresponding organic phase entered through the head, the high pressure side. Head entering $d > 1$ organic solvents, the open squares of Fig. 2, produced a low aqueous phase retention compared to tail entering $d < 1$ organic solvents (closed squares, Fig. 2). Although the regression line shown in Fig. 2 is not really significant, the open squares ($d > 1$ solvents) are all located below the line and most of the closed squares ($d < 1$ solvents) are above. There was not such a difference when water was the mobile phase. Head or tail entering water phase had little effect on the organic solvent retention (open and closed squares, Fig. 1).

Capillary wavelength

The capillary wavelength, L_c, was recently introduced in CCC by Menet *et al.*[14] as a parameter related to solvent behaviour in coil planet centrifuge CCC apparatus as the one we used. The capillary wavelength is a relation between the interfacial tension, $\Delta\gamma$, and the density difference, Δd, of a biphasic liquid system:

$$L_c = \sqrt{\frac{\Delta\gamma}{\Delta d \times g}}.$$

L_c is expressed in cm, Δd in g/cm^3, and g, the gravity field, in cm/sec^2. In Table 3, the capillary wavelengths were calculated with $g = 981$ cm/sec^2 although the actual field at 800 rpm inside the centrifuge is higher. There is no direct relationship between the capillary wavelength and the phase retention percentage. A slight trend to a decrease of phase retention with L_c increases is due to Δd, as shown by Figs 1 and 2. There is no obvious relationship between interfacial tension (Table 3) and stationary phase retention (Table 2). It may be interesting to relate the capillary wavelength to solvent polarity.

Solvent polarity

The characterization of a solvent by means of its polarity is an unsolved problem, since the term "polarity" itself has, until now, not been precisely defined. Solvent polarity was linked to the permanent dipole moment of solvent molecules, the dielectric constant and/or the sum of selected molecular properties responsible for interaction forces between solvent molecules (*e.g.* coulombic, inductive, hydrogen bonding, electron pair donor/acceptor interaction forces).[15] Different polarity scales were established. Hildebrand linked solvent polarity to its solubilization capability defining the solubility

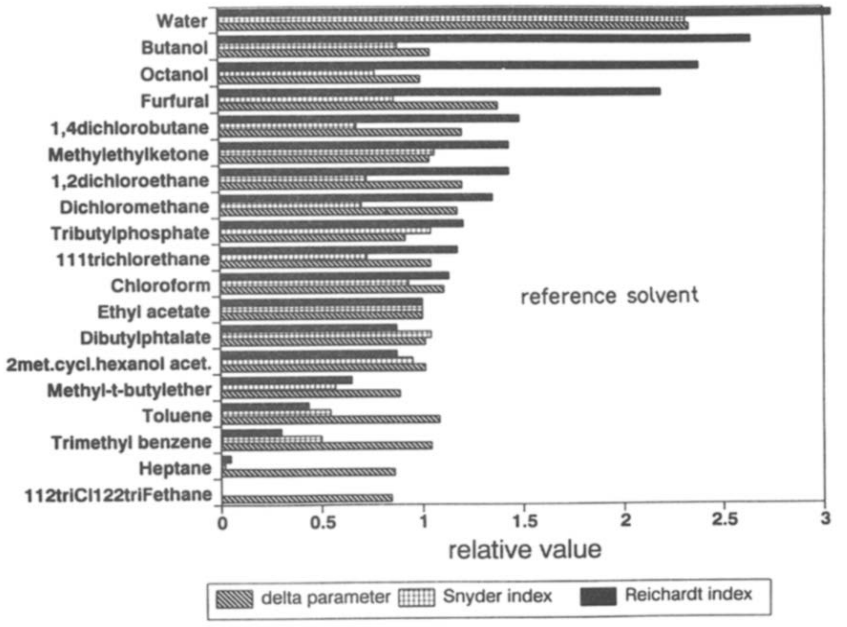

Fig. 3. The comparison of three polarity scales: the Hildebrand δ parameter (hatched bars), the Snyder E_0 index (dotted bars) and the Reichardt E_T index (closed bars). The relative values refer to the ethyl acetate values. The exact values are listed in Table 3.

parameter, δ, as the work necessary to separate two solvent molecules:[16]

$$\delta = \sqrt{\frac{\Delta H_v - RT}{V_m}}$$

in which ΔH_v is the solvent molar heat of vaporization and V_m is its molar volume. In this work, the δ parameter was computed using the Beerboweer approximation:[17]

$$\delta = 3.74 \sqrt{\frac{\gamma}{\sqrt[3]{V_m}}},$$

in which γ is the solvent surface tension.

The idea to link the polarity of a solvent to its overall solvation ability led to the definition of polarity scales in terms of experimental parameters. Snyder defined an eluant strength parameter, E_0, based on the eluting power of the solvent when used as a mobile phase in thin layer chromatography on silica or alumina plates.[18] Reichardt proposed a solvent polarity parameter, E_T, based on the transition energy for the longest wavelength solvatochromic absorption band of a pyridinium-*N*-phenoxide betaine dye. The E_T parameter was normalized using water ($E_T = 100$) and tetramethylsilane ($E_T = 0$) as extreme reference solvents.[15] Table 3 lists the δ parameter in $J^{1/2}cm^{-3/2}$ and the dimensionless Snyder and Reichardt polarity indexes. Figure 3 compares the three polarity indexes in a relative scale with ethyl acetate as the reference solvent. The three polarity indexes of all solvents were divided by the corresponding ethyl acetate value, $\delta = 17.1$ $J^{1/2}cm^{-3/2}$, $E_0 = 4.4$ and $E_T = 22.8$. The solvents were sorted by decreasing Reichardt values. Figure 3 shows that there is only approximate correspondence between the three polarity scales. For example, the butanol E_T value is 60.2 and the δ value is 17.8. The furfural E_T value is lower, 50, and its δ value is higher, 23.6. In liquid chromatography, the E_T index was elected as the best representation of solvent polarity.[19]

Obviously, the mixing of two solvents changes their polarity. An organic solvent saturated in water has a higher polarity than the dry solvent. The E_T values of water-saturated butanol, MEK, MTBE and ethyl acetate were measured using the visible spectrum (750–400 nm) of the Reichardt dye freshly dissolved in each solvent.[15] These four solvents were selected because they have a relatively high mutual solubility with water. Furfural was brown coloured and could not be used. With the measured water-saturated E_T values, all other dry solvent E_T values were weighted using their water content and water polarity. The measured and weighted E_T values are listed in Table 3.

Figure 4 shows the plot of the capillary wavelength, L_c, *vs.* the water-weighted Reichardt polarity index, E_T, of the solvents. In

this scattered point plot, short L_c values seem to correspond to high E_T indexes. However, there is no direct relationship; for information, the regression line shown in Fig. 4 is:

$$L_c = -0.004E_T + 0.42$$

$$(\pm 0.002)\,(\pm 0.12)$$

$$n = 18,\ r^2 = 0.270.$$

For example, dibutylphthalate (DBP) has a low mutual solubility with water and a high L_c value, 0.6, far from the other solvents. L_c is high because the density of DBP is very close to the density of water. It seems to be difficult to connect solvent density to solvent polarity.

Solute partition coefficient

In classical liquid chromatography, solute retention depends on numerous parameters: solute partition with an organic layer bonded on the solid stationary phase, adsorption on active sites of the surface, ion-exchange, size exclusion or binding with specific sites on the stationary phase. In CCC, the sole parameter responsible for solute retention is the liquid–liquid partition coefficient. CCC allows accurate determination of liquid–liquid partition coefficients.[20–22] These coefficients are dependent on solvent polarity. Table 2 lists the partition coefficient for formanilide, K_{fo}, used as a test solute. It was not possible to use the UV detector with furfural and DBP. Both solvents strongly absorb UV light. Figure 5 shows a plot of the K_{fo} partition coefficient *vs.* the water content-weighted E_T polarity index. The full line is the regression line obtained using all points:

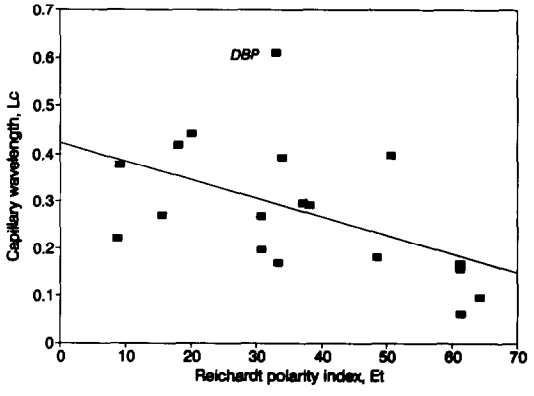

Fig. 4. The capillary wavelength L_c *vs.* the water-weighted E_T polarity index. The regression line is shown for convenience (regression parameter $r^2 = 0.27$, see text).

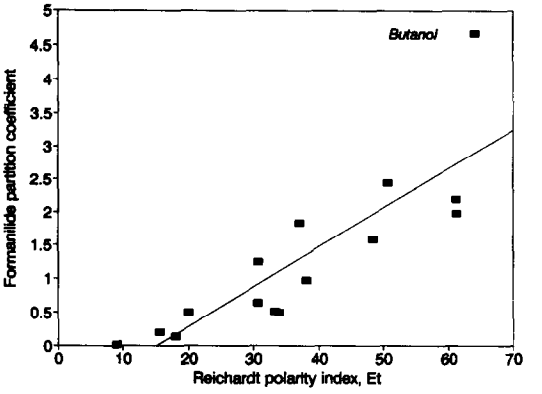

Fig. 5. Formanilide partition coefficient, K_{fo}, *vs.* the water-weighted E_T polarity index for the 15 solvents with which UV detection was possible. The full line corresponds to the regression line, whose equation is given in text.

$$K_{fo} = 0.060E_T - 0.91$$

$$(\pm 0.010)\,(\pm 0.66)$$

$$n = 15,\ r^2 = 0.725.$$

The representative point of butanol is posted on Fig. 5. With $K_{fo} = 4.66$, it is far from the regression line. We note that butanol has the highest mutual solubility with water (20.5% w/w water dissolves in butanol and 7.5% w/w butanol dissolves in water). Anyway, it can be concluded that the partition coefficient of a given solute is strongly linked to the polarity difference between the two liquid phases. For years, the octanol–water partition coefficient has been used as a hydrophobic scale in biochemistry, pharmaceutical and environmental studies.[23]

CONCLUSIONS

Separation using CCC is impossible if there is no liquid stationary phase retention. The liquid stationary phase retention percentage in a hydrodynamic countercurrent chromatograph is directly proportional to the density difference between the two liquid phases. The mutual solubility between phases increases as the polarity difference decreases and the density difference decreases if the two solvents used have a high mutual solubility. That is why the liquid stationary phase retention in a CCC apparatus is related to the polarity difference between the two liquid phases used. The retention of a solute depends on its partition coefficient in the biphasic liquid system used. This

coefficient is directly related to the phase polarity difference. This shows that the choice of the biphasic liquid system is essential to adjust selectivity in CCC.

From a practical point of view, this work demonstrates that the density difference between phases is the first parameter to be considered when dealing with liquid stationary phase retention in CCC hydrodynamic apparatuses. To obtain a high liquid stationary phase retention in coiled tubes, the two liquid phases used must have a high density difference whatever phase is used as the stationary phase. The chloroform–methanol–water and chloroform–acetic acid–water systems are very popular in CCC separations.[1-3] The density of chloroform, 1.5 g/cm^3, produces a high density difference with the $\sim$0.8 g cm^{-3} density of the methanol or acetic acid phases. The phase retention in CCC apparatuses is good. Also, these two liquid systems have very low viscosities.

EXTRACTION OF MANGANESE(II) WITH DITHIZONE AND POTASSIUM THIOCYANATE ON FOAM SORBENTS FOR SPECTROPHOTOMETRIC DETERMINATION IN SILICATES

NIBEDITA CHAKRABORTI and S. K. ROY
Analytical Chemistry Division, Central Glass and Ceramic Research Institute, Calcutta 700 032, India

(*Received* 10 *February* 1993. *Revised* 16 *April* 1993. *Accepted* 18 *April* 1993)

Summary—A method for selective extraction of Mn(II) with dithizone and potassium thiocyanate has been described. The method involves formation of a Mn(II)–thiocyanate–dithizone complex in a hexamine medium containing potassium thiocyanate (2.8*M*), dithizone (5.5–6.5 × 10^{-5}*M*) and hydroxylamine hydrochloride (0.25%) at pH ~6 followed by extraction of the complex on polyurethane foam using batch squeezing mode within 1 hr. The sorbed Mn–thiocyanate–dithizone complex is eluted with acetone and made alkaline with 0.5 ml of a stabilizer solution (19 ml 2*M* NH_3 solution + 1 ml 5% hydroxylamine hydrochloride). The absorbance of the solution is measured at 506 nm. The adverse effect due to Pb may be obviated by separating the Pb as the sulphate during decomposition of sample and that due to iron may be removed before extraction of Mn by any suitable method. The other interfering elements (Cd, Zn, Ni, Co, Cu, *etc.*) are masked with KCN (6 × 10^{-3}*M* optimum) solution. The method obeys Beer's Law from 0.1 to 2.0 μg Mn/ml. The method has been applied to various silicates, carbonates and glasses.

Diethyl dithiocarbazone (dithizone) reacts with various metal ions to produce coloured complexes[1] which have been utilized for their spectrophotometric determination for a long time. Numerous spectrophotometric methods involving solvent extraction with dithizone have been reported for determination of various elements.[2] Reaction of manganese(II) with dithizone,[1,3] is known to produce a violet coloured primary dithizonate, $Mn(HDz)_2$, in alkaline solution (pH 10–11) which can be extracted with chloroform or carbon tetrachloride. But $Mn(HDz)_2$ in alkaline medium is unstable and thus could not be utilized for the spectrophotometric determination. Akaiwa *et al.*[4] on further studies observed a change in the absorption curve of Mn-dithizonate produced in the presence of pyridine. This change was explained as pyridine forming an adduct with dithizonate (or the formation of an adduct by pyridine with dithizonate). Later Akaiwa and Kawamoto[5] extracted the Mn(II) complex produced by dithizone and pyridine reproducibly with CCl_4 at pH 9.5 in the presence of hydroxylamine hydrochloride which stabilized the lower oxidation state of manganese which can be determined spectrophotometrically at 530 nm. But the working range was established between 0.4 and 4 μg Mn/ml. Marczenko and Mojski[6] reported in another study that Mn(II)-dithizonate adduct with pyridine has the composition $Mn(HDz)_2/(Pyridine)_2$ developed a practical method for the determination of Mn(II). Later, in 1979 Akaiwa *et al.*[7] observed that Mn(II) forms a mixed ligand complex with dithizone (H_2DZ) and 1,10-phenanthroline (phen) and that can also be extracted into chloroform in the pH range 8–9. Further, they observed that the absorbance of the complex in chloroform solution is higher and more stable than the complex obtained by using pyridine or bipyridyl. The method was applied to carbonate rock and hot spring water. However, the present authors could not obtain satisfactory results during extraction of Mn(II) in the presence of phenanthroline and dithizone on polyurethane foam in the same pH range. But it has been reported that polyurethane foam (PUF) sorbents have been used in the separation and preconcentration of various elements by sorbing their dithizonate complexes from aqueous solutions.[8,9] It was reported in a study[10] where Mn(II) was extracted on PUF from a thiocyanate solution by a batch technique for understanding the reaction mechanism of thiocyanate complexes from aqueous solution. α-Dinonylphthalate (DNP)

plasticized 1,(2-pyridylazo)-2-naphthol (PAN) loaded foam has also been reported[11] for the extraction of Mn(II) at pH ~9 by a batch and column technique, and determined radiometrically. Furthermore, foam loaded with Kelex-100 has been reported for the extraction of Mn(II) by a column and batch technique and determined by AAS.[12] But sorption characteristics of Mn(II)-dithizonate in the presence of KSCN on unloaded polyurethane foam is yet to be studied.

The present paper describes a study in which manganese was extracted on PUF in the presence of dithizone and potassium thiocyanate from hexamine solution containing hydroxylamine hydrochloride. Based on these studies, a method was established for the spectrophotometric determination of manganese in silicates, carbonates and glasses. The method enables us to determine Mn down to the concentration of existing level (0.4 μg/ml Mn) reliably in a matrix free system using 1 cm cell.

EXPERIMENTAL

Apparatus—UV-VIS Spectrophotometer, Spectromom Model 361.

Reagents—A.R. grade. Double distilled water was used throughout the experiment. Potassium cyanide solution (1%, w/v), hydroxylamine hydrochloride solution (5%, w/v, neutralized with dilute ammonia solution), sodium fluoride (2%, w/v), hexamine solution (10%, w/v, purified by shaking with dithizone loaded polyurethane foam), dithizone (0.03% in methanol), potassium thiocyanate solution 8*M*, MIBK.

Standard Mn-solution—1000 μg/ml

Mn(II) solution was prepared by dissolving (99.9%) electrolytic manganese metal in dilute nitric acid (10 ml). Then, the volume was made up in a 1000 ml volumetric flask.

A working solution (5.1 μg/ml) was prepared by proper dilution of the stock solution with water and acidified with 2 drops of HNO_3.

Preparation of foam

The polyurethane foam (commercial U-foam) was cut into regular shapes and sizes with a cork borer. Each piece was about 2 cm in length and 0.5 cm in diameter and weighed about 0.01 gm. The pieces of foam were soaked in 4*M* hydrochloric acid in a beaker for 4 hr with squeezing at 15 min interval, then washed thoroughly in a 50 ml glass syringe and finally by refluxing with acetone for 6 hr in a Soxhlet apparatus. The washed foam pieces were dried in a desiccator and stored in a plastic container in the dark.

Procedure

Calibration. Manganese solutions (1–4 ml) containing 1–20 μg of Mn were pipetted into 50 ml glass beakers and evaporated to almost dryness on a water bath and the residue dissolved in 2 ml water. To that solution 6 ml of 10% hexamine, 1 ml hydroxylamine hydrochloride, 1 ml NaF, 1 ml KCN, 8 ml 8*M* potassium thiocyanate and 1 ml dithizone were added sequentially and kept for 5 min. Five pieces of foam chip were put into each solution and squeezed at 5 min intervals with the help of a flat ended glass plunger to facilitate the aqueous solution to flow freely through the foam cell for a period of 60 min. The chips were then transferred to a 5 ml glass syringe and washed thoroughly four times with a stabilizer solution (19 ml 2*M* NH_3 solution + 1 ml 5% hydroxylamine hydrochloride) and subsequently washed with water four times. Sorbed Mn-thiocyanate–dithizone complex was then eluted with acetone using four 2 ml volumes into a 10 ml volumetric flask and made alkaline with 0.5 ml stabilizer solution. The volume was finally made up with acetone and the absorbance was measured at 506 nm against a reference blank prepared in the same way as above. The calibration curve (absorbance *vs* μg of Mn) was plotted.

Analysis of samples. A 0.2 g sample (dried at 110°C) was digested with 5 ml H_2SO_4 (1 + 1) and 5 ml HF in a PTFE basin on a sand bath and digested until SO_3 fumes evolved, cooled and diluted with 10 ml water and filtered (if necessary for separation of $PbSO_4$) into a 100 ml beaker. The residue was washed four times with 1% H_2SO_4 solution (total 10 ml). A 20 ml volume of hydrochloric acid was added to the filtrate and was transferred to a 10 ml separating funnel. A 10 ml volume of methyl isobutyl ketone (MIBK) was added to the solution and the mixture was shaken to extract iron (if present). The process was repeated till the solvent layer became colourless. The aqueous layer was transferred to a 100 ml volumetric flask and diluted with water to make the volume.

Five milliliters of this solution was taken into a 50 ml beaker and evaporated to dryness on a water bath, 2 ml of water was added to dissolve the residue and the determination procedure

was applied. The MnO content was calculated from

$$\%MnO = 2.58 \times 10^{-2} A/W$$

where A is the number of μg of Mn corresponding to the absorbance measured and the sample weight is W in grams.

RESULTS AND DISCUSSION

It has been observed that Mn(II) reacts with dithizone to form a coloured complex in the presence of hydroxylamine hydrochloride in hexamine medium, but its extraction on polyurethane foam is incomplete and the colour of the eluted complex in acetone medium showed maximum absorbance at 490 nm. However, on further studies it was observed that if potassium thiocyanate was added to the solution before reaction with dithizone (in the presence of hydroxylamine hydrochloride and hexamine) the colour of the complex was notably changed to a stable pink colour and could be extracted on foam within 1 hr. The extracted complex could also be eluted with acetone and showed maximum absorption at 506 nm. This observation indicates a similarity in nature with that observed with pyridine and dithizone by earlier workers.[6,7] The shift of the absorption maxima from 490 to 506 nm suggests that Mn(II)-thiocyanate forms first and this reacts with dithizone probably to form a ternary complex like Mn(SCN)(HDz) although the nature of the complex has not been studied and established here. It has been reported that polyether type polyurethane foam is regarded to be analogous to oxygenated solvents. Therefore, sorption of Mn-thiocyanate–dithizone can be accounted for by a solvent extraction mechanism.[13,14]

However, quantitative formation of the probable complex Mn(SCN)(HDz) in hexamine medium at pH = 6 and its sorption on PUF is dependent upon the concentration of KSCN, dithizone, and equilibration time.

In the present study it has been observed that Mn(SCN)(HDz) complex can be well formed in hemamine medium at pH = 6 and the complex can be stabilized with hydroxylamine hydrochloride for a considerable period for its sorption on PUF and therefore for subsequent experiments, the hexamine medium (*i.e.* pH = 6) was chosen.

The effect of thiocyanate concentration was studied by taking 20 μg of Mn(II) in a 50 ml beaker containing 1 ml of 5% hydroxylamine hydrochloride, 1 ml dithizone, 6 ml hexamine solution, and varying only the concentrations of thiocyanate (from 2 to 3.2M) in a total volume of 20 ml. The solution was equilibrated for 1 hr and the absorption of the complex is measured at 506 nm after stripping the complex with acetone. It can be seen from Fig. 1 that formation and maximum extraction can be obtained only at, and above, 2.8M KSCN concentration.

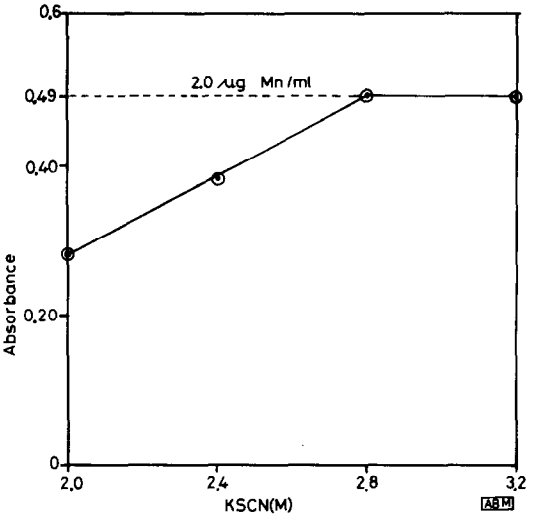

Fig. 1. Effect of potassium thiocyanate concentration on the extraction of Mn(SCN)(HDz): $[H_2Dz] = 5.85 \times 10^{-5}M$, [Hexamine] = $2.1 \times 10^{-4}M$.

Effect of dithizone concentration on the formation and extraction of Mn(II) was studied as above and by varying the concentration of

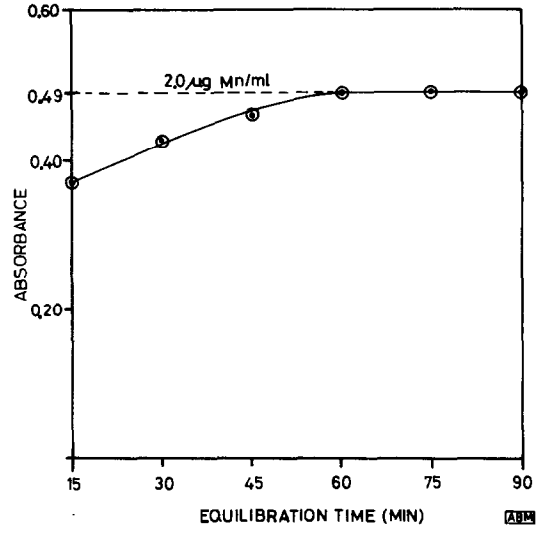

Fig. 2. Effect of equilibration time on the extraction of Mn(SCN)(HDz): $[H_2Dz] = 5.85 \times 10^{-5}M$; [KSCN] = 2.8$M$, [Hexamine] = $2.1 \times 10^{-4}M$.

dithizone ($3.0 \times 10M$–$12.0 \times 10^{-5}M$). It has been observed that the formation of Mn(SCN)(HDz) as well as quantitative extraction of the complex is possible only at, or above, $5.5 \times 10^{-5}M$ dithizone concentration. Below this concentration, the extraction efficiency was found to be less due to the formation of an unextractable species. Yet, at a concentration greater than $6.5 \times 10^{-5}M$ dithizone, a high blank value was obtained. Therefore, in further studies the dithizone concentration was kept between 5.5×10^{-5} and $6.5 \times 10^{-5}M$.

Equilibration time was studied by taking 20 μg of Mn(II) solution as mentioned above and the solution was equilibrated with foam chips by varying the time up to 90 min. After each time interval, foam pieces were washed and eluted as described. Absorbance of each solution was measured. The study indicated that maximum extraction was possible only after 1 hr of equilibration and no further extraction took place beyond that period. Acetone has been found to be suitable for the elution of Mn(SCN)(HDz) complex from polyurethane foam. It has been observed that the complex after elution with acetone was found to be unstable when made alkaline with only ammonia solution (0.5 ml of $2.0M$ NH_3 solution in 10 ml volume) probably due to oxidation of Mn(II) to Mn(III). Therefore, a stabilizer solution containing hydroxylamine hydrochloride (19 ml $2M$ NH_3 solution + 1 ml 5% hydroxylamine hydrochloride) was prepared for its addition to the acetone elute. It was found that the addition of such a stabilizer solution (0.05 ml) stabilizes the complex Mn(SCN)(HDz) for at least 5 hr before measuring its absorbance.

The effect of Mn concentration was studied by the following the procedure and observed that Beer's law is obeyed from 0.1 to 2.0 μg Mn/ml. From the regression analysis of the calibration curve, the correlation coefficient was calculated to be 0.99.

Dithizone forms coloured complexes with many other metal ions such as Cd, Zn, Ni, Co, Cu, and others which interfere seriously with the determination of Mn. To overcome these adverse effects, KCN solution was used for masking all such interfering cations. However, the effect of KCN on the formation and extraction of Mn(SCN)(HDz) complex on PUF was carried out as it has been reported[15] that KCN forms a complex with Mn(II) at higher pH. It was found that KCN at a concentration of $6 \times 10^{-3}M$ has no effect on the formation and extraction of the Mn(SCN)(HDz) complex. Moreover, $6 \times 10^{-3}M$ KCN is sufficient for masking interfering cations up to 10-fold the amount of Mn. It was further observed that an appreciable amount of fluoride ion has no effect on the extraction of Mn(II).

In conclusion it can be stated that manganese(II), stabilized with hydroxylamine hydrochloride (0.025%) in hexamine medium forms a ternary complex with thiocyanate ($2.8M$) and dithizone (5.5–$6.5 \times 10^{-5}M$) at pH = 6. The complex is extracted on PUF, eluted with acetone and made alkaline with 0.5 ml of a stabilizer solution (19 ml $2M$ NH_3 + 1 ml 5% hydroxylamine hydrochloride) and the absorbance is measured at 506 nm for the determination of manganese. The advantage of the method lies in the fact that manganese reliably and comfortably can be separated out from a complex system to a pure one so that the determination level can be four times lower than the existing level. The method has been standardized against standard lime stone NBS-1a and applied to the determination of manganese present in glass, silicate and carbonate samples. The results are presented in Table 1. It can be seen from Table 1 that results obtained are slightly higher than the values obtained by

the other method in some cases but within a maximum error of 5.1%.

SIMULTANEOUS KINETIC DETERMINATION OF PHENOLS BY USE OF THE KALMAN FILTER

ANTONIO VELASCO, XIONG RUI,* MANUEL SILVA and DOLORES PÉREZ-BENDITO
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Cordoba, Spain

(*Received* 29 *January* 1993. *Revised* 29 *April* 1993. *Accepted* 30 *April* 1993)

Summary—A multicomponent analysis method based on the Kalman filter algorithm is proposed for the determination of phenolic compounds. The method relies on the oxidative coupling of phenols (phenol, 2-chlorophenol and 3-chlorophenol) to *N,N*-diethyl-*p*-phenylenediamine in the presence of hexacyanoferrate(III), the reaction being monitored via changes in the absorbance at 660 nm of the dye formed. Phenols can be determined individually over the concentration range 1.25–25 μM with a relative standard deviation of *ca* 0.6–0.8%. Differences in the kinetic behaviour of the three species were exploited by using the linear Kalman filter to resolve mixtures of the phenols at the μM level in a widely variable concentration ratios with errors less than 10%.

Phenols are of a high significance to environmental studies since they are present in many organic pollutants, of which chlorophenols, widely used in pesticide production, are particularly hazardous owing to their highly toxic character. Several procedures have been developed for the determination of phenols at trace concentration levels. Both high-performance liquid chromatographic[1–4] and gas chromatographic[5–9] techniques, are widely used for this purpose; however, they are even employed for the determination of a single phenol (*e.g.* phenol in plasma,[10] urea,[11] industrial products[12]) or two compounds in mixtures (*e.g.* phenol and *p*-cresol in urine[13]). The sensitivity typically afforded by these methods is of a few micrograms per millilitre. In this context, it is interesting to note the development of new analytical methods for the resolution of mixtures of these compounds with adequate sensitivity by using simpler, faster instrumentation. Kinetic methods of analysis are powerful tools for this purpose, especially those based in new multipoint approaches which allow the resolution of closely related species.

In this work we developed simple, rapid simultaneous kinetic determination for phenol and chlorophenols using the Kalman filter algorithm. The method is based on the well-known oxidative coupling reactions of these compounds in a weakly basic medium. The singular features of the Kalman filter[14–17] allow these mixtures to be resolved over wide concentration ranges with a high accuracy even at low rate constant ratios.

Kinetic methods have rarely been applied to the individual or simultaneous determination of phenolic compounds;[18–20] in fact, the proposed method is the first attempt at the kinetic resolution of chlorophenol mixtures. Thus, metaperiodate is a common oxidant for hydroxyl compounds, which are individually determined by using a fixed-time method[18,19] based on absorbance measurements at the wavelength of maximum absorption of the resulting quinols and quinones. The determination range covered is *ca* 50–1000 μg/ml. The only reference to a simultaneous kinetic determination of phenol mixtures was concerned with cresol mixtures that were resolved by using the oxidative coupling reactions of the phenols with *N,N*-diethyl-*p*-phenylenediamine in the presence of potassium hexacyanoferrate(III). The quinonedi-imine formed reacts with the cresol to form a dye in a reaction that is monitored photometrically by using the stopped-flow technique.[20]

EXPERIMENTAL

Reagents

All solvents and reagents were of analytical-reagent grade and purified water was obtained from a Milli-Q apparatus. Stock solutions of $3 \times 10^{-2} M$ phenol, 2-chlorophenol and 3-

*Beijing Institute of Telemetry, Ministry of National Aerospace, Box 9200-74, Beijing, China.

chlorophenol (Merck) were prepared in ethanol and diluted 1:250 for use in the experiments as follows: 1.0 ml of the stock solution was mixed with 10.0 ml of 0.5*M* phosphate buffer of pH 8.0 and diluted to 250 ml with purified water. A $6 \times 10^{-3}M$ stock solution of *N,N*-diethyl-*p*-phenylenediamine (Merck) was prepared by dissolving 98.6 mg of the chemical in ethanol in a 100-ml volumetric flask. This stock solution was stored in a refrigerator to minimize degradation. A $2.4 \times 10^{-2}M$ stock solution of potassium hexacyanoferrate(III) (Merck) was prepared by dissolving 790 mg of the chemical in 100 ml of purified water. The 0.5*M* phosphate buffer (pH 8.0) was prepared by dissolving 87.1 g of di-potassium hydrogen phosphate (Merck) in *ca* 850 ml of purified water, adjusting the pH to 8.0 with hydrochloric acid and diluting to 1 l with purified water.

Apparatus

Spectrophotometric measurements were made on a Metrohm 662 spectrophotometer equipped with an immersion probe that was furnished with a Metrohm Dosimat 665 autoburette to dispense a small volume of reagent in order to start the reaction, as well as a data acquisition system consisting of a Mitac PC-AT 12-MHz compatible computer equipped with a PC-Multilab PCL-812PG 12 bit analog-to-digital converter. Data acquisition were synchronized with the start of the reaction by using a trigger that actuated the autoburette and computer simultaneously. The software required for application of the Kalman filter method was developed by the authors.

Procedure

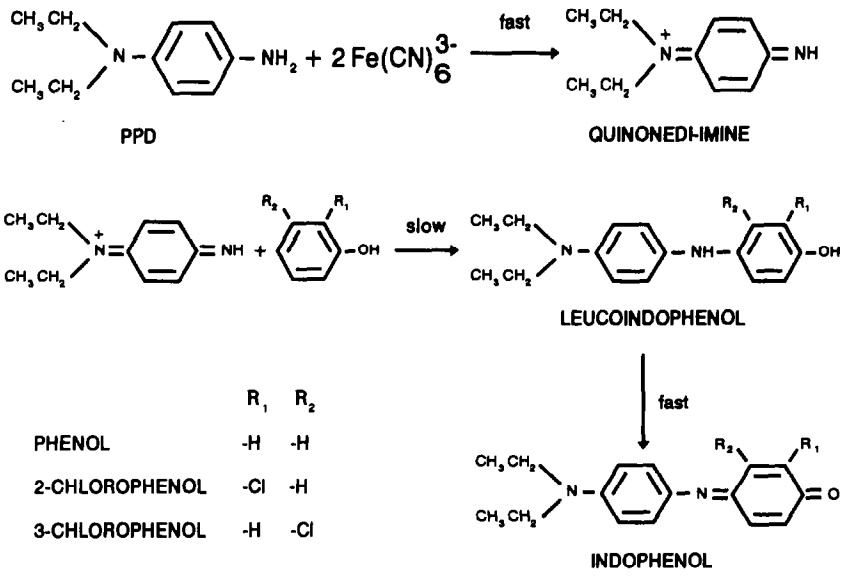
In an 80-ml reaction vessel were placed a solution containing 0.12–1.08 μmol of each phenol (binary mixtures), plus 2.0 ml of $6 \times 10^{-3}M$ *N,N*-diethyl-*p*-phenylenediamine solution, 5.0 ml of 0.5*M* phosphate buffer (pH 8.0) and purified water up to a final volume of 60 ml. The reaction was started by adding 1.0 ml of $2.4 \times 10^{-2}M$ potassium hexacyanoferrate(III) solution from the autoburette at a rate of 60 ml/min (addition time, 1 sec). Data were acquired at a rate of 1.5 sec per point and a wavelength of 660 nm for 5 min in both instances.

RESULTS AND DISCUSSION

Oxidative coupling reactions of *p*-phenylenediamines with amines and phenolic compounds are widely known by analytical chemists.[21–29] The kinetics and mechanism of these reactions were widely investigated in the late 1960s due to the great relevance of the dye formed to the photographic industry. The proposed method for the resolution of mixtures of phenolic compounds (phenol and chlorophenols) relies on this type of reaction, in which *N,N*-diethyl-*p*-phenylenediamine (PPD) is oxidized to its quinonedi-imine (QDI) by potassium hexacyanoferrate(III) in weakly basic medium. In the rate-limiting step, QDI reacts with the phenolic compound to give leucoindophenols, which are rapidly oxidized to coloured indophenols with the aid of a QDI[24] molecule, these last absorb maximally and with high molar absorptivities at *ca* 660 nm (see Scheme 1).

Preliminary studies on the kinetic behaviour of these phenolic compounds showed differences in their reactivity. The reaction rate for phenol, 2- and 3-chlorophenol was similar (the three reactions develop to completion within a few minutes) whereas that for 4-chlorophenol was very low, which is consistent with Scheme 1. Therefore, the last phenol can be determined in the presence of the others by using a simple sequential method (whether kinetic or equilibrium). This was not assayed in this work, even though it can be resorted to whenever this compound is present in the unknown mixture. The major problem arises from the resolution of mixtures of the other phenolic compounds owing to their similar kinetic behaviour (their pseudo-first rate constant ratios are *ca* 2.0, which precludes usage of classical differential reaction-rate methods). We chose to use the powerful Kalman filter algorithm to address this problem. This algorithm allows the reliable calculation of the concentrations of mixture components from the net signal changes for each (linear Kalman filter), as well as the determination of their pseudo-first rate constants (extended Kalman filter).

Figure 1 shows typical absorbance *vs* time curves for the three phenolic compounds, which were processed by the data acquisition system. As can be seen, the reaction was somewhat faster for 2-chlorophenol and very similarly rapid for phenol and 3-chlorophenol; therefore, the effect of the reaction variables was subsequently investigated in order to establish the experimental conditions resulting in the greatest possible discrimination between the kinetic behaviour of 2-chlorophenol and one of the other two phenols (phenol was selected because



Scheme 1

of its smaller reaction rate and greater practical relevance).

Influence of variables

In order to establish the most suitable conditions, several variables potentially affecting the oxidative coupling reaction were investigated. Their influence was studied individually for each phenolic compound and the selected value for each was determined as that resulting in the maximum ratio between the pseudo-first rate constant *vs* concentration plots for the two compounds concerned.

The influence of pH on the rate constants was studied over the range 7.7–10.3 (Fig. 2). The plot of the logarithm of the rate constant for each phenolic compound against pH was linear, whereas the rate constant ratio ($k_{2\text{-ClPh}}/k_{\text{Ph}}$) decreased with increase in pH; above pH 10, k_{Ph} became larger than $k_{2\text{-ClPh}}$. This relationship can be accounted for on the basis of the pK_a values of the two phenolic compounds, viz. 10.0 and 8.48 for phenol and 2-chlorophenol, respectively, and available knowledge on the influence of chlorine substituents on the reaction rate. In fact, according to Corbett,[28] the reactivity of phenoxide ion is decreased on chlorination. Thus, at pH $\simeq$ 8.0, 2-chlorophenol is in ionized form ($\simeq$25%) whereas phenol remains protonated, so this effect offsets that of chlorination. As the pH is raised (and phenol ionization increased), the two rate constants approach; above pH 10, where both species occur as phenoxide ions, phenol being more reactive according to Corbett. Taking into account the above kinetic relationships, pH 8.0, at which $k_{2\text{-ClPh}}/k_{\text{Ph}} = 2.3$, was selected for the simultaneous kinetic determination of these compounds. Even though this rate constant ratio was higher at lower pH values, the reactions were very slow and of no practical analytical

interest. In order to adjust the pH, 5 ml of 0.5M phosphate buffer (pH 8.0) was added to the reaction vessel as part of the procedure. Borate buffer was not used owing to its smaller buffering capacity and poorer solubility (concentrations above 0.1M are impossible to obtain).

The concentration of potassium hexacyanoferrate(III) was varied over the range 3.6×10^{-5}–$4.0 \times 10^{-4}M$ in order to investigate its effect on the rate constants (Fig. 3). In both cases, the pseudo-first rate constants increased with increasing oxidant concentration up to $2.4 \times 10^{-4}M$, above which they were virtually independent on such a concentration. In order to select the most suitable potassium hexacyanoferrate(III) concentration, another experiment was carried out as follows: the influence of the signal increments resulting from full conversion of phenol and 2-chlorophenol into their corresponding indophenols on the [oxidant]/[PPD] ratio was studied; *i.e.* the reaction stoichiometry was determined. As can be seen in Fig. 4, the ratio was 2 for both phenolic compounds, which is consistent with Scheme 1 and the exchange of two electrons in the reaction. A concentration of $4 \times 10^{-4}M$ (1.0 ml of a $2.4 \times 10^{-2}M$ solution) was thus selected for the simultaneous kinetic determination of these compounds.

The effect of the concentration of *N,N*-diethyl-*p*-phenylenediamine (PPD) was examined in the range 1.0–$4.0 \times 10^{-4}M$, the [oxidant]/[PPD] ratio being kept constant at the stoichiometric value. Both rate constants remained virtually constant throughout the assayed interval, whereas signal increments increased linearly with increase in the reagent concentration. A $2.0 \times 10^{-4}M$ PPD concentration (2.0 ml of a $6 \times 10^{-3}M$ ethanolic solution) was chosen as optimal.

Individual determination of phenols

Absorbance *vs* time graphs were plotted for solutions containing various concentrations of the phenolic compounds under the selected working conditions. The figures of merit of the individual determinations of these compounds are summarized in Table 1. The analytical sensitivity was taken as the slope of the calibration plot and the detection limit was calculated according to the IUPAC's recommendations.[30] The precision (expressed as the relative standard deviation) was determined by analysing 11 samples containing 10 μM of phenolic compound each, and the pseudo-first rate constants were calculated by applying the extended Kalman filter.[16]

Simultaneous kinetic determination of phenols

According to the reported pseudo-first rate constant values, the constant ratios between these phenolic compounds were $k_{2\text{-ClPh}}/k_{\text{Ph}} = 2.29$, $k_{3\text{-ClPh}}/k_{\text{Ph}} = 1.66$ and $k_{2\text{-ClPh}}/k_{3\text{-ClPh}} = 1.37$. The simultaneous kinetic determination of these phenols by traditional

differential reaction-rate methods is impossible as they require higher rate constant ratios for application. We thus chose to use the linear Kalman filter, a mathematical approach that is arousing growing interest for the resolution of mixtures by kinetic analysis.[14–16] Thus, we assayed the 2-chlorophenol/phenol and 2-chlorophenol/3-chlorophenol mixtures, which offer the maximum and minimum rate constant ratios, respectively. The resolution of ternary mixtures was impossible (high relative errors) owing to an inadequate difference between the fastest component (2-chlorophenol) and the slowest (phenol).

Provided that the signal increments are proportional to the initial analyte concentration, the signal measured at time t_j, $S(t_j)$, can be expressed by

$$S(t_j) = S_1[1-\exp(-k_1 t_j)] + S_2[1-\exp(-k_2 t_j)] + S_B + \text{Noise} \quad (1)$$

where S_1 and S_2 are the signal increments resulting from full conversion of compounds 1 and 2 in the mixture; S_B the background contribution; and k_1 and k_2 the pseudo-first rate constants of components 1 and 2, respectively. The measurement of N signals ($j = 1, 2, 3, \ldots N$) allows the establishment of a system of N linear equations in S_1, S_2 and S_B, which can be recursively solved by means of the Kalman filter algorithm. Equation (1) can be written according to the Kalman notation as

$$Z(j) = \mathbf{H}^T(j)\,\mathbf{X}(j) + v(j), \quad (2)$$

where $Z(j)$ denotes the absorbance measurement of the mixture sample; $\mathbf{H}^T(j)$ the measurement function vector; $\mathbf{X}(j)$ the state vector; and $v(j)$ the measurement noise. The actual values of these parameters as well as of the others required for the implementation of the filter are listed in Table 2. By applying the filter to the samples, the estimated net signal increments, S_1 and S_2 were determined, and subsequently interpolated in the corresponding calibration graphs in order to obtain the respective concentrations.

The results obtained for various binary synthetic mixtures containing different amounts of phenol, 2-chlorophenol and 3-chlorophenol are given in Tables 3 and 4; 2-chlorophenol/phenol mixtures in ratios from 7:1 to 1:5 can be satisfactorily resolved. These limits correspond to a relative error less than 7.5%. The precision of the method, expressed as the relative standard deviation (RSD), was also determined for mixtures containing 10 μM of each compound (11 samples), and turned out to be 1.8% and 2.5% for 2-chlorophenol and phenol, respectively. The 2-chlorophenol/3-chlorophenol mixtures in ratios from 4:1 to 1:4 were also successfully analysed. These limits correspond to a relative error less than 10%. The precision of the method was also determined for a mixture containing 10 μM of each phenol and was found to be 2.7% and 3.2% for 2-chlorophenol and 3-chlorophenol, respectively ($P = 0.05$, $n = 11$).

These results are quite satisfactory and testify to the good performance of the linear Kalman filter in the simultaneous kinetic determination of the phenols, even though the rate constant ratio is very low (only 1.3 for the 2-chlorophenol/3-chlorophenol mixture). On the other

2.00	18.00	2.43	+21.5	16.98	−5.66

hand, concentration ratios are quite acceptable (somewhat lower for 2-chlorophenol/3-chlorophenol mixtures owing to the lower rate constant ratio between the two) and the precision is good (the RSD is usually less than 3%). From a practical point of view, the method is simple and rapid and features modest requirements in terms of instrumentation and computational power. In addition, the proposed method affords higher concentration ratios and is more accurate than the stopped-flow method for the resolution of *o*- and *m*-cresol mixtures,[20] where the rate constant ratio is 1.54 (similar to that for the 2-chlorophenol/3-chlorophenol mixture).

COLUMN CHROMATOGRAPHIC SEPARATION OF MOLYBDENUM (VI) FROM ALLOYS WITH POLY-(DIBENZO-18-CROWN-6) FROM A HYDROCHLORIC ACID MEDIUM

B. S. MOHITE,* J. M. PATIL and D. N. ZAMBARE
Environmental Analytical Chemistry Laboratory, Department of Chemistry, Shivaji University, Kolhapur-416 004, India

(*Received* 4 *January* 1993. *Revised* 14 *April* 1993. *Accepted* 19 *April* 1993)

Summary—A very simple column chromatographic separation method has been developed for molybdenum (VI) using poly-(dibenzo-18-crown-6). The separations are carried out from hydrochloric acid medium. The adsorption of molybdenum (VI) on a poly-(DB-18-C-6) was quantitative from 2.5 to 10.0*M* HCl. Amongst the various eluents tested, 0.5*M* ammonium hydroxide was found to be an efficient eluent. Molybdenum (VI) was separated from a large number of elements in binary form, as well as from multicomponent mixtures. The method was applied for the analysis of molybdenum from various alloy samples. The method is very simple, rapid, selective and reproducible. The reproducibility of the procedure is ±2%.

Molybdenum has a large number of applications in various fields. It is used in radios, wireless sets, anticathodes of X-ray tubes and in the production of special steels. Along with tungsten, it is used in thermocouples for high temperature measurements. Molybdenum occurs in water, soil, plants and animals at trace level. Molybdenum is one of the seven micronutrients required for the growth and development of plants. It is required to change nitrogen into other forms the plant can use. Thus nitrogen-fixing-bacteria employ enzymes containing both molybdenum and iron.

The separation of molybdenum from other elements was carried out using various chelating resins. Chelex-100 was used for trace element analysis, in which, molybdenum along with other elements was determined from natural water samples using neutron activation analysis,[1] a significant increase in time and effort was required. The chelating resins containing amidoxime groups[2] such as Duolite ES-346, Duolite CS-346 and Chelite-N, *etc.* formed strong complexes with a number of metal ions including molybdenum (VI). Resin having an active oxime group was used for the extractive separation of molybdenum from aqueous sulfuric acid.[3] The molybdenum was then recovered by eluting with alkaline solutions. A chelating resin was prepared[4] by loading pyrogallolsulfonic acid on to Seralite SRA-400, it showed high selectivity towards Mo(VI), V(V) and Fe(III). Various amphoteric ion exchangers were tested for the recovery of molybdenum from sulfuric acid leaching liquors of molybdenum calcines,[5] the maximum sorption capacity for molybdenum was shown by the exchanger ANKB-7 and VP-14K, the elution of molybdenum was carried out with 7.5% NH_4OH.

Crown ethers have been extensively used in extraction analysis studies of various metal ions and those methods have been reviewed,[6] but the use of crown ethers for the extractive separation analysis of Mo(VI) is limited. DB-18-crown-6 was used for the solvent extraction of technetium from ascorbic acid medium, Mo(VI) showed very poor extraction.[7] DC-18-crown-6 was used in presence of polyurethane foam for the extractive separation of molybdenum from a thiocyanate–hydrochloric acid medium[8] but the separation of molybdenum from other elements was not achieved. Mo(VI) was quantitatively extracted from 7 to 10*M* hydrochloric acid with 0.01*M* DB-18-crown-6 in nitrobenzene.[9] Mo(VI) from the organic phase was then stripped with 2*M* nitric acid. It was possible to separate Mo(VI) from a large number of elements in binary as well as in multicomponent mixtures. The selective extraction of molybdenum permits its separation from a number of elements which are usually associated with it.

*Author for correspondence.

From the literature survey it is clear that no attempts have been made for the use of crown ethers or crown polymers in the column chromatographic separation studies of molybdenum (VI). This paper presents a systematic investigation of the column chromatographic separation studies of molybdenum (VI) from associated elements in hydrochloric acid medium using poly-dibenzo-18-crown-6. The method has been extended to the separation of molybdenum (VI) from a large number of other elements and also from a number of various alloy samples.

EXPERIMENTAL

Apparatus and reagents

A Zeiss spectrophotometer (German), a digital pH meter (Model LI-120 ELICO, India) with glass and calomel electrodes, a digital flame photometer (PEI, Model No. 041, India) and a Pyrex glass chromatographic column (20 × 0.8 cm i.d.) with a glass wool plug at the bottom were used.

A crown ether polymer (poly-(DB-18-C-6) Merck (German)) was used after screening with 100–200 mesh; 0.8 gm of poly-(DB-18-C-6) was slurried with distilled deionized water and poured into a Pyrex glass chromatographic column. The column was used after preconditioning with hydrochloric acid.

A stock molybdenum (VI) solution was prepared by dissolving 4.60 g of ammonium molybdate tetrahydrate (AnalaR) in 500 ml distilled deionized water and standardized gravimetrically.[10] A working standard solution (molybdenum 500 μg/ml) was prepared by appropriate dilution of the standard stock solution.

Procedure

An aliquot of solution containing 500 μg of molybdenum (VI) was mixed with hydrochloric acid in the concentration range of 0.5–10.0M in a total volume of 10 ml. The solution was then passed through the column, preconditioned with hydrochloric acid of the same acidity as that of the sample solution at a flow rate of 0.5 ml/min. The column was subsequently washed with hydrochloric acid of the same acidity and then with water. The adsorbed molybdenum (VI) was eluted with different eluting agents (described later) at a flow rate of 0.5 ml/min. Five millilitre fractions were collected and after evaporating the acid it was extracted with water and the molybdenum (VI) content was determined spectrophotometrically with Tiron[11] at 390 nm. The concentration of molybdenum (VI) was calculated from the calibration curve.

RESULTS AND DISCUSSION

Adsorption of molybdenum (VI) as a function of hydrochloric acid concentration on poly-(DB-18-crown-6)

In order to ascertain the optimum concentration of hydrochloric acid for the quantitative adsorption of molybdenum (VI) on poly-(DB-18-C-6) various studies were conducted by varying the concentration of hydrochloric acid from 0.5 to 10.0M. It was found that there was 75% adsorption of molybdenum (VI) at 0.5M hydrochloric acid, it was 90% at 1.5M, 98% at 2.5M and was quantitative from 3.0 to 10M hydrochloric acid (Table 1). Further adsorption studies of molybdenum (VI) were carried out at 5.0M hydrochloric acid concentration.

Elution studies of molybdenum (VI)

Molybdenum (VI) was adsorbed on poly-(DB-18-C-6) resin column at 5M hydrochloric acid concentration. After adsorption, molybdenum (VI) was eluted with various eluents such as ammonium hydroxide, hydrobromic acid, perchloric acid, sulfuric acid, acetic acid in the concentration range of 0.5–8.0M. Except for ammonium hydroxide and sulfuric acid other eluents were found to be inefficient for the

elution of molybdenum (VI). With 0.1*M* ammonium hydroxide there was 77% elution, with 0.5*M* ammonium hydroxide there was quantitative elution of molybdenum (VI). With 1*M* ammonium hydroxide there was 83% elution and subsequently elution of molybdenum (VI) decreased from 2.0 to 7.0*M* ammonium hydroxide, for 7*M* ammonium hydroxide the elution of molybdenum (VI) was 58%. There was no quantitative elution of molybdenum (VI) with perchloric and hydrobromic acid in the concentration range of 0.5–8.0*M* with 6.0–8.0*M* sulfuric acid there was quantitative elution of molybdenum (VI). The acetic acid in the concentration range of 0.5–8.0*M* was found to be an inefficient eluent for the elution of molybdenum (VI). The elution profiles of molybdenum (VI) with ammonium hydroxide are shown in Fig. 1. Further, elution studies of molybdenum (VI) were carried out with 0.5*M* ammonium hydroxide.

Effect of varying concentration of molybdenum (VI)

In order to ascertain quantitative adsorption of molybdenum (VI) on 1 gm of poly-(DB-18-C-6) resin column, various adsorption studies were carried out for the 5*M* hydrochloric acid concentration, by varying the concentration of molybdenum (VI) in the concentration range of 10–100 mg/l (Table 2). Ten millilitre solutions of the above concentration range were employed. After adsorption, molybdenum (VI) was eluted with 0.5*M* ammonium hydroxide. From Table 2 it is clear that there was quantitative adsorption of molybdenum (VI) up to 70 mg/l. The extent

of adsorption decreased with an increase in the concentration of molybdenum (VI).

Adsorption isotherm of molybdenum (VI) on poly-(DB-18-C-6)

The adsorption studies of molybdenum (VI) were carried out for 5*M* hydrochloric acid by varying the concentration of molybdenum (VI) in solution. The results are shown in Table 3. The capacity of poly-(DB-18-C-6) for molybdenum (VI) was found to be 7.81 mmol/gm of crown polymer.

Separation of molybdenum (VI) from a binary mixture

An aliquot of solution containing molybdenum (VI) and the foreign ions to be tested was taken and hydrochloric acid was added so that its concentration was 5*M* in a total volume of 10 ml. The tolerance limit of foreign ion was set as the amount of foreign ions required to cause ±2% error in the recovery of molybdenum (VI). The solution was then passed through the column preconditioned with 5*M* hydrochloric acid at a flow rate of 0.5 ml/min. Subsequently the column was washed with 5*M* hydrochloric acid and then with water. Those foreign ions which were not adsorbed on poly-(DB-18-C-6), passed through the column. Most of the foreign ions were not adsorbed (Table 4). Amongst the alkali metals, sodium was adsorbed to the extent of 70%, potassium 80% and rubidium 90%. From the alkaline earths only strontium and barium were adsorbed quantitatively. From the nontransition metals gallium (III) and thallium (III) were adsorbed quantitatively, whereas of the inner transition series, uranium (VI) was adsorbed to the extent of 94%. Iron (III) was

*Adsorption.

adsorbed partially which was eluted with 2.5*M* hydrochloric acid. Most of the non-transition and transition metals showed a higher tolerance limit. Similarly most of the anions were tolerated in higher ratios. The adsorbed sodium, potassium, rubidium, similarly strontium, barium and gallium were eluted by washing the column with water whereas molybdenum (VI) was eluted with 0.5*M* ammonium hydroxide. This condition was exploited for the separation of molybdenum in multicomponent mixtures.

Separation of molybdenum (VI) from multicomponent mixtures

Molybdenum (VI) was separated from various multicomponent mixtures, when a mixture of Pb, Sr/Ba/Ga and Mo(VI) was passed through the column at 6*M* hydrochloric acid concentration, lead was not adsorbed (hence passed through the column) whereas other elements were adsorbed on the column. The adsorbed Sr/Ba/Ga were eluted by washing the column with water and finally molybdenum was eluted with 0.5*M* ammonium hydroxide.

When a mixture of Th, Sr/Ba/Ga and Mo was passed through the column at 5*M* hydrochloric acid, thorium was not adsorbed (hence passed through the column). The adsorbed Sr/Ba/Ga was eluted with water and then molybdenum with 0.5*M* ammonium hydroxide. The separation of molybdenum from other multicomponent mixtures was accomplished similarly (Table 5).

The separation of molybdenum (VI) from other elements in multicomponent mixture are shown in Figs 2(a) and (b).

Application to analysis of molybdenum from various alloys and steel

The method was applied for the analysis of molybdenum from nickel base alloy (BCS-CRM No. 345), alloy steel (BCS-CRM 401/1), low alloy steel (SS-407/1) and high speed tool steel (SS-486/1), 0.1 gm of the alloy sample was dissolved in *aqua regia*, after evaporation of the acid it was extracted with water and diluted to 10 ml. An aliquot of this sample solution was mixed with hydrochloric acid so as to have its concentration of 5*M* in a total volume of 10 ml. The solution was passed through the column preconditioned at 5*M* hydrochloric acid. The column was subsequently washed with 5*M* hydrochloric acid to remove most of the unadsorbed elements. Then it was eluted with 2.5*M* hydrochloric acid to remove partially adsorbed iron. At this stage only molybdenum remained on the column. The column was then washed with water and molybdenum (VI) was eluted with 0.5*M* ammonium hydroxide and was determined spectrophotometrically with Tiron. The

results in triplicate analysis are shown in Table 6.

The strong binding of poly-(dibenzo-18-crown-6) for molybdenum (VI) can be explained on the following grounds. According to Pedersen[12] the selectivity of crown ether for a cation is based on (i) the relative size of ion and cavity of polyether, (ii) the number of oxygen atoms, (iii) the basicity of oxygen atom, (iv) the steric hindrance in a polyether ring, and (v) the tendency of the ion to associate with the solvent. Especially the relationship between the ion size and crown ether cavity has been extensively investigated and established as the primary principle for the cation selectivity. For the selectivity of crown ether polymer for a cation there is a simple rule. The polymer prefers[13] the cation for which the ratio of the diameter of cation to the diameter of polyether ring is 0.8. However, this relationship is not absolute. It was recently found[14] that the electrostatic interaction between lone pair orbitals of cyclic polyether and cation is the dominant part of the interaction energy. The stabilization energy which is accompanying the complex formation is divided into

Table 6. Determination of molybdenum (VI) in alloy sample

No.	Sample	Molybdenum (%) Present	Found
1	Nickel base alloy (BCS-CRM No. 345)	3.01	3.00
2	Alloy steel (BCS-CRM No. 401/1)	0.47	0.48
3	Low alloy steel (SS-407/1)	0.78	0.77
4	High speed tool steel (SS-486/1)	5.20	5.16

energies due to charge transfer interaction, electrostatic interaction, exchange interaction and polarization interaction. The strong binding of poly-(dibenzo-18-crown-6) for molybdenum (VI) may be due to the presence of electrostatic field in the crown ether cavity and high charge on molybdenum (VI) which results in the stabilization of the electrostatic and charge transfer interactions.

CONCLUSIONS

The important feature of this method is that it permits the separation of molybdenum from lead, strontium, barium, lanthanum, chromium, vanadium, iron, cesium and cobalt. The method was applied to the analysis of molybdenum from various alloy samples. The proposed method is very simple, rapid, selective and reproducible. The recovery of molybdenum in all instances from duplicate determinations is $100 \pm 2\%$.

FIRST DERIVATIVE SPECTROPHOTOMETRY FOR INDIVIDUAL AND SIMULTANEOUS DETERMINATION OF MAGNESIUM(II) AND COPPER(II) USING EMODIN(1,3,8-TRIHYDROXY-6-METHYLANTHRAQUINONE) AS REAGENT

TARASANKAR PAL and NIKHIL R. JANA
Department of Chemistry, Indian Institute of Technology, Kharagpur 721 302, India

(*Received* 15 *December* 1992. *Revised* 14 *April* 1993. *Accepted* 20 *April* 1993)

Summary—First derivative spectrophotometry are presented in comparison with simple spectrophotometric method for Cu(II) and Mg(II) determination with emodin in alkaline pH range. The molar absorptivity at the λ_{max} of 572 nm and 553 nm for Cu(II) and Mg(II) are 5.5×10^3 and 3.9×10^3 lit/mol/cm, respectively. Zero crossing measurement technique is found suitable for the simultaneous determination of the metal ions. The interference effects, statistical analyses and limits of detection are also reported.

Emodin, a polyphenolic anthraquinone, is a biochemically active[1,2] natural product and has been isolated from several plants as plant pigments.[3,4] It reacts with Cu(II) and Mg(II) ions in an alkaline medium to form coloured complexes. Recently, we reported its importance as photometric reagent.[5] It has been reported that Cu(II) interferes strongly in the determination of Mg(II) and both the complexes of Cu(II) and Mg(II) of emodin showed similar absorption profiles. This made the determination of Mg(II) impossible if present in a mixture with Cu(II) in the straight cut spectrophotometric process.

Recent development of the derivative spectrophotometry is now being used for eliminating the background interference and also for resolving the overlapping absorption bands.[6] It has been widely used in pharmaceutical analysis, amino-acid and protein analysis, clinical chemistry and environmental analysis.[7] The derivative method is being intensively used for the simultaneous determination of inorganic ions through the formation of complexes with the same organic ligands.[8–17] This advancement has led to the development of first derivative spectrophotometry for Cu(II) and Mg(II) for their quick determination without any separation if present singly or in mixtures and a comparison has also been made between normal and first derivative spectrophotometric determination of Cu(II) and Mg(II) to indicate the improved sensitivities.

The cations which interfere strongly in the determination of Cu(II) and Mg(II) includes Ni(II), Co(II), Mn(II), Cd(II), Cr(III), Fe(II) and Fe(III). The last three metal ions quench the absorbance values of Cu(II) and Mg(II) complexes of emodin. However, the remaining metal ions showed positive interference and because of their low molar absorptivities ($\sim 10^2$ lit/mol/cm), analytical procedure for their sensitive determination could not be developed. Moreover, these complexes have similar absorption profile and very close λ_{max} values. Hence simultaneous determination could not be achieved.

EXPERIMENTAL

Apparatus

All absorbance measurements were made with a Shimadzu UV-160 digital spectrophotometer with 1 cm quartz cells.

A digital (ECIL, Hyderabad, Govt. of India Enterprise) pH meter was used for pH measurements.

Reagents

All materials were of analytical reagent grade. Double distilled deionized water was used in all preparations.

A stock solution of emodin ($10^{-3}M$) was prepared by dissolving 67.5 mg of emodin (Aldrich Chemical Company, U.S.A.) in 250 ml volumetric flask using methanol as solvent. Fresh stock solutions of $Cu(NO_3)_2$ and $Mg(NO_3)_2$ were prepared using double distilled

water. The solutions were standardized[18] by using iodometric method for Cu(II) and complexometric method for Mg(II) and diluted to the range of $10^{-3}M$. Borate buffer with pH ranging from 8.0 to 9.2 were prepared with $0.2M$ boric acid and $0.05M$ borax solution. Buffer solutions with pH ranging between 9.2 and 11.0 were prepared with $0.05M$ borax and $0.2M$ sodium hydroxide solution. The pH was finally adjusted using a pH meter.

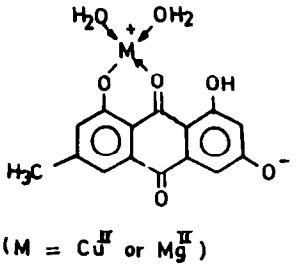

Fig. 2. Metal chelates at pH 9.8.

Procedure

In a 10 ml calibrated flask, 2.5 ml of the stock solution of emodin was mixed with varying amounts of Cu(II) and/or Mg(II) at a constant pH of 9.8, adjusted with 2.5 ml of the buffer solution. After 10 min the solution was diluted to the mark with methanol and the final methanol concentration in the solution was almost 75%.

For normal spectrophotometry of Cu(II), the absorbance values against reagent blank (emodin–methanol in alkaline buffer) were recorded at 572 nm.

The first derivative spectrum against reagent blank in all cases were recorded at a scan speed of 1500 nm/min and $\Delta\lambda = 11.2$ nm. The amplitudes were measured at 600 nm and 580 nm for Cu(II) and Mg(II), respectively when they were present alone, but in mixture the amplitudes used were 553 nm for Cu(II) and 572 nm for Mg(II).

RESULTS AND DISCUSSION

Effect of pH on complex formation

The effect of pH on the formation of Cu(II) and Mg(II) complexes with emodin were studied over the pH range of 2.0–12.0 at room temperature (25°C) and at 75% methanol–water mixture.

Cu(II) forms three types of complex in presence of emodin depending on the pH of the solution. In the pH range of 6.0–7.0 yellow coloured complex was formed which was insoluble in methanol, ethanol and water. In the pH range of 8.0–11.0, a pink coloured complex was formed having λ_{max} at 572 nm. The complex was soluble in both methanol and water. In the pH range of 11.0–12.2, another complex having λ_{max} of 585 nm with comparatively lower molar absorptivity than the second complex was formed. In each case emodin was in excess in comparison to Cu(II) and the complex formation was reversible and interconvertible depending on the pH condition of the medium.

Unlike Cu(II), Mg(II) forms two types of complex with emodin depending upon pH.

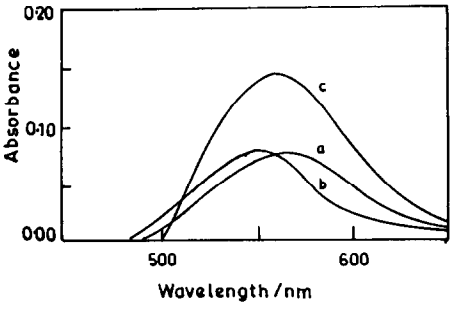

Fig. 3(a). Absorption spectra of emodin complexes of Cu(II) and Mg(II) against reagent blank at pH 9.8.

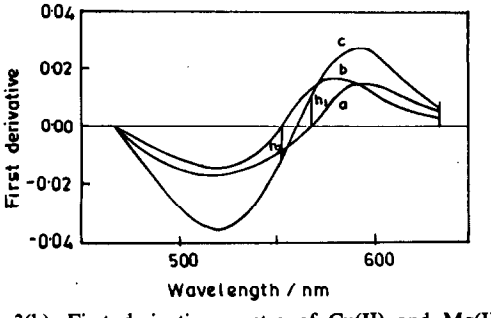

Fig. 3(b). First derivative spectra of Cu(II) and Mg(II) complexes of emodin at pH = 9.8.

Table 1. Statistical analyses of the determination of Cu(II) and Mg(II) from zeroth and 1st order derivative spectrophotometry

Element determined	Order of the derivative	Slope	Intercept	Correlation coefficient	LOD (*ppb*)
Cu(II)	Zeroth	0.087	4.5×10^{-4}	0.997	40
	First	0.017	5.8×10^{-4}	0.997	25
Mg(II)	Zeroth	0.162	-1.24×10^{-4}	0.995	20
	First	0.032	4.0×10^{-4}	0.994	10

When excess emodin was used, Mg(II) forms a coloured complex having λ_{max} at 553 nm, soluble in methanol and water in the pH range of 8.0–11.5, which was shown in our previous study.[5] In the pH range of 11.5–12.2 another complex having $\lambda_{max} = 575$ nm with comparatively lower molar absorptivity, was identified. These complex formations were also reversible and by changing pH one complex could be converted to the other. Detailed structural studies of all the complexes are in progress.

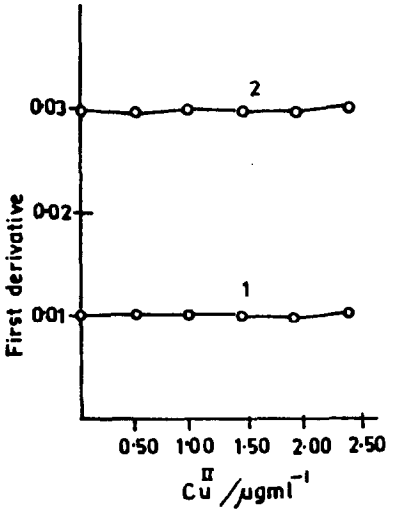

Fig. 4(a). Amplitude of the first derivative for Mg(II) = 0.36 μg/ml (1) and 0.97 μg/ml (2) at 572 nm in the presence of variable amounts of Cu(II).

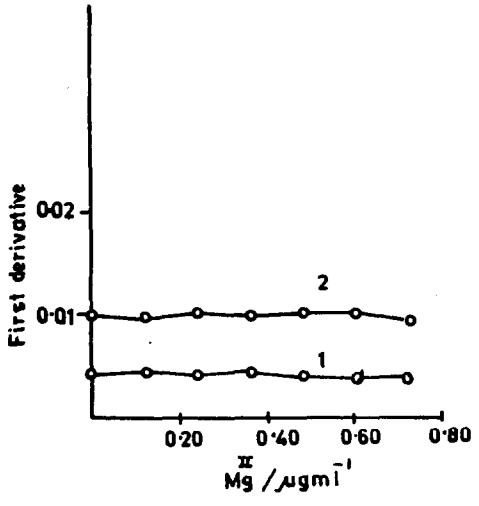

Fig. 4(b). Amplitude of the first derivative for Cu(II) = 0.32 μg/ml (1) and 0.79 μg/ml (2) at 553 nm in the presence of variable amounts of Mg(II).

Selection of optimum pH

In the pH range of 9.0–10.0 the absorbance of Cu(II)–emodin complex appeared to be constant and maximum (Fig. 1(a)). However, for Mg(II)–emodin complex, the constant and maximum absorbance was in the pH range of 9.7–10.0 (Fig. 1(b)). Considering the solubilities, maximum absorbance of both the complexes and quantitative complexation with the reagent, we developed the analytical method at 9.8 pH condition.

Effect of excess metal ions

When large excess of Cu(II) was used, a coloured precipitate was formed in the pH range of 8.0–12.1 and the solution becomes colourless. The precipitate was insoluble in DMF, chloroform, methanol, water, acetone but slightly soluble in DMSO when heated but it dissociates to release free emodin in acid medium.

Mg(II) forms a similar type of coloured precipitate, but at a higher pH range of 11.0–12.1. A large excess of metal ions precipitates both the reagent and the complex which may be due to flocculation. Therefore, in all measurements we have used large excess of emodin to inhibit the precipitation.

Effect of methanol concentration

The pK values of emodin in methanol–water system varies with the change in methanol concentration. This fact may be explained by the interaction of the solvent with >C=O group of the reagent.[19] It was observed that in the pH range of 8.0–11.0 Cu(II) forms a pink coloured soluble complex ($\lambda_{max} = 572$ nm) with emodin while the methanol concentration is >50%. Another yellow coloured Cu(II)–emodin complex may be obtained from the medium with

Table 2. Statistical analyses for simultaneous determination of Cu(II) and Mg(II) by first derivative spectrophotometry

Element determined	Other element present: Element	Concentration ($\mu g/ml$)	Slope	Intercept	Correlation coefficient
Cu(II)	Mg(II)	0.00	0.013	1.0×10^{-4}	0.995
		0.36	0.013	1.8×10^{-4}	0.992
		0.97	0.013	9.2×10^{-5}	0.993
Mg(II)	Cu(II)	0.00	0.030	2.0×10^{-4}	0.989
		0.32	0.029	3.3×10^{-4}	0.988
		0.79	0.030	6.0×10^{-4}	0.991

lower (<50%) methanol concentration and its λ_{max} is blue shifted from 572 nm. We developed the method for Cu(II) determination with the pink coloured complex ($\lambda_{max} = 572$ nm) only because the absorbance value of it remained constant for days together unlike the yellow complex.

On the contrary, Mg(II) formed only one type of complex with emodin unlike Cu(II) which was indicated by the unaltered λ_{max} value for varied methanol concentrations of the medium at a pH range of 8.0–11.5.

Stoichiometry and nature of the chelates

The stoichiometry and the nature of the complexes formed at pH 8.0–11.0 for Cu(II) and 8.0–11.5 for Mg(II) were studied. Cu(II)–emodin complex studied by continuous variation method at a pH of 9.8 showed that the metal–ligand ratio was 1:1 which was similar to Mg(II)–emodin stoichiometry.[5] The rate of complex formation with emodin was slower in case of Cu(II) than with Mg(II). The Cu(II)–emodin complex remained stable for 72 hr. In addition, non-extractability of the complexes in common organic solvents like chloroform, carbon tetrachloride and ethylacetate and fixation of the chelates as a counter ion in both cation and anion exchange resin, indicated the presence of cationic and anionic part in the complexes, and the following structures (Fig. 2) have been proposed. As the complex could not be isolated, the conductometric studies were not possible.

Optimum $\Delta\lambda$ and scan speed

The characteristic of derivative spectra depends on the choice of instrumental parameters. These were optimized with respect to reduction of noise levels and sensitivity. The best results were obtained at a scan speed of 1500 nm/min over the wavelength range of 450–650 nm, with a wavelength interval of 11.2 nm for the first derivative spectrophotometry.

Spectrophotometric measurements

Figure 3(a) shows zero order absorption spectra of (a) Cu(II)–emodin complex (0.95 μg/ml of Cu(II), (b) Mg(II)–emodin complex (0.49 μg/ml of Mg(II)), and (c) the mixture of Cu(II) and Mg(II) complexes (0.95 and 0.49 μg/ml of Cu(II) and Mg(II), respectively).

Figure 3(b) shows the first derivative spectra of the complexes showed in Fig. 3(a). The wavelengths corresponding to the maximum amplitude for the first derivative spectrum of Cu(II)–emodin complex are 522 nm and 600 nm, while those for Mg(II)–emodin complex are 530 nm and 580 nm. The zero point wavelength for Cu(II)–complex is 572 nm and that for Mg(II) complex is 553 nm.

Due to the closeness of the two overlapping spectra, the first derivative of their mixtures were not sufficiently resolved to generate two

Table 3. Determination of Mg(II) in rock samples by normal and first derivative spectrophotometry

Sample	Mg (%) Present*	Found: normal	Found: 1st D	Relative % error: normal	Relative % error: 1st D
Charnockite	0.14	0.14	0.14	0.0	0.0

Charnockite	0.25	0.25	0.26	0.0	+4.0

*Analysed by AAS.

distinct peaks. So we used the zero crossing measurement technique,[20] for the preparation of the calibration curves for mixtures. Amplitude h_1 and h_2 in the first derivative spectra of the mixture at wavelengths 572 nm and 553 nm were proportional to Mg(II) and Cu(II) concentration, respectively.

Determination of Cu(II)

A number of solutions of Cu(II)–emodin complexes were prepared at a variety of Cu(II) concentrations and at constant pH of 9.8. After 10 min the absorbance values corresponding to 572 nm were recorded. The plot of concentration of Cu(II) *vs* absorbance was a straight line while the Cu(II) concentration varies from 0.5 to 2.5 ppm, (Table 1).

Two wavelengths (522 nm and 600 nm) of maximum amplitude in first derivative spectrum for Cu(II) complex were noted. There was a shift in wavelength corresponding to maximum negative amplitude with varied Cu(II) concentrations. So we prepared the calibration curve by measuring amplitudes of first derivatives at 600 nm for different concentrations of Cu(II) ions. A linear relationship was obtained for 0.15–2.38 μg/ml of Cu(II) (Table 1).

Determination of Mg(II)

Use of first derivative method has improved the sensitivities in comparison to normal spectrophotometric methods reported earlier.[5]

The first derivative spectrum of Mg(II)–emodin complex had two wavelengths (530 and 580 nm) of maximum amplitude, but there was a small shift in wavelength of 530 nm, corresponding to maximum negative amplitude with the change of Mg(II) concentration. So we have used 580 nm for amplitude measurement to prepare calibration curves for Mg(II) and the linear relationship was obtained for 0.06–1.46 μg/ml of Mg(II) (Table 1).

Determination of Cu(II) and Mg(II) in mixtures

We have seen that a fixed concentration of Mg(II)–emodin complex has a sufficient and constant amplitude at 572 nm (the Cu(II)–emodin complex zero point wavelength) in the presence of various amounts of Cu(II) concentration (Fig. 4(a)). Similarly, the amplitude at 553 nm (the Mg(II)–emodin complex zero point wavelength) for Cu(II)–emodin complex was independent of Mg(II) concentration (Fig. 4(b)).

Two calibration curves were obtained for standards containing 0.12–0.73 μg/ml of Mg(II) in the presence of 0.32 μg/ml and 0.79 μg/ml of Cu(II). Similarly, curves for standards containing 0.48–2.38 μg/ml of Cu(II), in the presence of 0.36 μg/ml and 0.97 μg/ml of Mg(II) were prepared. Slope, intercepts, correlation coefficients are summarized in Table 2.

Precision and accuracy

In order to test the accuracy and precision of the method, eight successive measurements were done with stock solutions containing 1.91 μg/ml of Cu(II) and 0.49 μg/ml of Mg(II). Relative standard deviations for zeroth order and first order derivative method of Cu(II) were 2 and 1%, respectively and those for Mg(II) were 1.8% and 0.8%, respectively.

For simultaneous determination of Cu(II) (0.95 μg/ml) and Mg(II) (0.49 μg/ml), the relative standard deviations were 1.1 and 1.2%, respectively.

Effect of foreign substances

Investigations were carried out to examine the influence of common ions for the determination of Cu(II) and Mg(II),[5] when they were present separately in solution. Both the metal ions can be determined in presence of Sr(II), Ba(II), Na(I), K(I) ions. Cu(II) can be determined in the presence of equal amount of Ni(II), Cd(II), Pb(II) and two-fold excess of Co(II), Zn(II), Ag(I) and Mn(II) ions. Common anions NO_3^-, NO_2^-, $CH_3CO_2^-$, Cl^-, Br^- can also be tolerated if they are present in 1000-fold excess.

Application

Magnesium was successfully determined in several rock samples, following HF digestion method. The base metals were separated out at a pH of 6.0 as their hydroxides using NaOH solution. The process was repeated four times and peptization of the base metal precipitate was avoided using NH_4NO_3 solution to collect all the Mg(II) ions in the filtrate. Determination of Cu(II) was not possible as the percentage of Cu(II) in those samples were very low (<50 ppm) in comparison to Mg(II). However, the results were satisfactory for copper–magnesium synthetic mixtures.

Acknowledgement—The authors thank Dr T. Vo-Dinh, ORNL, U.S.A. for his invaluable suggestions for the completion of this work.

EXTRACTIVE SPECTROPHOTOMETRIC DETERMINATIONS OF SOME PHENOTHIAZINE DERIVATIVES IN PHARMACEUTICAL PREPARATIONS

S. L. BHONGADE and A. V. KASTURE

Dept. of Pharmaceutical Sciences, Nagpur University, University Campus, Nagpur 440 010, India

(*Received* 11 *December* 1992. *Revised* 24 *March* 1993. *Accepted* 18 *April* 1993)

Summary—Two sensitive methods for the determination of phenothiazine derivatives based on the formation of coloured salts of these drugs formed with Brilliant Blue or Orange-II in the presence of 0.1*M* HCl are described. The ion pair salts formed are quantitatively extracted into chloroform and the dried chloroform solutions analyzed using spectrophotometry.

Phenothiazine derivatives are widely used as antipsychotropic, anticholinergic and antihistaminic drugs.[1] In view of the importance of phenothiazines, considerable work has been done for their detection and quantification.[2,3,4] Many phenothiazine derivatives and their formulations are official in British Pharmacopoeia[5] and Indian Pharmacopoeia.[6] The methods used for their determination include spectrophotometry,[7] spectrofluorimetry,[8] conductometry[9] and chromatography.[10,11] The aim of the present work is to provide a simple and sensitive method for the estimation of phenothiazine in formulations. While the acid–dye method has been employed so far for the estimation of a single basic drug at suitable pH, the present method facilitates the analysis of the foresaid drugs in combination without buffer solutions.

The proposed extractive spectrophotometric methods are based on the formation of ion pair complexes with Brilliant Blue ($\lambda_{max} = 620$ nm) or Orange-II ($\lambda_{max} = 495$ nm) and their complexes are quantitatively extracted into chloroform.

Structures of Brilliant Blue and Orange-II and their chloroform soluble complexes with a phenothiazine (Promethazine hydrochloride) are shown in Fig. 1.

EXPERIMENTAL

Apparatus

Shimadzu UV-150 spectrophotometer with 1 cm matched quartz cells was used.

Reagents and solutions

The chemicals of analytical grade were used. Aqueous solutions (0.5%) of Brilliant Blue and Orange-II and 0.1*M* HCl were employed.

Standard solutions

Commercially available phenothiazines of I.P. or B.P. grade were used. Stock solutions of phenothiazine derivatives (1 mg/ml) were prepared in distilled water. Insoluble compounds were initially dissolved in a minimum amount of dilute hydrochloric acid. Working solutions were prepared by appropriate dilution of the stock solution with the same solvent.

Assay procedures

Method A. Aqueous aliquots containing 15–150 μg of standard drug were transferred into a series of separatory funnels, 1 ml of Brilliant Blue was added to each and the total volume of the aqueous phase was adjusted to 10 ml with distilled water. Fifteen millilitres of chloroform were added and the contents were shaken for 2 min. The two phases were allowed to separate and the chloroform layer passed through anhydrous sodium sulphate. Absorbance was measured at 620 nm against a reagent blank and the amount of drug was computed from a Beer–Lambert plot.

Method B. Aqueous aliquots containing 45–375 μg of standard drug were transferred into a series of separatory funnels. Two millilitres of 0.1*M* HCl and 2 ml of Orange-II solutions were added to each and the total volume of the aqueous phase was adjusted to 10 ml with distilled water. Fifteen millilitres of

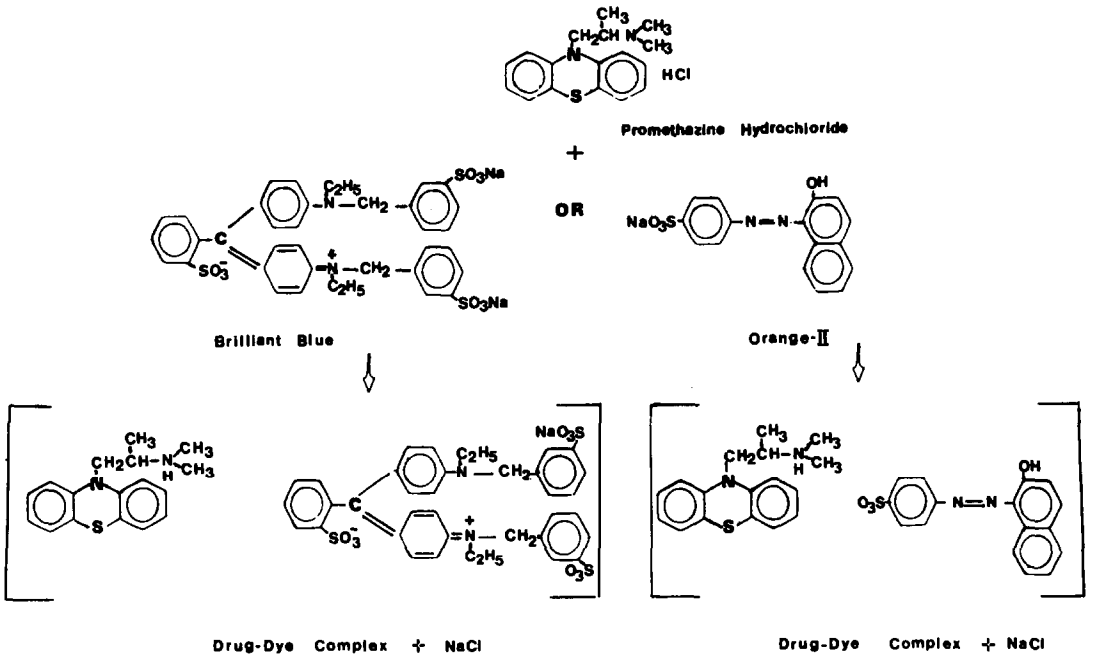

Fig. 1. Structure of Brilliant Blue and Orange-II and their respective complexes with promethazine hydrochloride.

chloroform was added and the contents were shaken for 2 min. The two phases were allowed to separate and the chloroform layer passed through anhydrous sodium sulphate. Absorbance was measured at 495 nm against a reagent blank and the amount of drug was computed from a Beer–Lambert plot.

In each case the absorbance value was plotted against the corresponding concentration of drug in μg/ml. These plots were linear through the limiting concentration as shown in Table 1.

British Pharmacopoeia methods include extraction followed by non-aqueous titration or spectrophotometric determination for individual phenothiazine drug.

Estimation from tablets. Twenty tablets were massed and powdered. The powder equivalent to 50 mg of active ingredient was transferred to a 100 ml volumetric flask and dissolved in 100 ml of distilled water (for dissolving Prochlorperazine maleate, minimum amount of dilute hydrochloric acid was used) and filtered. Ten millilitres of filtrate was further diluted to 100 ml with distilled water. Two millilitres of the resulting solution was used for determination by the Brilliant Blue and Orange-II methods. The amount of drug in these tablets was calculated using the observed absorbance, the mass of powdered sample and dilution factor. Results are given in Table 2.

For the determination of drug in a syrup or injectable dosage form, the mass of drug per ml

was determined. A quantity of syrup or injectable dosage form equivalent to 50 mg of drug was transferred to a 100 ml volumetric flask and diluted to 100 ml with distilled water. This solution was further diluted with water so that the final solution contained about 50 μg/ml, before analysis by the Brilliant Blue and Orange-II method.

Recovery experiment

To determine the precision and accuracy of the above methods, recovery experiments were performed using the method of additions. A fixed volume sample of solution was added to one of three different concentrations of the standard drug solution. The total amount of drug was then determined using Brilliant Blue and Orange-II and the amount of added drug found by difference.

Results obtained by the Brilliant Blue and Orange-II and the British Pharmacopoeia methods for the various dosage forms are compared in Table 2.

RESULTS AND DISCUSSION

These drugs form salts that exhibit absorption maxima at 620 nm with Brilliant Blue and 495 nm with Orange-II. Beer–Lambert law limits, molar absorptivity and Sandell's sensitivity values found for various phenothiazines are shown in Table 1. The mole ratio of drug to dye was found to be 1:1 for Brilliant Blue and Orange-II. To test the reproducibility and accuracy of these methods, six replicate determinations were made with each drug and the relative standard deviation from the mean are presented in Table 1.

A significant advantage of an extractive spectrophotometric determination is that it can be applied to the determination of individual compounds in a multicomponent mixture. This aspect of spectrophotometric analysis is of major interest in analytical pharmacy since it offers distinct possibilities in the assay of a particular component in a complex dosage formulation. In the present study, a number of phenothiazines were determined successfully as

pure compounds as well as components in representative dosage formulation.

Results of proposed methods show good agreement when compared with the official method (Table 2). Additives used in the formulation do not interfere with the proposed methods. These results indicate that the proposed methods are simple, rapid and accurate and offer advantage in that only a small amount of drug or dosage formulation is required for analysis.

SULPHATE PRECONCENTRATION BY ANION EXCHANGE RESIN IN FLOW INJECTION AND ITS TURBIDIMETRIC DETERMINATION IN WATER

MARINA M. SANTOS FILHA

(*Received* 3 *November* 1992. *Revised* 22 *March* 1993. *Accepted* 22 *March* 1993)

Summary—A preconcentration procedure was established for sulphate determination in rain waters at the mg/l level, employing a small column packed with the AG1-X8 (200–400 mesh) anionic resin inserted into a flow injection system. Sulphate determination was performed by using the turbidimetric method based on reaction with barium. For concentrations within 0.10 and 2.0 mgSO_4^{2-}/l, a throughput of 50 determinations/hr was achieved, and the relative standard deviation of results was better than 2%.

Research programmes in environmental science have caused a continuous increase in the demand for determinations of several analytes in a large number of water samples from dams, rivers or rain. Although some analytic methodologies are available for cations, only a few well-established ones have been reported for anions. Sulphate is one of the anions with less options, particularly for concentrations at low mg/l levels.

Flow injection analysis (FIA) is an attractive approach for automation when a large number of samples are to be processed, and has often been implemented with low cost instrumentation.[1] A few photometric FIA procedures for the determination of sulphate in water samples were proposed[2,3] and that based on barium sulphate turbidimetry[2] presents good characteristics, such as high sample throughput, low reagent consumption, high precision and accuracy. However, its detection limit of about 2 mg/l is not enough for some water samples.

This paper reports the development of a sulphate preconcentration procedure by anion exchange resin in order to improve the detection limit of the turbidimetric FIA method.

EXPERIMENTAL

Apparatus

A Micronal B342 II spectrophotometer equipped with a tubular flow cell (12 mm optical path, 200 μl inner volume) and coupled to a Radiometer REC 61 strip chart recorder was used. The Ismatec mp13GJ4 peristaltic pump was furnished with Tygon tubing.

A sliding bar automatic injector with three commutation sections[4] was used. It was controlled by a laboratory-made microcomputer based on the Intel 8085 microprocessor.[5] A software written in Assembly language run by the microcomputer provides facilities to program different time delays for both resin loading and elution steps.

Reagents

All chemicals were of analytical grade quality and freshly distilled and deionized water was used throughout.

The standard stock solution of sulphate 1000 mg/l was prepared by dissolving ammonium sulphate in water. Working standards within the 0.00–2.00 mg/l range were prepared daily. Sulphate solutions (50 and 100 mg/l) used as spike

were prepared by appropriated water dilutions of the stock solution.

A 20% w/v barium chloride dihydrate solution in 0.05% w/v polyvinyl alcohol (PVA-Du Pont Elvanol 71-30) was prepared by first producing a slurry of PVA in 100 ml of water and, while stirring, slowly adding 300 ml of boiling water. Thereafter, barium chloride was dissolved, the solution was cooled and the volume made up to 1000 ml with water.

Eluent solutions were prepared in the 0.1–2.0*M* range as sodium chloride or sodium nitrate by dissolving appropriate amounts of the respective salts in water.

Preparation of the resin column

The resin column (8 × 5 mm) was machined in a Perspex block as described elsewhere.[6] The AG1-X8 anion exchange resin 200–400 mesh (Bio-Rad Labs) was employed. The column was filled with a slurry of the resin up to its volume by using a syringe, the excess of water being drained. The resin, initially in chloride form, was converted to nitrate by pumping a 1.0*M* sodium nitrate solution through it at 3 ml/min, until the effluent showed no turbidity after addition of a few drops of 0.1*M* silver nitrate solution. Before use, the resin column was equilibrated with nitrate ions by pumping 0.5*M* sodium nitrate for about 20 min at 3 ml/min.

Experimental variables

To simplify the investigations of the variables involved in the preconcentration step, the resin column was coupled to the injector sliding bar. The amount of sulphate ions adsorbed by the resin is dependent on both, the sample flow-rate through the resin and the column loading time. These two parameters were investigated with the FIA network outlined in Fig. 1. In the specified position, the sample (S) is pumped through both loop (L) (previously loaded with a sulphate spike solution) and the resin column (C). The

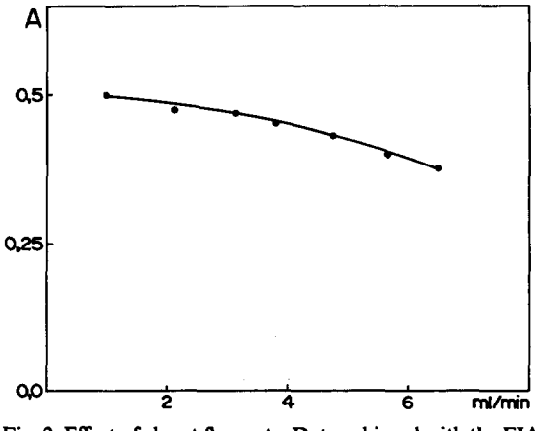

Fig. 2. Effect of eluent flow rate. Data achieved with the FIA manifold of Fig. 1. Preconcentration with 4.0 mg/l sulphate flowing at 6 ml/min sample during 30 sec column loading time, elution with 1.0*M* sodium nitrate over 20 sec, and spiked with 100 mg/l sulphate; *A* = absorbance.

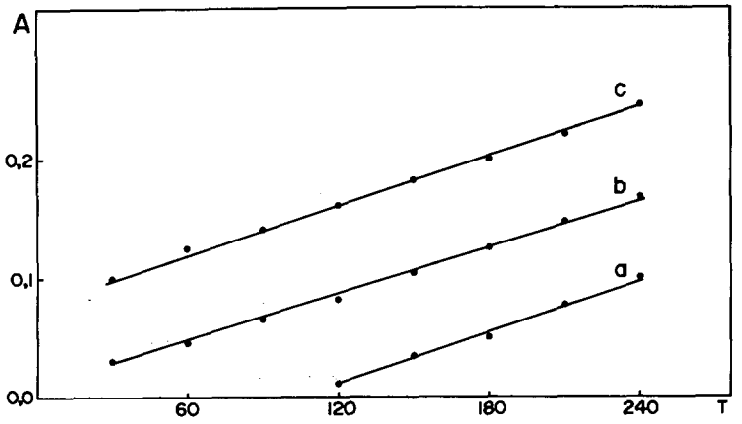

Fig. 3. Effect of sulphate spike solution. Preconcentration with 0.20 mg/l sulphate flowing at 7 ml/min, elution with 0.25*M* sodium nitrate solution at 3.1 ml/min. *T* is the column loading time in seconds, and *A* denotes absorbance values. Curves a, b and c correspond to 0, 50 and 100 mg/l sulphate spike solutions.

outlet flow depleted of sulphate ions is directed towards waste (W), while the barium chloride solution (R_1) is recovered and the washing solution (R_2) is added at confluence point x to clean the analytical path. When the injector is switched to the other position, the resin column is inserted into the analytical path and the eluent solution (E) is pumped through it. Reagent R_1 is added to the eluted sample zone at confluence point y and precipitation reaction takes place inside the reactor (Ra). The turbidity is monitored at 410 nm, yielding a transient signal proportional to analyte concentration in the sample which is traced by the stripchart recorder. At the same time the spike solution (Sp) is pumped to fill again the loop L. The spike solution was used to improve barium sulphate nucleation.[2] By moving the sliding bar back to position specified in Fig. 1 another preconcentration step is initialized.

Effects of both eluent flow-rate and concentrations were investigated with a 4.0 mg/l sulphate standard. Sample flow-rate was maintained at 6 ml/min and time delays for column load and elution were both 30 sec. When the injector was switched to the elution position the speed of peristaltic pump was changed accordingly at the same time. Experiments were carried out with flow-rates ranging from 1 to 7 ml/min. As eluent, 0.10, 0.15, 0.50 and 1.0*M* aqueous sodium nitrate or sodium chloride solutions were tested.

Influence of column loading time was investigated by maintaining a constant sample flow-rate of 7 ml/min and programming the microcomputer to increase the loading time from 30 to 240 sec in 30 sec steps. Effects of sample flow-rate were investigated in the range 2–15 ml/min by keeping the column loading time at 60 sec.

In order to evaluate the system performance, two sets of rain water samples were analysed. The first group was used to check the accuracy by analyte additions and the other one to verify the long term stability.

The analyte additions were performed manually by delivering aliquots of 100 μl (Finnpipette) from a 250 mg/l sulphate standard to 100 ml sample volume.

RESULTS AND DISCUSSION

Elution

The increase of the ions average velocity through the column can affect both the kinetic of ion exchange in the resin and the nucleation process in the analytical path, which could explain the signal diminution with the increase in flow-rate shown in Fig. 2. Better elution results were obtained with a 0.25*M* sodium nitrate solution. Lower nitrate concentrations

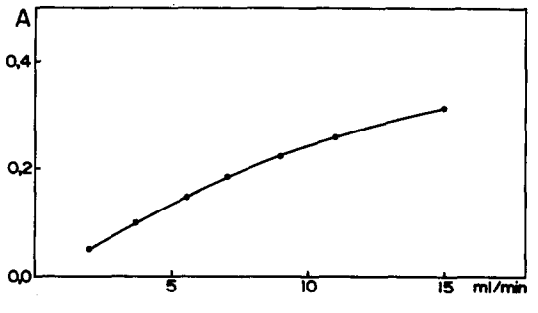

Fig. 4. Effect of sample flow-rate through the resin column. Preconcentration with 1.00 mg/l sulphate flowing at 7 ml/min during 60 sec, elution with 0.25*M* sodium nitrate solution at 3.1 ml/min, and spike with 50 mg/l sulphate solution. *A* = absorbance.

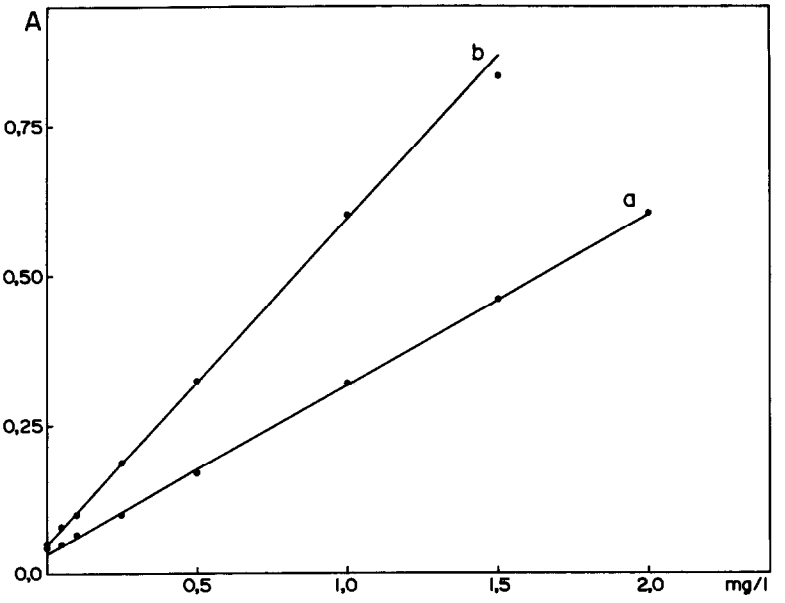

Fig. 5. Effect of column loading time. Sample flow-rate 7 ml/min, elution with 0.25*M* sodium nitrate solution flowing at 3.1 ml/min. Curves a and b refer to 120 and 240 sec column loading times, respectively. *A* = absorbance.

yielded lower measurements, and higher caused disturbance in baseline due to the "Schlieren" effect.[7] It should be pointed out that this effect in the refraction index was also caused by the added washing solution.

Preconcentration

As expected, an increase in the analytical signal with the column loading time was obtained, as shown in Fig. 3. Also, it can be seen that the sulphate spiking solution had an enhancement effect due to its influence on the barium sulphate nucleation, resulting in a remarkable improvement on detection limit. The 50 mg/l sulphate solution was the threshold concentration for this improvement and it was used in the subsequent experiments.

Figure 4 shows that absorbance also increased with the sample flow-rate, a linear response being obtained up to 7 ml/min. Beyond this value, a asymptotic behavior was observed. In this case, the analyte ions went through the resin column more quickly, impairing the kinetic of exchange. On the other hand, similar results would occur when the resin column capacity to exchange anions would tend to

saturation. In order to ascertain this assumption other experiments were carried out yielding the results shown in Fig. 5. It can be seen that the amount of sulphate ions adsorbed by the resin were directly proportional to the column loading time, the same signal being obtained for 0.50 and 1.00 mg/l sulphate standards flowing at 7.0 ml/min during 120–240 sec loading times, respectively. It can also be deduced that the ratio between the slopes of curves a and b is exactly 1:2. Thus, it can be ascribed that the main reason for the signal behaviour observed in Fig. 4 for sample flowing at values higher than 7 ml/min was associated to column efficiency. Although 7 ml/min seemed the threshold value for maximum resin efficiency, there is no practical restriction to work at 15 ml/min sample flow-rate. To get a better efficiency of preconcentration and also to avoid fluid leakage caused by hydrodynamic over pressure, a sample flow-rate of 7 ml/min was chosen for the remaining experiments.

The ability of the resin for complete sulphate ions removal from sample bulk solution was verified by using a 0.50 mg/l sulphate standard solution. The resin column effluent was collected during several column loading steps, and analyzed in the same way as the standard. Results were practically identical to those of the blank, indicating a high efficiency of the resin column for adsorbing sulphate.

Interference

Anions usually present in natural waters, such as orthophosphate, chloride, nitrate and carbonate, are also adsorbed by the resin and may cause its saturation. To evaluate the column exchange capacity, experiments were carried out, by using standard solutions containing 0.05, 0.50 and 2.50 mg/l sulphate plus 30 mg/l of each chloride, nitrate, carbonate and orthophosphate (sodium salts). Results summarized in the Table 1 show that, in general, negligible variations in the measured signal were observed, except for orthophosphate, where a 12% decrease in absorbance was noted for 0.05 mg/l sulphate. As this effect was less pronounced for higher sulphate concentrations, the effect cannot be attributed to the resin saturation. Identical results were obtained for a mixed solution containing 30 mg/l of chloride, nitrate, carbonate and orthophosphate. In this sense, the interference caused by orthophosphate ions was probably associated to its effect on the barium sulphate nucleation process. This assumption can be corroborated if one considers that the resin affinity for sulphate is 13 times higher than that for orthophosphate.[8]

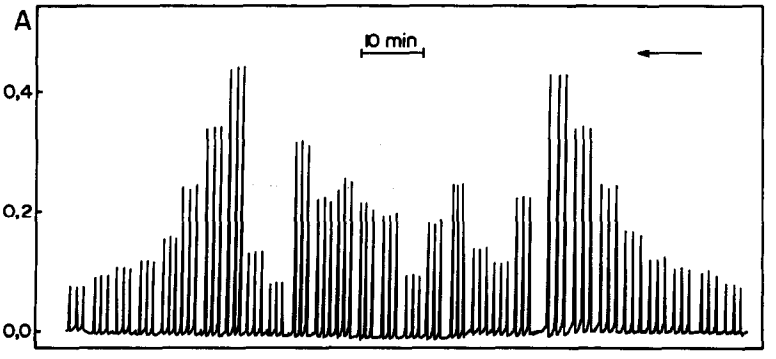

Fig. 6. Recorder tracing of a routine water analysis. From left to right, eight standard solutions (0.00, 0.05, 0.10, 0.25, 0.50, 1.00, 1.50, 2.00 mg/l), 13 samples and the standards again, always in triplicate. Arrow indicates the displacement of recorder chart. A = absorbance.

It should be pointed out that the concentrations of these anions in waters are quite variable depending on the origin of the sample, but they are generally much lower than the maximum levels tested, particularly orthophosphate. It should also be mentioned that the orthophosphate interference observed here was lower than that reported in the methylthymol blue method.[9]

Routine analysis

The working conditions for using the FIA network of Fig. 1 in routine scale were set up considering the results presented in the last section, *i.e.* preconcentration was done after pumping 7.0 ml/min of sample for 60 sec, and elution carried out with 0.25*M* $NaNO_3$ solution flowing at 3.2 ml/min for 15 sec. The 50 mg/l sulphate spike solution was introduced by a 20 cm loop L.

Table 2 shows the results obtained with 17 samples of rain water. The relative standard deviations of measurements ($n = 10$) for all samples were always lower than 2%, which can be considered very good for sulphate in the 0.50–2.00 mg/l range. The long term stability can be ascertained with the help of Fig. 6. An acceptable baseline drift, which was indeed insignificant, is observed. Also, it can be deduced from the same figure that a throughput of 48 samples/hr can be obtained with precision. In addition, it should be mentioned that this FIA system has proven to be analytically robust in the large scale routine programme at the author's laboratory, after processing more than 10,000 samples.

SOLVENT EXTRACTION SEPARATION OF COBALT(II) FROM NICKEL AND OTHER METALS WITH CYANEX 272

M. N. GANDHI,* N. V. DEORKAR† and S. M. KHOPKAR‡
Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India

(*Received* 15 *October* 1992. *Revised* 1 *March* 1993. *Accepted* 10 *March* 1993)

Summary—Cobalt(II) was quantitatively extracted at pH 8.0 with $5 \times 10^{-3}M$ Cyanex 272 [Bis(2,4,4 trimethyl pentyl) phosphoric acid] in chloroform. Cobalt(II) was stripped with $0.5M$ nitric acid and was determined by atomic absorption spectrometry as well as by spectrophotometry of the complex with nitroso R salt. Cobalt(II) was separated from vanadium, chromium, nickel, manganese, iron and zinc. Mixtures having different ratios of iron, cobalt and nickel were separated by proposed method.

Oxygen containing extractants have proven to be poor extractants for cobalt as well as for nickel.[1] The extraction of cobalt was effective with tributylphosphate (TBP) in the presence of salting out agents. It was quantitative from 10–12M hydrochloric acid.[2] This result facilitated the separation of cobalt and nickel as nickel was poorly extracted with TBP,[3] cobalt was extracted with MIBK from 4M ammonium thiocyanate.[4] Extraction with liquid anion and liquid cation exchangers was generally poor.[5] However, bis(diethyl hexyl phosphoric acid) (HDEHP)[6,7,8] was successfully used for extraction of cobalt. The extraction of nickel was poorer than that of cobalt, with most of the oxygen containing extractants like ethers and alcohols with TBP, extraction was not quantitative.[9] The separation factor for separating cobalt from nickel in TBP—10M hydrochloric acid system was 1700. The extraction with octyl alcohol[10] from bromide media was satisfactory.

The suitable extractants for separation were chelating extractants *e.g.* 1-nitroso-2-naphthol[11] or dimethylglyoxime.[12] Such chelating extractants were effective for the individual separation of nickel or cobalt from other elements but were not useful for mutual separations of cobalt and nickel.

Cyanex reagents[13] have come to the forefront in recent years. Of these, Cyanex 272, *i.e.* bis (2,4,4 trimethyl pentyl) phosphoric acid, Cyanex 301 and Cyanex 302 are versatile as the extractants. The last two are thio substituted derivatives of Cyanex 272. However, systematic studies with Cyanex 272 for cobalt are lacking. Therefore it was thought worthwhile to undertake the solvent extraction separation studies of cobalt and nickel with Cyanex 272. Both atomic absorption spectroscopy as well as spectrophotometric determination of cobalt with Nitroso R salt were carried out.

EXPERIMENTAL

Apparatus and reagents

GBC 902 Atomic absorption spectrometer (GBC Australia), ECIL Spectrophotometer Model as 866C; Orion microprocessor ion analyser model 901 (Orion, USA), wrist action flask shaker (Toshniwal Ltd, India).

A stock solution of cobalt(II) was prepared by dissolving 4.037 gm of cobalt chloride in 1 l of distilled water containing 0.5% of concentrated hydrochloric acid. The solution was standardized complexometrically.[14] It contained 1.009 gm/ml cobalt(II). The diluted solution containing 5 μg/ml of cobalt(II) was prepared by appropriate dilution. Cyanex 272, bis(2,4,4 trimethyl pentyl) phosphoric acid (American Cyanamid Co., USA), was used directly without further purification.

GENERAL PROCEDURE

An aliquot of solution containing cobalt(II) was taken and its pH was adjusted to 8.0 with 0.1*M* sulphuric acid or ammonium hydroxide. The total volume was made to 10 ml. The solution was then transferred into a separatory funnel, 10 ml of $5 \times 10^{-3}M$ Cyanex 272 in chloroform was added to it, and the mixture was shaken on a wrist action flask shaker for 5 min. The two phases were allowed to settle and separate. The concentration of cobalt from the aqueous phase after phase separation was determined by atomic absorption spectrometry. From the organic phase cobalt(II) was back extracted with 10 ml of 0.5*M* nitric acid and cobalt was determined either by atomic absorption spectrometry at 240.7 nm with an air acetylene flame or spectrophotometrically. From these data the distribution ratio (*D*) was evaluated. The results of the extraction were further confirmed by spectrophotometric determination of cobalt with Nitroso R salt in both phases.

During systematic investigation of various parameters influencing the process of extraction, cobalt from both phases was determined by atomic absorption spectrometry as multiple samples were involved. However during separation of cobalt from binary and multicomponent mixtures, cobalt was determined spectrophotometrically at 500 nm as the complex with Nitroso R salt. This also facilitated identifying the coextraction of certain ions during separations.

RESULTS AND DISCUSSION

Extraction as a function of pH

Cobalt(II) was extracted in the pH range of 2.0–10.0 with $5 \times 10^{-3}M$ Cyanex 272 in chloroform. The high pH was adjusted using ammonium phosphate and borax buffer. The extraction was quantitative between pH 8.0 and 9.5, hence all extractions were carried out at pH 8.0 (Fig. 1).

Extraction as a function of Cyanex 272 concentration

Cobalt(II) was extracted with varying concentrations of Cyanex 272 ($0.25–50 \times 10^{-3}M$). The extraction was quantitative with $5 \times 10^{-3}M$ of Cyanex (Table 1).

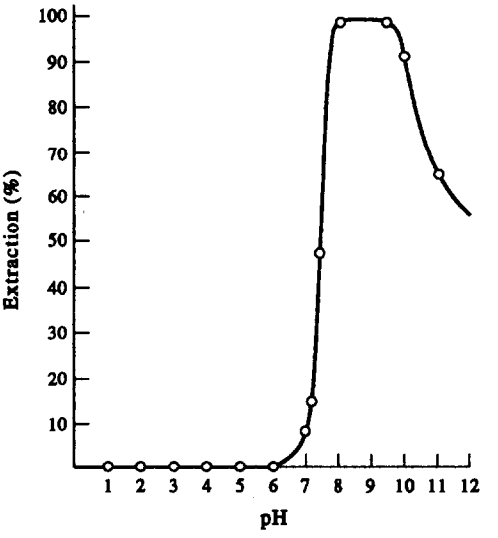

Fig. 1. Extraction as a function of pH with Cyanex 272.

Extraction with various diluents

Cobalt(II) was extracted with $5 \times 10^{-3}M$ Cyanex 272 in different solvents. The extraction was quantitative with benzene, toluene, xylene, carbon tetrachloride, and chloroform as the diluent, while with dichloromethane, 1,2 dichloroethane, *n*-hexane, cyclohexane and nitrobenzene the extraction was not quantitative (Table 2). Chloroform was preferred as the diluent since it provided better phase separation and ease of removal.

Effect of various stripping agents

Cobalt(II) was stripped with various mineral acids after extraction. Cobalt was quantitatively stripped with 0.5–5*M* hydrochloric, nitric, sulphuric and perchloric acids while with 2–6*M* acetic acids, it was complete. A solution of 0.5*M* nitric acid was used as the stripping agent (Table 3).

Table 1. Extraction as a function of Cyanex 272 concentration Co(II) = 25 μg, pH 8.0

Cyanex 272 conc. ($1 \times 10^{-3}M$)	% extraction (*E*)	Distribution ratio (*D*)

Chloroform	4.80	99.9
Dichloromethane	9.50	98.3
1,2 dichloroethane	10.2	77.5
Nitrobenzene	34.5	56.5

Extraction with varying metal ion concentration

Cobalt(II) was extracted with cobalt concentrations ranging from 25 to 250 μg/10 ml, *i.e.* 0.424–4.244*M*. The extraction was quantitative from 25 to 170 μg/10 ml, *i.e.* 0.424–2.886*M*. For complete extraction the molar ratio between metal and Cyanex should be $2.886:5 \times 10^{-3}$, *i.e.* 576:1.

Period of equilibration

The solution was shaken on a wrist action flask shaker for periods ranging from 1 to 20 min. The extraction was quantitative with 5 min or less of shaking. Therefore, a 5 min period of equilibrium was used.

Nature of the extracted species

It was necessary to evaluate *D* while varying extractant concentration, to ascertain the nature of the extracted species. The composition of the extracted species was ascertained from the graph of log [*D*] *vs.* log [Cyanex 272] at fixed pH of 8.0. The slope was 1.72 (Table 1). Therefore the Cyanex concentration range used was from 0.25 to $4 \times 10^{-3}M$ and the probable composition of the extractable species is 1:2 or Co(Cyanex 272)$_2$. Usually for extractions with Cyanex as extractant, the effective pH range for quantitative extraction is narrow.

Table 4. Tolerance limit

Separation of Cobalt(II) from binary mixtures

Cobalt(II) was extracted in the presence of a large number of elements. The tolerance limit was set as the amount of foreign ion causing interference of 1% in the extraction of cobalt. The alkali metals were tolerated at a ratio of 1:150. Magnesium, strontium, gallium, thallium(III), antimony, bismuth, scandium, molybdenum, chromium(VI), nickel, cerium(IV) and uranium were tolerated at a ratio of 1:40. Aluminium, indium, tin(IV), yttrium, vanadium(IV), titanium(IV), chromium(III), copper and thorium, were tolerated at a ratio of 1:20. Calcium, lead, zirconium, hafnium, manganese, iron(II), iron(III), zinc and cadmium were tolerated at a smaller ratio (*i.e.* 1:4). Anions like chloride, nitrate and perchlorate were tolerated at a ratio of 1:20, but acetate, citrate and malonate (Table 4) showed lower tolerance limits.

Separation of multicomponent mixture

Various metals showed different extents of extraction at different pH and varying concentration of Cyanex 272. Such differences were fully exploited to devise a different separation by resorting to a technique selective to extraction at different pH with varying concentration of Cyanex 272. However difference in stripping power was not much use for devising a novel separation.

Table 6. Separation from multicomponent mixtures

Sr. No.	Mixture	Amt. taken (μg)	pH	Extractant	Stripping agent	% recovery
1	Fe(III)	25	3.0	Cyanex 272 (0.005M)	1M HCl	99.8
	Zn(II)	25	6.7	Cyanex 272 (0.005M)	0.5M $HClO_4$	98.7
	Co(II)	25	8.0	Cyanex 272 (0.005M)	0.5M HNO_3	99.0
2	Fe(III)	25	3.0	Cyanex 272 (0.005M)	1M HCl	99.6
	Co(II)	25	8.0	Cyanex 272 (0.005M)	0.5M HNO_3	99.8
	Cr(III)	25	8.0	Unextracted	aq. phase	99.9
3	Mn(II)	25	6.5	Cyanex 272 (0.008M)	0.1M H_2SO_4	98.7
	Co(II)	25	8.0	Cyanex 272 (0.005M)	0.5M HNO_3	99.1
	Ni(II)	50	8.0	Unextracted	aq. phase	99.9
4	Mn	25	6.5	Cyanex 272 (0.008M)	0.1M H_2SO_4	98.7
	Co(II)	25	8.0	Cyanex 272 (0.005M)	0.5M HNO_3	99.1
	V(IV)	50	8.0	Unextracted	aq. phase	99.9

The mixture of iron(III), zinc, cobalt(II) and molybdenum(VI) was resolved by first extracting iron(III) at pH 3.0 with $5 \times 10^{-3}M$ Cyanex 272, then extracting zinc at pH 6.7 with $5 \times 10^{-3}M$ Cyanex 272 and then cobalt(II) at pH 8.0 with $5 \times 10^{-3}M$ Cyanex 272 during which molybdenum(VI) was not extracted. From the organic phase iron(III) was stripped with 1M hydrochloric acid as usual, zinc, with 0.5M perchloric acid and cobalt(II), with 0.5M nitric acid. The metals were determined by atomic absorption spectrometry.

The separation of cobalt from binary (Table 4) as well as a tertiary mixture (Table 6) was determined using more or less the same methodology. All of these separations are based upon the magnitude of the separation factor (α) (Table 5). Only those separations indicating a large separation factor ($\alpha = \infty$) was preferred while selecting optimum conditions for separation.

Sequential separation of iron(III), cobalt(II) and nickel(II)

This separation is interesting because these metals belong to the same group of the periodic table. It was possible to separate such mixtures by utilizing the differences in response of the extractions to pH. Iron was selectively extracted at pH 3.0 with $5 \times 10^{-3}M$ Cyanex 272 while cobalt(II) was extracted at pH 8.0 with $5 \times 10^{-3}M$ Cyanex 272. Nickel was not extracted under these conditions. It was possible to separate such mixtures in ratios ranging from 1:1:10 to 1:10:1.

The proposed method is simple, rapid and selective. It permits separation of cobalt from commonly associated elements like manganese, zinc, molybdenum, chromium and vanadium. The method permits the cleancut sequential separation of iron, cobalt and nickel. The results are reproducible with a relative standard deviation of $\pm 1.2\%$.

(*Received* 14 *July* 1992. *Revised* 14 *April* 1993. *Accepted* 20 *April* 1993)

Summary—The liquid organic salts studied here have wide stable liquid temperature ranges and act as efficient, highly selective gas–liquid chromatographic stationary phases. The effect of carbon number on the gas–liquid chromatographic stationary phase properties of this series of tetra-*n*-butylammonium *n*-alkylsulfonate salts was evaluated by the well-known Rohrschneider/McReynolds system. Several problems arose when attempting to characterize these polar liquid organic salts employing this system. The specific retention volumes for the polar selectivity probes were generally not affected by an increase in the carbon number for the series studied here. However, the specific retention volumes for the *n*-alkane retention index markers increased dramatically as the anion carbon number was increased. The overall effect was a net decrease in the calculated McReynolds constants with increasing carbon number, although the true selectivity of the different stationary phases remained constant. Additionally, the specific retention volumes of the basic test probe, pyridine, showed large erratic variations and, in some cases, was not recovered from the columns. The results suggest the possibility of on-column chemical reactions occurring with some of these salts, and an alternative test probe, 2,6-dimethylpyridine (lutidine) is proposed to eliminate this problem. As McReynolds constants are presently the most commonly used parameters for predicting retention and gas chromatographic stationary phase selection, it is important that workers are aware of the inherent limitations of this scheme.

Organic molten salts (OMS), also referred to as liquid organic salts (LOS) are a unique class of highly polar, selective solvents which make efficient, thermally stable gas chromatographic stationary phases.[1] Liquid organic salts exhibit unique selectivity compared to conventional polymeric nonionic liquid phases presently used. These salts exhibit unusually strong orientation and proton donor/acceptor intermolecular interactions, and also possess interionic forces, such as ion–dipole interactions, absent in molecular liquids. Retention of a solute in gas–liquid chromatography (GLC) is determined from the sum total of all interactions in the liquid stationary phase. The magnitude of individual intermolecular interactions is commonly described as the stationary phase selectivity; whereas, the extent of all possible intermolecular interactions for the stationary phase represents the stationary phase polarity. Therein lies the problem with conventional polarity/selectivity schemes. There are few test solutes (also called probes) which exhibit, and, therefore, test for, only one intermolecular interaction. Likewise, it is impossible to devise a single test probe which can test for all possible intermolecular interactions.

Generally, polarity/selectivity schemes are based on a relative measure of retention for several solutes which test for the dominant intermolecular interactions and a sum of all of the probes acts as an estimate of the stationary phase polarity. Although there are obvious deficiencies with such an empirical approach, contemporary knowledge of solution interactions is inadequate to calculate all forces involved for complex molecules. There have been numerous approaches to estimating the polarity/selectivity of stationary phases including the calculation of the reluctance of a stationary phase to retain non-polar solutes such as hydrocarbons, as

fundamental thermodynamic parameters of test solutes, as solubility parameters, and, recently, several solvation models have emerged. Critical reviews of conventional schemes as well as recent advances in solvation models have recently appeared.[2,3] These more rigorous solvation models should emerge pre-eminent as they are further refined and more evidence emerges, such as that presented here, which illustrates the inadequacies of current selectivity schemes.

In this paper, we discuss the various intermolecular forces which may contribute to GLC retention and the difficulty in devising a polarity/selectivity scheme to evaluate the magnitude of all of these forces. In particular, the inadequacies of the Rohrschneider/McReynolds scheme will be demonstrated for a series of tetrabutylammonium *n*-alkylsulfonate salts. Two significant limitations of the Rohrschneider/McReynolds system are discussed presently. First is the fact that the role of the *n*-alkane retention index standards in determining the magnitude of stationary phase constants is not accounted for. Secondly, questions regarding the type and number of test solutes appropriate for stationary phase characterization are discussed. Additionally, results presented here demonstrate a hereto unreported reactivity of the common test probe, pyridine, with these salts, which was eliminated by employing the sterically hindered pyridine analogues (2,6-di-tert-butylpyridine and 2,6-dimethylpyridine).

EXPERIMENTAL

Tetra-*n*-butylammonium ethane-, propane-, butane-, pentane-, and hexanesulfonate were synthesized as previously described.[4] The column support material, Chromosorb W-AW, was washed with deionized water several times until clear to remove the fines present in the commercially obtained support. After overnight drying at 110°C, the support was sieved to 40–60 mesh. Column packings containing 7–15% (w/w) of salt on the support were prepared using the rotary evaporator technique with methylene chloride as the slurry solvent. After coating, the packings were dried in a fluidized bed drier and packed into nickel columns (3 m × 2 mm I.D.) with the aid of suction and gentle vibration. Individual phase loadings were determined by initial weighings and by overnight Soxhlet extraction of the column packing with methanol after chromatographic measurements. No significant discrepancy was seen between these two measurements. Previous experimental tests have established that any contribution to retention due to solid or liquid surface adsorption is negligible.[4]

Chromatographic separations were performed on a Hewlett-Packard 5890 Series II Gas Chromatograph (Palo Alto, CA, U.S.A.) with a heated on-column injector and a flame ionization detector. The column temperature was determined with a digital platinum RTD thermometer checked against a NIST certified mercury thermometer and was stabilized at 120.1°C (±0.1°C). Helium carrier gas flow rates were determined with a thermostatted soap-film meter making the appropriate corrections for the saturation vapor pressure of the water. The column pressure drop was determined with a mercury manometer (±1 mm Hg). Solutions of the test solutes in hexane were injected to approximate the infinite dilution condition in the linear portion of the sorption isotherm. The symmetrical (Gaussian) peaks and retention volumes independent of sample size suggested that the condition of effective infinite dilution was attained.

RESULTS AND DISCUSSION

Stationary phase properties of the salts

The tetra-*n*-butylammonium *n*-alkanesulfonates studied here had low melting points and were easy to synthesize in high yield and purity. These salts were very hygroscopic and deliquescent under normal laboratory conditions. Even small amounts of hydration caused marked melting point depressions, and, therefore, all handling was performed in a glove bag and melting points were determined chromatographically. The phase transition corresponding to the melting point of a salt is often determined from plots of the logarithm of the specific retention volume for test solutes *vs* the reciprocal column temperature when the salt is used as the stationary phase.[1,4] Alternatively, a more straightforward approach is to plot the logarithm of the adjusted retention time ($\log t'_R$) or the number of effective theoretical plates (N) for solutes directly against the column temperature. The melting point is indicated by a sharp increase in $\log t'_R$ or N. A plot of this type is illustrated in Fig. 1 for tetrabutylammonium *n*-pentanesulfonate. Melting points determined

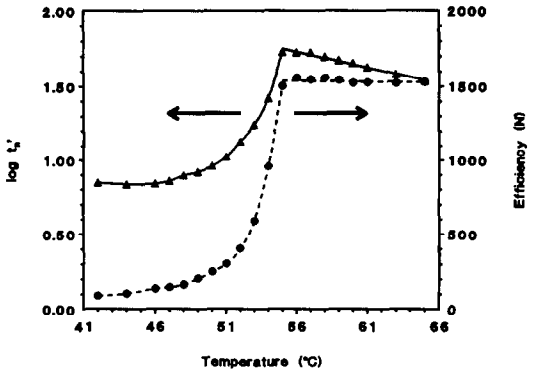

Fig. 1. Plot of the logarithm of the adjusted retention times (▲) and the number of effective theoretical plates (●) for dodecane on tetra-*n*-butylammonium *n*-pentane sulfonate at various temperatures.

by this method as well as some typical column operating conditions for the salts are summarized in Table 1. Most of the salts studied had wide useful liquid temperature ranges (several more than 100°C) and average column efficiencies either comparable to or higher than those observed for several common nonionic phases prepared from the same batch of support. Overall, these salts had desirable chromatographic stationary phase properties including stability, high purity (and therefore column reproducibility), high efficiency and good solute peak shape. However, characterization of the chromatographic polarity and selectivity of these salts by classical means proved problematic. Problems experienced when applying the well-known Rohrschneider/McReynolds system to these salts are also manifest with conventional phases and an explanation requires a thorough understanding of the components of this established method.

Possible intermolecular and interionic forces

Classical gas–liquid stationary phase polarity/selectivity schemes are designed to evaluate the various intermolecular forces which can occur between the chromatographic phase and various test solutes. Additionally, interionic forces may be important for the liquid organic salts studied here. Table 2 summarizes the various interactions which can possibly contribute to solute retention in gas–liquid chromatography. Of the 10 interactions listed, the first three are generally the most significant and are evaluated in the major polarity/selectivity schemes including the Rohrschneider/McReynolds system as well as in the Snyder selectivity triangle system, discussed below. The first two interactions listed are among the strongest intermolecular interactions exhibited by stationary phases, namely proton donor (acidity) and proton acceptor (basicity) complexation. The third interaction listed (dipole–dipole) can also be quite strong and any selectivity scheme must therefore test these first three interactions. The next three interactions listed (dipole–induced dipole, instantaneous dipole–induced dipole, and quadrupole) are non-specific and have varying strengths of interaction. Although London forces are often the dominant interaction in many liquids, they are non-polar in nature and are not generally evaluated in conventional selectivity schemes.

The last four interactions listed are highly-specific and generally present only in selective phases chosen for particular applications. These

Table 1. Column operating conditions for tetra-*n*-butylammonium *n*-alkanesulfonate salts

Table 2. Classification of some possible intermolecular and interionic forces in GLC systems

#	Solute–stationary phase interactions	Common name (Investigator)
1	Proton donor complexation	Hydrogen bonding
2	Proton acceptor complexation	Hydrogen bonding
3	Dipole–dipole forces	Orientation (Keesom)
4	Dipole-induced dipole forces	Induction (Debye)
5	Instantaneous dipole–induced dipole forces	Dispersion (London)
6	Quadrupole–dipole forces	Quadrupole
7	Electron pair donor–acceptor (EPD–EPA)	Charge-transfer complex
8	Solvophobic interactions	Hydrophobic in aqueous systems
9	Isomer recognition	Unique to chiral and liquid–crystal phases
10	Ion–dipole forces	Ionic interaction, unique to LOS

include electron pair donor–electron pair acceptor (EPD–EPA), or charge-transfer interactions and solvophobic interactions. Although specific forces such as isomer recognition and solvophobic interactions are not technically interactions, but rather the sum of interactions, they can contribute significantly to GLC retention and are included in this table for completeness. For example, solvophobic interactions are really the consequence of interactions, both attractive and repulsive (overlap of hard cores) but are, nonetheless, still commonly referred to as interactions.[5] Since the electron pair donor/acceptors may involve n-, σ-, or π-electrons, there are actually nine different possible types of EPD–EPA complexes, although π-EPD–π-EPA and π-EPD–σ-EPA have been studied in the greatest detail.[5] Hydrophobic interactions are well known in aqueous systems when apolar molecules or apolar groups in large molecules aggregate with expulsion of water molecules from the hydration shells. Similar interactions may be present in solvents resembling water including some liquid organic salts studied, and, the more general term, solvophobic interactions may be used. Such interactions have been reported in solvents including glycerol and ethanol.[5] Selective stationary phases can resolve enantiomers, as well as close-boiling positional and geometric isomers. Enantiomorphic resolution is the result of interactions between the enantiomers and the stationary phase, which form a transient diastereomeric association complex with a different sorption enthalpy and, therefore, different retention characteristics. Liquid–crystalline phases exhibit liquid mechanical properties while maintaining some of the anisotropic properties of the solid allowing close-boiling positional and geometric isomers of rigid molecules to be resolved.[6] Additionally, the liquid organic salts investigated here also exhibit ion–dipole forces which involve the Coulomb forces between ions and electrically neutral dipolar molecules.

Conventional polarity/selectivity schemes for stationary phase characterization

Of the scores of polarity/selectivity schemes proposed over the years, two major schemes have stood the test of time. Namely, the Snyder selectivity triangle,[7,8] which is the most common solvent classification method used in liquid chromatography, and McReynolds constants, which are widely used for evaluating gas chromatographic polarity and selectivity. The Snyder selectivity triangle has recently been re-evaluated by Rutan *et al.*[9] using new experimental measurements of the gas–liquid partition coefficients of Rohrschneider probe solutes and a set of normal alkanes. Although the Snyder selectivity scheme has been mainly applied in liquid chromatography, it can be applied with equal success to gas–liquid chromatographic system. Its application to the characterization of liquid organic salts is discussed elsewhere.[10]

McReynolds constants are based on theoretical considerations originally proposed by Rohrschneider which utilize retention indices. The retention index, originally proposed by Kovats in 1958 in the first of a series of papers[11–13] is widely used in studies of stationary phase characterization. The retention index uses the linear relationship that exists between the logarithm of retention parameters and the number of carbon atoms within a homologous series. Refinements of the retention index have been made since its introduction.[14] Retention behavior is most commonly expressed on a uniform scale of homologous n-alkanes. The retention index of a substance is equal to 100 times the carbon number of a hypothetical n-alkane with the same retention parameter (time, volume, *etc.*). The retention index scale is made up of the n-alkanes with retention index

values equal to 100 times the carbon number of the *n*-alkane. The retention index of a substance X is typically calculated by coinjection of bracketing *n*-alkanes differing by one carbon number, and using equation (1):

$$I = 100n + 100\frac{\log R_X - \log R_n}{\log R_{n+1} - \log R_n} \quad (1)$$

where R is the retention parameter (adjusted retention time, adjusted retention volume, specific retention volume, partition coefficient, *etc.*) n is the carbon number of the *n*-alkane eluting before substance x, and $n+1$ is the carbon number of the *n*-alkane eluting directly after substance x. One of the most commonly used parameters, due to its simplicity, is the adjusted retention time. In theory, the retention index of a substance should depend only on the stationary phase and the column temperature and should be independent of the other column variables (chromatographic support material, flow rate, column efficiency, *etc*). In fact, the retention index is only independent of column variables when the *n*-alkanes and the substance are retained by a single retention mechanism, namely partitioning. This is not true in many cases and the retention index may be subject to systematic errors.

The most widely used method for retention prediction and for characterizing gas chromatographic stationary phase polarity and selectivity is based on the retention index system and was introduced by Rohrschneider[15–17] and modified by McReynolds.[18] Rohrschneider proposed a scheme based on the principle that intermolecular forces are additive and can be evaluated from differences in the retention of test solutes (as Kovat's retention indices) on the phase being studied and on a nonpolar standard reference phase (such as squalane). In principle, for each type of intermolecular interaction, the interaction energy is proportional to a value (a, b, ...) characteristic of a particular test solute, and to a value (x, y, ...) characteristic of the stationary phase. The index difference can therefore be described as:

$$\Delta I = ax + by + cz. \quad (2)$$

Rohrschneider first tried to characterize ΔI with three terms, namely, benzene, ethanol, and methyl ethyl ketone. Subsequently, he found it necessary to add two additional terms (symbolized du and es).

"McReynolds Constants" are phase specific constants calculated by subtracting the retention index values measured on a non-polar reference phase, squalane (2,6,10,15,19,23-hexamethyltetracosane), from that measured on the phase to be characterized as indicated by the following equation:

$$C' = I^{\text{phase}}_{(\text{probe})} - I^{\text{squalane}}_{(\text{probe})} \quad (3)$$

where C' is the McReynolds constant, $I^{\text{phase}}_{(\text{probe})}$ is the Kovats retention index for the test probe on the stationary phase of interest and $I^{\text{squalane}}_{(\text{probe})}$ is the Kovats retention index for the test probe on squalane. The values for the retention indices of the test probes on squalane can be taken from McReynolds original work[19] as follows: $I_{(\text{benzene})} = 653$; $I_{(n\text{-butanol})} = 590$; $I_{(2\text{-pentanone})} = 627$; $I_{(1\text{-nitropropane})} = 652$; $I_{(\text{pyridine})} = 699$.

The calculation is repeated for each probe generally using a phase loading of 10% and a column temperature of 120°C. McReynolds chose some higher molecular weight homologues of Rohrschneider's original probes and added five additional probes in an attempt to more completely characterize stationary phase selectivity. The number of terms needed to adequately characterize GLC stationary phase selectivity and the test solutes most appropriate for this purpose continues to be a matter of debate.[20,21] The McReynolds probes and the key interactions they measure are listed in Table 3.

Table 3. Intermolecular interactions exhibited by common test probes

*Broad, tailing peak (values may be unreliable).

For comparison, the selectivity probes originally proposed by Rohrschneider are also listed in Table 3, as well as the three Snyder selectivity probes. McReynolds published phase constants for some 200 common liquid phases which led to the discontinuation of many phases with duplicate separation properties. Over the years, McReynolds constants have become the most quoted indicator of chromatographic selectivity. Column manufacturers customarily quote McReynolds constants for each stationary phase marketed to aid in the selection of phases for particular applications. Additionally, researchers normally determine the same constants for new phases as proof of the uniqueness of new phases. Finally, McReynolds constants are used "as an aid to the accurate prediction of chromatographic behavior".[22] It is this later application, particularly, where McReynolds constants can yield erroneous results, as demonstrated in the present study.

Limitations of retention index based schemes

The inherent limitation of any selectivity scheme based on retention indices is that any derived constants will be a composite of the index standards as well as the polarity probes used to evaluate specific interactions. For example, Kovats' retention indices calculated via equation (1) measure a stationary phases' retention of a selectivity probe, X, relative to the non-polar *n*-alkanes bracketing that probe. Therefore, Kovats' retention indices are a composite measure of how strongly a phase retains a polar solute relative to a non polar solute. So, ambiguous McReynolds constants due to the hydrocarbon index standards are inherent in the system, and must be considered whenever a stationary phase is chosen for a particular application. For the series of tetrabutylammonium *n*-alkanesulfonate stationary phases investigated here, we have observed that their McReynolds constants vary substantially, although they have very similar chromatographic retention properties for the McReynolds probes. Any apparent differences in polarity and selectivity for these stationary phases are entirely due to the variations in retention times of the alkane standards, rather than variations in the retention of the selectivity probes. Specific retention volumes for McReynolds and Snyder selectivity probes as well as the bracketing *n*-alkanes standards are listed in Table 4.

Figure 2 illustrates that while there was either no increase or, in fact, a small decrease in specific retention volumes for the major polarity probes for the series of liquid organic salts studied here, the retention of the *n*-alkane standards increases substantially. The resulting McReynolds constants calculated via equation (3) are given in Table 5. The net effect of the increase in retention of the *n*-alkanes is a substantial decrease in the calculated McReynolds constants for the polar probes with an average decrease of more than one third (*ca.* 36%) from methane to hexane sulfonate. The apparent observed differences in selectivities are entirely attributable to the hydrocarbon index standard, rather than the polar test probes. These data

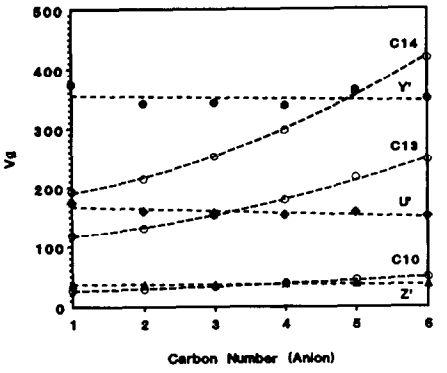

Fig. 2. Plot of the specific retention volume *vs* the carbon number of the anion for tetra-*n*-butylammonium *n*-alkanesulfonates at 120°C. Probe identification: Y′ = *n*-butanol (●); U′ = 1-nitropropane (◆); Z′ = 2-pentanone (▲); C14 = *n*-tetradecane (○); C13 = *n*-tridecane (○); C10 = *n*-decane (○).

support those previously published for very polar conventional non-ionic liquid phases;[23] namely, that the magnitude of McReynolds constants is determined primarily by a lack of solute–solvent interactions with the hydrocarbon index standards and, to a lesser extent, from specific solute–solvent interactions with the polar selectivity probes.

Limitation of using a single solute to evaluate a specific interaction

The earlier discussion of the multitude of possible intermolecular and interionic forces within the phases illustrates the inherent problem associated with assigning a single test probe for a single interaction. With the exception of the non-polar alkanes, any chosen test probe will necessarily exhibit multiple intermolecular interactions and thus serves as a composite measure of polar interactions. For example, Rohrschneider and McReynolds chose pyridine as their probe for stationary phase proton–donor interaction, when, in fact, pyridine may also exhibit orientative interactions and EPD–EPA complexation. Additionally, we have encountered what appear to be on-column reactions of pyridine with some of the phases studied. Possible on-column reactions were indicated by very broad, tailing peaks whose peak area was not representative of the amount of test solute injected and whose retention times were unpredictable. One possible explanation for such behavior is the possibility of a nucleophilic displacement reaction occurring with the liquid organic salts studied. Two sterically hindered bases, namely, 2,6-di-tert-butylpyridine and 2,6-dimethylpyridine were chosen to investigate this possible on-column chemical reaction. A higher temperature was chosen in an attempt to improve the excessively broad chromatographic peaks for pyridine at 120°C. Specific retention volumes for McReynolds and Snyder selectivity probes as well as the bracketing *n*-alkanes standards and 2,6-di-tert-butylpyridine and 2,6-dimethylpyridine at 140°C are listed in Table 6. Even at higher temperatures, the excessive tailing and peak breadth precluded the use of pyridine for characterizing the acidity of these phases. However, the two sterically-hindered (more weakly nucleophilic) bases, 2,6-di-tert-butylpyridine and 2,6-dimethylpyridine, exhibited expected peak symmetry, efficiency, and relative retention for the phases studied.

Table 5. McReynolds constants calculated for tetra-*n*-butylammonium *n*-alkanesulfonates at 120°C

Tetra-*n*-butylammonium	Test solute X′	Y′	Z′	U′	L′
Methanesulfonate	345	944	446	728	450
Ethanesulfonate	316	903	422	690	420
Propanesulfonate	290	871	396	656	389
Butanesulfonate	266	836	369	619	361
Pentanesulfonate	249	809	349	591	337
Hexanesulfonate	230	778	327	560	316

The absolute values of the retention indices for squalane were taken from McReynolds original work[19] as follows: $I_{(benzene)} = 653$; $I_{(n\text{-butanol})} = 590$; $I_{(2\text{-pentanone})} = 627$; $I_{(1\text{-nitropropane})} = 652$; $I_{(pyridine)} = 699$. Identification of symbols for McReynolds probes are given in Table 3.

The specific retention volumes for traditional basic probes, including 2-pentanone and pyridine, as well as for 2,6-di-tert-butylpyridine and 2,6-dimethylpyridine are shown in Fig. 3. Pyridine demonstrates erratic behavior for the phases studied. Whereas, the polar selectivity probes generally exhibited no significant change in V_g as the carbon number of the anion was increased, and the non-polar *n*-alkane index standards exhibited a substantial increase as a function of the carbon number, there is no systematic behavior for pyridine. The behavior of the two alternative bases investigated, 2,6-di-tert-butylpyridine and 2,6-dimethylpyridine, were more in keeping with the results for the other test solutes. However, the highly lipophilic 2,6-di-tert-butylpyridine displayed chromatographic retention behavior approaching that observed for the *n*-alkanes, and therefore, could also yield erroneous results if used as a test probe for bases. For example, the percentage of the slopes relative to the average V_g values (slope/Ave. $V_g \times 100$) for the plots in Fig. 3

Table 6. Specific retention volumes for test solutes on a series of tetra-*n*-butylammonium *n*-alkanesulfonate salts at 140.3°C

Test solute	Sulfonate anion					
	Methane	Ethane	Propane	Butane	Pentane	Hexane
Decane	14.9	16.0	18.4	20.5	24.3	26.7
Undecane	23.4	25.4	29.4	32.9	39.5	43.7

Nitromethane	75.5	66.8	64.5	61.4	65.1	60.7
Dioxane	27.2	25.1	24.9	24.6	25.8	25.5
2,6-di-t-butylpyridine	99.4	102.2	112.0	122.4	140.3	148.3
2,6-Dimethylpyridine	54.5	53.1	—	—	58.3	63.5

*Broad, tailing peak (values may be unreliable).

shows a marked difference between the polar probe pentanone and the alkane standard *n*-tridecane. The slope for pentanone is just 0.8% of the average value for pentanone; whereas, the slope for *n*-tridecane is 14.6% of its average value for the six salts studied. In contrast, the slope for 2,6-dimethylpyridine is 3.1% and that for 2,6-di-tert-butylpyridine is 8.7%. Not surprisingly, the more aliphatic a selectivity probe is, the more its chromatographic behavior will mimic that of the alkane markers. Of the limited number of basic test probes studied here, 2,6-dimethylpyridine was the best compromise between acceptable chromatographic behavior (peak symmetry, *etc.*) and minimal aliphatic character.

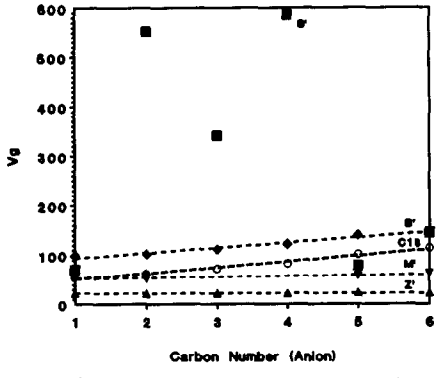

Fig. 3. Plot of the specific retention volume *vs* the carbon number of the anion for tetra-*n*-butylammonium *n*-alkanesulfonates at 140°C. Probe identification: S′ = pyridine (■); B′ = di-tert-butyl-pyridine (◆); M′ = dimethylpyridine (▼); C13 = *n*-tridecane (○); Z′ = 2-pentanone (▲).

These results support previous studies[24] illustrating that McReynolds constants can be an unreliable measure of selective solute-stationary phase interactions for stationary phases. McReynolds constants are a composite indicator of the strength of specific solute–solvent interactions for polar test probes, as well as a measure of the weakness of non-specific solute–solvent interactions for the *n*-alkane retention index markers. A large McReynolds constant may indicate a strong specific interaction between the stationary phase and the test probe and/or it may indicate generally weak interactions with *n*-alkanes. Additionally, the choice of single solutes to probe for specific interactions, and in particular basic interactions, is a difficult, if not impossible, task. Therefore, before selecting a stationary phase for a particular application, additional measures of stationary phase selectivity, including specific retention volumes, thermodynamic values, *etc.* for similar solutes as those to be separated should be sought. Ultimately, it is desirable that a more complete, and, subsequently, a slightly more complex, system of stationary phase characterization be adopted. Such systems are currently under development[2,3] and adoption of any new system by the community of practising chromatographers will require a thorough knowledge of the limitations of our current system as well as the attributes of any new scheme to be adopted.

VOLTAMMETRIC DETERMINATION OF BUSPIRONE

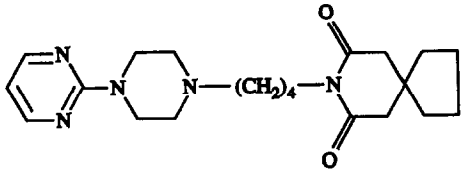
SHENG-ZONG CHEN, FENG XU, HONG ZHANG and ZHENG-QI ZHANG*
Department of Chemistry and Chemical Engineering, Hunan University, Changsha, People's Republic of China

(*Received* 18 *June* 1992. *Revised* 25 *September* 1992. *Accepted* 25 *September* 1992)

Summary—The electroanalytical chemical properties of buspirone are reported in this paper. A sensitive single sweep voltammetric procedure for trace buspirone determination was developed. The detection limit is $5.0 \times 10^{-9} M$. The method has been applied to the determination of buspirone in blood serum by simple dilution in a buffer.

Polarography and voltammetry are widely applied to the determination of drugs. Several reviews have appeared covering the voltammetric determination of drugs.[1-4] Volke[5] reviewed the development of polarographic and voltammetric assay of drugs, and investigated the relation between the polarographic data and the physiological action of drugs. The polarographic and voltammetric techniques applied in the assay of drugs include d.c. polarography, a.c. polarography, pulse polarography, cyclic voltammetry, linear sweep voltammetry and adsorptive stripping voltammetry. Differential pulse polarography (DPP) possesses higher sensitivity and better selectivity among these, so its application to the determination of drugs is the widest. The adsorptive stripping voltammetry has a lower detection limit, which has frequently prompted its use for the determination of drugs. Recently, Peng[6-8] used adsorptive voltammetry to determine chlorprothixene and haloperidol.

Buspirone (I, 8-(4-(4-(2-pyrimidinyl)-1-piperazinyl)butyl)-8-azaspiro(4,5)decane-7,9-dione) is an antidepressant which was synthesized in the 1970s. Its analytical methods, such as high-performance liquid chromatography[9] and DPP,[10] have been reported. However, other electroanalytical methods have not been reported yet. This paper describes the application of adsorptive voltammetry to the determination of trace amounts of buspirone. The drug can be adsorbed and reduced at the dropping mercury electrode. The cyclic voltammetric data show that the surfactants can promote the adsorption of buspirone at the mercury electrode. In the presence of Triton X-100 the limit of detection for buspirone was $5.0 \times 10^{9} M$.



I, Buspirone

EXPERIMENTAL

Apparatus

The single-sweep polarograms were recorded on a JP-1A polarograph. The polarographic cell has the three electrode system: a dropping mercury electrode (DME) as working electrode, a silver/silver chloride (saturated potassium chloride) reference electrode and a platinum wire auxiliary electrode. (A drop time of 7 sec was selected using a knocker, with a rest time of 5 sec and a scan time of 2 sec/250° mv/sec.) An XJP-821 neopolarograph in connection with an LZ3-100 X–Y recorder and a JM-01 (manual micro-metric screw delivery) hanging mercury drop electrode (HMDE) were used for linear scan voltammetry and cyclic voltammetry measurements.

Reagents

Standard buspirone solution. A stock solution ($1.0 \times 10^{-3} M$) of buspirone was prepared by dissolving the drug in ethanol.

Triton X-100 solution, 0.020%. Dissolve 0.10 g of Triton X-100 in 50 ml of water, and dilute to 500 ml.

The buffer solution was 0.20*M* sodium dihydrogenphosphate solution, adjusted to pH 5.80 with 2*M* sodium hydroxide.

Other reagents were of suprapure or analytical-reagent grade. Demineralized water was used throughout.

Procedure

Polarography of pure buspirone solution. Mix 2.0 ml of buffer solution (pH 5.80), 0.70 ml of 0.020% Triton X-100 solution and various amounts of standard buspirone solution. Dilute to 10 ml with water. The solution was transferred to the voltammetric cell, and purged with oxygen-free nitrogen for 10 min. A flow of nitrogen was maintained over the cell throughout the analysis to prevent interference from oxygen. Record the derivative polarogram, starting the potential scan at −1.0 V. The peak potential is −1.35 V.

Analysis of samples. Blood serum was prepared for centrifuging blood samples three times. Transfer 1–3 ml of the blood serum into a 10-ml standard flask, and continue as above.

Recovery experiment. Add the amounts of buspirone shown in Table 1 into a 50-ml beaker containing the serum samples and treat as described above.

RESULTS AND DISCUSSION

Single-sweep polarography

In a pH 3.0–10.0 buffer solution buspirone yields a sensitive polaragraphic wave, the peak potential shifting in the negative direction with increasing pH value of test solutions. In a pH 5.80 buffer solution the peak potential of the drug is −1.35 V [Fig. 1(b)]. In the presence of 0.0014% Triton X-100 the peak potential does not shift, but the peak height increases two-fold [Fig. 1(c)]. Over the range 3.0×10^{-8}–$5.0 \times 10^{-6}M$, the peak currents are linearly proportional to the concentration of the drug. The detection limit is $5.0 \times 10^{-9}M$, which was taken as the concentration that gave a signal equal to three times the standard deviation of the blank signal, calculated from the calibration slopes. The reproducibility was evaluated by 15 repetitive experiments on a $5.0 \times 10^{-7}M$ buspirone solution. The relative standard deviation was 1.5%.

Effect of pH and buffer concentration

Figure 2(a) shows the influence of the acidity of the test solution on peak current. A very low response to buspirone was observed in solutions more acidic than pH 4.0. Increasing the pH from 4.0 to 5.5 led to a rapid increase in the peak height. The increase in the pH beyond 6.0 caused the peak current to decrease. Over the pH range 5.5–6.0 the peak currents are very close. Accordingly, a pH of 5.8 was used throughout for maximum sensitivity. Various buffers such as 0.05*M* ammonium acetate, 0.05*M* sodium acetate and 0.05*M* NaH_2PO_4 were examined in $5.0 \times 10^{-7}M$ busiprone. The best results were obtained with NaH_2PO_4 buffer. Figure 2(b) shows the influence of the added amounts of the buffer on peak height. The peak current increases with increasing buffer concentration from 0.010 to 0.040*M* and decreases slightly when the buffer concentration exceeds 0.045*M*. In this paper the buffer concentration is 0.040*M*.

Effect of surfactants

In order to choose the most suitable surfactant, various cationic, anionic and non-ionic surfactants, all of them highly soluble in water, were tested. The surfactants were cetyl trimethyl ammonium bromide (CTMAB), sodium lauryl sulphate (SLS), *p*-octyl

Table 1. Determination of buspirone in serum samples

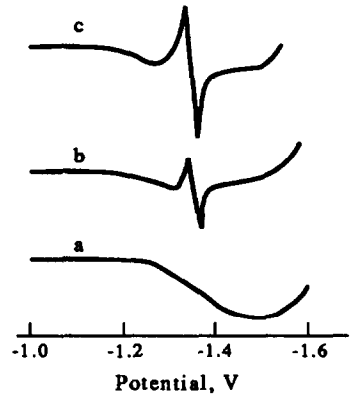

Fig. 1. Derivative single-sweep polarograms of buspirone (a) pH 5.80, 0.0014% Triton X-100; (b) pH 5.80, $1.0 \times 10^{-6}M$ buspirone; (c) pH 5.80, 0.0014% Triton X-100, $1.0 \times 10^{-6}M$ buspirone.

polyethylene glycol phenylether(OP), Tween-80 and Triton X-100. The results obtained are shown in Table 2. Obviously, cationic, anionic and non-ionic surfactants can all increase the peak current of the drug. Triton X-100 is the best and so we used it as a sensitizer. The influence of its concentration on the peak height is shown in Fig. 2(c). The peak current increases rapidly with increasing Triton X-100 concentration from 0.0006 to 0.0013% and decreases greatly when the concentration of Triton X-100 exceeds 0.0016%. A percentage of 0.0014% for the surfactant was chosen for subsequent studies.

Adsorptive characters of buspirone

The adsorption of buspirone at the dropping mercury electrode was demonstrated by constructing electrocapillary curves and by carrying out medium-exchange experiments.

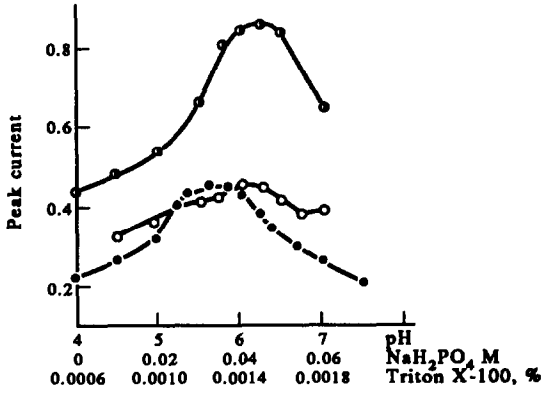

Fig. 2. Effect of the solution conditions $1.0 \times 10^{-6}M$ buspirone; (a) effect of pH: 0.0006% Triton X-100, $0.020M$ NaH_2PO_4; (b) effect of NaH_2PO_4 concentration: pH 5.80, 0.0006% Triton X-100; (c) effect of Triton X-100 concentration: pH 5.80, $0.040M$ NaH_2PO_4.

Table 2. The effect of surfactants*

OP	0.55
Tween-80	0.50
Triton X-100	0.75

*pH 5.80, $5.0 \times 10^{-7}M$ buspirone, 0.0010% each of surfactant.

The electrocapillary curves of the buspirone–Triton X-100 system are shown in Fig. 3. The electrocapillary curve of a solution containing buspirone [Fig. 3(b)] is lower than that of the pure buffer [Fig. 3(a)], indicating that buspirone is adsorbed at the dropping mercury electrode. The electrocapillary curve of the solution containing buspirone and Triton X-100 [Fig. 3(d)] is lower still than that of the buspirone solution, indicating that Triton X-100 promotes the adsorption of the drug at the mercury electrode.

For medium-exchange studies, the static mercury drop electrode (SMDE), J-shaped capillary, used as a working electrode, was kept in contact with a solution containing buspirone and Triton X-100 for 180 sec with stirring. Following this, the electrode was cleaned in water for 15 sec while stirring and transferred into another cell containing the background solution only. The reduction process shown in the voltamperogram obtained in the new cell closely resembled that in the original cell.

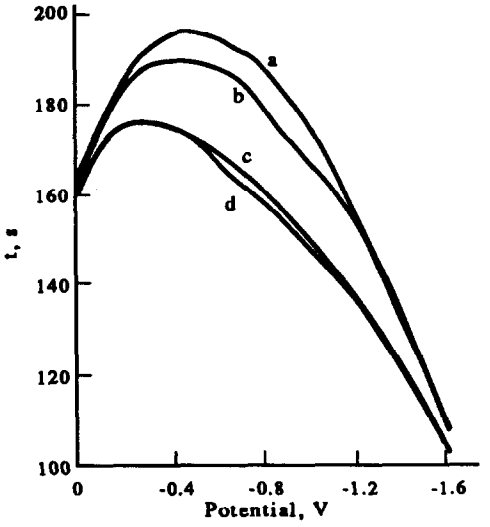

Fig. 3. Electrocapillary curves of the buspirone–Triton X-100 system (a) pH 5.80 ($0.040M$ NaH_2PO_4); (b) pH 5.80, $5.0 \times 10^{-7}M$ buspirone; (c) pH 5.80, 0.0014% Triton X-100; (d) pH 5.80, 0.0014% Triton X-100, $5.0 \times 10^{-7}M$ buspirone.

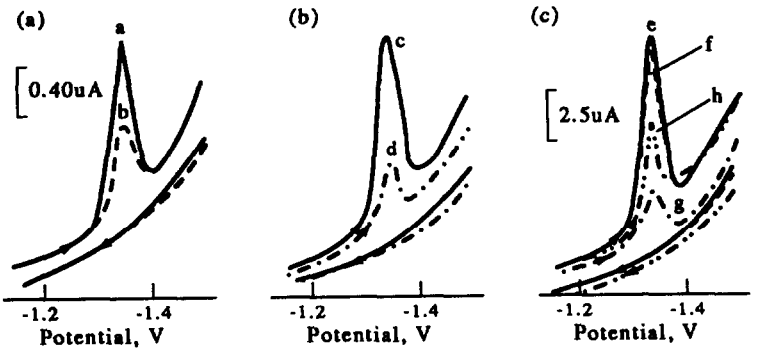

Fig. 4. The cyclic voltamperograms of buspirone system A: pH 5.80, 0.0014% Triton X-100, $5.0 \times 10^{-7}M$ buspirone, $V = 100$ mV/sec, $t = 15$ sec, electrode area of 0.012 cm^2, (a)—first scan, (b)—second scan; B: (c)—in the presence of Triton X-100, (d)—in the absence of Triton X-100, other conditions as same as A; C: $5.0 \times 10^{-6}M$ buspirone, (e) and (f) in the presence of Triton X-100, $t = 15$ sec, (e)—first scan, (f)—second scan, (g) and (h)—in the absence of Triton X-100, $t = 45$ sec for (g), $t = 180$ sec for (h), other conditions are same as for A.

Cyclic voltammetry

The redox and interfacial behaviour of the drug can be evaluated by using cyclic voltammetry. Figure 4 shows the cyclic voltamperogram for the buspirone–Triton X-100 system. From Fig. 4 the following information can be obtained.

In Fig. 4(a) subsequent repetitive scans yielded significantly smaller (but stable) cathodic peaks corresponding to the reduction of dissolved species. This behaviour indicates that the adsorption of the drug at the mercury electrode is reactant adsorption.[11] Buspirone shows cathodic peak at about -1.35 V due to its reduction, and no peak was observed on the anodic branch, indicating that the reduction of the drug is irreversible. The width at the mid-peak of buspirone was determined (curve a) and found to be 65 mV; the αn_α value can be calculated and found to be 0.96.[12] Squella[10] reported that the number of electrons involved in the buspirone reduction process is two, so the α value is 0.48.

In Fig. 4(b) the curve c is the cyclic voltamperogram in the presence of Triton X-100, and curve d, one in the absence of the surfactant. From curve d the width at half-peak of buspirone was determined and found to be 65 mV, so the αn_α value is 0.96, which indicates that Triton X-100 does not improve the reversibility of the reduction process of the drug. However, the peak height in curve c is two times that in curve d, which shows that the surfactant promotes the adsorption of buspirone at the mercury electrode.

Figure 4(c) shows the cyclic voltamperograms for $5.0 \times 10^{-6}M$ buspirone. Curves e and f are the cyclic voltamperograms in the presence of the surfactant for an accumulation time of 15 sec. The peak height during the first scan (curve e) is close to that during the second (curve f), indicating that for the buspirone concentration larger than $5.0 \times 10^{-6}M$ the adsorption of the drug at the mercury electrode achieves likely saturation adsorption. The curves g and h are the cyclic voltamperograms in the absence of Triton X-100 for an accumulation time of 45 and 180 sec, respectively. The adsorption time in the absence of the surfactant is longer than that in the presence of the surfactant, but the peak height of the former is smaller than that of the latter, demonstrating that the Triton X-100 promotes the adsorption of the drug at the mercury electrode.

Application

Serum samples are generally pretreated because the proteins interfere in the determination of drugs in serum. Using the single-sweep polarographic procedure proposed in this paper to determine the buspirone in serum, no sample pretreatment was required, other than a dilution with the supporting electrolyte.

Calibration graphs. Treat the standard buspirone solutions used for the preparation of the calibration line in the procedure as described in the section on analysis of samples. The regression equation of the calibration line has the form:

$$Y = 0.0145X + 0.0003 \quad (1)$$

where Y is the peak current in μA and X is the buspirone concentration in μg/ml. The correlation coefficient was 0.999. The results

of the determination of the buspirone in the serum samples and recovery of added buspirone by using the recommended method are summarized in Table 1. Samples 2 and 3 were from rabbits used in toxiological test for buspirone.

A NEW CHEMILUMINESCENCE SYSTEM: MnO_4^-–Na_2CO_3–KOH AND ITS APPLICATION IN THE DETERMINATION OF MANGANESE

ZHANG FAN and LIN QINGXIONG*
Department of Chemistry, Fuzhou University, Fuzhou, Fujian 350002, People's Republic of China

(*Received* 29 *March* 1992. *Revised* 24 *September* 1992. *Accepted* 6 *October* 1992)

Summary—A new, fast and simple inorganic chemiluminescence method for the determination of trace amounts of manganese is described. When MnO_4^- is injected into 0.40*M* Na_2CO_3–0.70*M* KOH mixed solution in a reaction cell, the strong chemiluminescence occurs and is recorded. The detection limit is 0.1 ppb Mn and the linear range extends from 0.1 to 10 ppb Mn. A 5-ppb Mn concentration can be determined with a relative standard deviation of 5.6% (15 replicates). The commonly encountered cations do not interfere with the determinations. This method has been successfully applied to the direct determination of manganese in bauxite. The reaction mechanism is also briefly discussed.

The use of chemiluminescence (CL) in analysis for organic and inorganic species at trace levels has received attention mainly because of the simplicity of the instrumentation, the low detection limits and the wide dynamic range. Chemiluminescence reactions based on reagents such as luminol, lucigenin, lophine and some oxalate esters[1] are most common. Many trace metals, including manganese, have been determined by their catalysis of CL reaction.[2,3] There are also some inorganic CL systems,[4–8] without organic CL reagents but generally containing some oxidants such as H_2O_2 and O_3, in the application of analytical chemistry. However, the lack of selectivity of these CL systems limits their direct application to analysis of complex, real samples.

Determination of manganese based on CL has been reported. Kalinichenko[9,10] determined 0.05–5 ng of manganese using luminol, but many other transition metals interfered. Dubovenko and Tovmasyan[11] reported a similar system for determining 0.1–1 μg/ml manganese with photographic rather than photoelectric detection. Seitz and Hercules[12] used ion-exchange to remove interferences for the determination of manganese, with a detection limit of 10^{-8}M manganese. Burguera and Townshend[13] re-investigated the determination of manganese with luminol, but no application was reported. Zheng *et al.*[14] obtained a detection limit of 8×10^{-6} μg/ml manganese using a luminol–KIO_4 system, but Co(II) and Cr(III) interfered. Lucigenin can be used in place of luminol, and Dubovenko *et al.*[15,16] used this system to determine 1–3 μg/ml manganese, but many metal ions interfered. Another CL reaction[17,18] between permanganate and siloxene has been reported for the determination of 0.1–10 μg of manganese. Yamada *et al.*[19] also described a new CL system to determine 0.01–10 ng manganese, but Fe(III) and Mg(II) interfered.

In this study we investigate a new, simple, sensitive and selective inorganic CL system–MnO_4^-–Na_2CO_3–KOH for the determination of manganese. The reaction of decomposition of MnO_4^- to MnO_4^{2-} and O_2 in alkaline medium is a common reaction, but no one has reported its CL behaviour in the past. We found that strong CL occurred when MnO_4^- was injected into Na_2CO_3–KOH mixed solution, but CL was hardly observed without Na_2CO_3. Because of the specificity of the reaction, the commonly encountered cations did not interfere with the determinations.

EXPERIMENTAL

Apparatus

An FG83-1 CL Photometer (made in our laboratory) and a XWT-104 Recorder (Shanghai) were used.

*Present address: Departamento de Química Analítica, Facultad de Química, Universidad de Sevilla, 41012-Seville, Spain.

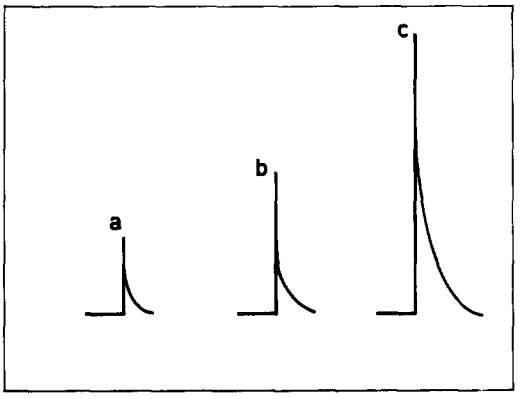

Fig. 1. Typical CL signals. (a) 0.5 ppb; (b) 1 ppb; (c) 2 ppb.

Reagents

Mn(II) standard solution (1 mg/ml). Dissolve 500.0 mg of high-purity manganese metal (cleaning the metal surface with diluting sulphuric acid before weighing) with 10 ml of 1:4 sulphuric acid, transfer the solution into a 500-ml standard flask and dilute to volume with water. Mn(II) standard solution (0.01 mg/ml) is prepared by dilution of this standard solution with water.

MnO_4^- standard solution (100 ppb Mn).[20] Add 0.5 ml of 0.01 mg/ml Mn(II) standard solution, 1.0 ml of concentrated nitric acid, 2.0 ml of 1:1 sulphuric acid by pipette to a 100-ml beaker and evaporate the smoke throughout. Then add 10 ml of water, 2.5 ml of 1:1 sulphuric acid to the beaker and heat to dissolve the salts. Also add 1.0 ml of phosphoric acid and 0.30 g of potassium periodate to the beaker, then heat the solution to produce a reddish colour, transfer the solution to a 50-ml standard flask, and preserve the solution in boiling water for 40 min. Cool and dilute to volume with water. Working standard solutions are prepared by dilution of the standard solution with water.

Na_2CO_3(0.40M)–KOH(0.70M) mixed solution. A 21.20-g portion of Na_2CO_3 and 19.64 g of KOH are dissolved in water. Dilute to volume in a 500-ml standard flask with water, mix and then transfer to a plastic bottle.

All reagents are analytical grade or better and water is doubly distilled in a fused-silica apparatus.

Procedures

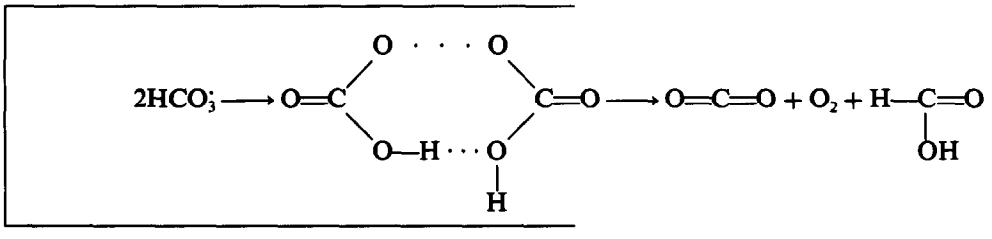
Pipette 1.00 ml of Na_2CO_3–KOH mixed solution to a reaction cell. The cell is then put into the cassette of FG83-1 photometer, close the cassette with a cover, then open a shutter in the photometer and start the recorder. The standard solution of MnO_4^- (or sample solution) is rapidly injected into the reaction cell through a fill orifice by an injector and the CL signal is recorded by the recorder (the signals are shown in Fig. 1).

RESULTS AND DISCUSSION

Possible mechanism of chemiluminescence reaction

The CL spectra, the products and their absorption spectra from the CL reaction are investigated. The CL spectra show three spectrum peaks at 420, 480 and 580 nm, which coincides with the emitting wavelength (480 and 580 nm) of excited double molecular oxygen $(O_4)^*$ reported by Khan *et al.*[21] except that at 420 nm, and it is proposed that $(O_4)^*$ is the main luminous species in this system. When we substitute 0.1*M* H_3BO_3 for 0.40*M* Na_2CO_3, the CL intensity becomes very low, only two spectrum peaks occur at 480 and 580 nm. It is evident that Na_2CO_3 is another luminous species in this system.

Wierzchowski *et al.*[22] studied the CO_3^{2-}–H_2O_2–$Fe(SCN)_6^{3-}$ CL system, and it was suggested that $^{\cdot}OH$, $^{\cdot}O_2^-$ and $^{\cdot}HCO_3$ radicals may be generated with one of the possible modes of recombination of the $^{\cdot}HCO_3^-$ radical and its decomposition being:



For this mode the energy difference is $\Delta E = E_{c=o} + E_{c=o} + E_{C-H} - (E_{2C-O} + E_{O-H}) =$ 305 kJ/mol that approximately corresponds to the spectrum peak at 420 nm.

The study of the reaction products shows that the absorption peaks of the solution of the reaction products are similar to that of MnO_4^{2-} solution at 600, 500 and 369 nm,[23] and $BaMnO_4$

(blue solid) is obtained when saturated $Ba(OH)_2$ solution is added to the solution of the reaction products. It is evident that one of the products is MnO_4^{2-}.

On the basis of these investigations, a possible mechanism of the CL reaction is proposed, and several conclusions can be drawn as follows.

(1) The main CL reaction is the decomposition of MnO_4^- to MnO_4^{2-} and O_2 accompanying CL, and the reaction is a free radical reaction. The possible mechanism of the reaction, in which reactions (1)–(5) have been reported by Symons,[24,25] is proposed as follows:

$$MnO_4^- + OH^- = MnO_4^{=} + {}^{\cdot}OH \quad (1)$$

$${}^{\cdot}OH + OH^- = {}^{\cdot}O^- + H_2O \quad (2)$$

$$MnO_4^- + OH^- + {}^{\cdot}O^- = MnO_4^{=} + HO_2^- \quad (3)$$

$$MnO_4^- + HO_2^- = MnO_4^{=} + HO_2^{\cdot} \quad (4)$$

$$HO_2^{\cdot} + OH^- = O_2^- + H_2O \quad (5)$$

$$MnO_4^- + O_2^- = MnO_4^{=} + O_2^{\cdot} \quad (6)$$

$$O_2^{\cdot} + O_2^{\cdot} = (O_4)^* \quad (7)$$

$$(O_4)^* \rightarrow 2O_2 + h\nu \quad (8)$$

$$4MnO_4^- + 4OH^- = 4MnO_4^{=} + O_2 + 2H_2O + h\nu \quad (9)$$

It is suggested that reaction (6) generates $O_2^{\cdot}$ radicals and their recombination may generate energy-rich precursors of excited molecules $(O_4)^*$, which decompose to O_2 accompanying CL with two spectrum peaks at 480 and 580 nm.

(2) It is suggested that CO_3^{2-}/HCO_3^- is another luminous species in this system. The CL spectrum peak at 420 nm possibly results from the decomposition of the complex in reaction (12):[22]

$${}^{\cdot}OH + HCO_3^- \rightarrow OH^- + HCO_3^{\cdot} \quad (10)$$

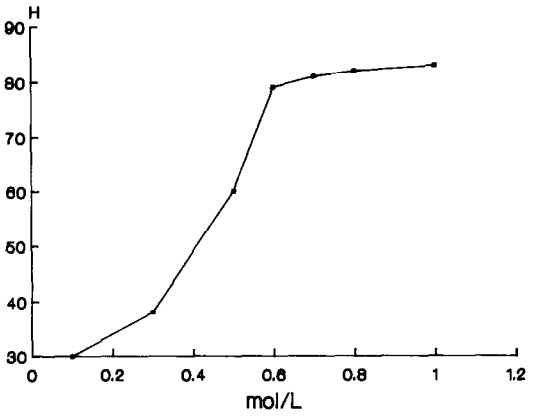


Fig. 2. Effect of KOH concentration, $[Na_2CO_3] = 0.4M$, 5 ppb Mn.

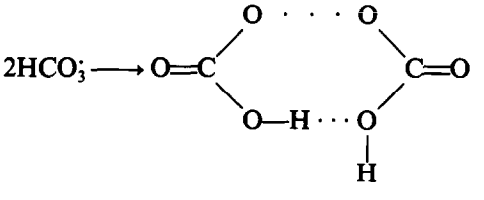
However, the contribution of reaction (12) cannot entirely account for the strong enhancement of CL by the presence of sodium carbonate. It is suggested that CO_3^{2-} or HCO_3^- can also catalyze the decomposition of MnO_4^-,[26] or that the radical reactions of CO_3^{2-}/HCO_3^- as reactions (10)–(12) induce the decomposition of MnO_4^-, which dramatically increase the intensity of CL.

Optimization of experimental conditions

The CL intensity is dependent on the concentrations of sodium carbonate and potassium hydroxide. If potassium hydroxide solution is freshly prepared and without addition of sodium carbonate, CL can hardly be observed, which indicates that CO_3^{2-}/HCO_3^- is as important as OH^- in this system. It is found out that $0.70M$ potassium hydroxide and $0.40M$ sodium carbonate are optimized conditions for this system, as shown in Figs 2 and 3. It is also found out that the Na_2CO_3–KOH system is the most sensitive system of those shown in Table 1. Under the optimized conditions, the relative standard



(11)

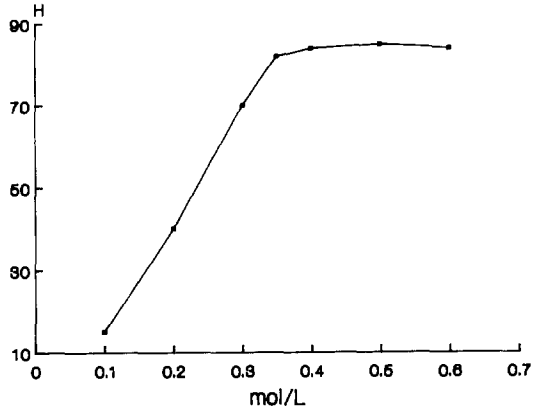

Fig. 3. Effect of Na_2CO_3 concentration, [KOH] = 0.7*M*, 5 ppb Mn.

Table 1. Comparison of CL intensity among various systems

System	Relative peak height
0.4*M* $(NH_4)_2CO_3$/0.7*M* KOH	0
0.4*M* Na_2CO_3/0.7*M* NaOH	1
Li_2CO_3 (saturated)/0.7*M* KOH	6
0.4*M* K_2CO_3/0.7*M* KOH	27
0.4*M* Na_2CO_3/0.7*M* KOH	43

deviation found (15 replicates) for 5 ppb Mn is 5.6%, the linear range extends from 0.1 to 10 ppb Mn (Fig. 4).

An investigation of interference in the determination of 5 ppb Mn shows that the following commonly encountered cations do not interfere with the determinations: Ca(II), Al(III), Pb(II), Mg(II), Fe(III), B(III), Cd(II), Ba(II), Zn(II) (>0.1 mg/ml); Co(II), Cr(III), Cu(II), Tl(III), Pd(II), Ga(III), Ge(IV), Te(IV), Ni(II), Ti(IV) (>0.01 mg/ml); La(III), Be(II), Sr(II) (>0.001 mg/ml). It is evident that the selectivity of this system is very good. However, some organic compounds, such as alcohol, acetone, mannitol,

ascorbic acid, sodium acetate, added into Na_2CO_3–KOH mixed solution, decrease the CL intensity, and some cations such as V(V) (>0.4 ppm), Ta(V) (>1 ppm) and In(III) (>2 ppm), like MnO_4^-, can generate CL in this system.

Application in analytical chemistry

The proposed method can be used to determine manganese in bauxite, without any preliminary separation, and good results are obtained, as shown in Table 2.

Acknowledgements—The authors would like to express their gratitude to Drs F. F. de la Rosa and R. Escobar from the University of Seville (Spain) for helpful discussions during the preparation of this manuscript.

(*Received* 8 *February* 1993. *Revised* 15 *April* 1993. *Accepted* 15 *April* 1993)

Summary—Periodate electrodes without inner reference solution based on tetraoctylammonium periodate plus solvent mediator (dibutyl phthalate or 2-nitrophenyl octylether) were constructed. Linear dynamic range, practical detection limit, slope, stability, selectivity coefficients, pH dependence, response time and lifetime were evaluated. A tubular version was further developed and coupled to a flow-injection system for glycerol determination in samples relevant to the industrial production of soaps, detergents and similar.

The method involves glycerol oxidation by periodate with potentiometric evaluation of its consumption. The influence of oxidizing agent concentration (10^{-5}–$10^{-2}M$ $NaIO_4$), ionic strength (0.0–1.0M Na_2SO_4) and mean resident time were investigated and the feasibility of using a single-line manifold was discussed.

The proposed system handles about 40 samples/hr, is very stable and suitable to industrial control. Results within the 1000 and 5000 mg/l range glycerol are precise (r.s.d. <0.005) and in fair agreement with conventional procedures. Baseline drift or noise is not observed and a thermostat water bath is not required. A noteworthy feature is the almost linear relationship between glycerol concentration and recorded peak height which is a consequence of combined effects of reaction kinetics and electrode Nernstian response.

Quaternary ammonium salts are frequently used as ion-exchangers in mobile carrier membrane electrodes.[1] Like these salts,[2–4] other ion-exchangers[5–8] have been reported for the preparation of periodate electrodes. As mediator solvents, nitrobenzene,[3,5] o-nitrotoluene[6] or decanol[2] have been used in conventional-shaped electrodes with internal reference solution. Elimination of the inner reference solution by direct application of the selective membrane on a conductive surface,[9] associated with the use of long-chain quaternary ammonium compounds and suitable plasticizers result in electrodes with good reproducibility, stability and response time.[10–13] Additionally, lifetimes are longer when compared with conventional electrodes.[14]

This construction process opens also the possibility of designing special devices such as microelectrodes,[15] low-volume potentiometric cells,[16] and sandwich[17] or tubular potentiometric detectors[10–12] for FIA systems. This justified the construction and evaluation of a periodate electrode without inner reference solution to be used as a flow-injection detector. Tetraoctylammonium periodate plus dibutyl phthalate or 2-nitrophenyl octylether were used as ionophore.

Oxidation by periodate is widely used in carbohydrate chemistry. The reaction proceeds at room temperature and usually takes place under mild conditions.[18] It has often been automated for sugar and glycerol determinations[18–20] and is the basis of the official method for free glycerol determination in soaps, detergents and similar.[21] Periodate consumption after glycerol oxidation has been usually estimated by titrimetry, spectrophotometry or potentiometry.[19]

For industrial control, flow analysis is worthwhile. In this context, flow injection systems become particularly attractive in view of its versatility, simplicity and suitability for large scale analyses.

The aim of this work was the development of a periodate tubular electrode and its use for the flow-injection determination of glycerol in

*Instituto de Química, Universidade Estadual de Campinas, Campinas SP, Brazil.

samples relevant to the industrial production of soaps, detergents and similar.

EXPERIMENTAL

Solutions

All solutions were prepared with de-ionized water (specific conductivity <0.1 μS/cm) and *pro analisi* reagents. Tetraoctylammonium bromide was purified by recrystalization in ethyl acetate.

Periodate solutions were freshly prepared by water dilutions of a $0.1M$ $NaIO_4$ solution which was protected from light. The glycerol stock (10.00 g/l) was iodometrically standardized[21] and the working standards within 1000 and 5000 mg/l were daily prepared in water.

Samples (bottom lixivia, industrial brine, washing solutions, and waters from evaporator/condensators) were collected in 250-ml bottles. Before dilution, they were heated (50–60°C) until clear solutions were obtained. Initial dilution was accomplished by accurately weighing 100 g of the clear solution and mixing with 500 ml water. Whenever needed, further water dilutions were performed immediately before sample injection into the flow system.

Apparatus

For performance evaluation of the conventional-shaped electrodes, a Crison 2002 potentiometer with an electrode switch and a double junction Orion 900200 reference electrode ($0.033M$ Na_2SO_4 external solution) were used.

The flow-injection system consisted of an Ismatec mp13 GJ4 peristaltic pump with Tygon pumping tubes, a home-made injector,[22] a manifold built-up with 0.8 mm (i.d.) polyethylene tubing, and a Micronal B352 potentiometer connected to a REC 61 Radiometer recorder. Alternatively, a six-port Reodyne 5020 rotary valve was used. Work and reference electrodes were assembled by means of a Perspex device.[23] The system was grounded as in early work.[24]

Electrode preparation

The ionic sensors were prepared as previously described[10–12] by adding 0.36 g tetraoctylammonium bromide plus 9.75 g dibutyl phthalate (Type I) or 4.71 g 2-nitrophenyl octylether (Type II) into 5 ml chloroform. The final mixture was shaken with six 15-ml aliquots of a $0.1M$ $NaIO_4$ solution. The aqueous phase was discarded and the chloroform was evaporated slowly in order to obtain the liquid ionophore.

For the membrane preparations, 0.18 g PVC, 6 ml tetrahydrofuran and 0.4 ml of the ionophore solution were mixed. The resulting solution was applied dropwise on the conductive surface of the conventional electrode[25] or inside the hole drilled in the conductive material of the tubular detector.[23] Drying was accomplished by leaving the electrodes at room temperature for one day. Thereafter, the electrodes were placed in contact with $0.01M$ $NaIO_4$ for at least three days, in order to achieve equilibrium of the inner reference system.

Evaluation of conventional-shaped and tubular electrodes

The conventional-shaped electrodes (Types I and II) were evaluated by using 10^{-1}–$10^{-7}M$ $NaIO_4$ solutions with ionic strength adjusted to $0.1M$ with sodium sulphate. A single line flow-injection system (Fig. 1(a)) with very low sample dispersion (volumetric fraction >0.95) was used to evaluate the response behavior of the tubular electrodes.[10–12] A 150-μl volume was injected into C carrier stream and the reaction coil was only 25 cm long.

Influence of pH between 2 and 13 was investigated for 10^{-1}, 10^{-3} and $10^{-5}M$ $NaIO_4$ by

simultaneously recording potential and pH variations after dropwise additions of sulfuric acid or sodium hydroxide solutions.

Interferences due to foreign ions (Table 1) were evaluated with the method of separated solutions[26] for 10^{-2}, 10^{-3} and $10^{-4}M$ in both periodate and interfering ions. Since iodate was formed after glycerol oxidation, its interference was also evaluated by injecting different iodate solutions (10^{-3}–$10^{-1}M$) into the 1(a) flow-injection system furnished with Type I tubular electrode. In this experiment, a slow confluent stream (0.4 ml min^{-1}) was used to add different periodate (10^{-6}–$10^{-4}M$) and sodium sulphate ($0.33M$) concentrations. The possibility of injecting concentrated glycerol was investigated within the 10^{-3}–$10^{-1}M$ range.

Determination of glycerol

The system of Fig. 1(b) with a Type I flow-through electrode was used to investigate the main parameters involved in the automated determination of glycerol. Glycerol standards within the 100.0–500.0 mg/l range were used. After sample injection, buffer and periodate reagents were added, allowing glycerol oxidation to proceed in the main reactor under buffered conditions and constant ionic strength. The passage of the sample zone through the detector resulted in a transient increase in measured potential recorded as a peak proportional to the glycerol content in the sample.

Influence of periodate concentration (10^{-5}–$10^{-2}M$), pumping speed (25, 50, 75 and 100% flow rates relative to Fig. 1(b)), ionic strength (0.0–1.0M Na_2SO_4 in R_1) and pH for glycerol oxidation were studied.

Subsequently, the system was simplified to a single line configuration (Fig. 1(c)). The sample volume was reduced to about 30 μl (6-cm sampling loop), the carrier stream was a combined reagent ($0.003M$ $NaIO_4$ plus $0.5M$ Na_2SO_4 plus $0.1M$ acetic acid $+0.1M$ sodium acetate) and the reactor length was selected as 300 cm. With this simplified system, the samples were run and the analytical characteristics evaluated.

RESULTS AND DISCUSSION

Response behavior of conventional-shaped and tubular electrodes to periodate

Regardless of the electrode configuration, the lower limit of linear response was always about $5.10^{-5}M$ periodate. During an 8 hr working period, variations of potential observed for 10^{-4}–$10^{-1}M$ IO_4^- were less than 0.2 mV. This means a baseline without any significant drift in the flow-injection systems.

Within this concentration range, the response of the conventional-shaped electrode was very fast: after doubling periodate concentration, equilibrium was attained in less than 2 sec. The dynamic response of the tubular electrode based on 2-nitrophenyl octylether was checked by using 10^{-1} and $10^{-3}M$ IO_4^- (also $0.1M$ Na_2SO_4) intermittent streams at 2.0 ml min^{-1} merging 10 cm from the detector. After switching the injector, the intermittent streams were interchanged.[22] Transition time between recorded steady state signals was about 2 sec, emphasizing the feasibility of this tubular electrode as a flow-injection detector. Studies concerning the use of this detector as a relocating sensor[27] are presently in progress.

Nernstian response (60.5 ± 0.2 mV/decade—Type I; 57.4 ± 0.3 mV/decade—Type II) was observed for both electrodes. Because of the low response times, similar slopes were calculated for tubular and conventional-shaped electrodes.

For $3.0 < pH < 7.5$, pH has no pronounced influence on electrode potential (Fig. 2) regardless of the electrode configuration. This is in

close agreement with predicted values based on calculations including periodate speciation.[2] This pH range is broad enough for analytical applications of this electrode, and permits measurements to be performed under good conditions at pH = 4.7, the recommended acidity for the present procedure.[19,20,28]

Selectivity data related to conventional-shaped electrodes are shown in Table 1. Data gathered in batch conditions were similar to those obtained in a flow-injection system with limited dispersion, emphasizing that the concentration reaching the detector was practically that of the injected solution and kinetic aspects were not relevant. Table 1 is globally better when compared to already reported values,[2,3,5,6,8] especially with regard to sulphate. Sodium sulphate was then elected to provide ionic strength adjustment in the experiments for electrode evaluation and further analytical application. Although periodate electrodes suffer from severe perchlorate interference, selectivity coefficients towards perchlorate were lower than the reported values.

The electrodes can be used for periodate monitoring in the presence of iodate formed after the glycerol oxidation since pK^{Pot} was determined as *ca.* $^{-4}$. Higher glycerol concentrations should be avoided, if higher than $0.1M$, membrane deterioration was observed, probably due to reduction of periodate ion constituents of the membrane. Since the drawback was not observed for glycerol concentrations $<0.01M$ under flow conditions, the flow-injection system was designed with large dispersion.

Determination of glycerol

The acetic/acetate buffer system was elected after considering the electrode operating plateau (Fig. 2) and the faster glycerol oxidation at pH about 4.7. No alterations in the behavior of the Type I tubular electrode in the presence of this buffer system were observed. As a consequence, the lower limit of linear response was maintained.

Periodate concentration was an important parameter in the procedure for glycerol determination. With a concentration lower than $10^{-5}M$ in the 1(b) flow system, the baseline was noisy and recorded peak heights were not measurable because the remaining periodate concentration approached the practical limit of detection. The time interval between peak maximum and baseline restoration was unacceptably high (>20 sec). For periodate concentrations within the 10^{-4}–$10^{-1}M$ range, baseline noise was about ± 0.2 mV (exception for $IO_4^- = 10^{-4}M$, see Fig. 3), washing time reached a constant value of 11 sec, and the tendency for linearization of the relation between glycerol concentration and recorded peak height was observed (Fig. 3). This was due to the combination of Nernstian response of the electrode and kinetics of glycerol oxidation which, in the initial development steps, tends to be of first order relatively to periodate.[19] Better linearity ($r > 0.99$) was observed for $IO_4^- = 3.0 \times 10^{-3}M$. For periodate concentrations higher than $10^{-2}M$, linearity decreased and lower peaks were recorded (Fig. 3). In this situation, glycerol concentrations were very low relative to periodate, so that the relative oxidant consumption underwent a pronounced reduction. Also, an oscillating baseline was observed, probably due to inefficient mixing conditions associated with the fast electrode response.

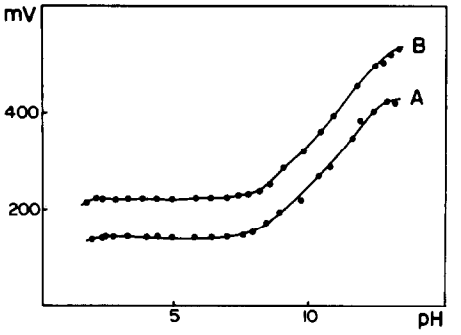

Fig. 2. Influence of pH on electrode potential. Reilley diagrams refer to Type I (a) and Type II (b) conventionally-shaped electrodes on a $10^{-3}M$ $NaIO_4$ solution.

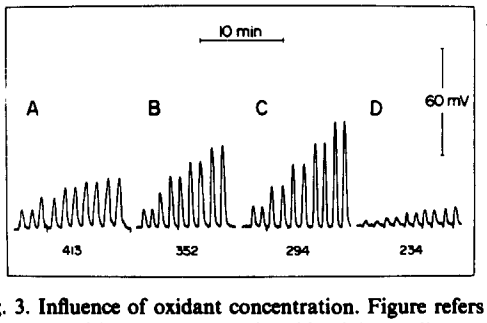

Fig. 3. Influence of oxidant concentration. Figure refers to (b) system with $R_1 = 0.1M$ acetic acid + $0.1M$ sodium acetate plus $0.1M$ sodium sulfate. A, B, C and D correspond to periodate concentrations of 10^{-4}, 10^{-3}, 10^{-2} and $10^{-1}M$ in R_2. From left, recorded peaks correspond to 100.0, 200.0, 300.0, 400.0 and 500.0 mg glycerol/l. Numbers refer to baseline potentials, in mV.

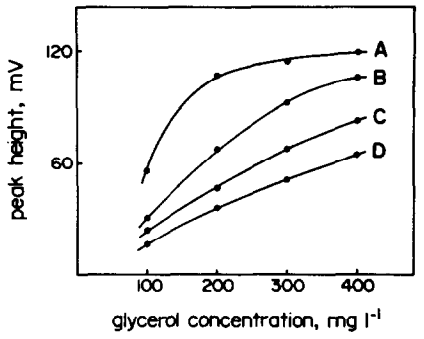

Fig. 4. Influence of pump speed. A, B, C and D correspond to 25, 50, 75 and 100% of flow rates specified in Fig. 1(b).

Sensitivity was very dependent on peristaltic pump speed which was proportional to the mean sample residence time (Fig. 4). However, this parameter could not be selected at will since linearity of the calibration curve was also affected by variations in mean available time for glycerol oxidation. The flow rates for the 1(b) system were then selected as a compromise between sensitivity, sampling rate and linearity of the calibration plot.

The 1(b) system is remarkably stable and suitable for glycerol determination in lixivia and similar up to 500.0 mg/l. As large dispersion is involved, variations in ionic strength of the injected solution within 0.0 and 0.5*M* are not relevant. Also, when sample alkalinity varied within the 0.1–0.5*M* NaOH range, slight variations (<5%) in peak heights were observed. When placed under a climatized ambient with temperature variations lower than about 5°C per day, a thermostat water bath is not required. The system can then be applied to soap analysis without restrictions.

After defining reagent concentrations, and studying the relevance of the main parameters and involved dispersions, a single-line system was designed. With this system (Fig. 1(c)), 40 samples are run/hr, corresponding to a consumption of 1.8 mg $NaIO_4$ per determination. Reproducible results (s.d. <0.2 mV) were achieved and baseline drift was not observed (see also Fig. 5) which in turn also confirms the stability of the periodate reagent. Accuracy can be assessed from Table 2.

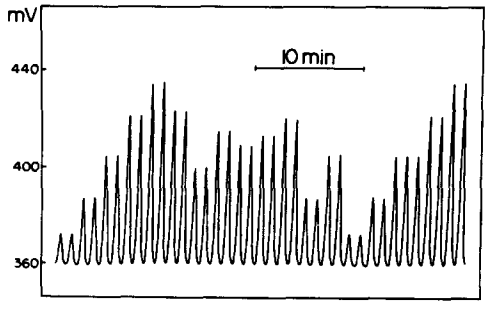

Fig. 5. Recorder output of a routine run carried out with the 1(c) system. From left, duplicate measurements of five glycerol standard solutions (1000, 2000, 3000, 4000 and 5000 mg/l), eight lixivia and the standards again.

Table 2. Comparative results. Glycerol contents in lixivia (in % w/v) as determined by the proposed system of Fig. 1(c) (FIA) and by iodometric titration[21] (AOCS). Standard deviations related to FIA values are always lower than 0.5% (see also Fig. 5) and related to AOCS are usually *ca.* 1%

Sample	FIA	AOCS
1	34.1	32.3
2	26.0	27.0

(*Received* 8 *February* 1993. *Accepted* 23 *March* 1993)

Summary—Pyrene immobilized in plasticized poly(vinyl chloride) (PVC) membrane is able to extract selectively picric acid from the sample solution into the organic membrane phase. Since this extraction equilibrium is accompanied by a change in the fluorescence spectrum of pyrene, the chemical recognition process can be directly translated into an optical signal. With the optode membrane described, picric acid in sample solutions from 8.7×10^{-6} to $4.3 \times 10^{-3} M$ can be determined. The calibration curve of the optode membrane for picric acid shows a good correlation with the mathematically derived formalism and thus confirms the theoretically expected behaviour. Besides a high reproducibility of the optical signals, the very short response times less than 35 sec are realized. The optode membrane presented exhibits good selectivity for picric acid over many other usual hydrophobic anions.

Picric acid, 2,4,6-trinitrophenol, is an important organic acid. The classical chemical method,[1] ultra-visible spectrophotometry,[2] gas chromatography methods[3] have been used for picric acid determination. These methods demand a cumbersome pretreatment of the sample solution and require expensive instrumentation. Potentiometry with ion-selective electrodes (ISEs)[4–7] has been applied and shows some remarkable advantages over other methods in the area of pharmaceutical analysis[8,9] and biological chemical determination.[10,11] Since picric acid ion-selective electrodes are generally based on classical ion-exchangers, their inherent selectivity pattern may cause interference problems. The selectivity of classical anion exchangers is governed by lipophilicity of the anions. It is a function of hydration energies of these anions and follows the Hofmeister sequence.[12,13] Careful consideration has to be given to potential interferences from SCN^- and ClO_4^-. Recently, the optical chemical sensor (optodes or optrodes) has become a rapidly expanding area of analytical chemistry.[14] Optodes for a variety of analytes have been reported.[15,16] Jian and Seitz have developed a fluorescent membrane for detection of organic nitro compounds,[17] in which pyrenebutyric acid is incorporated into a plasticized cellulose triacetate matrix. In this paper, a new optode membrane for the determination of picric acid is described. The optode membrane incorporates a polycyclic aromatic compound pyrene in a plasticized PVC matrix. Because the interaction between pyrene and picric acid is not controlled by the Hofmeister sequence, the interference of lipophilic anions such as SCN^- and ClO_4^- can be largely overcome.

THEORY

Pyrene is one of the polycyclic aromatic hydrocarbons which can emit strong fluorescence. After being immobilized in a plasticized PVC membrane, pyrene can selectively extract picric acid from the aqueous phase into the organic membrane phase to form the non-fluorescence ground state complex.[20] Figure 3 shows the fluorescence spectra of the optode membrane incorporating pyrene exposed to $1.9 M$ sulphuric acid solution containing different concentrations of picric acid. Fluorescence intensity measurements of the optode membranes were made at an excitation wavelength of 338 nm and an emission wavelength from 350 to 550 nm. The fluorescence intensity of the membrane decreased while the concentration of picric acid increased. It illustrates that the optode membrane can indeed be used to sense picric acid in sample solutions.

If the complex equilibrium between pyrene in the plasticized PVC membrane phase (org) and picric acid in the aqueous sample solution (aq) will form $m:n$ ground state complex, the overall equilibrium is described as follows:

$$m\mathrm{P(aq)} + n\mathrm{A(org)} = \mathrm{P}m\,.\,\mathrm{A}n\,\mathrm{(org)} \quad (1)$$

where P represents picric acid and A represents pyrene. The corresponding equilibrium constant K depends on the law of mass action:

$$K = \frac{{}^{a}\mathrm{P}_m\,.\,\mathrm{A}_n\mathrm{(org)}}{a^{m}_{\mathrm{P(aq)}} \times a^{n}_{\mathrm{A(org)}}} \quad (2)$$

where ${}^{a}\mathrm{P}_m\,.\,\mathrm{A}_n, a_{\mathrm{P}}, a_{\mathrm{A}}$ are the activities of respective species.

The following equilibrium was involved between the membrane and aqueous phases:

$$m\mathrm{P(aq)} = m\mathrm{P(org)} \quad (3)$$

$$m\mathrm{P(org)} + n\mathrm{A(org)} = \mathrm{P}m\,.\,\mathrm{A}n\,\mathrm{(org)} \quad (4)$$

$$k_{\mathrm{d}} = \frac{{}^{a}\mathrm{P(org)}}{{}^{a}\mathrm{P(aq)}} \quad (5)$$

$$\beta = \frac{{}^{a}\mathrm{P}_m\,.\,\mathrm{A}_n\mathrm{(org)}}{a^{m}_{\mathrm{P(org)}} \times a^{n}_{\mathrm{A(org)}}} \quad (6)$$

where k_{d}, β are the distribution coefficient and complex formation constant, respectively. If the difference between the activities and concentrations is neglected, one can write:

$$K = \frac{[\mathrm{P}_m\,.\,\mathrm{A}_n]_{\mathrm{(org)}}}{[\mathrm{P}]^{m}_{\mathrm{(aq)}} \times [\mathrm{A}]^{n}_{\mathrm{(org)}}} = k_{\mathrm{d}} \times \beta \quad (7)$$

where $[\mathrm{P}_m\,.\,\mathrm{A}_m]$, [P], [A] are the concentrations of the respective species. As the concentration of the undissociated picric acid is pH dependent, the acidity of the test solution should be kept constant.

The relative fluorescence value α (*vide infra*) equals the ratio of the concentration of free pyrene, [A], to the total amount of pyrene, C_{A}:

$$\alpha = [\mathrm{A}]/C_{\mathrm{A}} \quad (8)$$

α is shown to depend on the concentration of picric acid in aqueous sample solution, [P], as follows:

$$\frac{\alpha^{n}}{1-\alpha} = \frac{1}{(nKC_{\mathrm{A}}^{n-1}[\mathrm{P}]^{m})} \quad (9)$$

The relationship between α and [P] as expressed by equation (9) is the basis of quantitative determination of picric acid using this optode membrane.

EXPERIMENTAL

Apparatus

Fluorescence was measured using a Hitachi M-850 fluorescence spectrometer with a specially designed flow-through measuring cell similar to the device described elsewhere (*vide infra*).[18] Data processing were carried out on a Macintosh II computer.

Reagents

Pyrene (A.R; Aldrich), poly(vinyl chloride) (high molecular weight; Fluka Selectophore), bis(2-ethylhexyl)sebacate (C.P; Shanghai Chemical Reagent Corporation) and tetrahydrofuran (A.R; Shanghai Chemical Reagent Corporation) were used for membrane preparation.

The $1 \times 10^{-2}M$ stock solution of picric acid was prepared by dissolving 11.45 g of picric acid (recrystallized twice) in 500 ml of distilled water. The actual concentration of picric acid was determined by titration with sodium hydroxide standard solution. The picric acid solution of other concentrations were obtained from the stock solution by dilution with $1.9M$ sulphuric acid.

Membrane preparation

The optode membranes were prepared from a mixture of 2 mg of pyrene, 50 mg of PVC and 100 mg of bis(2-ethylhexyl)sebacate. The membrane components were dissolved in 2 ml of freshly distilled THF. A circular 35-mm diameter quartz plate was mounted on the end of an aluminum alloy rod which was rotating at high constant speed. From a syringe, 0.2 ml of the THF solution was injected to the central point of the plate. After a spinning time of only about 4 sec (rotating frequency, 600 rpm) two membranes of approximately 4-μm thickness were cast onto two 35-mm diameter quartz plates.[19]

Procedure

Two identical membranes on their respective plates were mounted in the special flow-through measuring cell (Fig. 1). The volume capacity of the cell was *ca.* 3.4 ml. The cell was introduced into the fluorescence spectrometer in an appropriate position (Fig. 2) to guarantee the detection of the intensity of fluorescence emission without interference from the excitation source.

2. O-ring seal.
3. Quartz glass support.
4. Optode membrane.
5. Plexiglas cell wall.
6. Screw for fixation.

About 3 ml of sample solution was introduced and the fluorescence intensity F was measured. The membrane was washed with the blank solution not containing picric acid until the fluorescence intensity (F_1) was stabilized. The limiting fluorescence intensity (F_0) for the case of complete complexation of pyrene in the membrane with picric acid was taken as zero. The relative fluorescence value α was calculated according to following formula:

$$\alpha = \frac{(F - F_0)}{(F_1 - F_0)} = \frac{F}{F_1} \qquad (10)$$

RESULTS AND DISCUSSION

Composition of the ground state complex

From equation (9), it is known that when the stoichiometric ratio of the ground state-complex changes, the relative fluorescence valued α has different functional relation with the concentration of picric acid. The experimental data were fitted to equation (9) by changing the ratio of m to n and adjusting the overall equilibrium constant K. The result showed that the curve (4) was the best one to represent the experimental data (Fig. 4). In other words, the complex ratio of picric acid to pyrene in the optode membrane should be 1:2. The actual

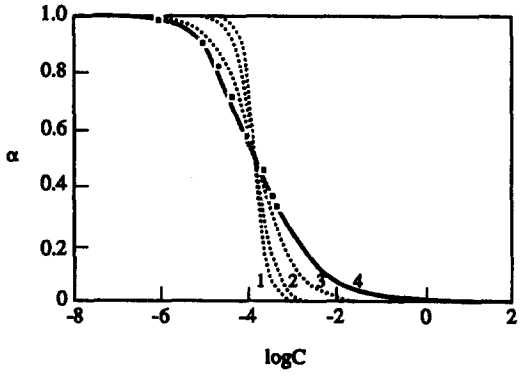

Fig. 4. Fitting the experimental data to equation (9).
$C_A = 5.3 \times 10^{-2} M$
1. $m:n = 3:1$, $K = 3.31 \times 10^{11}$
2. $m:n = 2:1$, $K = 4.78 \times 10^{7}$
3. $m:n = 1:1$, $K = 6.9 \times 10^{3}$
4. $m:n = 1:2$, $K = 1.3 \times 10^{5}$ (best fit).

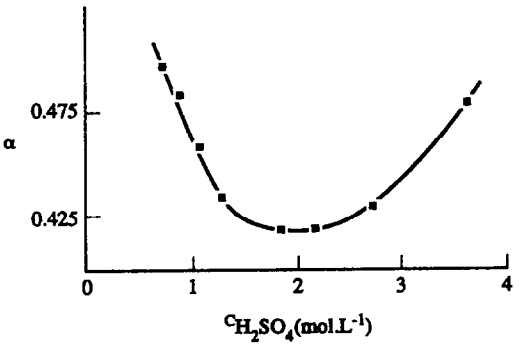

Fig. 5. Effect of acidity.

ratio of picric acid to pyrene was determined independently with molar ratio method in solutions by using dichloromethane as solvent. The results showed the ratio of picric acid to pyrene was 1:2, in exact agreement with the ratio obtained by curve fitting of the membrane fluorescence data. The curve (4) can serve as the calibration curve to determine the concentration of picric acid. It is clear that a sufficient response to picric acid is obtained from 8.7×10^{-6} to $4.3 \times 10^{-3}M$.

Effect of the acidity

Figure 5 shows the effect of acidity on the relative fluorescence value α of the optode membrane. The fluoresence intensity measurements were made for $3.6 \times 10^{-4}M$ picric acid in sulphuric acid solutions of different concentrations. With the increase of the concentration of sulphuric acid, the extent of picric acid ionization is reduced to increase the concentration of picric acid in the membrane. And therefore the ratio of the concentration of free pyrene to the total amount of pyrene, α, will be decreased. After the acidity reaches a relative high value, the ionization of picric acid will be completely inhibited so that the α value remains constant. On the other hand, too high acidity seems unfavourable to the extraction of picric acid from aqueous solution into the membrane phase, the α value will decrease with further increase of the acidity. It has been shown that the optode membrane has a better and constant response to picric acid in sulphuric acid solutions from 1.8 to $2.2M$.

Reproducibility and response time

Figure 6 shows the fluorescence intensity response *vs* time recordings for the picric acid optode membrane when it was exposed to repeated concentration step changes between 8.5×10^{-6} and $8.5 \times 10^{-5}M$ picric acid in $1.9M$ sulphuric acid solution. The results show a remarkably high reproducibility of the optical signals. The mean fluorescence intensity values with standard deviations were found to be 313.9 ± 1.2 ($n = 5$, $8.5 \times 10^{-6}M$ picric acid) and 206.4 ± 0.4 ($n = 5$, $8.5 \times 10^{-5}M$ picric acid). From this figure, it can also be seen that the response times of the optode membrane are less than 35 sec.

Lifetime

The fluorescence signal at a wavelength of 394 nm for the optode membrane in contact with a $4.3 \times 10^{-4}M$ picric acid in $1.9M$ sulphuric acid solution was recorded over a period of 6 hr. From fluorescence intensity values taken every 30 min ($n = 12$) a mean value of 110.0 and a standard deviation of ± 0.4 were obtained. It is shown that pyrene is not washed out significantly during this period of time. The fluorescence signal of the optode membrane at 394 nm dropped by 4% during the measurement of sample solutions over a week.

Selectivity

With the concentration of picric acid fixed at $3.6 \times 10^{-4}M$, there is no influence on the fluorescence signal of the optode membrane when less than $10^{-2}M$ potassium perchlorate and sodium thiocyanate exist. This shows the sensing device has much better selectivity over hydrophobic anions compared with picric acid ion-selective electrodes. Organic acids and inorganic salts, such as *o*-phthalic acid, benzonic acid, phenol, *o*-chlorophenol, sodium fluoride and mercury dichloride, at concentrations less than $10^{-1}M$ do not interfere with the determi-

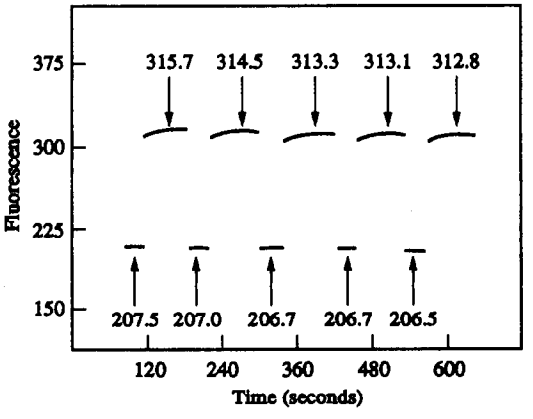

Fig. 6. Fluorescence intensity response *vs* time at 349 nm after several repeated concentration step changes.

nation. But when the concentrations of the nitrophenols, whose structures are similar to picric acid, at concentration levels one order of magnitude higher than the concentration of picric acid in sample solution, will quench the fluorescence signal of the optode membrane to some degree. The sequence of selectivity is picric acid > 2,4-dinitrophenol > *p*-nitrophenol > *o*-nitrophenol > *m*-nitrophenol.

Application

Since picric acid can react quantitatively with some drugs such as cinchonine and quinine to form insoluble precipitates, the optode membrane can be applied to the indirect determination of these drugs. The determination of cinchonine in drug samples, for example, was carried out by following the procedure. About 4 g of sample was dissolved in $0.014M$ sulphuric acid to make a 500-ml solution. To this solution, 100 ml of $4.27 \times 10^{-2}M$ picric acid was added while stirring. The solution was filtered and the filtrate was diluted to appropriate concentration. The picric acid content in filtrate was determined by using the fluorescent membrane. For $2.14 \times 10^{-2}M$ cinchonine, the measured mean concentration was $2.16 \times 10^{-2}M$. Seven repeated measurements for different aliquots from the sample solution gave a standard deviation of $2 \times 10^{-4}M$. A similar procedure was applied to the determination of quinine. For $1.08 \times 10^{-2}M$ quinine, the measured concentration was $(1.07 \pm 0.02) \times 10^{-2}M$ (seven measurements).

(*Received* 1 *December* 1992. *Revised* 29 *March* 1993. *Accepted* 22 *April* 1993)

Summary—The suitability of ion-selective electrode for the determination of ammonia in pyrolysis gases of fossil fuels was studied. The ammonia was absorbed into acidic solution and two kinds of determination methods were carried out. The ammonia was either measured directly from the acid solution, or ammonia was first released into the gas phase and then determined (air gap method) by the ammonia selective electrode. The electrode functioned well in both cases, but the linear calibration range was rather narrow, slightly more than one tenfold. The quantitative detection limit in the water phase was $5 \times 10^{-6}M$ (0.085 ppm) NH_3 and in gas phase operation solutions above $5 \times 10^{-4}M$ (8.5 ppm) NH_3 it was possible to measure quantitatively. The applications were carried out with Finnish energy peat samples and a coal sample.

The combustion of fossil fuels has a number of associated environmental consequences. One of the major problems is the formation of nitrogen oxides (N_xO_y). The two major routes for the formation of N_xO_y are the fixation of atmospheric nitrogen and the conversion of fuel nitrogen itself.[1,2]

The fixation of atmospheric nitrogen goes by radical reactions:

$$O^{\cdot} + N_2 \rightarrow NO + N^{\cdot} \quad (1)$$

$$N^{\cdot} + O_2 \rightarrow NO - O^{\cdot} \quad (2)$$

These reactions are sensitive to temperature, and therefore important at higher temperatures (>1300°C). However, in modern combustion furnaces, the formation of nitrogen oxides, originating from the air, are effectively controlled by air staging, or by using lower combustion temperatures. Thus the major source of N_xO_y in flue gases is usually fuel nitrogen.

Typically fossil fuels contain ≈0.5–3 wt % nitrogen, unfortunately the distribution of nitrogen containing functional groups in fuels is not accurately known. Recent X-ray photoelectron spectroscopy (XPS) studies have shown that in high rank fuels, like coal, the nitrogen occurs principally in pyrrolic and pyridinic type heterocyclic ring moieties that constitute the organic matter. In low rank fuels, like peat, other functional groups such as amines may also be important.[3,4]

The mechanism of the formation of N_xO_y from fuel is particularly complex and still not completely understood. A simple view of the process (Fig. 1) is that the volatile nitrogeneous fragments are initially converted into compounds such as HCN and NH_3 (the most important intermediates) which can subsequently react either with oxygen to generate NO, or combine with NO itself to produce nitrogen. The reactions involving the oxidation of char-nitrogen are similar to those for volatile-nitrogen although the direct reduction of NO by carbon and the char-catalysed reduction by CO may also be important.[5]

Several new and efficient techniques exist for sampling and determination of ammonia. Diffusion scrubbers have been used for the sampling of atmospheric gases[6] such as ammonia[7] and sulfur dioxide,[8] and for the collection of gaseous hydrogen peroxide.[9] A newly developed photoacoustic spectrometer method is now available for the determination of NH_3 with a detection limit below 1 ppm.[10,11] In this study the conversion of fuel nitrogen to NH_3 and HCN was measured for several fuels. Thus simultaneous sampling of both intermediates was needed and the classical wet-chemical approach, where the sample gas is passed through absorption solution, was selected. Therefore the ammonium selective electrode was used for determination of NH_3.

The collection solution used was dilute ($0.01M$) HNO_3. Besides ammonia, many other

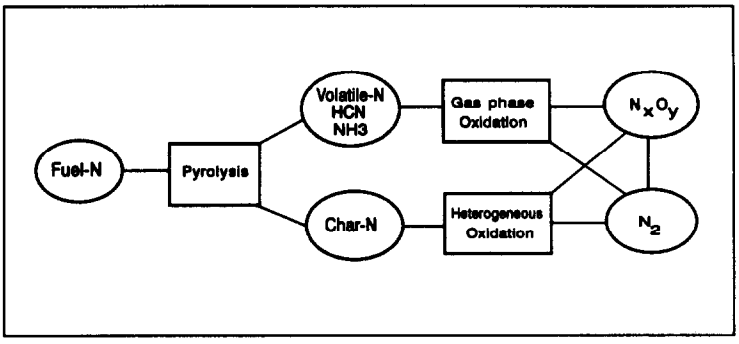

Fig. 1. Conversion of fuel nitrogen in combustion.

pyrolysis products will simultaneously be absorbed in the acidic solution, changing the composition and colour of the solution. Thus, there are only a few methods available for determining ammonia from the water phase. One possibility is the Kjeldahl method, but it is more complicated and slower than the potentiometric method. The colour of the water phase, on the other hand, is the main reason for rejecting the ordinary spectroscopic methods.

EXPERIMENTAL

NH_3-measurements

An Orion Ammonia Electrode Model 95-12 was used with an Orion mv/pH meter Model EA 920. The electrode consists of a hydrophobic gas-permeable membrane which separates the alkaline test solution from an internal solution 0.1*M* in ammonium chloride. A glass pH electrode and a silver–silver chloride reference electrode are immersed in the internal solution.[12] Electromotive force (e.m.f.) of the electrode obeys ammonia concentrations both in liquid and gas phases according to the Nernstian equation

$$E = E' + 2.3RT/F \log([NH_3]/[NH_4^+]), \quad (3)$$

where E' = standard potential, R = gas constant, T = temperature and F = Faraday constant.

The $pK_{NH_4^+}$ is 9.25. Thus the ammonia measurement must be performed in alkaline solutions at pH > 11. In gas phase operations one has to ensure that the pH is high enough for NH_3 liberation into gas phase. A 0.100*M* stock solution of ammonium chloride was made from p.a. reagent (Merck). The buffer solution (ISA) for pH adjustment contained 5*M* NaOH and 0.05*M* EDTA in 10% (v/v) methanol–water solution. Measurements were performed in a titration vessel (150 cm^3) with an air-tight cover. The electrodes and burette were also led air-tightly through the cover. In the tests with standard solution we had electrodes in each phase simultaneously. Thus it was possible to use the same test solution for simultaneous measurements of ammonia in both phases. The volume of the studied solution was 100 cm^3, so the volume of the gas phase was about 50 cm^3, 2 cm^3 ISA solution and a magnetic stirrer were used in the measurements.

Samples for application experiments

Four fuel peat samples, originally from Central and Northern Finland, and one coal sample were used. The peats were medium humified (H3–H8 by von Post) and represented the main peat constituents of Scandinavian peats: B, C and S-peats. The subsamples for pyrolysis experiments were dried, milled and sieved to a particle size of <63 μm before analysis. The main composition of samples is represented in Table 1.

Table 1. Fuel analysis (wt%)

Reactor design and pyrolysis experiments

The fuels were pyrolysed in an entrained flow reactor. The detailed structure of the reactor has been described in Fig. 2. The incoming gas (reaction gas) was heated to the desired temperature by a preheater and the flow rate and oxygen content in the reactor were adjusted by two mass flow controllers connected to a computer. The fuel feeding rate is higher in this reactor as is the case in drop tube furnaces which makes it possible to study the formation and emissions of flue gas components.

The conversion of fuel nitrogen to ammonia was studied at 800°C. At the beginning of the reaction there was a trace of oxygen in the reaction gas but the fuel consumed the oxygen rapidly as the fuel feeding rate was quite high for this reactor (0.2 g/s). Because N_xO_y was not observed in the pyrolysis gas (measured by F.T.-ir[13]), it is evident, that the pyrolysis of the sample took place in an inert atmosphere. The pyrolysis gas sample was taken with a short mobile probe after pyrolysis. The sample line was connected with a gas washing bottle (500 cm^3), and the NH_3 was absorbed in the 300 cm^3 of 0.01M HNO_3 solution. The sampling rate was 10 dm^3/min. Because the fuel feeding rate was adjusted to be constant and the pyrolysis conditions were also unchanged it was possible to use the not continuous determination of conversion of fuel nitrogen to ammonia.

RESULTS AND DISCUSSION

The linear range of the ammonia electrode was reported to be from 1M to $5 \times 10^{-7}M$ (0.01 ppm to 17,000 ppm) NH_3.[12] Because of the low amounts of nitrogen in fuels, the ammonia concentration in the gas phase remained low. Thus a careful study of the function of the electrode both in liquid and gas phases was first required.

Response time

The response time of the electrode was studied in both phases by using several concentration levels. The results are presented in Figs 3(a) and (b). The response time was generally a function of the concentration, and the time was usually longer in the gas phase than in the liquid phase. For instance, at the concentration level of about $10^{-5}M$ of NH_3 the response time in the water phase was about 2 min and in the gas phase operation about 4 min. At high concentrations ($10^{-2}M$), the response time had a minimum value of 1.5 min in both cases.

Calibration

We calculated the concentration of ammonia according to the equation (3) and fitted the experimental results into a linear or quadratic equation using the least square calculation method:

$$E = E' + S \times pC_{NH_3}, \quad (4)$$

$$E = B + A \times pC_{NH_3} + C \times (pC_{NH_3})^2, \quad (5)$$

where E = measured e.m.f.; E' = standard e.m.f. of the studied system; S = the Nernstian slope; A,B,C = parameters of the quadratic equation; $pC_{NH_3} = -\log C_{NH_3}$.

Water phase. The values of the parameters together with the results of the statistical calculations are in Table 2. The results of equation (4) in the water phase show that E' is roughly constant, and the value of S is constant but below the theoretical value of 59.1 mV. The r-values are excellent and the values of s_A and s_B are acceptable. The value of $s_B = 0.6$ causes an error of $<3\%$ at the midpoint of the regression line. The standard error estimate (s.e.e.) shows, however, that the more narrow the range the more accurate are the results. The experimental results fitted excellently to the quadratic equation. From a statistical point of view the results are good, but there is some fluctuation in the values of the parameters between different measurements.

Concluding the measurements of ammonia in the water phase showed some curvature in calibration line over a large concentration range. Within a narrower range (about two decades) we can use linear calibration line for measurements. The use of quadratic equation for calibration is not recommendable. The quantitative detection limit is about $5 \times 10^{-6}M$ (0.085 ppm) NH_3 in the water phase.

Gas phase. The measurements of the standard curves in the gas phase were made using an air gap technique. The values of the parameters for equation (4) (in Table 2) show that neither E' nor S are constants in the series of measurements performed although the statistical values for the curves are acceptable. As in the water phase, the measured data fitted better to the quadratic equation. The variation of the slope, especially in weak solutions, might be due to the

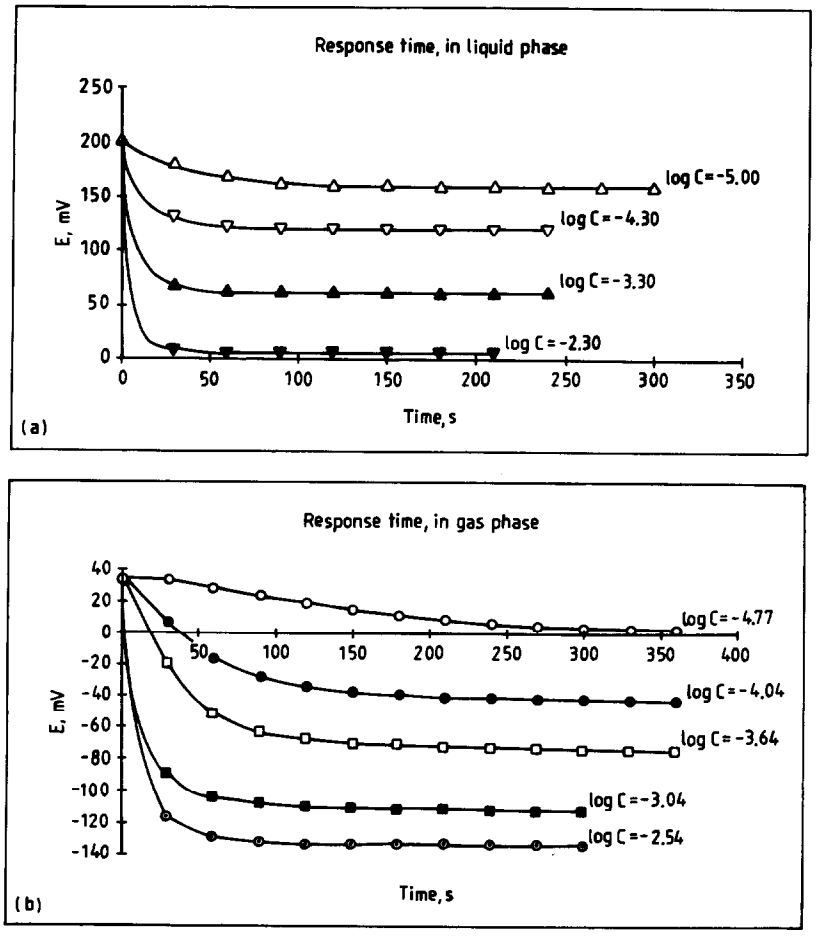

Fig. 3. Response time of the ammonia electrode in different concentrations. (a) In liquid phase; and (b) in gas phase.

fact that the ammonia concentration is low in the gas phase and the equilibrium between the electrode and the gas phase is difficult to reach in a moderate time. Because of a fluctuation in the values of the parameters between the different measurement series, a known addition technique should be used in air gap measurements. In the gas phase operation the quantitative detection limit of the electrode extends to $5 \times 10^{-4}M$ (8.5 ppm) NH_3.

Simultaneous measurements in liquid and gas phases

In these measurements two ammonium electrodes were used simultaneously: one in the liquid and the other in the gas phase. In this way random errors in the results could be minimized. The e.m.f. of the electrode was measured in both phases. Then a known amount of standard solution was added to the

Table 2. Calculated calibration curves in liquid and gas phases. Form of the equations are $E = E' + S \times pC_{NH_3}$ and the quadratic equation $E = B + A*pC_{NH_3} + C*pC_{NH_3})^2$. s_E and s_s are the standard deviations of intercept (E') and slope (S). A,B and C are parameters of quadratic equation.

2.252	2.284	−0.032

vessel and the concentrations were calculated after the change of the e.m.f. The response time used was in accordance with the gas phase. The results have been collected in Table 3.

Statistical methods were used in analysing the experimental data. Linear regression analysis showed very high regression between the liquid and gas phase operation methods: the equation being $Y = 0.132 + 0.929\ X$ with the value of $r \approx 1.000$. The slope of the equation was 0.929, which means that the air gap method gives slightly lower concentrations than direct determination from the water phase. This indicates that the slope of the electrode is higher in the gas phase than the theoretical value, and the real slope is quite difficult to measure precisely because of its fluctuation.

Generally, the statistically acceptable confidence level is $P = 0.05$ in analytical chemistry. We used the results in Table 3 to compare the accuracy of the results of the two phases by some statistical methods: The paired t-test gave $t_{calc.} = 1.39$ (critical value $t_{0.05} = 2.23$), the paired t-test for the means $t_{calc.} = 0.073$ ($t_{0.05} = 2.09$) and F-test for variances $F_{calc.} = 1.16$ ($F_{a,b} = 2.98$). All tests fulfilled the criteria above, which means that the results obtained from the different phases are the same at significance level $P = 0.05$.[14]

APPLICATION

In application experiments the conversion of fuel nitrogen into NH_3 was determined during pyrolysis at 800°C (see Fig. 1) for five fuels by using an indirect method described above. The concentrations of the sample solutions varied between $C = 5 \times 10^{-5}$–$4 \times 10^{-4} M$ (0.85–6.8 ppm) NH_3 with the peat and 1×10^{-5}–$1 \times 10^{-4} M$ (0.17–1.7 ppm) NH_3 with the coal sample. According to these results the concentration of NH_3 in the pyrolysis gas varied between 8 and 90 ppm depending on the fuel sample. The measurements were carried out using the air gap method, because peat samples have high volatile content and the water phase may thus contain interfering compounds. Ammonia was also measured directly from the sample solution in samples of low NH_3 content (coal, low volatile). The results show that there are differences in fuel nitrogen conversions between different fuels.[15]

The data can be used when studying the mechanisms of N_xO_y formation from fuel nitrogen through NH_3. Using experimental data as basic information it is possible to create kinetic models for combustion with greater accuracy. It is also possible to find evidence for existing combustion models on the basis of the experimental results.

CONCLUSIONS

In this study, the ammonia selective electrode was applied in a determination of NH_3 in pyrolysis gases. It is possible to accurately analyse dilute solutions of NH_3 with the electrode. By extending the sampling time, the sensitivity of the electrode can be increased. In addition, the electrode is available at a low price and is easy to use. The above benefits ensure that many application fields exist for NH_3 selective electrode. If the time cycle is long enough continuous detection of NH_3 is also possible. In our study the experiments did not take long and so the electrode was not suitable for ON-LINE detection because of the long response time.

BOOK REVIEWS

Vibrational Spectroscopy—Methods and Applications: A. FADINI and F.-M. SCHNEPEL, Ellis Horwood, Chichester, 1989. Pages 205. £50.00, US$85.00.

This book of 205 pages is a translation from German. It consists of five parts comprised of 24 short chapters (some very short) and aims to describe the theoretical background for the interpretation of vibrational spectra. According to the Introduction it is a textbook for undergraduate and postgraduate students and it attempts to give an overview of applications and "an understanding of some problem-oriented approaches".

Chapter 1 which is also part 1 contains some irritating errors in the units which are to be used. It states, for example that 1 nm = 10^{-3} mm instead of 10^{-3} μm. Also the standard abbreviation for seconds in SI units is s not sec. One needs to be circumspect in insisting on SI units since cm^{-1}, beloved of spectroscopists, for very good reasons, is not an SI unit. Nevertheless, the relation between wave number in cm^{-1} and wavelength λ in μm is $\nu(cm^{-1}) = 10^{+4}/\lambda$ (μm) not $10^{-4}/\lambda$ (μm). Theoretical results, concerning the mechanism by which IR and Raman spectra are obtained, are stated without proof and little explanation. The illustration (Fig. 1.6) of the IR spectrum and the Raman spectrum of CS_2 is in principle a good one and the diagrams to demonstrate them are potentially useful but they in no way indicate why the polarizability changes in either the asymmetric vibration or the degenerate bending vibrations. The text referring to the diagram is no help either and it is unfortunately separated from the picture by text.

Part II of the book contains three chapters on the non-mathematical interpretation of vibrational spectra. Most of the first of these chapters is an adequate description of "fingerprinting". The section on the use of vibrational spectroscopy for following the course of reactions is marred by some unfortunate misprints; the formula of N-pentafluoroethyltetrafluoro-sulphurimide is $C_2F_5—N{=}SF_4$ and the captions for Figs 2 and 3 have formulae where B has mysteriously replaced N. The third chapter of this part concerns the interpretation of the vibrational spectra of organic compounds and contains quite a useful reference list of group frequencies and also some useful rules of thumb about the intensities of IR and Raman bands.

Chapter 4 describes the quantitative analytical use of vibrational spectroscopy with some instructive examples.

Part III of the book develops the use of group theory in interpreting vibrational spectra. The description of point groups is accurate but the representation of groups is presented without any derivation and will be very puzzling to beginners. The diagram illustrating a table of group characters is fine but there is a misprint in one of the formulae concerning the orthogonality of irreducible representations. The selection rules are stated without proper explanation. Students will be able to get the right answer without any insight as to why it is correct. The small section on the extension of symmetry concepts to the solid state is very short and incomplete although the concepts are to be used later. Chapter 6 describes some applications, considering the vibrational spectra of AsF_6^-, the changes which occur when this ion behaves as a ligand and the use of vibrational spectroscopy to distinguish between conformational isomers. This useful chapter concludes with a short discussion of molecules in the solid state.

Part IV considers the interpretation of molecular spectra using mathematical tools and makes reference to a number of other books which contain the detailed development of the ideas. There then follows a chapter on elementary matrix algebra which stops short of the diagonalization of matrices; just the material necessary for a proper understanding of the use of F and G matrices which are considered in the next chapter. This may be useful to experienced users but is likely to be confusing to students. Then follows a number of such short chapters that one wonders whether this is a translation of the original book or a precis of it. Without seeing the original German edition it is not possible to decide this. There are a number of places where one line has been partially printed over another but this may just be the copy which I have.

Part V continues with a discussion of the vibrational spectroscopy of solids and again results are stated without derivation or reference.

Parts of this book may be a useful aide-memoire to experienced practitioners but students new to the field will not be helped to any great extent. I suspect that the price of the book will deter even those who would be able to follow it easily.

The Kirk–Othmer Encyclopedia of Chemical Technology: Volume 5, Fourth Edition. Carbon and Graphite Fibers to Chlorocarbons and Chlorohydrocarbons-C_1. J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley–Interscience, Chichester, 1992. Pages: xxviii + 1072. £150.00. ISBN 0-471-52673-8 (v. 5).

Volumes in the new edition of this encyclopedia now extend, alphabetically, to the topic of chlorocarbons and chlorohydrocarbons. An excellent softback index covering the first four volumes is also included with volume five.

Almost 70 authors have contributed to this volume which is divided into 31 topics. The main areas covered are: ceramics (129 pages), cardiovascular agents (95 pages), cellulose—esters and ethers (88 pages), chlorine oxygen acids and salts (86 pages), catalysts (79 pages) and catalysis (64 pages), and carboxylic acids (61 pages). The final topic—chlorocarbons and chlorohydrocarbons—is also extensive and continues into volume six of the encyclopedia.

Also the standard abbreviation for seconds in SI units is s not sec. One needs to be circumspect in insisting on SI units since cm^{-1}, beloved of spectroscopists, for very good reasons, is not an SI unit. Nevertheless, the relation between wave number in cm^{-1} and wavelength λ in μm is $\nu(cm^{-1}) = 10^{+4}/\lambda$ (μm) not $10^{-4}/\lambda$ (μm). Theoretical results, concerning the mechanism by which IR and Raman spectra are obtained, are stated without proof and little explanation. The illustration (Fig. 1.6) of the IR spectrum and the Raman spectrum of CS_2 is in principle a good one and the diagrams to demonstrate them are potentially useful but they in no way indicate why the polarizability changes in either the asymmetric vibration or the degenerate bending vibrations. The text referring to the diagram is no help either and it is unfortunately separated from the picture by text.

Part II of the book contains three chapters on the non-mathematical interpretation of vibrational spectra. Most of the first of these chapters is an adequate description of "fingerprinting". The section on the use of vibrational spectroscopy for following the course of reactions is marred by some unfortunate misprints; the formula of N-pentafluoroethyltetrafluoro-sulphurimide is $C_2F_5—N{=}SF_4$ and the captions for Figs 2 and 3 have formulae where B has mysteriously replaced N. The third chapter of this part concerns the interpretation of the vibrational spectra of organic compounds and contains quite a useful reference list of group frequencies and also some useful rules of thumb about the intensities of IR and Raman bands.

Chapter 4 describes the quantitative analytical use of vibrational spectroscopy with some instructive examples.

Part III of the book develops the use of group theory in interpreting vibrational spectra. The description of point groups is accurate but the representation of groups is presented without any derivation and will be very puzzling to beginners. The diagram illustrating a table of group characters is fine but there is a misprint in one of the formulae concerning the orthogonality of irreducible representations. The selection rules are stated without proper explanation. Students will be able to get the right answer without any insight as to why it is correct. The small section on the extension of symmetry concepts to the solid state is very short and incomplete although the concepts are to be used later. Chapter 6 describes some applications, considering the vibrational spectra of AsF_6^-, the changes which occur when this ion behaves as a ligand and the use of vibrational spectroscopy to distinguish between conformational isomers. This useful chapter concludes with a short discussion of molecules in the solid state.

Part IV considers the interpretation of molecular spectra using mathematical tools and makes reference to a number of other books which contain the detailed development of the ideas. There then follows a chapter on elementary matrix algebra which stops short of the diagonalization of matrices; just the material necessary for a proper understanding of the use of F and G matrices which are considered in the next chapter. This may be useful to experienced users but is likely to be confusing to students. Then follows a number of such short chapters that one wonders whether this is a translation of the original book or a precis of it. Without seeing the original German edition it is not possible to decide this. There are a number of places where one line has been partially printed over another but this may just be the copy which I have.

Part V continues with a discussion of the vibrational spectroscopy of solids and again results are stated without derivation or reference.

Parts of this book may be a useful aide-memoire to experienced practitioners but students new to the field will not be helped to any great extent. I suspect that the price of the book will deter even those who would be able to follow it easily.

The Kirk–Othmer Encyclopedia of Chemical Technology: Volume 5, Fourth Edition. Carbon and Graphite Fibers to Chlorocarbons and Chlorohydrocarbons-C_1. J. I. KROSCHWITZ and M. HOWE-GRANT (editors), Wiley–Interscience, Chichester, 1992. Pages: xxviii + 1072. £150.00. ISBN 0-471-52673-8 (v. 5).

Volumes in the new edition of this encyclopedia now extend, alphabetically, to the topic of chlorocarbons and chlorohydrocarbons. An excellent softback index covering the first four volumes is also included with volume five.

Almost 70 authors have contributed to this volume which is divided into 31 topics. The main areas covered are: ceramics (129 pages), cardiovascular agents (95 pages), cellulose—esters and ethers (88 pages), chlorine oxygen acids and salts (86 pages), catalysts (79 pages) and catalysis (64 pages), and carboxylic acids (61 pages). The final topic—chlorocarbons and chlorohydrocarbons—is also extensive and continues into volume six of the encyclopedia.

Topics covered in less detail include carbon dioxide, carbon monoxide, castor oil, cement and chemicals from brine. The elements surveyed in this volume are cerium and cesium. Other topics which I found to be of particular interest—from an intellectual as well as professional viewpoint—include carbonated beverages, chelating agents, chemicals in war, chemometrics and chemurgy. I would liked to have seen a little more on chemometrics but the extent to which a reader thinks a topic should be covered is related to personal interest as well as to the overall importance of the topic.

As usual, extensive bibliographies (including books, journals and patents) are included after each topic and the presentation is of a high standard. Highly recommended reading and a worthy purchase for all science libraries.

Soil Analysis—Modern Instrumental Techniques: Second Edition. K. A. Smith, Dekker, New York, 1991. Pages viii + 659. $150.00 (US and Canada), $180.00 (elsewhere). ISBN 0-8247-8355-7.

The second edition of Keith Smith's *Soil Analysis—Modern Instrumental Techniques* is a timely and very welcome addition to the literature of environmental, and especially soil, analysis. The new edition is substantially enlarged to reflect developments over the seven years since the first edition was published, and now, very appropriately, includes chapters on ion chromatography, ICP atomic emission spectrometry, and NMR spectrometry for functional group analysis. As in the first edition, the authors selected for each topic write from the viewpoint of extensive first hand experience, which contributes both to the reliability of the information and to the book's success in achieving its goals, namely to bridge the gap between excessively detailed monographs on individual techniques and the occasional superficiality of all-embracing general analytical texts. For those not familiar with the earlier addition, other topics covered include: atomic absorption and flame emission spectrometry, ion-selective electrodes, automated colorimetric analysis, automated C, N and S determination, nuclear and radiochemical methods, XRF, INAA, isotope ratio measurements for C, N and O, soil atmosphere analysis and pesticide analysis. The quality and style of presentation is commendably uniform and high for such a multi-author text, and the original literature is thoroughly referenced. The book will not date rapidly, and will remain an asset to researchers and higher education teachers in soil science, environmental science and analytical chemistry for years to come.

Macmillan's Chemical and Physical Data: A. M. James and M. P. Lord, Macmillan, London, 1992. Pages xxv + 565. £35.00. ISBN 0-333-51167-0.

Though we live in an age of information technology it can still be a painful and time-consuming experience to track down a particular fact, especially so if it relates to an unfamiliar field. This book attempts to address such problems by assembling a mass of diverse information—the density of the planet Mars, the melting point of calcium iodide, the half-life of ^{126}Sn, the volume of the Royal Opera House—but is yet sufficiently compact to drop into a briefcase. It ranges over many fields: properties of molecules, electrochemistry, kinetics, health and safety, optics, acoustics, astronomy and geophysics. About two thirds of the compilation is devoted to three topics: atomic and nuclear physics (102 pages), physical properties of compounds (146 pages) and thermodynamic properties of compounds (56 pages). The compilers have assumed that readers are familiar with underlying theory or have access to appropriate textbooks. Most of the tables indicate the sources from which they have been compiled and some give references to more specialist texts.

As a structural chemist I was disappointed in the fairly brief section on molecular structure. The existence of comprehensive structural databases is not mentioned and bond length compilations seem to be mainly based on Special Publication No. 18 of the Chemical Society (1965) rather than on recent average values from the Cambridge Structural Database (*J.C.S. Perkin II*, 1987, S1; *J.C.S. Dalton*, 1989, S1) which allow distances in most organic compounds to be estimated with fair reliability. Page 53 gives the benzene C–C distance as 139.5 pm whereas two pages later it has lengthened to 142.10 pm.

Nevertheless I consider that this is a helpful addition to the bookshelf of a working scientist. Coverage is wider and generally more authoritative than many of the paperback data books available. And, though the book is not as comprehensive as the Chemical Rubber Company Handbook, neither is it as bulky or expensive.

UltraFit—version 2.1: non-linear curve-fitter for the Apple Macintosh. Biosoft, Cambridge, U.K., £149.00, US $ 299.00.

UltraFit is a non-linear curve-fitter for the Apple Macintosh family of computers. Two versions of the program are supplied and this ensures that the program can be used on the whole Macintosh range provided that at least 1MB of RAM is present. The program also supports a maths' coprocessor, it is claimed to be fully compatible with systems 6 and 7 and this does indeed appear to be the case. The manual is clearly written in a style that most Macintosh users will instantly recognize. Although, on opening the manual it is surprising not to find an introductory chapter describing the installation of the program. However, this omission will inconvenience only the most inexperienced of Macintosh users. Chapter 1 of the manual guides the user through a series of tutorials which cover the main features of UltraFit. These include data entry, creating new graphs, adding plots to graphs, fitting curves to data and customizing plots. The following chapters provide detailed accounts of each feature illustrated in the tutorials. Chapter 2 introduces worksheets which allow for the entry and manipulation of data. The program allows data entry directly from the keyboard or to be imported from other

The program also supports a maths' coprocessor, it is claimed to be fully compatible with systems 6 and 7 and this does indeed appear to be the case. The manual is clearly written in a style that most Macintosh users will instantly recognize. Although, on opening the manual it is surprising not to find an introductory chapter describing the installation of the program. However, this omission will inconvenience only the most inexperienced of Macintosh users. Chapter 1 of the manual guides the user through a series of tutorials which cover the main features of UltraFit. These include data entry, creating new graphs, adding plots to graphs, fitting curves to data and customizing plots. The following chapters provide detailed accounts of each feature illustrated in the tutorials. Chapter 2 introduces worksheets which allow for the entry and manipulation of data. The program allows data entry directly from the keyboard or to be imported from other

programs. The data may be manipulated either by using a range of predefined transformations, for example, simple arithmetic functions, conversion to reciprocals or logs, or by using user-defined transformations. Chapter 3 describes the use of graphics in UltraFit. Graphic objects are created and edited using tools from a toolbox which includes a drawing line and ellipse, and a text editor. These tools and their use will be very familiar to all Macintosh users. The creation of graphs is somewhat different to the method used by the majority of plotting programs in that a blank graph is created using the graphing tool and then the data are plotted onto the graph. These data may be in the form of a worksheet or alternatively, UltraFit can use an equation to create a line. This equation may either be one of the 26 predefined equations supplied with the package or be user-defined. Graphs are plotted and manipulated in a very straightforward manner and the user quickly adapts to the program. The formats of the axes are user-defined and the control over the appearance of the plot is far greater than that normally found in similarly priced plotting packages. Graphs can be further customized using the toolbox. Chapter 4 introduces the use of equation documents in just two sides but this is then expanded in Chapter 5 which provides a nice account of the language used to enter equations. However, the strength of UltraFit rests largely with its ability to fit experimental data and this is described in the final chapter of the manual. An equation is chosen or is user-defined to fit the experimental data. Before the data are fitted one of four different weighting methods is used. The default is the simple method in which all residuals, *i.e.*, the difference between the fitted value and observed value, are weighted equally. The other three methods are: the statistical method which is suitable for handling data such as radioactivity counts, the proportional method for use if each point has the same proportional error and the explicit method. A further type of weighting, robust weighting, is also available and this allows for the suppression of data points that contain errors which deviate significantly from the overall error distribution. The residuals or weighted residuals can be added to a worksheet. The output from the fitting process is recorded in a log book and this contains such information as the type of weighting used, estimates of variable parameters and the goodness-of-fit index. UltraFit offers a choice of two fitting algorithms, the Marquardt or the Deming algorithm and there is a very brief description of these given as an Appendix. The manual also has Appendices describing fitting statistics, a particularly useful section on common errors and a list of the predefined equations. The program appears to be robust and the manual is well written. In addition, considering its functionality, the package is priced very reasonably. In consequence, UltraFit can be strongly recommended not only as a general plotting package but in particular, for the fitting of experimental data.

FOREWORD

While scientific and technological development in Spain rose dramatically in the past decade, Spanish analytical chemistry grew well above average in qualitative and quantitative terms, so much so that it makes an atypical scientometric model. This has been acknowledged by the analytical community worldwide but not so by domestic professionals, some of whom have been compelled to share or even yield ground to others as a result. Thus, we decided to accept the assignment of compiling a special issue for *Talanta* devoted to Spain as it not only reflected the interest in the late growth of Spanish analytical chemistry, but also might help in placing this discipline in its rightful place within the Spanish scientific and technological system. The 25 groups invited in mutual agreement with the journal editor gave a warm welcome to the proposal and contributed 25 papers of a high quality on a variety of topics which are a good reflection of Spanish analytical chemistry in the 1990s.

Two recently published complementary papers on analytical chemistry in Spain[1,2] showed the dramatic increase in the proportion of Spanish papers published in international analytical journals and their increasingly higher quality—particularly in the late 1980s—as well as a change from essentially inorganic analyses to a variety of other analyses in better accordance with worldwide practice in this respect.

Spanish contributions to *Talanta* have evolved very similarly to Spanish analytical chemistry in general (see Fig. 1). The earliest Spanish paper ever appearing in *Talanta* was contributed by Professor Lucena, of the University of Salamanca,[3] in the first year *Talanta* was released (1958). Up until 1979, Spanish papers never exceeded 2% of all contributions. However, in the 1980s, Spanish contributions grew in an almost exponential fashion though they had levelled off by the end of the decade. It is interesting to note the unusually high proportion of Spanish papers published in *Talanta* in 1986 (*ca.* 18%), which can probably be ascribed to the extra pressure placed on Spanish university researchers, who were compelled to pass some tests where their research curriculum was decisive. This was also the case with other scientific–technical disciplines. Spanish analytical chemists have contributed an average 4.4% of all papers published in the 35 years of *Talanta*; however, Spanish contributions between 1983 and 1992 accounted for more than twice that percentage, *ca.* 11.5%. This is quite a remarkable figure taking into account that *Talanta* publishes papers from a large number of countries. Hence it was logical to devote a special issue to this country, in the wake of those previously published in the U.S.A. and the former Soviet Union.

Finally, we wish to thank Professors Winefordner and Hansen for their initiative and the assignment they gave us in the course of Pitcon '92, held in Atlanta in February 1992. On accepting the assignment, we could hardly envisage such a warm welcome by Spanish analytical chemists, who have contributed their best. All of them deserve our earnest acknowledgement. We should also like to thank the 50 referees who acted as reviewers for their constructive criticisms. We believe our endeavour as guest editors was worth the while and hope this feeling will be shared by the readers of this special issue.

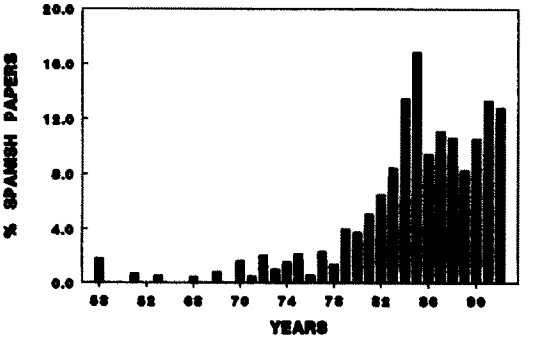

Fig. 1. Relative contribution of Spanish analytical chemists to *Talanta* (from the Teledocumentation Service, University of Extremadura, Spain).

CRYSTALLIZATION OF ORGANIC CRYSTALS WITH "TAILOR-MADE" INHIBITORS. DETERMINATION OF *L*-LYSINE USING *L*-GLUTAMIC ACID AS SUBSTRATE

F. GRASES and C. GENESTAR

Department of Chemistry, University of Balearic Islands, 07071 Palma de Mallorca, Spain

Summary—A very simple turbidimetric procedure is used for determination of *L*-lysine, based on its inhibitory action on the crystallization of *L*-glutamic acid. The obtention of supersaturated solutions of *L*-glutamic acid was accomplished by means of the change in the solvent composition. Thus, the addition of ethanol to stable aqueous solutions of this amino acid allows the obtainment of unstable supersaturated solutions. The method suffers from very few interferences and permits the development of an analytical procedure to determine *L*-lysine in the presence of *D*-lysine. The method was also applied to the determination of *L*-lysine in pharmaceutical products.

The analytical determination of chiral molecules has aroused notable interest due to their different behaviour, thus the biological activity of a chiral molecule can be different between the two configurations, *i.e.*, the efficacy of some therapeutic drugs or pesticides is a function of definite configurations of chiral structures, *etc.* The analytical resolution of racemic mixtures is nevertheless very difficult due to the practically identical chemical behaviour of the chiral substances. This usually implies the use of complex chromatographic procedures.[1]

The most common methods for determination of *L*-lysine implies enzymatic procedures.[2,3] Other general methods include the use of high performance liquid chromatography.[4–6]

We report a very simple procedure for *L*-lysine determination based on the interaction between a crystallizing substrate and a stereospecific "tailor-made" growth inhibitor. This permits the development of a specific analytical procedure to determine *L*-lysine in the presence of *D*-lysine. The application of crystallization inhibitory processes in analytical chemistry has been discussed previously.[7]

EXPERIMENTAL

Reagents and apparatus

L-glutamic acid and *L*-lysine, as all reagents used, were purchased from Sigma. The solvents (ethanol, methanol and acetone) were supplied by Merck. Solutions of *L*-lysine ($4.38 \times 10^{-3}M$) and glutamic acid ($5.85 \times 10^{-2}M$) were prepared in doubly distilled, deionized water and filtered through a disposable 0.45-μm filter membrane. These solutions were stable for a week.

Turbidimetric measurements were taken by means of a single-beam spectrophotometer (Bausch and Lomb Spectronic-21) at 550 nm. The usual cell compartment was replaced by a spiral copper tube surrounding a cylindric glass vial of 2.3 cm in diameter and 22 ml in volume. The suspension (solution) contained in the glass vial was stirred by a magnetic bar and a rotatory external magnetic field, placed under the photometer. The transmittance was continuously measured by a pen recorder.

A Hitachi S-530 scanning electron microscope was used to obtain the scanning electron micrographs.

Procedure

To a glass vial placed in the photometer containing 13.5 ml of ethanol (84.4%) were added the necessary volume of *L*-lysine solution to give a final concentration of 2.5–25 μg/ml (the pH of this sample solution was 4.5), water to achieve a final volume of 16 ml and 2 ml of $5.85 \times 10^{-2}M$ *L*-glutamic acid, while stirring. All solutions were filtered through a disposable 0.45-μm filter membrane before use. After addition of *L*-glutamic acid, the transmittance–time curves were recorded at a wavelength of 550 nm. From the resulting curve, the time elapsed before precipitation was detected (see

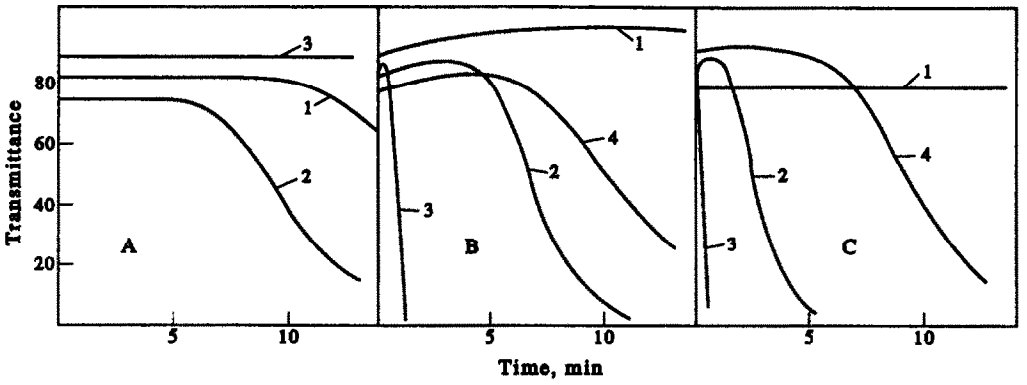

Fig. 1. Influence of the solvent on the crystallization of *L*-glutamic acid, in the absence and presence of *L*-lysine. [*L*-glutamic acid] = $7.31 \times 10^{-3}M$, temperature 26°. A (1) 84.4% of methanol, (2) 87.5% of methanol, (3) 84.4% of methanol and [*L*-lysine] = 10 μg/ml; B (1) 62.5% of ethanol, (2) 81.2% of ethanol, (3) 87.5% of ethanol, (4) 81.2% of ethanol and [*L*-lysine] = 10 μg/ml; C (1) 50% of acetone, (2) 75% of acetone, (3) 84.3% of acetone, (4) 75% of acetone and [*L*-lysine] = 10 μg/ml.

Fig. 4) and was used to prepare the calibration graph (Fig. 5). The duration of each measurement was *ca.* 10 min. The system was kept at constant temperature by circulating water at $26 \pm 0.2°$.

RESULTS AND DISCUSSION

Many crystal properties such as shape, size, stabilization of one or another polymorph, *etc.*, depend on the interactions between crystals and the environment in which the crystal grows. This influence can be non-specific, such as in solvent polarity or solubility effects, or highly specific as in the stereochemical correlation between growing crystals and crystal growth inhibitors as the "tailor-made" additives.[8,9] These substances are organic molecules whose chemical structure is only slightly modified with respect to the bulk component of the molecular crystal. As a consequence, this molecule can selectively absorb on to specific crystal surfaces and this causes dramatic changes in the growth rates. In the present study the effects of *L*-lysine as "tailor-made" inhibitor in the crystallization of *L*-glutamic acid has been studied with analytical purposes. The obtention of supersaturated solutions of *L*-glutamic acid was accomplished by means of the change in the solvent composition. Thus, the addition of an organic solvent to stable aqueous solutions of this aminoacid, allows us to obtain unstable supersaturated solutions. The results of several experiments using methanol, ethanol and acetone as organic solvents, in the presence and absence of *L*-lysine are shown in Fig. 1. The experiments were followed by turbidimetry. When the experiments were finished, a sample of the suspension was taken and examined by SEM. Optimum results are considered those

that correspond to maximum reproducibility and sensitivity and this coincided with the experiments performed with ethanol. Consequently this solvent was selected in further experiments. Analogous criteria was used to select the optimum ethanol and *L*-glutamic acid concentrations. The results obtained appear in Fig. 2. Optimum results were obtained with 84.4% ethanol and in the presence of $7.31 \times 10^{-3}M$ *L*-glutamic acid. Such conditions were chosen to prepare the calibration graph. As can be seen in Fig. 3, when applying the above conditions, a clear inhibition of the hexagonal *L*-glutamic acid crystals formation was observed.

Characteristics of the analytical methods

The transmittance–time curves (Fig. 4) recorded in the presence of different amounts of *L*-lysine under selected conditions were used in order to obtain the calibration graph. The time necessary to initiate the crystallization, the induction period and the relation between the time required to initiate the crystallization in the presence and absence of *L*-lysine were the methods applied. A linear calibration graph was

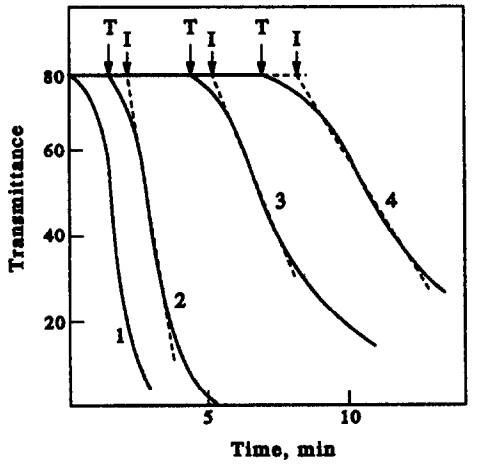

Fig. 4. *L*-glutamic acid crystallization runs in the absence and presence of *L*-lysine. [*L*-glutamic acid] = $7.3 \times 10^{-3}M$, 84.4% of ethanol, temperature 26°. (1) Without *L*-lysine, (2) [*L*-lysine] = 5 μg/ml, (3) [*L*-lysine] = 15 μg/ml, (4) [*L*-lysine] = 25 μg/ml.

obtained between 2.5 and 25 μg/ml in all methods applied. The calibration graphs obtained in the proposed methods by least-squares treatments are described by

$$T = 0.3942 + 0.2496[L] \quad (r = 0.997;\ n = 5)$$

$$I = 0.7410 + 0.2989[L] \quad (r = 0.991;\ n = 5)$$

$$R = 0.4126 + 0.5203[L] \quad (r = 0.996;\ n = 5)$$

where T is the time necessary to initiate the crystallization (time necessary for transmittance starts decreasing, Fig. 4), I the induction period (Fig. 4), R the relation between the time necessary to initiate the crystallization in presence and absence of analite, L the *L*-lysine concentration and r the correlation coefficient.

The three proposed methods exhibited good analytical characteristics, but due to their simplicity, the time necessary to initiate the crystallization was chosen for further experiments.

Reproducibility was measured on 11 replicates of *L*-lysine at 10 μg/ml (RSD = 3.15%) and on 11 replicates of a reference sample (without *L*-lysine) (RSD = 4.17%). These results were obtained when the time necessary to initiate the crystallization was applied to prepare the calibration graph.

Interferences

To evaluate the selectivity of the proposed method, the effect of other aminoacids on the crystallization of *L*-glutamic acid was studied. The aminoacids selected were those currently included in formulations together with *L*-lysine. Various volumes of stock solutions of

the different potential interferences were added to *L*-glutamic acid in order to know the tolerance levels. The results summarized in Table 1 show that only the assayed diaminocarboxylic acids such as *L*-lysine (*L*-histidine and *L*-ornithine) caused some disturbance. It is interesting to point out that the presence of *D*-lysine causes no important interference on the crystallization of *L*-glutamic acid. Scanning electron micrographs show no difference between samples obtained in presence of *D*-lysine and samples of the crystallization of *L*-glutamic acid, without additives, at the same percentage of ethanol.

Application

The resolution of racemic mixtures is an important and very difficult analytical problem. Due to the slight effects that the presence of *D*-lysine caused on the crystallization of *L*-glutamic acid, as it was commented above, the proposed method was applied to the determination of *L*-lysine in the presence of *D*-lysine in synthetic samples (Table 2).

To test the applicability of the proposed method, this was applied to the determination of *L*-lysine in pharmaceutical products. *L*-lysine constitutes a common constituent in pharmaceutical products to promote the muscular and osseous growth. The determination of *L*-lysine in one of these pharmaceutical products (sample No. 1, Table 3) was carried out without any previous treatment of the sample (except appropriate dilution).

On the other hand, *L*-lysine is one of those labelled essential amino acids and for this reason is included in pharmaceutical preparations of dietetic supplements. The proposed method allows the determination of *L*-lysine in the presence of other aminoacids (*L*-leucine, *L*-phenylalanine, *L*-threonine, *etc.*) without previous separation. The results obtained are shown in Table 3 (sample No. 2).

As can be seen, the results for *L*-lysine analysis in samples of pharmaceutical products using the proposed method are in good agreement with the certified values. The proposed procedure cannot be applied to the determination of *L*-lysine in pharmaceutical products that also contain quantities of *L*-histidine and/or *L*-ornithine similar to the former, due to their important inhibitory effects on the crystallization of *L*-glutamic acid.

DETERMINATION OF THE OXIDATIVE STABILITY OF OLIVE OIL BY USE OF A ROBOTIC STATION

JOSÉ A. GARCÍA MESA, M. D. LUQUE DE CASTRO and MIGUEL VALCÁRCEL
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

Summary—A gravimetric method for the determination of the oxidative stability of olive oil based on the use of a robotic station for the monitoring of the oxygen absorbed by a sample subjected to heating under controlled working conditions is proposed. The method was developed in order to relieve the typically heavy work load of olive oil laboratories in winter. The results obtained were consistent with those provided by a well-established method (Rancimat), which the proposed method clearly surpasses in sample throughput (6 samples/batch *vs* 150 samples/batch).

The number of samples to be analysed by some laboratories varies enormously from season to season, particularly for agricultural products and their derivatives. The seasonal factor compels laboratories to deal with large numbers of sample during the harvest period and remain virtually inactive the rest of the year. Laboratory automation has solved this problem in some cases[1] by means of analysers with high sample throughputs; however, the scarce flexibility of this type of instrument poses an additional shortcoming: such powerful, expensive tools must be kept inactive for rather long periods (8–10 months/year).

The potential final solution to this problem may lie in accomplishing flexible automation in order to meet the great demand for analyses of the harvest period and provide for other tasks during the rest of the year, thus maximizing the profitability of the initial costly investment. Such is the case with the use of robots.[2]

Olive oil industry laboratories are ideal targets for the proposed solution. The aim of this work was to show how robots can solve such problems; in particular the determination of the oxidative stability of oils. Resistance to oxidation is a measure of oil quality and dictates storage and usage stability. Such stability, the interval until the oil becomes rancid, depends both on intrinsic features (*viz*, type of olive in olive oils, and fatty acid and natural antioxidant—tocopherols and polyphenols—contents) and on environmental conditions (temperature, light, air exposure, type and material of the container, metal trace content, *etc.*).

Oil rancidity is assessed either by sensory or by laboratory procedures.[3,4] Because olive oils are stable for a few months under their usual storage conditions, oxidation is accelerated in laboratory tests by increasing the temperature and, occasionally, also by increasing exposure to oxygen. This "forced" side of the study conditions may distort the results compared with real conditions; notwithstanding this shortcoming, the long experience in accelerated stability assays has fostered usage of this type of analysis.

In previous work[5] the deficiencies of the methods used so far for studying the stability to oxidation of virgin olive oils were discussed and an alternative method based on the gravimetric monitoring of the oxygen absorbed by a sample subjected to heating under controlled working conditions was developed. This method features a much higher sample throughput than its earlier counterparts. The manual determination as performed by using this method is rather tedious because the experimental procedure involves an endless series of weighings which are prone to personal errors. This makes the method a good candidate for implementation by a robotic station.

EXPERIMENTAL

Instrument and apparatus

Analyses were performed by a Zymark Co. robotic station consisting of the following elements (Fig. 1). A Zymate II plus robot, a System V controller, a Printer, a Power, an

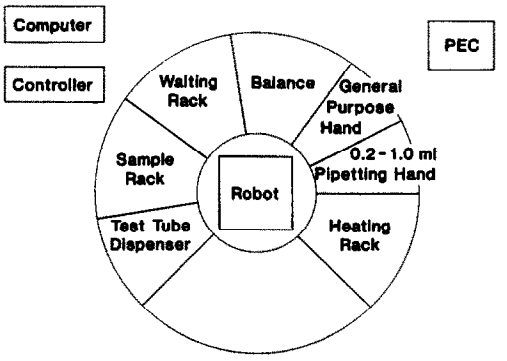

Fig. 1. Bench layout of the robotic station for the determination of oxidative stability of olive oil.

Event controller, a General purpose hand (with a disposable pipet tip rack), a 0.2–1.0 ml Syringe hand, a test-tube dispenser and racks for 16 × 100 mm tubes. A Mettler AE 200 balance, a Plactronic (P-Selecta) heating-plate and a Netset AT PC compatible computer were used. A lab-built aluminium bore heating block was also employed.

Gravimetric determination of the oxidative stability of olive oil

After the operator enters the number and identification of samples, the robot performs the following operations: weighing test-tubes equal to the number of samples to be processed, which are placed in the waiting rack; weighing 1 g of sample in its test-tube; transferring each sample to the heating rack; heating at 98° for 5 hr; transferral of all the samples to the waiting rack; pause for cooling (20 min); weighing the samples and final transferral to the waiting rack, the weights being stored in a disk in the controller device for subsequent treatment. The cycle is repeated as many times as required depending on the stability of the sample concerned, until the weight gain of all the samples has reached 9 mg (Fig. 2).

RESULTS AND DISCUSSION

Optimization of variables

On the basis of preliminary results, the manual method was adapted for implementation of the robotic station by establishing the most suitable conditions for the assay (a fast oxidation kinetics no detracting from the discriminating power of the method; minimal space occupancy per sample in order to maximize throughput; robot-friendliness; and results consistent with those provided by other methods. These requisites were met as follows:

(a) Working temperature. The temperature selected for sample heating was 98° in order to operate under thermal conditions similar to those of well-established methods since temperature was a key to the process rate.[5]

(b) Compatibility between the robot, heating system and productivity. A heating-plate was used to heat samples since ovens are not robot-friendly. The heating-plate provided uneven heating of the different samples (especially when small vessels were used), possibly because of the non-flat bottom of the containers. This shortcoming was circumvented by constructing a bore aluminium block that was used to hold the vessels (test-tubes), thus facilitating the robot operation. The block was placed on the heating-plate. Its dimensions and the position of the holes were adjusted to those of the rack from Zymark so as to take advantage of PyTechnology. A fairly small amount of sample was used to avoid filling the test tube (16 mm diameter) with sample to an excessive height which would delay the oxidation process through hindered access of oxygen to the sample. On the other hand, handling very small amounts of sample would give rise to small changes in

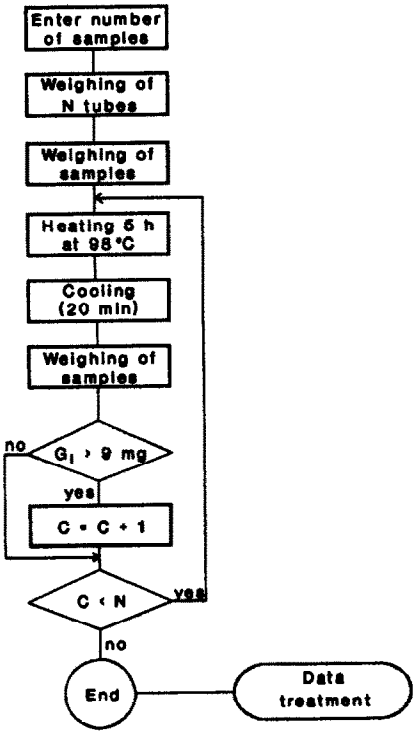

Fig. 2. Flow chart of the method.

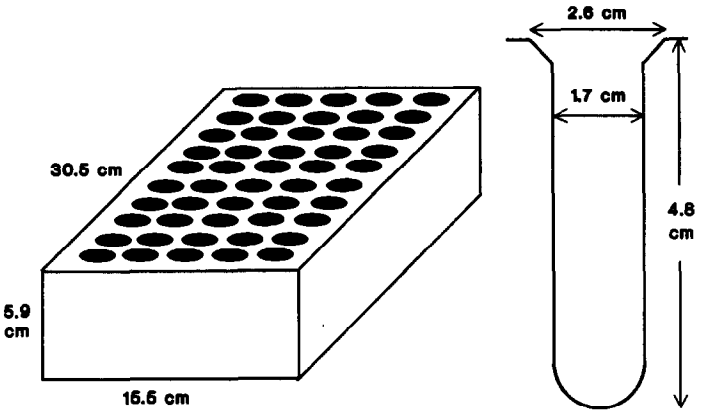

Fig. 3. Scheme of the heating block.

the weight to be monitored, which in turn would result in increased relative weighing errors. A 1-g sample was selected as it provided acceptable performance of the proposed method (see below) with less sample than other methods (2–3 g for Rancimat[6] and 10 g for AOM[7]) and a maximum sample thickness of 9 mm in the test-tube. This amount of sample is critical, as has been demonstrated[5] in order to achieve comparable results between laboratories.

(c) Cautions and peculiarities of the system. Special caution was exercised to avoid errors in the method arising from several potential sources, namely light, dust, electrostatic charges and delivery system.

(1) The heating block was protected by an opaque cover which did not hinder motion of the robot arm, but prevented light from directly impinging on the sample (which accelerated the oxidation process) and dust to settle (which would affect weighings). The use of a heating-plate instead of an oven had other additional advantages related to the robot safety: thus, the robot hand was not exposed to the typically high temperatures of ovens (*ca.* 100°) and the fingers were kept from contact with very hot vessels as the upper part of the test-tube was at a considerably lower temperature than the heated zone.

(2) Figure 4 shows how the test-tube underwent a weight loss between successive weighings under no heating. This arose from friction with the plastic material which caused electrostatic charges to build up; such charges could not be eliminated as all materials in contact with the test-tube (robot fingers included) were of insulator materials. This shortcoming, which has probably so far been overlooked in robotic methodologies was satisfactorily solved by having a small aluminium sheet establish electrical contact between the inside of the balance tube holder and the balance pant and drive the accumulated electrical charge to earth.

(3) Sample dispensing was different from that of PyTechnology owing to the high viscosity of oil. Zymate robots usually dispense liquids through a pipeting hand by twisting the wrist and leaning the pipette tip on the inner wall of the vessel. In this way, the liquid trickles down the tube wall, thus ensuring maximum accuracy. With oil samples and taking into account the subsequent heating steps, this dispensing procedure was inappropriate as the oil drops which remained randomly in the inner wall of the tube offered a large oxidation surface compared with the whole sample, so they were a source of high

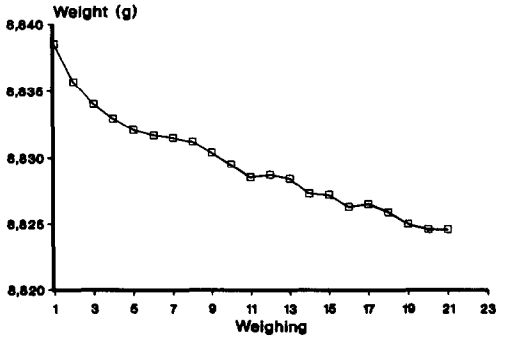

Fig. 4. Weight loss of a test-tube between successive weighings under no heating conditions.

irreproducibility. For this reason, the computer software was modified and the oil sample was dropped directly to the bottom of the test-tube without twisting the wrist of the robot at a small rate in order to avoid drops splashing on to the tube-walls.

(d) Temporal variables. The optimal heating, cooling and weighing times were also established. Inasmuch as the method is based on discrete exposure to the oxidation-promoting factor (a high temperature), each step must be precisely timed for every sample and any differences in this respect arising from the position of the tube in the batch be avoided as far as possible.

(1) Figure 5 shows the cooling weight change curves for a test-tube containing 1 g of oil after the heating block was removed. Although complete cooling required *ca.* 25 min, the weight remained stable after 15 min. However, a cooling time of 20 min was selected in order to increase the confidence level of the weighings.

(2) The heating time was chosen as a compromise since short heating times and high weighing frequency resulted in near-continuous monitoring of the oxidation curves, but detracted from evenness of the heating process and slowed down analyses as the heating time relative to the total analysis time was shorter. In addition, small weigh changes were more markedly affected by weighing errors. Figure 6 shows the real working times of the system for the analysis of a 100-sample batch heated for different times. It follows from the figure that too short heating times are inadvisable. On the other hand, too long heating times would provide insufficient

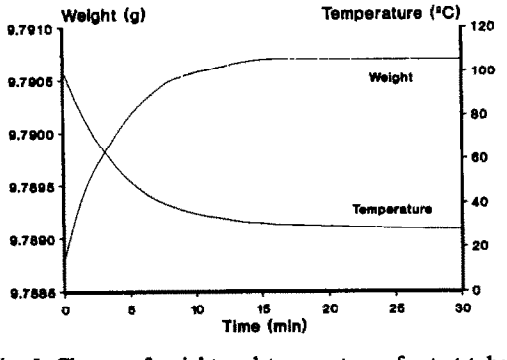

Fig. 5. Change of weight and temperature of a test-tube.

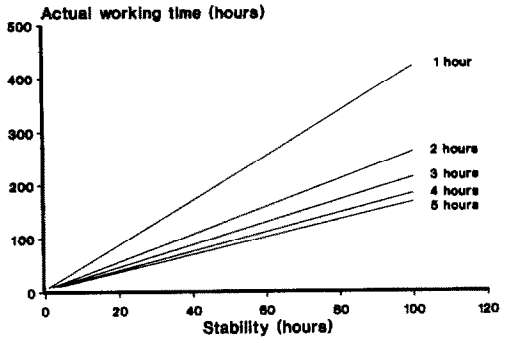

Fig. 6. Actual working time of the robot for analysis of 100 samples/batch by using different heating times.

information about the process, and hence give rise to errors, especially for unstable samples. A heating time of 5 hr was finally selected.

(3) The influence of the heating time on the overall kinetics was also investigated by heating a sample for different times (2.5, 5 and 10 hr). No differences between the oxidation curves were observed.

Processing of the chemical information

The results obtained by the robotic station were delivered as kinetic curves showing the weight changes with time. This information can be processed in different ways depending on how the time required for oil to become rancid is defined.

Some possible ways of defining the stability of oil are described in Fig. 7.

(1) The induction period (I), defined as the intercept of the tangent to the curve in the quasi linear portion of maximum slope (see Fig. 7).

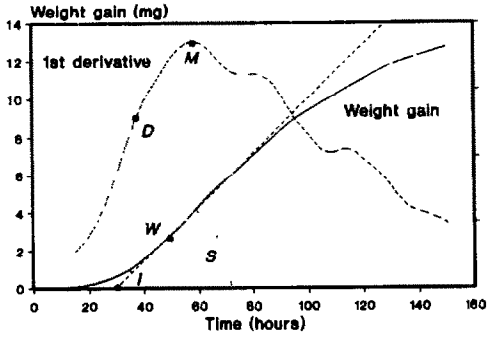

Fig. 7. Different ways of processing the experimental curves. *I*, induction; *W*, gain of a present weight; *S*, slope of the rising portion of the curve; *M*, and *D*, maximum and preset value, respectively, of the first derivative of the experimental curve.

(2) The slope of the above quasi linear portion of the curve (S).
(3) The time elapsed until the weight of the sample reaches a preset value (W).
(4) The time elapsed until the slope reaches a preset value (D) or the maximum value (M).

The use of one or another definition provides different results. Thus, one can: a) use one (or several) definitions to obtain characteristic results, or, b) use that (or those) definitions which provide results consistent with those obtained by other common methods (Rancimat and AOM). Since the final aim of this work was to solve the problems of the manual method (*viz* a low sample-throughput), option b) was the clear choice.

Among the above four definitions of stability, the fourth is the least precise as minimal changes in the kinetic curve give rise to great changes in its slope. In addition, there is no interval of maximum slope in many cases, but a plateau with a linear weight change. This definition was thus avoided.

Twenty virgin olive oil samples whose stability (between 25 and 170 hr) had been previously calculated by the Rancimat method were used for comparing with the proposal method. Only the heating time was considered here for greater consistency with the results provided by the Rancimat method.

The different correlations obtained between the selected parameter in the proposed method and the Rancimat stability are listed in Table 1. There was excellent correlation between the induction period of the robotic method and the Rancimat stability (also based on the induction period). The calculated correlation coefficient (0.9957) was similar to that obtained by Gutiérrez *et al.*[8] (0.9962) for comparison of Rancimat and AOM methods. Using other parameters resulted in lower correlations.

Table 1. Correlation between the Rancimat stability and several parameters of the curves of the robotic method†

y	x	a	b	r

W_{10}	"	6.276	0.129	0.9733

*W_i: Elapsed time for a gain of i mg.
†General equation: $y = a + bx$. For more details, see text.

It is worth noting that the data from two samples in the batch (those corresponding to 148 and 179 hr of Rancimat stability) were discarded as the results provided by the robotic method were inconsistent with the rest and lower than those provided by the Rancimat method. This discrepancy could have arisen from the Rancimat method giving rise to changes in the concentration of the solution in the conductivity cell due to water evaporation in the long heating period required with very stable oils,[7] and therefore, there is uncertainty in the validity of these results. The robotic method does not have this drawback; this makes the proposed method especially suitable for olive oil, whose longer stability is well-known.

A BASIC program for data treatment was written in the dedicated PC. After all the samples have been oxidized, this program read the weights stored in the controller disk and calculated the induction period of every sample.

Features of the method

The reproducibility of the proposed method, calculated as the relative standard deviation of the results for 11 samples of the same oil, was evaluated with two samples of low (12 hr) and high stability (100 hr). The RSDs obtained were 8.7 and 2.6%, respectively. These results show that the precision of the proposed method is not good for unstable oils (less than 15–20 hours), which is not usual in virgin olive oil.

The throughput of the proposed method as implemented in the design station is 50 samples/batch. However, the throughput can be increased to 150 samples/batch by taking advantage of the free space around the robot arm, where other racks can be placed. This requires only minimal changes in the computer program, but always using Zymark's PyTechnology.

Comparison of the results

Table 2 shows the induction periods obtained by analysing the same batch of 20 samples of virgin olive oil by using both the Rancimat and the robotic method. There is a clear difference between the Rancimat stabilities for samples of 148 and 170 hr, which can be explained for the reasons cited above.

CONCLUSIONS

A robotic station was designed for the determination of the oxidative stability of virgin olive oil by using a fully automated method based on monitoring the weight changes of heated samples.

The different analysis steps are described in detail in order to facilitate implementation of the proposed method at other laboratories.

The main advantages of the proposed method compared to its well-established counterparts are full automation of the process and a much higher sample throughput (150 samples/batch), which amply offsets the higher initial cost of the equipment required.

MULTIDATA TREATMENT APPLIED TO THE SIMULTANEOUS RESOLUTION OF CATECHOL–RESORCINOL MIXTURES BY KINETIC ENZYMATIC PROCESSES

E. GÓMEZ, A. CLADERA, J. M. ESTELA and V. CERDA*
Departament de Química, Universitat de les Illes Balears, 07071 Palma de Mallorca, Spain

Summary—This paper reports a multicomponent least-squares regression method based on the use of multiple standards for the simultaneous resolution of substrates involved in kinetic enzymatic processes. The proposed method was applied to the determination of catechol–resorcinol mixtures by oxidation with hydrogen peroxide in the presence of the enzyme peroxidase (EC 1.11.1.7) in a stopped-flow reversed flow injection system. The mathematical algorithm used is superior to other alternatives as it is not affected by side reactions between the oxidation products. The proposed method allows the simultaneous resolution of 50–150μM catechol and 30–180μM resorcinol over the wavelength range 340–500 nm. The concentration ranges can be modified by varying the injected amount of enzyme. The mathematical treatment is applied to the spectra of several standards and those of the samples, which are recorded 6 sec after the flow is stopped. This redounds to a high sampling frequency (up to 60/hr).

Multicomponent analysis methods have aroused increasing interest in the last few years on account of their ability to simultaneously resolve systems of two or more components by use of a variety of analytical techniques. However, because of the large number of data involved in the process, extensive development was only possible lately thanks to the advent of powerful computers in terms of processing capacity and data storage. Thus, a number of mathematical procedures including linear regression,[1] partial least-squares,[2] iterative methods[3] and factor analysis[4] currently allow mixtures to be resolved in very short times.

Multicomponent methods usually rely on the use of multichannel detectors to obtain a data set that is processed mathematically in order to determine the individual contribution of each analyte in a mixture. They simplify the analytical procedures required to a great extent as they allow several analytes to be determined without a previous separation step. UV–visible spectrophotometry has so far been the most frequently used technique in connection with multicomponent analysis.[5] The most commonly used kinetic enzymatic procedures use this technique and the initial slope or fixed time kinetic method, which have so far been applied to the determination of a wide variety of substances including metal ions and organic and biological substrates. As a rule, these determinations are highly selective thanks to the peculiar properties of the enzymes used. Alternative mathematical models such as the Kalman filter have been used in recent years to determine the rate constant and concentration of the substrate involved in this type of reaction. Thus, Rutan and Brown[6] addressed the kinetics of hydrolysis of *p*-nitrophenyl phosphate to *p*-nitrophenol by using the enzyme alkaline phosphatase.

Kinetic determinations of very similar substrates (*e.g.*, isomers), however are hindered by mutual interferences that cannot be overcome by the selective features of enzymes. Multicomponent determination techniques based on spectral differences between the analytes to be determined may come to the rescue in such cases. Also, unlike equilibrium methods, these techniques are in no way affected by the occurrence of background signals—provided they do not contribute to the kinetics of the process—as they will not vary over time. This type of determination has been addressed by some authors. Thus, Pardue *et al.*[7,8] accomplished simultaneous determinations by using real and simulated multipoint data, and a non-linear regression method. They also reviewed different aspects of kinetic methods in this context.[9] However, they did not use or even mention the possibility of using spectra for resolving simultaneous kinetic processes.

*Author for correspondence.

In continuation of previous research into the development of multicomponent analysis techniques[10–13] in this work we address the simultaneous resolution of kinetic enzymatic processes by applying a multistandard linear regression method to the kinetics of oxidation of various substrates by hydrogen peroxide, catalysed by the enzyme peroxidase (EC 1.11.1.7). We applied the method thus developed to the resolution of mixtures of catechol and resorcinol traces by using an automated FIA system and the stopped-flow mode for data acquisition.

EXPERIMENTAL

Reagents

A 0.1*M* phosphate buffer of pH 7.0 ± 0.1 was prepared from its monopotassium salt (Probus, PA, U.S.A.).

A peroxidase solution was made by dissolving 0.512 g of lyophilized enzyme (EC 1.1.11.7, purified from Grade II horseradish peroxidase, Boehringer Manheim, Germany) in 4 ml of 3.2*M* ammonium sulphate (Fluka, PA). The suspension thus obtained (D_1) was stored at 4° in a refrigerator and remained stable for at least 2 months. It was used weekly to prepare solution sets (D_2) by diluting 100 μl of D_1 in 25 ml of 3.2*M* ammonium sulphate which were subsequently refrigerated as well. Working strength solutions were made daily by dissolving 150 μl of D_2 in 10 ml of phosphate buffer. The working solutions thus contained 7.68 μg peroxidase/ml (1.5 U/ml, 25°, and guaiacol-hydrogen peroxide as substrate).

Individual standards of catechol and resorcinol of concentration $9.0 \times 10^{-3}M$ were prepared from PA-grade Sigma and Panreac chemicals, respectively.

Finally, a 0.030% hydrogen peroxide solution was made by dilution of 30% Panreac PA reagent.

Apparatus

The experimental set-up used for the automatic determinations is depicted in Fig. 1. It consisted of the following components:

A PC compatible computer for instrumental control and data acquisition and processing that was equipped with an HP-IB interface and a PC8255 I/O card from Flytech Technology.

Two laboratory-assembled valve electromechanical actuators that were commanded by the computer via the PC8255 card. One of them was used to effect enzyme injections and the other to divert the flow to the spectrophotometer inlet and enable stopped-flow readings.

A Hewlett-Packard HP-8452A diode array spectrophotometer furnished with a flow-cell of 18 μl void volume and 1-cm pathlength, and connected to the computer via the HP-IB interface.

An FIA manifold (Fig. 2) consisting of a Gilson Miniplus peristaltic pump, two valves (a Rheodyne injection valve and a Rheodyne six-way valve) that were switched by the mechanical actuator; PTFE tubing of 0.5 mm i.d. for reactors and the injection loop; a thermostatic bath and an automatic burette furnished with a 0.5 ml syringe intended to load the injection loop with the minimum possible consumption of enzyme.

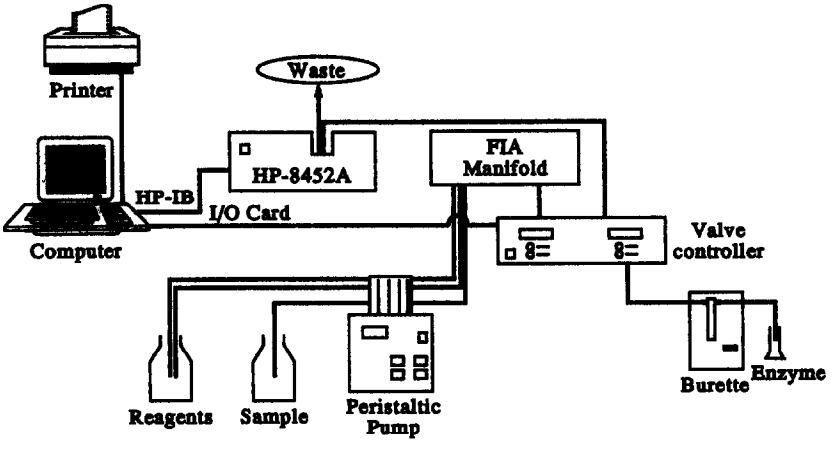

Fig. 1. Experimental set-up used for the simultaneous automatic determination of substrates involved in enzymatic kinetics.

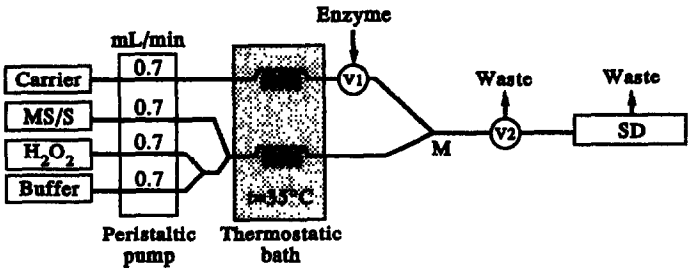

Fig. 2. FIA manifold used. Carrier and buffer: 0.1*M* phosphate, pH 7.0 MS/S: multiple standard/sample. V_1: enzyme injection valve. V_2: 6-way valve for stopping the flow. SD: spectrophotometric detector.

*Software**

We used essentially two programmes: DARRAY[14] and MULT13[15]. This latter was used in the multistandard mode: on the assumption that Beer's law is obeyed, the molar absorptivity of each component i at each wavelength j, ϵ_{ij}, is calculated by regression from mixtures of standards of each component at different concentrations. This requires solving an equation system at each wavelength given by

$$A_{jk} = z_j + \sum_{i=1}^{N} \epsilon_{ij} b c_{ik}; \quad k = 1 \ldots K \qquad (1)$$

where A_{jk} is the absorbance of standard k at wavelength j, z_j is the independent fitting term, b is the pathlength and c_{ik} is the concentration of component i in standard k. The above equation system can be solved by multiple linear regression provided the number of standards used (K) is greater than that of components. Solving the system will provide the ϵ_{ij} and z_j values, as well as the deviation of the fitting at each wavelength (D_j). The analyte concentrations in the samples can then be calculated by solving the overdimensioned equation system obtained by applying Beer's law to the mixture concerned at each working wavelength.

Procedure

Recording of the stopped-flow kinetic curves of the standards and sample. The process is started by setting reagents and a mixture of standards in motion along the manifold depicted in Fig. 2 and waiting for the system to stabilize. Then, an injection of 100 μl of the working solution of peroxidase is commanded and, 15 sec later—the time required for the maximum of the FIA peak to be reached—the flow is halted automatically in order to monitor the kinetic process. Subsequently, the computer commands loading of the injection coil with the enzyme solution and resumption of the flow. This cycle can be repeated as many time as required depending on the number of standards and replicates used.

Analytical data are acquired at 2-nm intervals over the wavelength range 250–550 nm and the absorbance corresponding to the 550 nm reading is subtracted. We used a data acquisition rate of 1 reading per second, even though this can be adjusted to the kinetic process concerned.

The same computer file where the kinetic curves of the multiple standards are stored can be used to save the kinetic data of the samples to be resolved. In this manner a single file can contain the data of all the standards required for calibration and sample analysis.

The above process is entirely carried out by the programme DARRAY.

Processing of data

Once the above computer file has been obtained, DARRAY saves the spectra of the different standards of the mixtures obtained at the preset time for data processing ($t = 6$ sec). These spectra are subsequently captured as multiple standards by the programme MULTI3 in order to perform calibration over the optimal wavelength range (340–500 nm in our case). Finally, the spectrum of the mixture to be resolved, recorded at the same time as those of the standards, is processed and the concentration of each analyte calculated.

RESULTS AND DISCUSSION

Optimization of experimental variables

The manifold employed is depicted in Fig. 2 and it was selected for the following reasons.

Reversed FIA manifolds use up very little reagent, which ensured minimal consumption of the enzyme.

*The software used in this work can be obtained on request from SCIWARE, Banco de Programas, Departament de Química, Universitat de les Illes Balears, 07071 Palma de Mallorca, Spain.

The enzyme was injected via V_1, which was placed as close as possible to the six-way valve V_2 in order to delay the start of the kinetic process as far as possible while allowing for efficient mixing with all other reactants.

The loops (0.5 m) that were immersed in the thermostatic bath (35°) were only intended to thermostat the stream containing the sample and carrier.

The injected volume used, 100 μl, was chosen as a compromise between a high sample throughput and low dispersion in order to achieve wide enough peaks to monitor the kinetics at their maxima.

The time elapsed between injection and the appearance of the maximum of the FIA peak was calculated previously (by using a dye) and was found to be 15 sec. The time elapsed between passage by the merging point (M) and stopping of the flow was also calculated (5 sec).

The oxidation reaction taking place up on injection of peroxidase (POD) can be represented by[16]

$$\text{Donor}(DH_2) + H_2O_2 \xrightarrow{\text{POD}} 2H_2O + \text{Oxidized donor}$$

where Donor denotes catechol and resorcinol in our case. The oxidized donor consists of several intermediate species presumably including semiquinone substances. The occurrence of radical intermediates from both catechol and resorcinol in their mixtures may account for the appearance of mixed coupling intermediates whose spectra would be different from those obtained in the presence of one component only. Under the working conditions used, this reaction only took place in the presence of the catalyst.

The absorption spectra of the oxidized forms of catechol and resorcinol, the maxima of which lie at 388 and 402 nm, respectively, are extensively overlapped.

However, we found the absorbance maximum of the two diphenol compounds to shift to shorter wavelengths with time, probably as a result of the occurrence of side reactions between intermediate radicals to yield other, new forms.

Thus, the kinetics of the mixtures were monitored by recording their absorption spectra over a given wavelength range (*e.g.*, 250–550 nm) at regular intervals (1 sec) by means of the diode array spectrophotometer. Each point of the kinetic curve was obtained by subtracting the absorbance measured at 550 nm from that obtained at a wavelength (*e.g.*, 388 nm) in order to offset the change in the refractive index arising from injection of the enzyme, thereby avoiding negative absorbance values.

The phosphate buffer and working temperature used were selected according to literature recommendations for similar processes.

With regard to the influence of the concentration of the different substances involved in the enzymatic reaction, we found H_2O_2 concentrations between 0.015 and 0.060% to have no effect on the initial reaction rate. We thus chose 0.030% as the working concentration. However, a linear dependence of the signals on the enzyme concentration throughout the range studied (2.56–7.68 μg peroxidase/ml) was obtained. We chose a concentration of 7.68 μg/ml as optimal—this can obviously be adjusted to the working concentrations of the substrates to be used.

Once the optimal working conditions were established, we calculated the linear determination ranges of the initial reaction rate *vs.* concentration plot and obtained 50–150μM for catechol and 30–180μM for resorcinol. The reproducibility in the initial rate for a mixture of the two diphenols was 3.4% ($n = 6$).

Resolution of catechol–resorcinol mixtures

A preliminary survey of the kinetic curves for the enzymatic action of peroxidase on the oxidation of the two substrates revealed both to conform to the Michaelis–Menten equation. Therefore, at initial substrate concentrations $[S]_0$ much smaller than the Michaelis constant, K_m, one can establish a linear relation between initial rate values and $[S]_0$—this is the typical working region for most enzymatic applications, even though some authors used alternative methodologies to extend the linear range beyond K_m.[17]

On the other hand, when the overall absorbance signal of the kinetic process arises from more than one substrate, the general procedure obviously cannot be used. Multicomponent analysis methods do allow mixtures to be resolved under these conditions. Among the various available options, that of multiple least-squares regression involves a fairly simple mathematical treatment that makes it advisable whenever the spectrum of each component to be determined or its oxidation product is known.

Table 1. Results and confidence intervals (95%) obtained in the resolution of catechol–resorcinol mixtures by using the multiple standard method

	[Catechol] (μM)		[Resorcinol] (μM)	
	Added	Found	Added	Found
S_1	100	107 ± 2	60	57 ± 2
S_2	100	93 ± 2	100	103 ± 2
S_3	50	50 ± 2	150	150 ± 3

Table 2. Catechol and resorcinol concentrations (μM) in the multiple standards used to resolve the mixtures in Table 1

	MS_1	MS_2	MS_3	MS_4	MS_5
Catechol	50	100	50	150	50
Resorcinol	50	50	100	50	150

However, the resolution of mixtures such as those of catechol and resorcinol poses some problems arising from side reactions between the oxidation products. Inasmuch as the oxidation products could not be readily identified, the customary regression procedure based on the use of individual standards of each of the substances significantly contributing to the overall signal was useless. Also, using the spectra of the two substrates was inadvisable as they would be fully overlapped and lie in an unsuitable region (274 nm). For the same reason, and due to the small absorbance values involved (a few milliunits), attempts at resolving the system by using an optimization method (*viz.* that of Gauss–Newton) for the kinetic curves of the samples from individual standards were also unsuccessful.

The above shortcomings can be circumvented by applying the multiple standard regression method[15] to the spectra of the oxidized forms. In this way, using mixtures of the two components in different proportions as standards will reproduce the same side reactions taking place in the sample. In practice, the regression procedure is applied to spectra recorded at the same time t as for the sample so that the results obtained may accurately reflect the concentration of each analyte.

Table 1 lists the results obtained in the resolution of three samples containing different proportions of the analytes. We used five mixtures of catechol and resorcinol at the concentrations given in Table 2, which provided significant information about their relative proportions. Even though, in mathematical terms, the system could be resolved with only four multiple standards, the deviations thus obtained were somewhat high, so we opted for using five standards. In resolving the mixtures at different times after halting the flow we found the results obtained to improve substantially within a few seconds of the start of the kinetic process.

Table 3 lists the concentrations obtained for each substrate in the three mixtures analyzed (S_1, S_2 and S_3) at times 0, 2, 4, 6 and 8 sec, as well as at saturation of the kinetic curve (120 sec). It follows from these results that both the concentrations and the confidence intervals obtained after 6 sec were quite reliable. On the other hand, the concentrations obtained at the saturation time were somewhat worse whereas the confidence intervals were slightly better. This can be ascribed to more reproducible spectra—absorbance values are greater than those measured at the beginning of the kinetic process—which, however, are also less accurate because of the side reactions involved. We thus chose to resolve the system with data from the initial kinetic segment, using a time of 6 sec following halting of the flow.

Figure 3 shows the kinetic curves yielded by two replicates of each of the three samples assayed (S_1, S_2 and S_3). The enzyme injection and flow stopping instants (the latter was

arbitrarily assigned $t = 0$), as well as the start of the loop loading process for the following injection ($t = 30$ sec) and flow resumption ($t = 120$ sec) are shown in the figure.

CONCLUSIONS

The results obtained testify to the usefulness of the multiple standard linear regression procedure for simultaneously resolving substrates on the basis of enzymatic reaction kinetics. Its advantages and disadvantages were clearly shown above.

The proposed method was automated by using an FIA system which allows the resolution of catechol–resorcinol mixtures within a few seconds of the start of the kinetic process by performing injections of the enzyme peroxidase. We found a set of five multiple standards to be more than adequate to ensure accurate resolution in spite of the very small absorbance values obtained as a result of working in the initial kinetic region.

The results were quite satisfactory in terms of accuracy, sensitivity and reproducibility, particularly taking into account that the chemical model used involved side reactions that would render resolution by any ordinary analytical method quite difficult.

In this work we resolved fixed-time kinetic enzymatic processes involving catechol and resorcinol only owing to the problems posed by the occurrence of side reactions between the oxidation products. However, the proposed procedure should be readily applicable to systems of more than two components provided they involve none of these undesirable side reactions.

ON-LINE MICROWAVE-ASSISTED DIGESTION OF SOLID SAMPLES FOR THEIR FLAME ATOMIC SPECTROMETRIC ANALYSIS

M. DE LA GUARDIA*, V. CARBONELL, A. MORALES-RUBIO and A. SALVADOR

Department of Analytical Chemistry, University of Valencia, 50 Dr. Moliner St., 46100 Burjassot, Valencia, Spain

Summary—A new procedure has been developed for the on-line digestion of solids in a microwave oven. The direct injection in a water carrier flow of dispersions of solid samples in concentrated nitric acid, the merging of these slurries with 30% (v/v) H_2O_2 and the microwave-assisted digestion in a Teflon coil of 100 cm permit a fast and quantitative extraction of Cu and Mn from different solid matrices, such as vegetables, powdered dietary products and sewage sludges. The development of an appropriate interphase, in which digested samples are cooled and degassified, previous to their introduction into the nebulizer of a flame atomic absorption spectrometer, makes possible the full automatization of the digestion and measurement steps of the elemental analysis of solids and it provides a sample frequency of 180 injections per hour. The developed procedure has also been applied for Pb and Zn determination in certified sewage sludge samples, with accurate results obtained for Pb but low results found for Zn.

The use of microwave ovens improves the acid digestion[1–4] and the dry ashing of solids,[5] and it provides an alternative to the preparation of samples for their analysis by atomic spectrometry.

Microwave-assisted decomposition methods are less time consuming than traditional ones and they reduce the digestion step from several hours to a few minutes; thus, they have opened up new possibilities to the full automatization of the analysis of samples including not only the measurement step but also the sample preparation.

The on-line digestion of liquid samples, such as serum or blood samples, can be carried out without difficulty by using a quartz digestion coil introduced into a microwave oven.[6]

The digestion of solids in flow injection (FI) analysis usually requires a higher irradiation time than that reported for liquids and it supposes a more sophisticated manifold.[7]

Slurries, obtained by dispersion of solids in water, have been used for the direct introduction of samples in atomic spectrometry.[8–11] Also, slurries have been introduced directly into the atomization systems by flow injection.[12,13] However, in several cases, elements to be determined are not easily atomized from dispersed solids and they need previous treatment in order to dissolve or to extract them from the solid to the aqueous phase by leaching. This treatment can be carried out using closed flow systems.[14,15] Other approaches, based on the digestion of slurries, employ stopped-flow systems[16] or very long digestion coils (20 m), and in-line filters,[17] in order to obtain a solids-free acid solution.

The aim of the present work is to develop a simple and inexpensive system for the on-line digestion of solid samples based on: (i) the direct injection of acid slurries in an FI manifold, (ii) the use of a domestic microwave oven, without any modification, to improve the sample digestion and (iii) the development of an adequate interphase to couple the FI manifold and the nebulizer of a flame atomic absorption spectrometer, which permits the cooling and degassing of the digested samples, in order to perform a fast analysis of the samples with a high sample frequency.

EXPERIMENTAL

Apparatus

A Perkin–Elmer 5000 atomic absorption spectrometer, equipped with a multielemental hollow cathode lamp of Cr, Co, Cu, Fe, Mn and Ni and monoelemental lamps of Pb and Zn, was used to carry out absorbance measurements in the instrumental conditions, reported in Table 1.

*Author for correspondence.

Table 1. Instrumental conditions employed for the determination of Cu, Mn, Pb and Zn

Parameter	Cu	Mn	Pb	Zn
Wavelength (*nm*)	324.7	279.5	283.3	213.9
Lamp current (*mA*)	12	12	10	8
Slit (*nm*)	0.7	0.2	0.7	0.7
Burner height (*cm*)*	1.3	1.3	1.3	1.3

Air flow (*l./min*)	12.1	12.1	12.1	12.1

*The burner height is the distance below the focal point of the optical system.

A domestic microwave oven (Balay Bahm 100) equipped with a 2450 MHz magnetron and with a nominal exit power of 650 W was employed for the digestion of samples, without any modification.

The manifold employed for the on-line digestion of slurries of solid samples is shown in Fig. 1. This manifold is a double channel assembly that includes two Rheodyne RS50 rotatory valves, which are operated at the same time in order to inject simultaneously the same volume of an acid slurry of the sample and a hydrogen peroxide solution. The two channels join in a Y-shaped merging zone and then the mixture passes through a Teflon digestion coil, located inside the microwave oven. This coil was introduced by making use of the vent holes of the oven and therefore no additional holes are required; thus there is no radiation leakage from the oven.

A Gilson P-2 Minipuls peristaltic pump, equipped with two vinyl chloride flexible tubes of 2.79 mm internal diameter, was employed for sample transport. All the parts of the manifold are made of Teflon and have 0.8 mm internal diameter.

A special interphase was designed to couple the FI manifold with the nebulizer of the atomic spectrometer (see Fig. 2). It consists of a 70 mm long glass tube (of 5 mm internal diameter) with an upper part 50 mm long (with an internal diameter of 26 mm). This form permits the degassing of the samples at the exit of the microwave oven, because, during the microwave irradiation of acid slurries in the presence of H_2O_2, a high amount of gases is produced. To avoid sample ejections, the end of the Teflon tubing, proceeding from the oven, is introduced into a fine glass tubing of 3 mm internal diameter. A waste vent, located 25 mm above the base of the interphase, avoids the excessive dispersion of samples when the aspiration flow (of the nebulizer) and the carrier flow (provided by the FI system) are not of the same order. An ice water cooling bath permits the cooling of the water carrier flow and condenses the sample plug before its introduction into the atomic spectrometer. The aspiration tubing of the nebulizer is introduced until the end of the interphase in order to carry out continuous aspiration of the solution coming from the microwave oven.

Reagents

A standard stock solution of Cu (1000 μm/g) was prepared from 1.0000 g of copper metal dissolved in a minimum volume of (1 + 1) HNO_3 and diluted to 1 l. with 1% (v/v) HNO_3. A stock solution of Mn was prepared from

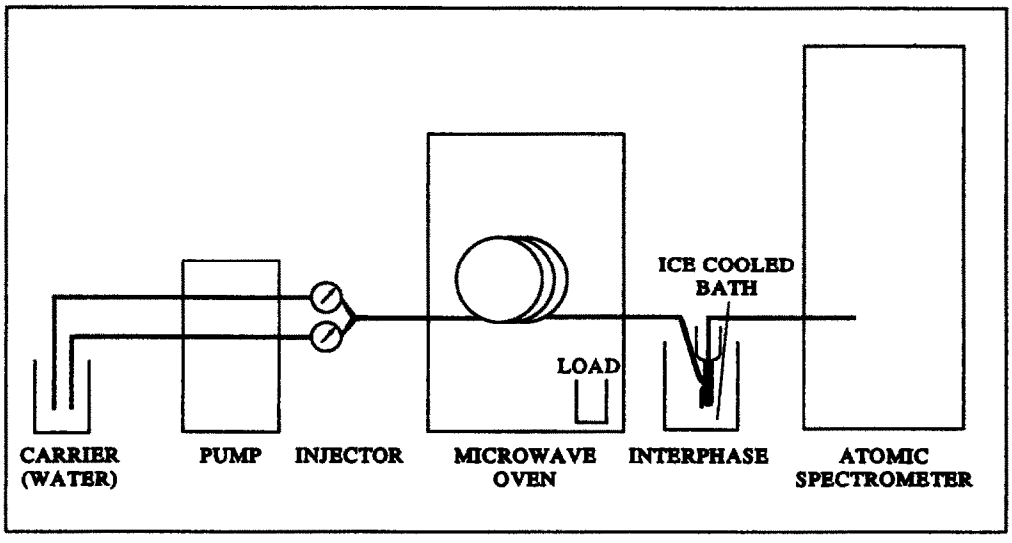

Fig. 1. FI manifold employed for the on-line digestion of solid samples.

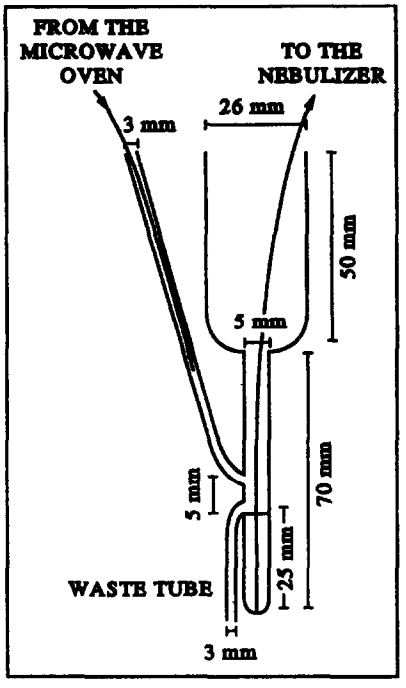

Fig. 2. Interphase employed to couple the FI manifold with the nebulizer of the atomic spectrometer.

1.0000 g of manganese metal dissolved in a minimum volume of HNO_3 (1 + 1) and diluted to 1 l. with 1%(v/v) HCl. A stock solution of 1000 μg/g of lead was prepared from 1.5980 g of analytical reagent grade $Pb(NO_3)_2$ dissolved in 1 l. distilled water and, a stock solution of 1000 μg/g of zinc was prepared from 1.0000 g of zinc metal dissolved in 30 ml of 5*M* HCl and diluted to 1 l. with distilled water. Working standards were prepared by diluting the stock solution with analytical grade concentrated HNO_3 (Panreac, Barcelona, Spain).

A hydrogen peroxide solution (30% v/v; Probus, Barcelona, Spain) was employed to improve the digestion of the nitric acid slurries of samples.

Samples

Real artichoke samples were supplied by the Instituto Valenciano de Investigaciones Agrarias (IVIA, Montcada, Spain). Full artichokes were dried in a thermal oven at 80° for several days, until a constant weight was obtained. They were then pulverized in a vegetable processor IKA model M-20, until a particle size lower than 100 μm was obtained.

Fine dry powder of dietary product samples (particle size lower than 100 μm) was provided by PENSA laboratories (Valencia, Spain).

Real sewage sludge samples were supplied from the water treatment plant of Pinedo (Spain). The sample was dried, in a thermal oven at 80°, and then pulverized in an agate ball mill until a fine powder with a particle size lower than 200μm was obtained.

Certified samples of tomato leaves (SRM 1573) and sewage sludges samples (CRM 144 and CRM 146) were employed to check the accuracy of the developed procedure.

General procedure

In order to study the effect of the experimental parameters on the on-line treatment of samples, 100 μl of dietary product slurries in concentrated nitric acid, containing 20 mg/ml of dispersed solids, were injected in a water carrier flow by using the previously described manifold, at the same time as 100 μl of H_2O_2 of different concentrations. Then, the mixture of both channels was passed through a reaction coil of 100 cm length, introduced into a microwave oven.

The aspiration flow rate of the nebulizer in these experiments was 8 ml/min and the total carrier flow rate was between 7 and 8 ml/min.

In the above mentioned conditions, the effect of H_2O_2 on the digestion of acid slurries and the influence of the parameters which control the digestion time were studied.

Recommended procedure

Between 20 and 250 mg of a solid sample were weighed in a glass beaker, 10 ml of concentrated nitric acid added and the mixture shaken vigorously to obtain a homogeneous dispersion. One hundred microlitres of this slurry were injected in the double channel manifold indicated in Fig. 1 at the same time as 100 μl of a 30% (v/v) H_2O_2 solution. Both carrier streams merge in a Y-shaped merging zone and then pass through a Teflon coil of 100 cm located inside a microwave oven. They were worked at 100% power level of the microwave oven and an additional load of 100 ml of distilled water was introduced into the oven, as a safety measure.

To obtain accurate results the total carrier flow in the FI system must be equal, or a little higher, than the aspiration flow of the nebulizer, and a value of the order of 8 ml/min of the latter is recommended.

Standard calibration curves can be established from the injection of different concentrations of conventional standards in concentrated nitric acid, treated in the same way as the samples.

RESULTS AND DISCUSSION

Stability of acid slurries

Solid dispersions, containing between 20 and 250 mg of sample in 10 ml of concentrated nitric acid, are stable for several minutes, after manual shaking, and the addition of surfactant agents is not required in order to improve their stability.

Figure 3 shows the variation of the absorbance at 500 nm, obtained using a UV–vis spectrophotometer, for an acid slurry containing 100 mg of a powdered dietary product dispersed in 10 ml of HNO_3 and then diluted 1:10 (in order to achieve absorbance values in the minor photometric error range). The continuous recording of absorbance as a function of time shows that, during the first 20 min, the change in the turbidity of the sample dispersion is lower than 10%. So, for the preparation of samples it is sufficient to obtain a fine particle size of the solid and to disperse these particles in HNO_3. After the homogenization of this dispersion, 100 μl of the slurry are injected in the FI manifold of Fig. 1.

Digestion of acid slurries

As was previously confirmed by using a closed FI manifold, the microwave-assisted digestion of vegetable and sewage sludge samples provides a quantitative recovery of inorganic elements in a few minutes when mixtures of nitric acid and hydrogen peroxide are employed.[15] So, for on-line digestion, solid samples were dispersed in concentrated nitric acid and then mixed with the same volume of H_2O_2 solution.

The on-line treatment of samples supposes a very low digestion time; so, the effect of digestion parameters such as digestion mixture and time of microwave irradiation were studied carefully in order to obtain the total recovery of the elements to be determined in a minimum time. The influence of the injection volume and solid content of the sample slurries was also studied.

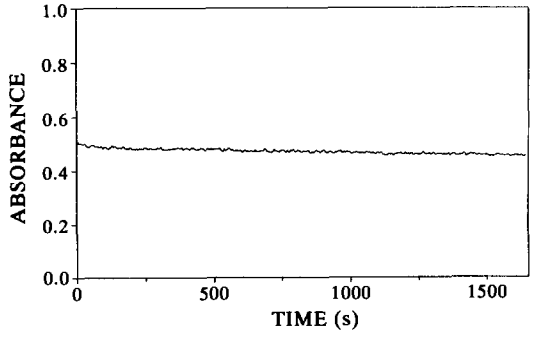

Fig. 3. Variation, as a function of time, of the absorbance at 500 nm of 10 mg of a dietary product dispersed in 10 ml HNO_3.

Table 2. Effect of H_2O_2 concentration on the determination of Cu and Mn in a dietary solid sample by on-line digestion

H_2O_2 (*v*/*v*) (%)	Cu ($\mu g/g$)	Mn ($\mu g/g$)
0	44 ± 4	11 ± 3
6	40 ± 2	43 ± 5
12	37 ± 3	47 ± 2
21	36 ± 2	50 ± 5
30	36 ± 2	45 ± 4
Actual concentration	41 ± 2	52 ± 2

Values of real concentration were established from the batch analysis of samples after a conventional wet ashing digestion. The total carrier flow employed was 7.8 ml/min and the content of solids in the slurries was 20 mg/ml. Results indicated are the mean of three independent analyses ± their relative standard deviation.

Digestion mixture

To improve the microwave-assisted digestion of acid slurries of solid samples, an H_2O_2 solution was added to increase the oxidizing power of HNO_3.

In the experimental conditions indicated in the general procedure, the effect of different H_2O_2 concentrations on the recovery of Cu and Mn was studied.

Table 2 summarizes the results found in the analysis of a real sample for the determination of Cu and Mn, and, as can be seen, the addition of H_2O_2 is necessary to obtain accurate concentration values of the same order as those found by a conventional wet ashing digestion procedure (real concentration) for Mn; however, a simple treatment with HNO_3 seems to be enough to obtain total recovery of Cu.

Digestion time

The digestion time of samples in the manifold employed, for a fixed internal diameter of manifold tubing, depends on the reaction coil length and the carrier flow rate. Therefore, we studied the effect of these two parameters on the determination of Cu and Mn in a sewage sludge sample, in order to obtain a good recovery and to take the shortest time possible.

A 0.8 mm internal diameter Teflon tubing was used, because tubing with diameters lower than this could be blocked easily with slurries and the use of tubing with a diameter higher than 0.8 mm could cause an excessive dispersion of samples (results not shown).

Table 3. Effect of digestion coil length on the recovery of Cu and Mn from slurries of sewage sludge

Coil length (*cm*)	Carrier 6.2 *ml/min* Cu ($\mu g/g$)	Carrier 8.8 *ml/min* Cu ($\mu g/g$)
50	720 ± 30	830 ± 50
100	890 ± 50	780 ± 20
200	780 ± 90	360 ± 30
250	860 ± 70	600 ± 60
Actual concentration of Cu	820 ± 2 $\mu g/g$	
Coil length (*cm*)	Carrier 6.2 *ml/min* Mn ($\mu g/g$)	Carrier 8.8 *ml/min* Mn ($\mu g/g$)
50	111 ± 7	145 ± 5
100	131 ± 8	87 ± 3
200	120 ± 10	50 ± 6
250	120 ± 10	54 ± 5
Actual concentration of Mn	141 ± 2 $\mu g/g$	

Note: aspiration flow was 8.4 ml/min. Data are the average of three independent analyses $\pm$ the standard deviation, for different slurries of the same solid sample.

Reaction coil length

Table 3 summarizes the results found for the digestion of a real sewage sludge sample by using different digestion coil lengths (from 50 to 250 cm) at two different carrier flow rates (6.2 and 8.4 ml/min) and for a fixed nebulizer aspiration flow of 8.4 ml/min. The comparison between the concentration values found for Cu and Mn with the actual concentration values, determined previously by flame absorption analysis after pressurized total acid digestion of these samples, provides information about the effect of the digestion time on the accuracy of the developed procedure.

The data on Table 3 indicate that in only few cases were accurate results found. These data show that the use of high length values of the reaction coil did not provide any enhancement of the digestion of samples, especially when a carrier flow of 8.8 ml/min was employed. An increase in the reaction coil length increases the residence time of the sample in the oven; however, we have observed that an increase in the digestion time provide an excessive amount of gases, which modifies the flow at the exit of the microwave oven and causes the gas segmentation of the sample plug. This latter effect can cause losses in the interphase, especially when high carrier flows are employed, and this could explain the bad precision values and the low recoveries obtained when long digestion coils were used. From these preliminary experiments, we selected a length of 100 cm for the digestion coil and then studied carefully the effect of the carrier flow for different values of the nebulizer aspiration flow.

Aspiration and carrier flow rates

The coupling between the FI manifold and the nebulizer makes necessary an adequate equilibrium between the carrier and the aspiration flows. The interphase mentioned above was developed in order to compensate the differences between these two flows, because the use of carrier flow values lower than the aspiration flow could cause instability of the measurements, due to the segmentation of the flow. On the other hand, the use of a carrier flow higher than the aspiration flow causes losses of the sample in the interphase.

The volume of the interphase, under the waste vent, was approximately 500 μl to assure a low dispersion of the digested samples and a sufficient amount to avoid the hold-up of the aspiration flow.

A series of experiments for the digestion of real dietary product samples was carried out in order to check the most appropriate flow values.

Table 4 summarizes the sensitivity and accuracy values found for the determination of Cu and Mn using different aspiration and carrier flows. It can be seen that the use of an aspiration flow of 7.7 ml/min provides more sensitive results than the use of a flow of 5.4 ml/min. On the other hand, carrier flow values lower than the aspiration flow provide inaccurate results. An aspiration flow of 7.7 ml/min and a carrier flow of 8.8 ml/min seem to be the most adequate conditions for the determination of both Cu and Mn in dietary samples. For these two carrier flows and for a digestion coil of 100 cm, the residence time of the samples in the microwave oven is of the order of 5 sec. However, in this

Table 4. Effect of the carrier flow and aspiration flow on the concentration fond for Cu and Mn in the analysis of dietary samples

Carrier flow	Aspiration flow	Slope	Cu ($\mu g/g$)	Error (%)	Slope	Mn ($\mu g/g$)	Error (%)
3.6	5.4	0.007	34.8 ± 0.1	−15	0.004	60 ± 14	+15
5.3	5.4	0.008	37.6 ± 0.1	−8	0.007	48.7 ± 0.1	−6
7.0	5.4	0.007	44 ± 7	+7	0.005	43.5 ± 0.1	−16
5.3	7.7	0.009	40 ± 5	−2	0.009	34 ± 3	−35
7.0	7.7	0.01	39 ± 4	−5	0.011	46 ± 5	−12
8.8	7.7	0.009	44 ± 3	+7	0.008	54 ± 6	+4
Actual concentration			41 ± 2			52 ± 2	

Note: The slope values of the calibration curves obtained in each set of experimental conditions are expressed in absorbance units per mg/l. The carrier flow and the aspiration flow are expressed in ml/min. In all cases a digestion coil length of 100 cm was employed. ± the standard deviation. The relative errors, expressed as percentages, were calculated from the difference between results found in the FI mode and actual values.

short period of time Cu and Mn are quantitatively extracted from the solid matrix.

In the above conditions, the dispersion coefficient of the manifold is equal to 15, taking into account that samples are diluted 1:2 with H_2O_2 and that the interphase also causes additional dispersion.

On the other hand, when acid slurries of real samples were injected in the FI manifold, at the same time as H_2O_2, carrying out the transport of samples without irradiation, the recovery of Cu was 91% in the sewage sludge sample and 66% in the dietary product sample, and for Mn, only a 79% recovery was found for sewage sludge and 33% for the dietary product. Thus, the microwave irradiation of samples is absolutely necessary in order to obtain accurate results in the determination of the elements studied.

An important aspect of the continuous on-line digestion of slurries is that the microwave irradiation of a sample plug, containing HNO_3 and H_2O_2, provides a high amount of gases, which improves the sample digestion, but can also cause problems of drawing back the carrier flow. So, the use of high values of this latter parameter is necessary. In the recommended conditions we have not encountered flow problems during working sessions of 1 or 2 hr and using a conventional peristaltic pump.

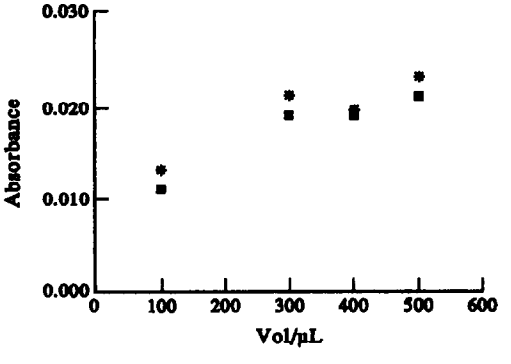

Fig. 4. Effect of the injection volume on the sensitivity of the determination of Cu in a dietary product sample by on-line digestion and FI atomic spectrometry. Absorbance values correspond to a standard solution of 1 mg/l (*) and a dietary product sample slurry with a similar content of Cu (■).

Effect of the injection volume

Figure 4 shows, as an example, the effect of the volume injected on the absorbance of Cu; it can be seen that the absorbance values increase when the sample volume increases, this effect being similar for standards and samples.

In these experiments, a standard acid solution of 1 mg/l and slurries of 500 mg of a dietary product sample (containing 41 ± 2 $\mu g/g$ of Cu) dispersed in 25 ml of HNO_3 (which corresponds to a Cu concentration of the order of 1 mg/l) were employed.

From the comparison between results found by on-line digestion in FI atomic spectrometry and those obtained in batch analysis (results not shown), it can be concluded that the injection of slurry volumes greater than 100 μl does not improve the accuracy of the developed procedure, but the use of high sample volumes reduces the sample frequency and could cause damage in the nebulizer due to the introduction of high amounts of acid. So, an injection volume of 100 μl was selected for the determination of elements which does not require a high sensitivity.

Effect of solid content

The direct injection of slurries in an FI system could cause clogging problems in different parts of the manifold and so it is important to establish the amount of dispersed solids that can be processed without problems.

Table 5. Effect of solid content of slurries on the determination of Cu and Mn in a dietary sample

Sample mass (*g*/10 *ml*)	Cu (*μg/g*)	Mn (*μg/g*)
0.1242	49 ± 6	56 ± 4
0.1705	41 ± 7	57 ± 5
0.2308	44 ± 3	57 ± 4
0.2620	50 ± 4	53 ± 5
0.2797	45 ± 4	47 ± 2
Actual concentration	41 ± 2	52 ± 2

Table 5 summarizes the results found in the determination of Cu and Mn in a dietary product sample for different amounts of sample, dispersed in a total volume of 10 ml of concentrated nitric acid. It can be seen that the content of solids does not seem to be a critical parameter on the accuracy and reproducibility of the analytical results, because in most cases values of the same order as the actual ones were found in FI atomic spectrometry.

To obtain a better representation of the solid samples the sample amount taken must be greater than or equal to 20–30 mg/ml.

Another way to increase the repeatability of the analysis of solids could be the use of higher sample amounts dispersed in higher acid volumes. However, the results in Table 6 show that, for a content of dispersed solid of the order of 20–25 mg/ml, the repeatability of the results found for the determination of Cu and Mn is similar for the different sample masses assayed.

Analysis of real and certified samples

In order to check the applicability of the developed procedure, three real samples of different nature, artichoke, dietary and sewage sludge, and three certified samples were analysed by the proposed method. The results found were compared with those certified or obtained by continuous aspiration after a traditional pressurized wet ashing digestion. Table 7 summarizes the results found for the proposed method, which have been tested by comparing them with those obtained by using the reference method. The *F*-test has been applied in order to check if the two methods provide standard deviations which are not significantly different and the *t*-test has been used to verify whether the difference between the means obtained by both methods differs significantly from zero. The critical values for *F* and *t*, for a confidence level of 95% and $n_1 + n_2 - 2$ degrees of freedom, are 19.16 and 2.78, respectively.[18]

In the Cu determination there is no significant difference between the two variances, except in the case of the real sewage sludge sample. The obtained values of *t*, for all the samples, are lower than the critical value; so, it can be assumed that the means of the results given by the two methods are equal.

In the Mn determination there is no significant difference between the two variances of each sample. Using the *t*-test, it can be assumed that the means of the results given by the two methods are equal except in the case of the certified CRM-144 sample, a domestic origin sewage sludge, probably due to the presence of very stable chemical forms of Mn.

Analytical features of the developed procedure

The FI flame atomic absorption procedure developed for the determination of Cu and Mn in solid samples permits a fast analysis.

Figure 5 shows, as an example, the typical FI recording obtained for the determination of Mn in certified samples. The time scale shows that more than 180 injections per hour can be carried out.

The high dispersion of slurries into the FI manifold reduces the analytical sensitivity of the flame atomic spectrometric measurements and so the limit of detection found for Cu determination is 0.033 μg/ml (for a probability level of 95%) which is equivalent to 1.2 μg/g of the dispersed solid. For Mn the obtained limit of detection is 0.037 μg/ml; thus, a minimum con-

Table 6. Effect of the dispersed sample mass on the determination of Cu and Mn in a dietary sample

Sample mass (*g*)	Dilution volume (*ml*)	Cu (*μg/g*)	RSD (%)	Mn (*μg/g*)	RSD (%)
0.2620	10	50 ± 4	8	53 ± 5	9
0.5239	25	47 ± 3	6	65 ± 2	3
1.0018	50	45 ± 3	7	62 ± 3	6
2.5955	100	45 ± 4	9	67 ± 6	9
Actual concentration		41 ± 2		52 ± 2	

Note: all the results are the average of five independent analyses of the same sample ± their standard deviation. RSD, relative standard deviation.

Table 7. Analysis of real and certified samples

Sample	Cu (μg/g)				Mn (μg/g)			
	Method 1 (reference)	Method 2 (proposed)	F	t	Method 1 (reference)	Method 2 (proposed)	F	t
Artichoke	—	—	—	—	54 ± 1	55 ± 4	16	0.42
Dietary	41 ± 2	41 ± 2	1	0	52 ± 2	50 ± 6	9	0.55
Sewage sludge	820 ± 3	826 ± 22	53	0.47	140 ± 2	144 ± 4	4	1.55
SRM 1573	—	—	—	—	238 ± 7	238 ± 7	1	0
CRM 146	713 ± 26	704 ± 13	4	0.38	449 ± 13	440 ± 20	2.37	0.65
CRM 144	934 ± 24	960 ± 10	2.25	1.73	588 ± 24	480 ± 20	1.44	5.99

F was calculated from the quotient between the variances of both methods, this quotient always being ≥ 1.

$$t = \left| \frac{\bar{x}_1 - \bar{x}_2}{\sqrt{s^2\left(\frac{1}{n_1} \frac{1}{n_2}\right)}} \right|$$

X_1 and X_2 being the average concentration obtained by each method, n_1 and n_2 the number of analyses and S^2 a pooled estimate of variance,

$$S^2 = \frac{[(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2]}{n_1 + n_2 - 2}.$$

centration of 1.3 μg/g in the solid sample is required.

The relative standard deviation obtained from five independent analyses of the same sample varies from 1 to 5% for Cu determination and from 2.7 to 12% for Mn, as a function of the different nature of the sample and the different concentration of the elements to be determined.

The above mentioned features show that the developed method can be applied for the accurate determination of Cu and Mn in a wide variety of solid samples, but it cannot be applied for the determination of very low concentrations.

Determination of Pb and Zn in sewage sludges by the recommended procedure

In order to demonstrate the applicability of the developed methodology for the analysis of solids, elements other than those studied were determined in slurries of certified sewage sludge samples. Table 8 shows that Pb can be accurately determined using the recommended procedure, but for the determination of Zn inaccurate results were found for the analysis of a domestic origin sewage sludge and, in summary, results found evidence that some samples need a stronger treatment to quantitatively leach the elements to be determined.

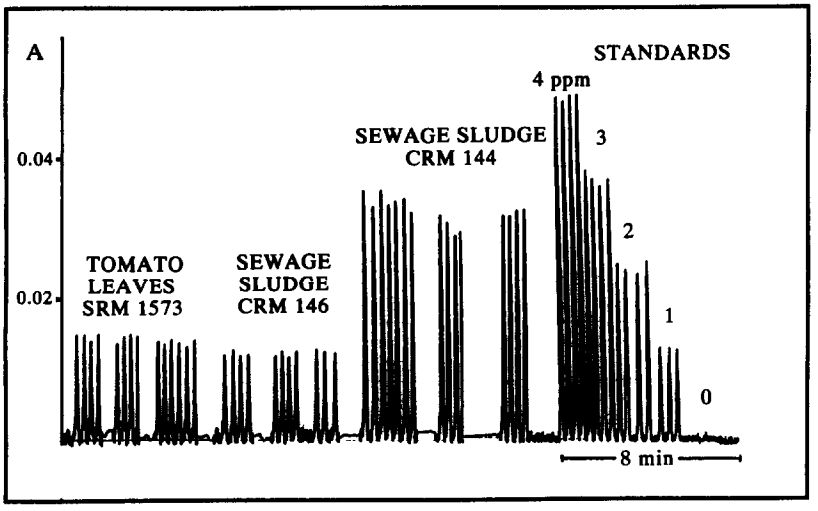

Fig. 5. FI recording obtained for the determination of Mn in certified samples. Records correspond to the injection of different acid standards and a series of injections of acid slurries of samples. In all cases, samples and standards were irradiated on-line following the proposed procedure.

Table 8. Determination of Pb and Zn in certified sewage sludge samples by on-line digestion and FI atomic spectrometry

	Pb (μg/g)			Zn (μg/g)		
Sample	Certified	Found	Error (%)	Certified	Found	Error (%)
CRM 146	1270 ± 28	1270 ± 80	—	4059 ± 90	3800 ± 150	−6
CRM 144	495 ± 19	505 ± 8	+2	3143 ± 103	2500 ± 100	−20

Safety considerations

The modification of a domestic microwave oven in order to be used in FI analysis can cause safety problems related to radiation leakage, which can be found when systems have been modified by drilling holes in the walls of the oven. In our case, we have employed the vent holes of the oven to introduce the Teflon tubing and so radiation leakage does not occur.

The introduction of an additional load of water into the oven is recommended in order to avoid magnetron damage if the oven operates with little or no load.

The use of a Teflon tubing of 0.8 mm internal diameter as digestion coil has provided good results; we have found no liquid or fume losses, nor coil damage, during 4 months working with the same coil.

The glass interphase is essential in avoiding acid leakages and it can be adapted without special safety precautions. It provides a cooling system in which acid vapours are condensed and its special design avoids acid ejections when samples are irradiated.

The only safety conditions required by the proposed method are related to the handling of sample slurries in concentrated acid, which must be treated carefully in order to avoid operator damage.

CONCLUSIONS

The developed procedure provides automation of the sample digestion and measurements steps of the determination of Cu and Mn in different types of solid samples. The method is six times quicker than those previously reported for the on-line digestion of solids and does not require the use of a closed flow system nor to work in the stopped flow mode. This method can also be applied to the determination of Pb and Zn in sewage sludges.

A BIOSENSOR FOR FERRIC ION

J. M. BARRERO, M. C. MORENO-BONDI, M. C. PÉREZ-CONDE and C. CÁMARA
Department of Analytical Chemistry, Faculty of Chemistry, Complutense University, 28040 Madrid, Spain

Summary—A new biosensor for monitoring iron has been developed. The active solid phase is pyoverdin, a natural fluorescent pigment biosynthesized by *Pseudomonas fluorescens* immobilized on controlled pore glass (CPG) and packed in a quartz flow-through cell. The biosensor is very selective for iron(III) and can be easily regenerated in about 2 min by passing 1*M* HCl through the cell. The optimum conditions and analytical characteristics (detection limit, precision and linear range) for the new sensor in solution (DL = 10 ng/ml) and in immobilized form (DL = 3 ng/ml) are reported. The biosensor has good stability and can be used continuously over a period for at least 3 months (over 1000 determinations). The sensor was successfully applied to determine iron in different water samples. There were no significant differences between the new method and the Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP–AES) reference method at the 95% confidence level.

Under iron deficiency conditions, most microorganisms synthesize iron carrier molecules called siderophores, which solubilize iron and transport it into the cell, and are considered a high specific transport system.[1] The bacterium *Pseudomonas fluorescens* is characterized by the excretion of pyoverdin, a yellow–green water soluble fluorescent siderophore. The structure of many pyoverdins has been elucidated by high field nuclear magnetic resonance (NMR) spectroscopy.[2] They consist of a peptide and, bound to it, a chromophore derived from 2,3-diamino-6,7-dihydroxyquinoline common to all pyoverdins. Each pyoverdin contains 3 bidentate chelating groups: a catechol group located on the chromophore and either two hydroxamates (as *N*-hydroxyornithines acylated on the nitrogen atom, or cyclic) or one hydroxamate and one hydroxyaspartic acid, belonging to the peptide portion. Each strain of *Pseudomonas fluorescens* produces several pyoverdins possessing the same peptide and differing only in the side chain bound to the chromophore. From strain to strain, the peptide can vary considerably.

Siderophores in general are characterized by the following properties: (1) they specifically complex Fe(III) and have a weak or negligible affinity for Fe(II), and (2) the Fe(III) complexes have very high stability constants[3] (about 10^{32}). These properties make pyoverdin a promising agent for iron determination and for the construction of an optical biosensor.

The development of chemical optical sensing of chemical species using an immobilized reagent[4,5] has provided a novel technique for "*in situ*" analyte monitoring without reagent consumption.

The most common analytical techniques for iron determination are flame atomic absorption and Vis–UV spectrophotometry, although the former is not sensitive enough to determine concentrations at the ng/ml level and the latter is not sensitive or selective enough for many purposes. A coulometric method has also been employed for seric iron determinations, although the colorimetric methods are considered more accurate for this type of measurements.[6] An optical fiber Fe(III) sensor using Chromazurol S immobilized on an ionic exchanger[7] has been described in the literature. This reflectance sensor showed a linear response range between 0.2 and 2.5 ppm but the measuring procedure was not appropriate for continuous determinations. This lack of suitable sensors prompted us to develop a biosensor for iron(III) measurements using the highly selective pyoverdin pigment. This paper describes the conditions for pyoverdin immobilization on CPG as well as the optimum chemical and physical variables for the fluorimetric determination of Fe(III) in a continuous flow-system.

EXPERIMENTAL

Apparatus

Fluorescence intensity measurements were made on a Perkin-Elmer LS-50 spectrofluorometer, equipped with a xenon-lamp as light source and an IBM Model 55 SX computer. This set up

Table 1. Optimum conditions to iron determination using pyoverdin immobilized and in aqueous solution

Parameters	Aqueous solution	Immobilized Pyoverdin
Maximum of excitation	390 nm	500 nm
Maximum of emission	465 nm	552 nm
pH	6.5	4.5
Buffer	0.05 *M* MES	0.01 *M* Biphtalate/Phtalate
Regeneration	—	1*M* HCl
Flow rate	—	5 ml/min

was used in combination with a Hellma flow quartz cell (3 mm light path). All measurements were made with 5 nm band widths for the emission and excitation monochromators. All spectra were uncorrected. A simultaneous ICP–AES Jobin Yvon JY-48 spectrometer was used as reference technique. Absorbance readings were made on a Hewlett Packard 8452-A diode array spectrophotometer. Readings of pH were made on a Crison 2001 pH-meter and temperature control was effected by means of a thermostated bath. A Gilson Minipuls 2 pump was used to pump all the solutions.

Reagents

Analytical reagent-grade chemicals were employed for the preparation of all solutions. Freshly prepared Milli-Q (Millipore) ultrapure water was used in all experiments. A 1000 μg/ml Fe stock solution was prepared by dissolving $Fe(NO_3)_3 \cdot 9H_2O$ in 1%HNO_3 and titrating it with potassium permanganate.

Pyoverdin was biosynthesized and purified from *Pseudomonas fluorescens*, strain AR-11, by a modified version of the method described by Meyer and Abdallah.[8] *P. fluorescens* was grown in a PMS_7Ca iron-deficient culture medium consisting of *N,N*-bis-[2-hydroxyethyl]-2-aminomethane sulphonic acid, sodium pyruvate, magnesium sulphate, ammonium chloride, dipotassium phosphate and calcium chloride. The pigment was isolated from the supernatant by centrifugation and passed through a G-25 Sephadex column. The eluate fractions were analyzed spectrophotometrically and only those with a peak in the visible region ($\lambda = 460$ nm) and an absorbance above 0.2 were used and treated with an excess of 8-hydroxyquinoline to remove traces of iron.

Controlled pore glass with different pore size (237 and 460 Å, particle size 37–74 microns was obtained from Pierce).

Buffer solutions like 2[*N*-morpholino]-ethanesulphonic acid (MES), tris[hydroxymethyl]aminomethane hydrochloride (TRIS), imidazole, phthalic acid, acetic acid, were used.

Procedure

Pyoverdin immobilization. About 0.2 g of CPG (460 Å) were cleaned with HNO_3, rinsed with distilled water, and activated with an aminoalkyl agent by the method described by León-González.[9] Four millilitres of $6.5 \times 10^{-5}M$ pyoverdin in biphthalate (0.01*M*, pH 6) were added to the activated glass (0.123 g), and immobilization was allowed to proceed at 4° for 2.5 hr in the absence of oxygen. The glass beads were rinsed afterwards to remove the excess of unlinked siderophore. Different fractions of the rinsings were analyzed by Vis–UV spectrometry at 460 nm to quantify the amount of siderophore linked to the CPG.

Iron determination. Buffer solutions containing a given iron concentration from 10 to 200 ng/ml and containing no iron were alternatively pumped at a flow rate of 5 ml/min through the flow cell, where pyoverdin immobilized on CPG was packed. Emission signal intensity *vs* time was measured at 552 nm upon excitation at 500 nm. Fluorescence intensity decreased when Fe(III) was passed through the cell. Once the signal had been recorded the pyoverdin reactor was regenerated by pumping 1*M* HCl for 2 min through the cell. This sequence was repeated several times to obtain a

Table 2. Analytical characteristics of immobilized pyoverdin–Fe(III) and pyoverdin–Fe(III) in aqueous solution

RESULTS AND DISCUSSION

Because of its natural procedure the selectivity of a siderophore for iron(III) determinations is advantageous over the use of artificial compounds for this analyte. On the other hand, fluorescence measurements are usually considered more sensitive than spectrophotometric ones for analytical purposes. In this sense, pyoverdin immobilization would allow the development of a highly selective and sensitive biosensor for continuous Fe(III) measurements.

Controlled pore glass has been widely used as solid support for enzymes and other reagents immobilization because it is fairly inert and therefore not subject to microbial degradation or swelling due to varying ionic strength. In this work two different CPG pore size (460 and 237 Å) have been tested. The emitted fluorescence of CPG immobilized pigment was significantly higher on the 460 Å CPG than on 237 Å CPG in agreement with Kurtz[10] observations that CPG yields higher enzyme immobilization efficiencies when higher porous size is used, so the 460 Å CPG was chosen for further experiments.

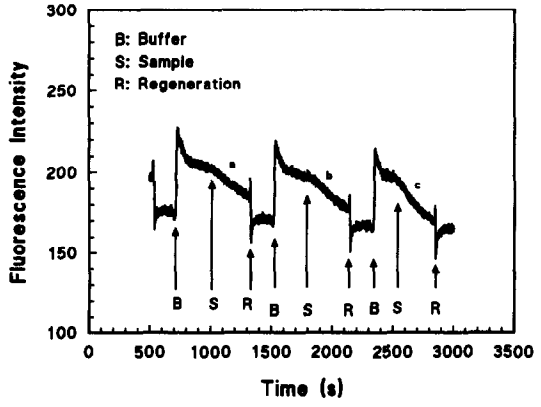

Fig. 2. Response curve at different concentrations of iron(III) -a- 50 ng/ml, -b- 70 ng/ml and -c- 100 ng/ml. Flurorescence intensity *vs* time.

In order to select the most suitable concentration of CPG immobilized pyoverdin, three different pyoverdin concentrations ($6.65 \times 10^{-5} M$, $1.33 \times 10^{-4} M$, $6.65 \times 10^{-4} M$) were tested using the same amount of CPG. The pyoverdin remaining in solution was monitored by Vis–UV spectrophotometry. In all cases the same concentration of the pigment (0.001 mmole/g) became attached to the CPG. The optimized parameters for iron(III) determination using aqueous and immobilized pyoverdin are summarized in Table 1.

In aqueous solution, pyoverdin has an emission maximum at 465 nm when excited at 390 nm, whereas if it is immobilized the emission maximum is shifted to 552 nm and the excitation to 500 nm. This shift could be attributed to a drastic change in the luminophore environment and/or electronic structure upon covalent bonding between the siderophore and the solid support. Another important feature of this indicator is that its high emission fluorescence pro-

portionately decreased with the ferric ion concentration. In aqueous solution the pyoverdin–Fe(III) system exhibits a linear range of 10–180 ng/ml Fe(III), with a detection limit of 10 ng/ml and precision of 4% ($n = 9$, 50 ppb) (Table 2).

The fluorescence emission intensity of pyoverdin and pyoverdin–Fe(III) complex formation are significantly affected by the pH of the solutions. The strength of this pH effect depends on whether the pigment is in solution or immobilized on CPG (Fig. 1). The largest differences between the fluorescence intensity of pyoverdin and pyoverdin–Fe(III) were in aqueous solution at pH 6.5 and at pH 4.5 in the immobilized system.

The nature of the buffer significantly affected reactivity in both the aqueous and immobilized systems. MES, TRIS, phosphate, imidazole and bipthalate buffers were tested and 0.01*M* biphthalate provided the greatest sensitivity in the solid system, whereas 0.05*M* MES was the optimum buffer in aqueous solution. However, the MES buffer produced considerable base line drifts in the immobilized system.

Electrolytes (NaCl, $KClO_4$) at concentrations 0.1–1*M* were used to evaluate the effect of ionic strength. No significant effect was observed below 0.5*M* electrolyte, while sensitivity decreased at concentrations above 0.5*M* (the fluorescence intensity of pyoverdin decreased less in the presence of Fe(III)). Temperature showed no significant influence on the sensor response when tested between 5 and 40°.

The flow-rate was varied from 0.5 to 5.0 ml/min to evaluate its effect on response time. The optimum flow selected was a compromise between time of pyoverdin Fe(III) contact and amount of iron passing through the cell. The reaction rate is extremely fast, as shown in Fig. 2. Thus, faster flow rates result in a greater slope because the effect of delivering more analyte overrides the effect of reduced contact time. An optimum flow of 5.0 ml/min was selected for further studies.

The bead surface is the active phase of our sensor and it must be periodically regenerated to regain the free pyoverdin. Different iron complexing agents, such as EDTA and 8-hydroxyquinoline and pH modifiers were tested for their regeneration efficiency, the regeneration effect of these complexing agents was slow because of the high formation constant of the pyoverdin–Fe(III) complex. In contrast, a low pH gave more promising results, 1*M* HCl was chosen as the optimum medium for regeneration since the analytical signal returned rapidly to the base line when it was used (Fig. 2).

The lifetime of the biosensor was at least three months, which was equivalent to about 1000 iron determinations. The analytical characteristics of the biosensor are shown in Table 2. The linear range, expressed as the slope of the response curve *vs* concentration, allows the determination of 10–200 ng/ml of Fe(III) with a coefficient of correlation of 0.997, the detection limit is 3 ng/ml and the relative standard deviation is about 3% for 10 determinations of 60 ng/ml of Fe(III). The interference study (Table 3) showed that none of the ions tested interferes seriously, which signifies that the biosensor is highly selective for iron(III). Notably, fluoride, a well-known complexing agent for iron, does not interfere at a concentration 100 times that of the iron.

Sample analysis

The proposed method using immobilized pyoverdin was applied to the determination of iron in tap and mineral water. Samples were analyzed without any special treatment; 1 ml of buffer was simply added to 5 ml of the water sample and was made up to 50 ml with deionized water. Determination was made as described in the "Procedure" section above.

The results obtained were compared with those provided by the ICP–AES reference technique (Table 4) and there were no

Table 4. Application of the biosensor to determine Fe(III) in different waters

Sample	Fluorimetric	ICP
Tap Water 1	0.36 ± 0.03 mg/ml	0.33 ± 0.04 mg/ml
Tap Water 2	0.26 ± 0.02 mg/ml	0.25 ± 0.03 mg/ml
Tap Water 3	0.22 ± 0.02 mg/ml	0.24 ± 0.03 mg/ml
Mineral water	0.08 ± 0.01 mg/ml	Below detection limit

significant differences at the 95% confidence level.

CONCLUSIONS

The proposed biosensor is sensitive and selective for iron and it has considerable advantages over methods based on pigment in solution; namely that a small amount of immobilized pyoverdin is sufficient for 1000 or more iron determinations and that the detection limit is three times smaller.

APPLICATION OF PHOTOCHEMICAL INHIBITION IN FLOW INJECTION SYSTEMS: DETERMINATION OF EPINEPHRINE AND *L*-DOPA

T. PÉREZ-RUÍZ, C. MARTÍNEZ-LOZANO, V. TOMÁS and O. VAL
Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, Murcia, Spain

Summary—An automated procedure for the photochemical determination of epinephrine and *L*-dopa has been developed. It is based on the strong inhibition by these catecholamines on the photochemical reaction between phloxin and ethylenediaminetetraacetic. The proposed flow-injection method allows the fluorimetric determination of epinephrine in the range 1.9–26.4 μg/ml and of *L*-dopa in the range of 1.5–12.7 μg/ml, with a sampling frequency of 35 samples/hr. The method was applied successfully to the determination of body catecholamines in pharmaceutical preparations.

Catecholamines are compounds with amines attached to a benzene ring bearing two hydroxy groups. The main sites of production of the catecholamines are the brain, chromaffin cells of the adrenal medulla and the sympathetic neurons. Epinephrine is the principal sympathomimetic hormone produced by the adrenal medulla in most species and occurs as the *L*-form in animals and man.

The determination of catecholamines in biological specimens normally requires the use of trace analysis techniques, mainly chromatography with fluorimetric or electrochemical detection.[1] In contrast, catecholamines in pharmaceutical preparations are present in relatively large amounts, and increasing efforts have been directed towards the development of simple and reliable analytical methods. Recently, spectrophotometric, fluorimetric, titrimetric, kinetic and photokinetic methods[2–9] have been widely used for the determination of catecholamines in pharmaceuticals. Some of these methods have been adapted to the stopped-flow technique and flow injection analysis.[10–13]

The last few years have seen a tremendous growth in the amount of research and the number of publications on the use of photochemical reactions in chemical analysis. This is not surprising if it is remembered that photochemical reactions have a number of favourable features not possessed by ordinary chemical reactions. For example, the reagent in photochemical reactions, the photon, can readily be changed by modifying the wavelength of the light used for irradiation, and by this means the selectivity of a reaction can be increased. The rate of a photochemical reaction can be influenced by regulating the intensity of the photon current. A further substantial advantage results from the fact that photochemical reactions are in general fairly sensitive and accordingly permit the determination of microcomponents.

Photochemical reactions have been applied to the determination of a large number of species using different approaches (kinetic methods, photochemical titrations, gravimetry, *etc.*) and reviews have already appeared on the results to date.[14–16] Many of the photochemical methods developed for batch analysis can be adapted to flow systems such as high performance liquid chromatography or flow injection analysis.[17]

The leuco-forms of thionine blue and thionine, generated through the photochemical reaction between these dyes and ethylenediaminetetraacetic acid, have been applied as reductive and chromogenic reagents for the determination of various oxidants using flow injection systems.[18,19] The amperometric determination of oxalate by the photochemical decomposition of ferrioxalate in the reaction coil or in the flow cell of the flow system has been reported.[20,21] Photochemical reactions coupled with flow injection systems have also been described for individual[22–24] and simultaneous[25] determinations of phenothiazine compounds, nitrite,[26] hydrogen peroxide,[27] organoarseni-

cals[28] and of the organic phosphorus in natural waters.[29]

The purpose of the present investigation was to develop a simple, sensitive and rapid assay for catecholamines (epinephrine and *L*-dopa) using a flow injection system coupled to a photochemical reaction. The method is based on the strong inhibition by catecholamines on the photoreduction of phloxin by EDTA, which is monitored by the fluorescence intensity of the dye.

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade and were used as received. Doubly distilled water was used throughout. Epinephrine and *L*-dopa stock solutions (1 mg/ml) were prepared from the Sigma product in 0.01*M* hydrochloric acid and stored frozen in a dark bottle before use. Working solutions were prepared daily from these solutions by diluting with doubly distilled water. Phloxin (tetrachlorotetrabromofluorescein, C.I. 45410) solutions were prepared by appropriate dilution of the stock solution (447 mg in 250 ml of distilled water) buffered at the desired pH with 0.10*M* phosphate buffer. EDTA solution, was prepared from Merck product (disodium salt) and adjusted to pH 6 with 0.2*M* sodium hydroxide.

Apparatus

A Hitachi F 3010 spectrofluorimeter equipped with a plotter unit was used for recording spectra and a Perkin-Elmer 3000 spectrofluorimeter connected to a Linseis 6512 recorder was used as the detector with a Hellma 176.052 QS flow cell (inner volume 25 μl). The irradiation was performed with an Olimpus Europe illumination device, which was equipped with a halogen quartzline lamp (General Electric, 20 V, 150 W) and optical fibers to guide the light from the lamp to the reaction coil (PTFE tubing, 0.5 mm i.d.).

The spectrofluorimeter parameters were: $\lambda_{ex} = 530$ nm, $\lambda_{em} = 543$ nm, excitation slit = 5 nm and emission slit = 5 nm.

RESULTS AND DISCUSSION

Basis of the method

When a solution containing phloxin (Ph) and EDTA in the absence of oxygen is irradiated with white light at a suitable pH, photoreduction of the dye occurs and the pink colour disappears:[30]

$$Ph_{ox} + EDTA \xrightarrow{h\nu} Ph_{red} + \text{EDTA oxidation products}$$

In the presence of epinephrine or *L*-dopa the rate of the photochemical reaction is strongly decreased, and this change can be measured by the fluorescence of phloxin. Figure 1 illustrates the excitation and emission spectra for a sample without irradiation (curve 1) and another irradiated for one minute in the presence (curve 2) and absence (curve 3) of epinephrine. The fact that epinephrine inhibits the photoreduction of phloxin by EDTA is shown by the fact that the change in the fluorescence intensity is much smaller in its presence.

At a fixed irradiation time, there was a linear relationship between epinephrine or *L*-dopa concentration and the fluorescence intensity of the photolyzed solution. This is the basis of the proposed method for the determination of these catecholamines.

Configuration designs

The flow injection configuration used for the determination of epinephrine and *L*-dopa was so designed to provide different reaction conditions for magnifying the inhibition effect of these two analytes on the photochemical reaction between phloxin and EDTA. Three different configurations were tested for this purpose (Fig. 2).

In configuration I, the sample and phloxin

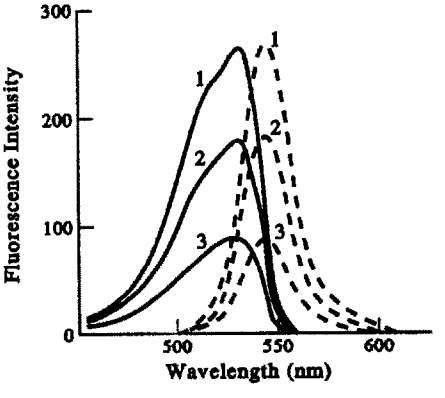

Fig. 1. Inhibiting effect of epinephrine of the photoreduction of phloxin by EDTA. Excitation spectra (solid line); emission spectra (broken line). Phloxin, $6 \times 10^{-6}M$; EDTA, 0.05*M*; phosphate buffer (pH 6.0), 0.01*M*. 1 = Without irradiation. 2 = Irradiation time, 1 min; epinephrine, 6.6 μg/ml. 3 = Irradiation time, 1 min; without epinephrine.

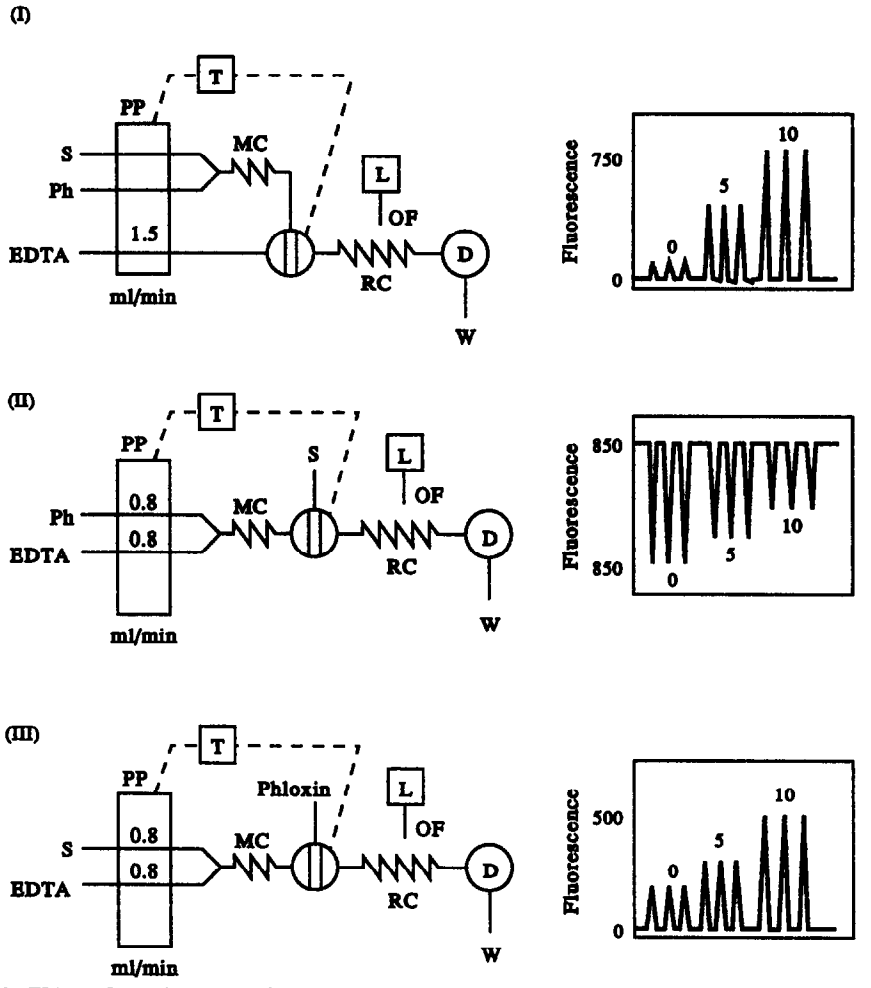

Fig. 2. FIA configurations tested for the determination of epinephrine and *L*-dopa. PP = peristaltic pump (with flow-rates given in ml/min); MC = mixing coil; RC = reaction coil; L = light source; OF = optical fibre; D = detector; W = waste; S = sample. Dashed lines represent synchronous control line. The values on the peaks are concentrations of epinephrine in μg/ml.

solutions were mixed before injection into the EDTA stream.

In configuration II, the reagents (Ph and EDTA) were propelled by two separate lines and mixed within the flow system prior to sample injection.

Configuration III was a reverse mode, the sample and EDTA streams being mixed before the injection of phloxin.

In all configurations, the sample and reagent solutions were de-aerated by bubbling argon through them, in order to minimize the presence of oxygen in the systems.

A laboratory-built timer was used in all cases to control the pump and the injection valve. The timer was programmed so that after 15 sec, when the sample zone was in the reaction coil (PTFE tube, 0.5 mm i.d.), the flow was stopped. The sample plug was then irradiated by the halogen lamp, after 25 sec of irradiation the pump was triggered by the timer and the sample zone was directed towards the detector.

Configuration I was finally chosen as it provided the greatest sensitivity and the fastest restoration of the baseline.

Optimization of manifold parameters

The variables studied were volume injected, length of the reactor, flow-rate and time of irradiation. The concentrations used in these experiments were as follows: EDTA line, 0.1*M*; phloxin line, $5 \times 10^{-5}M$ Ph and 0.1*M* phosphate buffer pH 6; sample solution $3 \times 10^{-5}M$. The mixing ratio between phloxin line and sample line was always 1:1. The manifold parameters used in the optimization procedure were a reactor of 150 cm × 0.5 mm i.d. and an irradiation time of 30 sec.

The volume injected was varied between 35 and 250 μl. The difference in peak heights between the sample and blank increased with increasing volumes injected up to 185 μl, above which it remained virtually constant. The volume chosen was 185 μl.

The reactor length selected was 200 cm; 100 cm of which was irradiated. To obtain as high a sensitivity as possible, the reactor was coiled around a glass tube (1 cm of diameter) and placed over a mirror; the end of the optical fibre was situated at a distance of 0.3 cm from the reactor.

Although the light source generated very little heat, a fan was used so that the temperature of the reactor was constant.

Flow-rates over the range 0.8–2.5 ml/min did not affect the analytical signal. A flow-rate of 1.5 ml/min was chosen.

Special attention was paid to the influence of the irradiation time on the analytical signal. Different irradiation times were achieved in two ways: (a) by using different length for the PTFE tube irradiated with an extended light source; (b) by stopping the peristaltic pump when the sample was located in the reaction coil and irradiating with a quasi-point light source. The last arrangement provided the best sensitivity and speed and was chosen for further experiments.

Figure 3 shows the influence of the irradiation time on the development of the photochemical reaction in the absence and presence of epinephrine. An exposure time of 25 sec was sufficient to obtain the maximum difference in peak height between the sample and blank (without catecholamine).

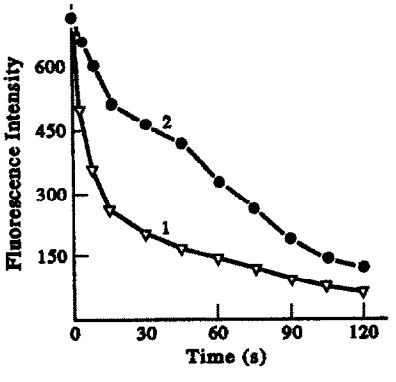

Fig. 3. Influence of irradiation time. Curve 1: Without epinephrine. Curve 2: [epinephrine] = 6.6 μg/ml.

Optimization of reagent concentration

The rate of photoreduction of Ph by EDTA and the inhibition by epinephrine and *L*-dopa on this photochemical reaction are very much pH-dependent.[30] A pH value of 6.0 gives a high degree of inhibition and a fast photochemical reaction.

The effect of EDTA concentration was studied in the range 0.04–0.2*M*. The rate of the photochemical reaction in the absence and presence of catecholamine increased with increasing EDTA concentrations up to 0.09*M*, above which it remained virtually constant. A 0.1*M* EDTA solution adjusted to pH 6.0 with 0.2*M* sodium hydroxide was used as carrier.

The peak height obviously increased with increasing pH concentration for the blank solution and analyte. However, the difference between them was found to increase with floxin concentration up to $4 \times 10^{-5}M$ and to be constant at higher concentrations. A $6 \times 10^{-5}M$ solution buffered at pH 6.0 with 0.1*M* phosphate buffer was selected in order to obtain a wide concentration range in the determination of the analyte.

Calibration graph and reproducibility

A series of standard solutions were pumped in triplicate to test the linearity of the calibration graph. The calibration graph was linear from 1.9 to 26.4 μg/ml with a correlation coefficient of 0.9998 for epinephrine and from 1.5 to 12.7 μg/ml with a correlation coefficient of 0.9989 for *L*-dopa. The sample rate was about 35 samples/hr. The statistical study performed on 10 samples of triplicate pumping of 3.3 μg/ml of epinephrine and of 1.9 μg/ml of *L*-dopa yielded relative standard deviations of 0.96% and 0.59%, respectively.

Interferences

The influence of foreign compounds that commonly accompany epinephrine and *L*-dopa in pharmaceutical preparations was studied by preparing solutions containing 3.0 μg/ml of the catecholamine and increasing concentrations of the potential interferent up to 300 μg/ml or by adding an amount to give an error of $\pm 3\%$. The errors were determined by comparing the peaks given by a solution of analyte containing no foreign substance. Glucose, sucrose, lactose, citrate and tartrate were tolerated in large amounts (100-fold excesses were the maximum ratio tested) and 50-fold excesses of antipyrine,

§Prepared by dissolving the capsule in 25 ml of distilled water.

pilocarpine and hydrogen sulphite were also tolerated in the determination of epinephrine and L-dopa.

Analysis of pharmaceutical preparations

The proposed method was applied satisfactorily to the determination of epinephrine and L-dopa in pharmaceutical preparations. Commercially available formulations were analysed and the results obtained are summarized in Table 1. As can be seen, for all the formulations the assay results were in good agreement with values for the nominal contents and with those obtained using the fluorimetric method based on the formation of the hydroxyindol derivatives.[1,31] The recoveries obtained to add epinephrine or L-dopa to each pharmaceutical formulation are shown in Table 2.

CONCLUSIONS

The results presented in this work clearly demonstrate that the inhibition of a photochemical reaction which takes place in a flow-injection assembly has great analytical potential for the determination of the inhibitor. The main advantages of this procedure are: on the one hand, the selectivity and sensitivity brought about by the photochemical reaction and on the other the rapidity, ease of automation and low sample and reagent consumption resulting from the flow injection system.

The phloxin–EDTA system was used to check the viability of the proposed method in the determination of epinephrine and L-dopa using fluorimetric detection.

E. RUBÍ, M. C. MEJUTO and R. CELA*
Department of Analytical Chemistry, Faculty of Chemistry, University of Santiago de Compostela, Santiago, Spain

Summary—A rapid method for speciation and determination of organomercury compounds in biological samples of marine origin using Capillary Electrophoresis (CE) is reported. Organomercurials were extracted from the samples by means of the classical Westöö procedure thus giving organomercury–cysteine complexes which can be separated from each other by means of CE resulting in effective speciation. Electrophoretic separation was achieved in an open silica capillary tube at 15–18 kV using a 100m*M* sodium borate buffer (pH 8.35). All mercury species were distinctively separated within 12 min. Results are presented for the analysis of real marine samples and reference materials, and compared with those obtained by the GC commonly accepted procedure.

Many studies[1] have reported that organic mercury forms, especially the methylated forms, are considerably more toxic than the inorganic ones. In fact, methylmercury is considered to be one of the most dangerous chemical species in the environment because of its intrinsic toxicity and availability to living organisms. However, the analytical measurement and speciation of organomercurials in complex natural world samples remains a very difficult problem with two main requirements: high selectivity and very low detection limits. Moreover, since high levels of methylmercury have been found in various marine organisms, especially in large predators (tuna, swordfish, *etc.*) analytical methodology for methylmercury must be at the same time fast, low in cost and reliable for use in the routine analysis of biological and environmental samples.

During the last few decades several procedures have been proposed for these purposes[2–15] but the most frequently used approach is the gas chromatography separation of the halogen derivatives of organomercurials with electron capture detection[4,16–20] based on the classical Westöö's method[4]. On the other hand, several papers[17,21–23] have focused on the drawbacks of these gas chromatographic procedures. In fact, the lack of consistent reproducibility, the tailing of peaks, the absorption of variable amounts of the organomercurial compounds in the GC-system and the need of special column conditioning or priming with inorganic mercury salts and related consequences in the analysis of real samples (dead times of operation, doubts about the real nature of the compound detected after the priming, frequent drop-out of the peaks, *etc.*) as well as in the life of the columns and detector itself, has led to search for alternative procedures to carry out the organomercurials analysis on a more reliable basis. Recently[24] some of these drawbacks have been overcome by means of the use of special narrow bore chromatographic columns.

Capillary electrophoresis has demonstrated in recent years powerful capabilities for the resolution and analysis of very complex samples.[25] Although several papers[26] were dealing with the separation of inorganic ions and neutral or charged complexes of metals, this technique had so far limited application for speciation studies.[27] The high resolution and peak capacity characteristics of this technique could be used favourably in speciation studies for very complex samples. However, since the time needed for separation is usually very short in this technique, having full possibilities in automation, it can be easily used for routine analysis.

In this paper, a procedure is presented for speciation of organomercurials and the quantitative determination of methylmercury in

*Author for correspondence.

marine samples by means of capillary electrophoresis. Cysteine has been used to complex organomercurials according to the classical extraction method of Westöö.[4] The resulting cysteine-organomercury complexes were well separated in an electric charge density, using an alkaline buffer. Parameters affecting the separation have been optimized and the results for some types of marine samples as well as for an existing reference material has been compared with those obtained by the usual gas chromatographic method.[19]

EXPERIMENTAL

Reagents

All reagents used were HPLC or analytical grade. Ultrapure water was obtained by means of a MilliQ system (Millipore Co.). Mercury(II) chloride, methyl, phenyl and ethyl-mercury chlorides (Merck) were used as calibrants. A stock solution (1.00 g/l.) in methanol was used to obtain weekly standards by suitable dilution with methanol:water (1:1). All the organomercury solutions were protected against light and stored at 4° in the dark when not in use.

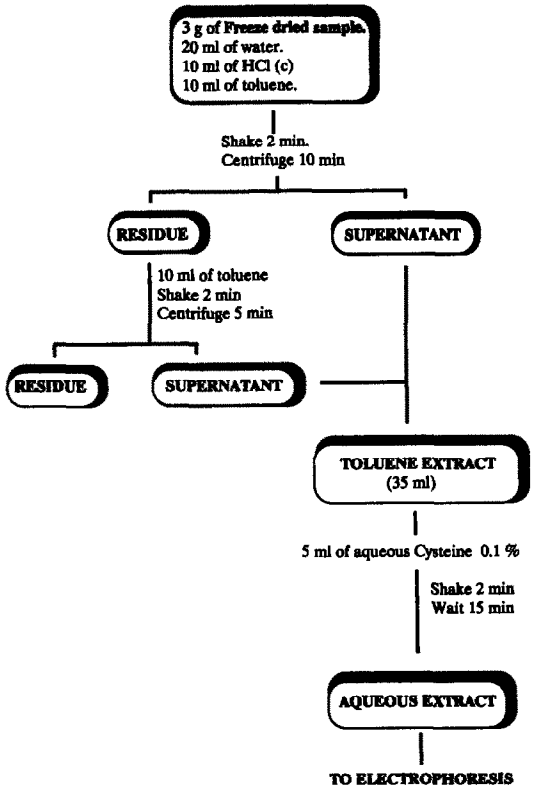

Fig. 1. Sample preparation scheme for methylmercury determination.

Aqueous cysteine chlorhydrate was used instead of cysteine acetate solution recommended by Westöö.[4] Buffers were prepared with boric acid and sodium hydroxide to pH 8.35. Aqueous cysteine and the buffer containing sodium dodecyl sulfate were prepared weekly and stored at 4° when not in use.

Standards

Standards for injection containing one or more organomercurials were prepared by mixing 400 μl of the appropriate standard solution of each organomercurial and 100 μl of 1% aqueous cysteine solution.

Preparation of samples

Samples were prepared in the way outlined in the scheme of Fig. 1 which essentially agrees with the Westöö procedure.[4] Final aqueous extracts were subjected to capillary electrophoresis separation.

Capillary electrophoresis

High performance capillary electrophoresis was carried out at 30° in a 75-μm (i.d.) 50-cm long fused silica capillary (window at 5 cm) using a PACE system 2050 (Beckman). Samples were introduced into the capillary by pressure injection over 8.6 sec (corresponding to a volume of 77.4 nl). Electroendosmosis was toward the cathode at 18 kV in a 100mM sodium Borate buffer (pH 8.35) during 12 min. UV detection at 200 nm and a System Gold (Beckman) equipment were used for detection, data acquisition and processing.

The capillary was daily prepared by flushing with 0.5M sodium hydroxide for 10 min, followed by a 10-min rinse with ultrapure water. A typical run consisted of a 2-min washing period with ultrapure water, followed by 3 min of capillary reconditioning with the selected buffer.

RESULTS AND DISCUSSION

Buffer selection

The pH of the buffer used to carry out the electrophoregram, was usually the most important operational parameter. For cysteine, the isoelectric point was 6.24 thus, in alkaline media, complexes formed by cysteine with organomercurials were charged negatively. As can be seen in Fig 2(a), using a 100mM borate buffer (pH 8.35) it was possible to separate the cysteine–methylmercury complex from the excess of ligand. Also a small peak having a

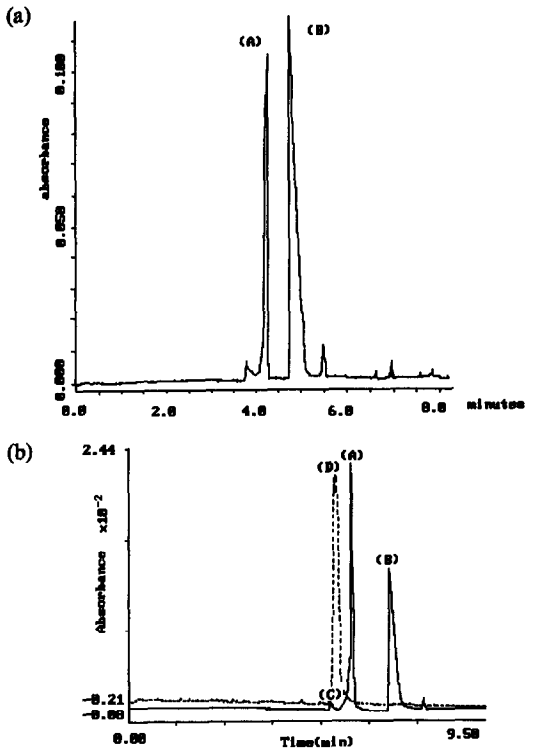

Fig. 2. Separation of cysteine complexed methylmercury and the cysteine excess by CE. a) Applied potential 20 kV, 100m*M* borate buffer (pH 8.35), 10% methanol. 13.5 μg of methylmercury chloride mixed with 1% aqueous cysteine, 27 nl injected. b) Same conditions as for a) but an injection of 27 nl of methylmercury chloride standard have been superimposed (dotted line). Key for peaks: (A) methylmercury–cysteine complex; (B) excess cysteine; (C) unknown; (D) uncomplexed methylmercury.

retention time lower than the one of the complex was observed. Since the standards for injection were prepared simply by mixing adequate solutions of methylmercury and cysteine just before the injection it was possible that this small peak would correspond to the not complexed form neutral methylmercuury. This hypothesis was confirmed by comparison with the behaviour of methylmercury alone (no cysteine added) as shown in Fig. 2(b). These data were in accordance with the electroendosmosis theory for alkaline media. In the same way the elution order of the complex and the free ligand form were according to the number of negative charges corresponding to the molecules:

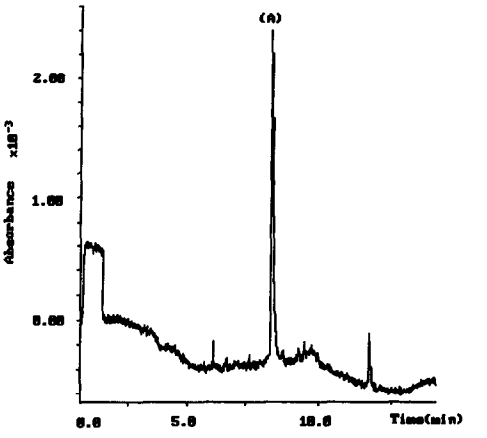

Fig. 3. Separation of cysteine complexed methylmercury in acidic buffer (100m*M* phosphate buffer pH 2.5, 10% methanol). Applied potential 20 kV, 13.5 μg of methylmercury chloride mixed with 1% aqueous cysteine. (A) methylmercury peak.

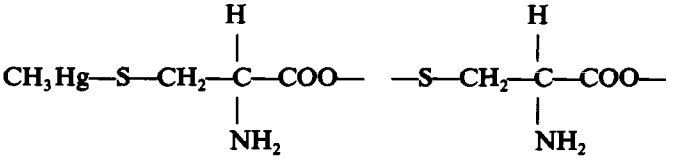
It was possible to obtain separations using media of pH lower than the isoelectric point. Experiments were carried out using a phosphate buffer (pH 2.5). However, as shown in Fig. 3, the peaks obtained were much less intense. In fact, the electrophoregram in Fig. 3 corresponds to the same standard solution as the one in Fig. 2 but the absorbance scale is 20 times greater. In this case the use of acidic buffers resulted in poor sensitivity.

The use of the borate buffer (pH 8.35) enabled the separation of the three organomercurials to be achieved as shown in Fig. 4. In alkaline media the (1:2) mercury(II)–cysteine complex had two negative charges which meant that inorganic mercury appeared to the right of the free cysteine peak in the electrophoregram. The order of elution was ethyl, methyl and phenylmercury. Decreasing the applied potential (up to 10 kV) did not improve the resolution of ethyl–methyl mercury pair. For phenylmercury, the contribution of the aromatic ring to the absorbance led to a greater sensitivity as compared to the others.

The influence of variable concentrations of a micellar agent [sodium dodecyl sulphate (SDS)] in the borate buffer was also studied, trying to



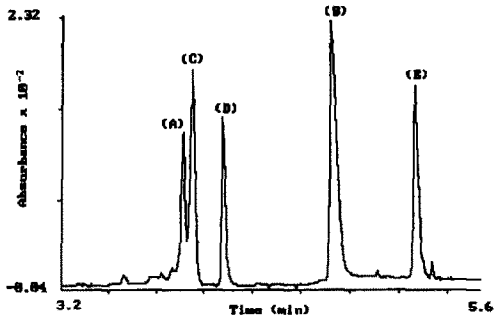


Fig. 4. Speciation of mercury forms complexed with cysteine, 1.5 μg methylmercury, 1.5 μg ethylmercury, 0.4 μg phenylmercury and 0.3 μg mercury(II) mixed in proportion 1:4 with 0.1% aqueous cysteine; 27 nl injected. Applied potential 15 kV, 100m*M* borate buffer (pH 8.35), 10% methanol. (A) ethylmercury; (B) excess cysteine; (C) methylmercury; (D) phenylmercury and (E) inorganic mercury.

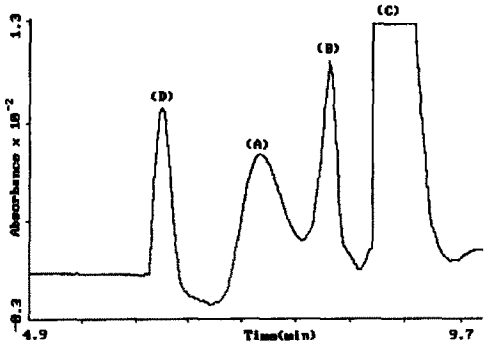

Fig. 5. Speciation of organomercurials in alkaline buffer containing SDS. Applied potential 15 kV, 100m*M* borate buffer (pH 8.35), 10% methanol, 25m*M* SDS. (A) methylmercury; (B) phenylmercury; (C) cysteine excess and (D) ethylmercury.

improve the resolution of the ethyl–methylmercury pair. However this possibility was discarded owing to the fact that the peaks appeared broader and with lower area values while no significant improvement in overall resolution was achieved. In Fig. 5 it can be seen that the methyl–ethyl pair was somewhat better resolved but in this case a significant overlap between methyl and phenyl peaks took place. Moreover, from a practical point of view, the inclusion of SDS into the buffer meant that it could not be used for more than 2–3 days. On the contrary a simple borate buffer remained usable during weeks.

Signal linearity

The relationship between the amount of methylmercury injected and peak area in the electrophoregram showed good linearity (correlation coefficient 0.9974, R-squared = 99.48% with a standard error of estimate of 4.39×10^{-3}) in the range 12–300 pg. The detection limit was 10 pg in the conditions described in the Experimental section for a signal to noise ratio of 10:1. Data for repeatability (retention times and peak areas) for five successive injections of a methylmercury standard (11.2 ng injected) were: average retention time = 4.28 ± 0.01 seconds; variation coefficient = 0.3% and, average peak area (arbitrary units) = 4.76 ± 0.10; variation coefficient = 2.1%. These data also indicated that the procedure sequence (programmed prerinse, *etc.*) were adequate for practical purposes. In Table 1 some data of reproducibility for several standard solutions of methylmercury determined in different days (one measurement each day) are listed. It is observed that variation coefficients were very similar with those of repeated injections, hence the ruggedness of the procedure was considered to be good.

Analyte recovery

Table 2 summarizes the results for recovery of methylmercury along the proposed procedure. For these experiments a freeze dried mussel tissue sample was used. This sample did not give any detectable signals for methylmercury nor for inorganic mercury so, it was considered as a matrix-blank sample. A 1.00-g sample of this material was used in the experiments adding variable amounts of a methylmercury standard in water. Once homogenized and dried, the resulting material was analyzed by means of the proposed procedure. Simultaneously the same

*Mussel means a freeze-dried mussel tissue sample having a non-detectable level of mercury; blank means the absence of biological material in the experiments.

standard solutions used for spiking the mussel sample were extracted and analyzed. Thus the only difference between the rows in Table 2 labelled as "sample" and those labelled as "blank" is the presence or absence of the biological matrix. The results in Table 2 indicate that important losses took place during the extraction process. Only 72% of the methylmercury initially present is extracted. Furthermore, the results of a two-way ANOVA carried out on the data in Table 2 indicated a significant effect of the matrix in the methylmercury recovery. This effect can be explained by considering the formation of persistent scums in the extraction stages which hampered correct phase separation. Taking this into account, the recovery for methylmercury in real samples by the proposed procedure was 64.7 ± 3.1%.

Analysis of real samples

The initial experiments with real samples were carried out using a 1% cysteine acetate solution as back-extractant, because this is the usual concentration used in the gas chromatographic method.[4] Soon, it was observed that this excess of cysteine hampered the effective separation of the methylmercury complex from the free ligand when methylmercury concentration in the samples was low. This effect was provocated not only by the relative size of both peaks but it is believed that the excess of free ligand blocked-out or saturated the walls of the capillary tube giving poor separations. After a series of experiments, it was demonstrated that the use of a 0.1% solution of cysteine chlorhydrate allowed to complexation of all the organomercurials in the samples without impairing the peak separation.

It was noted that one artifact occurred when analyzing real samples. This consisted of a gross peak at a retention time lower than the corresponding one for methylmercury. As shown in Figs 6 and 7, this peak did not overlap with that of methylmercury, so in most cases it was not necessary to take any special precaution. In any case, this unknown compound has a lifetime of about 10 hr, so, if the extracts were left to stand for some hours in a dark cool place before the analysis, the artifact peak almost disappeared (see Fig. 7) enabling a more easy and accurate integration of the methylmercury peak which area did not change in this time. Although we have observed this artifact in all the real samples analyzed, we are not sure that it was present in other types of samples. Table 3 summarizes some of the results obtained for real samples

using the proposed procedure. These results are compared in this table with the ones obtained by means of the usual gas chromatographic procedure[19] for the same samples. It can be seen that the results for CE analyses were systematically lower than those obtained by gas chromatography for which no cysteine back-extraction was carried out. This is because of the aforementioned losses in the back-extraction stage with cysteine. When the results for CE analyses were corrected for these losses (last column in Table 3) the obtained data were in good agreement with the gas chromatographic ones as well as with certified values for the reference material analysed.

CONCLUSIONS

Up to this date, capillary electrophoresis has been only used in a very limited extent in speciation studies. The presented results shows that this technique could be used as a powerful tool in the separation of several organometallic forms in biological and environmental samples. Even more, separations could be understood on the basis of a well-established background without the need for special or sophisticated separation schemes. In the particular case of organomercurials speciation, the use of capillary electrophoresis avoids the drawbacks associated with gas chromatographic procedures and is rapid, and simple enough to be used on a routine basis.

VOLTAMMETRIC DETERMINATION OF PIROXICAM IN MICELLAR MEDIA BY USING CONVENTIONAL AND SURFACTANT CHEMICALLY MODIFIED CARBON PASTE ELECTRODES

J. A. ACUÑA, C. DE LA FUENTE, M. D. VÁZQUEZ, M. L. TASCÓN and P. SÁNCHEZ-BATANERO
Department of Analytical Chemistry, Faculty of Sciences, University of Valladolid, Valladolid, Spain

Summary—A method for piroxicam determination based on adsorptive stripping voltammetric techniques, using conventional and chemically modified carbon paste electrodes in micellar media, is described. The employed surfactants were sodium dodecyl sulfate (SDS), Triton X-100, Triton X-405, Tween 80 and Brij 30. However, the purpose of this paper is, at present, to research the use of surfactants as carbon paste modifier because one of the mechanisms of hydrophobic drugs ad-accumulation on the carbon paste electrode is based on the chemical affinity. Besides, because of the water piroxicam insolubility, a special aqueous medium, such as a surfactant solution above its c.m.c. was used, this micellar media being very advantageous in relation to the use of organic or aqueous-organic media, in order to dissolve the studied drug and to remove the problems derived from the organic solvents use. In addition, a piroxicam ad-accumulation increase, on surfactant modified carbon paste electrode, with the surfactant mass incorporated into the electrode, was observed.

Piroxicam is a new non steroidian anti-inflammatory drug of the oxicam family that are carboxamic *N*-heterocycles derived from the benzothiazin-1,2-dioxyde-1,1. This drug acts as anti-inflammatory mainly by prostaglandin synthesis inhibition, as well as by leucocyte migration and phagocyte activity inhibition.[1]

Due to its hydrophobic properties, piroxicam molecule is quite insoluble in water, but soluble enough in organic and aqueous-organic media[1] as well as in micellar media.[2]

Regarding the electrochemical properties, piroxicam is polarographically reducible[1] and voltammetrically oxidizable.[1,2] Both processes have been sufficiently studied.[1,3–5]

On the other hand, regarding piroxicam determination methods, we can consider the spectrometric ones,[6,7] with detection limits of several ppm, the chromatographic ones,[8–14] with detection limits of several ppb and finally the electrochemical ones[15,16] with detection limits of several ppt.

All piroxicam electroanalytical methods require the presence of organic solvents because of its insolubility in water. The use of non-aqueous solvents in electrochemistry presents different problems, mainly derived from their toxicity, as well as from the necessary use of special reference electrodes. However, surfactant solutions with concentrations above a critical value (CMC), are able to dissolve hydrophobic substances, remaining in this these media their aqueous nature, therefore, we can employ the classical reference electrodes, such as Hg_2Cl_2/Hg, KCl or AgCl/Ag, KCl.

Use of surfactants in electrochemistry is well known, mainly by their polarographic maxima suppressor properties.[17,18] Nevertheless, when surfactant concentrations are above the c.m.c., we must consider this type of solution belongs to a new type of media, organized media, about which many reviews and books have appeared some years ago in the literature.[19–23]

The most important effects of micellar media in relation to electrochemistry are based on the following aspects[23]: (a) the presence of surfactant molecules in an aqueous solution modifies the double layer structure, the electrokinetic potential, and the charge transfer rate constant, and as an example we can mention the Iwunze *et al.* paper,[24] in which a very important potential shift of the medium oxidation is described; (b) surfactants can stabilize radicals or intermediate reaction products; (c) surfactants easily dissolve hydrophobic substances. Thus, the electrochemical spectra of an analyte in two different media, one fully aqueous and the other of micellar nature, can be completely different.

In our paper, several experiments about the piroxicam electrochemical behaviour study in micellar media, formed by an anionic surfactant, such as sodium sulfate dodecyl (SDS), or by non-ionic ones, such as Triton X-100, Triton X-405, Tween 80 or Brij 30, were carried out, in order to contribute to the best knowledge of surfactant-drug interactions, this knowledge being of great interest, because, actually, in human biological fluids, hydrophobic substances, as for example, cholesterol bonded to lipoproteins in the blood, are carried in the same manner.

Finally, we can consider that, according to the literature checked by us, the use of surfactants as carbon paste modifier has not been very general. Kalcher[25] and Albahadily and Mottola,[26] observed an uncompensed cell resistance decrease after the carbon paste electrode was treated with a 10% (w/v) aqueous surfactant solution, although in this case surfactants were not incorporated at the carbon paste formation step, but after the paste was prepared. We can also mention the papers of the Patriarche's group about the carbon paste modification by chemical substances like the surfactants, such as phospholipids and others.[27,28]

EXPERIMENTAL

To obtain the current–potential curves, an Amel 553 Potentiostat, an Amel 568 Function Generator and a Philips-PM 8271 XYt recorder were employed. A carbon paste working electrode, a saturated calomel reference electrode and a Pt wire as auxiliary electrode, were used. To obtain rapidly suitable micellar media, a Selecta Ultrasonic bath was also used. To control the temperature and the pH, a Tamson TC-3 Thermostat and a Crison pH-meter respectively, were employed.

All used surfactants, such as Triton X-100, Triton X-405, Tween 80, Brij 30 and SDS were supplied by Serva Feinbiochemica GMBH & Co., D-6900 Heidelberg, Germany, and used without purification. Piroxicam was supplied by Pfizer (Spain). All these reagents, buffers, supporting electrolytes, *etc.*, were of analytical grade. The employed water was deionized up to Nanopure II grade by the Barnstead system. The graphite powder, spectroscopically pure and particle size corresponding to 200 mesh, was supplied by Johnson Matthey S.A., Rue de la Perdrix, BP 50240, Paris, France.

Conventional carbon paste (without modification) was classically prepared, but surfactant modified carbon paste was prepared as follows: 500 mg of graphite were mixed with 250 or 300 μl of Nujol oil. To this mixture, 25 mg (or 50 mg) of surfactant dissolved in chloroform were added and mixed with the paste in an agate mortar, when an electrode modification was required.

With a conventional carbon paste electrode, two types of experiments were carried out: (1) direct voltammetry of piroxicam solutions; (2) adsorptive stripping voltammetry of piroxicam solutions. In all adsorptive experiments we must cut a paste disk about 1 mm thick to obtain a fresh and reproducible electrode surface.

With the surfactant modified carbon paste electrode only adsorptive stripping voltammetric measurements were carried out.

For the first type of experiments, the following solution was prepared: 10 ml of 0.1M $HClO_4$ (to obtain a pH 2), 1 ml of 0.1M $LiNO_3$, 1.54 g of SDS, 16.6 mg of piroxicam and deionized water to make 100 ml. This solution was $5 \times 10^{-4}M$ in piroxicam and $4 \times 10^{-2}M$ in SDS.

For the second type of experiments, the following solutions were prepared: (1) 25 ml of 0.1M $HClO_4$, 2.163 g of SDS, 8.3 mg of piroxicam and deionized water to make 250 ml. This solution, named "adsorption solution" was $3 \times 10^{-2}M$ in SDS and $10^{-4}M$ in piroxicam; (2) 3 ml of 0.1M $HClO_4$, 0.3 ml of 0.1M $LiNO_3$ and deionized water to make 30 ml. This solution was named "stripping solution".

RESULTS AND DISCUSSION

Direct voltammetry of piroxicam solutions

With the $5 \times 10^{-4}M$ piroxicam solution, the potential was cyclically scanned between 0 and 800 mV (*vs* SCE) at different scan rates, the optimal one being 100 mV/sec, as a result of a choice of residual current, peak height and recorder sensitivity values. Peak potentials of the voltammograms obtained were developed between 650 and 660 mV, as can be seen in Fig. 1, in which a well-defined piroxicam oxidation peak is shown.

In order to evaluate our method, several voltammograms of piroxicam solutions at different concentrations were obtained. By plotting i_p *vs* concentration, a straight line was also obtained, with equation:

$$i_p = 0.067 + 3612.67\ C$$

where i_p denotes the peak heights in μA and C denotes the molar piroxicam concentration. The correlation coefficient was 0.9981 and the detection limit 6.14 ppm. A linear variation of i_p *vs* piroxicam concentration was obtained, the sensitivity of the determination was acceptable but the detection limit, calculated by Miller and Miller's method,[29] was mediocre.

Adsorptive stripping voltammetry of piroxicam solutions

A previous adsorption process of piroxicam was carried out. For this, a new experimental parameter, ad-accumulation time, needed to be studied. For this, we introduced the carbon paste electrode, at open circuit, in a $10^{-4}M$ piroxicam solution (adsorption solution), at pH 2 and $3 \times 10^{-2}M$ SDS, over different times, while stirring. After a fixed ad-accumulation time, we introduced the electrode, washed with deionised water, in the stripping solution and scanned the potential at a scan rate of 100 mV/sec. The results obtained with the same paste, but different surfaces (cutting discs 1 mm thick), were practically the same, and very similar between different paste batches. Figure 2 shows an example of a peak obtained.

By plotting the peak heights *vs* ad-accumulation time, a straight line was obtained, in which i_p increased with the ad-accumulation time up to 11 min, and then decreased with time, as shown in Fig. 3.

Although the optimal value should be achieved in 10 min according to Fig. 3, the employed ad-accumulation time was only 7 min to save time in our experiments.

In order to evaluate the sensitivity of our adsorptive stripping method, by plotting i_p *vs*

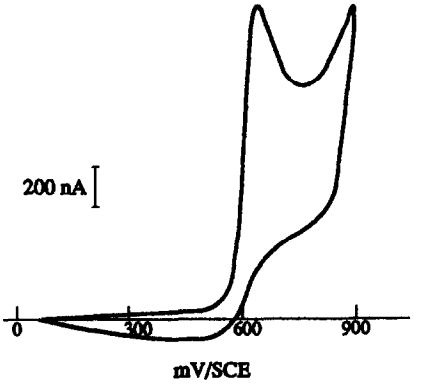

Fig. 1. Voltammogram of $5 \times 10^{-4}M$ piroxicam obtained at a conventional carbon paste electrode; V = 100 mV/sec; pH 2; $0.01M$ $LiNO_3 + 4.10^{-2}M$ SDS.

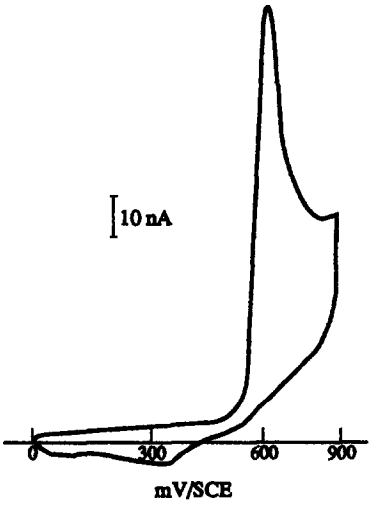

Fig. 2. Adsorptive stripping voltammogram of $10^{-4}M$ piroxicam at a conventional carbon paste electrode; V = 100 mV/sec; t_{ad} = 6 min; pH 2.

piroxicam concentration, a straight line was obtained, with equation:

$$i_p = 0.00346 + 1791.51\ C$$

where i_p denotes the peak heights in μA and C the molar piroxicam concentration. The correlation coefficient was 0.9993 and the detection limit 0.127 ppm, calculated by the method mentioned above.

Comparing Figs 1 and 2, taking into account the recorder sensitivity and the piroxicam concentration, we can deduce that i_p in Fig. 2 is lower, even though accumulation was used. This apparent anomaly can be explained by remembering that the experiment corresponding to

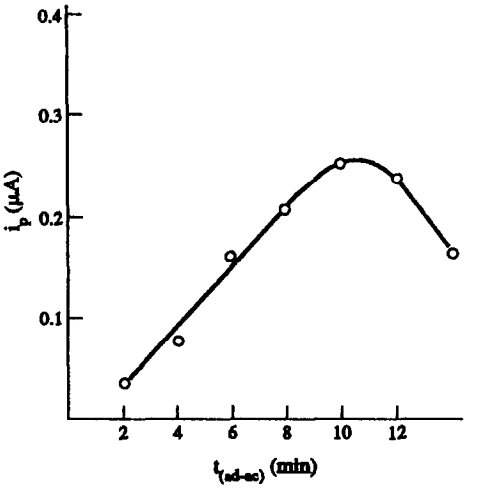

Fig. 3. Influence of ad-accumulation time on piroxicam adsorptive stripping peaks at a conventional carbon paste electrode; $10^{-4}M$ piroxicam; V = 100 mV/sec; pH 2.

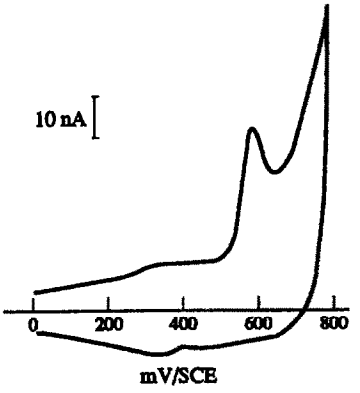

Fig. 4. Adsorptive stripping voltammogram of $10^{-5}M$ piroxicam solution at a conventional carbon paste electrode; $t_{ad} = 7$ min; pH 2; V = 100 mV/sec.

Fig. 2 was carried out to give an example, showing that a piroxicam preconcentration phenomenon can be produced on a conventional carbon paste electrode. Also, the voltammetric peaks in Figs 1 and 2 correspond to very different mechanisms, the first one diffusion and the second adsorption, which also has a lower slope than the first. The adsorption process has the advantage of giving lower detection limits. However, improved detection limits have not been obtained because piroxicam, at lower concentrations, does not readily adsorb on conventional carbon paste electrodes.

The voltammogram of $10^{-5}M$ piroxicam solution is shown in Fig. 4.

Adsorptive stripping voltammetry of piroxicam on surfactant modified carbon paste electrodes

In this case, the carbon paste electrode was previously modified by a surfactant, such as SDS, Triton X-100, Triton X-405, Tween 80 or Brij 30, in order to obtain an electrode surface with hydrophobic properties, so as to improve the piroxicam preconcentration. So, if the electrode surface contain a chemical modifier with the same chemical character than the analyte molecules, an attraction by chemical affinity is created between the two types of molecules, according to the literature.[27,28] Moreover, the electrochemical reactions were carried out in micellar media at a suitable pH, in order to dissolve the piroxicam and to improve its preconcentration on the electrode surface. In addition, the presence of surfactants could improve the selectivity of these preconcentrations, although, in our case, this point has not been studied, because only one drug was considered in this paper.

Our experiments have been carried out as follows.

Voltammetric study on carbon paste electrode modified with sodium dodecyl sulphate

A 500-mg sample of graphite powder was well mixed with 300 μl of Nujol oil in an agate mortar. To this mixture, 25 mg of SDS as modifier, solved in chloroform, were added and mixed up to evaporate the solvent, to obtain a paste with 5% concentration (surfactant/carbon).

The ad-accumulation time and potential scan steps were carried out as above.

In order to estimate the sensitivity of our adsorptive stripping method, i_p *vs* piroxicam concentration was plotted, obtaining a straight line whose equation was the following:

$$i_p = 0.0018 + 1640\ C$$

where i_p denotes the molar piroxicam concentration. The correlation coefficient and detection limit (calculated as above) were 0.9934 and 0.66 ppm, respectively.

Voltammetric study on carbon paste electrode modified with Triton X-100

This carbon paste electrode was prepared as follows: 500 mg of graphite powder were mixed with 250 μl of Nujol oil in an agate mortar. To this mixture, 25 mg of Triton X-100 solved in chloroform were added, giving a paste where the surfactant was 5% (surfactant/carbon).

By plotting voltammetric peaks heights *vs* piroxicam concentration, the following equation was obtained:

$$i_p = -0.002 + 604\ C$$

where i_p denotes the peak heights in μA and C the molar piroxicam concentration. The correlation coefficient was 0.9980, and the detection limit, obtained according to Miller and Miller,[29] was 2 ppm. By comparing these results with those obtained with SDS, we deduce that the determination sensitivity, using Triton X-100 as modifier, is lower, because of the lower calibration graph slope. The detection limit was also lower.

Increasing the Triton X-100 amount in the carbon paste electrode up to 10% (surfactant/carbon), that is to say, 0.300 g of graphite powder, 150 μl of Nujol oil and 30 mg of Triton X-100 solved in chloroform, a similar voltammetric study gave the following equation:

Table 1. Experimental adsorptive i_p values obtained for different electrodes, composition and surfactants

Conc. M ($\times 10^{-5}$)	Peak (μA) CPE without modification	Peak (μA) Modified CPE		
		5% SDS	5% Triton X-100	10% Triton X-100
1.0	0.0215	0.020	0.0040	0.025
0.8	0.0175	0.015	0.0030	0.021
0.6	0.0104	0.012	0.0015	0.019
0.4	0.0052	0.007	0.0004	0.015

$$i_p = 0.014 + 8900\ C$$

where i_p and C have the same significance as above, and whose correlation coefficient and detection limit, were 0.9985 and 1.3 ppm, respectively. In this case, an increase of the method sensitivity (higher slope), according to the slope increase, and a detection limit decrease (lower detected mass) were obtained.

In order to compare the influence of % Triton X-100 on peak heights, the corresponding voltammograms are plotted in Fig. 5, in which we can see that piroxicam peak height increases with the % surfactant. However, the most important result is the fact that with the % (surfactant/carbon) increase, both detection limit and sensitivity of the piroxicam determination method were improved, thus in order to have a comparative view about these improvements, obtained results are summarised in Table 1.

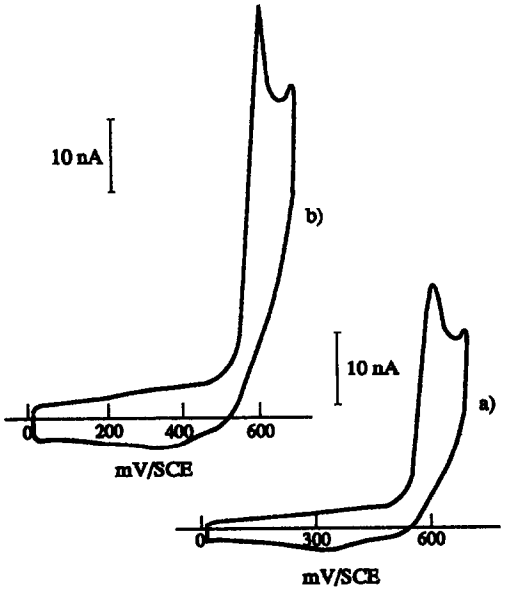

Fig. 5. Adsorptive stripping voltammograms of piroxicam on surfactant modified carbon paste electrode. Influence of % (Triton X-100/Carbon) into the electrode on peak heights: (a) $6.10^{-5}M$ piroxicam, pH 2, V = 100 mV/sec, t_{ad} = 8 min, 5% (Triton X-100/Carbon); (b) as (a) but with 10% (Triton X-100/Carbon).

We have used other surfactants, such as the non-ionic Triton X-405, Tween 80, and Brij 30; the first of which supplied the same results as Triton X-100, the second gave a very important residual current, and with the third, Nujol oil loses its properties as a binder, therefore these surfactants were not used as carbon paste modifiers in our experiments.

CONCLUSIONS

As we have mentioned above, the main purpose of this paper is to research the use of surfactants as carbon paste modifiers, in order to improve the sensitivity of drug determination by using electroanalytical methods. Because of the surfactant presence between the carbon particles on the electrode, a suitable lipoaffinity to preconcentrate hydrophobic substances, such as piroxicam molecules, is created, giving an increase of the piroxicam amount ad-accumulation, showing that the higher was the % surfactant on carbon paste and the higher was the piroxicam accumulation. However, this cannot be the only preconcentration mechanism on this type of electrode, because the Nujol oil can also preconcentrate hydrophobic substances by an extractive mechanism into the paste, as can be seen in the literature.[27,28,30,31] So, due to the extractive properties of Nujol oil, hydrophobic substances, such as promethazine, for example, can be extracted by this pasting, whereas celiptium, is adsorbed on carbon particles at the same electrode.[31] In this sense, we deduced, from our experimental results, that carbon paste electrodes without modification are also suitable in relation to the glassy carbon electrode to improve electroanalytical piroxicam determinations, probably due to an extractive process by the Nujol oil of the paste. Furthermore, according to our results, the use of surfactants as modifier carbon paste electrode have a promising future in studies of the carbon paste

modification because of the preconcentration increase, at least for hydrophobic drug determination whose solutions can be easily prepared without organic solvent addition.

SOLVENT EXTRACTION OF CADMIUM AS A PREVIOUS STEP FOR ITS DETERMINATION IN BIOLOGICAL SAMPLES BY ELECTROTHERMAL ATOMIZATION ATOMIC ABSORPTION SPECTROMETRY

J. M. ESPINOSA ALMENDRO, C. BOSCH OJEDA, A. GARCIA DE TORRES and J. M. CANO PAVON
Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071 Málaga, Spain

Summary—A method is proposed for the solvent extraction of cadmium using 1,5-bis(di-2-pyridylmethylene)thiocarbohydrazide (DPTH) as extractant. The optimum extraction conditions were evaluated from a critical study of the effect of pH, concentration of extractant, shaking time and ionic strength. The maximum volume ratio of the aqueous to organic phase was 30:1 for a single-stage extraction of 99–100% of the metal ion. The detection limit is 0.01 ng/ml cadmium, and the calibration is linear from 0.1 to 5 ng/ml. The relative standard deviation for 10 replicate measurements is 1.8% for 2 ng/ml cadmium. The extraction method was applied to the determination of cadmium in some biological materials using graphite furnace atomic absorption spectrometry.

The toxic effects of cadmium are now well recognized and many researchers have reported the determination of cadmium in biological materials by Electrothermal Atomization Atomic Absorption Spectrometry (ETA-AAS).[1–6] However, in most cases there is the problem of matrix interference. The application of the standard additions method increases the probability of correct results, but cannot guarantee them.[7] This problem can be overcome by diverse procedures: introduction of an active gas during the ashing step,[8] use of matrix modifiers,[9–11] use of an effective background correction system (Zeeman, habitually),[1,12] or separation of the cadmium from the matrix using electrodeposition,[13] ion-exchange[14] or, more frequently, liquid–liquid extraction.

Liquid–liquid extraction provides an easy method of reducing the interference of the matrix, and improving the sensitivity by concentrating the metal in a small volume of an organic solvent. Cadmium has been extracted by means of different extracting systems: ammonium pyrrolidine dithiocarbamate into methyl isobutyl ketone (MIBK),[15] hexamethylene ammonium hexamethyleneditiocarbamate into xylene[16] and tetrahexylammonium iodide into MIBK from a hydrochloric acid medium.[17] All these procedures have been used as a preconcentration step for the determination of cadmium by ETA-AAS.

In this work, a systematic study was made to determine the optimum conditions for cadmium determination in biological samples by ETA-AAS after extraction of the metal into MIBK containing 1,5-bis(di-2-pyridylmethylene)thiocarbohydrazide (DPTH). The proposed extraction method has some advantages. The complex formed is quite soluble in MIBK, so much so that it allows the use of aqueous-to-organic phase volume ratios up to 30 (*i.e.* much higher than those typically afforded by other extractants) and hence the determination of concentrations down to 30 times lower than those afforded by the direct non-extractive method.

The microwave digestion procedure was used for sample preparation. Microwave heating in sealed Teflon containers was applied with only one treatment. The advantages of this procedure include faster reaction rates which result from the high temperatures and pressures attained inside the sealed containers. The use of closed vessels makes it possible to eliminate uncontrolled trace element losses of volatile molecular species that are present in a sample. Another advantage of microwave dissolution is a decrease in blank values as compared to open-beaker work, both because contamination from the laboratory environment is much lower and because closed vessels make it possible to use smaller quantities of reagent.[18,19] In this work, due to the limited volume of the Teflon vessels, conventional digestion procedures were also used for sample preparation when the

concentration of cadmium in the sample analysed was too small, so that a great amount of sample should be dissolved.

EXPERIMENTAL

Apparatus

Atomic absorption measurements were made with a Varian 475 atomic absorption spectrophotometer with a standard air–acetylene burner, and a Perkin–Elmer Zeeman electrothermal atomic absorption spectrometer model 4100ZI equipped with an automatic sampling system model AS-70, a Zeeman background correction system and a PC-ICL computer. Pyrolytically coated graphite tubes, L'vov-type graphite platforms and a cadmium hollow cathode lamp were used. Argon was used as the purge gas. A cadmium hollow cathode lamp was used for atomic absorption measurement at 228.8 nm.

A Panasonic (National) microwave oven model NN-8507 and a Parr Microwave Acid Digestion Bomb, model 4782, were used for sample digestion. The bombs were cleaned before use with 10% nitric acid for 1 day followed by repeated rinsing with water.

pH measurements were made with a Crison Digit 501 pH-meter (combined electrode). A variable rate, time-programmable Gallenkamp mechanical flask agitator was used for sample agitation.

Reagents

All chemicals were of analytical reagent grade. Distilled and deionized water was used throughout.

The ligand for the DPTH solution was synthesized as described elsewhere.[20] A stock solution in MIBK was prepared by dissolving 0.1 g of DPTH in 9 ml of *N,N*-dimethylformamide and diluting to 100 ml with MIBK. The solution was found to remain stable for over a week.

A stock solution of Cd(II) was prepared from the nitrate (Merck P. A.) and standardized complexometrically. Standards of working strength were made by appropriate dilution as required.

An acetic acid–acetate buffer of pH 5.6 was prepared by mixing 4.8 ml of 0.2*M* HOAC and 45.2 ml of 0.2*M* NaOAc in a 100-ml volumetric flask and making to the mark with distilled water.

A 1*M* solution of $NaClO_4$ was also used.

Samples

The certified reference materials analysed to determine the accuracy of the proposed procedure were: Community Bureau of Reference (BCR), Certified Reference Materials (CRMs); 060 Lagarosiphon Major (Aquatic Plant); 061 Platihypnidium Ripariodides/Aquatic Plant); 150 Milk powder; 151 Milk powder; 184 Bovine Muscle; 186 Pig Kidney; National Research Council Canada (NRCC), CRMs DORM-1 Dogfish Muscle; DOLT-1 Dogfish Liver; TORT-1 Lobster Hepatopancreas; National Institute of Standards and Technology (NIST), Standard Reference Materials (SRMs) 2670 Freeze-Dried Urine (Toxic Metals at Normal and Elevated Levels); 1577a Bovine Liver.

Procedures

All glassware and plasticware were acid cleaned (25% v/v nitric acid) prior to use.

Choice of optimum extraction conditions. The metal ion was extracted as follows. In 500 ml separatory funnels was placed 20 μg of cadmium with variable volumes of HCl, NaOH and $NaClO_4$ solutions and the mixture was diluted to an overall volume of 20 ml in the aqueous phase. Then, variable volumes of DPTH solution in MIBK at different concentrations were added and the mixture was shaken vigorously on the mechanical agitator for different periods of time. Once both phases had been separated, the content of cadmium of the aqueous phase was determined by flame absorption spectrometry, using appropriate calibration graphs. From the concentration found, the fraction of metal extracted was calculated. Appropriate blanks were prepared and were run in the same manner.

Sample preparation. The samples of the various types of material considered were first dried in accordance with the norms of the respective analysis certificates. Each dried sample (with the exception of human urine) was mineralized according to one of the following two procedures.

(1) Microwave mineralization. An amount of 0.200–0.600 g of powdered sample (NBS 1577a, BCR 186, DOLT-1, TORT-1, CRM 060 and CRM 061) was placed in the reaction bomb together with 4 ml of 65% nitric acid. Then, after 30 min, 2 ml of 37% HCl was added and the digestion bomb was shut and placed in the microwave oven, where it was kept at 360 W for 4.0 min, followed by 10.0 min at 180 W. The oven was allowed to cool for 14 min (the same

time as the programme duration) after it was opened. After digestion, the solutions were evaporated to a small volume by heating in a hot plate to remove the nitric acid, neutralized with sodium hydroxide, and finally diluted with deionized water to 50 ml in a standard flask.

(2) Reflux mineralization with nitric acid and hydrogen peroxide. In a reaction flask were placed 2.000–4.000 g of weighed sample (BCR 184, DORM-1, CRM 150 and CRM 151) and 15 ml of concentrated nitric acid, and the mixture was heated under reflux up to the disappearance of nitrous fumes. Then, 3 ml of hydrogen peroxide were added and the mixture was evaporated to a small volume by heating in a hot plate to remove the nitric acid. Next, the mixture was neutralized with NaOH and made to 25 or 50 ml with deionized water.

Procedure 1 is quicker, but cannot be applied to a sample amount greater than 1 g, due to the small capacity of the digestion bomb. For this reason, if it is necessary to take a sample amount greater than 1 g (when the concentration of cadmium in the samples is very small), procedure 2 must be used.

The human urine SRM 2670 does not require mineralization; the sample was prepared from concentrates according to the directions supplied.

Aliquots of these sample solutions containing 0.015–0.75 μg of cadmium were placed in 250-ml separating funnels. The analysis of each sample, in triplicate, was completed as described in the Recommended Procedure.

Recommended analytical procedure. In separatory funnels were placed aliquots of samples or standards solutions containing 0.015–0.75 μg of cadmium, 0.5 ml of 1*M* $NaClO_4$ and 5 ml of acetic acid–acetate buffer, pH 5.6. Then, 5 ml of 0.1% DPTH in MIBK were added (the maximum volume ratio of the aqueous to organic phase was 30:1 for a single-stage extraction of 99–100%). The mixture was shaken vigorously at 3000 rpm for 5 min, after which the phases were allowed to separate and the solvent layer was transferred into a polypropylene centrifugate tube (some samples may need centrifugation for up to 5–20 min to improve separation between the layers). Aliquots (20 μl) of organic phase were injected, in triplicate, into the graphite furnace and the absorbance was measured at the wavelength of 228.8 nm using the instrumental conditions shown in Table 1. Triplicate determinations of each sample were made and the cadmium concentration was evaluated from the calibration graph; alternatively, the standard-addition method was also satisfactorily applied.

RESULTS AND DISCUSSION

Optimization of extraction conditions

Extraction of metal ions by organic reagent is known to depend on several factors such as type and amount of reagent, organic solvent, chemical form of metal ion, pH of solution, shaking time, etc. We have investigated the extraction process in order to obtain optimum conditions. MIBK has a significant solubility in water but was chosen as the organic solvent because of its high extraction efficiency for the Cd(II)–DPTH complex.

The effects of pH on the extraction of cadmium with DPTH into MIBK are shown in Fig. 1. As can be seen, the optimum pH range for quantitative extraction is around 4.0–10.7. All subsequent studies were carried out at pH 5.6; this pH was adjusted using an acetic acid–acetate buffer solution. The volume of this buffer added (3–8 ml) had no effect. The

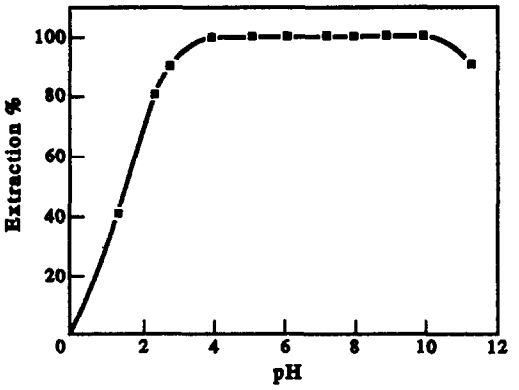

Fig. 1. Effect of pH on the extraction of Cd(II) with DPTH in MIBK in the presence of perchlorate. $[Cd(II)]_{initial} = 0.60$ μg/ml,[A] $[DPTH]_0 = 2.3 \times 10,^{-3}M$, $[ClO_4] = 0.75M$; shaking time: 10 min.

presence of $NaClO_4$ makes feasible a good separation of the phases, although it produces no significant changes in the extraction; for this reason, a concentration of $3.3 \times 10^{-3}M$ $NaClO_4$ was used in all experiments.

The minimum shaking time was determined by varying the shaking time from 1 to 7 min; 5 min was sufficient (Fig. 2a) and was selected in all subsequent work. However, prolonged shaking had no adverse effect on the extraction.

The extraction behaviour of Cd(II) was examined by the single extraction of a fixed amount of cadmium (1 μg/ml), varying the concentration of DPTH in the organic phase while keeping its final volume at 5 ml. The results obtained showed (Fig. 2b) that the extracted fraction remained constant for DPTH concentrations equal or greater than $2.3 \times 10^{-3}M$ (0.1%) for a Cd(II) concentration of 1 μg/ml. For a smaller concentration of cadmium, smaller concentrations of DPTH can be used. A molar ratio of 1:250 [Cd(II):DPTH] was used for subsequent experiments in order to ensure the presence of reagent excess.

The volume of the aqueous phase was varied between 10 and 200 ml while keeping that of the organic phase constant at 5 ml (0.1% m/v of DPTH); hence, the phase volume ratios have been varied between 2 and 40. For a ratio greater than 30, the phase separations were unsatisfactory and the procedure was thus inapplicable. Such a high phase ratio results in a sensitivity higher than that of the direct non-extractive method.

Under these optimum conditions, the recovery factors for the extraction of cadmium were calculated by means of a series of experiments in which the atomic absorption of cadmium in the organic phase was compared with that of a standard prepared in water-saturated MIBK. In all instances, cadmium in the range 0.015–150 μg was extracted completely from the aqueous solution by a single extraction with $2.3 \times 10^{-3}M$ DPTH solution in MIBK.

On the other hand, prior to the analysis of real samples it was necessary to optimize the instrumental conditions for the determination of cadmium by ETA-AAS. The complete programme developed as a result of the normal optimization procedure is as described in Table 1.

Analytical performance. Under the optimum conditions used, a linear calibration graph was obtained for 0.1–5 μg/l of cadmium in the aqueous phase. Ten determinations of standard

solutions containing 2 μg/l gave a relative standard deviation of 1.8% ($P = 0.05$).

The detection limit was calculated as the concentration of analyte giving an atomic absorption signal equal to three times the standard deviation of the blank plus the net blank intensity, under optimum operating conditions. The detection limit was found to be 0.01 μg/l of cadmium in the aqueous phase for an aqueous-to-organic phase ratio of 30.

Study of interferences. The effect of diverse ions on the determination of cadmium was examined under the optimum conditions of the procedure. The tolerance limit was taken as that concentration which does not cause more than a 5% change in the atomic absorption. For these studies different amounts of ionic species were added to a solution of 1 μg/l of cadmium. The starting point was a 5000-fold m/m ratio of interferent to cadmium, and if interference occurred the ratio was progressively reduced until interference ceased. The solutions were analysed three times on different days and the average result was calculated. The interference effects are shown in Table 2, which shows that cadmium can be determined in the presence of a large number of diverse ions. Interferences due to ETA-AAS detection were: Cr(III), Pb(II), Mn(II), Sb(III), Mg(II), Ca(II), Li(I) and Rb(I); the other interferences are due to the extraction step.

Analysis of samples. In order to test the accuracy and applicability of the proposed method to the analysis of real samples, several certified reference materials were analysed. Matrix interferences were verified by comparison of the slopes of the calibration graphs with those using the standard additions method. Only for SRM 2670 were matrix effects apparent for the ICP measurements and quantification was performed with the standard additions methods. The results are given in Table 3 as the average of three replicates. As can be seen, the cadmium concentrations determined by the proposed method are in close agreement with the certified values.

VOLTAMMETRIC STUDIES OF A PSYCHOTROPIC DRUG WITH NITRO GROUPS. DETERMINATION OF FLUNITRAZEPAM IN URINE USING HMDE

E. BERMEJO, A. ZAPARDIEL, J. A. PÉREZ, A. HUERTA and L. HERNÁNDEZ*
Department of Analytical Chemistry and Instrumental Analysis, Autonoma University, 28049 Madrid, Spain

Summary—The adsorption behaviour of flunitrazepam at the hanging mercury drop electrode was studied by staircase voltammetry and by adsorptive stripping differential pulse voltammetry. Flunitrazepam is adsorbed in the whole potential range, from the most positive values up to the reduction potential. Flunitrazepam reduction product is also adsorbed. The time dependence of the voltammetric response proves that a diffusion-controlled adsorption takes place. Flunitrazepam can be determined (down to nanomolar levels) by using adsorptive preconcentration prior to the differential pulse voltammetric scan. An application of such a method to flunitrazepam determination in human urine is described. The detection limit was 30 ng per milliliter of urine with a 20-sec accumulation time; the mean relative standard deviation was lower than 3.2% and the mean recovery 97.8%.

Flunitrazepam [5-(2-fluorophenyl)-1,3-dihydro-1-methyl-7-nitro-2H-1,4-benzodiazepin-2-one], a compound with interesting pharmacological applications marketed as the active ingredient in the commercial preparation Rohipnol-Roche, is a member of the 1,4-benzodiazepine group, undoubtedly the most important chemicals of those with ansyolitic properties. It is used as a sleep-inducing drug in all kinds of insomnia, as premedication prior to anesthesia and in cases where a preparation with anti-anxiety, antidepressive and relaxant properties is required.

As a direct result of its ansyolitic properties, flunitrazepam has become a much overused drug, to the point of being classified among the drugs of abuse. For this reason, the bibliography on different methods for its detection and determination[1] is extensive.

Several analytical data of the drug are described,[2–6] as well as the results of the different studies carried out: pharmacokinetic,[7–10] pharmacodynamic[11] and photochemical,[12–13] and dealkylation and diazotization studies.[14] Some flunitrazepam hydrolysis products (aminobenzophenones) have also been studied.[15–17]

Among the methods applied to flunitrazepam detection are gas chromatography,[2,18–27] thin-layer chromatography,[2,17,23,27–36] high-performance liquid chromatography,[37–43] infrared spectroscopy[44,45] and electrochemical methods.[46] Among those used for its determination are gas chromatography (usually with electron capture detection[47–54] coupled with mass spectrometry[55–57] or with Fourier transform I.R. detection[58]), high-performance liquid chromatography (with ultraviolet detection,[23,24,59–63] immunoassay[64,65] and radioimmunoassay.[66–69] Many of them can be used to determine flunitrazepam in different biological fluids.

As far as the electrochemical reduction studies are concerned, Smyth *et al.*,[46] Oelschlaeger[70] and Sengun and Calishan[71] studied the feasibility of identifying and determining flunitrazepam polarographically over a wide range of pH values. The studies conducted with differential pulse polarography[46] established that flunitrazepam reduction peaks appear at −0.16 V and −0.73 V (*vs* SCE) in Britton-Robinson buffer of pH 4.0, and at −0.61 V and −1.20 V in the same buffer when the pH is 12.0. The mechanism of the reduction has been discussed at mercury[70–73] and glassy carbon[72,73] electrodes. In acidic solution, the first is a four electron wave corresponding to reduction of the 7-nitro group to the hydroxilamine derivative and the second was due to the consumption of four electrons in the simultaneous reduction of 4,5-azomethine and the hydroxilamine (formed as an intermediate of the nitro group reduction). However, under alkaline conditions the second

*Author for correspondence.

process was only to the two-electron 4,5-azomethine reduction. Differential pulse polarography has been used to determine flunitrazepam in pharmaceutical preparations,[71] serum and plasma.[74] Moreover, flunitrazepam has been determined in pharmaceutical preparations by flow injection analysis with amperometric detection;[75] in serum and urine by stripping voltammetry using clay-modified carbon paste electrodes,[76,77] it has been applied to samples containing 1.5 μg of flunitrazepam per milliliter of urine.[76]

Electrochemical oxidation studies[78,79] using a glassy carbon electrode show that flunitrazepam is not electro-oxidable.

So far, none of the studies published have taken into consideration the fact that flunitrazepam is adsorbed at the mercury electrode. And that is the aim of the present work: to explore the properties of the adsorption process of flunitrazepam at the mercury electrode and see if such a phenomenon can be taken advantage of in order to be used as a preconcentration step prior to the voltammetric measurement of surface-bound species. The voltammetric measurement has been carried out on the reduction peak of the nitro group with the aim of determining the drug at nanomolar level using adsorptive stripping voltammetry. We have sought to develop a method for determination of the drug in urine that is at the same time sensitive, accurate, quick and easy to use.

Adsorptive stripping voltammetry has already been used in our laboratories to determine several benzodiazepines that can be adsorbed at the mercury electrode.[80-86]

The work presents a study of all the factors that may influence both the accumulation process and the voltammetric response; it also takes into account the influence exerted by the different urine components, develops a process for extraction of flunitrazepam from urine and gives interfacial and redox data that can help to achieve a better understanding of flunitrazepam activity.

EXPERIMENTAL

Apparatus

The experiments of adsorptive stripping voltammetry were performed using a Metrohm 646 VA processor in conjunction with a 647 VA stand. A three-electrode system was used made up of Ag/AgCl/3*M* KCl reference electrode, a glassy carbon auxiliary electrode and a multimode mercury drop electrode (Metrohm 6.1246.020) that served as the working electrode in the hanging MDE mode with a medium surface of 0.0060 cm^2.

The electrocapillary curves were carried out with a 564 Amel polarograph. A mercury drop working electrode, a platinum auxiliary electrode and a saturated calomel reference-electrode was used.

The cyclic staircase voltammetric measurements were carried out using a 384B PAR polarographic analyzer together with a 303A PAR static mercury drop electrode (GO 199 capillary) with a surface of 1.01 mm^2; the reference electrode was a Ag/AgCl/3*M* KCl and the auxiliary a platinum electrode. The polarograph was coupled to an AMETEK DMP-40 series digital plotter.

All measurements were performed at room temperature and all potentials are referred to the Ag/AgCl/3*M* KCl electrode unless other conditions are expressed in the text.

Reagents

Pure flunitrazepam was kindly supplied by Roche S.A., Spain. The compound and the electrolytes (Merck P.A.) were used without further purification. Stock solutions ($8.0 \times 10^{-4}M$) of flunitrazepam, prepared by dissolving the compound in methanol, were stored in the dark under refrigeration to minimize decomposition. The supporting electrolytes were Britton-Robinson, acetate, ammonium, carbonate and borate buffer of different pH and ionic strengths.

Aqueous solutions were prepared in purified water (Milli-Q and Milli-Ro, Millipore). Human urine samples were pooled from five subjects.

Procedures

Cyclic staircase voltammetry. A 10.0-ml flunitrazepam solution was put in the voltammetric cell and deoxygenated with nitrogen (99.999%) for 10 min. After a mercury drop had formed on the working electrode and was maintained at a potential of -0.350 V for the duration of the adsorption time, which is performed in still solutions, a cyclic potential scan (scan rate 500 mV/sec, step height of 4 mV and step width of 0.008 sec) was applied, beginning with the reduction scan.

Adsorptive stripping differential pulse voltammetry. A 25.0-ml flunitrazepam solution was used with an accumulation potential of −0.350 V. The solution was stirred at 1920 rpm throughout the accumulation time. After a 30-sec rest, a differential pulse scan towards more negative potential values (scan rate 30 mV/sec and pulse amplitude 75 mV) was employed to obtain the stripping voltammograms.

Treatment of urine samples. A 2.0-ml sample of urine containing from 100 to 500 ng of flunitrazepam per milliliter of urine were placed in an extraction funnel and 1 ml of 0.04*M* borate buffer at pH 9.2 was added. The drug was extracted by adding 3 ml of diethyl ether, shaking the funnel for one minute and letting it rest for 5 min. The organic layer was transferred to a conical centrifuge tube and evaporated under a nitrogen stream; the residue was reconstituted with 200 μl of methanol and diluted to 25.0 ml using 0.02*M* Britton-Robinson buffer of pH 10.0. The accumulation time was 20 sec and the stripping adsorptive voltammogram was recorded under the optimum instrumental conditions.

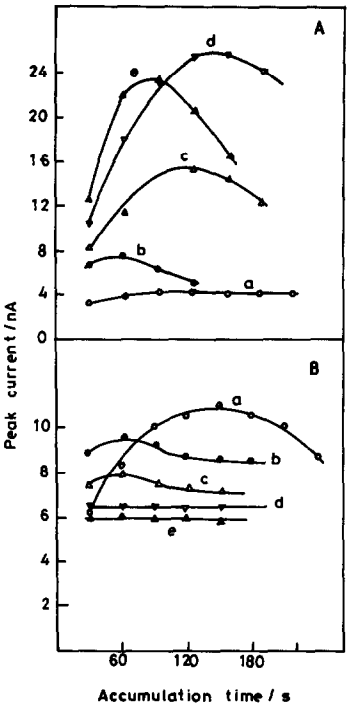

Fig. 1. Dependence of stripping peak current with accumulation time for $1.1 \times 10^{-7}M$ flunitrazepam (A) nitro group reduction peak, (B) azometine group reduction peak. Britton-Robinson buffers (0.04*M*) at pH (a) 5.0, (b) 8.0, (c) 9.0, (d) 10.0 and (e) 10.5. Scan rate 20 mV/sec, pulse amplitude 50 mV and electrode surface 0.0060 cm². The accumulation potential was optimized in every case.

RESULTS AND DISCUSSION

Influence of electrolyte and pH

Both the redox and interfacial behaviour of flunitrazepam are affected by the pH and supporting electrolyte of the solutions, an effect that is even greater in the peak current of the voltammetric response. Acetate, phosphate, carbonate, ammoniacal and Britton-Robinson buffers were used as electrolytes, with pH values between 5.0 and 11.0. The optimum accumulation potential was chosen first in every case. The differential pulse mode was employed for detection of the stripping voltammetry on the two reduction peaks of flunitrazepam.

Figure 1(A) shows the plots of peak current *vs* accumulation time for the nitro group response; Fig. 1(B) does the same for the second wave, which corresponds to the azomethine group reduction. Britton-Robinson buffers were used as electrolytes in both cases. The results obtained prove that the voltammetric response gives a higher peak current if the nitro group reduction wave is used in Britton-Robinson buffer of pH 10.0.

In both cases peak potentials move towards more negative values as pH increases. In the case of the nitro group peak, the variation in potential is expressed by the equation

$$E_p(V) = -0.011 - 0.0499\ \text{pH}\ (r = 0.995)$$

valid for pH between 5.0 and 10.5. The accumulation potential is approximately 150 mV (for the nitro group response) and 350 mV (for the azomethine group one) more positive than the potential of the reduction peak. Table 1 shows some significant data of the voltammetric responses. The study of the influence exerted by electrolyte concentration on the voltammetric response proved that the most sensitive response was obtained in 0.02*M* Britton-Robinson buffer of pH 10.0, which was thereafter used for the rest of the experiment.

Adsorptive behaviour of flunitrazepam

When measurements of drop time were carried out at the mercury drop electrode [Fig. 2(A)

Table 1. Stripping voltammetry data

	E_p (V)	t_a (sec)	E_p (V)	I_p (nA)
First reduction peak	−0.350	110	−0.490	26.0
Second reduction peak	−0.750	80	−1.100	6.5

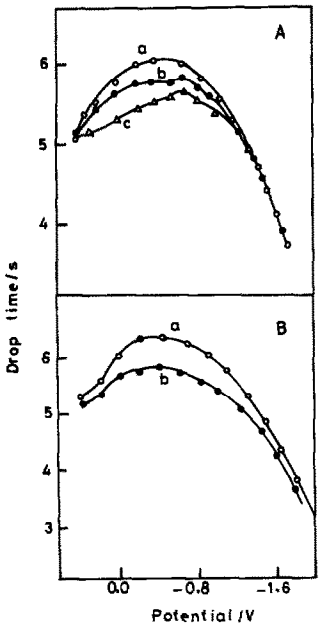

Fig. 2. Electrocapillary curves in 0.04*M*. Britton-Robinson buffer. (A) pH 5.0 in the (a) absence and (b) presence of $2.3 \times 10^{-4}M$ and (c) $4.8 \times 10^{-4}M$ of flunitrazepam. (B) pH 10.0 in the (a) absence and (b) presence of $2.3 \times 10^{-4}M$ flunitrazepam.

and (B)] in the presence and absence of flunitrazepam, it was observed that drop time shortens in the presence of the drug. This fact indicates that flunitrazepam is adsorbed at the electrode in the whole potential range; it is also adsorbed in the whole pH range studied (5.0–10.5). A decrease in drop time was also recorded after flunitrazepam had been completely reduced, indicating that the product is also adsorbed.

Adsorption of the compound was confirmed by the results obtained with cyclic staircase voltammetry, which was used because, under the conditions used in this work, it was virtually identical to cyclic voltammetry.[87] The response obtained using staircase voltammetry for flunitrazepam first reduction wave at the hanging mercury drop electrode is shown in Fig. 3. When the initial potential (−0.350 V) is maintained for 100 sec before beginning the cyclic scan, an irreversible, well-defined cathodic peak is observed whose peak current is nine times higher than the current obtained when the initial potential is applied for 2 sec only.

The morphology of this peak indicates that it is basically due to the reduction of the drug adsorbed. It has a potential that varies between −0.560 and −0.770 V depending on scan rate and concentration. The fact that peak potential moves towards more negative values as scan rate increases proves an irreversible electrode reaction.

Dependence of charge on concentration of flunitrazepam and on time. The adsorption of reducible substances can be adequately followed by measuring the cyclic or single-sweep voltammetric response at the HMDE.[88–91] And, since it is preferable, the charge (Q) transferred through the interface in the course of reduction was calculated. It is essential that the voltammetric response corresponds only to the reduction of the adsorbed substance, that is to say, contribution to the response due to reduction of the species that diffuses toward the electrode must be kept negligible at the working scan rate. A study of the influence of scan rate on the transferred charge (Q) (for $9.5 \times 10^{-5}M$ flunitrazepam in 0.02*M* Britton-Robinson buffer of pH 10.0 at a 110 sec adsorption time) proved the transferred charge to be constant between 160 and 800 mV, giving a value of 0.65 μQ with a relative standard deviation of 2.3% that demonstrates that, within that range, contribution due to the reduction response of the species diffusing toward the electrode is insignificant. A scan rate of 500 mV/sec was chosen for the rest of the study.

The influence of adsorption time on the charge transferred was studied using flunitrazepam solutions between 1.4×10^{-5} and $9.5 \times 10^{-5}M$. Figure 4 shows the results obtained. It can be observed that initially the charge rises linearly with the square root of the adsorption time, pointing to a diffusion-controlled adsorption of flunitrazepam before its reduction. Later on the charge reaches its highest value, this is indicating the total

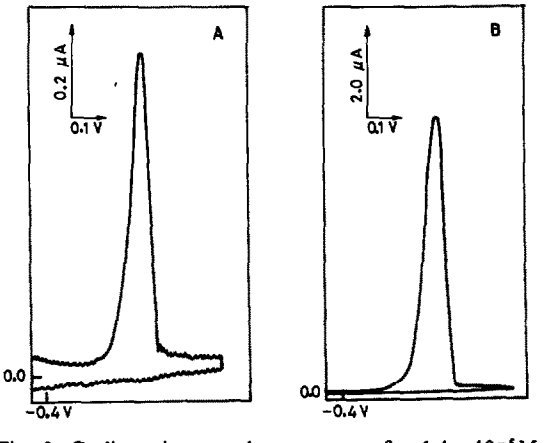

Fig. 3. Cyclic staircase voltammograms for $1.4 \times 10^{-5}M$ flunitrazepam in 0.02*M*. Britton-Robinson buffer of pH 10.0. Adsorption time (A) 2 sec and (B) 100 sec. Initial potential −0.35 V; scan rate 500 mV/sec.

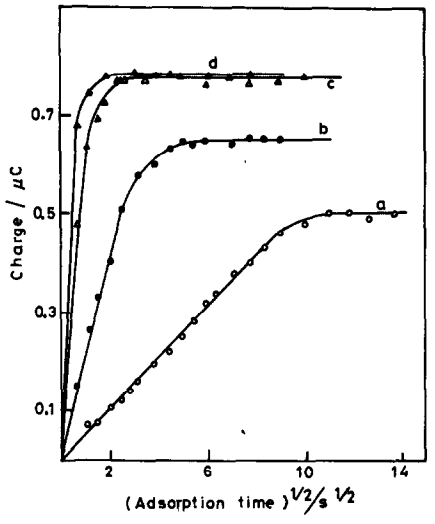

Fig. 4. Dependence of the reduction response (charge Q) on the adsorption time at adsorption potential −0.350 V. Britton-Robinson buffer pH 10.0, at different concentrations of flunitrazepam: (A) 1.4×10^{-5}M, (B) $2.4 \times 10^{-5}M$, (C) $4.8 \times 10^{-5}M$ and (D) $9.5 \times 10^{-5}M$.

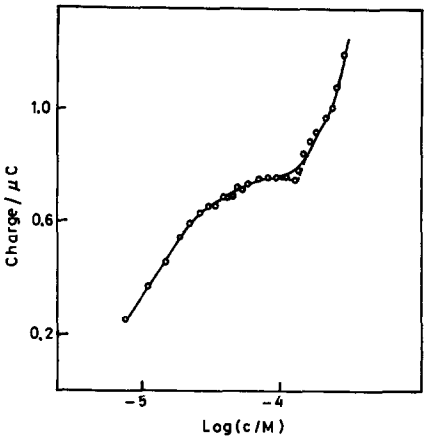

Fig. 5. Half logarithmic plot of flunitrazepam adsorption isotherm in 0.02M Britton-Robinson buffer pH 10.0. Adsorption potential −0.350 V, scan rate 550 mV/sec, adsorption time 60 sec.

covering of the electrode. The time elapsed until the electrode has been completely covered decreases when flunitrazepam concentration increases.

Adsorption isotherms. When the voltammetric response corresponds only to the reduction of the matter adsorbed, charge density (Q/A) is proportional to the surface concentration (Γ) of the matter adsorbed at the initial scan potential: $Q/A = nF\Gamma$, where $n = 4$, the number of electrons consumed in the reduction of the nitro group. The coverage θ is Γ/Γ_m, where Γ_m is the maximum surface concentration for full coverage with a monolayer. Since the electrodic reaction is known, the values of Γ and its maximum value Γ_m can be easily determined. Figure 5 shows the adsorption isotherm obtained; it is double-step adsorption isotherm. The second step of the adsorption isotherm does not appear at all, probably because, at this concentration range (2.0×10^{-4}–$1.00 \times 10^{-3}M$), contribution to the response coming from diffusion of the substance has not been totally eliminated at the working scan rates.

Figure 6(A) plots the variation in charge density (Q/A) as a function of concentration for the first step of the adsorption isotherm. The fraction of covered surface (θ) can be calculated from the Q/Q_m relationship.

The type of adsorption isotherm was assigned starting from the plots of log $[\theta(1-\theta)^{-1}C^{-1}]$ as a function of θ [Fig. 6(B)]. A straight line was obtained up to $3.4 \times 10^{-5}M$ flunitrazepam concentration (with a slope of 0.94, an intercept of 4.46 and a correlation coefficient of 0.994), indicating that flunitrazepam adjusts to a Frumkin-type isotherm $[\beta C = \theta(1-\theta)^{-1}\exp(-2\gamma\theta)]$. Starting from this plot, an adsorption coefficient (β) of 2.8×10^4 l./mole and an attraction factor (γ) of 1.08 were estimated. Starting from the value of the adsorption coefficient, the value of the free energy of adsorption ($-\Delta G°$) could be deduced,[88] giving a value of 35.4 kJ/mole.

Adsorptive stripping differential pulse voltammetry

For analytical purposes, the adsorption process of the drug can be used to increase the sensitivity of the voltammetric procedures. In the case under discussion, the accumulation step was carried out in stirred solutions and the

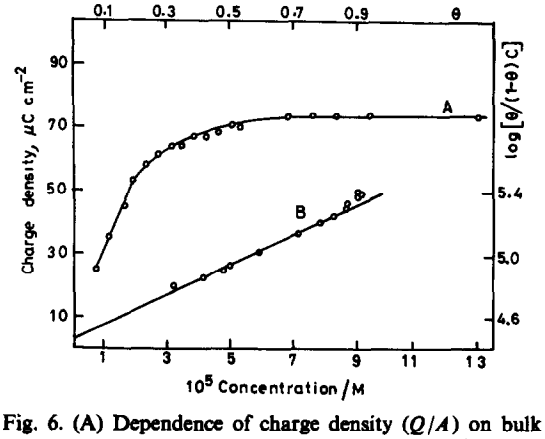

Fig. 6. (A) Dependence of charge density (Q/A) on bulk concentration and (B) dependence of $\log[\theta(1-\theta)^{-1}C^{-1}]$ on surface coverage (θ) for the first step of the adsorption isotherm. Conditions as in Fig. 5.

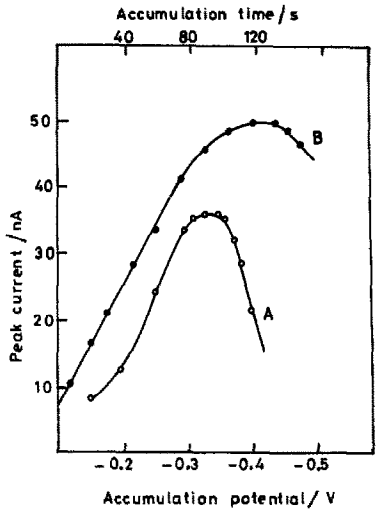

Fig. 7. Variation of stripping peak current with (A) accumulation potential at 60 sec accumulation time; (B) accumulation time at −0.350 V accumulation potential. $1.1 \times 10^{-7}M$ flunitrazepam in $0.02M$ Britton-Robinson buffer pH 10.0. Stirring rate 1920 rpm, scan rate 20 mV/sec, pulse amplitude 75 mV and drop size 0.60 mm².

stripping step quantified by differential pulse mode, since the response obtained is approximately five times higher than the one obtained by linear scan mode at scan rates in the same order of magnitude.

Factors influencing the accumulation step. The value of the potential at which the accumulation process takes place strongly affects the voltammetric response (see Fig. 7). The maximum values in peak current were obtained at values of potential between −0.31 and −0.36 V, therefore a value of −0.35 V was chosen for the analytical process.

For accumulation times shorter than 80 sec, peak current increases linearly with increasing accumulation time [see Fig. 6(B)] for a drug concentration in the $10^{-7}M$ range. In such a case, surface saturation is reached after 100 sec. The ultimate choice of accumulation time should depend on the concentration range studied.

Variations in stripping peak current with drop size, in mm² [I_p(nA) = −2.2 + 99.9A, $r = 0.994$] and with stirring rate between 1220 and 2620 rpm, for $1.1 \times 10^{-7}M$ flunitrazepam solutions, and a 60 sec accumulation time proved that a satisfactory voltammetric response was obtained with the maximum drop size (0.60 mm²) at a 1920 rpm stirring rate.

None of the factors studied affect peak potential values.

A rest time of between 10 and 30 sec does not affect the analytic signal either in its value or its reproducibility.

Factors controlling the stripping step. Peak current varies linearly with pulse amplitude between 30 and 80 mV [I_p(nA) = −7.14 + 0.47ΔE, $r = 0.9998$]; the half-peak width remained constant at 55 mV. Amplitudes wider than 80 mV not only do not increase sensitivity but slightly lower resolution. A pulse amplitude of 75 mV was chosen for further analytical work.

A rise in the scan rate of the potential causes an increase in the stripping peak current [I_p(nA) = 4.54 + 2.66 V (mV/sec), $r = 0.998$]. A rate of 30 mV/sec affords maximum sensitivity.

Influence of concentration. The influence of flunitrazepam concentration was studied at various accumulation times: 30, 60, 80, 110 and 180 sec. Linear variations were obtained with concentrations from 0.6×10^{-8} to $3.1 \times 10^{-7}M$, depending on the linearity range of the accumulation time used. Sensitivity varies from 0.78×10^8 nA l./mole (with 0 sec accumulation time) to 7.65×10^8 nA l./mole (with 180 sec). An accumulation time of 110 sec gives a peak current dependence on concentration that adjusts to the equation I_p(nA) = 2.3 + 6.58 × 10^8C(mole/l.), $r = 0.9996$.

Precision was determined by five successive measurements of 1.2×10^{-8}, 5.1×10^{-8} and $1.3 \times 10^{-7}M$ flunitrazepam solutions; the relative standard deviation was found to be lower than 2.7% and the relative error lower than 1.0%. A detection limit (3σ) of $9.0 \times 10^{-10}M$ and a determination limit (10σ) of $3.1 \times 10^{-9}M$ was calculated.

Table 2. Variation in the slope (in nA L mole^{-1}) of flunitrazepam calibration plot in the range of 1.0×10^{-8} to $2.0 \times 10^{-7}M$ in the presence of urine components

Accumulation time, sec	Without interferent	Albumin 6.4 ppm	Uric acid	Glucose, 8 ppm	Creatinine, 120 ppm	Urea, 2400 ppm
30	2.93 ± 10^8	4.62×10^7	*	2.76×10^8	2.95×10^8	2.45×10^8
60	4.67×10^8	1.64×10^8	*	4.77×10^8	4.32×10^8	3.83×10^8
110	6.58×10^8	—	*	5.60×10^8	4.05×10^8	4.47×10^8

*Flunitrazepam reduction peak not observed.

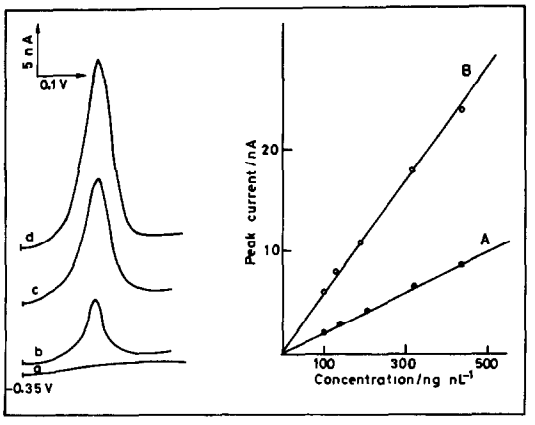

Fig. 8. Differential pulse stripping peaks for different concentrations of flunitrazepam in urine, (a) 0, (b) 100, (c) 190 and (d) 315 ng of flunitrazepam per milliliter of urine. Accumulation time 20 sec. Calibration plots of flunitrazepam in urine (A) 0, and (B) 20 sec of accumulation time. Other conditions were as in Fig. 7.

Interferences study

To study the effect of urine components on the analytical signal of flunitrazepam, calibration plots of flunitrazepam in the range 1.0×10^{-8}–$2.0 \times 10^{-7} M$ were obtained in the presence of albumin (6.4 ppm), uric acid (64 ppm), glucose (8 ppm), creatinine (120 ppm) and urea (2400 ppm) with different accumulation times (30, 60 and 110 sec). The values in parentheses correspond to the normal values of the compounds in the urine of healthy subjects, calculated taking into the account that 2 ml of urine is diluted to 25 ml for the analysis, as is the norm throughout this work.

Table 2 shows the slopes of the calibration plots in the absence and presence of the urine components studied. As can be seen, sensitivity is not affected by the presence of glucose, creatinine or urea as long as short accumulation times are used. The presence of uric acid, however, causes the signal to disappear entirely, while the presence of albumin greatly lowers sensitivity, down to 16% of the initial signal, even when working with short accumulation times.

Flunitrazepam determination in urine samples

The facts described above made it necessary to use an extraction procedure (described in the Experimental) in order to eliminate the aforementioned interferences.

Figure 8 is an example of the stripping peaks obtained and the resulting mean calibration graphs after analyzing five series of solutions of different concentration at zero and 20 sec accumulation times.

For the 20-sec accumulation time the determination of flunitrazepam in urine was possible in the range of 100–500 ng/ml with a sensitivity of 0.052 nA ml ng^{-1} (correlation coefficient 0.9991) and a mean relative error lower than 5.0%; the detection limit (estimated as the concentration corresponding to a signal-to-noise ratio of 3) was 30 ng/ml and the mean recovery 97.8% in the range mentioned above. Precision, expressed in terms of the relative standard deviations, was 3.2%.

HOST–GUEST STABILIZED ROOM TEMPERATURE PHOSPHORESCENCE IN β-CYCLODEXTRIN/ BROMOALCOHOL SOLUTIONS FROM 2-NAPHTHYL-OXY-ACETIC ACID AND 1-NAPHTHYL-ACETIC ACID

A. MUNOZ DE LA PENA,* F. SALINAS, M. J. GOMEZ, M. SANCHEZ-PENA and I. DURAN-MERAS
Department of Analytical Chemistry, University of Extremadura, 06071, Badajoz, Spain

Summary—Room temperature phosphorescence (RTP) from 2-naphthyl-oxy-acetic acid (NOA) and 1-naphthyl-acetic acid (NAA), with stabilization by use of β-cyclodextrin (β-CD) as a host system, has been examined. 2-Bromoethanol and 2,3-dibromopropanol have been evaluated as external heavy atom perturbers to enhance the rate of intersystem crossing and, consequently, populating the triplet state for phosphorescence emission. The deoxygenation of the solutions was achieved chemically by use of sodium sulphite. The spectral characteristics of the phosphorescence emission from these relatively polar compounds and the optimization of the chemical variables involved are reported. The role of the bulkiness of the bromoalcohol employed, in comparison with the unoccupied space of the interior of the cyclodextrin cavity by the guest, is an important factor in the attainment of an effective RTP emission, and should be taken into account in the selection of the appropriate external heavy atom for the observation of RTP from other organic molecules of interest by this approach. 2,3-Dibromopropanol seems a more adequate bromoalcohol than 2-bromoethanol for the observation of RTP emission in the systems investigated.

Apart from sensitized room temperature phosphorescence (RTP),[1] all the methods proposed for the observation of RTP in fluid solution involve the use of some kind of organization. This approach is particularly attractive as a potential detection method in dynamic methodologies. The first reported observation of RTP, by microscopically organized media stabilization, was made using sodium dodecyl sulphate (SDS) micelles in the presence of thallium.[2] Since then, several media have been investigated to stabilize the triplet state in fluid solution at room temperature. Both micelles and host molecules have been found to be useful media for achieving triplet-state emission at room temperature.[3]

Normal micelles, mainly SDS[4,5] and cetyltrimethylammonium bromide (CTB) micelles,[6,7] have been used in RTP analysis. Microemulsions, formed in heptane–SDS–1-pentanol, have also been evaluated as an alternative to normal micelles for RTP obtention.[8] A recent communication[9] claims the use of water-soluble co-polymers of 1-vinylnaphthalene and metacrylic acid as a new class of medium for RTP analysis in aqueous systems.

Among the host molecules, cyclodextrins (CDs) are by far the most common media for host–guest stabilized RTP. CDs are molecules formed from different numbers of α(1,4)-linked D(+)-glucopyranose units: α-, β- and γ-CDs comprise 6, 7 and 8 units, respectively. CD-stabilized RTP is a recently observed phenomenon, which was initially reported by Turro *et al.*[10–12] for halonaphthalenes and several 4-bromo-1-naphthoyl-alquyl surfactant probes. The β- and γ-CDs have been proposed as appropriate hosts to form inclusion complexes with various phosphor guest molecules, where the guest is embedded totally or partially in the CD cavity.[13–19] Another study uses CDs to enhance sensitized RTP emission from biacetyl.[20]

A new kind of host, the synthetic macrocyclic azaparacyclophanes, in mixtures with SDS, has recently been reported as capable of inducing RTP from several compounds.[21] Mixed organized media of β-CD and SDS have also been evaluated as organized assemblies for RTP stabilization.[21,22]

Apart from compounds including a heavy atom in their structure, the observation of RTP,

*Author for correspondence.

in the different organized media described, needs to fulfil two main conditions. Firstly, the use of external heavy atom compounds is required. By increasing the rate of the intersystem crossing process, the presence of heavy atoms in the environment of the potential phosphor usually enhances the phosphorescence of the phosphor. In addition, phosphorescence signals are only obtainable if quenching of the emitting triplet state, by small amounts of dissolved oxygen, is prevented.

The two conditions are common to micelles and cyclodextrins but, to obtain significant CD-stabilized RTP emission, the hydrophobic CD cavities need to allow sufficient interaction between the analyte and the heavy atom compound to produce effective population of the triplet states of the analyte. For this, both the lumiphor and the heavy atom need to be in close proximity at the same time, *i.e.* inside the CD cavity.[15]

Only a few compounds, mainly non-polar substances, have been found to phosphoresce when included in CDs. Cline Love's group reported on CD-stabilized RTP from polynuclear aromatic hydrocarbons (PAHs),[13] two- and three-nitrogen heterocycles,[14] biphenyl and the bridged biphenyls fluorene, benzofuran, dibenzotiophene and carbazole,[14] and the more polar drug naproxen,[15] in the presence of 1,2-dibromoethane. It was established that the observed phosphorescence emission resulted from the formation of a ternary association between the phosphor, the CD and the external heavy atom compound employed. Similarly, using two haloalkanes, 1,2-dibromoethane and 1,2-dibromopropane, Zhang *et al.*[16,17] reported on RTP emission from 1-naphthyl-acetic acid (NAA), included in β-CD.

As an alternative to the use of haloalkanes, Hamai[18] and Muñoz de la Peña *et al.*[19] proposed the use of bromoalcohols as heavy atom perturbers, and demonstrated the feasibility of using sodium sulphite for chemical deoxygenation in CD studies,[19] in a similar way to the approach used for micelle-stabilized RTP.[23]

The purpose of this work is to advance understanding of CD-stabilized RTP emission, in order to investigate the possibilities of expanding its applications and, eventually, to apply it to the detection of organic species of analytical interest. We report upon the observation of phosphorescence from two pesticides that are naphthalene derivatives. The stabilized RTP emission has been attained in β-CD, in the presence of 2-bromoethanol (2-BE) and 2,3-dibromopropanol (2,3-DBP) as external heavy atom perturbers. The relatively polar character of the compounds investigated is considered in order to evaluate the potential applications of this technique for the analytical determination of relatively polar compounds.

EXPERIMENTAL

Apparatus

Steady-state fluorescence and phosphorescence measurements were made on a Perkin–Elmer Model LS 50 luminescence spectrometer equipped with a xenon discharge lamp equivalent to 20 kW for 8 μsec duration. The instrument is connected via RS-232 with an IBM PS/2 80386-SX microcomputer. Data acquisition and data analysis were performed by use of the Perkin–Elmer Fluorescence Data Manager Software, version 2.70. Solutions were excited at 274 nm, the maximum excitation wavelength of 2-naphthyl-oxy-acetic acid (NOA), or at 284 nm, the maximum excitation wavelength of NAA. Fluorescence measurements were made with excitation and emission band widths of 5 nm and phosphorescence measurements with excitation and emission bands of 15 and 20 nm, respectively. The delay time and the gate time were typically maintained at 1.0 and 5.0 msec, respectively. The scan rate of the monochromators was maintained at 240 nm/min. All measurements were made at $20 \pm 0.1°$ by use of a thermostatic cell holder and a thermostatic bath Selecta Model 382.

Reagents

All experiments were performed with analytical grade chemicals. Purified LC-grade water (Millipore Milli-Q-system) was used. NOA (97%) was obtained from Chem Service (West Chester, PA), NAA (97%) was obtained from Aldrich-Chemie and β-CD was obtained from Sigma and used as received.

2-BE (95%) and 2,3-DBP (96%) were obtained from Aldrich-Chemie and used as received. Anhydrous sodium sulphite (>98%) was obtained from Merck. Sodium sulphite solutions were prepared daily and kept in tightly stoppered containers.

Methods and sample preparation

A $10^{-2}M$ stock solution of NOA or NAA was prepared in absolute ethanol. Aqueous $10^{-4}M$ NOA or NAA solutions were prepared

by pipetting an aliquot of the stock solution into a 250 ml volumetric flask. The ethanol was evaporated by use of dry nitrogen, deionized water was added and, after sonication, was diluted to the mark. Solutions of lower concentrations were prepared by appropriate dilution of the stock aqueous solutions.

General procedure for phosphorescence measurements

An aliquot of the NOA or NAA solution was transferred to a 10-ml volumetric flask and the appropriate amount of β-CD to give a $10^{-2}M$ final concentration was added. After dilution with water, the solution was mixed at the ultrasonic bath to dissolve the cyclodextrin and 1.0 ml of $0.3M$ Na_2SO_3 and 0.4% 2,3-DBP or 1.0% 2-BE were added. After dilution to the mark with water, the sample was introduced into the cell compartment and continuously irradiated with the xenon lamp at 274 nm for NOA or 284 nm for NAA. The RTP signal was monitored and measured at 504 nm for NOA and 494 nm for NAA, when it was stable for at least 5 min.

RESULTS AND DISCUSSION

The inclusion complexes between NOA or NAA and β-CD have been investigated previously in aqueous solution by absorption and fluorescence measurements.[24] At neutral pH, NOA and NAA are dissociated, as the respective carboxylic groups have acidic character. It was demonstrated that the naphthalene derivatives from 1:1 complexes when included in the CD in pure aqueous solutions. A possible structure with an axial inclusion of the naphthalene derivatives was proposed. In the case of the β-CD:NOA complex, the naphthyl moiety is practically included in the CD and the acetic acid group protrudes from the cavity, while NAA is only partially included because of the steric effect of the substituted group at position 1. Association constants of $560M^{-1}$ and $100M^{-1}$ were calculated for the β-CD:NOA and β-CD:NAA binary complexes, respectively.

Influence of bromoalcohols on the fluorescence of β-CD:NOA and β-CD:NAA

The only two classes of heavy atom perturbers reported to date, for CD RTP stabilization, are bromoalkanes and bromoalcohols. The use of a bromoalcohol for phosphorescence enhancement was suggested as a possibility[19] after the detailed study of the strong ternary complexes formed between pyrene, as a model compound, CDs and alcohols of different size and polarity.[25–27]

To investigate the possibility of RTP obtention from NOA and NAA, the influence of different bromoalcohols on the fluorescence emission of the binary complexes between the naphthalene derivatives and β-CD was evaluated. For this, several additions of bromoalcohols were made to an aqueous solution of NOA or NAA in β-CD. The final concentrations of NOA or NAA and β-CD were $1 \times 10^{-5}M$ and $1 \times 10^{-2}M$, respectively.

The results obtained for the β-CD:NOA complex in the presence of 2-BE and 2,3-DBP are plotted in Fig. 1. The concentrations of 2-BE and 2,3-DBP were varied between 0.1% and 3%. The fluorescence emission was monitored at 350 nm. The addition of the bromoalcohols produces a decrease of the fluorescence emission of the β-CD:NOA inclusion complex. In the case of 2-BE, the remaining fluorescence is around 20% of the initial emission, while in the case of 2,3-DBP, the decrease is more pronounced, leading to less than 10% of the initial fluorescence in 3% 2,3-DBP. The maximum decrease of the fluorescence was attained for bromoalcohol concentrations higher than 2%.

Similarly, the effect of the presence of 2-BE and 2,3-DBP on the fluorescence intensity of the binary complex formed between NAA and β-CD is shown in Fig. 2. The concentrations of 2-BE and 2,3-DBP were varied between 0.1% and 3%. The fluorescence intensity was monitored at 336 nm. As in the case of the NOA complex, it can be observed that an effective quenching of the fluorescence emission is produced in the presence of both bromoalcohols,

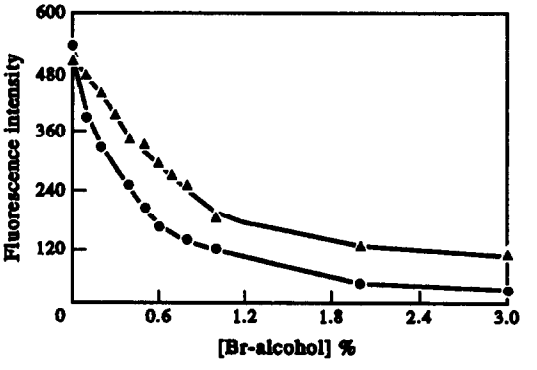

Fig. 1. Effect of 2-BE (▲) and 2,3-DBP (●) on the fluorescence intensity of the complex β-CD:NOA. $\lambda_{ex} = 274$ nm, $\lambda_{em} = 350$ nm. [NOA] = $1 \times 10^{-5}M$, [β-CD] = $1 \times 10^{-2}M$.

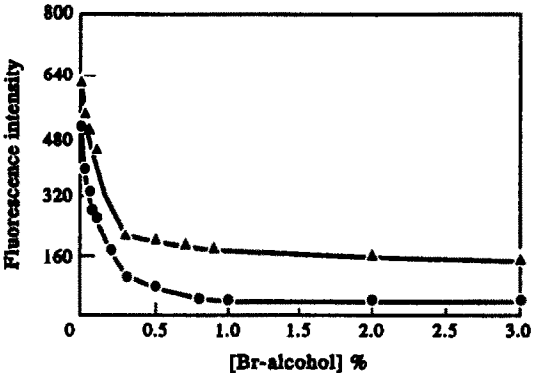

Fig. 2. Effect of 2-BE (▲) and 2,3-DBP (●) on the fluorescence intensity of the complex β-CD:NAA. $\lambda_{ex} = 284$ nm, $\lambda_{em} = 336$ nm. [NAA] = $1 \times 10^{-5}M$, [β-CD] = $1 \times 10^{-2}M$.

but the attenuation of the fluorescence is more effective in the presence of 2,3-DBP than in the presence of 2-BE. In this case, concentrations of bromoalcohol higher than 0.5% are enough for a maximum decrease of fluorescence. It is interesting to note that the quenching effect is more pronounced for the β-CD:NAA than for the β-CD:NOA complex. Smaller amounts are needed to obtain the maximum attenuation of the fluorescence.

The observed quenching can be explained as the result of an effective interaction between NOA or NAA and the bromoalcohols inside the CD cavity. The hydroxylic group of the bromoalcohol may interact at the hydroxyl edge of the CD, via hydrogen bonding, while the brominated part of the alcohol is facing and is totally or partially included in the cyclodextrin.

Obtention of RTP in the presence of bromoalcohols

RTP emission has been obtained from NOA and NAA in aqueous solutions of β-CD in the presence of both bromoalcohols and sodium sulphite. The addition of sodium sulphite is necessary in order to minimize the quenching effect of dissolved oxygen. This technique of chemical deoxygenation is an alternative to the classical pass of nitrogen and has been used for phosphorescence studies by other authors in different micellar and host systems.[6-8,19,21,23,28-33] Upon deaeration of NOA or NAA solutions containing both β-CD and 2-BE or 2,3-DBP, a new emission appears at longer wavelength regions than the fluorescence.

According to the literature, the low temperature phosphorescence (77 K) emission of NOA in ethanol–water (1:9, v/v) appears at 503 and 530 nm, and the room temperature phosphorescence in filter paper appears at 504 nm,[34] while it is reported to appear at 499 and 529 nm in filter paper treated with $1M$ NaI.[35] For NAA, the low temperature phosphorescence emission appears at 484 and 514 nm and the room temperature phosphorescence in filter paper at 494 and 516 nm.[34] When the filter paper is treated with NaI, the maxima reported appeared at 489 and 519 nm.[35]

In Fig. 3, the RTP spectra of NAA in $10^{-2}M$ β-CD, in the presence of 0.5% 2-BE and 0.5% 2,3-DBP, are shown. In the absence of bromoalcohol no phosphorescence signal appears. In contrast, an appreciable RTP emission is evident in the presence of the bromoalcohols. The phosphorescence bands for NOA in our experimental conditions appeared at 504 and 525 nm and for NAA at 494 and 521 nm, in close agreement with the reported literature values. In view of this, the longer wavelength emission observed can be assigned to the RTP of NOA or NAA.

In order to record the RTP spectra, temporal discrimination has been employed, as the fluorescence emission is not totally quenched and still remains in these conditions.

Although the RTP emission observed is much weaker than the fluorescence presented by these compounds, the results indicate a favourable microenvironment that stabilizes the triplet state of the NOA or NAA molecules. It is evident that the presence of the halogen atom of the brominated alcohol enhances the rate of emission of the phosphorescence via heavy atom spin–orbit coupling, although the intersystem

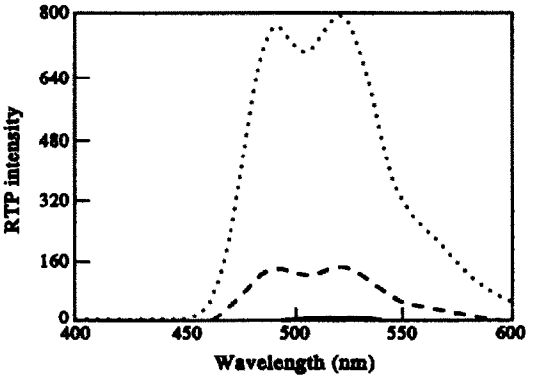

Fig. 3. RTP spectra of the complex β-CD:NAA in the absence of bromoalcohol (—), in the presence of 0.5%2-BE (– – –), and in the presence of 0.5% 2,3-DBP (..).

crossing process is not totally effective, as an appreciable fluorescence remains.

It is also evident that 2,3-DBP is more effective as a heavy atom perturber than 2-BE. This fact can be explained taking into account the following considerations.

The assignation of the phosphorescence emission to a ternary association has been suggested by various authors. Turro *et al.*[10] observed an increase in phosphorescence and lifetime when adding acetonitrile to a β-CD solution containing 1-bromonaphthalene, suggesting the formation of a complex composed of β-CD, 1-bromonaphthalene and acetonitrile. Scypinsky and Cline Love[13,14] attributed the RTP emission of selected analytes in CDs, in the presence of 1,2-dibromoethane, to the formation of a trimolecular complex.

The ternary complexes formed between pyrene, β-CD and alcohols of different size and polarity have been studied previously.[26] It was demonstrated that the stability of the ternary complexes was directly related to the proper geometry and volume of the alcohol to fill the residual void space of the interior of the CD unoccupied by the guest. For example, the ternary complexes formed in the presence of tert-butanol or cyclopentanol presented higher association constants than the complexes formed in the presence of *n*-propanol or ethanol.

From the data presented here, it can be inferred that 2,3-DBP, which is a bulkier molecule than 2-BE, is of a size that is more compatible with the remaining space of the interior of the CD cavity. Consequently, the interaction of the naphthalene derivatives and the heavy atom is more effective with 2,3-DBP than with 2-BE.

On the other hand, higher signals have been obtained, in the same experimental conditions, for the NAA complex than for the NOA complex. The fact that the quenching is more effective in the case of the NAA complex than in the NOA complex, and that the RTP emission obtained is higher, can be attributed to the more effective interaction of NAA with the bromoalcohol in the interior of the CD. The reason lies in that more void space remains in the interior of the CD in the case of the NAA complex than in the case of the NOA complex for the co-inclusion of the bromoalcohol.

An axial inclusion of both naphthalene derivatives in β-CD has been demonstrated previously,[24] and the inclusion of the NAA in the interior of the CD is only partial, because of the steric impediment of the substituted group in position 1, while NOA is almost totally included in the cavity.

In consequence, the bromoalcohol can enter more deeply into the CD cavity in the β-CD:NAA complex than in the β-CD:NOA complex, allowing a closer interaction between the heavy atom of the bromoalcohol and the guest.

The observed behaviour is similar to the effect reported by Turro *et al.*[10] with 1-bromonaphthalene and 2-bromonaphthalane included in β-CD. The addition of acetonitrile increased the phosphorescence intensity and the phosphorescence lifetime of 1-bromonaphthalene. Similar behaviour was observed for 1-chloronaphthalene. However, for 2-bromonaphthalene no appreciable effect of acetonitrile was observed. Similarly to our case, the 1-halonaphthalenes must be only partially included in β-CD, with more void space remaining for the third component to be included inside the cavity, while 2-bromonaphthalene is included more deeply in the cavity and the remaining space for the co-inclusion of acetonitrile is smaller.

Kinetics of the reaction. Optimization of chemical variables

The phosphorescence emission signal is not obtained instantly, but develops with time. The development of RTP emission with time suggests consumption of oxygen in the sample solution by sulphite, as already reported for a similar system.[19] It was also noted that higher signals were obtained when the sample was continuously irradiated at the excitation wavelength with the pulsed xenon lamp than without irradiation. The need for sample irradiation appears to be related to the oxygen consumption in the system. Similar irradiation effects have been reported for other systems and the effect was rationalized in terms of a photochemical catalysis of the reaction.[6,19]

The concentrations of 2-BE,2,3-DBP, Na_2SO_3 and β-CD were optimized by monitoring the phosphorescence emission from NOA and NAA in the presence of several concentrations of these compounds. The study was performed following the kinetics of development of the RTP emission with time under continuous irradiation of the samples with the pulsed xenon lamp.

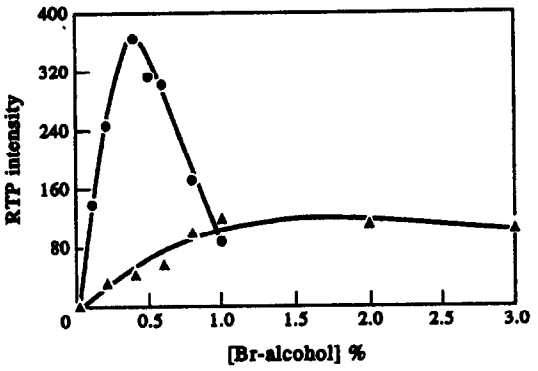

Fig. 4. Influence of the concentration of 2-BE (▲) and 2,3-DBP (●) on the RTP emission from β-CD:NOA:bromoalcohol. [NOA] = $3 \times 10^{-5}M$, [β-CD] = $10^{-2}M$, [Na_2SO_3] = $0.03M$, λ_{ex} = 274 nm, λ_{em} = 504 nm.

Influence of the bromoalcohols in CD-stabilized RTP

The influence of the concentrations of 2-BE and 2,3-DBP on the RTP emission from β-CD:NOA is represented in Fig. 4. Concentrations of 1% 2-BE and 0.4% 2,3-DBP were found as optima for both bromoalcohols, producing the maximum intensities without presenting turbidity.

It is interesting to note that the phosphorescence signals obtained in the presence of 2,3-DBP are always more intense than those in the presence of 2-BE. In addition, it has been observed that the deoxygenation reaction is slower when using 2-BE than when using 2,3-DBP. In consequence, for these particular systems, 2,3-DBP appears to be a more suitable heavy atom perturber than 2-BE for RTP obtention.

Influence of sodium sulphite and β-CD concentrations

Apart from the simplicity, one of the advantages of using sodium sulphite as deoxygenant is a more permanent protection of the solution against contamination with oxygen.[8] However, as stated above, the consumption of oxygen is not immediate, and a photo-induced catalysis of the reaction has been reported for an effective deoxygenation in some cases.[6,19]

The study has been performed by monitoring the signal as a function of time until the RTP signal was stabilized for at least 5 min. The deoxygenation kinetic is a complex process depending on various variables such as irradiation time, naphthalene derivative, and β-CD, bromoalcohol and sodium sulphite concentrations.

To find the optimum concentration of sodium sulphite, various amounts were added to a solution with a fixed amount of NOA ($3 \times 10^{-5}M$), β-CD and bromoalcohol. The concentration of β-CD was $1 \times 10^{-2}M$, and the concentrations of 2,3-DBP or 2-BE were 0.4% and 1.0%, respectively. The development of the RTP emission was followed kinetically by monitoring at 504 nm.

Figure 5 shows the influence of sodium sulphite concentration on the RTP emission from the β-CD:NOA inclusion complex in the presence of 2,3-DBP or 2-BE. The [Na_2SO_3] influences the intensity of phosphorescence and also the time of appearance of the emission. An increment of the concentration of sodium sulphite produces a more rapid obtention of the phosphorescence, because of a more effective deoxygenation. A $0.03M$ sodium sulphite concentration was selected as optimum.

An increment on the phosphorescence intensity has been found in both systems with the increment of β-CD concentration. [β-CD] = $1 \times 10^{-2}M$ has been selected as optimum because higher concentrations of the CD produced turbidity in the samples.

Analytical figures of merit

The phosphorescence intensities of solutions containing NOA in the concentration interval between $1 \times 10^{-5}M$ and $7 \times 10^{-5}M$ were recorded, in the presence of [β-CD] = $1 \times 10^{-2}M$, [Na_2SO_3] = $0.03M$ and 0.4% 2,3-DBP. Each of the samples was continuously irradiated with the pulsed xenon lamp at 274 nm. The phosphorescence was measured at 504 nm (Fig. 6). The results obtained show that a linear

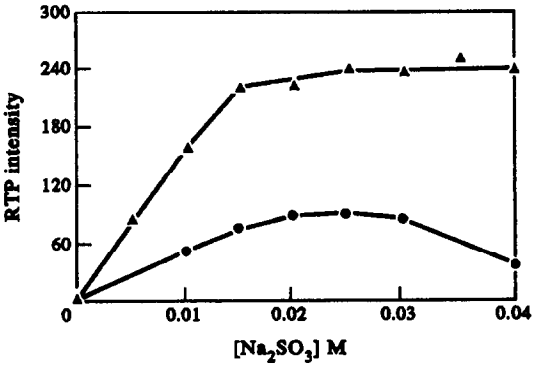

Fig. 5. Influence of sodium sulphite concentration on the RTP emission from β-CD:NOA:2,3-DBP. [NOA] = $3 \times 10^{-5}M$, [β-CD] = $10^{-2}M$, λ_{ex} = 274 nm, λ_{em} = 504 nm. (▲) [2-BE] = 1.0%; (●) [2,3-DBP] = 0.4%.

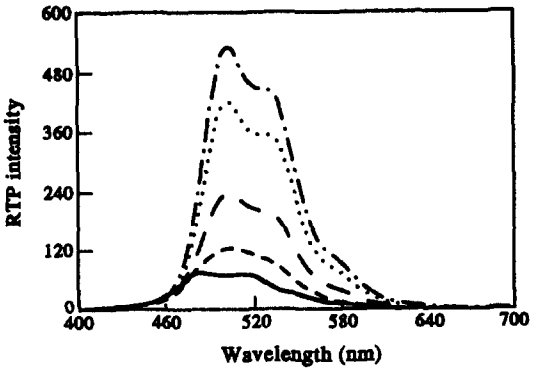

Fig. 6. RTP spectra of β-CD:NOA;2,3-DBP at different NOA concentrations: (a) 0; (b) $1 \times 10^{-5}M$;(c) $3 \times 10^{-5}M$; (d)$5 \times 10^{-5}M$; (e) $7 \times 10^{-5}M$.

relationship exists between the phosphorescence intensity and NOA in the concentration interval assayed.

In the same experimental conditions, exciting at 284 nm and measuring at 494 nm, the RTP emission obtained was linearly related to NAA concentration in the interval between $5 \times 10^{-6}M$ and $5 \times 10^{-5}M$.

The reproducibility of the assay was investigated by measuring the RTP signal of 11 replicated samples. Relative standard deviation values around 10% were obtained in both systems. Sample preparation is one of the critical aspects that must be carefully taken in consideration, as kinetic aspects are involved in the approach. Also, a recent article[36] reports on the use of commercially available β-CD, with respect to some absorption in the UV–visible region and solubility problems because of the lack of purity, which may contribute to the reproducibility problems encountered.

An emission signal from the blank, composed of β-CD and 2,3-DBP, is also evident. This fact has been observed previously by other authors,[37] who found phosphorescence signals from a blank of β-CD in the presence of 1,2-dibromopropane, attributing such emission to the low solubility of the inclusion complex β-CD:1,2-dibromopropane, which produces turbidity in the medium and a dispersion peak in the phosphorescence spectrum.

CONCLUSIONS

It has been shown that potential excited phosphorescent compounds of relatively polar character, such as NOA and NAA, when included in β-CD, in the presence of bromoalcohols, are partially deactivated in deaerated fluid solution at room temperature by triplet state emission. The photophysical characteristics of the triplet state emission for these naphthalene derivatives have been evaluated. 2,3-DBP has been found to be a more adequate external heavy atom perturber than 2-BE for RTP observation in the systems investigated, because of a better size compatibility with the void space of the interior of the CD. Such compatibility should be taken into account in the selection of the appropriate external heavy atom perturber for the observation of RTP emission from other organic molecules of interest.

It is interesting to note that, to date, the obtention of RTP in aqueous CD solutions has only been reported from a few compounds, mainly PHAs and some other compounds of non-polar character.[13,14] Naproxen[15] and NAA[16,17] were the only two compounds of relatively polar character that had been reported to produce RTP in the presence of bromoalkanes. In this work, the approach has been extended to the observation of RTP from NOA and NAA in the presence of bromoalcohols instead of bromoalkanes as external heavy atom perturbers.

A deeper understanding of the systems investigated should lead to a better optimization of the factors involved in the process and, consequently, to a better analytical exploitation of the phenomenon.

SOLID-PHASE EXTRACTION USING C_{18} BONDED SILICA DISKS: INTERFERENCES AND ANALYSIS OF CHLOROTRIAZINES IN SEAWATER SAMPLES

GAEL DURAND and DAMIA BARCELO*

Environmental Chemistry Dept., CID-CSIC, c/Jordi Girona, 18–26, 08034 Barcelona, Spain

Summary—The interferences in C_{18} Empore extraction disks were obtained by processing 5 l. of HPLC water with average blanks of 1 ng/l. A C_{19} alkane, plasticizers and the antioxidant Nonox A were identified in the blanks as possible interferences. The extraction of the components of the disks was carried out with methanol, acetonitrile and/or ethyl acetate with subsequent analysis by gas chromatography–mass spectrometry (GC–MS). The identification of interferences was a requirement for the determination of the chlorotriazine herbicides atrazine and simazine, and of a transformation product, de-ethylatrazine, at concentration levels varying between 2 and 140 ng/l. Seawater samples of 3–28 parts-per-thousand were pre-filtered through a 47-mm diameter of 0.7 μm and subsequently with 0.45 μm glass-fibre filters to trap particulate matter, followed by Empore extraction disks of 500 mg C_{18} bonded silica. Water volumes of 5 l. could be processed within 150 min. The disks were extracted with methanol, the extract was blown down under nitrogen, and the analytes were quantified by GC with nitrogen–phosphorus detection (NPD) with further confirmation using GC–MS in the selected ion monitoring (SIM) mode. The proposed method has been applied to the determination of the environmental levels of atrazine and simazine in seawater samples of varying salinity. The recovery of de-ethylatrazine was 10%, so the method was not appropriate for this compound. The concentration of the herbicides has been plotted against the salinity values, showing a decrease in the levels as the salinity increases, with two inflexion points that indicate a non-conservative mixing with loss of the herbicides in the mixing zone of the estuary.

Several hundred pesticides of different chemical nature are currently used for agricultural and non-agricultural purposes throughout Europe and the U.S.A. Pesticides applied to crops are eventually transported to surface waters by various mechanisms, such as non-point source run-off, groundwater discharge or atmospheric deposition. It has been estimated that pesticide losses are generally less than 0.5% of the amount applied.[1–3] Their residues are currently detected by gas chromatography with nitrogen–phosphorus and mass spectrometric detection (GC–NPD and GC–MS, respectively) in various environmental matrices, such as soil, water and air.[3–7] Atrazine, one of the herbicides most widely used in the U.S.A. and European countries over the last 30 years,[8,9] is employed for both pre- and post-emergency weed control among crops of corn, wheat, barley and sorghum, and also along railways and roadside verges. It has been detected in some U.S. groundwaters at concentrations in the range of 100 ng/l,[10] in the Mississippi river,[1] in Canadian rivers,[2] in the Po river and its effluents[11] and in the waters of various other European countries.[3,9] Recently we reported results on the monitoring of several herbicides in estuarine areas of the Rhône and the Ebro delta,[12,13] where levels varied from 10 to 30 ng/l. This monitoring is particularly important since the estimated annual use of atrazine and simazine in France alone is *ca* 7000 tonnes.[12] The transport of atrazine within river waters occurs through dissolved river matter[1,8] and as a consequence residues of chlorotriazines can easily reach the sea through estuarine areas. Recently, residue levels have been detected in estuarine samples from the U.K. and their concentration levels decreased with increasing salinity.[14]

In the last 2 years, alternative trace enrichment techniques for organic compounds, including pesticides, from water samples have become available. They are based on the solid phase extraction (SPE) principle and use membrane extraction disks, of similar diameter and size to liquid chromatographic (LC) solvent filters. Their main advantage over the conventional SPE cartridges is the high sampling flow

*Author for correspondence.

rate, which is more convenient for sampling in the field. At present, such disks have been tested for different groups of compounds, including pesticides, organotins and phthalates.[15–18]

One of the disadvantages of using SPE techniques, either with cartridges[19] or disks,[16,17] is the impurities which are present in the surface and which, when eluted during the analysis, can interfere with the final measurements. Although a detailed study has been published for C_{18} bonded silica cartridges,[19] only very general statements have been made concerning the interferences in the Empore disks, without giving a detailed description of the various interfering components.[16,17]

The purpose of the present research was to evaluate the presence of extraneous peaks from the Empore extraction disks that can interfere with low level determination of chlorotriazine pesticides in seawater samples. Real seawater samples of varying salinity have been determined by GC–NPD with further confirmation by GC–MS in the selected ion monitoring mode (SIM). The concentrations of chlorotriazines have been plotted against salinity values.

EXPERIMENTAL

Chemicals

HPLC grade water, methanol, acetonitrile and pesticide grade ethyl acetate from Merck (Darmstadt, Germany) were passed through a 0.45 μm filter before use. Simazine was obtained through Polyscience (Miles, IL, U.S.A.); atrazine was purchased from Promochem (Wesel, Germany). De-ethylatrazine was a gift from Ciba-Geigy (Basel, Switzerland).

Sample preparation

HPLC water (5 l.) was used for the blanks study, whereas 5 l. of seawater samples were collected with different salinity values of 0–34‰. The seawater samples were first filtered through fibre-glass filters (Millipore Corp. Bedford, MA, U.S.A.) of 0.70 μm and subsequently with filters of 0.45 μm. The SPE method used a standard Millipore 47-mm filtration apparatus. The membrane extraction disks were manufactured by 3 M (St. Paul, MN, U.S.A.) under the trademark Empore and are distributed by J. T. Baker and Analytichem International. The disks used in these experiments were 47 mm in diameter and 0.5 mm thick. Each disk contains about 500 mg of C_{18} bonded silica material.

The extraction procedure used was as follows: the HPLC blank water samples were passed directly through the Empore extraction disks, whereas the seawater sample solutions were prefiltered to eliminate particulate matter. The disk, placed in the conventional Millipore apparatus, was washed with 2 × 10 ml of methanol under vacuum. The disk was not allowed to become dry and 5 l. of water were immediately extracted with the vacuum adjusted to yield 2 hr 30 min extraction time. After this operation, the pesticides trapped in the disk were collected in 20 ml of methanol, acetronitrile or ethyl acetate (for the blank study) or in 20 ml of methanol for the real seawater samples. After careful evaporation of the methanol to dryness the samples were re-dissolved in 50 μl of ethyl acetate for determination by GC–MS.

In a previous paper,[18] recovery values for atrazine and simazine were, respectively, 100 and 85 with a coefficient of variation (CV) of 5–10%, whereas for de-ethylatrazine the recovery was 10% with a CV of 15%, when spiking the various pesticides at low μg/l levels in artificial seawater samples. The low recovery level of de-ethylatrazine was attributed to a surpass of the breakthrough volume and for this reason the values given in this paper for this particular compound are tentative, since the use of another adsorbent instead of C_{18} is recommended.

GC–NPD and GC–MS analysis

Following SPE, the extracts were injected onto the column of a gas chromatograph (GC 5300 Mega series, Carlo Erba, Milan, Italy) equipped with an NPD. A 15 m × 0.25 mm i.d. fused silica capillary column coated with chemically bonded 50% cyanopropylphenyl–50% methyl polysiloxane DB 225 (film thickness: 0.15 μm) and a 30 m × 0.25 mm capillary column coated with chemically bonded 5% phenyl–95% methyl polysiloxane DB-5 (film thickness: 0.25 μm) (J and W Scientific, Folsom, CA, U.S.A.) were used. Hydrogen was used as carrier gas at 60 kPa and helium as make-up gas at 110 kPa. The temperatures of injector and detector were held at 270°. Both columns were programmed from 60 to 90° at 10°/min and from 90 to 220° at 6°/min.

A Hewlett–Packard 5995 instrument (Palo Alto, CA, U.S.A.) interfaced to a 59970C data system was used. The fused silica column described above was used and was introduced directly into the ion source. Helium was used as the carrier gas (30 cm/sec). The temperature of

the injector was 250°. The ion source and the analyser were held at 200 and 230°, respectively. EI spectra were obtained at 70 eV. Identification of an analyte was from the signals of two ions and their proper ratio, and correct retention time. Ions used for identification were at m/z values of 173 and 215 (atrazine), 172 and 187 (de-ethylatrazine) and 173 and 201 (simazine).

RESULTS AND DISCUSSION

General considerations

The main advantage of using SPE membrane disks such as Empore, instead of SPE cartridges, is the increase in sample throughput as a result of the relatively high flow rates. In this study, only 2 hr 30 min sampling time was needed for the pre-concentration of 5 l. water samples, whereas SPE cartridges would have taken at least 5 hr for the same samples. These results were in good agreement with other studies using disks.[15,17] Pre-filtration of (sea) water samples through 0.45 μm PTFE filters has been recommended before when C_8[20] or C_{18}[14] cartridges, or Empore extraction disks,[15,17] were used. Pre-filtration[21] is extremely important when using membrane extraction disks. So, when using 1 μm over 0.45 μm, the filtration time was reduced by half and effectively removed the particles. When non-pre-filtering was used, the filtration time for 2 l. of natural water was 7 hr,[21] whereas 1.8 hr were needed when using 1 μm pre-filter.

Pre-filtering does not affect the determination of polar pesticides since they exhibit log K_{oc} (partition coefficient between soil organic carbon and water) values of 2, and consequently remain in the dissolved phase and not on the suspended particulates, according to Ref. 1 with a proportion of 99.5% *vs* 0.5%, respectively. In contrast, performing the same experiments with hydrophobic organochlorine pesticides (log K_{oc} of *ca* 6), when there is a strong tendency to adsorb onto the particulate matter on the filter,[22] the same pre-filtering would give much lower recoveries.

Blank levels

In a previous paper,[18] we examined the use of extraction disks for isolation of various pesticides from artificial seawater samples in combination with liquid chromatography–diode array detection (LC–DAD). In this case, blank levels of the cartridges were briefly examined by the use of DAD at 220 and 205 nm. Interferences were noticed in the range of a few μg/l (or ng/l) when isolating pesticides from 4 l. of artificial seawater (or surface water) samples. In the present paper, we have decided to undertake a more in-depth study of the interferences extracted from the SPE disks, since our purpose was to determine chlorotriazine pesticides in water at low ng/l levels. Three different eluting solvents were used: methanol, acetonitrile and ethyl acetate. The blanks obtained when isolating 5 l. of HPLC water samples are shown in Fig. 1. The different compounds identified in the extracts are shown in Table 1. Some of the compounds identified were similar to those found in C_{18} bonded silica cartridges, such as phthalates. The different plasticizers are added

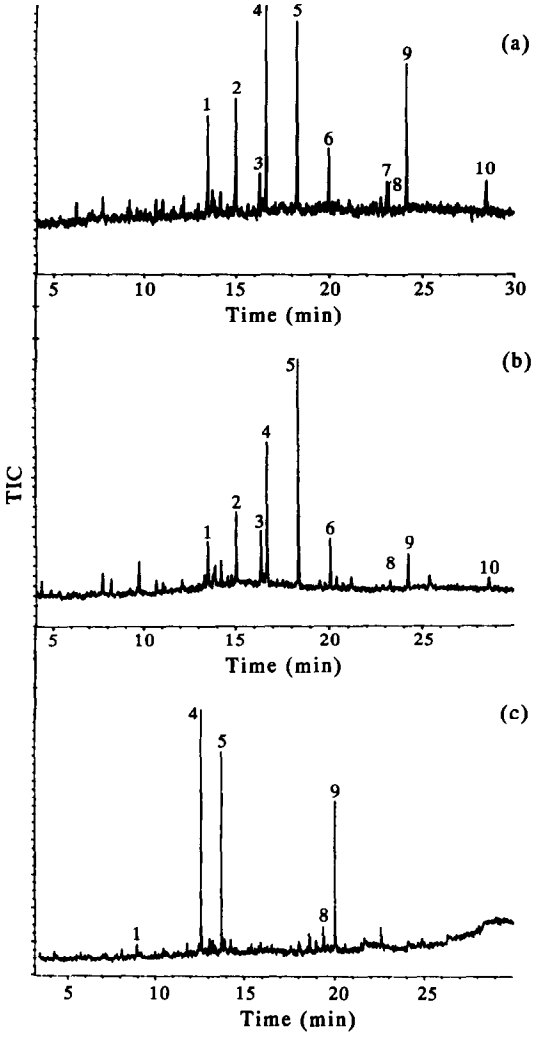

Fig. 1. GC–MS traces obtained on the extract of 5 l. of HPLC water after eluting with methanol (A), acetonitrile (B) and ethyl acetate (C). For compound numbers, see Table 1. For chromatographic conditions, see Experimental section. Two capillary GC columns, DB-225 (A and B) and DB-5 (C), were used.

Table 1. Compounds eluted from C_{18} Empore extraction disks using 5 l. of HPLC water. Unknown compounds are indicated by their m/z values and relative abundance (in parentheses)

Peak no.	Compound	Eluting solvent		
		Methanol	Acetonitrile	Ethyl acetate
1	Diethyl phthalate	+	+	+
2	$C_{19}H_{40}$ (alkane)	+	+	−
3	Dimethyl polysiloxane	+	+	−
4	Dibutyl phthalate	+	+	+
5	Butyl-2-ethylhexyl phthalate	+	+	+
6	Unknown			
	m/z 119 (70%), 213, 215 (100%)	+	+	−
7	Nonox A (antioxidant)	+	−	−
8	Unknown			
	m/z 57 (100%), 171 (50%)	+	+	+
9	Di-(2-ethylhexyl) phthalate	+	+	+
10	Unknown			
	m/z 91 (100%), 290 (30%)	+	+	−

either during manufacture or are present as contaminants in the polymer components. This is due to the polymeric housing used to house the bonded phase materials, in both cartridges[19] and disks.[17] The alkane C_{19} H_{40} was also found as an interference in the disks, as well as in the cartridges, although other alkanes and alkenes were also reported in the latter case.[19] In the case of cartridges, the antioxidant butahydroxytoluene (BHT) was reported,[19] whereas for the disks the antioxidant Nonox A has been found. One of the most relevant differences found between interferences in the use of C_{18} bonded silica cartridges and disks is that no dimethyloctadecylsilanol was found in the case of the disks. This was checked by using the m/z 89 ion corresponding to $[(CH_3O)Si(CH_3)_2]^+$. The absence of this particular ion, which caused great interference in a previous work using cartridges,[19] indicates that a better bonding is achieved in the Empore extraction disks, thus avoiding hydrolysis of the C_{18} bonded porous silica material. Consequently, no silanols are released from cartridges. Another compound, peak no. 3 (Fig. 1) corresponds to the dimethyl polysiloxane phase, which corresponds to the bleeding from the GC column used, DB-225, in Figs 1A and B, whereas in Fig. 1C a DB-5 column was used and this particular peak is not present.

Two previous papers on the use of disks reported a very vague indication of interferences.[16,17] Since interferences depend on the final analytical method of determination used, the GC–ECD traces showed higher background peaks compared to our experiments, but they were lower than when commercial C_{18} bonded porous silica columns were used.[16] This could be caused by the high sensitivity of the phthalates in the GC–ECD determinations. A second paper indicated that phthalate esters and similar plasticizers were probably present in the disks, causing systematic errors when using EPA method 525, with recoveries up to 149% for compounds such as diethyl phthalate.[17] This paper presents the first detailed description of the interferences present in C_{18} Empore extraction disks.

The interference in the blanks has been estimated to be in the range of 0.1–1 ng/l, when filtering 5 l. of water samples. When comparing the three eluting solvents used (see Fig. 1 and Table 1), we noticed that phthalates (compounds 4, 5 and 9) gave somewhat higher background levels when using ethyl acetate. This agrees with previous results when optimizing EPA method 506 for the isolation of phthalates from water samples with C_{18} extraction disks.[23] The percentage recovery for these compounds using ethyl acetate was higher than with the other solvents, with values up to 150%, thus indicating that this eluting solvent has the capacity of removing the phthalates from the C_{18} bonded silica disk more efficiently. The higher recoveries for phthalates match earlier results for the same disks.[17] When ethyl acetate is used as eluting solvent, higher amounts of phthalates are eluted, the polymer housing is wetted more extensively and emulsions are easily formed, causing practical difficulties. Therefore, methanol was preferred for the isolation of the different chlorotriazine pesticides from seawater samples since it is less toxic for routine work.

Environmental levels

The environmental degradation of atrazine has been studied in many agricultural environments, where rates are affected by factors such as pH, the amount of organic matter, soil type and temperature.[9,14,24,25] For example, in Chesapeake Bay, degradation studies indicated that sediments in the bay could easily degrade these contaminants at an accelarated grade compared to inland agricultural environments.[25]

In our experiments, we have studied the variation in concentration of atrazine according to salinity. To achieve this point, we have analysed real seawater samples ($n = 3$ at each sampling point, with a CV of 7% for atrazine and simazine) of different salinities. Typical total ion current GC–MS chromatograms of low and high salinity samples are shown in Fig. 2. Comparing both chromatograms of Fig. 2, it can be noticed that the GC–MS chromatogram obtained at 3 parts-per-thousand salinity has less noise level and is much cleaner than the one obtained at 28 parts-per-thousand salinity. This is due to two reasons: the lower levels of herbicide obtained at higher salinity values and, as consequence, the interferences in the GC–MS traces reach higher values when analysing the samples of high salinity. The different ions used for the identification of the various pesticides have been reported in the Experimental section.

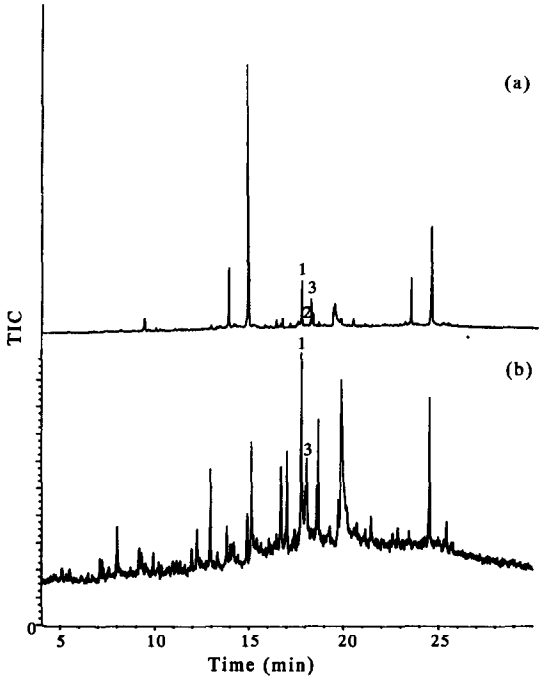

Fig. 2. GC–MS traces obtained on the extract of two estuarine waters of 3 parts-per-thousand (A) and 28 parts-per-thousand (B) salinity. Compounds identified were: (1) atrazine, (2) de-ethylatrazine and (3) simazine.

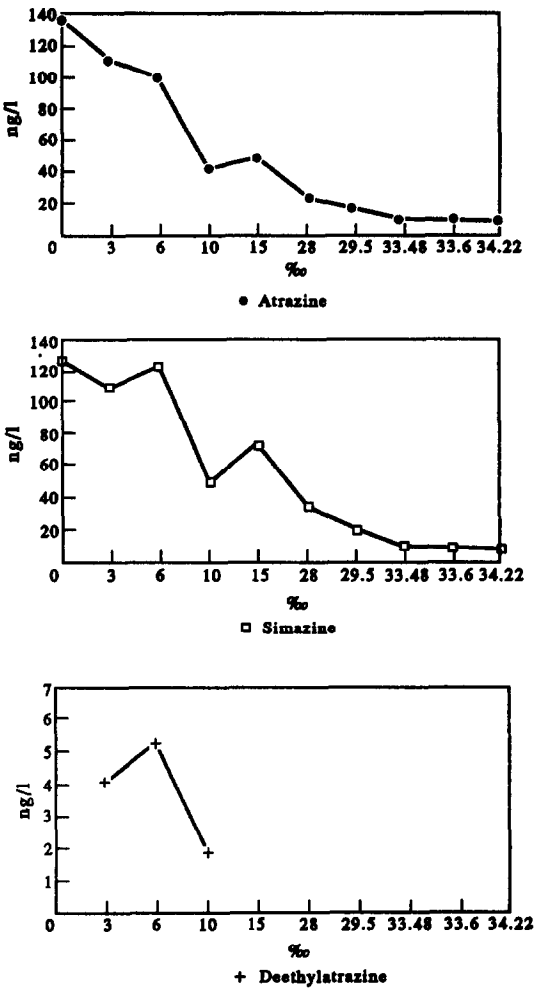

Fig. 3. Concentrations of atrazine, simazine and de-ethylatrazine *vs* salinity values of real seawater samples.

To distinguish between the influence of salinity in the concentration levels of the herbicides in the estuarine waters, in Fig. 3 the concentrations of the different herbicides were plotted against the difference in salinity. In principle, if there were no significant losses in the water column, relatively herbicide-free ocean waters would be expected to mix conservatively with fresh waters, producing a steady decline of the different herbicide concentrations as it progresses from low to high salinity values. A negative, in all three cases, with two inflexion points at the values of 3 and 10 parts-per-thousand salinity, indicates a non-conservative mixing with loss of the herbicides occurring in the mixing zone of the estuary. This behaviour, in the case of atrazine, agrees with that reported in Chakespeare Bay.[8,25] The concentration levels of simazine follow a similar degradation pattern in the estuarine waters. The values of

de-ethylatrazine exhibit poor recoveries (in the range of 10%) with the method used. The values of de-ethylatrazine obtained were in the range of 2–7 ng/l (without correction for the recovery) and are given as an indication. A second point to consider is that its value should always be lower than atrazine and simazine, since it is a compound formed mainly by microbial degradation of atrazine and depends on the application time of atrazine. Its content usually corresponds to *ca* 10–20% of the atrazine level in soil samples.[24]

CONCLUSIONS

The list of the different interferences obtained when using C_{18} bonded silica Empore extraction disks is reported for the first time, phthalates being the main interferences identified in the GC–MS traces. No silanol interference compounds were detected, thus indicating a better bonding of the C_{18} material in the case of these disks in comparison with conventional C_{18} bonded silica cartridges. One main advantage of the Empore disks over C_{18} cartridges is the shorter extraction time (5 l. of water are extracted in 2 hr 30 min, whereas the cartridges require 5 hr). It has been shown for seawater samples that pre-filtration is very important in order to remove the particulate material present in these samples. This operation will not affect the determination of chlorotriazine pesticides, since they are transported into the dissolved phase of the water. GC–MS allows the identification of atrazine, simazine and de-ethylatrazine from interferences and it is of help in avoiding false positives.

The use of SPE with Empore disks described here is recommended for screening chlorotriazine pesticides in real seawater samples at levels as low as 1 ng/l, with different salinity values. A limit of detection of 0.02 ng/l (at a signal-to-noise ratio of 3) has been estimated using GC–NPD or GC–MS with SIM detection. Since interfering compounds are present in real seawater samples, GC–MS is needed for confirmation of the triazines at levels as low as 10 ng/l.

The method proposed in this work can be used in remote places and it is an adequate method for carrying out monitoring studies with large amounts of water to be processed. This is much more convenient since smaller amounts of toxic solvents are used and it avoids the difficulties of handling 5 l. of seawater samples under liquid–liquid extraction procedures.

DETERMINATION OF ASCORBIC ACID IN PHARMACEUTICAL PREPARATIONS BY NEAR INFRARED REFLECTANCE SPECTROSCOPY

M. BLANCO, J. COELLO, H. ITURRIAGA, S. MASPOCH and C. DE LA PEZUELA
Departamento de Química, Unidad de Química Analítica, Universidad Autónoma de Barcelona, E-08193 Bellaterra, Barcelona, Spain

Summary—We developed a method for determination of ascorbic acid in pharmaceutical preparations containing various excipients by using near infrared diffuse reflectance spectroscopy and two different calibration methods, *viz.* stepwise multiple linear regression (SMLR) and partial least-squares (PLS) regression, which provided comparable results and resulted in prediction errors of 1–2%. However, the PLS method provided somewhat better results with the more complex samples.

Near infrared reflectance spectroscopy (NIRRS) has experienced great developments in the last two decades, during which it has been increasingly used in the field of food analysis.[1,2]

However, the appearance of commercially available instruments that allow fast recording of full NIR spectra (basically between 1100 and 2500 nm) and there use for implementation of modern chemometric methods for processing complex signals has extended their scope of application to include all types of solid samples. Control analyses by pharmaceutical industries, where the dependence of the NIRRS signal on both the chemical and the physical properties of the sample, and the accuracy and expeditiousness of this technique offer a great potential, has so far been one the chief applications of this technique.[3]

While early pharmaceutical applications of NIRRS relied essentially on the determination of moisture contents,[4,5] most published work in this respect is concerned with the characterization of compounds (*e.g.*, qualitative identification of pure substances,[6–8] determination of mixture homogeneity,[9,10] particle size,[11] enantiomeric purity,[12] *etc.*). In fact, there are relatively few references to the use of NIRRS for quantitative determination of compounds in end-products.[13,14]

Ascorbic acid (vitamin C) is a frequent occurrence in pharmaceutical preparations, where it is often the principal active component. Most of the host of methods developed for its determination are based on its redox properties;[15] the most commonly used of such methods involves titration[16] with iodine or Ce(IV). All these methods entail prior dissolution of the sample, which is time-consuming and a source of potential error arising from the instability of ascorbic acid solutions. In this work we develop a determination for ascorbic acid in solid pharmaceutical preparations by using the NIRRS technique. Calibration was performed by using two different multivariate procedures: inverse stepwise multiple linear regression (SMLR) and partial least-squares (PLS) regression. The results provided by each are compared below.

Calculation procedures

The SMLR method[17] is a least-squares approach based on the inverse of Beer's law; the concentration is modelled as a linear combination of absorbances in order to obtain the best possible correlation $[C = k_0 + k_1 A_1 + k_2 A_2 + \cdots]$ by using a small number of wavelengths.

The PLS method[17] is a factor-based procedure which can process full spectra. It factors the spectral data calibration matrix into the product of two smaller matrices. This involves a data compression step where the intensities measured at all the wavelengths used in the analysis are compressed to a small number of intensities in a new full-spectrum coordinate system which is composed of loading vectors that can be used to represent the original spectral data. A model is then applied to the intensities in the new full-spectrum coordinate system, called scores, that assumes the concentration to be a linear function of such intensities. The PLS method performs spectral factoring in order to account for the spectral variation while assuring that the

new basis vectors relate to the calibration concentrations:

$$Y = F_y L_y + E_y$$

$$X = F_x L_x + E_x$$

where Y is the concentration matrix, X the analytical data matrix, F_x and F_y the score matrices, L_x and L_y the loading matrices, and E_x and E_y the residual matrices. The score matrices are related by

$$F_y = F_x V + E_c$$

where V is the internal relationship and E_c the residual matrix.

The unknown sample is quantified by determining x_0 and y_0 from

$$y_0 = x_0 (F_y' X)' V L_y.$$

EXPERIMENTAL

Samples and reagents

We assayed two different commercial preparations, namely: Cebión® (Merck), which is commercialized in bags containing 1 or 2 g of ascorbic acid in granules, and Redoxón® (Roche), which is available as effervescent tablets. Ascorbic acid was the active principle in all three products, which contained various excipients (sweeteners, flavourings, *etc.*). The samples used were selected from five different batches of Redoxón, 11 of 1-g Cebión and 8 of 2-g Cebión.

The reagents used in this work included ascorbic acid, sodium bicarbonate, sugar and 0.1*M* KIO_3, 1*M* HCl and 0.5*M* KI solutions. All reagents and solutions were supplied by Merck or prepared from RA grade chemicals from this firm with the exception of sugar, which was for nutritional use. Figure 1 shows the NIRRS spectra of ascorbic acid, 1-g Cebión and Redoxón, while Fig. 2 shows their corresponding first derivatives.

Instrumentation and software

The experimental set-up used consisted basically of the following elements:

A NIRSystems 6500 near infrared spectrophotometer equipped with a reflectance detector and a Spinning Module for sample delivery. The instrument was controlled by the software package NSAS v. 3.20.

A dead-stop detection system composed of a Radiometer pHM29b potentiometer furnished with a Radiometer PP1311 platinum dual electrode, an adapter for connection of a Holder H22 electrode and a polarizer wire of 1 MΩ.

A set of sieves (C.I.S.A.).

Samples were handled and quantified by using the spectrophotometer's bundled software (NSAS), which included both the SMLR and the PLS algorithm. On the other hand, optimization of the PLS procedure and implementation of the multiplicative scatter correction (MSC) method were performed with the aid of UNSCRAMBLER v. 3.54, which required modifying the spectral format by using JCAMP.

Procedure

Laboratory procedure. The laboratory procedure used to determine ascorbic acid involved

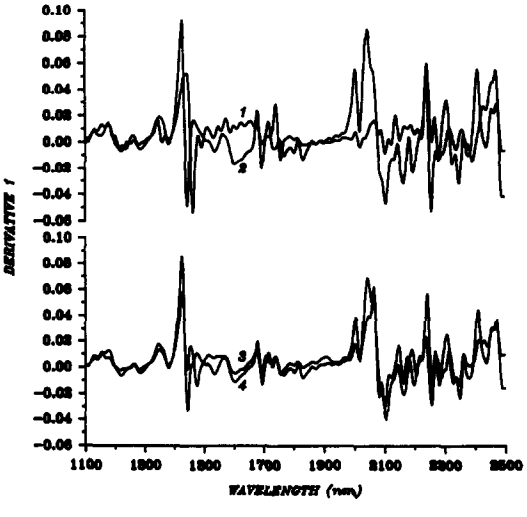

Fig. 2. First-derivative spectra of (1) ascorbic acid, (2) sugar, (3) Redoxón and (4) 1-g Cebión.

titration with potassium iodate[18] and biamperometric dead-stop detection. For this purpose, an amount of 0.3–1.1 g of sample was added to 25 ml of distilled water, 10 ml of 0.5*M* KI and 3 ml of 1*M* HCl, and the resulting solution was titrated with a KIO_3 standard. The ascorbic acid content in each sample was determined as the average of three replicates.

NIRRS procedure. Samples were ground and sifted through 250 μm (1-g Cebión and Redoxón) or 100 μm mesh (2-g Cebión). Each sample was used to record three spectra; the cuvette content was homogenized after each run in order to minimize errors arising from differences between sample fractions. The spectra thus obtained were averaged and the resulting spectrum was used to determine the ascorbic acid content by using the above-described procedures.

Overdosing procedures. In order to expand the calibration range, some samples were overdosed as follows: a known amount of sample was added to a known amount of ascorbic acid or the major excipient (sugar for Cebión and sodium bicarbonate for Redoxón). The mixture was then ground, sifted through 250 or 100 μm mesh and homogenized. Finally, the ascorbic acid content was determined by using the above-described laboratory procedure.

RESULTS AND DISCUSSION

An NIRRS signal is a complex function that depends both on the physical (grain size, crystal structure, *etc.*) and on the chemical properties of the sample. Its mathematical relationship to the concentration can be expressed as follows:

$$\log \frac{1}{R} = a\frac{C}{s} \qquad (1)$$

where R denotes reflectance, a absorptivity, C the concentration and s the scattering coefficient.

One of the factors most markedly influencing the scattering coefficient is the particle size and its distribution. In order to minimize its effect on a quantitative chemical analysis one should process the signal obtained by using a mathematical procedure before the calibration proper is started.[19] There are basically three such types of mathematical treatments, namely: multiplicative scatter correction (MSC), the use of derivative spectra, and signal scaling. We found neither MSC nor scaling to affect result quality, whereas quantification on first-derivative spectra provided substantially improved results. Consequently, all results given below were obtained from unscaled first-derivative spectra.

Table 1. Nominal ascorbic acid content (%) and calibration ranges

	Nominal content (%)	Comercial samples (%)	Overdosed samples (%)
1-g Cebión	16.67	16.33–18.68	14.88–19.16
2-g Cebión	40.0	38.69–45.09	36.60–51.08
1000-mg Redoxón	22.88	22.25–23.16	19.92–25.22

Sample overdosing

The intrinsic complexity of NIRRS signals requires calibration samples to be analogous to the unknown samples and, ideally, the calibration set to consist of samples whose content has previously been determined by a reference analytical method. However, constructing the calibration matrix for pharmaceutical analyses poses special problems. In fact, an appropriate quality control method must be able to accurately quantify both central values and the accepted pharmacopoeial limits. However, only real samples with near-nominal contents are normally available, which compels sample overdosing (*i.e.*, adding a given amount of analyte or excipient in order to expand the concentration range). This is a complicated process that calls for strict control in order to avoid altering the physical properties of the samples and hence the risk of spurious results. To check that the proposed overdosing procedure (*viz.* substance addition, grinding, sifting and homogenizing) did not alter the results at all, a set of real samples was chosen and quantified by using calibration matrices containing increasing numbers of overdosed samples and the sum of the squared differences $[\Sigma(C_{LAB} - C_{NIR})^2]$ calculated and compared. No significant differences were found in any case. The chief drawback of this

Table 2. Results obtained in the quantification of samples by SMLR

	C.E. (%)	V.E. (%)	Wavelength (nm)
1-g Cebión	0.67	0.72	1756, 1650, 2184
2-g Cebión	0.59	0.98	1756, 1646
1-g and 2-g Cebión	1.82	1.98	1756, 1582, 1454
1000-mg Redoxón	1.18	2.34	1462, 2318, 1492, 2372

C.E.: Calibration error, V.E.: Validation error.

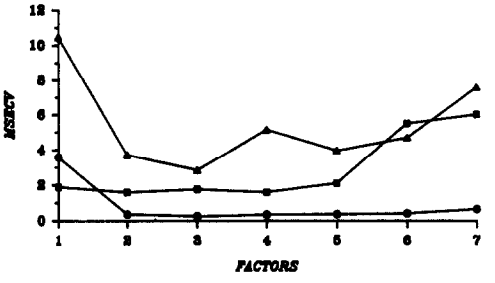

Fig. 3. Plot of the prediction error (MSECV) against the number of factors. (▲) Redoxón, (■) 2-g Cebión, (●) 1-g Cebión.

procedure is the need to subsequently grind and sift the samples to the same particle size as those used for calibration. Table 1 lists the concentration ranges encompassed by the samples and those used in this work.

The initial set of samples (unaltered and overdosed) was divided into two groups. The larger group was used for calibration while the smaller was employed as an external validation set. The accuracy of the analytical procedure was assured by having the validation set contain samples from batches that were not used for the calibration samples.

Quantification of samples by SMLR

One key to obtaining quality results was appropriate choice of the small set of wavelengths to be used. Ideally, one should test all possible combinations; however, this is quite impractical when a large number of wavelengths are involved, so one must use a stepwise selection procedure[20] even though the chosen set may not be the optimal. We choose the first wavelength of the model to be one that: (*a*) belonged to a region of the first-derivative spectrum in which the sample signal were mainly due to ascorbic acid; (*b*) belonged to a broad, non-jagged zone of the plot of the correlation coefficient against the wavelength; and (*c*) possessed a high correlation coefficient. The classical stepwise procedure was used to select a further three wavelengths at the most until the multiple correlation coefficient did not vary significantly. We found this procedure to provide better results than those achieved by having the NSAS algorithm automatically select the wavelengths to be used.

We assayed four calibration models for the quantification of the three commercial preparations and that of 1-g and 2-g Cebión jointly. In order to assess the quality of the results obtained we calculate the errors made in quantifying the mixtures used to construct the calibration matrix (CE) and validation matrix (VE) by using the following expression:

$$\text{Error}(\%) = \sqrt{\frac{\sum_{i=1}^{n} (C_{\text{LAB}} - C_{\text{NIR}})^2}{\sum_{i=1}^{n} C_{\text{LAB}}^2}} \times 100 \quad (2)$$

where C_{LAB} and C_{NIR} denote the ascorbic acid concentration determined by redox titration and spectroscopic quantitation, respectively, and n denotes the number of calibration or validation samples.

Table 2 lists the errors found and the corresponding wavelengths. It should be emphasized that the selection of the first wavelength is not independent of the composition of the sample. Thus, Cebión samples provided good results with 1756 nm as the first wavelength, which however, resulted in relatively large error (VE = 4.0%) for Redoxón samples.

In all cases, both calibration and validation, the intercept and slope of the plots NIR-values *vs.* Laboratory-values close to 0 and 1, respectively, and a regression coefficient $r \geqslant 0.99$, indicate that the NIRRS procedure is subject to no systematic errors relative to the laboratory procedure.

Quantification of samples by PLS regression

The PLS model was constructed by cross-validation; the number of factors to be used was calculated by plotting the prediction

Table 3. Results obtained in the quantification of samples by PLS regression

	C.E. (%)	V.E. (%)	Wavelength range (*nm*)	No. Factors
1-g Cebión	1.04	1.43	1100–2500	3
	1.04	0.89	1300–1800	2
2-g Cebión	0.69	1.30	1100–2500	2
1-g and 2-g Cebión	1.73	1.62	1100–2500	5
1000-mg Redoxón	2.46	2.85	1100–2500	2
	1.93	2.08	1300–1800	3

C.E.: Calibration error, V.E.: Validation error.

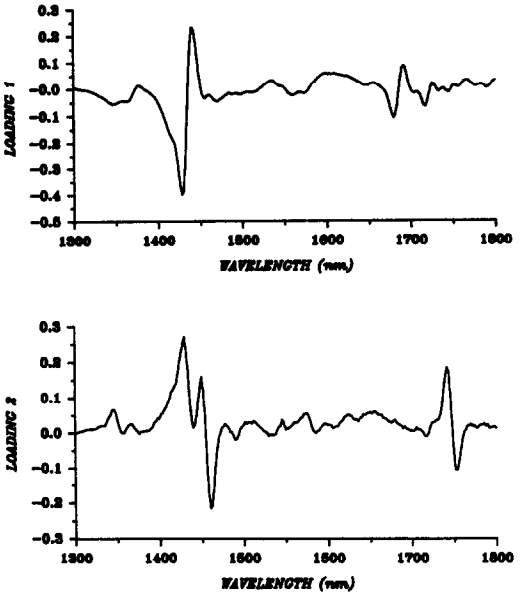

Fig. 4. Plot of the first (*a*) and second (*b*) loading of 1-g Cebión.

error (MSECV) against the number of factors (Fig. 3).

Even though PLS regression is a full-spectrum procedure, selecting the wavelengths to be used for quantification may be of aid, particularly if the calibration matrix is composed of a fairly small number of samples.[17] Such a selection was done by eliminating those wavelengths that either provide no information on the ascorbic acid content or resulted in an anomalously high residual. These two criteria coincided essentially with the two ends of the spectrum (the results were substantially better in the range 1300–1800 nm).

Table 3 compares the results obtained by applying the PLS procedure to the full spectrum and the above reduced wavelength range. As can be seen, the reduced range only improved on the results obtained for 1-g Cebión and Redoxón, which were sifted through 250 μm mesh; on the other hand, those obtained for 2-g Cebión, which was sifted through 100 μm, were virtually the same, which can be ascribed to the increased noise arising from the larger grain size, particularly high in the nearer end of the spectrum.

We used two factors for 1-g and 2-g Cebión separate determination. The corresponding loadings show that the first factor coincided essentially with the spectrum of sugar whereas the second corresponded to ascorbic acid minus the contribution of sugar at some wavelengths [Figs 4(a) and 4(b)]. The larger number of factors used in the joint determination was a result of the need to model the differences between the two types of sample. Redoxón was quantified from three factors, the loadings of which were linear combinations of the spectra of sugar, ascorbic acid and sodium bicarbonate.

CONCLUSIONS

We should emphasize that both the SMLR and the PLS results were very good. Validation errors were always less than 2.5%. Also, the SMLR results were more accurate for the simpler samples (Cebión), while the opposite was true for the more complex sample (Redoxón).

Even though the SMLR procedure is seemingly simpler to implement, it actually involves considerable work in selecting the wavelength set to be used, work which is difficult to systemize. In this respect, the PLS procedure is a much more powerful alternative that allows resolution of more complex samples and systematic optimization.

Finally, we should underscore that the NIRRS technique is accurate enough to ensure that the active principle content is within pharmacopoeial limits. In addition, its expeditiousness make it an appealing alternative to classical analytical control procedures.

FLOW INJECTION FLAME ATOMIC ABSORPTION SPECTROMETRY FOR SLURRY ATOMIZATION. DETERMINATION OF IRON, CALCIUM AND MAGNESIUM IN SAMPLES WITH HIGH SILICA CONTENT

IGNACIO LÓPEZ GARCÍA, JESUS ARROYO CORTÉZ and MANUEL HERNÁNDEZ CÓRDOBA*
Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, 30071 Murcia, Spain

Summary—A study on the use of slurries in flame atomic absorption spectrometry is reported. Samples with a very high silica content are ground and then slurried in a solution containing 2% hydrochloric and 3% v/v hydrofluoric acids. The suspensions are prepared in the 0.01–1% m/v range and introduced into the flame by means of a simple flow injection manifold. Relative standard deviations for the measurements of iron, calcium and magnesium in diatomaceous earth samples are in the 1.5–2.8, 2.2–5.3 and 2.8–5.0% ranges, respectively. To avoid the use of suspensions prepared with a very low percentage of solid sample and to improve the reproducibility, an on-line dilution manifold is tried. The use of an easy-to-construct variable volume dilution chamber allows the on-line dilution of the slurries, thus permitting the determination of calcium and magnesium over a wide range of concentrations. Calibration is performed using aqueous standards. The experimental conditions, optimized for the determination of iron, calcium and magnesium in diatomaceous earth samples, can also be applied to other silica-based materials, as is shown by the analysis of several standard reference materials.

Conventional sample introduction in flame atomic absorption spectrometry (FAAS) requires that solid samples be dissolved to obtain suitable solutions for measurement. In some instances, this involves a straightforward, easy-to-perform step but, in many other practical situations, the stage is time-consuming, involving tedious digestion or fusion procedures and the risk of contamination or analyte loss due to prolonged sample manipulation. If the dissolution step can be avoided and the solid sample is directly introduced into the atomizer, these drawbacks are overcome and the time needed to perform the determination is considerably shortened. For this, interest has focused on slurry-based methodology, in which, instead of a solution, a suspension prepared from fine particles of the sample is introduced into the atomizer. This is a recognized approach when electrothermal atomization is used,[1] but severe problems restrict its application with a flame. Firstly, there are transport efficiency problems through the spray chamber, which are strongly affected by the particle size and the density of the particles. As is to be expected, the greater the particle size and density, the lower the analytical signal and reproducibility obtained. A low particle size is also needed to minimize the risk of the nebulizer clogging when the suspension is being continuously aspirated. On the other hand, although the finest particles can reach the flame, atomization is hindered by the relatively low temperature of the flame and the short residence time. Thus, a sufficiently low particle size appears to be a pre-condition for the slurry–FAAS approach to be successful. How low the particle size must be for a good analytical signal to be obtained is related to the characteristics of the sample and the analyte. Predictably, a suspension prepared from biological material is easier to atomize than one prepared from a refractory material.

Despite the above difficulties, following the work of Willis,[2] a number of researchers have reported successful results in the flame atomization of slurries. O'Reilly and Hicks[3] carried out a detailed study of the direct analysis of coal samples. Fagioli *et al.* have also reported FAAS procedures for vegetables[4,5] after a partial wet-ashing with concentrated sulphuric acid. Other workers have also developed procedures for the determination of several elements in soils,[6] sewage sludges[7] and biological materials.[8,9]

As Fuller suggested many years ago,[10] the risk of nebulizer clogging when aspirating suspensions is greatly minimized if discrete

*Author for correspondence.

nebulization, instead of continuous aspiration, is used. This problem can also be overcome by using Babington nebulizers.[8] Flow injection (FI) methodology also appears to be a suitable method of avoiding clogging problems when introducing a suspension into the flame,[11] because this approach is similar to the one in which FI is used for the introduction of liquid samples with high concentrations of dissolved solids.[12] The FI–FAAS–slurry approach has been reported for the determination of several analytes in sewage sludges,[13] iron oxide pigments[11,14] and foods.[15–17] From our previous experience on this topic, the inclusion in the FI manifold of a simple three-way connector with a tip open to the air aids the fragmentation of the plug. This system of air compensation of the difference between the nebulizer uptake rate and the peristaltic pump flow rate, which is based on an idea from Yoza *et al.*,[18] and discussed by others,[19–21] is a simple, inexpensive way of improving nebulization, the T-piece acting as a pre-nebulizer. However, this approach does not improve slurry volatilization in the flame.

It has been shown that, when dealing with some slurries, a considerable fraction of the analyte is in the supernatant,[22,23] as a consequence of ultrasonic treatment or of the solubilizing action of the suspension media. For this reason, if the samples are pre-digested[4,5,7,13,17] or submitted to cold acid extraction processes,[24] a low particle size is not so critical, as most of the analyte is brought into solution.

On the other hand, the linear response range of FAAS is narrow. When dealing with suspensions from samples with high contents of the analyte, very dilute suspensions need to be prepared, which can generate reproducibility problems due to the low amount of sample to be weighed and to the errors associated with the sampling of slurries.[25] FI methodology can help solve this problem, as a variety of manifolds have been described which permit the on-line dilution of the sample.[26–35]

In this paper, we report the determination of iron, calcium and magnesium by direct introduction into the flame of slurries prepared from samples with a high silica content. The study was mainly performed using diatomaceous earth (DE) samples, a commercial product with very high silica content. The conclusions can be extended to other silica-based materials, as is shown by analysing several standard reference materials.

EXPERIMENTAL

Apparatus

Most of the measurements were obtained using a Pye Unicam Model SP1900 atomic absorption spectrometer. The analogical output of the instrument was connected to a personal computer via a PCLab 818PG data acquisition card. Home-made software written in C language together with a commercial package for the plotting of scientific data were used for the direct plotting of the absorbance–time relationship. The software also permitted the measurement of the area (integrated absorbance). Some experiments were performed using a Perkin–Elmer Model 1100B atomic absorption spectrometer equipped with deuterium-arc background correction. The measurements were made at 248.3, 422.7 and 285.2 nm for iron, calcium and magnesium, respectively. Air–acetylene flames were used exclusively. X-ray fluorescence measurements were made, for comparison purposes, with a Philips PW1400 wavelength dispersive X-ray spectrometer.

The two FI manifolds used are shown in Fig. 1. The simplest one (a) consisted of a Gilson Minipuls HP4 peristaltic pump with an Omnifit injection valve. Sample loops, as well as all connecting lines, were made of 0.8 mm i.d. polytetrafluoroethylene. For both manifolds, a three-way connector with a tip open to the air was included immediately before the spectrometer. The entry of air through this T-piece as a consequence of the difference between the nebulizer uptake rate and the pumping flow rate aids the fragmentation of the sample plug.[19] Manifold (b), which uses two injection valves, has recently been reported[35] and is shown here in a simplified manner. This manifold permits the on-line dilution of the suspensions. S_1 is a common plastic syringe used to inject a plug of air. S_2 is another similar syringe adapted as a variable volume dilution chamber.[34] V_3 is a two-way valve to switch between the upper and lower outlets of S_2. To obtain the on-line dilution, a plug of suspension and a plug of air, with a volume higher than that of the dilution chamber, are simultaneously injected into the manifold. When the sample plug reaches the dilution chamber, it is rapidly mixed with the carrier filling it. In this way, the diluted suspension leaving the chamber, pushed by the plug of air, has a constant concentration and a plateau is obtained for the absorbance–time

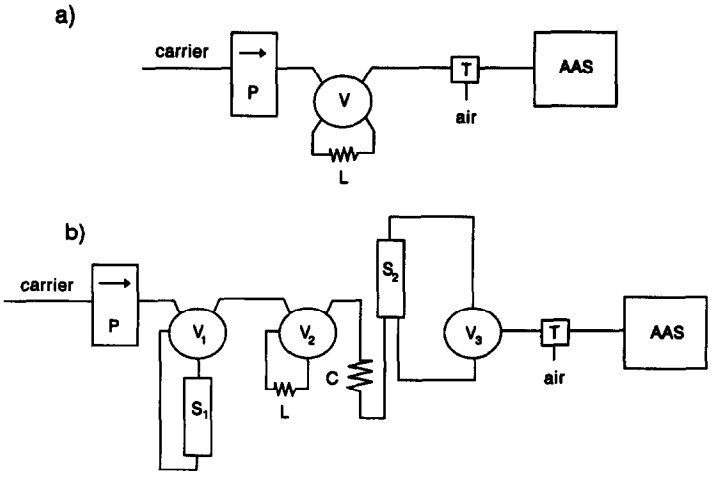

Fig. 1.(a) FI manifold for the direct introduction of the slurries. P, peristaltic pump; V, injection valve; L, sample loop; T, T-piece for air compensation. (b) FI on-line dilution manifold used for calcium and magnesium determinations (see text for details).

relationship. A detailed description of the manifold, its performances and its limitations is given elsewhere.[35]

Slurry procedures

DE samples were ground for 20 min using an agate ball mill. For the determination of calcium and magnesium, slurries were prepared in the range 0.01–0.05% by weighing the samples in 100 ml plastic containers and then adding 50 ml of a 2% v/v hydrochloric acid and 1% v/v hydrofluoric acid solution. For the determination of iron, the slurries were prepared in the 0.1–1% range and the hydrofluoric acid concentration increased up to 3%. The suspensions were submitted to ultrasounds for 10 min and then 0.5 g of solid lanthanum nitrate were added. After the slurries were magnetically stirred for another 10 min, and while they were being continuously stirred, a 150 μl volume was injected into the FI manifold reported in Fig. 1a. Bidistilled water was used as the carrier at a flow rate of 2.5 ml/min.

When the on-line dilution device was used, 0.1–0.8% suspensions were prepared in a similar way. For this case, the hydrofluoric acid percentage was increased up to 3% and no lanthanum was added to the slurries. A 2% v/v hydrochloric acid and 1% m/v lanthanum nitrate solution was used as the carrier at pumping rates ranging between 1 and 4 ml/min. The size of the sample loop as well as the internal volume of the dilution chamber were adjusted so that the response was in the linear range of the instrument. Typical values used for a representative DE sample were 50 μl for the injected volume and 4 ml for the dilution chamber, thus providing a dilution degree of about 80. In all cases calibration was performed using aqueous standard solutions.

For the analysis of standard reference materials, the same methodology was followed, the grinding time being increased up to 30 min.

Reference procedures

For comparison purposes, ground DE samples (0.1 g) were accurately weighed into a platinum crucible and 0.9 g of boric acid and 0.6 g of lithium carbonate were added. The powders were mixed carefully using a platinum rod and then fused (1000° for 30 min). The melt was treated with 10 ml of a 3*M* hydrochloric acid solution by heating until total dissolution. The solution was finally diluted up to 100 ml.

The samples were also analysed by using an acid dissolution procedure. For this, using a platinum crucible, 5 ml of a 1:4 sulphuric acid solution and 5 ml of concentrated hydrofluoric acid were added to 0.2 g samples. The crucible was heated until sulphur trioxide fumes were seen and, once cooled, 5 ml of a 1:1 hydrofluoric acid solution were added, and the final volume adjusted to 100 ml with water. The calcium content was also obtained using X-ray fluorescence spectrometry and the standard additions technique.

RESULTS AND DISCUSSION

A considerable number of previous experiments were devoted to studying the stability of suspensions prepared from ground DE samples.

Sodium hexametaphosphate, polyvinylalcohol and Triton X-100 provided only partial stabilization. A number of detergents of the Span and Tween series,[36] covering a wide range of hydrophilic/lipophilic ratios, were also tried. Partial stabilization was achieved using Tween 20 in a high percentage (10%) or 20% glycerol as the suspension media. However, the severe change in the physical properties of the suspensions led to low atomic absorption signals. For this reason, the use of stabilizing agents was discarded and the sample loops were filled while the suspensions were being continuously stirred.

Recovery

The difficulties in transporting the sample to the atomizer can be greatly alleviated if the samples are introduced by means of the simple FI manifold shown in Fig. 1a, as the discrete nature of the sample introduction mode and the continuous rinsing action of the carrier minimizes the risk of the system clogging. However, the problem of partial atomization remains, since this is more severely affected by particle size and the short residence time inside the flame. It is apparent that, in general, better performances should be obtained if plasma techniques are used, instead of FAAS, due to the higher temperature of plasma, which facilitates atomization and permits successful results.[37–39] In spite of these considerations, our efforts were directed at obtaining atomization efficiencies close to those obtained using aqueous solutions, which would enable the simplest calibration with aqueous standards. The quality of the approach can be followed by means of the recovery value. It can be defined as the ratio, expressed as a percentage, between the apparent concentration of the analyte obtained when atomizing the slurry and the true concentration obtained using a reference method. If the recovery is close to 100%, direct calibration with aqueous standards is valid, whereas if it is less, slurries prepared from previously analysed similar samples must be used for calibration or empirical correction factors are needed. Recovery values reported in the literature are in the 20–100% range, depending on the type of sample. As the particle size severely affects the recovery, previous experiments were devoted to studying the sample comminution. DE samples of several batches were submitted to grinding during different intervals of time; 0.1% suspensions were prepared in water and 150 μl aliquots injected into

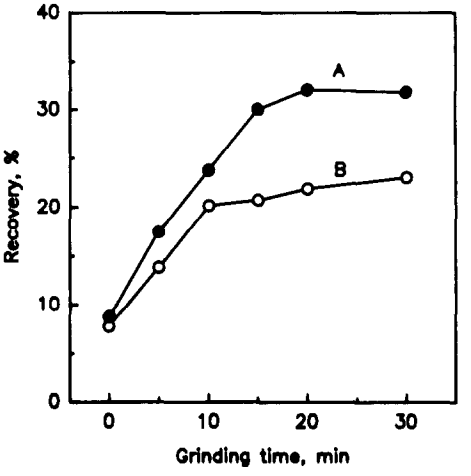

Fig. 2. Recovery of iron from 0.1% DE suspensions using water as the suspending medium. (A) A sample with high content of tridymite. (B) A sample with high content of cristobalite.

the simple FI manifold shown in Fig. 1a using water as the carrier. As can be seen in Fig. 2, where the recovery values for iron are plotted against the grinding time, 20 min was sufficient to obtain the maximum analytical signal, though the recovery was far from 100%. It was noted that the recovery values varied slightly among different batches of DE samples, and this was shown by X-ray diffractometry to be related to the mineralogical composition of the samples. Those containing higher amounts of tridymite provided higher signals than those in which cristobalite was the predominant crystallographic phase.

Previous experiments using the visual observation of electron micrographs indicated that, after a 20 min grinding time, the bulk of the particles was below 5 μm. However, this estimation was considered to be prone to error and not sufficiently accurate for FAAS purposes, and other approaches were considered. Since no instrumental facilities were available to measure particle size, 1% slurries were prepared in water using a DE sample which had been submitted to different grinding times. Next, aliquots were taken at different times and the mass of solid contained in each aliquot weighed. In this way, the application of Stokes' law allowed an estimation of the particle size distribution. The results, summarized in Fig. 3, indicated that grinding considerably decreased mean particle size, although not to the high degree that visual observation of electron micrographs suggested. It is clear that this particle size is not sufficiently low to allow complete atomization, which

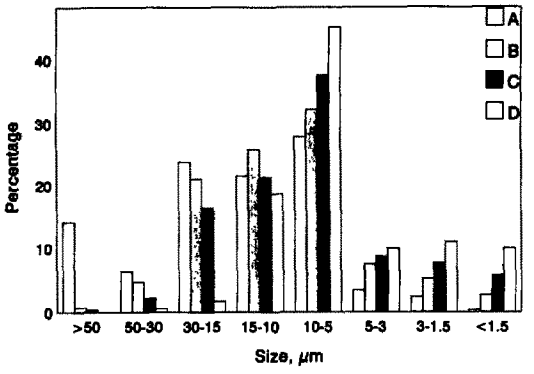

Fig. 3. Particle size distribution of a DE sample. A, B, C and D indicate 0, 5, 10 and 20 min of grinding time, respectively.

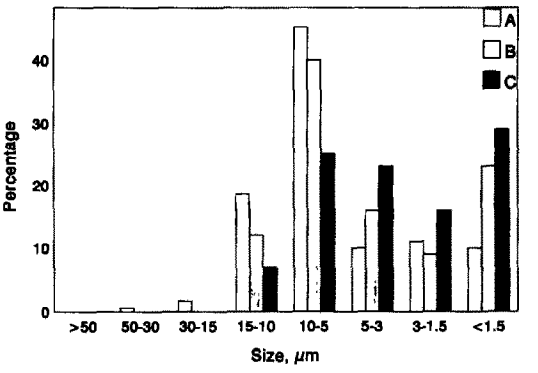

Fig. 4. Particle size distributions for a sample ground during 20 min and slurried using different media: (A) water; (B) 2% hydrochloric acid; (C) 2% hydrochloric acid and 3% hydrofluoric acid.

explains the low recovery values shown in Fig. 2. Thus, in addition to grinding, a modification of the procedure is needed to increase the recovery values.

It has been proved[22,23] that when dealing with slurries, in many instances, a considerable fraction of the analyte is extracted into the liquid phase of the suspension, as a consequence of the solubilizing action of the suspending media. If this occurs, a very low particle size is not so critical. With this in mind, diluted solutions of hydrochloric acid and mixtures of hydrochloric and hydrofluoric acids were assayed as the suspension media. Suspensions were prepared, in triplicate, from 14 DE samples and submitted to stirring for 20 min before injecting into the manifold; each slurry was injected three times. As is shown in Table 1, the use of a mixture of hydrochloric and hydrofluoric acids allowed recovery values very close to 100%. This approach of using dilute solutions of hydrofluoric acid as the suspending media has already been reported as a means to extract analytes into the aqueous phase and to increase the lifetime of the graphite material when slurries of samples of high silica content are introduced into electrothermal atomizers.[40-42]

The successful results obtained are mainly due to the extracting effect which brings to solution a considerable fraction of the analytes and, to a lesser extent, to the decrease in particle size as a consequence of partial solubilization. Figure 4 shows data obtained using Stokes' law for the particle size distribution when suspensions were prepared using different suspension media. From the experimental data it was calculated that when using water as the suspending medium, 90% of the particles were below 11 μm and 50% below 7 μm (these are the d_{90} and d_{50} values, respectively, as defined in the literature[43]). These values decreased to 9 and 3 μm, respectively, when the mixture of hydrochloric and hydrofluoric acids was used. The extracting effect is shown in Fig. 5a, in which the extraction percentage, obtained by analysing the supernatant after the suspensions were filtered through a 0.45 μm chromatographic membrane filter, is plotted against the time of contact between the solid sample and the suspending solution. As Fig. 5b shows, when using a 1% v/v hydrofluoric acid and 2% hydrochloric acid solution as the suspension medium, recoveries for iron were complete after the suspensions

Table 1. Recovery values for different suspending media

	Recovery* (%)		
Suspending medium	Iron	Calcium	Magnesium
Water	31 ± 9	23 ± 6	17 ± 5
2% hydrochloric acid	64 ± 5	71 ± 8	45 ± 6
2% hydrochloric acid and 1% lanthanum nitrate	65 ± 5	79 ± 3	57 ± 3
2% hydrochloric acid and 1% hydrofluoric acid	99 ± 2	92 ± 10	87 ± 8
2% hydrochloric acid, 1% hydrofluoric acid and 1% lanthanum nitrate	99 ± 2	101 ± 2	100 ± 3

*Mean value ± standard deviation for 14 DE samples.

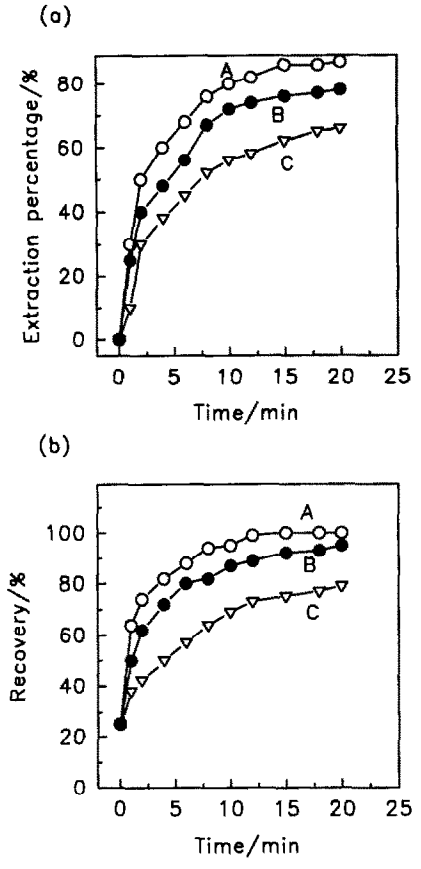

Fig. 5. Effect of hydrofluoric acid. (a) Percentage of iron extracted into the supernatant at different times after the addition of hydrofluoric acid. (b) Recovery of iron at different times. In all cases 0.1% suspensions and 2% hydrochloric acid were used. Curves A, B and C were obtained using 1, 0.1 and 0.05% hydrofluoric acid.

were stirred for a minimum of 15 min. Similar results were obtained for calcium and magnesium when lanthanum nitrate was added to the suspension medium (Table 1).

The effects of the sample loop and the flow rate were studied in the 26–350 μl and 0.5–4.5 ml/min ranges, respectively. Maximum and constant peak heights were obtained when the sample loop was above 130 μl. An injection volume of 150 μl and a flow rate of 2.5 ml/min are recommended.

It should be noted that in order to obtain the highest recovery values for calcium and magnesium, lanthanum nitrate was added to the suspending media. No practical problems related to calcium fluoride or lanthanum fluoride precipitates were encountered. On the other hand, in spite of the very high number of injections performed to carry out this work, clogging problems were only occasional, and were more frequent when dealing with slurries containing more than 1% of solid sample. When this occurred, clogging was invariably located at an FI connection.

Slurry percentage

A number of suspensions with different percentages of DE were prepared and the peak heights for the three analytes obtained (10 measurements in each case). In all cases, the percentages of the suspensions were chosen in such a way that the analytical signals were in the linear response range of the spectrometer. A linear relationship was verified between the percentage and the peak height in the 0.1–1% m/v range for iron and in the 0.01–0.05% m/v for calcium and magnesium for a DE sample containing 0.18, 2.4 and 0.12% m/m of iron, calcium and magnesium, respectively. The relative standard deviations (RSDs) of the measurements were 1.5–2.8, 2.2–5.3 and 2.8–5.0%, respectively.

When possible, the use of suspensions with a very low percentage of solid sample should be avoided because it is prone to poor reproducibility caused by weighing errors and problems of heterogeneity. To avoid this, the manifold shown in Fig. 1b was used to obtain the on-line dilution of the slurries. In such a way, in spite of the high calcium and magnesium content of the samples, suspensions more concentrated than 0.1% could be analysed. The manifold uses an easy-to-construct variable volume chamber[34,35] as an on-line dilution device. If a volume V_i of suspension is injected, the slurry inside the chamber suffers a degree of dilution, which is given by the V_c/V_i ratio[35] where V_c is the internal volume of the dilution device. The suspension leaving the chamber has a constant percentage, thus providing a plateau for the absorbance–time relationship. The height of the plateau or, better still, its area, can be used as the analytical signal.[35] One problem when suspensions are injected into such a dilution device is the risk of a partial sedimentation of the particles inside the chamber, which requires the use of a stabilizing agent. However, this was not observed for DE suspensions, which can be attributed to the low particle size and the low density of the sample, as well as to the short time the suspension remains inside the chamber.

In this case, due to the high degree of dilution suffered by the sample plug, lanthanum was added to the carrier instead of to the suspension media. The main FI conditions were again studied and the best results were found when a

1% lanthanum nitrate and 2% hydrochloric acid solution was used as the carrier and the slurries were prepared using a 2% hydrochloric and 3% hydrofluoric solution as the suspending medium. The manifold permits a wide range of degrees of dilution simply by moving the piston of the syringe used as the dilution chamber. In such a way, the suspensions can be prepared with percentages higher than 0.1% and the internal volume, V_c, can easily be adjusted, depending on the content of analyte in the sample, to provide a response in the linear response range of the instrument. It should be noted that it is not necessary to know the exact position of the piston and the consequent value of V_c, provided that samples and standards are injected under the same conditions, since they suffer an identical degree of dilution.

To check the behaviour of the device, a number of suspensions were prepared using a DE sample containing 6.3% of calcium. When these slurries were injected into the manifold, using a flow rate of 3.5 ml/min and a degree of dilution of about 80, a linear relationship was verified between the analytical signal (height or integrated absorbance of the plateau) and the slurry percentage in the 0.1–0.8% range. Values of RSD were in the range 2.3–3.6% (10 measurements). Similar experiments were carried out for magnesium as the analyte and using different DE samples. In all cases, excellent agreement was found between the experimental results and those expected.

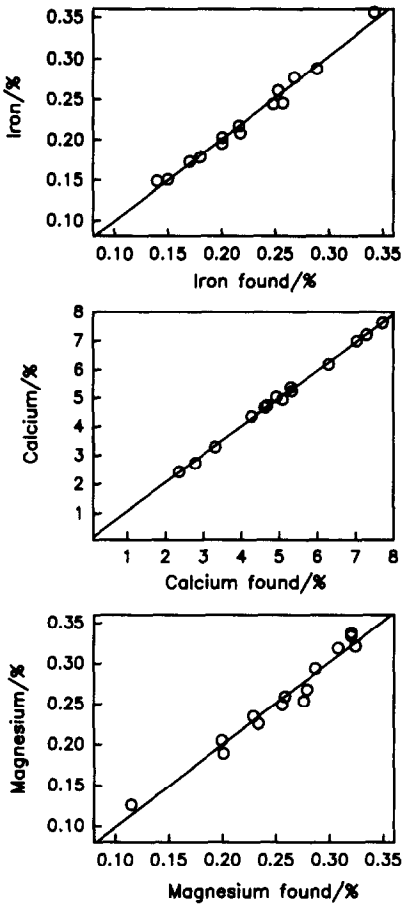

Fig. 6. Comparison of results for 14 DE samples. Values on the abscissae were obtained using the slurry procedure. Values on the ordinates were obtained using reference procedures.

Comparison of results

Taking into account all the above, direct calibration with aqueous standards is valid. To assess this, a considerable number of DE suspensions were prepared and standard addition calibration graphs for iron, calcium and magnesium were obtained using the simplest FI manifold. As can be seen from Table 2, the slopes of these lines agreed (95% confidence level) with those of calibration graphs obtained for aqueous standards, which are included for comparison.

Table 2. Slopes of standard addition calibration graphs

	Slope ± standard deviation (A *ml*/*μg*)	
Analyte	Aqueous standards*	DE slurries†
Iron	0.0182 ± 0.0002	0.0178 ± 0.0005
Calcium	0.0334 ± 0.0004	0.0336 ± 0.0008
Magnesium	0.256 ± 0.003	0.259 ± 0.004

*Values obtained from five calibration graphs. Each graph was constructed from four points and each point was measured three times.

†Values obtained from 14 DE samples. Three slurries were prepared from each sample. Each graph was constructed from four points and each point was measured three times.

To assess the reliability of the approach, the contents of iron, calcium and magnesium in 14 DE samples were obtained using alternative methods and the results compared with those found by means of the procedure discussed here. Three different procedures were used for comparison, two of them using AAS measurements after the samples were dissolved with a mixture of hydrofluoric and sulphuric acids or by means of a fusion with lithium carbonate and boric acid, as indicated in the Experimental. In the third procedure, calcium content was also obtained using X-ray fluorescence spectrometry. Figure 6 shows the correlation between the data obtained using the reference procedures and those found by the slurry procedure discussed

here. Data on the ordinate axis are the mean values obtained by the reference procedures. Data for calcium and magnesium on the abscissa axis are the mean of the values obtained using the simple FI manifold and the on-line dilution device.

To check that the experimental conditions studied for DE samples can also be applied to other silica-based samples, a number of reference standard materials were submitted to the discussed procedure and the results are summarized in Table 3. It is important to indicate that when these materials were analysed, the results were lower than those certified and problems due to a partial sedimentation of the solid particles inside the dilution device were encountered when this manifold was used to determine calcium and magnesium. The problems were overcome and the results agreed with those certified when the samples were previously submitted to grinding for 30 min.

MULTICOMPONENT ANALYSIS: COMPARISON OF VARIOUS GRAPHICAL AND NUMERICAL METHODS

R. D. BAUTISTA, F. JIMENEZ, A. I. JIMENEZ and J. J. ARIAS*

Departamento de Química Analítica, Bromatología y Toxicología, Facultad de Química, Universidad de La Laguna, E-38204 La Laguna, Tenerife, Spain

Summary—The performance of several graphical (zero-crossing and derivative quotient spectra with standardized divisor) and numerical methods (MULTIC and PLS) for the resolution of binary and ternary mixtures of species is compared. Numerical methods were found to be specially suited to multicomponent analysis, particularly for mixtures containing more than two analytes with highly overlapped spectra. The results obtained by using the compared methods to analyse various synthetic mixtures of acetylsalicylic acid, caffeine and thiamine were quite consistent and errors in the simultaneous quantification of the analytes amounted to less than 5% in all instances.

Resolving complex multicomponent systems with no prior separation of the constituent analytes is rather a difficult task. As a rule, the problem is worsened when two or more of the analytes involved interact with one another, as is often the case with biochemical and clinical samples. In the last few years, development of methods for the resolution of such systems has grown dramatically, probably as a result of the increasing affordability of powerful instrumentation and the availability of robust numerical methods.

Thus, the inception of derivative spectrophotometric techniques has brought about significant gains in spectral resolving power: changes in ordinary absorbance spectra can be detected more readily, which allows many complex mixtures to be assessed both qualitatively and quantitatively. The zero-crossing method, developed by O'Haver,[1] and that of derivative quotient spectra, designed by Salinas *et al.*,[2] are the most frequently used for this purpose.[3–6] In recent work we developed a modified version of the latter.[7]

On the other hand, the inception of computers in the analytical laboratory has fostered the development of a large number of mathematical treatments (*e.g.* Simplex, Multiple Linear Regression, Principal Component Regression, Partial Least Squares)[8] which facilitate the analysis of mixtures yielding highly overlapped peaks. By using a multiple linear regression procedure, these methods determine the concentration that best fits an over-dimensioned equation system that is, in turn, established by measuring the absorbance of a given sample at a larger number of wavelengths than that of analytes to be determined.

In this work we compare the performance of various graphical and numerical methods in the resolution of several binary and one ternary mixture of caffeine, thiamine and acetylsalicylic acid. All three are of pharmacological interest and had previously been determined individually,[9] but never in mixtures.

THEORY

Zero-crossing method

The method is based on the measurement of the absolute value of the derivative spectrum of the mixture at an abscissa value (wavelength) where the intensity of one of the components of the mixture goes to zero. At this wavelength the intensity is directly proportional to the other component.

Derivative quotient spectra method

The quotient spectrum method was originally developed by Blanco *et al.*[10] and subsequently modified by Salinas *et al.*,[11] who calculated the derivative of the spectrum obtained by dividing the Beer law expression as applied to a binary mixture into a standard spectrum recorded for

*Author for correspondence.

a solution containing a known amount of either component. Thus,

$$\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{A_{\mathrm{M},\lambda_i}}{\epsilon_{\mathrm{A},\lambda_i}C_{\mathrm{A}}^0}\right)=\frac{C_{\mathrm{B}}}{C_{\mathrm{A}}^0}\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{\epsilon_{\mathrm{B},\lambda_i}}{\epsilon_{\mathrm{A},\lambda_i}}\right), \quad (1)$$

where A_{M} is the absorbance of the mixture at wavelength λ_i and C_{A}^0 is the concentration of A in the dividing spectrum. From the above equation, it follows that the quotient spectrum of a mixture depends solely on C_{B} and C_{A}^0, so the former concentration can readily be calculated similarly; dividing equation (1) into C_{B}^0 provides an analogous expression for calculating C_{A}.

The chief shortcoming of this method lies in the need to empirically determine which standard spectrum is to be used as divisor. However, by dividing into an αC_{A}^0 spectrum (α = constant), one obtains

$$\frac{1}{\alpha}\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{A_{\mathrm{M},\lambda_i}}{\epsilon_{\mathrm{A},\lambda_i}C_{\mathrm{A}}^0}\right)=\frac{1}{\alpha}\frac{C_{\mathrm{B}}}{C_{\mathrm{A}}^0}\frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{\epsilon_{\mathrm{B},\lambda_i}}{\epsilon_{\mathrm{A},\lambda_i}}\right), \quad (2)$$

which coincides with the expression obtained by multiplying equation (1) by $1/\alpha$, *i.e.* decreasing the concentration at which the dividing spectrum is recorded has the same effect as diminishing α (namely increasing the signal). Therefore, calibration curves obtained at higher analyte concentrations have greater slopes, even though they do not provide increased sensitivity since background noise also rises concomitantly.

The goodness of the results obtained in resolving the mixtures is thus dependent on the experimental or instrumental errors made in recording the standard spectra, and is independent of the divisor concentration in any case. Thus, in order to minimize errors and expedite the process, we chose to use the normalized spectrum of each substance as divisor.[7] This variant of the derivative quotient spectrum method was thus applied to the resolution of the binary mixtures addressed in this work.

Use of the programme MULTIC for resolving binary and ternary mixtures

Application of MULTIC relies on the assumption that the analytes obey Beer's law and their absorbances are additive, and involves solving the matrix constructed from a mixture of N components at j wavelengths by using the expression

$$A_j=\sum_{i=1}^{i=N}\epsilon_{ij}bc_i+k_0,$$

where k_0 is the independent term corresponding to the experimental error, A_j and ϵ_{ij} denote the absorbances of the mixture components and their molar absorptivities at various wavelengths within the working range, and c_i is the concentration of each species.

ϵ_{ij} values can be obtained from standard solutions of the pure components (i), which are related to one another by the ($i \times j$) matrix. The equation thus formed is resolved by using a multiple regression procedure.

Use of the programme PLS for resolving binary and ternary mixtures

The PLS method[12,13] breaks down the absorbance matrix A obtained from absorbance measurements on N_s solutions at the selected wavelengths and the concentration matrix C constructed from the corresponding caffeine, thiamine and acetylsalicylic acid concentrations into two latent variable matrices:

$$A=F_{\mathrm{A}}L_{\mathrm{A}}+E_{\mathrm{A}},$$

$$C=F_{\mathrm{C}}L_{\mathrm{C}}+E_{\mathrm{C}},$$

where F_{C} and F_{A} are the latent concentration and absorbance matrices, L_{C} and L_{A} are the concentration and absorbance loading matrices, and E_{A} and E_{C} are the error matrices.

The latent variable matrices can be related by a diagonal regression matrix V such that

$$F_{\mathrm{C}}=F_{\mathrm{A}}V+E_{\mathrm{D}},$$

where E_{D} is an error matrix. Matrix V is used to estimate the concentrations from the absorbance spectrum a_0 for an unknown mixture by using the equation

$$C_0=a_0(F_{\mathrm{C}}^{\mathrm{T}}A)^{\mathrm{T}}VL_{\mathrm{C}},$$

where matrices F_{C}, L_{C} and A can be obtained by calibration.

EXPERIMENTAL

Apparatus

We used a Hewlett–Packard HP8452A diode array spectrophotometer furnished with quartz cuvettes of 1 cm light path and interfaced to a Vectra ES computer and a Think Jet printer, also from Hewlett–Packard.

Absorption and derivative spectra were acquired and processed with the aid of the spectrophotometer's bundled software.

A Radiometer PHM84 digital pH-meter furnished with a dual glass-saturated calomel electrode was used for pH measurements.

Reagents

Standard solutions containing 100 μg/ml of either acetylsalicylic acid, caffeine or thiamine were prepared by direct weighing of the required amount of commercially available chemical (Sigma) and dissolution in bidistilled water. An acetic acid–sodium acetate buffer (pH 5) and $C_t = 1.0M$ was also utilized. All reagents and solvents used were of analytical grade, and bidistilled water obtained from a quartz still was employed throughout.

Software

Multicomponent analysis was carried out by using the programme MULTIC[14] and a PLS version[15] for IBM PC XT/AT computers.

Procedure

Binary and ternary mixtures were prepared in triplicate by placing in a 25-ml volumetric flask 5 ml of HAcO–NaAcO buffer (pH 5.0), a volume containing 3.2–36.4 μg/ml of acetylsalicylic acid and another containing between 1.6 and 16 μg/ml of caffeine and/or thiamine, and the volume of ethanol required to obtain a 20% content in the alcohol after making to the mark with bidistilled water.

The spectra of the above mixtures were recorded between 190 and 350 nm against a blank prepared under the same conditions but containing none of the analytes. The integration time was set to 1 sec in all experiments.

Binary mixtures. (A) *Zero-crossing method.*

(1) Caffeine–thiamine mixtures were analysed by recording their first-derivative spectra and measuring signals at 266 and 286 nm for caffeine and thiamine, respectively. Finally, the contribution from caffeine was subtracted from the latter signal.

(2) Acetylsalicylic acid–thiamine mixtures were quantified by recording their first- and second-derivative spectra and determining the thiamine concentration by measuring the signal at 296 nm in the latter. On the other hand, the signal at 282 nm in the first-derivative spectra was used to determine acetylsalicylic acid by subtracting the signal from thiamine at such a wavelength.

(3) Acetylsalicylic acid–caffeine mixtures were analysed by recording their first-derivative spectra and measuring the signals at 266 and 236 nm for caffeine and acetylsalicylic acid, respectively. The contribution from caffeine was subtracted from the latter signal.

(B) *Quotient spectrum method (normalized divisor).* The spectra yielded by the mixtures were divided into the normalized spectrum of each component and the resulting spectrum was derived in order to determine the component that was not used as divisor. Thus:

(1) In caffeine–thiamine mixtures, caffeine was determined from the derivative of the quotient spectrum (using the thiamine spectrum as divisor) by measuring the signal at 266 nm, while thiamine was quantified from the derivative of the quotient spectrum (using the caffeine spectrum as divisor) at 250 nm.

(2) Acetylsalicylic acid–thiamine mixtures were analysed by measuring the signals at 230 and 292 nm on the derivatives of the quotient spectrum of the mixture using thiamine and acetylsalicylic acid, respectively, as divisor.

(3) Acetylsalicylic acid–caffeine mixtures were quantified by measuring the signals at 248 and 290 nm on the derivatives, respectively, of the quotient spectra.

In both methods, zero-crossing and derivative quotient spectra, the two components were finally quantified by comparing the measured signal with the corresponding calibration curves run.

RESULTS AND DISCUSSION

The simultaneous determination of acetylsalicylic acid, caffeine and thiamine in binary and ternary mixtures was tackled by first checking the temporal pH stability of the products.

The absorbance of caffeine and thiamine solutions over the wavelength range 230–350 nm did not change appreciably during the first 48 hr after they were made. On the other hand, the absorbance of acetylsalicylic acid solutions was somewhat different after only 12 hr, probably as a result of hydrolysis into salicylic and acetic acids, as supported by the presence in the recorded spectrum of the characteristic peak of the former at 296 nm.

The pH was found to scarcely influence the stability of caffeine solutions over the range 1–12. On the other hand, thiamine and acetylsalicylic acid provided the greatest signals at pH 5 (HOAc–NaOAc buffer), which was thus chosen as the optimum. In order to prevent the hydrolysis of the products, all the subsequent experiments were made using fresh solutions.

Figure 1 shows the individual spectra of the three analytes, as well as their first and second derivatives, obtained in a 1:4 ethanol–water

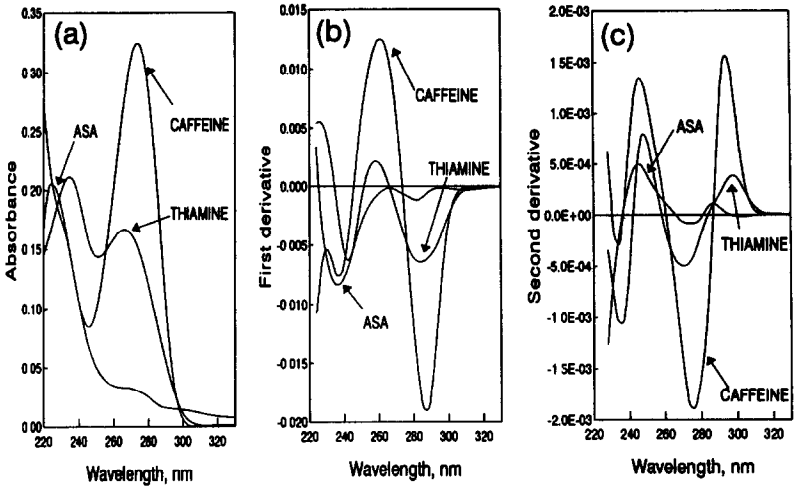

Fig. 1. Absortion (a), first- (b) and second-derivative (c) spectra of acetylsalicylic acid (6.5 μg/ml), caffeine (6.5 μg/ml) and thiamine (6.5 μg/ml) at pH 5.0.

medium at pH 5. As can be seen, the spectra were strongly overlapped.

Graphical methods

Zero-crossing method. Figure 2a shows the first-derivative spectra for caffeine–thiamine mixtures containing a fixed amount of the former and variable concentrations of the latter. As can be seen, the signal at 266 nm does not depend on the thiamine concentration.

Figure 2b shows the second-derivative spectra of the acetylsalicylic acid–thiamine mixtures obtained at a constant concentration of thiamine and various concentrations of acetylsalicylic acid. As can be seen, the signal at 296 nm depends on the concentration of thiamine alone.

Figure 2c shows the first-derivative spectra of acetylsalicylic acid–caffeine mixtures containing the same amount of the latter and a variable amount of the former. Note that the signal at 266 nm depends only on the caffeine concentration.

Table 1 shows the results obtained by analysing various synthetic mixtures using the zero-crossing method. Errors were less than 5% in all cases, even for analyte ratios of up to 10:1.

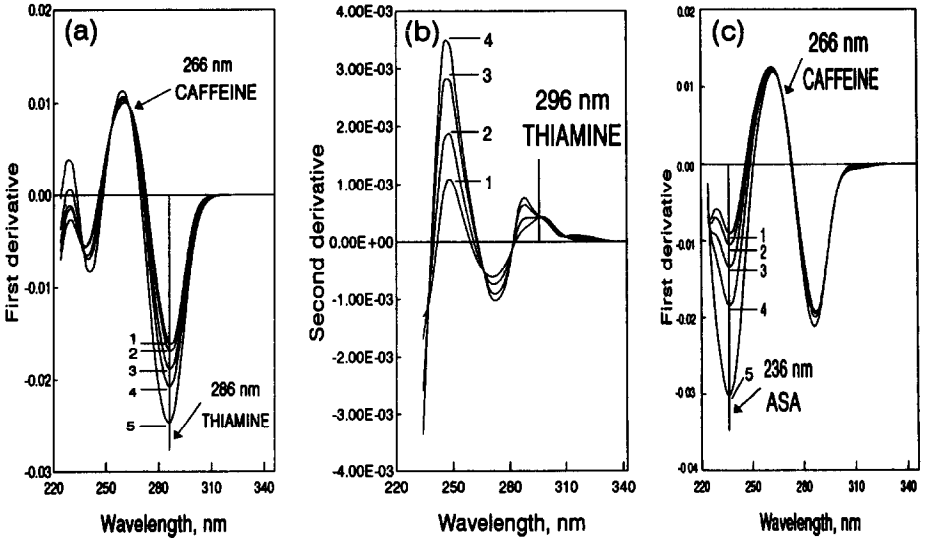

Fig. 2. (a) First-derivative spectra of $C_{Caf} = 5$ μg/ml = cte, $C_{Th} = 2$ μg/ml (1); 4 μg/ml (2); 6 μg/ml (3); 8 μg/ml (4); 10 μg/ml (5). (b) Second-derivative spectra, $C_{Thi} = 5$ μg/ml = cte, $C_{ASA} = 6.5$μg/ml (1); 13 μg/ml (2); 19.5 μg/ml (3); 26 μg/ml (4). (c) First-derivative spectra, $C_{Caf} = 5$ μg/ml = cte, $C_{ASA} = 3.2$ μg/ml (1); 6.5 μg/ml (2); 13 μg/ml (3); 19.5 μg/ml (4); 26 μg/ml (5).

*CAF, caffeine; THIA, thiamine; ASA, acetylsalicylic acid.

Derivative quotient spectra method. Figure 3a shows the derivative quotient spectra of thiamine obtained by dividing its absorbance spectrum into the standardized spectrum of caffeine and obtaining the first derivative of the resulting spectrum. The best wavelength for determining the concentration was 250 nm; in fact, other regions provided greater signals, but the noise arising from dividing the spectrum into the very small absorbances of the caffeine spectrum caused serious interference.

Figures 3b and c illustrate the determination of acetylsalicylic acid at 230 nm and of caffeine at 290 nm in mixtures with thiamine in both cases. Table 2 shows the results obtained by analysing various synthetic binary mixtures using this method. In any case, errors were less than 5% in all cases, even for analyte ratios of up to 10:1. Statistical analysis of the regression equations is reported in Table 3.

Numerical methods

Use of the programme MULTIC for resolving binary and ternary mixtures. In view of the results obtained and bearing in mind that, with few exceptions,[11] derivative methods cannot be applied to mixtures of more than two components, we addressed the resolution of the above-mentioned binary mixtures and that

of the three components jointly by using the programmes MULTIC and PLS.

We chose the wavelength ranges 228–350, 230–296, 236–330 and 246–296 nm as optimal for the resolution of the caffeine–thiamine, acetylsalicylic acid–caffeine, acetylsalicylic acid–thiamine and acetylsalicylic acid–caffeine–thiamine mixtures, respectively. The results obtained are listed in Table 4.

Use of the programme PLS for resolving binary and ternary mixtures. The experimental results were processed by using the PLS calibration method. The calibration matrix was designed at two factor levels. We thus used five and nine solutions, respectively, in addition to a central point, in order to design the model for the binary and ternary mixtures.

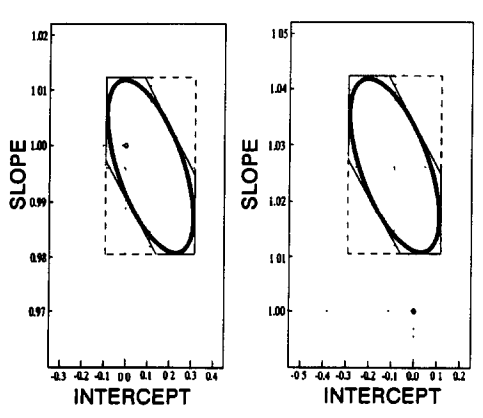

Fig. 4. Illustrative joint confidence region at the $p = 0.05$ level of significance for slope and intercept. Determination of one analyte in a binary mixture with good accuracy and with systematic error.

The lowest and highest concentrations used were 3.20 and 38.0 μg/ml for acetylsalicylic acid, 1.8 and 18 μg/ml for caffeine, and 1.6 and 18 μg/ml for thiamine, respectively.

The results obtained by analysing the different synthetic binary mixtures and the ternary one using the two above-described methods are summarized in Tables 4 and 5. As can be seen, added and found concentrations were quite consistent. However, the PLS method resulted in slightly larger errors with the binary mixtures. On the other hand, it provided better results for the ternary mixture and for binary mixtures with high analyte ratios than did the MULTIC method.

The determination of these three analytes in pharmaceutical preparations is currently under way at our laboratory.

ACCURACY AND PRECISION

The values obtained have been compared with the added value in each sample to quantitatively evaluate the accuracy. When the test on the joint confidence region for slope and intercept, given by Mandel and Lining,[16] is applied to all the binary samples solved by the four methods (24 possibilities), a systematic error appears only for a level of $\alpha = 0.05$ ($F = 9.55$) in the following cases: caffeine in the presence of acetylsalicylic acid determined by

Abstract components 3 and 5 for binary and ternary mixtures, respectively; number of wavelengths = 26 in all cases; calibration solutions 5 and 9 for binary and ternary mixtures, respectively.

the zero-crossing method and the quotient spectra, acetylsalicylic acid with caffeine by quotient spectra and MULTIC, and acetylsalicylic acid with thiamine by MULTIC.

The other 19 possibilities of comparison between added amounts and the values found give good results because the point of slope one and the zero intersection are inside the joint confidence region (Fig. 4). The ternary mixture is solved by PLS without systematic errors.

We have also applied a one-way ANOVA test with six replies during 3 days, and for all the cases an F-Snedecor value lower than the tabulated value is obtained ($F = 3.68$; $n_1 = 2$, $n_2 = 15$) for all the proposed models.

When we applied Bartlett's test for the four methods and the three binary mixtures, we found values for the M[8] parameter between 0.02 and 4.11, always lower than the tabulated value ($\chi^2_3 = 7.81$).

CONCLUSIONS

Both graphical and numerical methods were found to provide good results in the resolution of various synthetic binary and ternary mixtures of acetylsalicylic acid, caffeine and thiamine, whose spectra are strongly overlapped.

From the results obtained we can conclude that all the methods are precise although the graphical and MULTIC present systematic errors in some cases. The PLS is the method which offers better results relative to the accuracy and precision due to the elimination of the errors produced when the matrix effect is taken into consideration in the calibration.

On the other hand, the MULTIC bases the calibration on the standard spectra of the pure analytes without considering the possible interaction between them.

The numerical methods are much more expeditious and can be applied to a larger number of analytes in the same sample, although they need a specific software. On the other hand, graphical methods are much easier to implement and have a lower cost.

SIMULTANEOUS DETERMINATION OF CARBARYL AND *o*-PHENYLPHENOL RESIDUES IN WATERS BY FIRST-DERIVATIVE SYNCHRONOUS SOLID-PHASE SPECTROFLUORIMETRY

LUIS FERMIN CAPITÁN-VALLVEY, JAMAL ROHAND, ALBERTO NAVALÓN, RAMIRO AVIDAD and JOSÉ LUIS VILCHEZ

Department of Analytical Chemistry, University of Granada, E-18071 Granada, Spain

Summary—A spectrofluorimetric method for the simultaneous determination of carbaryl (CBL) and *o*-phenylphenol (OPP) residue mixtures in waters has been developed. Carbaryl was hydrolysed in alkaline medium to give 1-naphthol. This compound and *o*-phenylphenol were fixed on QAE Sephadex A-25 gel at pH 10.75. The fluorescence of the gel, packed in a 1-mm silica cell, was measured directly with a solid-surface attachment. Overlapping of conventional fluorescence spectra is resolved by using first-derivative synchronous spectrofluorimetry and allows for the complete resolution of the mixture. The range of application is between 0.4 and 25.0 ng/ml for OPP and 0.8 and 25.0 ng/ml for CBL. The detection limits for *o*-phenylphenol and carbaryl were 0.1 and 0.2 ng/ml, respectively. The accuracy and precision of the method are reported. The method is suitable for determination of carbaryl and *o*-phenylphenol residues in natural waters. Recoveries from 95 to 105% have been obtained for natural waters spiked with CBL and OPP.

(1-Naphthyl-*N*-methylcarbamate) and (1-1-biphenyl)-2-ol commonly named carbaryl (CBL) and *o*-phenylphenol (OPP), are two powerful pesticides used today as the active ingredients of several commercial formulations. OPP is a disinfectant and fungicide used in post-harvest applications.[1] CBL is an insecticide, used to control pests on more than 100 different crops, with a relatively short half-life, the final product by alkaline hydrolysis being 1-naphthol. CBL and 1-naphthol may cause toxic effect[2–4] and therefore determination of CBL (or 1-naphthol) and OPP residues in natural waters is clearly important.

OPP and CBL show native fluorescence enabling its determination in soils, waters, crops and commercial formulations.[5–9] On the other hand fluorimetric detection has been used in TLC[10–11] and HPLC.[12–18]

However, methods for determination of CBL or OPP, separately, in waters are frequent[19–21] and we are not aware of any methods so far for the simultaneous determination of the two compounds mixed without previous separation.

As fluorescent spectra of OPP and CBL overlap considerably, conventional fluorimetric methods do not allow simultaneous determination of these compounds. However, we have found[22–26] that synchronous spectrofluorimetry in combination with derivative techniques minimize overlapping effects and can be used for the analysis of mixtures involved in clinical and pharmacological preparations.

Solid-phase spectrofluorimetry (SPF) is a technique that combines preconcentration on a solid-phase, *e.g.*, an ion exchange and direct measurement of fluorescence.[27–34]. Use of conventional instrumentation, simplicity, high selectivity and low detection limits, are some of the advantages associated to SPF.

Here we propose a simple and sensitive method for simultaneous determination of OPP and CBL in waters by the use of SPF combined with derivative techniques. The method can be used at low concentrations of the mixtures without previous separation of the components.

EXPERIMENTAL

Apparatus

All the spectrofluorimetric measurements were conducted with a Perkin-Elmer LS 5 luminescence spectrometer as described earlier.[32] A STARNA standard rectangular silica cell (type 1,Q,1,6) with 1-mm path length and external dimensions 12.5 × 3.5 × 46.0 mm, was used.

The LS 5 spectrometer was interfaced to an IBM PS/2 30-286 microcomputer using RS 232C connections for spectral acquisition

and subsequent calculation of the excitation-emission matrices and of the derivative spectra.[35] Smoothed and derivative spectra were calculated by the Savitzky and Golay method[36,37] and contour plots in the excitation-emission plane were produced linking points of equal fluorescence intensity. A Cannon BJ-300 printer was used for graphical representations.

Further, we used a Braun Melsungen Thermomix 1441 thermostatic water-bath circulator for temperature control, a Crison 501 digital pH-meter with a combined glass-saturated calomel electrode and an Agitaser 2000 rotating bottles agitator.

Reagents

All reagents were of analytical-reagent grade unless stated otherwise. Reverse osmosis quality water was used throughout.

CBL stock solution (0.1 mg/ml) (Riedel-de Haën). Prepared by exact weighing and dissolution in absolute ethanol. This solution is stable for at least two weeks. Working solutions were prepared by appropriate dilutions with water maintaining a 1% (v/v) of ethanol.

1-Naphthol stock solution (0.1 mg/ml) (Merck). Prepared in the same way as described above for CBL stock solution.

OPP stock solution (0.1 mg/ml) (Laboratory Dr Ehrenstorfer). Prepared by exact weighing and dissolution in absolute ethanol. This solution is stable for at least one month. Solutions of lower concentration were obtained by dilution with water maintaining a 1% (v/v) of ethanol.

QAE Sephadex A-25 dextran type anion-exchange gel (Sigma). Used in the chloride form and without pre-treatment in order to avoid contamination.

Fluorescence measurements

The measured relative fluorescence intensity (RFI) of the gel beads containing the fluorescent analytes fixed and packed in a 1-mm silica cell, was the diffuse transmitted fluorescence emitted from the gel at the unirradiated face of the cell. The optimum angle formed between the cell plane and the excitation beam was 45° in all instances.[38]

Procedures

Basic procedure. A 500-ml water sample containing between 0.2 and 12.5 μg of OPP and between 0.4 and 12.5 μg of CBL was transferred into a one-litre glass bottle and 5 ml of 0.1*M* NaOH solution and 100 mg of QAE Sephadex A-25 gel were added. The mixture was shaken mechanically for 10 min. Afterwards, the gel beads were collected by filtration under suction and packed in a 1-mm silica cell together with a small volume (around 0.2 ml) of the filtrate with the aid of a pipette. A blank solution containing all the reagents except both OPP and CBL was prepared and treated in the same way as described for the sample.

The synchronous spectra were recorded (at $20.0 \pm 0.5°$) with the following fixed instrumental parameters: $\Delta\lambda = \lambda_{em} - \lambda_{ex} = 105$ nm, scan speed 240 nm/min, and spectrometer response time of 1 sec. The spectra were then stored on a disk file, corrected for the blank signal and the first derivative spectra were calculated using 25-nm intervals for this purpose.

Measurements on the first-derivative synchronous spectrum were made for OPP from the point located at $\lambda_{ex}/\lambda_{em} = 338/443$ to the baseline while for CBL the point chosen was located at $\lambda_{ex}/\lambda_{em} = 318/423$.

Calibration graphs were constructed in the same way with OPP and CBL solutions of known concentrations.

Procedure for natural waters. A volume of natural water sample containing an adequate amount of CBL and OPP was levelled off to 500-ml with water, placed in a one-litre glass bottle and additions of 5 ml of 0.1*M* NaOH solution, an amount of EDTA necessary to eliminate the interferences from metallic ions and 100 mg of QAE Sephadex A-25 gel. The mixture was shaken mechanically for 10 min and then treated as described under *Basic procedure*. The standard additions method was used for calibration.

Treatment of the sample. Natural waters were filtered through a filter-paper with a 0.45-μm size pore (Millipore) and collected in a glass container that had been cleaned carefully with nitric acid. The samples were stored at 4° until analysis and the usual precautions were taken to avoid contamination.[39] Analyses were performed with the least possible delay.

Distribution measurements. A 500-ml water sample containing 3.5 μg of pesticide was transferred into a one-litre glass bottle. Then the required amounts of QAE Sephadex A-25 gel and NaOH solution were added. Next, the mixture was treated in the same way as described under *Basic procedure*. The analyte concentration fixed in the gel was determined as

described above. The resulting aqueous phase was then treated in the same manner with a further batch of gel, and the analyte remaining in the aqueous phase was measured as before.

The distribution ratio was calculated in the usual way from the initial and equilibrium concentrations in the solution, according to the equation:

$$D = \frac{\text{mmol of analyte fixed gel}}{\text{kg of dry gel}} \Big/ \frac{\text{mmole of analyte solution}}{\text{dm}^3 \text{ of solution}}.$$

The following results were obtained: $D_{OPP} = 2054$ at 7.0 ng/ml of initial concentration of OPP and $D_{CBL} = 4520$ at 7.0 ng/ml of initial concentration of CBL.

RESULTS AND DISCUSSION

Spectral characteristics and effect of experimental variables

In neutral and acid media CBL in solution shows native fluorescence with excitation and emission maxima at 279 nm and 333 nm, respectively. While for its hydrolysis product, 1-naphthol, native fluorescence is limited to basic media, the maxima now being 332 and 460 nm, respectively. Although CBL is not fixed in QAE Sephadex A-25 gel, it shows fluorescence at pH > 8 due to the fixation of its hydrolysis product, 1-naphthol, the fluorescence maxima then being 332 and 450 nm, respectively. The hydrolysis of CBL in the presence of QAE Sephadex A-25 gel start at pH 8.0 and is complete at pH 11.0, occurring quickly. We have taken advantage of this fact previously[49] to evaluate CBL.

On the other hand, OPP is fixed on gel from an aqueous solution at alkaline media. The peak wavelengths of excitation and emission spectra in the gel phase are 320 and 414 nm, respectively.[41]

Figure 1 shows the pH dependence on the fluorescence for the fixation of CBL (obviously 1-naphthol) and OPP. OPP presents a maximum RFI for pH 10.2 while CBL requires a pH of 11.2. In order to obtain a fluorescence signal for both compounds simultaneously a pH value of 10.75 was selected, *i.e.*, the point where the value of fluorescence is identical for both samples.

The dependence of the fluorescence of the gel fixed compounds on temperature is small

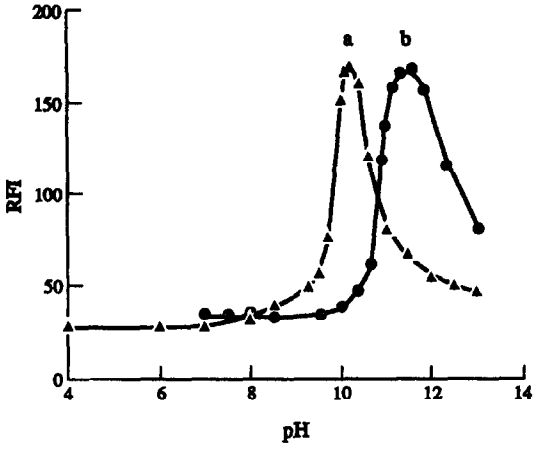

Fig. 1. Influence of pH on RFI in gel phase. (a) OPP, and (b) CBL; [OPP] = 8.0 ng/ml, [CBL] = 8.0 ng/ml, 500 ml of sample, 100 mg of QAE Sephadex A-25.

(−0.3%/°C for OPP and −0.25%/°C for CBL between 5 and 60°). The RFI decrease with temperature was totally reversible for both compounds. Nevertheless all RFI measurements reported here were made at 20.0 ± 0.5°, *i.e.*, about room temperature.

The retention of both analytes was carried out at room temperature, because the ion-exchange process was independent of temperature in the range 0–60° for both compounds.

The equilibration time necessary for maximum RFI development was 10 min for both compounds. RFI remains unaltered for equilibration times longer than 10 min. Fluorescence for both compounds remains constant for at least 3 hr after equilibration.

Variation in the order of addition of reactants was shown to have no effect on the emission intensity.

As the use of a large amount of the gel lowered the RFI, only the amount required to fill the cell (100 mg) was used in all instances.

Selection of the optimum $\Delta\lambda$ for synchronous scanning

The extent of the spectral overlap of these compounds has been examined by obtaining total fluorimetric information available in the excitation–emission matrix. Suitable plots of excitation *vs.* emission wavelengths have been drawn from the three-dimensional spectra. This allows us to examine the most suitable trajectory in the excitation–emission matrix to obtain synchronous fluorescence spectra for the total resolution of overlapping component peaks. The optimum scan path for determining OPP and CBL in mixtures seems to be a $\Delta\lambda = 105$

nm, because it passes near the maximum of both compounds, allowing the determination without a considerable loss of sensitivity.

Figure 2 shows synchronous spectra of CBL and OPP fixed on QAE Sephadex A-25 and of a mixture of both compounds, corrected for the blank signal, and maintaining 105 nm as constant interval between the emission and excitation wavelengths.

Because of the large overlap of the spectra, the determination of OPP and CBL by synchronous spectrofluorimetry is subject to considerable difficulties. This problem has been resolved by taking the first-derivative of the spectrum as shown in Fig. 3.

The technique used to choose suitable wavelengths to take measurements proportional to OPP and CBL concentrations for the preparation of calibration graphs was the "zero-crossing" method. Assuming that the derivative of a spectral band is equivalent to the sum of the derivatives of its individual bands, it is obvious that the total derivative spectrum is only a function of the concentration of the other component, and *vice versa* when the first-derivative spectrum of one of two components is zero. Thus, the height h_1 ($\lambda_{ex}/\lambda_{em} = 338/443$ nm) is proportional to the OPP concentration and h_2 ($\lambda_{ex}/\lambda_{em} = 318/423$ nm) is proportional to the CBL concentration (Fig. 3).

Instrumental parameters

We selected the most adequate parameters to register synchronous spectra in order to obtain good estimates of the derivatives, aiming to find a compromise between reasonable speed and reasonable time for the practical analysis. Therefore a scan speed of 240 nm/min and a luminescence spectrometer response time of one second were selected after verifying that these parameters hardly affect the signal obtained. Intervals of 25 nm for wavelength sampling were chosen as well in order to obtain numerically reasonable estimates of the first-derivative spectra by the Savitzky and Golay method.

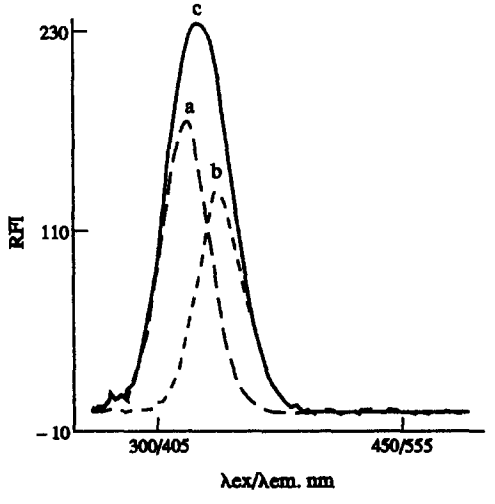

Fig. 2. Synchronrous fluorescence spectra of (a) OPP-QAE Sephadex A-25, (b) CBL-QAE Sephadex A-25 and (c) a mixture of both compounds-QAE Sephadex A-25. ($\Delta\lambda$ = 105 nm, [OPP] = 10 ng/ml, [CBL] = 10 ng/ml).

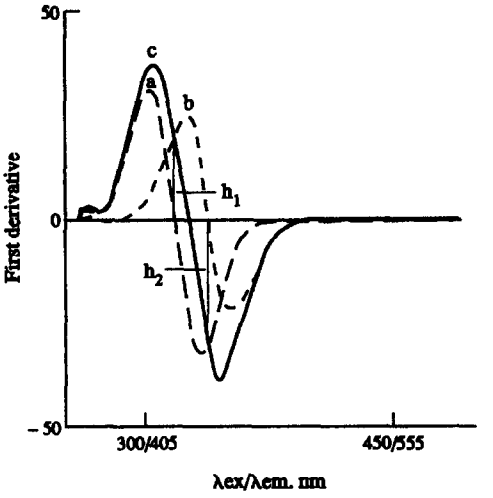

Fig. 3. First-derivative synchronous spectrum of (a) OPP-QAE Sephadex A-25, (b) CBL-QAE Sephadex A-25 and (c) a mixture of both compounds-QAE Sephadex A-25. ($\Delta\lambda$ = 105 nm, [OPP] = 10 ng/ml, [CBL] = 10 ng/ml).

Analytical parameters

In order to test the mutual independence of the analytical signals selected for OPP and CBL, showing that h_1 and h_2 are independent of CBL and OPP concentrations, four calibration graphs were obtained using the measurement height (h) for standard containing between 0.4 and 25.0 ng/ml OPP, in the absence of CBL and in the presence of 2.5, 5.0 and 8.0 ng/ml CBL, respectively.

Following the same procedure, four calibration graphs were prepared for standards containing between 0.8 and 25.0 ng/ml CBL, in the absence of OPP and in the presence of 2.5, 5.0 and 8.0 ng/ml OPP, respectively.

As Table 1 shows, the amplitude of the derivative signal of the mixture in the gel measured at the zero-crossing point of the derivative spectrum of one of two components, is a function of only the concentration of the other component, in accordance with theoretical predictions. Also, the values of the

correlation coefficients and the low values for the intercepts indicate good linearity for all the calibration graphs obtained from the first-derivative measurements.

The IUPAC detection limits ($k = 3$)[42] found were 0.1 ng/ml for OPP and 0.2 ng/ml for CBL and the quantification limits ($k = 10$)[43] were 0.4 ng/ml and 0.8 ng/ml for OPP and CBL, respectively. The relative standard deviation (RSD%) ($P = 0.05$, $n = 10$) were 0.9% for 8.0 ng/ml OPP and 0.9% for 10.0 ng/ml CBL.

For the sake of comparison and/or choice of method when other instruments are only available or to choose a measuring strategy for a given problem Table 2 provides information on each of the methods here compared.

The proposed method, compared with others described in the literature for water[19,21,44–49], shows two advantages: simultaneous determination of OPP and CBL in waters and an improvement of about one order of magnitude against other methods except HPLC.

The precision (RSD) of the packing operation, calculated for 10 measurements, was 0.8% for the gel with OPP and CBL fixed, 0.8% for the gel blank (gel with 0.1 *M* NaOH solution) and 0.8% for the gel alone.

Effect of foreign species

The effect of ions commonly found in water and other pesticides fluorescents and

not fluorescents and species as potential interferents was studied on determinations involving mixtures of 8 ng/ml OPP and 8 ng/ml CBL. A 50 μg/ml level of each potentially interfering species was tested first. If interference occurred, the ratio was reduced until it ceased. The tolerance level was defined as the amount of foreign species producing an error not exceeding $\pm 5.0\%$ in the determination of the analyte. The results obtained are summarized in Table 3.

The most serious interference was from Fe(III), owing to the absorption of ferric hydroxide on the gel surface. This negative interference can be eliminated by addition of appropriate amounts of EDTA. In this work the EDTA amount used was 1.0 μg/ml.

Determination of OPP and CBL in natural waters

The method was applied to the determination of both pesticides in natural water samples by the standard additions method in order to minimize the matrix effect observed. As representative samples we selected tap water and raw water from Granada City supplies. The volume of water used for the determination was 500 ml in all instances.

The levels found for both pesticides in all waters studied were lower than the detection limits of the proposed method.

To check the accuracy of the proposed method, a recovery study was carried out on the above waters. Various amounts of both OPP and CBL were added to 500-ml water samples and the percentage recovery was determined. The results obtained, summarized in Table 4, indicated that the proposed method can be applied satisfactorily to determination of both OPP and CBL in waters when they are present at levels at or above the detection limits. According to Table 4 the OPP/CBL ratio range over which the proposed method can be applied within an error limit, say $\leqslant 5\%$ goes from 5:1 to 1:5.

CONCLUSION

This paper provides a practical application of derivative synchronous spectrofluorimetry in combination with the solid-phase spectrofluorimetry to multi-component pesticide analysis at low levels without previous preconcentration nor separation.

CLOUD POINT METHODOLOGY: A NEW APPROACH FOR PRECONCENTRATION AND SEPARATION IN HYDRODYNAMIC SYSTEMS OF ANALYSIS

BERNARDO MORENO CORDERO,* JOSÉ LUIS PÉREZ PAVÓN, CARMELO GARCÍA PINTO and Mª ESTHER FERNÁNDEZ LAESPADA

Departamento de Química Analítica, Nutrición y Bromatología, Facultad de Química, Universidad de Salamanca, 37008 Salamanca, Spain

Summary—The analytical potential shown by the cloud point phenomenon for the separation and preconcentration of different analytes as an alternative method to other separation techniques is studied. We offer and discuss several examples that can be applied in flow injection analysis and high performance liquid chromatography with both optical (UV and fluorescence) and electrochemical detection.

The possibilities of micellar systems and of other organized molecular assemblies (vesicles, microemulsions, cyclodextrines, liposomes, *etc.*) were recognized many years ago and have been exploited in almost all fields of analytical chemistry with a view to improving or proposing new methods of analysis. This is currently a research area in constant development.[1–15]

These new microheterogeneous structures can interact—sometimes in a selective fashion—with molecules of a very different nature by drastically modifying solubility, reaction rates, the equilibrium position, the products obtained and spectral or analytical parameters, thus permitting, on one hand their use in reactions hitherto unexploited and on the other, the possibility of modifying the sensitivity and selectivity of determinations.

In addition, one of the most characteristic properties of micellar systems is their capacity to dissolve species that are rather water-insoluble; that is, the correct choice of a micellar solution permits direct insertion of insoluble analytes into both FIA and HPLC analytical systems. Other advantages have been described by different authors.[9–13]

The separation and/or preconcentration of an analyte in a sample before its quantification continues to be a stage that in some cases is indispensable; over the past few years many analytical schemes of preconcentration and/or separation have been proposed as alternatives to the use of organic solvents, mediated by surfactants;[16–26] these have opened new possibilities in research areas that are closely linked with analytical chemistry (clinical chemistry, biotechnology or environmental analysis).

In this work, an overview of the analytical possibilities of the cloud-point phenomenon is presented, considering these as alternatives to other techniques of separation and/or preconcentration. Different examples of their analytical potential in flow injection analysis and high performance liquid chromatography are discussed.

The cloud point phenomenon: analytical potential

Aqueous solutions of some surfactants, both non-ionic and zwitterionic, display the so-called cloud point or turbidity point phenomenon; that is, when an isotropic micellar solution is heated above a certain temperature (the cloud point temperature) it suddenly becomes turbid owing to the decrease in the solubility of the surfactant in water. The mechanism by which this separation occurs is still not very clear and continues to be a source of controversy among different researchers.[27–31]

After the two phases have formed, and after a given time (a stage that can be accelerated by centrifugation), two transparent liquid phases are obtained: one rich in surfactant; and the other aqueous, containing a concentration of surfactant close to the critical micellar concentration (cmc).

*Author for correspondence.

Table 1 shows the cloud points displayed by some surfactants. It should be stressed that both the presence of additives (organic or inorganic) and the surfactant concentration may change these values.

From an analytical point of view, the surfactant-rich phase can be used to separate and/or preconcentrate different analytes before their injection into any hydrodynamic analytical system (FIA or HPLC).

The use of micellar systems as an alternative to other techniques of separation has the following characteristics:

1. A high capacity to concentrate a wide variety of analytes of widely varying nature with high recoveries and very high concentration factors since the analytes can be collected in very small volumes (0.2–0.4 ml) of surfactant-rich phase; this allows one to obtain preconcentration factors identical to those of other techniques.

2. The separation yield depends on the greater or lesser hydrophobicity of the analyte under study, thus permitting one to use the same strategies as in liquid–liquid extractions. The preconcentration factor can readily be modified merely by changing the amount of surfactant since, on varying the volume of the surfactant-rich phase obtained, this allows one to design analytical schemes with a given separation factor as a function of the amount of analyte to be determined, of the volume of sample available and of the analytical technique to be used.

3. The surfactants used are not toxic and are less dangerous than the organic solvents habitually used in liquid–liquid extraction because they are neither volatile nor inflammable; additionally, the amount of surfactant required (generally a few milligrams) and the price of commercially available surfactants means that the use of these media is also cheaper.

4. The surfactant-rich phase is compatible with the carrier solutions used in FIA and with both micellar and hydro-organic mobile phases, thus enabling their later use in HPLC.

5. The low temperature of the cloud point of certain surfactants (see Table 2) allows one to design schemes for the separation or preconcentration of temperature-sensitive molecules of biological or environmental interest.

6. The experimental way of performing the process of separation and/or preconcentration is very simple and has been described by different authors.[7–13]

7. The phase separation phenomenon is reversible; this allows one to rapidly obtain one or two phases simply by varying the temperature of the solution.

8. Finally, it should be stressed that as well as commercially available surfactants, the possible synthesis of other types of more specific nature[23,32] and the mixing of several of them[22] confers this methodology great versatility, although more basic studies should be conducted to elucidate the phenomenon and its analytical applications.

EXPERIMENTAL

Reagents

The surfactants Triton X-114 and Brij 30 were obtained from Fluka and used without further purification. The pesticides parathion

and fenitrothion were purchased from Riedel-de Haen (Seelze-Hannover, Germany). Vitamins A and E were obtained from Fluka and vitamin K from Sigma. Dansyl aminoacids were obtained from Sigma and benzo(a)pyrene was purchased from Sugelabor Chemical Service. Stock solutions of $2.0 \times 10^{-3}M$ uranium were prepared by dissolving appropriate amounts of uranyl nitrate hexahydrate (Merck). Methanolic solutions of PAN (1-(2-pyridylazo)-2-naphthol) were obtained from the solid product (Merck).

Other reagents were of analytical grade; all solvents and analytes were filtered through 0.45-μm nylon membranes filters (Milipore); ultra-high-quality water obtained from a Elgastat UHQ water purification system was used.

Apparatus

The flow system consisted of a peristaltic pump (Gilson Minipuls 2 HP4) and a Rheodine 5020 six-port injection valve; all connections were 0.5 mm i.d. Teflon tubing. Other experimental details have been described elsewhere.[14]

A modular component liquid chromatographic system was used consisting of a Spectra Physics SP 8800 ternary pump, an SP 8450 UV detector, a Spectra FL 2000 fluorescence detector, an EG&G PARC 400 electrochemical detector and an SP 4290 integrator; the electrodes employed for electrochemical detection, their pretreatment and other additional details have already been described.[24,33,34]

Easyspin, Sorval Instruments, Du Pont (Giralt) and Beckman, Model J2-21M centrifuges were also used.

Procedures

Cloud point determination and ratio phases. The cloud point for TX-114 was determined by observing the appearance of the two phases on heating different previously cooled aqueous solutions of surfactant in a bath kept at constant temperature.

The ratio of phases was obtained by measuring the volumes of the respective phases in tubes calibrated for different amounts of surfactant under the same experimental conditions as those used for phase separation (heating at 40° and centrifuging at 3500 rpm).

Cloud point preconcentration. Aliquots of cold solutions containing the analyte and a given amount of surfactant were kept for 15 min in a thermostatted bath at 40°; the two phases were separated by centrifugation for 5 min at 3500 rpm. Sixty microlitres of the surfactant-rich phase were collected with a Hamilton syringe; 10 μl of these were injected in a chromatography system. Following this, elution was made with a suitable mobile phase for each analyte studied.

For injection in the FIA system, the aqueous phase was separated by inverting the tubes once the solution had been chilled in an ice-bath; before being injected the surfactant-rich phase was placed in 1 ml of $3.6M$ HCl medium in order to destroy the PAN–U(VI) chelate, to provide the appropriate medium for uranium reduction and diminish the viscosity of the sample; 100 μl of the mixture were injected into the carrier stream.

The detection of uranium was performed spectrophotometrically, employing a flow injection system previously developed by us.[14]

RESULTS AND DISCUSSION

Figure 1 shows the corresponding diagram of temperature–concentration phases for Triton X-114 (L means single isotropic solution and 2L indicates that two isotropic phases coexist); it may be seen that for surfactant concentration values ranging between 0.5 and 4% the temperature of the cloud point remains almost constant and equal to 25°, thus facilitating experimentation.

Figure 2 shows the percentage of surfactant-rich phase obtained and the theoretical preconcentration factor as a function of the concentration of Triton X-114. The percentage of surfactant-rich phase was calculated as the ratio of its volume to the volume of solution used for the cloud point separation. The theoretical preconcentration factor (maximum attainable value for 100% recovery) was calculated as

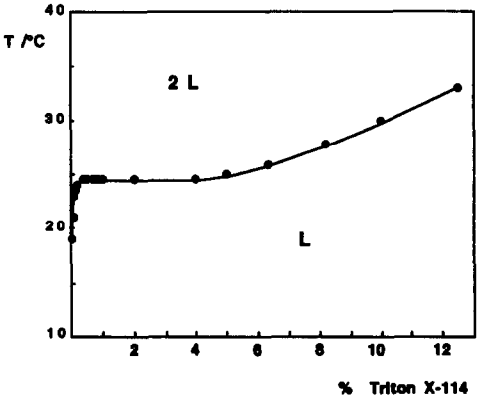

Fig. 1. Phase diagram of Triton X-114 in aqueous solution. L: single isotropic phase region, 2L: two isotropic phase region.

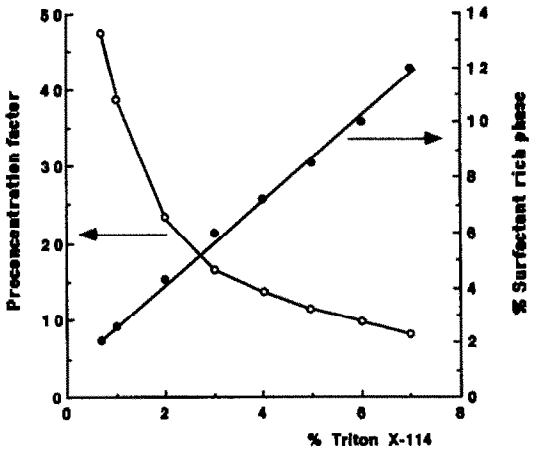

Fig. 2. Variation of the preconcentration factor and the % of surfactant rich phase obtained as a function of Triton X-114 concentration.

the ratio of the volume of solution used to the surfactant-rich phase volume.

Cloud point methodology prior to flow injection analysis

Flow injection analysis can be considered a new concept in continuous flow techniques and is currently used routinely in many laboratories both in chemical analysis and in research, owing to its versatility, simplicity and low instrumental costs.[35,36] However, as in many other analytical techniques, some of the proposed procedures lack the sensitivity and selectivity required for the analysis of trace amounts of substances, which makes it necessary to separate and/or preconcentrate the analyte of interest prior to injection into the FIA system.[35,38]

Although the literature reports some procedures that use micellar media in FIA[12,14] none of them has exploited the cloud point methodology for the preconcentration and/or separation of analytes.

Recently, with a view to checking the feasibility of this method in FIA determination, we have studied the separation and preconcentration of traces of uranium using the U(VI)–PAN–Triton X-114 system before inserting the samples in the analysis system;[25,26] the experimental results showed that it is possible to detect an amount of uranium close to $10^{-8}M$ starting out from only 10 ml of sample and using 0.2% of surfactant.

Watanabe[16,18,19,21] and Pramauro[20,22] have developed several procedures for the preconcentration of certain metal ions by the formation of a hydrophobic chelate using as non-ionic surfactants polyoxyethylene-7,5-nonylphenyl ether (PONPE 7.5) and a mixture of Triton X-100 and polyoxyethylene (4,2) dodecanol, respectively. In both cases the system could be readily adapted to the FIA technique with the advantages of simplicity and speed in the analysis.

Cloud point methodology prior to high performance liquid chromatography analysis

Having subjected a sample to phase separation, the surfactant-rich phase which will contain the compounds of hydrophobic nature can be injected directly into a liquid chromatograph since it is compatible with the mobile phases customarily used in this technique.

UV detection

When cloud-point preconcentration is used prior to HPLC analysis it should be taken into account that the time of elution of the surfactant injected depends on the composition of the mobile phase used for the elution of the different analytes being studied.

Figure 3 shows the blank signals obtained with a UV detector at 254 nm when 10 μl of a surfactant-rich phase containing only Triton X-114 or Brij 30 is injected after cloud point separation. Figure 3(a) corresponds to a mobile phase of 100% MetOH and Fig. 3(b) to 70:30 MetOH:H_2O.

When the mobile phase contains an amount of MetOH close to 100%, quantification of analytes would be possible as long as their elution times are above 8 min. However, for lower organic modifier contents, the peaks due to the surfactant [see chromatograms in Fig. 3(b)] would avoid any quantification of analytes and hence the methodology is unsuitable; this has already been reported by other authors.[23,24]

Figure 4 shows comparatively the chromatograms obtained when 10 μl of a solution containing 0.70 ppm of vitamin K are injected with UV detection at 254 nm; in the right part of Fig. 4 the signal for the injection of the cloud-point preconcentrated solution is shown.

Fluorescence detection

The high background absorbance displayed by non-ionic surfactants at the wavelengths usually used in UV detection[254-260] can be avoided using a fluorescence detector.

Figure 5 shows the chromatograms obtained when 10 μl of a solution containing 0.08 ppm of vitamin A are injected, with fluorescence detection ($\lambda_{ex} = 330$ nm and $\lambda_{em} = 480$ nm) and 0.01

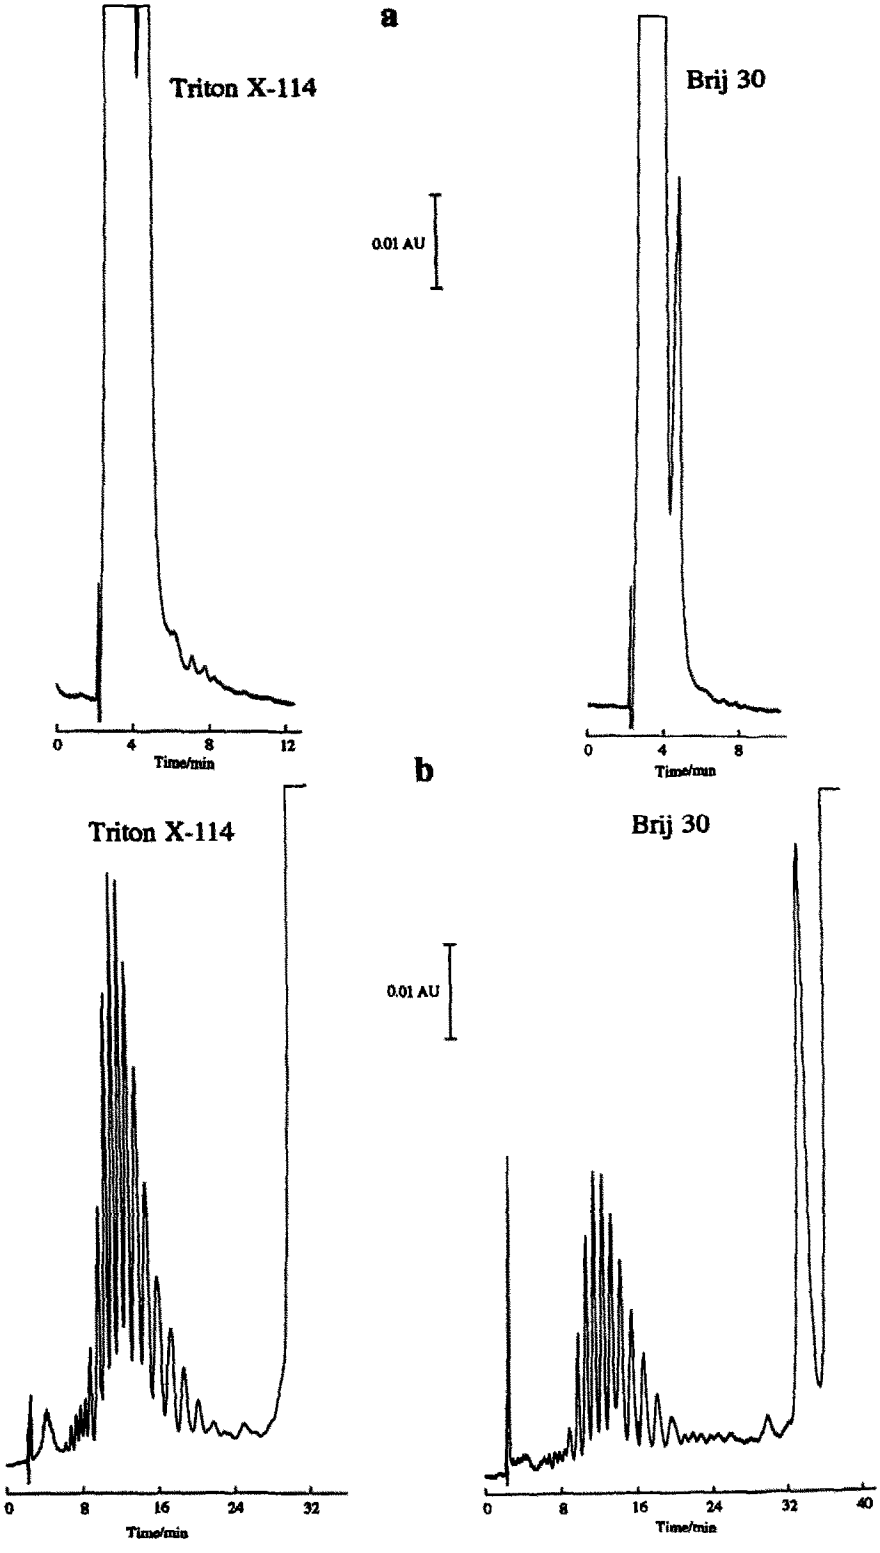

Fig. 3. Blank chromatograms obtained for the injection (10 μl injected) of a surfactant-rich phase of Triton X-114 and Brij 30 after cloud point preconcentration with UV detection at 254 nm. Mobile phases: (a) 100% MetOH (Q = 1.00 ml/min); (b) 70:30 MetOH/H_2O (Q = 1.00 ml/min).

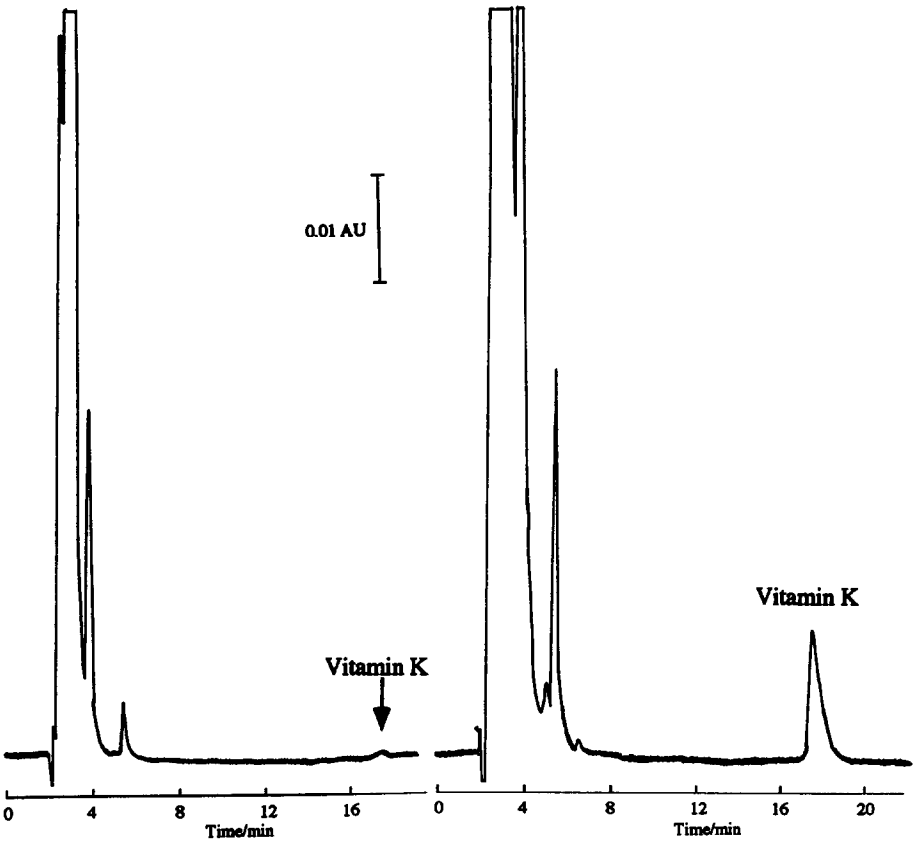

Fig. 4. Chromatograms obtained for the injection of 0.70 ppm (left) of vitamin K (10 μl injected) and of the surfactant-rich phase obtained after the cloud point preconcentration of 15 ml of the sample (right) with UV detection at 260 nm. Chromatographic conditions as described in the text.

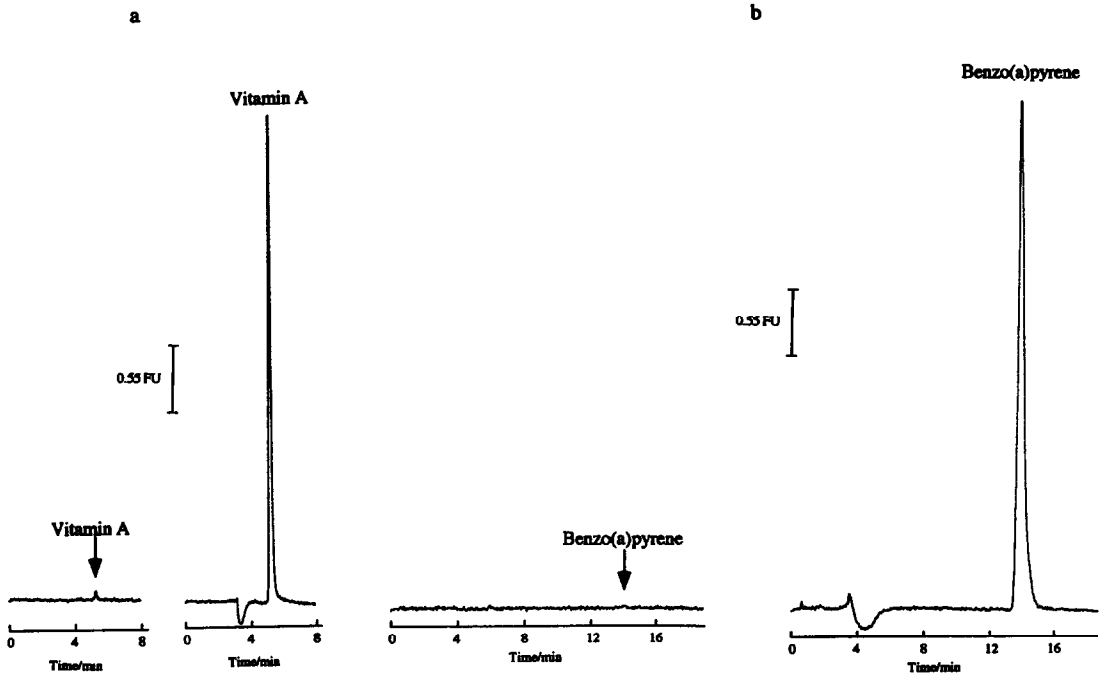

Fig. 5. Chromatograms obtained for the injection (10 μl injected) of (a) 0.08 ppm of vitamin A (λ_{ex} = 330 nm, λ_{em} = 480 nm) and (b) 0.01 ppm of benzo(a)pyrene (λ_{ex} = 300 nm, λ_{em} = 430 nm) before (left) and after (right) cloud point preconcentration of 15 ml of the sample. Chromatographic conditions as described in the text.

ppm of benzo(a)pyrene ($\lambda_{ex} = 300$ nm and $\lambda_{em} = 430$ nm) before and after cloud-point preconcentration, eluting with 95:5 MetOH/H_2O (Q = 1 ml/min) and 75:25 A CN/H_2O (Q = 2 ml/min), respectively.

The signals obtained show that for both mobile phases and under the experimental conditions used for detection, the surfactant (Triton X-114) does not show a blank signal that will prevent measurement and quantification of the analytes; secondly, it should be noted that the amounts of analyte injected, without the cloud-point preconcentration, would be very difficult to quantify.

Electrochemical detection

Bearing in mind that many commercially available surfactants do not contain any functional group subject to electrodic reaction, another feasible alternative for resolving the high background absorbance would be the use of electrochemical detectors, which would provide the additional advantage of a greater sensitivity (50–100-fold) and selectivity.

Recently[24] we have shown that under certain experimental conditions it is possible to use electrochemical detection without obtaining any background signal, making cloud-point preconcentration useful for the determination of important molecules that could not be measured if UV detection were employed.

Table 2 shows the relative increases in signal obtained for certain vitamins, dansyl aminoacids, pesticides and PAHs as representative analytes of biological and environmental interest dealt with by the cloud-point preconcentration method with different forms of detection. The relative standard deviation obtained for sets of replicates (8–10 samples) in which the procedures were applied (including the cloud point separation step and the chromatographic separation or the flow injection measurement) was below 5% in all cases; as this value includes the instrumental errors, it can be concluded that the reproducibility of the cloud point preconcentration is quite good (<5%).

The behaviour of other surfactants for use in the cloud-point methodology and its application to the preconcentration of different analytes is currently under study.

Table 2. Relative signal enhancement for different analytes after cloud point preconcentration in HPLC analysis

CONCLUSION

The present work shows that the cloud point methodology has great analytical potential yet to be exploited that may also offer a feasible alternative to other techniques of separation and/or preconcentration with good recoveries and similar standard deviation.

Cloud point preconcentration can be used as a sample preparation step prior chromatographic analysis or flow injection systems, specially for fluorimetric or electrochemical detection due to the low background signal of the surfactant.

So far this technique has been used for the preconcentration of hydrophobic and ionic analytes in samples of analytical interest.

Summary—The determination of the diuretics hydrochlorothiazide, bendroflumethiazide and furosemide by both conventional and thermal lens spectrophotometry (TLS, 100 mW of pump power at 514.5 nm) following previous hydrolysis, diazotization and coupling with *N*-(naphthyl)ethylenediamine (NED) in a sodium dodecyl sulphate (SDS) micellar medium of pH ≈ 1 was studied. *p*-Aminobenzoic acid (PABA) was used as a model compound to optimize the derivatization procedures. 3-Substituted indoles, such as 5-hydroxyindole-3-acetic acid and tryptophan, gave *N*-nitroso derivatives which interfered with the determination of the diuretics in urine. The derivatized diuretics in urine were separated using HPLC with a Spherisorb ODS-2 C_{18} column, and a 0.1*M* SDS mobile phase containing 5% *n*-propanol and 0.01*M* sodium dihydrogen phosphate (pH 3). The diuretics gave limits of detection (LODs) of *ca.* $5 \times 10^{-9}M$ for the TLS procedure. The LODs were 20–50-fold higher for the corresponding spectrophotometric procedure.

Diazotization and coupling of primary arylamines to form intensely coloured azodyes are highly sensitive and widely applicable chromogenic reactions. The amines are diazotized with nitrous acid in an HCl medium, the nitrite excess is eliminated with sulphamic acid and the diazonium ions are coupled with *N*-(naphthyl)ethylene-diamine (NED). In conventional procedures, coupling of most diazonium ions is too slow at low pH values, and a buffer is used to increase the pH. Usually, after coupling, excess HCl is also added, since the protonated azodyes give higher molar absorptivities at longer wavelengths than the corresponding conjugated bases.

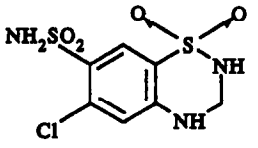
The use of a micellar medium of sodium dodecyl sulphate (SDS) has improved the colorimetric determination of arylamines and sulphonamides.[1–4] In this medium, the coupling rate increases greatly and the protonation constants of the azodyes are larger than in water. In an SDS micellar medium, the diazotization, coupling and measurement of the absorbance of the protonated azodye are thus possible at pH ≈ 1 for a large number of diazotizable substances. In a non-micellar medium, the pH should be modified twice during the procedure to form the chromophore.

Thermal lens spectrophotometry (TLS) allows the measurement of extremely low absorbances, often with dynamic ranges over two orders of magnitude.[5] Requirements of an advantageous TLS procedure are: (a) the absorptivity of the analyte should be large; (b) the absorbance of the blank should be negligible, otherwise the background noise and limit of detection increase, and the dynamic range is reduced; (c) the conditional constant of the chromogenic reaction should be very large. In addition, the use of a selective reaction, or the combination of the TLS determination with a separation technique to improve selectivity and to reduce the blank signal, has been recommended.[6]

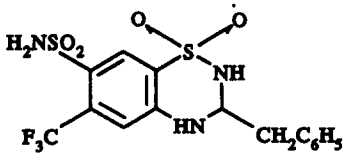
The diazotization and coupling reactions fulfil these requirements and should lead to advantageous TLS procedures for the determination of many drugs. The azodyes formed with NED by most diazotizable substances of interest show absorption maxima in the 540–560 nm range, with $\varepsilon = 20{,}000$ $mol^{-1}l.$ cm^{-1} or

*Author for correspondence.

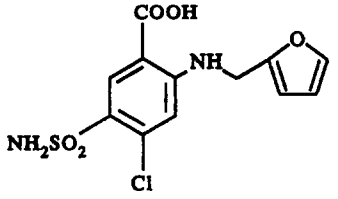
higher. Therefore, NED azodyes absorb the intense Ar^+ laser line at 514.5 nm which is most frequently used for pumping in TLS experiments. The determination of inorganic nitrite by azodye formation with NED and TLS has been described.[7]



I



II



III

In this work, the diazotization and coupling of the diuretics hydrochlorothiazide (I), bendroflumethiazide (II) and furosemide (III) with NED in an SDS micellar medium is described. These diuretics are secondary arylamines and, therefore, hydrolysis to give the primary arylamines was required before diazotization. The corresponding spectrophotometric and TLS procedures were optimized using *p*-aminobenzoic acid (PABA) as a model compound. A comparative study of the spectrophotometric and TLS procedures was performed. 5-Hydroxyindole-3-acetic acid (5-HIAA) and tryptophan also gave a chromogenic reaction with the reagents; therefore, 3-substituted indoles interfered in the determination of the diuretics in urine. Thus, an HPLC procedure with precolumn derivatization was tried.

During the last few years micellar liquid chromatography with UV absorptiometric detection has been studied as an alternative means of determining drugs in urine, including banned drugs in sports competitions.[8–13] However, in the corresponding procedures urine gives a high background during the first minutes of the chromatograms, thus hindering the detection of many drugs. As shown in this work, precolumn derivatization and absorptiometric detection in the visible can be an excellent auxiliary tool in micellar liquid chromatography of physiological samples, since the chances of interference are dramatically reduced.

An SDS mobile phase containing *n*-propanol, and conventional and TLS spectrophotometric detection at 514.5 nm was used. Urine samples were spiked with arylamine diuretics. After hydrolysis, diazotization and coupling in the micellar medium, the samples were injected in the chromatograph. The diuretics were well separated by this chromatographic system. The urine blanks gave almost flat chromatograms, with a single small peak which did not interfere with the determination of the diuretics.

EXPERIMENTAL

Reagents

Analytical grade PABA (Scharlau, Barcelona, Spain), sodium nitrite, sulphamic acid (Fluka, Buchs, Switzerland), NED dihydrochloride, SDS (Merck, Darmstadt, Germany), *n*-propanol, methanol, sodium dihydrogen phosphate and HCl (Panreac, Barcelona, Spain) were used.

Hydrochlorothiazide (Galloso Wellcome, Madrid, Spain), bendroflumethiazide (Davur, Madrid, Spain) and furosemide (Lasa, Barcelona, Spain) were kindly donated by the pharmaceutical laboratories. A $10^{-3}M$ stock solution of the diuretics in $0.15M$ HCl and $0.043M$ SDS was prepared. A small volume of methanol was initially added to facilitate dissolution of the drugs. The purity of the diuretics was checked using HPLC with UV absorptiometric detection at 254 nm, and was found to be *ca.* 100%.[14,15] The stock solutions of hydrochlorothiazide and furosemide are stable, but bendroflumethiazide solutions are not stable and, therefore, they were prepared daily. Distilled and nanopure deionized water (Barnstead deionizer, Sybron, Boston, MA, U.S.A.) was used.

Solid-phase extractions were performed with Bond-Elut SCX (strong cationic exchange) columns using a Vac-Elut SPS 24 vacuum station (Analytichem International, Harbor City, CA, U.S.A.).

Apparatus

The thermal lens set-up with an Ar^+/He–Ne coaxial pump-probe configuration has been described elsewhere.[16,17] The 514.5 nm line of the Ar^+ laser with 100 mW of pump power, modulated at 4 Hz, was used. A Hewlett–Packard 8452A spectrophotometer (Palo Alto, CA, U.S.A.) and 1 cm optical path cells were also used.

The HPLC system consisted of a Hewlett–Packard HP 1050 chromatograph with an isocratic pump, a programmable UV–vis detector and an integrator HP 3396A, connected to a compatible computer (μP 386SX) provided with the HP Peak-96 program package. When working with TLS detection, data acquisition and peak integration were performed using the TRAD-2 program.[18] Samples were injected with a Rheodyne valve (Berkeley, CA, U.S.A.) with a 20 μl loop. A Spherisorb ODS-2 C_{18} column (5 μm particle size, 12 cm × 4.6 mm i.d.) and a C_{18} precolumn of similar characteristics (3.5 cm × 4.6 mm i.d.) from Scharlau (Barcelona, Spain) were used.

Procedures

The solution containing PABA or the diuretics was made 0.15M in HCl (pH ≈ 0.8) and 0.043M in SDS (1.25%). The diuretics were hydrolysed in a water bath at 100° for 10 min. A 10 ml aliquot was introduced into a 25 ml volumetric flask and, for the spectrophotometric determinations, was mixed with 2 ml of $1.8 \times 10^{-2}M$ sodium nitrite. After 10 min, 2 ml of $7.5 \times 10^{-2}M$ sulphamic acid was added and the mixture was allowed to react for an additional 10 min. Finally, 2 ml of $7.5 \times 10^{-3}M$ NED was added, the volume was completed up to the mark with water and the absorbance was measured at 556 nm for PABA and at 530 nm for the diuretics. For the TLS determinations, $2.5 \times 10^{-3}M$ nitrite, $2.5 \times 10^{-2}M$ sulphamic acid and $2.5 \times 10^{-3}M$ NED solutions were used.

Only preliminary results are given in this work for the HPLC separation of the derivatized diuretics. The following non-optimized HPLC procedure was used: a 0.1M SDS mobile phase containing 5% n-propanol and 0.01M sodium dihydrogen phosphate (pH 3) was used, and the flow rate was 1 ml/min. Urine samples taken from healthy volunteers were spiked with the diuretics when necessary, and were forced through 0.45 μm pore size filters (Analytichem International). The procedure given above was used, but 8 and 3 ml urine were initially taken to obtain the UV–vis and TLS chromatograms, respectively. After derivatization, 20 μl of the sample was injected in the chromatograph through 0.22 μm pore size filters (Analytichem International). The UV–vis detector was set at 514 nm. With TLS, the standard cell of the HP UV–vis detector was located in the beam path, and 100 mW of pump power at 514.5 nm was used.

RESULTS AND DISCUSSION

Optimization of the reagent concentrations

Physico-chemical requirements of similar nature should be met for a chromogenic reaction to be successfully exploited in both conventional and thermal lens spectrophotometry; however, and as a consequence of the lower concentrations used, for TLS procedures those requirements are much more demanding.[6] Thus, for instance, in TLS the concentrations of the competing ligands should be frequently reduced, to increase the conditional stability constants of the chromogenic reactions. It may also be necessary to increase the concentration of the chromogenic reagents to displace the reactions to the right, or to increase reaction rates. Therefore, the simultaneous optimization of both the conventional and the corresponding TLS procedures can be of interest.

The HCl (pH) and SDS concentrations were optimized elsewhere for the spectrophotometric determination of a large number of diazotizable substances with NED.[4] Final HCl and SDS concentrations (0.06M and 0.017M, respectively) assure an optimal pH ($1 < pH < 1.5$), as well as formation of micelles. Therefore, these concentrations were also assumed to be optimal for the spectrophotometric and TLS determination of the diuretics. Optimization of the concentration of sodium nitrite, sulphamic acid and NED was performed using constant PABA concentrations, *i.e.* $8 \times 10^{-5}M$ and $8 \times 10^{-7}M$ PABA for the spectrophotometric and TLS experiments, respectively.

In Fig. 1, the absorbance and TLS signals obtained are represented against the log of nitrite/PABA molar ratio. The absorbance of the blanks was negligible and, similarly, the TLS

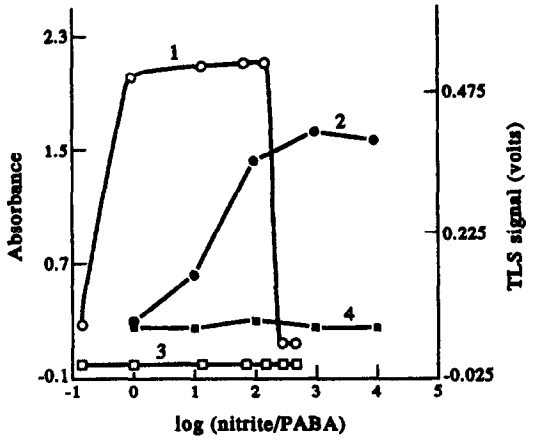


Fig. 1. Influence of sodium nitrite; 1) absorbance, series of single experiments; 2) TLS signal, means of series of duplicated experiments; 3), absorbance blanks; 4) TLS blanks. The logarithms of the nitrite/PABA molar ratios are represented on the X-axis. Final concentrations: $8 \times 10^{-5}M$ and $8 \times 10^{-7}M$ PABA for the spectrophotometric and TLS experiments, respectively; $6 \times 10^{-3}M$ sulphamic acid and $6 \times 10^{-4}M$ NED.

blanks gave a low and constant signal. A maximum and constant value of the absorbance was obtained for nitrite/PABA molar ratios between 1:1 and 200:1, but no dye formation was observed at higher ratios. Instead, the nitrite/PABA molar ratio had to be increased up to 1000:1 to achieve a reasonably constant value of the TLS signal. In comparison to spectrophotometry, the diazotization yield probably decreased at the much lower PABA concentration used in TLS.

Figure 2 shows the absorbance and TLS signal against the log of sulphamic acid/nitrite molar ratio. In TLS high blanks were obtained at sulphamic acid/nitrite ratios lower than 1:1, due to the incomplete destruction of nitrite (sulphamic acid eliminates nitrite following a 1:1 reaction). The use of sulphamic acid/nitrite ratios larger than 1:1 had a negligible influence on sensitivity. For the spectrophotometric and TLS experiments given below, 4:1 and 10:1 sulphamic acid/nitrite molar ratios were used, respectively.

The results obtained using different NED/PABA molar ratios are shown in Fig. 3. The values of the TLS blanks were low and constant, except at NED concentrations larger than $10^{-3}M$. In both spectrophotometric and TLS experiments, an NED/PABA molar ratio over the stoichiometric value (1:1) was enough to assure quantitative coupling, and no significant sensitivity changes were observed at the larger ratios studied. The following experiments were performed using the optimized procedure given above. The excess of NED assured quantitative reaction at relatively large analyte concentrations.

Optimization of the reaction time periods

The results obtained by varying the diazotization time are shown in Fig. 4. The blanks gave negligible absorbances and very low and constant TLS signals in all cases. Using $8 \times 10^{-5}M$ PABA, the absorbance was the

The logarithms of the sulphamic acid/nitrite molar ratios are represented on the X-axis. Final concentrations: PABA and NED as in Fig. 1; nitrite was $1.4 \times 10^{-3}M$ and $2 \times 10^{-4}M$ for the spectrophotometric and TLS experiments, respectively.

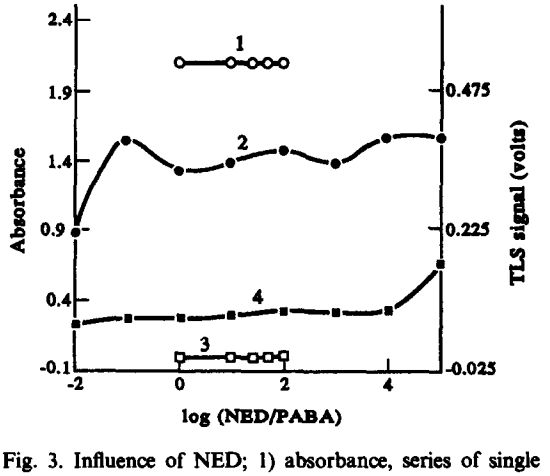

Fig. 3. Influence of NED; 1) absorbance, series of single experiments; 2) TLS signal, means of series of duplicated experiments; 3) absorbance blanks; 4) TLS blanks. The logarithms of the NED/PABA molar ratios are represented on the X-axis. Final concentrations: PABA as in Fig. 1; nitrite as in Fig. 2; sulphamic acid was $6 \times 10^{-3}M$ and $2 \times 10^{-3}M$ for the spectrophotometric and TLS experiments, respectively.

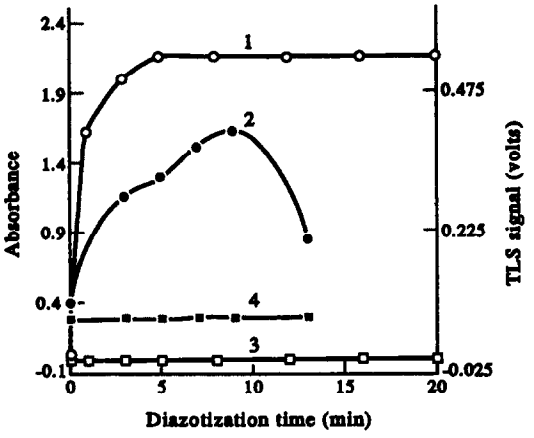

Fig. 4. Influence of diazotization time; 1) absorbance, series of single experiments; 2) TLS signal, means of series of duplicated experiments; curves 3 and 4 are the corresponding blanks. Concentrations are those given in the Procedures section.

same for diazotization times between 4 and 20 min. However, for $8 \times 10^{-7}M$ PABA, the TLS experiments showed a continuous sensitivity increase, followed by a decrease at diazotization times larger than 10 min. Therefore, at the low concentrations used in TLS, diazotization is slower but the decomposition of the diazonium ion in the presence of excess nitrite is more rapid than in the spectrophotometric experiments. The diazotization time was set at 10 min in the recommended procedure.

After addition of sulphamic acid, 2 min were enough to assure quantitative nitrite excess elimination in all cases, and no significant variations of the blank and PABA signals were observed for reaction times between 1 and 20 min. Finally, no sensitivity changes were observed when the absorbance and TLS signals were measured immediately after the addition of NED and 20 min later; therefore, coupling with NED was very rapid in the SDS micellar medium, and the azodye was stable.

Hydrolysis and azodye formation of the diuretics

The diuretics studied here are secondary arylamines and, therefore, diazotization required previous hydrolysis of the α N—C bond. However, some colour appeared when the procedure was applied directly to the diuretics. This was attributed to partial hydrolysis produced by the acid medium of the diazotization reaction. The yield of azodye formation increased largely when the solutions containing the diuretic, $0.15M$ HCl and $0.043M$ SDS, were put in a water bath at 100° for a few minutes. Brown precipitates were formed using hydrolysis times longer than 10 min for hydrochlorothiazide and bendroflumethiazide, and longer than 20 min for furosemide. The precipitates appeared in less than 1 min when hydrolysis was performed in a $1M$ HCl medium. The results shown in Fig. 5 suggested that hydrolysis was complete after 5 min for bendroflumethiazide and furosemide, and was about 50% for hydrochlorothiazide at 10 min.

The hydrolysis time was also optimized using $3 \times 10^{-7}M$ hydrochlorothiazide and TLS detection. Figure 5 also shows the TLS signal obtained for hydrolysis times between 1 and 15 min. Formation of a precipitate was observed for more than 15 min of hydrolysis.

Interference of 3-substituted indoles in urine

Application of an absorptiometric procedure to urine samples requires efficient separation of the analytes from the coloured substances of the urine matrix, or urochromes; otherwise, high blanks are obtained.[19,20] First, low blanks and isolation of the diuretics was attempted using SCX solid-phase extraction columns. Urine samples, taken from two different healthy volunteers, were centrifuged, passed through 0.45 μm pore filters, and made $0.043M$ in SDS to avoid protein precipitation.

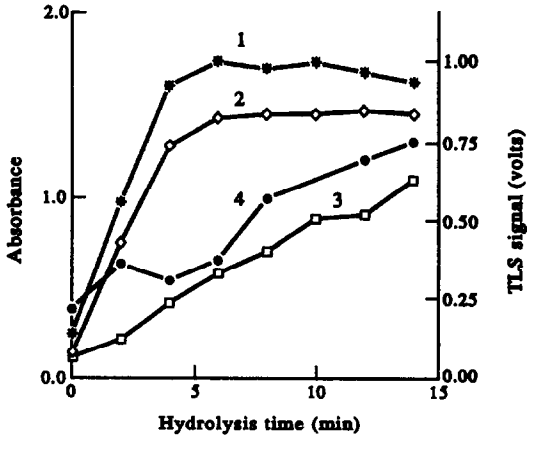

Fig. 5. Influence of hydrolysis time: spectrophotometric determination of $6 \times 10^{-5}M$ bendroflumethiazide (1), furosemide (2) and hydrochlorothiazide (3), and TLS determination of $2.5 \times 10^{-7}M$ hydrochlorothiazide (4). Series of single experiments.

The SCX columns were equilibrated with a solution of 0.2*M* acetic acid and 0.043*M* SDS. A 0.5 ml sample of the $10^{-3}M$ solutions of the diuretics, as well as 2 ml aliquots of urine in the same medium, were passed through the columns. Elution was performed by washing three times with 0.5 ml of 0.1*M* HCl. Recovery of the diuretics was not quantitative, *i.e.* $70 \pm 5\%$ and $50 \pm 5\%$ for hydrochlorothiazide and bendroflumethiazide, respectively (series of eight extractions). Urine samples gave transparent eluates which showed negligible absorbance at 514.5 nm, and a very low TLS signal. However, the slow formation of a red–blue colour was observed when the derivatization procedure was applied to the urine eluates. Absorbance increased slowly for 2 hr, a maximum being formed at 560 nm. The concentration of arylamines in urine (*e.g.* folic acid) is too low (nanomolar level) to explain colour formation upon diazotization and coupling.

Urine contains 3-substituted indoles, *e.g.* 5-HIAA, tryptophan, serotonine and other metabolites, at the millimolar level. When treated with nitrite, 3-substituted indoles give *N*-nitroso derivatives.[21] The derivatization procedure was applied to 0.5 ml of 0.01*M* 5-HIAA and tryptophan solutions (final volume was 10 ml). When nitrite was added, tryptophan gave a yellow colour. Further addition of sulphamic acid and NED slowly produced dark yellow and red–blue colours with 5-HIAA and tryptophan, respectively. No references about the possible reactions involved were found.

The apparent molar absorptivity of the colour developed by tryptophan was low ($\epsilon = 135\ \mathrm{cm^{-1}mol^{-1}\,l}$ at 560 nm), but the colour given by several urine samples in the same wavelength region was intense; thus, 3-substituted indoles seriously interfered in the determination of the diuretics in urine owing to their large concentration. The position of the maximum (560 nm) and colour intensity did not vary when the tryptophan solutions were previously made 0.15*M* and 1*M* in HCl, or 1*M* in NaOH, and were treated at 100° for 30 min.

HPLC preliminary results

Owing to the presence of these spectral interferences in urine, and to the lack of an adequate solid-phase extraction procedure, HPLC was tried. A micellar mobile phase of SDS was chosen. Using this phase, direct injection of the urine samples (without deproteinization or extraction) is possible, and the samples are ready to be injected immediately after derivatization in the same micellar medium.

A series of chromatograms, including unmodified and spiked urine samples, with both conventional and thermal lens spectrophotometric detection, are given in Fig. 6. Using both conventional and thermal lens detection, changes of the refractive index produced deformations of the background, beginning at 0.8 ml (0.8 min), *i.e.* at the dead volume. The same value was obtained by injecting an aqueous potassium iodide solution. The narrow isolated peak at 3.7 min was also produced by changes of the refractive index, and should be attributed to the mismatch of sodium concentrations between the mobile phase and the injected solution.[22] Sodium was retained by this chromatographic system owing to the ion-exchange processes on the negatively charged stationary phase.

The urine blanks gave a single small peak at 5 min which did not interfere. This peak was not present in the corresponding chromatograms performed with the reagents in the absence of urine. The peaks of hydrochlorothiazide, bendroflumethiazide and furosemide were observed at 6.5, 8.2 and more than 20 min, respectively. No significant modifications of the chromatograms were observed by spiking the samples with up to $1 \times 10^{-4}M$ 5-HIAA and tryptophan.

Analytical figures of merit

The limits of detection (LODs) were calculated as three times the standard deviation of the blanks (eight measurements), divided by the slope of the calibration curves (six points per curve). Spectral characteristics of the dyes, LODs and coefficients of variation of the batch procedures are given in Table 1 for PABA and the diuretics. The TLS procedures gave limits of detection 20–50-fold smaller than the corresponding conventional spectrophotometric procedures. Dynamic ranges were over two orders of magnitude for the TLS procedures; furthermore, in TLS the upper limit of the dynamic range can be extended up to high absorbance values by decreasing the pump beam power, as long as the probe beam is not significantly absorbed.

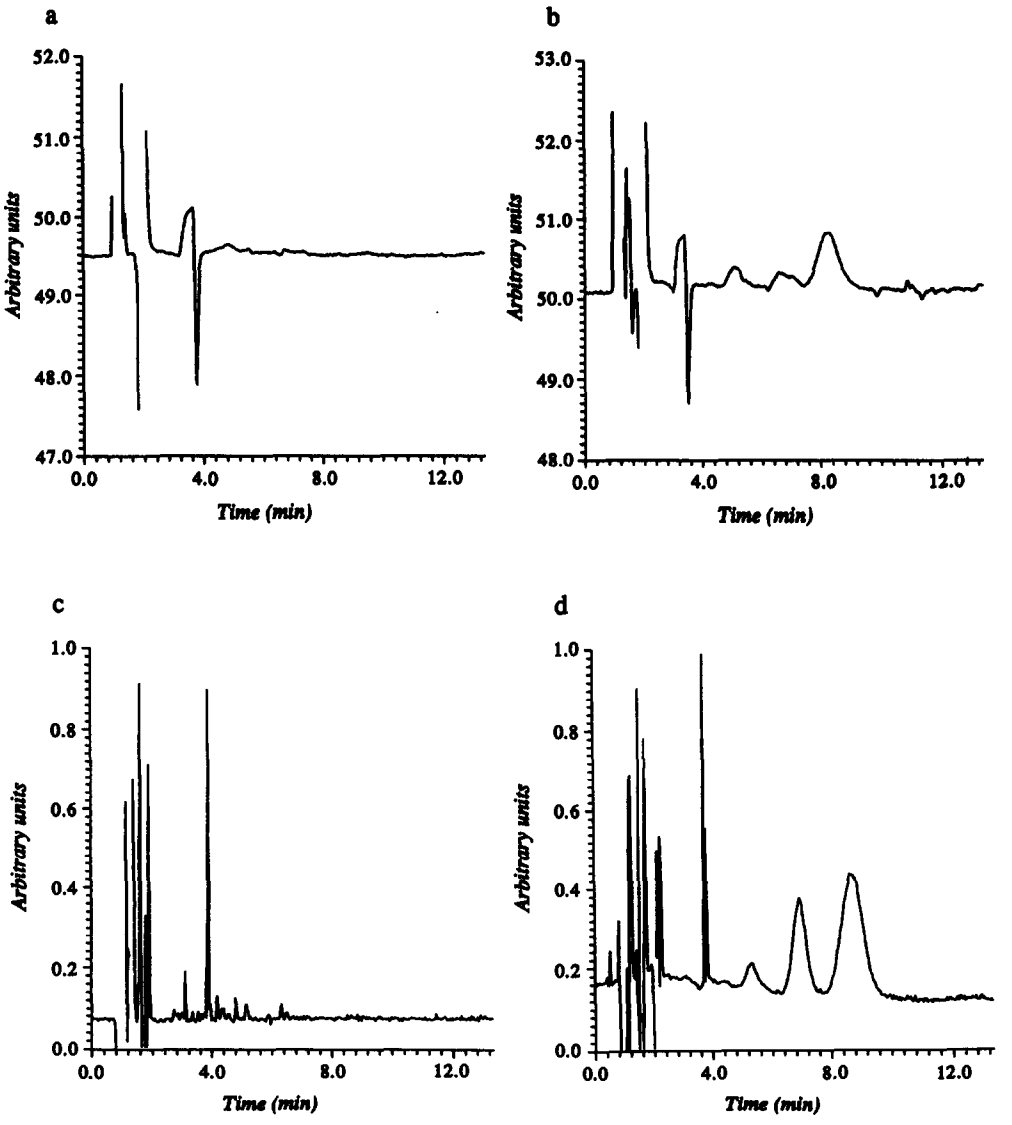

Fig. 6. Chromatograms obtained after derivatization of: (a) urine matrix, UV–vis detection; (b) urine spiked with 20 μg/ml hydrochlorothiazide and 28 μg/ml bendroflumethiazide, UV–vis detection; (c) urine matrix, TLS detection; (d) urine spiked with 15 μg/ml hydrochlorothiazide and 21 μg/ml bendroflumethiazide, TLS detection. Mobile phase: 0.1*M* SDS + 5% *n*-propanol at pH 3 (phosphate buffer).

CONCLUSIONS

The results have shown that the diazotization and coupling reactions were adequate to be exploited for the derivatization of arylamines in TLS determination procedures. The reactions were sufficiently quantitative and rapid at the low concentrations used, and the blanks gave negligible signals. In the batch procedures, the LODs were more than one decade lower than the corresponding values obtained with conventional spectrophotometry.

In addition, several new approaches which may be useful to determine drugs in physiological samples have been successfully tried in this work, *i.e.* it has been shown that arylamine diuretics can be determined in urine after hydrolysis, diazotization and coupling in a micellar medium, and micellar liquid chromatography of the corresponding azodyes. Both conventional and thermal lens spectrophotometric detection were possible, TLS giving lower LODs. Furthermore, the problem of the high background observed at the beginning of the chromatograms when micellar liquid chromatography of physiological samples is performed in the UV is overcome by using detection of the derivatized drugs in the visible region.

13-HYDROXYACENAPHTO[1,2-b]QUINOLIZINIUM BROMIDE AS A NEW FLUORESCENCE INDICATOR

M. A. MARTIN, B. DEL CASTILLO* and P. PRADOS

Laboratorio de Técnicas Instrumentales, Facultad de Farmacia, Universidad Complutense de Madrid, 28040-Madrid, Spain

Summary—13-Hydroxyacenaphtho[1,2-b]quinolizinium bromide (13-HQBr) was selected as a fluorescence indicator to determine basic compounds in non-aqueous media. This compound possesses an acidic phenolic hydroxyl group. It presents varying absorption (R—OH, 408, 430 nm; R—O^- 456, 478 nm) and excitation spectra (R—OH, 425 nm; R—O^-, 471 nm) depending on the pH of the media, but the same emission fluorescence spectrum (R—OH = R—O^-, 526 nm) at different pH in buffered aqueous solutions. However, in acidic non-aqueous media (acetic, formic and trifluoroacetic acids), it can be observed that the fluorescence emission spectra differ for the ionized (λ_{em} = 530 nm) and non-ionized (λ_{em} = 440, 470 nm) forms. The fluorescence intensity at the characteristic peaks depends on the acid–base equilibria in the ground and excited states. Therefore, this property could be used to evaluate the concentration of basic compounds, showing a good linearity range between fluorescence intensity and basic sample concentration.

Fluorescence sensors are devices able to indicate, continuously and reversibly, changes in either the concentration of the analyte or in the physico-chemical behaviour of a medium. Thus, the variation of the analyte concentration causes changes in the fluorescent properties of the sensor, such as spectral shifts, increase or decrease in the fluorescent intensity, quantum yield and fluorescence lifetime. In most cases, an indicator is included or immobilized onto the optical fibre and reacts with the analyte; the reaction produces a variation in the fluorescent properties which can be measured and related to the analyte concentration. Extensive reviews have been dedicated to this subject.[1-3] It is necessary to search for adequate fluorescent compounds sensitive to analyte concentration variations. Fluorescence pH indicators are very sensitive to pH variation and detect changes in the pH value of 0.01 units.[4] Bromothymol blue[5] and 7-hydroxycoumarine-3-carboxylic acid[6] have been immobilized onto optical fiber and used as fluorescence pH sensors. In the same way, NH_3 can be sensitively determined using an oxazine derivative[7] or *p*-nitrophenol[8] as fluorescent pH sensors.

There are many compounds which can behave as fluorescent sensors which can be incorporated on an optical fiber and thus allow the detection of non-fluorescent compounds. Quinolizinium salts show interesting chemical and spectroscopic properties, including the fluorescent intensity changes related to solvent polarity,[9] and can also be considered as good fluorescent probes for micellar media[10] as well as fluorescent reagents for nucleophiles.[11] We propose here 13-hydroxyacenaphtho[1,2-b]-quinolizinium bromide (13-HQBr) as a fluorescence pH indicator. This compound also shows changes in the fluorescent excitation and emission spectra in the presence of basic compounds in non-aqueous media and consequently it can be considered as a potential fluorescent sensor for amine determination.

EXPERIMENTAL

Apparatus and reagents

UV–visible spectra of 13-HQBr were obtained with an automatic, double beam Kontron Uvikon 810 spectrophotometer. Uncorrected excitation and fluorescence emission spectra and measurements at fixed wavelength were carried out with a Perkin–Elmer LS-3 spectrofluorimeter (Xenon lamp 150 W) commanded from a personal computer. A Radiometer Copenhagen PHM 72 MKZ pH meter was used to measure the pH values.

All the reagents and solvents were analytical grade. 13-HQBr was synthesized at the

Department of Organic Chemistry of the University of Alcalá de Henares.

Procedures

General procedure. In all of the experiments, a stock $1.0 \times 10^{-4}M$ ethanolic solution of 13-HQBr was prepared. Aliquots of 1 ml taken from this solution were evaporated to dryness under reduced pressure and redissolved in 10 ml of the desired solvent (buffered aqueous solutions or acetic, formic or trifluoroacetic acids). From this solution aliquots were taken in order to obtain final concentrations of $1.0 \times 10^{-8}M$ and $1.0 \times 10^{-7}M$ of the quinolizinium derivative.

Determination of the pK_a *and* pK_a^*. The pK_a and pK_a^* values of 13-HQBr were determined spectrophotometrically and spectrofluorimetrically. Measurements at specific pH values involved the use of McIlvaine buffers (0.1*M* citric acid–0.2*M* sodium biphosphate; enough potassium chloride for adjusting the ionic strength to 1.0*M*). Britton–Robinson titrated solutions (1.0*M* orthophosphoric acid,1.0*N* acetic acid, 1.0*N* boric acid, titrated with 0.2*N* sodium hydroxide solution) were also used, and in both cases two extreme values of pH were achieved by using 1.0*M* sulphuric acid and 1.0*M* sodium hydroxide solutions. The quinolizinium salt concentration was $1.0 \times 10^{-5}M$ for spectrophotometric measurements and $1.0 \times 10^{-6}M$ for spectrofluorimetric measurements.

The determination of pK_a^* was performed by adding 10 μl aliquots of triethylamine, corresponding to concentrations of $2.88 \times 10^{-6}M$ to $5.76 \times 10^{-3}M$, to a $1.0 \times 10^{-7}M$ solution of the quinolizinium salt in formic acid. The pH values varied from -2.21 to -1.10.

Assay of basic compounds. 13-HQBr behaves as a fluorescent indicator for amines and basic compounds. In order to prove this behaviour, $1.0 \times 10^{-6}M$ solutions of the quinolizinium derivative in acetic acid, prepared according to the general procedure, were treated with increasing concentrations of each basic compound. In the case of pharmacologically active compounds (benzocaine and phenylephrine hydrochlorides), they were treated with mercury acetate in order to obtain the free base. UV–visible and excitation and fluorescent emission spectra were obtained from these solutions and measurements of fluorescence intensity at fixed wavelength were also performed for the linear regression analysis.

Assay of humidity. Solutions ($1.0 \times 10^{-6}M$) of the quinolizinium derivative were prepared in acetic and formic acids according to the general procedure. Aliquots of 1 ml were taken from these solutions, to which increasing amounts of water were added; the final volume of 10 ml was then completed with acetic or formic acid. The final concentration of the quinolizinium was $1.0 \times 10^{-7}M$ and that of water covered the values from 0% to 5% (v/v).

RESULTS AND DISCUSSION

The presence of a phenolic hydroxyl group attached to the quinolizinium ring gives an acidic character to the compound. Its acid–base ionization equilibrium is presented in Fig. 1.

The acid (R—OH) and the ionized ($R—O^-$) forms present different absorption spectra, as can be observed in Fig. 2. Thus, the non-ionized form exhibits two absorption maxima in the visible region at 408 and 430 nm, while the ionized form absorbs at 456 and 478 nm, as well as having a molar absorption coefficient lower than the R—OH species. The existence of an isosbestic point at 370 nm shows that there are only two forms in the equilibrium.

These changes in the absorption spectra imply similar behaviour in the excitation and emission properties of 13-HQBr. Thus, the excitation maxima are 425 and 471 nm for the R—OH and $R—O^-$ species, respectively. In aqueous buffered solutions, only an emission maximum at 526 nm was observed for both forms. Similarly, the emission intensity for the phenolate anion is lower than that observed for the phenolic non-ionized form, as can be seen in Fig. 3. Therefore, we can propose the use of 13-HQBr as a sensitive fluorescence and absorbance pH indicator due to the pH-associated spectral changes observed in the positions and intensity of the

absorption, excitation and fluorescence emission spectra.

Figures 4 and 5 show the pK_a value (3.7) calculated for this compound on the basis of the spectrophotometric and spectrofluorimetric values. This strongly acidic character can be explained by the electron-withdrawing ability of the azonia nitrogen atom and the acenaphtho moiety. Similar effects explain the very low pK_a values of phenolic compounds such as picric acid.

In buffered aqueous solutions, the phenolic and phenolate forms exhibit different excitation spectra depending on pH. However, the emission maximum is the same and the fluorescent intensity decreases when the pH is increased (Fig. 3). This means that in the excited state, the ionized and non-ionized forms present the same fluorescence. Deactivation of excited state and acid–base equilbria are two competitive processes that take place in solution. If it is assumed that the proton transfer process is slower than deactivation of the excited state, the existence of only one fluorescent species in the pH range from 1 to 12 can be explained.[12,13] In

order to confirm this hypothesis, the fluorescence emission intensity was measured at the wavelength of the isosbestic point (370 nm) at different pH values; no significant differences in the fluorescence emission were found. In these conditions the fluorescence intensity should have changed if different excited species (R—OH*, R—O$^-$*) had existed.

However, the ionization rate for many ionizable compounds is very high compared to the deactivation rate of the excited state. In such cases, the fluorescence emission spectrum changes with pH, the pK_a* value (pK_a for the compound in the excited state) can be obtained and the ionization equilibrium can be observed in the excited state and therefore detected by changes in the fluorescence emission spectrum or fluorescent intensity. For such compounds, the pK_a* value is extremely different from the pK_a value and the ionization process corresponding to the excited state can be detected in strongly acidic or basic media.[14] This particular behaviour was observed for 13-HQBr in acetic, trifluoroacetic and formic acid solutions. In the last two solvents, whose pK_a values are lower

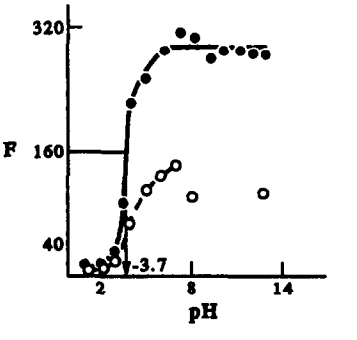

Fig. 5. Spectrofluorimetric determination of pK_a of 13-HQBr: (●) in titrated solution of Britton–Robinson; (○) in McIlvaine buffer. Fluorescence intensity (F) in arbitrary units ($\lambda_{ex} = 471$ nm, $\lambda_{em} = 526$ nm) against pH.

than that of the quinolizinium derivative in the ground state, excitation maxima are seen at 408 and 438 nm (formic acid), or 405 and 428 nm (trifluoroacetic acid). In formic and trifluoroacetic acids, the emission maximum at 520–530 nm cannot be observed because these solvents present pK_a values lower than those of the fluorescent compound; therefore, 13-HQBr is only present as the R—OH form, which emits at 442 and 467 nm; the R—O^- species does not exist. In the case of acetic acid ($pK_a = 4.75$), a solvent slightly less acidic than the quinolizinum derivative, both forms (R—OH and R—O^-) will exist and the maxima are located at 445 (excitation), and 467 and 534 nm (emission), as can be seen in Fig. 3. The different positions of the maxima, depending on the acidity of the solvent, allowed the calculation of pK_a^*, since addition of small amounts of base (triethylamine or water; see Figs 7 and 8) caused a decrease in the fluorescence intensity of the shorter emission maxima and an increase in the intensity of the maximum at 530 nm. The pK_a^* value thus calculated was -1.84 (Fig. 6). This value proves that the excited state is several orders of magnitude more acidic than the ground state, in agreement with previous observations on other compounds where an acid–base equilibrium has been observed in the excited state.[15]

The behaviour of 13-HQBr in solution is defined by the acid–base equilibrium, as well as the solvatochromic effects. The presence of small amounts of water causes significant differences in the emission spectra. However, high amounts of water originate the excitation and emission spectra of 13-HQBr dissolved in buffered aqueous solutions and the spectral resolution characteristic of acidic non-aqueous media is lost. Thus, solutions of the quinolizinium derivative in $10M$ trifluoroacetic, formic and acetic acids do not exhibit emission maxima in the vicinity of 440 and 470 nm and only the emission maximum at 520–530 nm is present. Therefore, this compound is very sensitive to changes in the polarity and pH of the media, and consequently it can be considered as an indicator for testing the pH of the media. In non-aqueous media (acetic acid), 13-HQBr shows emission spectra corresponding to the ionized and non-ionized forms, as can be seen in the following equation:

$$R—OH + BH \rightarrow R—O^-\cdot BH_2^+$$

$$\lambda_{ex} = 410 \text{ nm } \lambda_{ex} = 467 \text{ nm}$$

$$\lambda_{em} = 445 \text{ nm } \lambda_{em} = 530 \text{ nm.}$$

In such media, the indicator behaves as a strong acid and reacts with bases. The increase

†Formic acid at $\lambda_{ex} = 408$ nm, $\lambda_{em} = 442$ nm.
‡Acetic acid at $\lambda_{ex} = 410$ nm, $\lambda_{em} = 445$ nm.

or decrease in the emission intensity after addition of small amounts of a base allows the quantitation of basic compounds. The changes in the excitation and emission spectra of 13-HQBr in acidic solvents due to the presence of very low concentrations of water can be observed in Figs 7 and 8.

Table 1 shows the linear range obtained in the linear regression analysis for the indicator dissolved in acidic media and at different concentrations of basic compounds.

Low concentrations of water cause significant changes in the excitation and emission fluorescence spectra (Figs 7 and 8), which allows their quantitation. However, water at concentrations higher than 10% (v/v) produced an emission spectrum with only one maximum, at 526 nm, which precluded quantitation. This behaviour can be explained by the solvatochromic effect, as detailed elsewhere.[16]

This indicator is not specific because it allows quantitation based on the acid–base characteristics of the compounds; however, the good correlation coefficients proved the utility of 13-HQBr as a potential fluorescence indicator to detect basic compounds at low concentrations. Consequently, the use of 13-HQBr supported on an optical fiber allows its use as a potential fluorescence sensor for the sensitive and easy detection of amines with a good linear response.

A COATED PIEZOELECTRIC CRYSTAL SENSOR FOR ACETIC ACID VAPOUR DETERMINATION

J. A. MUNOZ LEYVA,* J. L. HIDALGO HIDALGO DE CISNEROS and D. GARCIA GOMEZ DE BARREDA

Department of Analytical Chemistry, Apdo, 40, 11510 Puerto Real, Cádiz, University of Cádiz, Spain

Summary—A novel sensor for acetic acid vapour determination is proposed. This sensor is based on a piezoelectric crystal covered with a film of diethylenetriamine. For the sensor development a system of our own design—consisting of testing chamber, oscillator circuit and measure instruments—has been employed. The sensor shows its activity to the acetic acid vapours for more than 60 days. The selectivity is adequate although some vapours interfere: hydrochloric acid, formic acid, formaldehyde, tributyl phosphate, chloroform, chlorobenzene, acetone and isobutylmethylketone. The sensor described can be applied to detect acetic acid vapours in the presence of other vapours: acetonitrile, acrolein, benzene, *n*-hexane, ethanol, propanol, *n*-butyl acetate, isopropyl ether, isoamyl alcohol, ethyl ether, methylene chloride, carbon tetrachloride and toluene. The major advantages of the proposed sensor over other existing techniques are its simplicity, reduced cost and capacity for use *in situ*.

Piezoelectric crystals, due to their special characteristics,[1] are very appropriate for the construction of portable, simple and cheap detection units. In recent years coated piezoelectric crystal sensors have attracted increasing interest for monitoring traces of toxic gases in the atmosphere as well as in the air of working environments.[2–15]

Acetic acid is a corrosive acid which has numerous industrial applications and hence it is present, mainly as vapour, in some industrial atmospheres. On the other hand, it is the principal constituent of the volatile acidity of wines[16] and its content in vinegars is not smaller than 50–60 g/l.[17] The Threshold Limit Value - Time Weighted Average (TLV-TWA) for the acetic vapours is 10 ppm (25 mg/m^3).[18] So for all these reasons, it is very important to have sensor systems to detect acetic acid.

The existing methods for detecting acetic acid vapours use gas chromatography with a preconcentration stage on a column with adsorbent;[19,20] determination has also been described using pulsed UV photoacoustic spectroscopy.[21] With these techniques a high level of sensitivity is achieved, but they involve the use of sophisticated instruments.

As for using sensors to detect acetic acid, only one process has been described and it is used to detect the acid in solution. The sensor described in the literature is based on the property of certain bacteria which produce oxygen from acetic acid, so the acid can be detected using immobilized *Trichosporon brassicae* on a Teflon membrane electrode and an amperometric oxygen electrode. The minimum concentration for determination is 5 mg/l.[22]

In the literature which we reviewed, we found no sensors for the determination of acetic acid in its vapour form. This paper describes for the first time one sensor for acetic acid vapours, based on AT-cut piezoelectric crystals coated with diethylenetriamine films. This sensor combines a good selectivity and an acceptable sensitivity.

For studying and perfecting the new sensor we used our own design system,[23] which is capable of working statically, and is thus easily adaptable to measurement *in situ*, unlike other techniques proposed with other sensors, which work dynamically.

EXPERIMENTAL

Reagents

All reagents, those used as coatings and those used in the interference study, were of analytical reagent grade. The nitrogen was type N-50 from S.E.O. (Spanish Oxygen Company).

Materials and equipment

The 8.9 MHz At-cut PZ crystals (Universal Sensors) were mounted on HC-25/U type bear-

*Author for correspondence.

ings. The oscillator circuits employed were made of common commercial electronic components (resistors, capacitors, transistors). The sensor unit was placed inside a testing chamber which was capable of reproducing atmospheric conditions. The rest of the equipment consisted of control and measurement instruments. The complete installation, of our own design, has been reported elsewhere.[23]

Procedures

Preparation of the coated crystal. The crystal, cleaned with ethanol, was dried in warm air and placed in the testing chamber under vacuum for 5 min, whereupon dry nitrogen was injected. After 30 min, the frequency was measured and noted, the crystal removed from the chamber and then coated by immersion for 5 sec or more (or by several immersions)—according to the amount of coating desired—in a solution of 0.100 g of diethylenetriamine in 10 ml of ethanol. The crystal was dried again and the frequency measured and noted. For storage the coated crystals were each protected with a metallic capsule and introduced in a vacuum dessicator.

Measurement of the response to acetic acid. The stabilized frequency of the coated crystals in an air or nitrogen atmosphere (in the testing chamber) was measured and noted. The chamber was evacuated and the acetic acid injected. The initial conditions (pressure and temperature) were re-established and the frequency again measured and noted, calculating the difference, Δf, between this measurement and the previous one. The sensor was restored to its original condition by vacuum and nitrogen after this second measurement. The time necessary for this restoration is defined as recovery time (T_R). In this manner, the measurements are all independent.

The concentration of acetic acid vapours was calculated from the previously constructed calibration graphs.

RESULTS AND DISCUSSION

Selection of coatings

The acidic nature of the sample for analysis led us to select basic coatings. With all the coatings tested, a reduction in frequency was noted in the coated crystal, but the magnitudes of variation were very different. For a fixed amount of 4.33 mg/l. of acetic acid in the chamber, the differences in frequency in Hz, Δf, of the crystal, in the absence and presence of the sample being analysed, were as follows:

Diphenylamine, 6 Hz
Thiosemicarbazide, 9 Hz
Diethylenetriamine, 32 Hz
Phenylhydrazine, 10 Hz
2,4-dinitrophenylhydrazine, 8 Hz
1,10-phenanthroline, 19-Hz
2,2′-bipyridine, 5 Hz
4-ethyl-3-thiosemicarbazide, 16 Hz
4-phenylthiosemicarbazide, 1 Hz
2,6-diacetylpyridine, 20 Hz.

On the basis of these results, diethylenetriamine was chosen as the coating. The fact that the aliphatic amine responds most sensitively to acetic acid suggests that interaction between the ethyl group of the acetic acid and the amine could help to attract acetic acid into the coating.

Variation of response with the amount of coating and with time

The decrease in the frequency of the coated crystal with respect to that of the non-coated crystal, Δf_O, is dependent on the coating amount: the greater the coating the greater the Δf_O value. We prepared coated crystals with two different quantities of diethylenetriamine, obtaining the decreasing frequencies (Δf_O) shown in Table 1.

On the other hand, we found that the frequencies of the coated crystals shift with time. Using the above mentioned crystals, we measured Δf_O of the coated crystals over 60 days and the results are also shown in Table 1.

The Δf_O values first decrease quickly and then slowly, indicating a loss of coating. After 19 days, Δf_O begins to increase slowly, probably

*In the absence of acetic acid.
†In the presence of acetic acid.

owing to progressive contamination of the crystals. Nevertheless, after 60 days the crystals are even sensitive to acetic acid vapours.

The frequency variations we observed have been borne in mind when realizing the experiments measuring Δf_0 at that time.

Variation in the measuring conditions

In order to study the alterations when the operating conditions are modified, we utilized a testing chamber which reproduces environmental conditions and enables us to study the influence on the sensor response to acetic acid vapours in several atmospheric conditions (pressure, temperature or relative humidity). For each value studied we measured the frequencies of the coated crystals (for a given Δf_0) first in the absence and then in the presence of a definite quantity of acetic acid, calculating the difference between them (Δf). Subsequently, the magnitude should be varied in both cases in the same way.

The influence of pressure

Experiments were carried out at a constant temperature of 27°, making a vacuum in the chamber and injecting dry nitrogen at different pressures with a fixed amount (10 μl) of acetic acid each time. The variation of frequency in the range from 720 to 829 mm Hg—in the absence as well as in the presence of acetic acid—is only 4 Hz, whereas Δf for crystals with and without acetic acid at the same pressure is constant in the range studied (Table 2).

The crystal response in a dry air atmosphere (obtained by passing laboratory air through silica gel) has also been studied, and was the same as in the case of a nitrogen atmosphere.

The influence of temperature

Experiments were carried out in a nitrogen atmosphere at a constant pressure of 787 mm Hg (crystal with $\Delta f_0 = 1435$ Hz), injecting in each case a volume of 10 μl of acetic acid (4.33 mg/l.), and measuring the Δf and the recovering times of the sensor. The results are shown in Fig. 1. An increase of 0.33 Hz/° is observed within the range 15–30°, and a decrease of 0.2 Hz/° between 30 and 35°.

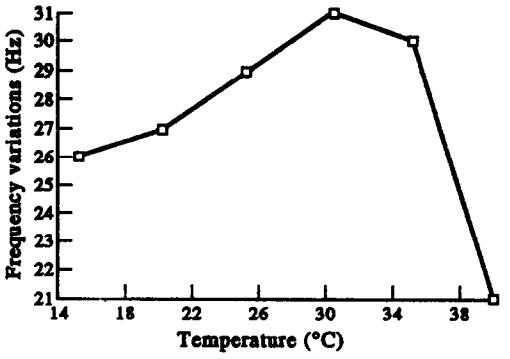

Fig. 1. Effect of temperature on the sensor frequencies.

The influence of humidity

Since the presence of water had a great influence on the frequency of some coated crystals,[23] we carried out a study on the effect of relative humidity (RH) on the oscillation frequency of the sensors tested (crystal with $\Delta f_0 = 1375$ Hz). To do this, we used a test chamber temperature of 25°, with a vacuum to cause the water to evaporate, and injected 5, 10 and 50 μl of water (equivalent respectively, to 10, 20 and 100% RH) and 10 μl of acetic acid each time. Then we injected dry nitrogen into the chamber until a pressure of 750 mm Hz was reached, measuring the oscillation frequencies of the crystal at that time, and comparing these with those measured in the absence of acetic acid.

The frequency of the PZ crystal with a diethylenetriamine coating shows a reduction of 2.8 Hz/% RH between 0 and 10% RH, whereas it is only 0.28 Hz/% RH between 10 and 100% RH (Fig. 2). The difference in frequencies in-

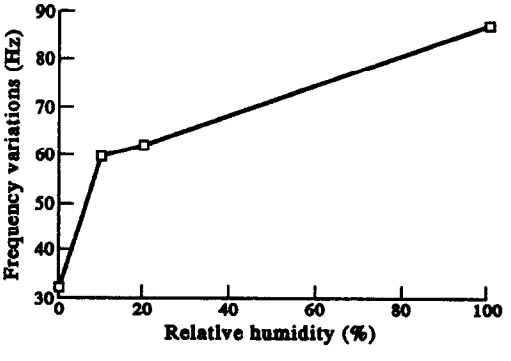

Fig. 2. Effect of relative humidity on the sensor frequencies.

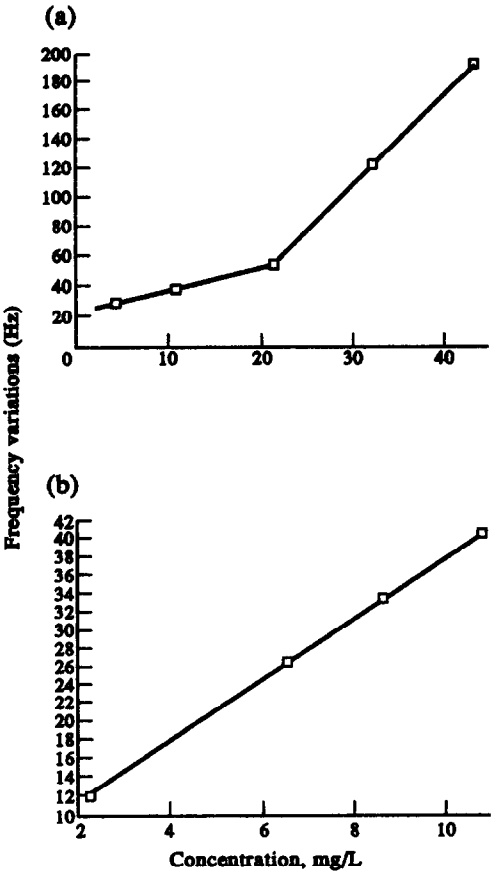

Fig. 3. Influence of acetic acid concentration: (a) $\Delta f_0 = 1490$ Hz; (b) $\Delta f_0 = 652$ Hz.

creases over the complete range, so we have to conclude that the humidity content interferes in the determination of acetic acid, but this interference is eliminated by passing the sample through silica gel.

Influence of acetic acid concentration

The calibration of the sensors in the presence of acetic acid was done in a dry air atmosphere (0% RH) at 25° and a pressure of 760 mm Hg. For each concentration of acetic acid we measured the frequencies, both in the presence and the absence of the acid, and calculated the difference between them (Δf).

We tested two crystals with different quantities of coating and with values of Δf_0 at the time of the experiments of 1490 and 652 Hz for the larger and smaller quantities of diethylenetriamine, respectively.

Figure 3 shows the results obtained for the coated crystals. The calibration equations for the crystals coated with diethylenetriamine were as follows:

($\Delta f_0 = 1490$ Hz) $\Delta f = 1.63$ [CH_3COOH] + 22.3, $r = 0.9981$ (4.33–21.7 mg/l.)

($\Delta f_0 = 1490$ Hz) $\Delta f = 6.28$ [CH_3COOH] – 79.0, $r = 0.9997$ (21.65–43.3 mg/l.)

($\Delta f_0 = 652$ Hz) $\Delta f = 1.31$ [CH_3COOH] + 8.00, $r = 0.9944$ (0.43–32.5 mg/l.).

Greater sensitivity was obtained for $\Delta f_0 = 1490$ Hz, *i.e.*6.3 Hz/mg/l. The detection limit—defined as the concentration of sample for analysis which produces a three-fold greater variation than the sensor in the absence of the sample—was 0.22 mg/l.

When we used coated crystals alone the sensitivity was much greater than that above (Δf_0: 5786 Hz; sensitivity: 46.9 Hz/mg/l.); nevertheless, it varies quickly with time. For this reason in this paper coated crystals alone are not used.

Recovery time (T_R and variation of response with time

Once the sensor had been exposed to the action of acetic acid, we studied the time it took to recover its original frequency for a content of acetic acid in the chamber of 4.33 mg/l. The average recovery time was found to be 14 min. Nevertheless, the recovery time is dependent on the acetic acid concentration.

Repeatability

In order to determine the repeatability, we carried out 11 measurements in the optimized conditions, in each case by injecting acetic acid

Table 3. Study of interferences

Interferences	Conc. (*mg/l.*)	Δf
Carbon tetrachloride	63	3
Acetonitrile	31	0
Ethanol	32	0

Formic acid	33	499

Acetic acid concentration = 4.33 mg/l.

into the chamber so that its concentration was 4.33 mg/l. Statistical treatments (95% probability level) for the greater amount of coatings used gave us the following data:

PZ coated with diethylenetriamine

$$(\Delta f_O = 1440 \text{ Hz}),$$

$$\Delta f_m = 29.63 \text{ Hz}, \ \delta_{\Delta f} = 1.43, \ (\delta_{\Delta f})_m = 0.45,$$

$$\Delta f = 29.63 \pm 1.01, \ \epsilon = \pm 5.4\%,$$

$$T_R = 14.36 \pm 1.48 \text{ min}.$$

Study of interferences

First, we measured the frequency with a given amount of acetic acid (10 μl, equivalent to 4.33 mg/l. within the chamber) and then the frequency with the same amount of acetic acid and a volume of the interfering substance 5–20 times greater.

We studied the responses of crystals coated with diethylenetriamine to 21 interfering species. In each case we worked under conditions of constant pressure (750 mm Hg) and temperature (25°). Table 3 shows the concentration of the interferents (mg/l.) and the decrease in frequency Δf.

From the results it can be concluded that the greatest interferences are caused by species of an acidic nature (hydrochloric acid, formic acid), with the effect of tributyl phosphate, chloroform, formaldehyde and acetone being significant as well.

The following do not have any effect on the sensors: acetonitrile, ethanol, 2-propanol, toluene, acrolein, *n*-hexane, benzene, isopropyl ether and *n*-butyl acetate. The rest of the specimens studied interfere to a lesser extent.

KALMAN FILTERING OF DATA FROM FIRST- AND SECOND-ORDER KINETICS

R. JIMENEZ-PRIETO, A. VELASCO, M. SILVA and D. PEREZ-BENDITO
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, E-14004 Córdoba, Spain

Summary—The Kalman filter algorithm was used to process data obtained in the simultaneous determination of species following first- and second-order kinetics. The performance of the algorithm in the quantification of chemical components from simulated data was assessed, and the influence of various parameters involved was estimated. The algorithm was applied to the resolution of cysteine–ascorbic acid and glutathione–ascorbic acid mixtures where the ascorbic acid followed pseudo first-order kinetics and the amino acids second-order kinetics in the reaction with the copper(II)–neocuproine system. Some features of the determinations (namely, afforded concentration ratios, accuracy and precision) are discussed.

The Kalman filter[1] is a mathematical algorithm which has aroused growing interest from analytical chemists in recent years.[2–7] In its various versions (linear, extended and adaptive), the algorithm has been used to address troublesome analyses in different areas. Thus, the basic principles of Kalman filtering have been widely used in high performance liquid chromatography[6] to resolve overlapped peaks[8–15] and optimize the chromatographic conditions,[16–18] as well as for quantitative multicomponent analysis in spectrophotometric applications.[7,19–25] Other uses of the Kalman filter include the resolution of fluorescence responses and background correction in thin-layer chromatography,[26–29] the resolution of overlapping lines in inductively coupled plasma atomic emission spectra,[30,31] that of strongly overlapped square wave voltammetric signals,[32,33] background correction and interference removal in first-derivative fluorimetry,[34] and a variety of applications to titrimetric methods.[35–38]

In addition, the Kalman filter is an interesting approach to reaction-rate analytical methods. In this context, the algorithm has been primarily used to develop error-compensated and multicomponent kinetic methods. With the former, the extended Kalman filter provides a powerful tool for offsetting changes in the variables influencing a kinetic process such as between-sample rate constant variations[4,39,40] and within-run temperature variations—the latter are offset by using a combined approach involving an integrated first-order rate expression and an Arrhenius equation as a model for the filter.[41,42] Because the algorithm is used in its non-linear form, its performance relies heavily on the initial parameters chosen and the number of iterations carried out. In multicomponent kinetic analysis, the linear form of the filter is also a suitable approach[43,44] to obtain accurate results in the resolution of mixtures of components in quite small rate constant ratios (even less than 2) as an alternative to classical differential reaction-rate methods.[44] The uses of this methodology include the resolution of mixtures of amino acids,[43] corticosteroids,[44] isoenzymes[45] and lower straight-chain alcohols.[46] The most recently reported application of this algorithm to multicomponent analysis involves using its extended form in combination with multiwavelength photometric detection.[47] This makes for accurate determinations under conditions where equilibrium methods based solely on spectral differences or kinetic methods relying only on rate constant differences typically fail.

In this work we extend the scope of application of the Kalman filter to the resolution of mixtures of species following different kinetics (pseudo first- and pseudo second-order) by using the algorithm both on simulated data and real data obtained in the simultaneous resolution of cysteine–ascorbic acid and glutathione–ascorbic acid mixtures by having these species react with the Cu(II)–neocuproine system, with which they form a coloured Cu(I) complex. The algorithm allows the accurate, precise resolution of the above mixtures in

widely different ratios over broad concentration ranges. Although the Kalman filter has previously been used to estimate initial reactant concentrations and rate constants for rate-based chemical assays employing a second-order chemical reaction,[48] the research reported in this work is the first attempt to apply this filter to the resolution of mixtures of species following different kinetics.

THEORETICAL BACKGROUND

Consider the following chemical system:

$$A + R \xrightarrow{k_A^*} P \qquad (I)$$

$$B + R \xrightarrow{k_B^*} P, \qquad (II)$$

the rate equations of which are:

$$d[P]/dt = k_A^*[A][R] \qquad (III)$$

$$d[P]/dt = k_B^*[B]^2[R]. \qquad (IV)$$

If $[R]_0 \gg [A]_0$ and $[R]_0 \gg [B]_0$, then, provided the analytical signal is proportional to the amount of product formed, the integrated equation for the above system can be expressed as

$$S(t) = S_0 + S_A[1 - \exp(-k_A t)] + S_B\left(1 + \frac{1}{k_B[B]_0 t}\right)^{-1}, \qquad (1)$$

where $S(t)$ denotes the signal measured at time t; S_0 the initial signal; S_A and S_B the signal increments resulting from full conversion of A and B; and k_A and k_B the pseudo first-order and pseudo second-order rate constants of A and B, respectively.

Application of the Kalman filter to the resolution of this binary mixture entails defining the state vector, $\mathbf{X}(j)$, which is what one wishes to determine: S_A, S_B and S_0, and the measurement function vector, $\mathbf{H}^T(j)$, which describes the dependence of the measurement on the states. The form of the vector for first-order kinetics is quite well known; however, that of the vector for pseudo second-order kinetics remains unknown as, to date, no reactions of this order have been studied in this context. Specifically, a measurement function vector for (II) is given by

$$\mathbf{H}^T(j) = \left[\left(1 + \frac{1}{k_B[B]_0 t}\right)^{-1} 1\right], \qquad (2)$$

which, unlike a first-order reaction, depends on the initial concentration of analyte. The algorithm was expanded by using an apparent first-order constant for this component, defined as

$$k_B^1 = k_B[B]_0, \qquad (3)$$

which is dimensionally analogous to the first-order constant. In addition, this constant allows one to compare the kinetic curves of the two species.

Under these conditions, the measurement function vector can be expressed as

$$\mathbf{H}^T(j) = \left[\left(1 + \frac{1}{k_B^1 t}\right)^{-1} 1\right], \qquad (4)$$

so the Kalman filter for this component is used to calculate k_B^1 recursively from k_B—known beforehand—and $[B]_0$, determined by the algorithm.

The procedure used involves the prior estimation of S_B at point j from its value at point $j-1$ by using the Kalman filter; the estimated S_B value allows vector $\mathbf{H}^T$ to be updated and used by the filter to update S_B. In summary, the Kalman gain and state estimation update in the linear Kalman filter are used twice: once to update $\mathbf{H}^T$ and also to update S_B from its initial value (*i.e.* S_B at point $j-1$). The linearization procedure used (one of several possibilities) largely obviates reliance of the filter on initial guesses for the parameter concerned. Specifically, if the reaction is monitored photometrically, the apparent constant k_B^1 is calculated recursively by substituting the estimated S_B values into the following expression:

$$k_B^1 = \frac{k_B}{\epsilon_B l} S_B, \qquad (5)$$

where $\epsilon_B l$ is the slope of the calibration curve.

In this work we deal with the kinetic determination of A and B in samples containing either and the simultaneous determination of both in mixtures containing them in various ratios by using the Kalman filter in three different versions, namely K_FIRST (A alone), K_SECOND (B alone) and K_MIX (mixtures of A and B).

The practical procedure involves the following steps: (a) construction of two calibration graphs relating S_A and S_B with their respective concentrations; (b) determination of the rate constants (the first-order constant k_A is obtained from the slope of a plot of $\ln[(S_A/(S_A - S_t + S_0)]$ against time, whereas the apparent first-order constant k_B^1 is calculated from the slope of a plot of $(S_t - S_0)/(S_B + S_0 - S_t)$ *vs.* time); (c) application of the pertinent filter to the samples in

order to obtain the estimated S_A and S_B; (d) interpolation of the previous values on the corresponding calibration graphs in order to obtain the respective concentrations.

The net absorbance increments—provided the reaction is monitored photometrically—required to determine the concentrations by interpolation on the pertinent calibration curves are obtained by applying the Kalman algorithm using the three BASIC programmes whose essential features are described in Table 1. The measurement noise variance, $\mathbf{R}(j)$, is taken to be $10^{-6} \times 10^{2\text{Abs}}$, which is quite realistic as it is equivalent to assuming that the standard deviation for the transmittance is 0.002 units. However, such a value must be increased when using K_SECOND and K_MIX in order to ensure that the filter eventually converges.[49] Taking into account that

$$\mathbf{K}(j) = \mathbf{P}(j/j)\mathbf{H}^{\mathrm{T}}(j)/R(j),$$

where $\mathbf{K}(j)$ is the Kalman gain vector and $\mathbf{P}(j/j)$ the error covariance matrix, the more $R(j)$ increases, the more slowly will the filter converge. Consequently, in using the programme K_MIX for the resolution of the mixtures, one must perform three iterations and use $R(j)$ values equal to one-half and one-quarter those listed in Table 1 in the second and third iterations, respectively. On the other hand, the elements of the principal diagonal of the matrix $\mathbf{P}(0/0)$ are assumed to be 0.5 in using all three programmes. Also, the state transition matrix is taken as the identity matrix and the system noise vector is assumed to be zero.

Simulated experiments

We simulated a set of kinetic curves for samples containing A (first-order) or B alone (second-order), and for others containing mixtures of both species. The signal recorded in each case was assumed to be due to a single reaction product and Beer's law was assumed to be obeyed. The results obtained for single component samples show determination errors to be less than 0.5% in all instances. We shall thus concentrate on the results obtained for simulated mixtures. The overall signal for a mixture of A and B will be given by

$$S(t) = S_0 + S_A[1 - \exp(-k_A t)] + S_B\left(1 + \frac{1}{k_B^1 t}\right)^{-1} + N(t), \quad (6)$$

where $N(t)$ denotes pseudo random noise, whose variance is taken to be $10^{-6} \times 10^{2S(t)}$. By using the programme K_MIX we calculated the errors made in estimating A and B as a function of two major parameters: (a) the constant ratio (k_B^1/k_A), which is directly proportional to the concentration of the second-order component in the mixture; (b) the signal ratio (S_A/S_B), *i.e.* the ratio of contributions to the end product formed. Since the degree of conversion is independent of the analyte concentration in first-order reactions, we chose to use a data acquisition time equal to the half-life of the first-order component (k_A^{-1}). From the results shown in Fig. 1, it follows that:

(a) The error made in the determination of component A (first-order kinetics) were less than 1% except for a k_B^1/k_A ratio of 4 or when this component contributed only moderately (*ca.* 30%) to the overall signal. If the constant ratio is unfavourable, then the accuracy in the determination of component A in a mixture increases with an increase in its concentration.

(b) The error in the determination of component B increases slightly with increasing k_B^1/k_A ratios of up to about 4, as well as with an increase in the concentration of the other component. Figure 1 does not include the curve corresponding to $k_B^1/k_A = 4$ because it oscillated

Table 1. Model information used by the programmes

Programme	$\mathbf{H}^{\mathrm{T}}(j)$	$R(j)/10^{2Z(j)}$	$\mathbf{X}(j)$	$\mathbf{X}(0/0)$	$\mathbf{P}(0/0)$
K_FIRST	$[1 - \exp(-k_A t) \quad 1]$	10^{-6}	$\begin{bmatrix} S_A \\ S_0 \end{bmatrix}$	$\begin{bmatrix} 0.5 \\ 0 \end{bmatrix}$	$\begin{bmatrix} 0.5 & 0 \\ 0 & 0.5 \end{bmatrix}$

K_MIX	$[1 - \exp(-k_A t)[1 + (k_B^1 t)^{-1}]^{-1} \quad 1]$	10^{-3}	$\begin{bmatrix} S_A \\ S_B \\ S_0 \end{bmatrix}$	$\begin{bmatrix} 0.5 \\ 0.5 \\ 0 \end{bmatrix}$	$\begin{bmatrix} 0.5 & 0 & 0 \\ 0 & 0.5 & 0 \\ 0 & 0 & 0.5 \end{bmatrix}$

$\mathbf{H}^{\mathrm{T}}(j)$, measurement function vector; $R(j)$, measurement noise variance; $Z(j)$, measurement; $\mathbf{X}(j)$, state vector; $\mathbf{X}(0/0)$ and $\mathbf{P}(0/0)$, initial guesses for state vector and error covariance matrix, respectively.

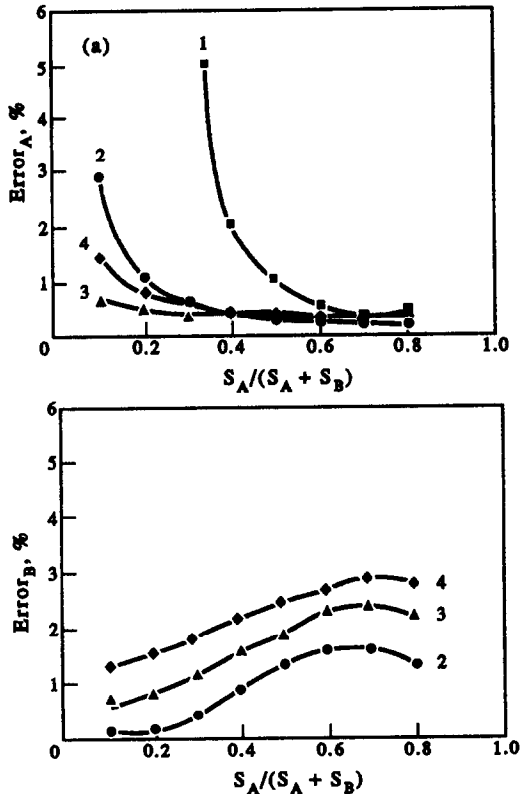

Fig. 1. Variation of the relative error in the determination of: (a) reactant A in a mixture with B and (b) reactant B in a mixture with A, as a function of S_A (contribution of A to the end product). Curves 1–4 correspond to k_B^1/k_A ratio of 4, 6, 8, and 10 h, respectively. $k_A = 10^{-2}$ sec^{-1}; $S_B = 0.250$.

somewhat, even though it gave rise to errors of less than 4% in all cases.

The filter used requires the rate constants for both reactions (k_A and k_B) to be accurately known, so errors in these constants arising from changes in the reaction conditions or inherent in their determination will detract from the accuracy of the results. We then investigated the effect of over- or underestimating such constants on the estimated concentrations of A and B in the mixtures. For this purpose we assumed a maximum variation of 5–10% in the rate constants. Figure 2 shows the results obtained at a fixed concentration of the second-order component, *i.e.* a constant k_B^1/k_A ratio (10 in this case), and three different concentrations of the first-order component. The symbols +, − and 0 in the figure denote positive, negative and nil errors in the rate constants of the two components. The results obtained allow one to draw the following conclusions:

(a) The largest errors in the determination of A (first-order kinetics) are made when those of the two constants are of opposite sign. In such cases, the errors in A are of the opposite sign to those in k_A.

(b) The errors in the determination of B are positive unless both rate constants are overestimated.

(c) The percent errors made in the determination of both A and B are much lower than those in the rate constants in most cases.

EXPERIMENTAL

Apparatus

Kinetic runs were carried out on a Metrohm 662 spectrophotometer equipped with an immersion probe and a Metrohm Dosimat 665 autoburette for dispensing a small volume of reagent in order to start the reaction. Data acquisition was done by means of a Mitac PC-AT 12-MHz compatible computer equipped with a PC-Multilab PCL-812PG AD converter and an HADC574Z industrial standard successive approximation converter featuring a conversion speed of 30 MHz. Acquisition of data was synchronized with the start of the reaction by using a trigger that acted simultaneously on the autoburette and the computer.

Reagents

We use the following solutions, all of which were made in distilled water: $10^{-3}M$ cysteine (Merck), $10^{-3}M$ ascorbic acid (Merck), $10^{-3}M$ glutathione (Sigma), $2.15 \times 10^{-2}M$ neocuproine hydrochloride, $3.15 \times 10^{-2}M$ $Cu(NO_3)_2$, $10^{-1}M$ sodium oxalate and $1M$ sodium acetate–acetic acid buffer (pH 4.8).

Procedure

In an 80-ml reaction vessel were placed an appropriate volume of an aqueous solution containing 0.06–7.0 μmoles of cysteine, 0.1–5.0 μmoles of ascorbic acid, 0.1–9.0 μmoles of glutathione or a mixture of these species (see Tables 3 and 4), plus 6.0 ml of $1M$ sodium acetate–acetic acid buffer (pH 4.8), 3.0 ml of $2.15 \times 10^{-2}M$ neocuproine hydrochloride, 15.0 ml of $10^{-1}M$ sodium oxalate and distilled water up to a final volume of 60 ml. The reaction was started by adding 1.5 ml of $3.15 \times 10^{-2}M$ $Cu(NO_3)_2$ from the autoburette at a rate of 30 ml/min (addition time, 3 sec). The addition half-interval (*i.e.* 1.5 sec) was taken as time zero. Data were acquired at a wavelength of 455 nm for 30, 40 and 180 sec for cysteine, ascorbic acid and glutathione, respectively, and for 40 and

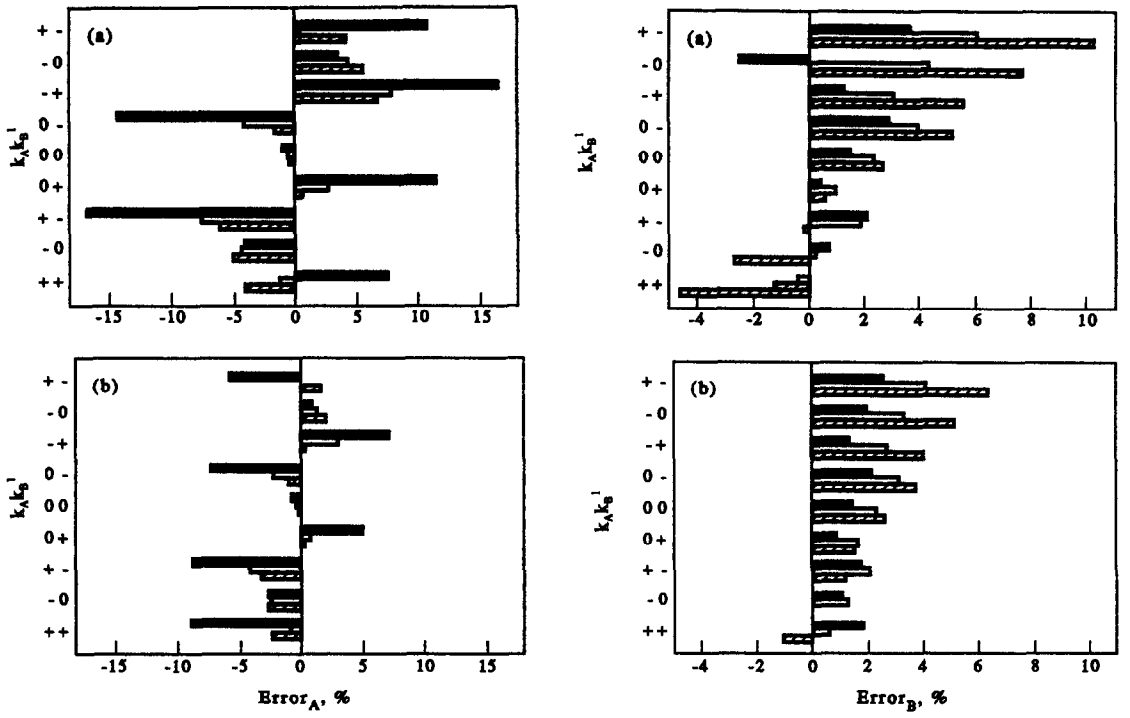

Fig. 2. Effect of: (a) a 10% error and (b) a 5% error in the determination of the rate constants on the determination of reactant A in a mixture with B and vice versa by using the Kalman filter. $k_A = 10^{-2}$ sec^{-1}; $k_B^1 = 10^{-1}$ sec^{-1}; $S_B = 0.25$; $S_A =$ 1.0 (▨), 0.25 (□) and 0.0625 (■).

180 sec in the resolution of the cysteine–ascorbic acid and glutathione–ascorbic acid mixtures, respectively.

RESULTS AND DISCUSSION

The chief aim of this work was to assess the potential of the proposed approach by applying it to the resolution of mixtures of species following different kinetics (namely first- and second-order). For this purpose, we chose the reduction of copper(II) by ascorbic acid, cysteine and glutathione in the presence of neocuproine, which yields the well-known Cu(I)–neocuproine orange complex. This system was previously employed by us for the kinetic determination of glutathione in blood serum using the continuous-addition-of-reagent technique.[50]

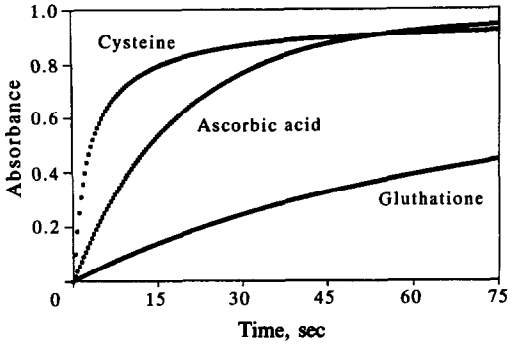

Fig. 3. Typical absorbance *vs.* time curve for cysteine (4.0 μmoles), ascorbic acid (2.0 μmoles) and glutathione (4.0 μmoles), each measured at 455 nm. For details, see Procedure.

Figure 3 shows the kinetic curves provided by the photometer as processed by the data acquisition system. As can be seen, the reaction rate for ascorbic acid (the component following pseudo first-order kinetics) lies between those of the two amino acids, which follow second-order kinetics. Consequently, we chose to use mixtures of ascorbic acid and either cysteine or glutathione to assess the performance of the proposed algorithm.

Effects of experimental variables

Given the aim of this work, the experimental conditions to be optimized were obviously those which resulted in the best possible accuracy and precision in the resolution of the mixtures. Thus, the following criteria were adopted for the reactions concerned to be usable for our purpose:

(a) They should allow precise recording of their kinetic curves by conventional means (*i.e.* they should not be too fast);

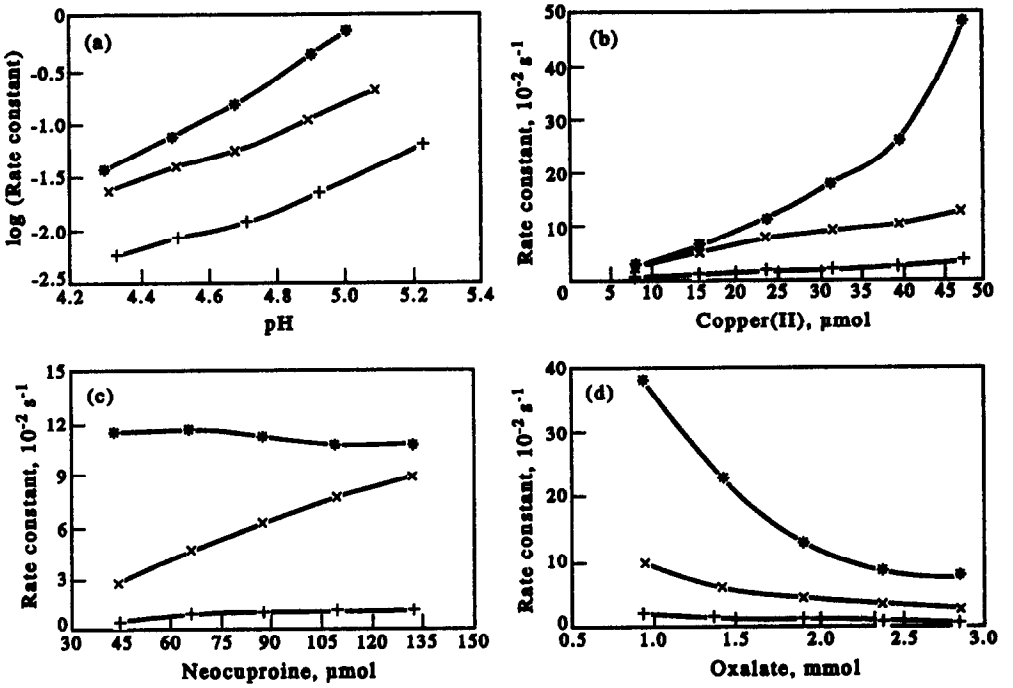

Fig. 4. Influence of chemical variables on the rate constant of ascorbic acid (X), cysteine (*) and glutathione (+). Conditions: [ascorbic acid] = 2 μmoles, [cysteine] = [glutathione] = 4 μmoles. (a) [Copper(II)] = 47 μmoles, [neocuproine] = 86 μmoles and [sodium oxalate] = 1.5 mmoles; (b) [neocuproine] = 86 μmoles and [sodium oxalate] = 1.5 mmoles; (c) [copper (II)] = 47 μmoles and [sodium oxalate] = 1.5 mmoles; and (d) [copper(II)] = 47 μmoles and [neocuproine] = 65 μmoles.

(b) they should conform to the kinetic model used, which is indispensable for correct application of the Kalman filter; and

(c) both the rate constants and their ratios should allow for kinetic resolution. Thus, if $k_A/k_B^1 \gg 1$, then either the first reaction would be too fast and hence difficult to record a kinetic curve or the second would be too slow, so the determination would have to be sequential rather than simultaneous. If, on the other hand, $k_A/k_B^1 \simeq 1$, then the mixture resolution would be subject to major errors arising from the similarity between the two kinetic curves.

Based on the above considerations, the initial chemical systems was modified slightly by introducing oxalate ion, which was chosen among a few tested copper(II) chelating agents. In fact, complexing Cu(II) ion slowed down its reduction to Cu(I), which in turn allowed us to select an appropriate reaction rate—and hence precisely record the kinetic curves—and achieve a more suitable rate constant ratio.

We thus chose to use the rate constants k_A and k_B^1 instead of the corresponding reaction rates—which are typically employed in kinetic methods—as measurement parameters.

In order to investigate the influence of pH on the development of the two reactions we added various small amounts of NaOH or HCl to the reaction vessel so as to keep the ionic strength constant throughout the process. The pH range studied was close to the initial pH of the buffer used, since more acidic media resulted in virtually no reaction development, whereas more basic media gave rise to too fast a reaction for

Table 2. Analytical figures of merit of the methods

2.10	1.25	2.10	0.0	1.41	+12.8
1.57	1.50	1.23	−21.6	1.86	+24.0

precise recording. As can be seen in Fig. 4a, the rate constants increased sharply with increase in the pH. Also, the k_{AA}/k^1_{GLU} ratio was almost constant over the pH range studied, whereas the k^1_{CYS}/k_{AA} ratio increased sharply (*e.g.* from 1.6 at pH 4.4 to 4.6 at pH 5.0). We chose the pH value directly provided by the buffer (pH 4.8) since it resulted in rates that allowed precise recording of the kinetic curves and acceptable rate constants; in addition, it was the pH where the buffering capacity was optimal.

Figure 4b shows the marked influence of the Cu(II) concentration on the rate constants, particularly on that of cysteine. Thus, the k^1_{CYS}/k_{AA} ratio increased linearly from 0.80 for 1.57 μmoles of copper to 3.87 for 110.2 μmoles of copper, and so did the k_{AA}/k^1_{GLU} ratio, though in a more gradual fashion. Bearing in mind the above prerequisites, we chose an amount of copper of 47.2 μmoles, which corresponded to 1.5 ml of a $3.15 \times 10^{-2}M$ solution.

Figure 4c shows the effect of the neocuproine concentration on the rate constants. As can be seen, that of ascorbic acid—the sole component following pseudo first-order kinetics—behaved differently in response to changes in the concentration of this reagent. Thus, k_{AA} increased sharply with increase in neocuproine concentration, whereas k^1_{CYS} and k^1_{GLU} hardly varied under the same conditions. An amount of neocuproine of 43 μmoles (2.0 ml of a $2.15 \times 10^{-2}M$ solution) provided the best possible k^1_{CYS}/k_{AA} ratio and quite an acceptable k_{AA}/k^1_{GLU} ratio.

The concentration of oxalate ion, which was added to the mixtures to slow down the reactions, had a similar effect on all three (Fig. 4d). Low concentrations of $C_2O_4^{2-}$ gave rise to favourable kinetic constant ratios; however, the reactions were too fast for precise recording with the instrumentation used. On the other hand, high oxalate concentrations resulted in poor rate constant ratios. We thus chose an amount of 1 mmole of oxalate (10 ml of a $10^{-1}M$ solution) as a compromise.

Individual kinetic determinations

The absorbance *vs.* time graphs constructed from different concentrations of ascorbic acid, cysteine and glutathione under the selected working conditions were analysed by using the programmes K_FIRST and K_SECOND. The figures of merit of the determinations are summarized in Table 2. The analytical sensitivity was taken as the slope of each calibration plot; as can be seen, the increased sensitivity of ascorbic acid relative to cysteine and glutathione arises since the former involves the loss of two electrons whereas that of the latter two involves S—S binding and the loss of a single electron. The precision, expressed as RSD, was determined by analysing 11 samples containing 1.0, 2.0 or 2.8 μmoles of ascorbic acid, cysteine or glutathione each.

Table 4. Resolution of synthetic glutathione–ascorbic acid mixtures

Micromoles added		Found

Analysis of cysteine–ascorbic acid mixtures

Table 3 summarizes the results obtained by analysing several synthetic mixtures of ascorbic acid and cysteine. From the results given in the table it follows that:

(a) The error in the determination of the two components was acceptable (less than 10%) above a cysteine–ascorbic acid concentration ratio of 2, where the k^1_{CYS}/k_{AA} ratio was much greater than unity.

(b) Below a concentration ratio of 2, the k^1_{CYS}/k_{AA} ratio was close to unity and the errors increased sharply with decreasing ratios.

(c) The fact that the errors made in the determination of mixtures containing lower proportions of cysteine were larger can be ascribed to a decrease in the apparent pseudo first-order constant, k^1_{CYS}, which was thus similar to that of ascorbic acid, as well as to the lower efficiency of the Kalman filter with components following kinetics of orders other than unity. One should bear in mind that k^1_{CYS} was unknown, so the filter had to calculate it iteratively in addition to the net signal increment.

In summary, the determination of cysteine–ascorbic acid mixtures was feasible over a molar ratio range of *ca.* 7.5:1 to 1.5:1 with accuracy better than ±10%. Application of the proposed algorithm to 11 samples containing 2.9 μmoles cysteine and 1.0 μmole ascorbic acid yielded an RSD of 1.6% for the former and 2.1% for the latter.

Analysis of glutathione–ascorbic acid mixtures

Table 4 lists the results obtained in the analysis of several synthetic mixtures containing various amounts of glutathione and ascorbic acid. As can be seen, the results were quite satisfactory (errors smaller than ±4%) for glutathione to ascorbic acid concentration ratios between 13.7:1 and 1.2:1. The k^1_{GLU}/k_{AA} ratios in the mixtures varied from 0.22 to 0.09. Mixtures with smaller amounts of glutathione still allowed ascorbic acid, though not glutathione itself, to be accurately determined. This is seemingly paradoxical since the k_{AA}/k^1_{GLU} ratios in the mixtures were quite high (above 10); however, one should take into account the potential effect of one other significant factor, namely the contribution of each component to the overall signal of the mixture. As one descends in Table 4, the relative contribution of glutathione to the signal not only decreases through its smaller concentration fraction but also through its smaller apparent first-order constant, k^1_{GLU}, which accounts for the increased errors made in the resolution of these mixtures.

Based on the above results, mixtures of these compounds can be accurately resolved (errors less than ±4%) in glutathione to ascorbic acid ratios between *ca.* 14:1 and 1:1. The precision of the determination was calculated by analysing 11 mixtures containing 2.0 μmoles of glutathione and 1.0 μmole of ascorbic acid and was found to be 0.63% and 0.76%, respectively.

CONCLUSIONS

The simulated and experimental results obtained in this work show that the Kalman filter allows one to distinguish between pseudo first- and second-order kinetics. In all the mixtures studied, the best features (wide concentration ratios and high accuracy and precision) were obtained when the rate constant ratio (k_A/k^1_B) was greater than unity (*i.e.* the first-order reaction was faster than the second-order reaction), even though this was dependent on the concentration of the component following second-order kinetics, which affected k^1_B. Consequently, unlike the resolution of mixtures of species following first-order kinetics, no generalizations can be made as regards the rate constant ratio. The performance of the Kalman filter is somewhat less reliable for ratios below 1, even though the results are still acceptable. Also, as in any other mixture resolution, the errors made in the determination of one component increase as its contribution to the overall signal decreases. This approach is of both theoretical and practical interest, since applying a mathematical treatment to a binary mixture on the assumption that both species react with pseudo first-order kinetics when one of them actually follows pseudo first-order kinetics occasionally results in inexplicable errors. In such a case, the proposed approach provides a correct treatment and minimizes errors.

SURFACE-ENHANCED RAMAN SPECTROMETRY FOR DETECTION IN LIQUID CHROMATOGRAPHY USING A WINDOWLESS FLOW CELL

L. M. CABALIN,* A. RUPEREZ† and J. J. LASERNA*‡

*Department of Analytical Chemistry and †Department of Physical Chemistry, Faculty of Sciences, University of Málaga, 29071 Málaga, Spain

Summary—A windowless flow cell has been developed for surface-enhanced Raman (SER) detection in liquid chromatography. Using colloidal silver as an active substrate, SER spectrometry of banned drugs in sport is presented. The experimental factors of primary influence on the analytical performance of the cell have been studied. The results of SER detection with the proposed cell have been compared to UV detection.

Surface-enhanced Raman spectrometry (SERS) on colloidal systems is a sensitive, selective and fairly simple method for the analysis of a variety of compounds of technical, environmental, biomedical and pharmaceutical interest. The requirement for analyte-induced aggregation of the colloidal system introduces a range of experimental variables that are difficult to control. Driven by the excellent separative and sample handling performance of modern analytical flowing systems, colloid SERS systems have been adapted for detection in flowing streams [flow injection analysis (FIA) and high performance liquid chromatography (HPLC)]. In the earliest configuration,[1,2] a relative standard deviation of 3% was reported for replicate injection of *p*-aminobenzoic acid on a stream of colloidal silver prepared on-line at room temperature. After these reports, other applications of colloid SERS on flowing streams were described.[3–7] The separation and determination of four purine bases (adenine, guanine, hypoxanthine and xanthine) by reverse-phase HPLC in combination with real-time SERS have been demonstrated.[8] Limits of detection in the nanomolar range were reported. In spite of these advantages, SERS detectors using conventional, closed flow cells have several drawbacks. Tailing in the chromatographic peaks results from memory effects caused by deposition of Ag sol and adsorbed compounds on the inner wall of the cell.[8] To eliminate the memory effect, it is often necessary to change the flow cell or to rinse it with nitric acid after each chromatographic run. Adsorption on the cell walls also results in baseline drifts, contamination problems and mixing of the spectra of the previously separated compounds.

The need for a reliable but simple analytical device for detection in HPLC remains an important goal in SERS. Open flow cells have been proposed for detection in HPLC under a variety of analytical principles. A windowless cell was first proposed for laser-induced fluorescence detection.[9] Using the 325-nm modulated output of a He–Cd laser and phase-sensitive detection, carcinogenic aflatoxins were linearly quantitated to 7.5×10^{-13} g. Later, the fluorescence and photoacoustic characteristics of an open flow cell intended for liquid chromatographic applications were compared with the respective characteristics of a static cuvette cell.[10] The advantage of such a detector is that photoacoustic detection is complementary to fluorescence detection and may be useful in quantitating substances which do not appreciably luminesce. A laser two-photon ionization technique was applied for the trace determination of pyrene using a windowless cell made of two stainless steel electrodes.[11] With 300-μl dead volume, the cell, in combination with a pulsed nitrogen laser, allowed the detection of 100 ng/ml pyrene in *n*-heptane. An open cell was developed that had simultaneous detection capabilities by molecular fluorescence, photoacoustic effect and two-photon photoionization processes. The cell was evaluated for drugs,[12] aromatic compounds[13] and polycyclic aromatic hydrocarbons.[14] In the present paper we discuss the utility of SERS detection in HPLC using an

open flow cell. The operating performance of the cell is illustrated for banned drugs in sport. The results of SER detection with the proposed cell have been compared to UV detection.

EXPERIMENTAL

Instrumentation

A schematic diagram of a coupled HPLC–SERS system is shown in Fig. 1. Spectra were obtained with a 0.22-m double-grating spectrometer (Spex Industries, model 1680B) with a 1200 grooves/mm classically ruled grating. The Raman scattering was collected at right-angles and detected with a cooled photomultiplier tube (Hamamatsu, model R-928), a fast preamplifier (Stanford Research Systems, model SR440) and a two-channel gated photon counter (Stanford Research Systems, model SR400). Operation of the photon counter was controlled by an AT personal computer with Stanford Research SR465 software. Spectral data were generated in binary code and converted to ASCII for processing in standard graphics software. The 488-nm line of an argon-ion laser (Coherent, model Innova 70-5) was used, and the laser power at the windowless flow cell was approximately 400 mW. A 25-cm focal length glass lens focused the laser beam onto the cell.

The liquid chromatography system consisted of an isocratic pump (Shimadzu model LC-6A) with a Rheodyne injection valve using a 20-μl sample loop. The analytical column was a 5-μm OD-MP Spheri-5 RP-18 (10 cm × 4.6 mm i.d.; Brownlee Labs). A model SPD-6A variable-wavelength UV–visible detector and a Chromatopac integrator, both from Shimadzu, were also used. The wavelength for UV detection was 254 nm. The mobile phase was methanol–water (1:1, v/v). Prior to use, the mobile phase was vigorously degassed and particulate matter was removed by passage through a 0.45-μm nylon membrane filter under vacuum. The flow rate was 0.2 ml/min. For flow injection analysis the Ag sol and drug solutions were pumped by two peristaltic pumps (Heidelberg model 131900 and Gilson model M312, respectively). The flow rate was 1.5 ml/min for silver hydrosol and 0.075 ml/min for the analyte sample.

The windowless flow cell was designed and constructed in our laboratory and consisted of two chromatographic stainless steel tubes of $\frac{1}{16}$ inch i.d. and 1.4 mm external diameter mounted on an aluminium frame. The dimensions of the cell are shown in Fig. 2. The eluent from the chromatographic column and the silver hydrosol are mixed on a chromatographic tee and then flow to the windowless cell. The draining liquid is supported by surface tension between the two tubes. The column of liquid is approximately cylindrical with a diameter of 1.4 mm and height of 1.6 mm. The dead volume of the cell is roughly 2.5 μl. The flowing liquid exits the flow cell through the stainless steel tubing to a waste beaker.

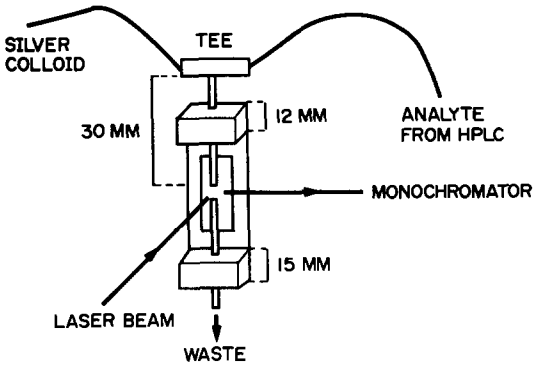

Fig. 2. Schematic diagram of the windowless flow cell.

Chemicals and procedure

All chemicals used were of analytical reagent grade or equivalent. Demineralized water was used throughout. Amiloride, amiphenazole, caffeine, chlorthalidone, hydrochlorothiazide, 2-mercaptopyridine, pemoline and triamterene were purchased from Sigma. They were used without further purification. Stock solutions (100 μg/ml) of the drugs were prepared in methanol–water (1:1, v/v). Silver hydrosols were prepared with fresh aqueous solutions of $1 \times 10^{-3}M$ silver nitrate and $2 \times 10^{-3}M$ sodium tetrahydroborate. Fifty millilitres of the silver nitrate solution were added dropwise to 150 ml of vigorously stirred, ice-cooled sodium tetrahydroborate solution. After mixing, the resulting colloid was maintained in an ice bath for 2 hr with constant stirring. With this procedure, the aggregation process of hydrosol has been stopped and the hydrosol remained stable for several days. Silver hydrosols were used at room temperature. Urine samples were obtained from healthy human volunteers not receiving any medical treatment and were filtered through a 0.45-μm membrane filter prior to injection.

RESULTS AND DISCUSSION

For SERS to be used as a detector for HPLC and FIA it is necessary that the analyte-induced aggregation kinetics of the colloid be rapid and that the solvent employed be adequate. Montes *et al.*[15] demonstrated that the kinetics of aggregation depend on the chemical structure of the analyte studied. On the other hand, it is also known[16] that the adsorptive behaviour of the analyte on the Ag surface can change when different types of mobile phase are used. One effect is the direct adsorption of the mobile phase onto the active sites of the colloidal particles, which diminishes the analyte's affinity

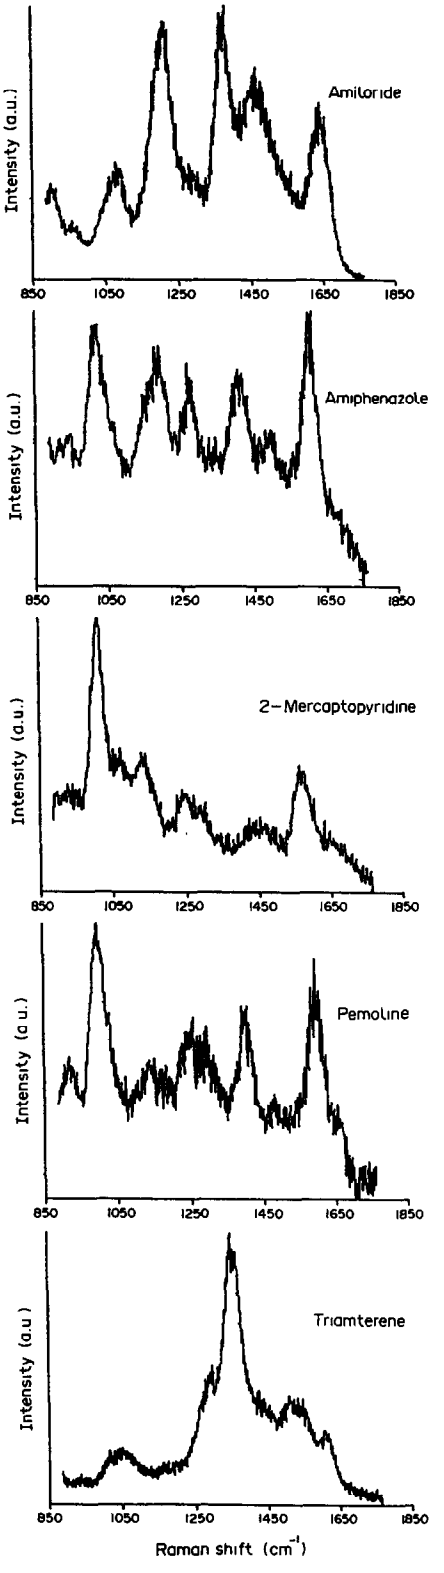

Fig. 3. Surface-enhanced Raman spectra of drugs in FIA system. Drug concentration, 100 μg/ml. The flow rates of silver hydrosol and drug solution were 1.5 and 0.075 ml/min, respectively.

for the Ag surface or affects the aggregation behaviour of the Ag colloid. In the present paper, a methanol–water (1:1, v/v) mobile phase proved adequate for the drugs of interest. On the other hand, the good optical alignment of the laser beam onto the SERS cell is a critical parameter for obtaining high-quality SERS data, because the optical path length has been shown to significantly affect the SERS measurements.[17]

In a previous work, we have studied the SERS activity on colloidal silver of a variety of drugs.[18] Five drugs have been chosen to evaluate the windowless flow cell, which provides aggregation kinetics fast enough to be processed in flow systems. Figure 3 illustrates the SER spectra of five drugs (amiloride, amiphenazole, 2-mercaptopyridine, pemoline and triamterene) obtained at room temperature by continuously flowing the analyte solution and the silver colloid through the windowless cell. The flow rates were optimized in order to maximize the signal intensity. The optimal flow rates of silver hydrosol and analyte were 1.5 and 0.075 ml/min, respectively. Few authors have reported SER spectra under flowing conditions.[1,8,19] The SER spectra in Fig. 3 demonstrate that the Raman bands are easily discernible, and each individual SER

spectrum can serve as a fingerprint for each compound. Table 1 summarizes the SER band positions of the drugs.

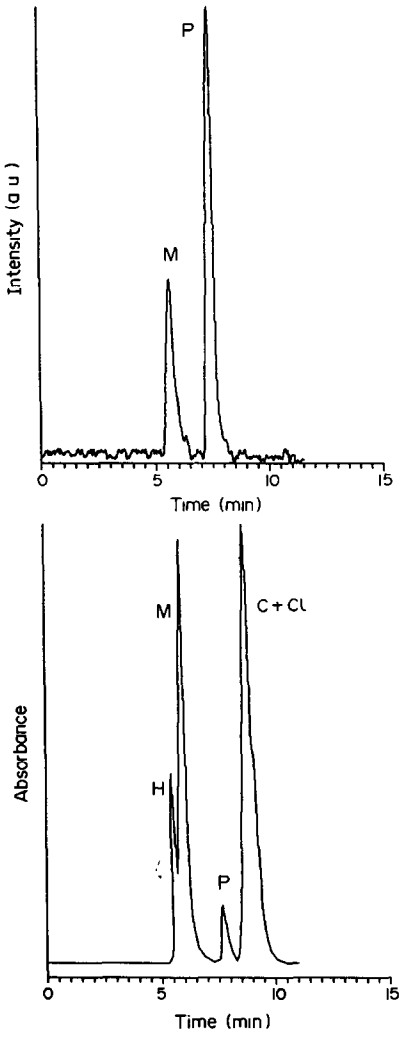

Fig. 6. Comparison of SERS and UV chromatograms for five drugs [caffeine (C), chlorthalidone (Cl.), hydrochlorothiazide (H), 2-mercaptopyridine (M) and pemoline (P)]. Other conditions as in Fig. 5.

It is important to note that the preparation of silver hydrosol affects the state of aggregation and consequently the reproducibility of results and signal stability. To eliminate this problem, silver hydrosols have to be prepared using consistent laboratory practices, as described in the Experimental section. With the procedure used, the aggregation process prior to analyte injection can be controlled. Figure 4 shows the signal reproducibility for five consecutive injections of amiloride. The absolute amount in each injection was 625 ng amiloride and the samples were injected at 6 min intervals. A band at 1375 cm^{-1} in amiloride was used to monitor the signal. The measured reproducibility was 1% (relative standard deviation). Similar reproducibility was reported by Freeman *et al.*,[5] for pararosaniline hydrochloride. Figure 4 also shows the rapid baseline restoration after each injection and the absence of memory effects.

The use of the windowless flow cell for SERS detection in HPLC is illustrated in Fig. 5. An SERS-detected chromatogram of a mixture of amiloride, 2-mercaptopyridine and pemoline and a UV chromatogram of the same mixture are shown. The HPLC flow rate was 0.2 ml/min. However, the mixing of the silver sol with the column eluent just prior to the SERS detector causes the retention time to be shifted to shorter times by about 20 sec over the UV chromatogram. The relative peak areas differ on going the SERS to the UV detection modes. For instance, pemoline is the largest peak in the SERS chromatogram while 2-mercaptopyridine is the largest peak in the UV chromatogram.

A comparison of efficiency, linear range, precision and detection power for 2-mercaptopyridine and pemoline using UV detection and SERS detection is summarized in Table 2. The lower efficiency of the SERS detection results from the mixing of the eluent with the silver sol.

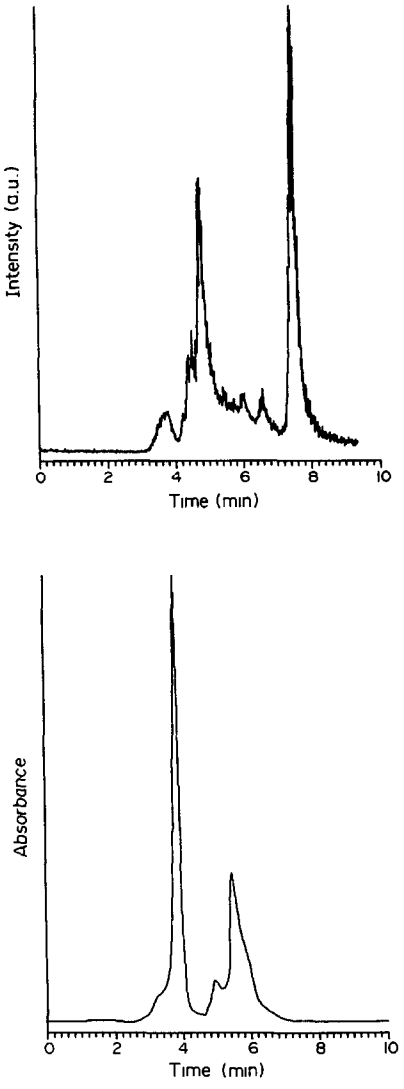

Fig. 7. Comparison of human urine chromatograms. (Top) SERS chromatogram. (Bottom) UV chromatogram. Other conditions as in Fig. 5.

The precision of SERS intensities has been one of the weakest points of this technique. Remarkably, with the windowless flow cell used here, RSD values for the SERS detection mode are comparable to those found by UV detection. On the other hand, the SERS mode provides higher limits of detection. The main reason for this effect is the dilution of the analyte resulting from mixing the chromatographic eluent with the silver colloid. At the flow rates used, the dilution factor is about 20-fold. The unique selectivity provided by the SERS detector can be illustrated by comparison of chromatograms of a mixture of caffeine, chlorthalidone, hydrochlorothiazide, 2-mercaptopyridine and pemoline. Figure 6 shows the UV and SERS chromatograms of the mixture monitored at 254 nm and at 1407 $cm,^{-1}$ respectively. Caffeine and chlorthalidone co-elute and appear as a single peak in the UV chromatogram ($t_r = 8.6$ min), while hydrochlorothiazide ($t_r = 5.42$ min) overlaps the peak of 2-mercaptopyridine ($t_r = 5.85$ min). The SERS-detected chromatogram presents only two peaks, at 5.6 and 7.25 min, corresponding to 2-mercaptopyridine and pemoline, respectively. Caffeine, chlorthalidone and hydrochlorothiazide are not detected since these drugs are not SERS active under the present conditions. No peak tailing or memory effets in the cell are observed. To further evaluate the selectivity of the SERS detector, an SERS chromatogram of human urine is compared with a UV chromatogram in Fig. 7. The peaks observed correspond to proteinaceous and other endogenous urine components. As shown, the peak at 7.5 min in the SERS chromatogram does not appear in the UV chromatogram. This fact indicates that there are urine components that can only be detected by SERS. On the other hand, the relative peak areas are also different in both chromatograms. For instance, the peak at 3.8 min is much higher in area in UV than SERS. The opposite is seen for the peak at 4.5 min.

CONCLUSIONS

There are advantages in using the windowless flow cell for SERS detection in HPLC. First, the open character of the cell provides continuous renewal of the aggregated colloid in the cell. This helps to remedy a recurring problem in conventional flow cell experiments, which is adsorption of aggregated silver on the cell walls resulting in undesirable memory effects. Also, baseline drifts and peak tailing are circumvented using this approach. The LODs achievable are within the limits reported for conventional batch systems, although they are much higher than in UV for two drugs studied. The unique band position and shape of spectral features in the SER spectra of the drugs could be beneficial in the dope analysis of these and similar compounds. This information could complement or supplement general gas chromatography–mass spectrometry data in confirmatory analysis. Presently, we cannot fully exploit the spectral selectivity of the SERS–HPLC approach because a monochannel detector is used to disperse the Raman scatter. Detection based on

charge-coupled devices or diode arrays will allow further refinement and evaluation of the technique. These modifications have been initiated.

CHEMOMETRIC CHARACTERIZATION OF 5TH CENTURY A.D. AMPHORA-PRODUCING CENTRES IN THE MEDITERRANEAN

J. A. REMOLÀ
CODEX SCCL-ARCHAEOLOGY & HERITAGE, 43003 Tarragona, Spain

M. S. LARRECHI and F. X. RIUS
Chemistry Dept. University of Tarragona, 43005 Tarragona, Spain

Summary—The application of two chemometric techniques for data structure analysis (Ward's hierarchical clustering and Principal Components Analysis) has permitted the characterization of 5th century A.D. amphora-producing centres in the Mediterranean on the basis of X-ray fluorescence data on 66 amphora fragments. The chemometric study complements and reinforces the conclusions drawn from typological and archaeological analysis. Nineteen samples of unknown origin have been classified (using the SIMCA method) into the eight proposed classes of amphora production.

Amphorae are a type of ceramic container used in antiquity for transporting liquid and semi-liquid foodstuffs (pickled, salted and other forms of preserved food) by sea. Because of their nature, the contents have rarely withstood the passage of time. Amphorae thus provide indirect evidence on these products as well as the commercial ties linking geographically separated regions. However, in order to establish this connection, it is essential to know the origin of the amphora itself and to be aware of the contents transported in it.

The traditional method used for identifying the place of origin of both amphorae and other pottery has a largely archaeological and typological basis. It was not until the 1970s that chemical information started to be used as a means of relating the composition of ceramic materials to their area of origin. To be more precise, in the case of amphorae, the most widely-used method to date is that known as petrological analysis, which consists of the identification of the mineral inclusions in the fabric, their physical characteristics and their rate of frequency. The results obtained from these analyses are compared with those obtained from samples taken from the waste materials of the amphora-manufacturing centres themselves or from the sources of raw material used in the production of a particular type of amphora. At present this method of relating the product's origin to the manufactured product itself has one serious drawback, namely the lack of a detailed register of reference material.

A second widely-used method for relating products to their origins is the chemometric analysis of chemical composition data; this technique enables groups of geo-chemically homogeneous samples to be established. After a seminal work by Kowalski *et al.*,[1] numerous applications have been published, many of them related to ceramic materials.[2–5] Nevertheless, amphorae which show a similar chemical composition may well come from geographically differing areas, and, in contrast, samples whose composition in geochemical terms is quite different may come from a zone which formed a historical unit in the past.

It is thus clear that only by combining all the possible means of analysis (typological, chemical, physical, *etc.*) that a suitable solution can be found for the problems raised in the identification of centres that produced amphorae (and other pottery).

In the present paper a chemometric characterization of 5th century A.D. amphora-producing centres in the Mediterranean is proposed on the basis of the data derived from X-ray fluorescence analysis on 85 amphorae fragments found in a waste dump at Tarragona (Imperial Tarraco, Hispania). This study complements the typological characterization of over 350

fragment samples and sets up an objective chemical foundation for the overall archaeological study.

In the first instance, our aim was to identify the groups that were established naturally, taking into account only the 66 samples of certain and doubtful provenance. This study made it possible to compare these groupings with those established through purely archaeological and typological considerations. Thereafter, we decided to use classification techniques to enable the association of the 19 pieces of unknown origin with their production area.

EXPERIMENTAL

Samples: the waste dump at Vila-roma

This waste dump, dated to between A.D. 425 and 450, is a site of exceptional significance in view of the fact that more than 30,000 fragments have been found, of which approximately 28,000 come from amphorae.[6]

Late Roman amphorae[7] are classified into three principal groups according to their area of origin: North Africa, Southern Hispania (Baetica and Lusitania) and Eastern Mediterranean (Fig. 1). In the case of the waste dump

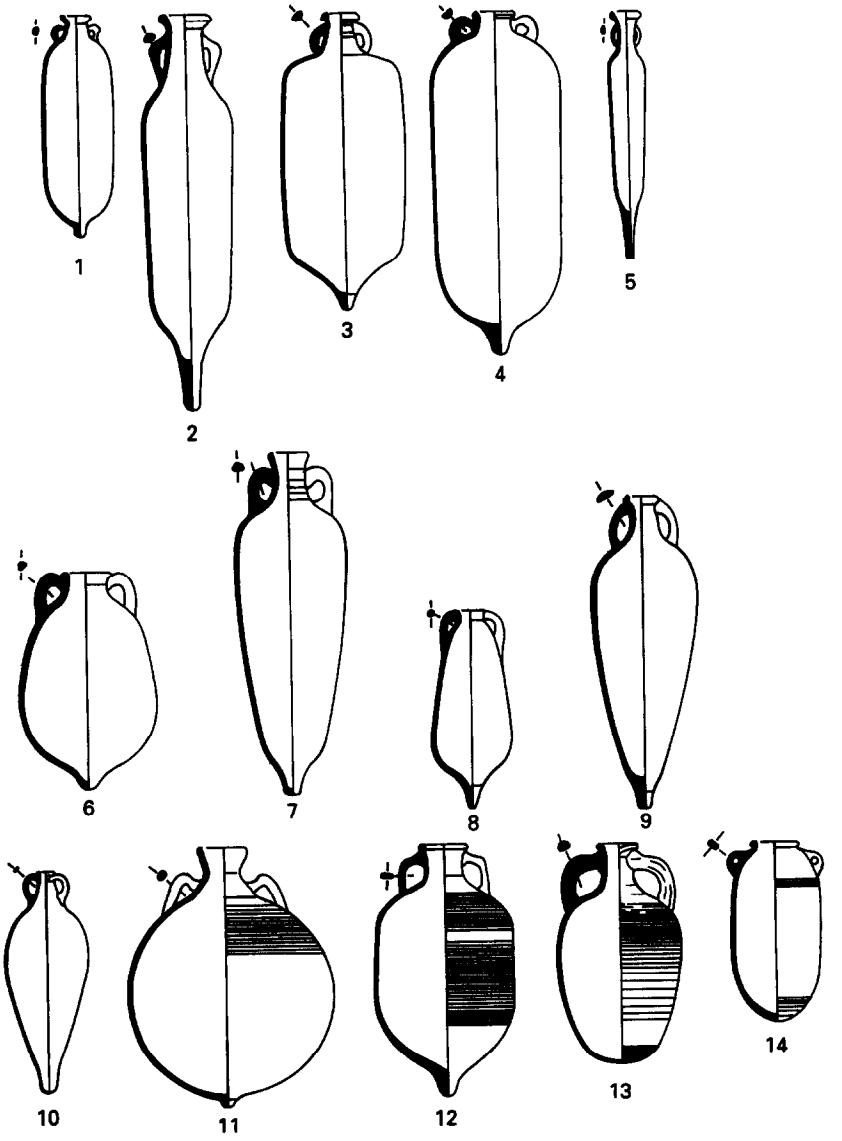

Fig. 1. Objects 1–5: main amphora types of North African origin (1: evoluted African group 1, 2: cylindrical containers of medium size, 3–4: cylindrical containers of considerable size, 5: spatheia). Objects 6–9: main amphora types of South Hispania origin (6: Keay 13a/c, 7: Keay 19a/b, 8: Keay 16, 9: Keay 23). at Vila-roma, of the estimated 400 or so examples of amphorae, 100 (25%) have their origins in the south of Hispania, 98 (24.4%) come from North Africa, while 102 (25.5%) were manufactured in the eastern Mediterranean.[8] To these should be added 79 examples of as yet uncertain provenance. The classification of samples to the above mentioned zones was carried out strictly on the basis of archaeological and typological criteria and the geographical names used do not necessarily imply the geo-chemical or typological homogeneity of the products. Table 1 presents a list of the 85 samples from this waste tip that are the subject of the present study, together with their type and their inventory number. Of these 85 samples, 57 are well identified according to archaeological criteria, 9 are of doubtful attribution, and 19 belong to the group of unknown provenance.

X-ray fluorescence analysis

Iron, manganese, titanium, calcium, potassium, silicon, aluminium, phosphorus and magnesium content, expressed as percentages of their respective oxides, were determined by X-ray fluorescence analysis. The samples were prepared by the fusion technique in a Perlex X2 oven. X-ray fluorescence intensities were measured on a computer controlled Philips PW/1400 dispersive wave length X-ray spectrometer equipped with rhodium and scandium sources.

The samples were prepared by weighing one gram of crushed sample of pottery and four

grammes of lithium tetraborate, mixing it and melting it in a platinum crucible. The instrument was calibrated with 20 international standard rock samples prepared by means of the glass bead technique. The effects of different types of potential interference were considered and the alpha correction factors were calculated to compensate. The results obtained are shown in Table 2. A summary of the raw data distribution is given in Fig. 2.

Chemometric techniques

Two unsupervised methods of analysis available in the pattern recognition packages CLUSTAN[9] and ARTHUR[10] were applied in order to show the overall structure of the 66 amphora samples of known origin in the multidimensional space. These methods are respectively, a hierarchical cluster analysis (the Ward method) and a representation method, Principal Components Analysis (PCA). Subsequently, the SIMCA classification method[11] from the statistical package SIMCA[12] was used in order to evaluate whether any of the amphora of unknown origin might belong to any of the previously established areas of origin.

RESULTS AND DISCUSSION

Figure 3 shows the dendogram obtained as a result of the application of the Ward clustering

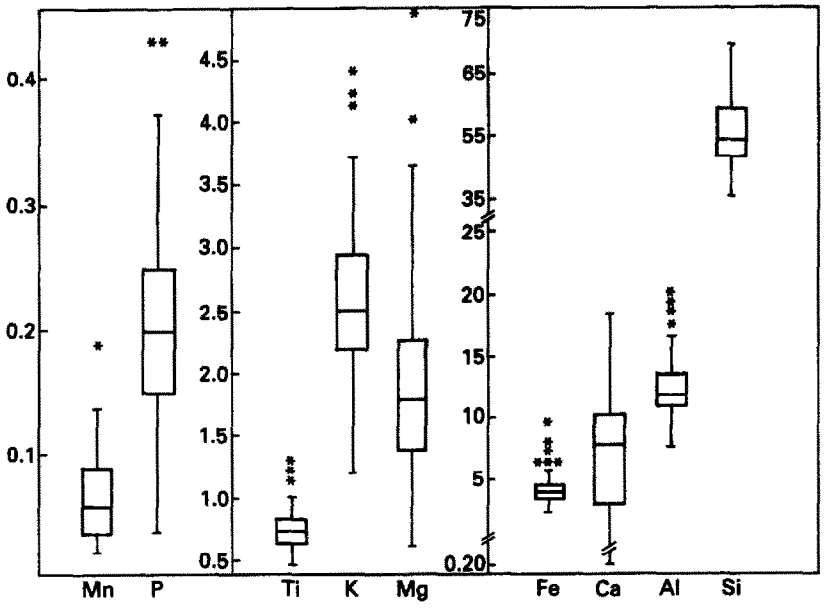

Fig. 2. Box and whisker plots of the raw data listed in Table 2.

method on the 66 samples characterised according to typological and archaeological criteria. The projection of the samples into the space defined by the first two principal components is displayed in Fig. 4. The results obtained from both the dendogram and the PCA plot indicate that even though the natural grouping according to chemical compositional data does not always agree with the three principal zones defined (northern Africa, the south of Hispania, and the eastern Mediterranean), aspects which had been evident on the grounds of purely archaeological evidence are confirmed. Thus, sample 10 (Keay type 54 bis), from Sardis, shows a considerable similarity, in the Ward diagram (Fig. 3), to samples 66 and 76

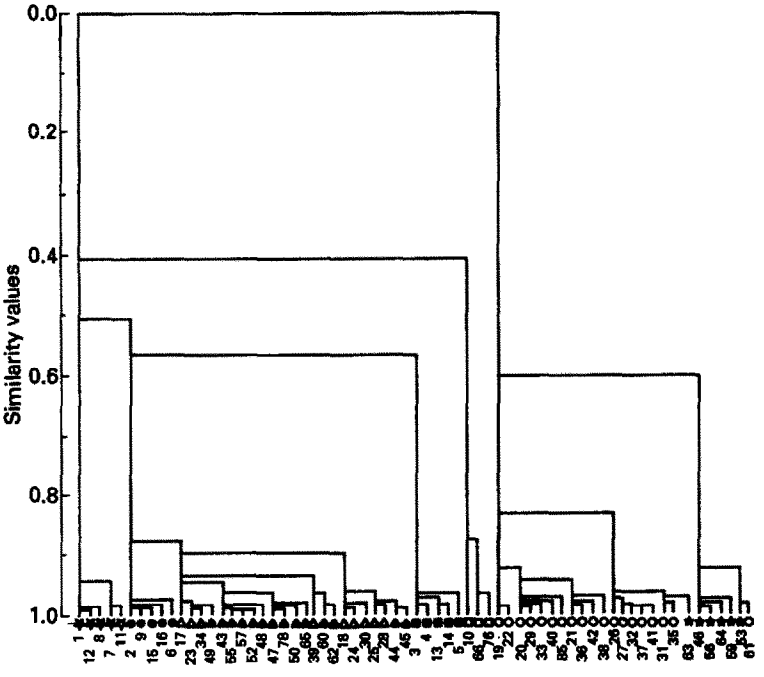

Fig. 3. Dendogram of the 66 objects in the 9th-dimensional space of the variables obtained by Ward's hierarchical clustering method. (☆) class 1, (★) class 2, (●) class 3, (○) class 4, (□) class 5, (■) class 6, (▲) class 7, (△) class 8.

(Athenian Agora type M.273), possibly from the western and northern Aegean. These samples, classified into the small class 5 in Table 3, appear in the PCA plot (Fig. 4) displaying a very different performance from the rest, on the variables analyzed, which may suggest an identical production area for both types, situated in an area of similar geo-chemical characteristics.

Samples included in the eastern Mediterranean group can be easily detected. Thus, a small class made up of pieces 3, 4 and 5, coming from the Black Sea/northern Aegean, and by samples 13 and 14, from the Antioch area, can be observed both in the dendogram and the PCA plot. It should be pointed out that in this class, numbered 6 in Table 3, samples of very different types (Keay 65 and Keay 53), which as far as can be seen were produced in very different areas, have been included. Principal Components Analysis (Fig. 4), supplies useful information on the variables that are responsible for the disposition of the eastern Mediterranean samples, the high Mn, Ca and Mg content of these samples in comparison with the others being particularly noticeable, which may indicate that the clays used in Antioch and in an area situated somewhat imprecisely on the Black Sea/northern Aegean coastline were very similar as regards their chemical composition, since the widely-differing typology of this set of pieces makes it unlikely that all of them came from a single production centre.

The presence of the elements in classes 5 and 6, well separated from the rest, leads to a bunching together of all other samples in the PCA plot, so a new PCA was carried out without considering these objects. After attempting several preprocessing data techniques to obtain better results, a principal components analysis of the logarithmically transformed reduced data set is shown in Fig. 5.

In this three-dimensional plot and the dendogram of Fig. 3 a small set (class 1) formed by pieces 1, 12, 8, 7 and 11 (examples of Keay type 54) can be easily detected; these come from the eastern Mediterranean, to be more precise from

Table 3. Classes of samples established on the basis of the Ward hierarchical clustering and Principal Components Analysis techniques

Class 1 (☆):	1-12-8-7-11 (Type K. 54, zone of Gaza)
Class 2 (★):	46-59-63-53 (Type K. 16. Lusitania) 56-64 (Type K. 21, unknown)
Class 3 (●):	2-9-15-16-6 (Type VLR 8.198, unknown)
Class 4 (○):	19-22 (Type K.24, probably from North-Africa) 61-20-29-36-21-40-27-26-31-32-35-37-38-41-33-85-42 (North-Africa)
Class 5 (□):	10 (Type K.54 bis, zone of Sardis) 66-76 (Agora of Athens M.273, Aegean zone)
Class 6 (■):	3-4-5 (Type K.65, North Aegean) 13-14 (Type K.53, zone of Antioch)
Class 7 (▲):	44-45-60-43-47-48-50-65-52-55-57-62- (Betica) 49 (Lusitania)
Class 8 (△):	17-18-23-25-28-30-39-24-34 (North Africa)

the Gaza area, and have little connection with the North Aegean samples in class 6.

The Ward diagram and the 3d PCA plot also corroborate the idea of considering samples 2, 6, 9, 15 and 16 as a homogeneous class. These samples might have their origin at some unknown point in the eastern Mediterranean. They appear as a group of high internal consistency, which is in accordance with the typological classification given, but, in chemical terms however, show a stronger tendency towards joining those samples from the south of Hispania and some from north Africa. In spite of this, these pieces have been considered members of a new class (class 3 in Table 3) quite different from all other classes.

Nevertheless, samples 19 and 22, corresponding to Keay type 24, which are morphologically related to the large north African containers, but which, because of the visual characteristics of their fabric had not been included within this geographical group, can be chemically grouped with the set of samples from this zone (class 4), and thus supply objective reasons for including them in it. The same does not occur with fragments 56 and 64 of Keay type 21, the technical (but not typological) characteristics of which point to a north African origin, but which, however, on the basis of the chemical evidence in the Ward diagram and the PCA plot, appear to be closer to numbers 46, 59 and 53, from the south of Hispania (class 2), more exactly Lusitania, and sample 61 of north African origin. Bearing in mind the clear separation in chemical terms of these fragments from the south of Hispania, more precisely Lusitania, from the remainder of the southern Spanish pieces from Baetica, it seems reasonable to consider that samples 63, 46, 56, 64, 59 and 53 form the large class 2. It should be pointed out that piece number 49, also from Lusitania, has been excluded from this group, for it is chemically included with those from Baetica. This is only to be expected since the same form may have been produced in different areas in the past.

Finally, by means of both the Ward diagram and principal component analysis, it can be seen that the samples from Baetica cluster together and display chemical characteristics similar, as far as the variables analyzed are concerned, to samples 17, 23, 34, 39, 24 and 42, which correspond to various forms of north African origin (class 8). Given that there exist typological

Table 4. Number of Principal Components and typical standard deviation for each group modeled with SIMCA method

and archaeological reasons for not considering them all as coming from a single manufacturing centre, they have been taken to be different groups.

By means of the combination of typological, archaeological and chemometrical criteria described, the existence of the eight classes summarized in Table 3 can be considered to be accepted. On the basis of these classes an attempt was made to classify the 19 remaining pieces, considered to be of uncertain origin, through the application of the SIMCA method. In this method, a Principal Components model is calculated for each class under consideration. Once the model is validated by means of the cross-validation technique, the prediction step is carried out by calculating the standard deviation of each of the pieces considered to be of unknown origin, s_i, which is compared to that of the model s_0 by means of a suitable F-test, in accordance with the expression:

$$F = s_i^2/s_0^2$$

for (M-Aq) and (Nq-Aq-1)(M-Aq) degrees of freedom, M being the number of variables, Aq the number of principal components calculated for each class, and Nq the number of objects. The full results are listed in Table 4.

The results of the SIMCA technique for the 19 samples of unknown origin are shown in Table 5. When their variance values (s_i^2) were statistically compared to that of the model (s_0^2) by means of the F-test, it was found that fragments 51 and 74 were able to be assigned to class 2, which, as has already been indicated, covers types of Lusitanian provenance; fragment 75 was assigned to the north African groups and 81 to the Baetican one. Nothing can be rigorously stated about the remaining pieces on valid statistical criteria, for, on the basis of the chemical variables analyzed, they present analogies with none of the established classes.

CONCLUSIONS

The usefulness of chemical and chemometric analysis in the characterization of amphora-producing centres in the Mediterranean basin has been shown. It is valuable in archeometry to spot the weakness of conclusions derived solely from the application of multivariate analysis to chemical composition data of materials such as ceramics or glass. Due to the composition of the raw material and the variations introduced during the manufacturing process, amphora having a similar chemical composition may come from different zones and, conversely, samples whose elemental composition is different may come from zones considered to be a historical unit in the past. However, this study shows the value of chemometrical techniques as complementary tools of typological and archaeological analysis in the characterization of samples. Moreover, pattern recognition techniques are very effective in establishing classes and classifying fragments whose origin cannot be assigned by means of any other technique.

SURFACTANT-BASED ORDERED MEDIA IN ANALYTICAL ATOMIC SPECTROMETRY*

A. SANZ-MEDEL,† M. R. FERNANDEZ DE LA CAMPA, M. C. VALDES-HEVIA Y TEMPRANO, B. AIZPUN FERNANDEZ and Y. M. LIU

Department of Physical and Analytical Chemistry, Faculty of Chemistry, University of Oviedo, Julián Clavería 8, 33007 Oviedo, Spain

Summary—During the last 10 years or so we have witnessed an enormous growth of interest and applications of surfactant-based ordered media in analytical chemistry. However, their use in analytical atomic spectroscopy (AAS) has been rather scarce and often controversial. The utilization of surfactants in this latter field is discussed here along two main lines: one refers to the favourable manipulation of physical properties of the sample solutions (Part A) while the other, demonstrated very recently, refers to the adequate manipulation of chemical reactions and/or interactions of analytes in solution by resorting to surfactants use (Part B). The control of physical properties of sample solutions, *e.g.* manipulation of the surface tension, allows three main applications of surfactants in atomic methods: possible increases of nebulization/atomization efficiencies in flame-AAS, improvement of aqueous/organic solvent compatibility (emulsification applications) and enhancement of the wettability of graphitic solid surfaces. The facts and controversies existing today on this method of utilization of surfactants to enhance atomic methodologies is critically discussed. The ability of surfactant-based "ordered media" to organize reactants at the molecular level has also been applied to enhance chemical generation of volatile species (*e.g.* hydride generation or cold Hg vapour generation) used in atomic methods. The analytical potential and usefulness of micelles and vesicles to improve the detection power of hydride generation ICP-AES methodologies are summarized for the determination of arsenic, lead and cadmium by plasma emission. Increases up to two-fold in the sensitivity of As and Pb have been observed by addition of organized media. A volatile Cd species is formed very easily in cationic vesicles with $NaBH_4$. This Cd species can be used to increase by five times the detectability of Cd by ICP-AES. Moreover, synergic combinations of liquid chromatography separations/atomic detection are possible by resorting to the use of micellar or vesicular mobile phases. The successful application of this principle to the modern problem of toxic arsenic HPLC speciation by using a vesicular solution [as mobile phase for the HPLC separation of As(III), As(V), monomethylarsonic and dimethylarsinic acids] and "on-line" surfactant-enhanced arsine generation is also described in detail and completes the whole picture of the present interface between analytical atomic spectroscopy and surfactant assemblies.

During the last 10 years or so we have witnessed an enormous growth of interest and applications of micelles, and other not so well known "organized" media, in analytical chemistry. It has been conclusively demonstrated that surfactant-based organized assemblies formed in solution (also referred to as "organized" or "ordered" media) may provide a peculiar type of reaction medium able to solubilize reagents, change equilibria and kinetics of reactions in solution or change the spectral characteristics of coloured/fluorescent compounds.

In brief, surfactants have become a special type of "analytical reagent" able to improve analytical reactions and performance of analytical methods in nearly all fields of modern analytical chemistry.[1–3] The favourable spectroscopic interactions of surfactants and their assemblies with absorptiometric dyes,[4] fluorescent[5] and phosphorescent[2] reagents and metal complexes[6] determined their wide utilization in the field of molecular UV–vis spectroscopy to improve absorptiometric,[1] fluorimetric[5] and phosphorimetric[2,6] analytical methods. This initial impetus of surfactants in molecular spectroscopy has moved slowly to other fields, such as electrochemistry[7,8] and separation science.[9–13]

Topics of particular analytical interest in the latter field are the use of mobile phases containing surfactants at concentrations above the CMC (critical micellar concentration), as is the case for micellar liquid chromatography[9]

*Invited Lecture presented at the "XIIIth National Meeting on Spectroscopy", Gandía, Spain, 1992.
†Author for correspondence.

and micellar electrokinetic capillary chromatography.[10] The use of surfactant-improved approaches for non-chromatographic new separation/preconcentration techniques, such as ion-pair liquid–liquid extraction,[11] flotation[12] or micellar "cloud-point" separations,[13] have also aroused considerable interest in the last few years.

It is noteworthy, however, that the use of surfactant-mediated methodologies in analytical atomic spectrometry is rather scarce and often controversial. The more popular application of surfactants in this field is probably their utilization to manipulate the surface tension of sample solutions. The changes observed in the physical properties of solutions by adding surfactants have been used to improve nebulization efficiency,[14–18] to achieve compatibility of aqueous phases with organic solvents allowing for emulsification[19–21] and to improve wettability of a graphitic solid surface.[22,23] Thus, in the light of presently available experimental evidence, in Part A we will critically review to what extent addition of surfactant organized assemblies, to manipulate the physical properties of dissolved samples, constitutes an effective method for enhancing analytical signals in atomic methods.

Very recently the ability of micelles, and other ordered media, to organize reactants at the molecular level (and thus to favourably modify equilibria or kinetic constants) has been utilized in atomic spectroscopy[24–26] to enhance chemical generation processes of volatile species (*e.g.* hydride generation) and this favourable effect can be combined with the potential of organized media as mobile phases in liquid chromatography[9] in order to pursue a possible synergic surfactant-mediated coupling of separation/detection. In fact, the favourable effect utilization of a vesicular solution as mobile phase for HPLC separation and "on-line" arsine generation has been demonstrated very recently.[27] The application of such a concept to the modern problem of arsenic analytical speciation[28,29] has also been addressed.[27] The utilization of surfactant assemblies to manipulate chemical interactions for atomic analytical methods is revised in Part B.

This paper intends to be a critical account of the interface surfactant assemblies/analytical atomic spectroscopy (see Fig. 1). Therefore, the potential and realized analytical applications of organized media in atomic spectroscopy will be systematically revised and critically discussed.

PART A. SURFACTANTS ENHANCING THE PHYSICAL PROPERTIES OF SAMPLE SOLUTIONS

1. Improving nebulization efficiency

The addition of surfactants to the sample solution in flame/atomic absorption spectroscopy (AAS) has been extensively studied as a means of enhancing the analytical sensitivity and of getting rid of some interferences.[14–18] Depending on the surfactant and system studied, the AAS signal increases, decreases or remains unchanged. Positive effects of surfactants

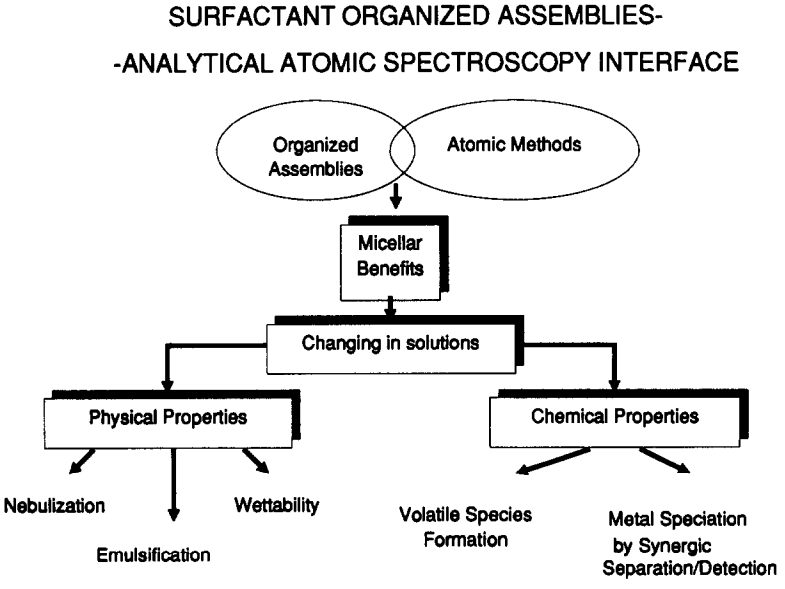

Fig. 1. The interface surfactant assemblies/analytical atomic spectroscopy.

on AAS signals have been attributed mostly to their effects on the nebulization process: the decrease in surface tension brought about by the surfactant should originate a finer aerosol and, hence, transport efficiency and/or atomization efficiency should be enhanced.[14] However, this explanation is questioned today by several authors because the surface tension values for aqueous solutions of surfactants are usually equilibrium values which might not apply in fast processes such as pneumatic nebulization. Surface tension is a property which requires a certain period of time to stabilize, the time required by the monomers of the surfactant to migrate from the bulk of the liquid or other surfaces to the surface which is being generated in the new drops. They also need time to redistribute and reorientate there (sodium laurilsulphate, SLS, requires about 10 msec for such processes). Thus, the actual surface tension ("dynamic σ") governing the drop formation in a nebulizer may not be different from that existing in the absence of the surfactant.[18]

The theory[15,30] of "aerosol ionic redistribution" (AIR) again suggests a selective enrichment of the analyte in the aerosol reaching the flame during the nebulization process if a surfactant (micelles) is present in the sample solution.

Recent work, however, tend to negate AIR's validity. Mora *et al.*[18] have shown that long-chain surfactants do not modify the basic features of the primary aerosol formed, nor the transport efficiency of the analyte to the atomizer. Yin Yan and Zhang[17] compared two atomizers, flame and ICP-AES, and concluded that enhancements are not related to nebulization/transport processes, but to a chemical effect in the atomizer. According to Yin Yan, inverted or "reversed micelles" would form around the analyte and this environment would benefit its atomization efficiency in flames. On the contrary, in ICP-AES no micellar enhancement effect was observed and this was attributed to the higher temperature in the plasma.[17]

Our experience on the determination of aluminium by conventional nebulization ICP-AES in the presence of surfactants of different charge and type tends to confirm the idea that in high temperature atomizers (plasmas) the micellar effect detected in flames, if any, is analytically unimportant.[31]

Summarizing, the enhancement of the nebulization characteristics of sample solutions for AAS by surfactants is not clear. It appears that the surfactant effect in flame-AAS is more related to atomization changes than to nebulization or analyte transport enhancement in the primary aerosol.[17,18] Much more work is needed to unveil such mechanisms of surfactant signal enhancement or surfactant interference elimination in flames. Meanwhile, trial and error techniques are mandatory to use surfactants in flame-AAS because the signals depend on experimental set-up, instrumental conditions, analyte and type of surfactant used, *etc.*

*2. Enhancing wettability of solid surfaces (*e.g. *graphite)*

A most useful alternative to conventional continuous sample introduction/atomization with nebulizer/flames or plasmas is discontinuous electrothermal atomization with graphite furnaces. There, a liquid microsample is deposited onto the surface of the usually graphite atomizer and therefore a reproducible spreading of the microsample drop over the surface is mandatory for good analytical precision. However, water has rather unfavourable surface properties to spread over graphite (surface tension, contact angle and film pressure are not as suitable as in an organic solvents/graphite system). Water/graphite systems can be made more suitable by adding surfactants. The resulting surfactant solution will have a lower surface tension, a much lower contact angle on graphite and will wet the surface in a more profound and stable manner. In this way, the formation of a thin liquid film over, *e.g.* the L'vov platform, becomes instantaneous, more stable and reproducible. Especially in connection with the use of autosamplers, the use of surfactants to decrease the surface tension, as with serum samples,[23] is most advisable in order to avoid splitting of the microdrop, sticking to the tip of the autosampler tubing, *etc*, which would bring about unreliability, lack of precision and eventually poor detection limits (by worsening the reproducibility of the measurements).

The present trend to use atomic emission techniques (AES) in connection with the graphite furnace (FAPES = furnace atomization plasma excitation[32]) should also consider this important use of surfactants when tested for real sample analysis (*e.g.* biological and other acuo-organic samples).

Lakatos *et al.*[22] have also reported on the use of surfactants to enhance conventional spark-atomic emission (AES) for the analysis of aqueous solutions with the rotrode technique.

Detection limits observed in aqueous solution were poorer than those in organic solvents. However, addition of surfactants to the aqueous phase improved the situation, even if the improvements were rather modest. In any case, the surfactant should be properly selected and applied at low concentration.[22]

3. Enhancing aqueous compatibility of organic solvents (emulsifiers)

Dispersion of an aqueous phase in an organic phase, or vice versa, increases the interfacial free energy of the system and, hence, decreases the thermodynamic stability of the liquid solution. Addition of a surfactant stabilizes the emulsion because it accumulates in the interphases forming an oriented interfacial film. This interphase reduces the surface thermodynamic instability of the system and the coalescence of drops in the dispersed phase, ensuring emulsion homogeneity.

The appropriate surfactant must be chosen to obtain stable emulsions for atomic spectroscopy. Unfortunately, this selection is generally done by trial and error. There are several factors to be considered: the nature of the phases and the type of emulsion (oil-in-water or water-in-oil), the structure of the surfactant amphiphatic groups (which should be akin to the solvent molecules), and the solubility of the surfactant (it must be very soluble and chemically similar to the continuous phase).

Oil-in-water (o/w) emulsions have been employed in AAS much more frequently than water-in-oil (w/o) ones, because of the lower viscosity and better transport behaviour of the former type. For the analysis of oil samples, however, it should always be borne in mind that the emulsification step is really a sample dilution of the oil in water and so o/w emulsification techniques could bring about an unacceptable worsening of the required detection limits. The vast majority of papers published on the use of emulsions in atomic spectroscopy techniques refer to flame-AAS analysis,[19] although a few papers on flame[21] and plasma[33,34] atomic emission, spectroscopy have appeared. The improvements observed in plasma work using emulsions are rather modest and very few papers have been published on this topic, in spite of the fact that it has been claimed that the use of emulsions in ICP-AES provides more stable emissions and lower background than pure organic solutions, while lower RF powers can be used. According to the literature, emulsion formation can be a useful alternative to organic solvent dilution in order to tackle the problem of analysing metallic elements in oils and other liposoluble matrices.

Recent developments on emulsions refer to the combination of an "on-line" treatment of solids in a flow system using a microwave oven and final dispersion of partially dissolved solids with a carrier flow containing a surfactant. The resulting suspension/emulsion feeds the nebulizer of the AAS instrument. Future work on the use of emulsions in atomic spectrometry, suggested by de la Guardia *et al.*,[19] should focus on their utilization for ICP-AES methodologies and, combined with flow injection analysis (FIA) technology, for improved on-line sample pretreatments before final atomic spectroscopic detection.

PART B. ANALYTICAL APPLICATIONS OF SURFACTANTS BASED ON THEIR ABILITY TO ENHANCE CHEMICAL REACTIONS

It is widely recognized today that the major limitation in atomic spectroscopy is the sample introduction system,[35,36] because conventional nebulizers provide a comparatively poor efficiency for the nebulization process (5–10% in AAS and 1–2% in ICP-AES and ICP-MS). Among the different approaches suggested to improve such limitations, and thus to enhance the analytical sensitivity achievable, some workers have proposed the addition of surfactants to aqueous solutions of the sample.[14–16] As discussed, in Part A, recent evidence[17,18] points to possible improvements in atomization processes taking place in flames, while addition of surfactant to samples to be analysed in high temperature atomizers (such as plasmas) might not provide significant enhancements.

A more effective approach to increase the efficiency of conventional sample introduction systems (nebulizers) is to resort to volatile species formation. Hydride generation (HG) in particular has proved to be a most adequate and sensitive technique for the determination of very low levels of hydride-forming elements by AAS,[37] ICP-AES[37,38] or ICP-MS[39] detection modes.

When one considers that the generation of volatile species for atomic spectrometry methods is a chemical reaction and that organized media exhibit unique properties in solution to enhance reactions, it seems likely that some improvement in HG by adding surfactants to the liquid samples is to be expected. Analyti-

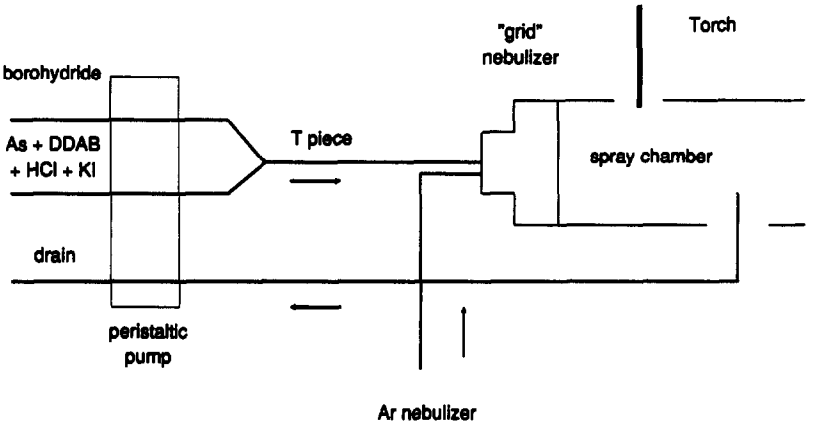

Fig. 2. The continuous HG flow system.

cal sensitivity and selectivity achieved with hydride generation/atomic detection could be improved with surfactants because: (a) they may concentrate reactants at a molecular level and so change thermodynamic and kinetic reaction constants. Thus, the analytical sensitivity can be substantially changed and improved in an adequate medium. (b) Surfactants may solubilize, in a selective manner, analytes and reactants (*e.g.* sodium borohydride) in organized "aggregates". Thus, the special microenvironment existing in/on these aggregates may change the reactions (interferences) observed in the bulk aqueous phase. In other words, analytical selectivity could be favourably changed in adequate organized media.

In fact, the analytical potential of using micelles and vesicles to improve volatile species chemical generation has already been realized, and demonstrated, in our laboratory.[24] In the following, a brief account of the progress on this topic is given.

1. Improving detection capabilities of hydride generation ICP-AES

Arsine generation in organized media. After a preliminary study on the effect of different organized media (including normal micelles with positive, negative or zwitterionic charge, non-ionic micelles and vesicles), positively charged vesicles of didodecyldimethylammonium bromide (DDAB) were selected as the most adequate medium for arsine generation using $NaBH_4$ (and iodide as the prereduction agent). As shown in Fig. 2, a commercially available continuous hydride generation system based on a de-tuned Hildebrand nebulizer was used in these studies[24] to introduce the hydride formed into the ICP (PU7000-Philips Instrument). The ICP operating experimental conditions and optimum chemical and flow conditions for HG from vesicles were first worked out. Using such optimal conditions, the analytical performance characteristics observed for HG-ICP-AES determination of arsenic from aqueous and vesicular media were evaluated for comparative purposes. Calibration graphs obtained in both media demonstrated that the sensitivity was improved by a factor of 2 using vesicles. The corresponding detection limits were 0.6 ng/ml of As for DDAB and 1.3 ng/ml in conventional aqueous medium. A significant improvement in the precision of the ICP emissions and greater tolerance to matrix interferences were also observed by using DDAB vesicles for HG. As a result of such basic studies, a new HG-ICP-AES method of As analysis has been proposed which was tested successfully for the determination of μg/g levels of As in real samples without preconcentration.[24]

Plumbane generation improvement in organized media. With a similar methodological approach, the effect of various organized media (see Table 1) on the HG-AAS signal of lead using the most commonly used mixture, $K_2S_2O_8$ and nitric acid, for the preoxidation to Pb (IV)[40] and using $NaBH_4$ for final reduction was thoroughly studied. As shown in Table 1, positively charged surfactants, cetyltrimethylammonium (CTAB) and DDAB, produced an important increase in the lead signal. This increase was dependent upon the final concentration of surfactant in a rather critical manner, particularly with CTAB (see Fig. 3). Kinetic studies using a batch hydride generator (discon-

tinuous device MHS-10 system from Perkin–Elmer) indicated that the observed increases were due to faster volatile species generation/transport processes in the presence of organized media, as shown in Fig. 4.

Using optimized chemical and flow conditions for HG from the different media (conventional aqueous medium, micelles of CTAB and vesicles of DDAB) and optimum instrumental parameters in the ICP, positively charged micelles of CTAB proved to provide a better reaction medium for plumbane generation and final determination of lead by continuous HG-ICP-AES.

These basic results have also been applied to develop a new HG-ICP-AES method for the determination of low levels of lead,[25] using CTAB micelles.

Cadmium volatile species generation in organized media. Generation of volatile CdH_2 in aqueous solutions at room temperature for analytical purposes is a rather difficult task due to the instability of this hydride at temperatures above liquid nitrogen.[41] In spite of such instability, CdH_2 has been proposed as the volatile species of Cd formed, and detected by AAS, when treating Cd^{2+}solutions with $NaBH_4$ in an organic medium of dimethylformamide.[42] It has to be stressed, however, that no conclusive evidence of the hydride nature, or otherwise, of such detected cadmium volatile species formed with borohydride from organic solvents has yet been provided.

In the light of the special aquo-organic microenvironment provided by surfactant-based organized assemblies, the formation of such volatile Cd species could be favoured in the presence of surfactants. Therefore, we have investigated the effect of micelles and vesicles on the HG-ICP-AES signals of Cd at 228.80 and 214.44 nm using the continuous HG system previously described for arsenic (Fig. 2).

Several types of organized assemblies were assayed, including cationic (CTAB), anionic (SLS), zwitterionic (ZW-3.16) and non-ionic (Triton X-100) micelles and also cationic ves-

icles (DDAB). Presence of cadmium in the plasma was always checked at both Cd emission lines given previously. The observed effect of the surfactants on the HG-ICP-AES cadmium signal intensities, on the background of the ICP and on the precision of the recorded Cd signals, have been summarized in Table 2.

As can be seen, results showed that the most promising analytical results were obtained using vesicles of DDAB. The importance of vesicle formation in order to obtain good ICP-AES Cd signals was tested with sonication experiments, which showed that when both the analyte, Cd^{2+} and the reducing agent, BH_4^-,were in the vesicles (that is, when both of them were present in the DDAB solution before the required sonication to form individual vesicles was carried out) maximum signals were observed for Cd. In order to verify if the analyte was actually in the vesicles, ultrafiltration experiments were performed: solutions of Cd^{2+}added to already sonicated DDAB and, alternatively, of $Cd^{2+}$and BH_4^- sonicated at the same time as the surfactant solution (in order to form the vesicles), were ultrafiltrated and the Cd^{2+}in the ultrafiltrate was determined by ICP-AES. The results observed are shown in Table 3. These results demonstrate that when sonication of DDAB solution is carried out with Cd^{2+}present, around 50% of the total Cd^{2+}added remains in the vesicles (which do not pass the ultrafiltration membrane). Maximum HG-ICP-AES signals for Cd are then obtained. If $Cd^{2+}$is added to DDAB vesicles, virtually all added Cd^{2+}seems to remain outside the vesicles in the bulk aqueous solution, because it passes quantitatively in the ultrafiltrable fraction, as seen in the results of Table 3.

On the other hand, our efforts to characterize the nature of the observed volatile species of Cd measured in the ICP (formed when the analyte and $NaBH_4$ vesicular solutions merge in the continuous HG system of Fig. 2) have failed so far. Attempts to "trap" the possible "hydride" (by passing the gases resulting from HG through a liquid N_2 cryogenic trap) and its eventual release by warming in the injection port of a GC-MS instrument (for elemental identification) have been unsuccessful so far.

In any case, this "vesicular hydride" generation technique offers five times better detection limits for Cd than conventional nebulization ICP-AES. Thus, it is presently being assessed as a new technique for determination of the metal in environment samples.[26]

A recent alternative for volatile species for-

mation is alkylcadmium generation using alkylboranes for alkylation. Honeycutt and Riddle[43] first reported the use of sodium tetraethylborate, $NaBEt_4$, in aqueous solutions to produce volatile organometallic species of lead and mercury from their inorganic salts, and this approach has already been applied to lead[44] and mercury.[45] D'Ulivo and Chen[46] have recently reported the use of such alkylation reactions for the atomic fluorescence determination of very low amounts of Cd. However, no conclusive identification of the exact cadmium species formed could be achieved.[46] Our preliminary results using alkylcadmium generation point to an even more efficient approach to increase the sensitivity of the ICP-AES determination of cadmium, as is needed in biological and environment samples today (see Fig. 5 for a comparison of the relative strength of the corresponding ICP signals observed). It is expected that the use of organized media may favour the efficiency of these alkylation reactions in aqueous solutions. Thus, alkylations in ordered media could offer a most exciting field of research, particularly in connection with speciation studies, where extremely high sensitivity for detection is required.

2. Improving separation/detection capabilities simultaneously

Adequate analytical technologies to tackle the present problem of element speciation are increasingly required in agricultural, environmental and clinical fields and also in the pharmaceutical and biotechnological industries.[47] It is accepted today that the most reliable approaches for speciation are tandem techniques, that is hybrid analytical methods involving interfaced chromatographic/atomic spectroscopic methods. The ICP-AES has been frequently used as a "specific" detector coupled to a liquid chromatograph for metal speciation.[48]

Unfortunately, common mobile phases for high performance liquid chromatography (HPLC) utilize organic solvents, which may be detrimental to the ICP's analytical performance (*e.g.* bringing about higher plasma background, increased instability and noise and even eventual extinction of the plasma due to excessive solvent loading). Therefore, the search for alternative mobile phases is worthwhile because it could result in better performance of HPLC-ICP-AES hybrid methods used for speciation purposes. In fact, micellar mobile phases have already been proposed for HPLC-ICP-MS speciation of alkyltin compounds.[49]

On the other hand, as we described before for the vesicle-enhanced HG-ICP-AES determination of arsenic,[24] the ability of "ordered media" to organize reactants at the molecular level can be utilized to improve the generation of volatile species (to enhance the detection power of the ICP-AES techniques). This favourable effect on detection could be combined with the potential of "ordered media" in HPLC separations.[9] That is, a synergic combination of HPLC separation/atomic detection can be achieved by resorting to the use of ordered media as mobile phases.

In fact, we have already developed such a new strategy for solving the problem of arsenic speciation[27] using synthetic vesicles of DDAB as the mobile phase. Toxic arsenic species, *e.g.* arseneous, arsenic, monomethylarsonic and dimethylarsinic acids, can be separated and determined by this HPLC-HG-ICP-AES coupling, enhanced by vesicles, within about 10 min, as shown in Fig. 6. The column is a typical C_{18} bonded silica column, modified previously by passing DDAB, while the mobile phase is phosphate buffer of pH 5.7 containing vesicles of DDAB at a surfactant concentration of $10^{-5}M$.

The detection limits observed for the different toxic species of As were found to be down to the sub-nanogram level, while the precision achieved, at the 10 ng As level, was always better than $\pm$ 5%. Thus, the synergic exploitation of beneficial effects of vesicles for both

HPLC separation and ICP-AES detection is demonstrated for the first time.[27]

CONCLUSIONS

The widespread variety of applications possible when using surfactants in analytical chemistry can be extended, as illustrated here, to the field of AAS. Two main lines of surfactant-enhanced progress can be envisaged: one refers to the favourable manipulation of physical properties of the sample solutions (*e.g.* surface tension), while the other is the intelligent manipulation of chemical reactions and/or interactions of analytes in the sample solution.

Important advantages of adding surfactants to control the physical properties of solutions include: possible increase of nebulization/atomization efficiencies in AAS, improvement of aqueous/organic solvents compatibility (emulsification purposes) and enhancement of the wettability of graphitic solid surfaces, particularly in graphite furnace techniques.

Substantial advantages of adding surfactants to manipulate reactions include the possible increase of kinetic reaction rates of volatile species formation and transport to the atomizer. By now, enhancements of about two-fold of the HG-atomic spectroscopy signals have been observed for various elements and in the cold vapour generation of Hg. Moreover, synergic combinations of the HPLC/atomic detector type are possible by resorting to micellar–vesicular mobile phases.

Summarizing, we can conclude that the advantages encountered so far by using surfactants in atomic spectroscopy methods are more modest than the enhancements observed when used in other detection techniques, *e.g.* fluorimetry.[5] However, the interface surfactant assemblies/analytical atomic spectroscopy (see Fig. 1) still holds a great potential for innovative applications, particularly so in the area of developing hybrid chromatography/atomic detector techniques, a combination which has proved extremely valuable for solving modern speciation problems.

BEHAVIOUR OF SOLID ADSORBENTS FOR THE SAMPLING OF ATMOSPHERIC ORGANOCHLORINE COMPOUNDS

C. NERIN, M. MARTINEZ, B. PONS and J. CACHO

Dept. Química Analítica, Centro Politécnico Superior de Ingenieros, Universidad de Zaragoza, Zaragoza, Spain

Summary—The behaviour of Tenax® GC, Polyurethane foam (density 0.022 g/cm^3), Amberlite® XAD-2 and Amberlite® XAD-4 alone or in combination has been studied. Standard atmospheres containing different concentration levels of hexachlorocyclohexane and chlorobenzene isomers were generated and trapped in adsorbent cartridges. The generation of the atmosphere, the adsorption by the cartridges, the extraction of the compounds, the evaporation of the final solution and the analysis of GC/ECD have been studied. The most efficient system for trapping the test gases is the use of two cartridges connected in series, one containing Polyurethane foam and the second one containing Tenax GC. Recovery values ranging from 72% for 1,3-dichlorobenzene to 98% for gamma-hexachlorocyclohexane are obtained, most of them >90%. The SD values for all the compounds under study are around 4% for a total sampled amount of 0.5 μg of each compound.

The environmental distribution of organochlorine compounds in water, sediments, fish, *etc*, has been studied.[1–13] There are many papers about their distribution in these different media. However, very few papers address the atmospheric distribution of these compounds even though they are used as pesticides and appear in the atmosphere around industrial waste dumps, *e.g.*, from Lindane factories. These emissions contain hexachlorocyclohexane and chlorobenzene isomers. Nevertheless, the atmospheric distribution of these compounds and the typical concentration level is not well known. Due to their relatively higher vapour pressure, the presence of these species in the atmosphere may be important.[1–3]

The classical methods of sampling organochlorine compounds in the atmosphere consist of trapping them in an organic solvent, usually iso-octane. Due to the evaporation of the solvent during sampling and the consequent difficulty of long term sampling, this is not very practical. Also, the use of an organic solvent in the impinger demands attention. To avoid these disadvantages, relatively few studies have been conducted to determine trapping efficiencies of adsorbents to airborne pesticides.[14–16] Polyurethane foams, Porapak® N and R, Tenax® GC and Chromosorb® 102 have been used for trapping several pesticides or related compounds; only hexachlorocyclohexanes, chlordane and heptachlor have been studied.[17] Their ability to trap more volatile compounds such as chlorobenzenes has not previously been checked.[16]

This paper describes the results of studies carried out with Polyurethane foam, Tenax® Amberlite® XAD-4 and Amberlite® XAD-2 in order to establish the optimum procedure for sampling organochlorine compounds, such as hexachlorocyclohexanes (HCHs) and chlorobenzenes, in the atmosphere.

EXPERIMENTAL

Apparatus

A Varian (Palo Alto, CA) Aerograph Gas Chromatograph and a silanized hollow glass column were used to generate the standard atmosphere. A Hewlett–Packard (Palo Alto, CA) Gas Chromatograph 5890 equipped with an Electronic Capture Detector (ECD) and automatic injector was used to analyse the samples. A capillary column DB-1701, 60 m × 0.25 mm × 0.25 μm film thickness, was used under the following conditions: inj. temperature: 250°; detector temperature: 350°. Split ratio 1:10. Initial temperature 50° for 5 min, 7°/min up to 250° and then held at 250° for 9.5

min. Column head pressure: 95 kPa; carrier H_2; make up gas N_2.

Reagents

Alpha-, beta-, gamma- and delta-hexachlorocyclohexane, 1,2-dichlorobenzene, 1,3-dichlorobenzene, 1,4-dichlorobenzene, 1,2,3-trichlorobenzene, 1,2,4-trichlorobenzene, 1,2,5-trichlorobenzene, 1,3,5-trichlorobenzene, 1,2,3,4-tetrachlorobenzene and 1,2,4,5-tetrachlorobenzene were obtained from Chem Service (West Chester, PA). Nitrobenzene standard was from Fluka (Buchs, Switzerland) and methyl chlorpyriphos was from Riedel-de Haën (Seelze, Germany).

Polyurethane foam (PUF) of 0.022 g/cm^3 density was specially produced by Pikolin (Zaragoza, Spain); Tenax GC, Amberlite XAD-2 and Amberlite XAD-4 were supplied by Supelco (Bellefonte, PA) and Florisil was from Fluka.

All glassware was cleaned using an ultrasonic bath with distilled water and neutral soap for 6 hr, after which it was washed sequentially with distilled water, acetone and hexane.

PUF cartridges of 100 mm length and 20 mm diameter were cleaned before using a hexane–diethylether mixture (19:1, v/v) for 12 hr in a Soxhlet extractor. After this treatment the cartridges were dried under a nitrogen current and stored in a clean glass container in the dark in a nitrogen atmosphere. Tenax was heated at 250° under N_2 current for 2 hr, in order to clean the adsorbent before using it. Amberlite XAD-2 and XAD-4 were extracted with a hexane–diethyl ether (19:1, v/v) mixture before use. Figure 1 shows the chromatogram of a blank of each adsorbent used after the mentioned clean-up.

Procedure

A hexane solution (0.5 ml) containing about 1 μg/g of the compounds mentioned was injected in an empty silanized glass column ($\frac{1}{4}$″ × 2 m, i.d.) placed in a GC at 60°, using synthetic air as carrier. The carrier flow is set at 0.8 l./min. In the GC outlet a glass cartridge containing a solid adsorbent is placed. After 1 hr the solid adsorbent sampling cartridge was introduced in a Soxhlet and a 12 hr extraction with the hexane–diethyl ether (19:1, v/v) mixture carried out. The extract obtained was concentrated under N_2 current up to 2 ml. This extract was transferred to a volumetric flask with a suitable amount of the internal standard, and then analysed by GC/ECD.

RESULTS AND DISCUSSION

Generation of standard atmosphere

Figure 2 depicts the scheme of the system employed. A GC with a hollow silanized glass column was used to evaporate a solution of known concentration of the compounds to be

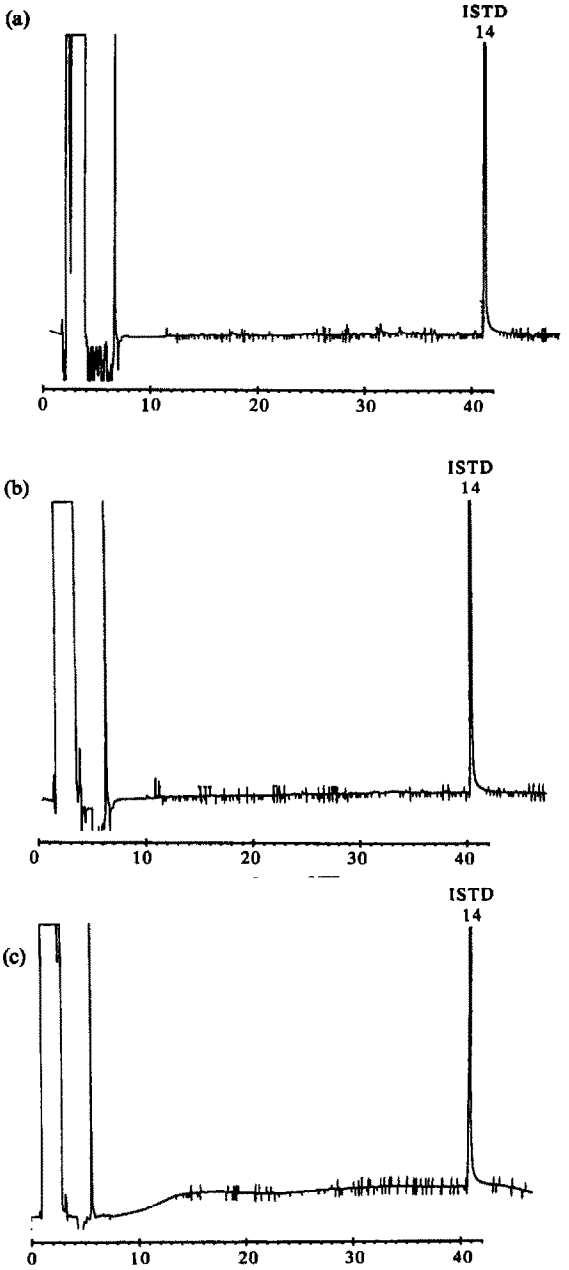

Fig. 1. (a) Chromatogram of a blank of PUF. (b) Chromatogram of a blank of Tenax GC. (c) Chromatogram of a blank of Amberlite XAD-2.

studied. To stimulate the real sampling conditions, the injection port was heated at 90°, whereas the empty column was kept at 60°, under the boiling point of the solvent used in the injected solution. In the first part of the glass column a small amount of glass wool was placed to give more homogeneity to the evaporation process. In these conditions the compounds were evaporated slowly and because of the low oven temperature, the adsorption occurred essentially at room temperature. One or more glass cartridges containing the solid adsorbents were placed at the column outlet to trap the compounds. Fifty minutes after injecting the solution in the glass column, the temperature of the oven was increased to 100° and all the exhaust from the column was trapped in the same cartridge. Synthetic air (0.8 l./min) was used as carrier gas for the evaporation of the compounds. After each injection, 0.5 ml of hexane was injected into the system and the exhaust was trapped in another cartridge; this was used as a blank. No analyte compounds were observed in this blank. Figure 3 shows a

Extraction study

Once the compounds were trapped on the solid sorbents it was necessary to extract them. A study was carried out to optimize the extraction procedure. A 50 ml Soxhlet extractor was used with a hexane–diethyl ether (19:1, v/v) mixture during 12 hr. Several spiked samples were prepared by adding 0.5 ml of a solution containing 2 μg/ml to a cartridge of PUF. After drying the PUF well, it was extracted in the Soxhlet extractor under the conditions mentioned above.

According to previous studies, one of the major sources of error in the analysis of volatile compounds is due to the loss of compounds during the concentration/evaporation step. Among evaporation methods reported in the literature,[18] the use of N_2 current at constant temperature was selected as the most appropriate. The extracts obtained from the spiked samples were evaporated and analysed. The results are shown in Table 1. No losses are apparent from the extraction and evaporation steps.

Behaviour of solid adsorbents

Some organic compounds cannot be sampled on charcoal owing to decomposition reactions, irreversible adsorption, or due to the adsorption of other compounds which can interfere in the analysis. In such cases adsorbents of the porous polymer type may be useful alternatives. Previous work[16] on PUF showed that this can be a good adsorbent for HCHs, but its applicability to the sampling of chlorobenzenes was unknown. Therefore, the first adsorbent checked was PUF. Tenax, Amberlite XAD-4 and Amberlite XAD-2 are mentioned in the literature as very efficient adsorbents of volatile compounds.[16,19–22] A second cartridge containing one of these adsorbents was connected serially after the cartridge containing PUF. Several standard atmospheres as calibrants were generated and these were sampled in the cartridges. In order to compare the trapping efficiency, when more than one cartridge was sequentially employed, the solid adsorbents from each cartridge were extracted together in the same Soxhlet. Table 2 shows the results obtained as an average of five independent determinations. These values include the recoveries obtained in the overall process, which includes the steps of generation, adsorption, extraction, concentration and analysis.

Two different aspects can be emphasized. The first is the different trapping efficiency of PUF

Table 2. Trapping efficiency of different solid adsorbents and combinations expressed as percentage recoveries

for chlorobenzene isomers compared to that for HCHs. The recovery of chlorobenzene is quite low. According to the literature,[14] the recoveries of volatile compounds from PUF are very low. As chlorobenzenes are quite volatile, especially dichlorobenzenes and trichlorobenzenes, PUF does not seem to be appropriate to trap them in the atmosphere. On the other hand, volumes of air around 1 m^3 have to be sampled in order to measure the low concentration of such compounds commonly found in the atmosphere. Obviously, in these conditions the breakthrough volumes for these volatile compounds on PUF are surpassed, which means that this adsorbent is not efficient enough to sample these compounds. It can be further observed that the higher the boiling point of the compound, the higher is the recovery. The second aspect is that when two cartridges are combined in series, one of them serves mainly to trap the more volatile compounds and the other to capture the HCHs. No differences were found in the behaviour of Tenax and the Amberlite adsorbents, except that the standard deviation was slightly higher for the PUF + Amberlite combination. Taking into account these considerations, the PUF + Tenax combination in series was selected for trapping atmospheric HCHs and chlorobenzenes.

Clean-up of the PUF cartridges

The typical atmospheric concentration of the compounds of interest is usually very low. Consequently, it is necessary to improve the sensitivity of the procedure. This can be achieved through the concentration step. However, in this way, other compounds present in the PUF which can also be extracted are concentrated as well and some interferences appear. On the other hand, it was observed experimentally that when PUF was recently prepared no interferences appeared from other compounds present in the PUF, even after this concentration step. This fact can be seen in Fig. 1a, in which a chromatogram of a new PUF cleaned with hexane–diethyl ether (19:1, v/v) as mentioned above is shown.

Nevertheless, as soon as the PUF became older, which happens after approximately 2 months of being produced, new interferences from the PUF appeared in the concentration step, as shown in Fig. 3a. Figure 4a shows a chromatogram of an extract of an old PUF before the clean-up step. It is obvious that a clean-up step is necessary in such a case.

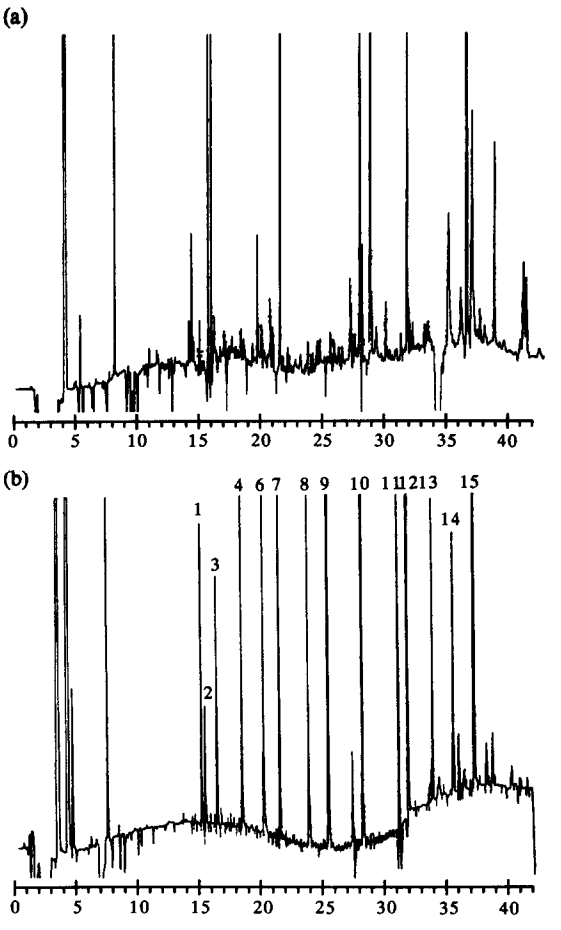

Fig. 4. (a) Chromatogram of an old PUF before clean-up. (b) Chromatogram of a spiked old PUF after clean-up with 10% Florisil. The peak identifications are the same as in Fig. 3.

It is well known that both Florisil® and silica are good adsorbents for the clean-up of different matrices.[23–25] Although in this particular case the interferences to be removed are not major components, several experiments were carried out using 10% deactivated Florisil. The columns used were of 20 mm internal diameter, filled with about 7 g of Florisil and topped with 1 g of anhydrous sodium sulphate. The Soxhlet extract, about 70 ml, was added to the column and the compounds were eluted with 15 ml of hexane. The final solution obtained was evaporated to 2 ml and analysed. Figure 4b shows the chromatogram of a spiked PUF obtained after the clean-up step. The results obtained show that the use of Florisil in the conditions mentioned is adequate to remove the interferences from the old PUF. Furthermore, no losses of the OCPs occur in this clean-up step. This is detailed in the data presented in Table 3.

Table 3. Percentage recoveries of spiked polyurethane foams after clean-up on Florisil

CONCLUSIONS

The system used here to generate standard calibrant gases is efficient and lets the user obtain a great variety of contaminated atmospheres at different concentration levels.

Among the solid adsorbents checked, the use of two cartridges connected in series, one containing polyurethane foam (PUF) and the other Tenax GC, is the most efficient trap for HCHs and chlorobenzenes in the atmosphere. This system has the advantage over other combinations that PUF is quite rigid and porous and the structure facilitates the handling of the cartridge. On the other hand, as two cartridges are independent, each cartridge can be recycled after use. Furthermore, in a real atmosphere, the PUF is not clogged by humidity from the air, and for this reason it is more convenient to place PUF in the first cartridge. As was shown in previous work,[16] humidity does not influence the efficiency of PUF to trap HCHs; this is a significant advantage over particulate polymeric adsorbents.

(*Received* 10 *May* 1993)

Summary—A method for the extraction and separation of the active ingredient diazepam (7-chloro-dihydro-1-methyl-5-phenyl-2H, -1,4-benzodiazepam-2-one) in pharmaceutical tablets is discussed. This method avoids the hydrolysis of diazepam. Polarographic studies with direct current (DCP), alternating current (ACP) and differential pulse polarography (DPP) were used under different sets of conditions. The pH value most suitable for these studies was found to be 4.6. The detection range for ACP was found to be from 17.4 to 167 μM, whereas for DPP, the range was 4.8–96 μM.

Commercial tablets of diazepam labelled to contain 10 mg per tablet were assayed. For five replicate samples, the relative standard deviations were lower than 1% and the contents were determined with errors lower than 4%.

Diazepam (7-chloro-dihydro-1-methyl-5-phenyl-2H,-1,4-benzodiazepam-2-one) belongs to the group of 1,4-benzodiazepines (see Fig. 1), commonly used as tranquilizers and ansiolytics. Their use has great therapeutic importance for the treatment of diseases of the central nervous system. For this reason, the quality control of these substances is rather important as well as the concentrations of their metabolites in biological fluids. These benzodiazepines possess both electroactive and chromophoric groups[1] that allow for their polarographic and spectrophotometric determination.[1,2] In fact, a flow injection analysis system (FIA) equipped with a polarographic and a spectrophotometric detector has been used in the analysis of clotiazepan.[1]

The official pharmacopeias[3,4] describe spectrophotometric assays for measuring diazepam and oxazepam in dosage forms. These methods require a previous dissolution in sulfuric and hydrochloric media. Like other benzodiazepines, these drugs are susceptible to acid hydrolysis with subsequent ring opening.[5] The kinetics of the hydrolysis of such compounds have been extensively studied.[6,7] Abdel-Hamid and Abuirjeie[8] have reported that the spectrophotometric methods produce variable and non-significant results, indicating that the official procedures are not specific for the intact drug and do not reveal the presence of the degradation products. For these reasons, it is necessary to develop procedures in order to solve these problems.

The HPLC procedure and the fourth-derivative spectrophotometry have been proposed for these purposes.[8] Brooks[9] reports a general review of the application of electrochemistry in pharmaceutical analysis, where the 1,4-benzodiazepines determination is extensively described, however the problems related to the drug extraction from the pharmaceutical products are not deeply discussed.

Kalvoda[10] has studied polarographically active ingredients such as diazepam, nitrazepam, papaverine and other nitroaromatic compounds. Jacobsen and Jacobsen[11,12] have measured with this technique the concentration of diazepam in pharmaceutical products as well as in biological samples (with a previous extraction). However, they used electrolytes that tend to hydrolyze diazepam. This hydrolysis may affect the accuracy of the polarographic analysis.

In this work, the extraction and identification of diazepam in pharmaceutical tablets is presented as well as its quantification with electroanalytical techniques. The aim is to design an

(a) (b)

Fig. 1. (a) General formula of 1,4-benzodiazepines, (b) diazepam formula.

exact and reproducible method that may be used for similar compounds in pharmaceutical products.

Experimental

The polarographic studies were performed with home-made polarographs. Direct current (DCP), alternating current (ACP) and differential pulse polarography (DPP) were performed. The electrochemical cell was a three-electrode cell with a dropping mercury electrode (working electrode), an Ag/AgCl reference electrode and a platinum wire as the auxiliary electrode.

The potential intervals where the polarographic studies were performed are: for DCP from -0.45 to -1.5 V, and for ACP from -0.4 to -1.2 V. The scan rate for both DCP and ACP was 5 mV/sec with a drop time of 1 sec. The spectrometric determinations were performed with a Perkin-Elmer 4 V spectrophotometer and a FTIR. The pH determinations were done with a Corning Ion Analyzer model 250.

The reagents used for the preparation of the solutions were of reagent grade; the buffer solutions were prepared with sodium phosphates 0.033*M*, sodium acetate 2*M*, sodium tetraborate 0.033*M*, acetic acid and KOH 2*M*, HCl for pH adjustment. DMF, methanol, sulfuric acid, ether and formaldehyde were also used. The active ingredient was extracted from a batch of 10 mg Valium tablets. The standard used was diazepam (Aldrich 99.31% purity).

RESULTS AND DISCUSSION

Extraction solvent selection

Ethyl ether, methanol, dimethyl formamide and a formaldehyde/H_2SO_4 mixture were tested as solvents for the extraction of diazepam from Valium tablets. Of these solvents, only ether facilitated the separation of the active ingredient from the filler; this led to the production of crystals. The infrared spectra of such crystals (Fig. 2) displays features that are characteristic of the groups corresponding to the structure of the diazepam molecule.[13] In addition, the melting point of the crystals was found to be 132°C which agrees well with that reported elsewhere.[13] These results indicate that the active ingredient does not undergo chemical changes in the extraction process with ether.

For the polarographic determination, a 2*M* solution of acetic acid/sodium acetate (pH = 4.6) was used as supporting electrolyte (see below). The diazepam crystals are not soluble in such an electrolyte. For this reason they were previously dissolved. The polarograms, shown in Fig. 3, were obtained after the addition of aliquots of diazepam, dissolved previously either in DMF (Fig. 3(a)) or else in H_2SO_4/formaldehyde solution (Fig. 3(b)), to the supporting electrolyte.

The well-defined reduction wave at -0.82 V in Fig. 3(a) is characteristic of diazepam.[10] Conversely, the polarogram in Fig. 3(b) shows two waves which indicate that the active ingredient is undergoing a hydrolysis reaction in an acidic medium, as previously reported.[14]

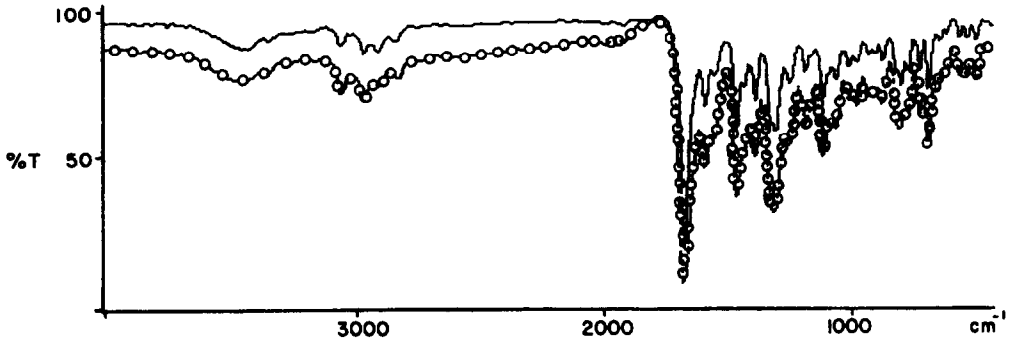

Fig. 2. Infrared spectra of pure diazepam crystals (– – –) and of the crystals from ether extraction of Valium tablets (00000).

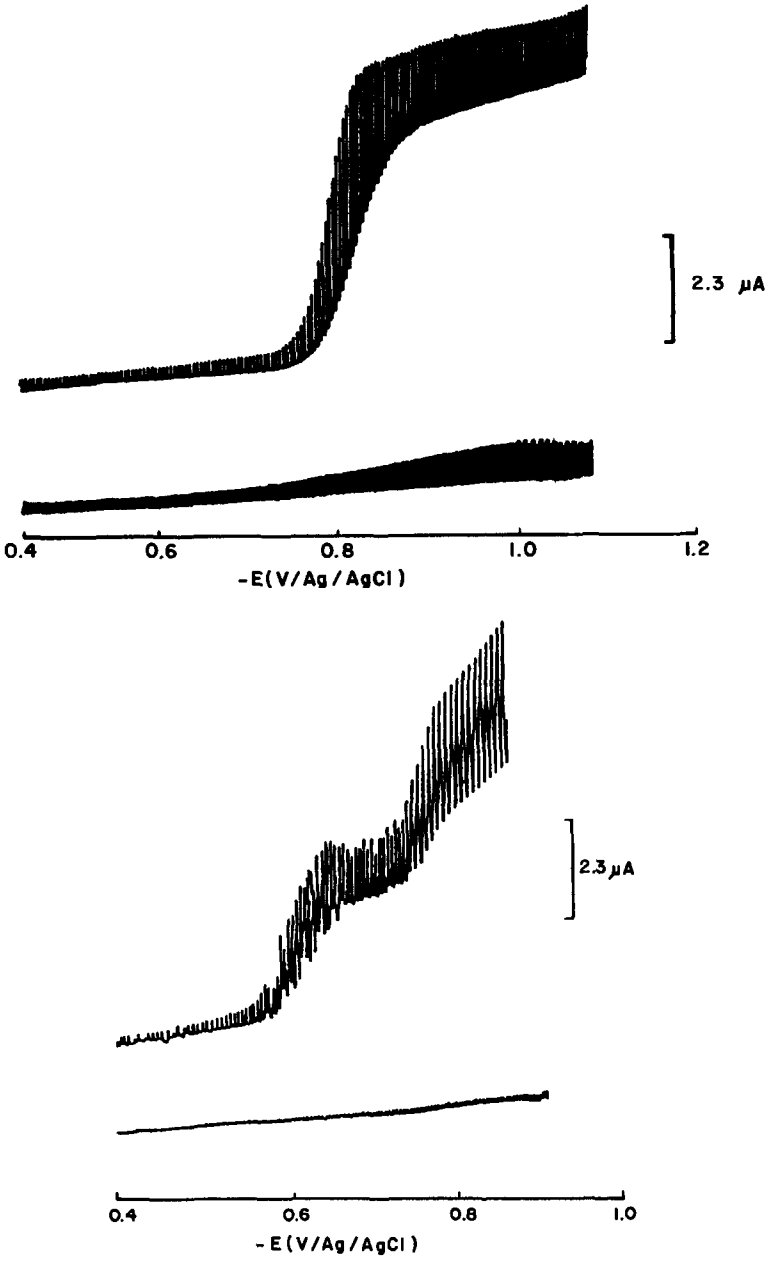

Fig. 3. DC polarograms in a 2M solution of acetic acid/sodium acetate (pH = 4.6) of diazepam extracted from Valium and previously dissolved in: (a) DMF, (b) H_2SO_4/formaldehyde. DC polarogram of support electrolyte is showed in both cases.

Figure 4 shows the spectrophotometric behavior of diazepam, previously dissolved in DMF or in a H_2SO_4/formaldehyde solution, in a 2*M* buffer solution, of acetic acid/sodium acetate. The diazepam band becomes wider if it is previously dissolved in H_2SO_4/formaldehyde, thus providing further evidence of its hydrolysis. The extraction and determination of diazepam is commonly carried out in H_2SO_4/formaldehyde media;[11,12] this may lead to a decreased precision in its quantification, by spectrophotometric methods, when the hydrolysis products are present. For this reason, the active ingredient is first dissolved in DMF.

The study of the hydrolysis of diazepam is not the objective of this paper. The kinetics of the hydrolysis of 1,4-benzodiazepines to benzophenones have been extensively studied.[6,7] This reaction is catalysed by the bisulfate anions.[15] Alonso *et al.*[1] have chosen acetate buffer, with pH that would prevent hydrolysis (pH > 3) and avoid the use of potentials so negative that

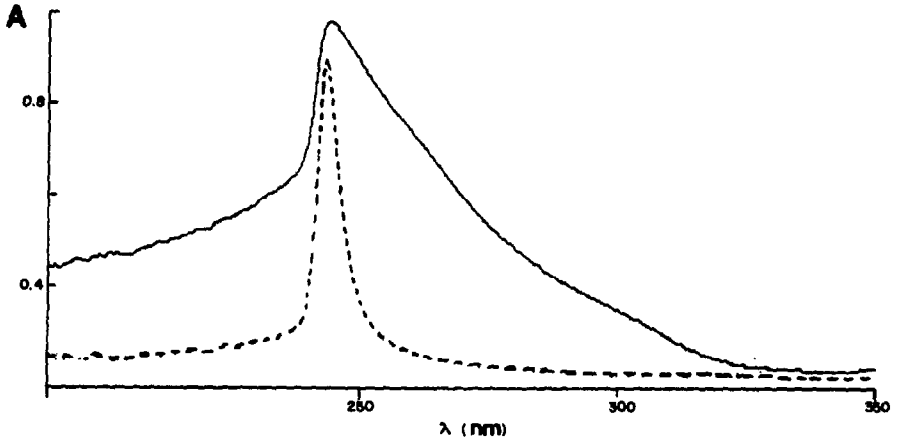

Fig. 4. Spectrophotometric behavior of diazepam (0.5 mg/l) in a 2*M* acetic acid/sodium acetate buffer solution (pH = 4.6). The diazepam was previously dissolved in: (a) DMF (– – –), (b) H_2SO_4/formaldehyde (– – – – – –).

problems would arise with mercury drop electrode. For this reason, we have selected the acetate buffer pH = 4.6 as supporting electrolyte.

Polarographic determination

The effect of pH upon the diazepam reduction peaks in DPP is shown in Fig. 5, at a constant diazepam concentration and a pH interval of 1–13. It can be noted that at intermediate pH values (pH 8–9) the peaks are wide, whereas they become sharper at either high or low pH values. This is an indication of a complication in the electron exchange process at intermediate pH values as compared to more extreme values; it is likely that the electron transfer occurs in two steps as has been suggested earlier.[16]

The peak potential is cathodically displaced with an increase in pH at a rate of −0.070 V per pH unit. The reduction of the azomethine group

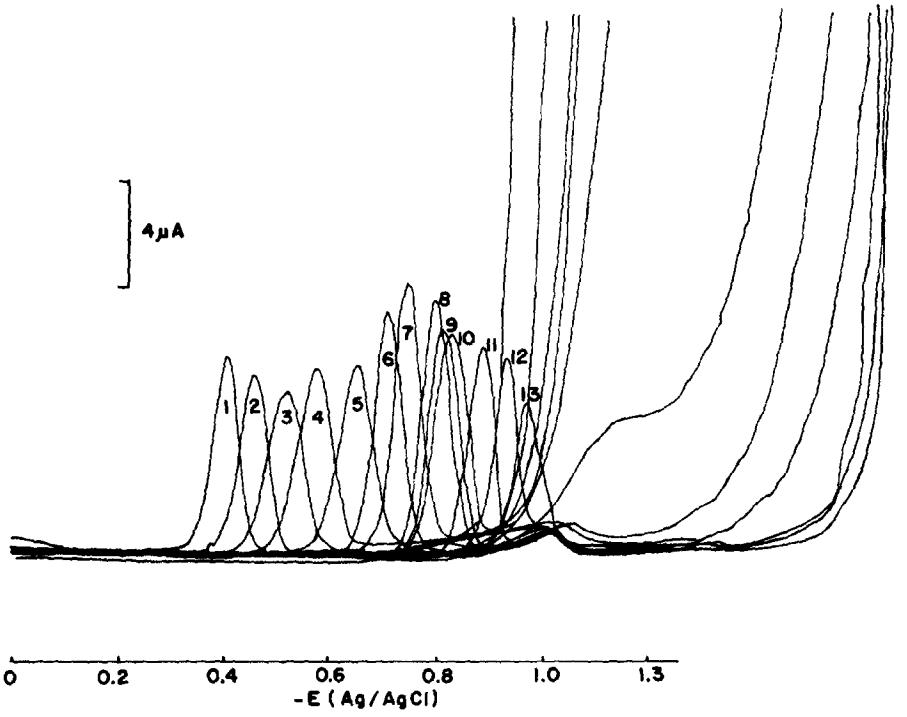

Fig. 5. Differential pulse polarogram in a 2*M* solution of acetic acid/solution acetate of diazepam previously dissolved in DMF. The pH values are individually shown.

Table 1. Determination of diazepam from commercial tablets, labelled to contain 10 mg, using DPP and spectrophotometric (UV) methods

Sample No.* (diazepam) Valium tablets (Roche—10 *mg*)	DPP	UV
1	9.97 ± 0.64	9.33
2	9.79 ± 0.24	9.06
3	10.31 ± 0.58	9.16
4	10.05 ± 0.05	9.45
5	10.40 ± 0.28	9.55
6	9.81 ± 0.40	9.41
7	10.61 ± 0.68	10.01
8	10.11 ± 0.27	9.50

*Each sample was realized five times.

involves two electrons and two protons,[16] which should yield a slope of −0.056 V per pH unit; this indicates that the observed process is kinetically limited.

The variation of i_p for the reduction of diazepam is linear with concentration both in ACP and in DPP; this permits the drawing of calibration curves for diazepam. Linear correlations over the concentration ranges 4.8–96 μM (DPP) and 17.4–167 μM (ACP) were obtained. Representative calibration graphs for diazepam resulted in the following linear regression equations:

$$y = 0.02017 + 0.01165x, \quad (r = 0.9975) \text{ (DPP)}$$

$$y = -0.00727 + 0.01261x, \quad (r = 0.9934) \text{ (ACP)}$$

where y, x and r correspond, respectively, to current peak (μA), drug concentration (μM) and linear correlation coefficient.

Commercial tablets of diazepam (Roche) labelled to contain 10 mg per tablet were assayed, using the extraction procedure proposed here. Table 1 reports the quantities obtained by DPP and spectrophotometric method (UV) (the adsorption lectures were performed at 266 nm). The precision of the polarographic technique was confirmed by analysing five replicate samples. The relative standard deviations are lower than 1% (Table 1), indicating good precision. The diazepam formulation can be detected by DPP with errors (<4%) lower than those obtained by the spectrophotometric method.

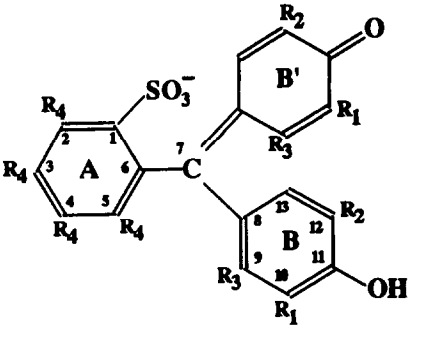
Summary—The pK values of the second ionization of a set of substituted sulfonephthaleins are studied by spectrophotometry and ^{13}C NMR spectroscopy. A study of the correlation between equilibrium and spectral data on the one hand and the substituent effects on the other is presented, using the dual substituent analysis of Swain and Lupton. This shows a complete dependence of pK values on the $\mathcal{F}$ field variable, and of the wavelengths of the bands of basic forms on the $\mathcal{R}$ resonance variable.

The study of the ionization of indicators dates back 70 years, when Kolthoff[1–5] published his first fundamental works on the subject. Since then the studies on this subject have been sporadic and unsystematic and unfortunately a classification of accurate data on indicators is lacking despite the widespread use of these substances, the upgrading of spectrophotometric methods, the availability of computing facilities and calculation techniques and IUPAC proposals.[6] In this work we present a spectrophotometric and ^{13}C NMR analysis of a class of indicators, the sulfonephthaleins, aimed at classifying in the first place their ionization and spectral features and secondly at accounting for the mechanism by which various substituents affect these properties. With a such knowledge the design and synthesis of indicators which satisfy user expectations will then be possible. In fact, because of their large and specialized use, indicators should be available with the greatest flexibility of colour and pK properties.

EXPERIMENTAL

Materials

The studied sulfonephthaleins, of the general formula here reported, were the 15 products shown in Table 1.



All these indicators were Aldrich products used without further purification.

Spectrophotometric measurements

Absorption spectra were recorded on a Hewlett-Packard 8452 diode array spectrophotometer; a flow cell was used joined to a titration vessel by a peristaltic pump; all the apparatus was thermostated at 25°C.

In order to make a reliable spectrophotometric determination of the ionization constant, 15–20 spectra (as those presented in Fig. 1) were collected at pH values equally spaced in a range ± 2 pH units around the pK value to be determined. This was achieved by titrating a weak non-absorbing $\cong 10^{-3}M$ acid, with a pK similar to that to be determined, using a $10^{-1}M$ base; in this way the concentration of the indicator undergoes only a very small dilution.

Table 1. Substituents R_1, R_2, R_3 and R_4 of the 15 studied sulfonephthaleins

Compound	Name	R_1	R_2	R_3	R_4
1	Cresol red	H	CH_3	H	H
2	Phenol red	H	H	H	H
2Br	3,4,5,6-Tetrabromophenolsulfonephthalein	H	H	H	Br
3	Bromocresol purple	Br	CH_3	H	H
4	Chlorophenol red	H	Cl	H	H
5	Bromochlorophenol blue	Br	Cl	H	H
6	Bromophenol blue	Br	Br	H	H
6Br	Tetrabromophenol blue	Br	Br	H	Br
7	3′,3″,5′,5″-Tetraiodophenolsulfonephthalein	I	I	H	H
$1CH_3$	Xylenol blue	H	CH_3	CH_3	H
$1'CH_3$	Thymol blue	H	$CH(CH_3)_2$	CH_3	H
$2CH_3$	Cresol purple	H	H	CH_3	H
$3CH_3$	Bromoxylenol blue	Br	CH_3	CH_3	H
$3'CH_3$	Bromothymol blue	Br	$CH(CH_3)_2$	CH_3	H
$6CH_3$	Bromocresol green	Br	Br	CH_3	H

In order to measure the 15 studied indicators (pK values 3.5–8.5) in the same medium, a mixture of seven acids (Table 2) with regularly increasing pK values was used.

The titration plot of such a mixture exhibits a typical trend in the 3–9 pH range (Fig. 2), which allows us to explore the neighbouring values of the pK of each studied indicator.

It was therefore possible to examine and record the spectra of the indicator at variable $[H^+]$ by titrating the mixture, containing the $\cong 10^{-5}M$ sulfonephthalein with KOH at an ionic strength of $0.1M$ KNO_3 and moving a portion of the solution to the flux cell after each KOH addition.

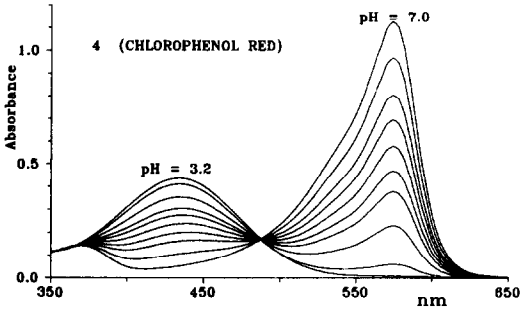

Fig. 1. Ten spectra of compound 4 (chlorophenol red) at a concentration of $2.8 \times 10^{-5}M$, collected in the 3.2–7.0 pH range are presented.

Table 2. Composition of the acid medium used for the spectrophotometric titration of the sulfonephthaleins. Refs 8–12 report the pK values for the above substances

Compound	Conc. $\times 10^3M$	pK_{exp}
Hydrochloric acid	8.000	—
Dichloroacetic acid[7]	0.6006	—
Monochloroacetic acid[8]	0.5250	2.837 ± 0.003
Acetic acid[9]	0.7725	4.629 ± 0.001
Pyridine[10]	0.7778	5.363 ± 0.002
2′-Aminopyridine[11]	1.001	6.812 ± 0.002
Ammonium hydroxide[12]	1.593	9.322 ± 0.001

Potentiometric studies

Titrations were performed on a Dosimat 655 Metrohm automatic titrator equipped with a Metrohm 654 pH meter, using a Metrohm combined pH electrode for highly alkaline solutions, at an ionic strength of $0.1M$ KNO_3. The solutions (25 cm^3) were titrated with KOH ($0.1M$) at 25°C under a nitrogen atmosphere and at the same conditions reported in a previous paper.[13]

Potentiometric data for the electrode standardization were analyzed with the Gran method[14] using our BASIC program GRANPLOT. The titrations for the potentiometric determination of the pK values reported in Table 2 were run under the same conditions and the concentration are $2 \times 10^{-3}M$. The ionization constants were calculated by a slightly modified version of the PSEQUAD program.[15]

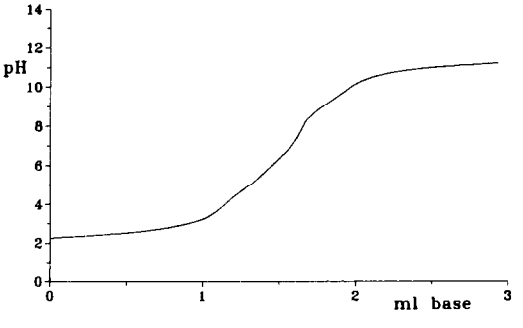

Fig. 2. Titration curve of the mixture of acids presented in Table 2. Absence of any net inflexion in the 2–10 pH range can be observed. Therefore also a region limited to two pH units can be thoroughly explored by proper titrant additions.

NMR measurement

Natural abundance ^{13}C NMR spectra were recorded on a Varian VXR-300 spectrometer at 75.43 MHz, using 10 mm diameter tubes. The ^{13}C spectra were ^{1}H decoupled by means of square wave modulation of the decoupler carrier, centred on the proton field. Solutions at pH > 8 were prepared in D_2O by adding NaOD. The carbon chemical shifts were measured at 25°C from the dioxane used as internal standard and the values so estimated were referred to TMS. Spectra were collected with a number of transients up to 10,000, depending on the aqueous solubility of the compounds.

Calculation of ionization constants of sulfonephthaleins

Matrix A of absorbance data for each sulfonephthalein, collected at N_w wavelength on N_s solutions of different pH, was analyzed with the program SPECFIT[16] which allows us to perform an Evolving Factor Analysis. EFA is a new powerful mathematical method for a model-free analysis of an ordered set of multi-wavelength data. When applied to spectrophotometric titration it allows to calculate both the concentration profiles and the spectra of all absorbing species, without using the law of mass action or defining the stoichiometric composition of the species. As a second step, SPECFIT allows the usual least-squares analysis of spectral data for calculating the equilibrium constants and spectra of all absorbing species.

RESULTS AND DISCUSSION

^{13}C NMR analysis

The NMR study has been limited to compounds exhibiting a sufficient solubility in water. The assignment of natural abundance ^{13}C spectra has been performed by comparing the NMR spectra with complete noise decoupling of the protons and the corresponding ^{1}H coupled spectra performed with gated decoupling.

It can be seen that the chemical shifts change significantly as the substituent group in the phenolic ring is changed, since they are induced by the usual inductive and mesomeric effects.

Particularly, we note that, unlike the remaining compounds, those with the methyl substituent in the *meta* position to the OH group give rise to two well distinct resonances for each carbon atom of the phenolic rings B and B′. This finding clearly shows that a hindered rotation of the phenolic rings around the C(7)–C(8) and C(7)–C(8′) bonds occurs, due to mutual steric interaction of the methyl substituents. This effect induces different average orientation of the two phenolic rings B and B′, which therefore experience different anisotropic shielding especially as far as the *meta* carbon atoms are concerned.

From these findings and considering that the chemical shifts of carbon atoms are in general affected by the substituent groups through a number of effects, such as electron densities, bond orders, orbital energies and

*No distinction can be made between C(3) and C(5) signals; the higher was therefore conventionally attributed to C(3).

local polarizations, which only rarely can be factored out, we estimated the substituent effects for the reported chemical shifts on a purely empirical basis. Subsequently the Grant and Paul[17] rules were also used to assign and/or substantiate the carbon resonances of the aromatic rings. The resulting assignments are reported in Table 3.

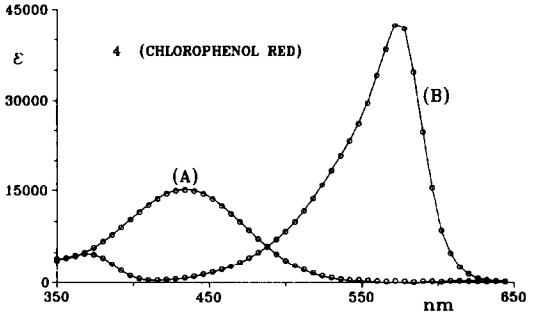

Fig. 4. The absorptivity spectra of the acid (A) and basic form (B) of chlorophenol red obtained by EFA are reported as continuous curves, while those obtained by least-squares calculations are reported as point.

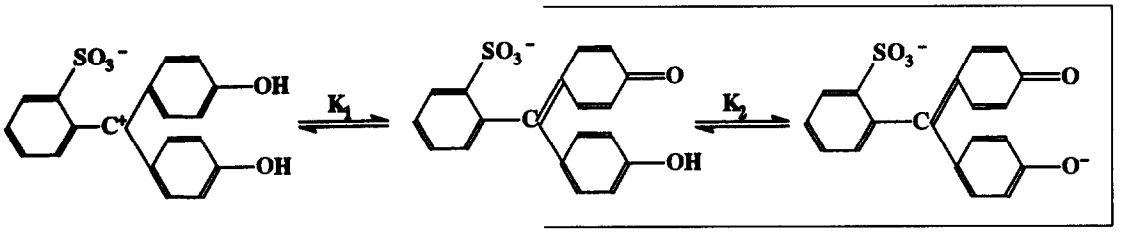
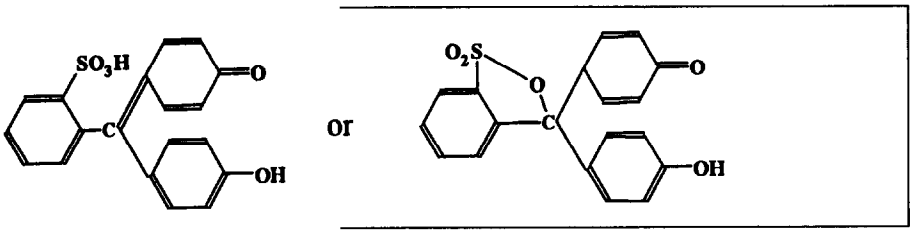
Equilibrium data

The dissociation scheme proposed by Kolthoff for this class of indicators takes into account two successive steps.



The structures of the neutral biprotonated form may also be represented as follows.



The pK_1 generally presents values below 2, while pK_2 ranges from 3.5 to 8.5 according to the substituents in the phenolic rings. In this work only the second ionization was taken into account. In Fig. 1 the experimental spectra of chlorophenol red in the 3.2–7 pH range are presented as an example. These data were analyzed by Evolving Factor Analysis (EFA): the factor analysis indicates the presence of only two absorbing species in the examined pH ranges. Without any model assumption, EFA has lead to the distribution curves in Fig. 3 and to the spectra in Fig. 4 reported as continuous lines.

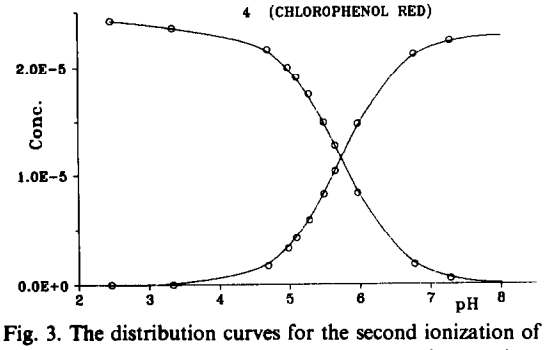


Fig. 3. The distribution curves for the second ionization of chlorophenol red obtained by EFA are reported as continuous curves, while those calculated with the pK 5.74 estimated by least-squares calculations are reported as points.

Still with the SPECFIT program, assuming a simple model of a single ionization and a guess of $pK_2 = 5.8$ obtained from the distribution curves in Fig. 3, it was possible to optimize both the pK value (5.74) and the spectra of the two species with a least squares procedure. The distribution curves and the spectra obtained with the optimized pK are reported as points in Figs 3 and 4, respectively. The very good agreement between the values obtained by EFA and those by the conventional least-squares method with model assumption can be clearly observed. This is not surprising in view of the very simple system studied and the high precision of the experimental measurements.

With an analogous procedure the pK values for all the studied indicators were calculated and are reported as pK_{exp} in Table 4.

The trend of pK values as a function of the substituents is shown in Fig. 5.

Using the unsubstituted indicator 2 as a basis for comparison, these data can be totally explained by assuming a proper ΔpK value for each kind of substituent. The $pK_{calc} = pK(2) + \Sigma\Delta pK$ calculated in this way are reported in the third column of Table 4. The Br substituents in the A ring seem to play no role in determining pKs.

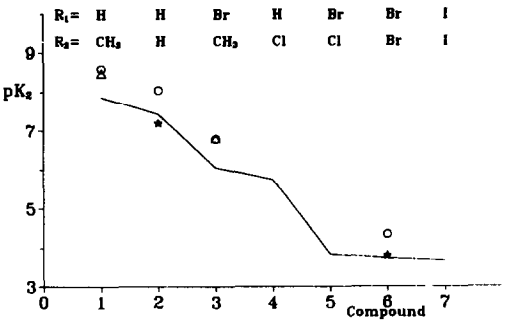

Fig. 5. The pK values of compounds 1–7 are reported as a continuous line; those of $1CH_3$, $2CH_3$, $3CH_3$ and $6CH_3$ as o, those of $1'CH_3$ and $3'CH_3$ as Δ and those of 2Br and 6Br as *.

UV–visible spectra

The spectra of the 15 indicators were also collected both in HCl and NaOH $10^{-2}M$ in the 250–700 nm spectral range, whereas in the equilibrium study it was not possible to collect data below 380 nm for the absorption of the buffer solution. The spectra of basic forms coincide with those obtained by SPECFIT least-squares calculations in the 400–700 nm range. In acidic medium, instead, a marked difference was observed in six cases. This is due to the high values of pK_1, and therefore to the existence of the completely protonated form in large amounts, since pH = 2. In these cases the spectra from SPECFIT, attributable to a single absorbing species, were therefore examined.

Some qualitative considerations can be made on the most intense band of the basic form:

(a) the absorptivity spectra of compounds 1–7 with only R_1 and R_2 substituents show a comparable intensity and reveal a shift from ≅560 nm for unsubstituted compound 2 to ≅575 nm for the monosubstituted compounds 1 and 4, to ≅595 nm for the disubstituted 3, 5 and 6 and to ≅600 nm for the disubstituted compound 7. The general pattern of the seven spectra is very similar;
(b) when R_4 = Br, a red shift of the spectra of about 30 nm is observed;
(c) the $R_3 = CH_3$ substituent causes a red shift of ≅25 nm of the band, accompanied by a drastic increase in halfbandwidth and a decrease in maximum absorptivity.

A very similar trend is also presented by the two bands of basic form at ≅300 and 380 nm, respectively, while the acid band at ≅450 nm does not show a sensible variation as a function of the substituents.

Table 4. pK values of the 15 studied sulfonephthaleins

†The pK_{calc} values were calculated with ΔpK values reported in Table 5.

Conclusive remarks

The good agreement between pK_{calc} and pK_{exp} values reported in Table 4 indicates that the effects of R_1 and R_2 substituents can be considered additive. An analysis of the substituent effects was therefore accomplished. The Swain and Lupton[19] dual substituent analysis, in the form $y = r_1\mathcal{F} + r_2\mathcal{R} + y_0$ was made on pK values, on wavelengths of maxima of basic forms and on NMR chemical shifts. On the basis of completely additive effects of substituents in

†C(11) exhibits two distinct NMR signals in the compounds of set 2, analyzed as set 2 and set 2*bis*, respectively.

R_1 and R_2, parameters $\mathcal{F}$ and $\mathcal{R}$ were taken as the sum of the tabulated values[19] for the various substituents. The data for the two sets of seven (1–7) and six ($1CH_3$–$6CH_3$) compounds, reported as set 1 and set 2, respectively, were analyzed, and the calculated r_1, r_2 and y_0 values are reported in Table 6.

A clear explanation of the dependence of the measured chemical properties of this class of indicators on the R_1 and R_2 substituents can be inferred on the basis of these results: 89% of variability of the pK values, for set 1, from the reference pK_0 value is explained by the $\mathcal{F}$ field variable; furthermore, if a linear regression of pK is calculated on the $\mathcal{F}$ field variable alone, as shown in Fig. 6, the value $\Sigma_{i=1}^{N} r_i^2$ of square residuals for this regression is greater than that reported in Table 6, for the dual substituent regression; nevertheless this difference is not significant at the confidence level 0.05, as can be calculated with an F test. Similar consideration can be made for the set of compounds with the CH_3 substituent on the C(9) carbon atom; the only observable difference is a shift of 0.6 pK units of the pK_0 values, while the slope is almost equal to that calculated for the first set. A purely inductive effect exerted by the R_1 and R_2 *ortho* substituents on the ionizable OH group is therefore evident, not perturbed by the CH_3 substituent in *meta*. The latter affects the pK values in the same direction as *ortho* CH_3; but its effect, which is greater than that of *ortho* CH_3, cannot be explained as only inductive; on the other hand no serious discrimination between inductive, resonance or steric contributions can be made on the basis of data for a single *meta* substituent. Steric contributions are certainly important according to NMR results.

The spectra of basic forms, which are the only ones to be affected by ring substituents, were decomposed in various components bands. The most important of these bands are reported in Table 7. The maximum wavelength of each band in the various compounds is strictly correlated with that of the other bands (except for band III, but this depends on the poor precision of its evaluation, connected to its low weight). Therefore any consideration made on the principal band can be generalized without loss of significance to the remaining bands. As for the pK values the Swain–Lupton analysis of the

band positions for the set of compounds 1–7 shows that the effect of substituents can be explained by only one independent variable; in this case, however, it isresonance parameter $\mathscr{R}$ that accounts for 94% of the variability around the reference value of the unsubstituted compound 2 as can be observed clearly in Fig. 7.

This total dependence on the resonance parameter is reasonable, since the spectra is due to a system of conjugated double bonds extended to the whole molecule. An analogous behaviour is observed for the set of the six *meta* substituted compounds, but two different behaviours are to be pointed out:

(i) a red shift of about 25 nm with respect to the analogous compounds without the *meta* CH_3 substituent;
(ii) a decrease of the intensities and an increase of half bandwidths.

These findings can be tentatively explained considering the non-equivalence of the two rings deduced from the NMR findings, upon R_3 substitution. Each of the two rings in this case should give a distinct single contribution to the electronic spectra, which therefore appear broader and lower.

As regards the swain and Lupton analysis of NMR chemical shifts, the C(11) carbon atom was examined, both because it is bonded to the studied acid group and because it does not feel vicinal effects, since it is the only carbon atom not in direct contact with any substituents. In this case both field and resonance variables $\mathscr{F}$ and $\mathscr{R}$ account for the chemical shift variations. The two examined sets do not depend on the two variables in the same way and this can be explained with steric effects of the CH_3 substituents, which play a further role in determining the $\delta_{C(11)}$ value: in fact in both sets 2 and 2*bis*, the contribution of the inductive effect with respect to the resonance effect is increased. This can be explained by a reduced resonance transmission in the hindered positions of rings B and B′ due to the CH_3 substituents.

Some considerations should be made on the two compounds with R_4 = Br: the pK values of these two compounds are not affected by the Br substituents and are equal to those of the parent compounds 2 and 6, respectively, as expected if one considers the behaviour of the other indicators. On the other hand, the spectra are affected to a great extent by the substituent Br group and show a red shift of about 30 nm. This confirms a resonance extended to the whole molecule, since C(7) is definitely not a carbocation, as demonstrated by its chemical shift.

To sum up, even though extended to a limited set of functional groups, the analysis of the mechanism of action of the various substituents can be considered reliable thanks to the additivity of the R_1 and R_2 effects, which expands the ranges of the independent variables. New indicators with particular features both of pK and colour can now be designed on the basis of the achieved knowledge.

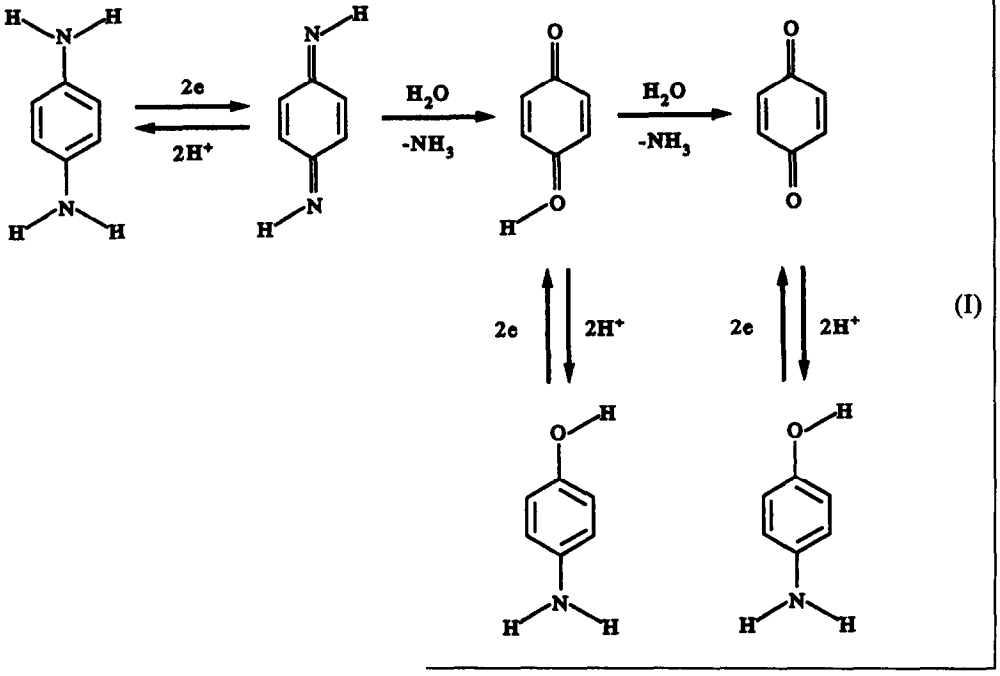
(*Received* 4 *February* 1993. *Accepted* 9 *April* 1993)

Summary—The electrochemical oxidation of 2,6-dichloro-1,4-phenylenediamine was studied at a glassy carbon electrode in a 50 vol% methanol–water mixture containing 0.1*M* $HClO_4$. Single sweep voltammograms are compared with curves obtained by digital simulation. Characteristic reaction parameters, such as formal potentials, charge transfer coefficients, rate constants of the electrochemical and the chemical steps, and diffusion coefficients, were determined from potential-step experiments in combination with a simulation–curvefitting routine.

The pioneering work of Adams *et al.*[1,2] on the anodic oxidation of *p*-phenylenediamine (PPD) and on several of its derivatives in aqueous media illustrates the complex coupling between electron transfer and chemical reactions.



(I)

Detailed investigations of electrode mechanisms require sophisticated electrochemical techniques, often combined with spectroelectrochemical experiments.[3–5] As pointed out by Heinze[6] and Gosser,[7] linear sweep (LSV) and cyclic voltammetry (CV) are among the most universal electrochemical techniques for qualitative and quantitative studies of complex electrode processes.

Based on the numerical solution of the corresponding integral equations for the LSV-and/or CV-response, Nicholson and Shain derived diagnostic criteria for various electrode mechanisms.[8–10] Their work was extended by contributions by Savéant *et al.* who introduced the concept of kinetic zones, defined via dimensionless rate constants for charge transfer and chemical steps, respectively.[11] The semi-integral technique, developed by Oldham *et al.*,[12,13] and

the equivalent convolution sweep voltammetry,[14] provide excellent tools to utilize all experimental data for analysis and parametrization of electrode reactions. Its application to nontrivial ECE-mechanisms was recently discussed by Neudeck and Dittrich.[15]

The concept of digital simulation developed by Feldberg[16] provides a powerful, independent route to the interpretation of linear and cyclic voltammograms. Model curves can be calculated for a multitude of electrode mechanisms and for various electrode geometries.[7,17,18] The original technique, based on an explicit approximation of the partial differential equations, has been complemented by two other methods. One is based on the implicit Crank–Nicholson technique to approximate the second derivatives of the digital concentration profiles.[19] The other uses orthogonal polynomials.[20]

The comparison between experimental and simulated linear sweep and cyclic voltammograms can provide qualitative information on the actual electrode mechanisms, as well as quantitative information on reaction parameters. Recent attempts have shown that the analysis of experimental data might be improved by combining digital simulation and/or semi-integration/semi-differentiation with multiple regression techniques.[21–24]

We have chosen to study the oxidation, at a glassy carbon electrode, of 2,6-dichloro-1,4-phenylenediamine (DCDP) in a 50 vol% water–methanol mixture containing 0.1*M* $HClO_4$. In view of the mechanism proposed for the oxidation of 1,4-phenylenediamine (Scheme 1), we have investigated the reduction of 2,6-dichloro-1,4-benzoquinone (DCQ), the oxidation of 2,6-dichloro-1,4-aminophenol (DAP) and DCDP at comparable experimental conditions by cyclic voltammetry and double potential step chrono-amperometry. The reaction parameters are determined (or, in some cases, optimized) by analyzing the cyclic voltammetric response in the slow scan regime with the simulation-fitting program CVFIT, described in[23]. In order to diminish the effect of adsorption, all quantitative experiments will be restricted to low scan rates and relatively high reactant concentrations (usually 1 m*M*).[25] Furthermore, we will assume that all protonations are at equilibrium.[26] The substitutions in the 2 and 6 positions prevent mechanistic complications due to the Michael reaction.

EXPERIMENTAL

All measurements were carried out at 298.2 K using a glassy carbon working electrode (Bio-Analytical Systems), a silver/silver chloride reference electrode connected via a liquid junction with the cell, and a platinum auxiliary electrode. The electrochemically active area was estimated from the analysis of the limiting diffusion current in cyclic voltammograms and single potential step transients[5] for aqueous solutions containing known concentrations $Fe(CN)_6^{3-}$ or $Fe(CN)_6^{4-}$. Using the literature values for the corresponding diffusion coefficients ($D = 7.6 \times 10^{-6}$ cm^2/sec and $D = 6.3 \times 10^{-6}$ cm^2/sec, respectively,[2] we calculated the electrode area A as 0.074 ($\pm$ 0.005) cm^2. The glassy carbon electrode was polished with Buehler 0.05 μm Micropolish alumina powder, and subsequently sonicated and rinsed with the base electrolyte solution before each measurement.

The electrochemical experiments were carried out with a home-built potentiostat, interfaced via a 12 bit ADC and a 12 bit DAC with a 80286-based computer. Positive feedback just short of oscillatory instability was used for compensation of the solution resistance. Generation of the excitation waveforms and data acquisition of the electrode response were controlled by commercially available software.[27]

The solutions were made from pyrodistilled water and from reagent grade (Baker "analyzed") methanol and $HClO_4$. All supporting electrolyte solutions were treated with activated charcoal and carefully deaerated before use. All solutions were freshly prepared and kept in an inert nitrogen atmosphere.

The 2,6-dichloro-1,4-phenylenediamine (DCDP) was synthesized[28] from 2,6-dichloro-1,4-nitroaniline (Aldrich) and recrystallized from ethanolic solutions. 2,6-dichloro-4-aminophenol (DCAP) was purchased from Aldrich and was recrystallized several times from ethanol before use. The 2,6-dichloro-1,4-benzoquinone (DCQ) was obtained from DCAP by oxidation and recrystallization,[29] 2,6-dichloro-hydroquinone (DCQH2) was synthesized from DCQ following Vogel's procedure,[30] and 2,6-dichloro-4-hydroxyaniline was prepared following the procedure described in Ref. 31.

DATA ANALYSIS

The cyclic voltammograms were recorded with a resolution of 1 mV per point, both for the

pure supporting electrolyte solution and in the presence of DCQ (reduction), DCAP (oxidation) or DCDP (oxidation). The charging current contribution of the base electrolyte was subtracted digitally, implying the assumption of a simple additivity of Faradaic and non-Faradaic currents. The scan rate varied between 5 mV/sec and 2 V/sec. The digital simulation and multiple regression were carried out with the program CVFIT,[23] which utilizes the modified simplex minimization procedure of Nelder and Mead to find the best fit between experimental and simulated results. The errors are estimated by unweighted summation of the squares of the differences between experimental currents i_{ex} and simulated currents i_{th} at the same potentials.

Fixed input parameters of the simulation were usually the electrode area A and the diffusion coefficients D_i of the individual species. The latter were determined from voltage step measurements under diffusion-controlled conditions according to

$$i = nFAc_i\sqrt{(D_i/\pi t)} \qquad (1)$$

where n is the number of electrons involved in the charge transfer, F, the Faraday constant, and c_i the bulk concentration of the electroactive species.

Initial parameter estimates for the simulation-fitting routine were provided for the formal potentials E_i, the standard heterogeneous charge transfer rate constants k_i, the transfer coefficients α_i and, in some cases, for the chemical rate constants k_{ci}. We note that the chemical rate constants have been determined independently from double potential step experiments $E_1 \rightarrow E_2(\tau) \rightarrow E_1$ and comparison with model curves of $i_c(t)/i_a(t-\tau)$ *vs* $k_{ci}\tau$ published by Schwarz and Shain.[32] Here τ is the time interval between the application of the two successive voltage steps.

In order to describe in a quantitative way the cyclic voltammograms of DCDP obtained at slow scan rates, we have assumed a mechanism similar to Scheme I. First we have analyzed the reduction of DCQ. Using the parameters so obtained for E_i, k_i and α_i as fixed input data, we have applied CVFIT to optimize simulated voltammograms for the oxidation of DCAP. Based on these results, we have tried to fit the experimentally obtained CV of the oxidation of DCDP with simulated curves. This approach decreases the number of freely adjustable input parameters.

RESULTS AND DISCUSSION

Reduction of 2,6-dichloro-1,4-benzoquinone

Figure 1 illustrates cyclic voltammograms at three different scan rates obtained for the

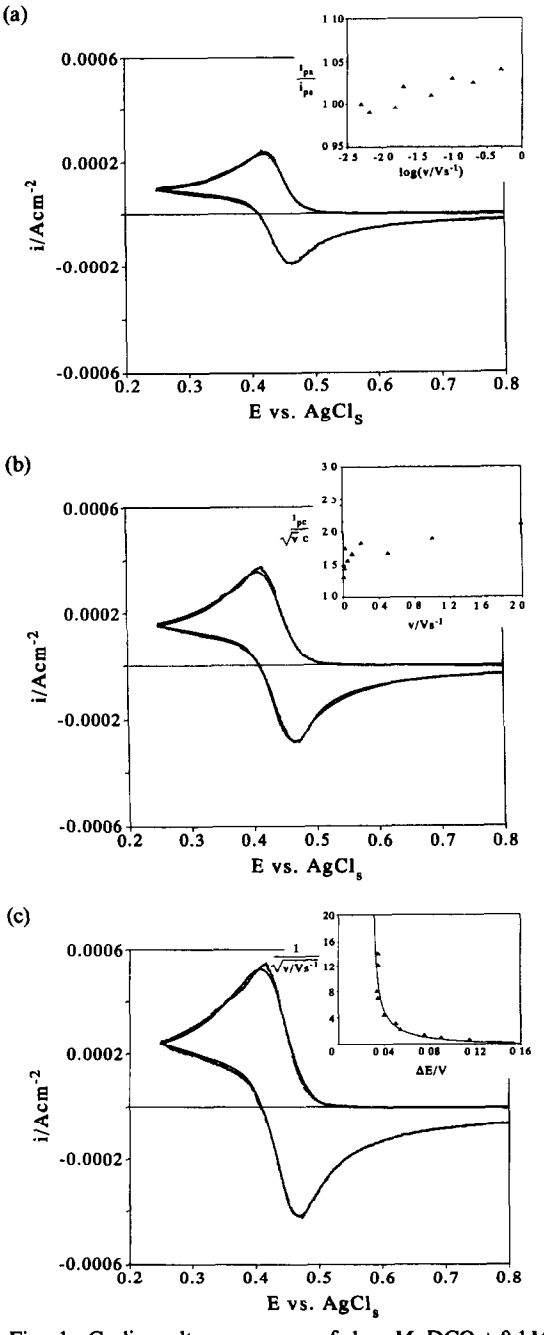


Fig. 1. Cyclic voltammograms of 1 mM DCQ + 0.1M $HClO_4$ in a 50 vol% methanol–water mixture at a glassy carbon electrode. The dotted lines are the experimental data, the solid lines are the result of the fitting routine, see Table 1. Scan rates: (a) 20 mV/sec; (b) 50 mV/sec; (c) 100 mV/sec. The insets illustrate (a) the ratio of the peak currents, (b) the normalized cathodic peak potential *vs* a scan rate function, and (c) $1/\sqrt{v}$ *vs* the peak-to-peak separation ΔE. The solid curve in Fig. 1(c) has been calculated with equation (3) using $k_{III} = 9.4 \times 10^{-3}$ cm/sec.

oxidation of 1 m*M* DCQ + 0.1 *M* $HClO_4$ in a 50 vol% methanol–water mixture at a glassy carbon electrode. We note that the peak current ratio i_{pa}/i_{pc} estimated from equation (2) is approximately 1 for scan rates between 5 mV/sec and 2 V/sec, see the inset in Fig. 1(a).

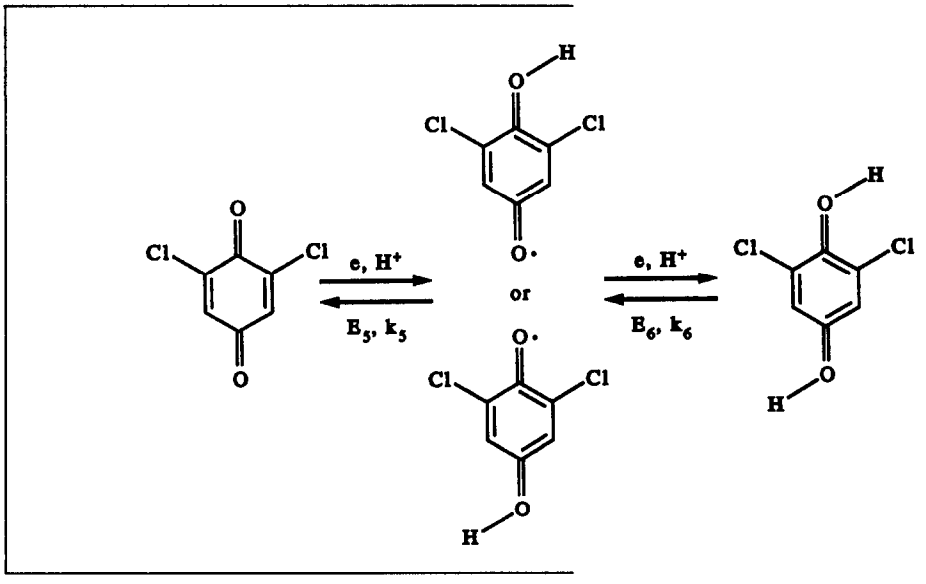
$$\frac{i_{pc}}{i_{pa}} = \frac{i_a(0)}{i_{pa}} + \frac{0.485 * i_s(0)}{i_{pa}} + 0.086 \qquad (2)$$

where $i_a(0)$ is the uncorrected anodic peak current, and $i_s(0)$ the uncorrected current at the switching potential E, both measured with respect to the zero-current base line[10].

Laviron[26] showed, on the basis of model calculations with $\alpha_i = 0.5$, that all protonations may be considered to be in equilibrium. Under those conditions, and at pH < 2, the complicated nine-membered square scheme reduces to a simpler CECE sequence:

$$Q \overset{H^+}{\rightleftharpoons} QH^+ \overset{e^-}{\rightleftharpoons} QH^\cdot \overset{H^+}{\rightleftharpoons} QH_2^+ \overset{e^-}{\rightleftharpoons} QH_2 \quad \text{(II)}$$

We have applied a similar approach to the reduction of DCQ under our experimental conditions. Assuming fast protonation reactions we formulate



(III)

Furthermore, the current function $i_{pa}/\sqrt{(vc)}$ increases with scan rate while i_{pa}/vc remains essentially constant, cf. the inset of Fig. 1(b). Both criteria point to weak adsorption of reactants and products.[25] At scan rates larger than 20 mV/sec the peak separation exceeds 30 mV and increases significantly with v, as shown in the inset of Fig. 1(c).

The more detailed analysis of our experimental voltammograms was based on results reported for the oxidation of the unsubstituted 1,4-benzoquinone (Q), at mercury[33] and platinum working electrodes.[34] Using those data, where E_5, E_6, k_5 and k_6 are apparent formal potentials and apparent rate constants of reactions 5 and 6, respectively. As shown by Laviron,[26] they reflect the coupling between charge transfer and protonation steps. In our case, the quasireversible electrochemical reaction should predominantly determine the values of k_5 and k_6. Finally, $E(\text{III})^\circ = \frac{1}{2}(E_5 + E_6)$ may be considered as the equilibrium potential for the reaction

$$DCQ + 2e^- + 2H^+ \rightleftharpoons DCQH_2 \qquad \text{(IIIa)}$$

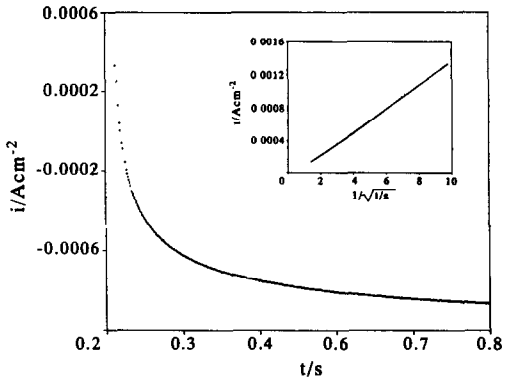


Fig. 2. Current response to a single potential step experiment $E_1 \rightarrow E_2$ with $E_1 = 0.800$ V, $E_2 = 0.200$ V and [DCQ] = $5.0 \times 10^{-4} M$. All other conditions were the same as in Fig. 1. The inset shows the experimental current i as a function of $1/\sqrt{t}$. The solid line was obtained from a linear regression analysis using $t > 0.016$ sec.

The application of Scheme III, with two subsequent one-electron reactions, to the description of our experimental data, was tested with the simulating-fitting routine CVFIT. In order to reduce as much as possible the contributions from adsorption, we have confined ourselves to low scan rates and to relatively high DCQ concentrations. Table 1 summarizes the parameters obtained, and Figs 1(a)–(c) illustrate the agreement between experimental and calculated voltammograms. The diffusion coefficients of DCQ and $DCQH_2$, under our experimental conditions, were determined with voltage step experiments $E_1 \rightarrow E_2$ where $E_1 = 0.800$ V and $E_2 = 0.200$ or 0.250 V, or with $E_1 = 0.250$ V and $E_2 = 0.700$ or 0.750 V, see Fig. 2. With the help of equation (1) we determined D_{DCQ} as $(7.0 \pm 0.3) \times 10^{-6}$ cm^2/sec and D^2_{DCQH} as $(7.0 \pm 0.2) \times 10^{-6}$ cm^2/sec. The diffusion coefficient D_{DCQH} was assumed to be equal to 7.0×10^{-6} cm^2/sec for the purpose of the simulation. The average value of the apparent formal potential E_6 is 54 mV more positive than E_5, which implies that the second one-electron step is thermodynamically more favored. The equilibrium potential E(III)° is estimated as (0.440 ± 0.005) V. The apparent rate constants k_5 and k_6, which primarily reflect the charge transfer step, differ by one order of magnitude, with k_5 being the smaller. A similar sequence was experimentally obtained for the reduction of 1,4-benzoquinone on platinum,[33] and was predicted on the basis of Laviron's theoretical analysis.[26] Both comparisons support the application of Scheme III to describe the reduction of DCQ from acidic media at low scan rates.

Furthermore, analysis of the peak separation as a function of scan rate,[15] using

$$k_{III} = 0.4325 \frac{nFDv}{RT} \times \{\sinh(9.428\ V^{-1}(nE - 0.05666))\}^{-1.044} \quad (3)$$

yields an overall rate constant of reaction III, $k_{III} = (9.4 \pm 0.9) \times 10^{-3}$ cm/sec. Equation (3) is

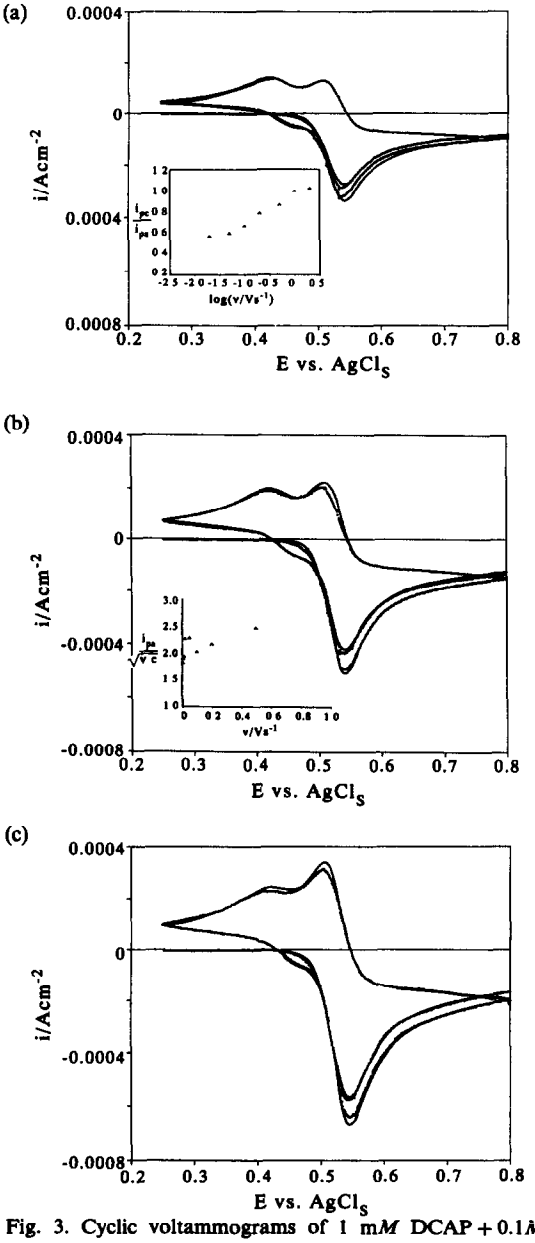

Fig. 3. Cyclic voltammograms of 1 mM DCAP + 0.1M $HClO_4$ in 50 vol% methanol–water at a glassy carbon electrode. The dotted lines show the experimental data, while the solid lines depict the results of the data fitting, see Table 2. Scan rates: (a) 20 mV/sec; (b) 50 mV/sec; (c) 100 mV/sec. The insets illustrate (a) the ratio of the peak currents corresponding to DCAP and (b) the normalized cathodic peak potential *vs* a scan rate function.

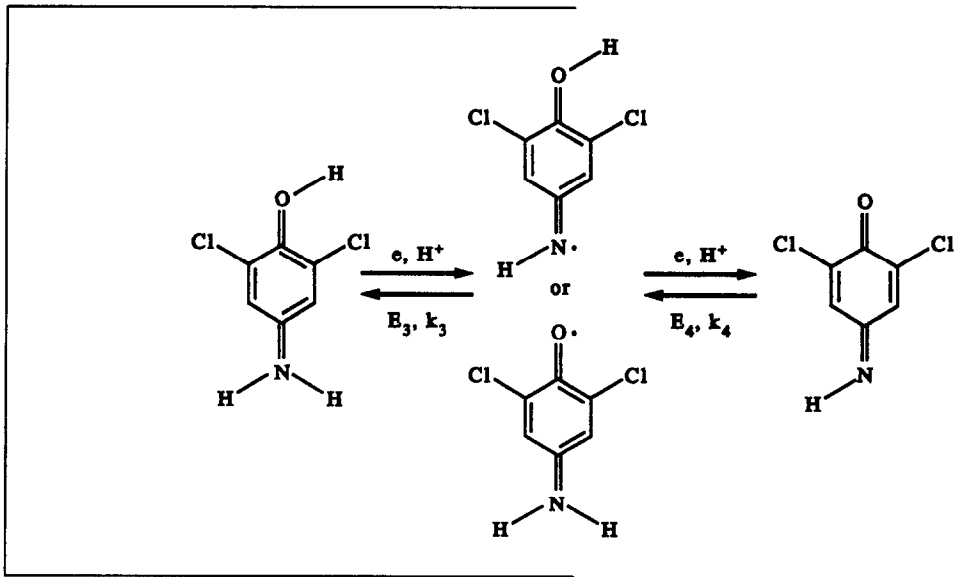
an analytical expression based on the parametrization of the kinetic parameters for quasi-reversible charge transfer reactions, as introduced by Nicholson and Shain.[8] The result is in agreement with the rate determining step obtained with CVFIT, see Table 1.



(IV)

We note that the values of the individual rate constants for the reduction of the unsubstituted quinone determined at mercury[32] and platinum electrodes[33] are lower than our results. This is likely to be caused by substituent effects, and possibly may also reflect the less pronounced interference from adsorption under our experimental conditions.

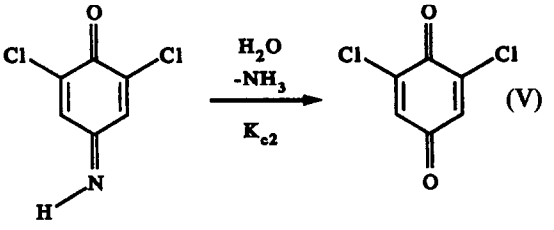
Oxidation of 2,6-dichloro-4-aminophenol (DCAP)

Figures 3(a)–(c) show typical cyclic voltammograms for the oxidation of DCAP at low scan rates and pH < 2. We observe one major anodic peak and two well developed cathodic waves. In view of Scheme I and the parameters obtained for the reduction of DCQ, we associate the more negative peak with the DCQ/DCQH$_2$-redox couple.

During the course of our further phenomenological analysis we will first focus on the processes responsible for the dominant anodic and cathodic peaks. The ratio of the peak currents i_{pc}/i_{pa}, estimated from equation (2), increases with scan rate, see the inset of Fig. 3(a). Furthermore, $i_{pa}/\sqrt{vc}$ increases slightly with v, cf. the inset in Fig. 3(b). The peak potentials E_{pa} and E_{pc} are not significantly influenced by the scan rate, provided that 0.005 V/sec < v < 2 V/sec.

Assuming fast protonation equilibria as in Scheme III we propose the following oxidation pathway:

The substituted quinone imine is unstable, and undergoes hydrolysis to the corresponding quinone:



(V)

The rate constant k_{c2} was obtained from double potential step experiments $E_1 \rightarrow E_2 \rightarrow E_1$, with $E_1 = 0.250$ V, $E_2 = 0.600$ V and $\tau_2 = 2.0$, 3.0, 4.0 or 5.0 sec, following the procedure described by Schwarz and Shain.[31] Figure 4 shows a typical transient as well as the ratio $i_c(t)/i_a(t-\tau)$ obtained for different times t. These experiments yield an average value for k_{c2} of (0.23 ± 0.04)/sec. The diffusion coefficient of DCAP in 50 vol% methanol–water mixture + 0.1M $HClO_4$ was obtained, according to equation (2), from the first part of the transient as $D_{DCAP} = (9.2 \pm 0.4) \times 10^{-6}$ cm^2/sec. For the purpose of the simulation, the diffusion coefficients of DCAP, of both semiquinoid species and of the corresponding quinone imines were considered to be identical.

The experimental voltammograms for the oxidation of DCAP were fitted to the

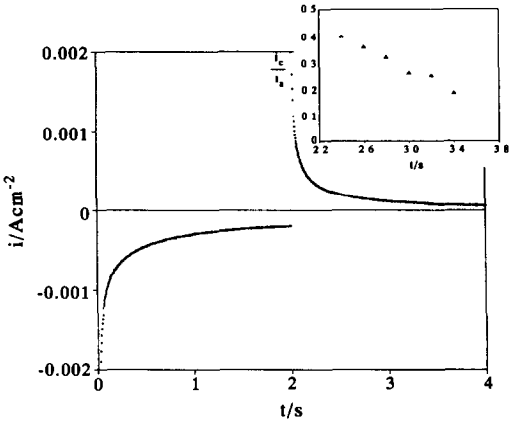


Fig. 4. Current response to a double potential step experiment $E_1 \rightarrow E_2 \rightarrow E_1$ with $E_1 = 0.250$ V, $E_2 = 0.600$ V, and $\tau_2 = 2.0$ sec. All other conditions were the same as in Fig. 3. The inset shows the ratio $i_c(t)/i_a(t-\tau)$ obtained for different times.

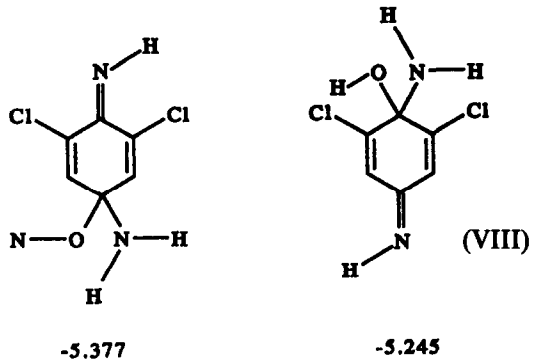
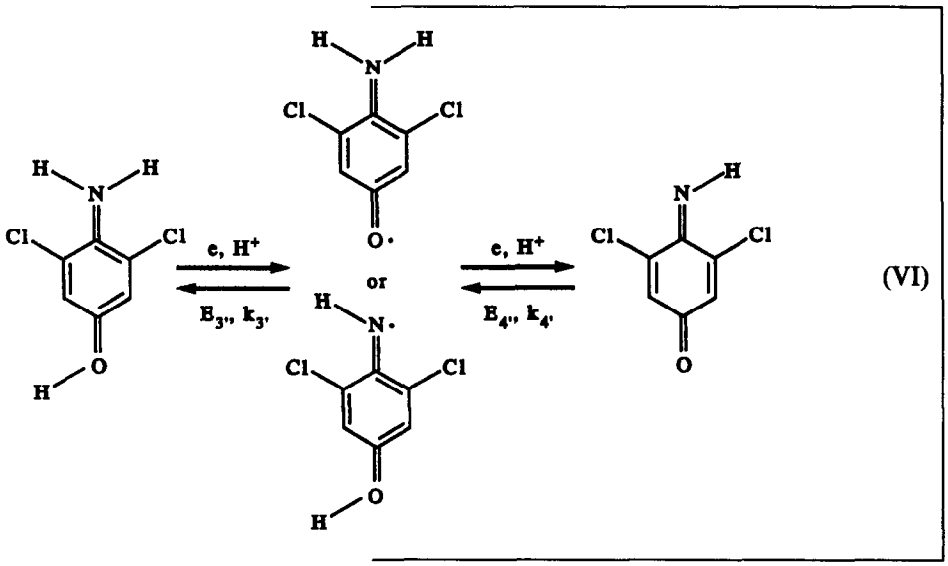
mechanism described by the combination of Schemes III–V. The DCQ data have been considered as fixed input data. The results are summarized in Table 2 and are plotted in Figs 3(a)–(c). We note that an alternative route to obtain DCQ from DCDP at our reaction conditions is via the second possible quinone imine formed by the oxidation of 2,6-dichloro-4-hydroxyaniline (DCHA).

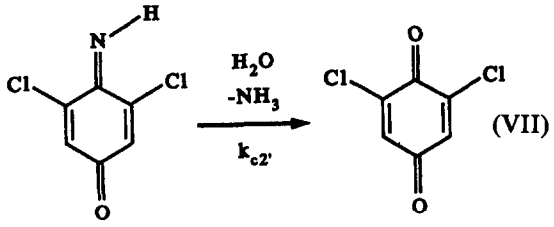


(VIII)

Our cyclic voltammetric and transient studies provided no distinguishable features on which to base a choice between the pathways represented by Schemes IV and V, or VI and VII, respectively. The parameter set compiled in Table 2 therefore represents both possible pathways. This approach is supported by the very similar values of the heats of formation of the two possible intermediates obtained from 2,6-dichloro-*p*-phenylenediimine, estimated with MNDO/2 calculations, Scheme VIII. The hydrolysis of 2,6-dichloro-*p*-phenylenediimine is initiated by the addition of water in either



(VI)



(VII)

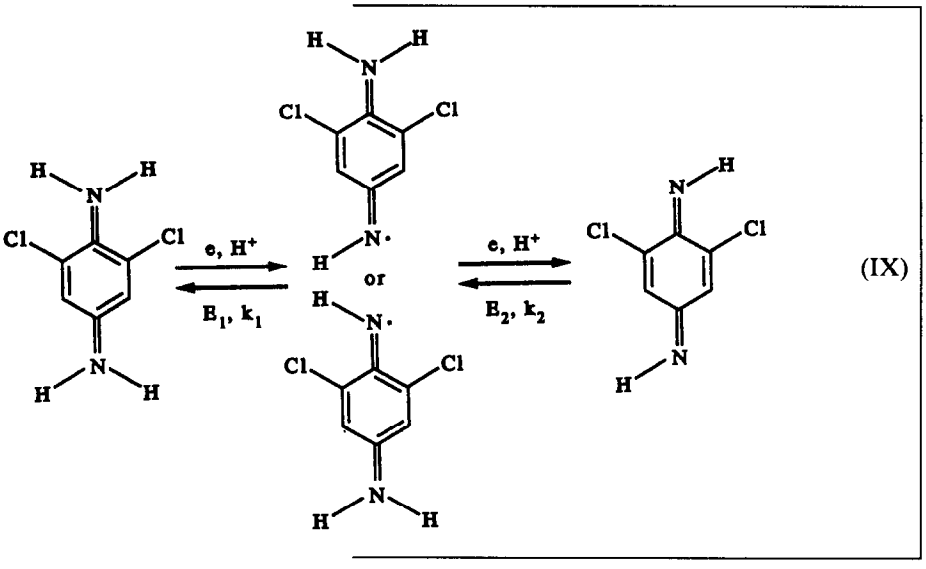
position 1 or 4. The elimination of ammonia then yields DCAP and/or DCHA.

Our results are close to those obtained by Adams *et al.* for the oxidation of DCAP at carbon paste electrodes from 0.05*M* H_2SO_4.[1] Comparison with the unsubstituted *p*-benzoquinoneimine shows that the presence of −I

and +M substituents such as chlorine increase the rate of hydrolysis.

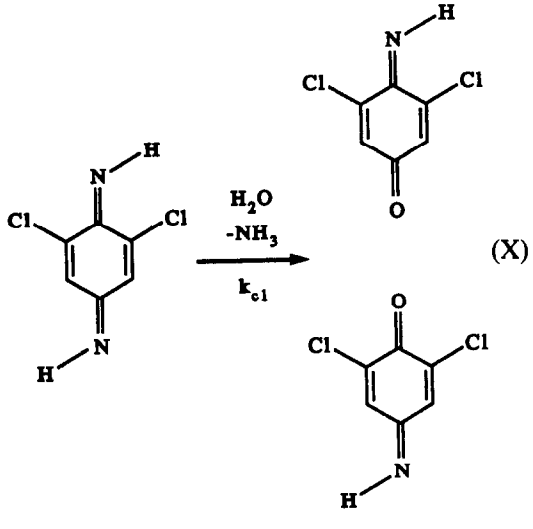
Oxidation of 2,6-dichloro-1,4-phenylenediamine

Representative voltammograms are shown in Figs 5(a)–(c). In view of our previous results, we associate the major anodic wave with the formulation of the 2,6-dichloro-1,4-quinonediimine according to:



(IX)

The latter is chemically unstable in acidic medium and, in a subsequent step, undergoes hydrolysis to one or both of the possible 2,6-dichloro-1,4-quinoneimines:



(X)

The peak ratio i_{pc}/i_{pa} of the major redox couple increases with increasing scan rate, which reflects the subsequent reaction X, see the inset of Fig. 5(a). As illustrated by the plot of $i_{pa}/\sqrt{(vc)}$ *vs* v, adsorption effects are not completely negligible cf. the inset of Fig. 5(b). The positions of the peak potentials are independent of the scan rate in the range 0.005 V/sec $< v <$ 2 V/sec. Diffusion coefficients and the rate of the chemical reaction shown in Scheme X were estimated from single and/or double potential step measurements along the lines described earlier. A typical experimental transient is shown in Fig. 6. The analysis of current transients in response to voltage step experiments yielded $D_{DCDP} = (9.2 \pm 0.6) \times 10^{-6}$ cm^2/sec. The value of k_{cl} amounts to (0.29 ± 0.05)/sec, determined from various double potential step measurements $E_1 \rightarrow E_2 \rightarrow E_1$ with $E_1 = 0.250$ V, $E_2 = 0.750$ V and $\tau_2 = 1.0$, 2.5 or 5 sec. Our experimental approach allowed no conclusive distinction between the two possible pathways of the hydrolysis of the quinonediimine as depicted in Scheme X.

Attempts to apply the simulation-fitting routine CVFIT to the theoretical description of the oxidation of DCDP, using the parameters determined for DCQ and DCAP, showed that a chemical rate constant $k_{cl} = (0.34 \pm 0.03)$/sec suffices to describe our experimental results. This is in reasonable agreement with the value obtained from current transients following voltage step experiments (Fig. 5, Table 3).

CONCLUSIONS

The anodic oxidation of 2,6-dichloro-1,4-phenylenediamine at a glassy carbon electrode can be described by the mechanisms II to

X, fully in accordance with the model originally proposed by Adams *et al.*[1,2] for the oxidation of *p*-phenylenediamine. The over-all fit shows considerable deviations at scan rates larger than 0.2 V/sec, due to adsorption effects, which are more pronounced at higher sweep rates.

Because of the complexity of the mechanism, independent control experiments were required in order to reduce the number of freely adjustable parameters to be used in the simulation routine. We believe that our results illustrate both the power and some of the inherent limitations of combining digital simulation with non-linear regression in the kinetic analysis of experimentally observed electrode processes.

SIMULTANEOUS DETERMINATION OF ACETYLSALICYLIC ACID AND CAFFEINE IN PHARMACEUTICALS BY FLOW INJECTION WITH FOURIER TRANSFORM INFRARED DETECTION

SALVADOR GARRIGUES, MÁXIMO GALLIGNANI and MIGUEL DE LA GUARDIA*

Department of Analytical Chemistry, University of Valencia, 50 Dr. Moliner St. 46100, Burjassot, Valencia, Spain

(*Received* 20 *January* 1993. *Revised* 7 *May* 1993. *Accepted* 21 *May* 1993)

Summary—A fast quality control methodology has been developed for the simultaneous determination of acetylsalicylic acid (ASA) and caffeine in pharmaceuticals by flow injection–Fourier Transform Infrared Spectrometry. The method is based on the solubilization of ASA and caffeine in CH_2Cl_2 and the use of a flow system to introduce samples and standards in the spectrometer. Two solutions, containing 90 and 110% of the reported concentration of the two active principles in the sample, were employed in order to control the extreme tolerance levels accepted by the International Pharmacopeia for the composition of formulations. A 300 μl volume of each solution was injected in turn, into a carrier stream of the sample, and their absorbances were measured at wavenumbers of 1770 and 1661/cm for ASA and caffeine, respectively. The absorbance values obtained for the carrier, at the same wavenumbers, were interpolated between those obtained for the standards. This rapid methodology provides a simultaneous quantitative evaluation of the concentration of ASA and caffeine in pharmaceuticals. The method permits us to carry out 53 injections/hr and provides a sensitivity of 0.231 absorbance units/mg ml/mm for ASA and 1.065 for caffeine. Accurate results were obtained for the analysis of different samples containing one or both compounds in the presence of excipients which are insoluble in CH_2Cl_2 and also in the presence of other active principles, such as acetaminophen or ergotamine tartrate.

Flow-injection (FI) is a well established sample handling methodology, based on the injection of samples or standards in a continuous flow carrier stream, which provides the automatization of different steps in the quantitative analysis.[1–3]

The use of FI in Infrared Spectrometric analysis (FI–IR) provides a simple and reproducible means of filling and cleaning the measurement cells[4] and offers important advantages in terms of reproducibility and saving of time and consumables. Moreover, the use of the Fourier Transform permits continuous monitoring of the spectral baseline[5] and simultaneous analysis of different components of the same sample.[6–8]

The few papers published until now on the use of FI–IR[4] and FI–FT–IR[5–13] have shown some of the possibilities offered by the synergistic combination of FI and infrared spectrometry. Some of these papers have been focused on the study of IR detectors in flow systems by means of the use of test molecules[4,10,11] and others have provided alternative methods for the analysis of paint solvents,[5,7,8] gasolines,[13] pesticides[14] and pharmaceuticals.[6,9,12] In this latter case several products, such as choline compounds,[6] aliphatic esters[9] and Ibuprofen[12] were determined in real samples.

In the analysis of pharmaceutical products, infrared spectrometry provides a suitable method for the identification[15] of drugs and also for their quantitative determination.[16,17] However, active principles in pharmaceuticals are usually determined by other spectrometric techniques, such as ultraviolet–visible spectrophotometry,[18] or by chromatographic methods,[19] specially when a multicomponent analysis must be made.

There are various reasons why IR quantitative analysis procedures have not been extensively developed for quality control of pharmaceuticals: (i) the excessive sample handling and time required for the traditional IR techniques, such as the use of alkali halide disks, mulls or thin films, (ii) the poor reproducibility of absorbance values obtained with liquid cells filled manually, (iii) the difficulty of establishing and controlling an appropriate baseline,

*Corresponding author.

especially when dispersive instrumentation is used, and (iv) the interferences among some active principles and also those due to the excipients commonly employed. However, most of these difficulties can be avoided by the hyphenation between FI and FT–IR and so, one of the objectives of the present paper is to evidence that FI–FT–IR can be a good choice for the simultaneous control analysis of different active principles in the same pharmaceutical product. Acetylsalicylic acid (ASA) and caffeine have been used as test molecules to prove the applicability of the FI–FT–IR for this purpose and so, a new analytical procedure has been developed for the simultaneous determination of these two compounds in pharmaceuticals.

Traditionally, ASA and caffeine are determined by volumetric procedures in non-aqueous media[18] or by ultraviolet–visible spectrometry.[20–23] Recently a series of chromatographic methods, based on the use of gas chromatography,[24] high performance thin layer chromatography (HPTLC)[25,26] or high performance liquid chromatography (HPLC), has been developed. This latter technique has been applied for the determination of ASA,[27] caffeine[28,29] or both[30–32] using ultraviolet detection.

FT–IR has been also employed as the detector for the analysis of mixtures of caffeine and ASA by HPLC[33,34] and by TLC.[35] Near infrared has been employed for the quantitative determination of caffeine[36] and mixtures of caffeine and ASA[37] and also FT–IR in the medium range, has been used for the quantitative determination of caffeine in pharmaceuticals[38–40] and for the determination of ASA.[41] However, to the best of our knowledge, no paper has been published on the simultaneous determination of caffeine and ASA by FT–IR either in batch or the flow analysis mode.

Direct injection of samples in a FI manifold is a convenient procedure to obtain a fast analysis but it provides, in general, an excessive dispersion of samples. In the present study, taking into account the reduced sensitivity of the infrared techniques, we have employed two alternative strategies in order to reduce the sample dispersion in the flow injection system: (i) the stopped-flow mode,[7,14] which enhances the limit of detection of the analytical measurements, by improving the signal to noise ratio in a series of accumulated scans, and (ii) the reversed mode flow injection, which was first suggested by Johnson and Petty[42] and has been extensively employed in ultraviolet–visible spectrometric analysis by the Valcárcel group.[43–45] This consists of injecting standards in a carrier stream of samples. In the case of analysis of pharmaceuticals, this opens up new possibilities in order to develop fast analytical procedures for the quality control of these materials.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Fourier Transform Infrared spectrometer, model 1750, with a temperature stabilized DTGS detector and equipped with a 7700 data station, was used to carry out infrared measurements, both in the stopped-flow and in the reversed flow mode. In all cases a micro-flow cell SPECAC (Orpington, U.K.) with KBr windows, with a 5 μl volume, for a 0.117 mm Pb spacer, was employed. To carry out the simultaneous FT–IR measurements in the reversed flow mode, a series of computer programs, developed by us and previously described,[5,8] were employed.

The manifolds indicated in Fig. 1 permit a fast and reproducible filling and cleaning of the micro-flow cell for the stopped-flow measurements (1A) and the reversed FT–IR flow analysis of pharmaceuticals (1B).

Two Gilson P-2 Minipuls peristaltic pumps with Viton (iso-versinic) flexible tubes of 0.15 cm internal diameter were used to transport CH_2Cl_2 or the corresponding carrier solutions and to introduce samples and standards into the flow cell. The use of a second pump to fill the injection valve, or to introduce the sample into the cell, avoids bubble formation, contamination and memory effects. The presence of

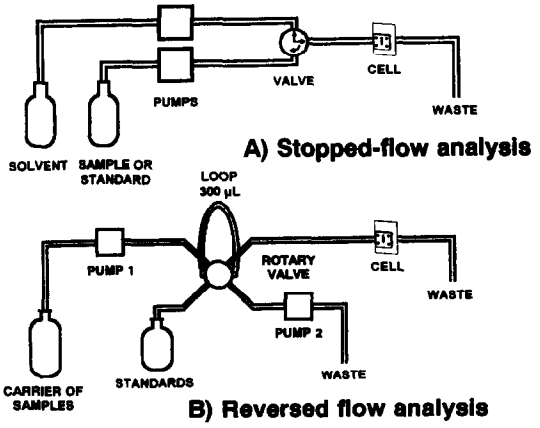

Fig. 1. Manifolds employed for: (A) stopped-flow FT–IR measurement, and (B) reversed flow analysis.

bubbles, observed when only one pump was employed in a single channel manifold, can be attributed to the low boiling point of CH_2Cl_2 which causes gas (vapour phase) formation in the coils when injected samples remain stopped inside flexible tubes during a period of time. So, the use of a second channel, employed for the continuous transport of samples is very convenient and avoids the formation of bubbles. On the other hand the use of a second pump permits reduction of the consumption of reagents because it is not necessary to operate continuously as when a second channel of the same pump is employed. A rheodyne 50 injection valve, with a fixed volume loop of 300 μl, was employed for the standard injection in the reversed flow mode, but, in the stopped-flow procedure, only a three way directional valve is required to select the solvent or the sample flow alternately.

All the tubes to connect the different parts of the two manifolds are made in Teflon[tm] and they have a 0.8 mm internal diameter.

Reagents

Acetylsalicylic acid and caffeine standards were obtained from FLUKA (Switzerland). Analytical grade dichlormethane (Panreac, Barcelona, Spain) was dried by using 4 Å molecular sieves obtained from SDS (France) and employed for the preparation of standards and samples. The choice of CH_2Cl_2 is due to the fact that it is very transparent to infrared radiation and it completely solubilizes ASA and caffeine but, in the samples excipients remain undissolved and so it avoids some matrix effects. Other solvents more commonly employed in IR analysis, such as CCl_4 and hexane, were not employed because they do not solubilize ASA.

The six following analgesic formulations were analyzed by FI–FT–IR: ASPIRINA® (from Bayer) tablets containing 500 mg of ASA per unit; CAFIASPIRINA® (from Bayer) tablets containing 500 mg of ASA and 50 mg of caffeine per unit; MEJORAL® (from Bayer) tablets containing 500 mg of ASA and 30 mg of caffeine per unit; CAFERGOT® (from Sandoz) sugar coated pills containing 100 mg of caffeine and 1 mg of ergotamine tartrate per unit; FIORINAL® (from Sandoz) capsules containing 200 mg of ASA, 40 mg of caffeine and 300 mg of acetaminophen per unit; NEOCIBALENA® (from Ciba-Geigy) tablets containing 200 mg of ASA, 50 mg of caffeine and 150 mg of acetaminophen per unit.

[*] All the names of the analgesic formulations analyzed are trade names registered in Spain by the Pharmaceutical Laboratories.

GENERAL PROCEDURE

FI–FT–IR determination of ASA and caffeine

To determine ASA and caffeine in a pharmaceutical preparation, an appropriate amount of sample must be accurately weighed and dissolved with CH_2Cl_2 in order to obtain an ASA concentration of approximately 10 mg/ml and a caffeine concentration of 1 mg/ml. Both compounds are highly soluble in CH_2Cl_2, but excipients in general and other active principles cannot be dissolved and thus, after manually shaking for a few seconds, the samples can be filtered or centrifuged to separate the undissolved part. After that, sample solutions are continuously introduced as the carrier in the manifold in Fig. 1(b) using a constant flow of 0.81 ml/min, and the absorbance peak height is measured at 1770/cm for ASA and 1661/cm for caffeine, using a common baseline established between 1900 and 1537/cm. 300 μl of a CH_2Cl_2 standard solution, containing ASA and caffeine in a concentration equal to 90% of the theoretical concentration of the sample to be analyzed, is injected in the above-mentioned sample carrier flow. After that, the same volume of another standard solution, containing 110% of the theoretical concentration of ASA and caffeine in the sample, is injected, and the absorbance measurements are carried out for both standard solutions in the same conditions employed for the samples. The two standards injected correspond to the lower and upper level permitted by the Pharmacopoeia for the specifications of pharmaceuticals. So, the absorbance values for the sample carrier must be between those found for the standards. To determine the ASA and caffeine concentrations, the absorbance peak height values of the sample are interpolated between the two points of the calibration line established for the two standard solutions injected. For the analysis of each sample, the carrier and the concentrations of the standard solutions must be changed according to the pharmaceutical to be analyzed.

RESULTS AND DISCUSSION

FT–IR spectra of ASA and caffeine

The FT–IR absorbance spectra of ASA and caffeine, obtained in CH_2Cl_2 solutions, present

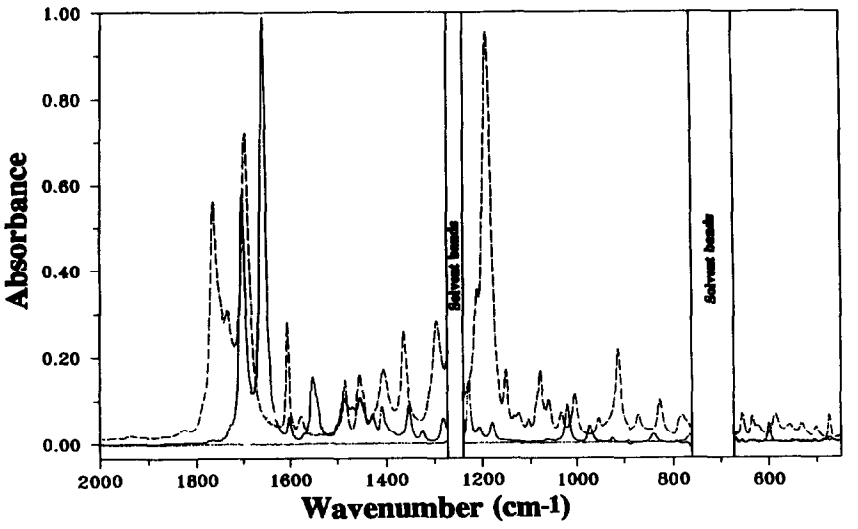

Fig. 2. FT–IR spectra of pure solutions of acetylsalicylic acid 20 mg/ml (– – –) and caffeine 8 mg/ml (——) in CH_2Cl_2.

well defined and very intense bands in the wavenumber range between 1800 and 1200/cm, being those at 1198/cm for ASA and 1661/cm for caffeine the most sensitive (see Fig. 2).

The ASA band at 1198/cm is too close to the non-transparent range of the CH_2Cl_2 and it is overlapped with small bands of caffeine. In the range between 1800 and 1675/cm ASA presents a series of intense bands. However, as it can be seen in Fig. 3, an increase in the concentration of ASA in the range between 0.2 and 20 mg/ml, modifies the relative intensity of these bands, being that at 1703/cm the most sensitive only for concentrations higher than 5 mg/ml. The band of ASA at 1770/cm is the only one which obeys Beer's law, as it can be seen in Fig. 3(c) and which is not overlapped with those of caffeine, and so it seems the most appropriate for the ASA determination.

Caffeine has been determined by IR spec-

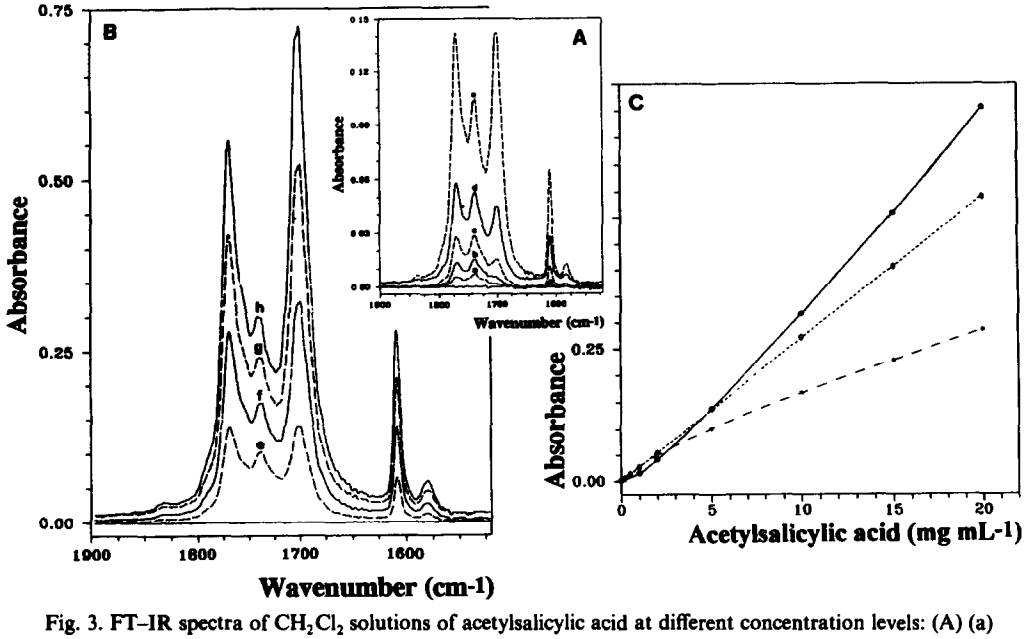

Fig. 3. FT–IR spectra of CH_2Cl_2 solutions of acetylsalicylic acid at different concentration levels: (A) (a) 0.2 mg/ml, (b) 0.5 mg/ml, (c) 1 mg/ml, (d) 2 mg/ml, (e) 5 mg/ml. (B) (f) 10 mg/ml, (g) 15 mg/ml, (h) 20 mg/ml. (C) calibration lines obtained for pure acetylsalicylic acid solutions in CH_2Cl_2, measured at different wavenumbers: (○) 1703/cm, (◇) 1770/cm and (*) 1738/cm.

troscopy in the region between 650 and 400/cm.[40] However, caffeine bands in this range are less sensitive than that at 1661/cm. Thus this latter band represents the best potential wavenumber for the determination of caffeine in the presence of ASA.

A common baseline between 1900 and 1520 or between 1900 and 1537/cm can be established for bands considered for the determination of ASA and caffeine. In standard solutions, both baselines provide comparable results, but in complex samples, which include other active principles, the base-line between 1900 and 1537/cm avoids interferences and provides the most accurate results.

Direct determination of ASA

Stopped-flow measurements, carried out in the above mentioned conditions, provides a typical calibration line for ASA (in the concentration range between 1 and 20 mg/ml) which corresponds to $A = 0.000_6(\pm 0.0006) + 0.0270_5(\pm 0.00006)C_{(\text{in mg/ml})}$ with a regression coefficient, R, of 0.99998. This equation is close similar to that obtained for another series of standards in the presence of a 1:10 caffeine: ASA proportion, which corresponds to an equation $A = 0.000_9(\pm 0.0005) + 0.0270_1(\pm 0.00005)C_{(\text{in mg/ml})}$ with $R = 0.99998$. So, a calibration line, defined from pure solutions of ASA in CH_2Cl_2, can be used for the direct determination of ASA in pharmaceuticals containing also caffeine. Accurate results can be also obtained in the presence of other compounds, such as acetaminophen, which do not interfere with the 1770/cm bands of ASA.

Interference of ASA in the FT–IR determination of caffeine

ASA interferes on the FT–IR determination of caffeine as it can be seen in Fig. 4. For a fixed concentration of 1 mg/ml of caffeine, ASA concentrations lower than 8 mg/ml cause a little negative interference in the absorbance of caffeine which provides a maximum interference of the order of −5% in relative absorbance. Higher concentrations of ASA cause a positive interference in the caffeine absorbance measurements; for an ASA:caffeine proportion higher than 20:1, the relative error of the absorbance is higher than +10%.

The interference of ASA on the caffeine determination by FT–IR can be attributed to the proximity between the absorbance bands of

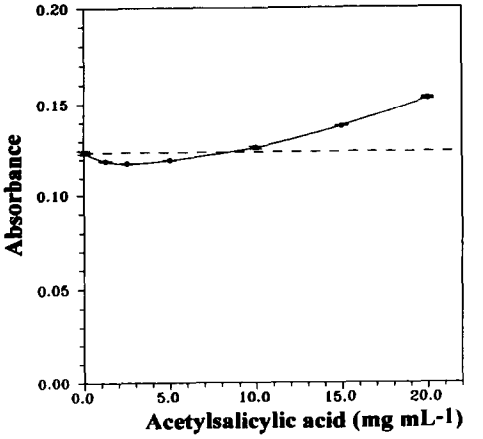

Fig. 4. Effect of the ASA concentration on the absorbance values of caffeine at 1661/cm for a fixed concentration of caffeine of 1 mg/ml.

these compounds and this is aggravated by the high concentration of ASA in pharmaceuticals containing caffeine. For low ASA concentrations this interference is very little and the small errors caused are due to changes in the baseline which reduces the peak height of the caffeine absorbance at 1661/cm. In this case caffeine concentrations lower than real ones were obtained due to the variation of the absorbance of ASA at 1703/cm as indicated in Fig. 3. The positive interference found at high ASA concentration levels must be attributed to the contribution of the intense band of ASA at 1703/cm which increases with the ASA concentration and overlaps with the 1661/cm band of caffeine.

The change in the relative absorbance of ASA at 1703/cm, as a function of the ASA concentration (Fig. 3), hinders the possibility of correcting its interference in the caffeine determination by means of the use of derivative measurements.

FT–IR determination of caffeine

A typical calibration line obtained from pure standards of caffeine in CH_2Cl_2, in a concentration range between 0.1 and 2 mg/ml, corresponds to an equation $A = 0.0008(\pm 0.0004) + 0.1246(\pm 0.0004)C_{(\text{in mg/ml})}$ with $R = 0.99997$. This equation has a slope of the same order than that obtained from standard solutions containing ASA and caffeine in a 10:1 proportion, which is $A = 0.003(\pm 0.001) + 0.123(\pm 0.001)C_{(\text{in mg/ml})}$ with $R = 0.9998$. For this proportion, the interference of ASA has a minimum value (see Fig. 4); however, the high value of the

intercept in this latter equation, evidences the overlapping with the band of ASA.

From these experiments it can be recommended to prepare standard solutions for the determination of caffeine with a similar content of ASA than that of the samples to be analyzed.

Some indications about the order of magnitude of the error which can be found by using standards of pure caffeine for the analysis of samples containing ASA and caffeine can be obtained from the following examples. A caffeine amount of 33.4 mg per tablet was obtained for a sample with 30 mg of caffeine and 500 mg of ASA and a value of 50.1 mg of caffeine per tablet was found for a sample containing 50 mg of caffeine and 500 mg of ASA. Using a calibration line in which ASA was added to the caffeine standards, the above mentioned samples provide values of 29.6 mg per tablet and 49.6 mg, respectively.

Effect of the sample weight

The high dynamic range provided by the FT–IR determination of ASA and caffeine, in the above mentioned conditions, makes possible to work at different dilution levels of the sample, and accurate and precise results were found for a sample amount from 50 to 750 mg dissolved in 25 ml of CH_2Cl_2.

Figures of merit of the FT–IR determination of ASA and caffeine

In the above mentioned conditions, the main figures of merit of the FT–IR determination of ASA and caffeine have been established from the characteristics of the analytical lines and also from a series of analysis carried out at different concentration levels. Table 1 summarizes the values found for the dynamic range, sensitivity, limit of detection and repeatability obtained for each compound considered.

Table 1. Figures of merit of the FT–IR determination of ASA and caffeine in CH_2Cl_2 solutions

Parameter	ASA	Caffeine
Dynamic range *mg/ml*	0–20	0–4
Sensitivity *au/mg ml/mm*	0.231	1.065
Limit of detection *μg/ml* (3σ)	22	5.8
Repeatability *RSD% $n^* = 5$	0.14	0.16
Precision RSD% $n^{**} = 3$	0.5	1.1

*RSD: relative standard deviation. $n^* = 5$ measurements of a sample containing 12 *mg/ml* ASA and 1.2 *mg/ml* caffeine, $n^{**} = 3$ independent analysis of the same sample.

The sensitivity was obtained from the slope of the calibration line and taking into account the bandpass of the cell employed for measurements.

The limit of detection was established for a probability level of 99.6% ($k = 3$), from the standard deviation of 10 independent measurements of a blank solution (3σ) and from the corresponding sensitivity for each compound.

The repeatability was calculated in terms of the variation coefficient (relative standard deviation expressed in percentage) obtained for five absorbance measurements of a same solution containing 12 mg/ml of ASA and 1.2 mg/ml of caffeine and the precision from the variation coefficient for three independent analysis of the same sample.

From results obtained, it can be concluded that FT–IR provides an adequate sensitivity and reproducibility for the determination of ASA and caffeine in pharmaceuticals; the sensitivity for this latter compound at 1661/cm in CH_2Cl_2 solutions being five times higher than that obtained for ASA at 1770/cm.

Analysis of real samples

Samples described in the Experimental section were analyzed in the stopped-flow mode by using a common calibration line obtained with standards containing ASA and caffeine in a 10:1 proportion. Results obtained are summarized in Table 2 and, although all the values found are in the range tolerated by the Pharmacopoeia, it could be convenient to use appropriate sets of standards for each kind of samples.

Reversed flow-injection–FT–IR simultaneous determination of ASA and caffeine

As has been previously indicated, FI–FT–IR can provide simultaneous information about different components of the same sample[6–8] and, as can be seen in Fig. 5, which shows the spectra of three solutions with different concentrations of ASA and caffeine, it is possible to obtain, from the same spectrum, absorbance peak values from which both ASA and caffeine can be simultaneously determined. Arrows in this figure indicate the ASA and caffeine peaks obtained for each solution. Bold lines show the maximum absorbance values reached for ASA and dotted lines evidences that the carrier

Table 2. Analysis of real samples by FI–FT–IR spectrometry

Pharmaceutical	Active principle	Theoretical content (mg per tablet)	Results found (mg per tablet) Stopped-flow	Reversed-FI
Aspirina	ASA	500	509	501
Cafiaspirina	ASA	500	504	501
	Caffeine	50	49.6	50.0
Mejoral	ASA	500	497	495
	Caffeine	30	34.1	29.6
Fiorinal	ASA	200	186	198
	Caffeine	40	38.6	43.2
Neocibalena	ASA	200	182	187
	Caffeine	50	43.6	47
Cafergot	Caffeine	100	94	101

solution of the sample to be analyzed (B) provides an absorbance peak value between those found for the two standard solutions injected (A and C). The sample effect can be also observed for caffeine by measuring the peak height at 1661/cm.

The use of reversed-flow injection FT–IR permits rapid determination of ASA and caffeine in pharmaceuticals. As has been described in the Experimental Part, the injection of standard solutions containing ASA and caffeine (in the same relative proportion as the samples) in a carrier stream of a CH_2Cl_2 solution of each sample provides reference values which can be used for the quantitative analysis of these two compounds. This basic idea, taken from the principles of reversed flow analysis[42–45] and on-line standard additions,[46,47] offers new possibilities in fast quality control of pharmaceuticals by providing a comparison of the samples with the extreme values permitted by the Pharmacopoeia for the content of active principles in pharmaceutical preparations (from 90 to 110% of the reported value).

Figure 6 shows the FI recording established at 1770 and 1661/cm, for the injection of two standard solutions containing 9 mg/ml ASA and 0.9 mg/ml caffeine and 11 mg/ml ASA and 1.1 mg/ml caffeine, respectively in a carrier of a sample of ASA and caffeine. As can be seen the carrier solution provides absorbance values between those obtained for the injected standards

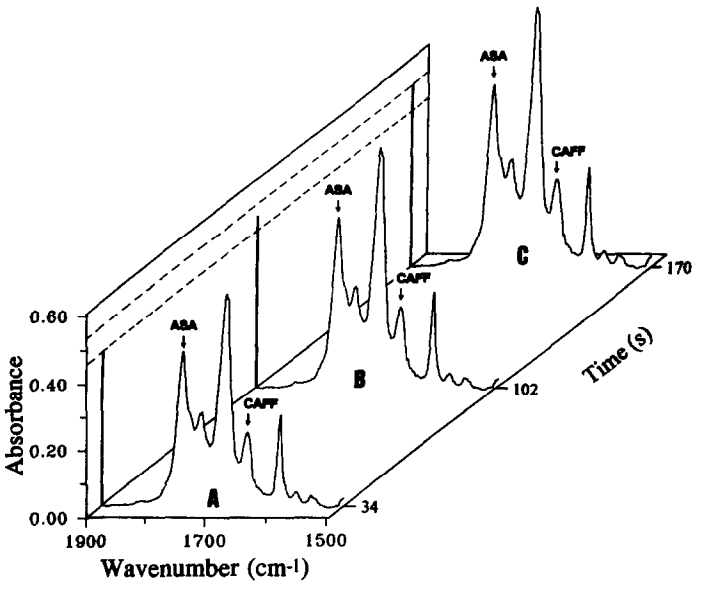

Fig. 5. FT–IR spectra obtained, as a function of time, for: (A) the injection of a standard solution of ASA and caffeine in CH_2Cl_2 containing 9 mg/ml ASA and 0.9 mg/ml caffeine, (B) a carrier solution of a sample with a theoretical content of 10 mg/ml ASA and 1 mg/ml caffeine and (C) the injection of a standard solution containing 11 mg/ml ASA and 1.1 mg/ml caffeine. These figures show only the maximum absorbance values reached for each one of the three solutions considered; intermediate values have been deleted in order to present the spectra from which the flow injection peak height values can be established.

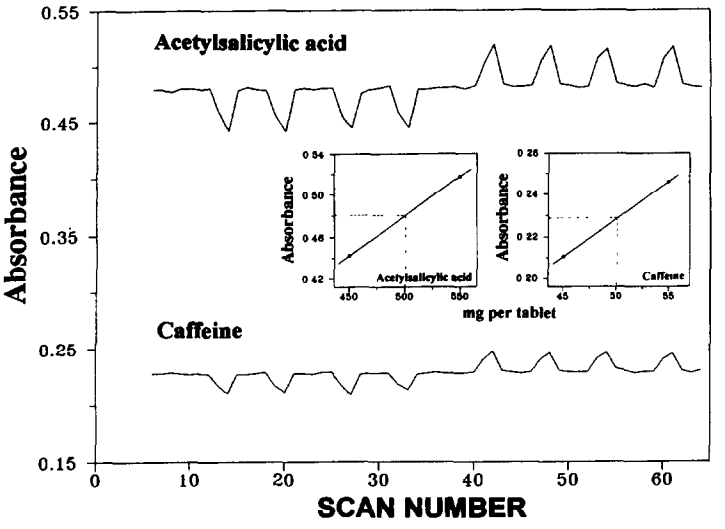

Fig. 6. Flow injection recording obtained by the reversed mode for the simultaneous determination of acetylsalicylic acid and caffeine in a pharmaceutical preparation. Inset: calibration lines obtained for the determination of ASA and caffeine from the injection of the two standard solutions in the sample carrier stream.

and it evidences that the concentration of the active principles in the sample agree with the reported value. Moreover, the content of ASA and caffeine in the sample can be determined from the peak height values found for sample and standards, by interpolation as described in the insets of this figure.

Following this procedure (described in the Experimental section) a series of real samples were analyzed and results found are summarized in Table 2. Results found evidence that the developed procedure is very accurate and permits a fast quality control of pharmaceuticals.

The FI–FT–IR procedure permits us to carry out 53 injections/hr (taking into account that the use of the 7700 Data Station requires more than 17 sec to obtain and store a full interferogram, working with a nominal resolution of 4/cm). However, this sample frequency can be increased by working with a faster instrumentation and software.

The quantitative analysis of a sample, by using the on-line injection of two reference standards in a sample carrier solution, takes less than 15 min to obtain results for both compounds from four repetitive injections of each standard solution.

CONCLUSIONS

ASA can be directly analyzed in pharmaceuticals by FT–IR at 1770/cm; caffeine, acetaminophen and ergotamine tartrate do not interfere with this determination.

The interference of ASA on the FT–IR determination of caffeine at 1661/cm can be avoided by using a baseline established between 1900 and 1537/cm and standard solutions with an ASA:caffeine proportion similar than that expected for samples.

The reversed FI–FT–IR procedure developed for the determination of ASA and caffeine in pharmaceuticals is very accurate and precise and permits us a fast quality control of these two active principles in formulations. This basic strategy could be applied for the simultaneous determination of several compounds in other pharmaceuticals and opens up new possibilities for on-line control analysis.

EVALUATION OF COLOUR QUALITY OF COMPLEXOMETRIC INDICATORS IN THE TITRATION OF NICKEL(II) WITH EDTA BY TRISTIMULUS COLORIMETRY

S. RAHEEM and K. M. M. KRISHNA PRASAD
School of Chemistry, Andhra University, Visakhapatnam 530 003, India

(*Received* 19 *January* 1993. *Revised* 15 *April* 1993. *Accepted* 20 *April* 1993)

Summary—Trichromatic colorimetry was applied to the specification of colour changes of metallochromic indicators viz., murexide, pyrocatechol violet, bromopyrogallol red, pyrogallol red and chromazurol S in the complexometric titration of Nickel(II) with ethylene-diaminetetraacetic acid (EDTA), in order to assess the quality of colour change at the equivalence point with the help of CIE $L^*a^*b^*$ 1976 system and the values of SCD (Specific Colour Discrimination) parameter. A screened indicator, a mixture of murexide and methylene blue in the ratio 10:1 (m/m), is proposed as an ideal indicator in this titration as evidenced by the plots of a^* *vs.* b^* and from the numerical values of standard deviation for a large number of visual titrations.

In spite of a large number of indicators available for the visual titrimetric determinations, it is difficult to choose the best indicator with a good quality of colour change. Tristimulus colorimetry is an important tool to study the quality of colour changes of the indicators.[1] Principles of tristimulus colorimetry have been applied for the evaluation of colour transition in acid–base indicators.[2–4] As per the recommendations of IUPAC, Analytical Chemistry division,[5] tristimulus coordinates were utilized for the specification of the colour changes of metallochromic indicators.[6–10]

Since the colour diagram is non-uniform, a more uniform colour space defined by CIE $L^*a^*b^*$ 1976[11] has been proposed by using the following expressions.

$$L^* = 116\,(Y/Y_o)^{1/3} - 16,$$

$$a^* = 500\,[(X/X_o)^{1/3} - (Y/Y_o)^{1/3}],$$

$$b^* = 200\,[(Y/Y_o)^{1/3} - (Z/Z_o)^{1/3}],$$

where X, Y and Z are tristimulus values of the solution and $X_o = 98{,}041$, $Y_o = 100{,}000$, $Z_o = 118{,}103$.

In the present study five metallochromic indicators, murexide, pyrocatechol violet, bromopyrogallol red, pyrogallol red and chromazurol S were used to assess the quality of their colour changes, by using tristimulus colorimetry, in the titration of nickel(II) with EDTA.

The accuracy of the titrimetric method depends upon the quality of colour change at the equivalence point, which in turn depends upon the nature of the colours before and after the end point and the rapidity with which the colour transition is occurring. The best colour transition involves a colour change between two complementary colours through greyness (colourlessness). Such a best colour change for the visual indicators can be obtained by screening it with an appropriate inert dye.[12–14] In this study a screened indicator murexide + methylene blue, was developed and the superiority of its quality of colour change over the unscreened indicator was verified utilising the parameter 'standard deviation'.

EXPERIMENTAL

Apparatus

A Shimadzu (U.V. 260) U.V./visible double-beam recording spectrophotometer with temperature control attachment was used for recording spectra. An 'Elico' digital pH meter and OMC Omega 58000 mini-computer were used for pH measurements and for the calculation of chromatic parameters, respectively.

Reagents

A $2 \times 10^{-2}M$ solution of nickel(II) sulphate (E. Merck GR) and a $2 \times 10^{-2}M$ solution of

ethylenediaminetetraacetic acid (EDTA) (BDH AnalaR) were prepared and standardized.

Some $1.0 \times 10^{-4}M$ solutions of the indicators, murexide (BDH AnalaR), pyrocatechol violet (Sigma) chromazurol S (E. Merck GR) in water and bromopyrogallol red (Sigma), pyrogallol red (Sigma) in 50% ethanol were prepared. 1.0×10^{-4} solution of methylene blue (BDH AnalaR) was prepared in triply distilled water.

Determination of chromatic parameters

A 10 ml portion of $0.01M$ solution of nickel(II) and 1 ml of indicator solution were taken in a clean, dry 100 ml beaker. After adjusting pH with appropriate buffer, the total volume of the titrand solution was made up to 50 ml by adding a requisite volume of EDTA and triply distilled water. The absorbance and transmittance values were recorded at different values of C_L/C_M (ratio of concentration of ligand to that of metal ion) in the wavelength range 380–770 nm with an interval of 10 nm. A computer program written in FORTRAN 77, was used for the calculation of chromatic parameters. The algorithm adapted is the weighted ordinate method with the coefficients of standard illuminant C.[15]

RESULTS AND DISCUSSION

The values of tristimulus coordinates (x, y) and complementary colour coordinates (Q_x, Q_y) for all the studied indicators, are determined at different values of C_L/C_M.

The colour transition curves drawn on the complementary colour diagram by using the complementary colour coordinates (Q_x, Q_y), are represented in Fig. 1. This diagram unequivocally indicates that the quality of colour change at the end point is much superior when murexide is used as the indicator in this titration because of long distance between the colour points at the end point and the relative position of colour transition curve. The colour transition curves of pyrocatechol violet, bromopyrogallol

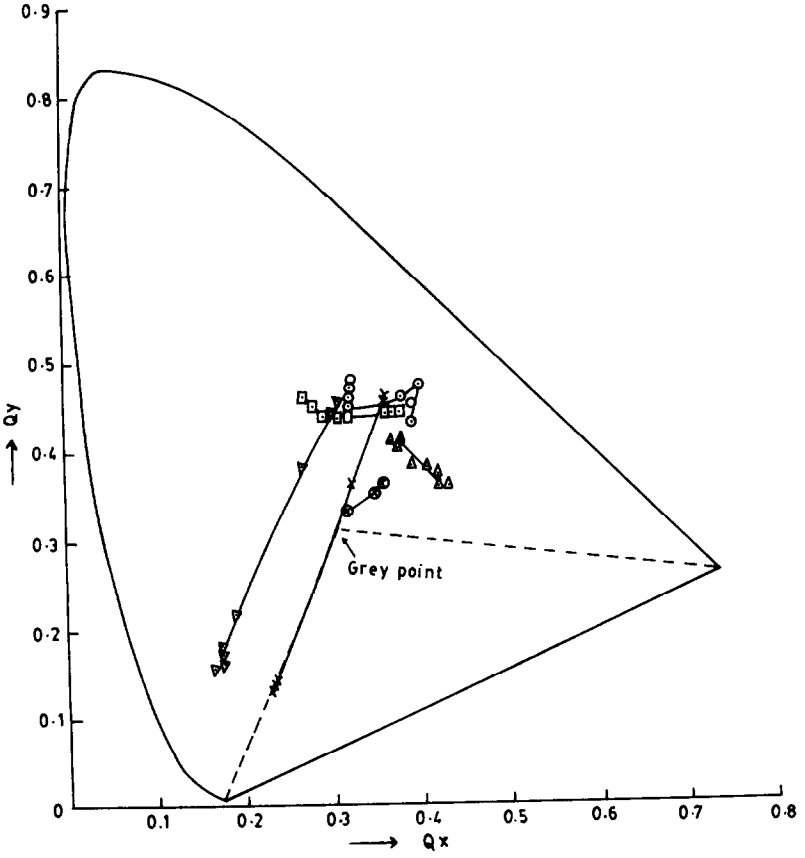

Fig. 1. Colour transition curves of the indicators on the complementary colour diagram: ▽–▽ murexide; △–△ pyrocatechol violet; ○–○ bromopyrogallol red; ◙–◙ pyrogallol red; ⊙–⊙ chromazurol S; x–x screened indicator.

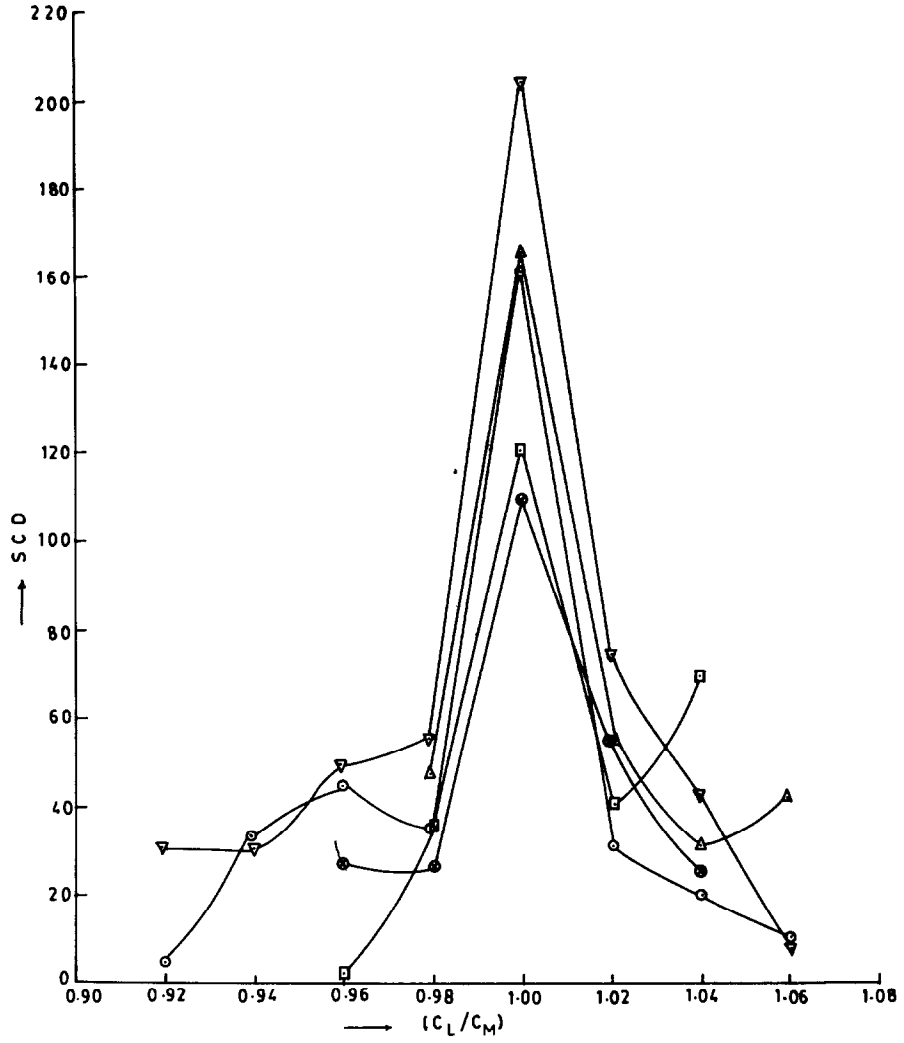

Fig. 2. Specific colour discrimination, SCD *vs.* C_L/C_M (index as in Fig. 1).

red and pyrogallol red are comparable in length whereas the colour transition curve of chromazurol S is short in length.

The values of Specific Colour Discrimination (SCD) are determined in each case in accordance with the method of Bhuchar,[16] for a quantitative measure of quality of colour change. The SCD *vs.* C_L/C_M curves are presented in Fig. 2. The greatest SCD peak exhibited by the indicator, murexide at $C_L/C_M = 1$, indicates that it exhibits a better quality of colour change at the end point, over the other studied indicators. From this graph the following order of quality of colour change of the indicators is concluded, based on the numerical value of SCD at $C_L/C_M = 1$.

Murexide > pyrocatechol violet > bromopyrogallol red > pyrogallol red > chromazurol S.

Figure 3 shows the colour transition curves of the indicators on a^* *vs.* b^* colour space from which it is observed that the colour transition curve of murexide passes very nearer to the origin (grey point). The colour transition curves of bromopyrogallol red and pyrogallol red are present in a single quadrant indicating that a decrease in saturation as the color change at the equivalence point.

The total colour difference, ΔE^* (CIE $L^*a^*b^*$ 1976) for all the studied indicators at different values of C_L/C_M are determined by using the equation

$$\Delta E^*[(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{\frac{1}{2}}.$$

The highest peak exhibited by murexide in the graph ΔE^* *vs.* C_L/C_M (Fig. 4) revealed that this indicator shows the best quality of colour change at $C_L/C_M = 1$. From this graph the

quality of colour changes of the indicators are arranged in the following order which is similar to the one observed in the case of SCD parameter.

Murexide > Pyrocatechol violet > bromopyrogallol red > pyrogallol red > chromazurol S.

Screening

In a visual titration a sharp endpoint can be achieved by using a screened indicator. In the present study to improve the quality of colour change of the indicator, (murexide) a screened indicator is developed by mixing murexide with an inert colorant, methylene blue. Different proportions of murexide and methylene blue are prepared and their chromaticity parameters are determined at different values of C_L/C_M to arrive at the suitable composition of screened indicator. The colour transition curve of the screened indicator having a composition of 10:1 (murexide:methylene blue), is passing through the origin (Fig. 3) indicating that the colour transition at the end point involves a colour change through colourlessness. The colour transition curve of the screened indicator (Fig. 1) also passes through the illuminant point. A number of visual titrations are carried out by using the screened indicator as well as the unscreened (murexide) indicator and the results obtained are presented in Table 1. The numerical values of the standard deviation for replicate titrimetric determinations, showed that the precision achievable while using the screened indicator is higher than that observed in the case of unscreened indicator.

CONCLUSIONS

A study on the quantitative measure of the quality of colour change of metallochromic indicators with the help of tristimulus parameters viz., SCD (Specific Colour Discrimination) and CIE $L^*a^*b^*$ 1976, revealed the following order of decreasing quality of

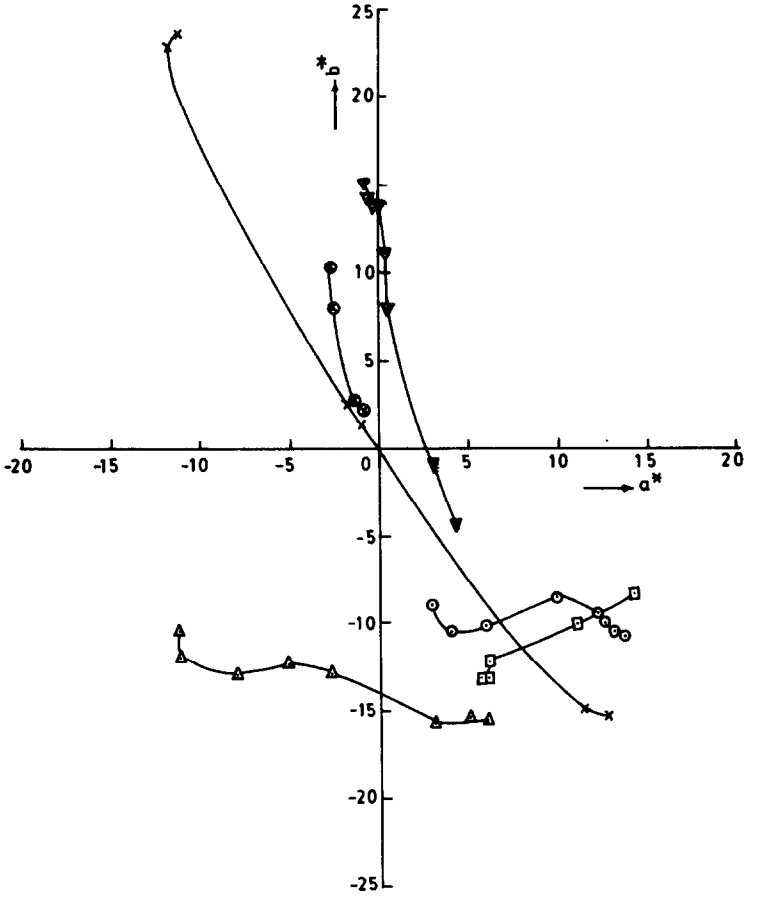

Fig. 3. Colour transition curves on CIE (a^*, b^*) colour space (index as in Fig. 1).

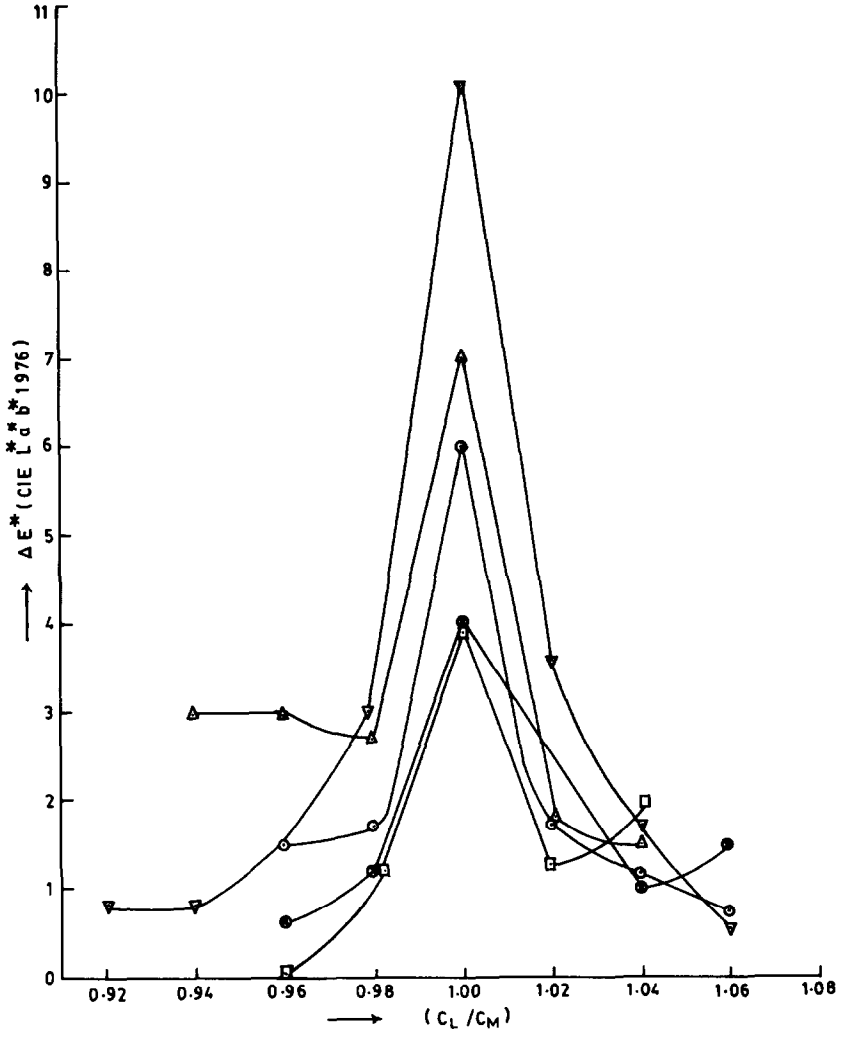

Fig. 4. Total colour difference, ΔE^* (CIE $L^*a^*b^*$ 1976) *vs.* C_L/C_M (index as in Fig. 1).

(*Received* 11 *January* 1993. *Revised* 10 *May* 1993. *Accepted* 11 *May* 1993)

Summary—A microdigestion procedure performed directly in the autosampler cup is proposed. Small quartz filter pieces loaded with the particulate material are transferred to the cup. The sample is digested by a mixture of nitric, sulfuric and hydrofluoric acid (1:1:1) under sonication. After the addition of a boric acid solution the elements are determined by graphite furnace atomic absorption spectrometry using the autosampler to deliver the slurry into the furnace. A mixture of palladium and magnesium nitrates was used as a modifier for Sb. Spiking studies showed recoveries close to 100% using aqueous analytical curves for Ni and Sb. For V, an analytical curve in the blank slurry, obtained by submitting an unloaded filter to the same procedure, was used. The method was applied to two standard reference materials, Coal Fly Ash (NIST 1633a) and Urban Particulate (NIST 1648) and the concentrations showed good agreement with the certified or recommended values using aqueous analytical solutions.

The analysis of airborne particulate material collected on filters is generally performed using a digestion step. For the analysis of quartz filters, acid mixtures, such as HNO_3–$HClO_4$[1] or HNO_3–H_2SO_4–HCl[2] have been proposed. In this case the quartz filter is not dissolved, and the bulk elements of its matrix are not completely released to the solution. However, acid mixtures containing HF were also suggested.[3,4] An alternative to the acid digestion is the direct analysis of the filter by GFAAS.[5,6] The direct analysis of solids avoids the chemical pre-treatment of the sample, reduces the risks of contamination or losses, and saves time. The full detection power of the instrument can also be used, as the dilution generally associated with chemical pre-treatment is avoided. Nevertheless problems involving high background, calibration difficulties, microweighing errors, sample representativity, *etc.* must also be considered.

A possibility that combines the advantages of the solid and liquid sampling is the analysis of slurried samples.[7–12] Slurry sampling can use the normal autosampler system of the equipment. This overcomes the intensive manual work of the direct analysis of solids related to weighing small sample amounts. The mass to volume ratio of the slurry can also be controlled, in order to extend the dynamic range of the analysis. Difficulties such as bringing the sample to a fine powder or sampling errors may still remain.[13,14] Sedimentation during the analysis is also a problem. Some authors suggest the use of stabilizing agents.[8,9] Mechanical agitation[15] or sonication[16,17] have also been proposed. More recently, an ultrasonic probe attached to the autosampler has become commercially available.[18]

In this work an alternative procedure for the determination of Sb, Ni and V in airborne particulate material collected on quartz filters (HI-vol) is proposed. Small filter pieces are partially digested by an acid mixture in the autosampler cup, using sonication. The resulting slurry is then introduced in the graphite tube via the autosampler.

The interest on Ni and V came from the possibility of using these elements as tracers for oil burning stationary sources. Sb can be used as a tracer to study the environmental impact of oil refineries since it is used as a catalyst during the cracking process.

EXPERIMENTAL

Instrumental

The Sb measurements were carried out on a Perkin-Elmer Zeeman 3030 atomic absorption spectrometer equipped with an HGA-600 graphite furnace and an AS-60 autosampler. For Ni and V the measurements were also carried out on a Model 1100 atomic absorption spectrometer (D_2 background correction), equipped with an HGA-300 graphite furnace and an AS-40 autosampler, all Perkin-Elmer. The light sources were an electrodeless discharge lamp for Sb and hollow cathode lamps for Ni and V. Pyrolytically graphite coated tubes (Perkin-Elmer no. B 0091 504) were used for V. For Sb and Ni, pyrolytically graphite coated tubes (Perkin-Elmer no. B 0109 322) with totally pyrolytic graphite platforms (Perkin-Elmer no. B 0109 324) were used. The microweighings were proceeded on a Perkin-Elmer AD-4 microbalance. For Ni and V a volume of 20 μl was pipetted in the furnace. For Sb, 10 μl of the sample solution and 10 μl of the modifier were used.

Reagents and solutions

The acids HNO_3 and HF were purified by subboiling distillation of the analytical grade reagents in a quartz (HNO_3) or Teflon (HF) subboiling apparatus (Hans Kürner). Analytical grade H_2SO_4 and H_3BO_3 were used. The water was purified by the Milli-Q process. The acid extraction solution (FNS) was prepared by mixing the same volume of HF, HNO_3 and H_2SO_4. The modifier for the Sb determination was a 0.2% m/v Pd and 0.5% m/v Mg, as nitrates, solution. The analytical solutions were prepared after convenient dilutions of 1000 mg/l stock solutions obtained from Titrisol ampoules (Merck) diluted to 1 l with 0.2% v/v HNO_3.

Samples

The airborne particulate material was collected with a Hi-vol sampler, on a 20 × 25 cm quartz filter (Pallflex). Only the particles with a diameter larger than 50 μm were retained. Also two reference materials from the National Institute of Standards and Technology, NIST were used: Coal Fly Ash (SRM NIST 1633a) and Urban Particulate (SRM NIST 1648).

Procedure

Proposed microdigestion procedure: small filter discs (d = 6.0 mm; surface area, 28 mm^2) were cut with a stainless steel cutting tool, from different parts of the filter. Four to eight pieces were placed in a polyethylene autosampler cup (Perkin-Elmer no. B 008 7056) and 150 μl of the acid extraction mixture were added. After placing the cup in an ultrasonic bath for 6 min, 750 μl of water and 150 μl of a saturated boric acid solution were added. After homogenization by manually stirring the slurry with a glass rod, the sample solution was measured for Sb. For V and Ni the sample slurry was diluted 10 times before being measured. In the analysis of the standard reference materials 5 mg aliquots, accurately weighed, instead of the filter pieces, were used.

Table 1. Maximum pyrolysis temperatures (°C) for Sb, Ni, V in different matrices. Atomization temperatures: 2200°C (Sb), 2500°C (Ni) and 2650°C (V)

Matrix	Elements		
	Sb	Ni	V
0.2% HNO_3	1600	1400	1600
Unloaded filter	1600	1300	1400
Loaded filter	1300	1500	1600
NIST 1633a	1300	1200	1600

RESULTS AND DISCUSSION

Temperature programs

Table 1 shows the maximum pyrolysis temperatures for the three studied elements in 0.2 HNO_3 and in different media resulting from the application of the procedure to different samples. These temperatures were derived from pyrolysis temperature curves. Some effects of the matrix on the optimum pyrolysis temperature are shown in Table 1 confirming that pyrolysis temperatures obtained from aqueous solutions cannot be acritically used in any matrix, even using a modifier as in the case of Sb. The temperature programs are shown in Table 2.

Optimization of the microdigestion procedure

Acid mixture volume. Figure 1 shows the effect of the acid mixture volume added to the

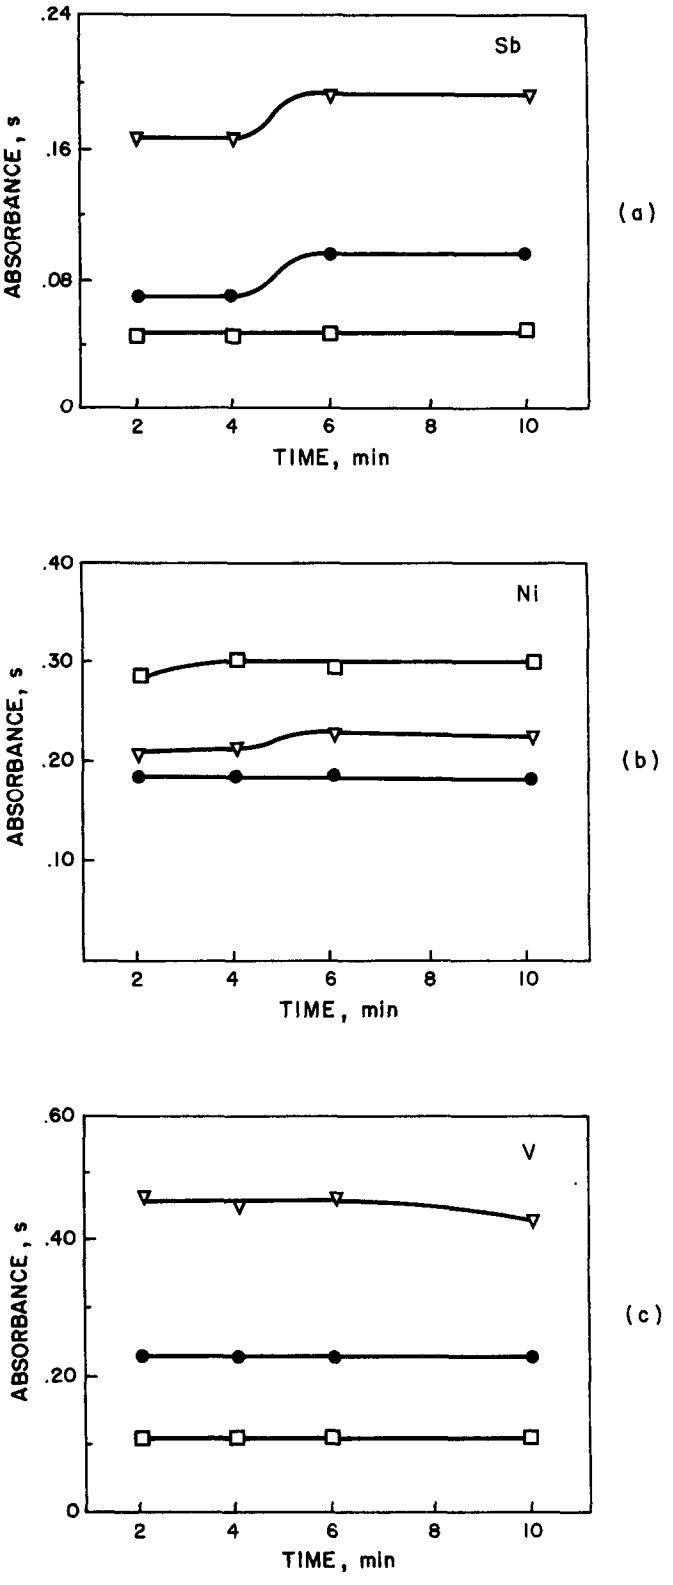

Fig. 2. Effect of the sonication time on the peak area of Sb(a), Ni(b) and V(c) in the final suspension resulting from the analysis of different materials by the proposed procedure: (□) SRM NIST 1633a, Coal Fly Ash; (▽) SRM NIST 1648, Urban Particulate and (○) airborne particulate material collected on a quartz filter. Acid mixture volume, 150 μl.

autosampler cup prior to the sonication on the Sb, Ni and V recovery from standard reference materials (SRM) and airborne particulate material collected on quartz filter. Five milligrams of SRM or four 28 mm^2 filter discs were used. The saturated H_3BO_3 solution volume was always the same as that of the acid mixture and the final volume was 1.0 ml. The drop in the Sb signal (Fig. 1(a)) for SRM 1648 could result from the effect of the higher acid concentration in the Sb signal. However this effect was not found for the other two samples. The volume of 150 μl was chosen as the best compromise for the observed tendencies.

Sonication time. Figure 2 shows the effect of the sonication time on the recovery of Sb, Ni and V from two SRMs and from an airborne particulate material collected on a quartz filter. Five milligrams of SRM or four 28 mm^2 filter pieces were used. The volume of the saturated H_3BO_3 solution was 150 μl and the final volume was made up to 1.0 ml with purified water. There was no significant influence of the sonication time for the studied range, except for the determination of Sb in the particulate material. This indicates that Sb is partially associated with larger particles and it is only partially leached, as it will be discussed later under Stability of the slurries. A sonication time of 6 min was chosen.

Filter homogeneity. As the filter part taken for analysis was small compared to the total filter area, two studies of representativity were performed. In the first one, a filter was divided in four quadrants and from each quadrant, two sets of four 28 mm^2 pieces were taken. The relative standard deviations were calculated for the eight samples. In the other one, 10 sets of four 28 mm^2 pieces were taken at random. For the first study the relative standard deviations were 10%, 6% and 5% for Sb, Ni and V, respectively. In the second experiment, the relative standard deviations were 29% (Sb), 11% (Ni) and 6% (V). Such results demonstrate that in spite of the small sampled filter area (4×28 mm^2) in comparison with the total filter area (50.10^3 mm^2), the distribution of Ni and V on the filter surface was homogeneous enough to permit a representative sampling. For Sb, the distribution was less homogeneous certainly due to its origin. To reduce the relative deviations the first procedure is recommended, specially for Sb.

Accuracy and precision

Table 3 shows the concentration of Sb, Ni and V in two SRMs (NIST 1633a, Coal Fly Ash and NIST 1648, Urban Particulate) obtained using the proposed procedure. The matrices of these materials are expected to have a composition similar to that of the intended samples. The masses taken ranged from 0.94 to 1.89 mg for the NIST 1648 and from 1.86 to 15.68 mg for the NIST 1633a. Aqueous analytical curves were used. There was a good agreement between the found and the certified or recommended values. The reproducibility was typically better than 8% (relative standard deviation) except for Ni in Urban Particulate. A significant part of this variation must be due to the sample inhomogeneity, a major source of uncertainty when such small masses are taken for analysis.

Matrix interferences

Possible matrix interference effects were verified submitting real samples (loaded filters) to the analyte addition technique and comparing the obtained slopes with that of an aqueous (0.2% HNO_3) analytical curve. The analyte addition curves were obtained spiking the suspension resulting from the proposed digestion procedure with known amounts of the analyte, directly in the furnace. The effect of the filter matrix alone was also investigated. In this case, 28 mm^2 discs of an unloaded filter were submitted to the proposed procedure and the resulting suspension was spiked in the same way. The results are summarized in Table 4. The comparison of the slopes shows that there is no significant matrix effect in the Sb and Ni determination in real samples. However, such effects are evident for V. The slopes in the presence of the matrix (loaded or unloaded filter) are significantly larger (57%) than the slope resulting from the aqueous (0.2% HNO_3) analytical curve. This enhancement is the same

Table 3. Concentrations, μg/g ($\pm$standard deviations) for Sb, Ni and V in the standard reference materials by the proposed procedure. Values between parentheses are recommended only

	Sb		Ni		V		
SRM	Certified	Found	Certified	Found	Certified	Found	n
NIST 1633a	(7)	7.0 ± 0.5	127 ± 4	120 ± 8	289 ± 7	325 ± 21	10
NIST 1648	(45)	42 ± 3	82 ± 3	83 ± 14	(130)	128 ± 10	22

Table 4. Linear regression parameters for Sb, Ni and V, resulting from analyte addition curves (number of additions: 3)

Analyte	Matrix	Slope ($s \cdot ml/ng \cdot 10^3$)	Slope standard deviation	Correlation coefficient
Sb	0.2% HNO_3	1.40	0.06	0.9999
	unloaded filter	1.43	0.07	0.9965
	loaded filter	1.39	0.03	0.9989
Ni	0.2% HNO_3	3.10	0.02	0.9996
	unloaded filter	3.25	0.06	0.9998
	loaded filter	3.18	0.07	0.9994
V	0.2% HNO_3	1.40	0.05	0.9980
	unloaded filter	2.20	0.09	0.9993
	loaded filter	2.21	0.06	0.9997

for loaded or unloaded filters. In a previous experiment, it was observed that the acids alone did not interfere in the V sensitivity. Also the analysis of the standard reference material showed no interferences. Therefore the observed slope enhancement can only be due to the quartz matrix. According to Matousek and Powell,[19] the atomization of V proceeds through the formation of vanadium carbide. Since Si also forms carbide,[20] it could be that in the presence of this element another atomization mechanism takes place. For other elements in slurries of glass materials, Bendicho and de Loos–Vollebregt[21] found that the silica matrix behaves as a chemical modifier, producing a retention of the analyte, which is released later in the atomization step. So this retention and also the reduction of the formation of vanadium carbide, could explain the improvement in the *V* signal produced by the silica matrix.

Recovery studies

Known amounts of the analyte were delivered to the cups containing four 28 mm^2 filter discs, before the digestion. The slopes of the curves and the recoveries are displayed in Table 5. For Sb and Ni, the recoveries were calculated from the ratio between the slope of the recovery curve and that of the aqueous analytical curve. For V, instead of the slope of the aqueous analytical curve, the slope of a spiked blank (unloaded filter) was used.

Detection limits

As it was not possible to obtain a "field blank",[22] the detection limits were estimated from the analysis of then unloaded filters. Four 28 mm^2 discs were used. The detection limits obtained ($k = 3$) were 15, 36 and 38 ng/cm^2 for Sb, Ni and V, respectively.

Stability of the slurries

Figure 3 shows the average of five consecutive measurements as function of the number of firings. Each cycle takes about 2 min, depending on the temperature program. For Sb a drop in the signal was observed if the suspension was standing for more than 20 min. For more than 40 min the signal was again stable, indicating that this element could be partially associated with larger particles, which are sedimented earlier. The Ni signal drops continuously after about 20 min, suggesting that this element was

Table 5. Recovery of Sb, Ni and V using the proposed procedure

Analyte	Matrix	Slope ($s \cdot ml/ng \cdot 10^3$)	Slope standard deviation	Correlation coefficient	Recovery (%)
Sb	0.2% HNO_3	1.40	0.06	0.9999	
	unloaded filter	1.43	0.06	0.9965	102
	loaded filter	1.39	0.03	0.9992	93
Ni	0.2% HNO_3	2.62	0.02	0.9996	
	unloaded filter	2.53	0.07	0.9993	97
	loaded filter	2.46	0.08	0.9945	94
V	0.2% HNO_3	1.52	0.05	0.9859	
	unloaded filter	2.20	0.06	0.9980	
	loaded filter	2.22	0.04	0.9963	101

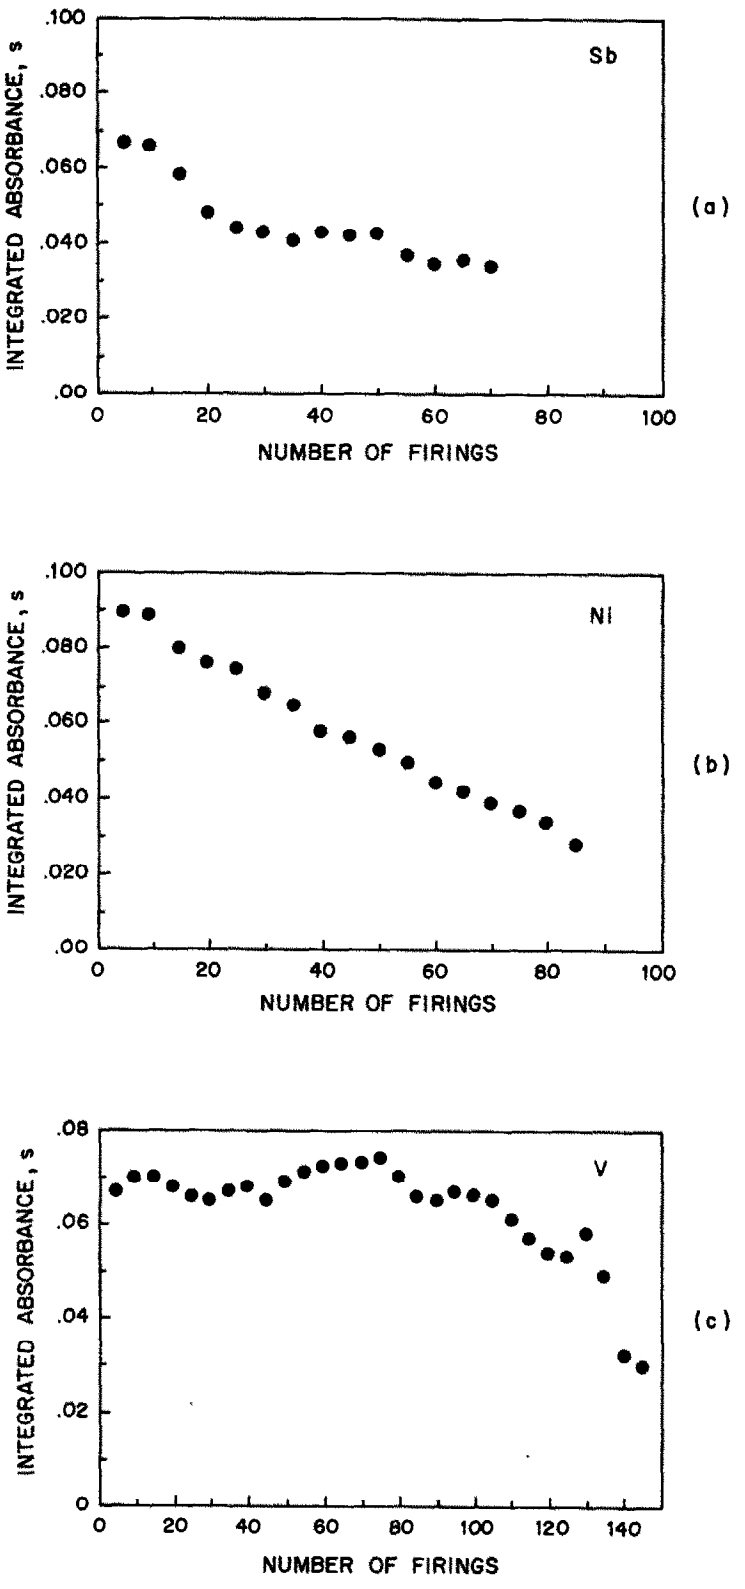

Fig. 3. Average peak area of five measurements for Sb(a), Ni(b) and V(c) in the slurry of a loaded quartz filter as a function of the number of firings.

not leached by the acid mixture, but remained in the particles. For V the signal is rather stable for very long period of time, indicating that this element is released to the solution or associated with very small particles. The drop for V after more than 100 firings is probably related to the end of the tube lifetime. In conclusion, the obtained slurry is stable enough to allow the analysis, but the determination should be performed just after the homogenization. The solution to be measured should not stand for more than 20 min, specially for the determination of Sb and Ni. Probably continuous sonication or agitation would allow longer standing times, but this procedure was not tested.

CONCLUSION

The proposed procedure is very rapid, taking about 15 min for the digestion and the determination. Also small quantities of reagents are used, making the analysis very economical.

Using the recommended background correctors, no interferences were detected for Sb and Ni, making the use of aqueous analytical solutions in the calibration possible. For V, the enhancement in the signal detected in the presence of the partially digested quartz filter, requires the use of analytical solutions prepared from a blank slurry resulting from the application of the procedure to an unloaded filter or the use of the analyte addition method. For the analysed standard reference materials, no interference was detected, not even for V, and aqueous analytical curves can be used.

A NOVEL AND HIGHLY SENSITIVE CATALYTIC METHOD FOR THE DETERMINATION OF ULTRATRACE AMOUNTS OF GOLD IN ORES WITH LINEAR SCAN VOLTAMMETRY AT A DME

ZHI-LIANG JIANG
Department of Chemistry, Guangxi Normal University, Guilin 541004 People's Republic of China

(*Received* 6 *January* 1993. *Revised* 29 *April* 1993. *Accepted* 5 *May* 1993)

Summary—Gold(III) has a strong catalytic effect on the slow redox reaction between Ce(IV) and Hg(I) in a sulphuric acid medium at 90°C, and the Ce(IV) unreacted in the catalytic reaction reacts with benzilic acid to form benzophenone that exhibits a sensitive linear scan voltammetric wave at −0.78 V *vs.* SCE. This provides the basis for a novel and highly sensitive and selective catalytic method with linear scan voltammetry at a DME for gold. Both reactions of Ce(IV)–Hg(I)–Au(III) and Ce(IV)–benzilic acid are investigated by means of linear scan voltammetry. The detection limit is 0.05 ng/ml with a fixed-reaction time of 15 min. A linear calibration graph from 0.15 to 5 ng/ml is obtained. Possible influences by co-existing ions are examined. Gold in ore samples is analysed by this catalytic method with satisfactory results.

Because gold(III) has a high redox potential, there are no good polarographic methods for gold. Several oscillopolarographic methods for the determination of gold have been reported.[1–4] A single sweep oscillopolarographic method for gold from 5×10^{-8} to $3 \times 10^{-6}M$ has been proposed, based on Au(III) oxidation of phenylthiourea to form symdiphenyldithioformamidine that exhibits a polarographic wave at −0.30 V.[1] Gao *et al.*[3] have reported a voltammetric method for determination of gold in the range 3×10^{-8}–$1 \times 10^{-6}M$ with a carbon paste electrode modified with chelating resin. The above polarographic methods for gold are not completely satisfactory, especially with respect to the detection limit.

Catalytic method with oscillopolarographic (linear scan voltammetry at a DME) detection is a sensitive means of catalytic kinetic analysis.[5–9] Catalytic methods for silver,[10] osmium,[11] ruthenium,[12] iridium,[13] rhodium[14] and palladium[15,16] with oscillopolarographic detection have been developed. However, a catalytic method for gold with oscillopolarographic detection does not seem to have been reported to date. Gold(III)–Ce(IV)–Hg(I) catalytic reaction has been applied to determining gold at ng/ml level by spectrophotometry.[17,18] Our experiments demonstrate that benzilic acid can be oxidized by Ce(IV) to form benzophenone that exhibits a sensitive oscillopolarographic wave at −0.78 V. In the present work, we first studied the coupled reaction of Au(III)–Hg(I)–Ce(IV)–benzilic acid by single sweep oscillopolarographic detection. A novel catalytic method with oscillopolarographic detection was proposed for the determination of ultratrace amounts of gold, with a detection limit of 0.05 ng/ml and a determination range of 0.15–5 ng/ml.

EXPERIMENTAL

Apparatus

A model JP-2 single sweep oscillopolarograph (Chendu Instrumental Factory) was used for the polarographic measurements. The settings on the JP-2 single sweep oscillopolarograph were: dropping mercury period 7 sec; scanning rate 250 mV/sec; scanning potential range of 500 mV in the negative direction; initial scanning potential −400 mV; I''_p (second derivative wave); and a three-electrode system-DME, SCE, and platinum electrode. A model JY-501B thermostatted water bath was used to control the reaction temperature.

Reagents

A 0.0020M ammonium ceric nitrate (containing 0.040M sulphuric acid) and a 0.020M $HgNO_3$ (containing 0.07M nitric acid) and a 0.0030M benzilic acid solution were used.

Standard solutions of Au(III) were prepared according to the following procedure: weigh out 10 mg pure gold and place in a 100-ml beaker. Add about 3 ml of concentrated hydrochloric acid and 1 ml of concentrated nitric acid, heat to dissolve, cool, then transfer to a 100-ml standard flask, add 20 ml of concentrated hydrochloric acid and dilute to the mark with doubly distilled water. The stock solution of Au(III) is 100 μg/ml. Take 25 ml of 100 μg/ml Au(III) solution to a 50-ml beaker, add about 0.2 ml of 10% NaCl solution, evaporate to dryness over a boiling water bath, add 2 ml of concentrated nitric acid and evaporate to dryness, repeat again to expel Cl^-, cool, add 0.0020M Ce(IV) solution to dissolve the salt, then transfer to a 250-ml standard flask and dilute to the mark with 0.0020M Ce(IV) solution. The standard solution of gold is 10 μg/ml. A working solution was prepared by dilution with 0.0020M Ce(IV) solution shortly before use.

Procedure

Into a 25-ml graduated test-tube fitted with a glass stopper, place 0.02–0.65 ml of 100 ng/ml Au(III) solution (containing 0.0020M Ce(IV)), and add 0.0020M Ce(IV) solution to 1 ml of the total volume. Add 2.5 ml of 5.0M sulphuric acid, dilute to 10-ml mark with water, mix well. Add 1.0 ml of 0.02M Hg(I) solution, mix vigorously, and place in a water bath at 90°C to start the reaction. After 15 min the reaction was quenched by addition of 1.0 ml of 0.0030M benzilic acid solution and cooled with tap-water. The second derivative peak current $(I''_p)_{c,t}$ was measured. The $(I''_p)_{u,t}$ for the uncatalysed reaction was measured in a similar manner.

The log $((I''_p)_{u,t}/(I''_p)_{c,t})$ values for a range of gold concentrations were plotted as a function of gold concentration to prepare a calibration graph.

RESULTS AND DISCUSSION

Study of the reaction of Ce(IV) and benzilic acid

The reaction of Ce(IV) and benzilic acid was investigated spectrophotometrically and oscillopolarographically. The results show that the reaction is slow at room temperature when Ce(IV) concentration is less than $4 \times 10^{-4}M$. It is fast when the reaction temperature is higher than 60°C. Several reaction media including sulphuric acid, perchloric acid and hydrochloric acid were tested. Sulphuric acid is best, and was chosen for use. In 1.0M sulphuric acid medium at 90°C, Ce(IV) reacts with benzilic acid to form an electroactive species which exhibits a sensitive single sweep oscillopolarographic wave at −0.78 V. The electroactive species was identified by a chemical method and oscillopolarography.[19] Figure 1 indicates that the second derivative peak current is most sensitive, and was selected for use. The experiment shows that I''_p is proportional to Ce(IV) concentration in the range 1×10^{-6}–$3 \times 10^{-4}M$. The oscillopolarographic behaviour of benzophenone has been studied.[19] The influence of Hg(I), Hg(II), and Ce(III) on the oscillopolarographic measurement of benzophenone was examined. No effect was observed.

Principle for the catalytic determination of gold with oscillopolarographic detection

Our experiments show that Ce(IV), Ce(III), Hg(I) and Hg(II) in the catalytic system of Ce(IV)–Hg(I)–Au(III)–H_2SO_4 have no oscillopolarographic wave. And the indicator reaction for gold can not be applied to the catalytic determination of gold with oscillopolarographic detection. We tried to utilize the Ce(IV)–Hg(I)–Au(III) system for catalytic determination of gold with oscillopolarographic detection by addition of an organic reagent that reacts with Ce(IV) to form an electroactive species.

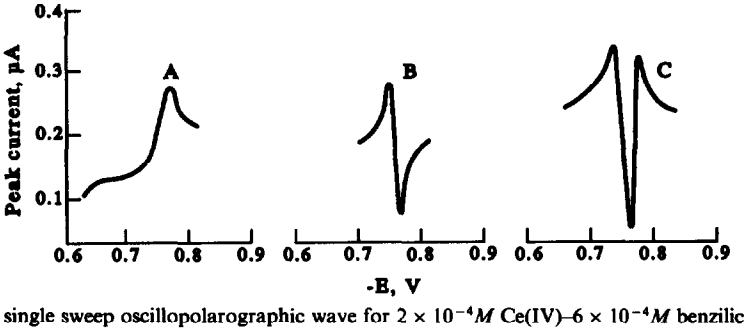

Fig. 1. The single sweep oscillopolarographic wave for $2 \times 10^{-4}M$ Ce(IV)–$6 \times 10^{-4}M$ benzilic acid, 90°C for about 1 min. (A) Normal wave; (B) first derivative wave; (C) second derivative wave.

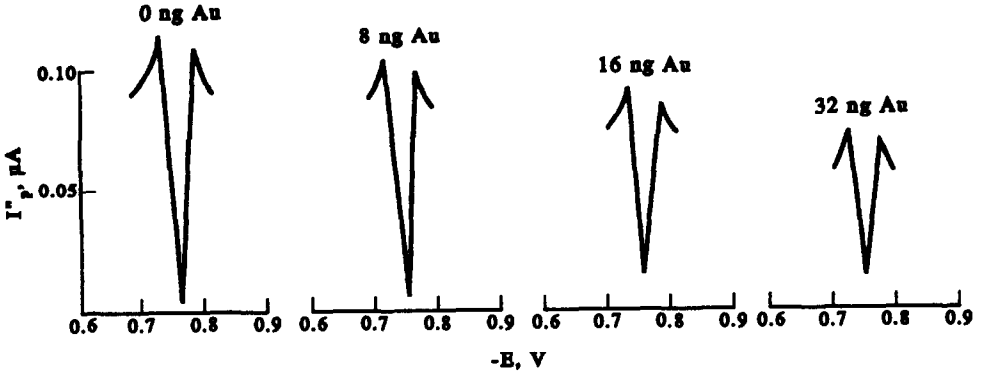

Fig. 2. The relationship of the I''_p and Au concentration.

Several organic reagents have been examined. The results show that benzilic acid can satisfy the need. Two millilitres of $3.0 \times 10^{-3}M$ benzilic acid were selected. On these grounds, we studied the coupled reaction of Au(III)–Hg(I)–Ce(IV)-benzilic acid by oscillopolarography. Figure 2 shows the relationship between I''_p and gold concentration.

In the catalytic reaction solution, both of the following reactions occur simultaneously

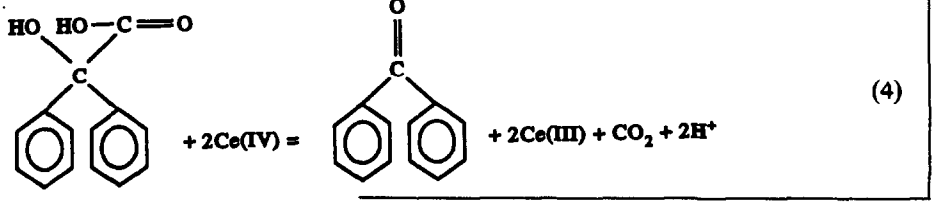
$$\mathrm{Ce(IV) + Hg(I) \xrightarrow[\text{fast}]{\text{Au(III) cat.}} Ce(III) + Hg(II)} \quad (1)$$

$$\mathrm{Ce(IV) + Hg(I) \xrightarrow{\text{slow}} Ce(III) + Hg(II)} \quad (2)$$

Refer to Ref. 20 and deduce the following equation

$$\log(C_{u,t}/C_{c,t}) = k \cdot C_{Au} \cdot t \quad (3)$$

where $C_{u,t}$ and $C_{c,t}$ are the concentrations of Ce(IV) in the uncatalysed reaction and catalysed reactions at reaction time t, respectively, C_{Au} is the concentration of gold, and k is a constant. Addition of benzilic acid when the indicator reaction is at time t, the following reaction takes place



(4)

According to the reaction, $C_{Ce(IV)} = 2 \times C$, where C is benzophenone concentration. Since $I''_p = k'C$, where k' is a constant, the equation may be rewritten as

$$C_{Ce(IV)} = 2k' \cdot I''_p. \quad (5)$$

Combining (3) and (5), we obtain

$$\log((I''_p)_{u,t}/(I''_p)_{c,t}) = k \cdot C_{Au} \cdot t. \quad (6)$$

Equation (6) shows that the logarithmic term is proportional to gold concentration, with the other variables held constant for the given system. This is in agreement with the experimental results.

Effect of variables

The effects of the concentrations of sulphuric acid, Ce(IV) and Hg(I), reaction temperature and reaction time on $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ were investigated by the fixed-reaction time procedure. In general the effect of each variable leads to higher $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ and larger $(I''_p)_{u,t}$ which is expected.

The reaction media tested were sulphuric acid, perchloric acid and hydrochloric acid. The results show that $1.0M$ sulphuric acid medium gives larger $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ and $(I''_p)_{u,t}$ values than the others and was chosen.

The effect of variation of Hg(I) concentration on $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ is shown in Fig. 3. When the concentration of Hg(I) is higher than $1.1 \times 10^{-3}M$, the $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ values are constant. A concentration of $1.54 \times 10^{-3}M$ Hg(I) was selected. Figure 4 indicates the relationship between $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ and Ce(IV) concentration. A concentration of $1.54 \times 10^{-4}M$ Ce(IV) was chosen, giving a good

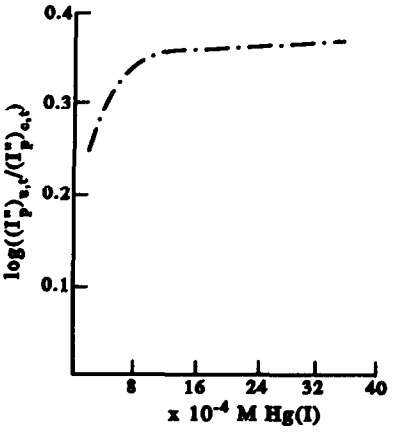


Fig. 3. The effect of Hg(I) concentration on $\log((I''_p)_{u,t}/(I''_p)_{c,t})$. Conditions as in the procedure.

compromise between high $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ and high $(I''_p)_{u,t}$ values.

The influence of reaction temperature in the range 60–95°C on the $\log((I''_p)_{u,t}/(I''_p)_{c,t})$ was studied. The logarithmic terms increase with reaction temperature. A reaction temperature of 90°C was used, giving high sensitivity, and the reaction temperature can be easily controlled by the thermostatted water bath. A fixed-reaction time of 15 min was chosen, giving a good compromise between high sensitivity and short analysis time.

Effect of foreign ions

The effect of 34 foreign ions on the catalytic determination of 1 ng/ml Au was examined. The results are summarized in Table 1. The tolerance limit is that giving not more than ±5% error. Most common ions do not interfere with the catalytic determination of gold.

Calibration graph

Under the conditions as in the Procedure, the logarithmic terms are proportional to the concentration of Au in the range of 0.15–5.0 ng/ml (Fig. 5). The detection limit is 0.05 ng/ml. The relative standard deviation for 0.5, 1.0 and 4.0 ng/ml Au was 4.0, 3.3 and 2.8%, respectively (10 determinations).

Table 1. Influence of foreign ions

Tolerance limit (Ion)/(Au)	Ion added
3×10^4	Ca(II), Mg(II), Sr(II), SiO_3^{2-}
1×10^4	Cu(II), Zn(II), Cd(II), Ba(II), Mo(VI)
5×10^3	Pb(II), F^-, PO_4^{3-}
4×10^3	Al(III), Ag(I), La(III), Mn(II)
2×10^3	Fe(III), Co(II), Ni(II), Cr(III), Hg(II)
1×10^3	W(VI), Ti(IV), Br^-
4×10^2	Os(IV), As(III)
1×10^2	Sb(III), Ru(III), Se(IV), Tl(I)
50	Pd(II), Pt(IV)
20	Rh(III)
10	Ir(IV)

Analysis of ore samples

Weigh out 1–10 g ore sample and place in a 30-ml porcelain crucible, set in a Muffle Furnace at 500°C for about 1 hr, then increase the temperature to 700°C for 1 hr. Cool, transfer into a 250-ml beaker, add 20–100 ml of the acid mixture ($V_{HNO_3}:V_{HCl}:V_{H_2O} = 1:4:2.5$), cover for about 1.5 hr, and shake. After the sample dissolved the solution was evaporated to a paste state. Add 10 ml concentrated sulphuric acid and evaporate again. After cooling add 50 ml of 2.5*M* hydrochloric acid, heat to boiling for several minutes, cool, transfer to a 250-ml separate funnel. Accurately add 10 ml of methyl isobutyl ketone (MIBK) that was balanced by 2.5*M* HCl, shake vigorously for about 1 min. After separation discard the water layer, add 15 ml of 0.1*M* HCl solution that was balanced by MIBK, shake for 15 sec. After separation

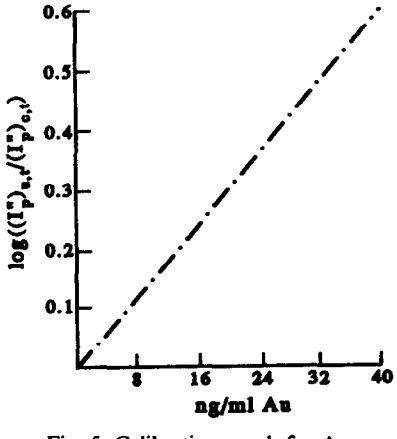

Fig. 5. Calibration graph for Au.

Table 2. Results and recovery

Sample	Added Au (g/t)	Found Au (g/t)	Recover (%)	Content (g/t)	
				This method	AAS
Ore I	0	2.25	—	2.25	2.35
	2.00	4.20	97.5		
Ore II	0	1.60	—	1.60	1.73
	1.00	2.58	98		
Ore III	0	0.84	—	0.84	0.83
	0.80	1.63	98.8		

discard the water layer. Pipet 4–10 ml of the organic layer into a porcelain crucible, add about 0.1 ml of 0.1M KCl solution, evaporate to dryness at low temperature. Add 3 ml concentrated nitric acid and 1 ml concentrated hydrochloric acid, cover and destroy the organic compound by heating, then evaporate to near dryness. Add 1–2 ml nitric acid, evaporate to dryness over a water bath, repeat again to expel Cl^-. After cooling, accurately add 10 ml of 0.1M H_2SO_4, and stir. Pipet a portion of the sample solution into a 25-ml graduated test tube, and follow as for the Procedure. The results are summarized in Table 2, which is in agreement with the results of AAS.

ANALYTE PRECONCENTRATION AND SEPARATION FROM SMALL VOLUMES BY ELECTRODEPOSITION FOR ELECTROTHERMAL ATOMIC ABSORPTION SPECTROSCOPY

JAROSLAV P. MATOUSEK* and H. KIPTON J. POWELL
Department of Chemistry, University of Canterbury, Private Bag 4800, Christchurch, New Zealand

(*Received* 23 *December* 1992. *Revised* 23 *April* 1993. *Accepted* 17 *May* 1993)

Summary—Electrodeposition of Pb from 50 μl volumes of 0.1*M* KCl solution was studied by electrolysis at uncontrolled potentials of 4.0–6.0 V on a pyrolytic graphite platform cathode. Deposition efficiency was evaluated as a function of time by ASV measurements on aliquots of the electrolysed solution. Quantitative separation of the analyte from the matrix was achieved in a relatively short time, aided by convective stirring of the sample achieved through gas evolution. Thus, the feasibility of rapid electrodeposition directly in a pyrolytic graphite-coated furnace has been demonstrated, allowing construction of an automated electrodeposition-electrothermal atomic absorption spectroscopic system.

Electrolysis in an attractive method for both preconcentration and separation of analyte from interfering matrix prior to electrothermal atomic absorption spectroscopy (ETAAS). While alkali metal halides cause most serious interferences in ETAAS, they are ideal media for electrochemical techniques. For this reason, a number of studies and systems have been reported which advantageously combine the ability of both techniques. These have included (i) electrodeposition onto Hg-coated graphite furnaces from a circulating solution,[1–3] (ii) electrodeposition (at 3–5 V)[4] or adsorption[5] on a tungsten wire followed by its insertion into a cold furnace (or a pre-heated furnace[6]), (iii) electrodeposition in a well in a porous carbon rod[7] and (iv) electrodeposition onto a Hg-coated pyrolytic graphite platform.[8] Circuitry has involved three-electrode systems[1,3,7] and simple two-electrode constant potential systems.[8]

The electrolytic method can achieve useful improvements in sensitivity, compared with conventional ETAAS, such as a 15-fold enhancement by 300 sec electrolytic deposition on a tungsten wire from an unstirred solution[4] and a 20- to 50-fold enhancement by 60 sec adsorption from a stirred solution.[5] More importantly it also achieves separation of analyte from a matrix which may be difficult to remove by thermal pretreatment and may be a source of both chemical and spectral interferences in ETAAS, *e.g.* NaCl in seawater or blood digests. In addition, controlled potential electrolysis may achieve speciation by plating only the labile species of a metal.[1,3] When coupled with ETAAS the electrode position technique is also applicable to metals which have low sensitivity by ASV (such as Ni, Mn, Cr and Co) due to their irreversible reduction.[1]

However, despite these advantages, the recovery of the analyte from the sample is generally low and slow. If quantitative deposition is required, prohibitively long electrolysis times are involved.[7] If, on the other hand, short deposition times are used only a small fraction of the analyte is recovered. For example, Fairless and Bard[7] reported an efficiency of 1% in plating Cu from 5 μl stationary solution on a porous carbon rod (60 sec at 0.18 V).

In addition to slow analyte accumulation all of the above approaches suffer from common problems that include contamination, complicated apparatus (especially for the recirculating technique) and invariably poor reproducibility. A possible solution to such problems is automation of the combined electrodeposition–ETAAS technique. *In situ* deposition as performed by Fairless and Bard[7] with subsequent removal of the exhausted electrolyte and washing of the deposit would lend itself well

to automated electrodeposition–ETAAS performed inside a conventional graphite furnace. However, the very inefficient analyte recovery which results from use of controlled potential electrolysis makes this approach unattractive for practical use.

Invariably, controlled potential deposition has been used when combining electrochemical separation and preconcentration with atomic spectroscopic techniques. Even for stirred electrolyte the deposition times are inordinately long.[9] This rather rigid adherence to controlled potential electrolysis (which is probably perceived as a well proven electrochemical approach) is not justified for techniques having the selectivity of ETAAS. Unless speciation is an objective, there is no need for controlled potential work.

A necessary prerequisite for automation of the electrodeposition–ETAAS technique is fast and efficient separation and preconcentration of the analyte elements from volumes compatible with the capacity of conventional graphite furnaces (usually in the range 20–100 μl). In order to evaluate if this can be achieved on the time scale similar to conventional graphite furnace analysis, we have studied electrodeposition from 50 μl volumes by applying relatively high voltages to sustain high electrolysis currents and to enhance the deposition rate further by convection created by gas evolution at both electrodes.

EXPERIMENTAL

To establish conditions for quantitative deposition, electrolysis was effected on samples deposited in the well of a Perkin-Elmer "V' pyrolytic graphite platform.[10] The platform with the "V"-shaped well 0.7 mm deep was 15 mm long, 4 mm wide and 1 mm thick. It served as a cathode, with a 0.5 mm dia. Pt wire anode mounted centrally 1 mm above the platform surface. In later experiments, the Pt anode was mounted on a micrometer attachment to allow accurate setting of the anode–cathode separation and a 0.5 mm dia. Ag/AgCl reference electrode was added to monitor the cathode potential.

The electrolyte used consisted of 0.1*M* KCl and 0.02*M* acetate buffer (pH 4.7) containing 0.02, 0.10 or 0.50 mg/l Pb. Each electrolysis was effected on a 50 μl sample for a fixed time using a constant potential power supply (4.0, 5.0 or 6.0 V). To determine concentration of the analyte element remaining in the electrolysed solution, a 25 μl aliquot was taken using a micropipette and transferred from the platform to a PAR 303 polarographic cell containing 5 ml Milli-Q water and 20 μl Aristar HNO_3. The solution was analysed by differential pulse ASV using a PAR 174A polarograph. ASV conditions were: N_2 flush, 9 min; stir, fast; drop size, medium; deposition time, 6 min; $E_d = -0.7$ V; scan rate = 5 mV/sec; modulation, 25 mV. After washing with 3% HNO_3 (electrodeposited Pb is dissolved readily by dilute HNO_3)[8] and drying the pyrolytic graphite platform was ready for a new electrolysis.

Since measurements of Pb concentrations down to sub-ppb levels were involved in the solutions remaining after electrolysis (and dilution in the polarographic cell), all experiments were performed in a class 100 clean room.

RESULTS AND DISCUSSION

In this study, we have simulated the problem of *in situ* deposition inside a graphite furnace by using a pyrolytic graphite platform and depositing from small volumes compatible with the size of the graphite furnace in ETAAS. Electrolysis was effected with uncontrolled potential set at 4.0, 5.0 or 6.0 V.

The efficiency of the deposition was evaluated as a function of time from the analyte concentration remaining after electrolysis. This was determined by differential pulse ASV measurements on aliquots of the electrolysed solution. The results presented in Fig. 1 show that the deposition efficiency increases significantly with the applied voltage. The increase in the depo-

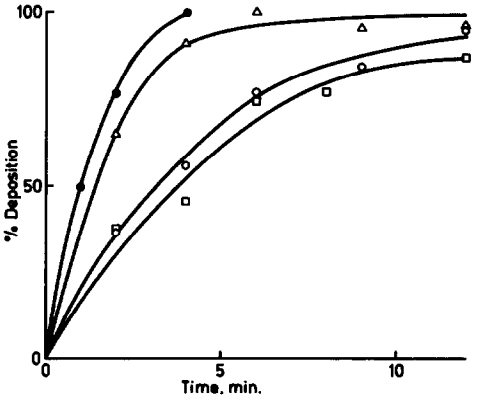

Fig. 1. The effect of applied voltage on efficiency of electrodeposition of 0.1 mg/l Pb from 0.1*M* KCl. Applied voltages used: (□) 4, (○) 4 with Hg co-deposition, (△) 5 and (●) 6 V.

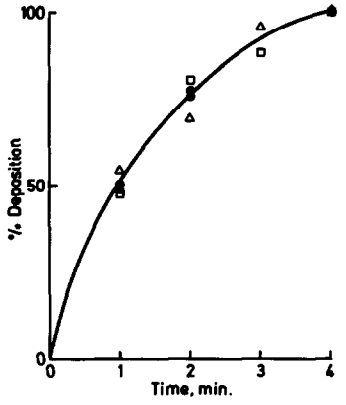

Fig. 2. The effect of Pb concentration on efficiency of electrodeposition from 0.1*M* KCl electrolysed at 6 V. Pb concentrations used: (□) 0.02, (●) 0.10 and (△) 0.50 mg/l.

sition rate with applied voltage is related to convective stirring of the sample which is achieved through adequate evolution of Cl_2, O_2 and H_2; gas evolution is apparent once the current exceeds 5 mA. Thus, deposition was complete in 4 min at 6.0 V and 90% complete in 12 min at 4.0 V. Co-deposition of Pb with Hg (from 0.0002*M* Hg^{2+}) did not significantly increase plating efficiency (Fig. 1). Our experiments further confirmed that the deposition rate was independent of the Pb concentration as shown in Fig. 2 for 0.02, 0.1 and 0.5 mg/l Pb. This indicates that the rate of deposition is controlled by the degree of convection achieved through the liberation of H_2, O_2 and Cl_2.

In order to characterize the pyrolytic graphite platform electrodeposition system, separate experiments were performed in which cathode potentials were measured relative to a Ag/AgCl reference electrode. With the anode–cathode separation set at 0.63 mm by a micrometer attachment, the cathode potential was established as −1.23, −1.52 and −1.87 V at $E_{applied} = 4.0$, 5.0 and 6.0 V, respectively. The current depended on the anode–cathode separation but was approximately 0.3, 2.0 and 4.5–6.0 mA at 4.0, 5.0 and 6.0 V, respectively.

The pyrolytic graphite platforms used in these experiments showed only limited lifetime. Exfoliation of pyrolytic graphite layers was observed to increase gradually with number of electrolyses performed, however this did not appear to affect the deposition rate for the first 50 electrolyses. The problem appears to be directly related to the number of pyrolytic graphite layers exposed in the manufacture of the platform used.[10] The electrolyte gradually forces its way between the layers, causing exfoliation, especially at higher electrolysis currents. It should be noted that similar problems, interpreted as being caused by intercalation, have been experienced when pyrolytic graphite platforms are used in ETAAS.[10]

CONCLUSIONS

The present report establishes that a batch electrolysis from 50 μl solution volumes can achieve quantitative deposition of the analyte element in relatively short times when conducted at a potential which can effect convective mixing by evolution of H_2, O_2 and Cl_2.

In recent publications, Sioda *et al.*[11,12] have suggested and experimentally verified that there are limits to electrolytic preconcentration caused by equilibrium concentrations of cations remaining in solution. It is possible to conclude that even though such limits apply to controlled potential work, they do not measurably affect the outcome of electrolyses performed under the conditions of our experiments.

Based on the principles established here, a recent paper by Matousek and Grey[13] has described instrumental modifications to allow automated *in situ* electrodeposition of analytes in the conventional pyrolytic graphite-coated furnace. The modified system consists of a GBC GF 2000 graphite furnace system equipped with a PAL autosampler and is capable of performing automated sample loading, electrolysis, withdrawal of the electrolyte, washing and chemical pretreatment of the electrodeposited metal.

(*Received* 15 *December* 1992. *Revised* 15 *April* 1993. *Accepted* 15 *April* 1993)

Summary—The electrochemical behavior of the relatively new antibacterial antibiotic Pipril (Piperacillin) at the dropping mercury electrode is investigated using both direct current polarography (DCP) and differential pulse polarography (DPP). At the hanging mercury electrode (HMDE), the reduction mechanism has been elucidated using cyclic voltammetric technique in the pH range from 2 to 10. The effect of some metal ions, *e.g.* Cu(II) and Pb(II) has been also tested. Determination of the drug using adsorptive stripping analysis was assessed in both aqueous and urine samples. The effect of the different experimental parameters affecting the drug determination, *e.g.* pH, supporting electrolyte nature, accumulation potential, accumulation time and other operational parameters are also mentioned. Detection limits of 5×10^{-9} and $1 \times 10^{-8} M$ Pipril in aqueous and urine samples, respectively, are achieved.

Pipril (Piperacillin) is a relatively new bactericidal semisynthetic penicillin with a broad spectrum of activity, encompassing both gram-negative and gram-positive anaerobic and aerobic organisms. The activities of Pipril was found to be more efficient than many other penicillins such as ticarcillin and carbenicillin.[1] The activity of piperacillin against pseudomonas may create a unique place for piperacillin amongst penicillins.[2] Piperacillin was shown to have considerable antibacterial activity against a wide range of 485 bacterial pathogens including anaerobic species which was generally superior to other beta-lactam antibiotics such as ampicillin, carbenicillin and cephalosporins.[3–6] Piperacillin has a potent bactericidal action since the ratio between the minimum bactericidal concentration (MBC) and the minimum inhibitory concentration (MIC) for it, was found to be equal to, or no more than twice.[7,8] Pipril has also a very high affinity for penicillin-binding proteins (PBPs).[9]

To date, no metabolites of Piperacillin have been found. In patients with normal renal function, Pipril is eliminated primarily (80%) by glomerular filtration and tubular secretion.[10,11] Its concentration in the urine is in excess of 10,000 μg/ml after a single 2 g intramuscular dose.[12] About 20% Pipril is excreted through the biliary tract.[10,13]

From the analytical point of view, Piperacillin have been determined using high-performance liquid chromatography.[14,15] It has been also determined using pulse polarographic technique by Schroeder *et al.*[16] They could determine the drug in both urine and serum samples but they could only reach a detection limit of 1 μg/ml. The aim of the present work is to elucidate the electrochemical reduction behavior of the drug and owing to the sensitivity of the adsorptive stripping methods of analysis,[16–19] we try to determine the drug in both aqueous and urine samples.

EXPERIMENTAL

Instrumentation

Direct current polarograms were obtained with a Tacussel (France) type PRG 5 in conjunction with a TV II GD built-in potentiometer and an EPL 1 B recorder. The capillary of the dropping mercury electrode has the following characteristics: $m = 2.10$ mg/sec, $t = 4.11$ sec (open circuit) and $m^{2/3}\, t^{1/6} = 2.07$ mg$^{2/3}$/sec$^{1/2}$.

*Author to whom correspondence should be addressed.

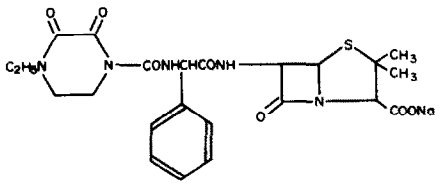

Fig. 1. Chemical structure of Piperacillin (Pipril).

Stripping and cyclic voltammograms were measured with an EG & G Princeton Applied Research Corp. microprocessor-controlled: (PAR) Model 264 A stripping analyzer, coupled with a PAR 303 A static mercury drop electrode SMDE (drop size; medium, area of the drop: 0.014 cm^2). The polarographic cell bottom (PAR model K 0060) was fitted with an AG/AgCl reference electrode, and a platinum wire was used as a counter electrode. A PAR 305 stirrer was connected to the 303 SMDE. For the collection of experimental data, a PAR Model RE 0089 X–Y recorder was used.

Reagents

Stock solutions ($1 \times 10^{-3} M$) of Pipril as Piperacillin sodium (CID Laboratories, Egypt) were prepared daily by dissolving the appropriate amounts in bidistilled water. Supporting electrolytes were analytical grade reagents and prepared also in bidistilled water.

Urine samples (from healthy people) were used in the analyses by spiking the drug under investigation in these samples, after dilution, 10 times with the supporting electrolyte.

Procedure

An aliquot of 10 or 50 ml of the supporting electrolyte was deareated with nitrogen for 12 or 20 min for differential pulse (DPP) and cyclic voltammetric (CV) or direct current (DC) measurements, respectively. The drug was then spiked and then polarograms or voltammograms were recorded.

For stripping voltammetric measurements, the accumulation potential was applied to a new mercury drop then the solution was stirred at 400 rpm. A negative-going scan was performed after the equilibration period (15 sec) when needed. Unless otherwise stated, the following parameters were used: accumulation potential (and initial potential) of -0.5 V *vs.* Ag/AgCl/$KCl_{(s)}$, equilibrium time 15 sec; scan rate 5 m V/sec, pulse amplitude 50 mV. The same procedure was repeated after spiking the solution with the analyte. Quantitative analysis was then performed by the standard addition method using different spikes. Quantitative measurements of the drug in urine samples were carried out by replacing the supporting electrolyte blank solution with another containing a urine sample diluted 10 times with the same supporting electrolyte and then repeating the foregoing steps under the same experimental conditions. All data were obtained at room temperature (25 ± 1°C).

RESULTS AND DISCUSSION

The structure of the drug under investigation is shown in Fig. 1.

Polarographic measurements

Preliminary investigation of the DC polarography of $2 \times 10^{-4} M$ Pipril (PIP) in $0.1 M$ phosphate buffer gives rise to only one reduction wave shifted to more electronegative potentials as the pH increases. Figure 2 shows these reduction waves; as the pH increases, the

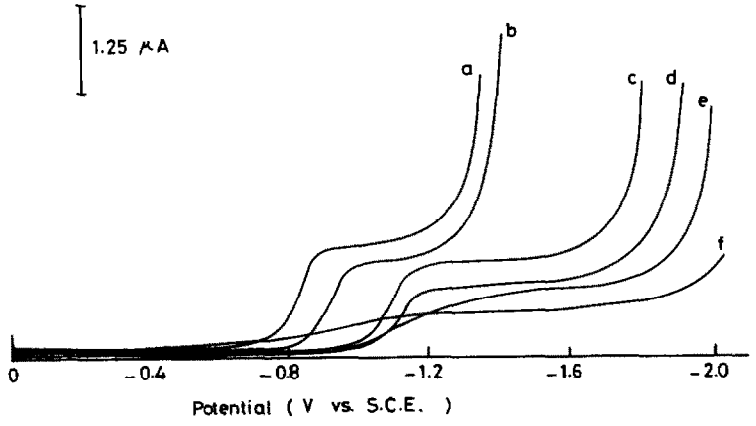

Fig. 2. Effect of the pH on $2 \times 10^{-4} M$ Pipril, $0.1 M$ phosphate buffer, pH: (a) 2.0, (b) 3.0, (c) 4.0, (d) 5.2, (e) 6.6, (f) 8.8. DC mode, 240 mV/min.

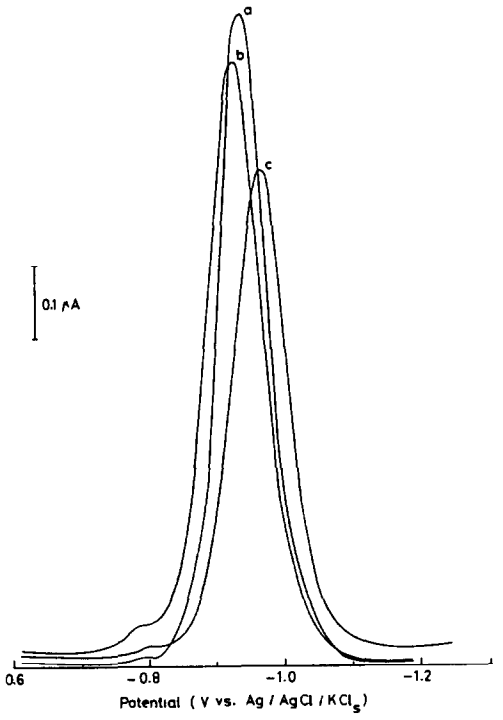

Fig. 3. Differential pulse polarography of $1 \times 10^{-5}M$ Pipril in different media, pH 1.5, $0.1M$ supporting electrolyte: (a) perchloric acid, (b) phosphate buffer, (c) acetate buffer. Pulse amplitude 50 mV, scan rate 5 mV/sec.

morphology of the wave changes until it disappears at about pH 9.0 probably due to hydrolysis of the drug in alkaline medium. By analyzing these polarographic waves, irreversibility of the reduction process have been elucidated; α is calculated to be 0.33 as the number of electrons consumed during this process was found to be two using coulometry. The shift of the half-wave potentials is drawn against the pH using the following equation:[20]

$$\frac{\Delta E_{\frac{1}{2}}}{\Delta pH} = -\frac{2.3\,PRT}{2\alpha F}.$$

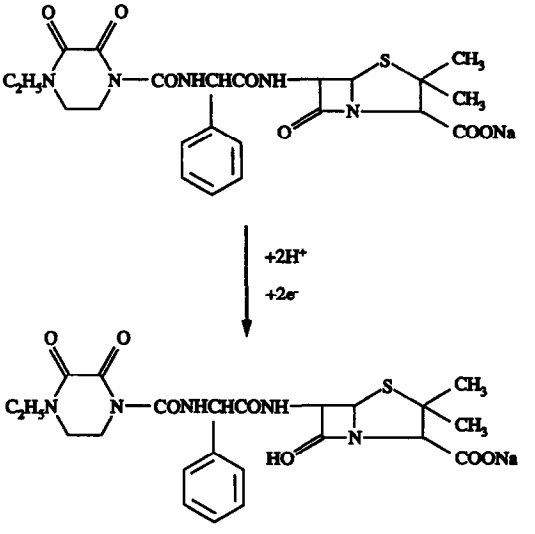
A straight line is obtained, and as the value of α being 0.33, the number of protons consumed in the reduction process is calculated to be 2. Therefore, the reduction mechanism involves two electrons and two protons/mole of the drug. The logarithms of the limiting currents of these waves are drawn against the logarithms of the corrected mercury height, slopes ranged from 0.47 to 0.53 are obtained indicating that the reduction is under diffusion—controlled in the pH range from 2 to 7, while it was difficult to test it in alkaline media as the morphology of the peak becomes distorted.

On applying the differential pulse mode on $1 \times 10^{-5}M$ PIP in perchloric acid, acetate buffer and phosphate buffer, one peak is obtained having a half-peak width of about 80 mV corresponding to irreversible two-electron process. It is obvious from Fig. 3 that both perchloric acid and phosphate buffer gave almost the same sensitivity while it decreases in presence of acetate buffer as supporting electrolyte. For this reason, further investigation of the drug have been carried out in phosphate buffer medium. It is worthwhile mentioning that a pre-peak always appears in acidic media, indicating that adsorption of the oxidized form may occur.

Voltammetric measurements

Cyclic voltammetric measurements of $1 \times 10^{-5}M$ PIP show one irreversible, cathodic peak. The effect of the scan rate on the cyclic voltammogram of $1 \times 10^{-4}M$ PIP is shown in Fig. 4. When the peak current is drawn as a function of the square root of the scan rate $v^{\frac{1}{2}}$, in the pH range from 1.5 to 7, diffusion-controlled process is elucidated as a linear plot is obtained.

From the DC, DPP and CV measurements, it could be concluded that the following reduction mechanism may occur:



On scanning multiple cycles on the same drop (Fig. 5) for $1 \times 10^{-4}M$ PIP over all the investigated pH values, fast desorption behavior of the drug is noticeable as a marked decrease in the peak current is measured on scanning the second, third, ... cycles on the same drop. It should be noted that this desorption is strong in relatively high pH (3–6) while in strong acidic

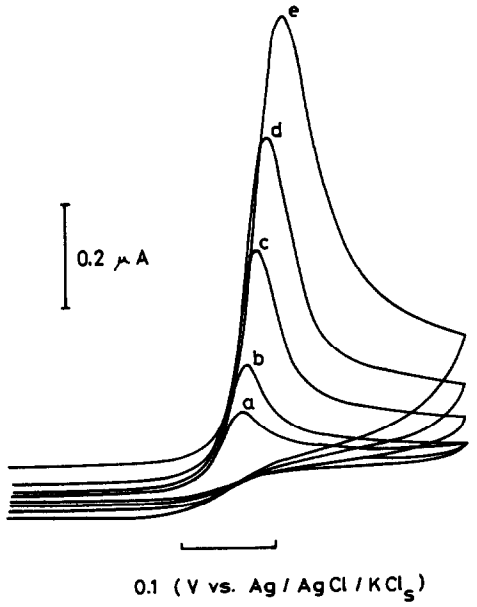


Fig. 4. Cyclic voltammograms of $1 \times 10^{-4}M$ PIP in $0.1M$ phosphate buffer, pH 5.8, scan rate: (a) 10, (b) 20, (c) 50, (d) 100, (e) 200 mV/sec. Starting potential -0.9 V *vs.* Ag/AgCl/KCl$_s$.

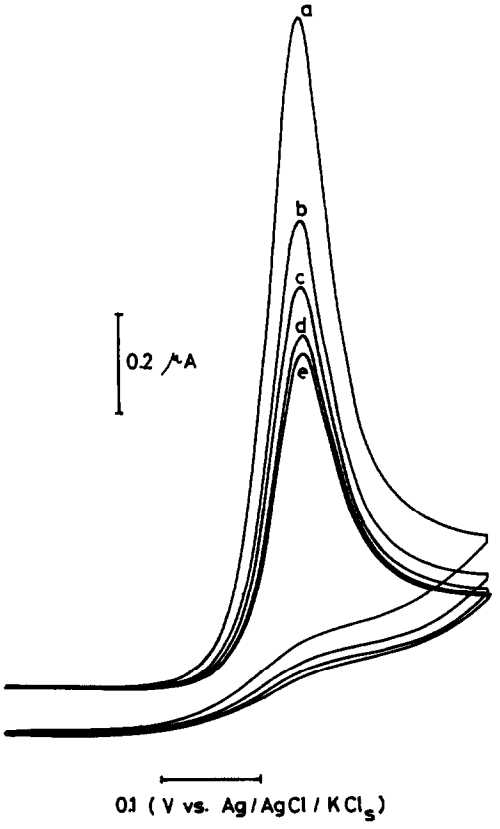

Fig. 5. Multiple cyclic voltammograms of $1 \times 10^{-4}M$ PIP in $0.1M$ phosphate buffer, pH 3.5, scan rate 200 mV/sec. Starting potential -0.8 V *vs.* Ag/AgCl/KCl$_s$. (a) First, (b) second, (c) third, (d) fourth, (e) fifth cycle.

media (pH < 3), it is relatively weak. This fact will be useful for the accumulation of the drug in strong acidic medic (pH $\leqslant$ 2) as will be mentioned later in this paper.

Effect of possible interfering metal ions

The effect of the possible interfering metal ions on the peak shape and height of Pipril has been also tested. We choose two metals, one essential non-toxic metal ion viz. Cu(II) and the other is non-essential, toxic metal ion viz. Pb(II).[21] On applying cyclic voltammetry on $1 \times 10^{-5}M$ Pipril in presence of up to $4 \times 10^{-4}M$ Cu(II), no noticeable change in either the Pipril peak height or potential is observed. The same behavior is also obtained in presence of up to $6 \times 10^{-4}M$ Pb(II). However, there is an observed shift in the peak potential of these metals indicating that a complexation reaction takes place. From the biological point of view, this interaction is useful as human fluid always contains Cu(II) because it is an essential metal ion while Pb(II) is a toxic non-essential-metal ion.[22] These facts are useful in the analysis of the drug itself in presence of either of these metals, as will be stated later.

Analytical application in aqueous and urine samples

Preliminary investigation on $1 \times 10^{-6}M$ Pipril showed that the drug has a tendency to be adsorbed and accumulated at the hanging mercury drop electrode (HMDE). However, on applying accumulation times of more than 15 sec, it begins to be desorbed again from the HMDE indicating that fast desorption behavior is almost finished. This fact has also been elucidated by applying multiple cycles (CV) on the same drop (HMDE) after the accumulation of the drug for a certain time, as on the second cycle the adsorptive peak begins to decrease and almost disappear.

The adsorptive behavior of the drug under investigation is studied by comparing two different techniques, direct current stripping voltam metry (DCSV) and differential pulse stripping

Table 1. Characteristics of Pipril, peak current–accumulation time plots ($0.1M$ phosphate buffer), pH 2.0

Concentration, (M)	Linearity range (*sec*)	Equation*	Correlation coefficient
5×10^{-8}	0–25	$Y = 0.042x + 0.003$	0.9973
1×10^{-7}	0–20	$Y = 0.002x + 0.070$	0.9969
5×10^{-7}	0–15	$Y = 0.011x + 0.120$	0.9961
1×10^{-6}	0–10	$Y = 0.008x + 0.180$	0.9971

*Y in μA, x in sec, slope in μA/sec, intercept in μA.

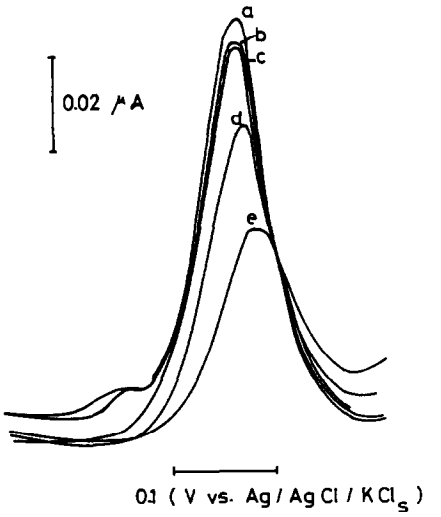

Fig. 6. Differential pulse cathodic stripping voltammograms of $1 \times 10^{-6}M$ Pipril in urine sample diluted 10 times with $0.1M$ phosphate buffer, pH = 2.0 $E_{acc} = -0.5$ V, $E_{initial} = -0.7$ V *vs.* Ag/AgCl.KCl$_{(s)}$, t_{acc}: (a) 0, (b) 5, (c) 10, (d) 30, (e) 60 sec.

voltammetry (DPSV). Although using the DCSV mode we can apply high scan rates to avoid desorption of the drug in measuring the adsorptive peak current I_{ps}, DPSV mode was found to be more sensitive. The effect of the different experimental parameters on the DPSV, *e.g.* pulse amplitude, scan rate, accumulation potential, supporting electrolytes and accumulation time has been tested. The optimum conditions to increase the sensitivity for the determination of the drug at the (HMDE) were found to be 50 mV pulse amplitude, 5 mV/sec scan rate, accumulation potential of -0.5 V *vs.* Ag/AgCl/KCl(s) and among four tested supporting electrolytes viz. perchloric acid, sulfuric acid, acetate buffer and phosphate buffer, the last one gives rise to more sensitive peak height and also to a more defined peak form.

The effect of the pH on the adsorptive behavior of $5 \times 10^{-7}M$ Pipril has been examined, the sensitivity was found to be more pronounced in acidic medium. Phosphoric acid adjusted to pH 2.0 gives rise to a good signal. It should be mentioned that almost the same sensitivity is obtained in weakly acidic solutions but with lower reproducibility. For this reason phosphoric acid (pH 2) was utilized for further investigations.

The influence of the accumulation time on the adsorptive behavior of Pipril has been tested using four different concentrations viz.; $5 \times 10^{-8}M$, $1 \times 10^{-7}M$, $5 \times 10^{-7}M$ and $1 \times 10^{-6}M$ Pipril. Table 1 summarizes the results obtained, the limit of linearity and their correlation coefficients. It is obvious from the data listed in the table that as Pipril concentration increases, the limit of linearity (expressed by the accumulation time) decreases.

Reproducibility was evaluated by performing 10 measurements on a $5 \times 10^{-8}M$ solution after a 10 sec accumulation, with stirring. A mean value of 0.065 μA was found, with a range of 0.06–0.07 μA and a relative standard deviation of 2.5%.

Calibration curves have been established with different accumulation times viz. 5, 10, 15 and 20 sec. In spite of desorption behavior described above, linearity could be obtained for a constant preconcentration time in the concentration range from 5×10^{-8} to $1 \times 10^{-6}M$.

Detection limit of $5 \times 10^{-9}M$ Pipril in 10 ml has been established considering the signal-to-noise ratio of 3. This means that 0.27 ng Pipril are detectable in 10 ml solution.

Urine analysis

Figure 6 shows the cathodic stripping voltammograms of spiked $1 \times 10^{-6}M$ Pipril in urine samples diluted 10 times with the supporting electrolytes. As seen from these voltammograms, applying accumulation times of more than 5 sec. the peak begins to decrease, part of this phenomenon is (as previously mentioned in this work) due to fast desorption of the drug and the other part may be attributed to the interference of the unknown potentially interfering urine constituents. Therefore, direct current measurements, *i.e.* DPP without preconcentration were preferable in such analysis. Linear relationships were obtained when the peak current is drawn as a function of Pipril concentration in the range from 5×10^{-7} to $5 \times 10^{-5}M$. However, as the concentration range found in human urine after a single 2 g intramuscular exceeds 10,000 μg/ml,[12] corresponding to $0.018M$ Pipril, our linearity range is very sensitive compared with the dose originally found.

Detection limit of $1 \times 10^{-8}M$ Pipril could easily be achieved based on the signal-to-noise ratio of 3.

KINETICS OF INDIUM ATOMIZATION FROM DIFFERENT ATOMIZER SURFACES IN ELECTROTHERMAL ATOMIC ABSORPTION SPECTROMETRY (ETAAS)

XIU-PING YAN and ZHE-MING NI*
Research Center for Eco-Environmental Sciences, Academia Sinica, P.O. Box 2871, Beijing, China 100085

Institute of Rock and Mineral Analysis, Beijing, China

GUO-QIANG HONG
Factory of Geological Instrument, Beijing, China

(*Received* 3 *December* 1992. *Revised* 18 *May* 1993. *Accepted* 20 *May* 1993)

Summary—The kinetic parameters of indium atomization in electrothermal atomic absorption spectrometry (ETAAS) have been determined by a newly proposed method. Effect of the atomizer surface and the palladium modifier on the kinetics of indium atomization has been investigated. The mechanisms of indium atomization seem to be identical for the pyrolytically coated graphite and the uncoated graphite tubes, *i.e.* the rate-limiting step for the atomization changes from a first order kinetics at lower temperatures into a nearly 1/3 order kinetics at higher temperatures, which may suggest that the analyte moves from a dispersed state to agglomates with increasing temperature. However, for the zirconium coated graphite tube, the atomization of indium is controlled by a single mechanism with the kinetic order of near 2/3 and the activation energy of 186 ± 13 kJ/mol. Relatively weak indium–zirconium carbide interactions and the release of indium from the sphere of molten indium metal on the zirconium coated surface are suggested. In the presence of palladium, a simple mechanism, *i.e.* the release of indium from the solid solution of the In and the Pd on the pyrolytically coated graphite surface, is proposed to account for the observed first order kinetics and the activation energy of 421 ± 27 kJ/mol.

The atomization of analytes in electrothermal atomic absorption spectrometry (ETAAS) has been studied by many researchers based on kinetic,[1–5] thermodynamic[6–10] and combined kinetic–thermodynamic considerations.[11–15] Usually, most of these reports focused on the atomization mechanisms of analytes without matrices nor modifiers from one type of graphite surface. However, it is more important to elucidate the mechanisms of analyte released in the presence of matrices or modifiers from different atomizer surfaces since normal analysis is often carried out under such conditions. Thus far, there have been a few papers appearing to deal with the atomization mechanisms of the analyte from various atomizer surfaces. Aggett and Sprott[16] compared the appearance temperatures for the atomization of various analytes from both graphite and tantalum surfaces, and concluded that the most possible mechanism for the analyte atomization from a tantalum surface was the thermal decomposition of the oxide. Gregoire *et al.*[17] studied the atomization mechanisms of U, V, Mo, Ni, Mn, Cu and Mg from pyrolytic graphite and tantalum surfaces. The atomization mechanisms of various analytes from molybdenum[18] and tungsten[19] surfaces were compared with those from the graphite surface. Gao and Ni[20] suggested that the atomization mechanism of germanium in the zirconium coated graphite tube was the vaporization of germanium following the reduction of GeO_2 or GeO by zirconium carbide, which was different from the thermal decomposition mechanism of the oxide in the uncoated graphite tube. Recently, Chakrabarti and Cathum[21] investigated the mechanism of cobalt atomization from different atomizer surfaces in ETAAS, and suggested that the atomization mechanism of

*Author for correspondence.

cobalt seemed to be the same for the pyrolytically coated graphite and the uncoated electrographite surfaces, but different for the glassy carbon furnace. Fonseca *et al.*[22] studied the vaporization/atomization characteristics of Cu sample from graphite and Ta-lined tubes using both Ta and graphite platforms and found first order release of Cu from both Ta and graphite surfaces.

Much less attention has been paid to the behavior of indium in the graphite furnace compared with other analytes. Grinshtein *et al.*[23] studied the interaction between indium and the graphite surface at various temperatures by using a tube-in-tube, spatially isothermal furnace. At temperatures less than 1900 K, indium adsorbed to the graphite surface and the effective residence time of this element was greater than theoretically predicted residence time. However, at temperatures greater than 1900 K, no significant adsorption of In occurred. In an earlier study, Katskov *et al.*[24] determined an activation energy of 234 kJ/mol at lower temperatures followed by 134 kJ/mol at higher temperatures for the atomization of In. Recently, McNally and Holcombe[25] studied the topology and vaporization characteristics of indium in a CRA- 90 min. Massmann furnace. Two activation energies of 238 ± 29 and 138 ± 21 kJ/mol were obtained over the course of release from In using manual pipetting. An appearance order of greater than one was suggested for indium release from the concentration study, and the aggregate surface was proposed as one of the generation mechanisms for indium. They also observed the relatively weak interaction between indium and graphite.

The purpose of this work is to study the atomization kinetics of indium from different atomizer surfaces, *i.e.* pyrolytically coated, uncoated and zirconium coated graphite surfaces, and the effect of the palladium modifier on the kinetics of indium atomization from the pyrolytically coated graphite surface by using a newly proposed method.[26]

THEORY

In a previous report,[26] a method was developed for the simultaneous determination of the kinetic parameters of atom formation from a single absorbance signal profile under normal analytical conditions in electrothermal atomic absorption spectrometry (ETAAS). The change of the absorbance, A, with time, t, was given by the following equation:

$$dA/dt = P^{x-1}k_1\left(\int_t^\infty k_2 A\,dt - A\right)^x - k_2 A \quad (1)$$

where k_1 and k_2 are the temperature and subsequently time dependent rate constants for the formation and dissipation of gaseous atoms, respectively; P a proportionality factor, x the kinetic order of the atom formation reaction. According to the Arrhenius' law, the temperature dependence of k_1 can be expressed as follows:

$$k_1 = k_0 . \exp(-E_a/RT) \quad (2)$$

where k_0 and E_a are the frequency factor and activation energy for atom formation, respectively; R the gas constant and T the absolute temperature at time t. Substituting equation (2) into equation (1) and rearranging yields:

$$dA/dt + k_2 A = k_0 P^{x-1} \times\left(\int_t^\infty k_2 A\,dt - A\right)^x . \exp(-E_a/RT) \quad (3)$$

Taking logarithm of equation (3), differentiating and rearranging give

$$\Delta \ln(dA/dt + k_2 A)/\Delta \ln\left(\int_t^\infty k_2 A dt - A\right) = x - (E_a/R)\Delta(1/T)/\Delta \ln\left(\int_t^\infty k_2 A\,dt - A\right). \quad (4)$$

Equation (4) shows that if the atomization of the analyte from the atomizer surface is governed by a single kinetic mechanism, a plot of $\Delta \ln(dA/dt + k_2 A)/\Delta \ln(\int_t^\infty k_2 A\,dt - A)$ *vs* $\Delta(1/T)/\Delta \ln(\int_t^\infty k_2 A\,dt - A)$ should be a straight line. From the slope of such a plot, the activation energy (E_a) can be calculated, while the kinetic order (x) can be obtained from the intercept. The validity of equation (4) has been confirmed both by computer simulation study[26,27] and the ETAAS experiments.[26]

To obtain the kinetic order and activation energy by using equation (4), the temperature dependence of k_2 should be known. In this study, the gas-stop mode is used in the atomization step and the dissipation of the analyte by convection is distinctly negligible. Therefore, k_2 is the total rate constant for the dissipation of the analyte by diffusion and thermal expansion only, *i.e.*

$$k_2 = k_d + k_e \quad (5)$$

where k_d and k_e are the constants for atom dissipation by diffusion and thermal expansion at any time, respectively; K_d is defined as[28]

$$k_d = k_d^0 (T/T_0)^y \quad (6)$$

where k_a and k_d^0 are diffusional rate constants at temperature T and T_0, respectively; y varies between 1.5 and 2.0,[28] K_e is given by[29]

$$k_e = (dT/dt)/T \quad (7)$$

where dT/dt is the heating rate at any temperature T.

For determining the temperature dependence of k_2, the values of k_d^0 and y should be obtained. For indium, the y value of 1.84 can be found from Ref. 30. The value of k_d^0 can be determined from the decay portion of the absorbance signal profile based on the method proposed by Akman *et al.*[29]

To determine E_a and x based on equation (4), the terms of dA/dt and $\int_t^\infty k_2 A\, dt$ should be calculated. To this end, mathematical expressions of $A = f_1(t)$ and $k_2 A = f_2(t)$ are obtained by polynomial regressions. Thus, the functions of $dA/dt = f'_1(t)$ and $\int_t^\infty k_2 A\, dt = F_2(t)$ can be obtained by differentiating the expression of $A = f_1(t)$, and integrating $k_2 A = f_2(t)$, respectively.

Data from the appearance to the maximum in the absorbance signal can be used to construct the plot based on equation (4) for determination of the kinetic order and activation energy since the amount of the analyte unatomized on the tube surface at time t, $P(\int_t^\infty k_2 A\, dt - A)$, is greater than zero from the beginning at least to the maximum in the signal. In addition, special conditions to isolate the supply and removal function, and linear temperature ramp are indeed not required with the use of equation (4) because of no such assumptions made during the derivation of equation (4).

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 4000 atomic absorption spectrometer, equipped with a deuterium background corrector and a model HGA-400 graphite furnace was used for the measurement of the atomic absorption in the gas-stop mode. An indium hollow-cathode lamp (Shanghai Tienkuang Scientific Instruments Works, Shanghai, China) was employed at a lamp current of 5 mA. The 303.9 nm line of indium was used as the analysis line, with a spectral bandpass of 0.7 nm. High purity argon gas was used as both sheath and purge gas. The furnace programme is given in Table 1.

Table 1. Furnace programme

	Dry	Ash	Atomize	Clean
Ramp time (*sec*)	20	5	1	1
Hold time (*sec*)	50	30	5	2
Temperature (°C)	130	Various	Various	2650
Int. gas flow (*ml/min*)	300	300	0	300

The graphite tube wall temperature was obtained from the output of a germanium phototransistor (B 1918-01, Hamamatsu), which was calibrated by focusing a disappearing filament optical pyrometer (Ircon Inc., UX-10, USA) through the sample injection hole in the graphite tube. The absorbance and temperature signal were synchronously acquired by a microcomputer-based data acquisition system at 20-msec intervals.[26] The signals could be subsequently stored on a diskette for further use.

Three different atomizer surfaces were used for the atomization of indium: Pyrolytically coated (PG), uncoated graphite tubes (UG) and the zirconium coated PG (ZrPG). The ZrPG were prepared according to Ref. 31.

Reagents

The stock solution containing 1000 mg/ml In was prepared by dissolving In_2O_3 in an adequate volume of diluted nitric acid and subsequently diluting with deionized water. Working standards of the element were prepared daily from this stock solution with deionized water just before use. Indium working solutions were manually introduced into the furnace in 20-μl volumes using an Eppendorf pipette.

A 5% m/v of $ZrO(NO_3)_2 . 2H_2O$ solution was prepared by dissolving $ZrO(NO_3)_2 . 2H_2O$ in diluted nitric acid and then diluting with deionized water.

All chemicals were of analytical-reagent grade.

RESULTS AND DISCUSSION

Atomization from the pyrolytically coated graphite tube (PG)

The concentration study, which is illustrated in Fig. 1, contains absorbance–time plots for various initial masses of In deposited on the

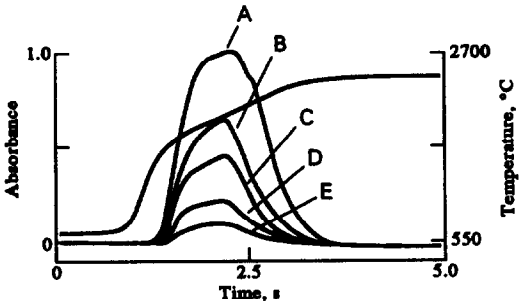

Fig. 1. Absorbance signal profiles for various masses of In from the pyrolytically coated graphite tube: (a) 5 (b) 3 (c) 2 (d) 1 (e) 0.5 ng. Ashing temperature: 500°C, atomization temperature: 2600°C, other conditions as listed in Table 1.

bottom of the PG. As the initial amount of In deposited on the surface of the PG is increased, peak times are similar and there is a slight shift to earlier appearance times. Thus, the apparent kinetic order for indium atomization from the PG appears to be unity.[25] To obtain the kinetic order of indium atomization accurately, the plot of $\Delta \ln(dA/dt + k_2 A)/\Delta \ln(\int_t^\infty k_2 A \, dt - A)$ *vs* $\Delta(1/T)/\Delta \ln(\int_t^\infty k_2 A \, dt - A)$ is constructed from the absorbance signal profile. Figure 2 shows such a plot obtained from Fig. 1(c). As can be seen, the plot exhibits curvature, and so assignment of a single straight line from this plot is difficult, which may, in fact, reflect a continuous varying slope. This could imply gas-phase dissociation as step governing atom formation or a temperature dependence of activation energy (E_a) and kinetic order (x) on surface coverage. Figure 3 shows the decomposition (curve A) and atomization (curve B) curves for indium from the PG. As can be seen, there is a gap between the temperature in the decomposition curve at which the absorbance begins to decrease (the maximum tolerant ashing temperature), and the appearance temperature in the atomization

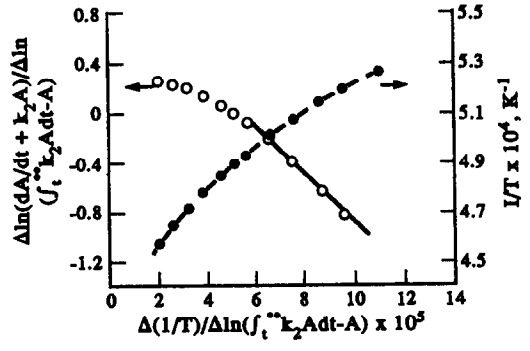

Fig. 2. Plot obtained from Fig. 1(c) based on equation (4) for 2 ng of In from the pyrolytically coated graphite tube.

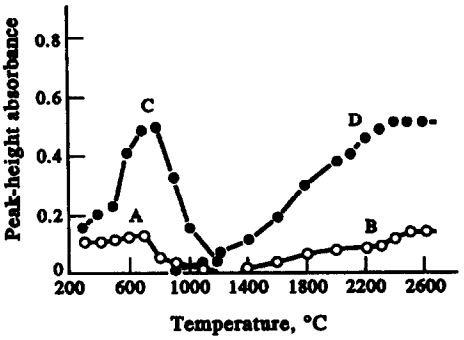

Fig. 3. Decomposition and atomization curves for 0.5 ng of In by atomization from the pyrolytically coated graphite tube; (a) decomposition curve, at the atomization temperature of 2600°C (b) atomization curve, at the ashing temperature of 500°C, and from the zirconium coated graphite tube; (c) decomposition curve, at the atomization temperature of 2400°C and (d) atomization curve, at the ashing temperature of 800°C.

curve. This means that the decrease in the absorbance is not only due to loss of $In_{(g)}$ but also to the formation of other gaseous species at temperatures above 700°C. Calculations of thermodynamic equilibrium in the In–O–C system over the temperature range of 500–2000 K have shown that $In_2O_{(g)}$ is likely to be formed at either high ashing or lower atomization temperatures, but that $InO_{(g)}$ should not play a significant role in the atomization of In.[32] This has been confirmed by means of graphite furnace-mass spectrometry (GFMS) experiment.[32] However, it is not easy to discuss the formation of free indium via gas-phase dissociation of an oxide in terms of kinetics since one must take into account the change in partial pressure of oxygen as well as the generation function of the indium oxide from the surface and the generation of the metal from the gas.[33]

An alternative explanation for the curvature observed in Fig. 2 may be that multiple release mechanisms contribute to the atomization of indium from the PG surface. If two straight lines are used to fit the plot in Fig. 2, then the activation energy (E_a) and kinetic order (x) could be found to be 134 kJ/mol and 0.97 at lower temperatures, 63 kJ/mol and 0.37 at higher temperatures, respectively. This probably indicates that the rate-limiting step for the atomization of indium changes from a nearly first order kinetics with larger E_a value at lower temperatures into the kinetics of $x = 0.37$ with lower E_a value at higher temperatures.

If we assume that either two straight lines or a continuous curve exists in Fig. 2 and that the

intercept of any portion of the curve (*i.e.* the kinetic order x) would represent the state of the morphology of the analyte on the surface at that time, then one could conclude that the material moves from a dispersed state of $x = 1$ to agglomerates (*i.e.* $x = 0.37$). This suggests that the analyte begins as dispersed atoms or molecules containing indium and then forms droplets with increasing temperature. Although indium metal indeed exhibits weak interactions at the graphite observed by McNally and Holcombe,[25] some indium molecular species may have a strong interaction which causes it to be dispersed on the surface and exhibited nearly first order release at lower temperatures. The obtained larger E_a value (134 kJ/mol) could represent indium molecular species-graphite interaction energy. Furthermore, the weak indium metal–graphite interactions would foster the formation of droplets which is consistent with the higher temperature order of release ($x = 0.37$). The observed lower E_a value may represent the energy required for indium release at the edge of the metal–graphite interface.[25,34] It is possible that indium metal would be formed either through carbon reduction of the oxide or the thermal decomposition of the oxide at higher temperatures. In addition, no significant influence of the initial injected mass of indium studied on the indium atomization from the PG is observed, as shown in Table 2.

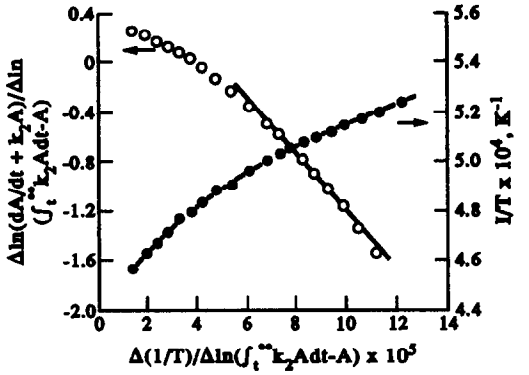

Fig. 4. Plot constructed based on equation (4) for 2 ng of In from the uncoated graphite tube. Other conditions as in Table 1.

Atomization from the uncoated graphite tube (UG)

In order to examine surface spreading and penetration by the aqueous solution of the sample on the atomization of indium, the kinetic parameters of indium atomization from the uncoated graphite tube (UG) have been determined. Figure 4 illustrates the plot of $\Delta \ln(dA/dt + k_2A)/\Delta \ln(\int_t^\infty k_2 A \ dt - A)$ *vs* $\Delta(1/T)\Delta \ln(\int_t^\infty k_2 A \ dt - A)$ from the absorbance signal profile for 2 ng of indium ashed at 500°C and atomized at 2600°C from the UG. Compared with Fig. 2, similar results can be obtained from Fig. 4, *i.e.* Fig. 4 also exhibits nonlinearity, reflecting a continuous varying slope and intercept. If two straight lines are

Table 2. Kinetic parameters for indium atomization from different atomizer surfaces (±standard deviation of three determinations)

used to fit Fig. 4, the kinetic order and activation energy can be found to be 0.97 and 155 kJ/mol, at lower temperatures, respectively; while at higher temperatures, the kinetic order of 0.38 and activation energy of 67 kJ/mol can be obtained. Although the uncoated graphite surface is expected to show much more porous than the pyrolytically coated graphite surface, the near identity of the kinetic parameters indicates that the atomization mechanisms of indium are similar for both atomizer surfaces.

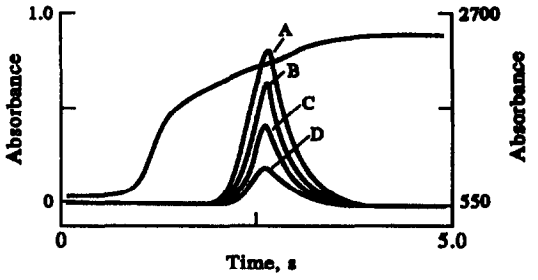

Fig. 6. Absorbance signal profiles for various masses of In from the pyrolytically coated graphite tube when 2 μg of Pd is used as a modifier: (a) 1; (b) 0.75; (c) 0.5; (d) 0.25 ng. Other conditions as in Fig. 1.

Atomization from the PG surface in the presence of palladium

It has been shown that palladium is an effective matrix modifier for the determination of indium, which greatly improves the sensitivity and raises the maximum tolerant ashing temperature.[35] In this work, the effect of the presence of palladium on the atomization mechanism of indium is investigated. The palladium modifier is pretreated before each determination by injecting a 20 μl of 100 μg/ml Pd into the PG through the sample injection hole, drying at 150°C for 30 s and heating at 900°C for 30 sec. Figure 5 shows the plot of $\Delta \ln(dA/dt + k_2A)/\Delta \ln(\int_t^\infty k_2A\,dt - A)$ *vs* $\Delta(1/T)/\Delta \ln(\int_t^\infty k_2A\,dt - A)$ from the absorbance signal profile for 0.5 ng of In ashed at 500°C and atomized at 2600°C from the PG surface in the presence of palladium. In contrast to Figs 2 and 4, a single straight line can be fit well to the plot shown in Fig. 5. This means that a single mechanism is active in the atomization of indium with palladium. From Fig. 5 the activation energy and kinetic order are found to be 414 kJ/mol and 0.95, respectively. No significant influence of the initial injected mass of indium studied on the kinetics of indium atomization is observed, as shown in Table 2. The first order kinetics can also be seen from the concentration study depicted in Fig. 6. These results suggest that the atomization mechanism of indium in the presence of palladium is different from those for the PG and UG in the absence of palladium.

Figure 7 shows the absorbance signal profiles for 0.5 ng of In ashed at 500°C and atomized at 2600°C from the PG with (curve A) and without (curve B) the palladium modifier. Obviously, in the presence of palladium the appearance of the absorbance signal is significantly delayed, and both the peak height and peak area are increased. The increase in the sensitivity indicates that the use of a palladium modifier prevents the formation of gaseous species in the presence of palladium. By using Fourier transform infrared spectrometry, Volynsky *et al.*[36] found that the palladium modifier sharply decreased the reduction temperature of the metal oxides with graphite. It was regarded that the catalytic property of palladium facilitated the carbon reduction of oxides at low ashing temperatures.[36] Thus, we assume that in the presence of palladium the oxide $In_2O_{3(s)}$ is rapidly reduced to metallic indium, and the resultant indium metal forms the intermetallic compounds or solid solution[37,38] with the

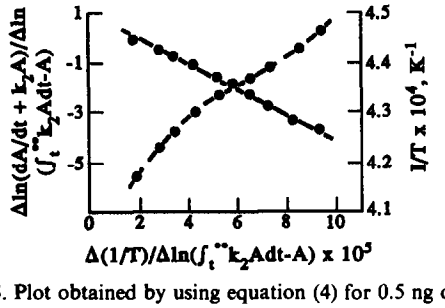

Fig. 5. Plot obtained by using equation (4) for 0.5 ng of In in the presence of 2 μg of Pd from the pyrolytically coated graphite tube. Other conditions as in Fig. 1.

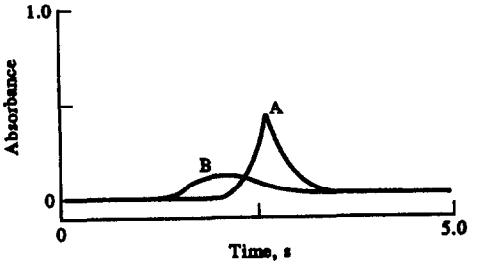

Fig. 7. Effect of palladium modifier on the absorbance signal profile of indium from the pyrolytically coated graphite tube: (a) 0.5 ng In + 2 μg Pd; (b) 0.5 ng In. Conditions as shown in Fig. 1.

palladium metal, thus decreasing or almost eliminating loss of the analyte due to the formation of gaseous oxide. At the atomization stage, the absorbance is produced owing to the release of indium from the solid solution with Pd, which may cause the observed first order kinetics. The obtained E_a value (421 ± 27 kJ/mol) represents the energy required to release the indium in molten palladium, which depends on the heat of solution of the In and the pd.

Atomization from the zirconium coated graphite tube (ZrPG)

The absorbance signal profiles for different amounts of indium atomized from the zirconium coated graphite tube (ZrPG) under optimum conditions are depicted in Fig. 8, from which the fractional kinetic order for the atomization of indium from the ZrPG can be seen since the peak maximum occurs later with increasing analyte mass.[34] In order to obtain the accurate value of the kinetic order, plots of $\Delta \ln(dA/dt + k_2 A)/\Delta \ln(\int_t^\infty k_2 A\ dt - A)$ *vs* $\Delta(1/T)/\Delta \ln(\int_t^\infty k_2 A\ dt - A)$ are constructed. Figure 9 shows such a plot from Fig. 8(d). The obtained values of the kinetic order and activation energy from Fig. 9 are 0.64 and 192 kJ/mol, respectively. There is no remarkable change in the kinetic parameters for indium atomization from the ZrPG with the initial injected amount of In studied, as can be seen from Table 2. The above results imply that the atomization mechanisms of indium are different for the ZrPG and PG.

Figure 3 also shows the decomposition (curve C) and atomization (curve D) curves for indium from the ZrPG. As can be seen, there is no significant gap between the maximum tolerant ashing temperature and the appearance

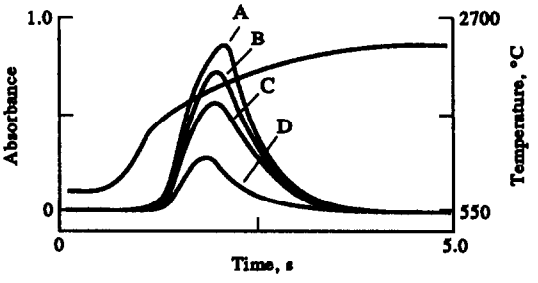

Fig. 8. Absorbance signals for various amounts of In from the zirconium coated graphite tube: (a) 0.9 (b) 0.7 (c) 0.5 (d) 0.25 ng. Ashing temperature: 800°C, atomization temperature: 2400°C.

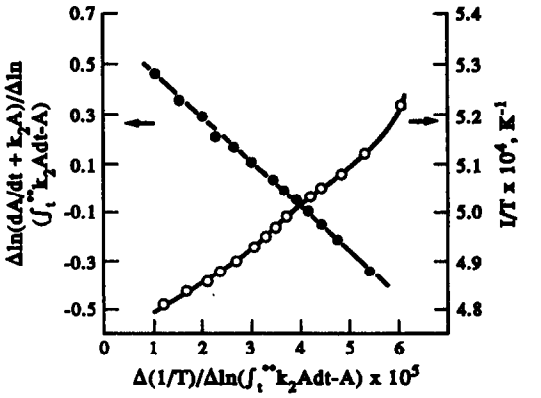

Fig. 9. Plot obtained from Fig. 8(d) by using equation (4) for 0.25 ng of In from the zirconium coated graphite tube.

temperature in the atomization curve. Thus, compared with the PG (curves A and B in Fig. 3), the ZrPG seems to prevent the formation of gaseous species and greatly improves the sensitivity. It has been suggested that prevention of oxide formation may be the main reason for the better sensitivity of determinations on the refractory element coated furnace.[39] Probably more active reducing properties of refractory element carbides than graphite are responsible for the prevention of gaseous oxide formation.[20,40] Increase in the absorbance with ashing temperature below 700°C (curve C in Fig. 3) indicates that the reducing activity of ZrC may increase with temperature.

On the basis of the above, the following reactions are supposed for indium atomization from the ZrPG, similar to those discussed in Refs 20, 41;

$$ZrC_{(s)} + In_2O_{3(s)} \rightarrow Zr_{(s)} + In_{(s/l)} + CO_{(g)}$$
$$ZrC_{(s)} + In_2O_{(g)} \rightarrow Zr_{(s)} + In_{(s/l)} + CO_{(g)}$$
$$In_{(s/l)} \rightarrow In_{(g)}$$

The resulting metallic zirconium reacts with graphite to form ZrC again at high temperatures, while the formed indium metal vaporizes with increasing temperature. The obtained kinetic order of near 2/3, along with the activation energy of 192 kJ/mol, indicates that the atomization of indium may be governed by the surface area of the sphere of molten metal, and the interaction between indium metal and zirconium carbide surface is relatively weak.

CONCLUSION

The kinetics of indium atomization seems to be similar for the pyrolytically coated and the

uncoated graphite tubes, but different for the zirconium coated graphite tube. The use of a palladium modifier or of the zirconium coated tube changes the path of indium atomization, inhibiting the formation of gaseous indium oxide, and hence greatly improves the sensitivity for indium determination.

A NEW SENSITIVE REAGENT FOR IDENTIFYING Ag^+ AND Hg^{2+}

DONGLAN MA,* YUYING DONG and YULU WANG
Department of Chemistry, Henan Normal University, XinXiang, Henan 453002, China

(*Received* 2 *December* 1992. *Revised* 8 *March* 1993. *Accepted* 10 *March* 1993)

Summary—This paper describes the synthesis of a new reagent: N,N′ -difuroyl thiourea for the purpose of improving coordination capacity of thiourea compounds. It has been characterized by IR, UV, MS and ^{1}H-NMR as well as elemental analytical data. According to the studies on its analytical performance, it is found that this reagent can be used to identify Ag^+ and Hg^{2+}. Both of their sensitivities and selectivities are the best in all methods for the time being. The new methods are simple and convenient, and can provide satisfactory results on synthetic and standard samples.

With many good properties,[1–7] thiourea derivatives have been widely applied in industry, agriculture, biology, medicine and analytical chemistry. Among them, aromatic thioureas have been studied in detail.[8–11] However, heterocyclic thioureas have been little reported recently. In order to extend the studies on thiourea compounds and improve their coordination capacities, we report here the preparation of a new reagent: N,N′-difuroyl thiourea (DFT). Its spectroscopic and chemical properties are described. It has been found that DFT can be used to identify Ag^+ and Hg^{2+}. The optimum conditions are studied, and the processes are compared with other classical and common methods.[12–17] The applications of the new reagent to identify synthetic and standard samples are also investigated.

EXPERIMENTAL

Instruments and reagents

^{1}H-NMR spectra were recorded on a JEOL-FX-90Q spectrometer. Chemical shifts are expressed in parts per million (δ) relative to internal TMS. IR spectra were recorded on a Shimadzu IR-408 spectrophotometer and only noteworthy absorptions are listed. Mass spectra were determined on a KRTOS-AEI-MS50 (U.K.) instrument. UV spectra were obtained on a Perkin-Elmer Lambda 17 UV/VIS spectrophotometer. Melting point was determined on a Kofler apparatus.

All chemicals are analytical grade reagents. The concentration of DFT is 0.05% or 0.2%. The aqueous solutions of usual anions and cations are of 10 mg/ml.

Preparation of DFT

First, to a 250-ml, round-bottomed flask equipped with a reflux condenser protected from moisture by a drying tube, was added 11.2 g (0.1 mol) of 2-furoic acid and 70 ml of thionyl chloride, and the flask was put into a water bath of 90°C for about 3 hr until no gas was given out. The resultant mixture was distilled under vacuum and 10.3 g of the expected fraction at 66°C (10 mmHg)[18] was collected, which is furoyl chloride. The reaction is,

$$C_4H_3OCOOH + SOCl_2 \rightarrow C_4H_3OCOCl + SO_2 + HCl$$

Second, thiourea (0.02 mol) and chloroform (50 ml) were mixed in a 250-ml, three-necked, round-bottomed flask installed with a stirrer, reflux condenser and pressure equalizing dropping funnel. While sharply stirring, 5.22 g of the furoyl chloride prepared above, was added drop by drop at room temperature. Then, the system was removed into the water bath of 70°C. The stirring was continued, and six portions of triethylamine (1 ml) were put in at intervals of 30 min, this neutralized the gases produced in the process of synthesis. Triethylamine added into the system, not only improved the yield, but also shortened the reaction time. After 6 hr the suspended solid had completely disappeared and the reaction had ended. The solvent

*Author for correspondence.

($CHCl_3$) evaporated and the residue cooled and filtered. The crude solid obtained was recrystallized from 50% alcohol solution to give 3.45 g of pale yellow powder (DFT). The yield reached 65.3%. The reaction is,

$$2C_4H_3OCOCl + (NH_2)_2CS \rightarrow (C_4H_3OCONH)_2CS + 2HCl$$

Reactions of DFT and usual ions

We carried out experiments on the reactions of DFT and usual ions in different media. Among them, usual cations include K^+, Na^+, NH_4^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Fe^{3+}, Cr^{3+}, Al^{3+}, Fe^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, Bi^{3+}, Hg^{2+}, Sb^{3+}, Sb^{5+}, Sn^{2+}, Sn^{4+}, Ag^+ and Pb^{2+}, *etc.*; usual anions involve F^-, Cl^-, Br^-, I^-, S^{2-}, SO_4^{2-}, $S_2O_3^{2-}$, SO_3^{2-}, SCN^-, CO_3^{2-}, NO_3^-, NO_2^-, PO_4^{3-}, $B_4O_7^{2-}$, MoO_4^{2-}, WO_4^{2-}, VO_3^-, AsO_4^{3-}, AsO_3^{3-}, $C_2O_4^{2-}$ and AC^-, *etc.*

RESULTS AND DISCUSSION

The characterization of DFT

The following values of different items were listed to characterize DFT.

IR (KBr, cm^{-1}): 3340 (N—H), 3125 and 3110 (C—H), 1740 (C=O), 1240 (C=S). ^{1}H-NMR (acetone-d_6, δ):

5.86 (m, 2H, ),

7.80 (t, 2H, ),

8.83 (d, 2H, ),

The application in analytical chemistry

Physical properties. DFT, m.p. 180, is quite stable. No changes took place with long periods of storage. It is insoluble in water, slightly soluble in alcohol, but soluble in acetone, chloroform, DMF, DMSO and hot alcohol.

Table 1. Reactions of DFT with some cations

Cation	Medium	DFT concentration (%)	Phenomenon
Ag^+	$NH_3 \cdot H_2O$	0.05	Brown sol.
Hg^{2+}	HCl	0.2	White precip.
Hg_2^{2+}	HNO_3	0.2	Brown precip.
Cd^{2+}	$NH_3 \cdot H_2O$	0.2	Yellow precip.
Cu^{2+}	Neutral medium	0.2	Yellow precip.

Chemical properties. No characteristic phenomena were observed in either acid or alkaline media when DFT is mixed with usual anions; neither were the usual cations except Ag^+, Hg^{2+}, Hg_2^{2+}, Cd^{2+} and Cu^{2+}, which can react with DFT to give distinct phenomena in certain media. The conditions listed in Table 1 were determined in light of the clearest phenomena.

As shown by the characteristic phenomena in Table 1, it is deduced that DFT can be a potential specific reagent to identify ions. Since Ag^+ and Hg^{2+} showed higher sensitivity and selectivity, we chose the two cations for further studies.

Identification of Ag^+ *and* Hg^{2+}

(1) Identification of Ag^+. In a centrifugal tube, one drop of Ag^+ stock solution was treated by one drop of $NH_3 \cdot H_2O$ (6 mol/l), and two drops of 0.05% DFT solution. After the tube was shaken, the brown color appeared, which indicated the presence of Ag^+.

(2) Identification of Hg^{2+}. In a centrifugal tube, one drop of Hg^{2+} stock solution was acidified by one drop of HCl (6 mol/l); three drops of 0.2% DFT solution were added, and the tube was shaken. The appearance of white color precipitation indicated the presence of Hg^{2+}.

Conditional experiments

(1) Effects of media. Usual acids (H_2SO_4, HNO_3, HCl, HAC) and alkalis (NaOH, $NH_3 \cdot H_2O$) of different concentrations were used as media in which the ions were revealed

Table 2. The sensitivities of Ag^+ and Hg^{2+}

Sensitivities ions	Limit of identification (μg)	Concentration limit ($\mu g/ml$)	*PD^{20}
Ag^+	0.015	0.5	6.3
Hg^{2+}	0.03	1	6

*$PD = 6 - \log \frac{m}{v}$ (v is the volume of ion solution (ml), m is limit of identification).

with DFT. According to experiments, the optimum media and concentrations for identifications of Ag^+ and Hg^{2+} are $NH_3 \cdot H_2O$ (6 mol/l) and HCl (6 mol/l), respectively.

(2) Dosage test of DFT. One drop of stock solution of metal ion was treated with ammonia or acidified according to the methods described above. DFT solution was added drop by drop to reveal them thoroughly. It was finally shown that DFT dosages were two and three drops for identifying Ag^+ and Hg^{2+}, respectively.

(3) Sensitivities. The process was carried out according to the standard method[19] on sensitivity. The results are shown in Table 2.

(4) Interference of coexistent ion. Tolerance limits of interfering ions were expressed as the ratio of amount of identified ions to that of interfering ions, which are shown in Table 3.

(5) Elimination of interfering ions. (a) For Ag^+ identification. Interference of S^{2-} could be eliminated by acidifying the sample with HNO_3, then heating the solution to vaporize the excess nitric acid. Interferences of large amounts of Cu^{2+}, Co^{2+} and Ni^{2+} could be eliminated by precipitating them with ammonium salt, and the supernatant can be identified after centrifugation.

(b) For Hg^{2+} identification. The interference of I^- could be eliminated by adding Ag^+; S^{2-} and SCN^- could be dispelled with *aqua regia* ($HCl:HNO_3$=3:1). No interferences of Ag^+, Hg_2^{2+} and Pb^{2+} were involved because they were precipitated in the HCl medium.

(6) Application to samples. (a) Identification of synthetic samples. The results with DFT as an identification reagent showed a good agreement with known samples (Table 4).

(b) Identification for standard samples. By means of the appropriate methods, we disposed of standard samples including polluted farmland, positive mud of copper, deposit of hydrographic net, lead and zinc minerals. The results

SIMULTANEOUS DERIVATIVE SPECTROPHOTOMETRIC DETERMINATION OF THORIUM AND URANIUM IN A MICELLAR MEDIUM

NARINDER KUMAR AGNIHOTRI, VINAY KUMAR SINGH and HAR BHAJAN SINGH*
Department of Chemistry, University of Delhi, Delhi 110007, India

(*Received* 2 *December* 1992. *Revised* 4 *March* 1993. *Accepted* 8 *May* 1993)

Summary—Derivative photometric methods for trace analysis of Th(IV) and UO_2(II), and their simultaneous determination in mixtures using 5,8-dihydroxy-1,4-naphthoquinone in a micellar medium are reported. Molar absorptivity and Sandell's sensitivity of 1:2 Th(IV) and 1:1 UO_2(II) complexes at their λ_{max}, 614.5 nm and 637.0 nm are, 1.19×10^4 l/mol/cm and 1.12×10^4 l/mol/cm and 1.95×10^{-2} $\mu g/cm^2$ and 2.13×10^{-2} $\mu g/cm^2$, respectively. Calibration graph is linear over the range 9.28×10^{-2}–18.56 μg/ml of Th(IV) and 9.52×10^{-2}–19.04 μg/ml of UO_2(II). Though presence of Th(IV) and UO_2(II) causes interference in each others determination, 9.28×10^{-1}–9.28 μg/ml Th(IV) and 9.52×10^{-1}–9.52 μg/ml UO_2(II) when present together, can be simultaneously determined using derivative spectra.

Important reagents for spectrophotometric determination of Th(IV) and UO_2(II) include arsenazo I, arsenazo III, thorin and chlorophosphonazo III, usually require a preliminary step to extract the analyte from complex matrix by organic solvent(s).[1–3] The aforesaid reagents, though sensitive, lack selectivity. Besides being cumbersome, such procedures have inherent sources of errors. The spectrophotometric determination of Th(IV) and UO_2(II) must be preceded by pre-separation when the two are present together in a mixture as interference is caused due to spectral overlap.[4,5]

Though claims are often made regarding the sensitivity and selectivity of NAA, ICP–AES, and ICP–MS some of the interferences, to which these procedures are subjected to, are poorly understood and continue to cause problems.[6,7] Therefore, development of sensitive and selective photometric methods continue to be of interest in spite of recent developments in ASS, ICP–AES and ICP–MS.[6]

The use of micellar media[8–10] and derivative spectrophotometry[11,12] not only offers convenient solutions to a number of analytical problems such as avoiding extraction processes, resolution of multicomponent system and matrix background, but also enhances the sensitivity and selectivity of the method.

The present communication describes sensitive and inexpensive methods for the determination of microamounts of Th(IV) and UO_2(II) using 5,8-dihydroxy–1,4-naphthoquinone(DHNQ), as a chromogenic ligand[13–15] in a micellar medium generated by Triton X-100, a neutral surfactant. A simple and rapid procedure is developed for simultaneous determination of Th(IV) and UO_2(II) in aqueous phase without any pre-separation or extraction using derivative spectrometry.

EXPERIMENTAL

Chemicals

Stock solutions (0.01M) of Th(IV) and UO_2(II) were prepared by dissolving requisite amounts of $Th(NO_3)_4 . 5H_2O$ and $UO_2(NO_3)_2 . 6H_2O$, respectively in water containing few drops of nitric acid. Solution ($4.0 \times 10^{-4}M$) of DHNQ was freshly prepared everyday by dissolving 7.61 mg of the ligand in minimum amount of 0.2M sodium hydroxide at 40°C. This solution was acidified after adding 4.0 g Triton X-100 and finally diluted with water to 100 ml.

Appropriate amounts of the solutions of Th(IV) or UO_2(II), DHNQ, Triton X-100 and ammonium acetate (buffer) were taken to give final concentration of $4.0 \times 10^{-5}M$, $2.0 \times 10^{-4}M$, 2.0% w/v and $5.0 \times 10^{-3}M$ in all working solutions, respectively, unless stated otherwise.

*Author for correspondence.

Instruments

Absorption spectra were recorded on a Shimadzu UV–visible recording spectrophotometer (Model UV-260), capable of taking first to fourth order derivative spectra with $\Delta\lambda$ values 1, 2, and 4 nm; 10-mm fused silica cells were used for absorption measurements taking water as reference. The pH of the solutions were measured on an EC digital pH-meter (Model PH 5662).

First and second derivative spectra were recorded directly on UV-260 using data command-chain mode, with $\Delta\lambda$ 2 and 4 nm, respectively and a bandwidth of 1 nm.

Procedure

Determination of Th(IV)/UO_2(II). To study the effect of pH on complex formation, two series of solutions, one with metal ion and the other without it, each in the same pH range (2.0–12.0) and containing DHNQ, Triton X-100 and ammonium acetate, were prepared.

To investigate the effect of surfactant concentration on the ligand and the complex, a set of solutions containing increasing amount of Triton X-100 and a fixed amount of DHNQ, the metal ion and ammonium acetate at optimum pH, was prepared for each system.

To evaluate the impact of varying metal ion concentration on complexation, a series of solutions containing increasing amount of the metal ion and a fixed amount of DHNQ, ammonium acetate and Triton X-100 at optimum pH, was prepared.

Simultaneous determination of Th(IV) and UO_2(II). A set of solutions containing increasing amounts (9.28×10^{-1}–9.28 μg/ml) of Th(IV) and another containing increasing amounts (9.52×10^{-1}–9.52 μg/ml) of UO_2(II) ions, each having a fixed amount of DHNQ and Triton X-100, were prepared. The first and second order derivative spectra of both sets were recorded on the same chart in order to locate the isodifferential points. To obtain the isodifferential points on zero-line, spectra have been recorded with reference to ligand blank. The calibration graph for the determination of Th(IV) was prepared by measuring derivative amplitudes at isodifferential points of UO_2(II) and vice versa for UO_2(II). Concentration of Th(IV) and UO_2(II) ions in the mixture was then determined using these graphs.

RESULTS AND DISCUSSION

Effect of pH on the absorbance of the systems

Th(IV)–DHNQ and UO_2(II)–DHNQ complexes in neutral micellar media show pH dependent absorption maximum at 614.5 and 637.0 nm, respectively whereas DHNQ shows maximum absorption at 490 nm. As the ligand also absorbs at the λ_{max} of the complexes, the absorbance due to complex was calculated by taking the differences between the absorbances of the complex and the ligand, each recorded against water. It was then plotted against pH of the solutions in each case (Fig. 1). The graph indicates that complexation of Th(IV) and UO_2(II) commences at pH 4.7 and 5.0, respectively and increases up to pH 5.9 and 6.1. Relative absorbance w.r.t. ligand of the solutions containing the complex remains practically constant ($\pm$2.0%) from pH 5.9 to 7.2 and 6.1 to 7.3 in the two cases but decreases thereafter due to higher extinction of the deprotonated DHNQ formed at pH $\geqslant$ 7.3. Furthermore, it is inferred from the plot that maximum complex formation takes place at pH 6.4 and 6.5 in case of Th(IV) and UO_2(II), respectively. All absorption studies are carried out at these pH values and at 614.5 and 637.0 nm, the wavelengths of maximum absorption of the complexes in the two cases.

Effect of the nature of surfactant

Effect of the presence of anionic surfactant [sodiumlauryl sulphate (SLS)], cationic surfactants [cetylpyridinium chloride (CPC) and cetyltrimethylammonium bromide (CTMB)]

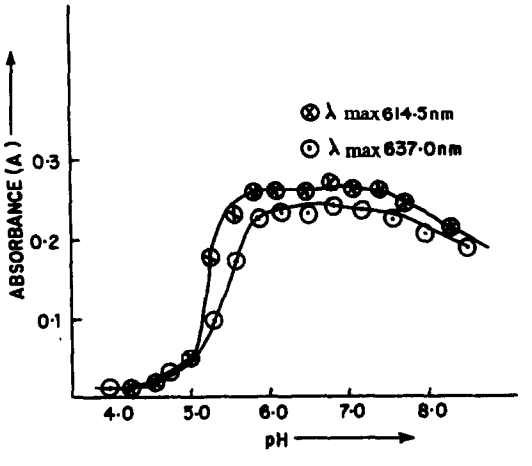

Fig. 1. Effect of pH on complex formation; (⊗) DHNQ–Th(IV) and (⊙) DHNQ–UO_2(II) complexes in micellar media.

and non-ionic surfactant (Triton X-100, CMC $3.2 \times 10^{-4}M$)[16] on the absorption profiles of each system has been studied. As anionic surfactants generally sequester the metal ions, the complexation reaction is inhibited in their presence in contrast to cationic and non-ionic surfactants.[9] Moreover, cationic and non-ionic surfactants have a marked effect on the absorbance characteristics of DHNQ as well as its thorium and uranyl complexes. Since cationic surfactants form ternary species of different optical properties as a function of pH, a non-ionic surfactant, Triton X-100 was selected for micelle formation during the present study. A sharp increase in absorbance with increasing Triton X-100 concentration up to 2.0% was observed in case of both the complexes. As a small decrease in absorbance was observed at concentration $\geqslant$2.25% w/v, the amount of the Triton X-100 was, kept at 2.0% w/v (which is greater than CMC) during subsequent investigations.

Effect of time and reversibility of the complexation reactions

It is inferred from the absorbance spectra that DHNQ and its Th(IV) and UO_2(II) complexes are optically stable up to 24 and 12 hr, respectively at room temperature (20–25°C). Change in absorbance of the system on reverting from a higher pH to the optimum pH was investigated for each system. The complexation reaction, in the two systems are found to be reversible between pH 6.4–12.0 and 6.5–12.0, respectively.

Effect of varying DHNQ concentration

To study this effect, spectra of a set of solutions containing fixed amount of the metal ion and the surfactant but increasing amount (4.0×10^{-6}–$2.8 \times 10^{-4}M$) of DHNQ was recorded. In each case, the absorbance has been found to increase with concentration of the ligand. It is attributed partly to the increased amount of the complex formed and partly to the absorption by the ligand at λ_{max} of the complexes. Absorbance values were, therefore, corrected for the absorption of the uncomplexed ligand and plotted against molar concentration of the ligand for each system. The plot remains practically constant ($< \pm 4.0\%$), between 5:1 and 20:1 (L:M) in case of Th(IV) and 4:1 to 30:1 (L:M) in the case of UO_2(II) complex (Fig. 2). During further studies, therefore, concentration of the ligand was kept between the above mentioned limits, wherever possible.

Number of chromogenic species and their stoichiometry

The number of chromogenic species formed in each case has been evaluated by computerized calculation on the rank of the absorbance matrix,[17] prepared by measuring absorbance of a set of solutions at a number of different wavelengths (from 400 to 740 nm) and at various pH or concentration of the components, assuming additivity of absorbances. The rank of the matrix defines the number of non-zero elements on the diagonal of the matrix and corresponds to the number of absorbing species in

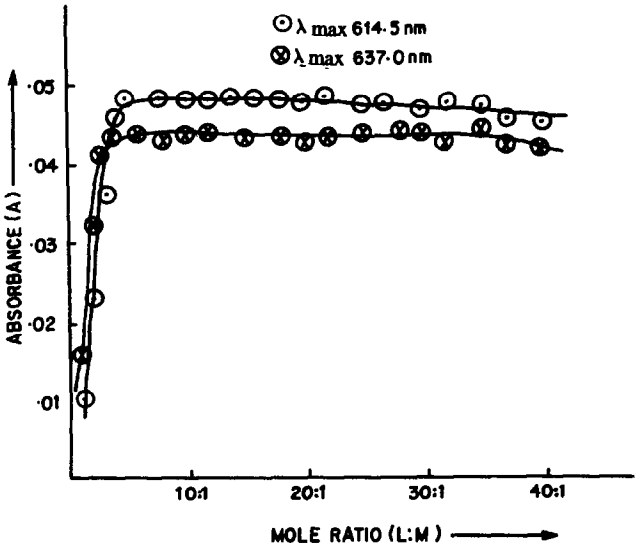

Fig. 2. Effect of DHNQ concentration (4.0×10^{-6}–$2.8 \times 10^{-4}M$) on absorbance of (⊙) thorium and (⊗) uranyl complexes in micellar media.

the system. The rank is determined by triangularizing the absorbance matrix (*i.e.* all elements below principal diagonal are zero) based on the method of Gaussian elimination. Rank is then determined by comparing the diagonal elements of reduced absorbance matrix with an assumed error matrix. Consequently, three absorbing species have been inferred to be present in the solution of DHNQ-Triton X-100 when the overall absorbance error for the absorbance matrix of DHNQ-Triton X-100 system was varied from 0.0026 to 0.0120 absorbance units. This was consistent with the expected presence of three species, *i.e.* H_2NQ, HNQ^{1-}, NQ^{2-} in the pH range 2.0–12.0. However, only the first two exist under experimental conditions. Three species also exist in solution following complexation in each case, when the value of error matrix is varied between 0.0028 and 0.0150 absorbance units. Thus, it may be inferred that only one new chromogenic species is formed during complexation of Th(IV) and UO_2(II) with DHNQ in a neutral surfactant medium.

Stoichiometry of the complexes formed under optimum experimental conditions was determined by Job's method of continuous variations.[18] The ratio of Th(IV) to DHNQ and UO_2(II) to DHNQ in the neutral micellar medium is found to be 1:2 and 1:1 (M:L), respectively; stoichiometry of the thorium complex is in agreement with the value in the organic phase reported by Moeller *et al.*[13] The complexes existing in solution are, therefore, represented as $[Th(HNQ)_2]^{2+}$ and $[UO_2(HNQ)]^+$, where H_2NQ denotes the molecular form of DHNQ.

Effect of varying metal ion concentration

Normal as well as derivative spectra of a set of solutions containing increasing amount of metal ion at a fixed and excess amount of the ligand have been investigated to use the developed method for trace analysis of these metal ions. An increase in concentration of the metal ion linearly increases the absorbance [Figs 3(a) and 4(a)] at λ_{max} of the complexes. Linear regression of the plot between metal ion concentration and the absorbance gives a straight line equation with positive intercept in both systems (Table 1). The observed absorbance values have, therefore, been corrected for absorption of the uncomplexed ligand to give $[A_i]_c$, the corrected absorbance at λ_{max} of the complex (equation (1)).

$$[A_i]_c = (A_i)_{comp} - [(V)_L - R \times (V_i)_M]\left[\frac{(A')_{comp}}{(V)_L}\right] \quad (1)$$

where $(A_i)_{comp}$ is absorbance of the complex at λ_{max}; $(A')_{comp}$ is absorbance of the ligand alone at λ_{max} of the complex and $(V_i)_M$, the molar volume of the metal ion solution. Subscript i denotes the serial number of the solution; R, the stoichiometry of the complex and $(V)_L$, the molar volume of the ligand are constant throughout the experiment. Linear regression of $[A_i]_c$ values gives improved linear plot in each case, as shown by the value of linear regression coefficient (Table 1).

The first order derivative spectrum in both systems is of great analytical value as λ_{max} of Th(IV) and UO_2(II) complexes corresponds to

Table 1. Linear regression analysis of Th(IV) or UO_2(II) ion concentration (μg/ml) and absorbance in normal and derivative modes

Specific absorptivity (*a*) (*ml/g/cm*)	5.13×10^{-2}	4.71×10^{-2}
Sandell's sensitivity (*S*)[5] ($\mu g/cm^2$)	1.95×10^{-2}	2.13×10^{-2}
Detection limit (IUPAC)[19] $n = 25$, $k = 3$ (*ng/ml*)	25	33
Stoichiometry (M:L)[18]	1:2	1:1

the cross-over point at 614.5 and 637.0 nm, respectively [Figs 3(b) and 4(b)]. Peak height [PH] and trough depth [TD], measured from the base line of the ligand or zero-line of the derivative spectrum of the complexes are proportional to the metal ion concentration [Figs 3(b) and (c), and 4(b) and (c)], as shown by a good linear fit (Table 1). These are, therefore, recommended for the determination/detection of the metal ions. Beer's law is found valid between 9.28×10^{-2}–18.56 μg/ml and 9.52×10^{-2}–19.04 μg/ml of Th(IV) and UO_2(II) ions, respectively.

Photometric parameters of both systems, calculated from the corrected absorbance value, $[A_i]_c$ (all w.r.t. metal ions), as well as IUPAC detection limits[19] are summarized in Table 2.

Conditional stability constant

The conditional stability constant[20,21] of the complexes formed under optimum conditions was calculated on the basis of the following equilibrium as only one complex is inferred to be formed on the basis of spectrophotometric studies reported above.

$$Th^{4+} + 2H_2NQ \rightleftharpoons [Th(HNQ)_2]^{2+} + 2H^+$$

$$UO_2^{2+} + H_2NQ \rightleftharpoons [UO_2(HNQ)]^+ + H^+$$

The conditional stability constant (k') based on concentration and absorbance (corrected, $[A_i]_c$)

values of Th(IV) and UO_2(II) complexes has been found to be 2.29×10^5 l/mol and 1.12×10^5 l/mol (average of six values), respectively.

Effect of diverse ions on the determination of the analyte

Interference in the photometric determination of Th(IV) and UO_2(II) from a number of common cations and anions has been investigated in normal as well as derivative modes to evaluate the practical utility of DHNQ. This was studied by adding the varying amount of the foreign ions (in μg/ml) to a solution containing fixed amount of Th(IV) (4.760 μg/ml) or UO_2(II) (9.520 μg/ml), DHNQ, Triton X-100 and ammonium acetate, and measuring the change in absorption profiles. Limiting concentration of the diverse ions that does not interfere in the analysis of Th(IV) and UO_2(II) ions are summarized in Table 3. The complexation reaction of Th(IV) and UO_2(II) ions with DHNQ in presence of neutral micellar media are masked

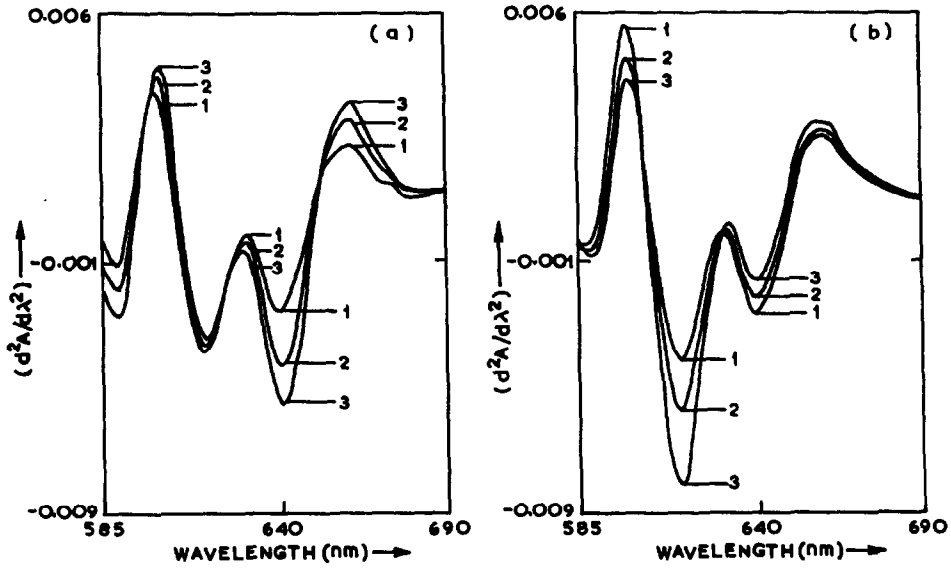

Fig. 6. Second order derivative spectra of DHNQ complexes of Th(IV) and UO_2(II); (a) Th(IV) 3.712 μg/ml and 3.808 (1), 5.712 (2) and 7.616 (3) μg/ml UO_2(II) and (b) UO_2(II) 3.808 μg/ml and 3.712 (1), 5.568 (2) and 7.424 (3) μg/ml Th(IV).

Table 4. Comparison of the analytical methods for simultaneous determination

Element determine	Method	Sensitivity, $S_A = S_s/m$ (ng/ml)	$C_L(k=3)$ (ng/ml)	Linear dynamic range (ng/ml)	RSD, % ($n=6$)
Th(IV)	1st derivative	39.6	1.19×10^2	3.96×10^2–9.28×10^3	1.12
	2nd derivative	13.0	39.0	1.30×10^2–9.28×10^3	0.23

	2nd derivative	9.3	27.9	9.30×10^1–9.52×10^3	0.24

by the presence of tartrate, EDTA and phosphate, and citrate and EDTA, respectively. Further, masking agents such as citrate, tartrate, EDTA and phosphate have also been used to overcome the interference from a number of cations, but these did not help. High order derivative spectrophotometry, a relatively new and fast developing technique has also been used to determine Th(IV) and UO_2(II) in the presence of interfering ions, as derivatization of spectra resolves overlapping peaks of normal spectra into separate peaks and troughs, and crossover points. This technique is useful in case of strongly interfering cations of Be, Al, Fe, Au, Ce, VO, Th or UO_2 and Ni. Amongst these Th and UO_2 have been selected for detailed investigations; UO_2 has been determined in presence of Th and vice versa, using derivative spectrophotometry.

Simultaneous determination of Th(IV) and UO_2(II)

Since presence of Th(IV) and UO_2(II) ions causes interference in each other's photometric determination, a pre-separation is to be carried out before their determination in a mixture. Analytical advantages offered by derivative spectrophotometry[22,23] have been made use of to analyze a mixture containing these two ions without any prior separation. For this purpose, instrumental parameters such as scan speed, wavelength increment ($\Delta\lambda$) over which derivative spectra were recorded, response time and slit width, which affects the shape of derivative spectra, were optimized w.r.t. reduction of noise level, stability of zero points or crossover points and isodifferential points. Consequently, a $\Delta\lambda$ of 2 and 4 nm for first and second derivative modes is found optimum for the least signal-to-noise ratio for recording derivative spectra. A 1 nm slit width was selected as it does not significantly alter the spectral resolution. A scan speed of 40 nm/min was found optimum. This automatically optimizes the response time.

Th(IV)–DHNQ and UO_2(II)–DHNQ complexes show one isodifferential point in each derivative mode [Figs 5(a) and (b)]. Calibration graphs for the determination of uranyl ions were prepared by measuring change in derivative amplitude, $dA/d\lambda$ [T_1] and $d^2A/d\lambda^2$ [T_2] at 614.5 and 604.5 nm, respectively, the isodifferential points of thorium complex. Similarly for Th(IV) ions, change in derivative amplitude, $dA/d\lambda$ [U_1] and $d^2A/d\lambda^2$ [U_2] at 637.0 and 651.5 nm, respectively, the isodifferential points of uranyl complex have been measured. The linear regression analysis of the change in derivative amplitude at isodifferential points on the metal ion concentration shows following relationship with good linear fit as evidenced by their residue square values (r).

$$[T_1]_{614.5\,nm} = 3.386\,[U] + 1.392; \quad (r = 0.9984) \quad (2)$$

$$[T_2]_{604.5\,nm} = 5.087\,[U] + 3.339 \times 10^{-1}; \quad (r = 0.9985)^* \quad (3)$$

$$[U_1]_{637.0\,nm} = 6.782\,[T] - 1.601 \times 10^{-2}; \quad (r = 0.9972) \quad (4)$$

$$[U_2]_{651.5\,nm} = 2.505\,[T] + 4.698; \quad (r = 0.9992)^* \quad (5)$$

Table 5. Quantitative determination of thorium (9.28×10^{-1}–9.28 μg/ml) and uranyl (9.52×10^{-1}–9.52 μg/ml) in mixtures using DHNQ

Sr. No.	Taken (μg/ml)		Found (μg/ml)		Relative error (%)	
	Th(IV)	UO_2(II)	Th(IV)	UO_2(II)	Th(IV)	UO_2(II)
1	0.928	0.952	0.936	0.939	0.86	−1.37
2	0.928	3.808	0.938	3.875	1.08	1.76
3	1.856	2.856	1.841	2.877	−0.81	0.73
4	3.712	3.808	3.693	3.736	−0.51	−1.89
5	3.712	4.760	3.650	4.820	−1.67	1.26
6	6.496	2.856	6.638	2.803	2.19	−1.86
7	6.496	4.760	6.444	4.795	−0.80	0.73
8	4.640	6.664	4.665	6.685	0.54	0.31
9	5.568	2.856	5.668	2.785	1.79	−2.49
10	7.424	9.520	7.503	9.492	1.06	−0.29
11	9.280	4.760	9.403	4.730	1.32	−0.63
12	9.280	9.520	9.204	9.573	−0.82	0.56

*Determination of UO_2(II) at T_2 and Th(IV) at U_2 is recommended, based on large dynamic range and better sensitivity (Table 4) and large values of r; [U] and [T] is concentration in (μg/ml) of UO_2(II) and Th(IV) ions, respectively. Linear plots are obtained for Th(IV) and UO_2(II) ion concentration from 9.28×10^{-1} to 9.28 μg/ml and 9.52×10^{-1} to 9.52 μg/ml at the isodifferential points of uranyl and thorium complexes, respectively.

Presence of Th(IV) ions in UO_2(II)–DHNQ complex and UO_2(II) ions in Th(IV)–DHNQ, changes amplitude at the isodifferential points of UO_2(II) and Th(IV) complexes in each derivative spectrum. Concentrations of UO_2(II) and Th(IV) ions in synthetic mixtures with different concentration ratios have been calculated using equations (2) or (3) and (4) or (5), respectively but better results are obtained using second order derivative spectra, shown by better observed RSD values (Table 4) calculated from six replicate samples containing 3.712 μg/ml of Th(IV) in presence of UO_2(II) ions, and 3.808 μg/ml of UO_2(II) in presence of Th(IV) ions [Figs 6(a) and (b)]. The calculated analytical sensitivity, S_A ($S_A = S_s/m$, where S_s is the standard deviation of the analytical signal measurement and m, is the slope of the calibration curve) detection limit, C_L ($k = 3$) and linear dynamic range of the method as defined by IUPAC are also given in this table.[24] The limit of quantitation, LOQ ($k = 10$) is used to establish the lower limit of dynamic range. The results obtained for simultaneous determination of Th(IV) and UO_2(II) ions in various binary mixtures are shown in Table 5 [using equations (3) and (5)]. The mixture containing 9.28×10^{-1}–9.28 μg/ml of Th(IV) and 9.52×10^{-1}–9.52 μg/ml UO_2(II) ions can be analyzed with a relative error less than 2.50%.

In addition to developing a simple procedure for the determination of thorium and uranyl ions when present alone or in a mixture, analytical advantage of incorporating a micellar medium and recording derivative spectra is well established on the basis of the above studies.

SIMULTANEOUS SPECTROPHOTOMETRIC DETERMINATION OF CADMIUM, COPPER AND ZINC

A. M. GARCIA RODRIGUEZ, A. GARCIA DE TORRES, J. M. CANO PAVON and C. BOSCH OJEDA
Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071 Málaga, Spain

(*Received* 16 *November* 1992. *Revised* 17 *May* 1993. *Accepted* 19 *May* 1993)

Summary—A method for the simultaneous spectrophotometric determination of cadmium, copper and zinc based on the formation of their complexes with 1,5-bis(di-2-pyridylmethylene)thiocarbonohydrazide is proposed. The absorption curves of these complexes overlap severely in the scanning range 380–480 nm. The analyte concentrations are calculated by a least squares fit of the pure spectra to the mixture spectra. A linear determination range of 0.1–1.7 μg/ml for cadmium, 0.1–1.3 μg/ml for copper and 0.2–1.2 μg/ml for zinc were obtained. The effect of interference was studied. The method has been applied to the determination of these metal ions in various type of materials.

Until recently, multicomponent determinations by spectrophotometry have been done by using a single wavelength for each component. Recently, the strategies available in analytical chemistry and, in particular, those using molecular spectroscopy have diversified. Thus, multicomponent determinations have been improved by using multiple wavelengths and different algorithms. Such algorithms include those of classical least-squares (CLS),[1] the simplex interaction method,[2] the inverse least-squares (ILS),[3] the principal component regression (PCR),[4] the partial least-squares (PLS)[5] and other multivariate statistical method.[6]

Recently, Sala *et al.*[7] applied a computer program, like MULTIC, to the resolution of a mixture of pharmaceuticals. Also, this program has been used by Gomez *et al.*[8] for the simultaneous determination of calcium and magnesium in water. MULTIC is a multilinear regression program that involves fitting the calculated mixed spectrum to its experimental counterpart through the standard deviation, correlation coefficient and an independent term corresponding to the intercept on the absorbance axis. For simultaneous spectrophotometric determination of M components in a mixture to be achieved, each species must absorb according to Beer's law, and the absorbances must be additive. Both conditions (using 1 cm of the optical path-length) can be described by a mathematical model of the form:

$$x = \Sigma S_A C_A + e \quad (1)$$

where x is the measured (sum) spectrum, S_A is the pure spectrum of analyte A, C_A is the concentration of analyte A in the mixture and e is the residual (difference between the observed response and the response calculated from the model). The equation (1) can be rewritten in shorthand matrix notation as:

$$x = Sc + e. \quad (2)$$

Where S is the matrix containing the pure spectra as columns (size: p,M; where $p >= M$ is the number of wavelengths employed and M is the number of analytes) and c is a vector containing the coefficients/the unknown concentrations (size: $M,1$). When $p > M$, the least squares solution to equation (2) is:

$$C_{est} = (S'S)^{-1}S'x, \quad (3)$$

and the error vector is:

$$e = x - Sc_{est} \quad (4)$$

with the length:

$$e = (e_1^2 + e_2^2 + e_3^2 + \ldots e_p^2)^{0.5}. \quad (5)$$

This paper reports a method for the simultaneous spectrophotometric determination of cadmium, copper and zinc, based upon the formation of their respective complexes with 1,5-bis(di-2-pyridylmethylene)thiocarbonohydrazide (DPTH). The resolution of the mixtures was carried out by using the multiple linear regression mathematical algorithm included in the program MULTIC.

EXPERIMENTAL

Reagents

Analytical-reagent grade chemicals were used throughout.

Standard solutions of cadmium(II) (1039 mg/l), copper(II) (1042 mg/l) and zinc(II) (1047 mg/l) were prepared from their respective nitrates and standardized titrimetrically with EDTA. Working standard solutions were prepared by suitable dilution of the standard solutions.

A stock DPTH solution ($2.3 \times 10^{-3}M$) in DMF was prepared by dissolving solid reagent samples prepared and purified by the authors.[9] This solution was spectrophotometrically stable for at least a week.

Buffer solutions (pH 7.5) were prepared by mixing 8 ml of $0.2M$ NaH_2PO_4 with 42 ml of $0.2M$ Na_2HPO_4 and diluting to 100 ml with distilled water.

Apparatus and software

A Hewlett-Packard Model 8452A diode-array spectrophotometer was used for recording spectra. An H.P. Vectra QS/165 personal computer was used to control the spectrophotometer and collect data from it via an HP–IB interface. The programs used to obtain and process the spectra were supplied by the spectrophotometer manufacturer as bundled software. Mixtures were resolved using a multiple linear regression mathematical algorithm included in the program MULTIC.[7]

Procedure

Preparation of standards. The program MULTIC requires the standardized spectrum of each component. With this purpose, four solutions for each component were prepared in 25 ml standard flasks with different concentrations of the metal ion (0.2, 0.4, 0.6 and 0.8 μg/ml), 3 ml of 0.1% m/v DPTH solution in DMF, 12 ml of DMF (to prevent precipitation of the reagent), 5 ml of buffer solution (pH 7.5) and dilution with distilled water to the mark. After a thorough mixing, the solutions were allowed to stand for 30 min. The absorbance spectra of these solutions were recorded over the wavelength range 390–480 nm at an integration time of 1 sec. Appropriate reagent blank was prepared, in triplicate, and was run in the same manner. The spectra of these three reagent solutions were recorded five times and the average spectrum was considered as the DPTH standard.

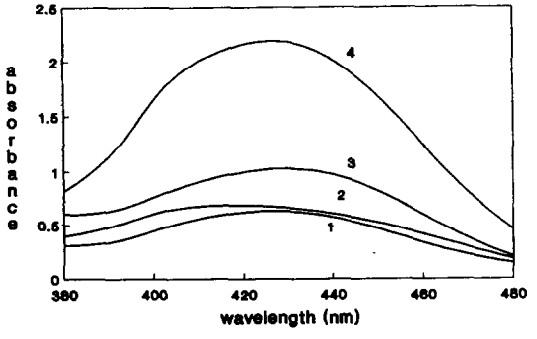

Fig. 1. Absorbance spectra of the cadmium (1), copper (2), zinc (3) complexes and their mixture (4). Concentration of each ion is 1 μg/ml.

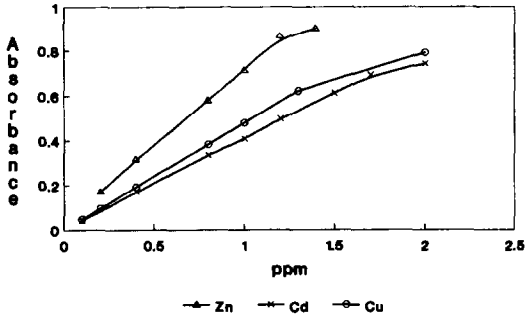

Fig. 2. Linear range for Zn, Cd and Cu.

Each of the spectra of the Zn–DPTH, Cd–DPTH and Cu–DPTH complexes were corrected by subtracting the standard spectrum of the reagent and were standardized by dividing them into the Zn, Cd or Cu concentrations at which they were recorded; the average spectrum of each complex (corresponded to a 1 μg/ml) was used as standard for each ion. These standard spectra were stored in the corresponding computer subdirectory as a working model for subsequent determinations.

The average, corrected and standardized spectra were obtained using a subroutine of the spectrophotometer's bundled software.

Sample preparation

The certified reference materials (CRM_s) analysed to determine the accuracy of the proposed procedure were: Community Bureau of Reference (BCR), Certified Reference Materials (CRM_s) 186 Pig Kidney and 184 Bovine Muscle; National Institute of Standards and Technology (NIST) Standard Reference Materials (SRM_s) 1577a Bovine Liver. Analysed Samples LTD 32a Aluminium Bronze; 20b Aluminium Alloy and 8e White Metal. These samples were prepared according to the following procedure:

(a) *Alloys.* Dissolve a known amount of accurately weighed sample (0.1 g) in about 30 ml of *aqua regia*; evaporate the resulting solution to dryness and add 1 ml of hydrochloric acid (1 + 1); then dilute with distilled water to 50–100 ml.

(b) *Biological materials.* The samples were first dried in accordance with the norms of the respective analysis certificates and mineralized as follows: in a reaction flask were placed 0.5–2.0 g of weighed sample and 10 ml of concentrated nitric acid, and the mixture was heated under reflux up to the disappearance of nitrous fumes. Then, 3 ml of hydrogen peroxide was added and the mixture was concentrated (this step was repeated until the solution was completely colourless). Next, the mixture was neutralized with NaOH and made to 25 ml with deionized water.

Simultaneous determination of Zn, Cd and Cu

In 25 ml standard flasks were placed aliquots of sample solutions to obtain Zn, Cd and Cu concentrations over their respective linear determination ranges (0.2–1.2 μg/ml for Zn, 0.1–1.7 μg/ml for Cd and 0.1–1.3 μg/ml for Cu), 3 ml of 0.1% m/v DPTH solution in DMF, 12 ml of DMF and 5 ml of buffer solution (in the case of aluminium alloys 1 ml of a 1.1*M* fluoride solution was added to prevent interference from Al(III)). The solutions were then diluted to the mark with water, after a thorough mixing, the

*The results correspond to the mean and standard deviation obtained from three consecutive determinations of each solution.

solutions were allowed to stand for 30 min and their absorbance spectra were recorded and corrected by subtracting that of DPTH. To these absorption spectra was applied the MULTIC program for quantification of the components using the normalized spectra of Zn, Cd and Cu as standards (see equation (3)).

RESULTS AND DISCUSSION

The zinc(II) reacts with DPTH in the range pH 6.2–9.8 forming a soluble yellow complex with an absorption maximum at 415 nm and a molar absorptivity of 6.01×10^4 l/mol/cm; the stoichiometric ratio of this complex is 1:3 zinc:reagent. The complex is spectrophotometrically stable, after 30 min, for at least 24 hr. The cadmium(II) forms a complex with DPTH in the pH range 5.8–8.3 with an absorption maximum at 415 nm and a molar absorptivity of 5.64×10^4 l/mol/cm; the stoichiometric of this chelate is 1:3 cadmium:reagent and the complex solutions are stable for at least 24 hr. When dilute copper(II) solutions and DPTH solutions are mixed, two different complexes, one orange ($\lambda_{max} = 420$ nm), and the other red ($\lambda_{max} = 500$ nm), are formed according to the pH, thus, the red complex is formed in the pH range 13.2–13.6 with a molar absorptivity of 4.2×10^4 l/mol/cm and its stoichiometry is 1:2 copper:reagent. The graph of absorbance *vs* pH for the orange complex shows that the absorbance at 420 nm is maximum and constant in the alkaline region and also shows two possible optimum pH ranges of 1.8–4.4 and 7.1–8.4, the stoichiometry in both cases is 1:1 and the molar absorptivities are 2.8×10^4 l/mol/cm and 4.3×10^4 l/mol/cm, respectively. The orange copper complex is stable for at least 12 hr.

The simultaneous determination of these ions with DPTH by use of the traditional spectrophotometry technique is difficult because the absorption spectra overlap in a bright region and the superimposed curves are not suited for quantitative evaluation. Figure 1 shows the bands of the three standards and that of a mixture.

Considering these facts, the optimum working conditions for the simultaneous determination were investigated by assaying different Zn–Cd–Cu mixtures of known composition. A disodium hydrogen phosphate–sodium dihydrogen phosphate buffer solution, pH 7.5 was selected because in this medium the absorbance of a Zn–Cd–Cu mixture was maximum (the volume of DMF added in the preparation of the solutions increased the pH over 2.0 units). The effect of DPTH concentration was also investigated, a reagent concentration of $2.8 \times 10^{-4} M$ was chosen because it ensures a sufficient reagent excess. The absorbance depends critically on the order of addition of reactants, the most suitable order of addition was: metal ions solutions, DPTH, DMF and buffer. Under these optimum working conditions the absorbance spectrum of a Zn–Cd–Cu mixture remains constant, after 30 min, for at least 12 hr.

On the other hand, it is also well known[10,11] that the quality of the results obtained in multicomponent analyses from extensively overlapping spectra depends on the wavelength range used. In order to study this factor different wavelength ranges (400–480, 415–480, 430–480, 450–480 and 465–480 nm) for recording the absorbance spectra of mixtures containing various concentrations of the three ions were applied. The best results (accuracy and precision) were obtained by recording the absorbance spectrum over the wavelength range 430–480 nm at an integration time of 1 sec and using the wavelength scan interval of the spectrophotometer (2 nm) except in the case of samples containing fluoride, tartrate, citrate, Sb(III), Cr(III), Bi(III), Al(III), Hg(II) and Hg(I). In these instances the optimum wavelength range was 465–480 nm.

Once the optimum conditions had been established, the linear range for Zn, Cd and Cu was calculated. With this purpose, a series of solutions containing different concentrations of the metal ion were prepared for each analyte. The absorbance spectra of these solutions were recorded over the working wavelength range (430–480 nm). Then, the average absorbance of each spectrum was obtained and used to construct the univariate calibration graph. The curves obtained (Fig. 2) were linear over the ranges 0.2–1.2 μg/ml for Zn, 0.1–1.7 μg/ml for Cd and 0.1–1.3 μg/ml for Cu.

Finally, four pure standard solutions of each component of the mixture, with a concentration lying in the linear concentration range and giving absorbance readings lower than 1.0 were used to obtain the normalized spectrum for each component.

Under the optimum conditions and using the equation (3) for prediction of concentrations, 10 determinations of standard solutions containing 0.8 μg/ml of each metal ions gave a relative standard deviation of 6.4% for Zn, 5.1% for Cd and 3.5% for Cu.

Effect of foreign ions

The interference due to several cations and anions was studied in detail. For these studies different amounts of the ionic species were added to a mixture of Zn, Cd and Cu containing 0.8 μg/ml of each. The starting point was a 1000 fold m/m ratio of interferent to metal ions, and if interference occurred the ratio was progressively reduced until interference ceased. The tolerated limits were taken as those concentrations causing changes no greater than ±5% in the concentration of analytes.

The ions which interfere most strongly were Co(II), Ni(II), Fe(III), Hg(II) and Hg(I) because they form coloured complex with DPTH. While quantitatively significant, the interferences from these ions posed no insurmountable problems for the simultaneous determination of Cu–Zn–Cd because the interference can be overcome by determining the interfering metal together with the three analytes, which can be most readily accomplished by using the program MULTIC (this program allows the resolution of a maximum five components).

The tolerance limits are depicted in Table 1. The tolerance level for some metal ions can be increased by addition of thiosulphate, fluoride or tartrate as masking agents. Thus, 400 ppm of thiosulphate will mask 32 ppm of Ag(I) or Cr(III), 6 ppm of Hg(II) or Hg(I) and 4 ppm of Co(II); 800 ppm of fluoride will mask 32 ppm of Fe(III) or Al(III) and 4 ppm of Ni(II); and 800 ppm of tartrate will mask 32 ppm of Bi(III).

Applications

To verify the utility of the recommended procedure, the method was first used for the simultaneous determination of zinc, cadmium and copper in a set of synthetic samples containing different Zn, Cd, and Cu proportions. The results obtained by applying equation (3) to the resolution of the mixtures are summarized in Table 2, where the actual values are compared with the predicted concentrations. From these results (samples 1–8) we can conclude that the concentrations obtained for copper and zinc by the proposed method are in good agreement with those added, resulting in an RMSEP (root–mean–squared error of prediction) of 0.045 μg/ml for copper and 0.083 μg/ml for zinc. The amounts of cadmium found can be considered to be correct with the exception of those mixtures containing low concentrations of cadmium with regard to the other mixture com-

ponents; in these instances negative errors for cadmium were obtained. The RMSEP for cadmium was 0.122 μg/ml. On the other hand, in those instances where the analytes concentrations present in the mixture was higher than 3.1 μg/ml (*e.g.* sample 9) the method was not able to predict the true concentrations of metal ions with sufficient accuracy. This can be attributed to the high absorbance signals corresponding to these mixtures.

In order to test the applicability and matrix interferences of the proposed method to the analysis of real samples, the method was applied in a variety of situations. For this purpose, diverse spiked samples and reference materials were analysed. Thus, standard solutions containing different concentrations of Zn and Cd were added to 0.1 g of Al bronze 32a and Al Alloy 20b; standard solutions of Cd were added to 0.5 g of TORT-1-Lobster Hepatopancreas and Bovine Liver; standard solutions of Cu were added to 0.5 g of Bovine Muscle. These samples were prepared and analysed as described under the Experimental section. In the case of Aluminium Alloys, 1 ml of 1.1*M* fluoride solution were added to prevent interference from Al(III) and the absorption spectra of these solutions were recorded over the wavelength range 465–480 nm. The results obtained for the analysis of different aliquots of the prepared solutions containing known concentrations are shown in Table 3. These data indicate that the method would be effective for the analysis of samples of similar complexity.

RESIN BEAD DETECTION AND SPECTROPHOTOMETRIC DETERMINATION OF OXYPHENBUTAZONE WITH *p*-DIMETHYLAMINOCINNAMALDEHYDE: APPLICATION TO BULK DRUG AND DOSAGE FORMS

AHSAN SAEED,* SEEMA HAQUE and SAIDUL ZAFAR QURESHI

Analytical Research Division, Department of Chemistry, Aligarh Muslim University, Aligarh—202002, India

(*Received* 5 *November* 1992. *Revised* 19 *April* 1993. *Accepted* 20 *April* 1993)

Summary—An analytical method for resin bead detection and spectrophotometric determination of oxyphenbutazone with *p*-dimethylaminocinnamaldehyde as a reagent is described. Acid hydrolysed product of oxyphenbutazone produced a red color product with *p*-dimethylaminocinnamaldehyde that absorbs maximally at 520 nm. The detection limit is 0.8 μg in resin phase and 4.0 μg in aqueous phase. Beer's law is obeyed in the concentration range of 0.4–4.0 μg/ml of oxyphenbutazone. The method is unaffected by the presence of acetylsalicylic acid, salicylamide, phenylbutazone and number of other excipients but paracetamol gives a positive reaction and novalgin being reductone interferes with the test, both should be removed by extraction with dilute sulfuric acid.

Oxyphenbutazone [4-butyl-2-(4′-hydroxyphenyl)-1-phenylpyrazolidine-3,5-dione] has analgesic, anti-inflammatory and antipyretic action and is found with novalgin, aspirin and paracetamol in drug formulations. A simple and sensitive spectrophotometric method for the oxyphenbutazone determination has been proposed by El Kheir *et al.*[1] Another method for the spectrophotometric determination of oxyphenbutazone is based on chelate formation with $NaNO_2$ in 6*M* HCl in the presence of 0.125*M* solution of Cu^{2+} acetate and Co^{2+} sulphate and chelate formed are extracted with Me-iso-Bu-ketone and $CHCl_3$, respectively.[2] Oxyphenbutazone has also been determined by pH-induced difference spectrophotometric methods in pharmaceutical preparations.[3,4] Binary mixture of analgin-paracetamol and analgin-oxyphenbutazone have also been analyzed using ultraviolet spectrophotometric technique.[5] El Sadek[6] has proposed a colorimetric method based on nitration of oxyphenbutazone and treatment with dimendone and triethylamine to form colored complexes and measurement of absorbance at 400 nm. Naphthaquinone and $Pb(OAc)_4$ have been used as analytical reagents for determination of oxyphenbutazone.[7] A number of other methods for the spectrophotometric determination of oxyphenbutazone are also available in the literature.[8–17]

p-Dimethylaminocinnamaldehyde (*p*-DAC) is a useful analytical reagent which has been utilized for the detection and spectrophotometric determination of various pharmaceutical and related compounds like paracetamol,[18] isocarboxazide[19] hydrochlorothiazide and fursomide[20] and 4-aminoantipyrine.[21] However, *p*-DAC has not, so far, been used for the determination of oxyphenbutazone.

As far as we are aware there is no method available for the qualitative detection of oxyphenbutazone in bulk or in dosage form neither in aqueous phase nor in resin phase. The proposed method is perhaps the first one to attempt on such detection. The spot test technique for qualitative detection is the most versatile and widely used technique. It is simple and sensitive technique. Maximum specificity, sensitivity and selectivity is attained only by proper choice of reaction conditions and suitable media for analysis that is why the conventional spot test technique has been replaced by the resin spot test technique. The possible use of resin beads as a reaction medium and to concentrate the colour on resin surface was first demonstrated by Fujimoto[22] particularly for the detection of inorganic ionic species and few organic compounds of known colour reaction.[23–24] The

*Present address: Camel Research Centre, P.O. Box: 72437, Abu Dhabi, United Arab Emirates.

use of resin beads as a detection media raised the sensitivity, selectivity and specificity many fold in many colour reactions because it concentrated the colour on the surface and side reactions are minimized and so the purity of product enhanced. The stability of colour in resin phase is often more than that in aqueous phase. Sometimes the colour in resin phase progressively intensifies with the passage of time. In some reactions it also acts as catalyst to facilitate their acid hydrolysis.[25-26] Recently resin beads have been used for the qualitative detection of ascorbic acid[27] and chlorpromazine[28] in pharmaceutical preparations and human urine. Usually for quality control, the analysis of drugs calls for a rapid, sensitive and cost effective method. So in the proposed method the resin beads have been used for qualitative detection of oxyphenbutazone.

It was found that hydrogen ions are necessary to effect the condensation of an amine with *p*-DAC which results in the formation of the red chromophore for the determination of bulk drugs and in dosage forms. The method developed is presented and a postulated reaction mechanism is discussed.

EXPERIMENTAL

Apparatus

A bausch and Lomb spectronic-20 (U.S.A.) spectrophotometer was used.

Reagent and ion exchange resin

A solution of *p*-DAC (Kochlight) was prepared by dissolving 0.16 gm in 50 ml ethanol.

Oxyphenbutazone. Oxyphenbutazone was obtained as a gift sample from Cadila Pvt. Ltd. (India) and was used for preparation of calibration curve.

All drug samples of oxyphenbutazone were purchased locally. A cation exchange resin (BDH) was used in H^+ form.

Test solution

Preparation. Accurately weigh 100 mg oxyphenbutazone and mix with 10 ml of ethanol and 5 ml of concentrated hydrochloric acid in a 50 ml round bottom flask and reflux for 40 min. Cool the content and transfer into a 250 ml beaker, dilute to 150 ml with water by continuous stirring for few minutes. Filter the solution on Whatman no. 42 in 250 ml standard volumetric flask and make the filtrate up to the mark with water. Use this solution for detection and determination purpose.

Detection of oxyphenbutazone in aqueous phase

Procedure. Take one drop of test solution in the depression of a white spot plate. Add a drop of reagent. A red color is developed indicating the positive test.

Detection of oxyphenbutazone in resin phase

Procedure. Place about 2–3 ion exchange resin beads in H^+ form in the depression of white spot plate and dry them by blotting with filter paper. Add one drop of test solution followed by one drop of reagent. The resin beads turn red to indicate a positive test.

Spectrophotometric determination of oxyphenbutazone

Procedure. To an aliquot volume of oxyphenbutazone containing 1–10 ml, add 10 ml of reagent in a boiling tube. Dilute the content by approximately 30 ml ethanol. Heat the solution at $40 \pm 1°C$ in a water bath for 5 min. After that cool the content and transfer into a 100 ml standard volumetric flask. Make the solution up to the mark with ethanol. Measure the absorbance at 520 nm against a reagent blank.

Determination of oxyphenbutazone in pharmaceutical preparations

Procedure. Hydrolyse the finely ground tablets containing oxyphenbutazone equivalent to 100 mg and follow the recommended procedure as described above.

If the drug sample contains paracetamol or novalgin (which must be removed) a known mass of powder drug containing 100 mg of oxyphenbutazone is stirred with 50 ml of 2% sulfuric acid for a few minutes and centrifuged. The supernatant liquid is discarded and residue is washed with water and treated as mentioned above.

RESULTS AND DISCUSSION

The absorption spectrum of colored product obtained by interaction between hydrolyzed product of oxyphenbutazone and *p*-DAC was prepared. The optimum wavelength for the determination was found to be 520 nm. The optimum conditions for the formation of red color were studied and maintained throughout the work.

Effect of temperature and time

A 1 ml aliquot was mixed with 10 ml of reagent in a boiling tube and diluted by 30 ml of ethanol. The solution was heated at 25 ± 1, 30 ± 1, 40 ± 1, 50 ± 1°C in water bath for 5 min. The content was cooled, transferred into a 100 ml standard volumetric flask and made up to the mark with ethanol. It was observed that absorbance becomes constant at 30°C and remains unaffected by increasing temperature. Therefore, the absorbance measurement was done at 40 ± 1°C.

The same contents were heated at different intervals of time on each temperature and observed that the absorbance becomes constant after 5 min heating and remains constant for more than 1 hr.

Beer's law is obeyed in the concentration (C, μg/ml) range of 0.4–4.0 μg of oxyphenbutazone (the slope and intercept for line are 0.18 and 0.006, respectively) with molar absorptivity of 0.23×10^4 l/mole/cm and equation for line is $A = 0.18$ [oxyphenbutazone] + 0.006.

The determination of oxyphenbutazone was done in various pharmaceutical preparations, the results are presented in Table 1. The method cannot be used for the determination of oxyphenbutazone in the presence of paracetamol as it also forms 4-aminophenol on acid hydrolysis and therefore undergoes a similar color reaction. Being a reductone novalgin interferes with the test. However, interference of paracetamol and novalgin present in the combination can be removed by extraction with the dilute sulfuric acid.

Some excipients, and other drugs commonly, added to dosage forms were found not to interfere. These are salicylamide, acetylsalicylic acid, phenylbutazone and propyphenazone.

N,N′-Diarylhydrazine undergoes the acid catalysed reaction benzidine rearrangement, yielding diaminobiaryls[29] usually the 4,4′-diaminobiaryl predominates, except one or both of the *para* positions of the diaryl hydrazine are occupied, in which event a 2,4′ or 2,2′-product is formed. On acid hydrolysis oxyphenbutazone forms N-4-hydroxyphenyl-N′-phenylhydrazine which has one *para* position occupied with a hydroxyl group and therefore the benzidine rearrangement produces 2,4-diamino-5-hydroxybiphenyl.[11]

The resulting compound picks up one proton from the excess of acid present in the hydrolysed product, resulting in the formation of a cation which reacts with *p*-DAC losing one water molecule. This reaction may be assumed to be analogous to, occurring between diphenylamine and *p*-dimethylaminobenzaldehyde.[30] The sequence of reaction mechanism is shown in Scheme 1. The resulting red chromophore is adsorbed on a cation exchange resin indicating that the species is positively charged.

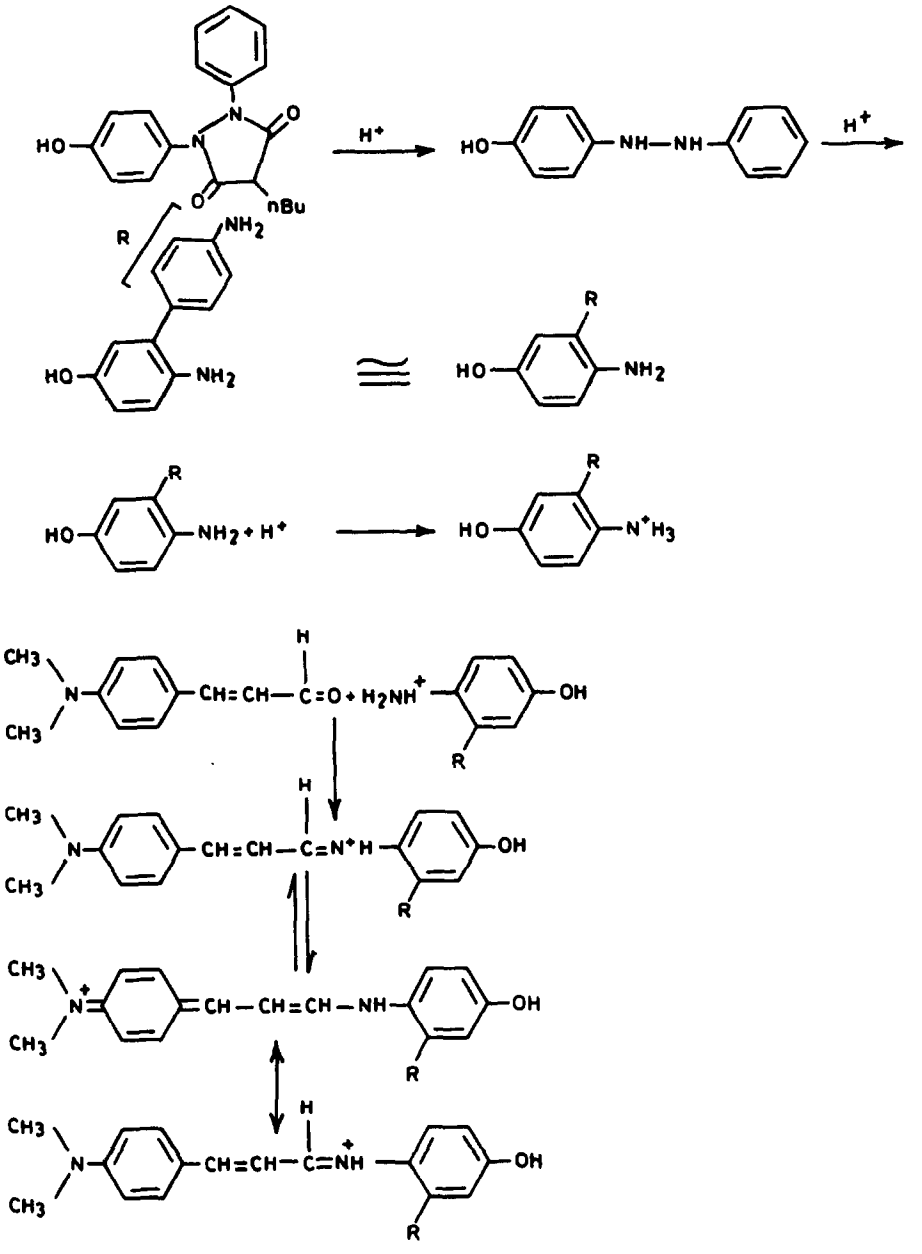
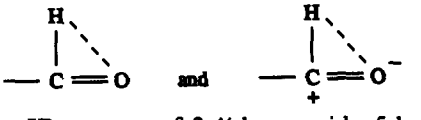


Scheme 1.

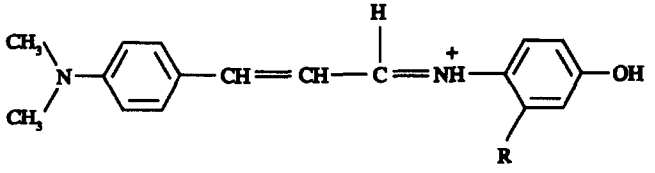
The proposed scheme may further be supported by IR studies. The IR spectral evidence in favour of the product proposed is based on a peak to peak analysis of the IR spectra and its subsequent correlation with various groups present. Since both reactants contain -OH and -NH groupings this will be considered first. The IR spectra of *p*-dimethylaminocinnamaldehyde shows a broad continuum between 3500 cm^{-1} and 1900 cm^{-1} which could be due to a polarizable intramolecular hydrogen bond.



The IR spectra of 2,4′-benzamido-5-benzoyloxybiphenyl shows a sharp band in the region of 3500–3000 cm^{-1} which seems to be due to an unhydrogen bonded -OH stretch. Intramolecular hydrogen bonding seems unlikely due to probable steric hindrance in the large molecule.

In the spectra of the product there is no evidence of a conjugated carbonyl group of the

p-dimethylaminocinnamaldehyde moiety as no absorption is found between 1685 and 1666 cm^{-1}. A band at 1650 cm^{-1} is probably due to disubstituted *cis* C = C grouping as proposed in the product. There is a strong and broad absorption between 2700 and 3500 cm^{-1} which has the characteristics of an amine salt stretching frequency and may also contain within a sharp absorption of the lone -OH (stretch) grouping which again is unlikely to form intermolecular hydrogen bonds. The peak at 1370 cm^{-1} is strongly indicative of an aromatic tertiary amine salt (N–H bending vibration). A strong bending mode at 870 cm^{-1} is indicative of the presence of both 1,4-disubstituted and 1,2,4-trisubstituted benzene molecules as proposed. The final structure is postulated as



The results presented in Table 1 shows the proposed method is simple and sensitive and *p*-DAC is a sensitive reagent for the qualitative detection and quantitative determination of a compound containing an amino group.

Recently a paper appeared[11] describing the spectrophotometric determination of oxyphenbutazone based on indophenol formation. This method perhaps not suitable for a quality control laboratory keeping in view the tedium of the procedure, especially due to the extractions involved which may have their own inherent errors. Moreover, this method does not describe any procedure for the detection of drug which is perhaps equally important. In Table 1 the results of our studies and that of Verma and Sanghi[11] are compared. Since the above mentioned method requires the use of three or four reagents it certainly becomes less cost effective than our method. Furthermore our method is simpler as it does not involve extractions in the product formation.

(*Received* 13 *October* 1992. *Revised* 30 *April* 1993. *Accepted* 6 *May* 1993)

Summary—A detailed study of the species formed in the complex equilibria involving adipic acid dihydrazide (AADH)/2-furoic acid hydrazide (FAH) with Ni(II) using pH titration with glass electrode is performed. The results of modeling studies and effect of errors on the equilibrium constants of AADH/FAH with Ni(II) refined by the non-linear least squares program MINIQUAD75 are reported. Based on the expert system approach developed in our laboratory for the species formed from secondary formation data ($\bar{n}$ and $\bar{n}_H$), several preliminary chemical models were tested. For the four species identified (MLH, ML, ML_2H, ML_2), an exhaustive search of a different combination of models (15) was performed. Then other suspected minor species (ML_2H_2, ML_3 and ML_3H) were tested. The final best fit chemical model was found to contain ML_3H to an extent of 3% along with the other four major species. In order to ascertain the accuracy of the stability constants and consequently distribution of the species, a detailed error analysis is attempted. As the existing least squares procedures cannot suppress the systematic errors, three-dimensional plots of the simultaneous effects of pH and TLO:TMO (1.5:1 to 5:1) on the percentage of species are drawn which are of immense use in arriving at optimum conditions for the preparation of a complex of definite stoichiometry.

Adipic acid dihydrazide (AADH), apart from its vital role in epoxy resins[1] and semi-conductor devices,[2] finds application in vaccines[3] and other compounds of biological importance.[4] Several antibacterial/antileukemic compounds[5] have been synthesized from 2-furoic acid hydrazide (FAH). Since AADH has been employed in the presence of metal ions[6] in coatings and varnishes, speciation studies in presence of water miscible solvents and/or micelles may throw some light in understanding the mechanism of reactions and enable one to choose optimum experimental conditions. The results of exhaustive modeling studies for the interaction of AADH and FAH with Ni(II) in aqueous solution using the MINQUAD75[7] program are reported in this communication.

EXPERIMENTAL

Tenth mol/l aqueous solutions of AADH and FAH, obtained from Fluka AG, Switzerland, were prepared in doubly glass distilled deionized water. All other chemicals are of AnalaR grade. Tenth mol/l nickel(II) chloride (Fluka AG) solution was rendered acidic to suppress hydrolysis of metal ions.[8]

Complex equilibria experimental design (CEED)

Since the accuracy of equilibrium constants of metal–ligand complexes depends upon complex mathematical functions of errors in ingredient concentrations and the data acquisition system, a systematic investigation of possible sources of errors are considered. The extreme errors in concentrations of ingredients were determined by COSWT[9] (concentration of solution by weight method) and COST (concentration of solution by titrimetry). As the glass electrode calibration with buffer solutions alone is a two point method, Gran analysis[10] of titration of a strong acid with alkali is employed as recommended by the commission on equilibrium data (IUPAC)[11–19] and by Babu.[14] A plot of $GA = 10^{-(B_i + \log F)} \times (V_0 + V_i)$ *vs* V_i intersects the volume axis at the equivalence point (V_e) only if the errors $\{e_1\}$, $\{e_2\}$, $\{e_3\}$ and OH_i in equation (1) are negligible:

$$(FH_i + e_1) \times (V_0 + V_i + e_2) = (ALK + e_3) \times (V_e - V_i - e_2) + OH_i \times (V_0 + V_i + e_2) \quad (1)$$

*Presented at 11th IUPAC Conference on Chemical Thermodynamics, Como, Italy, August 1990.
†Author for correspondence.

where V_i is the volume of alkali of concentration ALK added to a strong acid of total volume V_0, B_i is the pH meter dial reading, log F is the correction factor and OH_i is the concentration of hydrogen ion due to auto ionization of water. These are related to equilibrium hydrogen ion concentration (FH_i) by the equation

$$FH_i = 10^{-(B_i + \log F)}. \quad (2)$$

The determination of log F, pK_w (negative logarithm of auto ionization constant of water) and titration assembly are same as described earlier.[15,16]

RESULTS AND DISCUSSION

Data processing

AADH contains two functional groups a carbonyl oxygen and a terminal amino nitrogen which are potential sites for co-ordination of metal ions. Since in this investigation we are confined to ligand-to-metal ratios greater than one, only mono-nuclear complexes are considered. As the highest protonated species of ligand is LH_2^{++}, the expected metal complexes are $M(LH)_{Maxl}$. Plots of a (moles of alkali per mole of ligand), m (moles of alkali per mole of metal ion) and $\bar{n}$ (average number of ligands bound per mole of metal ion) against pH suggested two ligand molecules are involved in metal complexes. However, considering Maxl to be three, the expected binary complexes are {MLH, ML, MLOH, $ML(OH)_2$, ML_2H_2, ML_2H, ML_2, $ML_2(OH)$, $ML_2(OH)_2$, ML_3H_3, ML_3H_2, ML_3H, ML_3, $ML_3(OH)$, $ML_3(OH)_2$}. Here the maximum number of hydroxyl ions are limited to two, based on the pH region of the investigation.

Although in principle it appears that it is possible to resort to complete searching of models,[17] it is not pragmatic as modelling of complex equilibria is a non-linear problem. Large computer time is required to solve each model, unlike in multiple-linear regression where the solution is obtained in one attempt. Therefore the species to be considered are short listed using heuristics and chemical principles.

A perusal of literature reveals that the maximum ligand number (Maxl), hydrogen ions (Maxh) and hydroxyl ions (Maxoh) in a mononuclear metal complex were 6, 5 and 2, respectively. However, not more than 6–8 species are reported except in bovine. It appears that the exclusion of the species is definitely not based on systematic elimination of the species but based on implicit knowledge and experience which can be coded as heuristics. In the present case some of the factors considered are density of the ligand, coordination number of metal ion and average number of ligands bound per mole of metal ion. A few heuristics are described in Fig. 1.

Work is in progress to use the complementary knowledge contained in $\bar{Z}$ (moles of alkali per metal ion or ligand) to judge the presence of protonated species, core and link hypothesis and chemical theories of Sylva to reduce the state search space of polynuclear species.

```
If    minimum ratio of initial concentration of ligand to metal
      (TLO/TMO) ≥ 1.0
Then Maxl. = 1
-------------------------------------------------------------
If    n̄ analysis is performed &
      formation curves exhibit ascending slope
Then Maxl = max(n̄) + 1.6
If    formation curves do not exhibit ascending slope
Then Maxl = Max(n̄) + 0.6
-------------------------------------------------------------
If    different TLO : TMO are investigated &
      formation curves are not overlapping
Then different protonated, hydroxylated, ML_x species exhibt
-------------------------------------------------------------
If    total number of protons(NAP) or ionizable protons(NIP) > 1 &
      highest protonated form of the ligand in the pH range of n̄ is
      HxL & x > 1
Then protonated species (Maxh = X - 1)
```

Fig. 1. Heuristics for the detection of protonated metal complexes and maximum ligand number.

This preliminary screening of the species resulted in identification of MLH, ML, ML_2H and ML_2. For exhaustive modeling of these four species, two popular approaches available in multiple-linear regression analysis are forward selection wherein different models are generated starting from the lowest number of variables (one), and backward elimination, in which species are successively eliminated from a model with highest number of species (four). We have followed the forward selection principle[17] and several statistics for residual analysis for 15 chemical models (stoichiometric coefficients and log β with standard deviations) are given in Table 1.

The relative concentration of different species formed is not only a function of their equilibrium constants but also the ratio of ligand-to-metal. In an attempt to model the complexation of Ni(II) with hydrazides, different ratios of ligand-to-nickel(II) (TLO/TMO) of 2:1 to 6:1 were investigated, by varying the initial analytical concentration of metal ion. Alkalimetric titrations of the titrand containing above mixtures were performed using a glass electrode. At the lowest ratio, information content of MLH_h will be obtained, while with increasing ratio that due to ML_2H_h will be obtained.

Selection of best fit model

A perusal of the literature reveals that there is no unique set of rules to arrive at the best fit chemical model and hitherto this has been a matter of subjective decision. We have employed an expert system approach involving heuristics based on some of the popular statistical parameters (Table 1). The numerical values of R[18] (crystallographic R factor) and U[19] (sum of the squares of residuals in all mass balance equations) corrected for models with one, two and three are significantly larger in numerical magnitude than that with four species, indicating that the last one better explains the solution processes. However, care was taken to avoid the overambitious modeling (including more species) which also results in decrease of statistics based on residuals.

From the analysis of the individual experimental data at each of the metal-to-ligand ratios (1:1.5 to 1:5) for different analytical concentrations of the metal ion (0.003 and 0.0045M) (Table 2) it is clear that complexes ML and MLH are favored at low (1:1.5 and 1:2) values of TLO/TMO while the species ML_2 and ML_2H were rejected by MINIQUAD75. When TLO/TMO > 2, ML_2H and ML_2 were refined, and ML and MLH are rejected. This shows that a proper experimental design includes an increasing number of experimental points by performing more titrations, keeping TLO/TMO optimum for the species of interest. Braibanti *et al.*[20] also observed the rejection of species of higher stoichiometry at low ratios of Ni(II) to glycine. After arriving at the best fit model, the species rejected in the preliminary scrutiny were again tried. It was found that these species were rejected during MINIQUAD75 refinement. The stability constants of model 1 of Table 2 are used to generate simulated primary data. From Fig. 2 it is clear that the simulated data predict the experimental one within the limits of accuracy of data acquisition system.

Precision of log β values

The very low standard deviation in the log β values and the small values of U suggest, (a) a sufficient number of data points corresponding to each species (as otherwise very high SD would result), (b) precision of refined log β values, and (c) the best fit of the chemical model for the systems under the above experimental condition. The correlation matrix of log β values for Ni(II)–AADH (Table 3) provides a measure of linear dependence of one equilibrium constant on the other. This information is very important as a good statistical fit of the data is possible even when one parameter is erroneously estimated, because the error in this log β can be offset by appropriate change in the other.[21] The apparently high correlation coefficients between some of the log β values are an artifact of the algorithms employed in MINIQUAD, SUPERQUAD[22] and ESTA.[23] A real picture is, however, possible only when the stepwise constants are refined as in SCOGS2[24] and in one of the modes of DALSFEK.[25] A system wherein $r_{ij} > 0.8$ indicates that (1) one or more of log $K(s)$ are not sufficiently defined by the available primary data or (2) equilibria are highly overlapping and thus only a linear combination (but not individual constants) can be calculated.

Residual analysis

The χ^2 values for Ni(II)–FAH and Ni(II)–AADH obtained are 36 and 99, respectively. They are less than $\chi^2_{\nu,0.5}$, indicating that the unweighted residuals form a part of normal distribution. This χ^2 statistic drew the attention

of equilibrium chemists only recently and the values reported till now range from about 10 to 400 for chemical equilibria of increasing complexity.[26,27] Further, very small values of standard deviation (1.93×10^{-4} and 1.09×10^{-4}) and mean deviation (1.48×10^{-4} and 6.51×10^{-5}) corroborate the above assumption. However, the deviation of kurtosis (5.8 and 17.7) and skewness (−1.12 and −2.95) from 3 and 0, respectively, suggest that the residuals concentrate to the left of the peak. The confidence contours of log β values calculated (Table 1) thus represent only an approximate range as log β values are partially correlated and only part of the residuals form normal distribution with a slight distortion.

Species distribution plots

Conventional two-dimensional distribution diagrams (Fig. 3) depict the variation of percentage of the concentration of species to the total metal ion concentration *vs* pH. From Fig. 4, it is clear at lower ratios of TLO to TMO, ML_2 is not formed while at higher ratios, ML does not exist. Mathematical solutions in N-dimensional space where $(N-1)$ variables

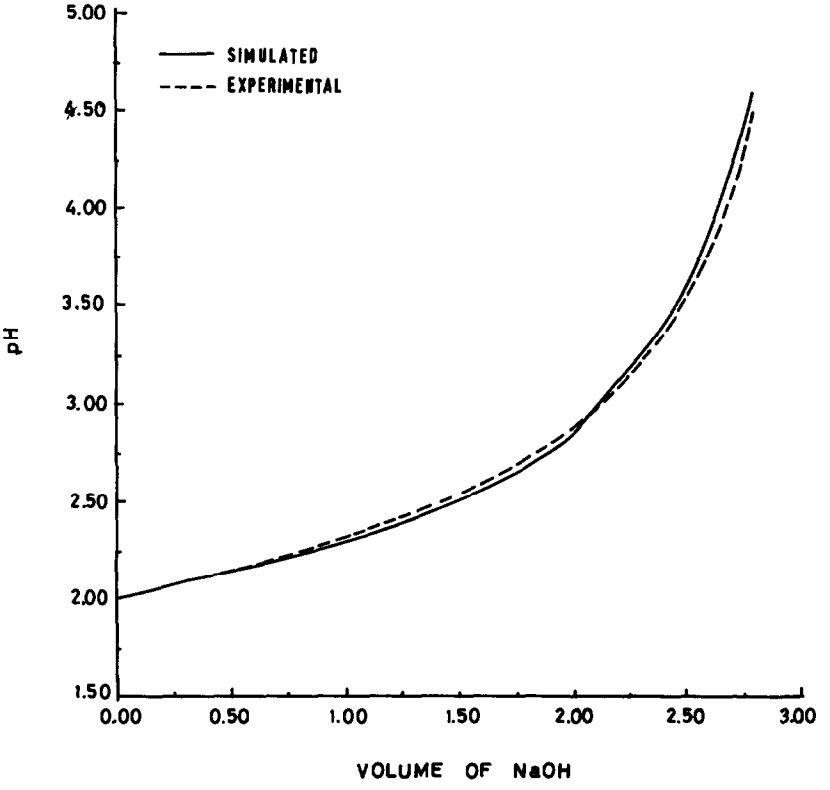

Fig. 2. Comparison of the experimental titration curve with the simulated one TLO:TMO = 1:1.5. log $\beta_{110} = 4.080$, log $\beta_{111} = 6.716$ and log $\beta_{121} = 10.253$.

Table 3. Correlation matrix of log β values of Ni(II)–AADH (aq) system

	MLH^+	ML	ML_2H^-	ML_2^{2-}
MLH^+	1.0	0.056	0.918	0.925
ML		1.0	−0.212	−0.215
ML_2H^-			1.0	0.954
ML_2^{2-}				1.0

(TLO:TMO, analytical concentration of the metal ion, pH, etc.) affecting the concentration of the species, provides important chemical information such as:

- optimum conditions for the preparation of a solid complex with minimum interference from other complexes;
- understanding the relative concentrations of different species under given experimental conditions which throw light on biologically active forms;
- performing a feasibility study of metal ion buffers;
- detecting stoichiometric asymmetry and over-compensation effects of a specific equilibrium.

In an attempt to achieve this goal, we have considered three-dimensional plots wherein the simultaneous effects of pH and TLO:TMO ratio on percentage of species is described (Fig. 5). The chemical equilibria in solution phase are represented by

(1) $Ni(II) + LH_2 \rightleftarrows NiLH^+ + H^+$

(2) $Ni(II) + LH_2 \rightleftarrows NiL + 2H^+$

$NiLH^+ \rightleftarrows NiL + H^+$

(3) $Ni(II) + 2LH_2 \rightleftarrows NiL_2H^- + 3H^+$

$NiL + LH_2 \rightleftarrows NiL_2H^- + H^+$

$NiLH^+ + LH_2 \rightleftarrows NiL_2H^- + 2H^+$

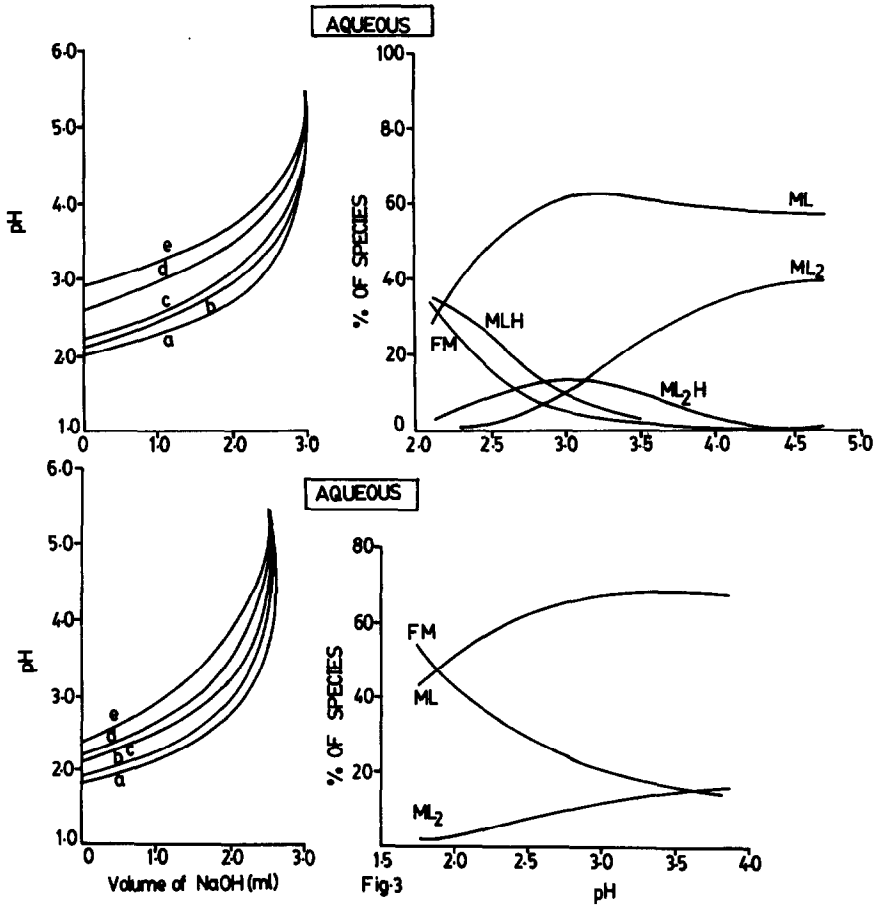

Fig. 3. Protometric titration curves and species distribution diagrams of Ni(II)–AADH (or FAH) complexes. Titrand: TMO (Ni^{2+}): 3.482×10^3 mol/l, E_0: 21.85×10^{-3} mole/l, μ: 0.10 mole/l, V_0: 50.0 cm^{-3}, temp.: 301 K, titrant: NaOH:0.3902 mole/l. AADH = (a) 5.982, (b) 7.976, (c) 9.970, (d) 14.955 and (e) 19.940 mmole/l and FAH = (a) 6.035, (b) 8.048, (c) 10.059, (d) 15.089 and (e) 20.119 m mole/l.

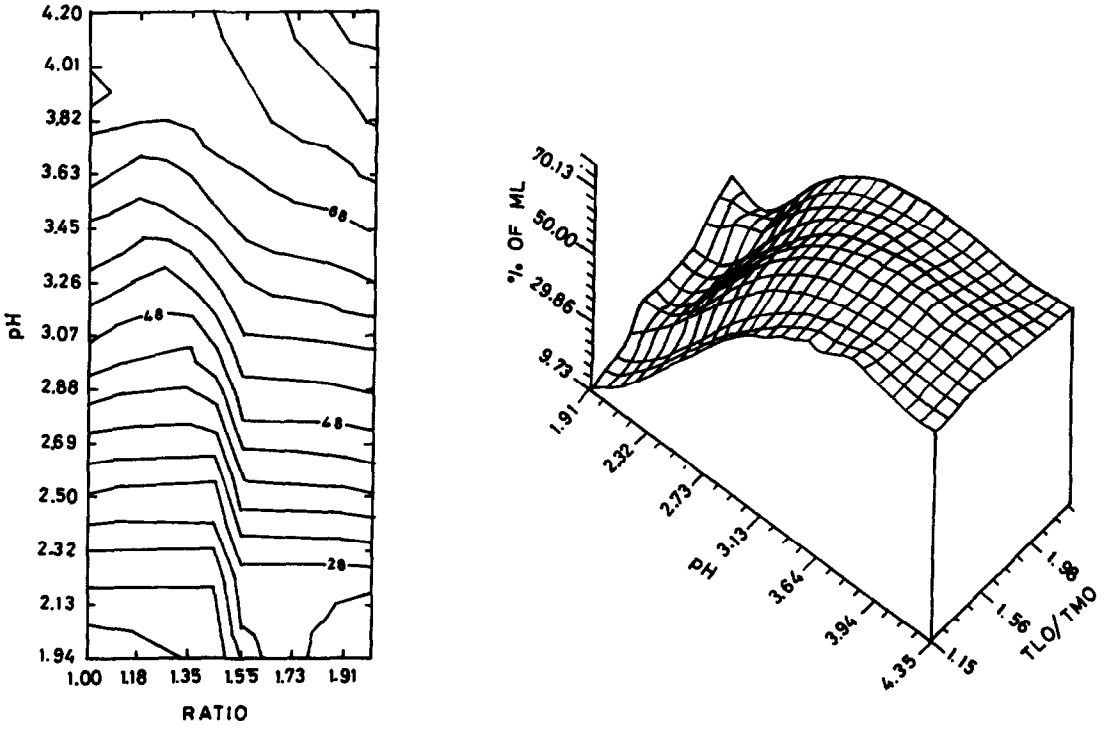

Fig. 5. Three-dimensional plot and surface contour for the simultaneous effect of pH and TLO:TMO on percentage of ML of Ni(II)–AADH system. Projection: orthographic; rotation about z-axis: 310°; tilt after rotation: 30°.

(4) $NiL_2H^- \rightleftarrows NiL_2^{2-} + H^+$

$NiL + LH_2 \rightleftarrows NiL_2^{2-} + 2H^+$

$NiL + LH^- \rightleftarrows NiL_2^{2-} + H^+$

However, from pH metric studies alone it is not possible to assess the relative importance of the micro equilibria contributing to the release of one and two protons.

CHEMOMETRIC APPROACH FOR THE RELIABILITY OF LOG β VALUES

The standard deviations in log β values and any statistic representing the sum of squares (U, SD in pH, *etc.*) reflect how best the algorithm explains the variation in the dependent variable (pH) in terms of explanatory variables (chemical model). However, the errors which creep into the system at various stages, like those in concentration of ingredients, electrode parameters and derived constants (proton ligand stability constants), have a tremendous cumulative effect on the metal ligand stability constants. But MINIQUAD75 or other similar programs do not have any built in provision to recognize or overcome these effects.

Effect of errors in proton–ligand stability constants on metal complexes

Table 4 incorporates the results of the effect of introducing an error of $\pm$ 3SD (where SD is the standard deviation in proton ligand stability constant) and an extreme value ($\pm$ 0.20) in log β_{011} and log β_{012} on the chemical model refined for the Ni(II)–AADH system. The very small effect on metal ligand stability constants when +3SD error is introduced indicates the consistency of the reported model (Table 4). However, considerable (+0.2) errors in proton ligand complexes result in rejection of some of the species actually existing (ML) or a stability constant differing by one log unit (ML_2 for $\pm$ 0.2 and ML_2H for $\pm$ 0.2). This re-emphasizes the need for the experimental design and accurate determination of an acid–base equilibria of systems under identical conditions employed for metal ligand complexes.

Retrieval of proton–ligand stability constants from metal–ligand titration data

Keeping all the stability constants corresponding to metal complex species fixed, log β values of acid–base equilibria of AADH are retrieved using MINIQUAD75. The good agreement with the reported values (given for comparison in Table 5) indicates the absence of any other chemical reactions changing hydrogen ion concentration in the pH regions (1.8–4.6) of acid–base equilibria of the ligand.

Simultaneous refinement of proton–ligand and metal–ligand equilibrium constants

The general non-linear algorithms, in principle, do not restrict the simultaneous refinement of any number of parameters, for example, stability constants of proton ligand and metal ligand complexes and all dangerous parameters. However the error surfaces exhibit distortion when (1) a non-existent species is introduced by chance, (2) there is a hidden mathematical relationship between two or more species (correlation) and (3) the model is made over sophisticated to account for small residues (in the primary data) which are less than the accuracy of the data acquisition system. Further increased complexity of non-linearity (from PL to MLXY), different ranges of β values and lack of restriction on the range of parameter space are added disadvantages. The difficulties in the simultaneous refinement of free concentration of ingredients and β values were experienced in the earlier version of MINIQUAD and these problems are overcome in MINIQUAD75[7] by a two level refinement. Our earlier investigations of interaction of *L*-dopa with Mn(II) and Zn(II)

1	1	0	6.299	
1	1	0	4.087	
1	2	1	9.442	
1	2	0	6.287	

showed that simultaneous refinement resulted in agreement of values,[28] this being a case in which many of equilibria are non-overlapping. However, the present study clearly establishes simultaneous refinement of results in stability constants that are quite different from the best fit model (Table 6). This can be explained in terms of simultaneous solution (acid–base and metal–ligand) equilibria and major changes in the concentration profiles of different forms of ligand. This results in difficulties in determining individual stability constants accurately due to inadequacy of the algorithms adopted in complex equilibria.

Effect of systematic errors on ingredient concentrations

In order to rely upon the best fit chemical model for critical evaluation and application under varied experimental conditions with different accuracies in the data acquisition system, a study of the effect of systematic errors of different magnitudes up to extreme limits in the concentration of EO (strong acid), ALK (concentration of alkali used as titrant), TLO and TMO have been made adopting a factorial design. It was found that errors in EO and ALK have more pronounced effects than those in TLO and TMO. Further, even very large errors in initial total volume (V_0) which is important in understanding the effect of mixing volumes and pK_w have been found to have little effect. Since the errors in the ingredient concentrations in the present investigation are less than 1%, the chemical model proposed is accurate to 0.02 units in log β.

A study of systematic errors introduced in the measurement of hydrogen ion by the glass electrode is of paramount importance. A very large error (± 0.10 pH) distorts the stability constants of some of the species appreciably or the very model is rejected during refinement process.

Robustness of MINIQUAD75

Recent investigations by Sylva *et al.*[29] and Pardue[30] and by our group established the necessity for fairly good initial estimates of stability constants, especially for highly complex systems (with more than two overlapping equilibria). This is because the species that really exist are rejected or yield ill-conditioned matrices that are not solvable. A point of interest here is to note that this is not the limitation of MINIQUAD75 alone but a difficulty in numerical analysis of mathematically complex systems and there are no attempts based on chemometric principles to overcome this hurdle.

Nurchi and Crisponi[31] reported non-convergence by a Gauss–Newton algorithm[32] when the approximate stability constants are less than 0.5 units for protonation equilibria with log $K_1 <$ log K_2. Recently Babu[14] showed that the algorithm plays an important role even in describing the range of approximate stability constants and MINIQUAD75 produced identical results even when the initial constants were three log units away from the true (log $K_1 = 5.0$,

Table 6. Simultaneous refinement of proton–ligand and metal–ligand stability constants Ni(II)–AADH (aq) system

m	l	h	log β	β_{01h} fixed
0	1	1	3.203(0.02)	3.521
0	1	2	5.962(0.02)	6.172
1	1	1	6.619(0.06)	6.299(0.090)
1	1	0	3.712(0.23)	4.087(0.035)
1	2	1	10.088(0.07)	9.422(0.080)
1	2	0	5.671(0.07)	6.287(0.090)

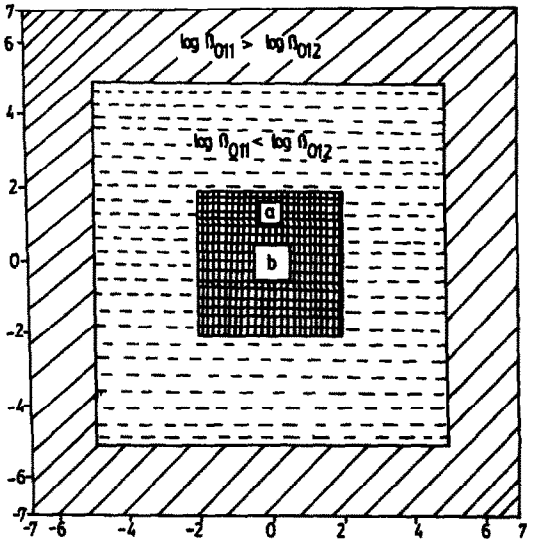

Fig. 6. Effect of wild initial estimates of log β for successful convergence by MINIQUAD75.

log $K_2 = 6.0$) values. Further, a detailed study indicated that for the acid–base equilibria of AADH with log K_1 (3.5) > log K_2 (2.5), MINIQUAD75 is robust to an extent of 5 log units. Since the robustness of a program depends on (1) the algorithm (2) the pattern of log β values (3) the number of equilibria and complexity, (4) optimization function and (5) over all accuracy and precision of potentiometric titration data. The Ni(II)–FAH system was chosen to establish a valid range of initial constants and Fig. 6 indicates this to be log $\beta_{110} \pm 2.0$ units. As such an investigation for Ni(II)–AADH species is a formidable task requiring approximately 360 MINIQUAD75 runs, only preliminary calculations were attempted. These indicated that the safe area decreases with increasing complexity.

Abbreviations and symbols

TMEi, TLEi, THEi = Total concentrations of metal, ligand and hydrogen ion (experimental).

TMCi, TLCi, THCi = calculated concentrations of total metal, ligand and hydrogen ion.

NP = Number of experimental points.

m = Number of stability constants refined.

$R_i = [(\mathrm{TME_i} - \mathrm{TMC_i}) + (\mathrm{TLE_i} - \mathrm{TLC_i}) + (\mathrm{THE_i} - \mathrm{THC_i})]$.

POLAROGRAPHIC DETERMINATION OF Ce(III) AND Tm(III) USING RARE EARTH–DBF–CHLOROPHOSPHONAZO COMPLEX

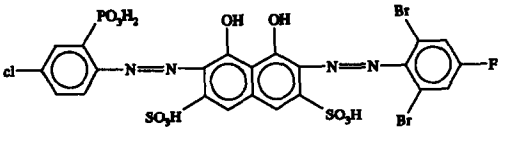
YAN RONG,* LU XIAOHUA and SHI WENZHAO
Department of Chemistry, Huazhong University of Science and Technology, Wuhan 430074, People's Republic of China

(*Received* 11 *September* 1992. *Revised* 16 *March* 1993. *Accepted* 19 *March* 1993)

Summary—The electrochemical behaviour of the DBF–chlorophosphonazo (DBF–CPA)–rare earth (RE) complex has been investigated in this paper. A highly sensitive polarographic adsorption wave was found in the RE(III)–DBF–CPA system and a new method for determination of trace total RE(III) has been established. The limit of detection was $1.8 \times 10^{-8} M$. The results of determination of the total RE(III) content in Chinese standard reference materials of cast-iron and alloy steel were in good agreement with the certified values. The polarographic adsorptive waves of Ce(III) and Tm(III)–DBF–CPA overlap seriously. In order to improve the selectivity of determination, a non-linear regression model was employed to fit the peak height of the polarographic wave and the concentrations of Ce(III) and Tm(III). The predictive accuracy of this model for simulant mixtures was satisfied.

Natural resources of rare earth(RE) are abundant in China. Because of their special photogenic, magnetic, mechanical and nuclear properties, rare earth elements are widely applied in the fields of industry, agriculture and natural science. Chemists are increasingly paying attention to the study of environmental, medical and biological effects of rare earth elements. Therefore, methods for their rapid, sensitive and accurate determination and separation are of great importance.[1]

DBF–CPA is a new colour with molecule structure



It has been used as a sensitive colourant in the spectrophotometric determination of total rare earths, but its electrochemical behaviour has not been investigated. In this paper the polarographic behaviour of rare earth–DBF–CPA complexes at the mercury electrode was studied. A sensitive and selective polarographic adsorptive wave (PAW) of RE(III)–DBF–CPA complexes was established in the determination of trace amounts of RE. To improve the selectivity of the method, a non-linear regression model was applied to determine Ce(III) and Tm(III) simultaneously in the rare earth mixtures and the results of this determination were satisfactory.

EXPERIMENTAL

Apparatus

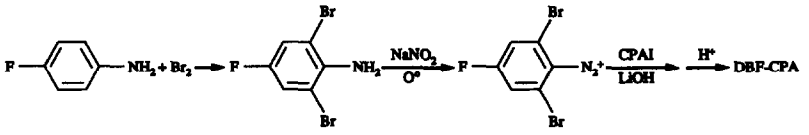
Single sweep oscillopolarographic experiments were performed on a oscillopolarograph model JP-2A with a dropping mercury working electrode (DME), a saturated calomel reference electrode (SCE) and a platinum-wire counter electrode. Cyclic voltammetry was performed with a neopolarograph model XJP-821(B) with a conventional three-electrode cell; a hanging mercury electrode, an Ag/AgCl (saturated KCl) reference electrode and a platinum-wire counter electrode. Voltamperograms were recorded on an X–Y recorder model LZ03-204. A spectrophotometer model UV240(Simazu) was used with 1 cm glass cells and a pH meter model PHS-25C was used for pH measurement.

Reagents

DBF–CPA was synthesized in the Chemistry Department of Wuhan University of China.[2]

*Author for correspondence. Present address: National Key Laboratory on Coal Combustion, Huazhong University of Science and Technology, Wuhan 430074, People's Republic of China.

The synthetic route is as follows:



Other chemicals used were of commercial analytical grade reagents. All solutions were prepared in doubly distilled water. Stock solutions of 1 mg/ml RE(III) in 0.1*M* NH_4Cl solution were prepared from RE_2O_3. A 6.1×10^{-4} *M* DBF–CPA solution (0.05%) were prepared in water. A 0.1*M* NH_4Cl solution (pH = 4.5) was used as background electrolyte.

Procedures

A 5.0 ml portion of 0.1*M* NH_4Cl buffer and 0.15 ml of 6.1×10^{-4} M DBF–CPA solution were mixed with a known volume of the sample solution, and the mixture was diluted to 25.0 ml with water. Shake the solution and then transfer 10 ml of it into an electrolyzer. Record the secondary differential response of the single sweep oscillopolarography of the RE–DBF–CPA complex and read the peak height at the reductive potential about −0.78 V (*vs.* SCE.).

RESULTS AND DISCUSSIONS

The PAW of the RE–DBF–CPA complex and experimental conditions

The secondary differential peak of DBF–CPA and RE(III)–DBF–CPA complex in 0.1*M* NH_4Cl system are illustrated in Fig. 1. The P_1 and P_2 peaks (solid line) corresponded to the reduction of the two azo linkages of the DBF–CPA reagent. When trace RE was added in the DBF–CPA and NH_4Cl system, the height of P_2 decreased and its reductive potential moved slightly to a negative position, P_2'(dashed line in Fig. 1). At the same time a new peak P_3' with a more negative reductive potential appeared at −0.78 V (*vs.* SCE). P_3' was the reductive peak of the RE–DBF–CPA complex. The height of the secondary differential peak($i''p_3'$) had a good linear relationship with concentrations of RE in the range 2.0×10^{-8}–1.0×10^{-8}*M*. The detection limit was 1.80×10^{-8}*M*.

Several electrolytes such as HCl, NaH_2PO_4, $Na_2B_4O_7$, KCl, $NaNO_3$, NH_4Cl, NH_4Ac, and NH_4Br were studied. In NH_4Cl, NH_4Br or NH_4Ac solution, the peak P_3' appeared, but in NH_4Cl solution the sensitivity and the peak shape were better than those in NH_4Br and in NH_4Ac. The p_3' peak appeared when pH was in the range 3.7–10.2, while the heights of p_3' were stable when pH was between 4.0 and 8.0. Therefore, we selected pH = 4.5 with NH_4Cl solution as supporting electrolyte.

The influence of the concentration of DBF–CPA on the current was studied. With increasing concentrations of DBF–CPA, the current $i''p_3'$ increased first and then when the complex formed completely, the peak currents became stable, and finally because of the competition of adsorption between RE(III)–DBF–CPA complex and the free DBF–CPA at DME, the $i''p_3'$ decreased (see Fig. 2).

The height of $i''p_3'$ increased from 2.0 to 3.7 cm while the height of the mercury column(*h*)

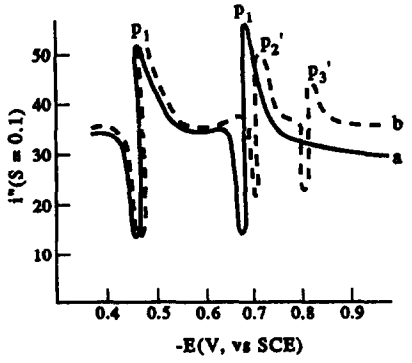


Fig. 1. Single sweep oscillopolarography: (a) 3.6×10^{-6}*M* DBF–CPA + NH_4Cl (pH = 4.5); (b) a + 2.8×10^{-7}*M* Ce(III).

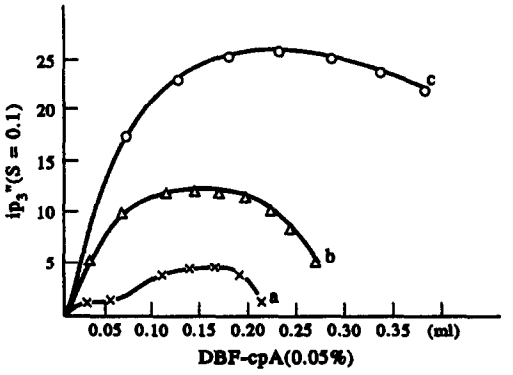

Fig. 2. The influence of DBF–CPA content on $i''p_3'$: (a) 0.572×10^{-7}*M* RE(III); (b) 2.86×10^{-7}*M* RE(III); (c) 7.16×10^{-7}*M* RE(III).

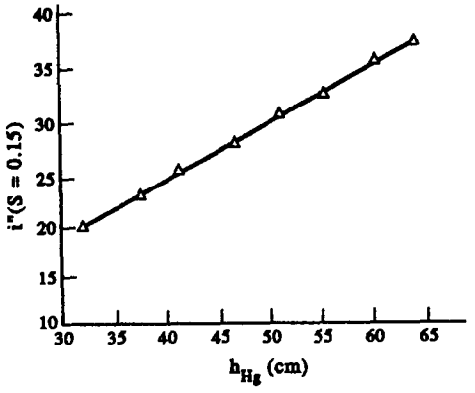

Fig. 3. Effect of height of Hg column on $i''p_3'$.

was changed from 35 to 65 cm. A linear relationship between $i''p_3'$ and h is shown in Fig. 3.

The effect of temperature on current was also studied. The variation of $i''p_3'$ with temperature is recorded in Table 1, showing that the effect of temperature on the height of $i''p_3'$ was not significant.

The effect of enrichment time and the size of the mercury drop on $i''p_3'$ had been studied by a neopolarograph with a hanging mercury electrode. The results are listed in Table 2.

The experiments showed that the longer the enrichment time and the bigger the size of the mercury drop, the larger the current ($i''p_3'$). This may be because of adsorption of more complex on the surface of the mercury drop while the size of the drop and enrichment time increased. The results also showed that the reductive wave of RE(III)–DBF–CPA has an adsorptive property.

Determination of the composition of the complex

The composition of the complex was determined by an equilibrium method and a straight line method.[3] The results are shown in Fig. 4(a) and Fig. 4(b). In the equilibrium method if the concentration of ion is kept constant and the concentration of DBF–CPA is changed, the plot

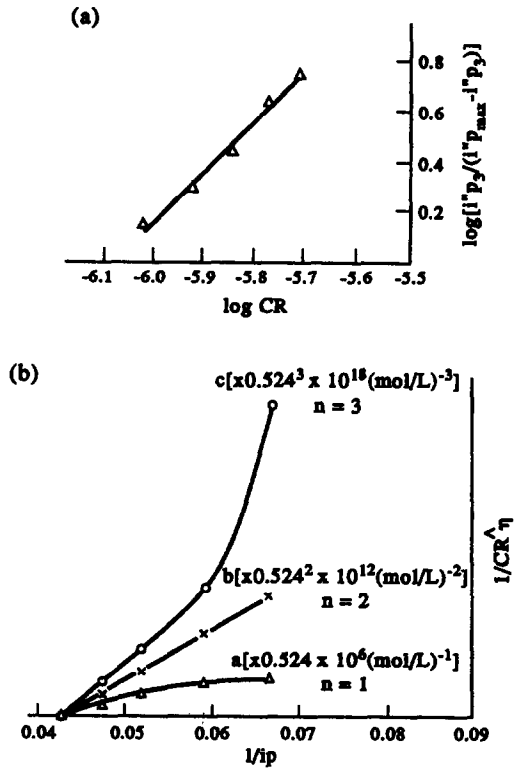

Fig. 4. (a) Determination of composition by equilibrium method; (b) determination of composition by straight line method.

of $\log[i''p_3'/(i''\text{pmax} - i''p_3')] \sim \log CR$ should be a straight line. The slope of this line is just the ratio of concentration of ligand to metal. Where i''pmax is the maximum peak current of the complex, $i''p_3'$ is the peak current corresponding to different concentrations of ligand and CR is the equilibrium concentration of DBF-CPA. When the concentration of ligand is largely more than that of metal, CR is almost equal to the total ligand concentration. So we can easily determine the composition of a complex. In Fig. 4(a), the slope of the straight line is equal to 2.

Because the height of the reductive peak is directly proportional to the concentration of the

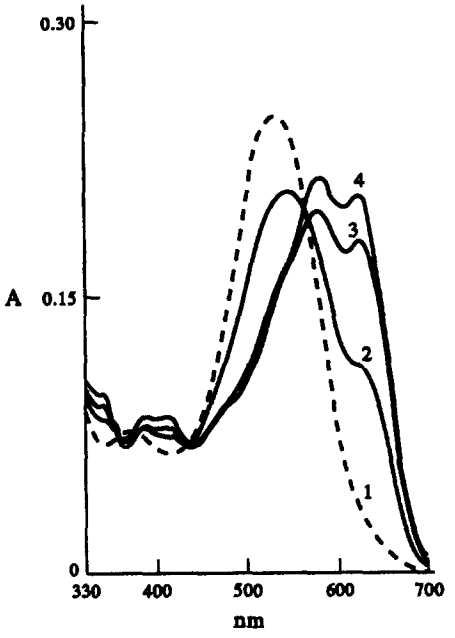

Fig. 5. Adsorption spectra: (1) 0.05% DBF–CPA + 0.1M NH_4Cl (pH = 4.5); (2) 0.1 ppm RE(III) + (1); (3) 0.2 ppm RE(III) + (1); (4) 0.3 ppm RE(III) + (1).

complex of RE–DBF–CPA, the equation $1/ip = 1/ip_{max} + 1/(b \times ip_{max} \times CR\wedge n)$ holds true. Where ip_{max} is the maximum peak height, CR is the concentration of DBP–CPA and ip is the peak height corresponding to different concentrations of ligand. When n is an integer we can obtain the different curves of $1/ip \sim 1/CR\wedge n$. So the ratio of ligand to metal can be obtained when the plot of $1/ip \sim 1/CR\wedge n$ shows a linear relationship. From Fig. 4(b) we can see the value of n equals 2. The results of the straight line method and the equilibrium method both show the composition of the complex is RE: DBF–CPA = 1:2.

Figure 5 shows the absorption curves of DBF–CPA and RE–DBF–CPA. We also determined the composition of the complex using the absorption peak of the RE–DBF–CPA complex (650 nm). The results are in agreement with that of the reported spectrophotometric method,[2] and DBF–CPA: RE is also equal to 2.

The reduction mechanism of RE(III)–DBF–CPA complex

The present paper investigates the cyclic voltammogram, electrocapillary curve, temperature coefficient of the polarographic current, the relationship between potential, scanning speed (v) and peak height, the influence of surfactants on current, the effect of acidity of the solution on peak potential(E_p), *etc.* were investigated.

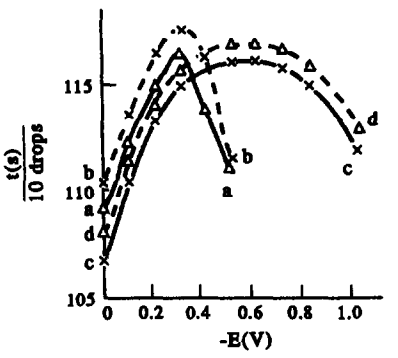

Fig. 6. Electrocapillary curve: (a) 0.05% NH_4Cl (pH = 4.5); (b) 7.16 × $10^{-5}M$ Ce(III) + a; (c) 6.1 × $10^{-5}M$ DBF–CPA + a; (d) 7.16 × $10^{-5}M$ Ce(III) + 6.1 × $10^{-5}M$ DBF–CPA + a.

The electrocapillary curves are shown in Fig. 6. Comparing curves (c) and (d) with (a) and (b), we can see the zero charge potential shifted negatively when DBF–CPA was added to the solution, and the left part of curves (c) and (d) were both lower than curves (a) and (b).

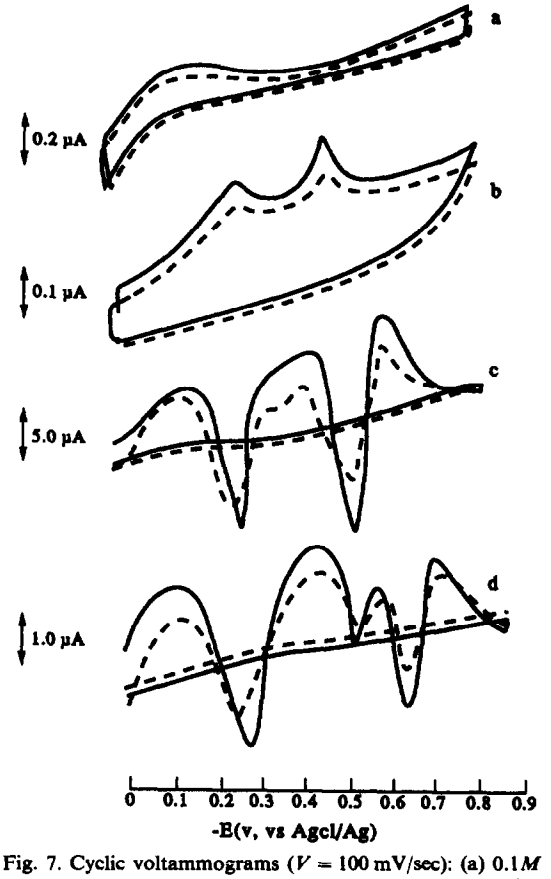

Fig. 7. Cyclic voltammograms (V = 100 mV/sec): (a) 0.1M NH_4Cl (pH = 4.5) + Ce(III), $i \sim E$(V); (b) 6.1 × $10^{-4}M$ DBF–CPA + 0.1M NH_4Cl (pH = 4.5), $i \sim E$(V); (c) 6.1 × $10^{-4}M$ DBF–CPA + 0.1M NH_4Cl (pH = 4.5), e″ ~ E(V); (d) 5.73 × $10^{-5}M$ Ce(III) + c, e″ ~ E(V).

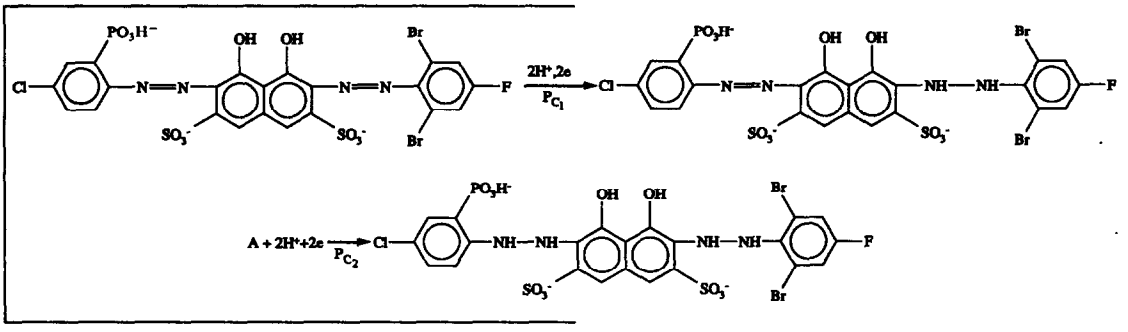
It shows that DBF–CPA and RE–DBF–CPA were both adsorptive on the surface of the mercury drop in the form of negative ions.

The cyclic voltammograms are shown in Fig. 7. From this figure, we can see both DBF–CPA and RE–DBF–CPA complex show completely irreversible reduction processes. According to the Randle-Sevoik equation: $ip = 269n^{3/2}AD^{1/2}V^{1/2}C^{b}$, we know the curve of $ip \sim V^{1/2}$ should be a straight line. When electroactive substances possess adsorptivity on the surface of DME, the ip should be higher than the predictive value. The experimental results of the relationship between potential scanning speed and the peak height are shown in Fig. 8. From this figure we can see that the RE–DBF–CPA complex possesses adsorptivity at DME. The experimental results of the electrocapillary curve, and the influence of surfactants on current all showed an adsorptivity of RE(III) ~ DBF–CPA complex at the DME.

The electron number of the electrode reaction was determined. The results showed a two-electron reaction in the reduction of the complex. Therefore, the electrode process of the complex may be considered as the reduction of the ligand of the complex at DME.[4]

The result of the effect of acidity on peak potential is listed in Table 3. We can see that the potential became negative with an increase of pH, showing that the hydrogen ion acts as a reactant in the reduction process. So the mechanism of the electrode process may be as follows:



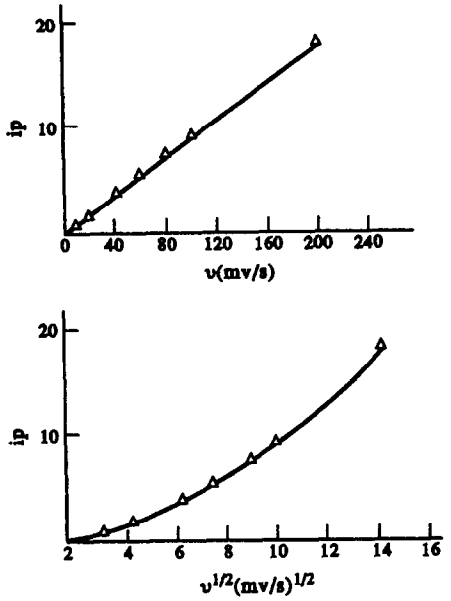


Fig. 8. Relationship between potential scanning speed (V) and the peak height (ip).

PMBP–benzene extraction and determination of RE(III)

The influence of some coexisiting ions in the determination of RE(III) were investigated. At the concentration of 7.16×10^{-7} *M* RE(III), the permissible concentrations of foreign ions for determination of RE(III) were 7.16×10^{-4}*M* Na^+, K^+, NH_4^+, As(III), Ag^+, NO_3^-, SO_4^{2-}, I^-, Br^-, Ac^-: 7.16×10^{-5}*M* Mg^{2+}, Ca^{2+}, Sr^{2+}, B_a^{2+}, Mn^{2+} and 7.16×10^{-6}*M* Sn(IV), Pb(II), Sb(III), Te(IV), Ni(II), Mo(VI) and Cd(II). Co(II), Cr(III, VI), Fe(II, III), V(V), W(VI) and Se(VI) interfered with the determination of RE appreciably. These interferences can be eliminated by PMBP–benzene extraction.

Jiao *et al.*[5] studied the optimum condition of the separation of rare earth cations from non-rare earth elements by extraction with PMBP(1-phenyl-3-methyl-4-benzoyl-pyrozolone-5) under the presence of masking agents NH_4CNS and sulphosalicylic acid. This extraction system was

Alloy-steel (CrNiCuMoRE)	0.084	0.0820	3.7

used in this paper, and the selectivity of the proposed method was improved. The total RE(III) contents in standard reference materials of cast iron and alloy-steel were determined. The results are shown in Table 4.

The results show that method of PMBP–benzene extraction separation combined with PAW of the RE(III)–DBF–CPA complex could be applied to the determination of trace RE(III) successfully.

Simultaneous determination of Ce(III) and Tm(III) in the polarographic system of RE(III)–DBF–CPA by non-linear regression

The PAWs of the Ce(III)– and Tm(III)–DBF–CPA complexes overlap seriously. In order to improve the selectivity of the determination of RE(III), a non-linear regression model was applied to determine Ce(III) and Tm(III) in the RE(III) mixture simultaneously.

Principles. To a mixture containing n components, the concentration of each component (x_i) is regarded as a regression variable, and the peak height of the polarographic wave (h_i) was regarded as a function of concentration. Considering the interaction of the components, a non-linear mathematical model was proposed to fit the x_i and h_i:

$$h_i = b_0 + \sum_i b_i x_i + \sum_{i,j} b_{ij} x_i x_j \quad (i,j = 1, 2, 3 \ldots n) \quad (1)$$

Where b_0, b_i and b_{ij} can be obtained by a calibration procedure. The partial derivatives of equation (1) are as follows:

$$\partial h_i / \partial x_i = b_i + \Sigma b_{ij} x_j \quad (i,j = 1, 2, 3, \ldots, n) \quad (2)$$

Under the experimental conditions, a series of standard solutions of each individual component (x_i) were added to a sample of Ce(III) and Tm(III) mixture. The peak heights (h_i) of single sweep oscillopolarographic waves were then measured and a calibration curve of h_i–x_i was obtained. The slope of the calibration curve was regarded as the partial derivative ($\partial h_i / \partial x_i$). Thus, for a system of n components, n partial derivatives can be obtained and the concentration of each component in a mixture can be calculated by solution of the simultaneous linear equations (2).

Experimental design. A two-factor (Ce and Tm) four level orthogonal regression experiment was designed. Setting the standard level of concentration of RE(Ce and Tm) at 0.24 ppm, the interval of concentration change was 0.08 ppm. The same experimental procedures were performed and the peak heights at −0.78 V (*vs.* SCE) were recorded. The results are listed in Table 5.

The regression equation obtained by the multifactor regression program is:

$$h = -7.348904 + 45.12561 \times C_{Ce} + 68.25055 \times C_{Tm} + 20.31035 \times C_{Ce} \times C_{Tm} \quad (3)$$

The calculated peak heights by regression equation (3) are listed at the bottom of Table 5. The standard deviation between the determined results and calculated ones is less than 0.3. It can be shown that the precision of the regression equation is satisfied.

Determination of $\partial h_i / \partial x_i$. Under the same experimental conditions as the regression procedures, two groups of individual component standard solutions with different concentrations of Ce(III) or Tm(III) were prepared respectively, and then a known volume of simulant and unknown mixture of Ce(III) and Tm(III) was transferred into the above-mentioned standard

A GENERIC FIA SYSTEM FOR DETERMINATION OF ENZYME ACTIVITIES : ASSAY OF CELLULASE

ELO H. HANSEN and ALLAN JENSEN
Chemistry Department A, The Technical University of Denmark, Building 207, DK-2800 Lyngby, Denmark

(*Received* 9 *February* 1993. *Accepted* 13 *March* 1993)

Summary—The concept of a generic FIA system is described that allows multi-points assays of enzyme activities, that require a coupled chemical derivation reaction for detection. The enzymatic degradation procedure and the ensuing chemical indicator reaction are completely separated, which inherently allows each of these processes to be individually optimized with respect to operational parameters such as heating, cooling or possibly stopped flow manipulations. The applicability of the approach is demonstrated for the determination of the activity of cellulase using spectrophotometric detection via a couple chromogenic indicator reaction.

For the enzymatic degradation of a substrate S to a product P, as described by the reaction sequence

$$S + E \leftrightarrow SE^* \xrightarrow{k_2} P + E$$

where E denotes the enzyme, and k_2 is the rate constant for the rate-determining step, the overall reaction rate is given by the expression

$$d[P]/dt = (k_2[E]_o[S]_t/([S]_t + K_m)$$

where K_m is the Michaelis–Menten constant. For $[S]_t \gg K_m$, the expression reduces to

$$d[P]/dt = (k_2[E]_o)$$

that is, the reaction becomes pseudo-zero-order with respect to the substrate, and the reaction rate is directly proportional to the concentration of enzyme, or, more precisely, its activity. Most enzymatic reactions also involve the interaction of appropriate cofactors. Thus, oxidases consume oxygen and generate hydrogen peroxide, while dehydrogenases require the presence of $NAD,^+/NADP^+$ which in turn are converted to NADH/NADPH. Therefore, the activity of an enzyme can be measured either by determining the substrate/cofactor consumed or the product/cofactor generated. For the dehydrogenases, this task is fairly straightforward, because NADH/NADPH can be monitored both optically and electrochemically. If none of the constituents in an enzyme reaction are directly determinable, one of them might be quantified via an accompanying indicator reaction. For instance, hydrogen peroxide, as generated by the oxidases, can be measured photometrically by coupling to a chromogenic reagent, or by chemiluminescence through reaction with luminol and hexacyanoferrate (III).[1,2]

The determination of the activity of an enzyme is in practice most often performed by incubating the substrate and the enzyme for an appropriate period of time, whereupon the concentration of one of the constituents is measured, possibly by an accompanying indicator reaction. However, such an approach yields only a single point measurement. And merely assuming that the enzymatic degradation process, as recorded by the change in detector response over a fixed of period of time, necessarily will follow a linear relationship, might, as is depicted in Fig. 1, easily be most hazardous. In fact, it could very well be that the degradation reaction followed a course as the one outlined in the figure, that is, initially comprising an inherent lag-phase followed by a period during which the signal were to change linearly as a function of time, the process eventually reaching a level where pseudo-zero-order reaction condition with respect to substrate no longer is fulfilled. Hence, the single-point measurement approach would obviously lead to a false answer, and therefore it is inherently much to be preferred to rely on multi-point assays for quantifying the enzyme activity.

Flow injection analysis (FIA) entails exactly such possibilities, namely by applying the stopped-flow approach, where a suitable section

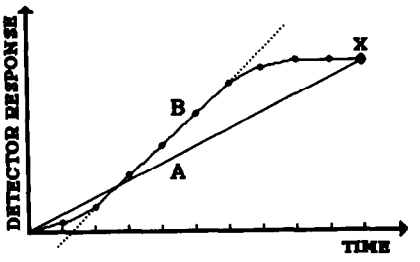

Fig. 1. Single-point (curve A) and multi-point (curve B) determination of the activity of an enzyme as obtained by measurement over identical time spans, that is, from time zero to a time t corresponding to endpoint X. The slope of the linear part of each curve is a measure of the enzyme activity. Curve B illustrates how the detector output might possibly develop if the degradation process were to be monitored intermittently.

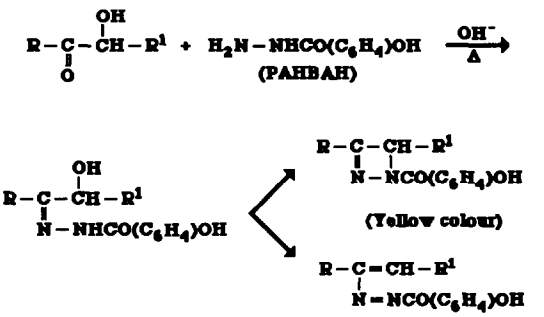

Fig. 3. Representation of the chemical derivation of reducing sugars with PAHBAH, the reaction sequence in strongly alkaline solution at elevated temperature ultimately yields yellow-coloured products.

of the injected and dispersed sample zone is arrested within the observation area of the detector.[3] Provided that the conditions are manipulated in such a manner that they conform with pseudo-zero-order with respect to substrate and pseudo-first-order with respect to the enzyme, the slope of the reaction rate curve will be directly proportional to the concentration of enzyme and hence to the enzyme activity. Reaction rate measurements in which the the rate of formation (or consumption) of a certain species is measured from a larger number of data points not only improve the reproducibility of the assay, but also ensures its reliability. Thus, the stopped-flow method is an efficient and convenient vehicle for measuring substrates and indeed determining enzyme activities. Furthermore, in FIA an added feature can be exploited, that is, the sample might be stopped at different parts of the the concentration gradient corresponding to different ratios of substrate to enzyme, so that it might be feasible to select exactly that part of the dispersed sample zone where the operational parameters are optimal.[1]

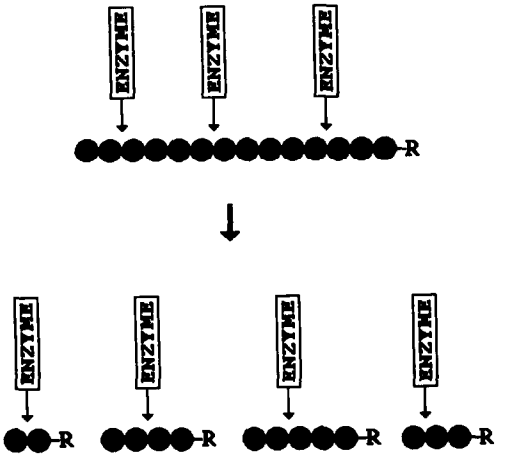

Fig. 2. The degradation of cellulose by cellulase. The enzyme degrades the substrate randomly, yielding sugar entities with reducing terminals (R). The quantification of the sugars is based on chemical derivation with these reducing terminals (*cf.* Fig. 3).

However, an absolute condition in order to employ the FIA stopped-flow method for enzyme activity measurements is that the enzymatic reaction either generate or consume a species which can be detected directly (*e.g.*, NADH/NADPH), or that the coupled indicator reaction is much faster than the enzymatic degradation reaction itself (*e.g.*, the use of luminol for the chemiluminescence detection of hydrogen peroxide) because the ensuing chemical reaction must not, of course, become the rate determining step in the overall reaction sequence. Fortunately, most auxiliary chemical reaction are generally much faster than the enzymatic degradation procedure, yet this does not always hold true. A prime example of this is the assay of the enzyme activity of cellulase which recently has been the subject of intensive studies at this laboratory. Cellulase is an enzyme which selectively degrades cellulose randomly, giving rise to the formation of sugar entities with reducing terminals (Fig. 2). The enzyme is much used for pretreating blue denim materials and as an additive in washing powders, yet it must be administered with utmost care, and for that reason there is a great need for assaying its activity. All available chemical derivation procedures rely on determining the reducing sugars entities, which can be effected by various means, the most promising avenue being the reaction sequence shown in Fig. 3.[4] Here, the reducing sugar terminals are made to react with *p*-hy-

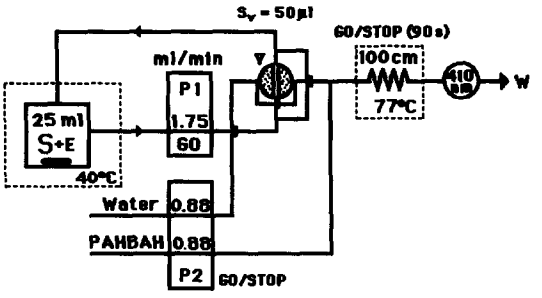

Fig. 4. Integrated system as used for enzyme activity determinations, essentially comprising two entirely separated subsystems communicating via a common valve (V). The subsystems on the left is the enzyme reactor where substrate (S, in large excess) and enzyme (E) react, while the chemical derivation subsystem is depicted to the right. For further details, see text. The operational parameters shown on the figure reflect the ultimately adopted ones. S_v is the sample volume injected.

droxybenzoylhydrazine (*p*-hydroxybenzoic acid hydrazide, PAHBAH), which in strongly alkaline solution at elevated temperatures give rise to the formation of a yellow compound which can be measured spectrophotometrically at 410 nm.[5,6] The problem is that not only is the enzymatic degradation reaction slow, but the coupled indicator reaction is very slow indeed.

Various, more or less ingenious, solutions have been attempted to circumvent this problem, the most promising being based on separating the enzymatic degradation procedure and the accompanying indicator reaction. Thus, Worsfold and coworkers[7] designed a FIA manifold where they injected a sample of cellulase sandwiched between two zones of substrate which during its travel through the FIA manifold partly overlapped and reacted and subsequently was merged with the colour forming reagent so that it became feasible to measure consecutively both the background (the substrate itself contains, as depicted in Fig. 2, some inherent reducing sugar terminals) and the sugar entities formed by the enzymatic degradation process. Still, this solution gives only a single-point assay, and therefore it suffers from the drawbacks mentioned previously.

In another approach, undertaken by Pfeiffer *et al.*,[8] a multicoil FIA-manifold was employed,[3] where individual samples and the matrix solutions concurrently could be stacked and stored for an appropriate length of time. However, although this method potentially might be applicable for multipoint assay, that is, by incubating aliquots of the same analyte solution for different lengths of time, it was not used for this purpose. Rather it was, in fact, merely employed for speeding up the sample throughput via incubation of different samples at equal time intervals, and therefore it yielded only single-point measurements. Although an interesting concept, it does appear as a rather cumbersome and difficult system to administer in practical work.

Therefore, in order to effect the assay of the enzyme activity irrespectively of the coupled chemical reactions and its particular characteristics (absolute reaction rate, and relative reaction rate in respect to that of the enzymatic degradation procedure) it was decided in the present study to take an entirely different approach, that is, not only to try to solve the actual problem of assaying the activity of cellulase, but to attempt to design a generic enzymatic system which inherently would allow handling of any type of sample. Furthermore, it was a prerogative that such a system should be versatile, *i.e.*, it should not only allow the enzymatic degradation procedure to be completely separated from the chemical detection procedure, but it should also permit each of the processes to be optimized individually, and it should inherently allow multipoint determinations to be performed.

These conditions were met by employing the approach described in this communication, and illustrated in Fig. 4 (the parameters depicted show the optimal values, (see Results and Discussion section). In part based on a concept devised for an entirely different purpose,[9] it consists in essence of two individually and totally separated subsystems, one for the enzymatic degradation reaction, consisting of a well-stirred reactor vessel, and one for the ensuing chemical indicator reaction, comprising a FIA manifold, the two subsystems communicating via a common valve. The content of the enzyme reactor is via an external loop constantly circulated through pump 1 and the injection valve at such a rate that the solution in the loop at all times is identical to and representative of the solution in the reactor vessel. At preselected times the injection valve is switched to the inject position and a metered sample volume is by pump 2 introduced into the FIA system where it is mixed with suitable reagent(s) and carried towards the detector. During its path through the manifold the sample/reagent mixture might, if required, be arrested in order to gain additional reaction time, heated, or possibly cooled, or manipulated in any other

appropriate manner before it is guided into the detection device. Sample injection can be repeated as often as required so that a suitable number of data-points on the concentration/time curve can be recorded. The performance of the system is illustrated for the assay of the activity of cellulase.

EXPERIMENTAL

Reagents

All reagents were of analytical reagent grade quality, and distilled, degassed water was used throughout. The medium for the enzyme degradation procedure was a 4 g/100 ml of sodium carboxymethylcellulose (CMC), ultra low viscosity (Fluka BioChemika), dissolved in 0.01*M* sodium phosphate buffer adjusted to pH 7.0. It was prepared by adding the CMC to a boiling solution of the buffer and heating until all CMC was dissolved (*ca* 5 min). After cooling the solution was filtered (glass filter) and degassed. In the initial experiments for optimizing the derivation chemistry, aqueous glucose solutions (*D*(+)-glucose monohydrate, Sigma) in the concentration range 50–500 μM were used as model reducing sugar substrates.

The cellulase enzyme (Carezyme, activity 10070 U/g at pH 7.0 and 40°) was supplied by Novo-Nordisk, Copenhagen, and used as received. For actual enzyme activity assays, an appropriate amount of the enzyme was dissolved in 1.0 ml of the 0.01*M* phosphate buffer (pH 7.0) and added to the thermostatted enzyme reactor vessel. In all experiments, a total volume of 25.0 ml solution was used, that is, the reactor contained initially 24.0 ml CMC/buffer medium.

A 0.10*M* solution of *p*-hydroxybenzoylhydrazine (PAHBAH, Sigma) was obtained by dissolving 0.761 g in 50 ml of 1.0*M* sodium hydroxide. As mentioned in the Results and Discussion section, Bi(III), added as sodium bismuth (III) tartrate at a level of a few m*M*, has proven to be a catalyst in the reaction of PAHBAH with reducing sugar entities. Since this constituent was not available, its presence was effected by first adding to the 50 ml of 1.0*M* sodium hydroxide 0.097 g of bismuth nitrate pentahydrate and 0.057 g of potassium sodium tartrate. After gently heating the solution for 3–5 min, the solution was filtered and the above-mentioned amount of PAHBAH was added. The reagent solution was made freshly every day and degassed prior to use.

Apparatus

In the system used (Fig. 4) the reactor vessel consisted of Perspex container of a volume of *ca* 50 ml[9] equipped with a water-thermostatted jacket. As discussed later, a total volume of 25.0 ml of 0.01*M* phosphate buffer (pH 7.0) containing the CMC-substrate was used in each experiment. The container was fitted with a magnet and placed on a stirring table. After having attained the preset temperature (40° unless otherwise stated) the enzyme was added. Samples were thereafter withdrawn at preselected times. The solution of the well-stirred enzymatic degradation vessel and the FIA manifold were served by two peristaltic pumps (for optimal operation parameters, see Results and Discussion). All connecting lines and the 100 cm reaction coil, which was made as a knotted reactor and emerged into a second water-thermostatted bath, consisted of 0.5 mm i.d. microline tubing. For most of the actual assays was used a commercial Perkin-Elmer FIA system, comprising a Lambda 2 UV/VIS spectrophotometer, fitted with a 18 μl flow-through cell, and a FIAS-400 unit equipped with two individually controlled peristaltic pumps and a 5-port FIA valve. The operation of the pumps and the injection valve, in addition to data retrieval, handling and display, were all facilitated via the provided Perkin-Elmer FIA-DMS software program and an external PC. Results were communicated on an FX-80 printer. Because the injection valve of the Perkin-Elmer system merely is provided with five individually accessible ports on the rotor and stator, and therefore cannot accommodate both a bypass for the circulation solution from the reactor vessel and for the FIA manifold, it was necessary to eliminate one of them and replace it by an appropriate stop/go sequencing. Thus, the bypass for the carrier stream was abandoned, that is, when the injection valve was in the load-position (to fill the metered sample volume) pump 2 was stopped.

RESULTS AND DISCUSSION

As the proposed system (Fig. 4) essentially consists of two individually operated subsystems which communicate via the common injection valve it is possible to optimize their performance virtually independently of each other. In fact, the only constriction is the time required for the derivation chemistry in the FIA manifold, which therefore will set a limit as to

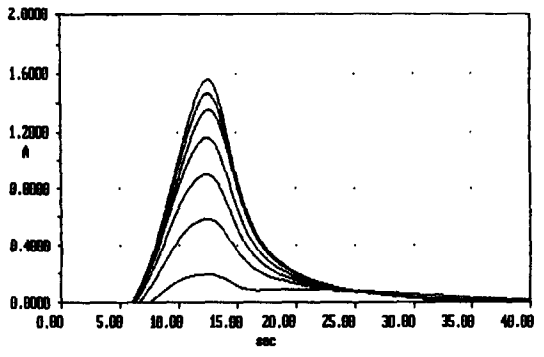

Fig. 5. Signal readouts for monitoring of a cellulase enzyme activity of 1.0 U/ml as obtained with the system shown in Fig. 4. The first sample (lower curve) was taken after 30 sec incubation, while the following ones were taken at 3.5 min intervals.

how often samples can be withdrawn from the enzyme degradation subsystem.

Enzymatic degradation subsystem

In order that the sample solution circulating in the external loop of the enzyme system at all times is truly representative of the composition of the solution in the reactor vessel, the loop should be made as short as physically possible and the circulation rate should be maintained at a fairly high level. In the present case it was found sufficient to set the pumping rate of pump 1 to 1.75 ml/min. Furthermore, since aliquots of sample solution at regular intervals are to be removed it is important that the volume of the reaction vessel is much larger than the injected volume so that even 8–10 withdrawals do not alter the contents of the reaction vessel to any appreciable extent. For that reason the injected volume was set at 50 μl while the volume of the reaction vessel was affixed at 25.0 ml, that is, 500 times larger than the injected volume. As Fig. 4 indicates, the return of the valve from the inject-position to the load-position will for each cycle imply that a volume of carrier equal to the sample solution removed is added to the reactor vessel. As a result, the volume of the reactor vessel will remain constant, yet the solution in it does continuously become slightly diluted with carrier. However, since the volume of the reactor vessel is much larger than the metered injection volume, this dilution can either be neglected or compensated for. It might seem reasonable to make the carrier identical to that of the buffer employed in the reaction vessel (phosphate buffer, pH 7.0). However, since the subsequent chemical indicator reaction in the present assay of cellulase has to proceed at a very high pH value, any appreciable buffer capacity in the carrier would be unwarranted. For that reason water was selected as carrier, and the buffer capacity in the reactor vessel was initially affixed at such a level (0.01*M* buffer concentration) that on one hand the pH would be maintained constant during the enzymatic degradation procedure, and on the other hand the buffer content of the injected sample volume would not affect the pH value of the derivation reaction (pH 13.5, which, incidentally, effectively serves to stop the enzymatic reaction upon introduction of the sample into the chemical derivation subsystem). The temperature for the enzymatic degradation procedure was set to 40° (in order to simulate ordinary washing conditions), that is, all substrate/buffer solutions added to the reactor vessel were thermostatted to this temperature prior to enzyme addition.

Chemical derivation subsystem

The conditions for the chemical derivatization reaction, where reducing sugars react with *p*-hydroxybenzoylhydrazine (PAHBAH) to form a yellow product (Fig. 3), has previously been studied in detail.[5,6] Thus, in batch experiments it was found that optimal conditions were encountered for temperatures in the range 70–100°, that the pH should be 13.7 (0.5*M* sodium hydroxide), the concentration of PAHBAH should be 0.05*M*, and that the reaction is catalyzed by Bi(III) ions.[5] Still, the reaction rate was found to be very low, and more than 10 min were required to reach equilibrium. Pfeiffer *et al.*,[8] who in their FIA experiments used a homologue of PAHBAH, that is, *p*-amino-

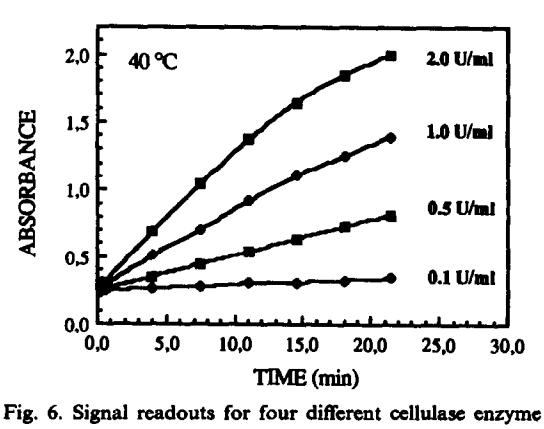

Fig. 6. Signal readouts for four different cellulase enzyme activities in the range 0.1–2.0 U/ml at 40°. The slopes read off the individual curves are plotted in Fig. 7. For the two highest cellulase activities the first 3 and 5 readouts, respectively, were used for evaluation of the slopes.

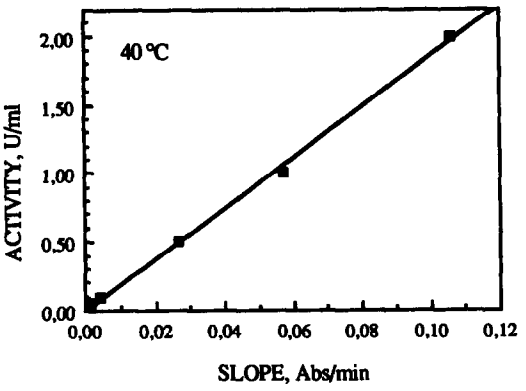

Fig. 7. Calibration curve at 40° for cellulase in the activity range 0.05–2.0 U/ml, as obtained by plotting the calculated slopes (in absorbance change per minute) for five individual experiments against the enzyme activities (in U/ml) monitored.

benzohydrazide (PABH), confirmed that a concentration of 0.05*M* of the chromogenic reagent was adequate. But as indicated previously, they also established that it was imperative to apply stopped-flow in order to obtain sufficient residence time of the sample/reagent mixture. For that reason the present FIA manifold was made to mix the sample and reagent in confluence and to contain a 100 cm knotted coil in which the sample/reagent mixture could be stopped. The coil was submerged in a thermostatted bath while the remaining conduits, which merely are communicating entities with the valve and the detector, were made as short as possible. It was therefore decided to affix the pH and the PAHBAH concentration at the levels quoted and to optimize the other operational parameters, that is, temperature for the derivation reaction, concentration level of Bi(III), pumping rates of carrier (water) and PAHBAH reagent, and the extent of the stopped-flow period. Optimization was performed with the consideration that the blind (background) value should be as low as possible (the substrate, CMC, contains reducing sugar terminals and therefore a certain blind value will be present), the sensitivity should be as high as possible, and the temperature applied should not give rise to the formation of bubbles which would interfere in the subsequent detection process. The optimization studies yielded the values depicted in Fig. 4, that is, the pumping rates for the carrier and PAHBAH should be identical and each set at 0.88 ml/min (and for that reason the the sodium hydroxide concentration in the reagent solution was affixed at 0.1*M* in order to give a final concentration in the combined stream of 0.05*M*); the stop-time should be 90 sec, and the reaction temperature should be 77°. Furthermore, it was found that addition of Bi(III) at a level of 1–2 m*M* to the PAHBAH reagent was optimal.

Assay of cellulase activities

The system was then used for assaying the enzyme activity of cellulase at different levels. The enzyme was in each experiment administered to the reactor vessel at time zero (in the following, all activity levels refer to the concentration in the enzyme reactor). The first sample was withdrawn after 30 sec, and thereafter samples were taken at 3.5 min intervals over a time range of 21.5 min, that is, seven samples were monitored in total. Thus, in Fig. 5 is shown the actual readouts as obtained by the consecutive monitoring of the enzymatic degradation of a 1.0 U/ml cellulase solution, while in Fig. 6 is depicted the readouts for four different enzyme activities, that is, 2.0, 1.0, 0.5 and 0.1 U/ml, where the substrate concentration in all cases amount to 4 g CMC/100 ml. Clearly, the highest enzyme concentration does not result in a straight line relationship over the entire time range. Possibly primarily because pseudo-zero-order reaction conditions with respect to substrate are not fulfilled at extended times, but maybe also because of the relatively high absorbances recorded. Therefore only the first three points in the response/time relationship are used in the evaluation of the slope, which is the quantitative representation of the enzyme

Table 1. Repetitive runs ($n = 5$) for the determination of a cellulase activity of 1.0 U/ml as performed with the system shown in Fig. 4, operated at 40°C. The individual parameters (average slope, standard deviation and relative standard deviation) are calculated for 3–7 measuring points, corresponding to 7.5–21.5 min monitoring, respectively

Measuring points	3	4	5	6	7
Time (*min*)	7.5	11.0	15.5	18.0	21.5
Ave. slope (*Abs/min*) $\times 10^3$	43.6	42.2	41.3	40.5	39.6
Stand. dev. (*Abs/min*) $\times 10^3$	2.5	2.1	1.9	1.6	1.4
Relative stand. dev (%)	5.7	4.9	4.6	3.9	3.6

activity. Nor does the 1.0 U/ml sample result in an absolutely straight line relationship over the entire time range, although the first five points (used for evaluation of the slope) appear to fall on a straight line, while the two low enzyme activities conform perfectly well to the pseudo-zero-order reaction conditions with respect to substrate concentration over the whole time frame. Relative to each other, the slopes are generally in good agreement, which is more clearly seen in Fig. 7, which shows the activity of the individual samples (in U/ml) depicted against the calculated slopes (in Abs/min). Included in this figure is also the slope recorded for an enzyme activity of 0.05 U/ml, which at 40° was close to the lowest value which could be measured. At 50°, where the enzymatic degradation reaction is faster, and resulted in approximately 50% higher signal readouts, the detection limit was found to be 0.02 U/ml.

Because the system for practical work is to be used for measuring an unknown activity as based on calibration with known activities, it is important that it is reasonable stable in operation. This was investigated by repeating the set of experiments mentioned above five consecutive times and comparing the results. Thus, Table 1 shows the average slopes and relative standard deviations determined for the 1.0 U/ml cellulase activity as obtained on the basis of the recorded response/time curve. For comparison, these values are calculated for 3–7 measuring points, corresponding to accumulated times of 7.5–21.5 min, respectively. As it appears, the relative standard deviations are within a range of *ca* 3.6–5.7%, depending on the number of measuring points included. For the entire activity range tested (0.1–2.0 U/ml) the precision was generally found to be of the order of ±3–12%, which for practical routine applications should be adequate.

While the enzyme activities in this exploratory investigation all were monitored at 3.5 min intervals over a time frame of 21.5 min, it is evident that shorter periods in most cases would suffice (Table 1). On one hand, it is possible with the present system—although the derivation reaction for cellulase, in fact, is relatively slow, to sample approximately every 2 min (stop time 90 sec plus *ca* 40 sec required to clear the sample through the detector cell, *cf.* Fig. 5), and on the other hand 3–5 data points should obviously be enough to determine the slope with sufficient reliability. Thus, the total time required for each experimental sequence could in this particular case readily be reduced to less than 10 min, which is actually 3 times less than what is presently spent to accomplish one measurement at Novo-Nordisk with their current single-point method.[10]

CONCLUSIONS

As demonstrated for the assay of cellulase, the present system does offer possibilities as serving as a generic system for determining enzyme activities. Thus, it entails the advantages that the enzymatic degradation reaction and the ensuing indicator reaction are completely separated, that the handling of these two reactions are (virtually) independent of their individual reaction rates, that each reaction can be individually optimized, and, most importantly, it does allow multi-point determinations to be executed thereby securing a much more reliable assay than that achieved by the conventional single-point assay. Besides, it should be perfectly adaptable to the promising sequential injection analysis (SIA) approach as described by Ruzicka.[11]

Acknowledgements—The authors wish to express their appreciation to Perkin-Elmer, Denmark for the loan of the FIAS-400 equipment and the Lambda 2 spectrophotometer employed, and to Julie Damms Foundation for partial financial assistance of this project, especially making it possible for one of us (EHH) to present this material at WCFIA '93. Thanks are also due to Jens Mindegaard of Novo-Nordisk, Copenhagen for useful discussions.

(*Received* 12 *February* 1993. *Revised* 5 *April* 1993. *Accepted* 6 *April* 1993)

Summary—A solid-phase competitive immunoassay is performed in flow injection analysis for the measurement of the hormone 17-β-estradiol. The flow injection analysis system incorporates a column-type reactor packed with solid silica particles onto which we have covalently immobilized the antigen 17-β-estradiol. Anti-estradiol is noncovalently conjugated to the liposome through a streptavidin–biotin linkage. When mixed with a sample containing the antigen, the antibody binding sites on the liposomes are complexed which reduces the binding of liposomes to the solid support in a concentration-dependent manner. Sequential immunoassays are performed on-column following a simple regeneration step.

Researchers have known for a number of years that the onset of some cancers associated with breast and uterine tissue is strongly linked to the binding of estrogens to estrogen receptors.[1] The most prevalent form of estrogen in a woman's body is secreted by the ovaries as 17-β-estradiol. This bioactive form of estrogen binds irreversibly to estrogen receptors, inducing a transformation in the structure of the receptor–hormone complex. This final form of the complex thereby initiates the production of proteins which stimulate these sex-related tissues. It has been postulated that the presence of higher concentrations of bioactive forms of estrogens (estrogen metabolites which bind to estrogen receptors) influences the development of breast cancer. Researchers in this area have established that suppression of the preferred metabolic pathway of estrogen is linked with the onset of cancer in mammary tissue in clinical trials.[2,3] A portion of the metabolic pathway of 17-β-estradiol is outlined in Fig. 1. The first step involves a reversible oxidation to the ketone, estrone, followed by conversion to estrone sulfate, or alternatively, hydroxylation at the 2 or 16 positions to form the products 2-hydroxyestrone or 16-α-hydroxyestrone. The 2-hydroxylation product occurs more frequently and retains little, if any, estrogenic activity.[4] The 16-hydroxylation product is a minor metabolic product but may be of significance since it retains estrogenic activity and is therefore considered bioactive.[5] With the occurrence of breast cancer, the 2-hydroxylation pathway is suppressed with a simultaneous increase in the 16-hydroxylation of 17-β-estradiol.[6] This mechanism is thought to precede and enhance tumor promotion in breast tissue.

The measurement of estrogens is a difficult and expensive task to perform on a routine basis since they are present in very low levels in serum. The concentration of 17-β-estradiol is approximately 200 pM in serum and concentrations of the resulting metabolic products are in the low picomolar range.[7] The reference

*Author for correspondence.

method for measurement of 17-β-estradiol is by mass spectrometry[8] and clinical measurements are currently performed by radioimmunoassay. Given the increasing cost of radioactive waste disposal, immunochemical techniques that provide an alternative to isotope labeling are coming into favor.

In this paper we describe an automated system for liposome-based flow injection immunoassays (FIIA) which can compete in sensitivity with radioimmunoassays. A liposome is a spherical structure composed of a phospholipid bilayer membrane which contains an aqueous cavity. The micro-encapsulation of detectable marker molecules in the aqueous compartments of liposomes provides the opportunity for immediate and significant signal enhancement in the performance of immunoassays. Previously, we reported on the measurement of a therapeutic drug in serum using a liposome-based FIIA method with an immobilized antibody immunoreactor column.[9] The assay involved a direct competition between the analyte in serum and the analyte-coated liposomes for binding to an immobilized antibody. The minimum detectable concentration for theophylline, an anti-asthmatic drug, was determined to be 40 nM using a moderate affinity antibody. The accurate measurement of theophylline in serum was achieved using < 1 μl of sample since the analyte is present in serum at high concentrations (> 50 μM).

For the purpose of measuring estrogens by FIIA, modifications of the existing system are required in order to significantly lower the detection limits and maintain reasonable regeneration times. Preliminary dose–response curves are demonstrated for 17-β-estradiol as a testbed for the measurement of all estrogen metabolites. The system is currently being mathematically modeled and we describe simple ways to tailor the assay in order to enhance detection limits for a specific need.

EXPERIMENTAL

Reagents

Phosphate-buffered saline (PBS) solution (pH 7.4, 10 mM) containing 0.01% sodium azide was used as the carrier buffer in the FIIA system and was used to prepare all working solutions. A solution of 1-*o*-octyl-β-D-glucopyranoside (OG, Sigma, St. Louis, MO) was used in the flow system at a concentration of 21.4 mM in PBS. A stock solution of 17-β-estradiol (Sigma) was prepared in absolute ethanol stored over molecular sieves at a concentration of 3.67 mM (1 mg/ml). β-Estradiol 6-(*o*-carboxymethyl) oxime:bovine serum albumin (estradiol-BSA; Sigma) was reported to contain 30 moles of steroid per mole of protein. A method for preparing and characterizing this steroid–protein conjugate is reported in the literature.[10] Solutions of the steroid–protein conjugate in PBS were used in the immobilization protocol outlined in a following section.

A monoclonal antibody with a reported affinity constant of $9.1 \times 10^9 M^{-1}$ for 17-β-estradiol was obtained from Biodesign International (Kennebunkport, ME). The monoclonal antibody was derivatized to include biotin molecules on the protein surface with sulfosuccinimidyl 6-(biotinamido)hexanoate (NHS-LC-biotin, Pierce, Rockford, IL). The biotinylation protocol was as follows: (1) a 0.1 mg/ml solution of the antibody was prepared in 5 ml of 50 mM carbonate buffer, pH 8.5; (2) 1.7 mg of NHS-LC-biotin were added and the solution was incubated in ice for 2 hr; and (3) the solution was dialyzed in PBS and stored at 4°.

Liposome reagent

The carboxyfluorescein-filled (100 mM) liposomes were prepared by the injection method described in a previous publication.[11] The lipid composition of this preparation was modified with the addition of 0.8 mole% biotin–lipid (*N*-(biotinoyl)-1,2-dihexadecanoyl-sn-glycero-3-phosphoethanolamine, Molecular Probes, Eugene, OR). Streptavidin was added to the formed liposomes in an amount equal to the quantity of biotinylated lipid in the outer membrane. The solution was stirred at room temperature for 2 min to allow binding of the streptavidin to the biotin–lipid. Biotinylated antibodies were added so that the molar ratio of biotinylated antibodies to streptavidin on the liposomes was 4:1. This solution was stirred for an additional 5 min. There was no evidence of aggregation of liposomes due to biotin–streptavidin binding as determined by light scattering. The liposome solution was diluted by a factor of 200 to a final concentration of approximately 2×10^{10} liposomes/ml.

Sample preparation

Working solutions containing 17-β-estradiol in ethanol were prepared by serial dilutions from the original stock, and ranged in concentration from 0.37 mM to 0.37 nM (100 μg/ml to

100 pg/ml) in decade changes. Calibration samples were prepared by adding 1 μl of each working solution to 200 μl of the final liposome dilution. These were allowed to equilibrate for at least 30 min at room temperature prior to injection into the system.

Particle derivatization

Solid particles of high-purity fused silica, 80–100 mesh, were obtained from Vitrifunctions (Greensburg, PA). The particles were refluxed overnight in concentrated nitric acid, and rinsed exhaustively with water to remove any trace metals from the preparation process. The particles were reacted for 1 hr at 90° in a 10% aqueous solution of (3-glycidoxypropyl)trimethoxysilane (GOPS, Petrarch Systems, Inc., Bristol, PA) adjusted to pH 3. The GOPS solution was subsequently removed, and distilled water was added to the flask. The particles were gently shaken, the water was removed, and the particles were heated to 110° overnight. The covalent attachment of estradiol-BSA to the particles is similar to the antibody immobilization described elsewhere.[12] The particles were stored at 4° until packed in the glass columns for use in the FIIA system.

Analysis of protein coupled to silica

The amount of estradiol-BSA bound to the surface of the silica particles was determined using the Micro-BCA Protein Assay™ (Pierce) according to the protocol supplied with the reagents (no. 23235). The amount of immobilized protein was determined to be $1.3 \times 10^{-14} \pm 6.8 \times 10^{-16}$ moles/mm^2 for three samples.

Apparatus

The FIIA system is described in detail in a previous publication.[12] The packed reactor column containing the immobilized estradiol-BSA particles had an internal diameter of 2 mm, and was either 4 or 10 cm in length.

Procedure

The FIIA protocol is outlined in Fig. 2. Step 1 represents estradiol-BSA bound to silica particles in the reactor column. In step 2, 50 μl of a liposome–estradiol calibration solution was injected into this column. The binding of liposomes to the column was inversely related to the concentration of 17-β-estradiol in the calibration solution. Liposomes that did not bind flowed past the column and through the detector. After 4 min, OG solution was injected into the column for 5 min, causing the liposomes to lyse, releasing the entrapped fluorophor in step 3. The height of this peak was plotted as the analytical signal. Buffer was allowed to flow over the column for an additional period of 6 min in step 4 to effect dissociation of the antibody–antigen bond by mass action and regenerate the analytical column for the next injection of sample. The total analysis time for a single sample including regeneration was 16 min.

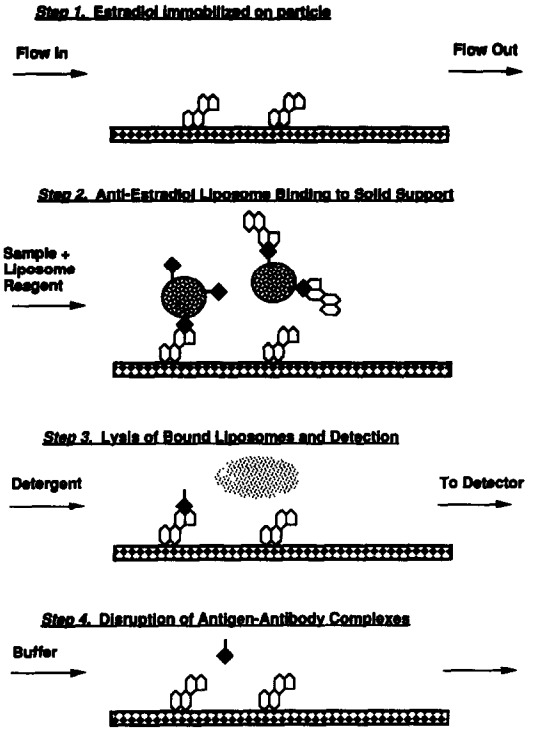

Fig. 2. Schematic of the FIIA protocol. Steps 1–4 are repeated for each sequential assay. See text for details.

RESULTS AND DISCUSSION

In earlier studies, we have shown that there are clear advantages to performing liposome immunoassays in flow injection analysis. The efficient mixing which occurs in a packed column promotes diffusion and reaction of the bulky liposome reagent to the immobilized sites on the solid support. A continuous flow of solution over the surface of the immobilized reagent maintains infinite dilution of the reactants, which encourages gentle dissociation of the antigen–antibody complexes by mass action for column regeneration. The sequential nature of the assay allows for calibration and reuse of

the immobilized reagent. Finally, a change in immunoassay format is easily accomplished by (1) incorporating new columns with different immobilized reagents, (2) introducing new reagents into the flowing stream, or (3) altering the sequence of sample, liposomes or regeneration reagents into the system. Our studies have shown that minor changes in assay format can have a profound effect on the sensitivity and detection limits of the measurement.[12]

We use liposomes with encapsulated fluorophors as powerful amplification agents to improve sensitivity and to provide reliable quantitation of the analyte. Liposomes also exhibit other characteristics which are important in the performance of immunoassays. Liposomes derivatized with a large number of surface antigenic sites have very different binding affinities for immobilized reagents than the corresponding individual antigen molecules.[12] In general, as the number of binding sites on the liposomes decreases, the apparent affinity decreases; as the number increases, the apparent affinity increases to a maximum, then reaches a plateau.[13] In this assay, the solution analyte is allowed to equilibrate with the antibody-coated liposomes prior to injection onto the column. Therefore, the number of uncomplexed antibody sites on the liposome, and the corresponding mean apparent affinity constant of the liposome population, should be indirectly related to the solution concentration of that analyte. Increasing sample analyte concentration will therefore decrease liposome binding to the immobilized analyte in the packed column. In order for the assay to be most effective, the valency of the liposome membrane (*i.e.*, number of available binding sites) should be high enough to encourage rapid binding to the immobilized support and low enough that small changes in valency cause large changes in binding characteristics. We are currently modeling the effect of these assay parameters with these assumptions to optimize sensitivity, speed, and dynamic range.

Initial experiments in the estrogen FIIA system were performed to validate the regeneration protocol. A high affinity antibody was used in this assay; therefore, it was necessary to determine if disruption of this antigen–antibody complex by mass action was completed in an 11-min regeneration time. Reproducibility of the measurement using sequential injections of a single liposome solution was used to determine the effectiveness of regeneration. Figure 3 is a representative FIIAgram for the immunoassay. Peak A is the fluorescence peak associated with the liposomes which exhibit little or no binding to the column. Carboxyfluorescein is encapsulated in the liposomes at a high concentration so that the fluorescence of these intact liposomes is quenched. Peak B is due to the bound fraction of liposomes following disruption and removal from the column. The fluorescence of this peak is unquenched due to dilution and dispersion in FIIA. The peak height of peak A for five sequential injections was 16.8 mV $\pm$ 0.37%. The average peak height for peak B is 97.6 mV $\pm$ 5.3%; however, with each sequential injection a decreased intensity of $<2\%$ was observed, indicating some residual binding.

Figure 4 represents two calibration curves generated with the 17-β-estradiol calibrators. Both curves were generated using a 4-cm column. Curve A was produced first with sequential injections of the calibrators tested in order of least concentrated to most concentrated. Curve B was produced next with sequential injections of the calibrators in reverse order. The signal associated with the same column using the same liposomes decays by approximately 5% in the next calibration cycle. These results, as well as the decreasing trend in the data from repeat injections, can be attributed to (1) incomplete regeneration of the immobilized antigen binding sites which becomes limiting at the fifth or sixth injection, or (2) instability of the diluted antibody-conjugated liposome re-

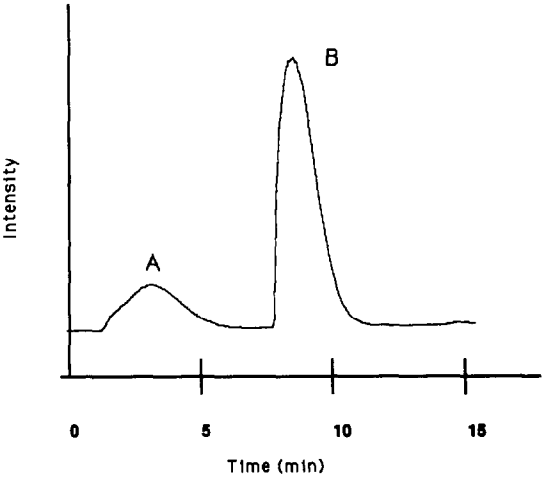

Fig. 3. FIIAgram of a single injection of antibody-coated liposomes into the column. Peak A is from liposomes which do not bind to the column; peak B results from liposomes which bind to the column following lysis with OG.

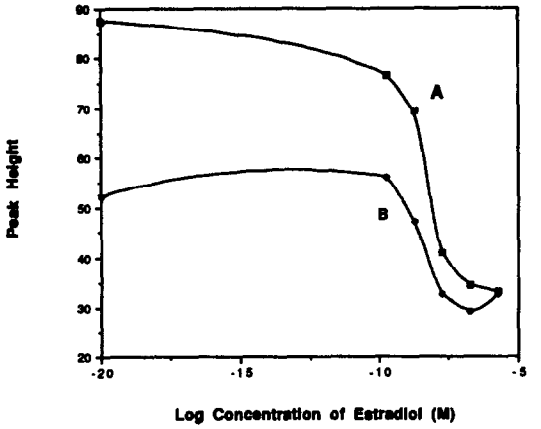

Fig. 4. Repeat calibration curves using the 4-cm packed column. Curve A was generated first; curve B was generated next using the same estradiol/liposome calibrators. The value reported as $10^{-20}M$ estradiol in the log plot corresponds to the data acquired when no estradiol was added to the solution.

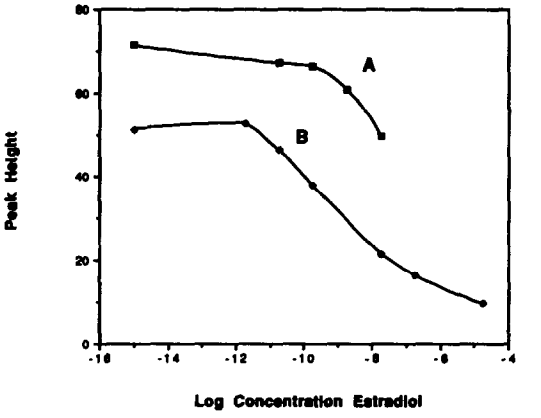

Fig. 5. Calibration curves for the 17-β-estradiol using varied column lengths. Curve A represents data taken using a 10-cm packed column. Curve B represents data acquired with a 4-cm column.

agent. We are currently testing other regeneration protocols based on the use of chaotropic agents, high salts, or large pH changes to induce faster removal of the antibody from the column. Although these reagents typically denature and inactivate the antibody, it is inconsequential for this FIIA format in which the antigen is covalently immobilized and reused.

Previously, the FIIA system was modeled under the conditions used in a typical solid phase immunoassay, *i.e.* where the solution analyte-conjugated liposome competed for binding to an immobilized antibody. It was determined that the assay sensitivity (as defined by the slope of the calibration curve) and the detection limits of the method were most affected by the valency of the liposome reagent, and the number of immobilized binding sites.[14] In FIIA, a simple way to change the number of immobilized binding sites is by varying the size of the packed column. The two calibration curves depicted in Fig. 5 demonstrate the influence of column size on the 17-β-estradiol assay sensitivity. Curve A was generated using a packed column 10 cm in length and curve B was generated using a packed column 4 cm in length. The curves were measured on different days using fresh preparations of biotin–liposome stock solution. The slope of curve B is lower than that of curve A due to the decreased number of binding sites in the shorter column; however, the sensitivity of the measurement in curve B is still high due to the signal enhancement of the liposome reagent. At the same time, the assay detection limits have shifted in curve B such that lower concentrations of the analyte can be detected. Detection of 17-β-estradiol in serum, as well as the lower concentrations of the serum metabolites, should be achievable using the 4-cm column. In order to push the detection limits further, we will continue to use smaller columns until we become limited by the sensitivity of the method.

CONCLUSIONS

FIIA using liposome amplification has the sensitivity and reproducibility to measure many clinical analytes without the generation of hazardous waste products of common radiolabeled assays. As demonstrated, changes in sensitivity and dynamic range of the assay can be easily accomplished in FIIA by incorporating columns of varied length into the system. We are currently studying the effect of liposome valency to induce similar changes in assay sensitivity. In our latest estradiol FIIA system, we have immobilized antigens, rather than antibodies, to allow more aggressive use of chaotropic agents for regeneration. Studies are currently underway to determine the most efficacious method for regenerating and re-equilibrating the column for sequential measurements of estrogens.

ORGANIC-PHASE BIOSENSORS—NEW TOOLS FOR FLOW ANALYSIS: A SHORT REVIEW

JOSEPH WANG

Department of Chemistry and Biochemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 21 *January* 1993. *Accepted* 8 *February* 1993)

Summary—The ability of enzymes to operate in nonaqueous media offers a great potential for monitoring flowing streams. In particular, organic-phase biosensors can be applied for on-line assays of previously inaccessible sample matrices or for measuring analytes with poor water solubility. This paper reviews the fundamental aspects of organic-phase biosensors, together with their performance as flow injection detectors, examples of relevant applications and future opportunities.

Electrochemical biosensors, which combine the inherent specificity of biological recognition processes with the high sensitivity of amperometric flow detectors, are gaining considerable attention for monitoring flowing streams.[1-3] In particular, over the past decade enzyme electrodes have found useful applications for industrial processing and quality control testing. Such probes couple their specificity and sensitivity advantages, with other attractive properties such as speed, portability, simplicity and low cost.

Until recently, on-line applications of biosensors have relied on the use of aqueous media. However, the introduction of sensors for non-aqueous environments opens many unique opportunities for flow analysis, because many industrial processes occur in organic solvents. In particular, organic-phase enzyme detectors can be applied toward many (water-insoluble) analytes and for new challenging environments. In addition, due to solvent-induced changes in the biocatalytic activity, we can expect improved operating stability, reduced side reactions or microbial inactivation, and simplified immobilization schemes. The present article examines the behavior of electrochemical flow detectors based on organic-phase enzymology, and discusses the opportunities offered by these devices for on-line monitoring of flowing streams.

ORGANIC-PHASE ENZYMOLOGY

In order to successfully implement the unique detection opportunities accrued from biocatalysis in organic media, it is essential to understand the behavior of enzymes in non-aqueous environments. Pioneering studies, particularly by Klibanov and coworkers.[5,6] and Dordick's group[7] have elucidated the factors that govern enzymatic reactions in organic media. These include the influence of the solvent and the water content upon the biocatalytic activity and stability. These and other factors are crucial for optimizing the biocatalytic reaction (and accordingly the detector performance).

The organic solvent can greatly alter the enzyme structure and function. Many factors related to the solvent effect upon the enzymatic activity are not fully understood. In general (but not always), the biocatalytic activity is correlated to the polarity of the solvent, as expressed by its log P value.[8] (P is the partition coefficient of the solvent in the two-phase octanol–water system.) Hydrophobic solvents (with log P values higher than 4) are preferred because they do not strip the essential water layer surrounding the enzyme. Other factors, such as the thermostability and solubility of the substrate and product (and their partition to and from the aqueous environment of the enzyme) should also play a role in solvent selection. Hydrophobic solvents also offer increased structural rigidity and hence thermostability. Such behavior is attributed to the minimization of enzyme unfolding, as compared to the conformational flexibility common in aqueous media. For example, porcine pancreatic lipase has been shown to exhibit high catalytic activity and stability at temperatures as high as 100°C.[6] The improved thermostability may greatly extend the lifetime of biosensors and may thus be

advantageous for monitoring many industrial processes occurring at high temperatures.

Related to the media is the amount of water. The exact role of water is not fully understood. While some water is absolutely essential for the enzymatic activity, this water can be localized (as a small hydration layer) around the enzyme molecules. The optimal degree of hydration differs from enzyme-to-enzyme and from solvent-to-solvent. For example, while chymotrypsin needs only 50 molecules of water per enzyme molecule for activity in octane, the activity of tyrosinase in chloroform requires about 3.5×10^7 molecules of water per enzyme molecule.[7] The thermostability, however, decreases upon increasing the water content.

As for the pH, while organic solvents have no distinct measurable pH, the enzyme "remembers" the pH of the last aqueous solution to which it has been exposed. Accordingly, it is often desired to employ enzymes that have been lyophilized from an aqueous solution of optimal pH for the biocatalytic activity.

Solvent-induced changes in the biocatalytic efficiency and substrate specificity may be advantageous for flow analysis. For example, extended linearity may result from the change in the apparent Michaelis–Menten constant in organic media, while higher sensitivity can be offered by changes in the reaction velocity. Current research activity focuses on the use of solvent engineering for tailoring the enzyme function in organic media.[9]

FLOW DETECTORS BASED ON ORGANIC-PHASE BIOSENSORS

Detector design and performance

Conventional detector geometries (such as thin-layer or wall-jet flow cells) can be employed for on-line organic-phase biosensing. In addition, flow detectors based on ultramicroelectrodes are useful for minimizing ohmic drop distortions in resistive organic media (containing little or no supporting electrolyte).[10,11] Enzyme immobilization schemes, originally developed for work in aqueous media, are not always compatible with organic environments. The organic-phase operation may actually simplify the immobilization procedure. One rapid, simple and effective immobilization scheme for on-line organic phase operation is direct adsorption onto the detector surface.[12] Other useful enzyme immobilization schemes include an entrapment within Eastman AQ polymer films,[13] or incorporation with the bulk of composite carbon materials.[14] Whenever needed, the mediator should be insoluble in the organic solvent (so it can be stably coimmobilized by entrapment or adsorption). For example, the coimmobilization (coadsorption) of ferrocyanide and peroxidase onto a graphite foil surface yielded a reagentless sensor for hydrogen peroxide in organic media.[15]

Because of stability problems in non-aqueous environments, most polymeric films or the carbon paste matrix cannot be used for the task of enzyme immobilization. One exception, the Eastman AQ ionomer is stable in different organic solvents. This poly(ester–sulfonic acid) coating is thus very attractive for entrapping enzymes onto flow detectors.[13] Such an immobilization scheme offers additional advantages of permselective and fast response and high enzyme loading. The incorporation of enzymes within the bulk of a rigid graphite–Teflon matrix is another useful immobilization scheme.[14] Such use of Teflon as the binder (instead of mineral oil) eliminates dissolution problems characterizing the operation of conventional carbon paste biosensors in organic solvents. This type of bioelectrode can also be renewed by polishing, and (in the absence of membrane barriers) offers a fast and sensitive response.

The attractive properties of electrochemical flow detectors are not compromised by the organic-phase operation. For example, Fig. 1 illustrates the flow injection response of the carbon-fiber based (A) and Eastman AQ coated thin-layer (B) tyrosinase flow detectors for repetitive injections of different phenolic compounds. Both biosensors exhibit a rapid increase and decrease of the current, with a sample frequency of 60 hr^{-1}. The high injection rate is coupled with high sensitivity and reproducibility (with micromolar detection limits and relative standard deviations of 1–2%).

Even living cells, such as plant tissues, can be exploited for organic-phase biosensing operation.[16] For example, mushroom and horseradish-root bioelectrodes (rich with tyrosinase and peroxidase) have been shown to be useful for monitoring phenolic and peroxide species, respectively, in different organic solvents. Spreading of the tissue layer onto a rough graphite surface results in a close proximity between the biocatalytic and sensing sites, and hence in a fast and sensitive response.

The recent introduction of non-covalently

immobilized enzyme reactors operating in non-aqueous media[17] should also facilitate the development of analytical flow systems for on-line monitoring of organic streams. Cholesterol oxidase and horseradish peroxidase were thus immobilized (by adsorption) onto the solid support, and exhibited a remarkable stability over more than 4 months of operation. The throughput was 60 samples/hr, with a detection limit $1 \times 10^{-6}M$. Such reactors may also be useful for the removal of interferences.

Applications

There are numerous opportunities in employing organic-phase biosensors in flow analysis. Most organic compounds of commercial interest are very sparingly soluble in aqueous media. In addition, many important samples from the food, pharmaceutical, petrochemical and cosmetic industries are highly hydrophobic and require tedious sample pretreatment steps prior to their assays in aqueous solutions. Organic-phase biosensors, in contrast, obviate the need for such sample pretreatment procedures and allow rapid flow analysis of challenging sample matrices. Such direct and fast on-line bioassays should be extremely attractive for quality control testings and industrial process control. Recent advances in organic-phase biosensors can greatly facilitate these industrial applications.

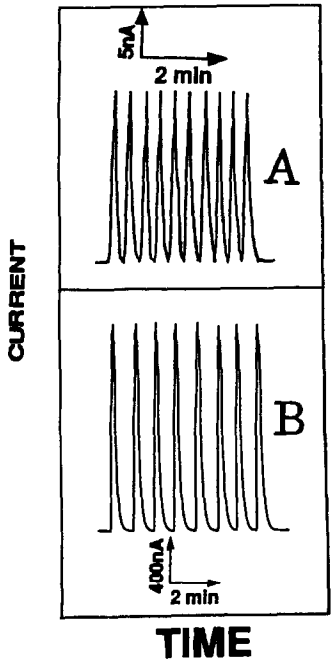

Fig. 1. Repetitive flow injection measurements of $1 \times 10^{-3}M$ *p*-cresol (A) and $6 \times 10^{-4}M$ phenol (B) at the tyrosinase carbon fiber and glassy-carbon detectors, respectively. Carrier: (A) chloroform; (B) acetonitrile.

For example, the food industry, with its many challenging hydrophobic products, represents a prospective market for organic-phase biosensors. Such devices offer direct assays of many previously inaccessible food samples. For example, the phenol content of olive oil is an important factor in the quality and stability of this product. Accordingly, we developed recently a rapid flow injection procedure, based on a tyrosinase electrode, for determining the phenol content of olive oil samples.[18] By adsorbing the tyrosinase onto the surface of the graphite wall-jet flow detector, and by using chloroform as a carrier solution, reliable quantitation of the phenol content of various Spanish and Italian olive oils was achieved.

Butter and margarine represent other challenging food samples. Hall and Turner[19] demonstrated the utility of a cholesterol-oxidase sensor for rapid measurements of cholesterol in butter and margarine samples (after dissolution in a chloroform–hexane media). Organic-phase biosensors should benefit assays of other fats and oils. For example, the organic-phase activity of lipase and peroxidase could be exploited for monitoring triglycerides and peroxide species in these matrices.

Many pharmaceutical products are not readily dissolved in aqueous media. Organic-phase flow-injection operation can thus benefit quality control testings in the pharmaceutical industry. For example, the tyrosinase- and peroxidase organic-phase enzyme electrodes were applied recently for reliable measurements of phenol and peroxide antiseptics in different anti-infective formulations.[20] Excellent agreement with the labeled values was achieved. Similar capabilities were demonstrated for measurements of peroxide bleaching agents in cosmetic products.

On-line assays of petrochemical samples represent another important challenge. A new organic-phase biosensor, based on alcohol dehydrogenase (from *Ta. Brockii*) has been shown to be useful for monitoring secondary alcohols in untreated gasoline samples.[21] Other opportunities come from the fields of clinical diagnostics, environmental surveillance or the defense industry. These possibilities were discussed by Turner and coworkers.[4]

Flow measurements of trace water in non-aqueous media represent a novel application of organic-phase enzyme electrodes.[22] Such appli-

Table 1. Applications of organic-phase enzyme electrodes

cation relies on the strong influence of low levels of water upon the rate of organic-phase biocatalytic reactions. By maintaining a fixed substrate concentration (*e.g.*, phenol in the case of the tyrosinase electrode), it is possible to follow small changes in the water level. Such an indirect biosensing approach offers an attractive alternative to the well-known Karl–Fischer titration method, which requires special equipment and suffers from various interferences.

Measurements of enzyme inhibitors can also be carried out in organic media.[25] For example, the inhibition of tyrosinase by various (poorly-water soluble) inhibitors can be monitored from the decrease of the flow-injection peak for the phenol substrate. Solvent-induced changes in the inhibition action hold great promise for manipulating the response of inhibitor biosensors.

The applications of organic-phase enzyme electrodes are summarized in Table 1.

FUTURE PROSPECTS

While detectors based on organic-phase enzymology are still in an early developmental stage, there is no doubt that they will play an important future role in flow analysis. Many real industrial processes are expected to benefit from the unique features of organic-phase flow bioelectrodes. Besides flow-injection operations, such devices can be easily adapted to other analytical flow systems, including continuous flow analyzers (for real-time monitoring of various processes), liquid chromatography or sequential injection analysis. The characteristic procedure parameters must be adjusted to suit the requirements of each case. *In situ* monitoring of on-line solvent extraction is also envisioned. In addition to enzyme electrodes, we expect to see organic-phase biosensors based on other detectors (*e.g.*, optical devices) or utilizing different biocomponents (*e.g.*, antibodies for immunoassays). New on-line analytical applications are expected based on the isolation or engineering of new enzymes (suitable for organic-phase operation) and the identification of new environments (*e.g.*, supercritical fluids or gas phase). The key for such future developments is improved understanding of the biocatalytic behavior in non-aqueous environments. Such knowledge will greatly facilitate a predictable detector development and optimization. Indeed, flow-injection systems should be extremely useful for fundamental studies on the behavior of enzymes in non-aqueous media (*e.g.*, in a manner analogous to reaction-rate kinetics performed in aqueous solutions). Overall, the development of organic-phase flow detectors should lead to a wide range of important applications using previously inaccessible matrices or analytes.

FLOW INJECTION AMPEROMETRIC DETERMINATION OF HYDROGEN PEROXIDE BY OXIDATION AT AN IRIDIUM OXIDE ELECTRODE

JAMES A. COX* and KRZYSZTOF LEWINSKI
Department of Chemistry, Miami University, Oxford, OH 45056 U.S.A.

(*Received* 8 *February* 1993. *Revised* 1 *March* 1993. *Accepted* 2 *March* 1993)

Summary—Either an iridium electrode that was anodically pretreated or a glassy carbon electrode that was coated with a film that contained iridium oxide promoted the oxidation of hydrogen peroxide. With flow injection methodology, linear calibration curves were obtained over the 2×10^{-5}–3.6×10^{-8} *M* range with 0.1 *M* KOH as the carrier. With solutions of pH ≥ 11, oxidation occurred at applied potentials of near 0.0 V *vs.* SCE, which is much lower than potentials needed at bare Pt or glassy carbon. The low overpotential suggests applications to systems where oxidation of other species limits the use of bare electrodes. Cyclic voltammetric studies show that HO_2^- is the electroactive species and that catalysis rather than mediation promotes the charge transfer. Dissolved oxygen does not interfere with the measurement.

Electrochemical determinations of hydrogen peroxide are generally performed by oxidation at a platinum electrode, an approach which was first described by Harrar.[1] Depending upon the pH of the solution, a quite large positive potential must be applied in order to cause the oxidation to occur; typical applied potentials are in the range 0.6–0.9 V *vs.* SCE.[2] As a result, many substances can interfere with the measurement. Ascorbic acid, uric acid, and acetaminophen are among the interferents which are especially important in a common application of such measurements of hydrogen peroxide, namely the indirect amperometric determination of glucose based upon the amount of hydrogen peroxide released in the enzymatic reaction involving glucose oxidase.[3]

Numerous methods to alleviate problems related to the need for a high overpotential for the oxidation of hydrogen peroxide have been described. One is to use reduction as the electrode reaction. However, at both platinum[4] and mercury[5] electrodes, the reduction is highly irreversible, thereby requiring a large negative overpotential. A lower overpotential for the reduction is obtained by coating the electrode with an electron transfer mediator. Armstrong and Lannon[6] used a cytochrome c peroxidase film on graphite along with gentamycin as a promoter to perform the reduction of hydrogen peroxide, and modification of an electrode with a clay film that was impregnated with $Ru(NH_3)_6^{2+}$ allowed the reduction of H_2O_2 at −0.2 V *vs.* SCE.[7] The use of modified electrodes such as these in practical analytical methodology has been limited because, in general, they lack the necessary long term stability.

Certain inorganic polymers and metalated phthalocyanine polymers show great promise as stable modifiers of electrode surfaces.[8,9] Among these is a film that was electrolytically deposited on glassy carbon from a mixture containing $PdCl_2$ and Na_2IrCl_6.[10] This film, in which oxides of iridium are the promoters of electron transfer,[11] permitted the determination of hydrogen peroxide by linear scan voltammetry on the basis of its reduction in 0.1 *M* KCl at −0.2 V *vs.* SCE.[12] Unfortunately, dissolved oxygen, which is often present in experiments where the determination of hydrogen peroxide is an objective, interferes with the measurement. Fujihara *et al.*[13] illustrated that a dodecyltriethoxysilane film on an Au electrode attenuated the interference of oxygen on the reduction of H_2O_2, but analytical data were not provided.

The present study was initiated to determine whether the procedure that used a glassy carbon electrode that was modified with a film containing iridium oxide could be altered to eliminate the interference of dissolved oxygen on the reduction of H_2O_2. Although this was not accomplished, as detailed below, a method for the determination of H_2O_2 in the presence of dissolved oxygen was developed based upon the

*Corresponding author.

electrocatalytic oxidation of hydrogen peroxide. The process occurs at perhaps the lowest overpotential yet reported for this electrode reaction.

EXPERIMENTAL

All chemicals used were ACS reagent grade from Fisher Scientific Co. except that the $PdCl_2$ was from Johnson Matthey Electronics, Inc.; the Na_2IrCl_6, $LiClO_4$ and LiOH (99.95% purity) from Aldrich Chemical Co.; and the 1 mm dia. iridium wire (99.8% purity), from Johnson Matthey Materials Technology. The hydrogen peroxide solutions were made by fresh dilutions of 30% reagent.

A Bioanalytical Systems, Inc. electrochemical detector (Model MF 1000) for HPLC measurements was modified in two ways. One was to incorporate an iridium electrode. Here, the unit that held the dual glassy carbon electrodes was replaced by an identically-shaped Teflon block through which a threaded hole was machined. A hole was drilled down the central axis of a matching Teflon screw, and an iridium wire was sealed therein with Torrseal epoxy. The second modification was on the portion of the BAS cell that was intended to be used as the working electrode holder. One of the glassy carbon electrodes was used to ground the solution (the second was left at open circuit). Holes to accommodate the entry and exit of the carrier stream were machined in this block. A Pt electrode was placed downstream of the cell to serve as the counter electrode. This modification, along with placing the entire cell assembly in a Faraday cage, minimized noise in the system.

The iridium was polished to provide a disk-shaped electrode surface that was flush with the Teflon block. The polishing was performed with sandpaper grades of 250, 600, and 1200 grit and, finally, with 1, 0.3, and 0.05 μm alumina (Mark V Laboratory, metallographic equipment and supplies) on a polishing cloth with distilled water as the lubricant. Each polishing step (5 min) was followed by a 5 min sonication in distilled water.

An oxide layer on the iridium electrode was formed by applying 100–1000 1 sec pulses between 600 and -1100 mV in a 0.1 *M* LiOH, 1 *M* $LiClO_4$ mixture. The reference electrode was isolated from the plating mixture with a saturated NaCl salt bridge.

Before performing experiments, the iridium oxide electrode was aged for at least 48 hr at open circuit in the plating solution. Except for flow injection experiments, the electrode was pretreated by cyclic voltammetry (50 cycles between 200 and -300 mV at 100 mV/sec) in a solution containing 0.05 *M* H_2O_2 and 1 *M* NaOH. The electrode was stable whether stored in the dry state or in contact with 1 *M* KCl (9 months).

Iridium oxide electrodes were also prepared by electrodeposition of a film on glassy carbon from a solution containing 0.1 m*M* $PdCl_2$ and 0.2 m*M* Na_2IrCl_6 with a 0.2 *M* K_2SO_4, 0.1 *M* KCl mixture as the supporting electrolyte.[10] A glassy carbon electrode of a MF 1000 BAS amperometric detector was polished as described above and plated by applying 100 cycles between 1150 and -350 mV at 50 mV/sec. As previously demonstrated,[11] iridium oxide is the catalytic species in the resulting film. None of the plating solutions were deaerated prior to use.

All electrochemical measurements were made with either a BAS 100 electrochemical analyzer, BAS CV37 voltammograph, or a EG&G PAR 273A galvanostat/potentiostat. All potentials are reported *vs.* an SCE. A Gilson Minipuls 2 peristaltic pump, pulse dampener, Rheodyne type 50 four-way rotary Teflon valve with a 500 μL injection loop, and the above-described electrochemical detectors comprised the flow injection analysis system. The reference was either an SCE (Fisher) or a BAS Ag/AgCl, 3 *M* KCl electrode.

RESULTS AND DISCUSSION

A preliminary set of cyclic voltammetry experiments on hydrogen peroxide solutions with the oxidized iridium metal electrode was performed in order to compare the behavior at this electrode to that at the palladium-containing film.[12] The behavior of the electrodes was found to be the same for the reduction of H_2O_2 in neutral and basic solution. A more interesting observation was that oxidation of H_2O_2 was observed in 1 *M* NaOH at a low overpotential relative to previous reports. A typical set of cyclic voltammograms is shown in Fig. 1. Because a Faradaic process, the oxidation of H_2O_2, is occurring at the initial potential, the shapes of the current–voltage curves are unusual. Nevertheless, it is apparent that there is an increase in anodic current which is related to the hydrogen peroxide concentration. Analytical utility of this electrode process is suggested by the fact that neither the background nor the current due to

the oxidation of hydrogen peroxide is influenced by the presence of dissolved oxygen in the solution.

Based upon the results in Fig. 1, experiments were performed to determine whether linear scan voltammetry is suited to the oxidative determination of H_2O_2. With 1 *M* KCl as the supporting electrolyte and oxide-coated iridium as the working electrode, cyclic voltammograms were obtained at 100 mV/sec with H_2O_2 varied over the concentration range 11–0.5 m*M* (11 points). A linear least squares fit of the peak current (corrected for background) at 100 mV *vs.* concentration yielded a slope of 0.91 mA/*M* with a correlation coefficient of 0.9986. A repeat of the experiment except with 1 *M* NaOH as the electrolyte and 13–0.5 m*M* (18 points) as the concentration range yielded an anodic peak potential of −40 mV, a slope of 3.13 mA/*M*, and a correlation coefficient of 0.9989. These data show that linear scan voltammetry is suited to the determination of hydrogen peroxide at high concentrations. Extension to lower concentrations was precluded by the background signal. The usual approach to improving the signal to background ratio in voltammetry, applying a pulsed potential and time-resolving the Faradaic and background currents, is not well-suited to modified electrodes because a Faradaic process contributes to the background current. Further studies were, therefore, performed by flow injection amperometry (FIA).

Figure 2 shows hydrodynamic voltammograms obtained at the iridium oxide electrode in 0.1 *M* KOH in the presence and absence of H_2O_2. These point-by-point measurements of FIA peak currents as a function of applied potential have two significant characteristics. First, dissolved oxygen does not contribute to the electrode process at potentials more

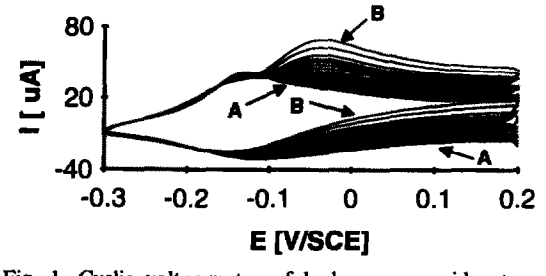

Fig. 1. Cyclic voltammetry of hydrogen peroxide at an iridium oxide electrode. (A) 1 *M* NaOH; (B) 1.3×10^{-2} *M* H_2O_2 in 1 *M* NaOH; scan rate, 100 mV/sec. The family of voltammograms from (A) to (B) are for successively higher H_2O_2 concentrations; the concentrations were raised in 0.5 m*M* increments.

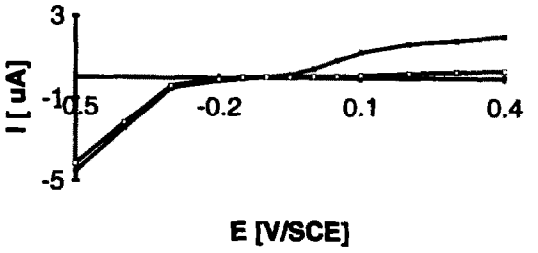

Fig. 2. Hydrodynamic voltammogram of 1×10^{-4} *M* H_2O_2 in 0.1 *M* KOH at the iridium oxide electrode. The carrier was 0.1 *M* KOH. The conditions are in the Experimental section.

positive than −200 mV. Second, a potential window for the FIA determination of H_2O_2 in this medium at the iridium oxide electrode exists from about −50 mV to more positive values. The ability to work at low overpotential suggests practical applicability of oxidative determinations of hydrogen peroxide; as mentioned previously, the use of less positive applied potentials than are necessary at conventional electrodes minimizes the number of candidates for interference.

The electrochemistry of hydrogen peroxide at the iridium oxide electrode is highly dependent upon pH. This is illustrated by examination of the influence of pH on the height and position of the anodic peaks in the cyclic voltammetry of H_2O_2. Figure 3 contains a plot of peak current *vs.* pH. Clearly, the sensitivity is enhanced by working in a medium with pH greater than 11. The shape of the plot resembles a potentiometric titration curve, which suggests that the electroactive species is HO_2^-. That the inflection point of this curve is near the pK_a of H_2O_2 (11.6) supports this conjecture. The dependence of the anodic peak potential on pH (Fig. 4) demonstrates that to obtain the low overpotential which makes this electrode process promising the pH must also be greater than 11. The fact that the peak potential is quite constant over the pH range 3.5–11 is interesting in that the cyclic

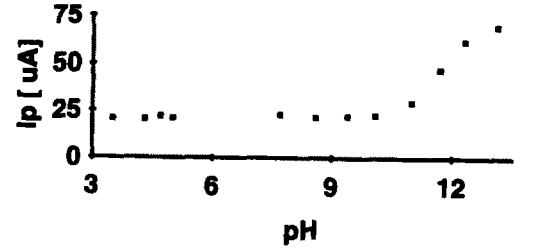

Fig. 3. Dependence of the anodic peak current on pH in the cyclic voltammetry of 1.1×10^{-2} *M* H_2O_2 in 1 *M* KCl at the iridium oxide electrode. The pH was adjusted by addition of KOH or HCl. Scan rate, 100 mV/sec.

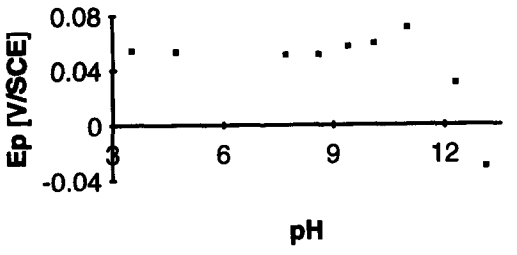

Fig. 4. Dependence of the anodic peak potential on pH in the cyclic voltammetry of H_2O_2 at an iridium oxide electrode. The conditions are those in Fig. 3.

voltammetric peaks for the iridium oxide couple(s) in the film vary in potential over this range. This contrasting behavior demonstrates that the film is not mediating the hydrogen peroxide oxidation. Instead, it is acting as a catalyst. Based on these results, the FIA experiments were performed with either 0.1 or 1.0 *M* KOH as the carrier.

Figure 5 contains sets of FIA curves for various concentrations of hydrogen peroxide. At the 99% confidence limit (peak current is three-times the noise), the detection limit is 30 n*M* H_2O_2. The characteristics of calibration curves prepared under the conditions in Fig. 5, except with the tabulated values of KOH concentration and applied potential, are summarized in Table 1. Two points are important. First, increasing the KOH concentration will increase the sensitivity at a given potential. Second, with a given concentration of KOH as the carrier, a more positive applied potential will increase the sensitivity. Since an application of this electrode process to a practical FIA procedure will require addition of base in a mixing coil, the lower KOH concentration is recommended even though the sensitivity is decreased. Whether more positive applied potentials are employed than those in Table 1 (see Fig. 2) will depend on the anticipated interferences in the proposed application. A recent discussion of possible interferents in experiments when measurements of hydrogen peroxide are used to indirectly determine glucose in biological samples is available.[3]

The use of an oxide film on an iridium electrode rather than a film deposited on glassy carbon from a $PdCl_2$, $IrCl_6^{2-}$ mixture may be inconvenient in some cases. The former requires modification of a commercially-available detector and the use of iridium wire which is quite expensive. Experiments were performed to determine if the iridium oxide film deposited on glassy carbon provided a suitable electrode for this FIA method. Results comparable to those obtained at the oxidized iridium metal electrode (Table 1) were obtained over the concentration range 20–0.47 μM; a linear least squares calibration curve (10 points) yielded a slope of 2.5 mA/*M* and r^2 of 0.9999 when 0.1 *M* KOH was the carrier. The applied potential was 0.00 V. The detection limit (99% confidence limit) was 37 n*M*.

In summary, iridium oxide films provide an attractive surface for the oxidative determination of hydrogen peroxide. Although the results presented herein are based upon flow injection amperometry, this surface may find application to other electrochemical methods for this analyte. Moreover, our preliminary work on other species that are generally oxidized or reduced at high overpotential indicates that iridium oxide may find a wide range of application. Nitrogen oxides are one general class of compounds for which promising preliminary data have been obtained. The combination of the freedom from interference by

Table 1. Linear least squares calibration curves for the flow injection amperometry of H_2O_2 at an iridium oxide electrode

Carrier	Conc.H_2O_2 (M)	E (mv)	slope, (mA/M)	r	n
1 M KOH	1.0×10^{-4}–1.0×10^{-6}	0.0	4.3	0.9996	9
1 M KOH	1.0×10^{-6}–1.0×10^{-7}	50	8.1	0.9889	7
0.1 M KOH	2.0×10^{-5}–3.6×10^{-8}	0.0	2.9	0.9993	14

dissolved oxygen with the low overpotential that is required suggests suitability of this system to bioanalytical applications; however, for such studies a means to adjust the sample to pH $\geq$ 11 must be included in the FIA system. A second drawback is that modified electrodes generally promote electron transfer of many compounds at the same potential, so selectivity must be achieved by a prior separation step or through a chemical reaction.

FLOW INJECTION ON-LINE ACID DIGESTION AND PRE-REDUCTION OF ARSENIC FOR HYDRIDE GENERATION ATOMIC ABSORPTION SPECTROMETRY—A FEASIBILITY STUDY

BERNHARD WELZ, YOUZHAO HE* and MICHAEL SPERLING
Department of Applied Research, Bodenseewerk Perkin-Elmer GmbH, D-88647 Überlingen, Germany

(*Received* 7 *April* 1993. *Revised* 14 *June* 1993. *Accepted* 14 *June* 1993)

Summary—A flow injection (FI) manifold is described which makes possible on-line microwave-assisted acid digestion, followed by pre-reduction of As(V) to As(III) and its determination by hydride generation atomic absorption spectrometry. The merging zone technique is used in order to reduce acid consumption for digestion. The efficiency of acid digestion is increased by pressure which is built up in-line by a flow restrictor. Flows for sample pretreatment and hydride generation can be optimized independently. *L*-cysteine was found superior to potassium iodide as the pre-reductant because much lower reagent and acid concentrations are required, much harsher conditions can be tolerated for acid digestion, and the integrated absorbance signals for arsenic in blood and standards are essentially identical, making possible the use of the standard calibration procedure.

The sampling frequency is 7–10/hr, depending on the conditions chosen, and the limit of detection, *i.e.* the concentration giving a signal equal to three times the standard deviation of the signal of the blank solution, is 0.25 μg/l for a 500 μl sample volume. The recovery of 10 μg/l As(V) added to a blood sample was 94 ± 2 and $98 \pm 2\%$ ($n = 3$) in absorbance and integrated absorbance, respectively.

Sample preparation is often the bottle-neck of an analytical procedure because it is a manual process which makes it slow, work-intensive and a frequent source of errors. It is therefore not surprising that with the increasing use of flow techniques, particularly flow injection (FI), various attempts have been made to incorporate sample preparation on-line with the detection in an automatic procedure. The state of the art at the end of the 1980s in on-line techniques coupled to FI is summarized in a review article by Puchades *et al.*[1]

The most frequently investigated approach for on-line sample preparation is that of microwave assisted acid digestion,[2] which was coupled with amperometric[3] and colorimetric[4] detection, ICP atomic emission,[5] flame,[6–10] cold vapour[11–13] and hydride generation atomic absorption spectrometry (HG AAS).[12–14] The application of on-line acid digestion to the latter two techniques was complicated by the fact that the oxidative reagents had to be compatible with sodium tetrahydroborate which was required for the reduction of the analyte to the element and the hydride, respectively.[13] In addition, some analyte elements, such as antimony and arsenic were oxidized to their highest oxidation state during the digestion which resulted in about an order of magnitude lower sensitivity in their determination by FI–HG AAS.[13–16] A pre-reduction step must therefore follow after the oxidative digestion.

Sperling *et al.*[17] successfully used a mixture of sodium sulfite, hydrochloric acid, sodium thiosulfate and potassium iodide for the on-line reduction of pentavalent to trivalent arsenic for solid sorbent extraction of total arsenic from natural water samples. The reduction was complete within 5 sec, however, the reagents used were not compatible with sodium tetrahydroborate reduction, and hence with HG AAS. The reagent used most frequently for the reduction of pentavalent arsenic in HG AAS is potassium iodide, alone or mixed with ascorbic acid. Marshall and van Staden[18] and Tyson *et al.*[19] have described on-line procedures for the reduction of As(V) using FI techniques. A significant disadvantage of that reducing agent is, however, the extremely high hydrochloric acid concentration required if the reduction had to be completed within a short period of time. Brindle *et al.*[20] proposed *L*-cysteine as an

*On leave from Department of Applied Chemistry, University of Science and Technology of China, Hefei, Anhui, China.

alternative to potassium iodide with the big advantage that this reagent was usable at low acid concentrations. In addition, *L*-cysteine was found to be much more stable than potassium iodide and provided a higher freedom from interferences.[16]

Although on-line microwave assisted acid digestion and on-line reduction of As(V) for HG AAS have been investigated by several authors, no attempt was made to combine acid digestion and pre-reduction on-line in a flow system. The aim of the present work was to investigate the feasibility of combining an acid digestion with a pre-reduction on-line in an FI system for the determination of arsenic in biological materials, and blood was chosen as a model matrix. We have limited ourselves to inorganic arsenic in this study, not considering organic arsenic compounds, which will be the topic of another publication. Our first goal was to investigate the possibility of a fully automatic procedure for measuring elevated arsenic levels due to occupational exposure, *i.e.* to determine inorganic arsenic. For that purpose it was only necessary to break down the organic matrix to an extent that it did no longer interfere with HG. Insufficient digestion of organic matter resulted in excessive foaming in the gas–liquid separator and penetration of foam into the atomizer, causing severe contamination and loss of sensitivity. The antifoam reagent, which was added routinely to the sodium tetrahydroborate solution, did not control excessive foaming.

Carrier 1 (2x)	0.76	40	0.65
Pre-reductant	0.51	40	0.35
GLS waste	2.54	40	6.4

EXPERIMENTAL

Instrumentation

A Perkin-Elmer Model 2100 atomic absorption spectrometer with continuum source background correction and an arsenic electrodeless discharge lamp, operated at a power of 8 W, was used throughout. The wavelength was set to 193.7 nm with a spectral slitwidth of 0.7 nm (low). A Perkin-Elmer FIAS-200 flow injection system with an AS-90 autosampler was used and the temperature of the quartz tube atomizer was set to 900°. The atomic absorption spectrometer, the flow injection system and the autosampler were controlled by an Epson PC AX 2e personal computer which also calculated the absorbance and integrated absorbance values. The time-resolved absorbance signals were displayed on an EIZO 14-inch color data display and printed, together with the analytical results, on an Epson EX-800 printer.

The extended and modified FI system, the manifold and its operation are shown in Fig. 1. An Ismatec (Wertheim-Monfeld, Germany) peristaltic pump (P3) was added for circulating the water of the pre-reduction heating bath. A Maxidigest MX350 oven (2.45 GHz, 300 W) with TX 31 programmer (Prolabo, Paris, France) was used for microwave digestion. The standard value of the FIAS-200 was replaced by a prototype 8-channel valve (Tecator, Sollentuna, Sweden).

All pump tubes were Tygon. Their inner diameters, the pump rotation and the resulting flow rates are summarized in Table 1. Material, dimension and configuration of the various conduits and coils are given in Table 2.

Method

The sequence of operation for on-line acid digestion and pre-reduction is summarized in Table 3. In sequence 1, 500 μl of sample and 1000μl of digestion reagent were filled into L1 and L2, respectively. Sequence 2 actually consisted of five steps because the maximum time which could be programmed in the FIAS-200 software was 99 sec. The same pump rotation speed of 40/min was used throughout that sequence although it would have been possible to save some time by using faster flow rates at certain stages of that sequence. In the first stage, after the valve had turned, sample and digestion reagents were mixed. The merging zone technique was applied in order to save reagent because water could be used as the carrier in this case. In the next stage sample and digestion reagent were conducted through the microwave oven. Details of the arrangement within the microwave cavity are shown in Fig. 2.

Because of the flow restrictor which was installed downstream, a pressure of about 6 Bar was built up which increased the efficiency of the digestion. The pressure also reduced the

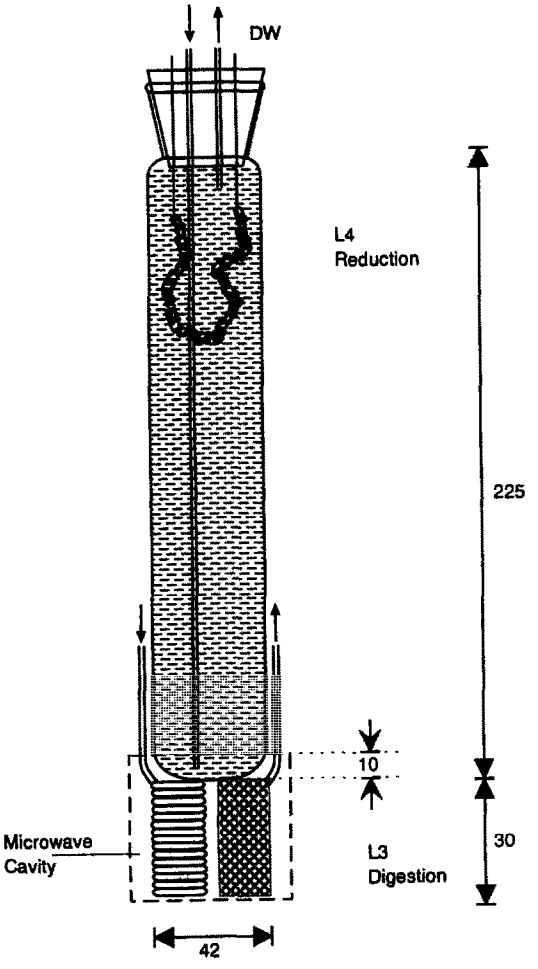

Fig. 2. Arrangement of digestion coil (L3), reduction coil (L4) and water bath for pre-reduction in the microwave digestor. All dimensions in mm.

formation of gas bubbles during the microwave-assisted acid digestion, and a steady flow of liquid with only a few bubbles was obtained after cooling in C 1. In the next stage the reducing agent was added and the sample conducted through a water bath which was kept boiling by immersing its bottom into the microwave cavity, as is shown in Fig. 2. After passing through another cooling bath and the flow restrictor the sample bolus reached the store coil. The total time had to be programmed in such a way that the sample was contained quantitatively in the store coil at the end of sequence 2.

In sequence 3 pump 1 was turned on and a second carrier stream added in order to transport the sample quickly through the hydride generation stage and into the gas–liquid separator (GLS). This arrangement made it possible to optimize flow rates independently for the different processes of sample preparation and analyte element determination.

Reagents

All reagents were of analytical reagent grade or higher purity except for sodium tetrahydroborate, for which no purity was given. Doubly deionized water (18 MΩ/cm) was used throughout. Arsenic(V) stock solution, 1000 mg/l As in 0.5 mol/l HNO_3 was prepared from Titrisol concentrate (Merck, Darmstadt, Germany). Standard solutions were obtained by serial dilution with 0.1 mol/l HCl. For blood analysis standards were prepared to contain 0.2% (m/v) Triton X-100.

Sodium tetrahydroborate solution, 2% (m/v) was prepared by dissolving sodium tetrahydroborate powder (Riedel-de Haen, Seelze, Germany) in water containing 0.05% (m/v) sodium hydroxide (Merck) and 1.0% (m/v) antifoam reagent (Greiffenberg, Krefeld, Germany).

Cysteine reductant, 0.6% (m/v), was prepared by dissolving *L*-cysteine (for biochemistry, Merck) in 0.5 mol/l HCl.

Potassium iodide pre-reductant was prepared by dissolving 10 g of potassium iodide, KI, (Merck) and 10 g of ascorbic acid (Merck) in 100 ml of 2.5 mol/l HCl. Lower concentrations of these reagents were used in some experiments.

A mixture of 1 mol/l HNO_3 and 0.04 mol/l $HClO_4$ was used as the digestion reagent together with the potassium iodide pre-reductant and a mixture of 2 mol/l HNO_3 and 0.2 mol/l $HClO_4$ was used with *L*-cysteine.

Table 3. Sequence of operation for on-line acid digestion and pre-reduction for HG AAS

Step	Function	Time (*sec*)	Rotation speed (*/min*) Pump 1	Pump 2	Valve position	Read
1	Fill loops L1 and L2	50	120	40	Fill	
2*	Merge zones, digestion, pre-reduction, fill store tube	440*	—	40	Inject	
3	Hydride generation	30	120	40	Inject	ON

*Step 2 consists of five identical steps of 90, 90, 90, 90 and 80 sec duration. See text for details.

Pool blood samples were obtained from Baden–Württemberg blood supply center (Ulm, Germany). Blood samples were diluted 1:10 with 0.1 mol/l HCl and 0.2% (m/v) Triton X-100.

Method development

The optimization of the procedure was carried out step by step, *i.e.* one parameter at a time, starting from the end, *i.e.* the hydride generation. On going upstream step-by-step it was anticipated that optimization of an earlier stage would not impair the previously optimized parameters. The standard calibration technique was used throughout and the analyte addition technique (method of additions) was only applied occasionally in order to exclude the presence of matrix effects.

RESULTS AND DISCUSSION

Optimization of hydride generation

One of the advantages of the FI manifold used in this work was that the different stages of the analytical procedure, *i.e.* acid digestion, pre-reduction and hydride generation, could in essence be optimized independently. Whereas low flow rates were obviously advantageous for sample pretreatment because of the associated longer residence times in the microwave oven, *etc.* and the less pronounced dispersion, they would inevitably result in very broad absorbance peaks in the hydride generation stage. For that reason an additional carrier was introduced downstream of the flow restrictor in order to push the sample bolus quickly from the store coil through the rest of the FI system and to the detector.

The effect of this additional carrier flow rate on the arsenic signal is shown in Fig. 3. Without an additional carrier flow an extremely low and broad signal was obtained which had not reached its maximum even after 50 sec. Although integrated absorbance decreased about 30% when the additional carrier flow rate was increased from 2.9 ml/min (20 r.p.m.) to 17.5 ml/min (120 r.p.m.) the significantly improved peak shape and much shorter signal duration (measurement time) were considered a great advantage.

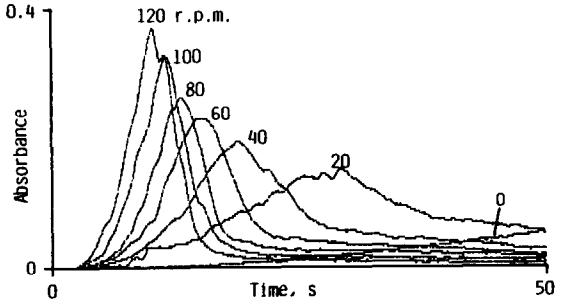

Fig. 3. Effect of additional carrier flow rate (expressed in rotations per min of PI) on the absorbance signal of 10 μg/l As; 120 r.p.m. corresponds to a flow rate of 17.5 ml/min.

The acidity of the additional carrier solution had no influence at all on the absorbance signal of arsenic. Variation of the acid concentration between 0 and 2 mol/l HCl resulted in identical results, and water was used as the carrier for all further investigations.

The flow rate of the auxiliary argon had only a minor effect on the arsenic signal. The integrated absorbance decreased by about 15% when the argon flow rate was increased from 20 to 90 ml/min. The peak height absorbance showed a slight maximum around 60 ml/min which was used for our future work.

In contrast to conventional FI–HG AAS where the carrier and sodium tetrahydroborate flow rates are similar,[21] we have chosen a high flow rate for the additional carrier for the reasons discussed above. In order not to increase the total flow rate too much we used a low flow rate of 2.2 ml/min for the tetrahydroborate which necessitated a higher concentration than usual. The arsenic signal increased under these conditions significantly up to a reductant concentration of 1% (m/v) tetrahydroborate, with a slight additional increase up to 2% (m/v) tetrahydroborate. The 2% concentration was chosen for our future work because a much better performance was obtained in the analysis of blood samples, *etc.* which contained the oxidative reagents from acid digestion.

Optimization of acid digestion and pre-reduction

The optimization of the microwave-assisted acid digestion and of the prereduction could obviously not be separated entirely because the reagents and conditions had to be compatible. All investigations were carried out with *L*-cysteine and potassium iodide–ascorbic acid, respectively, as the pre-reduction reagents. Matrix-free standard solutions as well as 1:10 diluted blood samples, which were spiked with arsenic(V), were used for all investigations.

The following criteria were applied to select the best conditions

(i) Completeness of acid digestion. The main indicator for that criterion was foam formation

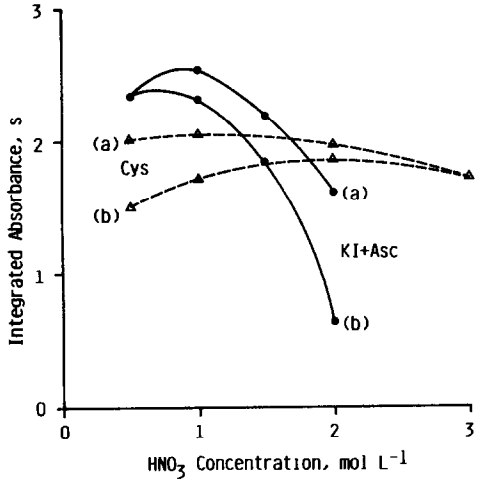

Fig. 4. Effect of nitric acid concentration on the integrated absorbance signal of 10 μg/l As(V). Microwave power: 150 W for potassium iodide–ascorbic acid (KI + Asc) and 210 W for *L*-cysteine (Cys). (a) As in 0.1 mol/l HCl; (b) As added to 1:10 diluted blood.

in the GLS as no organic arsenic compounds were investigated in this study. In addition a system that could tolerate higher microwave power and/or higher acid concentrations would obviously provide more complete acid digestion, and was hence considered superior.

(ii) Sensitivity. That parameter obviously also included completeness of reduction of As(V) to As(III). All data in this optimization study were based on integrated absorbance. Peak height absorbance gave similar results for matrix-free standards but significant deviations for the blood samples and was therefore not considered in this work.

(iii) Applicability of standard calibration technique. One of the goals of this work was to avoid the time-consuming standard addition technique, which means that standards and samples must exhibit an almost identical behaviour.

(iv) Ruggedness. As analytical conditions may change for different samples, ruggedness against such changes was considered important.

(v) Reagent consumption. A reduced requirement for reagents, particularly when they were toxic and/or corrosive, was a major criterion for cost reasons, because of the waste problem and to better protect operators and instruments.

This last point was the main reason why we have chosen the merging zone technique to mix sample and oxidative reagents for acid digestion. This approach made it possible to use water as the carrier instead of a corrosive and toxic acid mixture.

Various combinations and concentrations of nitric and perchloric acid were investigated as the oxidizing medium for acid digestion. The influence of the nitric acid concentration on the integrated absorbance signal of arsenic is shown in Fig. 4. A lot of foam was formed in the GLS due to incomplete digestion of blood if the nitric acid concentration was only 0.5 mol/l. Higher nitric acid concentrations, however, were not quite compatible with the potassium iodide–ascorbic acid pre-reductant. Firstly, there was a significant difference in the response for arsenic in the standards and blood samples and this difference increased with increasing acid concentrations. Secondly, the sensitivity for arsenic depended strongly on the nitric acid concentration. The behaviour of *L*-cysteine pre-reductant was much better in both respects. Although there was a difference between standards and blood samples for 1 mol/l HNO_3, this difference essentially disappeared for nitric acid concentrations of 2–3 mol/l. There was also very little influence of the nitric acid concentration on the sensitivity for arsenic in the presence of *L*-cysteine, which was clearly the better reductant from that point of view.

Perchloric acid had very little additional effect up to 0.1 mol/l in the case of potassium iodide–ascorbic acid pre-reductant and up to 0.4 mol/l in the case of *L*-cysteine. A mixture of 2 mol/l HNO_3 and 0.2 mol/l $HClO_4$ was therefore chosen for most of our further investigations.

The efficiency of the microwave-assisted acid digestion was further increased by a pressure of about 6 Bar which was caused by the backpressure of the flow restrictor. The influence of the microwave power on the integrated absorbance signal for arsenic is shown in Fig. 5. At power

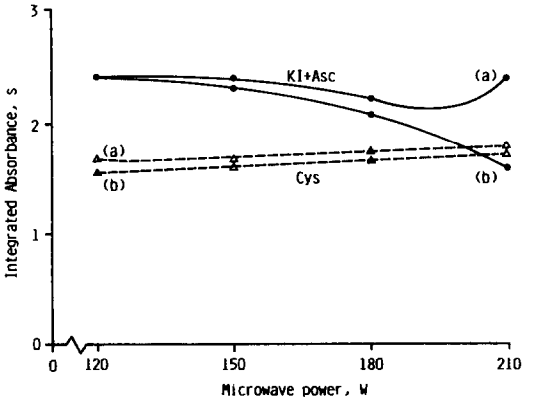

Fig. 5. Influence of microwave power on the integrated absorbance signal of 10 μg/l As(V). (a) In 0.1 mol/l HCl; (b) added to 1:10 diluted blood.

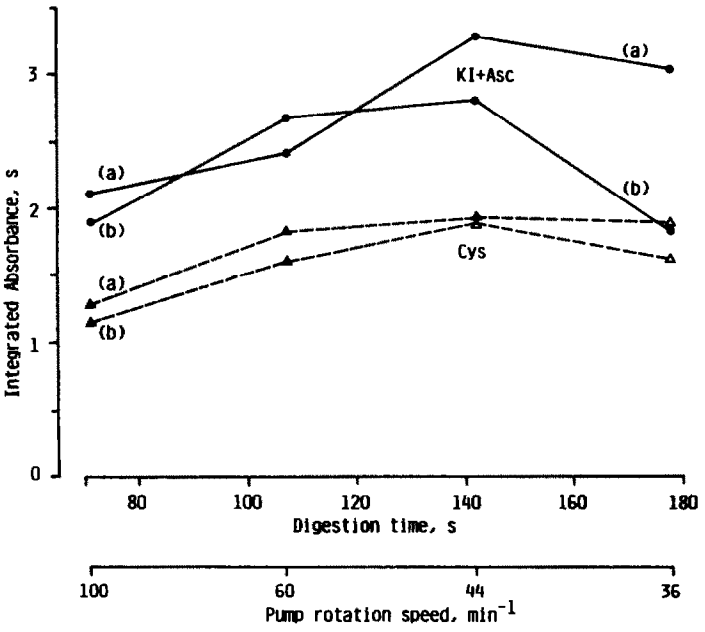

Fig. 6. Influence of residence time of the sample bolus in the MWD on the integrated absorbance signal of 10 μg/l As(V). (a) In 0.1 mol/l HCl; (b) added to 1:10 diluted blood.

settings below 120 W the foam formation in the GLS became excessive. Although the sensitivity for arsenic was better in the presence of potassium iodide–ascorbic acid, the discrepancy between standards and blood samples became quite significant for higher power settings which was considered a disadvantage. No such effects were observed with the *L*-cysteine pre-reductant so that 210 W could be used without problems.

The residence time in the microwave digestor (MWD), which was controlled by the pump rotation speed, had a similar effect on the arsenic signal as the microwave power as is shown in Fig. 6. Significant foam formation in the GLS, *i.e.* incomplete digestion, was observed for a pump rotation speed of 100/min which corresponded to a residence time of about 70 sec. If potassium iodide–ascorbic acid was used as the pre-reductant, increasing digestion times resulted in an increasing discrepancy between the signals for standards and blood samples. This effect would not permit to use long digestion times, which might be essential to attack acid-resistant organic compounds of arsenic, and to use the standard calibration procedure. The behaviour of *L*-cysteine was one more time much more favorable in that respect. A pump rotation speed of 40–50/min, corresponding to a residence time of 140–150 sec gave best performance. The reason for the discrepancy in the behaviour of potassium iodide and *L*-cysteine was that different acid and reagent concentrations were found optimum, which resulted in different reactions and reaction products upon digestion and hence a different overall performance.

The cooling coil which was installed between the MWD and the confluence with the pre-reductant primarily served the purpose to condense gaseous products and hence reduce the bubbles in the conduits. It was found that a coil length of 1 m, in the configuration of a knotted reactor, was sufficient to reduce bubble formation significantly and produce an even flow of liquid at the confluence point. The pressure of 6 Bar in the system undoubtedly contributed

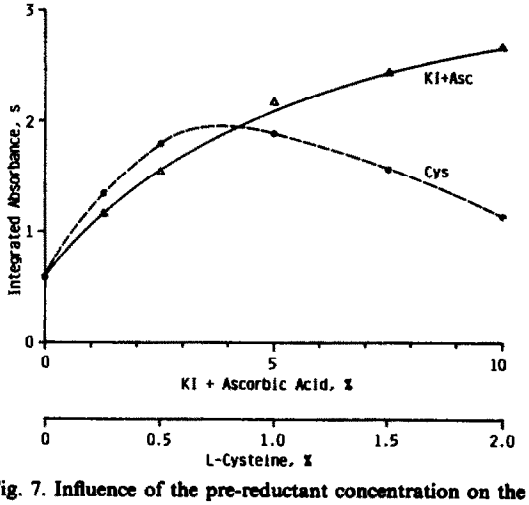

Fig. 7. Influence of the pre-reductant concentration on the integrated absorbance signal of 10 μg/l As(V).

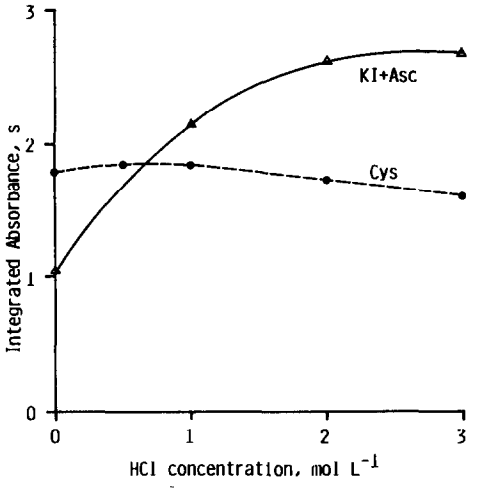

Fig. 8. Influence of HCl concentration of the pre-reductant solution on the integrated absorbance signal of 10 μg/l As(V); 7.5% potassium iodide and 7.5% ascorbic acid (KI + Asc) and 0.6%*L*-cysteine (Cys).

very significantly to the fact that bubble formation did not cause any problems under the conditions chosen in this work. The influence of the pre-reductant concentration on the integrated absorbance signal for arsenic is shown in Fig. 7. In essence the results were consistent with those obtained earlier with conventional FI–HG AAS.[16] The efficiency of the potassium iodide–ascorbic acid pre-reductant increased with increasing concentration, but a concentration of at least 5% (m/v) was required to obtain a sufficient reduction power. *L*-cysteine, in contrast, had its optimum performance at concentrations of 0.5–1% (m/v). The decrease of the arsenic signal in the presence of higher cysteine concentrations was *not* due to a decreasing reduction efficiency but to an interference in the hydride generation stage.[16] In addition to a higher reagent concentration, the potassium iodide–ascorbic acid pre-reductant also required a higher acid concentration of 2–3 mol/l HCl in order to perform properly, as is shown in Fig. 8. *L*-cysteine, in contrast, developed its full reduction potential even in aqueous solution. This significantly lower consumption of reagents and acids, together with the improved ruggedness and the much more similar behaviour of standards and blood samples finally made the *L*-cysteine the pre-reductant of choice for our future work.

The best sensitivity for arsenic was obtained when the water in the reduction vessel was boiling, *i.e.* had a temperature of 97° in our case. In order to prevent excessive boiling the water was pumped continuously through a cooling bath. The pump speed required to keep the water at gentle boiling obviously depended on the applied microwave power. This correlation is summarized in Table 4.

The influence of the residence time of the sample bolus in the boiling water bath on the arsenic signal is shown in Fig. 9 for *L*-cysteine. Three different lengths of reduction coil, 3, 6 and 9 m, all in the form of knotted reactors, were used with a variety of pump rotation speeds. However, there appeared to be no influence of the length of the tubing, and the residence time was the only significant parameter. For a residence time longer than 150 sec the integrated absorbance did not increase any more which could be interpreted that the reduction of As(V) to As(III) was complete under these conditions. This was in quite good agreement with Chen *et al.*[22] who found quantitative reduction of As(V) in a boiling water bath and in the presence of 1% *L*-cysteine within 5 min. A direct comparison with the signal of As(III) could not be made because any trivalent arsenic was readily oxidized to its pentavalent form under the conditions used in our work.

Performance of the system

The total time required for one on-line acid digestion, pre-reduction and HG AAS determination cycle, using the program in Table 3, was

Table 4. Rotation speed of pump 3 at which the water in the pre-reduction vessel reaches the boiling point (97°) for different microwave power settings.

Microwave power (W)	120	150	180	210	240
P3 rotation speed (/*min*)	30	58	75	85	99

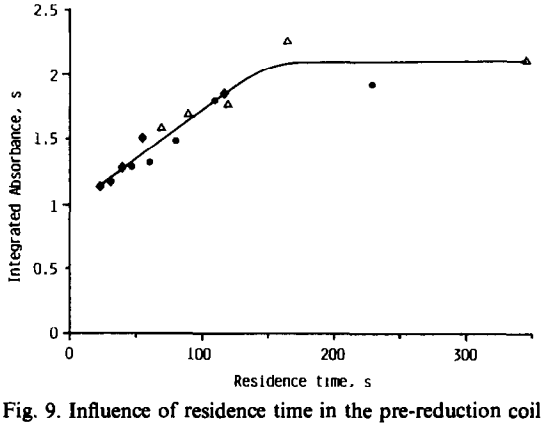

Fig. 9. Influence of residence time in the pre-reduction coil (L4) on the integrated absorbance signal for 10 μg/l As(V). Pre-reductant *L*-cysteine. Coil length: ◆ 3 m; ● 6 m; △ 9 m.

520 sec which resulted in a sampling frequency of 7/hr. That program was, however, not at all optimized with respect to sample throughput. The low pump rotation speed of 40/min, which resulted in best performance for digestion and pre-reduction with *L*-cysteine, was used throughout the entire stage 2. Faster pump rates could obviously be used for to transport the sample bolus to the MWD, from the MWD to the pre-reduction bath and from pre-reduction to the store coil. About 100 sec could be saved that way without causing any disadvantages. Another 50–60 sec might be saved at the expense of a 15% lower sensitivity if the reduction coil length was reduced to 6 m or the pump rate increased to 60/min with the 9 m coil. The fact that As(V) would not be reduced quantitatively under these conditions would have no effect on accuracy and precision because FI is capable of performing quantitative determinations reproducibly under thermodynamically non-equilibrium conditions.[23] If all these measures were taken, the total time for one cycle would be reduced to about 6 min and the sampling frequency increased to 10/hr.

When the standard conditions described in the Experimental section were used, the precision of the entire procedure, expressed as the relative standard deviation of 11 determinations of a 10 μg/l As(V) standard was 2.6% for the potassium iodide pre-reductant and 2.8% for *L*-cysteine. The detection limit, *i.e.* the concentration giving a signal equal to three times the standard deviation of the signal of a blank solution ($n = 11$) was 0.2 and 0.25 μg/l As(V) for potassium iodide and *L*-cysteine pre-reductants, respectively.

The linear regression equations for the calibration range 0–30 μg/l were $y = 0.10525 + 0.13055\ x$ with a correlation coefficient of $R = 0.998$ in integrated absorbance and $y = 0.0221 + 0.02021\ x$ with a correlation coefficient of $R = 0.994$ in peak absorbance; 10 μg/l As(V) added to a diluted blood sample gave an average integrated absorbance reading of 1.386 ± 0.024 sec ($n = 3$) and a peak absorbance of 0.210 ± 0.004, corresponding to a recovery of 98 ± 2 and $94 \pm 2\%$ in integrated and peak absorbance, respectively.

CONCLUSIONS

It could be shown in this work that an on-line combination of a microwave-assisted acid digestion with a pre-reduction of As(V) to As(III) and its determination with HG AAS is feasible. It could also be shown that *L*-cysteine is better suited as pre-reduction reagent than potassium iodide because its performance was much less affected by the oxidizing acids and their reaction products. The efficiency of the microwave-assisted acid digestion of a dilute blood solution, which was increased by a pressure of 6 Bar produced in-line by a flow-restrictor, could not really be tested in this work. The only indications for an incomplete digestion were foam formation in the GLS when blood samples were analyzed and a low recovery of arsenic added to the blood. The key question regarding the practical use of the proposed procedure will be to which extent the various organo-arsenic compounds are mineralized under these conditions. This question will finally also determine the acid concentrations and the time required for the on-line digestion and, hence, the total analysis time.

The degree to which the various organo-arsenic compound are attacked by the procedure will eventually determine the application fields. Possible applications are for instance differentiation between inorganic (toxic) and organic arsenic (from sea food) in blood and urine, or total arsenic in water and waste water. These investigations are the topic of future work.

ON-LINE MICROWAVE SAMPLE PRETREATMENT FOR THE DETERMINATION OF MERCURY IN BLOOD BY FLOW INJECTION COLD VAPOR ATOMIC ABSORPTION SPECTROMETRY

TIEZHENG GUO and JÖRN BAASNER

Atomic Absorption Product Department, Bodenseewerk Perkin-Elmer GmbH Postfach 101164 W-7770 Überlingen, Germany

(*Received* 1 *June* 1993)

Summary—A method for on-line treatment of whole blood in a microwave oven and determination of mercury by flow injection cold vapor atomic absorption spectrometry was developed. After dilution of the whole blood and addition of oxidant, all further treatment and measurement were performed automatically, on-line. Recoveries of five mercury compounds were complete. Good agreement between measured and recommended values of mercury in whole blood reference materials was obtained. Measured mercury values also agreed with results from other accepted methods. Sample throughput was about 45 measurements/hr. Detection limit (3s) in diluted sample was 0.1 μg/l corresponding to 1 μg/l Hg in whole blood. The RSD value at 0.5 μg/l Hg in the diluted sample was 6–7% (11 measurements and 0.5 ml sample volume). Mercury concentrations between 1 and 150 μg/l in whole blood can be measured using this method. For three replicate measurements, 0.5 ml of whole blood is required.

It is generally agreed that oxidative conversion of all forms of mercury in environmental, biological samples to Hg(II) is necessary prior to reduction to elemental Hg,[1–5] especially when tin(II)chloride is used as the reductant. $NaBH_4$ can more readily attack those organic mercury compounds that are not reduced to Hg(II) by tin(II) chloride.[6] Some workers report that $NaBH_4$ does not reduce all organic mercury compounds to elemental mercury equally.[5] During this work and previous work,[7] decomposition of organic mercury compounds in urine and blood samples was not complete when using $NaBH_4$ as the reductant in a normal flow injection setup. This was thought to be due to the low $NaBH_4$ concentration and short reaction time used.

A bewildering variety of combinations of strong acids (HCl, H_2SO_4, HNO_3), oxidants (H_2O_2, $KMnO_4$, $K_2Cr_2O_7$, $K_2S_2O_8$), UV irradiation, and elevated temperatures have been used and recommended[1–5,8–13] for off-line digestion. However, on-line sample pretreatment is of particular interest in mercury determination because of the well known problems associated with the mobility of this element, the risk of contamination, and volatilization and adsorption losses, *etc.* during extensive off-line sample pretreatment procedures. These problems become more important at the low concentrations now being measured.

Now a very wide variety of different on-line manipulations of samples and standards have been carried out by FI techniques providing a safe, contamination-free enclosed sample handling system, this has been reviewed by Tyson.[14]

Recently, a system for on-line treatment of liquid samples in a microwave oven and determination of mercury by cold-vapor atomic absorption spectrometry was designed and evaluated.[15] Mercury in water and urine was measured.

In the present work, the possibility for on-line treatment of whole blood in a microwave oven and determination of mercury by cold vapor FI atomic absorption spectrometry was investigated. In this work, a digestion coil in a knitted (or so called three-dimension reactor) form was used which reduced the dispersion drastically. A cooling coil after the microwave oven allowed the system to work properly at higher microwave energy and improved the reproducibility. Further decomposition of organic mercury compounds in blood was achieved by adding a channel for on-line addition of $KMnO_4$.

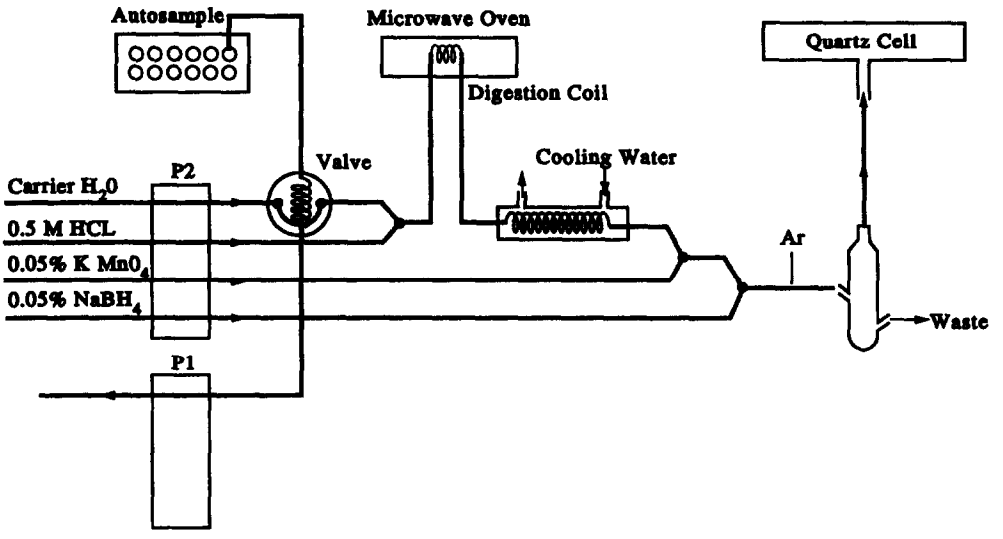

Fig. 1. Instrumental setup.

EXPERIMENTAL

Blood samples were first diluted by a factor of 10 with Triton-X 100 in water, and oxidation reagent added. Subsequent treatment and measurement proceeded automatically in a FI system. Figure 1 shows the FI-manifold and the working principle.

Diluted whole blood sample containing oxidation reagent is injected into the carrier stream (in this work H_2O is used as the carrier) via the FI valve. The carrier stream is then mixed with acid in the manifold, and the mixture flows through the digestion coil located inside the microwave oven and is heated by microwave energy. On leaving the microwave oven the heated mixture cools in the cooling coil and is then mixed with $KMnO_4$ solution. $NaBH_4$ is added to the mixture and Hg(II) is reduced to Hg(0). Argon is added as the carrier gas. In the gas–liquid separator, the gas phase (argon, generated hydrogen and mercury vapor) separates and flows into the quartz cell while the liquid phase drains to waste. In the quartz cell, the generated mercury vapor is measured by the spectrometer.

Instrumentation

Perkin-Elmer Models 2100, 3100 and 4100 atomic absorption spectrometers, FIAS-200, and FIAS-400 flow-injection systems and an AS-90 autosampler were used during this study. A Maxidigest MX 350 microwave station, with TX 31 Maxidigest programmer, (Prolabo, Paris) was used. Later the microwave oven was controlled by the spectrometer's software. The whole system was controlled by an Epson personal computer.

A Perkin-Elmer Hg EDL (system II) operated at 190 mA was used as the primary light source, the measurement wavelength was set to 253.6 nm, with a slit width of 0.7 nm (low). An integration time of 30 sec and peak height measurement mode were used. The temperature of the quartz cuvette was 200°.

The digestion coil was made in a knitted form. A 10 m long PFA tube (i.d. 0.9 mm, wall thickness 0.4 mm) was knitted around a PTFE backbone tube (i.d. 2 mm, wall thickness 1 mm) in the form depicted in Fig. 2. This method was adopted from Ref. 17. The backbone tube with the knitted coil was then folded again into a shape which fitted within the microwave oven cavity.

The cooling coil was placed between the digestion coil and the manifold. The cooling coil was made from PFA tube (i.d. 0.9 mm, 1.5 m long) in a knitted form in order to reduce dispersion. This coil was sealed inside a plastic tube 16 cm long, i.d. 2 cm through which cooling water was circulated using one of the FIAS pumps. The pump tubes used and the associated flow rates are listed in Table 1. The argon flow rate was 90 ml/min.

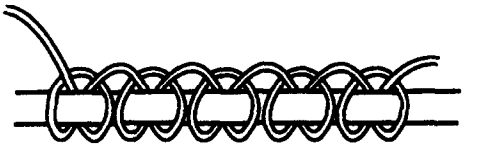

Fig. 2. Construction of the knitted digestion coil.

Table 1. Pump tubes and corresponding flow rates

Solution	Pump tube (Color code)	Flow rate (*ml/min*)
Sample	blue–yellow	9–10
Carrier	blue–yellow	9–10
$NaBH_4$	red–red	5–6
Acid	red–red	5–6
$KMnO_4$	red–red	5–6
Cooling	black–white	32
Waste	violet–violet (two tubes)	36

Sample coil 500 µl. The connecting tubes used between confluence points in the manifold were of 110 mm, 300 mm length with 1 mm i.d. The tube between the gas–liquid separator and the quartz cell was of 1 m long with an i.d. of 1 mm. Details refer to Fig. 1.

The gas–liquid separator used was a commercially available one made of glass from Perkin-Elmer.

A Perkin-Elmer MHS-20 system with amalgamation accessory was also used to measure Hg in blood to check the method developed in this work.

Autoclave-3 and PTFE vessels were used for off-line digestion of blood samples.

Reagents

All reagents were of analytical-reagent grade, unless stated otherwise. Double deionized water (18 MΩ/cm) was used throughout.

Dow Corning DB 110A: Silicon anti foaming agent for FIAS/MHS analyses.

Reductant solution: 0.05% m/v $NaBH_4$ in 0.05% m/v NaOH, 1.5 ml of anti foam reagent (Dow Corning) was added to 1 l of $NaBH_4$ solution.

Carrier solution: Deionized water,

Acid solution: 0.5 *M* HCl (50 ml 32% m/v HCl in 1 l deionized water),

Oxidation reagent: 2 g KBr and 0.56 g $KBrO_3$ dissolved in 25 ml deionized water. 0.5 g $KMnO_4$ dissolved in 1 l water (0.05% $KMnO_4$).

Triton solution: 0.6 g Triton X-100 (Triton® X-100: Merck for scintillation grade) dissolved in 50 ml deionized water.

Calibration standards. Stock standard solution of mercury, 1000 mg/l, was prepared from Merck "Titrisol®". Stock solution: 10 mg/l was prepared by dilution of the stock standard solution.

Working standard solutions of 100 µl and 500 µg/l were prepared by further dilution of the stock solution.

All the diluted mercury standard solutions should contain 1% v/v stabilizer solution (0.5% m/v $K_2Cr_2O_7$ in 1 + 1 HNO_3) in order to ensure stability during storage.

The addition calibration method was used. Calibration solutions at different mercury levels were prepared by spiking blood samples with appropriate amounts of mercury standard solution.

In this work, bovine whole blood, human whole blood and concentrated blood for transfusion were used.

Samples and reference materials

Five mercury compounds were used for the recovery test. The compounds, the suppliers, and information about stock solution preparation[5] are listed in Table 2.

Sterile bovine whole blood, and human whole blood from hospitals were used for the recovery studies. Some freshly collected samples of human whole blood were measured by this method and also by two other methods.

Lyophilized human reference whole blood samples were used to check the method, refer to Table 4. Seronorm® Trace Elements Whole

Table 2. Mercury compounds used and their solvents

Compound	Formula	Supplier	Solvent*
Methylmercury chloride (MMC)	CH_3HgCl	Merck	10 *ml* CH_3OH
Mercury (II) acetate (MA)	$Hg(CH_3OO)_2$	Merck	20 *ml* CH_3OH 5 *ml* CH_3COOH
Mercurescein sodium (MS)	$C_{20}H_8Br_2HgNa_2O_6$	Riedel-de Haen	10 *ml* CH_3OH
Phenylmercury chloride (PMC)	C_6H_5HgCl	Riedel-de Haen	0.2 *ml* Diisobutyl Ketone†
Mercury (II) nitrate (MN)	$Hg(NO_3)_2$	Merck	Standard solution

*Dilute to 1 l with deionized water.
†Dilute to 1 l with CH_3OH.

Added compound	Recoveries %* In bovine blood	In human blood
CH_3HgCl (MMC)	96 ± 6 ($n = 23$)	99 ± 3 ($n = 6$)
$Hg(CH_3COO)_2$ (MA)	99 ± 5 ($n = 15$)	99 ± 3 ($n = 6$)
$C_{20}H_8Br_2HgNa_2O_6$ (MS)	100 ± 8 ($n = 23$)	97 ± 8 ($n = 6$)
C_6H_5HgCl (PMC)	96 ± 6 ($n = 26$)	99 ± 5 ($n = 6$)

*The recovery is the mean of n measurements $\pm$ SD.

Blood from Nycomed Diagnostics, Oslo. Kontrollblut für Metalle 2, Lot No. 620401 from Behring Institute, Marburg.

PROCEDURE

Method development

For the method development the following parameters were considered and each was tested at the given values.

The main criteria applied to select a parameter was that it could provide good results for the recovery test and for the sample measurement. The concentration of each reagent used was as low as possible.

The amount of Triton added to the sample solution in 10 ml: 0.5 ml, 1.0 ml, 1.5 ml and 2.0 ml.

Table 4. Results of mercury measurements on control blood samples

Samples	Measured value $\mu g/l$	Rec. value $\mu g/l$
Seronorm® No. 905	9.5 ± 0.8 ($n = 6$)	10 (0.49)*
Seronorm® No. 906	15 ± 0.8 ($n = 7$)	15 (1.1)*
Seronorm® No. 010010	4.1 ± 0.6 ($n = 5$)	4.2 (3.3–5.1)†

§Confidence range.
‖The text is cited from manufacturer's instructions. The measured value is the mean of n measurments $\pm$ SD.

The amount of antifoam reagent added to the reductant solution in 1 l volume: 0.2 ml, 0.4 ml, 0.8 ml, 1.0 ml, 1.5 ml and 2.0 ml. Acids used for on-line addition: HNO_3: 1 mol/l, 2 mol/l, 3 mol/l, 4 mol/l and 5 mol/l.

HCl: 0.5 mol/l, 1 mol/l, 2 mol/l, 3 mol/l and 5 mol/l. Mixed acids: 0.3 mol/l HCl + 0.4 mol/l HNO_3, 0.5 mol/l HCl + 0.6 mol/l HNO_3, 1 mol/l HCl + 1.2 mol/l HNO_3, 2 mol/l HCl + 2.4 mol/l HNO_3, 0.1 mol/l $HClO_4$ + 0.4 mol/l HNO_3.

Oxidation reagents. Bromate–bromide added to 10 ml diluted sample solutions: 0.2 ml, 0.4 ml, 0.6 ml, 0.8 ml, 1.0 ml, 1.2 ml and 1.5 ml.

$K_2S_2O_8$(4%) added to 10 ml sample: 1.0 ml, 2.0 ml and 4.0 ml. $KMnO_4$ for on-line addition: 0.025%, 0.05% and 0.1% m/v. $NaBH_4$ concentration: 0.02%, 0.05%, 0.07%, 0.08% and 0.10% m/v. Carrier solution: H_2O, 0.1 mol/l HCl, 1 mol/l HCl, 0.5 mol/l HCl + 0.6 mol/l HNO_3, 0.25 mol/l HCl + 0.3 mol/l HNO_3. Sample coils: 0.5 ml, 1.0 ml. Digestion coil: 10 m long made from PFA 0.9 mm i.d. in three-dimensional form or wounded on a PTFE shaft (280 × 38 × 15 mm). Cooling coil: 1.5 m, 2.0 m long PFA tube, i.d. 0.9 mm. Microwave heating power: 20%, 30%, 40% and 50%.

Sample preparation

To a 10 ml plastic test tube (Manufacture SARSTEDT) add 0.5 ml Triton solution, 0.5 ml blood sample and dilute the mixture to 5 ml with water. Then add 0.6 ml oxidation reagent solution mix well and load onto the autosampler.

Calibration solutions

Into the test tube, add 0.5 ml Triton and 0.5 ml blood. To avoid coagulation, it is recommended to dilute the blood to about 4 ml, before adding the acidic Hg working standard solution, and then dilute the content in the test tube to 5 ml and add the oxidation reagent solution.

Less bromate–bromide solution should be added to the calibration blank to avoid high background and depression of sample signals (see Discussion). In this work, 0.2 ml oxidation reagent was added to blank.

Setting up the flow injection microwave digestion system

The microwave system needs about 3 min to warm up. Run the system with the microwave oven on at the specified power level for the measurement for a few minutes before starting

measurements. In this work 20% energy level of the microwave oven was used. Make certain that $KMnO_4$ never flows through the system unless $NaBH_4$ is also flowing.[7]

Recovery test

Four organomercury species and one inorganic mercury compound were used in this work (see Table 2).[5]

For the recovery tests, both bovine blood and human blood samples were used. Mercury compounds were spiked into 1:10 diluted blood solutions. 10 ml of these diluted solutions contained 0.7 ml bromate–bromide reagent. The concentrations of the spiked mercury maintained at the level of 10 μg Hg/l. The microwave power applied was 20%. As a comparison, the recoveries test of the same samples were also measured with the microwave oven off while keep all the setup unchanged.

Digestion with autoclave. One millilitre whole blood and 2 ml 1 + 1 diluted HNO_3 were added to the PTFE vessel inside the Autoclave. The autoclave was then heated at 150° for 45 min. After cooling, the digested mixture was diluted to 10 ml and mercury was measured using normal FI CVAAS.

Using MHS-20

The method developed by Schierling and Schaller,[16] was adopted.

Maintenance of the system

It is suggested that after every day's measurements the system be cleaned by pumping 1:1 HNO_3 through both the carrier channel and the acid channel for a few minutes with the microwave oven on. Rinse the system by pumping water through it. A slight precipitation may occur in the manifold at the point where the sample and acid stream merge. This can be removed by adding a few drops of concentrated HNO_3 to this place, and then rinsing with water.

RESULTS AND DISCUSSION

Results

The detection limit of this method calculated as 3 × SD is 0.1 μg/l Hg in 1 to 10 diluted whole blood. This corresponds to 1 μg/l Hg in blood.

The RSD of this method measured at 0.5 μg/l of mercury in diluted blood is between 6% and 7% (11 measurements).

Table 5. Mercury levels in whole blood determined by different methods

Sample No.*	Mercury content (μg/l) MW–FI	Autoclave	MHS-20
1	2.6 ± 0.3	2.2 ± 0.3	2.1 ± 0.4
2	2.4 ± 0.2	2.7 ± 0.9	1.1 ± 0.2
3	2.4 ± 0.2	2.2 ± 0.6	1.7 ± 0.3
4	4.9 ± 0.4	4.6 ± 0.2	3.7 ± 0.4

*The list of values are the means of three measurements ± SD. Samples were fresh human whole blood.

The recoveries of organic mercury compounds in spiked blood samples were between 96% and 100%: see Table 3.

Bovine whole blood, human whole blood and lyophilized human reference whole blood were measured in this work. The results of the reference whole blood are listed in Table 4. They are in good agreement with the recommended values.

With the method developed, no measurable background signal was obtained.

To compare the new method developed with other accepted methods whole blood samples were measured using the method described, and a method using the MHS-20, and autoclave off-line digestion followed by FI CVAAS. Comparable results were obtained by using this method and the autoclave off-line digestion method. Lower results were obtained using the MHS-20 without prior digestion of sample. The results are summarized in Table 5.

Knitted digestion coil

The decomposition of organic mercury compounds occurs mainly while the sample flows through the digestion coil in the microwave oven. The reaction in the digestion coil occurs at a slightly elevated pressure, caused by the high temperature and the long length of tubing used. A 10 m long digestion coil was used in order to allow a reasonable reaction time. However, such a long tube normally would cause substantial dispersion resulting in a decrease of peak height sensitivity and need longer integration time.

At first the digestion coil was wound on a PTFE shaft (280 × 38 × 15 mm) as described in Ref. 15. This arrangement resulted in a 4–6 fold reduction of the peak height sensitivity when a 0.5 ml sample loop was used, and about two-fold reduction with a 1 ml sample loop.[15]

Knitted or three-dimensional coils have been suggested and tested for postcolumn chromatography,[17,18] and have also been applied in

FI.[19,20,21] The sample dispersion in the axial direction is much less in a knitted coil than that in a straight tube of the same length and inner diameter.[22]

In order to reduce the dispersion but maintain the required reaction time while using a long tube, the digestion coil in the present work was made into a knitted form. This effectively reduces the axial dispersion. Figure 3 shows the signals of 10 μg/l Hg obtained with a digestion coil as used in Ref. 15 and with a three-dimensional form coil (with the same length and inner diameter).

Cooling coil

Without the cooling coil, the microwave power applied to the sample was limited to ensure that the sample solution was not heated above about 90°. At a higher microwave power, the sample solution will be heated to boiling point resulting in copious bubble formation, irregular flows, distorted peak shapes and impaired precision. Even at 90°, without a cooling coil, there are problems such as aerosol formation and vapor evolution due to the violent reaction between the heated sample, carrier and the reductant within the manifold and the gas–liquid separator. It is necessary to have a filter between the gas–liquid separator and the quartz cell to prevent aerosol droplets from entering the quartz cell or the amalgamation accessory. The filter has to be changed after every 2–3 hr of continuous operation.[15]

In order to be able to use a higher microwave power, for the decomposition of more complicated samples, while avoiding the problems mentioned above, it is necessary to cool the heated mixture before it merges with the reductant. This is especially important for the treatment of blood samples since they generate foam when reacting with $NaBH_4$. At elevated temperatures this reaction is more vigorous and the large amount of foam generated can enter the quartz cell interrupting the measurement.

A cooling coil was used in this work, which allowed the sample solution to be heated to boiling point or totally gasified. The reactions within the manifold and the gas–liquid separator then proceeded quietly.

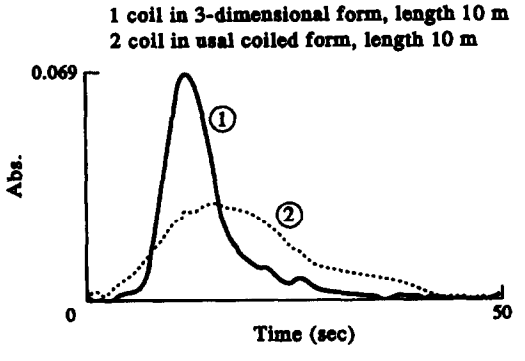

Fig. 3. Using the knitted coil can effectively reduce the dispersion of the sample. Signal 1: obtained with the knitted coil. Signal 2: obtained with the original coil. Both coils have the same length and inner diameter. Hg concentration: 10 μg/l.

Low concentration $NaBH_4$ and antifoam reagent reduce the generation of foam

One of the problems with the measurement of mercury in whole blood is the production of foam, especially when a higher concentration of $NaBH_4$ is used. The generated foam can enter the quartz cell and interrupt the measurement. Earlier work,[23] showed that the measurement of mercury by the cold vapor technique can be carried out at very low $NaBH_4$ concentration. However the addition of antifoam reagent was necessary even when low concentration $NaBH_4$ was used.

The addition of Triton X-100 to the samples can improve the fluidity of the sample solution and also helps reduce foam generation. The addition of antifoam reagent to the $NaBH_4$ solution and the addition of Triton to the sample solution had almost no effect on the sensitivity.

On-line addition of acid

With the method used here the decomposition reaction between organic mercurials and the oxidation reagent needs an acidic medium. However, blood normally coagulates when it is mixed with acid (in concentrated acid, *e.g.* 65% m/v HNO_3, a homogeneous solution can be obtained, but on dilution coagulation will reoccur). The situation is even worse when the acidified blood solution is heated. This is detrimental to the FI system because it will block the FI valve and tubing. During this work it was found that in a dilute acid solution, *e.g.* 0.5 mol/l HCl or less, coagulation could be delayed for quite a long time. However, when the sample solution contained both dilute acid and other chemicals, *e.g.* oxidation reagent, coagulation occurred more readily. If the diluted blood sample contained oxidation reagent only, it could stand for many hours, even up to one day without coagulation. In this work, the oxidation

reagent was added to the samples first, and acid solution added on-line just before the digestion in the microwave oven started. In this way the problem of coagulation of the blood sample on addition of acid was kept under control.

HCl and HNO_3 at different concentrations and their mixtures, and a mixture of HNO_3 and $HCLO_4$ were tested for on-line addition. The oxidation reagents in a suitably acid medium played the main role in the decomposition of organic mercury compounds. The type of acid used was not important. At higher acid concentrations, especially when HNO_3 was used, a deposit formed more easily inside the manifold at the confluence of sample and acid and on the wall of the tube connecting the manifold and the digestion coil. This affected the measurement and resulted in lower recoveries for certain organic mercury compounds. Using HCl at as low an acid concentration as possible is advisable and in this work, 0.5 mol/l HCl was used successfully.

Carrier solution

Deionized water, 0.1, 0.5, and 1.0 mol/l HCl, and a mixed acid of 0.5 mol/l HCl + 0.6 mol/l HNO_3 were used as carrier. When 0.5 mol/l HCl was used as the carrier, subsequent on-line addition of acid was omitted because the sample mixed with the carrier while flowing through the system. However it was found that when using acid as the carrier, even at a low concentration such as 0.1 mol/l HCl, precipitation of blood occurred on the inner wall of the sample loop, sample pump tube, and within the FI valve. With water as the carrier, even after a few weeks intensive measurements, the sample coil, the sample pump tube and the valve remained clean.

The use of $KMnO_4$ and bromate–bromide reagent together as the oxidizing reagent

Several oxidation reagents, including $K_2S_2O_8$, $KMnO_4$ and bromate–bromide reagent were used for the decomposition of organic mercurials. The combination of bromate–bromide reagent and $KMnO_4$ was effective for the decomposition of organic mercury compounds.

Potassium permanganate is known as a powerful oxidation reagent which can oxidize many organic mercurials. It is also known that there are problems associated with the use of $KMnO_4$ if it is added to water and urine samples long before the measurements are started. The most serious problem in this case originates from the adsorption of mercury onto hydrated manganese (IV) oxide which forms a film on the surface of sample vessels, tubing, and other system components.[15] Using FI and on-line addition, the above-mentioned problems associated with $KMnO_4$ can be effectively avoided while the advantage of using the powerful oxidizing property of $KMnO_4$ can be utilized.

At first, $KMnO_4$ was added on-line to the samples before they entered the microwave oven. However, it was found that the system was very easy blocked by the decomposition products produced during the heating process. Later $KMnO_4$ was added on-line to the sample stream after it left the microwave oven. The mixing coil used for the sample and $KMnO_4$ was 11 cm long. The concentration of $KMnO_4$ used should be in accordance with the concentration of the $NaBH_4$ solution. With a $NaBH_4$ reductant concentration of 0.05% m/v, a $KMnO_4$ concentration of 0.05% m/v was suitable.

Another advantage of using $KMnO_4$ is the enhancement of the Hg(II) signal when $KMnO_4$ was added on-line. This effect has been described in Ref. 7.

The use of bromate–bromide reagent was first proposed by Farey *et al.* for organic mercury measurement in natural water.[11,12,13] A bromate–bromide reagent in hydrochloric acid was used to generate bromine in the sample. Later it was also used by other workers for mercury measurement in water and urine with slight modifications.[7,15]

The use of bromate–bromide reagent and $KMnO_4$ together has been successful for the measurement of mercury in urine.[7] The combination has also been proved to be very effective for the measurement of total mercury in whole blood.

In the present work the bromate–bromide reagent was added off-line to the blood samples, the oxidation reaction between the sample and the reagent started only after they were mixed with acid. The mixture flowed through the digestion coil in the microwave oven and the decomposition reaction of organic mercury compounds was speeded up by the microwave heating.

The abilities of the bromate–bromide reagent and $KMnO_4$ to attack organic mercury compounds in blood both separately and together (without microwave heating) were studied. Data were collected under the following conditions: the microwave oven was off and the digestion coil was replaced by a short tubing (30 cm long

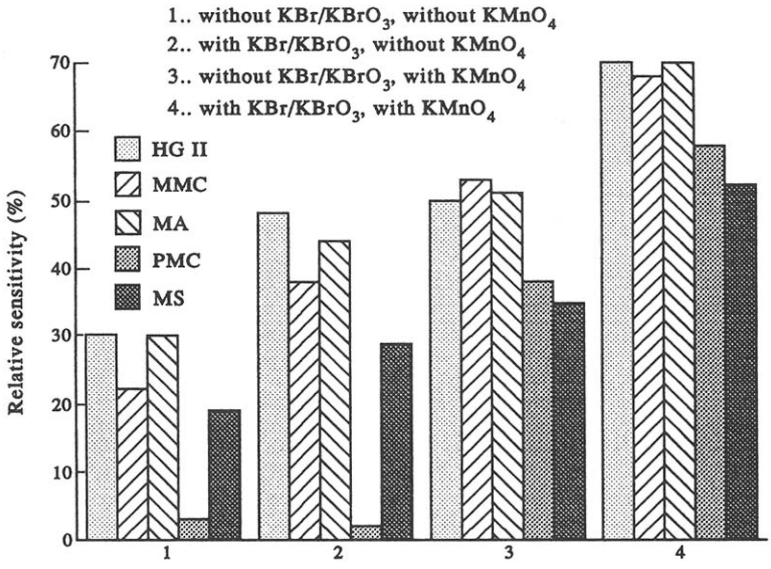

Fig. 4. The effects of using bromate–bromide reagent and $KMnO_4$ for the decomposition of organic mercurials. (1) Without bromate–bromide reagent and $KMnO_4$. (2) With bromate–bromide reagent only. (3) With $KMnO_4$ only. (4) With both bromate–bromide reagent and $KMnO_4$. 100% is value obtained with microwave heating and both oxidation reagents.

and 1 mm i.d.). The results are depicted in Fig. 4. A 100% signal represents the value obtained with microwave heating and both bromate–bromide reagent, and $KMnO_4$.

Recovery test and microwave heating

Most of the recovery test were performed in 1–10 diluted blood samples. Recovery tests of the above mentioned organic mercury compounds were also carried out in 1:5 diluted blood samples. However, 1:10 dilution of the whole blood sample for the measurement is recommended, since this ensures that the system remains clean when performing intensive measurements.

In the recovery test, the measured signals of the organic mercury compounds spiked into blood were compared with that of the inorganic mercury spiked into blood, rather than compared with aqueous standards. This is because, with microwave heating, the Hg(II) signals from blood and from aqueous solutions are not comparable. The heating effect of microwaves depends on the ionic conduction, dipole rotation and sample viscosity.[24] For this reason, the addition calibration technique was used in this work.

The measured signals of both organic and inorganic mercury compounds in blood were related to the amount of bromate–bromide reagent added. Ten millilitres of 1:10 diluted blood solution containing 0.7 ml bromate–bromide reagent was found to provide good recoveries. Less than 0.7 ml bromate–bromide reagent would result in lower recoveries. Further increasing the amount of bromate–bromide reagent did not increase the recoveries. For sample measurements, the amount of bromate–bromide used was higher than that used in this recovery test, see sample preparation part.

Energy levels between 20 and 50% of the microwave oven were used for the recovery test. At the 20% level the recoveries of the organic mercury compounds were already complete. Further increase the energy level did not increase the recoveries.

Without microwave heating, the recoveries of the mercury compounds only reached about 50–70% of the values obtained when microwave heating was applied, see Fig. 5.

The results of the recovery test are summarized in Table 3. The recoveries of organic mercury compounds spiked into blood were nearly complete.

The organic compounds used in this recovery test do not represent all of the organic mercury compounds existing in human blood. Some may not exist in blood, whereas other organic mercury compounds which exist in blood were not tested. The compounds: MA, PMC and MS were deliberately chosen for the test because it was known that they had very low recoveries, even in distilled water, and when using $NaBH_4$

as the reductant.[5] MMC is the major organic mercury compound existing in blood. It is reasonable to infer that when the recoveries of these compounds in blood are complete under the selected conditions, then other organic mercury compounds would give similar results. This has been shown by the measurement of whole blood reference materials using this method and by comparing this method with other established methods.

Calibration technique

The addition calibration technique was used in this work, because it is important to match the matrices of samples and standards. Different blood samples were used for the preparation of the addition calibration curve; these include: bovine whole blood, human whole bloods, and whole blood reference materials. An almost constant slope was found for all of these different blood samples. The statistics obtained from 14 calibration curves which were established with different blood samples and at different dates show: $Y = (0.0074 \pm 0.0005)X + C (n = 14)$. This shows that all of the calibration curves obtained were basically parallel to each other, which is in agreement with the observation in the batch system.[16]

The mercury standard solution contains a small amount of acid stabilizer. To avoid adding too much acid to the blood matrix when preparing the calibration solutions, it is important to choose a suitably concentrated Hg standard solution. Adding too much acid causes precipitation from the calibration solution during the measurement, which causes errors and may even block the system tubes.

For example, to prepare a calibration series to cover the concentration range of 1–20 μg/l, mercury in blood, we suggest using a standard solution of 100 μg/l Hg. For the highest calibration standard, 100 μl of this 100 μg/l Hg standard solution in a 5 ml final volume is required. The final concentration of HNO_3 in this solution is about 0.0011 mol/l, and this solution is stable for at least 8 hr.

As mentioned earlier less bromate–bromide solution should be added to the calibration blank. In this work, it was 0.2 ml. If the calibration blank solution contains more than this amount of bromate–bromide reagent, it will generate a background signal and depress the signals of subsequent measurements. This is because there is less matrix in the blank solution, the consumption of bromate–bromide reagent is low, and the generated molecular bromine from the excess reagent will result in background absorption.

The use of less oxidation reagents for the blank solution can cause error when the oxidation reagents, *i.e.* bromate–bromide, contain mercury. So attention should be paid to use mercury-free reagents. In this work, the used potassium bromate and potassium bromide were Merck product GR, and they provided good results.

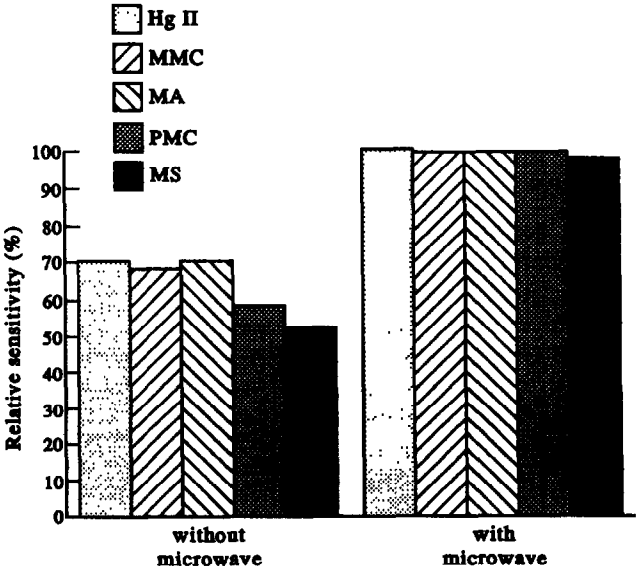

Fig. 5. The effect of microwave heating on the signals of mercury compounds.

Measurement of samples

Bovine whole blood, normal human whole blood and lyophilized human reference whole blood were measured in this work. The results of measurements on the blood reference materials are listed in Table 4. They are in agreement with the recommended values.

It is known that some compounds other than mercury can absorb at 253.7 nm and simulate higher mercury levels. Measurements in this work were made using both AA–BG mode and BG mode at 253.7 nm separately. No measurable background signal was observed.

Determination of mercury in whole blood by this method and some other methods

As a further check on the accuracy of the method developed, mercury in samples of freshly collected human whole blood was measured using this method, and using two other methods.

The methods used were: the method developed by Schierling and Schaller with MHS-20 batch system[16] and off-line digestion of whole blood in an autoclave and the subsequent measurement of mercury by flow injection CVAAS. The results are summarized in Table 5. Comparable results were obtained between the method developed in this work and the method of autoclave off-line digestion, lower results were obtained using MHS-20 batch system. This was thought probably to be due to no digestion prior measurements.

Using autoclave off-line digestion, background correction may be required since this method sometimes yields high background signals, especially when more HNO_3, *e.g.* 4 ml $1 + 1$ HNO_3 is used.

CONCLUSION

This work describes an accurate, fast and simple on-line microwave sample pretreatment procedure for the determination of mercury in blood by flow injection cold vapor atomic absorption spectrometry. The samples need only limited manipulation prior to automatic on-line treatment and measurement. With the present method, the risk of contamination, volatilization and adsorption losses are reduced drastically.

Another advantage of this method is the low sample consumption which is important for the measurement of samples such as human blood.

AUTOMATED TITRATIONS WITH AN ALTERNATE FLOW EXPONENTIAL SPEED VARIATION SYSTEM

CHAIM N. YARNITZKY, NAPHTHALI KLEIN and ORIT COHEN
Department of Chemistry, Technion, Israel Institute of Technology, Haifa, Israel 32000

(*Received* 25 *January* 1993. *Revised* 10 *May* 1993. *Accepted* 11 *May* 1993)

Summary—The alternate flow exponential speed variation system for automatic titrations is described. The system consists of two peristaltic pumps, two three-way valves, a mixing coil and a detector. Each determination consists of a twin cycle titration procedure. In the forward cycle, the sample and the reagent are propelled by the first and the second pump with the rotation speeds of the first and second pump decreasing and increasing with time, respectively. In the reverse cycle the solution inlets are switched so that the sample and the reagent are now propelled by the second and the first pump, respectively. This procedure allows the calculation of the accurate sample concentration without recourse to a precalibration step and, at the same time, eliminates the error caused by tubing deterioration. Results indicate accuracy better than 0.5%. Titration time and sample volume are of the order of 2 min and 2 ml, respectively.

Accurate titrations in analytical chemistry involve the addition of a reagent solution of known concentration to the analyte solution, usually by means of a burette. The equivalent point (*i.e.* the point at which the amount of added reactant is equivalent to the amount of analyte) is detected by an appropriate indicating system (visual chemical indicator, pH meter, conductometer, spectrophotometric detector, *etc.*).

Manual titrations are performed by adding small aliquots of the reagent solution, and monitoring visually, the status of the indicating system. In automatic titrations, a piston-driven burette and an indicating device connected to an electronic data processing unit are employed; the latter controls the rate of addition and volume of reagent solution dispensed up to the equivalence point. For S-shaped titration plots, the output of the indicating device, during the early stage of the titration, changes very slowly (in contrast to linear plots such as those pertaining to conductometric titrations); in the vicinity of the equivalent point the output of the indicating device varies very rapidly. Accordingly, the initial rapid rate of addition of reagent solution is significantly decreased near the equivalent point, to allow complete mixing of the reactants.

The overall time required for the titration is largely governed by the period of "slow reagent addition", and usually lasts 3–5 min. In addition, the fabrication of an accurate piston driven burette is extremely expensive and complicated when a small number of units are required. This is probably, the main reason for the numerous papers published describing various home-made, automated flow systems. In general, the flow rate of the sample is constant and the administration of the reagent is controlled by changing the reagent flow rate or its concentration. Gradient titration suggested by Fleet and Ho[1] and programmed coulometric titration[2] are typical examples. A more sophisticated approach was suggested by Valcarcel *et al.*[3] The rotation speeds of the two pumps were computer-controlled. In his recent papers[4,5] the flow rate of one pump was constant while the second one was changed in the range of 0–5 ml/min.

FIA titrations first proposed in 1977,[6] carried out with an unsegmented continuous flow single-channel gradient chamber system, are, by comparison, very fast (20–30 sec). Here, the reagent flow is of the order of 1 ml/min and the sample (100 μl) is injected into the flow, mixed in a 1 ml gradient chamber, and streamed on towards the detector. The mathematical relationship between the analyte concentration and the FIA curve (logarithmic scale) has been developed. The limited accuracy of the method is governed by flow rate stability, and by the measurement of time elapsed between two points on the FIA curve.

A common feature of all flow titrations employing peristaltic pumps has been the

deterioration of the tubing with time and temperature. This affects the flow rate and the accuracy of the titration. Frequent calibration is, therefore, necessary. This point was emphasized by Martinez-Calatayud *et al.*[7]

Variable sample and reagent flow rates were generated with high accuracy by mechanically driving two syringe pumps with two specifically profiled cams.[8] The pistons, however, are very similar to those employed in commercial systems. Stopped-flow titration[9] also requires accurate and complicated mechanical syringes.

The "alternate flow method" outlined below is based on a system which consists of two computer-controlled variable-speed peristaltic pumps and two three-way valves. As a rule, the rotation speed of the first pump decreases with time, while that of the second increases. Each determination consists of a twin-cycle procedure. In the forward cycle the sample and reagent are propelled by the first and the second pump, respectively. In the reverse cycle, the sample and the reagent are propelled by the second and the first pump, respectively. This operation is achieved by appropriately activating the three-way valves. The concentration of the sample is shown to be directly determinable with high accuracy; no pre-calibration is required. In addition, this procedure eliminates any errors due to the deteriorating of tubing. The sample volume is decreased considerably (1–2 ml) and the throughput is of the order of 20–40 samples/hr.

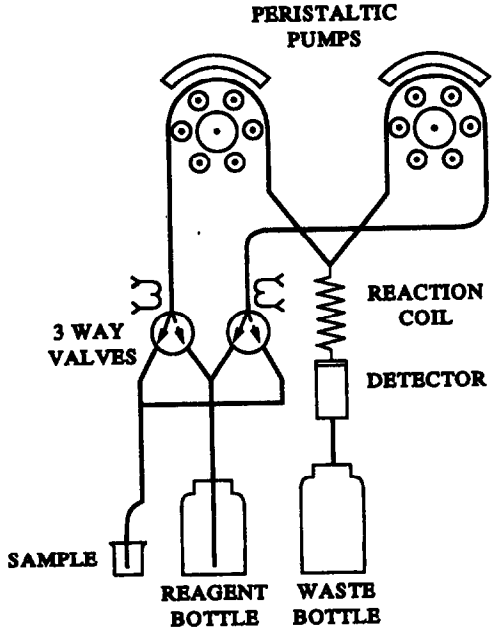

Fig. 1. Schematic diagram of the alternate flow system.

THEORY

The system (Fig. 1) consists of two peristaltic pumps with variable flow rates:

$$F_1 = Q_1 R_1; \quad F_2 = Q_2 R_2 \tag{1}$$

where F is the flow rate (ml/min); Q is the solution volume per revolution of the motor and R is the rotation speed (number of revolutions/min). The rotation speeds are monitored continously. At the beginning of the titration the sample is added at the highest rate by means of the first peristaltic pump; the reagent stream is added at the lowest rate by means of the second pump. The speeds of both pumps are gradually varied until the end point is reached (as shown by the indicating system). The relationship between the concentrations and flow rates at the equivalence point is as follows:

$$F_1 C_s = F_2 C_r \quad \text{or} \quad Q_1 R_1 C_s = Q_2 R_2 C_r \tag{2}$$

where C_s and C_r are the concentrations of the sample and the reagent, respectively. R_1 and R_2 are displayed very accurately (stepper motor technique).

Next, the three-way valves (Fig. 1) are activated and as a result, the first pump now causes the reagent to flow into the mixing coil while the second is connected to the sample bottle, and the titration is restarted. The second equivalence point is reached when

$$Q_1 R_3 C_r = Q_2 R_4 C_s \tag{3}$$

where the rotation speeds of the first and the second pumps are R_3 and R_4, respectively. Assuming that Q_1 and Q_2 remain constant during the short time required for the two titrations, we have:

$$C_s/C_r = \sqrt{R_3 R_2 / R_1 R_4}. \tag{4}$$

This result is totally independent of Q_1 and Q_2 and C_s may be calculated from the knowledge of C_r and the rotation speeds (R_1, R_2, R_3, R_4). This "alternate flow method" actually solves the problem caused by the ever-changing tubing.

The end point, however, registered by the data processing unit at the moment the mixed stream (at the stoichiometric ratio) passes through the detector flow cell, occurs at a certain delay with regards to the true equivalent

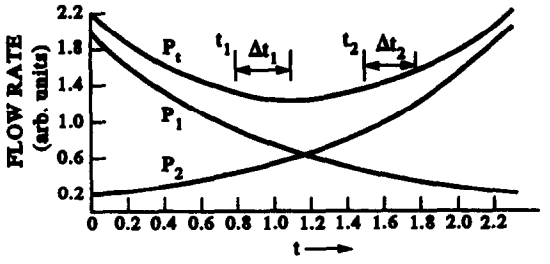

Fig. 2. The dependence of the individual and the total flow rates on time.

point. This delay originates from the flow-system configuration, in which mixing (mixing loop) and detection (flow-through detector) are necessarily spatially distinct. To minimize the "titration error" caused by this delay, the rate of change of the solution flow rates must also be minimized near the end point. Essentially, this brings up back to the main limitation (slow end-point approach) discussed above in connection with automatic titration systems.

The advanced "alternate flow exponential speed variation method" has been developed to provide an answer to the practical difficulties mentioned above.

The system remains the same (Fig. 1) except for the change of the rotation speeds $R_1(t)R_2(t)$ with time:

$$R_1 = R_0 e^{-kt}; \quad R_2 = \frac{A}{R_0} e^{kt} \tag{5}$$

where R_0, A, k, are experimentally chosen values (*e.g.* $R_0 = 200$ rev/min; $A = 4 \times 10^3$ rev^2/min^2; $k = 2$/min, $Q_1 = Q_2 = Q = 10 \pm 1$ $= \mu$l per revolution). The final rotation speed of the first pump is one-tenth of R_0 (regardless of the sample-reagent concentration ratio).

The dependence of the rotation speeds (or flow rates) and the total flow rate (at the mixing coil) on time are shown in Fig. 2. Let us assume that at a certain time, t_1, the equivalence point is reached, and the rotation speeds are R_1, A/R_1. As explained above the solution with the stoichiometry at the equivalence point will flow through the detector after a short delay caused by the mixing coil, Δt, equal (approximately) to:

$$\Delta t \equiv V_L(Q_1R_1 + Q_2R_2)^{-1} \tag{6}$$

where V_L is the volume of the mixing loop. The rotation speed readings, as displayed by the unit at the time $t_1 + \Delta t_1$ will be R_1^a and A/R_1^a, respectively. To correct for this inherent titration error, Δt_1 must be subtracted; and therefore, at the end point, these values must be multiplied by $e^{k\Delta t_1}$ and $e^{-k_1\Delta t_1}$, respectively.

Since

$$Q_1R_1C_s = Q_2\frac{A}{R_1}C_r \tag{7}$$

then

$$Q_1R_1^a e^{k\Delta t_1}C_s = Q_2\frac{A}{R_1^a}e^{-k\Delta t_1}C_r \tag{8}$$

where R_1^a is the actual reading at the time when the end point is sensed by the indicating system.

Analogously, for the second titration, after switching the pump inlets, the corrected values will be $R_2^a e^{k\Delta t_2}$ and $A/R_2^a \cdot e^{-k\Delta t_2}$, respectively.

$$Q_1R_2^a e^{k\Delta t_2}C_r = Q_2\frac{A}{R_2^a}e^{-k\Delta t_2}C_s. \tag{9}$$

After dividing equation (9) by (8), we obtain:

$$C_s = C_r\frac{R_2^a e^{k\Delta t_2}C_r}{R_1^a e^{k\Delta t_1}} = C_r\frac{R_2^a}{R_1^a}e^{k(\Delta t_2 - \Delta t_1)}. \tag{10}$$

Equation (10) shows that, provided Δt_2 and Δt_1 are calculated, the concentration of the sample can be derived directly from the actual readings of the rotation speeds displayed when the solution with the stoichiometry at the equivalent point flows through the detector.

To find Δt_1 and Δt_2, the total flow rate, which is a function of time, is integrated and compared to the volume of the mixing coil.

For the first titration:

$$V_L = Q_1R_0\int_{t_1}^{t_1+\Delta t} e^{-kt}\,dt + \frac{Q_2A}{R_0}\int_{t_1}^{t_1+\Delta t_1} e^{kt}\,dt \tag{11}$$

and for the second:

$$V_L = Q_1R_0\int_{t_2}^{t_2+\Delta t_2} e^{-kt}\,dt + \frac{Q_2A}{R_0}\int_{t_2}^{t_2+\Delta t_2} e^{kt}\,dt. \tag{12}$$

The difference in time $(\Delta t_2 - \Delta t_1)$ is a function of the mixing loop volume, the exponential constant k, and the concentration ratio C_s/C_r. For the conditions mentioned above and a mixing loop volume of $100 = \mu$l, the practical deviations ($e^{k(\Delta t_2 - \Delta t_1)}$) for 1:1, 1:2 and 1:4 concentration ratios are 0, 0.69 and 0.97%, respectively. The accurate concentration value is however easily determined by calculating the value of $e^{k(\Delta t_2 - \Delta t_1)}$. In principle, this approach should be useful for most titration systems, provided the appropriate detector is used. In the following, its application to an acid–base system, using a conductometric detector, is presented to demonstrate it.

EXPERIMENTAL

Instrumentation

Homemade peristaltic pumps driven by stepper motors were employed. The step angle was 1.8° and the holding torque was 53 *onze* inch. Pulses were generated by means of voltage-to-frequency converter. The exponential time dependent potential of the first pump was generated by a follower amplifier connected to a precharged capacitor. The capacitor was discharged after connecting a resistor in parallel to the capacitor. The follower was also connected to an analog divider (home made, pulse width modulation method, 0.05% accuracy). The output of the divider was connected to the voltage-to-frequency converter of the second pump. A simple flow through conductivity cell with a fast response served as detector. Glass electrodes cannot be used, since they respond sluggishly to pH changes and their response rate also depends on the direction of the titration (acid–base or base–acid). Other pH sensitive electrodes like antimony–antimonyoxide, mercury wetter platinum or silver electrodes may be used instead. Some experiments were carried out with homemade spectrophotometric detectors.

Reagents

All solutions were prepared from analytical-grade reagents and triple distilled water. Solutions were calibrated using common analytical procedures.

RESULTS AND DISCUSSION

Figure 3 shows the effect of the constant k on the display. Conductometric titration curves of

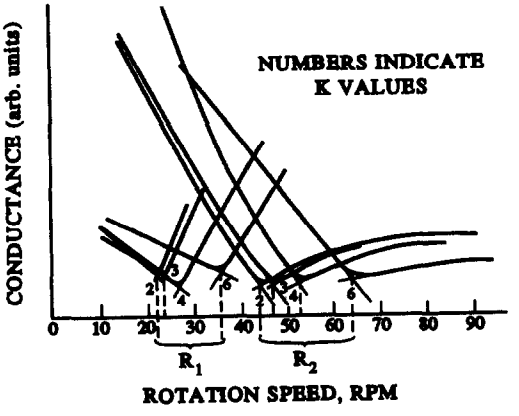

Fig. 3. Titration curves for 0.1*M* HCl titrated with 0.05*M* NaOH at different decay constant (k) values. Conductivity detector.

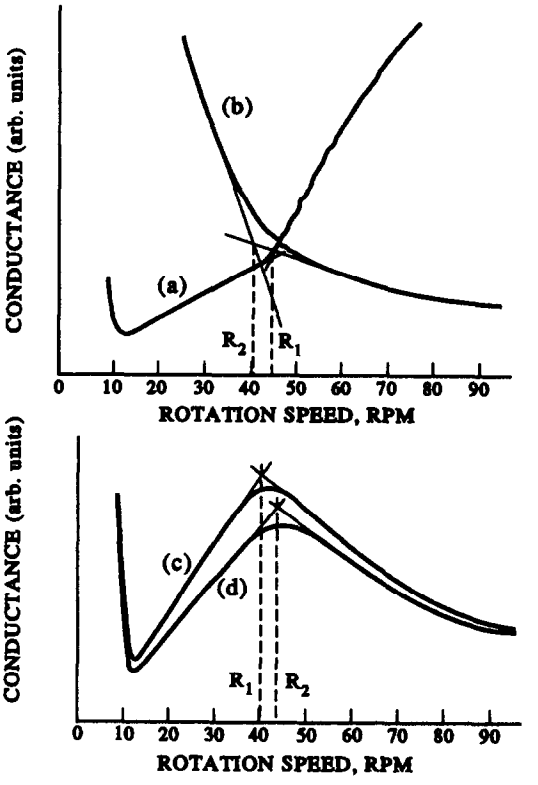

Fig. 4. Titration curves for 0.1*M* AcOH titrated with 0.1*M* NaOH (a,b) and 0.1*M* NH_4OH (c,d). Conductivity detector, $k = 2$ min^{-1}.

0.100*M* HCl with 0.0500*M* NaOH (resembling manual titrations) are displayed according to the procedure described. Each experiment involves two titrations (with the same k value). The expected value of the ratio of the rotation speeds at the extrapolated end points of each pair of titrations is 2.00. For low k values, the theoretical and practical deviations caused by the mixing coil are, indeed, small (less than 0.5%). For k values of 4 and 6, the deviations are 2.5 and 10%, respectively.

Figure 4 shows the titration curves recorded when a sample of acetic acid (~0.1*M*) was titrated with 0.1*M* NaOH and 0.1*M* NH_4OH, respectively. In the first titration with NaOH (curve a) the flow rate of the sample (acetic acid) decreases with time; the solution flowing through the detector at the beginning of the titration is thus virtually acetic acid plus a small amount of sodium acetate and the conductivity, therefore, low. During the course of the titration, the flow rate of the base increases with a concomitant increase of conductivity. After the end point, a sharp increase in conductivity mirrors the increased flow rate of the hydroxide. In the second titration (curve b) at the

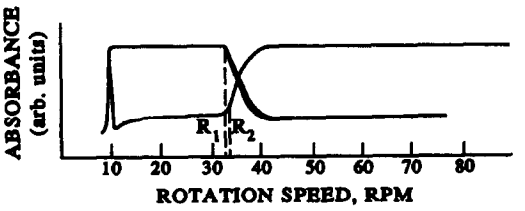

Fig. 5. Titration curves of 0.01*M* HCl titrated with 0.01*M* NaOH. Spectrophotometric detector, $k = 2$ min^{-1}.

beginning, both the flow rate of the reagent (hydroxide), and the conductivity, are high. As a result of the increasing flow rate of the sample (acetic acid) and the decreasing reagent flow rate, a sharp decrease of the conductivity occurs. Beyond the end point, the change of conductivity with the flow rate is relatively small.

The shape of the titration curves obtained for the acetic acid–ammonium hydroxide system are the same for the forward and reverse cycle (curves c, d); at the beginning and sufficiently beyond the end point of each titration, the solutions flowing through the conductivity cell contain either acetic acid or ammonium hydroxide (both mainly undissociated species) and a small amount of ammonium acetate, and, therefore, the conductivity of the solution is low. In contrast, at the end point, due to the presence of highly dissociated ammonium acetate, the conductivity is high.

A spectrophotometric detector in conjunction with an acid–base indicator has also been employed (Fig. 5). The S-shaped photometric titration curves, obtained in the forward and reverse cycles, are mirror images. The accuracy of the determination depends on the steepness of the S-shaped curve, which, obviously is the result of the correct choice of the wavelength.

The titration of up to 60 samples/hr should be feasible with a completely computerized system. The software should:

(a) command the autosampler to introduce a new sample;
(b) activate both pumps at the highest rotation speed to start up the system by filling the tubing;
(c) start programming the speed as detailed above, and monitor the output of the detector;
(d) activate the solenoid valves and repeat step (b);
(e) repeat step (c) (second titration);
(f) calculate the concentration of the sample, on the basis of the data collected in steps (c) and (e) above.

CONCLUSIONS AND FUTURE DEVELOPMENT

The reproducibility of all experiments is excellent and is in accordance with the theory. The error encountered when fast exponential time decay experiments are performed, can be correct to yield $<0.5\%$ analytical error. The titration time can be reduced to less than 1 min.

The operation of the new system in conjunction with potentiometric detectors (redox, silver) is now under inspection. The determination of the number of ligands in a metal complex has been carried out and will be reported later. The feasibility of using the system for Karl–Fisher titrations has also been considered.

(*Received* 22 *February* 1993. *Revised* 5 *April* 1993. *Accepted* 6 *April* 1993)

Summary—This paper evaluates the feasibility of two systems—the Sequential Injection (SI) analyzer and the Zymark Benchmate (ZB) robot—for the automation of a recombinant human Factor Thirteen (rhFXIII) fluorometric assay. The goal was to develop a routine analytical procedure suitable for the quality control lab environment. The experimental efforts focused on monitoring of the product formation for the condensation reaction between monodansyl cadaverin and dimethyl casein. The acquired kinetic data demonstrated that both systems are capable of automating the solution handling operations associated with the assay. Using a method developed with the SI system, samples containing 0–410 μg/ml of rhFXIII were analyzed, with a throughput of one sample per 8 min, and a total solution consumption of 0.8 ml. The relative standard deviation for 10 injections of 100 μg/ml rhFXIII sample was 0.91%. With the ZB robot, samples containing 0–2500 μg/ml of rhFXIII were analyzed, and the linear response was obtained for a concentration range between 0 and 1250 μg/ml of rhFXIII. The method had a sample throughput of one sample per 11 min and a total solution consumption of 6.3 ml for each analysis. Due to its commercial availability, the ZB system was preferred over the experimental SI system for the purpose of routine automated analysis of a large number of samples in the quality control lab environment.

Flow injection analysis (FIA) and robotics are two versatile techniques used for the automation of analytical procedures.[1] Although the two techniques provide means for automating a variety of sample handling and sample pretreatment operations, they exhibit fundamentally different working principles and, as such, provide different sets of rules which must be followed during the method development. Sequential injection analysis (SIA), which was introduced 3 years ago as the latest branch of FIA, [2] is like FIA, based on principles of controlled dispersion and reproducible sample handling. Liquid samples are delivered to the various pretreatment and detection sites in micro channels using pumps and valves. On the other hand, robots, such as the Zymark Benchmate (ZB), rely strictly on reproducible sample handling. Typically, samples are transported to a specific pretreatment station in sample vials grabbed by a moving arm. Samples analyzed by robots are treated as discrete entities and, therefore, the analyte concentration through the sample bolus remains constant, while samples analyzed by the FIA technique are treated as a continuum, which leads to the formation of an analyte concentration gradient.

Since FIA and robotics have different working concepts, it is no surprise that certain operations can be performed only by one of the two techniques, while the other offers only an inferior alternative. For example, in FIA, optosensing and gas diffusion techniques, which have not been attempted with robotics, represent unique and highly effective strategies for selectivity and sensitivity enhancement.[3] Robots, on the other hand, have the ability to automate sample handling of solids and aerosols, which are tasks not suitable for FIA.

Although these examples indicate a certain complementary role of the two techniques, a number of operations, such as dilutions, filtrations, liquid–liquid extractions, sorbent extractions or addition of multiple reagents, were previously automated by both the FIA and the robotics approaches.[3,4] Despite this, there are no references in the literature which describe a direct comparison of the two techniques.

The rhFXIII assay represents an application which involves sample handling and sample

pretreatment operations previously automated by both techniques. As described in a preceding paper, [5] the assay consists of two subsequent reactions. First, the inactive form of rhFXIII is activated by thrombin in the presence of calcium ions and UV radiation. Second, the activated rhFXIII acts as a catalyst for the condensation reaction between monodansyl cadaverin and *N*, *N*-dimethyl casein, which form a fluorescing product. The first order kinetics of the second reaction exhibit a linear relationship between the concentration of the active rhFXIII and the rate of product formation. Thus, monitoring either the product concentration at given reaction times or the slope of the kinetic curve over a given time range provides information for predictions of the active rhFXIII concentration in the sample. The concentration value is used for approximating the activity of rhFXIII in analyzed samples.

This paper describes the application of two analysis automation tools, the sequential injection (SI) technique and the ZB robot, to the rhFXIII assay. In addition to depicting the two options for the assay automation, the experimental work illustrates some of the similarities and differences between the SIA and robot concepts.

EXPERIMENTAL

Chemicals

The concentration of standard rhFXIII solutions ranged from 0 to 2500μg/ml. The protein is currently under evaluation for replacement therapy in FXIII-deficient individuals. It is produced by ZymoGenetics, Inc., Seattle, WA. Additional solutions included 0.05*M* bicine buffer at pH 10, which was used as a carrier, a bicine cocktail solution containing 0.05*M* bicine, 7 m*M* calcium chloride and 0.16 m*M* monodansyl cadaverin (MDC), 2% dimethyl casein (DMC) and 100 NIHU/ml thrombin. Details regarding these reagents are given in Ref. 4.

Assay automation using the SI system

SI configuration. The original work[5] demonstrated the feasibility of the SI technique for the automation of the manually performed sample handling and sample pretreatment operations associated with the rhFXIII assay, including sample dilutions, additions of multiple reagents, solution mixings, and controlled initiations of two subsequent reactions.[6] The emphasis of the current work shifted towards development of a system which would allow technical personnel to perform a reliable analysis of rhFXIII samples in a quality control laboratory environment. Therefore, issues such as robustness, mechanical simplicity, sample throughput, auto sampling abilities and long term reliability of the system were addressed.

The evaluation of the original single pump–single valve design (Fig. 1) led to the identification of four disadvantages which lowered the robustness standard of the SIA system. First, using a holding coil having a volume significantly larger than that of the syringe, the initial filling of the system was cumbersome and

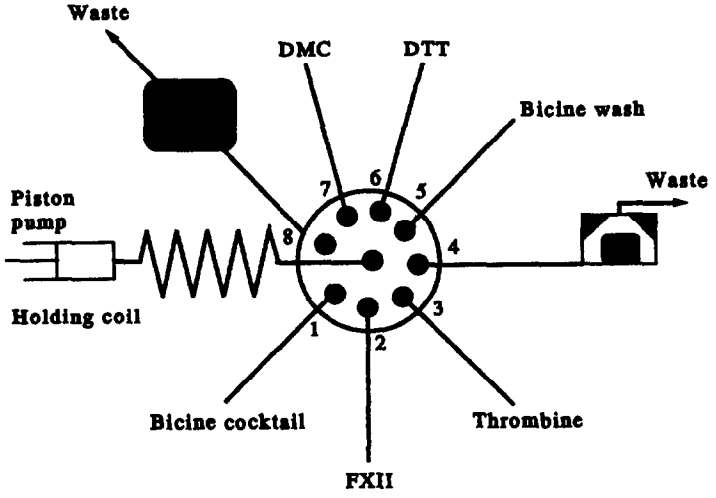

Fig. 1. Single pump–single valve SI configuration used in the earlier experimental work.[4] DTT (dithriothreitol) solution was used as a quenching agent for the FXIII activation. Later results showed that the assay can be performed without FXIII quenching.

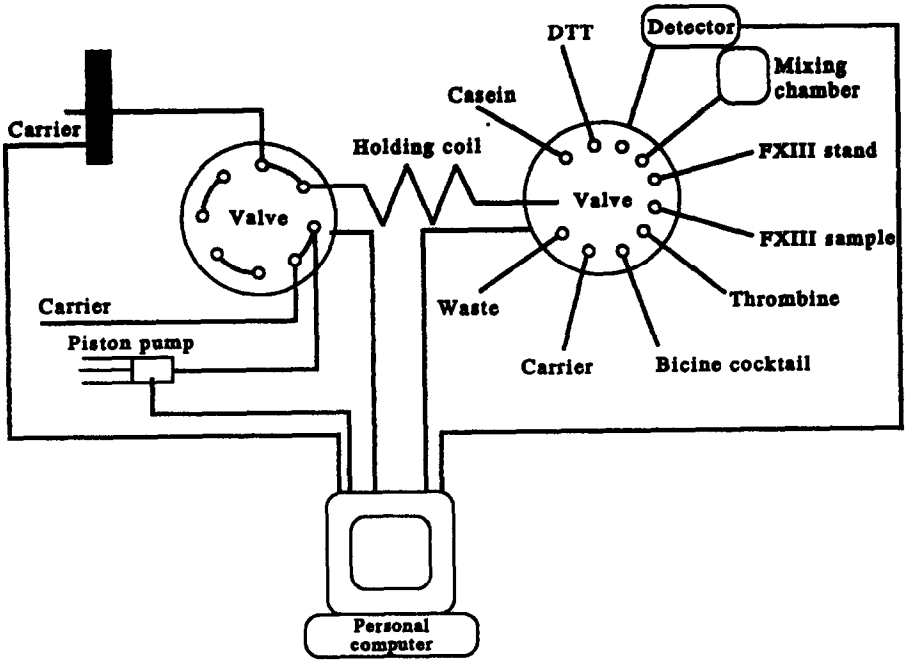

Fig. 2. Two pumps–two valves SIA system used for the automation of rhFXIII fluorometric assay.

needed a human interaction. The most straightforward procedure required disconnecting the holding coil from the syringe, filling the syringe manually with the carrier, reconnecting the holding coil and propelling the syringe content through the system. Although, when the volume of the holding coil was less than that of the syringe, it was possible to use repeated cycling for the initial filling, the required configuration left the carrier in the syringe prone to contamination when a high volume aspiration (volume of the aspirated solution was equal to or larger than volume of the holding coil) occurred by mistake from a reagent or sample port. Once a sample or reagent entered the syringe, the system had to be disassembled and cleaned before further use. For the single piston pump–single valve design the choice is, therefore, between the system which can use cycling of the pump for the initial filling, but does not minimize the risk of possible contamination of the carrier in the piston ($V_{\text{holding coil}} < V_{\text{syringe}}$) and the system which requires manual initial filling but practically eliminates the possibility of carrier contamination in the syringe ($V_{\text{holding coil}} \gg V_{\text{syringe}}$). Third, when using the later configuration, air bubbles were occasionally trapped near the head of the syringe (even though solutions were routinely degassed before use) and their elasticity caused errors in the volume accuracy of transferred solution zones. The air bubbles were difficult to remove without disassembling the SI system, mainly because of the low volume capacity of the piston pump. Finally, the time required for the system clean-up after each analysis was long, once again due to the low volume capacity of the syringe and time spent on the refill cycle.

Although substituting a piston pump with a peristaltic pump would eliminate cumbersome system filling, make removal of trapped air bubbles easy and speed up the cleaning process after the analysis, the elimination of the piston pump would sacrifice its high volume accuracy, which is an especially important advantage for methods requiring solution zone transfers of volumes as low as 10 μl, and superior long term robustness.[7,8] It seemed that this specific application would benefit if the SI system could offer both the accuracy and robustness of the piston pump and the continuous flow capabilities of the peristaltic pump.

The newly designed SI system consisted of both a piston and peristaltic pump configured with a two positional valve and a 10-port selector valve (Fig. 2). As in the single pump–single valve design, reagent lines, a sample line, a mixing chamber and a detector line were clustered around the selector valve. The holding coil did not, however, lead directly from the selector valve to the pump, but rather to the two positional valve, to which the micro tubing channels from both pumps were also connected. As

a result, depending on the position of the valve, either the peristaltic or the piston pump was in the active mode at any particular time and could deliver solutions through the holding coil. In these experiments, the active piston pump mode was used for transfer of sample and reagent zones in and out of the holding coil, thus taking advantage of its high volume accuracy, and the active peristaltic pump mode was employed for the initial system fill-up and for the system clean-up after each analysis, thus utilizing the continuous flow capabilities of the peristaltic pump. Note that the piston pump refilled in a passive mode, disconnected from the holding coil, which minimized the possibility of carrier contamination in the syringe and allowed for effective use of time, since other tasks, such as the system clean-up, were performed simultaneously. Although the complexity and size of the SI system increased, the advantages gained by the integration of the two additional components outweighed this drawback. In addition, the system developed for this application was not intended to be highly portable and, once properly configured, exhibited the same mechanical reliability as the original single pump–single valve design.

Hardware. The assembled SI set-up consisted of an Alitea (S-2) piston pump (cam driven, sinusoidal flow) equipped with a 1 ml syringe, an Alitea peristaltic pump (Alitea U.S.A., Seattle, WA), a Valco two positional eight-port valve, a Valco 10 positional selector valve (VICI, Houston, TX), a desktop personal computer, a mixing chamber (1.0 ml internal volume) equipped with a PTFE stirring bar, a stirring plate, Tygon pump tubing [0.5 ml internal diameter (i.d.)] and PTFE channel tubing (0.5 mm i.d.). Figure 2 shows the configuration of solutions and components around the selector valve. The final product was monitored with an HP 1046 fluorescence detector (Hewlett–Packard, Palo Alto, CA).

Procedure. The SI method simulated to a large extent the chronology of the manual procedure. First, using the peristaltic pump, the holding coil, the detector line and the mixing chamber were flushed with the carrier (bicine buffer solution). After the flush, the carrier solution was removed from the detector and from the mixing chamber. Next, the piston pump was put in the active mode to aspirate 500 μl zone of bicine cocktail, 10 μl of thrombine and 90 μl of the rhFXIII solution into the holding coil. Then, 600 μl of the solution were propelled from the holding coil to the mixing chamber, where it was mixed for 10 sec and allowed to sit for an additional 170 sec in order to activate the rhFXIII molecules. During this period, the peristaltic pump was used to flush the holding coil with the carrier solution. Next, using the piston pump, two zones were aspirated into the holding coil: 100 μl of bicine cocktail and 50 μl of casein. Then, 150 μl of the solution just introduced to the holding coil were added to the solution in the mixing chamber and mixed for 10 sec. As a result, the condensation reaction between casein and monodansyl cadaverin, which is catalyzed by the active rhFXIII, was initiated. At the same time, the SI system was switched to the active peristaltic pump mode and the holding coil was flushed for 5 sec with the carrier. Then, the piston pump was used to introduce air to the holding coil from the detector line. Following the solution mixing step, 180 μl of the reaction mixture were aspirated from the mixing chamber to the holding coil and immediately delivered to the detector. Note that the solution was separated from the carrier by an air packet and, therefore, no further dilution of the sample occurred during this step. Once the solution zone filled the detector's flow cell, the flow was stopped and the data acquisition was initiated. Data were acquired for 100 sec to monitor the formation of the fluorescent product. Finally, the system was thoroughly flushed and prepared for the next sample analysis. The entire analysis took 8 min, and total solution consumption was 0.8 ml.

Assay automation using the Zymark Benchmate 3.0

Hardware. The Zymark Benchmate 3.0 (Zymark Corp., Hopkinton, MA) system was purchased to accomplish the assay automation on a commercially available system. The system used for this work consisted of a moving arm, four vial racks (each having 50 vials capacity), a liquid transfer station, a vortex station, and a pumping system which included four syringes, one 12-port selector valve and three two-positional valves. An HP 1046 fluorescence detector was used for monitoring the final product and its signal was recorded on an HP 3396 series II integrator (Hewlett–Packard, Avondale, PA).

Procedure. The procedure developed for the assay automation consisted of 13 segments (Table 1), which, as with the SI system, mimicked the chronology of the manual method. First, sample vials were filled with 0.5 ml of

Table 1. Zymark Benchmate procedure for the FXIII assay

Step 1	Add 5 ml of 50 m*M*, pH 9.0 bicine
Step 2	Add 0.5 ml of MCD–Ca–Bicine cocktail
Step 3	Add 0.2 ml of 100 NIHU/ml thrombin
Step 4	Vortex for 5 sec at speed 3
Step 5	Wash syringe with 2 ml of 50 m*M*, pH 9.0 bicine
Step 6	Pause for 0.5 min
Step 7	Add 0.1 ml of 0.2% casein
Step 8	Vortex for 10 sec at speed 3
Step 9	Load sample into cell and read UV–vis spectrophotometer
Step 10	Rinse UV–vis cell once with 2 ml of 50 m*M*, pH 9.0 bicine
Step 11	Wash syringe with 1 ml of 50 m*M*, pH 9.0 bicine
Step 12	Wash syringe with 1 ml of 50 m*M*, pH 9.0 bicine
Step 13	End

rhFXIII samples and placed into the vial rack. The moving arm began the sequence by grabbing a sample vial at position 1 and transferring it from the rack to the liquid transfer station. Here, the sample was diluted by adding 5 ml of bicine buffer, 0.5 ml of bicine cocktail and 0.2 ml of thrombine. Next, the arm transported the vial to the vortex station, where the mixture was vortexed for 5 sec, which initiated the rhFXIII activation. The vial was moved back to the liquid transfer station, and the activation progressed for 30 sec. After 30 sec, 0.1 ml of the casein solution were added, using the internal standard line, and the mixture was vortexed once more. This led to the initiation of the condensation reaction. After returning the vial to the liquid transfer station, 1 ml of the solution was withdrawn from the vial and transferred to the detector's flow cell, where the formation of the reaction product was measured for 1 min. Following the data acquisition, the syringes and the tubing channels were washed with the carrier solution and the system components were prepared for the next sample. Now, the ZB system was ready for analysis of a new sample. The moving arm began the repeat cycle by grabbing a vial from position 2 on the rack.

The assay was carried out at room temperature. Casein and thrombine solutions were stored in an ice bath at 0°, other solutions were stored at room temperature. The flow rates used at different stages of the method are shown in Table 2.

Table 2. Flow rate and mixing parameters for the Zymark Benchmate FXIII method

RESULTS AND DISCUSSION

Assay automation using the SI system

Figure 3 shows the raw data acquired on the HP integrator by monitoring the formation of the fluorescent product. Standards of rhFXIII with concentrations ranging from 0 to 410 μg/ml were analyzed. Different initial values for each curve are due to the reaction progress between the time of casein addition to the mixing chamber and the start of the data acquisition. About 35 sec were required for the solution mixing step and the solution transfer from the mixing chamber to the flow cell. The signals for the 200 and 410 μg/ml of rhFXIII standards saturated the detector prior to the end of data acquisition, which is indicated by the horizontal part of their corresponding data curves. Curves from duplicate injections of standard solutions containing 67, 100 and 200 μg/ml of rhFXIII are shown to illustrate the excellent reproducibility of the method. The relative standard deviation (RSD) value of the slope of the kinetic curves for 10 injections of 100 μg/ml of rhFXIII standard was 0.91%.

Figure 4 shows the linear relationship between the concentration of the active rhFXIII and the slope of the kinetic curves. The correlation coefficient R for the first order fit equals 0.9998. The y intercept equals 0.063, which indicates that the condensation reaction takes place even in the absence of rhFXIII.

Apart from confirming the feasibility of the SI method for automation of the rhFXIII assay procedure, the experiments also revealed some additional facts. First, by eliminating a number of mechanical steps associated with repeated sampling from the mixing chamber, which was

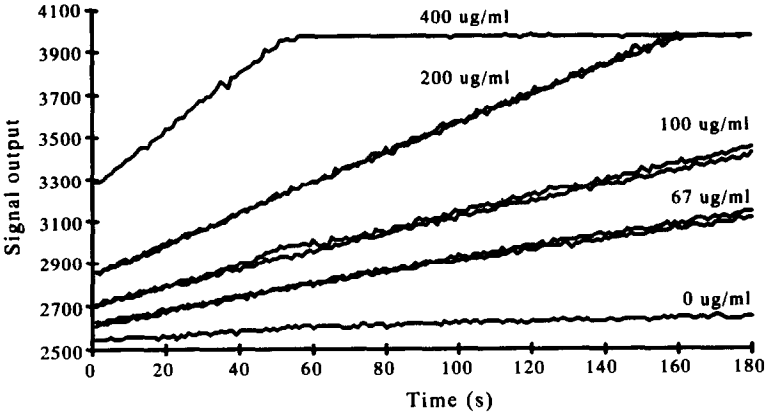

Fig. 3. Plot of signal *vs.* time. Data resulting from product monitoring of the condensation reaction on the SI system. FXIII concentration varied from 0 to 410 μg/ml. Duplicate injection data are shown for three samples.

required for the previously performed continuous flow SI method,[5] the stopped flow SI method, which monitored the kinetic process using a single sample zone, proved to be easier, faster and more reliable.

Second, it was shown that the assay can be successfully carried out even at room temperature, which suggested that the elevated temperature controlled system was not necessary. Experiments which were designed to evaluate the SI system performance at elevated temperatures (around 37°) displayed poor repeatability of the method. It was concluded that the small temperature variations within the system, which were difficult to control, had a significant impact on the reaction kinetics. To minimize these variations, the assay was performed at room temperature. The RSD of 0.91% for 10 injections of 100 μg/ml of rhFXIII standards represents 20-fold improvement over the results obtained for analyses performed at 37°.

Third, the stability of various solutions was investigated. As expected, casein and thrombine solutions were most susceptible to degradation. When either of the two solutions was stored at room temperature, the rate of product formation decreased by as much as 30% within 8 hr, when using the same rhFXIII standard. On the other hand, when thrombine and casein solutions were kept in an ice bath, the rate remained constant over the 8 hr period. The next least stable component was rhFXIII, but, in this case, the rate decrease due to rhFXIII breakdown was observed only when the rhFXIII samples remained stored at room temperature for at least 16 hr. The bicine cocktail did not show any signs of instability while stored at room temperature for periods as long as 2 weeks.

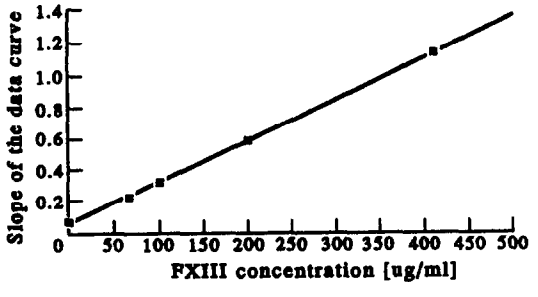

Fig. 4. Plot of the slope of the kinetic curve *vs.* FXIII concentration. The plot reveals a linear relationship over this concentration range. The correlation coefficient for the first order fit is 0.9998 and the *y* intercept is 0.063.

Assay automation using the Zymark Benchmate 3.0

Figure 5 presents data acquired on the HP integrator from the analysis of rhFXIII standard solutions containing 0–2500 μg/ml of rhFXIII. The results confirm successful completion of the assay and illustrate the effect of rhFXIII concentration on the condensation reaction over a wide concentration range. Figure 6 shows a good linear relationship between the slope of the kinetic curve of the condensation reaction and the rhFXIII concentration up to 1250 μg/ml of rhFXIII. The correlation coefficient for the first order fit was 0.9949 and the *y* intercept was 0.389.

The method design was more straightforward at this stage of the project. The development of the ZB system benefitted from the experiments performed on the SI system, because the observations about the solution stability and

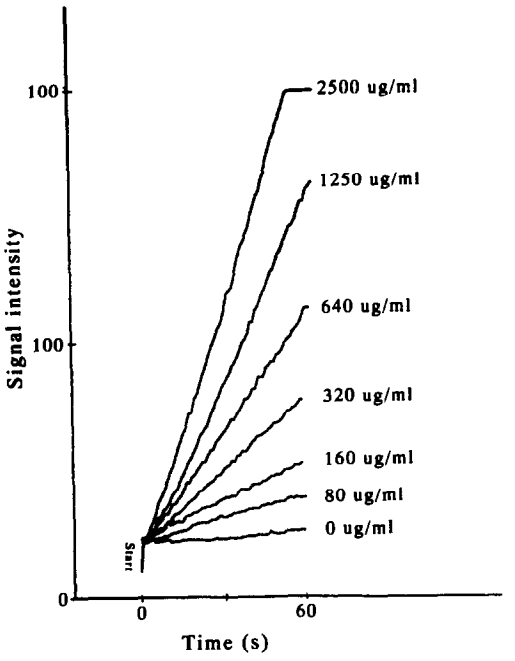

Fig. 5. Plot of signal *vs.* time. Data resulting from product monitoring of the condensation reaction using the ZB system were acquired on the HP integrator. FXIII concentration varied from 0 to 2500 μg/ml.

temperature effects also applied to the ZB method. Volumes of reagents, carrier and sample solutions used for the analysis increased almost 10-fold, because the ZB system did not have the ability to deliver volumes of the order of 10 μl with the same accuracy as the SI system equipped with a 1 ml syringe pump. The time of analysis was 11 min for each sample, 3 min longer than the time required for the SI analysis. The ZB system however, had, the ability to analyze up to 200 samples without any human intervention.

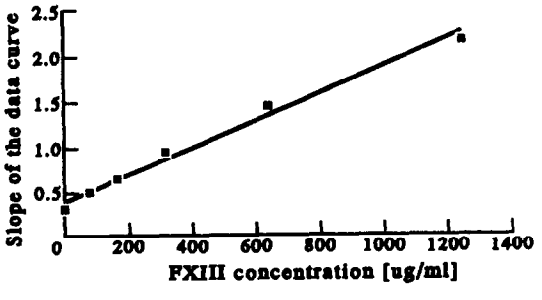

Fig. 6. Plot of the slope of the kinetic curve *vs.* FXIII concentration. The plot reveals a linear relationship over the concentration range from 0 to 1250 μg/ml. The correlation coefficient for the first order fit is 0.9949 and the *y* intercept is 0.389.

CONCLUSIONS

The two described methods demonstrated that the rhFXIII assay can be performed reliably in an automated mode with minimal human interaction. Although the two techniques differ in concept, they both provided methods for performing two subsequent reactions and monitoring the final product in an automated, controlled and highly reproducible manner.

The work presented showed some obvious differences between the two concepts. In the SI procedure, segments of the samples and reagents were introduced from vials to the holding coil channel, where they dispersed into the carrier and into each other, thus forming a concentration gradient. The controlled, reproducible dispersion and continuous sample handling represent the fundamental difference between assay automation by the flow injection approach and by robotics.

The SI technology is, however, quite versatile. For example, the gradient does not have to be formed every time. There is the option to treat a specific zone as a discrete sample, as was shown in the final stages of the rhFXIII assay. Here, it was undesirable to further dilute the reaction mixture in order to achieve a low detection limit within short data acquisition time. Therefore, an air pocket was introduced into the holding coil just before the aspiration of the reaction mixture from the mixing chamber. When the zone of the final mixture was aspirated to the holding coil, it was effectively isolated from the carrier solution and the dilution of the sample plug was prevented. Although the same result can be achieved by aspirating a large volume of the mixture from the mixing chamber (dispersion coefficient equals 1 for the center portion of the zone), it was found that, in this specific case, the flow cell was cleaned more easily when the amount of the final mixture going through the detector was limited. The air pocket introduced at this later stage did not present any significant problems.

With the ZB robot, the sample is always treated as a discrete entity. With the exception of final solution transfer to the detector, the sample never enters the tubing channels. The analyte either remains in the same sample vial or, if pretreatment steps such as sorbent extraction or filtration are performed, is transferred from one vial to another. The concentration of the analyte in the sample bolus remains

constant. This is why robots can handle solid samples but cannot master some techniques, such as optosensing or gas diffusion, which are commonly performed on flow injection systems.

Currently, more robots than SI systems can be found in quality control laboratories. Although SI technology is an attractive tool for the automation of chemical assays, the instrumentation is still in the experimental stages of development. A system which features an auto sampler, software and different configuration options of pumps and valves is not currently commercially available. This is an obvious drawback, if the goal is to implement a system for the sole purpose of automating high sample throughput assay. On the other hand, a variety of robotics systems are available on the market. The manufactures, which went through more than a decade of development, provide strong technical support. As a result, a large number of quality control assays have been successfully automated by robotics. Although there is no question about the potential of SI technology, until a reliable SI system appears on the market, robots will be the primary source for automation of quality control assays which require high sample throughput and tedious sample handling.

Summary—Since flow injection (FI) is a dilution technique, efforts have been undertaken to minimize online dilution or dispersion. Solutes in supercritical fluids exhibit increased diffusion coefficients which have been shown to decrease dispersion of the sample zone. This work investigates the use of supercritical fluids (or CO_2 modified fluids) as carrier streams for FI. Both a non-reacting tracer and an online chemical reaction were employed to investigate the behavior of solutes in supercritical and near critical systems. Further, these results are compared to those obtained in the system studied with a conventional carrier stream. Plots of peak response *vs*% CO_2 modifier increase with a sharp break at moderate modifier composition (20–30%). Plots of peak variance *vs*% CO_2 modifier show decreased variance with increasing % modifier. The system was also optimized with regards to temperature and pressure. The optimized system displayed improved limits of detection and decreased variance relative to 0% CO_2 modifier carrier streams.

Flow injection (FI) is a means of automating a wide variety of analyses with improved precision and throughput.[1,2] Like chromatography, it is a dilution technique. Therefore, the limit of detection (LOD) in FI is never as good as that for a batch analysis. In order to improve the LOD, the dilution (dispersion) must be minimized. Efforts to this end have included reduction of injection variance,[3] enhanced reaction kinetics,[4] and decreasing viscosity.[5] The viscosity of supercritical and near-critical fluids can be varied greatly using temperature and pressure. The effect of varying viscosity results in higher solute diffusion coefficients, D_m ($\sim 10^{-4}$–10^{-3} cm^2/sec compared to $\sim 10^{-5}$ cm^2/sec in pure liquids).

Supercritical fluids (SFs) are of widespread use in supercritical fluid chromatography (SFC) and supercritical fluid extraction (SFE).[6] The properties which make supercritical fluids attractive for these techniques also make them attractive for FI. Deye *et al.*[7] employed Nile Red as a solvatochromic dye to investigate a series of fluids and mixtures of normal, supercritical and near critical fluids. Eighty-seven normal liquids were investigated ranging in polarity from pentafluorophenol to CO_2. The system was operated without a column and the normal liquids and other fluids were mixed online.

Leach and Harris[8] performed thermal lens measurements with a supercritical fluid system. This system employed a short column for solvent separation and the measurements were then taken under either stopped flow or continuous flow conditions. The use of supercritical CO_2 provided enhancement to the thermal lens effect. This system is analogous to the solute focusing work presented by Johnson and Dorsey.[9]

Olesik *et al.*[10] studied online reactions with Fourier transform infrared spectrometry (FTIR). Samples of allyldiisopropylamine oxide were injected into a length of capillary to allow dispersion. The flow was then stopped and the thermal decomposition reaction monitored by FTIR. This system employed a supercritical fluid-flow injection (SF–FI) system operated at low dispersion to monitor the reaction. The reaction was found to follow different pathways (to the same product) if performed above or below the critical conditions.

†Author for correspondence.

Several works have been aimed at investigating transport effects in SFC. Two important works in this area examined coiling-induced secondary flow in capillary SFC. Springston and Novotny[11] demonstrated enhanced radial mass transfer in coiled columns. The radius of curvature for a coil of capillary tubing can be halved by shaping the coil into a figure-8 and folding over. Coil diameters, d_c, were reduced in this fashion from 30 to 15 to 7.5 cm. Plots of reduced plate height, h, *vs* reduced flow velocity, v, were constructed and evaluated. The results from these van Deemter plots showed that near the critical pressure, reductions in coiling diameter produced slight decreases in h. For pressures well in excess of the critical point, more noticeable decreases in h were exhibited. Janssen *et al.*[12] showed similar results over coiling diameters of 10.5, 4 and 1.6 cm. In that study, a relatively low value for d_c was chosen (2.7 cm). This allowed study of effects other than coiling.

The choice of solvents in the study presented here was guided by binary mixture behavior.[13] In Type I phase behavior, the materials being mixed are miscible as liquids, but separate liquid and vapor phases can be formed at pressures and temperatures between the individual critical points. Fluids forming Type I mixtures with CO_2 include n-alkanes ($n \leq 8$), methylene chloride, chloroform, carbon tetrachloride, benzene and methanol. The most polar solvent in the above list is methanol and was chosen for this study.

The final preliminary consideration is the choice of detector. The most common detector in SFC is the flame ionization detector (FID). Figure 1 shows a typical chromatogram in SFC with FID detection. Note the relatively large void peak. While this is acceptable in SFC where the analytes are retained and separated from the solvent peak, this void peak is where the reaction occurs in FI. A more selective detector is required for an SF–FI system. The choice here is UV/vis absorbance. Of particular use is an absorbance detector optimized for use with capillary tubing (see Apparatus section for a description).

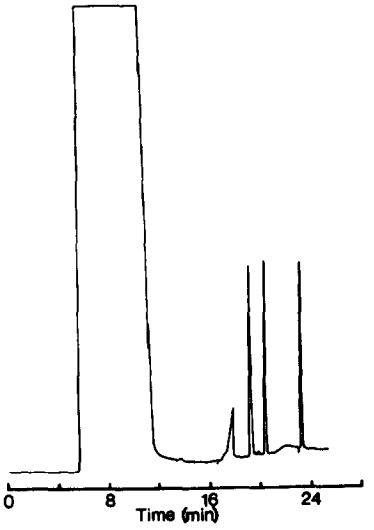

Fig. 1. Typical SFC peak showing large void volume peak. Adapted from Ref. 15.

The SF–FI system was further developed and employed to study a model reaction system. This work was aimed toward reducing overall peak variance (the second central moment) and thereby improving limits of detection in flow injection systems and demonstrating a further utility of supercritical fluids in analytical chemistry.

EXPERIMENTAL

Apparatus

A modified Varian Analytical Instruments (Sunnyvale, CA) Model 8500 Syringe Pump propelled the carrier streams for all studies.[14,15] Samples were injected via a Valco Instruments Company, Inc. (Houston, TX) EC14W.06 Internal Loop Injection Valve with a 60-nl sample loop. All connecting tubing downstream of the injector was polyimide-coated fused silica capillary (three sizes: 75-μm ID, 365 μm OD; 50-μm ID, 370-μm OD and 13-μm ID, 144-μm OD) from Polymicro Technologies, Inc. (Phoenix, AZ). The two manifolds used in this system consisted of a 50-μm ID × 2-m long manifold and a 75-μm ID × 3-m long manifold. The 50-μm ID manifold was evaluated in the initial studies and the 75-μm ID manifold was evaluated in all subsequent studies.

Manifolds were held at elevated temperatures and in relative confinement (for safety) by a Hewlett-Packard Company (Palo Alto, CA) 5730A Gas Chromatograph. This GC was used solely for its oven. The detector and injector septum were removed to allow easy access to the oven. Valco Fused Silica Adapters and other miscellaneous fittings were also employed. These included a flow restrictor to control pressure and density, placed post-detector, made of a 5–15-cm length of 13-μm ID capillary. A 300-ml sample cylinder and angled valve with 1800 psi rupture disc (for preparation of carrier streams) was obtained from the Whitey Co.

(Highland Heights, OH). The cylinder and the pump syringe were cooled by a Fisher Scientific (Pittsburgh, PA) Model 9100 Isotemp Refrigerated Circulator.

Detection of solutes in the carrier stream was by an ISCO (Lincoln, NE) CV[4] Capillary Electrophoresis Absorbance Detector, wavelengths used are noted in the figure captions. A small area of the capillary was carefully heated and the polyimide coating removed to form a window to allow passage of the light beam. The output recording was by connection to a Series 4500 Microscribe Strip Chart Recorder (the Recorder Company, San Marcos, TX).

Solutions

Methanol, HPLC grade, was obtained from Fisher Scientific Co. The *p*-dimethylaminobenzaldehyde (Fisher Scientific Co.) was used as received and was stored purged with dry nitrogen when not in use. Barbituric acid was obtained from Sigma Chemical Co. ("PFS" grade) and was used as received. SFC grade CO_2 was from Matheson Gas Products, Inc. (Secaucus, NJ). This cylinder had a full length eductor tube to allow the delivery of liquid CO_2 and was fitted with appropriate adapters for connection to the syringe pump. The headspace was not charged with helium, as many manufacturers provide. Eriochrome Red B (Fig. 2(a)) was prepared in house. The absorbance spectrum of the dye solution was verified against the literature $\lambda_{max} = 464$ nm.[16] The reaction studied in this system was the addition reaction of barbituric acid with *p*-dimethylaminobenzaldehyde (Fig. 2(b)).

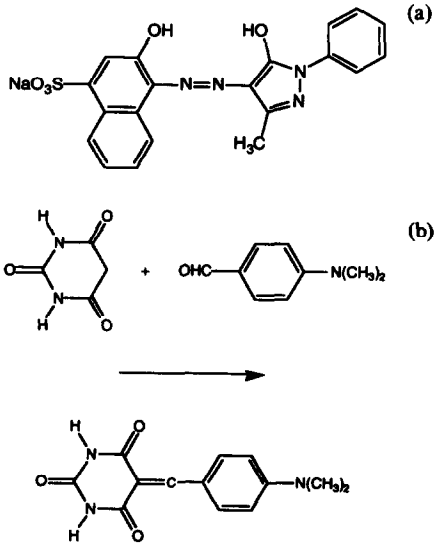

Fig. 2. Species injected/detected: (a) Eriochrome Red B (C.I. 18760). (b) reaction of barbituric acid with *p*-dimethylaminobenzaldehyde forming 5-*p*-dimethylaminobenzylidene-barbituric acid ($\lambda_{max} = 464$ nm).

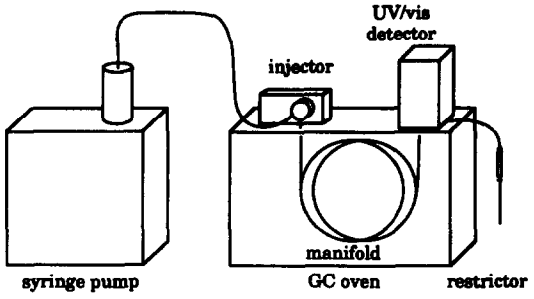

Fig. 3. SF/FI system configuration.

Procedure

The system configuration is shown in Fig. 3. Mixtures of methanol, CO_2 and reagent were prepared as follows. The 300-ml sample cylinder was cleaned and rinsed with methanol. A fixed volume of 0.01 *M* *p*-dimethylaminobenzaldehyde in methanol solution was then pipetted into the clean cylinder. The appropriate volume of methanol was then added to reach the required volume% of methanol. The cylinder valve was attached and the assembly was connected to the CO_2 cylinder (with both valves shut). The sample cylinder was then cooled to 0°. The valves were slowly opened allowing liquid CO_2 to fill the remaining volume of the sample cylinder. It was then isolated, disconnected and agitated to provide gross mixing of the liquids.

The charged sample cylinder was then connected to the inlet check valve of the empty pump and the pump cylinder was then cooled to 0° while the sample cylinder was allowed to warm in the room air. Once the pump was chilled, it was filled from the sample cylinder. After filling, the cylinder was again isolated, removed and the pump inlet check valve was then capped. The filled pump was allowed to equilibrate under pressure (100–200 atm) and at room temperature for at least 12 hr to allow complete mixing of the components.

RESULTS AND DISCUSSION

High% CO_2 carrier streams

Since the greatest variation in density and viscosity of CO_2-modified carrier streams occurs as methanol is first added to pure CO_2, this seemed the logical first experiment. Figure 4

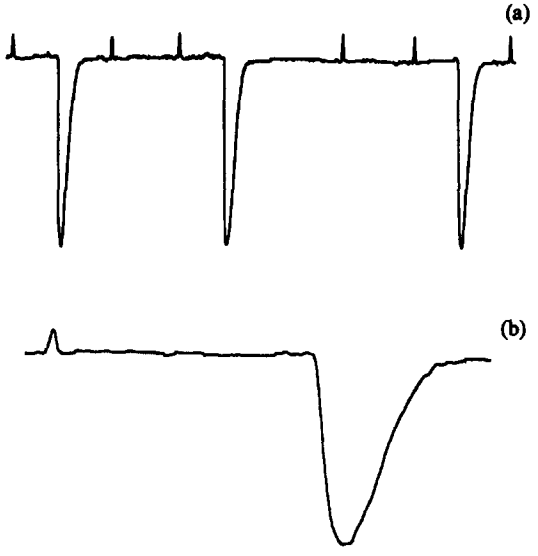

Fig. 4. Methanol blanks in a 100% CO_2 carrier stream. Conditions: 200 atm, 40°C, $\lambda = 360$ nm, 60 nl injection volume and 50 μm × 2 m capillary column. (a) Chart speed = 5 cm/min and (b) chart speed = 60 cm/min.

shows methanol blanks injected into 100% CO_2 at 200 atm. and 40°, conditions at which no phase separation is possible. The upward deflection to the left of the individual injections is the injection mark. The upper trace (a) represents multiple injections. In each case there is an enormous negative peak. This occurs due to the refractive index difference between liquid CO_2 (1.195 at 15°C[17]) and liquid methanol (1.3288 at 20°C[17]). The lower trace (b) shows the same peak at faster chart speed. The shape of this peak is symmetric and confirmed that connection to the capillary post-injection and pre-detection (one, at injector outlet) is free of unswept dead volume.

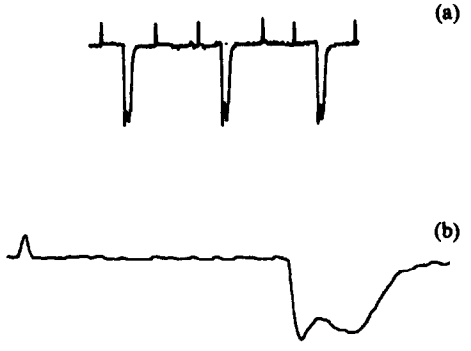

Fig. 5. $5 \times 10^{-2} M$ *p*-dimethylaminobenzaldehyde in methanol blanks injected in a 100% CO_2 carrier stream. (a) Chart speed = 5 cm/min and (b) Chart speed = 60 cm/min. Other conditions as Fig. 4.

To confirm that the detector would reveal solutes present in this background response, the same system was run with injection of *p*-dimethylaminobenzaldehyde dissolved in methanol. Figure 5 shows these results. The upper trace (a) is at a slow chart speed. Note that there is a small peak from the *p*-dimethylaminobenzaldehyde located in the refractive index peak. This indicates that *p*-dimethylaminobenzaldehyde is either totally nonretained, or is retained only very slightly by the uncoated fused silica, because the solute elutes with the solvent peak. Since this is the lowest-polarity carrier stream (or weakest mobile phase) used in these experiments, the *p*-dimethylaminobenzaldehyde should be unretained throughout the range of CO_2 compositions studied, and we assume that no wall adsorption of the *p*-dimethylaminobenzaldehyde is occurring. The lower trace (b) further confirms this with symmetric peak shape.

A second problem experienced in high% CO_2 carrier streams is shown in Fig. 6. Trace (a) represents 100% CO_2. The methanol blank displays a discontinuity preceding the peak maximum. This may indicate the presence of an on-line phase transition between the 100% methanol sample solvent and the 100% CO_2 carrier stream. Trace (b) represents a 95% CO_2 carrier stream. The result is the same as shown by the 100% CO_2 carrier stream. There is a slight decrease in magnitude as % CO_2 decreases.

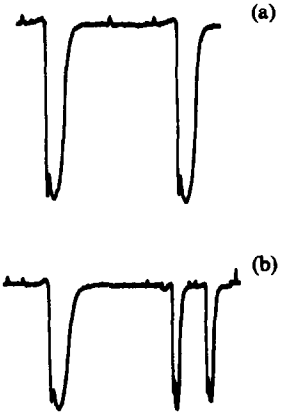

Fig. 6. Methanol blanks exhibiting online phase separation between carrier stream and sample solvent. Conditions: 100 atm, 50°C, $\lambda = 464$ nm, 60 nl injection volume, chart speed = 5 cm/min and 50 μm × 2 m capillary column. (a) 100% CO_2 carrier stream. (b) 95% CO_2 carrier stream and chart speed = 3 cm/min (two peaks on right side).

Low % CO_2 carrier streams

The high % CO_2 results led to investigation of low % CO_2 carrier streams. These types of systems were recently investigated in capillary high-performance liquid chromatography (HPLC) by Cui and Olesik.[18] Their study involved porous glassy carbon (PCG) packed columns and% CO_2 mobile phases ranging from 0 to 100% (% v/v in methanol). These mobile phases were operated below the critical temperature of CO_2 and were termed "enhanced fluidity"[18] mobile phases, where fluidity was defined as the reciprocal of viscosity. For a variety of solutes these researchers found that optimum results were often obtained at intermediate compositions (50% CO_2). Of course, higher temperatures may be used with binary mobile phases or carrier streams in both chromatography and flow injection analysis if care is taken to operate in a single-phase region of pressure–temperature–composition (p–t–x) space. However, there is no standard practice for naming the fluid when operating between the critical points of the constituents. In this work, we will continue to refer to the fluid as a supercritical fluid because we are in a single-phase region well above the bubble-point curve for the binary mixture at the composition used, and we exceed the critical pressure of the mixture.

Preliminary results

The preliminary carrier stream employed with the flow injection system was 10% CO_2 in methanol with 0.01 M p-dimethylaminobenzaldehyde in methanol. Representative injections are shown in Fig. 7. The repetitions shown on the left (a) represent 0.5% RSD in the peak height. The peak shape (b) is good, revealing a well plumbed system free from phase transitions. The conditions in this system are somewhat above the critical point for CO_2 ($P_c = 72.9$ atm and $T_c = 31°C$,[17]) but are below the critical temperature for the mixture. Note that from this point on, 75 μm ID capillary was employed.

Calibration of this system was performed with both a non-reacting solute and an on-line reaction. The figures of merit for plots of absorbance *vs* amount injected are summarized for these two sets of calibration data in Table 1. The plots show reasonable linearity and, as preliminary data, show strong evidence of correlation between peak height and amount injected. Note that the sensitivity for detection is 10 times greater for the reacting system. The linear dynamic range (LDR) is similar (two orders of magnitude).

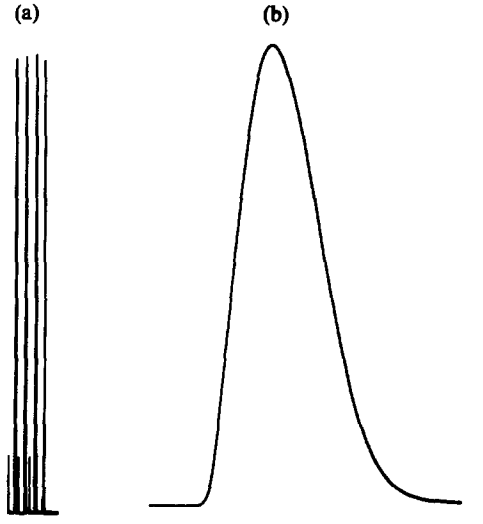

Fig. 7. Injections of 0.005 m barbituric acid into a 10% (% v/v) CO_2 carrier stream with 0.01 M p-dimethylaminobenzaldehyde in methanol. P = 100 atm, T = 100°C, injection volume = 60 nl, λ = 464 nm. (a) chart speed = 2 cm/min and (b) chart speed = 10 cm/min.

Before proceeding it is useful to calibrate the actual compositions of CO_2 present. This was done by collecting the major component (methanol) with a calibrated buret at a known flow rate. The CO_2 is then driven off by ultrasound degassing and the resulting volume of methanol divided by the calibrated volume delivered to yield the % methanol. Table 2 shows the comparison of nominal CO_2 compositions *vs* measured compositions. In this table, the value of CO_2 determined is always less than the nominal value.

This difference has two explanations, and neither is separable from the other. The first is

Table 1. Figures of merit for the SF–FI system initial calibration curves

	ERB*	BA†
% CO_2 (by volume)	10	10

Table 2. Nominal modifier concentration compared to actual delivered modifier concentration

Nominal	% CO_2(% v/v) Actual	Difference
0	0	0
10	8	−2
20	15	−5
30	27	−3
40	36	−4

that the composition determination performed this way assumes that the density of the CO_2 remains constant. It does not, but changes with pressure and temperature. The determinations were performed at constant room temperature but the pressure varied with composition to maintain constant flow rate. This would result in the measured value being lower than the true produced value (not the nominal value).

The second explanation is that at least some of the difference between measured and nominal is real. The cylinder is filled by the vapor pressure difference between the room-temperature aluminum storage cylinder and the cooled steel sample cylinder. There must be a small volume of the sample cylinder filled with CO_2 that does not remain condensed. This produces a systematic error which should remain constant throughout the range of compositions since the cylinder is always filled at the same temperature. Whether the difference between measured and nominal is either a systematic error or an actual difference is not important. The difference is quantified and all subsequent plots are *vs* measured composition. The measured value should be a more accurate representation of the compositions produced than the nominal composition.

Optimization

With the functional SF/FI system, it is useful to optimize the response of the system with respect to pressure, temperature and CO_2 composition. The most used method for this is univariate optimization. This method is time and labor intensive in that it requires singly changing each parameter while keeping the other parameters constant. An alternative is the simplex or modified simplex method.[19,20] This approach reaches the optimum value in a rapid fashion with fewer experiments than the univariate approach. Another advantage is the location of a more accurate maximum with the simplex than with the univariate maximum (which does not account for two or more factor effects). The problem with this method is that it would require an enormous number of different % CO_2 compositions to be prepared in a short period of time. As described in Procedures this preparation is not trivial and would prove impractical for optimization.

An optimization scheme based on factorial design is one alternative. In this method, the available experimental space is divided into points and four adjacent points are evaluated. The maximum of these values is then taken as the corner for a new set of four points. In this system, pressures between 100 and 400 atm were divided into 50 atm increments, temperatures between 100 and 300°C were divided into 50°C increments and % CO_2 was taken starting at 0% and increasing by 10% increments. The sample experimental space (for a given % CO_2) is shown in Fig. 8(a).

Figure 8(b) shows a sample result. The initial starting point is irrelevant in this case. A relatively large region was explored to reveal whether or not local maxima were present in this region. Experimentally there is only a single maximum, at 100 atm and 100°C.

% *CO_2 composition studies*

Optimization experiments were performed for a series of CO_2 compositions and are summarized in Table 3, along with the composition results. In each case, the maximum is found in

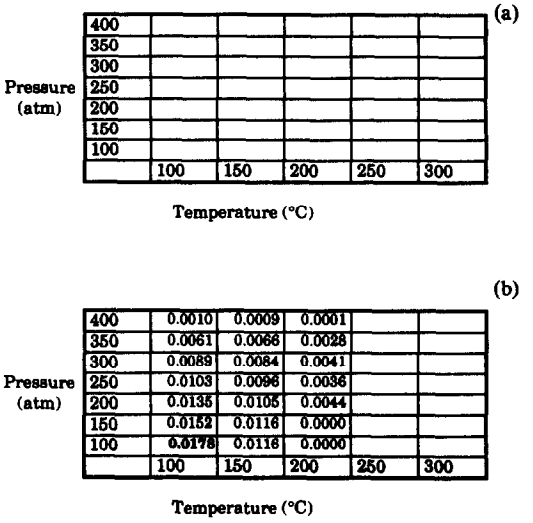

Fig. 8. Optimization examples (a) sample experimental space diagram and (b) results for 60 nl of 0.001 *M* barbituric acid injected into 20% (% v/v) CO_2 in methanol with 0.01 *M* *p*-dimethylaminobenzaldehyde.

Table 3. Results of optimization of the SF/FI system with respect to pressure, temperature and % CO_2 (% v/v)

% CO_2 (% v/v)	P (atm)	T (°C)	Absorbance
0	200	100	0.0138
8	100	100	0.0158

27	100	100	0.0182
36	100	100	0.0158

the low pressure and low temperature corner of the experimental space. These maxima in response correspond to two physical parameters of the system. The first is the density/viscosity of the carrier. At lower temperatures and pressures, the carrier stream becomes more gas-like with corresponding increases in solute diffusion coefficient. Further, the lower pressure corresponds to a slower linear velocity and a maximum in residence (reaction) time. Since the solute is in the manifold for a longer period, the reaction proceeds farther towards completion, yielding greater peak maxima.

Figure 9 is a plot of the data for the barbituric acid (BA) in Table 3, along with the data for Eriochrome Red B (ERB). For the non-reacting system, the absorbance increases with increasing % CO_2 initially. Beyond 15%, the response begins to decline with a sharp break after 25%

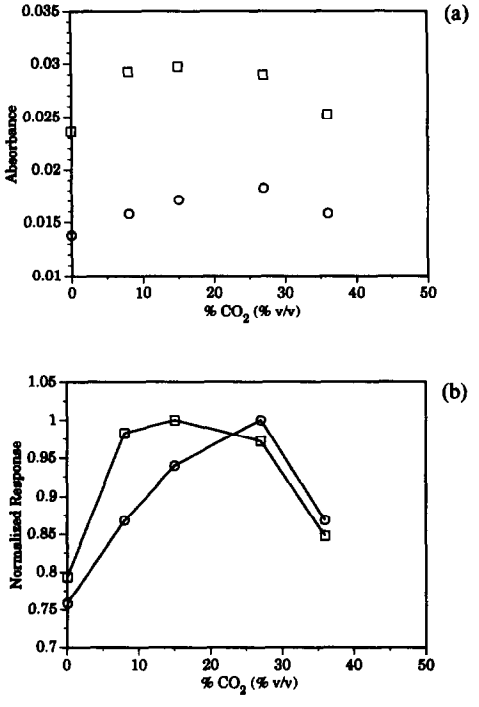

Fig. 9. Plots of peak height *vs* % CO_2 for (□)—Eriochrome Red B and (○)—barbituric acid. (a) absorbance and (b) normalized peak height. Other conditions as in Fig. 8.

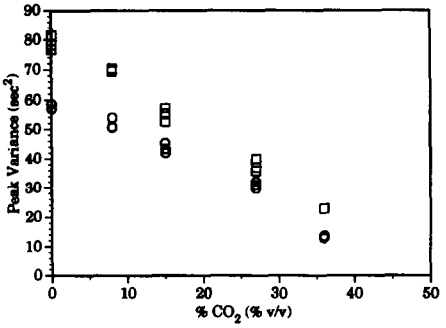

Fig. 10. Plots of peak variance *vs* % CO_2 for (□)—Eriochrome Red B and (○)—barbituric acid. Other conditions as in Fig. 8.

CO_2. Consulting a phase diagram for methanol/CO_2 solutions[13] and comparing the measured compositions of CO_2 from above reveals that at compositions up to 27% (% v/v) the mixture is single-phased. At 36% CO_2, however, the mixture lies in the two phase region of the phase diagram. The presence of two phases produces a sharp decline in response. At low concentrations, these peaks exhibit the same behavior shown in Fig. 6.

Figure 10 shows the results of plotting peak variance *vs* % CO_2 (% v/v). This plot shows variance decreasing continuously with increasing % CO_2. It is somewhat surprising that no break is seen when the system splits into two phases. The explanation for this behavior is stated above, at higher concentrations the absorbance of dye or product is sufficient to dampen out the change in sample profile from the phase boundaries.

This leads to two results which must be reconciled for the optimized system. The variance was found to decrease continuously for increasing % CO_2. The peak height, however, exhibited a sharp break as the system crossed the vapor–liquid critical locus. Since peak height is the parameter of analytical interest, the maximum in peak height should be taken as the important parameter to optimize.

Figure 11 shows the results of the calibration plots under the optimum conditions for both a non-reacting (a) and a reacting solute (b). In both cases, the supercritical fluid carrier stream exhibited greater sensitivity relative to normal methanol carrier streams.

Table 4 summarizes the figures of merit for the optimized systems. For ERB the ratio of sensitivities between 0 and 27% CO_2 is 1.49 and for BA this ratio is 1.85. This means that for a non-reacting solute, the change in viscosity

*ERB Eriochrome Red B
†BA Barbituric Acid
‡LOD = 3 s_B/m, where s_B = $Noise_{p-p}$/5 and m = sensitivity.

yields a 1.49 times increase in signal. For a reacting system, this increase is 1.85. Changes in viscosity have a dual effect in the case of a reaction. Not only is dispersion of product lessened but the extent of reaction is improved. This is due to the improvement in collision rate (controlled by diffusion coefficients of the reactants) between the reactants. Therefore in supercritical fluids the dispersion without reaction improves as do the actual reaction conditions.

For decreased viscosity in supercritical fluid carrier streams, the LOD is improved relative to normal fluids. This results from the increase in sensitivity. This indicates that while sensitivity is improving, the noise is remaining roughly constant. The upper limit of the LDR decreases for the non-reacting solute in the supercritical fluid carrier stream. This is a consequence of the increase in sensitivity.

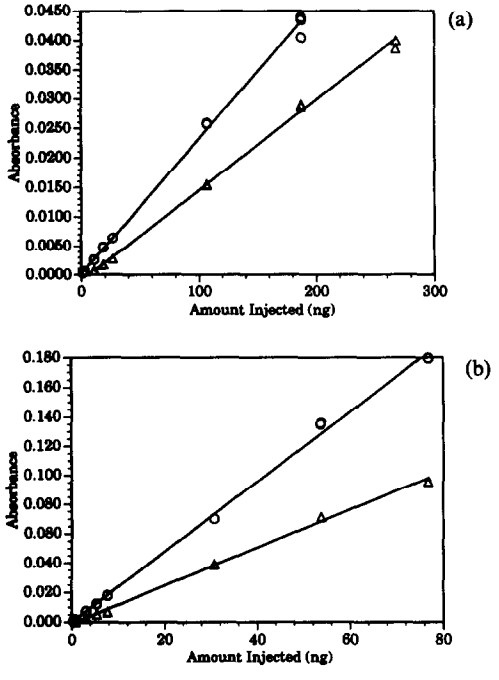

Fig. 11. Calibration curves for optimized systems for (△)—0% CO_2 (% v/v) and (○)—27% CO_2 (% v/v) with (a) Eriochrome Red B and (b) barbituric acid.

CONCLUSIONS

The investigation of supercritical fluids has some practical use to the field of FI. Supercritical and near-critical carrier streams provide decreased dispersion relative to normal liquid carrier streams. They also provide variable properties for the carrier stream to suit particular needs of the analyst. Further, sensitivity is directly improved via enhanced rate of collision relative to normal fluids.

The goals of this investigation were to demonstrate that decreased variance improves LODs and throughput. The LOD was shown to improve in SF/FI *vs* normal fluid FI. The throughput is inversely proportional to the standard deviation, σ. Since there was a two-fold decrease in variance, σ^2 (average between non-reacting and reacting solutes) there is a corresponding 1.4-fold increase in throughput for the supercritical fluid carrier streams.

The use of carbon dioxide-modified carrier streams provides all of the above advantages and others. The replacement of 30% of the carrier stream volume represents a substantial reduction in organic waste. The resultant effluent is also more concentrated once the gas leaves the solution.

REVERSE DUAL PHASE GAS DIFFUSION FLOW INJECTION ANALYSIS

K. J. SMITH and G. E. PACEY
Department of Chemistry, Miami University, Oxford, OH 45056, U.S.A.

(*Received* 20 *January* 1993. *Revised* 21 *July* 1993. *Accepted* 21 *July* 1993)

Summary—A flow injection gas diffusion system for gas acceptor to liquid donor stream, reverse dual phase gas diffusion flow injection analysis, has been demonstrated. Feasibility was shown with a carbon dioxide chemistry. A series of methods was investigated for hydrazine determinations. Using bromthymol blue indicator and a Celgard 2500 membrane a detection limit of 0.01 ppm v/v hydrazine was observed.

The technique of gas diffusion flow injection analysis, GDFIA, has been used for a variety of analytes.[1] The advantages of GDFIA are that the analyte of interest is removed from potential interferences and/or difficult matrices, the donor stream is optimized for diffusion while the acceptor stream can be optimized for detection, and the membrane itself may add some selectivity between the gaseous analyte and any gaseous interferences. Selectivity factors as high as 1500 have been reported.

GDFIA has been extensively used where there is liquid donor and liquid acceptor streams. In liquid–liquid GDFIA, an analyte in the donor stream is either present as a gas (*e.g.* NH_3) or undergoes some reaction to produce a gaseous analyte (*e.g.* sulfuric acid reacts with bicarbonate to produce CO_2). The gaseous analyte passes under a membrane where some of the analyte diffuses through the membrane into the acceptor stream.

The next development in GDFIA was a dual phase technique which involved a liquid donor and a gaseous acceptor stream. An example of this technique is the determination of metal hydrides.[2,3] Metal hydrides are generated in the liquid donor stream and then diffuse through the membrane into a hydrogen gas acceptor stream. The gaseous acceptor stream carries the metal hydrides to an atomic absorption spectrophotometer for detection. Additional examples of dual phase gas diffusion include its use as a sample introduction technique to mass spectrometry.[4]

The last area in GDFIA to be investigated has been the gas–liquid system. This paper reports work performed on a gas–liquid GDFIA system. The initial investigations involve carbon dioxide in an effort to study the basic characteristics of gas–liquid GDFIA and to determine if this technique is a viable, less complicated, approach to ambient monitoring. Then the technique was extended to include hydrazine.

EXPERIMENTAL

A Tecator 5020 FIA unit was used in conjunction with a Milton Roy Spectronic 3000 UV–VIS diode array. The gas diffusion manifold was a CHEMFOLD™ TYPE V from Tecator. The tubing used to carry the indicator solution was Teflon 0.5 mm i.d. The nitrogen and carbon dioxide were controlled by a flow controller and a flow meter (AARMGO). A pressure gauge was built, consisting of a 130 cm Pyrex tube with an i.d. of 2 mm. The pressure gauge used a solution of CO_2 saturated 1*M* HCl. A diagram of the FIA manifold is shown in Fig. 1.

The carbonate buffer acceptor solution, with cresol red indicator, is based on previous work done by Van der Linden.[5] Van der Linden measured CO_2 in liquid samples by measuring the absorbance at 430 nm. Cresol red indicator stock solution was made by dissolving 1 g of cresol red in 20 ml of 0.1*M* NaOH and then diluting to 1 l. The working acceptor solution was made by adding 10 ml of stock cresol red solution diluted to 1 l with 1 m*M* carbonate buffer adjusted to pH 8.85. Carbon dioxide and prepurified nitrogen were from Airco. The buffer solution with cresol red indicator should be able to measure CO_2 concentrations of 1–6 m*M*.

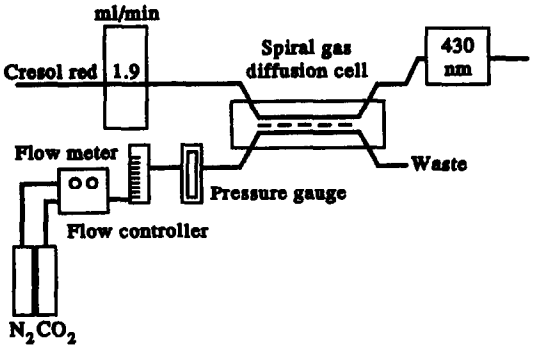

Fig. 1. Manifold for gas–liquid gas diffusion FIA.

The hydrazine source was a gas diffusion tube from VICI Metronics (Santa Clara, CA), which was calibrated to produce 700 ng/min of hydrazine hydrate at 50°C. Gas flow meters from Matheson were used for flow control and gas dilution. The hydrazine manifold is shown in Fig. 2.

Bromophenol blue (BPB) indicator solution was made by dissolving 0.050 g of BPB (Fisher) in 500 ml of doubly distilled, deionized water and the pH adjusted to 3.9 with 0.5*M* HCl. During the BPB experiments the absorbance was measured at 460 nm.

The Gore Tex Teflon membranes were supplied W. H. Gore. The silicon membranes were supplied by General Electric. The Celgard membranes were purchased from Fisher Scientific.

RESULTS AND DISCUSSION

Initially, a determination had to be made as to whether the CO_2 would in fact cross the membrane. A 50% CO_2/50% N_2 stream was passed in front of the membrane at a flow rate of 40 ml/min, while the acceptor stream was stopped on the opposite side of the membrane for 15 sec. A visible color change occurred in the stopped acceptor stream which indicated that CO_2 was crossing the membrane. The color change occurred rapidly and would not quickly change back to the original color when pumping was continued. Therefore, a more dilute CO_2/N_2 stream (5%/95%) was passed under the membrane at 40 ml/min. Again a color change occurred, but this time the color of the indicator in the stopped acceptor stream changed back to its original color when pumping continued.

Typically, the flow rate of the donor stream is critical to the amount of analyte diffusion across the membrane. As depicted in Fig. 3, if the donor flow rate is below a certain value, the amount of CO_2 being transported across the membrane is not detectable. This is related to the partial pressure of CO_2 in the donor stream. As the flow rate is increased, and subsequently the pressure in the manifold increases, the partial pressure of CO_2 increases proportionally. The amount of CO_2 which crosses the membrane increases due to both as the increased pressure in the manifold increases and the increased amount of CO_2 that passes the membrane. This results in a significant signal. Therefore, an optimum flow rate which allows the greatest amount of CO_2 to cross the membrane during the analytical stop flow period, but does not give a significant background signal, while the acceptor stream is flowing, can be determined. In the case of CO_2 the optimum flow rate for the Celgard 2500 membrane is seen at 62 ml/min (Fig. 4). The *y*-axis for Fig. 4 is the total absorbance minus the blank absorbance.

Five different membranes were tested for their suitability in the gas diffusion manifold. Two of the membranes were microporous Gore Tex (tetrafluoropolyethylene). The first had a 0.2 μm average pore size while the second had a 1.0 μm average pore size. Two Celgard membranes

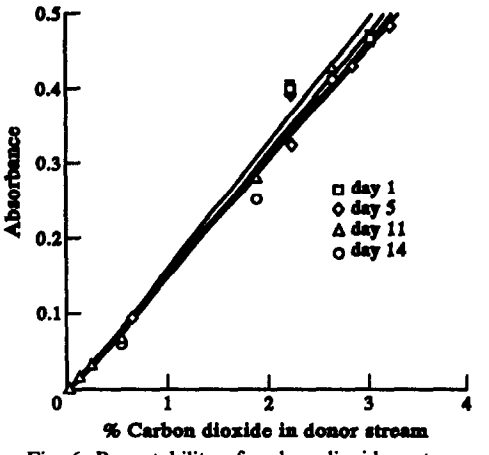

Fig. 6. Repeatability of carbon dioxide system.

(polypropylene) were tested with pore sizes of 0.5 μm and 0.75 μm. A 1 mil thick silicone rubber membrane was also tested. Each membrane was tested using the 5% CO_2/95% N_2 gas donor stream which was held constant at 40 ml/min. A scrim was not used to support any of the membranes because it resulted in the manifold leaking. A comparison of the response for each membrane is shown in Fig. 5. Due to the relation of gas permeability and pore size, the 1.0 μm pore size Gore Tex membrane has the greatest response.

However, due to the mechanical stress on the membrane from the pressure changes occurring during the stop and start of flow, the 1.0 μm Gore Tex was unable to last for more than 4 hr (420–480 determinations) before tearing. The Celgard membrane was much more durable and lasted for weeks without significant loss of performance as shown in Fig. 6.

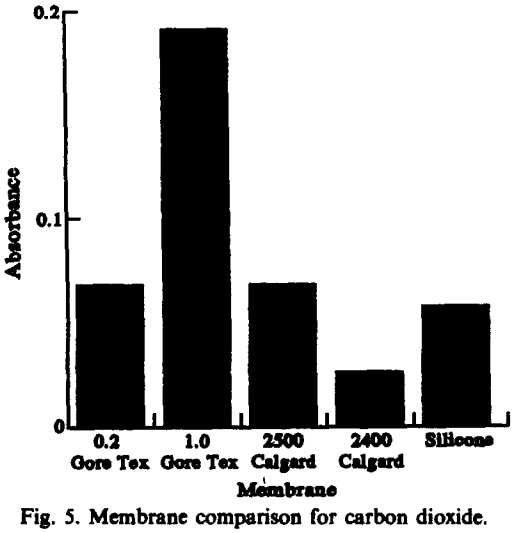

Fig. 5. Membrane comparison for carbon dioxide.

In liquid–liquid GDFIA, the typical efficiency of the membrane without a stopped-flow period where the gaseous analyte is consumed is between 8 and 15%.[4] This represents the amount of analyte which crosses the membrane and can be detected in relation to the amount of analyte in the donor stream. For liquid–gas GDFIA the efficiency increases to around 12–30%.

The efficiency for the Celgard 2500 membrane in the gas–liquid FIA system was 30.6%. The efficiency was determined by calculating the amount of CO_2 necessary to change the pH of the acceptor solution. The pH of the acceptor solution was measured before and after exposure to a known amount of CO_2. The absorbance of the solution was also measured before and after exposure to CO_2. The change in absorbance was correlated to the change in pH. Then when a sample was run using FIA, the change in absorbance could be related to a change in pH. The amount of CO_2 required to change the pH of the acceptor stream was calculated. The amount of CO_2 determined to have crossed the membrane was then divided by the amount of CO_2 available on the donor side of the membrane.

The linear range in this system is dependent on the concentration of the buffer in the acceptor stream. For the determination of membrane efficiency, detection limit and linear range the carbonate buffer concentration was 1 mM, adjusted to pH 8.85. Using this buffer system, with $5 \times 10^{-5}M$ cresol red indicator, the linear range was 6.7–197 g/m^3 of CO_2. The limit of detection (LOD) defined as the intercept divided

by the slope times three was 2.0 g/m^3. Due to the limited precision of the CO_2 dilution system, the LOD of this system is difficult to determine for buffer concentrations lower than 1 mM. In a related experiment, with varying buffer concentrations, a stream of 5% CO_2/95% N_2 caused all solutions with a buffer concentration below 0.75 mM carbonate to form the acid color of the indicator from the amount of CO_2 continuously moving across the membrane. This occurred at flow rates as low as 10 ml/min. With a membrane efficiency of 30% and with the 1 mM carbonate buffer system used in these experiments, the calculated minimum amount of CO_2 which would be detectable in the donor stream is 3 ppt v/v.

The stability of the membrane was investigated by running a series of standard curves over a two week period, totalling more than 1000 injections. The data collected from these trials show that the method is consistent over the time period investigated, as seen in Fig. 6. No significant deterioration of the membrane was seen and the sensitivity does not vary by more than $\pm 2\%$. In Table 1, the slope, intercept, and correlation coefficient for each calibration curve are presented. The average slope was 0.152 ± 0.003. The average intercept was -0.003 ± 0.001.

At this point it was believed that reverse dual phase gas diffusion FIA is a viable technique for the analysis of gaseous samples. The applications of this technique are potentially significant. This particular technique for determination of CO_2 may find application for real time monitoring of CO_2 because CO_2 will readily cross the membrane if the flow rate and manifold pressure are high enough. If CO_2 concentrations are higher than 5% of the total volume, for example in fermentation reactors, the carbonate buffer concentration can be increased to establish a linear range which would accommodate the amount of CO_2 present.

One of the objectives of this research was to develop the reverse dual phase GDFIA system so it could be applied to hydrazine analysis. One of the findings has been that the flow rate of the donor stream is the single largest factor involved in the transport of analyte across the membrane. This information will be very valuable for future work.

The choice of method for the hydrazine determination was based on previous work performed in this laboratory.[6] Earlier, a search of the literature on gas sampling techniques lead to vapor detection tubes for hydrazine with a linear range was 0.3–2.5 ppm.[1] The tube used bromphenol blue and acid as the indicator reagent. Using this preliminary information, the BPB chemistry was investigated as a possible alternative to standard dimethylaminobenzaldehyde method.

In order to determine the optimum preconcentration time and flow rate of the sample, both factors were varied to determine the optimum results. The results are shown in Figs 7 and 8, respectively. At a 200 ml/min flow rate used in Fig. 7, 20 min was chosen as the amount of time required for sample preconcentration. The minimum necessary flow rate of the sample stream was 180 ml/min as seen in Fig. 8. The y-axis of Fig. 8 is the total absorbance minus any blank absorbance. The flow rate used in the rest of the experiments was 225 ml/min.

Several different membranes were tested to determine the most suitable membrane for

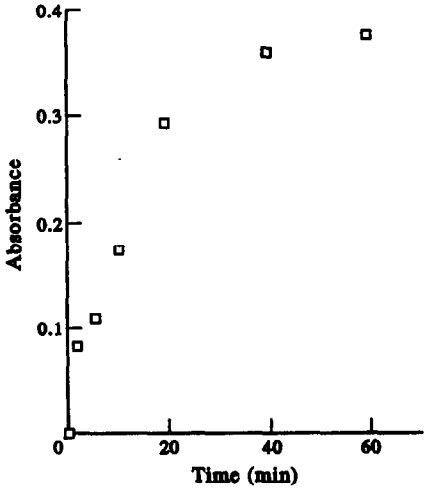

Fig. 7. Optimum flow rate for hydrazine system.

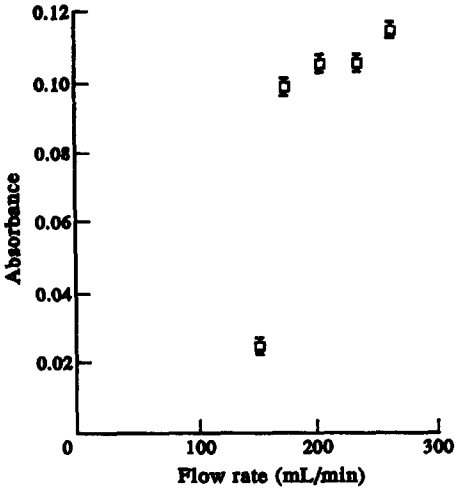

Fig. 8. Optimum preconcentration time.

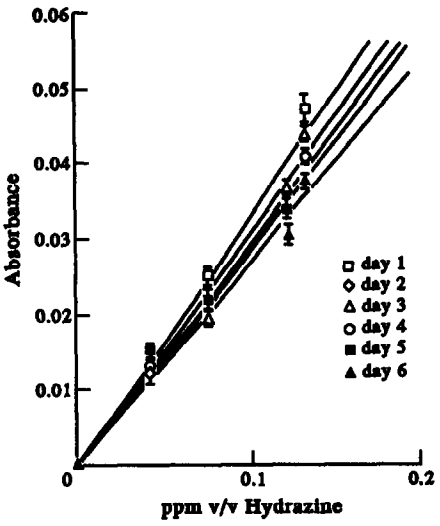

Fig. 10. Repeatability of BPB hydrazine system.

hydrazine transfer. The relative response of different membranes is shown in Fig. 9. The Celgard 2500 membrane is the most suitable in terms of response and durability.

In Chapter 3 the membrane efficiency for the CO_2 system was 31%. In the hydrazine–BPB system, the membrane efficiency was 17.4%. This efficiency was determined by calculating the concentration of hydrazine necessary to cause a pH change corresponding to 0.100 absorbance units. With that information and knowing the concentration of the gaseous hydrazine sample stream, the efficiency can be calculated by dividing the amount of hydrazine determined to be in the acceptor stream by the amount of hydrazine available.

The linear range of the BPB system is 0.035–0.140 ppm v/v hydrazine. The detection limit, defined as three times the signal-to-noise, is 0.010 ppm v/v hydrazine. The equation for the curve is $y = -1.076 \times 10^{-4} + 0.3163x$, and $R = 0.9997$. With the gas dilution system used in this research, the detection limit of 0.010 ppm v/v is the more realistic value for the system being investigated. The membrane in the hydrazine system did not last as long as the membrane in the CO_2 system. Hydrazine is more reactive than CO_2 and subsequently is more likely to react with or adsorb to the membrane. Daily calibration runs showed that the sensitivity decreased steadily over six days. The daily calibration runs are show in Fig. 10. The daily slope, intercept and correlation coefficient are shown in Table 2. The membrane degraded steadily over the six day period. A diffusion vial from VICI Metronics (Santa Clara, CA) was put in the flow diagram in place of the hydrazine source. The potential interferants were put in the diffusion vial separately to determine the impact of each one. The interference from monomethylhydrazine (MMH), 1,1-dimethylhydrazine (UDMH), and ammonia are shown in Table 3. The interference from carbon dioxide is negligible. Because the pK_{a1} for carbonic

acid is around 6, the impact of carbonic acid dissociation is minimal. Carbon dioxide in the atmosphere is present at about 210 ppm v/v.[7]

CONCLUSION

The goal of this work was to be able to reach a detection limit which would be low enough to meet the 8 hr time weighted average level set out by the National Institute of Occupational Safety and Health (NIOSH).[8] This research has been successful in several ways. First, the detection limit is 0.010 ppm v/v of hydrazine. This limit of detection is 10 times lower than the TLV of 0.1 ppm v/v. The method gives a response every 10 min. This is much more attractive than an accumulator type of device which cannot give information about hydrazine levels at specific times during the 8 hr period. The method is very simple.

(*Received* 5 *January* 1993. *Revised* 15 *March* 1993. *Accepted* 18 *March* 1993)

Summary—A simple and flexible time-based injector is described for the introduction of almost any desirable volume of sample and reagents in flow systems. The feasibility of application is demonstrated by improving the azomethine-H spectrophotometric method for the precise and accurate determination of boron in soil and coffee plant tissues. On-line programmed functions include: sequential injections and zone trapping, with a significant reduction of sample and reagent consumption.

Flow injection analysis (FIA) is by definition the insertion of a defined and reproducible volume of the sample into a carrier stream.[1] Instead of insertion or intercalation, the term injection is now understood and used under a broad sense of reproducible introduction of a well-defined zone of fluid into a carrier stream, quite regardless of the means of introduction.[2] Conceptually, the means of injection, and devices designed for this purpose can be divided into two categories: (1) volume-based injectors; and (2) time-based injectors, or a combination thereof,[3] which are reviewed elsewhere.[1,3,4] Since the proposal of FIA,[5] the sample introduction devices have evolved from simple dispositives with one syringe operated manually, to microcomputer controlled rotary[4] and solenoid valves.[6–8] An electronically operated time-based injector, using a two-way solenoid valve is presented here. It permits the reproducible and sequential introduction of variable volumes of sample and reagents into flowing systems with zone trapping and with a significant reduction in their consumption. Although, a large number of analytical methods have been employed for determining boron in water, soil and plant material samples,[9–11] the spectrophotometric method using azomethine-H–boron complex has been selected for its simplicity, sensitivity and speed.[12] The procedure does not involve concentrated acid, which makes it readily suitable for automated routine operation.

EXPERIMENTAL

Apparatus

A schematic diagram of the flow system is given in Fig. 1. Determinations were performed with a Varian 634 spectrometer with a home-made flow through cell of quartz of 1.0 mm i.d., 2 cm length and 30 μl capacity. The system also included a Gilson Minipuls 2 peristaltic pump, a home-made time-based injector (see below),

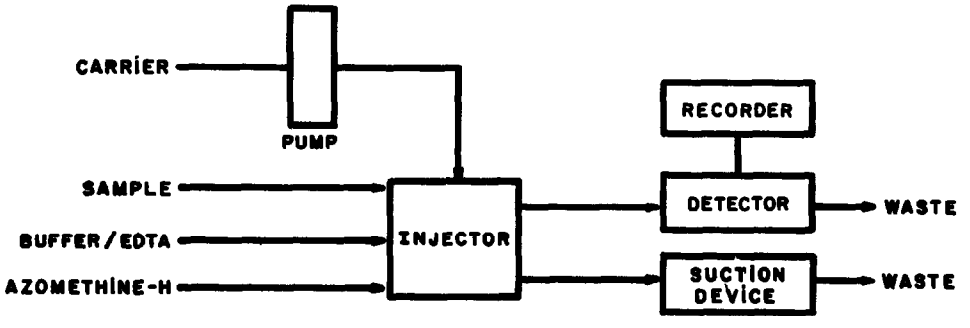

Fig. 1. Schematic diagram of the flow system.

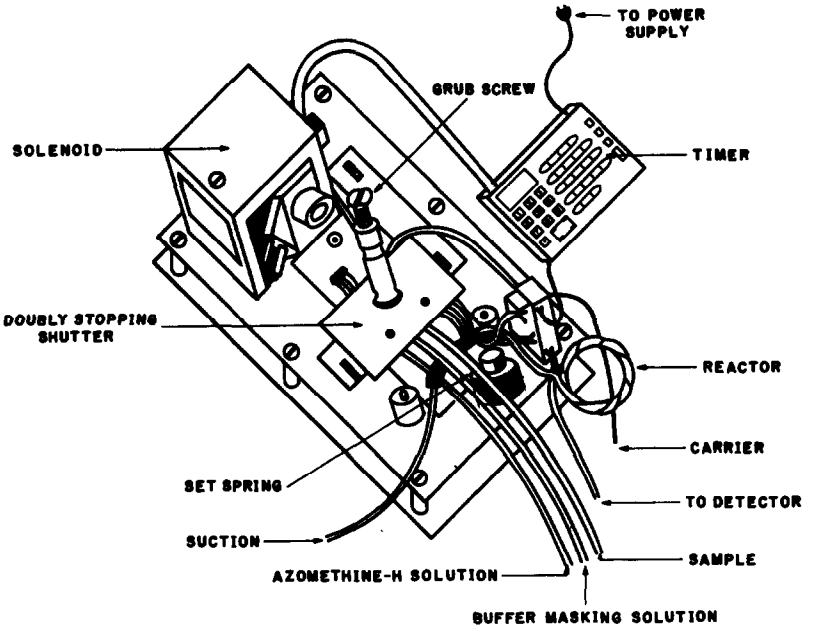

Fig. 2. Diagram of the time-based injector. The grub screw controls the doubly stopping shutter.

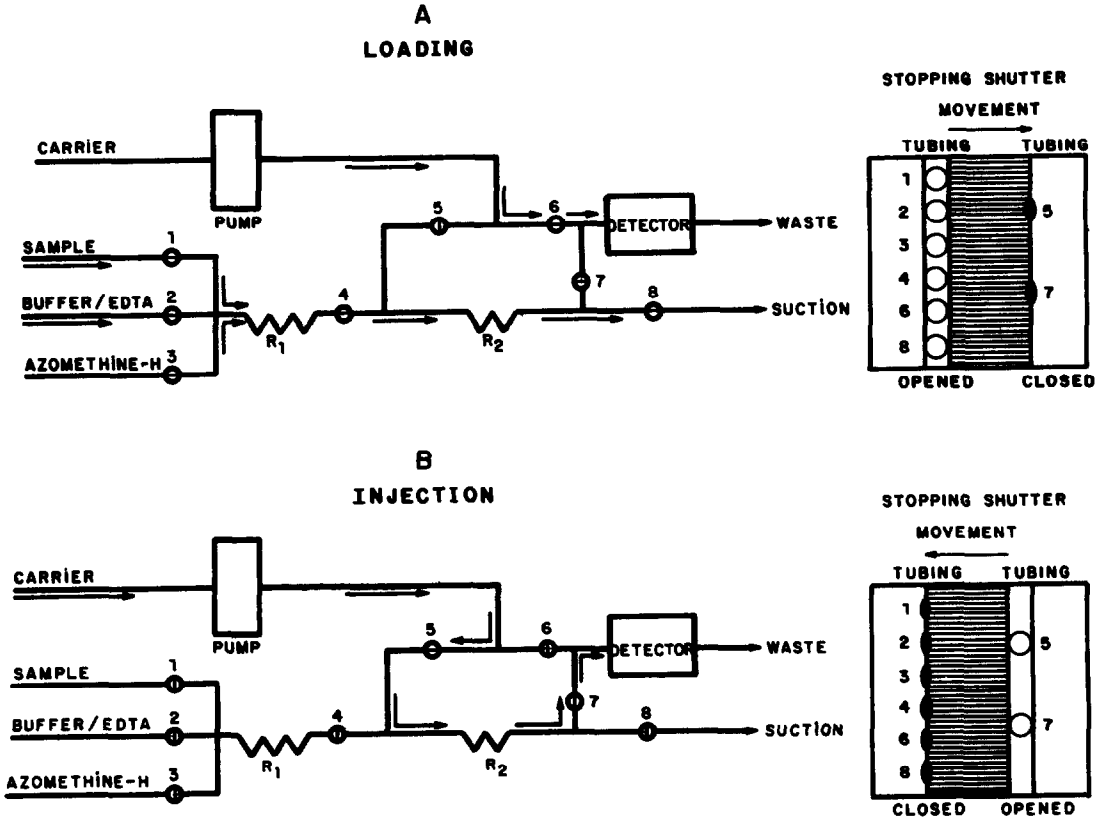

Fig. 3. Operating principle of the configuration designed for the determination of boron by the azomethine–H spectrophotometric method. R_1, reactor; R_2, connecting line to the detector. Each number correspond to a given tubing as indicated in both figures.

a Cole–Parmer 156 recorder and a suction air-pressurized device, 0.8 mm i.d. Tygon tubing was used throughout, unless otherwise stated.

The suction air-pressurized device consists of a bottle with a pressure regulator up to 40 cm Hg and a Iwaki AP-115 air pump which produces the suction pressure. The time-based injector (Fig. 2) consists of a Gralab 900 timer which permitted to dispense electronically controlled pulses to the solenoid valve. In this way, a doubly stopping shutter either closed or opened (by pressing or releasing) any selected set of tubing at a fixed time, thus allowing sequestration of sample and/or reagents and sequential injection.

For the present work the flow system and setup shown in Fig. 3 was used. In the loading position (Fig. 3a) the sample and buffer/masking and azomethine–H reagents are drawn through different sampling loops, confluence at point "a", mix inside R_1 and R_2. When the solenoid valve is switched to the alternate position (injection cycle), aliquots of the trapped sample/reagents mixture in R_2 are intercalated in the carrier stream and therefore directed to the analytical path (Fig. 3b), allowing the detector to quantify the formation of the coloured species. The absorbance, which is proportional to the boron content in the sample, constitutes the basis of the measurements. When the solenoid valve is operated back to the loading position aliquots of the sample/reagent mixture fill a given section of R_2, which are also intercalated at will in the carrier stream. The alternation of both solenoid positions allows the repetitive and reproducible intercalation of sample/reagent mixture plugs in the carrier stream.

Reagents

Unless stated otherwise, all solutions were prepared from analytical-reagent grade chemicals and kept in polyethylene flasks. Deionized, distilled water was used throughout. A stock boron solution (1.000 g/l.) was prepared by dissolving 5.716 g of boric acid in water and diluting to 1 l. Working solutions of boron were prepared by suitable dilution with 0.1*M* hydrochloric acid. The derivatizing reagent was prepared by dissolving 0.25 g of azomethine–H (Sigma) in 25 ml of water and kept at 4° in a refrigerator (where it remains stable for at least 1 week). A buffer/masking solution was prepared by dissolving 115 g of ammonium dihydrogen phosphate (2*M*), 132 g of diammonium hydrogen phosphate and 25 g of EDTA in water to give 500 ml of solution; the final pH of this solution was 6.8.

Sample preparation

Tissue samples were dried in an oven at 70° for 3 days, ground and ashed in covered porcelain crucibles at 500° for 2 hr. Ashes were taken up in 10 ml of 0.1*M* hydrochloric acid and filtered through Whatman No. 40 filter paper, and finally diluted to 25 ml with 0.1*M* hydrochloric acid.

The soils were selected from the root of each coffee tree. The samples were air dried for 5 days and crushed to pass through an 80 mesh sieve. Ten-gram soil samples were transferred to a 150-ml boron-free round bottom flask. Then 50 ml of water were added and the flask was attached to a reflux condenser and boiled for 10 min. After cooling, 0.05 g of calcium chloride dihydrite were added and the mixture was filtered through Whatman No. 2 filter paper. Twenty-five millilitres of the solution were transferred to a covered porcelain crucible, and after the addition of 2 ml of a saturated calcium hydroxide solution, evaporated to dryness, ignited gently to destroy nitrates and organic matter, cooled, taken up in 10 ml of 0.1*M* hydrochloric acid, filtered through Whatman No. 40 filter paper, and finally diluted to 25 ml with 0.1*M* hydrochloric acid.

Procedure

All reagents were fed through their respective lines at room temperature. Polyethylene sample cups were used to avoid possible boron contamination from glass containers. The operating conditions chosen were optimized to produce the highest and most reproducible signals (Table 1). After sequentially activating the solenoid valve to complete the loading and injection cycles, the absorbance signals were monitored at 420 nm. When the analyses of each sample was completed, the system was cleaned by circulating 0.1*M* hydrochloric acid solution through the sample line for at least 30 sec. A calibration curve was obtained by using the absorbance readings for each standard concentrations. The recorder signals were evaluated as well in order to control more strictly the dispersion processes. The boron concentration of each sample was determined by reference to this analytical curve. The carrier solution was pumped continuously throughout the process to ensure a stable baseline. In this work, the blank

Table 1. Optimized operating conditions for the determination of boron by the azomethine-H spectrophotometric method using a multipurpose time-based injector for flow injection systems

Component	Parameter	Value
Spectrophotometry	Wavelength	420 nm
	Slit width	2 nm
Chemical	pH of buffer/masking solution	6.8
	Ammonium–phosphate buffer concentration	2*M*
	Azomethine-H concentration	1% (w/v)
Injector	Time of sample/reagents entrapment	2 min
	Time of loading	
	Time of injection	2 sec
	Buffer/masking, azomethine-H and sample solutions mixing ratio	1:1:3
	Suction pressure	34 cm Hg
	Length of reactor R_1	1 m
FIA	Length of connecting tube R_2	47 cm
	Carrier flow rate	5.5 ml/min
	Volume of sample (90 μl), buffer/masking (30 μl) and azomethine-H (30 μl) mixture solution	150 μl

was always substracted from the signal by performing measurements with and without any boron content in the sample solution.

RESULTS AND DISCUSSION

In the injector under study, only the trapped portion of the sample zone inside R_2 is intercalated in the carrier stream, whereas selected portions of the sample zone inside R_1 is used for further measurements. The instrumental parameters used were: 420 nm wavelength and 2 nm spectral slit width.

A systematic investigation was necessary in order to establish the optimum experimental conditions. Various chemical and instrumental operating parameters were varied individually while the others were kept constant, and were optimized with respect to absorbance measurements. Although the calibration graph was essentially linear up to 80 mg/l. (see below), for practical reasons, in all cases, the boron concentration used for optimization studies was within the working range (from 0.5 to 6 mg/l.). Initial studies were carried out to determine the influence of the injector solenoid activation time and suction pressure of sample and reagents on sample volume and its reproducibility. The sample volume was assessed by a procedure similar to that used earlier,[6] by the differences in weight over cycles of 50 injections. Almost any desirable injection volume can be injected by increasing the solenoid activation time (Figs 4a, b) and the pressure of aspiration or suction of sample and reagents (Figs 4c, d). However, the sample volume cannot be increased at will

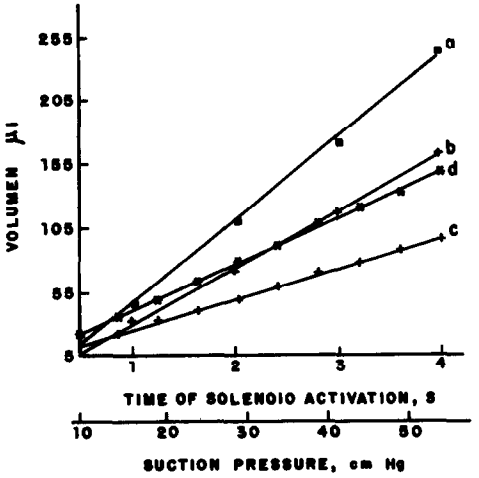

Fig. 4. Effect of solenoid activation time (a, 1 sec; b, 2 sec) and of suction pressure (c, 34 cm Hg; d, 54 cm Hg) on sample volume.

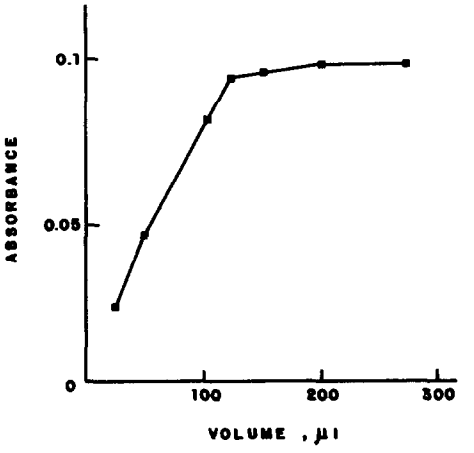

Fig. 5. Effect of sample/azomethine-H/buffer mixture volume on absorbance. 5 mg B/l. Other conditions are as specified in Table 1.

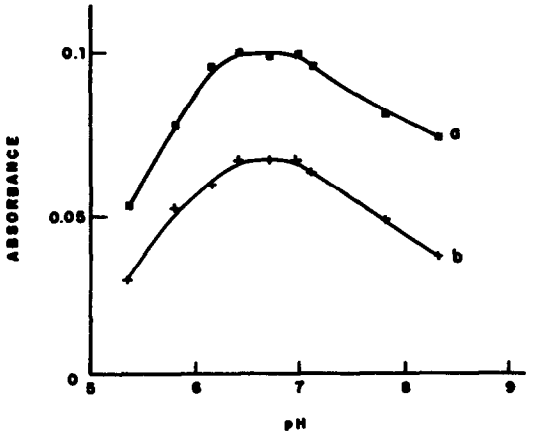

Fig. 6. Effect of pH on absorbance. (a) 5 and (b) 3 mg B/l. Other conditions are as specified in Table 1.

(Fig. 5), over 250 μl, the precision deteriorated, the relative standard deviation (r.s.d.) being usually increased from 0.7 to about 4.5% for 500 μl sample volumes (10 measurement series). This drop in reproducibility at higher injected volumes is probably due to either a large reduction of the suction pressure or to limitations of the injector internal bore diameter (0.8 mm). It should be reported that day-to-day measurements of sample volume in function of pressure of aspiration varied considerably from one day to another (up to 7% r.s.d.); therefore, it was preferred to vary the solenoid activation time in order to fix a given volume.

The color of the azomethine–H–boron complex is highly pH sensitive,[12] specially in the 6.4–7.0 range (Fig. 6). As the pH difference between buffer and the solution within the FIA manifold may vary, strict pH control is necessary during the course of the measurement in order to maintain the color development reproducible, constant and sensitive. A high ammonium–phosphate buffer concentration (2*M*) has several advantages. It has a high buffering capacity at the required pH 6.8, as the pH between buffer and the solution sent to waste was found to decrease only to 6.6, the absorbance decreased at pH below 6.4 and above 7.0. Also, this buffer is not corrosive and the preparation is simple, without creating offensive fumes.

The influence of the azomethine–H concentration ranging from 0.5 to 1.75% (w/v) was investigated. Figure 7 shows that the absorbance values increase with an increase in the concentration of azomethine–H. The absorbance markedly decreased at concentrations below 1.0%, and the increments are small at values above this concentration. Considering that high concentrations of azomethine–H will cause larger reagent blanks and also the reagent cost factor, its concentration was fixed at 1.0%.

Absorbance grows slowly, as the time of the reaction involved, discussed elsewhere,[13,14] proceed inside R_1 after the loading cycle, and as the boron content in the sample increases (Fig. 8). The boron concentration affects the time of increasing formation of the coloured condensation species. The decreased signals obtained during the first minutes were due to insufficient development of the chemical reaction, and it seems that they do not appreciably increase above 3 min. Times of 2–3 min after the loading cycle seem to be a good compromise between good sensitivity, sampling frequency and the formation of the coloured species. After this time, the injection cycle proceeds and then

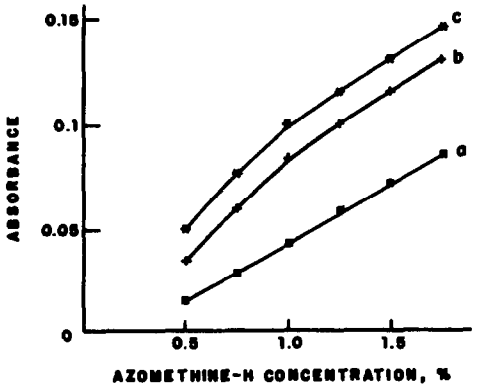

Fig. 7. Effect of azomethine–H concentration. a, reagent blank; b, with 4 mg/l boron; c, with 5 mg/l. boron. Other conditions are as specified in Table 1.

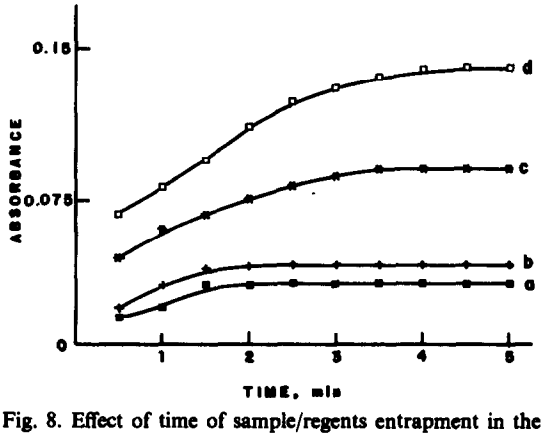

Fig. 8. Effect of time of sample/regents entrapment in the reaction coil and of boron concentration on absorbance. a–d indicate 15, 20, 50 and 80 mg B/l. Other conditions as specified in Table 1.

aliquots of sample are sequentially delivered at a rate of about 6 min.

Initially, the tubing diameter of sample and reagents was kept at 0.5 mm i.d., which allowed the mixing of equal volumes of the solutions during the loading cycle in R_1. By varying the tubing diameter, the flow-rate ratio of the solutions and therefore their mixed volumes in R_1 were different. For buffer/masking, azomethine–H and sample solutions flow-rate ratios of 2:2:1, 1:1:1, 2:1:2, 1:2:2 and 1:1:3 the absorbance values were of 0.020, 0.035, 0.041, 0.043 and 0.050, respectively. The results obtained by the 1:1:3 mixed volume ratio were just as reproducible and more sensitive by 43% than those obtained with the 1:1:1 mixed volume ratio. The various absorbance values obtained are related to the different sample-reagents mixing ratios and therefore to different sample dispersion patterns within this trapping zone tubing, whose i.d. was always kept at 0.8 mm.

In order to study the effect of the matrix on absorbance, standard addition graphs for fruit, leaves and soil digested samples were prepared by adding various amounts of boron (from 2 to 8 mg/l.). When no masking agent was used the sensitivities of the analytical graphs obtained were approximately the same from that obtained with the aqueous standard solution. This suggested that the proposed procedure is slightly affected by interfering species.[15–17] Although the full composition of the samples under study is not known, the addition of EDTA in the buffer solution was found to minimize the effect of matrix interferents, as the slope of standard additions graph in the presence of EDTA were not significantly different (difference between slopes <3%) from those obtained with the boron standard (0% digested sample).

On the bases of these observations, appropriate conditions for flow injection were examined. In this system, the response increased linearly up to 150 μl of injected volumes of mixed solutions in R_2, however, the injection of larger volumes produced only slight effect on the response because it surpasses the physical volume of the flow-through cell. Therefore, an injected volume of 150 μl was found to be the optimum. The effect of the reaction tube (R_1) length, was investigated. The length of this tube was found not to be critical due to the characteristics of the flow system used, where the entrapment of the sample/reagent mixture occurs in order to increase the formation of the coloured species. The effect of the dispersion tube (R_2) on absorbance was examined for various coil lengths between 47 and 225 cm. The absorbance decreased with increasing coil length owing to dispersion (Fig. 9), the instrumentation did not allowed the use of coil length below 47 cm.

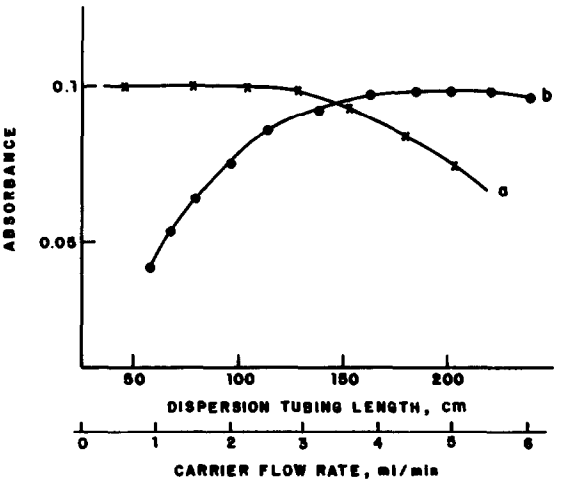

Fig. 9. Effect of the (a) tubing length connecting the injector–detector section and (b) carrier flow rate on absorbance. 5 mg B/l. Other conditions are as specified in Table 1.

Different flow-rates of the carrier solution were tested by changing the pumping rate. The sensitivity increased with increasing flow-rate until an almost steady-state signal was obtained in the range 4.0–5.5 ml/min, thereafter a slight decrease over 5.5 ml/min was observed (Fig. 9).

The calibration graph was prepared using the spectrometer, chemical and flow injection conditions given in Table 1. The maximum peak height increased linearly with element concentration as expressed by the equation $A_B = 0.016 + 0.017C_B$, $r = 0.9996$, where A represents absorbance and C_B (0.1–80 mg/l.) represents the boron concentration. This calibration graph was essentially linear up to 80 mg/l. of boron and thereafter starts to deviate to almost invariable values over 120 mg/l. due to the absorbance of the azomethine–H reagent.[12,15] However, for practical reasons, working calibration graphs were prepared daily in the concentration range from 0.1 to 6 mg/l. The detection limit was evaluated by calculating the mean standard deviation of eight sets of replica blank determinations. The detection limit considered as the amount of boron which gives an absorbance value correspondent to three times the standard deviation of the blank signal was found to be of 4.5 ng (0.05 mg/l.).

Table 2. Boron as determined by the proposed azomethine–H procedure using the time-based injector for flow injection systems compared with the manual curcumin method ($n = 10$)

Sample	Boron content* ($\mu g/g$)	
	This work	Manual curcumin method
Coffee-tree leaves	116.2 ± 7.8	114.4 ± 9.2
Coffee fruits	45.3 ± 5.0	44.0 ± 6.7
Soil	28.5 ± 4.4	27.4 ± 5.2

*Mean ± S.D.

The FIA manifold under evaluation is remarkably stable: after 6 hr of continuous operation, only minor changes in the sample and reagent volumes injected (usually less than 3%) and in the coefficients of the calibration equation (usually less than 5%) were detected. From successive measurements of typical samples the standard deviation of the absorbance signals were typically below 1%, whereas from measurements of five different portions of the various digests of soil and plant tissues, were calculated as 1.2, 1.5 and 2.8, respectively.

To check the accuracy of the method, five pooled specimens of the samples under evaluation were also analysed by the conventional manual curcumin spectrophotometric method.[16] The results given in Table 2 show a good agreement with the present results, which is an indication that the accuracy of the proposed method is satisfactory. The accuracy was further checked by recovery tests. Recovery of boron was checked by the addition of μl-aliquots of boron standard solution to five samples before the digestion process. The recoveries of 2, 4 and 6 μg B/g added were between 98.0 and 101.7% (for leaf tissue), 96.5 and 99.2% (for fruit tissue) and 96.0 and 98.5 (for soil).

Various plant tissues and soil samples ($n = 20$) were analysed in the proposed FIA system. The boron contents varied from 109.4 to 125 μg/g (mean ± S.D. = 116.2 ± 6.2 μg/g) for coffee-tree leaves, from 38.5 to 49.8 μg/g (mean ± S.D. = 43.9 ± 4.0 μg/g) for coffee fruits and from 22.4 to 34.6 μg/g (mean ± S.D. = 27.8 ± 3.8 μg/g) for soils. The soils analysed were from coffee plantations located in Santa Cruz (Mérida State, Venezuela) areas, and contained boron concentrations in the range typical for most soils reported in the literature.[12,17,18] The values reported in this study for coffee-tree leaves for boron tend to be higher than those values reported for orange-tree leaves, tobacco leaves,[14] non-edible plant leaves,[12,19] some fruits, vegetables and grains,[17] but are lower with those reported for edible leaves[20] and citrus limonum.[17] Our values of boron for coffee fruit are in close agreement with those previously reported for different edible seeds and fruits[15] in the same range as those reported for legumes,[17,21] but higher than those reported for some fruits, vegetables and cereal grains.[17]

The FIA injector described here allows the injection or intercalation of reproducible variable volumes into flowing systems, mixing of different solutions at different ratios on-line and entrapment of sample/reagents mixture. As the sample and reagents are not consumed during the stoppage of the sample zone, the system utilizes sample, azomethine–H and buffer/masking solutions of 90, 30 and 30 μl, respectively, per measurement (Table 1), which are considerably less than those consumed in previously reported in-batch[14] and automatic methods.[9,10,12,15] A measurement rate (*ca.* 200 measurements/hr) is readily achieved. However, the sampling rate will depend on the characteristics of the chemistry involved in the procedure. The FIA system provides precise, and accurate results for the determination of boron in soils and plant tissues using the selected azomethine–H spectrophotometric method.

(*Received* 12 *April* 1993. *Accepted* 12 *June* 1993)

Summary—Microamounts of Pt(II/IV) (0.25–800 μg/ml) and Pd(II) (5–600 μg/ml) in >0.5 *M* hydrochloric acid can readily be determined by means of a simple FIA method based on the selective reaction of tin(II)chloride with these metals. The FIA method has a high linear dynamic range, and is relatively free from interferences of many transition metals, with the exception of Au and Rh; small amounts of other PGMs can be tolerated. Determination of Pt on a hydrogenation catalyst by this method compares well with that found by flame atomic absorption spectroscopy. By monitoring at two or more wavelengths, Pt and Pd can be determined in mixtures by this means, to yield a simple, cost-effective FIA method for possible on-line determinations and quality control of, in particular, Pt containing acidic refinery and other process streams.

The platinum group metals (PGMs), widely used in many important chemical processes as efficient catalysts, are of importance in the electronics industry, while the significance of, particularly, Pt is growing in cancer chemotherapy.[1] The control of automobile exhaust-gas emissions using Pt and Rh rich catalytic converters is currently utilizing the largest share of the world production of these metals,[2] while use in this application is set to grow substantially in the next decade as ever more stringent exhaust emission standards are being introduced by legislation in the developed world.[3] Against this background, the need for the rapid and accurate determination of the PGMs in process and quality control is obvious. A recent survey of methods for the determination of these metals attests their importance, and shows that overall the predominant analytical methods in use are based on atomic absorption and/or emission spectroscopy.[4] While the power of such instrumental methods is indesputable, these methods are usually laboratory based, rather expensive and not readily suited for automation and on-line analysis. The development of the family of flow-injection based techniques has recently been reviewed,[5] and it is clear that such methods offer many advantages in the performance of process control and on-line analysis. Surprisingly however, a survey of the literature reveals only very few flow-injection analysis (FIA) based determinations of the PGMs, although recent reports of the determination of Pd[6–8] and Pt[9] by FIA methods suggest a growing interest in this area.

In this paper we report the first part of the development of a simple, cost effective method for the determination of the potentially simultaneous photometric determination of Pt(II/IV) and Pd(II) in hydrochloric acid solution by means of FIA. Our method is based on the long known,[10] but until recently poorly understood[11,12] reaction of tin(II)halides with Pt(II/IV) and Pd(II) in aqueous acid solution. This reaction formed the basis of a highly selective batchwise spectrophotometric determination of Pt(II/IV) some four decades ago.[12–15] In the batchmode however, the latter method suffers from substantial disadvantages, principally the need for accurate timing, careful control of reaction conditions and working under anaerobic atmospheres, so that often erratic results are obtained. We have found that this chemistry is ideally suited for the flow-injection determination of Pt and Pd, making it possible to exploit the high selectivity of the reaction of tin(II)chloride with these metals in hydrochloric acid solution.

*Author for correspondence.

EXPERIMENTAL

Apparatus

A single line FIA manifold using 0.8 mm ID PTFE tubing, equipped with a Spetec Perimax 12 four channel pump and a Rheodyne 5020 6-port PTFE rotary injection valve with a 180 μl sample loop, was used for preliminary experiments. Commercially available Omnifit PTFE/PEEK connectors and mixing tees, and reaction coils of variable lengths were coiled around a fixed 15 mm diameter plastic rod. A 2 mm path length U-shaped quartz flow cell and a Varian Superscan-3 UV/visible spectrophotometer operation in fixed wavelength absorbance mode with the abscissa in a time drive configuration served as a detector. For determinations of trace amounts of Pt (<5 μg/ml) a modified computer controlled manifold consisting of a carrier (1 *M* HCl) and reagent stream ($SnCl_2$) merged into a single line with a mixing tee after the sample injection valve, was found to be advantageous (Fig. 1).

Materials and methods

All solutions were prepared with glass distilled water and concentrated Analar grade HCl, using glassware previously soaked in nitric acid. Stock solutions containing 1000 μg/ml each of Pt(II) and Pd(II) were prepared from K_2PtCl_4 and K_2PdCl_4 obtained from Johnson Matthey, the salts being used without further purification.

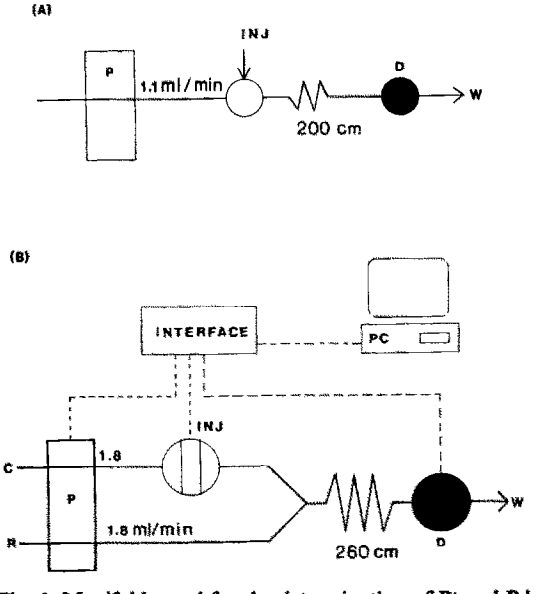

Fig. 1. Manifolds used for the determination of Pt and Pd: (A) carrier 0.1 *M* $SnCl_2$, 1.0 *M* HCl (B) carrier 1.0 *M* HCl, reagent 0.3 *M* $SnCl_2$.

A 1000 μg/ml BDH atomic absorption standard solution served as independent calibrant and source of Pt(IV) solution. Tin(II)chloride solutions were prepared from Analar grade $SnCl_2.2H_2O$, by dissolving the desired amount of salt in the required amount of conc. HCl and allowing the initially cloudy solution to stand for 15–20 min in a warm water bath until completely clear, followed by dilution to volume with water. These solutions were standardized by titration with potassium iodate, after which a few small pieces of metallic tin were added to the tin(II)chloride solution to preserve them from oxidation by atmospheric oxygen. It should be noted that the hydrochloric acid concentration of these tin(II)chloride solutions should be kept above 0.5 *M* to prevent hydrolysis of the stannous chloride. Platinum solutions were standardized where necessary by means of flame atomic absorption spectroscopy using a Varian Techtron 1000 AAS with a strongly oxidizing air–acetylene flame at 265.9 nm, slit width 0.2 nm and 10 mA lamp current. All Pt containing solutions were made up to contain 0.2(w/v)% La^{3+} (with $La(NO_3)_3.6H_2O$) as interference suppressant.

RESULTS AND DISCUSSION

Determination of platinum

The reaction between $SnCl_2$ and $PtCl_4^{2-}$ or $PtCl_6^{2-}$ in >0.5 *M* hydrochloric acid solutions rapidly leads to the development of an intensely cherry red colour, the origin of which is now known to result from the rapid reduction of any Pt(IV) species,[16] followed by or concomitant with, complex formation of $PtCl_4^{2-}$ with the $SnCl_3^-$ species to yield a series of anionic $[Pt(SnCl_3)_nCl_{4-n}]^{2-}$ ($n = 1$–4) complexes, as well as the relatively stable $[Pt(SnCl_3)_5]^{3-}$ complex anion.[11,12] The latter complex has been characterized by X-ray crystallography in the solid state[17] and has been shown to predominate in aqueous HCl containing sufficient $SnCl_2$.[12,18] These solutions show characteristic UV/visible absorption spectra with absorption maxima at $\lambda = 310$ nm (molar absorptivity $\sim 3.95 \times 10^4$), 400 nm (absorptivity $\sim 7.8 \times 10^2$), and 475 nm (shoulder) as shown in Fig. 2. Although the overall rate of the complex formation is not accurately known, in the presence of excess $SnCl_2$, steady state is reached within a few minutes.

Preliminary experiments to establish optimum conditions for the determination of Pt by

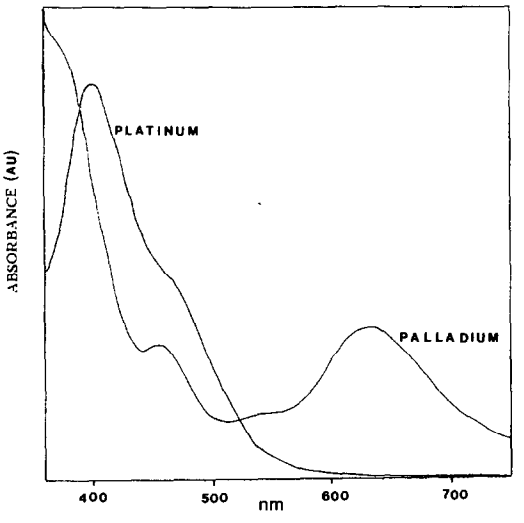

Fig. 2. Absorption spectra of Pt(IV) and Pd(II) in 1.0 *M* HCl containing excess $SnCl_2$ at steady state.

means of FIA were undertaken with a simple single line manifold equipped with a 2 m reaction coil and monitoring at 400 nm. Using a carrier stream with fixed $[SnCl_2] = 0.057$ *M*, the hydrochloric acid concentration was varied from 0.3 to 3.9 *M* and peak height monitored for separate injections containing 20 μg/ml Pt(IV) and Pt(II). Within experimental error there was no difference between the heights of the Pt(II) and Pt(IV) signals, confirming rapid reduction of the latter to Pt(II) followed by complex formation. The variable HCl concentration of the carrier stream does affect the peak height in a non-linear way, relatively higher values being obtained in the 0.3–0.8 *M* and >2.1 *M* HCl range, reaching a plateau in the 1.0–2.1 *M* range, where peak heights were effectively constant. We thus arbitrarily chose to fix the HCl concentration of the carrier stream at 1.0 *M* throughout; variations of ± 0.2 *M* do not significantly affect the peak heights other factors being equal.

The optimum $SnCl_2$ concentration was then found by varying its concentration in the carrier in the range 0.025–0.5 *M*. For the more concentrated solutions substantial viscosity differences between the carrier stream and sample injections result in undesirable effects, so that for this and for reasons of economy, the $SnCl_2$ concentration was kept as low as practical and set at 0.1 *M* $SnCl_2$ using the single line manifold. The flow rates and reaction coil lengths were also varied taking into account other variables, which led to a set of near optimum conditions: 1.0 *M* HCl, 0.1 *M* $SnCl_2$, flow rate 1.1 ml/min, reaction coil length 2 m and sample injection volume 180 μl. With these conditions 20 repeat injections of 20 μg/ml Pt(IV) gave highly reproducible peak heights (absorbance ~0.1 AU, RSD = 0.6%) and excellent day-to-day reproducibility (RSD < 1.1%), so that 30 injections per hr could comfortably be achieved with negligible carryover between successive high (100 μg/ml) and low (10 μg/ml) Pt(IV) injections.

With the above conditions, a rapid method for the determination of Pt(II/IV) obtains which has a high dynamic range, the analytical sensitivity of the response depending only on the selected wavelength. At $\lambda = 460$ nm completely linear calibration plots are obtained without dilution for a Pt(IV) range of 10–800 μg/ml, as shown in Fig. 3a. Such high dynamic ranges are generally not achievable in flame atomic absorption (FAAS) or atomic/plasma emission spectroscopic (AES/PES) methods without sample dilution.[4] High dynamic ranges can be a substantial advantage in methods designed for on-line applications which may have to deal with highly variable Pt(II/IV) concentrations. On the otherhand, using the single line manifold and monitoring at $\lambda = 400$ nm in the absence of interferents, Pt concentrations in the 1–200 μg/ml range can readily be determined. We found that the sensitivity of the determination could be further improved using a slightly modified two-line manifold with 1.0 *M* HCl as carrier stream into which the sample is injected followed by merging this zone with a 0.3 *M* $SnCl_2$ reagent stream prior to the detector (Fig. 1b). With this manifold monitoring at $\lambda = 400$ nm, the sensitivity of the determination

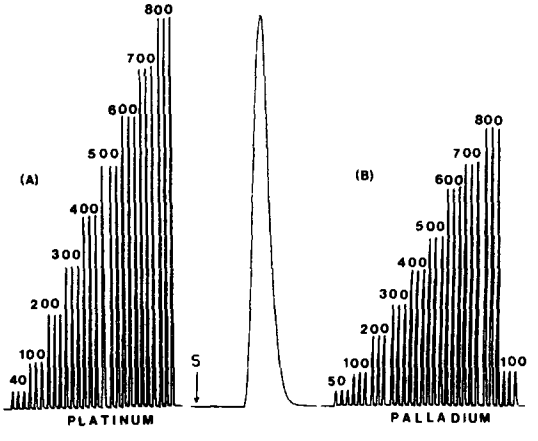

Fig. 3. Typical calibration data using a single-line manifold monitoring at 460 nm for (a) Pt(IV) and (b) Pd(II). Numerals refer to concentrations in μg/ml.

of Pt can be improved by a factor of 10 to cover the range of 0.1–2 μg/ml with a limit of quantification of *ca* 0.05 μg/ml. In principle by monitoring at $\lambda = 310$ nm, a further sensitivity improvement of between 2 and 4 times is possible, but some background effects complicate this and we are investigating ways of circumventing these.

A comparative study of the determination of Pt by the proposed FIA method and FAAS using a sample of hydrogenation catalyst of platinized asbestos yielded satisfactory agreement. Dissolution of the Pt using *aqua regia* followed by volatilization of excess HNO_3 with conc. HCl and suitable dilution yielded 12.0% (w/w) Pt as found by FIA compared to 12.2% (w/w) Pt obtained by FAAS for triplicate determinations.

Determination of palladium and platimum simultaneously

The reaction of $PdCl_4^{2-}$ with $SnCl_2$ is much more rapid and apparently more complicated than that with $PtCl_4^{2-}$, resulting in a series of rapid colour changes, from yellow–orange to red ($\lambda = 355,420$ nm) through blue and finally to green ($\lambda = 635$ nm). The origin of these changes is not well understood, although it has been established that several complex species are involved the nature of which depends on *inter alia* the Pd:Sn mole ratio and the HCl concentration.[19,20] Under conditions used in this work the $PdCl_4^{2-}$ reacts with the $SnCl_2$ to rapidly yield yellow–red species, which convert into an olive-green form, which is stable for *ca* 1 hr. Figure 2 shows the absorption spectrum of the Pd–Sn species at steady state. The latter form shows absorption maxima at $\lambda = 635$, 460 and 380 nm which approximately follow the Beer–Lambert law over a reasonable range of Pd concentrations (10–200 μg/ml). Since above 600 nm the absorption of any Pt–Sn species is negligible, it is possible to determine Pd(II) by monitoring at 635 nm with no interference from Pt(II/IV). On the other hand, since the Pd–Sn species also absorbs light in the 300–500 nm range, the presence of Pd(II) may constitute a serious interference in the determination of Pt by the proposed method and vice versa. However, in view of the absorbance of the Pd–Sn species at 635 nm, this apparent disadvantage may be used to determine Pt and Pd in the same solution by sequential injection of two identical samples and monitoring at the two wavelengths separately, so that from the peak height at 635 nm the Pd concentration may be estimated, which then allows the Pt concentration to be obtained from the peak height at 460 nm. Alternatively the use of a diode-array photometric detector will allow for rapid multiwavelength monitoring[21] over a range of wavelengths in the absorption spectrum, from which both Pt and Pd can in principle be determined simultaneously. We did not have access to such a detector at the time of undertaking this work and thus carried out simple sequential injections and manual monitoring at 460 and 635 nm in order to determine both Pt and Pd in HCl solutions using the single-line manifold.

Table 1. Recovery experiments for sequential determination of Pt and Pd in synthetic mixtures monitoring at 460 and 635, respectively using a single-line manifold (see text)

Taken ($\mu g/ml$)		Found ($\mu g/ml$)	
Pt	Pd	Pt	Pd
80.0	20.0	79.8	20.1
60.0	40.0	59.9	40.0
40.0	60.0	39.4	60.8
20.0	80.0	19.5	81.4
10.0	100.0	9.9	102.6

As may be seen from Fig. 3b, it is readily possible to determine only Pd(II) in the absence of Pt(II/IV) in an exactly analogous way to Pt(II/IV) using similar conditions, monitoring in the 400–500 nm range. (In this wavelength range the sensitivity for Pd is considerably higher than when monitoring at 635 nm.) Furthermore we found that the absorbance (peak height) of solutions containing mixtures of Pt–Sn and Pd–Sn species are additive at selected wavelengths within the concentration ranges studied in this paper, so that for solutions known to contain both metals, two sequential injections of the same sample, monitoring at 460 and 635 nm allows the determination of both Pt and Pd, as shown in Table 1. These data were obtained by determining the [Pd(II)] at 635 nm from one injection, followed by a second injection of the same sample, monitoring at 460 nm which allows the calculation of the [Pt(II/IV)] from the total peak height by subtraction of the Pd–Sn contribution at this wavelength. A series of calibration curves for pure Pt and Pd standard solutions at the selected wavelengths can be setup to assist in this task. We monitor at 460 nm in mixed metal solutions since the difference in molar absorptivity between the Pt–Sn and Pd–Sn species is a maximum at this wavelength,

resulting in the most accurate calculation of the respective Pt and Pd concentrations, by this method.

The feasibility of potentially simultaneous determinations of Pt(II/IV) and Pd(II) in hydrochloric acid solution has thus been demonstrated monitoring at two wavelengths, so that the use of a diode-array detector should facilitate the accurate and rapid determination of these two metals over a relatively large concentration range.

Interferences

An extensive evaluation of potential interferences is essential if the proposed method is to be of practical value. Consideration of the chemistry of the reaction of tin(II)chloride with the PGMs involved, allows one to roughly group potential interferences into three categories: (i) oxidative interferences, leading to competitive consumption of Sn(II); (ii) absorptive interferences, having high molar absorptivities in the wavelength region of interest; and (iii) non-selective reactions of $SnCl_2$ with substances other than the PGMs. In general the established high selectivity of the reaction of $SnCl_2$ with the PGMs[10–15] makes interferences of (iii) unlikely but implies that interferences from other PGMs and Au(I/III) may be expected in the determination of Pt and Pd. Since the carrier stream is 1 *M* in HCl, substantial interferences of type (i) and (ii) from first row transition metals are unlikely, with the possible exception of Fe(III) and Cr(VI) (as $Cr_2O_7^{2-}$) in relatively high concentration. Anions such as SO_4^{2-}, NO_3^-, ClO_4^- and PO_4^{3-} do not interfere at relatively high levels (<0.1 *M*), although Br^- and I^- ions should be kept to a minimum.

We find that the determination of Pt and Pd by the proposed method tolerates fairly large amounts of many transition metals remarkably well in keeping with our expectations above, as is evident from data in Table 2. The table shows the maximum amount of interferent tolerated, resulting in a peak height of 20 μg/ml Pt(IV) (at 400 nm) and Pd(II) (at 400 and 635 nm) to not differ from that obtained from pure standard solutions, by more than 1%. It is clear that Pt(II/IV) and Pd(II) can be determined in the presence of relatively large amounts of the first row transition metals, particularly Fe(III) and Cr(VI), monitoring at 400 nm. In reasonably pure Pt and Pd containing concentrates in HCl, the interference of many first row transition metals thus appears to be insignificant.

Table 2. Interference tolerance at 20 μg/ml Pt and Pd level monitoring at the given wavelengths using the single-line manifold

Interferent	Pt(IV) 400 *nm*	Pt(IV) 460 *nm*	Pd(II) 400 *nm*	Pd(II) 635 *nm*
Mg^{2+}	200	—	200	400
Cr(VI)	100	—	100	200
Mn^{2+}	400	—	200	400
Fe^{3+}	960	—	400	400
Co^{2+}	400	—	200	200
Ni^{2+}	400	—	200	200
Cu^{2+}	400	—	100	(a)
Al^{3+}	400	—	200	400
Te(IV)	400	—	200	400
Pb^{2+}	200	—	200	400
Au^{3+}	10	10	*	(a)
Rh^{3+}	~2	~2	*	200
$Ru^{4/3+}$	~2	10	~2	10
Ir^{4+}	10	50	(a)	120

*Not tested but likely to interfere at low levels.

On the other hand, the interferences from Au(III), Rh(III) and other PGMs can be significant in the determination of Pt and Pd. Nevertheless, with the exception of Au, it is in principle possible to determine other members of the PGMs in the same way as Pt and Pd using a multiwavelength detection approach alluded to above. Preliminary studies suggest that it is indeed possible to determine Pt in the presence of substantial amounts of Ru and Ir, while we are examining ways to determine Rh simultaneously with Pt and Pd by this means.

In conclusion we have found that the described FIA method monitoring at a single wavelength is suitable for the rapid and cost-effective determination of Pt(II/IV) and/or Pd(II) in relatively pure hydrochloric acid medium as may be encountered in process streams, using only small sample volumes. The presence of many transition metals in reasonable amounts does not interfere, although Rh(III), Ru(IV/III), Au(III), and to a lesser extent Ir(IV) interferes with the determination at low levels. Nevertheless with the aid of a photodiode-array detector it appears to be possible to circumvent these interferences as has been shown in the determination of Pt and Pd in this work. We are currently studying the potential multielement determination of the PGMs using multiwavelength detection.

(*Received* 16 *February* 1993. *Revised* 29 *March* 1993. *Accepted* 30 *March* 1993)

Summary—A study of the factors affecting separation and detection of dissolved organic and inorganic phosphorus species found in waters and sediments is reported. The system involved the use of gel filtration and flow injection analysis (FIA). Orthophosphate and *myo*-inositol hexakisphosphate, as model solutes representative of low molecular weight P (LMWP) and high molecular weight P (HMWP), were separated on a Sephadex G25 column incorporated into a flow-injection manifold which utilized photo-oxidation and spectrophotometry for detection of dissolved reactive phosphorus (DRP) and dissolved organic phosphorus (DOP). The influence of eluent pH and ionic strength on adsorption and anionic exclusion of the model solutes is described, and the optimum eluent composition and sample size are described. The method was used to determine LMWP and HMWP in natural and waste waters, and in sediment extracts. Potential limitations of this approach are discussed.

Phosphorus in natural waters and sediment is known to occur as orthophosphate and a variety of organic and condensed phosphorus species with a wide range of molecular weights.[1] Some components of the dissolved organic phosphorus (DOP) fraction are thought to hydrolyse rapidly to orthophosphate when acidic molybate is used in the spectrophotometric analysis of orthophosphate as phosphomolybdenum blue, and for this reason the term "dissolved reactive phosphorus" (DRP) is used in reference to "orthophosphate". Consequently, DRP concentrations may overestimate orthophosphate[2] which is undesirable because orthophosphate is currently the best chemical measure of the dissolved phosphorus concentration biologically available for photosynthesis.

In soils and sediments, phosphorus may occur as organic compounds such as sugar phosphates, phosphatidyl phosphates, inositol phosphates, phosphoamides, phosphoprotein, aminophosphonic acids, phosphorus-containing pesticides and organic condensed phosphates.[3] Of this group, *myo*-inositol hexakisphosphate (also called phytic acid), is among the most stable;[4] this compound occurs in free and iron-complexed forms in soils and marine and lake sediments.[5] It has been conjectured that this species and its hydrolysis products will be present in natural waters through groundwater input,[1] and may comprise a significant proportion of dissolved organic phosphorus (DOP).[6,7] However, only a few studies have actually demonstrated the existence of inositol phosphates in natural waters,[8,9] and to date little is known of the transport of these species from sediments and soils into stream and lake waters.

Analysis of the DRP concentration in natural and wastewaters is commonly performed in an attempt to estimate the concentration of bioavailable phosphorus in the dissolved fraction. While orthophosphate has been shown in a number of studies to be the most bioavailable phosphorus species,[10] higher molecular weight phosphorus (HMWP) species display varying degrees of bioavailability.[11,12] In order to determine the concentration of both "true" orthophosphate and HMWP in natural water samples, we attempted to separate these species according to differences in molecular weight using gel filtration followed by photo-oxidation

*Author for correspondence.

and subsequent phosphomolybdenum blue detection of the liberated orthophosphate using FIA.

Separation of orthophosphate and HMWP in natural waters by gel filtration chromatography has been described by a number of authors[6,11,13–15] using a variety of eluent conditions, large gel columns, slow flow rates and correspondingly long (30 min–2 hr) elution times. The aim of the work described here was to develop a rapid technique allowing discrimination between these two molecular weight fractions. Small Sephadex G25 columns were investigated for the separation of model solutes representative of LMWP and HMWP, *viz*; orthophosphate and *myo*-inositol hexakisphosphate. Significant irreversible, or very slowly reversible, adsorption of phytic acid was found to occur when previously documented eluent conditions were used. In an attempt to overcome these problems, the influence of both ionic strength and pH on elution of orthophosphate and phytic acid was investigated.

EXPERIMENTAL

Flow injection manifold

LMWP and HMWP were determined post-separation using a flow injection manifold for determination of DRP + DOP similar to that described by McKelvie *et al.*[16] and shown in Fig. 1. An Applied Biosystems ABI 757 UV–Vis chromatographic detector was used. For the high range standards, a detector sensitivity of 0.1 AUFS (absorbance units full scale) was selected, whereas 0.02 AUFS was used for the lower range. Accurel S6/2 (ENKA AG) microporous tubing was used for debubbling photolysed carrier/reagent solutions prior to the addition of chromogenic reagents.

Reagents

Alkaline persulphate reagent. A 0.148*M* potassium persulphate (BDH, AnalaR) solution in 0.025*M* sodium tetraborate (May and Baker, Pronalys) was used.

Acid molybdate reagent. Ammonium molybdate (BDH, AnalaR) ($8.1 \times 10^{-3}M$) in 0.63*M* sulphuric acid (Ajax Chemicals).

Tin(II) chloride reagent. A $8.9 \times 10^{-4}M$ solution of tin(II) chloride (May and Baker, Pronalys) and 0.015*M* hydrazine sulphate (Ajax Chemicals, LR) in 0.50*M* sulphuric acid were prepared.

Model phosphorus compounds

Potassium dihydrogen orthophosphate (BDH, Pronalys) (mol. wt. of anion *ca.* 97.0); *myo*-inositolhexakis (dihydrogenphosphate), disodium salt dihydrate (*i.e.*, phytic acid), 78% pure (Aldrich) [mol. wt. of phytate anion (−8) *ca.* 837.8]; both prepared as 100 mg P/l. stock solutions.

Gel filtration conditions

Two Sephadex G25 columns were used:

Column A. A C10/10 column equipped with an AC10 adaptor was packed with pre-swollen Sephadex G25 Superfine (all from Pharmacia Fine Chemicals AB) to a bed height of 42 mm (bed volume = 3.3 ml), and used for eluent optimization and sediment extract separations.

Column B. A Fast Desalting HR10/10 high resolution column of bed height 100 mm (bed volume *ca.* 7.8 ml) (Pharmacia Fine Chemicals AB) was used for analysis of water samples.

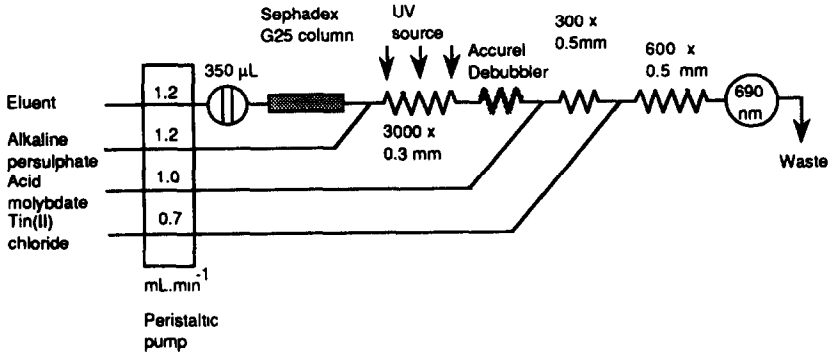

Fig. 1. Flow injection manifold for gel filtration separation with post-column DRP + DOP detection. Pump flow rates shown as those used for the Sephadex HR10/10 column. Flow rates were halved when column A was used.

Columns were stored refrigerated in 0.02% (w/v) sodium azide when not in use.

Injection volumes of either 100, 350 or 600 μl were used depending on the size of column and concentration range of the samples. For the separation optimization studies using column A, 350-μl injections were made throughout.

Gel filtration separations of phytic acid and orthophosphate were investigated using eluents of either 0.034–0.137M NaCl (pH 5–9),[11,14] 0.025M sodium tetraborate (pH 9.1),[15] or Tris–HCl buffers adjusted with 0.1M NaCl to give total ionic strength (I) values of between 0.001 and 0.007M as required. All eluents were filtered through 0.45-μm Sartorius Type SM membrane filters and allowed to degas for 15 min prior to measurement of pH and use.

To investigate the feasibility of separating orthophosphate and HMWP by gel filtration, columns were calibrated using a range of solutes of varying molecular weights. Elution of these solutes was detected by measurement of UV absorbance, or in the case of phytic acid and phosphate, by detection as DOP and DRP, respectively. Blue Dextran (Pharmacia Fine Chemicals AB), with a nominal molecular weight of 2×10^6 Dalton was used to determine the void volume, V_o, and nitrate ion (FW = 62.0) was used to estimate the total pore volume, V_i, of the gel column.[17] In NaCl and borate eluent solutions, direct UV detection at 220 nm was used to determine nitrate. However, the Tris buffer used in later experiments had a large background absorbance, and a nitrate ion selective electrode (Activon) was used for detection of nitrate.

Sample preparation

Water samples were collected from several lotic and lentic environments in Victoria, a sewage treatment works and a leachate pond at a rural landfill tip. Samples were filtered on-site using a 0.45-μm Lida disposable syringe filter and stored at $\leqslant 4°$ prior to analysis, which usually occurred within 48 hr. Filtered water samples were injected in triplicate (600 μl) onto a Sephadex G25 HR10/10 column (B) and eluted with a Tris/HCl eluent of $I = 0.005M$ at pH 4.6–4.7 at a flow rate of 1.2 ml/min.

Lacustrine sediments (1–2 g) were extracted in 0.025M disodium tetraborate (*ca.* pH 9.2) and mixed end-over-end for 1 hr at room temperature. Diluted (1:10) sediments extracts were analysed using the same Sephadex G25 Superfine column (A) used for the elution optimization. Standard solutions of phytic acid and orthophosphate were prepared in the same matrix as the extracts. A Tris/HCl eluent of $I = 0.005M$ and pH 4.65 at a flow rate of 0.65 ml/min was used, and triplicate 350-μl injections were made.

DRP and DOP + DRP analyses were also performed on all water and sediment samples for comparative purposes.

RESULTS AND DISCUSSION

Molecular weight calibration

From molecular weight calibration data (Fig. 2), it is evident that an essentially linear relationship between the distribution coefficient, K_d, and log(molecular weight, MW) applies over the MW range which includes phytic acid and orthophosphate. Those which are significantly larger (aprotinin, myoglobin) fall outside this linear portion. Extrapolation of this linear portion of the calibration graph indicates that the *operational* exclusion limit is approximately 10^3 Dalton, rather than the value of 5×10^3 Dalton for globular proteins normally quoted.[17] The observed K_d values of *ca.* 0.2 and 0.8 for phytic acid and orthophosphate respectively, are close to those previously reported for separation of these solutes on Sephadex G25 under similar elution conditions,[18] and it is evident that phytic acid is eluting with a K_d consistent with that of a non-aggregated, monomeric form.

The calibration data, while indicating molecular weight-dependent elution behaviour, do not show resolution of the solutes. For the fast gel filtration separations on column (A), phytic

acid and orthophosphate were incompletely resolved, but nevertheless quantifiable. However, separation of solutes with intermediate molecular weights was not feasible, and consequently analytical results are reported non-specifically as *high molecular weight phosphorus* (*HMWP*) and *low molecular weight phosphorus* (*LMWP*), rather than as DOP of a particular MW and orthophosphate.

Eluent selection

Initial attempts to separate phytic acid and orthophosphate on even quite large Sephadex G25 columns (200 mm × 10 mm i.d.) using 0.2% (w/v) NaCl resulted in poor recoveries of phytic acid, and it was evident that some specific interaction, or slow reversible adsorption was occurring which was only slightly affected by pH. Despite poor recovery, phytic acid eluted with a V_e/V_o value which was consistent with its molecular weight, as shown in Fig. 2.

It was observed that when either standard or sample was prepared in deionized water and injected into an eluent of higher ionic strength, notably better recovery of phytic acid was achieved compared with the situation where sample or standard was prepared in a matrix of the same ionic strength as the eluent. This is clearly seen in Fig. 3(a) and (b) where injections of mixtures of phytic acid and orthophosphate have been made in triplicate. Figure (3a) shows that when sample

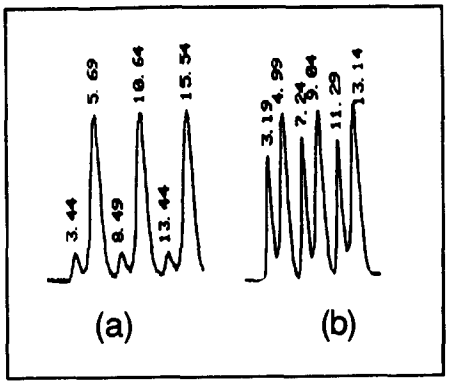

Fig. 3. Triplicate injections of 300 μg P/l each of phytic acid and orthophosphate, showing the influence of sample zone ionic strength on elution of both species (a) eluent and sample zone: 0.2% NaCl (w/v) pH 9.7 with 5 min between injections, and (b) eluent: 0.2% NaCl (w/v) pH 9.7 with 4 min between injections, sample zone: deionized water. Elution conditions: column A, flow rate 0.62 ml/min, injection volume 350 μl. The numerals shown on the chromatograms are retention times in minutes. In both cases, the phytic acid peak elutes first.

zone and carrier had the same ionic strength, significant adsorption of phytic acid occurred (peaks at 3.44, 8.49 and 13.44 min). However, when the sample zone matrix was of much lower ionic strength, markedly improved recovery of phytic acid was noted [Fig. 3(b)], as indicated by the peaks at 3.19, 7.24 and 11.29 min.

This effect is similar in some respects to the *salt boundary* elution effect previously described by Posner.[10] Posner suggested that preparing a sample with a higher ionic strength would cause solute adsorption when the sample was added to a gel column. Elution with distilled water would then cause the progressive desorption of the adsorbed solute and this would move down the column as a concentrated zone at the distilled water-saline eluent interface. In the case illustrated by Fig. 3(b), the sample was dissolved in deionized water, and injected into a carrier/eluent of 0.2% (w/v) NaCl. However, despite these conditions being the opposite of those described by Posner, the same type of elution persisted; *i.e.*, phytic acid in a deionized water matrix showed much less adsorption than the same sample prepared in eluent. It is possible that the adsorptive process occurs at the head of the sample zone where there is considerable dispersion and hence mixing, with the saline eluent. Given that a large injection volume of 350 μl (10.6% of total column volume, V_t) was used, it could be expected that the relatively undispersed mid-region of the sample zone would have a lower ionic strength than that of the eluent, and it is conceivable that it is this low ionic strength zone which causes the partial desorption of phytic acid which is observed.

Although the mechanism of this process is unclear, it is quite evident from the relative sizes of the peaks, that better, albeit not complete recovery of phytic acid occurs when an ionic strength gradient exists across the sample zone, and for this reason the influence or ionic strength and pH on separation of orthophosphate and phytic acid in a deionized water matrix were studied systematically to obtain the optimum condition for separation and recovery of phytic acid. Mixed standards of phytic acid and orthophosphate in deionized water were injected onto the same column and eluted with carrier having a variety of pH and ionic strength conditions using Tris–HCl–NaCl solutions ranging from $I = 0.001$ to $0.07M$. The results of these experiments are shown in Fig. 4 from

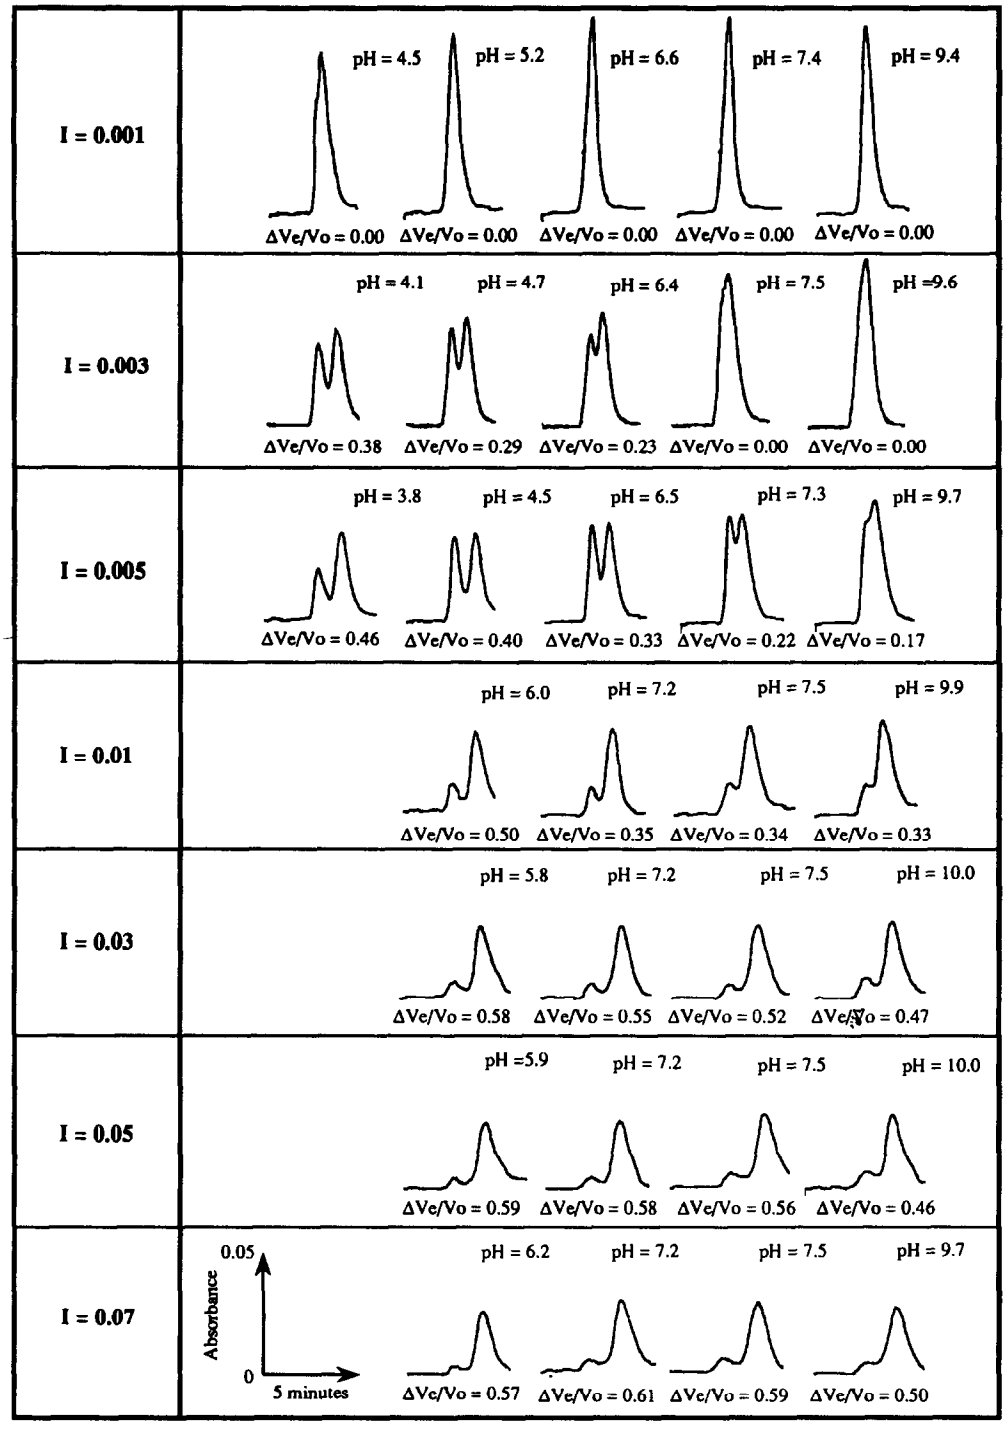

Fig. 4. Variation in the elution of orthophosphate and phytic acid species as a function of total ionic strength and pH. Peak separation is expressed as $\Delta V_e/V_o$, where V_e is the solute elution volume and V_o is the void volume of the gel bed.

which a number of features of the chromatography are evident:

(i) At low ionic strength ($I = 0.001M$), phytic acid and orthophosphate co-elute under all pH conditions tested.

(ii) At slightly greater total ionic strength ($I = 0.003M$), orthophosphate shows partial resolution from phytic acid ($\Delta V_e/V_o =$ 0.23–0.38). However, at pH > 6.4, loss of separation is observed.

(iii) At total ionic strength in excess of $0.005M$, significant adsorption of phytic acid was found to occur. Very slow desorption of some species (presumably phytic acid), indicated by a gradual return to baseline, was observed after elution of the orthophosphate peak (not shown by the data in Fig. 4).

The co-elution of orthophosphate and phytic acid found to occur at the lowest ionic strength conditions tested ($I = 0.001M$) was probably due to anionic exclusion of the orthophosphate. At $I = 0.003M$ some separation of the two species occurred at lower pH, but at pH >6, the double- and triple-charged phosphate species are more prevalent, and the anion exclusion effect overcame the influence of increased ionic strength; a similar trend to this was observed for an eluent with $I = 0.005M$.

This anion exclusion effect appears to have been completely suppressed when the ionic strength was increased to $0.01M$, and the phytic acid and orthophosphate peaks are as well separated as might be expected given the short column used. Predictably, however, there is significant adsorption of the phytic acid under these higher ionic strength conditions.[20] Figure 5 shows the variation of V_e/V_o of both orthophosphate and phytic acid species with increasing ionic strength within the pH range 7.3–7.5. The orthophosphate shows a pronounced increase in V_e/V_o, but a much smaller effect of ionic strength on phytic acid. This is perhaps surprising, given the highly charged nature of the phytic acid species (within the pH range used, the average charge on the phytic acid would be *ca.* −8). The value of V_e/V_o for phytic acid is, however, always larger than that of Blue Dextran, and even at high ionic strength (*e.g.*, $I = 0.07M$), with a large amount of adsorption occurring, there is only a small shift in the value of V_e/V_o. Despite the high charge on the phytic acid species, it appears that its elution is dictated by steric factors rather than charge considerations. This is consistent with the findings of Neddermeyer and Rogers[21] who suggested that larger charged ions would not be influenced by the Donnan exclusion effect to the same extent as smaller ions because they would be sterically excluded from the gel interior containing most of the charge. This may provide an explanation for the apparent absence of anion exclusion behaviour of phytic acid, despite its high charge.

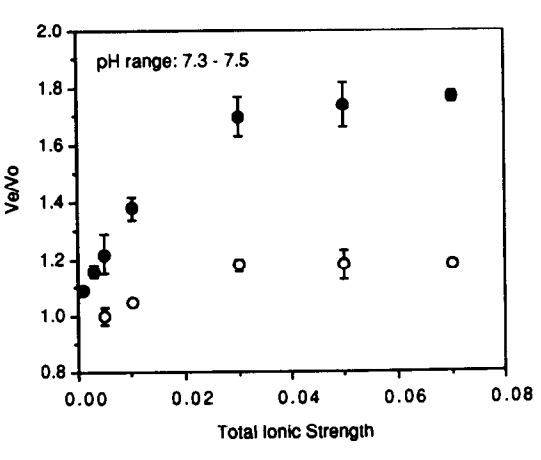

Fig. 5. Variation of V_e/V_o for orthophosphate (●) and phytic acid (○) species as a function of total ionic strength within the pH range 7.3–7.5.

Neddermeyer and Rogers have also noted that solutes subject to the influence of anion exclusion display broadened front and sharp back edges, behaviour which is the converse of that normally observed in chromatography.[21] Examination of orthophosphate and phytic acid peaks reveals that while the orthophosphate peaks show broadened leading edges, phytic acid peaks do not, providing further evidence in support of the hypothesis that steric effects control the behaviour of phytic acid.

Maximum recovery of phytic acid with respect to orthophosphate, based on peak height, was achieved for the specified column and flow conditions using eluents with $I = 0.005M$ and pH 4.5–6.5. Under optimal elution conditions ($I = 0.005M$, pH 6.5, *cf*, Fig. 4), the % recovery of phytic acid with respect to orthophosphate calculated using peak height was 97.4% ($\sigma_{n-1} = 0.2\%$, $n = 3$), but when calculated on the basis of peak area, was only 78.2% ($\sigma_{n-1} = 3.2\%$, $n = 3$). Given that a common phosphomolybdenum blue detection chemistry was used, it is evident that significant adsorption of phytic acid had occurred even at this so-called optimum condition. Furthermore, when columns were cleaned with dilute sodium hydroxide solution (pH >10) after the injection of several samples of phytic acid, a large desorption peak was observed; however this was not the case for orthophosphate. It was also apparent from the uniformity of peak area data, obtained over a wide range of ionic strength and pH conditions, that little orthophosphate adsorption occurred.

It is unfortunate that even under salt-zone elution conditions adsorption of phytic acid persisted. It would have been preferable to use only one calibration substance, *i.e.*, orthophosphate

Table 1. Calculated limits of detection (lod) and sensitivity data for phytic acid and orthophosphate for the 42-mm bed height column (A)

Analyte	High range (100–1000 μg P/l.) Limit of detection (μg P/l.)	High range (100–1000 μg P/l.) Sensitivity (AU/μg P/l.)	Low range (10–100 μg P/l.) Limit of detection (μg P/l.)	Low range (10–100 μg P/l.) Sensitivity (AU/μg P/l.)
Phytic acid	44	1.338×10^{-4}	27	8.88×10^{-5}
Phosphate	12	1.318×10^{-4}	1.1	1.323×10^{-4}

and a common peak-height:concentration calibration equation for all eluting species. This would only be possible in the absence of solute–gel interactions, given that all eluting species are converted from DOP to DRP before detection. There was, however, only a narrow range of pH and ionic strength conditions for which the separation and % recovery of phytic acid (by peak height) was maximal. Even slight departure from the optimum ionic strength and pH conditions ($I = 0.005M$, pH 4.5–6.5) would cause the % recovery of phytic acid with respect to orthophosphate to change markedly. Such variations in the ionic strength could occur in the preparation of reagents, or may arise from some hydrodynamic artefact of the FIA manifold causing a variation in the degree of dispersion of the sample zone, and hence altering the ionic strength regime of the sample zone. Such artefacts may involve changes as simple as a fluctuation in carrier flow rate, or a variation in the sample volume.

For these reasons, mixed standards of phytic acid and orthophosphate were used for quantitation of HMWP and LMWP, in preference to quantitation using orthophosphate alone and applying a response factor. It is recognized that this calibration approach may be deficient if an HMWP species elutes from the gel in a manner different to that of phytic acid.

Linearity, sensitivity and limit of detection of mixed standard calibrations

Mixed standards of phytic acid and orthophosphate were prepared over the ranges 50–1000 μg P/l. and 10–100 μg P/l. Triplicate injections of 350 μl of these standards were made onto the same Sephadex G25 Superfine column that was used for all previous experiments under optimal separation conditions.

At concentrations greater than approx 200 μg P/l., phytic acid and orthophosphate graphs were essentially co-linear, giving regression equations of

$$A = (-2.63 \times 10^{-3}) + (1.34 \times 10^{-4})\mu g\ P/l,\ r^2 = 0.999,$$

and

$$A = (3.00 \times 10^{-4}) + (1.32 \times 10^{-4})\mu g\ P/l.,\ r^2 = 1.000,$$

respectively.

However, below *ca.* 100 μg P/l., the orthophosphate calibration is linear, but the phytic acid exhibits non-linear behaviour. At 50 μg P/l., there is a loss of approximately 50% of the phytic acid, while at < 10 μg P/l., phytic acid peaks were scarcely detectable, even though orthophosphate signals were still clearly discernible. Clearly, at concentrations of less than 100 μg P/l., the specific adsorption of phytic acid onto the gel poses a difficulty.

Limits of detection (lod) have been calculated for these data using the linear regression method described by Miller and Miller[22] and are listed with calibration sensitivity (slope) values in Table 1.

Effect of sample volume on peak response, resolution and % recovery

The influence of sample volumes ranging from 100 to 600 μl on peak response, resolution, and % recovery (based on comparison with orthophosphate peak height) was investigated. A linear relationship between injection volume (S_v) and peak height (Absorbance, A) was observed over the concentration range tested. For the dilute solutions analysed here, it can be shown that the relationship between the absorbances of undispersed (A°) and dispersed (A) sample,

$$\frac{A}{A^\circ} = 1 - \exp(-k\,S_v)$$

quoted by Ruzicka and Hansen[23] approximates to: $A \approx k\,S_v$ for a range of A values from 0.001 to 0.1. $S_{1/2}$, the injection volume required to give a dispersion coefficient of 2, can be determined from

$$S_{1/2} = \frac{0.693}{k}.$$

Using this relationship, and the k (slope) value from an A *vs.* S_v plot, very high $S_{1/2}$ values of

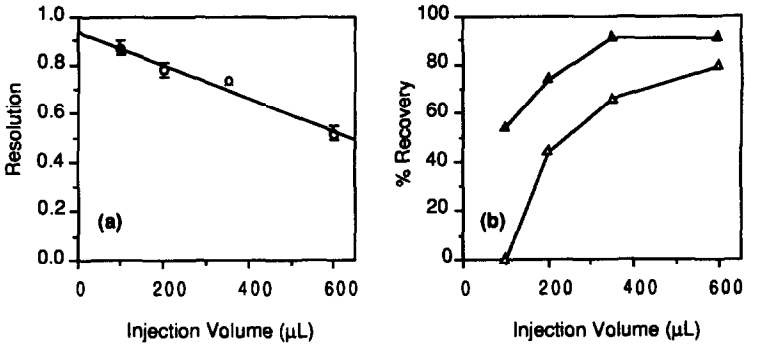

Fig. 6. Influence of sample volume on (a) resolution (for 500 μg P/l. each of phytic acid and orthophosphate), and (b) % recovery of 50 μg P/l. (—△—) and 500 μg P/l. (—▲—) phytic acid with respect to orthophosphate. Column A, eluent flow rate 0.62 ml/min.

>20,000 μl at 50 μg P/l. and >4,000 μl at 500 μg P/l. were obtained.

The very large values of $S_{1/2}$ at 50 μg P/l. reflect the consideration dispersion that occurs in the gel column. Clearly, use of a smaller gel-filtration column would be preferable and more in agreement with conventional FIA–chromatographic practice. Smaller columns would necessitate the use of small injection volumes if column overloading and attendent loss of resolution are to be avoided. However, the combination of small injection volumes and the high dispersion of the DOP + DRP detection manifold would result in poor sensitivity, and consequently the use of small columns and small injection volumes is precluded in this context.

Figures 6(a) and (b) show the improvement in peak resolution and the corresponding decrease in % recovery of phytic acid (calculated from peak height data) as the injection volume is decreased to 100 μl. The lower recovery of the 50 μg P/l. standard with respect to the 500 μg P/l. standard is probably due to a combination of preferential adsorption of phytic acid to the gel and dispersion. These results highlight the interrelationship between phytic acid adsorption and factors such as eluent-sample zone ionic strength difference, and hydrodynamic factors like sample injection volume, column size, and flow rate which influence dispersion.

Influence of phytic acid concentration on apparent concentration of orthophosphate for short columns

Phytic acid and orthophosphate peaks were only partly resolved on the short G25 Superfine column (A). Under these circumstances, the measured peak heights, and hence concentrations of both HMWP and LMWP calculated from peak height may be mutually influenced by peak overlap. To determine the magnitude of this effect, several mixed standards all containing 300 μg PO_4–P/l. and phytic acid concentrations varying between 50 and 400 μg phytic–P/l. were analysed. Figure 7 shows that the absorbance of the 300 μg PO_4–P/l. standard increased linearly, by as much as 10.3%, as the concentration of phytic acid was increased from 50 to 400 μg phytic–P/l. Similarly, the absorbance *vs.* concentration plot for phytic acid displayed increasing deviation from linearity at higher concentrations because of overlap from the leading edge of the orthophosphate peak. Because this effect proved problematic in the analysis of some sediment extracts, a larger, high resolution column was employed for the analysis of water samples, as described in the following section.

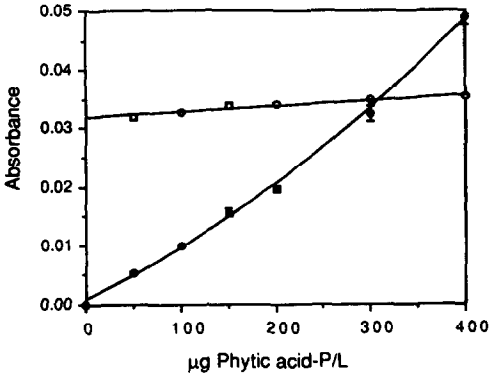

Fig. 7. Effect of differing phytic acid concentrations (●) on peak height of 300 μg P/l. orthophosphate (○) in short column gel filtration chromatography. Tris/HCl eluent at pH 4.75 and $I = 0.005$. Column A, injection volume 350 μl. Eluent flow rate 0.62 ml/min. Lines of best fit for phytic acid and orthophosphate given by: $y = (7.49 \times 10^{-4}) + (7.77 \times 10^{-5})x + (1.04 \times 10^{-7})x^2$ $r^2 = 0.998$ and $y = (3.20 \times 10^{-2}) + (9.47 \times 10^{-6})x$ $r^2 = 0.923$, respectively.

Analytical results—concentrations of HMWP and LMWP found in sediment extracts and waters

Preliminary extractions of sediments with deionized water gave low yields of HMWP. Minear[24] has noted that only about 40% of DOP was extracted from particulate material and *Chlamydomonas* cultures by distilled water, but that 85–100% was extracted when alkaline conditions (*ca.* pH 13) were used. Extraction of phosphorus from sediments was tested using Olsen's reagent (0.5*M* $NaHCO_3$ at pH 8.5);[25] however, the high bicarbonate concentration was found to interfere with the photo-oxidation of DOP, presumably through hydroxyl radical scavenging. Aluminium may also interfere in the photo-oxidation of DOP at concentrations >100 μg Al/l.[26] and for this reason acidic sediment extractions were avoided.

HMWP and LMWP concentrations of the sediment extracts obtained by separation on the short (42 mm × 10 mm id) Sephadex G25 column with subsequent DOP analysis are shown with corresponding DOP and DRP data, expressed on a dry weight basis, in Fig. 8(a)–(c).

The concentration of LMWP was significantly greater than the corresponding DRP data ($P = 0.0058$, paired t-value 3.91, d.f. = 7). Two possible explanations can be tendered, *viz*;

(i) Desorption of phytic acid, or other late eluting species, may enhance the LMWP peak. While the separation has been optimized to give maximum recovery of phytic acid, some phytic acid appears to undergo very slow desorption. Other phosphate-species, such as Vitamin B12 and 4-nitrophenylphosphate, exhibited reversible adsorption and late elution when injected under these elution conditions.

(ii) Organic phosphorus species of similar molecular weight range to orthophosphate (*e.g.*, lower phosphate esters of *myo*-inositol) may be present and elute with the orthophosphate. Given the fairly poor resolution of the small column used, discrimination between orthophosphate and other low molecular weight phosphorus species would not be possible.

From Fig. 8(a), it is evident that DOP values are significantly greater than those for HMWP ($P = 7.0 \times 10^{-4}$, paired t-value = 5.76, d.f. = 7). Between 65 and 97% of the DOP is represented by the HMWP of similar MW to *myo*-inositol-hexakisphosphate, and this is consistent with suggestions regarding the stability of this phosphate ester and its probable role in the storage of phosphorus in sediments.[1] Other researchers have reported similar recoveries of inositol phosphate esters from soils[27] and lake sediments.[28] The fact that the DOP values are all greater than the HMWP values [Fig. 8(b)] also lends some credence to any one of the explanations provided for the apparent discrepancy between LMWP and DRP.

Moreover, it can be seen that when (DRP + DOP) and (HMWP + LMWP) data are compared [Fig. 8(c)], there is excellent agreement, as shown by the regression equation:

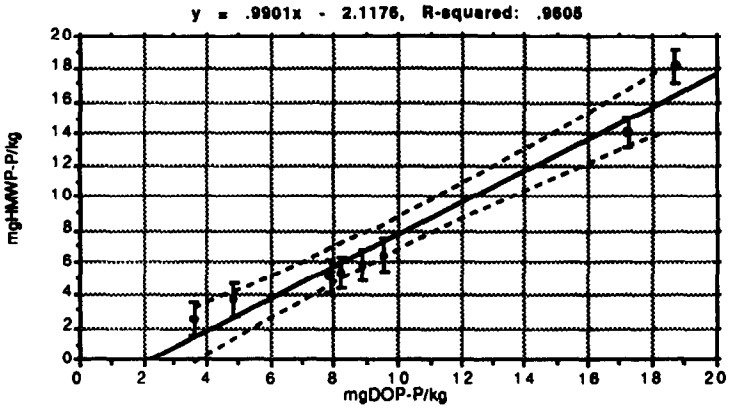
$$(\text{HMWP} + \text{LMWP}) = 1.05(\text{DRP} + \text{DOP}) - 1.34, \quad r = 0.987$$

(r significantly different from zero at $P > 99\%$).

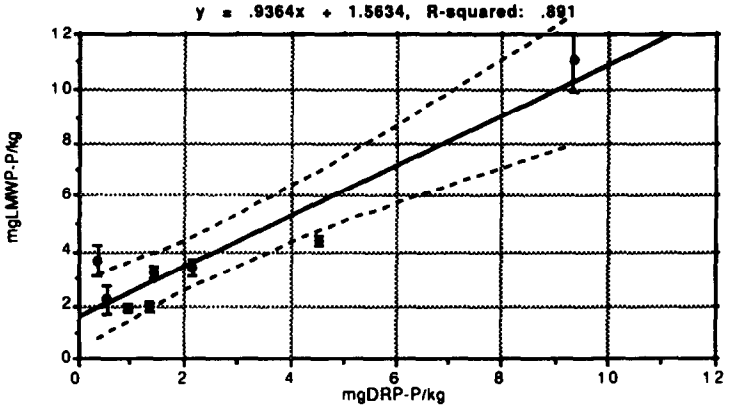
The agreement between (HMWP + LMWP) and (DRP + DOP) suggests that there are no major recovery losses associated with the gel filtration separation that cannot be accounted for by calibration. It also supports the hypothesis that differences between DRP and LMWP can be explained by the co-elution of lower MW organic phosphorus species with orthophosphate.

For water samples, LMWP and HMWP were separated on the larger, high resolution HR10/10 column (B). Sample injections of 600 μl were necessary to compensate for the added dispersion associated with use of a large column, but this was compensated for by the complete resolution of phytic acid and orthophosphate, and the ability to use high eluent flow rates with this column. Flow rates of up to 6 ml/min are permissible, but in experiments reported here, flow rates in excess of 1.2 ml/min were avoided because the debubbler in the DOP photo-oxidation manifold did not function efficiently at these higher flow rates.

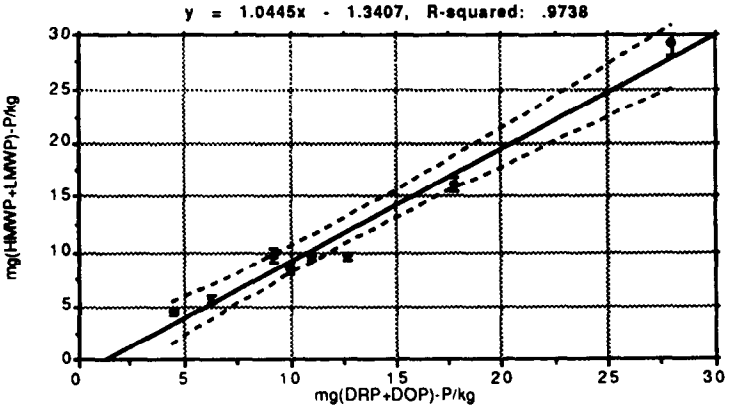
Results of the analyses of the water samples are shown in Fig. 9(a)–(c). The importance of HMWP as a constituent of some waters is noted, as it comprised from 0 to 97% of the total HMWP + LMWP detected. There was no significant difference between the (HMWP + LMWP) gel filtration data and the (DRP + DOP) data for the same samples ($P = 0.79$, paired $t = 0.27$, d.f. = 9). However, HMWP was significantly greater than the DOP fraction ($P = 0.03$, paired t-value = 2.67, d.f. = 9) and LMWP is significantly less than the DRP fraction ($P = 0.02$, paired t-value = 2.85, d.f. = 9). These trends are opposite to those found for the extractable phosphorus in the



(a) DOP significantly > HMWP ($P = 7.0 \times 10^{-4}$, paired t-value = 5.76, d.f. = 7)



(b) LMWP significantly > DRP ($P = 0.0058$, paired t -value = 3.91, d.f. = 7)



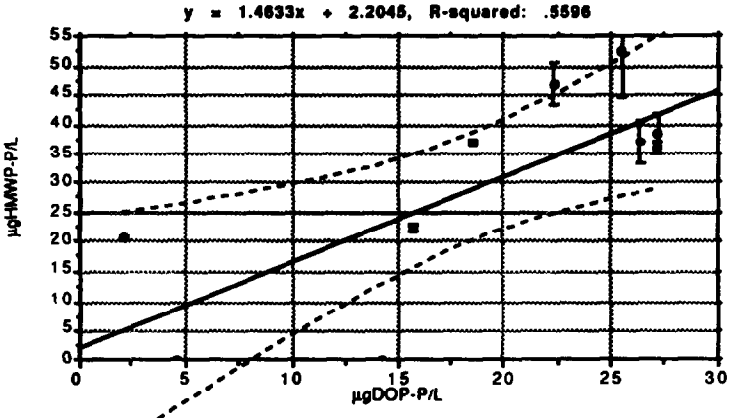
(c) No significant difference between HMWP+LMWP and DRP+DOP ($P = 0.14$, paired t-value = 1.68, d.f. = 7)

Fig. 8. Comparison of (a) HMWP and DOP, (b) LMWP and DRP and (c) HMWP + LMWP and DRP + DOP for sediments, expressed on a dry weight basis. The broken lines indicate the 95% confidence intervals for the true mean of the y values.

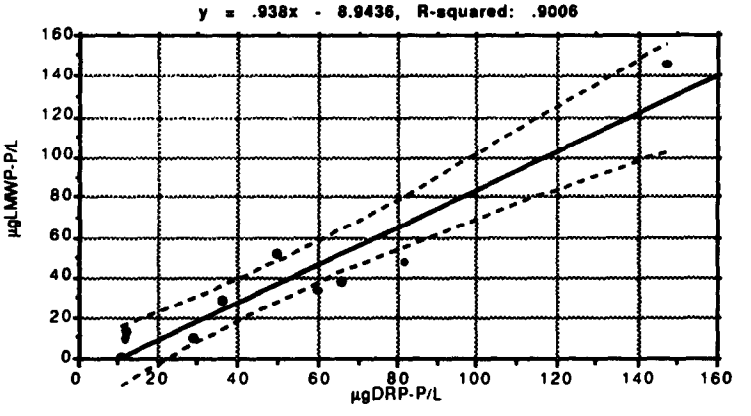
sediment samples. One possible explanation for the higher DRP than LMWP data is that some of the DRP measured includes the products of rapidly hydrolysed dissolved organic phosphorus, a problem which has been reported extensively.[2,29,30] As DOP is determined by subtracting DRP from the total DRP + DOP, the effect of an inflated DRP value will result in significantly reduced DOP values. Chamberlain and Shapiro, for example, in a batch method,

limited mixing and reaction between sample, molybdate and reductant to 6 sec, but noted that some hydrolysis of DOP occurred even under these rapid reaction conditions.[31] For the flow injection DRP method used here, the time between injection and emergence of the peak maximum was only 20–25 sec, but it is feasible that some hydrolysis of DOP could occur even in this short period.

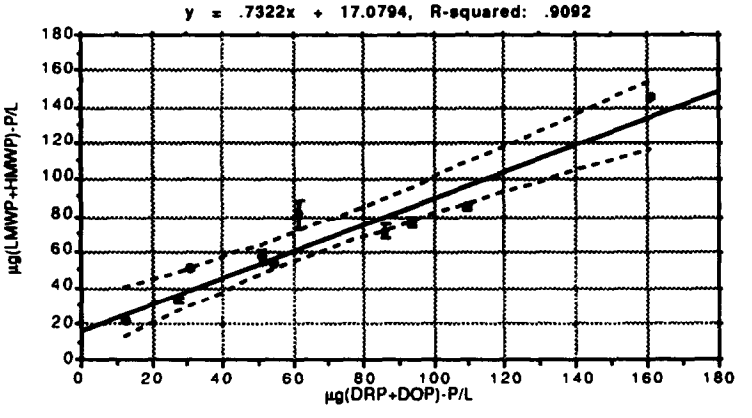
Six of the samples analysed had LMWP



(a) HMWP significantly > DOP (P = 0.03, paired t-value = 2.67, d.f. = 9)



(b) DRP significantly > LMWP (P = 0.02, paired t-value = 2.85, d.f. = 9)



(c) No significant difference between HMWP+LMWP and DRP+DOP (P = 0.79, paired t-value = 0.27, d.f. = 9)

Fig. 9. Comparison of (a) HMWP and DOP, (b) LMWP and DRP and (c) HMWP + LMWP and DRP + DOP for water samples. The broken lines indicate the 95% confidence intervals for the true mean of the y values.

values which were significantly lower than the DRP concentrations. However, there is no significant difference between (LMWP + HMWP) and (DRP + DOP) for most samples, and it is arguable that measurement of LMWP and HMWP provide better measures of non-hydrolysed organic phosphorus and orthophosphate than do DOP and DRP. In two diluted effluent samples the HMWP was undetectable; however, these samples were high in DRP and required dilution of 1:50 prior to analysis in order to get them into the same concentration range as other samples. It is probable that this was sufficient to dilute the low concentration of HMWP to below the detection limit, or that the low concentrations of DOP (14 and 5 μg Pl/l. respectively) were comprised of late-eluting species.

This study has highlighted some of the problems associated with the use of Sephadex G25 for the fractionation of dissolved phosphorus species in natural waters and sediment extracts, *viz.* partial adsorption of phytic acid species and late elution of other higher molecular weight species. This gel filtration approach to the separation of HMWP and LMWP is apparently the most rapid yet reported with an analysis rate of 12–15/hr, but it is not sufficiently sensitive for the analysis of dilute or pristine waters. It is envisaged that further research in this area could involve the use of complexing eluents to eliminate adsorption of HMWP species through complexation by metals adsorbed to the gel, along similar lines to that described by Town and Powell.[32]

In this study, only Sephadex G25 has been used, and it would be useful to repeat the ionic strength–pH studies on a wide range of gels, including the macro/microreticular Ultrogels, to determine optimum separation conditions. This would be labour-intensive by conventional gel filtration, but could be performed within a reasonable time using the gel filtration-FIA approach described. Separation of HMWP and LMWP in waters with a range of gels of different MW cut-off would provide further information on the concentration and speciation of dissolved organic phosphorus in natural waters.

Detection of low concentrations of DOP compounds using the gel filtration–FIA system is clearly a problem. However, it was shown that phytic acid and phosphate could be concentrated onto an ion exchange precolumn prior to injection[33] and DOP analysis. This approach could be applied to the preconcentration of at least the anionic HMWP species prior to gel filtration.

While this study has identified that waters and sediment extracts contain HMWP in the same molecular weight range as phytic acid, and it is probably reasonable to assume that phytic acid is a major constituent of the HMWP, no information about the presence of other phosphate esters of *myo*-inositol can be obtained because of the inability of the gel to resolve the small differences in molecular weight involved. Low pressure anion exchange chromatography has been used extensively to separate *myo*-inositol phosphate esters,[6,28,34] and from the experience of this study, it should not be difficult to couple an anion exchange column with an FIA–DOP manifold to achieve rapid separations.

Finally, the relevance of the HMWP and LMWP data in waters needs to be evaluated in terms of their bioavailability by comparison with appropriate algal bioassay techniques.

BOOK REVIEWS

Comprehensive Dictionary of Physical Chemistry: L. ULICKY and T. J. KEMP (editors), Ellis Horwood, Chichester, 1992. Pages 472. £49.95. ISBN 0-13-151747-3.

Ellis Horwood and Prentice Hall have collaborated to produce this English edition in conjunction with ALFA publishers of Bratislava. Sixteen authors contributed to the dictionary and there were eight translators from the Slovak. The book was published in Czecho-Slovakia and I would describe the quality of printing and binding as 'adequate'.

On first perusal I was surprised to find apparent omissions such as chemometrics and chromatography but I then realized that this was the first of seven volumes in a range of comprehensive chemical dictionaries. The missing topics may appear in the other volumes which cover organic chemistry, biochemistry, inorganic chemistry, analytical chemistry, nuclear chemistry and various chemical technologies.

The first volume deals with topics from the theory of the structure of matter, states of matter, thermodynamics, electrochemistry, chemical kinetics and colloid and surface chemistry. These are indeed covered very comprehensively. The editors state that special attention is devoted to theoretical and quantum chemistry, and to symmetry and crystallography so I was surprised not to find any mention of molecular mechanics (another volume perhaps?).

Entries in the dictionary are extensively cross-referenced, for example, during the explanation of Donnan equilibrium the reader is cross-referenced to separate entries on 'osmotic pressure of a colloid', 'colloidal electrolyte', 'membrane hydrolysis' and 'membrane potential'. Overall there are approximately 2000 entries, 200 figures and 42 tables. A bibliography mentions numerous textbooks that were used to aid the compilation of the dictionary.

I did find the contents useful for succinct definitions of topics within physical chemistry and the dictionary will be especially useful in those areas where the reader needs to discover, or be reminded of, definitions and techniques. It should attract a wide readership.

P. J. Cox

Practical Surface Analysis—Second Edition, Volume 2—Ion and Neutral Spectroscopy: D. BRIGGS and M. P. SEAH (editors), Wiley, Chichester, 1992. Pages xvii + 738. £90.00. ISBN 0-471-92082-7.

Practical Surface Analysis was originally published in 1983 and was devoted to the birth, growth, and diversification of Auger and X-ray photoelectron spectroscopies in the period 1960–1983; it gained a high reputation among surface scientists world-wide. The Second Edition, Volume 1, was published in 1990 and is essentially a revision of the first edition. Volume 2 of the second edition is a new book dealing with the complementary topics of ion and neutral spectroscopy. The book opens with chapters on instrumentation, sputter depth profiling, and quantification, and this is followed by chapters on dynamic SIMS and its applications in microelectronics, and on the use of static SIMS in the surface analysis of inorganic and organic materials. Sputtered neutral spectrometry, which offers a better opportunity than SIMS for quantification, is the subject of another chapter. The remaining two chapters deal, respectively with low-energy and medium-energy ion scattering techniques. About one-sixth of the book is devoted to substantial appendices on angle-resolved electron-simulated ion desorption, the role standards in SIMS, computer codes and simulation, pure element sputtering yield data, masses and abundances of naturally-occurring isotopes, and fundamental physical constants and energy conversion factors.

Volume 2 maintains the same format, quality, breadth and depth of coverage of its subject as did Volume 1. Each chapter is well written, well-illustrated, well-documented, and up-to-date (1992). For all surface scientists interested in the decyphering of the elemental composition and structural arrangement of atoms in the first few monolayers of a solid, this volume will also be essential reading. This book is relatively inexpensive and good value for its price, and I understand that Volumes 1 and 2 can be purchased as a set at a discount.

J. B. CRAIG

Concepts and Calculations in Analytical Chemistry—A Spreadsheet Approach: H. FREISER, CRC Press, Boca Raton, 1992. Pages 315. US$19.95. ISBN 0-8493-4717-1.

Professor Freiser has written this book in an attempt to convey to readers his enthusiasm for "the magic of spreadsheets". He covers a wide range of topics related to Analytical Chemistry, including chemical equilibrium, the role of activity, acid–base, metal complex, precipitation and redox equilibria, titrations, statistical data treatment, spectrometry, separation processes, kinetic methods, and the determination of equilibria, and also attempts to provide a tutor for the use of the spreadsheet QuattroPro.

I found the book to be a valuable resource for teachers of analytical chemistry, but I feel that it is not all together successful as a text for students, possibly because the author is so much a master of the material he is presenting. My impression is that, in trying to show how elegant and easy this chemistry is when done by spreadsheet, he has sometimes lost sight of the student who is totally unfamiliar with the chemistry.

J. B. CRAIG

Concepts and Calculations in Analytical Chemistry—A Spreadsheet Approach: H. FREISER, CRC Press, Boca Raton, 1992. Pages 315. US$19.95. ISBN 0-8493-4717-1.

Professor Freiser has written this book in an attempt to convey to readers his enthusiasm for "the magic of spreadsheets". He covers a wide range of topics related to Analytical Chemistry, including chemical equilibrium, the role of activity, acid–base, metal complex, precipitation and redox equilibria, titrations, statistical data treatment, spectrometry, separation processes, kinetic methods, and the determination of equilibria, and also attempts to provide a tutor for the use of the spreadsheet QuattroPro.

I found the book to be a valuable resource for teachers of analytical chemistry, but I feel that it is not all together successful as a text for students, possibly because the author is so much a master of the material he is presenting. My impression is that, in trying to show how elegant and easy this chemistry is when done by spreadsheet, he has sometimes lost sight of the student who is totally unfamiliar with the chemistry.

The book is seriously let down by the type-setting: there is no consistency in the use of different type-faces, particularly italics. In a chemical text, the symbols for constants (*e.g.*, K_{sp}) and variables in equations should be set in italic, and the symbols for chemical species (*e.g.*, NH_3) should be in upright text. Here, chemical species often appear in italics and constants in upright type, and both forms for each often appear on the same page. For example, on page 69, the hydrogen ion concentration is first shown correctly as $[H^+]$, then as H, and finally as H.

M. MASSON

Internal Reflection Spectroscopy—Theory and Applications: F. M. MIRABELLA, JR., Dekker, New York, 1993. Pages vii + 374. US$ 145.00. ISBN 0-8247-8730-7.

Internal reflection spectroscopy (IRS) has come a long way since the pioneering work of Taylor in the 1930s and that of Fahrenfort and Harrick in the 1950s. Advancement of the methodology and of its applications has been relatively slow; indeed until recently the main problem with IRS was its restriction to samples (*e.g.*, films, sheets, coatings on rigid surfaces, *etc.*) that would allow good surface contact between the material and the internal reflection elements.

The development of commercial Fourier transform IR instruments and of sampling systems that permit the analysis of liquids, powders and pastes have increased greatly the applications of this technique. Although most IRS work is done in the mid-infrared region of the spectrum applications are being developed using UV, visible, Raman and fluorescence spectroscopy.

The book is published at a most exciting time. Instrumental problems have been overcome and the range of applications is growing rapidly. The book consists of 12 chapters by acknowledged experts in the field (mostly from industry); the first two chapters deal with historical and theoretical aspects and the remainder of the book is devoted to applications (industrial, electrochemical, process monitoring, biomedical, semi conductors, *etc.*).

Dr Mirabella has done a first class job in editing this book and I have every hope that it will achieve his stated aim: 'to stimulate progress in this promising field'. My only reservation is that the price ($145) will inevitably prevent this book achieving the wide readership that it deserves.

B. A. MCGAW

Guide to Flow Cytometry Methods: W. M. GROGAN and J. M. COLLINS, Dekker, New York, 1990. Pages x + 228. $99.75 (U.S. and Canada), $119.50 (elsewhere). ISBN: 0-8247-8330-1.

This book will be of value to those who are already working in this field, particularly those involved in clinical analysis and in research.

As would be expected due emphasis is given to the basis of, and the practical applications of, DNA analysis in a variety of tissue types. The unique aspect of this book is that in one small volume, in a readily understandable form, it successfully brings together all the current, and possible future, applications of cytometry methods. Particularly pleasing is that throughout the text the practical aspects of the methodology involved for a particular determination are described in a uniform, simple and stepwise fashion making the particular analysis immediately possible without recourse to a large literature search. For those who require further information the text is well referenced with recent, pertinent literature references.

A drawback of the black and white presentation of the illustrations in the text, particularly the two-dimensional bit diagrams, is that it makes it difficult to clearly differentiate between the shaded areas and this hinders correct interpretation.

The text is accompanied by a useful appendix which allows rapid identification of the dyes and stains needed for the main applications, the suppliers of instruments, and other generally required materials.

R. R. MOODY

Pharmaceutical Chemistry—Volume 2, Drug Analysis: H. J. ROTH, K. EGER and R. TROSCHÜTZ, Ellis Horwood, Chichester, 1991. Pages: 767. £74.50. ISBN 0-13-663360-9.

Pharmaceutical Chemistry is published in three volumes: 1—drug synthesis, 2—drug analysis and, 3—drug bioreactivity. Each volume forms part of the Ellis Horwood series in Pharmaceutical Technology. This second volume was originally published, as a third edition, in the German language (*Pharmazeutische Chemie 2—Arzneistoffanalyse*) and it has been translated into English by Anthony Dunson. Several sections of this volume make reference to the German Pharmacopoeia *Deutsches Arzneibuch* (DAB).

The foreword to this book anticipates the main criticism that will be broached, namely that the many reactions described have diminished in importance compared to instrumental analytical procedures. The authors counter this by noting that colour and fluorescence reactions are frequently employed for detection by TLC. I would suggest that a better argument would be that many non-instrumental analytical procedures are recognised as being official procedures and can be performed in many laboratories without the need for expensive instrumentation. Simple colour reactions are also useful in initial stages of drug identification—especially for drugs of abuse. However, the reader is forewarned that this is not a book giving extensive details of instrumental analyses—those interested in procedures based on HPLC, atomic absorption, spectrofluorimetry, *etc.* will need to look elsewhere.

The book is seriously let down by the type-setting: there is no consistency in the use of different type-faces, particularly italics. In a chemical text, the symbols for constants (*e.g.*, K_{sp}) and variables in equations should be set in italic, and the symbols for chemical species (*e.g.*, NH_3) should be in upright text. R. R. MOODY

Pharmaceutical Chemistry—Volume 2, Drug Analysis: H. J. ROTH, K. EGER and R. TROSCHÜTZ, Ellis Horwood, Chichester, 1991. Pages: 767. £74.50. ISBN 0-13-663360-9.

Pharmaceutical Chemistry is published in three volumes: 1—drug synthesis, 2—drug analysis and, 3—drug bioreactivity. Each volume forms part of the Ellis Horwood series in Pharmaceutical Technology. This second volume was originally published, as a third edition, in the German language (*Pharmazeutische Chemie 2—Arzneistoffanalyse*) and it has been translated into English by Anthony Dunson. Several sections of this volume make reference to the German Pharmacopoeia *Deutsches Arzneibuch* (DAB).

The foreword to this book anticipates the main criticism that will be broached, namely that the many reactions described have diminished in importance compared to instrumental analytical procedures. The authors counter this by noting that colour and fluorescence reactions are frequently employed for detection by TLC. I would suggest that a better argument would be that many non-instrumental analytical procedures are recognised as being official procedures and can be performed in many laboratories without the need for expensive instrumentation. Simple colour reactions are also useful in initial stages of drug identification—especially for drugs of abuse. However, the reader is forewarned that this is not a book giving extensive details of instrumental analyses—those interested in procedures based on HPLC, atomic absorption, spectrofluorimetry, *etc.* will need to look elsewhere.

The authors have assigned individual drugs to a particular class of organic compound and each of these 14 compound types is dealt with in a separate chapter. The chapter headings are: Hydrocarbons and halogenated hydrocarbons; Hydroxylated hydrocarbons; Carbonyl compounds; Carboxylic acids; Carbonic acid derivatives; Nitro-compounds; Amines; Sulphur-containing compounds; Polycarbocyclics; *O*-containing heterocyclics; *N*-containing heterocyclics; *S*-containing heterocyclics; *N,O*- and *N,S*-containing heterocyclics and, *O,N,P*-containing heterocyclics. The three largest chapters: *N*-containing heterocyclics (188 pages), carboxylic acids (142 pages) and amines (83 pages), occupy more than half the book. The chapters are further subdivided, *e.g.* under carbonyl compounds, information is given on quinones, aldehydes and ketones, and carbohydrates. General details of these drug types are given and individual drugs are also selected for specific treatment. Each drug selected is mentioned with a common and a systematic name, *e.g.* ethisterone, 17-hydroxy-17α-pregn-4-en-20-yn-3-one together with a structural formula. A rectangular box is drawn around these three items of information.

What follows after these rectangular headings is somewhat variable. In the best cases some physical and chemical properties are presented along with identification, purity testing and assay procedures. Where the drug is mentioned along with very closely related compounds very little information, if any, is provided. As previously mentioned there is very little on instrumental analysis and no spectra are included but λ_{max} values for UV work are occasionally presented. Good features include the many reactions that are given, many showing the appropriate mechanisms, and the use of structural formulae throughout the book. There are also extensive literature references and a good index is included.

It would be impossible to include all drugs in a single text of this size but I was surprised to find that ibuprofen, which rivals acetylsalicylic acid and paracetamol in the lucrative analgesics market, was omitted. A small section on inorganic and organometallic drugs would also have been welcomed along with mention of important substances such as zinc insulin.

Assays are normally performed to determine if the chemical content of a drug substances lies within certain acceptable limits, *e.g.* 99.5–100.5% of the stated amount. Such limits, which are unfortunately not given in this book, also indicate the precision required for the assay.

There are also a number of errors present, *e.g.* paracetamol does not have more than one phenolic hydroxy group available and the opening sentence under Promazine—"The base is only."—is meaningless. I am sure a translation editor would have corrected many of the errors. On the whole an interesting addition to, but not a replacement for, the standard works on drug analysis.

P. J. Cox

Polymer Characterisation: B. J. Hunt and M. I. James (editors), Blackie, Glasgow, 1992. Pages xiv + 362. £69.00. ISBN 0-7514-0082-3.

This is a well written book and makes a very able attempt at covering the methods used in the characterisation of polymers. Following a brief introduction the second chapter highlights the need for preparation of polymers prior to analysis by using specific examples. The spectroscopic techniques are then very well covered in the next two chapters. The fifth chapter looks at the methods available for molecular mass determination. The remaining six chapters cover techniques such as chromatographic methods, thermal analysis, small-angle neutron scattering and neutron reflectometry, mechanical and rheological analysis, microscopy and finally XPS and SIMS. The text covers each of the topics in considerable detail, numerous examples are provided and good use is made of figures throughout. For those who desire to go that little bit further there are also many references provided with each chapter. An improvement may have been to provide more examples from the medical and pharmaceutical fields as it is stated in the Introduction that this has been "pursued with great vigour in recent years". The book should prove useful to anyone involved with polymers, particularly those involved in analysis and characterisation.

K. I. Cumming

Detectors for Capillary Chromatography: H. H. Hill and D. G. McMinn (editors), Wiley–Interscience, New York, 1992. pages xvii + 444. £79.00. ISBN 0-471-50645-1.

This is a book in the Chemical Analysis series which represents a series of monographs on Analytical Chemistry and its applications. As anticipated it maintains the high standard expected of a book in this series.

Very few, if any, chromatographers would disagree with the fact that once column separation of a mixture of analytes has been achieved, the qualitative and the quantitative analysis of the eluted components then becomes a function of the specificity, sensitivity and reproducibility of the detecting system used. Thus the value and the importance of this text, to chromatographers, should be obvious.

There are 14 chapters in the book, 12 of which deal with particular detector or detecting systems. The range covered is from the well known *e.g.* FID, EC detectors, to the lesser known or used, *e.g.* surface ionisation, Fourier transform infrared detectors, to the more complex, relatively widely used GC/MS detecting systems. One of the final two excellent chapters, reviews the current detectors available for use in capillary supercritical fluid chromatography, and the other, detectors for micro-column LC. The importance of the choice of a detector, how it functions, its limitations and applications are all covered in a uniform manner throughout the first 12 chapters of the book: Introduction, Design, Operating Characteristics, Applications and Possible Future Developments.

All chapters have individual, up-to-date (1991), reference lists and a high standard of presentation, *e.g.* chromatograms, tables, figures, diagrams, *etc.*, is maintained throughout the text.

The enthusiasm, knowledge and the expertise of the many individual authors involved in producing this book comes over clearly to the reader. A very, worthwhile reference source for those scientists working in the GC and/or LC fields.

R. R. Moody

The authors have assigned individual drugs to a particular class of organic compound and each of these 14 compound types is dealt with in a separate chapter. The chapter headings are: Hydrocarbons and halogenated hydrocarbons; Hydroxylated hydrocarbons; Carbonyl compounds; Carboxylic acids; Carbonic acid derivatives; Nitro-compounds; Amines; Sulphur-containing compounds; Polycarbocyclics; *O*-containing heterocyclics; *N*-containing heterocyclics; *S*-containing heterocyclics; *N,O*- and *N,S*-containing heterocyclics and, *O,N,P*-containing heterocyclics. The three largest chapters: *N*-containing heterocyclics (188 pages), carboxylic acids (142 pages) and amines (83 pages), occupy more than half the book. The chapters are further subdivided, *e.g.* under carbonyl compounds, information is given on quinones, aldehydes and ketones, and carbohydrates. General details of these drug types are given and individual drugs are also selected for specific treatment. Each drug selected is mentioned with a common and a systematic name, *e.g.* ethisterone, 17-hydroxy-17α-pregn-4-en-20-yn-3-one together with a structural formula. A rectangular box is drawn around these three items of information.

What follows after these rectangular headings is somewhat variable. In the best cases some physical and chemical properties are presented along with identification, purity testing and assay procedures. Where the drug is mentioned along with very closely related compounds very little information, if any, is provided. As previously mentioned there is very little on instrumental analysis and no spectra are included but λ_{max} values for UV work are occasionally presented. Good features include the many reactions that are given, many showing the appropriate mechanisms, and the use of structural formulae throughout the book. There are also extensive literature references and a good index is included.

It would be impossible to include all drugs in a single text of this size but I was surprised to find that ibuprofen, which rivals acetylsalicylic acid and paracetamol in the lucrative analgesics market, was omitted. A small section on inorganic and organometallic drugs would also have been welcomed along with mention of important substances such as zinc insulin.

Assays are normally performed to determine if the chemical content of a drug substances lies within certain acceptable limits, *e.g.* 99.5–100.5% of the stated amount. Such limits, which are unfortunately not given in this book, also indicate the precision required for the assay.

There are also a number of errors present, *e.g.* paracetamol does not have more than one phenolic hydroxy group available and the opening sentence under Promazine—"The base is only."—is meaningless. I am sure a translation editor would have corrected many of the errors. On the whole an interesting addition to, but not a replacement for, the standard works on drug analysis.

R. R. Moody

Quality Assurance Principles for Analytical Laboratories: Second Edition F. M. GARFIELD, AOAC International, Arlington, 1991. Pages 196. $63.00 (North America), $69.00 (Elsewhere). ISBN 0-935584-46-3.

The first edition of this book, published in 1984, enjoyed wide circulation and there is every reason to suspect that the second edition will do even better. One has only to turn the pages of *Chemistry in Britain*, or a similar journal, to realize just how many independent laboratories now offer analytical services in this country. In order to compete successfully in this ever-increasing market, recognition in the form of Laboratory Accreditation must surely be the minimum requirement. This book leads the potential applicant through the various aspects of quality assurance to accreditation, and does it thoroughly, systematically, and in a pleasing manner.

There is much to praise and very little to criticize in the content and layout of this book. There are 10 chapters, six appendices, and a comprehensive index. The chapters are: Quality Assurance Planning, Statistical Applications and Control Charts (new), Personnel Considerations, Management of Equipment and Supplies, Sample and Record Handling, Sampling and Sample Analysis, Proficiency and Check Samples, Audit Procedures, Design and Safety of Facilities, and Laboratory Accreditation. A very useful feature at the end of each chapter is a summary, entitled "Recommendations", and a quick glance here provides one with enough sound advice on which to base plans of action. Following the recommendations is an up-to-date bibliography for each chapter. The references therein are largely North American in origin, as are the majority of Regulations, Acts, and Reports quoted, but there are also present a number of references to QA guidelines from other countries. Indeed, the appendix on Accreditation Criteria, which is new in this edition, draws on a variety of national sources for the criteria.

The appendices are most useful in that they present some pictorial as well as written information. Examples of forms used by Federal Agencies are shown in one appendix, whilst in another a checklist, in chart form, lists a set of procedures to be used for monitoring analytical instrument performance, and to aid in detecting the first stages of deterioration in performance.

To summarize, the book is a mine of practical information for anyone wishing to learn about Quality Assurance methods from scratch, or for an experienced manager seeking accreditation for his/her laboratory.

D. F. RENDLE

Chromatographic Retention Indices—An Aid to Identification of Organic Compounds: V. PACÁKOVÁ and L. FELTI, Ellis Horwood, 1992, Pages 285. £65.00. ISBN 0-13-772328-8.

Despite the many well documented problems of reproducibility and transferability between instruments, columns and laboratories, many chromatographers still hold an unjustified faith in the validity of absolute measurements of retention as a method of identification. Alternative relative and preferably robust measurements such as retention index values are required and have found adoption throughout chromatography, most particularly for gas–liquid chromatography (GLC). The extent of their adoption can best be exemplified by a review paper in 1983 on the first 25 years of Kovats indices, which contained over 1350 references.

The aim of this book is to explain the background to the analytical application of retention indices and to illustrate their various roles for the analyst. It starts with a general discussion of retention measurement data and the use of relative measurements and retention index scales. The Kovats retention index scale based on *n*-alkanes, which is the most important for GLC, is described and is compared with alternative scales based on other homologous series of standard reference compounds. Retention indices scales for high-performance liquid chromatography and supercritical fluid chromatography are reviewed but are not discussed further in the book.

For the remainder of the book the authors concentrate on selected aspects of the applications of retention indices in GLC. The effects of temperature, including the changes caused by temperature programming, on the indices of difference structural types are discussed. These structural influences are then described in greater detail and are related to the physical properties of the analytes and the presence of particular functional groups. These lead to methods to calculate or predict retention indices. The widespread role of retention indices as the basis of the Rohrschneider and McReynolds methods to characterize GLC stationary phases is described.

The second half of the book is an extensive compilation of the retention indices of selected groups of analytes on a range of stationary phases. However, most of the analytes are relatively simple in structure and would principally be useful for theoreticians or molecular modelling. The value of these tables to the practising chromatographer is not clear as they are essentially model compounds and for the retention indices of most compounds of practical importance it will be necessary to consult commercially available databases.

The first part of the book is useful and would be valuable reading for most gas chromatographers as a guide to the use of retention indices and as a warning of the problems that can be encountered.

XXVIII COLLOQUIUM SPECTROSCOPICUM INTERNATIONALE

Invitation

The Organising Committee cordially invites you to attend the XXVIII CSI which will be held from Tuesday to Sunday, June 29th to July 4th, 1993, in York, United Kingdom.

This traditional biennial conference provides a forum for the international community of analytical spectroscopists to meet and exchange ideas.

Participants are invited to submit contributions for presentation in English, French or German (there will be no translation facilities) on the following topics:

Basic Theory, Techniques and Instrumentation of:

Atomic Spectroscopy (Emission, Absorption, Fluorescence)
Computer Applications and Chemometrics
Electron Spectroscopy
Gamma Spectroscopy
Laser Spectroscopy
Mass Spectrometry (Inorganic and Organic)
Methods of Surface Analysis and Depth Profiling
Molecular Spectroscopy (UV, VIS, IR)
Mössbauer Spectroscopy
Nuclear Magnetic Resonance Spectrometry
Photoacoustic Spectroscopy
Raman Spectroscopy
X-ray Spectroscopy

Applications of Spectroscopy in the Analysis of:

Biological Samples
Environmental Samples
Food and Agricultural Products
Geological Materials
Industrial Products
Metals and Alloys

The scientific programme will consist of plenary lectures and four parallel streams of contributed lectures (e.g. atomic, molecular and mass spectrometry, and surface analysis and characterisation)

CHROMATOGRAPHIC FUNDAMENTALS COURSE

7–11 June, 1993

Kent State University's Chemistry Department will co-sponsor a course, "Fundamentals of Chromatographic Analysis", during 7–11 June 1993. This will be the tenth offering of this course which has been well received by the industrial community.

The course will provide a coherent overview of chemical separations via chromatographic methods. It is unique from most other short courses in that material will be included on gas, liquid and thin-layer methods. It will emphasize the three techniques as complementary rather than competing processes. The course will be a blend of fundamental information on theory and instrumentation with emphasis placed on the latest developments and trends. Additional periods will provide time to discuss practical problems related to HPLC, GC, GC-MS, TLC and CE instrumentation.

Dr Roger K. Gilpin, Chairman of Chemistry at Kent State University, and Dr Neil D. Danielson, Professor at Miami University, will be the principle lecturers. Ronald L. Lewis of Varian will discuss/demonstrate laboratory instrumentation.

Information on this course can be obtained by writing to: Carl J. Knauss, Chemistry Department, Kent State University, Kent, OH 44242, U.S.A. *Tel.* 216/672-2327.

XXVIII CSI POST-SYMPOSIUM: GRAPHITE ATOMIZER TECHNIQUES IN ANALYTICAL SPECTROSCOPY

4–7 July, 1993, University of Durham, U.K.

Following the successful XXVII CSI Pre-Symposium meeting in Loftus, Norway, 1991, the organizers of the 1993 meeting intend to keep a similar format and scope. The symposium will focus on recent research using graphite electrothermal furnaces in atomic absorption, emission, fluorescence and mass spectrometry with an emphasis on achieving accuracy in practical analysis.

The topics will include:

reaction and interference mechanisms
temperature and atom distribution measurements
absolute analysis
coupling with hydride–generation, chromatography and flow-injection
laser applications
solid and slurry sampling
metal and other non-graphite surfaces
and all applications in these areas.

The meeting will be an excellent forum where scientists both with a great deal of experience in these techniques and others new to the field can meet to exchange ideas and views and present their research data.

NOTICE

FIRST ANNOUNCEMENT

The **XIIth Conference of Analytical Chemistry** from ROMANIA will take place between 22–24 September 1994 at the "OVIDIUS" University in Constanta. This Conference will be organised under the auspices of the Romanian Society of Analytical Chemistry. If you are interested in participating in this event please write, by 1 May 1993, to Dr. G.-L. Radu for the Organising Committee for the 12th Conference of Analytical Chemistry at the following address:

ROMANIAN SOCIETY OF ANALYTICAL CHEMISTRY
13, Bul. Carol I, Sector 3, 70346 Bucharest, Romania

More information will be sent to you after 15 September 1993 by a second announcement.

6th INTERNATIONAL CONFERENCE ON FLOW ANALYSIS

Toledo, Spain
8–11 June 1994

Topics

The Conference shall basically be concerned with the following flow analysis topics: general aspects, FI-chemometrics, detection systems, separation techniques (on-line sample treatment), sensors and continuous flow techniques, applications (environmental, food, clinical, industrial analysis), and process control (Biotechnology). Two special sessions devoted to "Flow Analysis Nomenclature" and "Foundation of an International Society for Flow Analysis" shall be arranged.

Scientific programme

The scientific programme shall consist of invited lectures and oral and poster presentations. There shall also be an exhibition of commercially available intrumentation for flow analysis.

Scientific committee

THIRD EUROPEAN FEDERATION OF CORROSION WORKSHOP ON MICROBIAL CORROSION

Hotel Palacio, Estoril, Portugal

13–16 March 1994

The workshop will cover all aspects of microbial corrosion in natural and industrial environments. The aim is to promote the exchange of information and ideas between research and industry and to provide a forum for people dealing with this problem from around the world.

Workshop topics will include:

- Fundamental studies
- Bacterial processes
- Diffusivity of biofilms
- Monitoring
- Preventative measures
- Ecological aspects

Call for papers

Authors are invited to submit titles of papers covering any of the above topics, and/or related topics.

These titles should reach C. A. C. Sequeira, Instituto Superior Técnico, Av. Rovisco Pais, 1096 Lisboa Codex (Phone/Fax 351-1-7783594), Portugal, not later than 15th October 1993.

Programme details will become available by the end of October 1993.

David Coleman and Felix Schneider
General Chairs

FACSS National Office
198 Thomas Johnson Dr., Suite S-2
Frederick, MD 21702-4317 (301-846-4797)

Scientific Program and Submission of Papers
The FACSS meeting is one of the world's leading analytical chemistry conferences with over 2500 delegates and an anticipated program comprising almost 1000 presentations. This year, as well as the core topics of atomic and molecular spectrometry, chromatography, and electroanalysis, the meeting will feature a number of sessions concerned with materials characterization, including abrasives, coatings, fuels, and silicones. Contributed original research papers are solicited in all areas of analytical chemistry.

Awards Symposia
It is anticipated that several awards symposia will be arranged including symposia for the ANACHEM Award and Society for Applied Spectroscopy (SAS) Awards such as the Lester Strock and Lippincott Awards. In addition, this conference will serve as the forum for the presentation of other SAS Awards and FACSS Student Awards.

Instrument Exhibit
The instrument exhibit is one of the more useful and exciting components of the conference and is designed to complement the scientific program. The exhibition area can accommodate 125 booths and will serve as the primary gathering place for many of the social events associated with the conference.

Workshops, Short Courses, and Employment Bureau
Workshops and short courses conducted by leading scientists will be offered in conjunction with this conference. Typical topics include ICP-MS; GC-MS, LC-MS, Sample Preparation, Lasers in Analytical Chemistry, and Chemometrics. The Employment Bureau will offer both local and national job listings. In addition, workshops on resume preparation and career planning will assist professionals seeking employment.

5th European Conference on Electroanalysis

The 5th Conference on Electroanalysis (ESEAC' 94) will be held at Jesolo Lido (Venice), Italy, from 22–26 May 1994. The program will embrace all aspects of electroanalysis including theoretical developments and instrumental applications.

For information contact:

XXVIII COLLOQUIUM SPECTROSCOPICUM INTERNATIONALE

Invitation

The Organising Committee cordially invites you to attend the XXVIII CSI which will be held from Tuesday to Sunday, June 29th to July 4th, 1993, in York, United Kingdom.

This traditional biennial conference provides a forum for the international community of analytical spectroscopists to meet and exchange ideas.

Participants are invited to submit contributions for presentation in English, French or German (there will be no translation facilities) on the following topics:

Basic Theory, Techniques and Instrumentation of:

Atomic Spectroscopy (Emission, Absorption, Fluorescence)
Computer Applications and Chemometrics
Electron Spectroscopy
Gamma Spectroscopy
Laser Spectroscopy
Mass Spectrometry (Inorganic and Organic)
Methods of Surface Analysis and Depth Profiling
Molecular Spectroscopy (UV, VIS, IR)
Mössbauer Spectroscopy
Nuclear Magnetic Resonance Spectrometry
Photoacoustic Spectroscopy
Raman Spectroscopy
X-ray Spectroscopy

Applications of Spectroscopy in the Analysis of:

Biological Samples
Environmental Samples
Food and Agricultural Products
Geological Materials
Industrial Products
Metals and Alloys

The scientific programme will consist of plenary lectures and four parallel streams of contributed lectures (e.g. atomic, molecular and mass spectrometry, and surface analysis and characterisation)

each session beginning with an invited lecture from a prominent scientist in the relevant field. Separate times will be made available for poster sessions.

Plenary and Invited Speakers

To date the following scientists have accepted invitations to present keynote lectures:

Plenary:

M L Gross, *Lincoln, NE*
R E Hester, *York*
C L Wilkins, *Riverside, CA*
J D Winefordner, *Gainesville, FL*

Invited:

F C Adams, *Antwerp*
F V Bright, *Buffalo, NY*
J A Caruso, *Cincinnati, OH*
B T Chait, *New York, NY*
R Donovan, *Edinburgh*
D E Games, *Swansea*
G L Glish, *Oak Ridge, TN*
P Hendra, *Southampton*
F Hillenkamp, *Munster*
J A Holcombe, *Austin, TX*
J Reffner, *Stanford, CT*
B L Sharp, *Loughborough*
M Sigrist, *Zurich*
M Thompson, *London*
J C Vickerman, *Manchester*

Workshops, Pre- and Post-Symposia

In connection with the XXVIII CSI, a number of symposia and workshops will be organised. Full details can be obtained from the Secretariat.

Social Programme

The scientific programme will be punctuated with memorable social events and excursions of scientific, cultural and tourist interest. The social programme is open to all participants and accompanying persons.

Organising Committee

Chairman:	E B M Steers	*Polytechnic of North London*
Vice-Chairman:	L Ebdon	*Polytechnic South West, Plymouth*
Peripheral Events:	C S Creaser	*University of East Anglia*
Publicity:	S J Hill	*Polytechnic South West, Plymouth*
Local Events:	C W McLeod	*Sheffield City Polytechnic*
Secretary:	B L Sharp	*Loughborough University*
Exhibition:	D Steele	*Royal Holloway and Bedford New College, London*
Treasurer:	T L Threlfall	*University of York*
Scientific Programme:	A Townshend	*University of Hull*

ASIANANALYSIS II

9–13 August, 1993
Changchun, China

Second Asian Conference on Analytical Chemistry, ASIANANALYSIS II will be held in Changchun, China, 9–13 August, 1993. For further information please contact: Prof. Erkang Wang, 109 Sitalin Street, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, China.

THIRD INTERNATIONAL SYMPOSIUM ON SEPARATION TECHNOLOGY

22–27 August, 1993
Antwerp, Belgium

The Third International Symposium on Separation Technology will take place in the Congress Centre of the University of Antwerp (UIA), Antwerp, Belgium, from August 22 to 27, 1993.

The Symposium will deal with both fundamental aspects and practical applications of gas and liquid separations. Major emphasis will be put on the fundamentals of the separation science including thermodynamics, kinetics, operational aspects and modelling, together with the latest developments in the separation techniques using sorbents, membranes, cryogenic techniques, extraction, chemical processes including catalysis and membrane reactors, filtration and other techniques.

Separation methods, useful for product purification, pollution control (treatment of waste water and off-gases), and air separation will be discussed in detail. A special session will be devoted to accurate measurement techniques.

For further information contact: the Congress Secretariat: Mrs M Stalmans, University of Antwerp (UIA), Dept. of Chemistry, Universiteitsplein 1, B-2610 Antwerp-Wilrijk. Tel.: +32-3-820.2375, Fax: +32-3-820.2374, Telex: 33646 UIA B.

EUROANALYSIS VIII
EUROPEAN CONFERENCE ON ANALYTICAL CHEMISTRY

5–11 September, 1993
University of Edinburgh
Organised by THE ROYAL SOCIETY OF CHEMISTRY

The Working Party on Analytical Chemistry of the Federation of European Chemical Societies and the Analytical Division of The Royal Society of Chemistry cordially invite your participation

SUBJECT INDEX

THE THIRTY-SECOND ANNUAL EASTERN ANALYTICAL SYMPOSIUM

15–19 November, 1993

The Somerset Plaza Hotel and Garden State Convention and Exhibit Center, Somerset, NJ, U.S.A.

EAS welcomes contributed papers to complement the invited oral and poster sessions. Prospective authors should submit a 100–200 word abstract (a special form is *not* required for this) of their proposed presentation before 15 April, 1992. Care should be exercised in listing the title and authors of the proposed presentation, since the title and authors are considered final, and are *not* subject to change. Please indicate your preference for oral or poster format. Send your abstract to the EAS Program Committee, P.O. Box 633, Montchanin, DE 19710-0633. Authors of accepted papers will receive forms in May 1993 for submission of the final 200–300 word abstracts.

For additional information, please contact: the EAS hotline—(302) 738-6218, *or* the EAS Faxline—(302) 738-5275.

EUROANALYSIS VIII
EUROPEAN CONFERENCE ON ANALYTICAL CHEMISTRY

5–11 September, 1993
University of Edinburgh
Organised by THE ROYAL SOCIETY OF CHEMISTRY

The Working Party on Analytical Chemistry of the Federation of European Chemical Societies and the Analytical Division of The Royal Society of Chemistry cordially invite your participation

in the eighth triennial European Conference on Analytical Chemistry to be held at the University of Edinburgh from Sunday to Saturday, September 5th–11th, 1993.

LOCATION

Euroanalysis VIII will be held at the University of Edinburgh. The Scientific Sessions will be held at the Appleton Tower, George Square.

Edinburgh is the beautiful and historic capital city of Scotland. It is easily reached by road and rail, and has an international airport.

Participants may be interested to know that the Conference immediately follows the world renowned Edinburgh Festival, which will be held from August 15th to September 4th, 1993 (the last performance of the Edinburgh Military Tattoo will be on Saturday August 28th).

SCIENTIFIC PROGRAMME

Euroanalysis VIII will cover developments in instrumentation and methodology in all areas of analytical chemistry, with emphasis on industrial, biomedical and environmental analysis. The programme will be designed to appeal both to practising analytical chemists in industry and to those in academia who are teaching and doing research.

The programme will consist of invited keynote lectures, and contributed oral and poster papers. In order to ensure high quality, all contributed papers will be refereed.

SOCIAL PROGRAMME

A comprehensive programme is being planned for participants and accompanying persons. It will include half- and full-day excursions, and various evening events including a whisky tasting and a Buffet Reception at the Royal Museum of Scotland.

ACCOMMODATION

Accommodation has been arranged in the Pollock Halls of Residence of the University of Edinburgh. Single room accommodation only will be available. Participants are asked to make their own arrangements if they wish to stay in hotels. A list of local hotels may be obtained from the Conference Organiser; early booking is advised.

CONFERENCE LANGUAGE

The official language of the Conference will be English; no translation service will be provided.

BOOK EXHIBITION

An extensive Exhibition of Books and Journals is planned, and will be held in the Appleton Tower, close to where the lectures and posters will be presented.

CONTRIBUTED PAPERS

All those intending to participate in the Conference are welcome to submit papers to be included in the scientific programme. The Scientific Committee will consider papers according to their relevance to the Conference programme and their scientific content. A listing of possible topics is presented below but other areas of analytical chemistry will also be considered. In order to facilitate the planning of the scientific programme, authors are asked to complete the relevant section of the form on the last page and return it to the Conference Organiser as soon as possible. Instructions for authors will be given in Circular 2; the final date for the receipt of abstracts is November 30th, 1992.

TOPICS

Some of the topics expected to be covered are:

Industrial Analysis

A1) Validation of Analytical Measurements
A2) Process Control Analysis
A3) Materials Analysis (including Surface Analysis)
A4) Energy Related Analysis

Pharmaceutical and Biomedical Analysis

B1) Pharmaceutical Methods and Drug Metabolism
B2) Forensic Science
B3) Bioselective Methods
B4) Trace Elements in Medicine

Environmental Analysis

C1) Atmosphere
C2) Soils/Sediments
C3) Food/Drink
C4) Water

Instrumental Techniques

D1) Separation Science
D2) Molecular Spectrometry
D3) Atomic Spectrometry
D4) Electroanalytical Techniques
E1) Expert Systems and Chemometrics
E2) Coupled Techniques
E3) Sensors
E4) Laser-based Techniques
E5) Flow Analysis

PUBLICATIONS

All invited lectures will be published in a collected volume as the Proceedings of the Conference. Authors of contributed papers will be invited to submit manuscripts for publication in the RSC journals. Abstracts of all papers will be available to registered scientific participants.

ADDRESS FOR CORRESPONDENCE

The Conference Organiser and address for all correspondence are:

Miss P E Hutchinson,
Analytical Division,
The Royal Society of Chemistry,
Burlington House, Piccadilly,
London W1V 0BN, UK.
Tel.: 071 437 8656; Fax: 071 734 1227; Telex: 268001.

Travel, etc.

The Tourist Office in Edinburgh will be happy to assist with the arranging of pre- or post-Conference tours. The address and telephone number are:

Edinburgh Tourist and Information Centre,
3 Princes Street, Edinburgh EH2 2QP.
Tel.: 031 557 1700/2727; Fax: 031 557 5118

4th ISEC

5–8 October, 1993
Changchun, China

The Fourth International Seminar on Electroanalytical Chemistry (4th ISEC) will be held in Changchun, China, 5–8 October, 1993. For further information please contact: Prof. Erkang Wang, 109 Sitalin Street, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, China.

5th BCEIA

8–13 October, 1993
Beijing, China

The Fifth International Beijing Conference and Exhibition on Instrumental Analysis (5th BCEIA) will be held in Beijing, China. Conference: 9–12 October, 1993. Exhibition: 8–13 October, 1993. For further information please contact: General Service Office, 5th BCEIA, Room 5412, Building No. 4, Xi Yuan Hotel, Er Li Gou, Beijing 100046, China.

ANALYTICAL CHEMISTRY IN SPAIN

DECEMBER

Talanta, Vol. 40, No. 11, p. V, 1993

0039-9140/93 $6.00 + 0.00
Pergamon Press Ltd.

EDITORIAL

As any keen reader of international scientific journals undoubtedly has observed, the number of analytical chemical publications from Spain has increased dramatically over the past decades. Only 10% of all Spanish papers were published in international periodicals in 1945, while 90% found their outlet in national journals (mainly *Anales de Química*, *Afinidad* and *Química Analítica*. The distribution ratio in 1981 was approximately 50/50; now, according to a recent survey published by Peñn and Pulgarin in the *Analytical Proceedings* (1992, **29**, 517), 88% of all papers from Spanish scientists are published in international journals. And in many of these journals the Spanish share is astonishing. Thus in *Talanta*, Spain actually ranks as the second largest national contributor, in the *Analyst* and the *Analytical Letters* Spain is also second; in *Analytica Chimica Acta*, fourth, and in *Analytical Chemistry*, seventh. This surge in Spanish contributions to analytical chemistry is very evident at international meetings, too. At the Euroanalysis VII Conference in Vienna in 1990, Spain was the country that presented the largest number of communications (96) followed by Germany (71) and Austria (66).

The increase of the presence of Spanish analytical chemistry at the international scene can presumably be attributed to a combination of rather complex circumstances. A possible key to a deeper understanding of the reasons was aired by Professor Miguel Valcárcel from Universidad de Córdoba at the 1992 Pittsburgh Conference in New Orleans, during a special session entitled "The Status of Analytical Chemistry in the World," when he said that "The changeover from a dictatorship to a democratic political regime has promoted scientific and technological development in our country". This political change meant that concentrated efforts were made to modernize the curricula, that a considerable number of young scientists became attached to the Spanish universities, that stable research groups were formed, and, importantly, that international collaboration greatly increased. Such collaboration was undoubtedly facilitated by Spain's entry into the European Community, which entailed appropriations of substantial sums earmarked for scientific activities, in addition to broadening Spain's international contacts.

With the increased international significance of Spanish analytical chemistry, it is not only appropriate, but in fact, also natural that the Editorial Board of *Talanta* decided to honour Spanish analytical chemistry by devoting an entire issue to this country, calling upon two of its most distinguished and internationally renowned analytical research chemists, Professors Miguel Valcárcel and Maria Dolores Luque de Castro, to act as Guest Editors. We sincerely extend our personal thanks to the two Guest Editors for their formidable work in collecting and editorially supervising this fine array of communications, and congratulate our Spanish colleagues on their scientific endeavours as presented in this issue.

Elo H. Hansen
Gary D. Christian

OBITUARY

Izaak M. Kolthoff
1894–1993

Izaak Maurits Kolthoff, Professor Emeritus at the University of Minnesota, died on 4 March 1993 in St. Paul, Minnesota, U.S.A. Professor Kolthoff is considered the father of analytical chemistry in the U.S.A., and in 1982 over 1000 Ph.D. analytical chemists could trace their roots to him. Kolthoff, in fact, is the academic great grandfather of one of us (GDC).

James J. Lingone, a student of his, published a biography of Kolthoff in the Kolthoff Honor Issue of *Talanta* in 1964 (Vol. 11), with a complete list of his publications up to then.

The U.S.A. Honor Issue of *Talanta* (Vol. 36, No. 1/2) published in 1989 was dedicated to Kolthoff, and Professor Peter Carr at the University of Minnesota presented a narrative annotation of an interview with him, recounting some of his early experiences. Earlier publications of Kolthoff's historical perspectives can be found in *J. Electrochem. Soc.*, 1971, **125** 5C and *Am. Lab.*, May, 1979, p. 42. The late Professor Herbert Laitinen, a student of Kolthoff's, conducted a videotaped interview with him for the American Chemical Society archives. Extensive biographical, bibliographic and autobiographical material is assembled in the Archives of Contemporary History of the University of Wyoming, Laramie, in the "Dr. Izaak M. Kolthoff Collection". The collection contains reprints of most of his scientific publications and two dozen newspaper articles written by him based on his experiences abroad.

The analytical chemistry world has benefitted immensely from the contributions of this giant, and his presence will be missed.

GARY D. CHRISTIAN

EDITORIAL

PROFESSOR JÁNOS INCZÉDY—70 years

This month, one of the senior members of the Advisory Board of *Talanta*, Professor János Inczédy from Hungary, celebrates his 70th birthday.

He joined the journal as early as 1975, when *Talanta* was just emerging from its teens. With his expert advice and pointed comments he has on numerous occasions contributed to establishing *Talanta* as one of the leading periodicals in analytical chemistry. And for the present European editor, his help has been invaluable, particularly during the editor's early stages of editorial responsibility. Always ready to help, Professor Inczédy has served as a most revered referee, conscientious and meticulous in his constructive criticism.

Professor Inczédy was born in Budapest, Hungary, on 26 June, 1923. He graduated from the Technical University of Budapest in Chemical Engineering in 1946, received his Ph.D from the same university in 1957 and was awarded the Doctor of Science Degree in 1967 by the Hungarian Academy of Science Most of his professional career has been spent at the University of Veszprém, where he was Head of the Department of Analytical Chemistry from 1970 to 1990 when he retired. Still active, however, he continues at the university as a research professor

Professor Inczédy's interests cover a wide spectrum of analytical chemistry. His major research areas comprise separation sciences with development and application of ion exchangers, including chromatography, calculation of chemical equilibria for analytical purposes, and chemical process instrumentation and automation. During his career he has published more than 250 scientific papers and a number of books, several of which have been translated into English and other languages. He has been honoured with numerous national awards, including the State Award for his research work in the field of ion exchange (1980), the Award of Excellence in Teaching (1973), the Than Károly Award of the Hungarian Chemical Society (1977), the Award of the Technical and Natural Science Society (1983), and the Schulek Elemér Award of the Hungarian Pharmaceutical Society (1978). He has served on the Advisory Board of several international journals and on the IUPAC commission; from 1981 to 1991 he was President of the Hungarian Chemical Society. He has also been a frequent attendee and speaker at international conferences.

Although neither of the editors of this journal has ever had the pleasure of studying under or with Professor Inczédy, we believe all his former students when they, with genuine reverence, describe him as a thoroughly engaged and enthusiastic teacher and a most stimulating adviser. Therefore we have the pleasure in announcing that *Talanta* wishes to dedicate a special issue to Professor Inczédy, to be published later, with contributions from scientific colleagues and friends.

OBITUARY

Sidney Siggia, 72, Emeritus Professor of Analytical Chemistry at the University of Massachusetts, Amherst, died on 15 October in Amherst after a considerable period of failing health. Born in New York City, he received his bachelor's degree from Queens College in 1942 and his doctorate in analytical chemistry from the Polytechnic Institute of New York in Brooklyn in 1944.

Sid Siggia's life's work in analytical chemistry comprised two distinctive parts. For more than 20 years he pursued a distinguished career in chemical industry which included positions of director of analytical research and service at the General Aniline and Film (GAF) Corporation and the Olin Corporation. During this time he published actively in the area of organic functional group analysis and with the focus upon the analytical chemist as "problem solver". His definitive text *Quantitative Analysis Via Functional Groups* went into four editions.

In 1966 he joined the faculty of the University of Massachusetts at Amherst where he was Professor of Chemistry until his retirement in 1986. The transition from industry to academia allowed Sid Siggia to put into action his goal of developing a strong "academic–industrial interface" in analytical chemistry. He used his industrial experience as a basis for the development of undergraduate and graduate teaching and of analytical chemical research. He directed the doctoral dissertations of more than 35 students, many of whom have since assumed leadership positions in the discipline, retaining the active problem-solving philosophy developed under his guidance. Under his guidance also the Analytical Division at the University of Massachusetts developed one of the leading academic programs in the United States.

Sid Siggia was very active in ACS and in particular in the Analytical Division, for which he served as chairman (1969–1970) and in numerous other capacities. He was a Titular member of the Commission on Analytical Reactions and Reagents of the International Union of Pure and Applied Chemistry—IUPAC. He received recognition for his work with the ACS Fisher Award in Analytical Chemistry, the Anachem Award, and the Kolthoff Award from the Academy of Pharmaceutical Science of the American Pharmaceutical Association. He was the first recipient of the Theophilus Redwood lectureship of the Analytical Division of the British Royal Society of Chemistry. He twice was named American Chemical Society, Tour Speaker of the Year.

He authored and co-authored 11 books and more than 120 papers and book chapters. He also held five patents. He was a member of numerous journal advisory boards including that of *Talanta*, he chaired the Gordon Conference on Analytical Chemistry and was a member of many learned societies.

Sid Siggia has left a lasting legacy to present and future generations of analytical chemists. He always combined chemical fundamentals with practical applications, never neglecting the "applied nature" of our field. He was a fine mentor, leader and colleague.

Travel, etc.

The Tourist Office in Edinburgh will be happy to assist with the arranging of pre- or post-Conference tours. The address and telephone number are:

Edinburgh Tourist and Information Centre,
3 Princes Street, Edinburgh EH2 2QP.
Tel.: 031 557 1700/2727; Fax: 031 557 5118

4th ISEC

5–8 October, 1993
Changchun, China

The Fourth International Seminar on Electroanalytical Chemistry (4th ISEC) will be held in Changchun, China, 5–8 October, 1993. For further information please contact: Prof. Erkang Wang, 109 Sitalin Street, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, China.

5th BCEIA

8–13 October, 1993
Beijing, China

The Fifth International Beijing Conference and Exhibition on Instrumental Analysis (5th BCEIA) will be held in Beijing, China. Conference: 9–12 October, 1993. Exhibition: 8–13 October, 1993. For further information please contact: General Service Office, 5th BCEIA, Room 5412, Building No. 4, Xi Yuan Hotel, Er Li Gou, Beijing 100046, China.
